The agriculture of Southeast Asia and the Middle East is mainly dependent on rain and groundwater which is, with current crops and management practices, neither sufficient nor reliable to meet the requirements of the crops (Noorka and Afzal 2009). Due to this, crop production is under serious threat, and potentially for survival, given the vagaries of abiotic and biotic stress under the changing climatic conditions. The consequences of climate change, water stress, and salinity have not only affected huge areas but also health and socioeconomic issues throughout the world particularly in the developing countries, leading to severe poverty, shaken resources, food insecurity, internal and external security issues, and catastrophes. Under the burgeoning population pressure including increasing urbanization, and severe weather conditions, Southeast Asia and Middle East countries will suffer food shortage in the coming decades if the present momentum of climate change situation persists for longer time as it is predicted. So short- and long-term planning over timescales, according to the wishes and necessities of human lifespan, is needed.

Climate Change and Agriculture

Climate is considered as the average weather and variations in relevant quantities for a number of decades, centuries, or potentially years. According to the World Meteorological Organization, the classical periods lag for a long time with the surface variables like wind, rainfall, and prevailing temperature. Change in climatic conditions result from natural climatic variations, solar cycles, volcanic eruptions and atmospheric changes and have direct consequences on land and water inhabitants flora and fauna (Pahl-Whost 2007; O'Brien et al. 2008). The climate change commitment is simply an account of predicted future changes in shape of hydrological cycle, changes in sea level, and rise and fall in weather conditions with constant anthropogenic emissions. It is anticipated that climate change takes place over a few decades or less, which directly or inversely has the potential to provide substantial interferences in humans as well as in ecosystems (Kashyap 2004; New et al. 2007). The immediate action to combat climate change is adaptation, a process of larger and smaller changes required to anticipate expected outcomes of climatic effects, by exploiting beneficial opportunities and minimizing harmful effects. In our natural systems, the process of sectioned resources management by augmentation of applied and basic research is suggested to tackle the forthcoming climatic threats (Power et al. 2005; One World Sustainable Investments 2008). Climate change and agriculture are interrelating and dependent on each other (IPCC 2007). Climate proofing and domestication of plants have played significant role to counteract changes in climate over the 10,000 years of human agriculture and have the potential to meet the challenges of global warming which have significant impacts on agriculture by the interaction of various elements like rainfall, fluctuating temperature and carbon dioxide concentration, glacial runoff, etc. to ensure crop maximization (Challinor et al. 2009; Fischer et al. 2002).

Lobell et al. (2008) concluded that due to climate change, by 2030, Southern Africa may show 30 %yield loss of maize (*Zea mays*) crop, while in Southeast Asia is predicted 10 % yield loss in staple crops such as rice (*Oryza sativa*), maize, and millet (*Pennisetum glaucum*). It is a matter of grave importance that agricultural production will definitely be affected by the predominance and pace of climate change, if it will transpire step by step, but in contrast the rapid climate change will upset the present momentum of agriculture production in a lot of countries, exclusively having poor and degraded soil with hot weather and under drought condition (Ziervogel et al. 2010) (Fig. 1).

The optimum natural selection and adaption could lead to genetic erosion as well as nonconservation of genetic resources, so care must be taken to avoid such loss of valuable genetic resources. Thus, the affiliation in climate change and agriculture is in multiple ways confounded and contrasted: agriculture significantly contributes towards climate change, and climate change can detrimentally distress agriculture.

Adverse Consequences of Water Status Under Changing Climatic Conditions

Water, the necessity of life, has emerged as the top commodity of present and future time and shall remain on top of planning concerns for farmers, policy makers, and researchers (Noorka et al. 2013a). Frontline workers responsible for water management to combat water stress and occasional drought have been as well as seasonal climate forecasts support decision making to manage water resources and dam management (David et al. 2008; Noorka and Schwarzacher 2013). Drought is

Fig. 1 Shallow terracing seen here allows efficient use of water in rainfed agriculture while preserving soil and slowing runoff

considered as the complex natural hazard that causes corrosion of water resources by quantity and quality (Noorka and Teixeira da Silva 2012). Droughts have imposed a serious menace to agricultural production and development of socioeconomic activities in the semiarid and arid regions which are more susceptible to the effect of drought (Noorka et al. 2013b). Agricultural production in semiarid and arid regions is constrained by low rainfall, poor or low-nutrient soils, high temperatures, high solar radiation, and low precipitation, raising food insecurity. IPCC (2007) highlighted the large potential for biofuels to meet the growing energy needs as well as contributing to GHG emissions reduction and enhancement of carbon sequestration in soils and biomass (Fig. 2).

Agriculture in Southeast Asia and the Middle East

The agriculture of Southeast Asia and the Middle East is under threat due to ultimate vagaries of abiotic stress including climate change and water-related factors (Angus and Van Herwaarden 2001; Ahmad 2005), and it is expected that it will affect the agriculture by a series of steps, e.g., change in rainfall, extreme temperature, and water stress will open the doors of severe drought by direct and indirect ways. With the increase in temperature, some specific areas like the Philippines will lose its agriculture production, while Indonesia and Malaysia are projected to gain the rice yield. Resultantly the driving force in agriculture is

Fig. 2 Overgrazing and lack of terracing lead to low grassland productivity, soil erosion, and invasion by aggressive aliens (here, *Argemone mexicana*)

Fig. 3 Wheat trials exploiting diversity in the search for plants with efficient growth under rainfed conditions. Here, selections with and without awns are being trialled under low-input conditions

increasing the demand for food and fiber throughout the globe. With particular focus on the challenges facing developing countries, this paper attempts to create a framework for policy makers and planning commissions as well as increasing national and regional water stress awareness (Singh 2002) (Fig. 3).

The geographical situation in this area predicts that under the changing set of climatic situation up to 2050, most countries will become hotter, have less and un-reliable rainfall, and as a consequences sever reduction in agricultural production if the current policies, crops and genetic attributes are retained unchanged.

Agriculture Eminence

Agriculture is the social and economic core and main employer in many developing countries. Drought and its consequence of desertification with salinity and soil loss are expected to increase in the coming decades, with disastrous consequences from climate change (Moss and Dilling 2004; Hampel 2006). Droughts impose a serious threat to agricultural production and development of socioeconomic activities in the semiarid and arid regions by low rainfall, poor or low-nutrient soils, high temperatures, high solar radiation, and low precipitation. A viable charter of climate proofing and super-domestication through genetic improvement, in combination with optimized agronomy, is the way to success from on-farm to lab and lab to field outreach to mitigate declining crop productivity and food issues. The regional and international collaborative efforts are focused on research and experiments to modernize the crop genetics, agronomy, field-to-fork scrutiny, and adaptation training to increase quantity and quality of food with sustainable water harvest.

Current Barriers in Understanding

Introduction and problem identification of climate change is expected to make this seasonal distinction even stronger, with more frequent summer droughts coupled with increased winter rainfall and more floods. On-farm water storage of the higher winter flows is one of the main options for securing a more reliable water supply for irrigation. The media, the most effective weapon of present time, have to play a major role in converting the people's perception to portraying climate change (Hampel 2006). Sometimes, media reports create confusion using their own perception without considering the expertise and scrutiny of the scientific community (Moss and Dilling 2004). Water availability and its predicted more frequent shortage are important barriers for efficient crop productivity that vary from one spatial scale to another. Reckoning crop water productivity, it is determined that there is gap among policy makers, consultant, researcher, extensionist, agronomist, and farmers themselves to enjoy the full supply of crop water productivity. However, a big breakthrough was observed with the employment of molecular breeding, domestication, and climate proofing (Heslop-Harrison and Schwarzacher 2012).

Farmer's Perceptions

The farmers are the most beleaguered community of Southeast Asia and Middle East societies. The governmental policies to confront the negative image of climate change, food insecurity, middleman role in agricultural marketing, insufficient storage facilities, conventional agricultural production practices, lack of extension services, and technology transfer (Schulze 2000; Roux et al. 2006). The young people in the farming community are absconding towards the big cities in search of livelihood and ignoring their small landholdings. The old people, their forefathers, are unable to understand the latest technologies to employ in agriculture and to achieve the potential of the varieties. The media and agriculture department can play an important role to educate the farmers (Jury and Vaux 2005), while governmental healthy and farmer-friendly policies like timely announcement of support price of staple food as well as cash crops, farms to market road access, water provision, water stress tolerant varieties, and quality production.

Concrete Efforts to Save Regional Agriculture for Sustainable Food Security

Genetic resources are the vital source of crop production and food security across the borders (Von Bothmer et al. 1992; Skovmand et al. 1992). The range of genetic diversity within crops and their relatives is a precarious source for potential increase in crop production and for new sources of resistance and tolerance against biotic and abiotic stresses (Ahmad et al. 2010). The Food and Agriculture Organization of the United Nations (FAO), the Commission on Genetic Resources for Food and Agriculture, the International Plant Genetic Resources Institute (IPGRI), and the International Board of Plant Genetic Resources (IBPGR) have played an important role in the publication and preservation of germplasm (Skovmand et al. 1992). The International community has the obligation to aid agricultural research systems world-wide in the context of climate change to ensure world's food security and peace. Building a partnership for development is one of the United Nations' Millennium Development Goals.

Conclusions

The consequences of climate change, water stress, and salinity have affected huge areas of developing countries from an economic and resource security perspective, which leads to disaster and unstable law and order issues. Long-term planning – over timescales beyond the human lifespan – and anticipation of threats and opportunities are required. Consequently, an emergency plan is also needed for international, national, and regional footprints including procedures for climate change mitigation and to implement inclusive plans to combat prevailing poverty, social changes (including urbanization of populations and changes in diets), and allied anticipated risks. The researchers urge more climate proofing infrastructures, water scheduling, improved drainage, and water harvesting. The water resource management, use of treated wastewater, serious attempts to limit greenhouse gas emissions, societal impacts on climate change, and shortening/shifting the growing periods of crops will definitely help the researchers to cut down the negative impact of climate change. The study attempts to provide a framework for policy makers and political understanding to check the hidden but viable issues relating to risks of climate change in local and global scenarios.

Approaches to Climate Change Adaptation of Vulnerable Coastal Communities of India

Chinmai Hemani

Contents

Abstract

In the context of developing countries, climate change and variability poses a serious threat to the coastal rural communities due to their poor adaptive capacities, weak implementation of developmental activities, and lack of technological solutions needed to address this challenge. In order to address the current vulnerabilities of these coastal communities where development initiatives are itself lacking, adaptation measures will play a crucial role in streamlining and collaborating with development initiatives. Literature review in Indian context suggests that there are no estimates available of

impact of climate change on coastal agriculture and fisheries and therefore on agricultural, pastoral, and fishing communities. This research addresses the aforementioned research gap with a case study from Western India focusing on livelihood security and human well-being while integrating development plans to climate change adaptation. Based on vulnerabilities identified for the study areas, adaptation plan consisting of goals with several measures were created which were linked to existing national development schemes along with their co-benefits and barriers to implementation. Development choices made today will influence the adaptive capacity of people in the future. Thus, there is an urgent need to undertake development activities and decision making with climate lens, and this research will be the first step in the process.

Keywords
Mainstreaming climate change adaptation • Adaptation plan and options • National and state development plans • Millennium development goals

Introduction

First time in the human history, a record was set when global concentration of carbon dioxide (CO_2) measured at Mauna Lao lab crossed 400 parts per million (ppm) in May 2013 (National Geographic 2013). The rise in CO_2 levels is a result of an increase in anthropogenic greenhouse gas emissions (GHG) leading to increase in the global mean temperature. Climate change projections for 2100 suggest a best estimate of global average surface temperature to rise by 4 ºC (IPCC 2007). A 4 °C rise could be potentially devastating leading to inundation of coastal areas, increased intensity of tropical cyclones; unprecedented heat waves, exacerbated water scarcity; increasing risks for food production potentially leading to higher malnutrition rates; and irreversible loss of biodiversity (The World Bank 2012). Even if efforts are made to cap and mitigate the GHGs today, air and sea temperatures will continue to rise as a result of past emissions. Thus, mitigation efforts alone will not work; adaptation is also needed in order to tackle increasing impact of climate change.

Surrounded by Himalayas, with a coastline of 7,500 km and 70 million hectares of forest, India is one among 17 mega biodiverse countries in the world which is exposed to climate change on multiple grounds. No country in the world is as vulnerable on so many dimensions to climate change as India (INCCA 2010). Disasters caused due to increasing extreme events like the recent Uttarakhand floods in June 2013 left thousands dead while severely damaging the infrastructure illustrate super imposing effect of an extreme weather event accompanied by poor mitigation, adaptation, and disaster management practices. Depending on the level of preparation by local and national institutions to manage the hazard, an extreme event can turn into a disaster; thus, socioeconomic systems play a vital role in regulating climate change impacts.

India has nine densely populated coastal states comprising of 20 % of the entire population (INCCA 2010) with livelihood dependence on agriculture, fisheries, mining, petrochemical and other industries, ports, and various tourism centers. Increasing population and subsequent land use changes have led to environment degradation, biodiversity, and freshwater stresses which would increase many folds due to climate change.

Literature review in Indian context suggests that there are no estimates available of impact of climate change on coastal agriculture and fisheries and therefore on agricultural, pastoral, and fishing communities which are expected to be significant (Revi 2008).

This study attempts to address research gap mentioned above by studying vulnerabilities of coastal rural communities while addressing following research question:

- What national and state development plans and policies are appropriate for more adaptation friendly path in order to overcome the current vulnerabilities and whether they need to be leveraged to address future climate change?

In spite of planned development path, the development challenges in India are quite high with 29.8 % of population still living below poverty line (BPL) (Planning Commission of India 2012). With weak implementation of planned development, India is yet to curb the inequitable share of resources. Climate change is likely to exacerbate these inequalities in turn increasing their vulnerability, but if development goals are systematically considered and implemented by linking them with adaptation options, enormous cost reductions can be achieved while trying to address development and climate change challenges.

The complete research comprised of three stages: (1) identifying the problem (vulnerabilities), (2) exploring applicability of existing development policies and evolve inclusive adaptation options, and (3) reducing vulnerability by choosing adaptation options.

Support tools used for methodology to derive climate change adaptation options for this research are depicted in Table 1.

The Need to Rethink Our Current Approach

Humans over their evolution have been coping and adapting ex post to climatic variations. A new approach suggests adaptation measures ex ante by incorporating future climate risk into policy making. Integrating adaptation into development projects is an iterative process of incorporating considerations of climate change into policy making, budgeting, implementation, and monitoring processes at

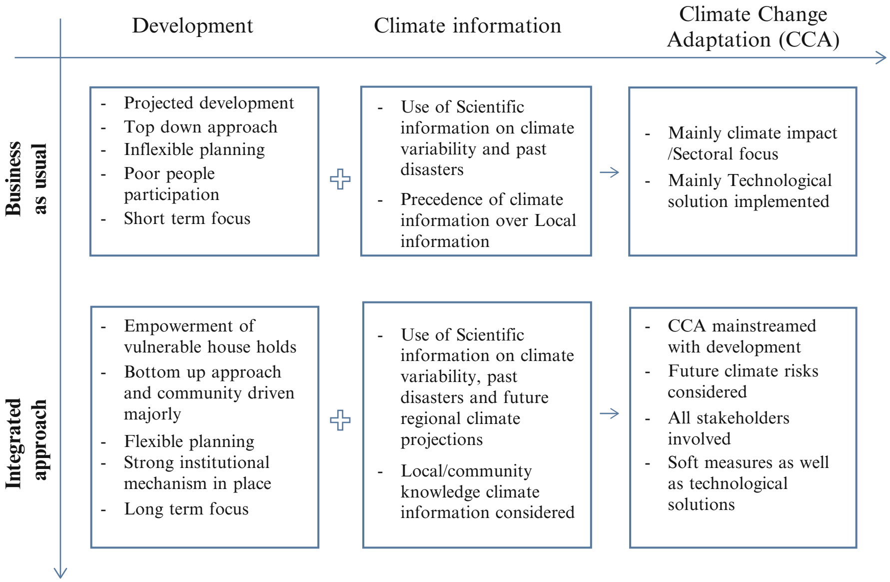

Fig. 1 Integrated approach for climate change adaptation (Source: Adapted from Faulkner (2012))

national, sectoral, and subnational levels which entails working with a range of government and nongovernmental actors (UNDP-UNEP 2011). Figure 1 depicts comparison of business as usual development approach to an integrated approach which addresses development and climate change adaptation issues.

For developing countries, where there is lack of basic infrastructure especially in the rural areas, increasing evidences of climate change impacts will increase the adaptation deficit unless adaptation program is incorporated into development initiatives. Such development projects would help build readiness in times of crises in context of proper shelter; food, water, and agriculture security; and livestock protection to the target population so as to ensure increased adaptive capacity and reduced impacts of climate hazards. Without focus on adaptation, climate change impacts would erode development gains and deepen the development divide between geographical regions (developed and developing) and sections of society which are marginalized, poor.

In order to reduce vulnerability, efforts need to be made in the direction of good policies at national and state level to be relayed into local-level action facilitated by the local actor (CARE International, July 2010). Figure 2 suggests a joint effort of public – civic and private – institutions for implementation and governance of adaptation measures needed to facilitate adaptation efforts.

For India to achieve its National Development Goals and the Millennium Development Goals (MDGs), development with climate change lens incorporating adaptation measures is a must.

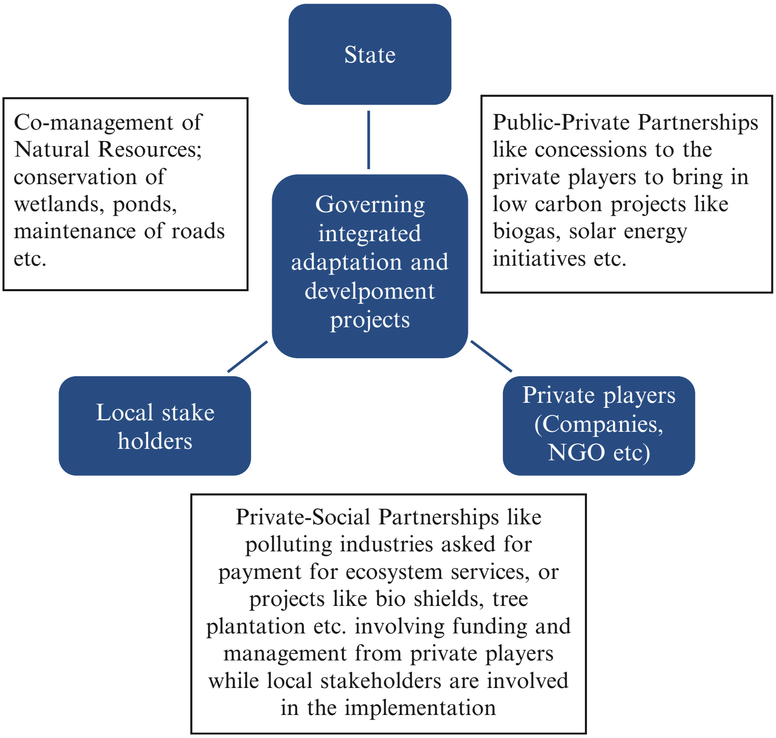

Fig. 2 Institutional arrangement for integrated adaptation action (Source: Adapted from Wreford et al. (2010))

Case Studies

Jamnagar district[1] lies between 21° 47′ and 22° 57′ north latitude and 68° 57′ and 70° 37′ west longitude in the state of Gujarat. It has a coastline of 355 km which accounts to 20 % of Gujarat's coastline with 3 coastal talukas.[2] Due to the presence of wetlands and bird sanctuary of Khijadiya, corals and Marine National Park (MNP) make Jamnagar taluka environmentally significant. Industrially, it has petrochemical special economic zones (SEZ) and many salt pan units; major brass part works along with two ports and two fishing centers. Socially also due to the presence of highest marginalized population with respect to other talukas in the district according to Census of India 2001, Jamnagar taluka was chosen for study. Four out of twelve coastal villages falling within 0–5 km from coast were chosen to understand the vulnerability of the coastal rural communities.

[1]District: administrative division within a state managed by local government

[2]Taluka: a smaller administrative division within district

They are unique in selection and are a representation of a class of such villages which have fishing/agriculture/mining or ecosystem dominance. Village demographics is presented in Table 2 and Fig. 3.

In order to understand the current vulnerabilities of these villages' to climate change, various questions were sought under vulnerability assessment, viz., what were the major impacts of past disasters, which group of population is most vulnerable to these disasters and why? What is the adaptive capacity of these villages and what measures needs to be developed such that adaptive capacity helps in reducing vulnerability and thus adapt to the changing climate, what barriers are there to the implementation of these measures? Reducing vulnerability thus becomes basis of adapting against climate change.

Next section briefly explains how vulnerability assessment was done for the study villages.

Climate Change Vulnerability Assessment Framework Used

Three factors, viz., extent of exposure to climate change, vulnerability of the region/community to climate change, and adaptation measures carried out, will define how regions and sectors will be impacted by future climate change (IPCC 2001).

Vulnerability assessment involves analysis of current exposure to climate shocks and stresses and model-based analysis of future climate impacts on basis of which adaptation strategies can be made. There are many conceptual frameworks to conduct vulnerability assessment, but many focus on any one stressor like drought, earthquakes, or tsunamis; multi-stressor vulnerability assessments while more difficult are slowly emerging (Adger et al. 2007). A thorough vulnerability assessment can be complex and intensively dependent on data.

Data and Methods

A vulnerability assessment framework as suggested by Hemani (2013) is a bottom-up approach which focuses on temporal reference as current, with vulnerable system as coastal villages, and the valued attribute as livelihood security and human well-being. It suggests how regional downscaled climate data can be integrated with the social vulnerability assessment and environment vulnerability to make overall vulnerability of the study region.

Climate information is one of the several factors that are needed to be taken into account in decision making. It also requires understanding of how regional scale climate variability leads to local manifestations and sectoral consequences.

In this study physical vulnerability consisted of scientific analysis of climate data of temperature and rainfall along with past trends of droughts, storms, and SLR based on secondary data.

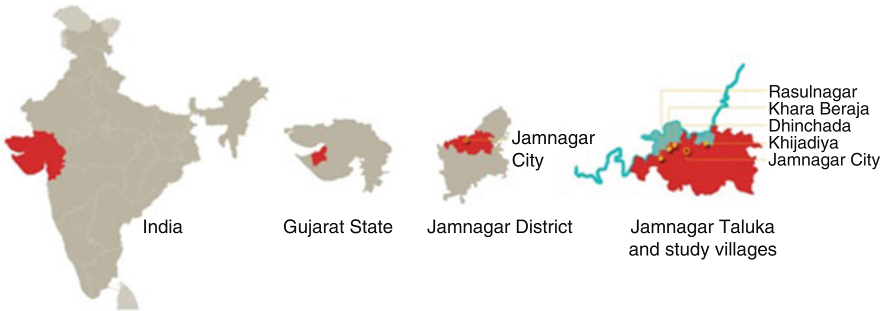

Fig. 3 Maps showing location of case study villages

10-year moving average analysis of 40 years temperature data from 1960 to 2009 of Jamnagar weather station reveals an increase in mean surface temperature by 0.72 ºC. Numbers of heat waves have increased and the winter has shortened. While future temperature projections for 30-year period between 2070 and 2100 were analyzed by Taru (2010), using downscaled regional model (PRECIS) (developed by Hadley Research Center in collaboration with Indian Institute of Tropical Meteorology) for Emission scenarios A2 and B2 suggests that average annual minimum temperature may increase by 3.7 ºC and 2.7 ºC as per the A2 and B2 scenario, respectively. Increasing trend of temperature and future projections indicate a high level of vulnerability.

For rainfall, 30-year moving average analysis for Jamnagar weather station from 1901 to 2011 for monsoon months (June to August) suggests that there is a steady increase of 0.66 cm per year in the rainfall over the 11 decades on an average. While future climate change projections for rainfall study done by Taru (2010) suggest that there would be moderate increase in rainfall, increase in number of dry spells with increase in extreme precipitation single-day events exceeding 100 mm reaching 14 each in A2 and B2 scenario between 2070 and 2100 for Jamnagar district. Decreasing number of wet days and increasing rainfall trends and future projections indicate high level of vulnerability. A detailed analysis covered by Hemani (2013) categorizes level of physical vulnerability into high, medium, and low for various climate variables like temperature, rainfall, sea level rise, cyclones, and storm surges based on the past trends and the future climate projections by Taru (2010).

Environment vulnerability of villages was made based on the presence of biodiversity, the characteristics of geology of that area, and availability and quality of water sources. A detailed analysis covered by Hemani (2013) categorizes environment vulnerability into high, medium, and low level depending on the deviation of the indicator value from the designated standards which were obtained from secondary data sources available at Gujarat Ecology Commission (GEC), MNP, etc.

Social vulnerability assessment used primary data obtained through different tools like FGD, transect walks, personal interviews, and key informant interviews. LVI-IPCC (Livelihood Vulnerability index) Indexing method as suggested by (Hahn et al. 2009) was found most appropriate and was applied for the assessment. Indicators chosen were based on extensive literature review and were categorized according to IPCC definition of vulnerability into those that define exposure, sensitivity, and adaptive capacity. While some indicators were based on Hahn et al. (2009), Mohan and Sinha (2011), and Vincent (2004), others were created due to necessity based on the field observations. Most of the indicator values were derived from the field surveys while values for some were derived from secondary sources. Table 3 suggests the list of indicators and major components used for the social vulnerability assessment.

The outcome of the assessment is depicted in Figs. 4 and 5. Figure 4 suggests villages performance on each of the major components mentioned in Table 3. Vulnerability of each village ranged from −1 to +1 where −1 indicated least vulnerable and +1 indicated most vulnerable. Figure 5 suggests Rasulnagar being the most vulnerable and Dhinchada being least vulnerable of the four study villages.

Social vulnerability assessment helped ascertain the dimensions of current vulnerability and the underlying causes for the same. It also led to understanding as to how does community cope and adapt to it currently, who are the stakeholders.

An overall vulnerability profile for each village was made by combining physical, environment, and social vulnerability as depicted in Figs. 5 and 6 through, e.g., of Rasulnagar village (Fig. 7).

A full analysis and the corresponding charts of vulnerability are covered by Hemani (2013).

Main Findings from Vulnerability Assessment

Based on the overall vulnerability of all the study villages, the concerns of the fishing and nonfishing villages are consolidated and summarized in Table 4 below:

Table 3 Social vulnerability indicators

Major component	Indicators
Sociodemographic	Dependency ratio, sex ratio (inverse), % of household (HH) where head of the HH has not attended the school
Economic well-being	% of HH that borrow money, % of HH that live in semipermanent house, % of HH without vehicle, % of HH below poverty line, % of HH having at least one vehicle (inverse), access to information services (telephone connections – wireless, wireline, TV, radio) (inverse)
Livelihood	% of HH with family member working in different community, % of HH into agriculture/fishing, average agriculture/fishing livelihood diversification index
Health	Average time to health facility, % of HH with family member with chronic illness, % of HH with no sanitation facility
Food	% of HH dependent on family farm for food, average months the HH store food, % of HH that do not save seeds from each harvest, average crop diversity index
Water	% of HH reporting water conflict, % of HH that utilize natural water source, average time to water source, % of HH that do not have consistent water supply, average number of liters of water storage
Natural resource dependence for fuel wood needs	% of HH dependent on natural resources for fuel wood
Institutional stability and strength of public infrastructure	Presence of unmetaled road, % of HH that travel out for medical treatment
Biophysical	Distance from coast/river/reclamation bund, distance from the major city, un-irrigated area, salinity intrusion, presence of wetland
Natural disasters and climatic variability	Average no. of floods/droughts/cyclones events faced in the past, % of HH that did not receive warning about pending natural disaster, % of HH that reported death or injury of family member of past natural disasters, mean maximum and minimum monthly average deviation temperature by year, and average deviation of monthly rainfall of rainy season

Source: Hemani (2013)

While the findings of the assessment suggests, it is the poor who are disproportionately affected, few crosscutting issues which add to the vulnerability across all strata and across all the study villages were categorized into following on basis of which adaptation goals were created:

Institutional barriers consisting of lack of:

– Institution setup like primary healthcare centers, banking facilities/credit societies
– Infrastructure like metaled roads, piped and dependable water supply, drainage network, conveyance facilities, and sanitation facilities
– Solid waste management
– Communication facilities like that of weather forecast systems

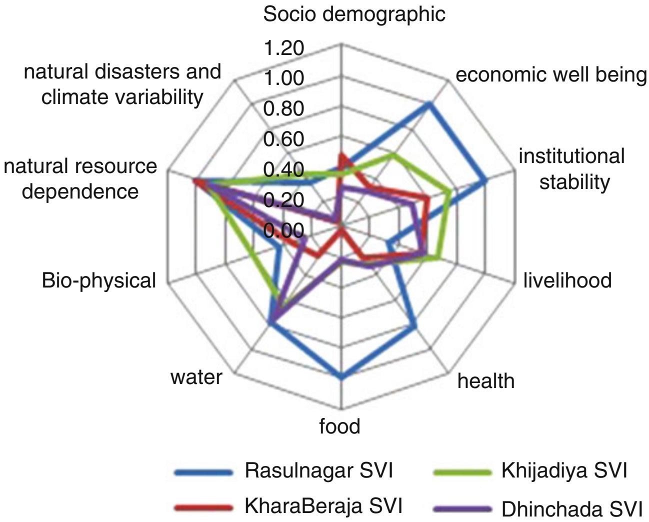

Fig. 4 Highlighting major component issues of study villages (Source: Hemani (2013))

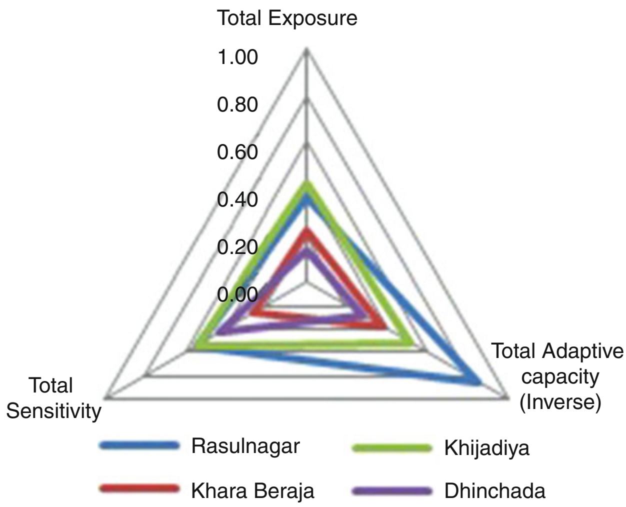

Fig. 5 Vulnerability of study villages (Source: Hemani (2013))

Financial barriers:

– Lack of funding

Technical barriers consisting of lack of:

– Education level and hence lack of alternative livelihoods
– Awareness on climate change and its impacts

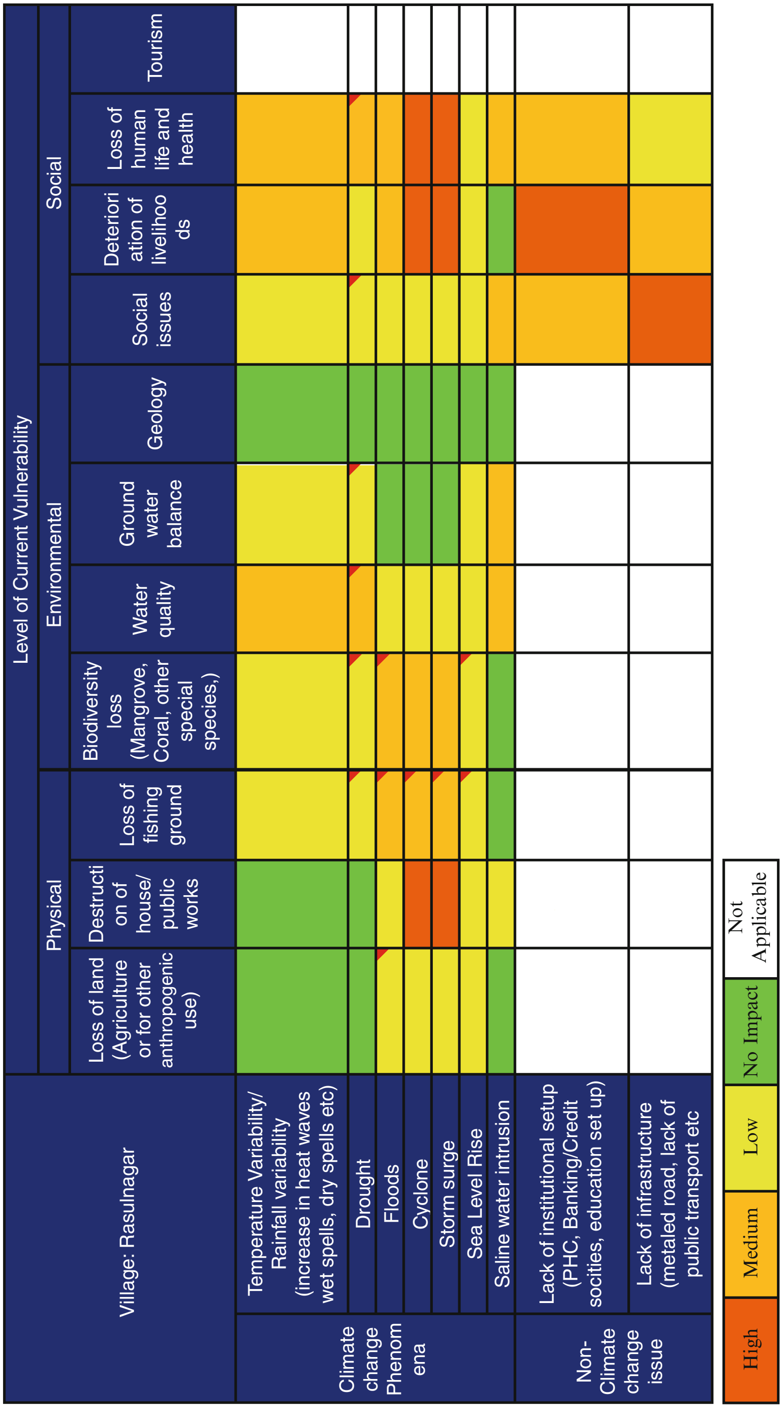

Fig. 6 Current vulnerability (Source: Hemani (2013))

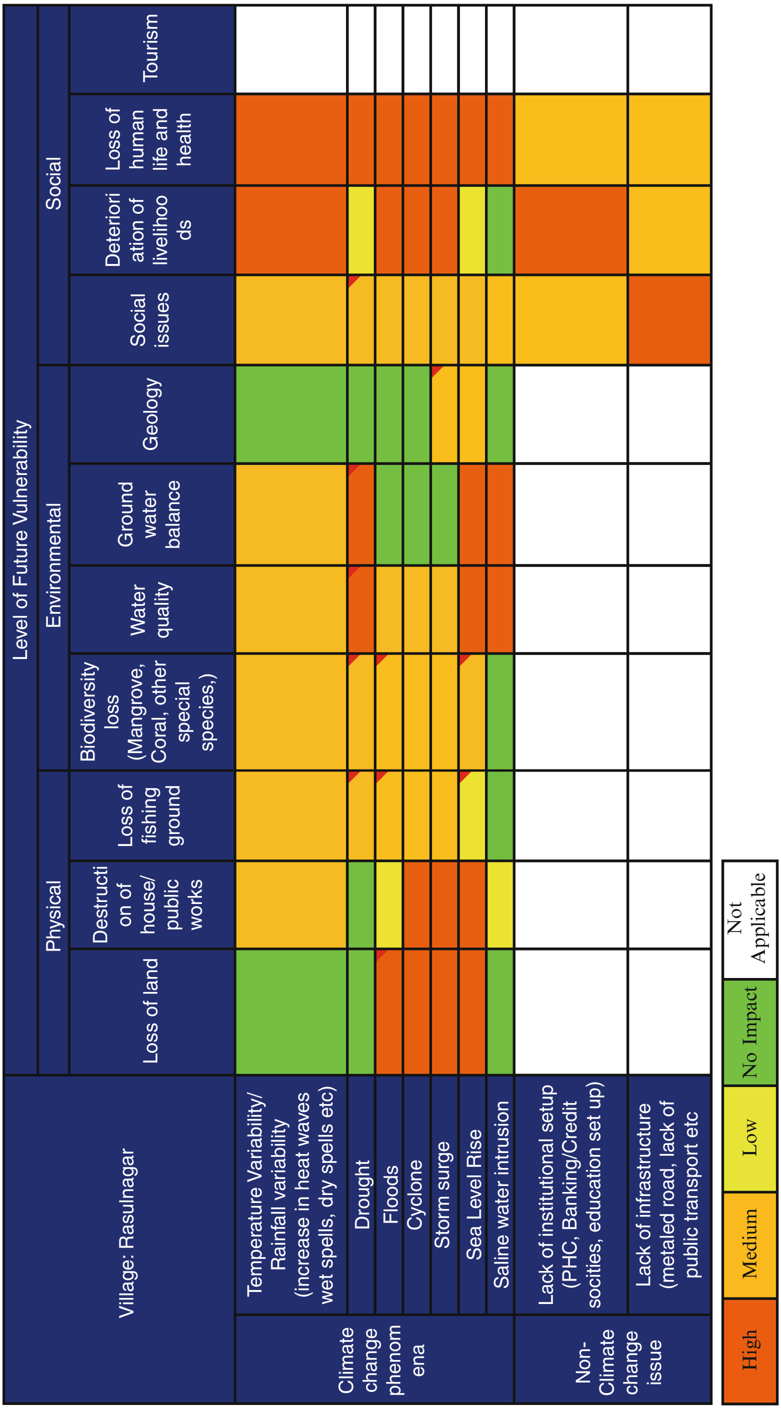

Fig. 7 Future vulnerability (Source: Hemani (2013))

Table 4 Vulnerability assessment findings

Aspect of vulnerability	Impacts	Agricultural/mining village concerns	Fishing village concerns
Physical	Loss of land	Future climate event concerns leading to loss of land due to floods, SLR, etc.	
	Destruction of house and public works	Lack of proper infrastructure, lack of adaptive capacity	
	Loss of fishing ground		Climatic concerns, wrong fishing practices, chemical industry presence, leading to loss of livelihood
Environmental	Loss of biodiversity/ wetland	Lack of awareness of the importance of biodiversity, climate change leading to loss of biodiversity	
	Change in water quality	Over extraction practices leading to salinity ingress, future climate change concern	Lack of proper infrastructure for freshwater resources
	Change in ground water balance	Over extraction practices and minimal ground water recharge, future climate change concern	
	Change in geology	Future SLR, salinity intrusion in agriculture driven villages, mining basalt trap rocks in mining villages will change the geology and make them more vulnerable	SLR will lead to inundation
Social	Increase in social issues	Lack of education and women empowerment, inequality	
	Deterioration of livelihoods	Loss of land due to salinity ingress leading to deterioration of livelihood, alternate source of livelihood needed	Presence of chemical industry, port activities affecting fishing, and hence deterioration of livelihood. Future climatic changes
	Loss of human life and health	Lack of medical facilities, lack emergency warning systems	
	Loss of tourism	Lack of awareness of value of wetlands, birds, and other important species at Khijadiya sanctuary	Lack of awareness of corals, sea grasses, dugongs, and other important species at MNP

Source: Hemani (2013)

Social and cultural barriers consisting of lack of:

– Women empowerment
– People ownership
– Villager's willingness to learn, change bad fishing and agricultural practices
– Alternate to dependence on biomass for fuel wood needs

Such vulnerability assessment provides a base for identifying areas of concern and points of intervention by estimating the likelihood of future climate change and its impacts along with the socioeconomic and environment conditions in future. Current climate variability always becomes starting point of adaptation at the local level.

To address each area of concern, adaptation plan consisting of goals with various adaptation options for each goal with time frames, barriers in achieving these measures, co-benefits, and key stakeholders were created.

Thus, six adaptation goals which would increase livelihood security and human well-being were:

1. Creating public awareness about climate change, disaster prevention response: helps in capacity building
2. Provide safe and consistent drinking water and water for other (domestic, agriculture) needs: helps in adapting against decreased water availability
3. Provide diversified livelihoods and aid in livelihood sustenance: helps in improvement of livelihoods
4. Improvement of built environment: helps in strengthening and building infrastructure
5. Human safety and enhanced human safety: helps in adapting against health impediments
6. Functioning of healthy coastal ecosystem: helps cater to enhancing and conserving of coastal ecosystem

Since current vulnerability is majorly due to lack of development, it would be implementation of development plans which by default become the entry points for mainstreaming climate change adaptation. Next section brings an understanding of the mechanisms of governmental, institutional, and political efforts which can be contextualized and leveraged to define pro-poor adaptation outcomes while addressing developmental goals.

Lowering Vulnerability Through Linking of Development Initiatives to Climate Change Approach

In order to curb impacts of global climate change, effort needs to be made from global to local level as shown in Fig. 8. It also shows link between global, national, and state development goals with global, National, and State Action Plans for Climate Change (NAPCC and SAPCC).

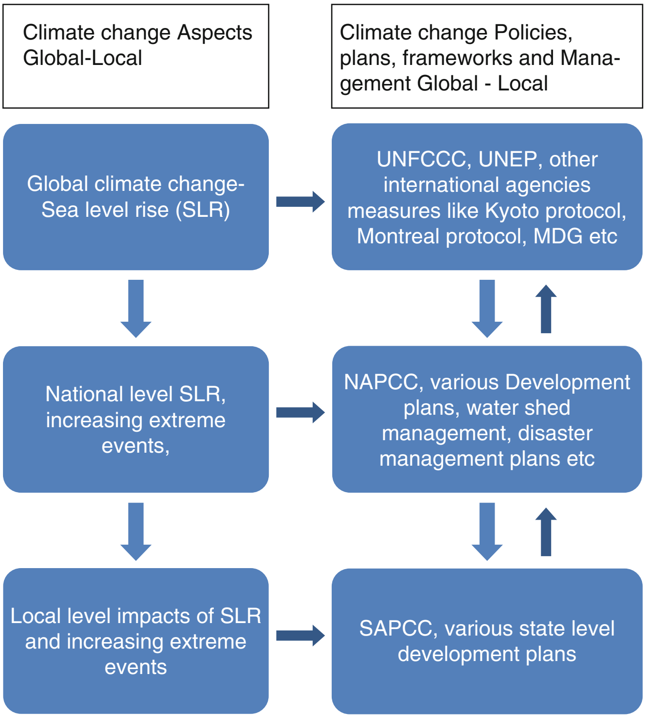

Fig. 8 Institutional arrangement for addressing climate change global to local

To address the research question with the purpose of mainstreaming climate change, six adaptation goals identified for the study area were linked to four MDG and various development goals at national and state level to address their current vulnerabilities (Table 5).

To execute this step, against each adaptation goal, relevant national and state development scheme were judged for its applicability to cater to current vulnerability, its relevance to adaptation efforts, and whether there is a need to enhance that scheme to cater to future climate vulnerability. Table 6 shows link between existing development plans to climate change adaptation.

Adaptation Strategy

Once the current concerns were identified, the remaining part of the strategy involved creating adaptation plan by leveraging development plans to cater to identified issues. The adaptation plan was based on identification and prioritizing of the adaptation options.

This stage involves contribution of the stakeholders, keeping in mind the needs of the most vulnerable groups. Implementation of the identified adaptation measure should be based on the prioritization of the adaptation options. Stakeholder review

Table 5 Linking MDG to development goals

Millennium development goals	Various development plans national level	Various development plans state level	Linked to which adaptation goals of this study
MDG 1: Eradicate extreme poverty and hunger	• Mahatma Gandhi National Rural Employment Guarantee Act (MGNREGA) • National rural livelihood mission • Indira housing scheme	Sardar Patel housing scheme	Goal 3. Provide diversified livelihoods and aid in livelihood sustenance
MDG 2: Achieving universal education	• Universal Elementary Education (UEE) • Mid-day meal scheme		Goal 3: Provide diversified livelihoods and aid in livelihood sustenance
MDG 3: Promote gender equality and empower women	• Targeted provision for girls under UEE • Kasturba Gandhi Balika Vidyalaya (resident girl child school) scheme • Balika Samriddhi scheme (girl child development scheme)	Women self-help group (SHG) scheme	Goal 3: Provide diversified livelihoods and aid in livelihood sustenance
MDG 7: Ensuring environment sustainability	• National Rural Drinking Water Program (NRDWP) • Green India mission under NAPCC • Total Sanitation Campaign (TSC) • Nirmal Gram Puraskar to boost TSC (award for village leading TSC) • IWMP (integrated water management) program • ICZMP (Integrated Coastal Zone Management Program) • National Solar Mission under NAPCC • Social forestry • Prime minister village road scheme • SIPC (salinity ingress prevention cell) •MGNREGA	• Gokul gram scheme (village development scheme) • Nirmal Gujarat scheme (clean and healthy village scheme) • Panchavati scheme (Village Greening scheme) • Jamin Sampadani scheme (village development scheme) • Gram Mitra scheme (friends of village scheme)	• Goal 2: Provide safe and consistent drinking water and water for other (domestic, agriculture) needs • Goal 4: Improvement of built environment • Goal 5: Human safety and enhanced human safety • Goal 6: Functioning of healthy coastal ecosystem

Table 6 Linking national and state development goals to adaptation goals

Component: Goal	Policy/project	Policy brief	National/state driven	Target group	Relevance and applicability w.r.t climate change adaptation (CCA)	Rationale	Policy updation needed w.r.t CCA?
Creating public awareness about climate change, disaster prevention response	Friend of village scheme	It appoints individuals in the village who educate villagers on various development schemes. Each appointee would deal in the area of agriculture, education, health, development, and human welfare, respectively	State driven	Rural community	High	Awareness is the first step towards change	Yes, keeping in view future climate changes, appointed staff can be trained to train the villagers to increase the awareness and need of community and individual-level participation to increase their adaptive capacity

(*continued*)

Table 6 (continued)

Component: Goal	Policy/project	Policy brief	National/state driven	Target group	Relevance and applicability w.r.t climate change adaptation (CCA)	Rationale	Policy updation needed w.r.t CCA?
Water: provide safe and consistent drinking water and water for other (domestic, agriculture) needs	National rural drinking water program	Aims to provide every rural person with adequate safe water for drinking, cooking, and other domestic basic needs on a sustainable basis	Center driven, partial funding, state into partial funding and implementation	Rural community	High	To ensure the 40 l/capita/day water for rural population needs even in the face of climate variability and make provision for alternate source of potable water	Yes, to ensure the fulfillment of sustained water needs in face of climate change and variability
	Integrated watershed management program	Aims to restore ecological balance by harnessing, conserving, and developing degraded natural resources such as soil, vegetative cover, and water	Center driven and funded, state implementation	All community	High	Climate variability is affecting the drought-prone areas with reduced forest cover, reducing water table, and a shortage of drinking water, fuel, and fodder IWMP caters to these needs	Yes, to ensure soil and water conservation in case of future climate change

	MGNREGA	Aims at enhancing the livelihood security of people in rural areas by guaranteeing 100 days of wage employment in a financial year to a rural household whose adult members volunteer to do unskilled manual work	Center driven, partial funding, state: partial funding and implementation	Rural community	High	Along with livelihood security, it also provides environment protection, hence enhancing adaptive capacity and reducing vulnerability	Yes, already guidelines are there to converge MGNREGA and IWMP program and agriculture program
	Salinity ingress prevention and control scheme	Due to salinity ingress in the underground water, suggested construction of tidal regulators and weirs near the ocean bank, refilling lakes, refilling reservoirs, check dams, and spreading channel, etc., near the inside land area coastal Gujarat state	Center funded	Coastal communities	High	Efforts are such that it prevents salinity from spreading further	Yes, keeping in view the consequences of future climate change of (SLR and coastal inundation)

(*continued*)

Table 6 (continued)

Component: Goal	Policy/project	Policy brief	National/state driven	Target group	Relevance and applicability w.r.t climate change adaptation (CCA)	Rationale	Policy updation needed w.r.t CCA?
Livelihood: provide diversified livelihoods and aid in livelihood sustenance	Universal education for all	Free primary education for children	Center driven, state implementation	All children	Medium	Increasing the education level may bring other opportunities of employment rather than just natural resource-dependent employments	–
	MGNREGA	As mentioned previously					
	Women SHG scheme	To enable the poor women, particularly in rural areas of Gujarat to improve their access to resources and strengthen livelihoods and quality of life	State driven	Rural community	Medium	Women empowerment can lead to better decision making and alter source of income and hence increasing adaptive capacity of the household	–

	National rural livelihood mission	Aims to reduce poverty among rural BPL by promoting diversified and gainful self-employment and wage employment opportunities which would lead to an appreciable increase in income on sustainable basis	Center driven, state implementation	Rural – BPL	High	May bring other opportunities of employment rather than just natural resource-dependent employments	–
Infrastructure and institutional setup: improvement of built environment	MGNREGA	As mentioned previously					
	Jamin Sampadani scheme	In order to increase standard of rural life, structural facilities, viz., drinking water, sewerage, street lighting electricity in house internal roads, and approach roads, should be included under the scheme	State driven	Rural community	Medium	It provides basic amenities, hence increasing adaptive capacity	Yes, can enhance keeping in mind climate lens. Sewerage network must be developed keeping in mind the extreme rainfall and runoff

(*continued*)

Table 6 (continued)

Component: Goal	Policy/project	Policy brief	National/state driven	Target group	Relevance and applicability w.r.t climate change adaptation (CCA)	Rationale	Policy updation needed w.r.t CCA?
	Prime minister village roads scheme	To provide connectivity, by way of an all-weather road, to the eligible unconnected habitations in the rural areas with a population of 500 persons and above in plain areas	Center driven, partial funding, state into partial funding and implementation	Rural community	Medium	Internal village roads are temporary, while main road is still tar road and connected to highway	–
	Total sanitation campaign	It is a comprehensive program to ensure sanitation facilities in rural areas with broader goal to eradicate the practice of open defecation	Center driven, partial funding, state into partial funding and implementation	Rural community	Medium	Increasing frequency of floods in the future would increase water-borne diseases, reach to poor community toilets or at household remains	–

	Gokul Gram Scheme	For overall development and fulfilling basic amenities of the villages	State driven	Rural community	Medium	Helps building the infrastructure, reduces vulnerability	–
	Clean village, healthy village scheme	Financial assistance given for clean village	State driven	Rural community	Medium	Flooding of areas, unpicked and untreated solid waste increase diseases, affects health	–
	Indira Gandhi housing scheme/ (Sardar Patel Housing Scheme)*	Provides assistance to BPL who are either houseless or have inadequate housing facilities for constructing a safe and durable shelter for environmentally sound habitat with adequate provisions	Center policy making and partial funding, state into partial funding and implementation/ (state funded)*	Rural – BPL	High	Poor and marginalized households are more vulnerable as their houses are majorly built on temporary structures as they lack monetary support	Yes, keeping in mind the extreme events, location of the houses, and construction of the houses should be revised which will depend on the state- and village-specific development plans

(*continued*)

Table 6 (continued)

Component: Goal	Policy/project	Policy brief	National/state driven	Target group	Relevance and applicability w.r.t climate change adaptation (CCA)	Rationale	Policy updation needed w.r.t CCA?
	Panchavati scheme	Aims at the welfare of rural people to develop parks in the village with necessary facilities. Trees can be suggested by villagers and may also be grown in wasteland near the village	State driven	Rural community	High	Increase in green cover can lead to co-benefit of mitigation along with adaptation. Horticulture trees can reap monetary benefit to the community along with increase in water table	–
Natural resource dependence: functioning of healthy coastal ecosystem	Social forestry	Aims to take off pressure from existing forests by planting trees on all unused and fallow land, thus helping in social, rural development, and environment protection	Central Ministry driven	All population	High	-do-	–

	NAPCC: Solar mission	Promotes ecologically sustainable growth while addressing India's energy security challenge by introducing solar renewable energy	Central Ministry driven	All population	High	Leads to energy-efficient economic development having co-benefit of adaptation and mitigation	–
	Integrated Coastal Zone Management Program	Promotes (1) coastal resource conservation and management, (2) monitoring, (3) socioeconomic development, (4) geo-spatial mapping for scientific database	Central Ministry driven	Initiated for states of Gujarat, Orissa, and West Bengal later for all remaining 6 coastal states	High	Contribute towards increased understanding and acceptance of the need to protect, conserve, and regenerate coastal natural resources by local rural communities	Yes, revision of the hazard mapping and shoreline protection measures keeping in view the future extreme events

and prioritization of the options was not done in this case as this was a part of academic research work, but it is a must for live projects.

Identifying Adaptation Options

In this research emphasis was on identifying interventions from the existing development plans and policies. This step was author initiated, but in live projects, it involves finding feasibility of implementation of the measure, evaluation of estimated benefit, and cost from the measure along with stakeholder consultation involving government officials, local community groups, and experts from the field. This would also create awareness about the views of different stakeholders, promote dialogue, and create collective interpretation and ownership of suggested modifications. It needs to be documented.

Table 7 consists of list of adaptation options. Under each adaptation goals, various adaptation measures are listed.

Prioritizing and Selecting Adaptation Options

For prioritizing adaptation options, various tools like cost-benefit analysis, cost-effectiveness analysis, expert judgment, multi-criteria analysis can be used. When quantification and valuation of adaptation options is not possible in monetary terms such as the benefits of preserving biodiversity, MCA is used for prioritizing options (OECD 2009).

This research uses MCA for prioritizing options. Here weightage is given to each of the parameter from 0 to 1 depending on flexibility, potential cost, and ease of execution. An overall score of each action is obtained through summation of the weightage to each parameter, and the options with the highest scores are prioritized accordingly where there are multiple competing criteria (UNFCCC 2011).

Some of the parameters used in this study helped determine the assessment of adaptation options for prioritizing them including:

- Economy-wide impacts: Many impacts are influenced by global market events in response to climate change.
- Hard as opposed to soft adaptation options: Hard including technical/engineering options and soft options including those dealing with behavior change, policies, and instruments.
- Ancillary benefits: Along with the reduction of damages caused by current climate variability, they also bring in other ancillary benefits like job creation, net benefits to the economy through energy or water efficiency, etc.
- Public as opposed to private adaptation: It is important to recognize that individuals will respond to future climate variability, and their response will depend on the public actions that are taken.
- Adaptation-mitigation linkages: Adaptation actions that have consequences for mitigation. For example, improving green cover can bring in reduced CO_2, reducing heat stress, improving health, as well as improving ground water table.

Refer Table 7 for the MCA.

Table 7 Adaptation options and MCA

Major component	Adaptation options for noted issues	Hard (0.25)/ soft option (1)	Economy wide impact (changes with global (0.25)/ national (0.5) and local economy/ none (1)	Public (hard −0.25, soft – 0.5)/private (0.5)/Public Private Partnership (1)	Adaptation – mitigation linkages 1/0 if none)	Ancillary benefits (1/0 if none)	Total score (out of 5	Ranking options
Sociodemographic	Training and raising public awareness on what is climate change and for active adaptation to disasters and climate change impacts	1	1	1	1	1	5	1
	Making a climate change committee and maintaining a climate change register and impacts on various sectors like health, agriculture, biodiversity, etc., for each village	1	1	1	1	1	5	1
Water	Training on climate change and water variability and the need to conserve water especially to farmers	1	1	1	1	1	5	1
	Training for optimum use of water, water conservation techniques demonstration, and improving agricultural practices under Gram Mitra scheme	1	1	1	1	1	5	1

(*continued*)

Table 7 (continued)

Major component	Adaptation options for noted issues	Hard (0.25)/ soft option (1)	Economy wide impact (changes with global (0.25)/ national (0.5) and local economy/ none (1)	Public (hard −0.25, soft – 0.5)/private (0.5)/Public Private Partnership (1)	Adaptation – mitigation linkages 1/0 if none)	Ancillary benefits (1/0 if none)	Total score (out of 5	Ranking options
	Provision of tap water in 90:10 partnership with villages	1	1	0.5	0	1	3.5	5
	Existing ongoing SIPC works	0.25	1	0.25	1	1	3.5	5
	Building of community rain water harvesting tanks to store rain water	0.25	1	1	1	1	4.25	3
	Building of conservation ponds and recharge wells under MGNREGA scheme	0.25	1	1	1	1	4.25	3
Livelihoods	Creation of microfinance banking facilities	0.25	0.5	0.5	0	1	2.25	9
	Awareness camps for benefits of education/ teaching under CSR (corporate social responsibility)	1	1	1	1	1	5	1

	Training for use of optimum fertilizers, switching to organic farming, and growing indigenous grains	1	1	1	1	1	5	1
	Shifting to drought resistant variety of grains	0.25	0.5	0.5	1	1	3.25	6
	Training and awareness among villagers on usage of proper net and about fish catch season	1	1	1	1	1	5	1
Infrastructure	Build pucca roads under MGNREGA, Jamin Sampadani scheme, prime minister village road scheme	0.25	1	1	0	1	3.25	6
	Provision of bins for waste segregation	1	1	0.5	0	1	3.5	5
	Clean village competition among villages	1	1	0.5	0	1	3.5	5
	Provision of storm water drain network*	0.25	0.5	0.25	1	1	3	7
	Channelizing storm water to ponds for recharging*	0.25	0.5	0.25	1	1	3	7
	Building Sanitation	0.25	1	1	0	1	3.25	6
Health and communication	Health camps	1	1	1	0	1	4	4
	Private visiting doctors	1	1	1	0	1	4	4
	Infrastructure setup for PHC (can turn out to be long term)	0.25	1	1	0	1	3.25	6

	Training and awareness among villagers of importance of biodiversity	1	1	1	1	1	5	1
	Vigilance and recording of species loss if any	1	1	0.5	1	1	4.5	2
	Plantation activity by the green committee already in the village formed under ICZMP	1	1	1	1	1	5	1
	Payment in terms of environment taxes for ecosystem services by the industries	1	1	1	1	1	5	1

*Info. from data collected by Village head in 2011

Adaptation Plan

Finally an adaptation plan was created for the study region as enlisted in Table 8. For each adaptation measure suggested enlists a time frame by when they should be implemented, who would be the stakeholders, what are the constraints, which existing developmental plan or policy that targets similar concern, and what are the co-benefit if it exists (whether the adaptation measure can be also linked to mitigation action) and the category of the measure (whether the adaptation measure category is of no regret, low regret, or climate justified).

Literature review suggests “no regret” adaptation measures as those which provide net benefits regardless of climate change. “Low regrets” measures as the ones where moderate levels of investment increase capacity to cope with future climate risks (UNDP-UNEP 2011) while “climate justified” measures as the ones which depend on projections of changes in climate to justify their benefits (OECD 2009). It is important to know the level of regret as it suggests different implications with respect to climate information, timing of investment, planning horizon, and economic evaluation (UNDP-UNEP 2011) and also suggests which measure can be taken up easily and first.

Adaptation measures suggested here either deal with asset upkeep, protection needed during a natural disaster like bio shields, etc., and asset building like salinity ingress prevention canals needed to withstand projected long-term gradual climate changes along with some measures like training leading to awareness and behavioral changes and investment into early warning system which are important for enhancing livelihood resilience. Financial resources like credit or insurance are vital for recovery and long-term adaptation (CARE International, July 2010).

Some Practical Challenges

Such studies are always bound with some practical challenges which would need local intervention, some of which would be common for developing countries in general are enlisted here.

While social vulnerability assessment is indicator based, complex social interactions may be difficult to be factored in the form of indicators and hence may get left out in the overall vulnerability assessment.

Political and social will for adoption of development initiatives which also enhance climate change adaptation is a challenge. Appropriate intervention by stakeholders is needed.

Moreover, climate change and variability will bring various issues which have cross-sectoral impacts; hence, a need for alliance between various sectoral departments while comprehensively designing the adaptation options with multi-stakeholders needs to be taken up which is generally found lacking.

Also future adaptation measures are sought by projecting future vulnerability that is based on future scenarios of climate change, socioeconomic, and environment conditions. It can only be validated once the future climate event occurs and the other socioeconomic and environment conditions then.

Table 8 Adaptation plan

Major component	Issues	Short-term measure (1 to 5 years) action plan (2013–2017)	Time frame	Stakeholder	Medium-term measure (5 to 10 years) long term (10 to 20 years)	Stakeholder	Existing policy/ program which is/can be used	Constraints	Additional/ co-benefits	Adaption measure category (no regret/ low regret/ climate justified)
Adaptation goal (1) creating public awareness about climate change, disaster prevention response										
Sociodemographic	Lack of awareness on climate change and its impacts	1. Training and raising public awareness on what is climate change and for active adaptation to climate change impacts	2013 onwards on continuous basis	NGO, state climate change department, Gram Panchayat[a]	1. Upkeep of training sharing scientific information wrt sectors, status of issues	NGO, state climate change department, Gram Panchayat	Can be targeted under SAPCC	1. Lack of fund	1. Public support during the execution of other actions mentioned below and hence ease of execution	No regret
		2. Making a climate change committee and maintaining a climate change register and impacts on various sectors like health, agriculture, biodiversity, etc., for each village	2013		2. Discussion and revision of action plan[a]			2. Lack of willingness and acceptance to learn from villagers side	2. People ownership created for works done	
								3. Lack of quality staff and material to train in vernacular language		

(*continued*)

Table 8 (continued)

Major component	Issues	Short-term measure (1 to 5 years) action plan (2013–2017)	Time frame	Stakeholder	Medium-term measure (5 to 10 years) long term (10 to 20 years)	Stakeholder	Existing policy/ program which is/can be used	Constraints	Additional/ co-benefits	Adaption measure category (no regret/ low regret/ climate justified)
Adaptation goal (2) provide safe and consistent drinking water and water for other (domestic, agriculture) needs										
Water	Water quality and availability	1. Training on climate change and water variability, the need to conserve water especially for farmers	2013 onwards	NGO, state climate change department, Gram Panchayat	Upkeep of training sharing scientific information w.r.t sectors, status of issues	Gram Panchayat, villagers	Can be targeted under SAPCC	1. Funding 2. Willingness to take ownership among villagers		No regret
		1. Training for water conservation techniques demonstration and improving agricultural practices under Gram Mitra scheme	2013 onwards on continuous basis	State govt. Gram Panchayat, NGO local people	1. Maintenance and upkeep of ponds, regular desilting, repairing, etc. 2. Water pricing schemes 3. Compulsory use of drip irrigation in case of irrigated land			Willingness by farmers to change practices		No regret
		Provision of tap water in 90:10 partnership with villages	2013–2017	WASMO (Water and Sanitation Monitoring Organization), NGO, villagers, private	Upkeep and maintenance of piped water	Gram Panchayat, villagers operations and maintenance committee	NRDWP			No regret

				company owning land (in case of Khijadiya salt pan workers colony)						
		Existing ongoing SIP works	Ongoing –2017	Narmada water resources, water supply, and Kalpsar department	Incorporating climate resiliency features in the SIPC future and pending activities	High-level committee for salinity ingress study	SIPC	Cost, other logistical arrangement for SIP works	Benefit to farmers for irrigation	Climate justified
		1. Building of community rain water harvesting tanks to store rain water	2013–2015	NGO, state climate change department, Gram Panchayat	Upkeep of ponds and recharge wells	Gram Panchayat, villagers operations and maintenance (O&M) committee	MGNREGA	1. Funding	Increases the water recharge and availability of water sources	No regret
		2. Building of conservation ponds and recharge wells under MGNREGA scheme						2. willingness to take ownership among villagers		
								3. Gram Panchayat's willingness to take activities under MGNREGA		

(*continued*)

Table 8 (continued)

Major component	Issues	Short-term measure (1 to 5 years) action plan (2013–2017)	Time frame	Stakeholder	Medium-term measure (5 to 10 years) long term (10 to 20 years)	Stakeholder	Existing policy/ program which is/can be used	Constraints	Additional/ co-benefits	Adaption measure category (no regret/ low regret/ climate justified)
Adaptation goal (3) provide diversified livelihoods and aid in livelihood sustenance										
Livelihoods	Lack of credit societies (high level of interest rate to middle men esp. for Rasulnagar village)	Creation of microfinance banking facilities	2013–2015	Banks				Willingness by banks to set up small units		Low regret
	Lack of education level and lack of livelihood	1. Awareness camps for benefits of education	2013 onwards	State government, NGO	Introduction of vocational classes	NGO	UEE	1. Willingness to learn among villagers	Improved adaptive capacity with increased livelihood options on being educated	No regret
		2. Teaching under CSR activity	2014 onwards					2. Willingness among companies to come and teach		
	Lack of good agricultural practices	1.Training for use of optimum fertilizers, switching to organic farming, and growing	Various camps throughout 2013–2017	State government, National Bank for Agriculture and Rural Development (NABARD), agriculture	Removing subsidies on water, electricity, and fertilizers	State government		Willingness by farmers to change practices		No regret/ low regret

		indigenous grains		department NGO						
		2. Shifting to drought resistant variety of grains								
	Lack of good fishing practices	Training and awareness among villagers on the usage of proper net and not to catch fish in the spawning season		Fishers department, NGO				Willingness by fishermen to change practices		No regret
Adaptation goal (4) improvement of built environment										
Infrastructure and institutional setup	Poor infrastructure and lack of conveyance to connecting highway or major city	Build metaled roads	2013–2015	Gram Panchayat, villagers	Upkeep and maintenance of roads under MGNREGA	Gram Panchayat, villagers	MGNREGA, Jamin Sampadani scheme, Prime minister village road scheme	Lack of resources (time, money, manpower) and rural look out may be low on priority	Reduced health hazards	Low regret
	Lack of solid waste collection management	1. Provision of bins for waste segregation	2013–2014	State govt. for fund, Gram Panchayat, NGO, local people			Nirmal Gujarat scheme, Swatchcha Gram scheme	Funding, willingness to take ownership among villagers	Reduced health issues	No regret
		2. Clean village competition among rural villages	2014 onwards

*Gram Panchayat: local self-government at village level

Conclusion

This research is a preliminary attempt to address the current vulnerability issues through integration of development and adaptation measures for coastal rural communities. The main objective of this study was to leverage national and state development goals in creating adaptation plan catering to current vulnerability for the study region.

With respect to Indian coastal village's vulnerability study, developmental issues like lack of infrastructure, literacy levels, etc., along with malpractices in agriculture and fishing, several social setup issues, and effect of pollution due to the presence of chemical industries in the vicinity can be considered as the major causes for increasing vulnerability. Developing specific indicators and a comprehensive field survey along with involvement of stakeholders from the beginning will help to find the current baseline and underlying issues which could be addressed in the adaptation measures.

This case study illustrates many and varied opportunities of intervention and highlights how development and adaptation can be interlinked. However, these interlinkages are yet to be recognized by the government. For example, existing development plans like the ongoing ICZMP project can be leveraged by integrating climate lens into it in order to reduce the current and future vulnerability.

Adaptation plan along with short-term and long-term measures with realistic time frame was made where stakeholder consultation was not done, but it can be taken up as way forward to make the suggested plan functional.

Although local stakeholders and civic institutions have a role to play in addressing the current climatic challenges, it is the government institution to take lead with strong policy, political will, and good governance mechanism. Moreover, cross sectoral linkages to address climate change impacts could be handled by existing climate change department of the state. It can act as a steering body to alias with all the necessary departments and leverage their work to incorporate climate variability and change.

Further such studies can be supported by policy researches so that national- and local-level policies and programs can be leveraged keeping in view the global perspectives, researches, and advancements in the field of climate science.

Acknowledgments This paper is partly based on my Masters Dissertation work at Centre for Environment Planning and Technology (CEPT) University, Ahmedabad. Vulnerability assessment section of this paper is under the process of getting published as working paper for CEPT University publication along with Mr. Ashwani Kumar (Assistant Professor, Faculty of Planning, CEPT University). I would like to thank him for his comments, discussions, and support provided during the dissertation and while writing working paper.

Arable Crop Farmers' Decision Making and Adaptation Strategies on Climate Change in Ogun State, Nigeria

S. B. Ibrahim, Carolyn A. Afolami, I. A. Ayinde, and C. O. Adeofun

Contents

Abstract

Climate and rural farmers' resource allocation behavior are primary determinants of agricultural productivity in Nigeria. Hence, knowledge of the rural farmers about climate change is important in order to offer adaptation practices

that mitigate its adverse effects. This study thus investigated the effects of climate change at the grassroots by considering the determinants of the communities' adaptation to changes in climate in Ogun State, Nigeria. The study utilized primary data collected from 150 arable crop farmers selected across Ogun State through a multistage sampling technique. The data were obtained through administration of questionnaire designed to elicit information on socioeconomic characteristics and adaptation behaviors of the respondents to climate change. The multinomial logit regression model was used to capture choice probabilities across the various options of climate change adaptation strategies. Most (81.08 %) of the arable crop farmers were males with an average farming experience of 24 years. Some (22.97 %) respondents did not take up any climate change adaptation strategy, 45.95 % targeted rains to plant, 12.16 % used multiple strategies, 10.81 % adopted good soil conservation techniques, while 8.11 % adopted wetland farming. The significant factors explaining the choice of climate change adaptation strategies taken up by the respondents were household size ($p < 0.05$), gender ($p < 0.10$), years of residence in a community ($p < 0.05$), educational level ($p < 0.10$), frequency of extension contact ($p < 0.01$), access to agricultural credit, and income from secondary occupation ($p < 0.05$). This paper provides interesting information on natural adaptation practices and these indigenous approaches would be useful to researchers and policy makers worldwide.

Arable crop farmers • Decision making • Adaptation strategies • Climate change

Introduction

Agriculture places heavy burden on the environment in the process of providing humanity with food and fiber, while climate is the primary determinant of agricultural productivity. Studies indicate that Africa's agriculture is negatively affected by climate change (Pearce et al. 1996; McCarthy et al. 2001). Given the fundamental role of agriculture in human welfare, concern has been expressed by federal and state agencies and other countries regarding the potential effects of climate change on agricultural productivity. Climate change according to IPCC (2001b) can be defined as the change in the state of the climate that can be identified using statistical data by changes in the mean and variability of climate properties that has persisted for an extended period, typically decades or longer. It also refers to any change in climate over time, whether due to natural variability or as a result of human activity. This usage however differs from that in the United Nations Framework Convention on Climate Change (UNFCC, 1992), where climate change refers to a change of climate that is attributed directly or indirectly to human activity that alters the composition of global atmosphere and that is, in addition to natural climate variability, observed over comparable time period (Currents 2008).

Interest in this issue has motivated a substantial body of research on climate change and agriculture over the past decade (Fischer et al. 2002; Wolfe et al. 2005; Lobell et al. 2008). Climate change is expected to influence crop and livestock production, hydrologic balances, input supplies, and other components of agricultural systems. However, the nature of these biophysical effects and the human responses to them are complex and uncertain.

Adaptation to climate change refers to adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects, which moderates harm or exploits beneficial opportunities (Intergovernmental Panel on Climate Change 2001a). Common adaptation methods in agriculture include use of new crop varieties and livestock species that are more suited to drier conditions, irrigation, crop diversification, mixed crop livestock farming systems, and changing planting dates (Bradshaw et al. 2004; Kurukulasuriya and Mendelsohn 2006; Nhemachena and Hassan 2007).

It is evident that climate change will have a strong impact on Nigeria – particularly in the areas of agriculture, land use, energy, biodiversity, health, and water resources. Nigeria, like all the countries of sub-Saharan Africa, is highly vulnerable to the impacts of climate change (IPCC 2007; Nigeria Environmental Study Team 2004). Rain-fed agricultural practice and fishing activities from which two-third of the Nigerian population depend primarily on foods and livelihoods are also under serious threat besides the high population pressures of 140 million people surviving on the physical environment through various activities within an area of 923,000 km^2 (IPCC 2007; NEST 2004).

Food crop farmers in Southwestern Nigeria provide the bulk of arable crops that are consumed locally and transported to other regions in the country. These farmers are also experiencing climate change even though they have not considered its deeper implications. This is evidenced in the late arrival of rain, the drying-up of stream and small rivers that usually flow year-round, the seasonal fluctuation of rains, and the gradual disappearance of flood-recession cropping in riverine areas (Building Nigeria's Response to Climate Change 2008).

Consequently, this research intends to investigate the effects of climate change at the grassroots by considering the determinants of the communities' adaptation to changes in climate. This is important because sustainability of agricultural production depends largely on actions of farmers and their ability to make decisions given the level of knowledge and information available to them. This study takes into account the local communities' understanding of climate change and assumed that these communities have an inborn, adaptive knowledge from which to draw and survive in high-stress ecological and socioeconomic conditions. The study further described the adaptation strategies of arable crop farmers to climate change and also estimated the determinants of arable crop farmers' decision on climate change adaptation strategies.

Methodology

Description of the Study Area

This study was carried out in Ogun State. Ogun State is one of the 36 states of the Federal Republic of Nigeria. It was carved out of the defunct Western State on the 3rd day of February, 1976, and it has a total land area of 16,409.26 km^2. The estimated population is 3,728,098 according to Nigerian 2006 National Census figure (Federal Republic of Nigeria (FRN) 2009). The climate of Ogun State follows a tropical pattern with the raining season starting about March and ending in November, followed by dry season. The mean annual rainfall varies from 128 mm in the southern parts of the state to 105 mm in the northern areas. The average monthly temperature ranges from 23 °C in July to 32 °C in February. The northern part of the State is mainly of derived Savannah vegetation, while the Central part falls in the rain forest belt. The southern part of the State has mangrove swamp. The geographical landscape of the state comprises extensive fertile soil suitable for agriculture and savannah land in the northwestern part of the state, suitable for cattle rearing. There are also vast forest reserves, rivers, lagoons, rocks, mineral deposits, and an oceanfront. The rivers in the state provide veritable opportunities for farmers' to access the potentials of dry season as well as *fadama* farming.

The main occupation of the people of the state is farming, which is largely subsistence in scale.

The state is known to have a virile Agricultural Extension Programme which comprises four agricultural zones identified by OGADEP as Abeokuta, Ilaro, Ijebu, and Ikenne. Each zone is divided into blocks, and each block into circles or cells and each of these is anchored by a Village Extension Agent (VEA) who oversees the activities of farmers in his coverage area, while a Block Extension Agent (BEA) anchors a block by overseeing activities of farmers in the coverage area.

Data Types, Sources, and Sampling Technique

This study was based on primary data. The primary data were obtained through administration of structured questionnaire on arable crop farmers in the study area. Data collected included the arable crop farmers' socioeconomic and production characteristics, actual adaptation strategies adopted by the respondents, as well as barriers to adaptation faced in the study area. The sample size used for this study was 150 arable crop farmers. Multistage sampling technique was used to select arable crop farmers from whom data were generated for this study. The first stage of sampling involved a random selection of two zones from the four Ogun State Agricultural Extension Development Programme (OGADEP) zones, that is, Abeokuta and Ikenne zones (OGADEP divided the state into four zones – Abeokuta, Ilaro, Ijebu, and Ikenne, on the basis of geographical spread and ease of administration. Each zone is divided into blocks and each block into circles or cells and each of these is anchored by a Village Extension Agent (VEA) who oversees the activities of farmers in his

Table 1 Sampling procedure for the study

Stage	Procedure	Sampling frame
1.	Random selection of two zones from the four OGADEP zones	List of all the four OGADEP agricultural zones
2.	Proportion random selection of half of the total number of blocks within each selected zone	List of all blocks under the OGADEP agricultural zones selected
3.	Simple random selection of three cells each from the above selected blocks	List of all cells under the five OGADEP agricultural blocks selected
4.	Simple random selection of 10 respondents from each of the cells selected above	List of all arable crop farmers under each cell obtainable from OGADEP was the sampling frame

coverage area, while a Block Extension Agent (BEA) anchors a block by overseeing activities of farmers in the coverage area). The second stage involved a random selection of 50 % of the total number of blocks in both Abeokuta and Ikenne zones, resulting in the selection of three blocks from Abeokuta zone, and two blocks from Ikenne zone using list of blocks in the zones as the sampling frame. The third stage involved a random selection of three cells from each of the selected five blocks in each zone using the list of cells obtainable from OGADEP as the sampling frame. The fourth stage involved a random selection of 10 arable crop farmers from each of the selected cells (using a list of arable crop farmers from each cell obtainable from OGADEP) thereby giving a total number of 150 respondents.

The sampling procedure for this study is summarized in Table 1.

Analytical Techniques

Descriptive statistics and multinomial logit (MNL) regression model were used to analyze the data collected. The advantage of using MNL is that it permits the analysis of decisions across more than two categories, allowing the determination of choice probabilities for different categories of climate change adaptation being modeled by the study. It is also known for its computational simplicity in calculating the choice probabilities that are expressible in analytical form (Tse 1987). Hence, this model provides a convenient closed form for underlying choice probabilities with no need of multivariate integration, making it simple to compute choice situations characterized by many alternatives. The main limitation of the model is the independence of irrelevant alternatives (IIA) property, which states that the ratio of the probabilities of choosing any two alternatives is independent of the attributes of any other alternative in the choice set (Hausman and McFadden 1984; Tse 1987).

The decision of whether or not to use any adaptation option could fall under the general framework of utility and profit maximization. Consider a rational farmer who seeks to maximize the present value of expected benefits of production over a specified time horizon and must choose among a set of J adaptation options.

The farmer i decide to use j adaptation option if the perceived benefit from option j is greater than the utility from other options (say, k) depicted as

$$U_{ij}\left(\beta'_j X_i + \varepsilon_j\right) > U_{ik}\left(\beta'_k X_k + \varepsilon_k\right) \tag{1}$$

where j is not equal to k;

U_{ij} and U_{ik} are the perceived utility by farmer i of adaptation options j and k, respectively; and ε_j and ε_k are the error terms.

Under the revealed preference assumption that the farmer practices an adaptation option that generates net benefits and does not practice an adaptation option otherwise, we can relate the observable discrete choice of practice to the unobservable (latent) continuous net benefit variable as

$$\mathrm{Y}_{ij} = 1 \text{ if } U_{ij} > 0, \text{ and } \mathrm{Y}_{ij} = 0 \text{ if } U_{ij} < 0$$

In this formulation, Y is a dichotomous dependent variable taking the value of 1 when the farmer chooses an adaptation option in question and 0 otherwise. The probability that farmer i will choose adaptation option j among the set of adaptation options could be defined as follows:

$$P(Y = 1/X) = P\left(U_{ij} > U_{ik}\right)/X \tag{2}$$

$$\begin{aligned} &= P\left[\left(\beta'_j X_i + \varepsilon_i - \beta' k\, X_i - \varepsilon_k\right) > 0/X\right] \\ &= \mathrm{P}\left[\left(\beta'_\mathrm{j} - \beta'_\mathrm{k}\right) \mathrm{X}_i + \varepsilon_\mathrm{j} - \varepsilon_\mathrm{k}\right) > 0/\mathrm{X}\right] \\ &= \mathrm{P}\left(\beta^* \mathrm{X}_i + \varepsilon^* > 0/\mathrm{X}\right) = \mathrm{F}\left(\beta^* \mathrm{X}_i\right) \end{aligned} \tag{3}$$

In this analysis, the five climate change adaptation categories considered are given below:

1. Good soil conservation techniques.
2. Irrigation/drainage/wetland farming.
3. Targeting rains to plant.
4. Multiple strategies.
5. No adaptation: this was used as the reference category. In order to estimate this model, there was the need to normalize one category of the adaptation strategies, for effective analysis. This is also known as “reference state.”

where ε^* is a random disturbance term,

β^* is a vector of unknown parameters that can be interpreted as the net influence of the vector of explanatory variables influencing adaptation,

X_{is} are the explanatory variables, and they included the following:

X_1 = Farming experience in years

X_2 = Educational level

X_3 = Age in years

X_4 = Household size

X_5 = Years of residence in a community
X_6 = Secondary occupation income in naira
X_7 = Frequency of extension contact
X_8 = Gender
X_9 = Marital status
X_{10} = Religion (Islam = 1, Christianity = 2, traditional worshipper = 3)
X_{11} = Land size (ha)
X_{12} = Access to credit (access to credit = 1, and 0 if otherwise)
and F (β^* X_i) is the cumulative distribution of ε^* evaluated at β^* X_i.
The multinomial logit model is thus specified according to Green (2003) as

$$P_{ij} = \text{prob}(Y = 1) = \frac{e^{x'\beta}}{1 + \sum_{J=1}^{j} e^{x'\beta}} \tag{4}$$

where j = 1 ... n and

β is a vector of parameters that satisfy ln (P_{ij}/P_{ik}) = X' ($\beta_j - \beta_k$) (Greene 2003).

Unbiased and consistent parameter estimates of the MNL model in Eq. 4 require the assumption of independence of irrelevant alternatives (IIA) to hold. Specifically, the IIA assumption requires that the likelihood of a household using a certain adaptation measure needs to be independent of other alternative adaptive measures used by the same household. Thus, the IIA assumption involves the independence and homoscedastic disturbance terms of the adaptation model in Eq. 3. The validity of the IIA assumption is based on the fact that if a choice set is irrelevant, eliminating a choice or choice sets from the model altogether will not change parameter estimates systematically. Differentiating Eq. 3 with respect to each explanatory variable provides marginal effects of the explanatory variables given as

$$\partial p_j / \partial x_k = Pj \left[\beta_{kj} - \sum_{J=1}^{j-1} P_j \beta_{jk} \right] \tag{4}$$

Results and Discussion

Distribution of Respondents by Personal Characteristics

Age is generally believed to be an important factor in farming activities. This is because younger farmers are believed to commit more energy into production activities, while older ones are likely to be more experienced which may also impact positively on their productivity. As shown in the Table 2, majority (79.70 %) of the respondents were between the economically active age of 31–60 years with a mean age of 45.7 years. With respect to gender of surveyed respondents, 81.08 % of the respondents were males, while only 18.92 % of the respondents were females showing that arable crop farming in the study area was more popular

Table 2 Description of respondents by personal characteristics

Personal characteristics	Frequency	Percentage	Mean
Age (years) of respondents			
30 or less	20	13.51	
31–40	26	17.57	
41–50	48	32.43	47.5
51–60	44	29.73	
Above 60	10	6.76	
Gender of respondents

among the males. Furthermore, most (86.49 %) of the respondents were married. Majority (60.81 %) of the respondents were Christians, while 37.16 % of the respondents were Muslims. Traditional worshippers constituted 2.03 % of the respondents.

In terms of education, 36.49 % of the respondents had no formal education, 30.41 % were educated up to the primary school level, and 19.59 % up to secondary school level. Only 7.43 % of the respondents have tertiary education. This suggests a reasonable level of literacy among the respondents. From Table 4, about 43.92 %

of the sampled respondents have secondary occupation, while the remaining 56.08 % do not have. The secondary occupation included mainly artisanship, trading, carpentry, hunting, and cattle rearing, among others. Furthermore, 86.49 % of the respondents had extension contact, while the remaining 13.51 % do not have. This implies that the farmers would have access to regular update of improved farming technologies which is likely to boost their productivity. Out of this, 86.49 %, majority (72.3 %) of the respondents had up to 12 times of extension contact in the last production season, while the mean contact frequency is 11 times in the last production season.

The study further showed that 82.43 % of the respondents had no access to credit facilities. This may limit the ability of the farmers to expand their scale of production. This lack of access to credit facilities may be due to high interest rates being charged by financial institutions, and other bureaucratic bottlenecks which always characterize loan acquisition and disbursement in the country, in general.

The distribution of respondents by household size is also shown in Tables 2 and 3. From the table, 52.03 % of the respondents had between 1 and 4 household members, while 27.07 % have household size of between 10 and 14 members. The mean household size for the sampled respondents is approximately eight persons, implying that other members of the household can provide family labor in agricultural production. This could however lead to the use of child labor at the expense of formal education.

It is obvious from Table 3 that 65.54 % of the respondent cultivated less than 1 ha of farmland and 10.81 % cultivated between 1.101 and 1.5 ha of farmland, while 13.51 % cultivated between 1.50 and 2.0 ha of farmland. This corroborates the true picture of subsistence nature of arable crop farming in Nigeria. The mean land size cultivated by the respondents' was approximately 1 ha. The table also revealed that the predominant crop types grown by the arable crop farmers was maize, followed by cassava and vegetables, while other crop types grown included rice melon and pepper.

Distribution of Respondents by Adaptation Strategies to Climate Change

As indicated in Fig. 1, targeting rains to plant (leading to either early or late planting) was the most commonly (45.95 %) adopted strategy to reduce the effect of climate change. Use of irrigation coupled with construction of proper drainage channels as well as wetland farming was the least practiced (8.11 %) adaptation strategy among the major adaptation methods identified among arable crop farmers interviewed for the study. Targeting rains for planting as an adaptation strategy by the farmers was not surprising giving the inherent nature of peasant farmers as they rely on natural weather conditions for crop production. Furthermore, the limited use of irrigation coupled with construction of proper drainage channels as well as wetland farming, was due to the resource-poor nature of the farmers in the study

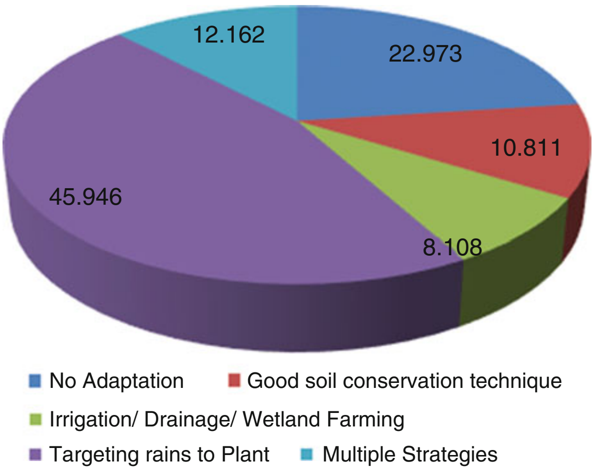

Fig. 1 Distribution of respondents by adaptation strategies to climate change

area. Moreover, 10.81 % of the respondents adopted good soil conservation techniques (such as planting cover crops, mulching) as a strategy in this respect, while only 12.16 % of the respondents engaged in multiple strategies to combat climate change. It was, however, interesting to note that 22.97 % of the arable farmers reported that they have not used any adaptation strategy.

Determinants of Arable Crop Farmers' Decisions on Climate Change Adaptation Strategies

Multinomial logit model was used in this study to estimate the determinants of respondents' adaptation behavior to climate change in the study area. Eight adaptation strategies were practiced by the sampled respondents in the study area. These are:

1. Good cultural practices such as mulching and resupplying of seedlings
2. Planting cover crops
3. Irrigation of farmland
4. Construction of proper drainage channels
5. Wetland/Fadama farming
6. Targeting rainfall to plant, leading to either early or late planting
7. Praying for God's intervention
8. No adaptation

For the purpose of analysis using multinomial logit, these adaptation strategies were restructured by grouping closely related choices together in the same category. Good cultural practices and planting of cover crops were grouped in the same category labeled as "good soil conservation techniques," while irrigation of farmland, construction of proper drainage channels, and wetland farming were grouped and labeled as "irrigation/drainage/wetland farming" category. The third category is "targeting rains to plant," followed by "multiple strategies" category which is a series of combination of the first three categories. Lastly, the fifth category is a combination of praying for God's intervention and no adaptation, and it is labeled "no adaptation."

Accordingly, the choice set in the restructured multinomial logit model included the following adaptation options:

1. Good soil conservation techniques
2. Irrigation/drainage/wetland farming
3. Targeting rains to plant
4. Multiple strategies
5. No adaptation

In this analysis, the last category (no adaptation) was used as the "reference state." Thus, results obtained from the multinomial logit analysis were in reference to no adaptation, and the result is presented in Table 4.

Table 4 Determinants of adaptation behavior of respondents'

Source: computed from survey data; 2010
Standard errors are in parenthesis
[a]Coefficients significant at 1 %
[b]Coefficient significant at 5 %
[c]Coefficient significant at 10 % chi-square of log likelihood = 117.76[a]

The result revealed that explanatory variables in the model significantly explain the determinants of adaptation behavior of respondents to climate change in the study area. The chi-square value of 117.76 associated with the log likelihood ratio was significant ($p < 0.01$) suggesting strong explanatory power of the model. The study found out that household size is significant ($p < 0.05$) but negative, implying that an increase in household size will decrease the probability of respondents' choosing good soil conservation techniques such as good cultural practices and planting cover crops as an adaptation option. Also, the odds of choosing good soil conservation adaptation option as opposed to not adapting at all is 0.70 (70 %) per unit decrease in household size.

The coefficient of number of years of residence in a community is also significant ($p < 0.05$) and positive both for "good soil conservation techniques" and "irrigation/drainage/wetland farming," implying that an increase in this variable will increase the probability that the respondents will choose each of these adaptation options, respectively. This is because with increase in the years of residence of an individual in the community, there is higher possibility of an individual having access to more social capital in the community, thus aiding his ability to adopt new innovations to improve his farming activities and livelihood in general. In the same vein, the odds of adopting each of these strategies by the respondents compared to not adopting at all are 1.08 and 1.09, respectively, for each of the adaptation strategies mentioned above. Moreover, coefficient of income from secondary occupation was also found to be significant ($p < 0.05$) and positive for the adaptation strategy of good soil conservation technique, implying that a change in income from secondary occupation will likely cause an increase in the respondent's behavior towards choosing this adaptation strategy. This is because wealthier households are likely to be willing to adapt by investing in good soil conservation techniques. This follows the view of Knowler and Bradshaw (2007) that the adoption of agricultural technologies requires sufficient financial well-being. Thus, expanding smallholder farmers' access to off-farm sources of income increases the probability that they will invest in good farm practices. The associated odd of respondents adopting this strategy compared to the reference category for each unit increase in income from secondary occupation is 1.00.

Coefficient of educational level of respondent was also found to be significant ($p < 0.10$) and positive for strategies of irrigation/drainage/wetland farming and multiple strategies, implying that an increase in this variable will increase the likelihood of sampled respondents choosing these strategies, with associated odd values of 1.78 and 2.17, respectively . Generally, higher level of education is believed to be associated with access to information on improved technologies and productivity consequences as evidence from various sources indicates that there is a positive relationship between the education level of the household head and the adoption of improved technologies and adaptation to climate change (Maddison 2006). Therefore, farmers with higher levels of education are more likely to better adapt to climate change by taking up multiple strategies.

Furthermore, the coefficient of frequency of extension contact was found to be significant and positive, for strategies of good soil conservation techniques

($p < 0.01$), targeting rains to plant ($p < 0.01$), and for multiple strategies ($p < 0.05$) implying that an increase in this variable will increase the likelihood of sampled respondents choosing these strategies, respectively. The associated odd values of choosing the strategies by respondents as opposed to not adapting at all are 1.16, 1.14, and 1.12, respectively. With these in mind, farmers who have access to extension services are more likely to be abreast of information on changing climatic conditions and the various management practices they can use to adapt to these changes. In terms of credit access, the result revealed that this variable is significant ($p < 0.10$) and positively affects adaptation behaviors of respondent to good soil conservation techniques, with an associated odd value of 5.21 per unit increase in access to credit facility. From the table, an increase in the number of respondents having credit access will increase the likelihood of this adaptation. This is true because poverty or lack of financial resources is one of the main constraints to adjusting to climate change.

The result further shows that the dummy variable representing religious beliefs of the respondents is in favour of those practicing Islam, despite majority (60.81 %) of the sampled respondents' being Christians. Religion is significant ($p < 0.10$), and positively affecting adaptation behaviors of respondent to taking multiple adaptation strategies with an associated odd value of 4.41 per unit increase in this variable. This implies that farmers who are Muslims show positive disposition towards using multiple adaptation strategies towards combating climate change. In the same vein, the analysis result of gender, which is also a dummy variable in this model, is in favor of the males given the fact that the males constituted 81.08 % of the respondents, while the females constituted 18.92 % of the respondents. Gender is significant ($p < 0.10$) and negatively affecting adaptation behaviors of respondent to irrigation/drainage/wetland farming as well as targeting rains to plant, each with associated odd values of 0.10 and 0.28, respectively, per unit increase in number of male respondents. From the table, as male respondents increase, there is likelihood of decrease in taking up these adaptation options.

Conclusion and Recommendations

This study establishes the fact that arable farmers adapt to climate change situation in their local settings. The multinomial logit results clearly emphasized that household size and gender in favor of the males negatively influenced adaptation behaviors to climate change. On the other hand, years of residence in a community, educational level, frequency of extension contact, access to agricultural credit, married respondents, and income from secondary occupation are variables which engender positive adaptation behaviors of respondents to climate change. From the foregoing, the study recommends that:

Policies from government and other stakeholders should ensure that farmers have access to sufficient credit; this will increase their ability and flexibility to change production strategies in response to the harsh forecasted climate conditions.

There should also be investment on yield increasing technology packages to increase farm income.

Also, there should be encouragement of informal social networks among farmers and in rural communities as it has the potentials of increasing social capital useful for adaptation.

Farmers should be encouraged to acquire formal education as it has the likelihood of increasing the possibility of responding to positively to adaptation strategies against climatic change. Allied to this is the need for increased access to extension services by farmers in order to educate farmers more and disseminate useful agricultural innovations that will improve living agricultural production in the face of changing weather condition while also improving the standard of living of the farmers.

Assessing How Participatory/Community-Based Natural Resource Management Initiatives Contribute to Climate Change Adaptation in Ethiopia

Hannah Reid and Lucy Faulkner

Contents

Abstract

This chapter assesses the role of community-based/participatory natural resource management (CB/PNRM) in supporting adaptation to current and potential future climate change impacts among pastoral communities in Ethiopia. Such communities are expected to experience significant changes in the natural environments on which their livelihoods rely. Climate impacts are set to exacerbate and intensify an existing dynamic risk landscape characterized by persistent poverty, social and political marginalization, land degradation, and conflict largely due to policy and governance failures undermining dryland productivity. Present pastoralist coping

DOI 10.1007/978-3-642-38670-1_68

capacities are not sufficient to cope with existing recurrent drought periods and other climate variability impacts, with climate change risk factors likely rendering traditional coping strategies unsustainable. In response, this chapter focuses on selected CB/PNRM initiatives undertaken by Save the Children to show the value of CB/PNRM as an adaptation strategy that builds climate resilience and delivers adaptation benefits for targeted pastoralists/agropastoralists. While climate change was not a specific focus of development investment design, important contributions to strengthening local adaptive capacity through the implementation of transformative processes and practice have been made. This suggests that newer fields of study such as community-based adaptation can learn from older disciplines such as CB/PNRM, with the potential role that development actors can play in the context of building climate resilience meriting further attention among governments and policymakers. Drawing on the development of bespoke methodology for monitoring and evaluating effective adaptation, this chapter also contributes to adaptation evaluation knowledge.

Introduction

Many pastoralist communities in East Africa experience persistent poverty, social and political marginalization, land degradation, and conflict (although experiences vary widely both within and between pastoral groups and pastoral areas). These are due to failures of policy and governance rather than the pastoral system itself. Pastoralism is often (wrongly) viewed as economically inefficient and environmentally destructive despite evidence that it often brings economic and environmental benefits beyond those achieved by alternative land uses such as ranching. In addition, the pastoralist way of life is often more resilient to changing climatic conditions because over the years pastoralists have developed strategies to cope with difficult conditions (Riché et al. 2009). In many instances, pastoralists are able to positively exploit greater climate variability to increase their resilience and generate higher returns than would be the case if the environment/climate were more stable or predictable (Krätli and Schareika 2010; Hesse 2010). This is because pastoral systems often have institutions and strategies that can harness the ephemeral, variable, and unpredictable distribution of resources (particularly highly nutritious pastures) to their advantage. This in turn contributes to greater accumulation of assets, better diets, and more income – in other words a more resilient community. Well-functioning pastoral systems can also often cope better with periodic extreme events such as drought when compared with institutions and strategies better suited to managing more stable resources. This is because they reduce the loss of assets and have a greater capacity to "bounce back" and resume high productivity once the extreme event is over (Ced Hesse personal communication, Nov. 2012).

Climate change is predicted to have severe impacts in East Africa. While some of these impacts will be positive, including bringing more rainfall to certain dry areas, most are likely to be negative. The natural environments on which many of the poorest rely are expected to experience significant changes. Sound risk management to increase livelihood resilience and maintain ecosystem services can be an important component of a cost-effective approach to help people adapt to climate change, especially the most vulnerable groups, including women and children (Ambani and Nicholles 2012).

While most development interventions are not designed with climate change adaptation as a key objective, it is likely that they influence community capacity to adapt to changing shocks and trends – whether as a result of climate change or other pressures associated with development (Jones et al. 2010). There is the potential for "double dividends" resulting from adaptation and development interventions due to the strong synergies between the two (Ambani and Nicholles 2012). There is also a growing appreciation that newer fields of study, such as community-based adaptation, have much in common with older disciplines such as CB/PNRM and can both learn and adopt many principles from this older field of study (Chishakwe et al. 2012; Munroe et al. 2011). Research that assesses the role of CB/PNRM interventions in adaptation, however, are in short supply, and evidence of these "double dividends" is mostly anecdotal.

This chapter aims, in part, to help fill this information gap by conducting a more rigorous assessment of the contribution that selected Save the Children CB/PNRM initiatives have in contributing to climate change adaptation through building climate resilience and delivering adaptation benefits to the poorest and most marginalized pastoralists and agropastoralists. This includes details of the bespoke methodology developed to achieve this goal and the results and recommendations generated from applying this methodology at the study sites.

Study Site Profiles

Selected Save the Children CB/PNRM interventions are located in Liben, Gordola, and Arero districts ("woredas") in the lowlands of Borana and Guji Zones of Oromia Regional State in Ethiopia (Fig. 1). Similar sites in Horbtor Kebele, Yabello District, with the same history of preexisting development and humanitarian initiatives, but no Save the Children CB/PNRM interventions, were also visited for comparative purposes. Both study sites experienced droughts in 2011, which is the primary climate-related hazard (Riché et al. 2009).

Study sites are predominantly arid and semiarid rangelands dominated by tropical savannah vegetation with open grassland and perennial woody vegetation. People are primarily pastoralists with cattle, sheep, goats, and camels, or agropastoralists cultivating maize, teff, sorghum, and haricot beans (Riché et al. 2009). Average annual rainfall

Fig. 1 Oromia Regional State showing the Borana Region in the south and the study sites in this region

ranges between 350 and 900 mm, with considerable spatial and temporal variability in quantities and distribution. Rainfall usually occurs from March to May and September to November. Average annual temperature ranges between 19 °C and 26 °C.

Ethiopia is considered one of the most vulnerable countries to the impacts of climate change (World Bank 2010; Adem and Bewket 2011). Potential climate change impacts in the study sites are increasing temperatures and changing rainfall patterns, with study sites located in medium and high drought probability zones (NAPA 2007). Mean annual temperature increases of 1 °C, 1.8 °C, and 2.9 °C by 2030, 2050, and 2080, respectively, are expected compared to 1961–1990 levels (NAPA 2007). Existing trends in increased hot days and hot nights and decreasing annual cold days are set to continue (Conway et al. 2007; Levine et al. 2011). Precipitation patterns are less certain with discrepancies between climate models on modest increases or reductions in rainfall (Conway et al. 2007; NAPA 2007). Similarly, Ethiopia's exposure to drought and floods is heavily influenced by the El Niño/La Niña phenomena, and the impacts of climate change on these phenomena are currently unclear (ACCRA 2012). Models are, however, broadly consistent in suggesting that rainfall across the study sites will fall more in heavy events (McSweeney et al. 2007). Likewise, local and scientific observations are consistent with drought frequency increasing from every 6–8 years to every 1–2 years (Riché et al. 2009).

These climate changes however form only part of the study sites' vulnerability landscape (McDowell 2011). Changes in non-climate contextual trends regarding livelihood and resource needs have contributed to reducing pastoralist resilience over time. This includes a reduction in natural resource and rangeland availability, especially to key dry season grazing areas due to commercial farming and increasing population pressures resulting in a constant flow of people moving from highland areas to lowlands in search of productive natural resource assets for livelihood sustainability. Pastoralist communities themselves have also increased in number, contributing to an overall increase in human population size. Widespread bush encroachment has increased pressures on reduced rangeland resources, and changes in government regional administrative boundaries between Oromia and Somali states have resulted in many Boran and Guji pastoralists losing previously available land. Furthermore, increasing state government administrative influence at local community level has resulted in reduced power and influence yielded by traditional customary institutional leaders. This shift has seen traditional pastoralist processes ignored by formal administrative bodies who provide legal backing and policy support to permanent settlements and farming, therefore reducing access to, for example, existing migration routes and water points that are key to pastoralist livelihoods. Additional changing trends of increased social and economic differentiation combined with weakened indigenous safety net systems, resulting in smaller herd sizes per household with increasing poverty levels, have also contributed to increased livelihood vulnerability for pastoralist households.

In light of the above, although the future landscape of risk is uncertain, it is evident that climate change will provide an additional stressor for study site communities. Drought combined with extreme heat events is set to increasingly negatively affect the availability, productivity, and quality of pastures and farmland leading to negative consequences on household food and income levels and human and livestock health. With pastoralists identified as among those most vulnerable to climate change impacts (NAPA 2007), present coping capacities are not sufficient to cope with recurrent drought periods, including those of 2008 and 2010/2011 (Weiser 2012). Other impacts of current climate variability and poverty combined with climate change risk factors are set to render traditional coping strategies unsustainable (Adem and Bewket 2011; Venton et al. 2012).

Project Structure

Phase II of the Pastoral Livelihoods Initiative began in 2009 (Box 1 below), yet this study focuses on Save the Children's upgraded CB/PNRM work implemented under this initiative in 2012 (Box 2 below). Prior to 2009, Save the Children was engaged in the same CB/PNRM project sites where this study was conducted through phase I of the Pastoral Livelihoods Initiative (2004–2008), that focused on short-term drought response, child education, and health initiatives.

Box 1: The Pastoral Livelihoods Initiative (Stockton et al. 2012)
Phase II of the Pastoral Livelihoods Initiative is a US$16-million US-Aid-funded project implemented by Save the Children, CARE, Mercy Corps, and International Rescue Committee from 2009 to 2013 (Stockton et al. 2012). It aimed to improve pastoralist and ex-pastoralist livelihoods in the above study sites through a range of initiatives including:

1. Improving community-based natural resource management
2. Improving the ability of pastoralists to gain more economic value from their livestock
3. Diversifying their ability to generate income
4. Improving the effectiveness of early warning systems
5. Implementing selected interventions relating to maternal and child health and HIV/AIDS
6. Integrating drought response and recovery through crisis modifier mechanisms to protect livelihoods during drought periods

Box 2: Save the Children's Upgraded CB/PNRM Strategy
Overall goal: Enhanced community resilience to shocks, especially drought, through strengthening of pastoral livelihood systems and their resource management

Strategic objectives
1. Stronger stakeholder institutions, cooperation, and cohesion
2. Institutionalized, mutual learning for enhancing adaptive capacities and transformation
3. Improved land use (including secured assess) and sustainable NRM in the context of increasing climate variability

Measuring Adaptation Benefits

To assess the effectiveness of Save the Children CB/PNRM interventions in building resilience to climate change risk and delivering adaptation benefits for targeted pastoralists and agropastoralists, new methodology developed for the monitoring and evaluation of community-based adaptation (M&E for CBA) by research program Action Research on Community Adaptation in Bangladesh (ARCAB) is used. In line with current frameworks under development at the international level for successful adaptation M&E, this M&E for CBA system is universal in application and use and has been adopted for this study based on its rapid recognition and uptake by the international community.

The approach measures and evaluates the processes used and results obtained by Save the Children's CB/PNRM interventions in building *transformed resilience*. This means resilience is built at scale across the following three key components, resulting in climate vulnerable poor communities being able to successfully adapt to long-term uncertain future climate change impacts through sustainable adaptation strategies (Ayers and Faulkner 2012; Faulkner 2012b):

1. **Geographic scale**: Resilience is achieved beyond isolated development projects. Effective practice is mainstreamed into long-term institutional structures (scaled up), and activities are replicated beyond immediate project boundaries (scaled out).
2. **Time scale**: Resilience is sustainable, with communities continuing to maintain and build resilience after project activities have finished.
3. **Beyond business as usual approaches**: Resilience-building challenges existing development and DRR approaches and retargets efforts towards building the knowledge, capacity, and practice of vulnerable groups to longer-term climate and other risks, not just current risks. This requires using a climate lens to rethink the way existing development and DRR is done as part of the progression towards adaptation to climate change. It also requires refocusing how projectized development and DRR have been operationalized to date.

ARCAB describes the range of stakeholders and scales across which change needs to occur in order for the above to take place. These include the following: (1) the climate vulnerable poor, who are generally the poorest and most marginalized people in society (Smith et al. 2003); (2) the local formal and informal institutions needed to deliver adaptation services to these groups at the local level, including community-based organizations, local NGOs, and local government service delivery providers; and (3) the wider "community of practice" including national governments, international finance institutions and funds, and national and international learning forums such as the annual international community-based adaptation conferences.

Two components of this approach are used in this study. First, a framework for the identification of priority indicators to measure progress of Save the Children's CB/PNRM intervention towards *transformed resilience*. To realize this goal, the framework focuses on three domains of change:

(i) Meaningful and locally relevant **knowledge** (K) about climate change and adaptation science, and non-climate-related information, for the design of feasible, credible, and useful adaptation options.
(ii) Knowledge is not enough unless people and institutions have the **capacity** (C) to act on it. This means having the skills, power, and ability (including finances) to turn knowledge into practice. This applies in the context of both the individual, in terms of having access to the basic assets, resources, and

institutions that enable them to adapt to climate variability and change. It also applies to institutions that need access to resources and incentives to turn knowledge into action and the mandate to do this.

(iii) Supporting knowledge and capacity will lead to changes in **practice** (P). These can be adaptive strategies undertaken by local people or shifts towards a more integrated, long-term, flexible, strategic, and participatory way of development planning.

These domains are applied to the following outcome areas under which indicators are formed in light of climate and other risks identified as important at local level (Fig. 2 below):

- Indicators assessing the knowledge and capacity of climate vulnerable poor community stakeholders to improve their long-term adaptive capacity through the following prerequisites for adaptation: good development coupled with access to and ability to use information related to climate and non-climate risks
- Indicators assessing mainstreaming and institutional capacity to demonstrate if local institutions have the knowledge, capacity, and incentives to provide climate risk management and deliver adaptation benefits to climate vulnerable project participants
- Indicators of evidence that people and institutions are adapting to climate change risk through changing practice as a result of improved adaptive capacity and access to adaptation services

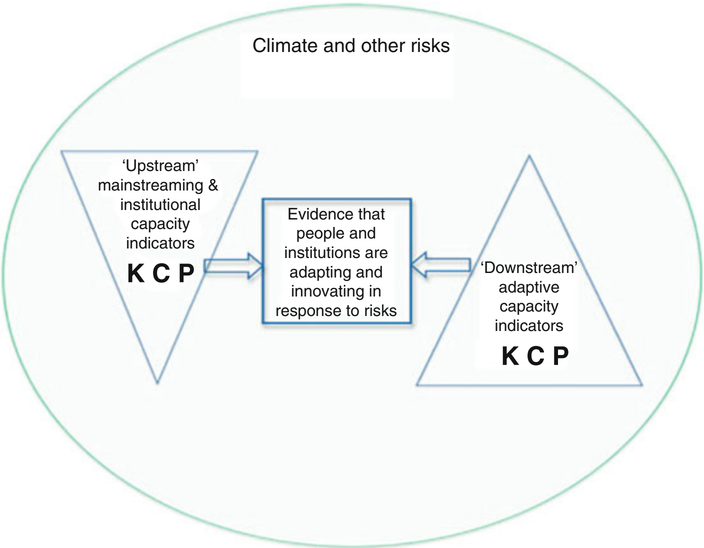

Fig. 2 Conceptual framework for outcome indicator areas used in the ARCAB M&E for CBA framework translated to fit Save the Children's CB/PNRM intervention (Ayers and Faulkner 2012; Faulkner 2012b) adapted from Brooks et al. 2011

Indicator choice for this study was guided by an extensive review of literature and external expert advice on the specifics of adaptation in the context of dryland pastoralist systems in Ethiopia and East Africa. In addition, strong collaboration with Save the Children staff ensured indicators were not only scientifically rigorous but also locally relevant, meaningful, and context specific (Ayers et al. 2012).

Data Collection in the Field

Mixed methods of data collection were employed. This consisted of predominantly qualitative but also quantitative measurements of evidence through focus group discussions (FGDs), key informant interviews, participant observation, and field notes. Households from different gender, wealth, age, and livelihood systems were selected based on random sampling. Where possible, research validity was strengthened through the triangulation of data sources. Supplementary secondary evidence was also collated during fieldwork to support information required for quantitative data analysis from Save the Children CB/PNRM project documents.

Analytical Framework Used

To aid analysis of field and desk-based research results, another component of the selected methodology was adapted: the CB/PNRM Resilience Scale (Fig. 3 below).

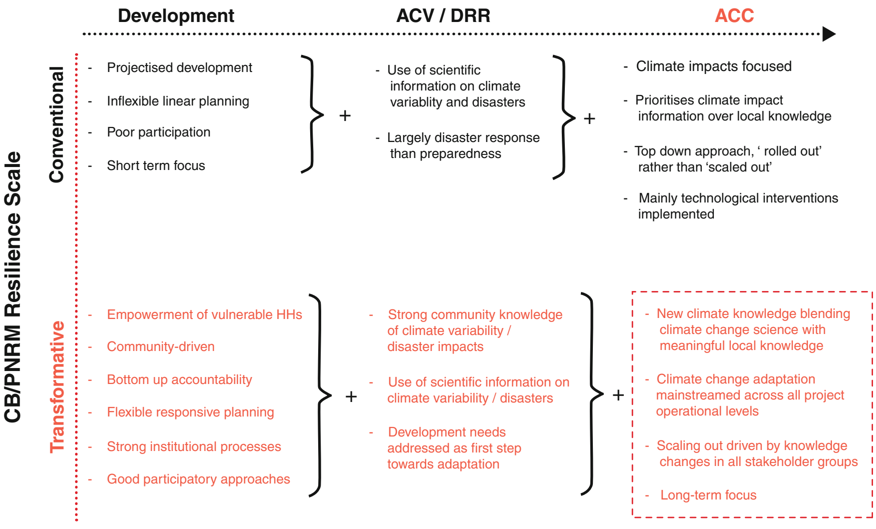

Fig. 3 An analytical framework for assessing CB/PNRM through a climate change lens – the CB/PNRM Resilience Scale (Faulkner 2012a)

The CB/PNRM Resilience Scale moves horizontally from development to adaptation to climate variability, including disaster risk reduction (ACV/DRR), to adaptation to climate change (ACC). Vertically, the scale moves from *conventional* approaches to development, ACV/DRR and ACC, to those that are *transformative*. To move towards "transformed resilience," progress towards the bottom right-hand box is recommended: "transformative ACC."

To move towards this goal, changing the methods undertaken and approaches used under what is classed conventional development and ACV/DRR in Fig. 3 above is required. This includes:

- Revisiting conventional development and ensuring that the basic needs of the poorest and most marginalized people vulnerable to climate change are being addressed
- Empowering climate vulnerable poor groups to ensure that their knowledge and demands are reflected in decision-making processes
- Moving beyond short-term projectized approaches to planning towards integrated approaches that engage with and build the capacity of local to national institutions, with associated sustainable institutional and resource bases
- Creating spaces for knowledge sharing and knowledge transfer, to support the scaling up and scaling out of effective processes and practice
- Ensuring flexible approaches to planning that can respond to changing needs and incorporate a range of knowledge bases, especially that generated by ultimate project participants.

Moving towards transformative ACC is largely driven by the integration of *new knowledge about adaptation and future climate change*. This knowledge is coproduced from both improved scientific information about future climate change impacts and adaptation science and locally generated knowledge from the climate vulnerable poor about past climate trends and the interaction between climate impacts, vulnerability, and adaptation. This blending of scientific and local knowledge is transformational, because it forces development practitioners to rethink the way development planning and implementation are undertaken. Scientific information specifies that climate impacts are becoming more uncertain; hence, a lens that provides more dependable information on possible outcomes at the local scale is needed in order to understand what matters to local people. Relying solely on scientific expertise is not enough. Local knowledge is also needed to develop a new kind of knowledge that all stakeholders can use in practice.

However, moving towards transformative ACC is not just about new climate change information and adaptation science. It also requires transformative development and transformative ACV/DRR approaches to be operationalized (along with associated transformations in attitudes, skills, and actions) to support moving towards this goal. This is shown on the scale by the addition signs (+). Transformative ACC requires transformative development, *plus* transformative ACV/DRR approaches, and *plus* other components that may be required. This is particularly important for this assessment, where project activities were not initiated with improving climate change resilience as a key goal – and yet many of the development-oriented interventions implemented will likely still make important contributions to transformed climate change resilience.

Similarly, making the distinction between conventional and transformative ACC is important, because moving towards more sustainable and transformative resilience does not advocate undertaking *any* adaptation measures. Adaptation interventions can be viewed on a continuum ranging from specific climate change impacts-based approaches to those that view adaptation *as* development (Ayers and Dodman 2010; McGray et al. 2007). On the CB/PNRM Resilience Scale in Fig. 3 above, conventional ACC takes the former approach where climate change impacts such as droughts or floods are taken as the starting point for vulnerability assessments, giving rise to largely technological adaptation solutions through a top-down approach such as insurance schemes for livestock losses. In comparison, transformative ACC takes the latter approach that views adaptation as increasing the adaptive capacity of people to climate and non-climate risk by taking a livelihoods-based view to assessing vulnerability. Consequently, this results in adaptation interventions that target the underlying drivers of vulnerability as specified by climate vulnerable poor groups themselves, such as improved household access to safe water sources. This perspective is important in the context of this assessment where confidence in what to expect in terms of specific climate change related impacts for project sites in the coming years is not high.

Results and Analysis of CB/PNRM Effectiveness Through a Climate Change Lens

The following results and analysis of Save the Children's CB/PNRM intervention have been made to provide insight into how much it contributes to building resilience to current and potential future climate change impacts and delivers adaptation benefits for targeted pastoralists and agropastoralists. For ease of comparison, results are summarized alongside those from the non-Save the Children intervention site in Table 1 below. Discussion and analysis of results follows, including examples of key differences between research study sites and justifications to support why results are placed in each position on the CB/PNRM Resilience Scale in Figs. 4 (Save the Children site) and 5 (non-Save the Children site) below.

Save the Children's CB/PNRM Intervention

1. **Awareness of, access to, and integration of weather and seasonal forecasts in planning and decision-making processes at community and local institutional level**

   Community and local institutional stakeholders have access to up-to-date weather and seasonal forecasts from a mix of traditional and more scientific sources. These are harmonized at community scale to respond to local needs

Table 1 Fieldwork results comparing resilience-building outcomes of Save the Children's CB/PNRM intervention site with the non-Save the Children site

Results from Save the Children's CB/PNRM intervention site	Results from the non-Save the Children site
1. Awareness of, access to, and integration of weather and seasonal forecasts in planning and decision-making processes at community and local institutional level	Lack of access to and integration of short-term weather and longer-term climate information in planning and decision-making processes at community level, but understanding of need for longer-term climate information to support community preparedness measures to increasing drought risk
2. Shift from seasonal planning to more forward-thinking longer-term foresight, including community perceptions of increased ability to cope with and adapt to future drought conditions	Lack of long-term, forward-thinking foresight in planning processes including ability to trade off possible futures and consequences given uncertainty
3. District government engagement supporting revitalization and potential sustainability of upgraded traditional pastoralist rangeland management systems	Good relationship with local government institutions offering community support with rangeland management through by-law enforcement
4. Implementation of new and improved livelihood and rangeland management practices increasing respondent knowledge and capacity skills sets leading to improved livelihood outcomes, land productivity, and biodiversity	Implementation of existing livelihood and land use strategies despite perceived climate variability changes to local context leading to reduced livelihood outcomes, land productivity, and biodiversity
5. Two-way knowledge exchange on NRM processes between local government and community facilitating improved practices in a climate variability context	Lack of community access to new and improved information and capacity bases required for alternate livelihood strategies, improved rangeland management practices, and adaptation
6. Reducing development deficits through appropriate seasonal mobility and improved access to nutritious pasture, water sources, salt licks, and forest areas facilitating increase in wealth, livestock health, and food security	Appropriate seasonal mobility restricted due to reduced access to nutritious pasture and water sources in wet and dry seasons facilitating increased livelihood and livestock insecurity
7. Community perceptions of increased ability to cope with and adapt to future drought conditions including appropriate seasonal mobility and new knowledge and capacity to produce and store hay	Community perceptions of inability to cope with and adapt to current and future climate/drought conditions due to lack of access to new and improved knowledge and capacity bases required for adaptation
8. Increased female inclusiveness in decision-making processes across pastoralist institutional scales, including women empowerment with perceived ownership of and right to rangeland and natural resources coupled with shift in male mindset on cultural role and value of women	Male-orientated decision-making processes undertaken with lack of female inclusiveness and empowerment, but new understanding and insight into the beneficial role of women in NRM processes

(*continued*)

Table 1 (continued)

Results from Save the Children's CB/PNRM intervention site	Results from the non-Save the Children site
9. Utilization of participatory resource mapping and action plans supporting collective problem solving and consensus building, possible reduced conflict situations, and perceived system flexibility	Evidence of collective problem solving and consensus building through discussion within male community committee members
10. Community openness to test indigenous knowledge systems with external relevant information bases	Community openness to improve traditional NRM knowledge bases through expert information integration and learning-by-doing approaches
11. Responding to climate vulnerable poor needs through inclusivity respectful of pastoralist traditions, including benefit sharing mechanisms resulting in reduced livelihood vulnerability and improved coping capacity	Inclusion of poorer and more marginalized households in community planning with specified benefits and needs addressed unclear

and are used in planning and decision-making processes. Information is useful, yet access to comprehensive earlier weather forecasting is needed to strengthen community climate preparedness. Similarly, local institutional weather-related information provided is primarily short-term in focus, with weather information not the same as rigorous scientific information on longer-term climate change trends. As Save the Children's CB/PNRM intervention did not consider climate change from its outset, this weak integration of climate change foresight is unsurprising. Yet, to support project participants adapt to current and potential future climate changes, engaging with the scientific community to provide access to locally relevant and meaningful scientific and adaptation information is required. When integrated with local knowledge on vulnerability and adaptation, new knowledge is formed that can support changes in practice that lead to stronger resilience outcomes. It is not just *what* is being done that is important, but *why* and *with what knowledge* that is key. Undertaking practice that is not planned action based on climate change foresight reflects a coping paradigm compared to practice driven by new climate change knowledge. Consequently, this result is placed under *conventional ACV/DRR* on the CB/PNRM Resilience Scale in Fig. 4 below.

2. **Shift from seasonal planning to more forward-thinking longer-term foresight, including community perceptions of increased ability to cope with and adapt to future drought conditions**

   Although community climate change foresight is not strong, CB/PNRM planning processes have supported pastoralist and agropastoralist groups in shifting beyond the immediate confines of a seasonal planning approach towards a longer-term vision incorporating longer-term contextual trends. This includes the proper utilization of wet and dry season grazing areas and the systematic management of increasing herd mobility that promotes sustainability of key natural resources supporting improved capacity to adapt to

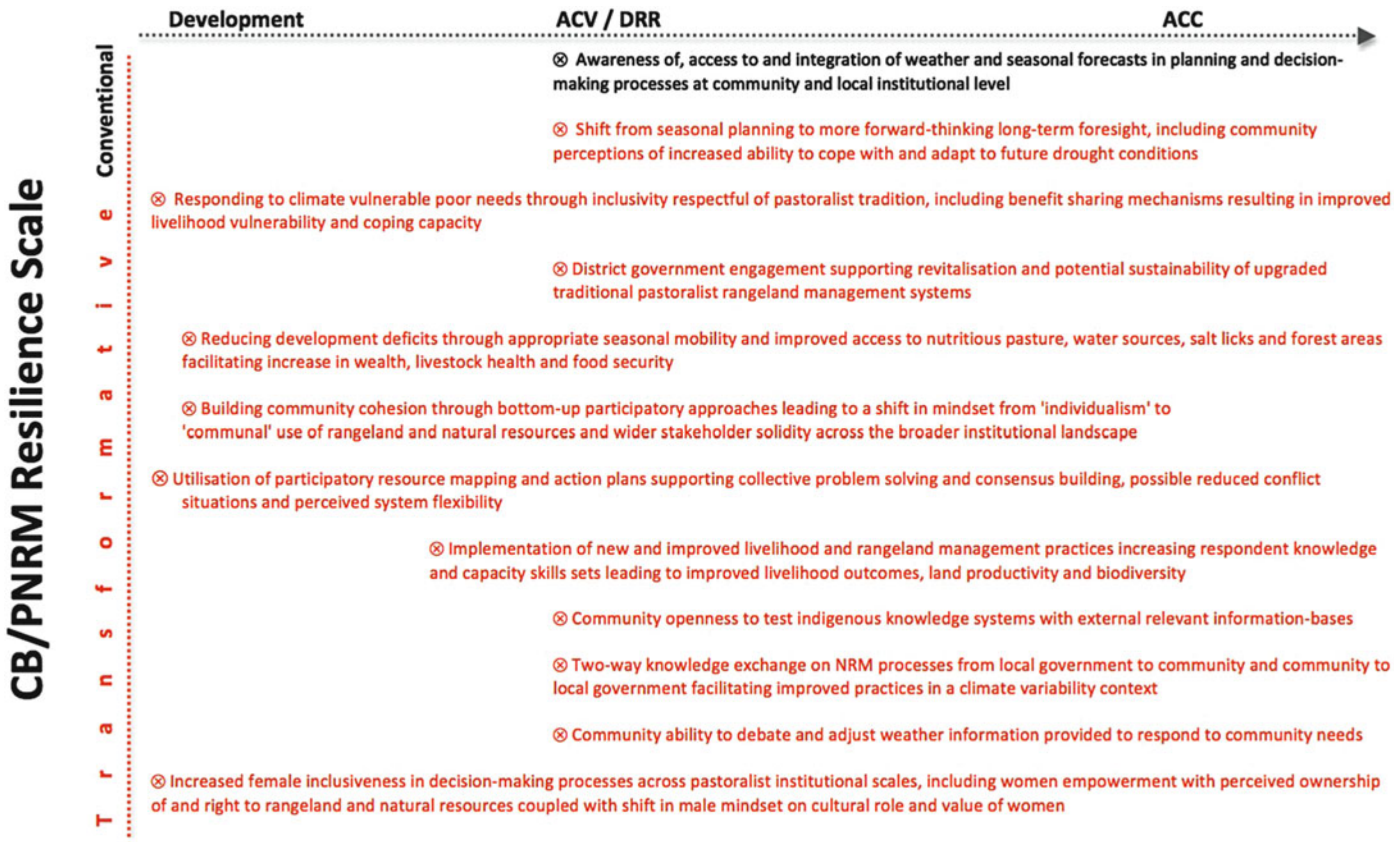

Fig. 4 Assessment of Save the Children's CB/PNRM intervention in building resilience to climate change risk for pastoralists and agropastoralists

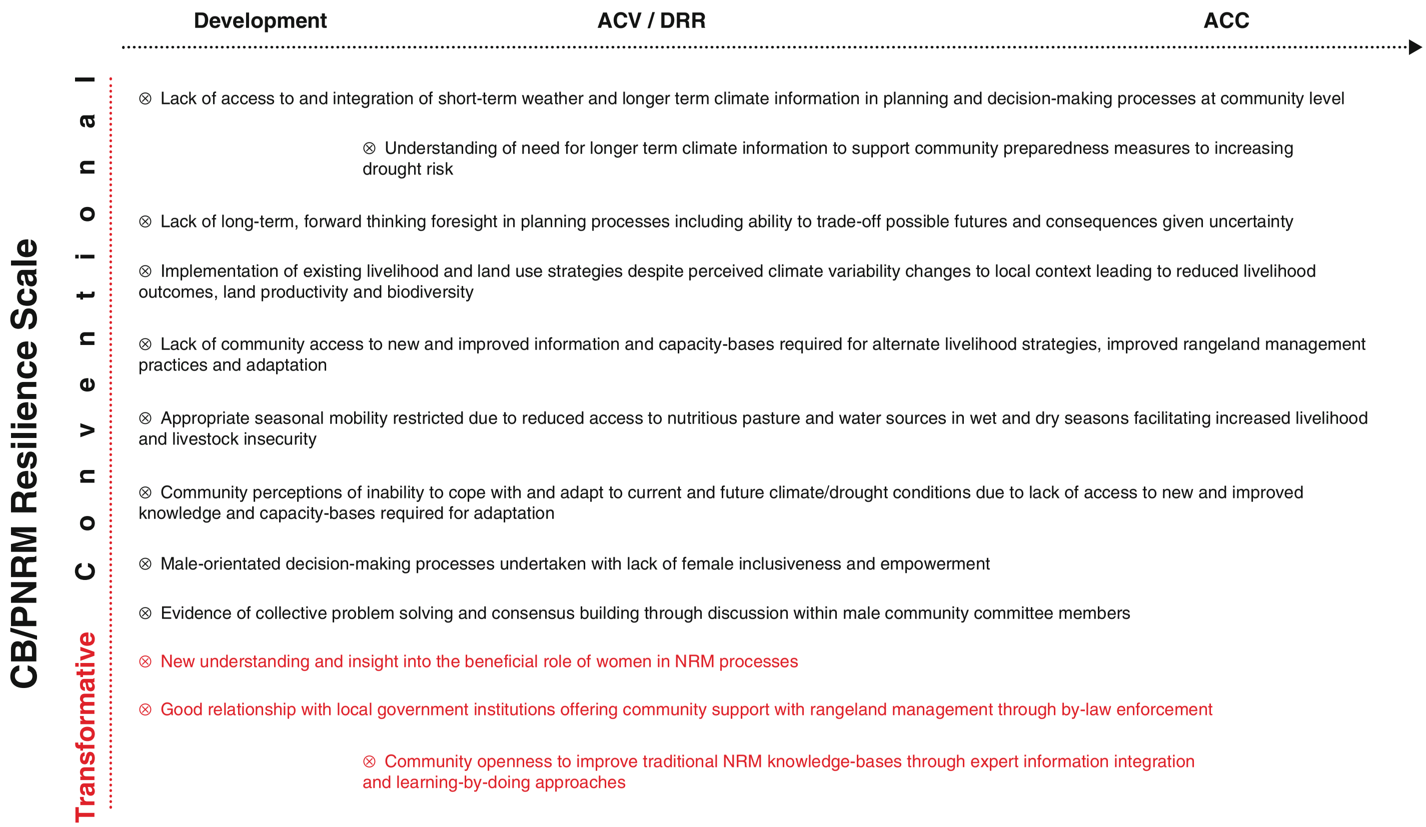

Fig. 5 Assessment of the non-Save the Children CB/PNRM intervention site in building resilience to climate change risk for pastoralists and agropastoralists

current climate variability impacts. This change in planning foresight is a strong entry point to build upon for adaptation to future climate change risk through the incorporation of locally meaningful scientific climate change information as discussed above. As a result, this evidence is placed under *transformative* on the CB/PNRM Resilience Scale. It is considered *ACV/DRR* as it supports community adaptation to current climate risk.

3. **District government engagement supporting revitalization and potential sustainability of upgraded traditional pastoralist rangeland management systems**

   Save the Children's CB/PNRM intervention has strengthened the existing relationship between relevant government departments, customary institutional leaders, and male and female community members – an important factor for adaptation. This includes government enforcement of traditional pastoralist rangeland management systems providing more secure access to and control over land and resources for community stakeholders. This strengthened government-community partnership signals a foundation for sustainability. Community stakeholders perceive they will reap benefits beyond initial project time boundaries. This is an important aspect of building resilience that moves beyond short-term projectized approaches to planning towards longer-term approaches that are integrated with key institutions for an enabling environment for adaptation. This evidence is *transformative* on the CB/PNRM Resilience Scale in Fig. 4 below, because it facilitates institutional processes that enhance longer-term access to resources communities require to adapt to climate and other risks. It is *ACV/DRR* because institutional engagement supports reduction of development deficits of community stakeholders as the first step towards adaptation. By improving access to the institutions and key assets people need to fulfill their basic capabilities, the ability of project participants to cope with and manage the additional stresses presented by climate variability and climate change are likely to be enhanced.

4. **Implementation of new and improved livelihood and rangeland management practices increasing community knowledge and capacity skill sets leading to improved livelihood outcomes**, **land productivity, and biodiversity management**

   Save the Children's CB/PNRM intervention provided community stakeholders with access to relevant and meaningful knowledge and capacity bases for the implementation of new and improved livelihood and NRM practices (examples in Table 2 below) that build resilience to current and potential future climate change impacts – *ACV/DRR* on the CB/PNRM Resilience Scale.

   Similarly, a learning-by-doing approach was undertaken, which is important in the context of adaptation, as not all future climate change impacts are known. Learning what works and what does not will need to be iterative as is discussed in further detail below. Likewise, evidence shows project participants view their surrounding ecosystem and its services in a holistic manner, rather than just as the provider of natural resources. Both these aspects form important components of resilience-building that are considered *transformative* on the CB/PNRM Resilience Scale.

Table 2 Examples of new and improved NRM-related knowledge, skills, and competencies for project participants under Save the Children's CB/PNRM intervention

Proficiency sets			
"Hard" asset oriented		"Soft" process oriented	
New	Improved	New	Improved
– Hay preservation and storage	– Selected bush clearing	– Participatory resource mapping	– Ability to organize wet/dry season grazing areas leading to herders and households undertaking appropriate seasonal mobility
– Debarking for bush clearing	– Soil/water conservation	– Shift in understanding from land and water being only perceived key resources to inclusion of forest capital (leading to forest protection)	– Ability to assign and reallocate appropriate settlement locations
– Aloe vera soap production	– Use of crop residue (for livestock fodder)		
	– Upgrading drought reserves for weak and lactating livestock		

5. **Two-way knowledge exchange on NRM processes between local government and community facilitating improved practices in a climate variability context**

   Local government stakeholders feel CB/PNRM fosters two-way knowledge exchange between government, customary institutional leaders, and community members on effective processes and practices. This merging of knowledge to create new knowledge is important. It suggests potential sustainability of CB/PNRM processes in light of changing contexts. "We can continue with PNRM because we have the knowledge, skills and capacity to manage resources effectively" (Deedha Customary Institution members). This improved capacity to combine local knowledge and "expert" scientific knowledge is important in the context of building resilience to climate change impacts as scientific predictions at a geographical and time scale that would help pastoralists plan livelihood activities accordingly are currently lacking and are not always in agreement with local knowledge of what has been experienced so far, and what changes local people feel are likely to be experienced in the future. This evidence is placed under *transformative ACV/DRR* on the CB/PNRM Resilience Scale. It is "transformative" based on the strong network between community respondents and local government and the corresponding two-way flow of knowledge sharing between these stakeholders. It is considered ACV/DRR because it results in improved respondent resilience and ability to adapt to climate variability risk. This result would move closer towards "transformative ACC" if knowledge sharing included the integration of longer-term scientific climate information with local vulnerability insights to form new knowledge required to support changes in planning and practice.

6. **Reducing development deficits through appropriate seasonal mobility and improved access to nutritious pasture**, **water sources**, **salt licks, and forest areas facilitating increases in wealth**, **livestock health, and food security**

   Evidence suggests that development capacity to cope with and respond to climate variability and environmental hazards has improved by ensuring that the basic needs of community stakeholders are addressed as a first step towards adaptation. Examples of this are presented in Table 3 below. Looking through a climate change lens on the CB/PNRM Resilience Scale, this result is considered *transformative development*.
7. The above evidence, together with new hay making skills, links to another result on the CB/PNRM Resilience Scale: **increased community perceptions of ability to cope with and adapt to drought conditions**.
8. **Increased female inclusiveness in decision-making processes across pastoralist institutional scales**, **including women empowerment with perceived ownership of and right to rangeland and natural resources coupled with shift in male mindset on cultural role and value of women**

   Female inclusiveness in CB/PNRM decision-making processes across pastoralist management system scales presents a considerable change in cultural values within the traditional male-orientated pastoralist system. "The past system is wrong. Women are equal in NRM. They know the problems we face so it's advantageous for us to have them as part of the process" (Aardha Customary Institution members). Female benefits include attending meetings to discuss and disseminate issues within the community and perceived increases in rights and empowerment. Community benefits include the provision of instrumental support with access to natural resources through active engagement in decision-making processes. This result moves beyond conventional towards *transformative development* on the CB/PNRM Resilience Scale in Fig. 4 below.
9. **Utilization of participatory resource mapping and action plans supporting collective problem solving and consensus building**, **possible reduced conflict situations and perceived system flexibility**

   Undertaking resource mapping has fostered collective problem solving and consensus building reflecting priorities of all rangeland users resulting in "reduced conflict through sharing and saving resources" (Reera Customary Institution members). In light of an uncertain future climate where potential demand and competition for natural resources and ecosystem services may increase, this outcome is important. Likewise, the participatory approach used provides perceived system flexibility, with community plans regularly monitored and changed if required. These results provide examples of *transformative development* processes on the CB/PNRM Resilience Scale that aid building climate resilience: community-driven responses; flexible planning approaches; empowerment of respondents through increasing knowledge and capacity bases; and the facilitation of spaces where people can unite to discuss, share, and generate meaningful information deemed important by them.

Table 3 Example results, short-term benefits, and outcomes as a result of traditional pastoralist rangeland management processes being revitalized under Save the Children's CB/PNRM intervention

Result of Save the Children CB/PNRM intervention (in which research for this study took place)	Short-term benefit	Outcome
– 2,000,000 ha of rangeland under improved management, including wet season grazing areas – 4,365 ha of private enclosures dismantled – 16 settlements relocated – 10,396 ha of communal enclosures established/ upgraded	– Increased access to nutritious pasture for livestock during dry seasons leading to improvements in livestock body condition and reduced livestock mortality	– Increase in livestock market price – Shift in livestock market value from wet season to wet and dry season – Two-year-old bull increase in price during dry season from 1,000–2,000 Ethiopian Birr (ETB) without access to communal grazing enclosures to 3,000–4,000 Birr with access under PNRM – One-year-old shoats and calves now hold market value – Perceived shift in livestock market access: traders coming to the community – Increase in number and more drought resilient livestock types owned per household (i.e., camels)
	– Increase in meat and milk production due to access to increased number of improved (nutritious pasture quality and size of pasture available) communal grazing areas for livestock in dry seasons	– Increased food security for children and households – Change from no dry season milk pre-intervention to 2–3 caps of milk per day per cow – Ability to sell excess dry season milk production in the local market
– 67 migration routes reopened – 55 salt lick routes reopened – Nine traditional water points rehabilitated – Seven shallow well water points rehabilitated – Three pond water points rehabilitated	– Better access to existing grazing and water sources due to reopening of roads/ migration routes – Salt licks reopened facilitating improved access to a key natural resource for livestock health	– Improved access to water sources for livestock during wet seasons after the rainy season has ended, although secure access still problematic leading to potential early migration to dry season grazing areas – Increase in access to mineral and salt lick sites resulting in improved livestock health especially during wet seasons – Farmers reducing enclosed land holding areas to perimeters of cultivatable

(*continued*)

Table 3 (continued)

Result of Save the Children CB/PNRM intervention (in which research for this study took place)	Short-term benefit	Outcome
		agricultural land rather than extended plots blocking road and migration route access and privatizing large areas of key rangeland resources that were previously "common" property
	– Reduced water collection time for women due to improved access to water sources (from a 3-am start and 6-pm finish to a 10-am start to 3-pm finish) and change in water management structures reducing manpower required to physically retrieve water (from eight to four people needed) – Reduced time searching for grass for livestock during dry seasons due to wet/dry season grazing divisions and new hay making skills fostering availability of grass in dry seasons	– Increased time for alternate household responsibilities, including attending decision-making meetings for women engaged in PNRM processes

This links to another result on the CB/PNRM Resilience Scale in Fig. 4 below: **building community cohesion through bottom-up participatory approaches leading to a shift in mindset from "individualism" to "communal" use of rangeland and natural resources and wider stakeholder solidity across the broader institutional landscape**. The bottom-up approach used at large in Save the Children's CB/PNRM intervention is also *transformative development* as it moves beyond conventional development planning and project processes that focus on "outcomes" rather than "process" as well. The "conducive environment to participate actively in managing resources properly" has facilitated a change in community mindset from individualism to communal use of rangeland resources (Deedha and Reera Customary Institution members). It has also enabled community and institutional cohesion with increased accessibility to government institutions identified as important for livelihood support at community level. "Before all stakeholders worked separately. PNRM is best as it brings people together" (Liben District Land and Environmental Protection Office). Working together through collaborative practice is also *transformative development*. This is because it breaks the boundaries of conventional practice that often isolate different stakeholders and their needs from each other.

10. **Community openness to test indigenous knowledge systems with external relevant information bases**

    By merging traditional knowledge with external expert information to generate improved community outcomes, community stakeholders are open to move beyond the boundaries of their own traditional knowledge base and adjust systems with relevant information to meet community needs in light of changing circumstances – a key component of adaptive capacity. "Save the Children told us to enclose an area but we knew this before. What is different now is that we use new skills in this area such as piling of hay [and prescribed fire] so the area of land is more productive for us" (Reera Customary Institution members). Also, project participants are innovating through altering practices shared on a small scale – another key component of adaptive capacity. These results suggest a move beyond conventional approaches to those that are more *transformative*, and closer to *ACV/DRR* than development, because the mechanisms in place facilitate improved practice in the current context of climate variability.

11. **Responding to climate vulnerable poor needs through inclusivity respectful of pastoralist traditions, including benefit sharing mechanisms resulting in reduced livelihood vulnerability and improved coping capacity**

    In a climate change context, ensuring the needs of the poorest and most marginalized are identified and addressed is important, as climate impacts will potentially increase respondent vulnerability levels. Save the Children has targeted most vulnerable needs through an inclusive community approach that is culturally appropriate for pastoralist groups. This evidence is viewed as *transformative development* on the CB/PNRM Resilience Scale. Similarly, this evidence is transformative as empowerment of the climate vulnerable poor has been increased through benefit sharing mechanisms that adjust previous structures that did little to support the poorest and most marginalized households engaged in NRM (Napier and Desta 2011). For example, shifting allocation from livestock grazing to hay making in upgraded community enclosures results in less well-off households incurring more benefits than better off households due to increased numbers of poorer households engaged in improved hay making practices. Likewise, assigning less well-off households without livestock designated areas to practice improved irrigated farming supports reduced livelihood vulnerability and improved coping capacity.

The non-Save the Children CB/PNRM Intervention Site

The overriding comparison between study sites is that Save the Children's results primarily fall between *transformative development* and *transformative ACV/DRR* on the CB/PNRM Resilience Scale. Results from the non-Save the Children site fall largely under *conventional development*. In addition to the results presented in Table 1 above, discussion and analysis highlighting key differences is presented here.

Community stakeholders at the non-Save the Children study site were operating on an existing pastoralist livelihood system paradigm that was no longer producing effective results in light of local changing circumstances with respondents unable to adapt with change. One component contributing towards this outcome is as follows: **lack of access to and integration of short-term weather and longer-term climate information in planning and decision-making processes at community level**. This result is placed under *conventional development* on the CB/PNRM Resilience Scale in Fig. 5 below. New climate change and adaptation science that integrates local knowledge with relevant and meaningful scientific climate information is required for effective adaptation.

Another key component for why coping strategies undertaken were not forming the basis of successful long-term adaptive strategies needed to address current and future climate change risk is that non-Save the Children respondents lacked understanding, ability, innovation, and access to relevant information regarding how to adapt their livelihood and rangeland management strategies to address perceived climate variability changes. "We're still keeping livestock in the old ways when there was grass and water" (male non-Save the Children intervention site members). In addition, community stakeholders view their surrounding ecosystem not as a holistic functioning system for resilience-building but as the provider of key natural resources that their livestock depend on. The results of this approach are shown in Table 4 below. The outcome of **implementation of existing livelihood and land use strategies despite perceived climate variability changes to local context leading to reduced livelihood outcomes**, **land productivity, and biodiversity**, and its associated results highlighted in Table 4 below are placed under *conventional development* on the CB/PNRM Resilience Scale.

Likewise, **lack of community access to new and improved information and capacity bases required for alternate livelihood strategies**, **improved rangeland management practices, and adaptation** that contributes towards the results in Table 4 above renders its position under *conventional development* on the CB/PNRM Resilience Scale in Fig. 5. Non-Save the Children community stakeholders do have access to local government institutions, but government capacity for meaningful support through desired learning-by-doing approaches is lacking. "We want practical training so we can learn properly" (male non-Save the Children intervention site members). Nevertheless, community openness to improve traditional NRM knowledge bases through expert information integration and more beneficial learning mechanisms to support adaptation moves towards *transformative development*.

One important difference between study sites relates to gender. Women at the non-Save the Children site were not empowered. They were unable to raise their voices and participate in community decision-making and therefore unable to realize their potential role as strategic agents of community adaptation processes. Consequently, this result **of male-orientated decision-making processes undertaken**

Table 4 Results showing lack of rangeland resilience and its consequences for non-Save the Children community stakeholders

Absence of new/improved action	Outcome of absence of new/improved action
– Wet/dry season mobility operational but ineffective in providing access to sufficient pasture and water access in changing context circumstances – Increasing lack of access to water in dry season for livestock and households – Lack of access to salt lick resources – Lack of conservation of degraded land (e.g., through soil/water conservation techniques; planting grasses) – Lack of diversified livelihoods (e.g., hay making) – Lack of improved crop cultivation techniques	– Pasture in dry season enclosures being consumed quickly due to increased number of livestock rendering insufficient pasture for length of dry grazing seasons – Reduction in livestock body condition and livestock price (6,000–8,000 ETB to 300–1,000 ETB) – Reduction in milk availability for household consumption – Livestock able to migrate when grass is available – Salt licks not easily accessible as located in far distances – Teff/crop residue/straw/hay purchased from highland areas at high prices – Understanding of need to keep hay for crisis periods – Donkeys used for water collection from far distances to support access to water, especially for weaker calves – Women undertake a 14-h journey to collect and carry 20 l of water from nearest town areas – Trees and plants drying out and dying – Reduction in wildlife – Reduction in land productivity and ecosystem services – Shift from multi- to mono-crop cultivation

with lack of female inclusiveness and empowerment is placed under *conventional development* on the CB/PNRM Resilience Scale.

Evidence does however highlight signs of male community stakeholders potentially shifting mindsets on women's role in NRM processes. "Our previous thinking was that women are not fit for our work as it requires strength. But now we realize that women would be beneficial. A kallo protected by women in another area is in much better condition that ours" (Male non-Save the Children intervention site members). This **new understanding and insight into the beneficial role of women in NRM processes** is considered *transformative development* on the CB/PNRM Resilience Scale.

Key Recommendations

This study has shown the value of CB/PNRM as an adaptation strategy in the context of the Ethiopian dryland pastoralist communities. While climate change was not a specific focus of the Save the Children CB/PNRM intervention design, many of the activities implemented made important contributions to building local adaptive capacity. Comparisons with the non-Save the Children site, where most activities were closer to *conventional development* than *transformative development* or *transformative ACV/DRR*, reinforced these observations. This suggests that the potential role that development actors, such as Save the Children, can play in the context of adapting to climate change merits further attention among governments and policymakers. Likewise the role that sustainable natural resource management can play as an adaptation strategy, particularly for poor and vulnerable groups such as the Borana pastoralists, merits further attention when compared to alternative infrastructure or technological adaptation solutions. Chishakwe et al. (2012) and Munroe et al. (2011) argue for the need for newer fields of study such as community-based adaptation to learn from older disciplines such as CB/PNRM, and this study reinforces this recommendation.

Conclusions

The aim of this study has been to assess the effectiveness and contribution of CB/PNRM in building resilience to current and potential future climate change impacts for pastoralists and agropastoralists in Ethiopia. To achieve this, the processes used and the results obtained by Save the Children's upgraded CB/PNRM intervention compared to CB/PNRM with no external support has been analyzed in light of local climate and non-climate risk factors.

Based on the long-term presence and existing rapport between Save the Children and project stakeholders in the selected CB/PNRM intervention sites, together with a thorough understanding of the pastoralist systems in play and a more conducive institutional environment for change supported by recent government learning, Save the Children's CB/PNRM work has produced strong results.

Results show that much has been done towards moving from conventional approaches to development (and adaptation to climate variability including disaster risk reduction) to *transformative development* approaches that empower local people and support bottom-up, participatory, flexible decision-making and planning processes within a strong institutional context. This includes incorporating local and scientific climate knowledge focused on climate variability trends into planning. However, locally meaningful scientific climate change information still needs to be merged with local knowledge bases so it can be mainstreamed into community and institutional decision-making processes across scales to support adaptation to uncertain future climate change impacts.

Much has also been done towards moving from conventional development approaches towards those that support adaptation to climate variability including disaster risk reduction (ACV/DRR). Although project activities were not initiated with improving climate change resilience as a key goal, evidence shows that many of the development-oriented processes implemented have made important contributions towards this outcome. In an adaptation to climate change context, this is significant as it means that Save the Children has largely moved beyond conventional development and ACV/DRR methods that typically lack the ability to foster sustainable resilience-building in an uncertain and changing environment.

Save the Children's CB/PNRM intervention has achieved this through the following means:

- Moving from a short-term projectized approach to planning towards the facilitation of longer-term change processes
- Application of an integrated project approach that has engaged local institutions and improved partnerships between government and community members, including joint action between government and traditional customary institutions
- Strengthening local institutional processes fostering an enabling environment for adaptation by addressing basic needs through improved access to key assets and resources and new and improved livelihood strategies leading to enhanced local adaptive action
- Meaningfully engaging respondents in PNRM community-driven planning and decision-making processes, especially women, through strong participatory and collaborative methods increasing individual and community empowerment plus bottom-up accountability, especially for those most marginalized community members
- Project participants shifting their mindset from viewing their ecosystem as a provider of natural resources to a more holistic understanding of environmental system linkages
- Targeted community members possessing improved development capacity to cope with and respond and adapt to current context situations including climate variability, with subsequent decreases in poverty levels, and increases in food security and livelihood outcomes

As a result, targeted community stakeholders feel they possess the knowledge and capacity to cope with and adapt to increasing drought scenarios. Joint community and local government action plans and agreements by local government authorities facilitating improved access to appropriate wet and dry season grazing areas, combined with new livelihood and rangeland management techniques, have led to an increase in adaptive capacity which evidence suggests is likely to increase respondent resilience in light of, or in spite of, climate risk. This means that Save the Children's CB/PNRM intervention has helped strengthen the local institutions and strategies required by respondents to ensure higher productivity levels and thus greater accumulation of assets, improved diet and income, and the increased capacity to protect these gains, in a context of unpredictable distribution of resources and periodic extreme events.

In stark comparison, a site visited without Save the Children CB/PNRM interventions to provide comparative results of project and adaptation outcomes showed that existing pastoralist livelihood systems were no longer producing effective results in light of local changing circumstances with respondents unable to adapt with change. Evidence showed that respondents' were not bouncing back to previous productivity levels before changing drought conditions, with productivity levels appearing to be in slow decline over time. Coping strategies undertaken were not forming the basis of successful long-term adaptive strategies needed to address current and future climate change risk.

This reflects the results of previous research in the Borana Zone, which found that while communities were in agreement "that diversification of financial resources and income generating activities is key to adapting to changing conditions, whether this means engaging in petty trade, sale of firewood and charcoal, construction and renting of houses, honey and alcohol sale, business creation and management, or learning to save money using financial institutions," limited access to information and "limited education, skills and access to financial services and markets required to diversify their livelihoods" limited pastoralists' ability to adapt (Riché et al. 2009). The research found that a lack of appropriate knowledge and experience meant that communities suggested different and sometimes contradictory adaptation strategies in light of expected changes: "For example, pure pastoralists suggested that agro-pastoralism would be a better livelihood strategy to deal with climate change, while agro-pastoralists would like to drop out of their farming activities due to increasing crop failure" (Riché et al. 2009).

The results of Save the Children's CB/PNRM intervention have contributed towards reducing livelihood vulnerability and increasing resilience for its project participants by leaving behind a legacy of empowered people more able to cope with and adapt to current climate variability risk through strong development-based outcomes of "good" development and improved institutional governance.

However, more progress needs to be made to further strengthen respondents' ability to adapt to current climate variability risk and importantly to future climate change impacts. Undertaking *transformative development* and *transformative ACV/DRR* approaches is necessary but is only part of the process towards the long-term goal of *transformed climate change resilience*, whereby resilience is built at scale, resulting in the successful longer-term adaptation of the climate vulnerable poor to climate change impacts through sustainable adaptation strategies (Ayers and Faulkner 2012; Faulkner 2012b). Among others, improvements in generating and integrating new knowledge about adaptation and future climate change across scales from community to local institutional levels is required.

Abstract

Rainfall scarcity is a constraint to productivity in arid and semiarid regions of Kenya. This chapter identifies the common rainwater harvesting technologies used in Makueni County, a semiarid region, both for domestic and agriculture production as a way of adapting to climate change and variability. Household interviews were held for 134 households from five villages in addition to collection of secondary data from the area. The results revealed that 30 % of farmers have water tanks in their home, 90 % are members of communal sand dams and ponds, while 70 % use road water harvesting to supplement rain-fed agriculture. The constraints for adoption included lack of labor and skills. Different coping strategies applied by small-scale farmers who practice rain-fed agricultural production in this region include soil moisture retention practices such as terracing and use of sand dams as well as storage of water for domestic use in tanks. This valuable information will provide best home-grown practices and reveal gaps on rainwater harvesting which can be implemented by extension officers and local stakeholders. The adoption of these important technologies can be a basis of curbing related problems under similar conditions.

Adaptation strategy • Makueni County • Rainwater harvesting • Climate change and variability

Introduction

The Effect of Climate Change on Water Resources

Africa is characterized by a wide variety of climate systems ranging from humid equatorial systems through seasonally arid tropical to subtropical Mediterranean-type climates (Hulme 2001). These climates exhibit differing degrees of temporal variability, particularly with regard to rainfall amount and distribution. Climate change is often used to include the occurrence of medium-term changes in weather patterns, increased climate variability, and more frequent climatic extremes such as droughts and floods (IPCC 2001). It is usually associated with increasing frequency and intensity of droughts and water scarcity that aggravate food insecurity and poverty in rural communities.

The Fourth African Assessment Report on climate change released by the Intergovernmental Panel on Climate Change (IPCC) highlights major issues related to potential impacts due to climate change (IPCC 2007). It indicates that Africa is one of the most vulnerable continents to climate change and climatic variability. This is a result of the interaction of multiple stresses including land degradation and desertification, declining runoff from water catchments, high dependence on subsistence agriculture, HIV/AIDS prevalence, inadequate government mechanisms, and rapid population growth occurring at various levels. Africa also has low adaptive capacity due to factors such as extreme poverty, frequent natural disasters such as droughts and floods, and rainfall-dependent agriculture (Boko et al. 2007). Due to this vulnerability, it is estimated that between 75 and 250 million people are likely to be exposed to increased water stress by 2020. The rain-fed agricultural yields could also be reduced by up to 50 % (Boko et al. 2007). These impacts will be aggravated by climate change unless strategies to address climate change-induced water stress are adopted.

In an attempt to overcome climate change and other challenges facing them, many African countries have crafted strategic plans detailing how they intend to deal with these global issues. For instance, Kenya has developed the Kenya Vision 2030 plan. One of the key factors of Kenya Vision 2030 is to transform Kenya into a newly industrializing middle-income country providing a high-quality life to all its citizens by the year 2030 (GoK 2007). This is also emphasized in the Kenya Economic Stimulus Program (ESP) objectives of investing in long-term solutions to the challenges of food security and economic opportunities in rural areas for employment creation (KNAMP 2010). The Millennium Development Goals (MDGs) 1 also aim at eliminating extreme poverty and hunger using sustainable methods by the year 2015. However, by the projections of the year 2008, it was apparent that no African country was likely to achieve all its goals by 2015 (Achim 2006). Despite the Kenyan new constitution promulgated in 2010 stating that "Every person has the right to clean and safe water in adequate quantities" (GoK 2010), an estimated 41 % of Kenya's population live without access to safe drinking water, relying on unprotected wells, springs, or informal water providers (UNICEF 2010). With regard to water availability, like many other countries, Kenya is below the international water scarcity threshold (1,000 m^3 per person per year) with only 935 m^3 available per person per year (FAO 2007), and population growth is forecasted to reduce this figure to 359 m^3 by 2020 (UN-Water 2006).

To curb water scarcity, programs such as the Integrated Water Resources Management (IWRM) project were established in 2002. This project promoted and coordinated development and management of water, land, and related resources in order to maximize the resultant economic and social welfare in an equitable manner without compromising the sustainability of vital ecosystems (GWP 2010). The project was done in Makueni County. Makueni County, located in Eastern Kenya, is hot and dry with erratic and unreliable rainfall. The people of Makueni rely on an inadequate, fragile, and uncertain resource base under constant threat of drought, resulting in food insecurity and undernutrition (Ismail and Immink 2003).

Introduction to Makueni County

Makueni County is one of the most food-insecure areas of the country with over 70 % of households classified as poor or very poor (WMS 1998). The farmers practice subsistence farming under rain-fed agriculture. It is for this reason that Makueni County was selected as a case study, and any results obtained in the county would be fairly representative of the other parts of the arid and semiarid regions. The county is unique because climate in this region falls under two climatic zones: arid and semiarid with most of the district being classified as arid. Researching in this county therefore offers a very good opportunity to see the difference in the coping strategies to climate change for the people in arid and semiarid regions. This is important because with the high rate of impacts of climate change, the semiarid regions may in the future be arid. The lessons learned in the arid regions may be used to prepare the people in the semiarid areas in Makueni County and other currently semiarid areas to cope with the expected and impending aridity in the near future.

Adaptation of Makueni Residents to Climate Change

Some of the adaptation measures to water stresses during droughts and high rainfall variability include adoption of supplemental irrigation, rainwater harvesting, and storage (Nkomo et al. 2006; Osman et al. 2005). Measures used specifically for agriculture in Makueni include planting of drought-resistant crop varieties, use of certified seed as opposed to planting grain from previous harvests, early-maturing crops, promotion of small livestock improvement, establishment of group seed bank, promotion of credit access and food storage, and improvement of water exploitation methods such as shallow wells, roof catchment, and sand dams among other water harvesting technologies (Speranza 2008). Crop and animal diversification, income diversification, and feeding animals on preserved hay and mineral salts are also some of the strategies for adapting to climate change (Mutambara et al. 2012). Adaptation to climate change and its variability necessitates the adjustment of a system to moderate the impacts of climate change through taking advantage of new opportunities and coping with the resulting consequences (IPCC 2001).

The Need for Rainwater Harvesting in Makueni

Makueni has only one perennial river with numerous streams. Therefore, alternative ways of addressing the drawbacks and water scarcity in this region are through maximizing the use of rainwater through rainwater harvesting (RWH) as well as improving soil and water management. Rainwater harvesting is mainly the collection of runoff for its productive use. It can also be defined as a method for inducing, collecting, storing, and conserving local surface runoff for agriculture in arid and semiarid regions (Boers and Ben-Asher 1982). It is one adaptation measure that does not require large capital investment and is essentially a management approach, to provide water resources at the community level and ensure livelihoods are maintained (IRIN 2006). The use of rainwater harvesting leads to a reduction in water costs, ease of water acquisition, and control of floods and soil erosion (Reiz et al. 1988; Zhao 1996; Li et al. 1999; Wang et al. 2005). RWH is also simple to operate and manage and therefore ideal to rural communities such as those in ASAL regions (Li et al. 1999).

Soil and water management is a must for agricultural production in ASAL regions. The harvested water seeps into the ground through embankments and impediments such as bunds and terraces, where it is stored in mulch in the case of in situ micro-catchments for prolonged use by plants. Encouraging infiltration of rainwater also raises the water table and makes water readily available for plants or in shallow wells.

While RWH systems can improve agricultural production and reduce drought in semiarid environments, their performance and effectiveness is limited by high water losses, inadequate storage capacity, and poor water management (Ngigi 2009). Thus, improving the access of poor people to water has the potential to make a major contribution toward poverty eradication through improved agricultural production as well as enhanced food security.

RWH promotes gender equality and empowers women by availing water close to their homes and limiting the distance they have to travel to fetch it as well as increasing food production and nutrition (Lehmann 2010). It has however been shown that water-related enterprises such as agricultural development projects have a far greater success rate when women are involved than when they are excluded (Achim 2006). According to the World Water Development Report, many girls are prevented from attending school because they are in charge of collecting domestic water (Achim 2006). Thus, rainwater harvesting as a decentralized water supply system eliminates women's burden of collecting domestic water. Rainwater harvested from rooftops supplies relatively clean water, which when filtered, treated, and stored, provides a safe and clean source of drinking water. Thus, women and the girl child use the time saved from collecting water on education and other income-generating activities.

Adoption of RWH ensures environmental sustainability because communities are able to engage in more crop production including tree planting activities that lead to increase in the proportion of land area covered by forest, which help to maintain biodiversity. According to Mati (2006), rainwater harvested from rooftops coupled with storage and use of drip irrigation kits has relatively increased in East Africa.

Description of RWH Systems Commonly Used for Domestic and Agricultural Use

Inadequate access and quality water for both domestic and agricultural use was identified as the main challenge in the Makueni District Vision and Strategy 2005–2015 (PWC 2005). Due to this there exist various water harvesting technologies in the county.

Water Tanks

Water tanks mostly harvest water from rooftops. Tanks are popular for saving water, are easy to use, and are available in styles to suit most homes. Harvesting water with tanks involves three primary components: catchment, conveyance, and a collection device. Rainwater drains down the slanted rooftop to the conveyance instruments, or gutters, at the base of the roof. The gutters transport the water from the rooftop to the collection device. The advantages of water tanks include the fact that it is a simple technology which provides free soft water that lathers easily, saving on soap and detergent. It also provides extra water available for kitchen gardening and one can get any size of the tank. However, the cost of tanks is high for most smallholder farmers with the rainwater tanks needing careful management to prevent mosquitos from breeding in them (Kheradi 2011). Figures 1 and 2 show different types of tanks used by the community.

Sand Dams

Sand dams are small impermeable barriers constructed across the bed of seasonal streams. Sandy riverbeds are required for a sand dam to work properly. Sand dams vary in size according to the riverbed. It is a very simple technology and inexpensive since construction materials are locally available. In most cases, the labor

Fig. 1 Water tank 1 for domestic use

Fig. 2 Water tank 2 for domestic use

required to build the barrier comes from the local community. Another benefit of having the water stored underground is that it is less vulnerable to contamination and disease-carrying insects, such as mosquitoes, since there is no medium for laying their eggs. Sand dams are very low in construction costs. All that is needed to build them is wood to form the barrier, reinforcing material, and concrete or masonry as shown in Fig. 3. Being a simple structure, there are minimal to zero maintenance costs associated with sand dams (PA 2008; RHIN 2007; Stern 2011).

Zai Pits and Negarims

Zai pits were traditionally invented by farmers in Burkina Faso (NDMA 2011). In Kenya, they are referred to as planting pits and are boxlike structure in cross section as shown in Fig. 4. They are constructed by excavating the soil and returning the rich top soil with organic mulch, while the subsoil acts as an embankment behind the pit. A tree crop or several plants like maize and beans are then planted in the pit.

Fig. 3 Sand dam at Makueni County

Fig. 4 Zai pits at Makueni County

The mulch soaks up the water and stores it throughout the dry season. Similarly, negarims act in the same way except that they are mostly used for tree crops and involve a formation of square embankments. Some of the advantages of using Zai pits and negarims are the fact that they can be reused for up to four crop seasons or two seasons without the need to add more manure. In addition they increase crop yield and enable better crop survival in drought time, promote ease of weed control, conserve water through reduction of soil erosion, as well as improve soil fertility and environmental conservation (NDMA 2011). However, Zai pits require heavy labor for preparation and may not work well in waterlogging soil.

Rock Catchment

Rock catchments are systems which mainly use natural rock surfaces to divert rainwater to a central collection area (Fig. 5). The collected rainwater passes through sand and gravel before storage in a water reservoir or tank. The sand and gravel act to filter and make the water clean.

Bunds

Bunds are large earth banks on the contour that trap runoff (Fig. 6). Bunds vary in shape. They are usually built to prevent runoff and conserve water. Bunds are simple to build, improve productivity, and keep water in the soil. Despite this, bunds use a lot of land, may create temporary logging, and may interfere with farm operations if the bunds are too close to each other. However, they are labor intensive (Yongon 2008).

Water Pans and Ponds

Water pans and ponds are excavations or embankments that are constructed on the path of natural rainwater catchments and used as water reservoirs (Fig. 7). To create a leakproof water reservoir, it is necessary to use an impervious layer of soil or line the reservoir with plastic material to form the plastic-lined dam. A recent

Fig. 5 Rock catchment

Fig. 6 Trapezoidal bunds

Fig. 7 Water pans

innovation in Kenya used by farmers that lack a large catchment area is the diversion and collection of rainwater from road drainage, a method commonly known as road runoff harvesting. This method has become so popular along some roads, some farmers have conflicts as farmers up the road divert all the water

Table 1 Classification of uses of RWH technologies

Water tanks	Water pan	Water pans
Water pans	Road harvesting	Farm ponds
Farm ponds	Zai techniques	Sand dams
Sand dams	Bunds	

leaving little or no water for farmers down the road (Ngigi 2009). This study identified the types of rainwater harvesting method for domestic and agricultural use and the impact to smallholder farmers in Makueni County (Table 1).

Methodology

Description of the Study Area

The study was conducted in Makueni County which is located in the southern part of the Eastern Province of Kenya in East Africa. The elevation is 1125 m above sea level, latitude 1° 50′S and longitude 37° 14′E in the transitional zone between agroecological zones IV and V. Makueni County is characterized by extreme rainfall variability. The region receives mean annual rainfall of about 500–600 mm annually (Njiru 2012). The rainfall pattern is bimodal with two rainy seasons with two peaks in March/May (long rains) and October/December (short rains). The dry period occurs from June to October and from January to March. Precipitation is highly influenced by topography; the hill masses receive higher amounts of rainfall in the range of 1,200 mm, the medium zone receives up to 750 mm, and the very low-lying zone averaging 600 mm of rainfall per year, respectively.

Temperatures in Makueni County are high throughout the year which causes high evaporation. The area experiences temperature ranges of between 18 and 24 °C during the cold seasons and 24 and 33 °C in the hot seasons. The mean annual potential evaporation in the central and northwestern ranges between 1,800 and 2,000 mm, while in eastern and northeastern is from 2,200 to 2,400 mm (PWC 2005). However, the overall drainage pattern in the county is from west to east. Figure 8 shows a map of Makueni County.

Sampling Techniques and Data Analysis

A two-stage sampling technique was applied to select the households. In the first stage, 178 households were randomly interviewed from a list of 400 households. In the second stage, a total of 134 households from 178 households who were practicing at least two rainwater harvesting systems were considered for the analysis. Data analysis involved both the primary and secondary data. The analysis of quantitative data was done using MS Excel and presented as percentages in graphs. The study was conducted in June 2011.

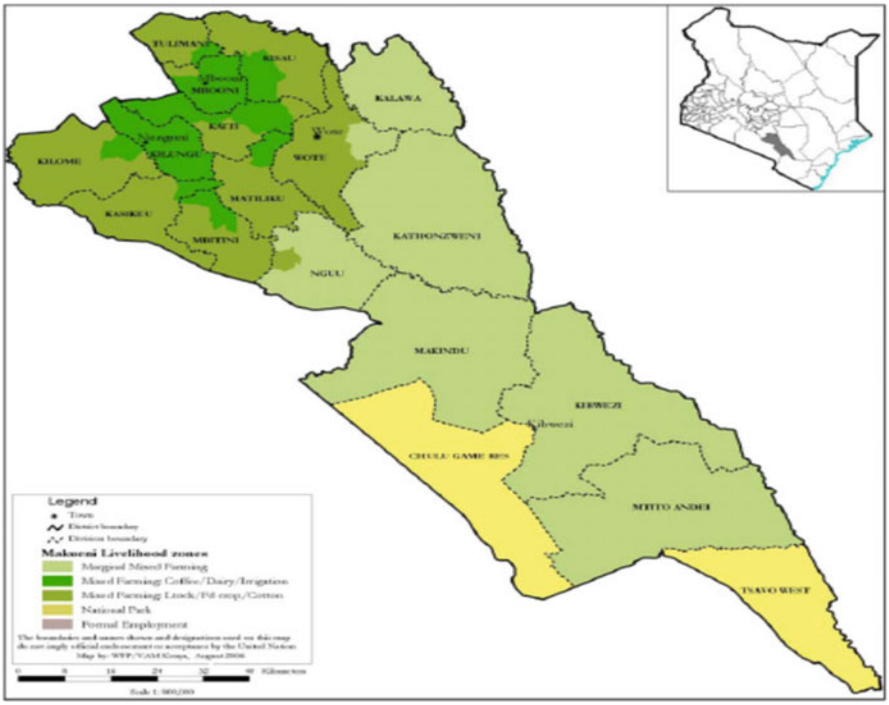

Fig. 8 Map of Makueni County (CRA 2012)

Results and Discussion

Summary of Results

Farmers were asked to point out the rainwater harvesting technologies they were using. Majority (95 %) were using terraces, with 90 % mentioning communal sand dams. Road harvesting (70 %) was also popular among the farmers. Water tanks were used by 30 % of households, and this may be due to the fact that only 48.1 % of the housing units in Eastern Kenya are roofed with iron sheet roofs, asbestos cement sheets, concrete, or clay tiles. Figure 9 indicates that on average, 51 % of the households were using water pans, farm ponds, and sand dams for multipurpose use, while 30 % used water from water tanks for domestic use especially for drinking.

The Adoption of Rainwater Harvesting Technologies

The rainfall data presented in Fig. 10 gives an interesting picture of rainfall in Makueni. Although most references talk of a bimodal rainfall pattern, it would seem that there is only one rainy season that starts around October and peaks in

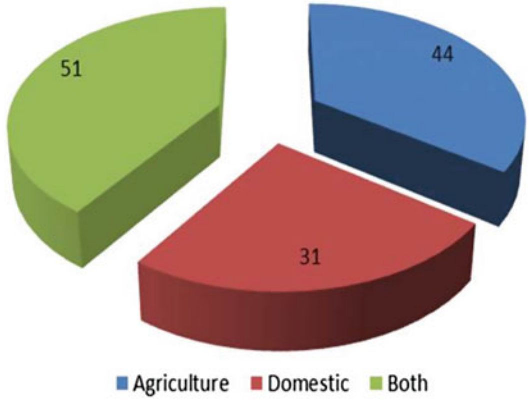

Fig. 9 Classification of rainwater harvesting technologies according to use

Fig. 10 Rainfall (mm) in Makueni County (GoK 2011)

November or December. These rains continue through April, albeit in suppression save for a small blip in March or April. There is then a 6-month dry spell with almost no rain at all. This is the period where rainwater for domestic use becomes a critical factor. This is because of the need to have a storage structure large enough to store water to last households over the 6-month dry spell.

It may therefore be concluded that the construction of water tanks may not be as viable as construction of water pans. This is because one would require a relatively large (and costly) tank to cater for the household for half a year. On the other hand, sand dam stores large volumes of water for long distances behind the barrier. Since the water is under the sand, it is safe from the high evaporation due to the high temperatures in the dry spell. In this study, 90 % were harvesting water from sand

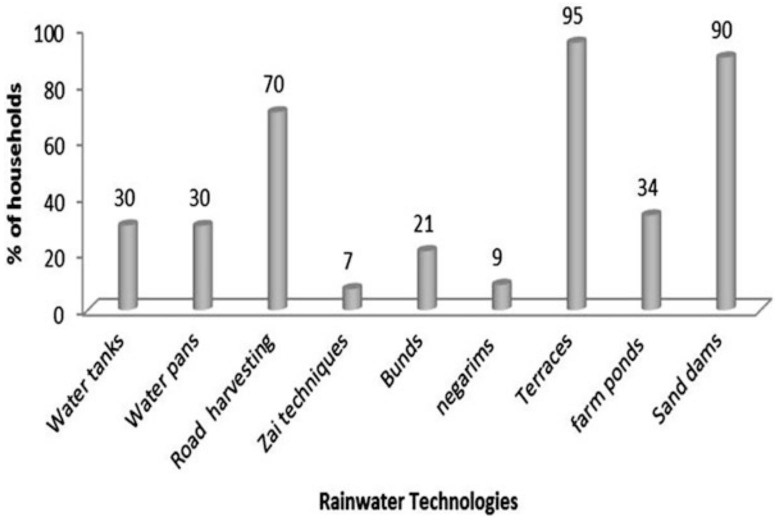

Fig. 11 Rainwater harvesting technologies

dams as to 30 % from water tanks. However, there was no difference in terms of the percentage of households harvesting water from water tanks and water pans (Fig. 11). Of the farmers, 95 % use terraces for soil and water conservation while 70 % harvest water from roads. This shows that almost half the farmers understand the importance of in situ rainwater harvesting technologies for improvement of yields. The unpopular technologies included Zai pits (7 %) and negarims (9 %). The reason for the low adoption was that these are relatively recent technologies on which the farmers have not been fully sensitized. However, Zai pits have been shown to increase yields in Kitui and Mwingi (Tran 2011; Njue 2012). For this reason, sensitization should be done to farmers by extension workers and other stakeholders particularly for the improvement to fruit trees like mangoes.

The case of Zai pits and negarims is in sharp contrast to terracing which has been adopted by 95 % of the residents. There was aggressive promotion of terracing in the area by the Ministry of Agriculture since the 1960s, and the wide adoption of terracing shows that farmers understand the need for soil and moisture conservation. All the in situ RWH technologies such as bunds, negarims, Zai pits, and terracing are labor intensive. But given the enthusiastic adoption of terracing, it seems that the farmers are not discouraged by the labor intensity of the technology.

The results of this study were different from the CSTI (2009) whereby the most common sources of water in Makueni for domestic use during the dry season were rivers/streams (72 %), followed by wells (28 %) while boreholes and dams had 2.7 %. However, during the wet season the sources of water change with 46.7 % using rainwater for domestic use. The use of shallow wells also increases from 6 % during the dry season to 16 % during the rainy season. This points to the fact that even though the residents are increasingly adopting rainwater harvesting, the volume of water stored is low, and this is probably the reason why they resort to stream water as soon as the dry season sets in.

Motivation for Adoption of Rainwater Harvesting Technologies

According to Makabila (2013), the rainwater flowing on the seasonal rivers of Makueni County gets harvested in close to 100 sand dams. The water harvested is later used for domestic and agricultural use when the dry spell sets in. Between 2007 and 2008, Welthungerhilfe (WHH), a German relief organization, constructed five rock catchments in the Makueni District in Kenya's Eastern Province, providing safe drinking water to more than 19,000 people. However, this did not feature among the farmers interviewed. This may be because the project was implemented in a single village or it had not been adopted largely by most inhabitants as to spread to all farmers.

Rainwater harvesting systems are mostly practiced in ASAL regions. These regions are characterized with intense runoff events which make water storage a necessary integral part of the system (Oweis et al. 1999). This helps in mitigating the effects of temporal shortages of rain for domestic and agricultural purposes (Oweis et al. 1999; TWDB 2006). With Makueni being a semiarid region, the main reason for harvesting the rainwater was due to low and unreliable rainfall with 96 % of households. The second motivation was presence of seasonal rivers with 81 % (Fig. 12). The presence of seasonal rivers provided a conducive environment for construction of sand dams. Promotion and creation of awareness from Nongovernmental Organizations (NGO) besides subsidizing of the materials to the farmers also made 65 % of the household harvest water from the rainfall as shown in Fig. 12.

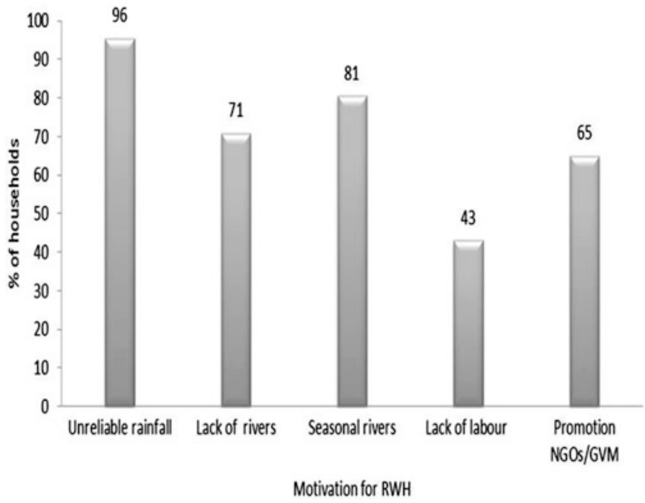

Fig. 12 Motivation for harvesting rainwater

Water availability saves energy, time, labor, and money, since water does not have to be carried to households from distant sources. While the harvested water leads to more reliable and greater yields, the members of the households can use their saved time to do other work, therefore generating more income as an output of the saved time. On the other hand, RWH at schools improves hygiene and nutrition, and pupils can spend more time learning, as they do not need to carry water to the school (Lehmann et al. 2010). Rainwater harvesting has also been found to increase the number of children attending school as well as decrease the walking distance to fetching water (Hauser 2012).

Since women are usually in charge of the household water supply (Lehmann et al. 2010), adoption of RWH empowers women because it gives them the possibility to get paid work where the presence of local employment is allowed. Also, RWH provides them with more time at their disposal, which can be utilized in other daily chores. Thus, their status as a decision-maker in the household increases. Most importantly, properly stored rainwater provides households with safe and hygienic water which reduces the risk of infection and child mortality and helps combat other severe diseases. It was estimated that poor water quality is responsible for the deaths of 1.8 million people every year worldwide (WHO 2004). RWH ensures environmental sustainability and can provide access to safe drinking water without threatening natural water sources.

Adoption of Rainwater for Domestic and Agricultural Use

The success of rainwater harvesting in arid and semiarid lands (ASALs) depends on the high demand of clean water supplies given that in Kenya, more than 67 % of rural households still have no access to clean and safe drinking water (Wanyonyi 1998). One of the main reasons the farmers were harvesting water was to increase yield (96 %) and get water for domestic use (96 %). Other reasons were to preserve water for use during the dry season (66 %) which is connected to increased yields, prevention of soil erosion (39 %), as well as irrigation (29 %) (Fig. 13). The availability of this water increases crop production because of the continuity in supply of this water to the farms in the form of drip irrigation or kitchen gardening. Most of the collected rainwater is used for irrigation, aquifer recharge, and storm water abatement (WHO 2006).

Factors Limiting the Uptake of Water Harvesting Technologies

Some of the identified constraints for implementing water-related projects in Kenya are financial constraints as well as lack of skills (Kinyua 2010). This is because rainwater harvesting technology can either be a complex or a simple technology to implement. However, for the people in Makueni, the major constraint was lack of labor with 69 % citing it (Fig. 14). From the study it was also found that the more compelling reason for the adoption of terracing is the recognition of its role in soil

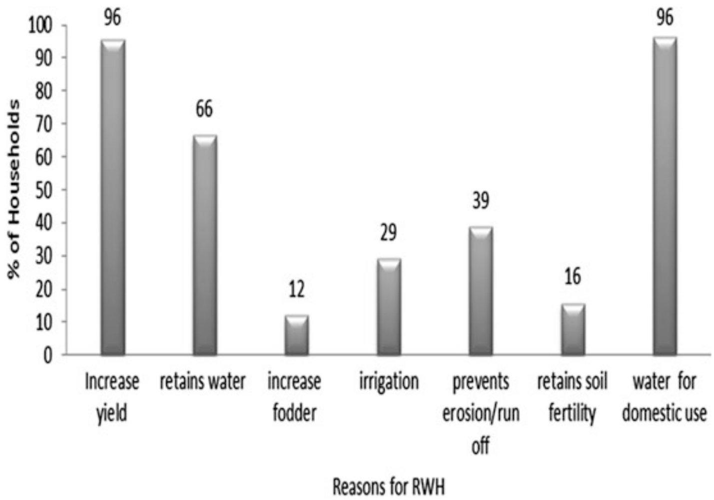

Fig. 13 Reasons for rainwater harvesting

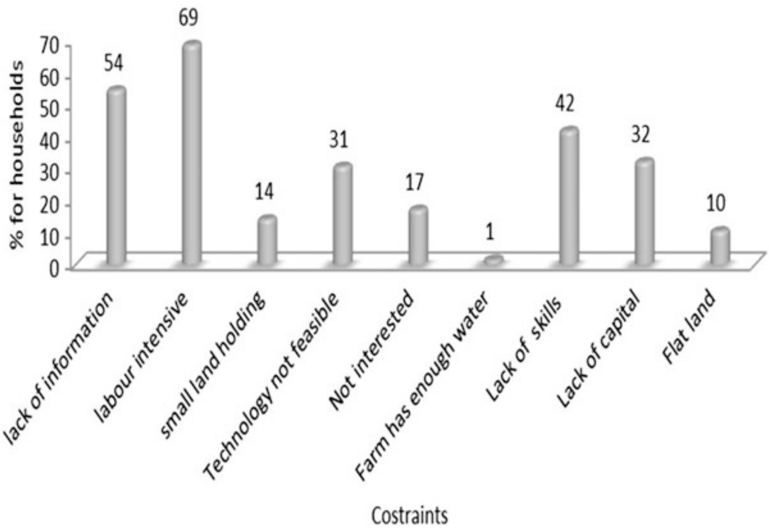

Fig. 14 Constraints of implementing rainwater harvesting

and water conservation arising from active promotion by extension officers over the years. To encourage increased adoption of terracing, perhaps the government can invest in community earth movers for hire or train the farmers in the use of animal draft technology for terracing and scooping dams.

The second constraint was lack of information about some of the technologies. This was evident in the low adoption of technologies such as negarims, bunds, and

Zai pits. Lack of capital did not feature as a main problem with 32 % of the farmers citing it. Only 1 % indicated that their farms had enough water (Fig. 14). RWH technology in Kenya is mostly implemented by self-help groups or communities that are not registered as required by the Water Act 2002. It has to be assumed that the Water Act 2002 does not encourage people to invest in RWH when there is no other option but to act outside a legal framework. Many organizations operating in community self-help water systems are not formally registered by the Ministry of Water.

Conclusion and Recommendations

It may be concluded that sand dams are an important source of domestic water with over 90 % of the population using it, while terracing is the preferred method of soil and water conservation. There is need to sensitize farmers on new technologies such as the use of negarims, Zai pits, and trapezoidal bunds since these are beneficial technologies that have not been adopted.

The high rate of adoption of terraces indicates that farmers are aware of the need to conserve soil and water, and even the labor intensity of the technology may not hinder them from practicing conservation measures that may help them to boost production of crops. However, investment in machinery for hire may encourage faster adoption.

Rainwater use seems to be confined to the wet season, with the residents using the streams and wells during the dry season. It may therefore be concluded that there is a problem of water storage that would otherwise extend the water availability through the dry season. It is therefore necessary to invest in water storage structures to ensure water availability all year round. Alternatively, groundwater recharge may be encouraged so as to raise the water table and ensure water availability close to the surface for enhanced crop production. Since the dry spell is long, the only viable technology for storage of water for domestic use is sand dams and more investment in this technology should be encouraged.

Rainwater harvesting forms the basis of solving water shortage problems in the ASALs. The government should fund such projects through the concerned Ministries of Water Resources Management and Development and provide reasonable percentages in the annual budget. Nonetheless, NGOs and Community-Based Organizations at national and local levels should be encouraged and allowed to play a role in putting rainwater harvesting in the limelight. Though this has been seen through the Southern and Eastern Africa Rainwater Network (SearNet) established with the assistance of the International Rainwater Catchment Systems Association and the support of the Regional Land Management Unit of UNEP (2009), more outreach programs should be put in place to expand the knowledge of water harvesting. Related workshops should also be used to expand this knowledge. The research recommends that at the local level, the government should fund water harvesting projects and provide farmers with harvesting materials such as gutters, roofing materials, concrete, and water tanks. An adaptation of the Kenya Water Act (2002) is necessary, in order to clarify the conditions under which various RWH structures can be implemented.

Changes of South Baltic Region Climate: Agroecological Challenges and Responses

Galina M. Barinova, Evgeny Krasnov, and Dara V. Gaeva

Contents

Abstract

In this chapter, the regional dynamics of climate change and the subsequent agricultural challenges and responses are discussed by referring to the Kaliningrad region of the Baltic coast and some neighboring areas. The impacts of temperature and fluctuations in precipitation are discussed in relation to grain-crop harvesting and yields and other green crop productions. Furthermore, we observe the connection between pests and diseases and climate change, which affects livestock breeding, arable farming, and human living conditions. Some forms of adaptation to climate-related events (flooding, soil erosion, selection of appropriate crops) are also presented. In the past, during the Soviet era, new uncertainties and consequently

deplorable ecological changes for the investigation area were caused by excessive use of pesticides, deforestation, and expansion of monoculture. Mathematical modeling and system approaches are thus becoming important tools for the creation of forecasting procedures and solution strategies and measures for feasible future development of agriculture. Special attention is given to a decreasing number of pollinators (domestic and wild). Finally, new forms of agricultural management (landscape planning, balanced and environmentally friendly agriculture practices) are stressed.

Keywords
Regional climate aspects • ecosystem impacts • strategies of adaptation

Methodology and Methods

The selection of materials for this study is based on annual and monthly averages of surface air temperature and precipitation at meteorological stations in the southern Baltic region from 1949 to 2011. A set of statistics referring to the period of time from 1960 to 2011 was collated relating to the agrarian structure in the Kaliningrad region (Russia) and the dynamics of crop yields and, more particularly, the total yield of grain and honey production from 1990 to 2011. Anomalies in average values of air temperature and precipitation were measured and recognized as deviations from the reference value recommended by the World Meteorological Organization for the period between 1961 and 1990. In order to analyze the variability of extreme air temperatures, minimum and maximum temperatures were each selected for every month in the period from 1949 to 2011.

These data serve to determine the ratio between climatic aridity and humidity and, therefore, in concrete terms, the index of aridity (understood here as the ratio between air temperature and precipitation values). The analysis reveals a significant interannual variability. The calculation of the atmospheric aridity index (S) (Frolov and Strashnaja 2011), using the values of temperature and precipitation for a certain period of time, reveals an increase in air temperature and a destabilization of hydrothermal conditions for the period 1949 to 2011:

$$S = \frac{\Delta T}{\sigma T} + \frac{\Delta P}{\sigma P}$$

ΔT, ΔP = air temperature and precipitation deviations from monthly mean values, respectively.

σT, σP = air temperature and precipitation from mean monthly values, respectively.

The atmospheric aridity index (S) is evaluated using the following scale:

– "Norm" = $1 \leq S \leq 1$.
– "Humid" = $S \geq -1$.
– "Arid" = $S \geq 1$.

History

This chapter focuses on the analysis of regional climate changes based on published studies, but also from different sources of information such as ancient chronicles, traditional knowledge and folklore, and natural scientific items such as the speed of lake sedimentation, analysis of annual rings, and measurements of land near-surface air temperature.

Three climate periods can be distinguished over the last thousand one hundred years:

(a) The warming during the first period, the Medieval Warm Period (from the end of the ninth to the beginning of the twelfth century), which began in the Baltic Sea area, resulted in shifts of vegetation zones and changes in vegetation. Thus, grapes were cultivated in northern Germany and even in Latvia. The increase in temperature during the early middle ages led to a corresponding increase in the numbers and concentration of different sections of the ancient population.
(b) The second main period (from the thirteenth to the eighteenth century), known as the "Little Ice Age," followed, during which the sea level lowered considerably, with extremely cold winters occurring over the ensuing centuries and the Baltic Sea being completely frozen. People could move over the ice-bound sea from Sweden to Denmark and could cover even longer distances by sledge, conquering new frontiers in the true sense of the word by traveling hundreds of kilometers, for instance, from Latvia to Sweden.
(c) It was only at the end of the nineteenth century that a new warming of the climate started to introduce the current climate conditions we live under and which are still going on, leading to the rise of the average global temperature and earth warming.

Reliable climate observations concerning climatic historical temperature variations are accessible at numerous meteorological stations that have existed for some centuries and deserve to be mentioned, such as St. Petersburg (beginning observations in 1725), Vilnius (1777), Warsaw (1779), Riga (1796), Tallinn (1806), Konigsberg-Kaliningrad (1848), and Tartu (1876). Analysis of the long-term data allows some conclusions to be drawn about the variation of air temperatures in the last two centuries:

- The second half of the eighteenth and the beginning of the nineteenth centuries are characterized by distinctive oscillations and low values of annual air temperature.

For example, the average annual temperature in the period between 1781 and 1790 in St. Petersburg was 2.8 °C.

- The lowest average annual air temperature of 4.7 °C was registered in both Warsaw in 1829 and in Königsberg/Kaliningrad in 1871. The coldest annual temperature (1.2–1.3 °C) was measured in St. Petersburg in 1809 and 1810.
- A new warming of the climate began at the end of the nineteenth century, leading to an average annual temperature of 7.5 °C in Kaliningrad and 8.4 °C in Warsaw.

Climate Change Dynamics

In the Kaliningrad region there are three main types of climate that, on the whole, can be subdivided into ten types of microclimates (Barinova et al. 2012):

1. Marine type:
   (a) A long period without freeze (190–200 days), a large number of serene days (30–32 days), normal humidity (750 mm) with strong winds and possible fog
   (b) The longest period without freezing (over 200 days), high recurrence of winds, annual rainfall of 600–650 mm
2. Transitional type:
   (a) Sufficient amounts of heat, strong winds, high temperature differences, and microclimatic difference in soil moisture
   (b) The lowest amounts of heat or a short period without freezing (<150 days), annual precipitation of 800–850 mm, excess humidity, moderate winds, frequent fogs
   (c) Sufficient amounts of heat, short period without freezing, weak winds
   (d) Sufficient amounts of heat, short period without freezing, moderate winds, increase in cloudy days, thunderstorms, fogs
3. Continental type:
   (a) A substantial an annual total (2,200 °C), mostly short periods without freezing (155 days), moderate winds, sufficient moistening
   (b) The greatest amounts of annual heat (2,300 °C), sufficient humidity, weak winds with sufficient amounts of annual heat (2,200–2,250 °C), an annual amount of precipitation of 700 mm, moderate winds, some days with fog
   (c) Sufficient amounts of annual heat (2,200 °C) or a short period without freezing (150 days), moderate winds, significant differences in temperature, and microclimatic soil moisture

Warming, especially evident in the last decade, has become a tangible factor in the development of agricultural production. Over the last 60 years (1949–2010), there has been a marked positive trend in the Kaliningrad region that involved an increasing mean annual air temperature and annual precipitation (Fig. 1). While in the first 30 years of the observation period the average annual air temperature varied between 6.5 °C and 7.5 °C, it has been 8.0–9.0 °C for the last 30 years, with a

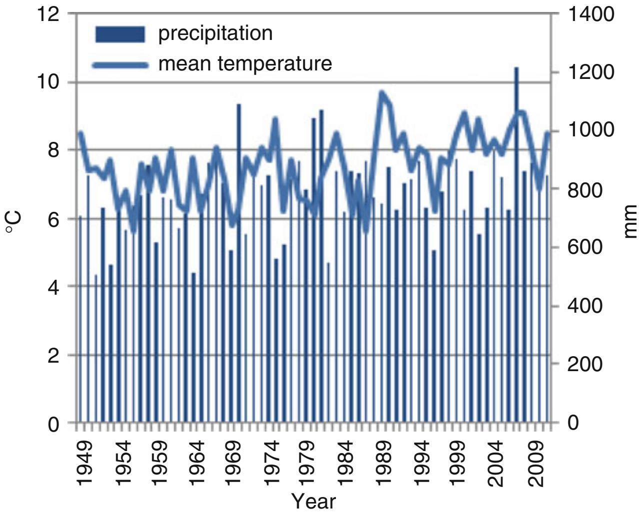

Fig. 1 Average annual air temperature and annual precipitation in Kaliningrad (According to data from the Federal Service for Hydrometeorology and Environmental Monitoring)

maximum value of 9.7 °C in 1989. The annual amount of precipitation in 2007 reached a record for the entire period of observation of 1,214 mm.

Between the fourteenth and nineteenth centuries, there were observed temperature anomalies and abnormal humidity conditions: a cold winter in 1322/1323 with a frozen Baltic Sea, a great drought in 1427 and 1474, very warm summers in 1506 and 1832 in which fruit trees bloomed two times, and a very cold summer in 1832 with a late frost in July. Figure 1 illustrates the current climate development in the region of Kaliningrad.

In the South Baltic region, according to data from the weather stations in Kaliningrad (Russia) and Rostock (Germany) for the last 30 years, the coldest temperature values were observed in 1980, 1985, 1987, 1997, and 2010, and the warmest years were 1983, 1989, 2000, and 2007 (Fig. 2).

Abnormally wet years were observed in 1970 and 2007 and abnormally dry years in 1982, 1996, and 2002. According to the meteorological station in Königsberg/Kaliningrad, changes were also observed in the average surface air temperature in the first decade of the twenty-first century (1901–1910); the positive deviation from the mean average in January was from 0.3 °C to 2.0 °C and in April, July, and October was +2.3±0.2 °C above, confirming the positive trend, which is particularly evident in spring and summer.

The trend of a decreasing frequency in the category of "normal" in the aridity index, beginning in the second half of the twentieth century and continuing until the 1990s, was replaced by a counter-tendency in the beginning of the twenty-first century (Table 1). In the same period, the number of years (40 %) characterized by high aridity dramatically increased, thus affecting the risk factors in agriculture. Moisture deficiency in the beginning of the growing season (April–May) negatively

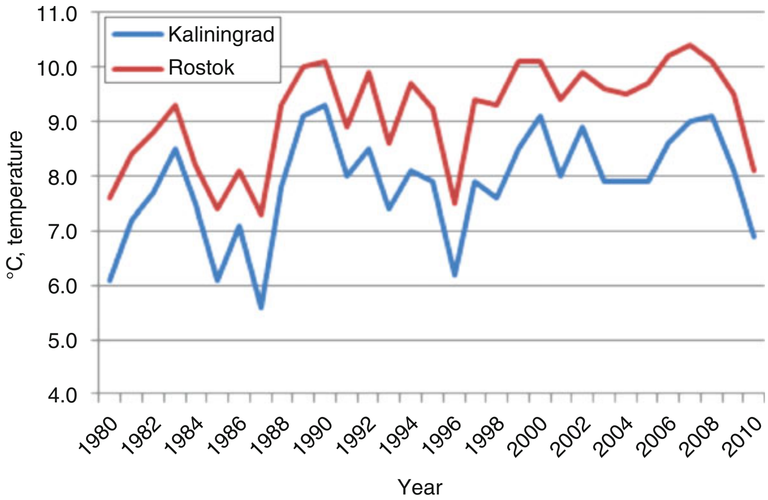

Fig. 2 The average annual air temperature (°C) in Kaliningrad and Rostock (According to data from the Federal Service for Hydrometeorology and Environmental Monitoring 2012; Deutsche Wetter Dienst 2012)

Table 1 Recurring atmospheric aridity index (S) by decade in May

Period	Normal (%)	Too wet (%)	Arid (%)
1950–1959	90	10	0
1960–1969	60	30	10
1970–1979	40	30	30
1980–1989	30	20	50
1990–1999	60	20	20
2000–2009	50	10	40

influences the growth and development of most crops, so the observed trend could be dangerous. A solution to the problem may be found in dual regulation of the water regimen: drainage and irrigation. Table 2 shows the combination of agroclimatic conditions and the yield.

Agroclimatic conditions of crops growth are characterized by the duration of the growing season and the amount of accumulated temperatures during this period. According to the long-term average in the Kaliningrad region, the sum of temperatures for the period with temperatures >5.0 °C was 2,200 °C, and the duration of the period was 201 days. For the period 1980–2010, there was a markedly significant fluctuation in the duration of the growing season and the amount of heat. Combined with the moisture regimen, this is reflected in the varying yields of cereals (wheat) and perennial grasses. The index of aridity of the atmosphere (S) (the ratio between air temperature and precipitation) showed a significant interannual variability. Therefore, 2002 was characterized by an aridity index in May of 3.7, with the amount of heat during the growing season being 2,940 °C, and low yields of wheat and perennial grasses: 23 and 15.3 hwt/ha, respectively (Table 2).

Table 2 Indicators of vegetation conditions in abnormal years

Year	Precipitation (% of the norm)				Deviation of the temperature from the norm				Aridity index					Yields (hwt/ha)	
	IV	V	VI	VII	IV	V	VI	VII	IV	V	VI	VII	VIII	Perennial grasses	Wheat
2002	65	53.9	104.4	55.6	2.0	4.4	1.2	2.4	2.0	3.7	0.9	2.5	5.0	15.3	23
2007	52.7	269.4	145.2	232.3	1.7	1.8	2.2	−0.1	2.1	−2.0	1.0	−2.7	−0.2	20.0	29
2008	130.5	28.4	78	66.4	2.1	0.4	1.0	1.2	0.7	1.6	1.3	1.5	−0.4	21.8	44.8

hwt/*ha* yield capacity per hectare; IV, V, VI, VII, and VIII refer to months

The highest wheat yield in a single year was in 2008, when the total accumulated air temperature was 3,029 °C and the growing season was the longest. The highest wheat yield was observed from 2005 to 2009, with accumulated temperatures from 2,900 °C to 3,055 °C (Figs. 3 and 4).

At the same time, the areas of perennial grasses were reduced due to the high temperatures and high aridity index.

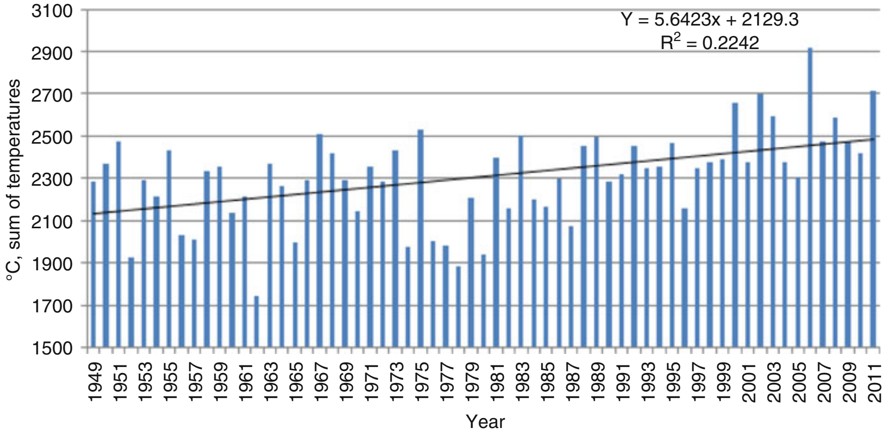

Fig. 3 Total accumulated temperatures for the growing season in Kaliningrad

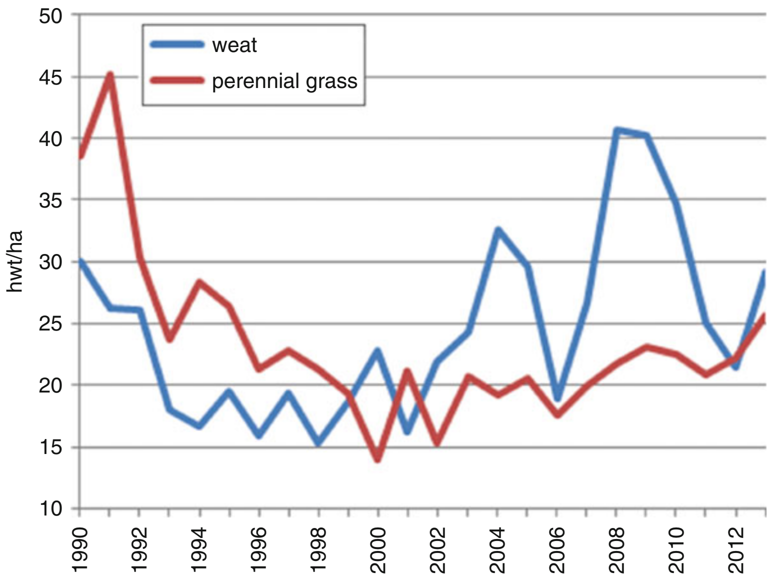

Fig. 4 Crop yields in the Kaliningrad region (hwt/ha). *hwt/ha* yield capacity per hectare

Long-term dynamics of crop yields reveal that, with the intense warming from 2000 to 2009, a substantial growth in wheat yields was achieved compared with the previous decade. In contrast, the growth of perennial grasses was abundant in cool and wet years (Figs. 1 and 3). Analysis of hay yields on the floodplain meadows (Romanenkova 2008) also shows that the temperature has a significant cumulative effect.

In connection with climate change (Roger and Pielke 2005; Fedoroff et al. 2010; Eckersten et al. 2012; Fedorov and Krasnov 2012) and rising accumulated temperatures in the Kaliningrad region, there is the possibility of introducing thermophile plants (in particular soya), both as rotation elements and as crops used for the expansion of production areas. At the same time, considerable interannual air temperature fluctuations and snowless winters pose a risk for the cultivation of winter crops. In winter 2010, for example, the average January temperature reached -8.10 °C, the lowest average in the preceding 20 years, causing a loss of about 70 % of the winter rapeseed crop, which has been actively introduced in the rotation since 2000 and covered about 20 % of arable land in 2009.

Therefore, a prerequisite for increasing the profitability of agriculture in the current climate conditions in the South Baltic area should be conversion to other crops such as perennial legumes and grasses that are resistant to temperature changes. This could increase the duration of the grazing season and reduce the nutrient load of the water by reducing the doses of organic fertilizers required for annual crops.

Meanwhile, one can say for certain that the increasing negative impacts of climate change enhance the frequency of extreme and unpredictable situations (Lobell et al. 2011). Official statistics show that the frequency of freak weather (such as heavy cloudbursts accompanied by floods, frequent heavy storms, etc.) has increased in the Kaliningrad region. This of course raises the question of what to do given the effects of climate change. The first approach could be to examine the features of natural resources in the Kaliningrad region taking into consideration the current phenomena of climate change (Chistyakov 1997; Drozdov and Smirnov 2011). The materials for the study are based on data relating to the near-surface air temperature and precipitation in the Kaliningrad station for the period from 1949 to 2010 and the anomalies of temperature and precipitation calculated as deviations from the long-term average for the period from 1961 to 1990, recommended by the World Meteorological Organization as the basis for such calculations.

The main air temperature trends in the southeastern Baltic coast are comparable with trends observed in the average temperature of the Northern Hemisphere (temperature rise in the last quarter of the nineteenth century; rapid temperature rise in the last decades of the twentieth century). Globally, there are an increasing number of natural disasters involving hazardous meteorological or, more precisely, hydrometeorological processes (storms, strong winds, very intense rainfall, floods, glaze effects, etc.) as well as rigors of temperature (extremely high temperature values, increasing forest fires, higher incidence of heat waves and droughts, etc.). Linear trends in air temperature reveal a sharp rise in temperature and a rise in its variability from year to year. Climate warming in the late twentieth and early twenty-first century exceeds the rate of increase during the rest of the twentieth century by far (Jacob 2005; Kyslov et al. 2008; Getzlaff et al. 2011). Analysis of changes in annual precipitation values during the study period also reveals a significant positive trend, namely, an average growth rate of 20 mm within 50 years, an additional symptom of global warming. An essential feature is the increase in the amplitude range of precipitation beginning in the late 1970s. Of considerable interest is a large asymmetry in the number of positive and negative deviations of air temperature during the study period: the number of positive deviations is two times higher than negative deviations. The largest positive deviations, exceeding the value of 1.5 °C, were observed in 1975, 1989 (the warmest year of the twentieth century), 1990, 2000, 2002, 2006, 2000, and 2008. The largest negative deviations were observed in 1956 and 1987 (the coldest years). Air temperature anomalies, calculated as deviations from the average for the 1961–1990 period, ranged from −1.5 °C to 1.5 °C. The highest average annual temperature abnormality of 2.5 °C was seen in 1989. In the past decade there have been several record temperatures that had not previously been observed in the history of meteorological observations (Fig. 5). The annual air temperature in 1989, 1998, 2007, and 2008 exceeded the normal values by 9 °C. The maximum air temperature was 12.6 °C in January and 34.6 °C in July 2007. In July 2010 a maximum value of 33.8 °C was reached.

The average air temperature (the norm), defined for the period 1961–1990 in Kaliningrad, was 7.2 °C. However, the last quarter of the twentieth and the beginning of the twenty-first century are characterized by a significant increase in the surface air temperature (Fig. 5). For example, the average annual air temperature measured over the decade from 1991 to 2000 increased by 0.9 °C compared with an average of 7.8 °C in the decade from 1961 to 1970. In 1989, there was a maximum average annual air temperature of +9.7 °C. A high average annual temperature exceeding the “norm” by 1.5–2 °C was observed in 1990, 2000,

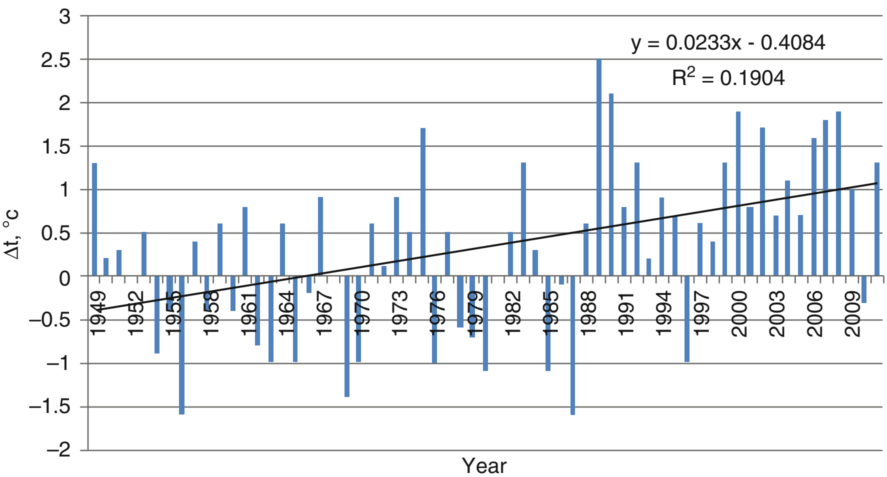

Fig. 5 Deviation from the norm in air temperature in Kaliningrad

2002, 2004, and 2007. This very strong warming is typical for the autumn–winter period; the speed of summer temperatures rising is lower.

The beginning of the study period is characterized by negative deviations from the long-term average precipitation level. In the late 1970s there was a change in the rise of precipitation values (Fig. 6). In general, noticeable sharp fluctuations could be observed from year to year for the period of investigation. In 2006, for example, rainfall levels were almost two times lower than in 2007, which was characterized by wet weather during the entire study period with 1,214 mm of precipitation. This can be compared with the rates of deviation in rainfall for the two 30-year intervals, namely, from 1949 to 1979 and from 1980 to 2009. In the first period, especially at the beginning of the period, there were more frequently observed adverse deviations, whereas in the second period there were years in which the rainfall exceeded the normal rate by threefold.

The graphs in Figs. 5 and 6 show clearly visible sharp short-period fluctuations that characterize the interannual variability of temperature and precipitation. Seasonal variability of temperature is also quite evident. Comparing the monthly average and the annual air temperature for the two 30-year periods observed, we can record the following fact: the average annual temperature for the last 30 years (1981–2010) is higher by 0.8 °C than for the period with normal values (1961–2010). As can be seen, the speed of the trend differs in some months: the most intense warming occurs during the winter and spring months, and the most significant warming is evident for January and February. The average temperature in the last 30 years has increased by 1.7 °C to a value of 1.4 °C in February.

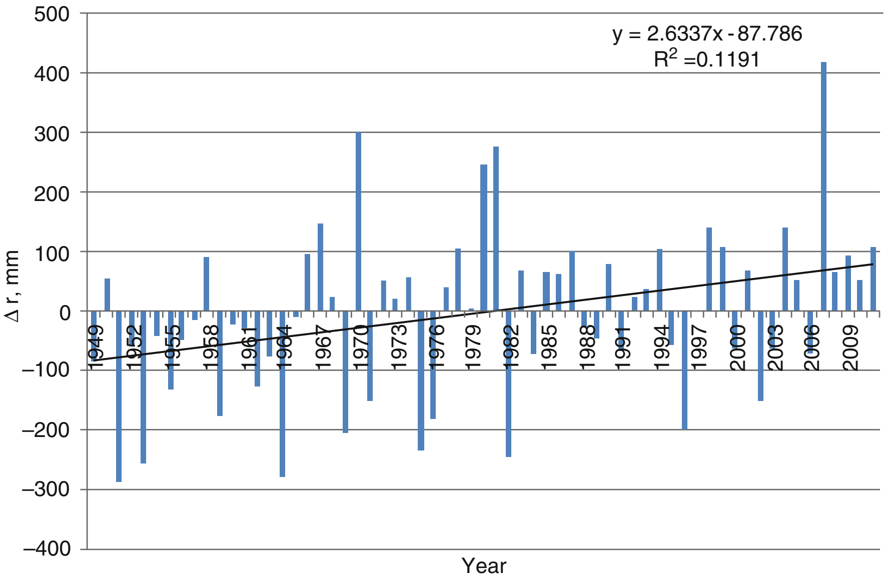

Fig. 6 Deviation from the norm in precipitation in Kaliningrad

In summer and autumn, the rate of warming is reduced, especially in June, September, and October. In the last 30 years of abnormally warm winter seasons, mild spring temperatures have become more frequent than cold ones in Kaliningrad. As a result, a comprehensive statistical analysis of long-term climate indicators makes it clear that during the study period there were sharp fluctuations in both temperature and precipitation. Variability of extreme temperature indices for the period 1949–2011 is shown in Fig. 7. As can be seen, the maximum amplitude of the oscillations of air temperature is characteristic of the winter months. In January, the lowest temperature was observed in 1956 (−32.5 °C) and the highest in 2007 (12.7 °C); the range of variation was 45.2 °C. During the summer, the oscillation amplitude of extreme values of air temperature is significantly reduced and is about 32 °C. It is noticeable that the lowest temperature in all seasons of the year can be observed until 2000, whereas the highest temperature could be fixed to three times, namely, in January 2007, April 2000, and December 2006.

In recent decades, there have been some maximum values that had not occurred in the previous history of the observations, with comparable positive annual temperature anomalies. In Kaliningrad, the mean annual air temperature amounted to 9.2 °C in 1989 and 9.3 °C in 1998.

The growth of weather variability:

- The number of severe weather events and associated risks: strong winds, very heavy rainfall, and rising of water levels in the rivers above alarming marks.
- Since most precipitation falls as rain rather than as snow and water seeps faster, the soil absorbs less moisture than with a melting snow cover. This has a negative effect on the moisture balance, leading to more erosional activity.

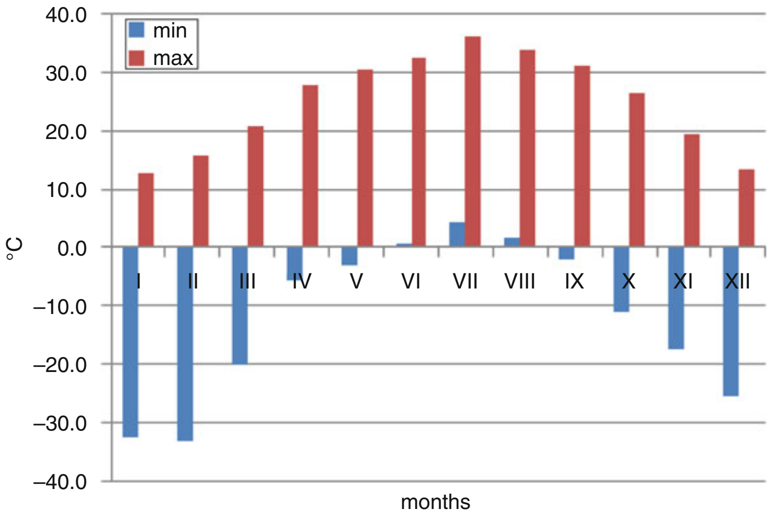

Fig. 7 Extreme maximum and minimum air temperatures for the period from 1949 to 2011 in Kaliningrad

- In western Russia, dramatically higher river flow rates are expected up to 2015. This will lead to lower soil freezing due to a rise of groundwater levels and poor drainage capacity.

As the region of Kaliningrad is situated in the west wind belt, westerly, southwesterly, and southerly winds predominate in various meteorological manifestations with diverse effects. Above all, in autumn and winter intense low-pressure systems can sweep across the Baltic Sea in the form of heavy storms causing floods and other damages. Environmentally negative impacts can also occur such as transboundary contamination (sulfur oxides, nitrogen oxides, heavy metals, etc.).

The most frequently measured speeds during storms are 12.5–15.2 m/s (52.9 %) and 15.3–18.2 m/s (21.4 %). Winds with a speed of more than 8 m/s occur in 13 % of all cases. This is a problem as unfavorable conditions for treating agricultural crops with pesticides occur.

Analysis of the Impacts of Climate Change

In connection with climate change, there are also negative effects affecting human and animal health. For example, infections such as Lyme borreliosis (Lyme disease) that have been by no means unusual in the Kaliningrad region spread more and more like an epidemic. Thus, the increase of ticks creates a critical situation when cattle are kept in outdoor husbandry systems in the Kaliningrad region. Human infection may occur through tick bites as well as by drinking the milk of infected animals. Table 3 provides an overview of tick-borne morbidity.

Table 3 Regional specificity of the morbidity of tick-borne encephalitis and Lyme disease during the period from 1999 to 2008

	Morbidity (per 100,000 population)				
	Tick-borne encephalitis			Lyme disease	
Year	Kaliningrad region	Karelia region	Belarus	Kaliningrad region	Belarus
1999	1.3	4.4	0.3	8.2	1
2000	1.2	5.6	0.2	19.9	1.9
2001	1.2	6	0.6	7.8	1.8
2002	1.2	7.2	0.2	7.2	1.8
2003	3.8	15.2	0.5	22.7	5.1
2004	1.3	11.6	0.4	13.3	5.2
2005	1	9.2	0.5	13.2	5.4
2006	0.9	7.6	1.1	20.9	9.1
2007	0.8	8.8	0.8	20.8	6.7
2008	0.8	–	0.7	12.5	6.6
Annual mean	1.4	8.4	0.5	14.6	4.5

Long-term analysis of natural focal infections of the population (1999–2008) detects different trends in the number of victims in some regions of Russia and the world, including the Kaliningrad region (Barinova and Kochanowskaja 2011). Also, the morbidity of tick-borne encephalitis in the Kaliningrad region for the period under review decreased from 1.3 per 100,000 population in 1999 to 0.8 in 2008. A similar trend is observed in Karelia. In Belarus, the spread of tick-borne encephalitis as well as Lyme disease also has a tendency to increase (Table 3). This may be associated with an increase in winter air temperatures and, at the same time, an increased frequency of extreme weather conditions. Growth in the number of insect pests increased pesticide use. A long-term analysis of natural focal infections among the population provides evidence that there is a connection between the high frequency of morbidity, particularly in encephalitis, and high temperatures. Thus, in 2003 and in 2010, the morbidity values were clearly higher than in previous years, and it was that summer in which the temperatures were the highest measured since the beginning of weather records.

Growth in the number of insect pests and diseases of plants depends on the following factors:

- Measures need to be improved to keep pests in the soil during the winter.
- High humidity, high frequency of surface inversions, weakening of the wind in the second half of the growing season, and air stagnation cause the growth of fungal diseases of plants.
- Cultivation is sensitive to weather variability in monocultures (corn, rape).

New Uncertainties and Needs

In the context of climate warming, a relatively large impact is expected on the productivity and structure of agroecosystems; forest biotic communities; the quality of agricultural, pastoral, and forest land; the spread of diseases; and the survival of some wild plants, domestic animals, and cultivated plants. For the Kaliningrad region, one has to face up to major challenges relating to climate change and measures that are suited to mitigate at least the most dangerous effects need to be proposed (Table 4).

The structure of rural landscapes has changed when viewed in the context of natural and agricultural factors that, unfortunately, have not necessarily had desirable effects. The invisible chemical changes in connection with pesticide use, the continuing urbanization process, and even the military activities are the negative and yet dramatic consequences. Total forest coverage is now no more than 17–18 %. Deforestation is probably the biggest environmental problem for the Kaliningrad region. However, to stop cutting the forests down is nearly impossible without the political will of regional and federal decision makers.

Another environmentally harmful example is the planting of crops without using rotation to avoid soil degradation. Thus, rapeseed is sowed over several years.

Table 4 Adaptation of land use management to climate change in the Kaliningrad region

Type of nature management	Challenge	Adaptation
Agricultural	Increased frequency and variability from year to year of severe weather events (storms, frosts, droughts, storms)	Restore drainage
	The danger of erosion processes	Regulation of the soil water regimen (including bilateral) on the polder lands
	Loss of humus, soil salinity increased	Selection of thermophile crops
	Increased risk of infectious and parasitic diseases of plants and animals	Increase the area of meadows
Forestry	The loss of forests	Increase forest area up to 25–30 % with the introduction of broad-leaved trees
	Water logging, changes in groundwater levels	
	Growth pathology of tree crops	
	Expansion of distribution ranges of tick-borne encephalitis	Pathology monitoring

The abovementioned negative processes occur because of a lack of collaboration for various reasons. Being ready to start dialogue with different groups of society is a prerequisite to generate an institutional and social consensus to preserve the natural foundations for both humans and animals.

Pollinator's Drama

The almost complete anthropogenic transformation of nature in the Kaliningrad region – like in most countries of the Baltic region (Palang and Ryden 2003) – has resulted in only a small remnant (not more than 18 % nowadays) of an originally widespread forest area, thus creating one of the major problems in agriculture and forestry, namely, a small number of pollinators, in particular bees. In addition, the increase in precipitation and intraday fluctuations in temperature during the winter also cause a decrease in the bee population (Gaeva and Barinova 2013).

Documentary sources in East Prussia mention beekeepers for the first time in 1367. From this year on, free hunting, fishing, and beekeeping were allowed. Everything that was found in the forests or that could be caught in the rivers was allowed to be sold, but the authorities set stringent prices for honey. Furthermore, each beekeeper could possess part of the forest. On the trunk of a tree inhabited by bees, the beekeeper (or "bee hunter") marked a sign by cutting a square, cross, crescent, etc. As the parts of the forest with good honey yield were mostly to be found on the edges, within clearings, and burnt areas, beekeepers often set fire to the young forest. Beforehand, the hives were gathered up and put in a suitable place with a ditch dug around it. Later, in the fifteenth century, due to frequent uncontrolled fires, a law prohibited forest burning after 8 April, when the dry season began. From the mid-fifteenth century onward, anyone who lived in the forests of Prussia had to obey the laws and pay taxes – apiaries in the gardens around the houses, however, were exempt from taxation and, thus, from that time on, hives were moved from the forests into the villages.

The "rules for bee hunters" stipulated penalties for those persons who damaged hives and who failed to act in case of fire. By law, beekeepers had to keep forest areas in order, and in case they did not know how to cut down or burn wood in their territory, they had to repair any possible damage.

In the middle of the nineteenth century, there was quite high productivity in beekeeping in East Prussia. In 1773, in the area around Schlohauer, a beekeeper was given 507 thalers for the production of honey in comparison with 14 thalers given as profit from the sale of timber harvested in the same piece of forest.

However, as early as the nineteenth century, a decline of beekeeping took place because of the war in 1812 and adverse weather conditions in later years (cold winters in 1824/1825, 1844/1845, and 1848/1849).

Moreover, in the middle of the nineteenth century, active deforestation began. All trees with hollows were allowed to be cut down. Yet, according to estimates, at the end of the nineteenth century, one single hive yielded 13–20 kg of honey per year. Over the 48 years from 1864 to 1912, the number of bee colonies in East Prussia increased from 85,168 to 186,644.

The distribution of bee colonies in East Prussia (with distribution in the Kaliningrad region after 1945 in brackets) was as follows: in 1907, 4.3 beehives existed on 1 km^2 (5.9 beehives on 1 km^2 of farmland), and in 2010, 5.9 beehives existed on 1 km^2 (2.5 on 1 km^2). In 1938, there were 244,024 beehives in the whole of Prussia and 96,757 in East Prussia (in 1943, there were 88,000 bee colonies); the average productivity of bee colonies was 30 kg of gross honey and up to 10–15 kg of salable honey (Hansen 1916; Bloech 1932).

During the Second World War, honey production almost came to a stop, but in the first years after the war, in the newly established collective farms, specialists began to restore beekeeping.

Before the Second World War, the European dark forest bee (*Apis mellifera mellifera*) was prevalent. This bee species was well adapted to the cold and wet climate: their natural habitat extended from the tundra to the steppes. In the postwar period, a new bee species, the gray Mountain Caucasian bee *Apis m. caucasica*, was introduced, and the Carpathian bee *Apis m. carpatica*, bred in Maykop, was imported to the Kaliningrad region. These breeds of bees did not tolerate long winter periods (over 4 months) or high humidity, and crossbreeds with local bees were often susceptible to infectious diseases and proved unproductive. Uncontrolled importation of unadapted species of bees to the Kaliningrad region led to the loss of local bee populations, which were more adapted to the habitat, especially to the cool climate.

Finally, 50 or 60 years later, more than 5,000 bee colonies were killed through fungal infections and the first reports of the tick-borne disease varroa appeared. In the 1990s, beekeeping in the Kaliningrad region fell into decay. Apiaries were destroyed or subdivided among private owners. According to the National Agricultural Census held in 2006, the number of bee colonies totaled 14,000 in the Kaliningrad region, but by 2008 there were only 6,588 registered bee colonies left. According to our data, approximately 20,000 beehives show no more than an average productivity of 15–20 kg of honey per family. Thus, beekeeping can be classified as an informal sector in agriculture. A significant problem lies in the fact that there is a lack of annual records of bee colonies, especially of the morbidity of bees and their intoxication by pesticides in different areas of the Kaliningrad region.

The increase in the use of high doses of pesticides (Fig. 8) is a threat to wild pollinators (wild bees, bumblebees) and to populations of honeybees (*Apis mellifera*) in agro-geosystems. In order to control pests, farmers now use registered insecticides that are toxic to bees from the class of neonicotinoids. According to environmental restrictions on the use of this kind of substance, regulations on temperature and spatial isolation within 5 km of the honeybee (*Apis mellifera* L.) have been established, but solitary bees are not covered (Dixon 2003; Tyliniakis 2013; Burke et al. 2013). Evidence of a negative impact from the use of neonicotinoids on entomophilous crops has been found. Processing of wheat crops in a farm leads to the death of solitary bees and to a lack of pollinators, even in neighboring farms, and to a ten times higher reduction of yields of sunflower and alfalfa (Artohin et al. 2013). Under such conditions, controlled pollination of cultures is only possible with the help of honeybees.

Modern beekeeping is an agricultural branch, engaged in breeding honeybees for beeswax and other bee products as well as for the pollination of crops in order to increase their productivity. The main challenge for beekeeping is based on its environmental and economic efficiency for specific regions. As the demand for environmentally friendly products is still high, beekeeping requires suitable regions

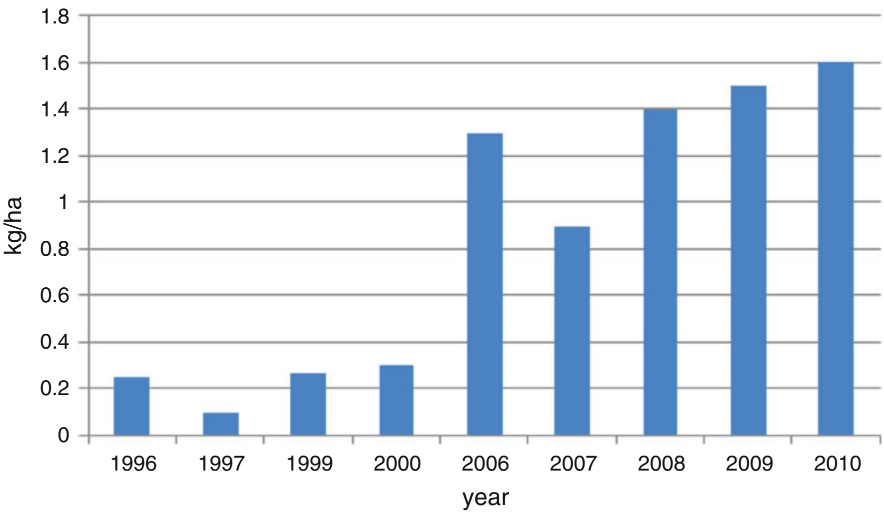

Fig. 8 Pesticide use on arable land in the Kaliningrad region (kg/ha)

to be found for honey production, as well as exploring the possibility of combining crops, livestock, and beekeeping in the same area without any of these inflicting damage on any of the others.

Modeling of Climate-Dependent Events in Agriculture

Mathematical models and system analysis of data play a more and more decisive role in the environmental sciences against the background of regional climate change and its consequences for agricultural development.

Methods of mathematical simulation describing the Pregel river basin (the main drainage basin in the Kaliningrad region) were presented as a balance system of differential equations where a variety of variables relating to the different components of a climate system such as temperature and precipitation and elements of vegetation such as forested area and cultural phytomass, soil humus, etc. (Zotov 1997) are put in. Retrospective experiments were conducted using data from the years 1960 to 1989 (showed the sufficient exactness).

Scenarios in a model with climate warming [average annual temperature (T) = 9 °C] show a significant increase in the forest and agricultural phytomass (10–15 %) with the level of underground water going down. In scenarios with a colder climate (T = 5 °C), the variable quantities showed the opposite trends.

By generating development models we have the possibility to calculate the quantitative character of changes in agroecosystems. So, for a change in forest phytomass, humus, and nitrogen content in the soil dependent on climate change, more than 100 years will be needed, and for the regeneration of soil humus, more than 1,000 years will be needed, whereas for 1-year crop phytomass, production under new climatic conditions only 1 year of data will be required.

Nitrogen content in river water reacts to climate change (increase of precipitation) in a similarly sudden rapid way (i.e., a sudden leap). The use of mineral fertilizers is the main cause of water nitrogen pollution. If we increase the normal level of fertilizers by two to four times, the nitrogen content in underground water grows at a rate of between 1.3 and 1.5 times and in river water at a rate of between 2.0 and 2.5 compared to the norm. It is evident that the eutrophication of Baltic coastal bays and lagoons will continue without changes in the management of agriculture.

In scenarios with an increasing forested area (and other equal conditions), the content of nitrogen in waters is decreased, whereas the level of underground water grows in such a negative way that the Kaliningrad region registers a historical excess of moisture.

Increased drainage of farmland is leading to a decrease in the groundwater level, but the surface nitrogen flow is growing. So, in order to reduce the complex negative environmental consequences, it is necessary to use the right complex method for modeling climate-dependent parameters.

For example, a scenario with a four- or fivefold increase in the application of organic and mineral (nitrogen) fertilizers compared to the former level, an increase in land drainage by 10 %, and an increase in woodland to a level 1.5 times higher than before ended with the best results, namely, an increase of cultural phytomass production and soil fertility on the one hand and a decrease in the nitrogen content of surface water and in the groundwater level on the other hand.

The most significant aspect of balanced land use in agriculture is the creation of natural space differentiation in accordance with environmental (including meso-climatic) conditions. To achieve this, it is important to consider the landscape–basin approach, in which the area model is described in relation to elementary landscape–basin systems. The model also has to include the space changes in local climate caused by rivers, lakes, the coastal zone, etc. (Orlenok et al. 2000).

To define the causes of excessive moistening of sandy soil in the Curonian Spit, the "meteofactor-level regime of subterranean waters" model was used. The following parameters play a significant role: the coefficient of filtration, the average viscosity of underground waters, the duration of filtration of the soil horizon, the initial level of underground water, and the position of these levels on the borders between the sea and the lagoon.

On the basis of the model calculation, there was a fixed time for water coming to the surface on the low parts of the sand spit in connection with the intensity of filtration and its position to the earth surface. Such a forecast can help to organize protection against erosion and destruction of the spit by the outcropping of subterranean waters in a timely fashion (Korneevets 1998).

These scenarios are based on the knowledge of modern natural processes and the mechanisms of their effects that are possible under the current system of wildlife management in the Kaliningrad region. For example, in the next 15 years, along with a continued growth of the mean annual air temperature and annual precipitation, the waterlogged area of the farmland could grow by 15–20 %. On the flat plains with poorly drained soil, the moraine ridge on upland plains along with the current trend of deforestation will exacerbate the risk of erosion, the rise of groundwater levels, and the flooding of low landforms. Adverse climate conditions, especially in the form of an increase of precipitation in the South Baltic area as described in the REMO is regional climate model with horisontal resolution 50*50 km scenario for the period between 2020 and 2029, could lead to an expected increase by 15–20 % compared with the norm of 800 m. According to the model that HIRHAM projected for the South Baltic, winter temperatures will range between 4 °C and 5 °C during the period from 2071 to 2100. In the Gwardejsk District (Kaliningrad region), the area of waterlogging and flooding of arable land had increased by 43 %, hayfields by up to 46 %, and pastures by up to 40 % by 2008. If current trends continue for 15 years from 2008, i.e., by 2023, the flooded area and waterlogged arable land will increase by up to 47 % (corresponding to 10,800 ha), hayfields by up to 48 % (4,625 ha), and pastures by up to 48 % (6,620 ha). It should be noted that there is a current increase in flooded agricultural land, especially arable land. The results of a survey of overgrown farmland show that by 2009, the Kaliningrad region had undergone an increase of scrubby parts of arable land by 5.2 %, of grasslands by 15.8 %, and of pastures by 17.6 %.

Geoinformational Databases: A New Strategy in Agricultural Management

A geoinformational database is a necessary aspect of regional environmental management. It is an ecological cartography and regionalization, modeling and prognosis. The cartography may be complex and branch out in different directions and reflects spatial temporal coherence (maps and atlases characterize the areas and estimate the state and reproduction of bioresources). The relationship between the climate, biosphere, and environment and the increasing adverse human influence on the ecosystem require a systematic and methodical approach. It is necessary to estimate the conditions of natural and economic activities and their effects. To provide the composition and quality of geoinformation, models and expert values are needed to build a system that is best adapted to changing environmental conditions.

Conclusion

With the current state of knowledge, we cannot exhaustively estimate the negative impacts of climate change from a quantitative and qualitative point of view; however, we can assume some of the possible consequences. Regarding the Kaliningrad region, we should consider the following factors of climate change:

- An increase in the average air temperature
- Changes in the amount and patterns of precipitation
- A shift of agroclimatic zones to the north
- An increased atmospheric aridity
- An increased frequency of severe weather events (storms, hail, floods) occurring more or less frequently over the years

The rational use of agricultural landscapes under conditions of climate warming is a combination of arable land with seminatural areas (Tishkov 2006). The use of waterlogged and flooded areas as meadows will reduce the leaching of the soil. Reducing the crops that are sensitive to fluctuations in temperature and humidity and that require multiple treatments with pesticides will help to stabilize the size of pollinator populations.

Contents

Abstract

The chapter elaborates the adaptation initiatives undertaken by farmers in South Asia, and advocates the need for strong policies to support agricultural adaptation. It elicits the farmers' perceptions and adaptation measures toward climate change and extent of adaptation through computing an index and

supports strong extension and policy initiatives to enhance agricultural adaptation for combating food insecurity. It has identified the fact that rises in temperatures, decreases in rainfall, and frequent incidences of pests and diseases are the common perceptions of farmers toward climate change, both for drought and floods. Adaptation measures practiced by farmers' for drought are buying insurance, change in planting dates and planting times, work as labor, and construct water harvesting structures. For floods, early sowings, saltwater spray for harvested paddy stalks, strengthening of riverbanks, and improved drainage are the adaptation measures.

South Asia • Climate change • Perceptions • Adaptation measures • Policy

Introduction

The impacts of climate change on agriculture are being witnessed all over the world, but countries especially like India in South Asia are more vulnerable in view of the large population depending on agriculture and excessive pressure on natural resources. Rainfed agriculture is likely to be impacted severely in view of its high dependency on monsoon and the likelihood of increased extreme weather events due to aberrant behavior of southwest monsoon in this part of the world. While reducing the greenhouse gas emissions holds key in addressing the problem, successful adaptation to climate change is important to stabilize the productivity. Adapting to climate change is a continuous process, and communities have wealth of information. Climate change is becoming a major driver of disasters, with increasingly frequent and intense floods and storms affecting more people globally. Increased forced displacement is an extremely likely consequence of such events. Heightened drought risk, desertification, sea-level rise, and changes in the availability of water and fertile land, coupled with reduced access to basic resources, will also fuel longer-term migration and forced displacement. As a first step, there is a need to document all the indigenous practices farmers have been following over time for coping with climate change. A better understanding of the farmers' perceptions toward climate change, the practices they adopt, and the factors that contribute to the decision-making help in formulating policies and programs aimed at minimizing the losses and reducing the risk due to climate variability and change. Understanding how and why farmers have responded to climatic change is a necessary step to informing how to support current and future adaptation.

Climate Change Impacts on Agriculture in India

Agriculture is one of the largest contributors to India's gross domestic product (GDP), approximately 20 %. It is the main source of livelihood for almost 60 % of the country's total population. The impacts of climate change on agriculture will therefore be severely felt in India. It has been projected that under the scenario of a 2.5–4.9 °C temperature rise in India, rice yields will drop by 32–40 % and wheat yields by 41–52 % (GOI 2011; Guiteras 2007; OECD 2002). This would cause GDP to fall by 1.8–3.4 %. Despite the gloomy predictions about the negative impacts for India's agricultural sector, changing climate is expected to bring opportunities as well, e.g., production gains through the CO_2 fertilization effect or the expansion of cultivated land to higher altitudes and northern latitudes. The share of Indian livestock in the GDP is about 7 %. Indian livestock are responsible for about 54 % of total methane emission in India. Increasing sea and river water temperature is likely to affect fish breeding, migration, and harvests. A rise in temperature as small as 1 °C could have important and rapid effects on the mortality of fish and their geographical distributions, and hence climate change effects could be very significant for fisheries (Climate Change and 12th Five Year Plan 2011).

Agricultural Adaptation to Climate Change

Food production is vulnerable to climate shifts because crops and cropping systems are adapted to local conditions: slight perturbations such as temperature fluctuations at critical points in crop development can have substantial impacts on productivity (Hatfield et al. 2011). Climate change also threatens the long-term capacity for food production through increased soil erosion and reduced soil fertility (Lal et al. 2011). The certainty of increased need for food to feed a burgeoning global population and the uncertainty of the short- and long-term impacts of climate change on agriculture combines to make efforts to enhance the resilience of agricultural systems a top societal priority (IFPRI-International Food Policy Research Institute 2010). The recognition that climate change-related threats to agriculture also represent threats to quality of life on a global scale has led to an increasing amount of attention to adaptation and mitigation strategies for agriculture (e.g., Howden et al. 2007; McCarl 2010). Calls for adaptive action have acknowledged that farmers are both among the most vulnerable groups to climate change and the ones on whom the task of adapting to climate change and mitigating agriculture's contribution to it largely falls (Berry et al. 2006). At the same time, farmer willingness and capacity to respond to climate change is a social process based on the social construction of the risks and vulnerabilities of increasingly variable climate conditions. The farmer is a critical decision maker if agricultural lands are to be effectively managed to adapt to changing climate conditions (Gordon et al. 2013).

Agriculture in developing countries is one of the most vulnerable sectors of the global economy to climate change (Kurukulasuriya et al. 2006; Seo and Mendelsohn 2008a). Farmers whose livelihoods depend on the use of natural resources are likely to bear the brunt of adverse climate impacts. Farmers will be hard hit if they do not adjust at all to new climates (Mendelsohn et al. 1994; Rosenzweig and Hillel 1998; Reilly et al. 1996). Adaptation to climate change requires that farmers first notice that climate has changed and then identify useful adaptations and implement them (Maddison 2006). Adaptation is widely recognized as a vital component of any policy response to climate change. Studies show that without adaptation, climate change is generally detrimental to the agriculture sector, but with adaptation, vulnerability can largely be reduced (Easterling et al. 1993; Reilly and Schimmelpfennig 1999; Smit and Skinner 2002). The degree to which an agricultural system is affected by climate change depends on its adaptive capacity. The adaptive capacity of a system describes its ability to modify its characteristics or behavior so as to cope better with changes in external conditions. Adaptive capacity is determined by various factors including recognition of the need to adapt, willingness to undertake adaptation, and the availability of, and ability to deploy, resources (Brown 2010). Recent empirical studies indicate that farmers have already adapted to the existing climates that they face by choosing crops or livestock or irrigation (Kurukulasuriya and Mendelsohn 2007, 2008; Nhemachena and Hassan 2007; Seo and Mendelsohn 2008b, 2008c) ideal for their current climate. The adaptation strategies must not be used in isolation. For example, the use of early-maturing crop varieties must be accompanied by other crop management practices such as crop rotation or the use of cover crops. This, however, requires additional institutional support, such as credit and access to input, markets, and information. Information about farmers' awareness of climate change and current adaptation approaches would assist policymakers in their efforts to decrease the country's vulnerability to the adverse impacts of climate change (Deressa et al. 2008). However, limited information exists on the impact, vulnerability, and adaptation to climate change, especially at household levels. Given this knowledge gap, there is a need to carefully evaluate the impact of climate change on rural livelihoods in order to provide authorities with timely information for adaptation strategies.

The objective of the present study was to identify farmers' perceptions toward climate change (both drought and floods) along with their farm-level adaptation measures in South India with a view to suggest appropriate research/policy issues which help in facilitating farmers' adaptation. Role of extension in facilitating adaptation to climate change is discussed.

Methodology

Among South Indian states, Andhra Pradesh was chosen as the locale of this study since (a) the farmers in this region are exposed to a great degree of climate variability resulting in high vulnerability and (b) researchers' familiarity with local language and culture. Anantapur, Mahbubnagar, and East Godavari districts representing three different regions of the state were selected randomly. Anantapur and Mahbubnagar have a semiarid climate with average annual rainfall being

Table 1 Selected study mandals with villages in parentheses, for Anantapur, Mahbubnagar, and East Godavari districts

District	Mandals (villages in parentheses)
Anantapur	Bukkarayasamudram (*Bhadrampally, Siddharamapuram*)
	Chenne Kothapalli (*Nagasamudram, Chenne Kothapalli*)
	Mudigubba (*Podarallapalli, Mangalamadaka*)
Mahbubnagar	Mahbubnagar (*Machanpalli, Appaipally*)
	Kothakota (*Nirven, Palem*)
	Ghatt (*Penchikalapadu, Aragidda*)
East Godavari	Gollaprolu (*Gollaprolu, Chendurthi*)
	Peddapuram (*J.Thimmapuram, Kattamoru*)
	Marredumilli (*Narsapuram, Dora Chintalapalem*)

560 and 600 mm, respectively, whereas East Godavari has a coastal climate with annual rainfall of 1,100 mm. The predominant crops are groundnut in Anantapur; maize, groundnut, and cotton in Mahbubnagar; and paddy in East Godavari district, so the semiarid districts of Anantapur and Mahbubnagar grow dryland crops, whereas the coastal district of East Godavari grows waterlogged crops like paddy. A sample of 180 farmers at the rate of 60 each from Anantapur, Mahbubnagar, and East Godavari districts of Andhra Pradesh in South India were selected randomly. Three mandals (a mandal is a unit of administration above village and below district level in a state and comprises several villages) each from the selected districts, with two villages under each mandal, were chosen randomly. From each village, ten farmers were selected randomly for collecting data. The selected mandals, with villages in parentheses, for the above three districts are given in Table 1. Data was collected using a pretested interview schedule from the farmers along with focused group discussions. Percent analysis and composite index (adaptation index was computed by the formula: adapted measures/total recommended measures × 100) developed in the study were used for analyzing data.

Results and Discussion

Farmers' perceptions and Adaptation Measures Toward Climate Change

From Table 2, it is evident that rise in temperatures followed by decrease in rainfall, advanced onset of monsoon, middle long dry spells, terminal heavy rains, prevalence of pests and diseases, and ITKs for weather forecast failing are the major farmers' perceptions in that order of magnitude regarding climate change in

Table 3 Farmers' adaptation measures toward climate change in Anantapur

S. no.	Farmers' adaptation measures	Number[a]	%	Rank
1.	Buying insurance	56	93	I
2.	Change in planting dates of groundnut (go for early sowings may be between May end to early June)	55	92	II
3.	Intercropping with red gram in 8:1 or 12:1 ratio	48	80	III
4.	Intercropping with castor contemplated	47	78	IV
5.	Construction of water-harvesting structures under Mahatma Gandhi National Rural Employment Guarantee Act (MGNREGA)	45	75	V
6.	Requiring of quick-maturing, drought-resistant varieties	42	70	VI

Anantapur. Bryan et al. (2009) in their study in Ethiopia and South Africa reported that farmers experienced increased temperature and decreased rainfall. Similar observations were reported by Vedwan and Rhoades (2001), Hageback et al. (2005), and Dejene (2011) in their studies. Results of a study conducted in Bundi district of Rajasthan, India, revealed farmers' perceptions to climate change as increase in temperatures, decreased rainfall, and long dry spells. The chief adaptation measures followed by farmers are change in planting time, intercropping, soil and water conservation, and planting drought-tolerant crops (Dhaka et al. 2010).

Table 3 illustrates that buying insurance, changing planting dates of groundnut, intercropping with red gram, construction of water-harvesting structures, and requiring of quick-maturing, drought-resistant varieties in that order of magnitude are the major adaptation measures followed by farmers toward climate change in Anantapur. This finding is consistent with that of Swanson et al. (2008) who reported that crop insurance was widely used by farmers in Foremost region of Canada (which is similarly dry), and the common feeling was that even though it might not provide sufficient returns for losses incurred, it does offer some

Table 4 Farmers' perceptions regarding climate change in Mahbubnagar

S. no.	Farmers' perception	Number[a]	%	Rank
1.	Rise in temperatures	55	92	I
2.	Decrease in rainfall	53	88	II
3.	Advanced (some places timely) onset of monsoon	51	85	III
4.	Middle long dry spells accompanied by cloudy weather during flowering	48	80	IV
5.	Terminal heavy rains	46	77	V
6.	Prevalence of pests and diseases (powdery mildew, mold in castor; smut and jassids in paddy)	41	68	VI

protection. It has allowed them to continue farming. Agricultural insurance can help people to cope with the financial losses incurred as a result of weather extremes. Insurance supports farmers in their adaptation process and prevents them from falling into absolute poverty. Apart from stabilizing household incomes by reducing the economic risk, insurance can also enhance farmers' willingness to adapt, make use of innovations, and invest in new technologies (Anna et al. 2011). Agricultural adaptation involves two types of modifications in production systems. The first is increased diversification that involves engaging in production activities that are drought tolerant and/or resistant to temperature stresses as well as activities that make efficient use and take full advantage of the prevailing water and temperature conditions, among other factors. Crop diversification can serve as insurance against rainfall variability as different crops are affected differently by climate events (Orindi and Eriksen 2005; Adger et al. 2003). The second strategy focuses on crop management practices geared toward ensuring that critical crop growth stages do not coincide with very harsh climatic conditions such as mid-season droughts. Crop management practices that can be used include modifying the length of the growing period and changing planting and harvesting dates (Orindi and Eriksen 2005).

From Table 4, it is clear that rise in temperatures followed by decrease in rainfall, prolonged dry spells in between rains, terminal heavy rains, and prevalence of pests and diseases (powdery mildew, mold in castor; smut and jassids in paddy) are the major farmers' perceptions in that order of magnitude regarding climate change in Mahbubnagar. It is striking to note that farmers across the world show a remarkable unanimity in observations of seasonal change, particularly regarding rain falling in most intense bursts, and generally higher temperatures and longer hot, dry spells within rainy seasons, with effects on soil moisture (Jennings and Magrath 2009). Kemausuor et al. (2011) reported that a large percentage (93 %) of farmers was of the opinion that the timing of the rains is now irregular and unpredictable.

As stated by farmers in Table 5, staggered sowings, change in planting dates, requiring of drought-resistant crops, and construction of water-harvesting structures are the major adaptation measures followed by farmers toward climate change in Mahbubnagar.

Table 5 Farmers' adaptation measures toward climate change in Mahbubnagar

S. no.	Farmers' adaptation measures	Number[a]	%	Rank
1.	Staggered sowings (dry paddy, castor, red gram, and cotton in kharif), (groundnut, paddy, chilies, and tobacco in rabi)	50	83	I
2.	Change in planting dates and planting different crops	49	82	II
3.	Requiring of drought-resistant varieties	45	75	III
4.	Construction of water-harvesting structures started under MGNREGA	41	68	IV

Table 6 Farmers' perceptions regarding climate change in East Godavari

S. no.	Farmers' perception	Number[a]	%	Rank
1.	Rise in temperatures	54	90	I
2.	Decrease in rainfall	53	88	II
3.	Pest and disease incidence is high for kharif paddy like BPH, BLB, and stem borer (at transplanting stage)	51	85	III
4.	Terminal heavy and unseasonal rains	49	82	IV
5.	ITKs for rain forecasts are failing	45	75	V

Also, the farmers in Mahbubnagar are used to observe the pattern of rainy season, and if it gets copious rains, they will continue farming. Otherwise, they migrate and work as construction labor at Gangavati, Hyderabad, and Bangalore. Higher temperatures and pest and disease attack on crops were the chief perceptions of farmers toward climate change, while planting different crops and water conservation were the main adaptation strategies of farmers in Ogbomosho Agricultural Zone of Oyo State in Nigeria (Ayanwuyi et al. 2010).

Table 6 points to rise in temperatures, followed by decrease in rainfall, incidence of pests and diseases, terminal heavy cyclonic rains, and ITKs for rain forecast failing as the major farmers' perceptions in that order of magnitude regarding climate change in East Godavari.

Table 7 indicates that early sowings, saltwater spray for harvested paddy stalks, strengthening of riverbanks and improved drainage, survey number wise insurance, and loans to tenant farmers are the major adaptation measures perceived by farmers toward climate change in East Godavari. Migration of construction labor if monsoon fails (June–September rains) in rainfed areas of the district is another common phenomenon (Ravi Shankar et al. 2013).

Since most smallholder farmers are operating under resource limitations, lack of credit facilities and other inputs compounds the limitations of resource availability, and the implications are that farmers fail to meet transaction costs necessary to acquire the adaptation measures they might want to and at times farmers cannot make beneficial use of the available information they might have (Kandlinkar and Risbey 2000). Lack of access to credit has been observed in previous studies (Nhemachena and Hassan 2007) to be a barrier to responding to climate change. Furthering adaptive capacity is in line with general sustainable development, and

Table 7 Farmers' adaptation measures toward climate change in East Godavari

S. no.	Farmers' adaptation measures	Number[a]	%	Rank
1.	Going for early (June) sowings to avoid November cyclones coinciding with harvests	56	93	I
2.	Saltwater spray for harvested paddy stalks to avoid discoloration and regermination. For paddy in field, tying with rope and sticks on four sides to keep them erect and not falling down	55	92	II
3.	Strengthening of riverbanks and improved drainage	53	88	III
4.	Survey number wise insurance covering low lands	50	83	IV
5.	Loans to tenant farmers, though introduced, fall short of actual requirements in terms of coverage	48	80	V

policies that help reduce pressure on resources reduce environmental risks and increase the welfare of the poorest members of the society.

A better understanding of how farmers perceive climate change, ongoing adaptation measures, and the factors influencing the decision to adapt farming practices is needed to craft policies and programs aimed at promoting successful adaptation of the agricultural sector (Bryan et al. 2009).

Computation of Adaptation Index to Assess the Extent of Farmers' Adaptation to Climate Change

Each farmer was scored for adaptation by assigning scores of 0, 1, and 2 for non-, partial, and full adaptation of a measure, respectively. In case of drought and floods, total adaptation measures were 8 for each, respectively, and hence maximum adaptation score that can be obtained is 16, while minimum adaptation score that can be obtained by a farmer is 0. Adaptation indices were computed by dividing adapted measures with total recommended measures and multiplied with 100 for assessing the extent of adaptation. Adaptation index is expressed in percentage (%).

The adaptation indices for the three districts along with their SD (standard deviation) and CV (coefficient of variation) values are presented in Table 8. Table 8 shows that the mean adaptation index value for floods (12.13) (East Godavari) is greater than that for droughts (11.90, 11.65) (Anantapur and Mahbubnagar, respectively).

Village-Wise and Practice-Wise Adaptation Scores of Farmers

Adaptation to climate change is the adjustment of a system to moderate the impacts of climate change to take advantage of new opportunities or to cope with consequences (Adger et al. 2003).

Table 8 Adaptation indices of farmers for drought and floods

Statistic/category	Anantapur (drought)	Mahbubnagar (drought)	East Godavari (floods)

CV	46.90	63.78	9.20	9.20	42.36	33.61	0.00	22.41

From Table 14, practices A3 (construction of water-harvesting structures), A4 (drought-resistant crops), A7 (crop management by adjusting planting dates), and A8 (soil management by mulching, conservation tillage) showed highest adaptation in Anantapur. This amply illustrates the need for water harvesting, storage, and reuse.

From Table 15, practices A3 (construction of water-harvesting structures), A4 (drought-resistant crops), A7 (crop management by adjusting planting dates), and A8 (soil management by mulching, conservation tillage) showed highest adaptation in Mahbubnagar. This amply illustrates the need for water harvesting, storage, and reuse.

From Table 16, practices A3 (flood forecasting and early warning systems), A4 (drainage aspects), A5 (better soil and crop management practices), and A8 (community-based water management) showed highest adaptation in East Godavari. The problem here is managing excess water.

Conclusion

Common perceptions of climate change across the three regions in AP are rise in temperatures, decrease in precipitation, and incidence of pests and diseases to crops. Adaptation measures practiced for drought are insurance, change in planting dates, working as migrant laborer, and construction of WHS. For floods, early sowings, saltwater spray for harvested paddy stalks, strengthening of riverbanks, and improved drainage are the chief adaptation measures. The mean adaptation index value for floods (East Godavari) is greater than that for droughts (Anantapur and Mahbubnagar). Practice A7 (crop management by adjusting planting dates) showed highest adaptation in Anantapur and Mahbubnagar. Practice A5 (better soil and crop management practices) showed highest adaptation in East Godavari.

Rise in temperatures is almost always echoed by farmers irrespective of season and place. Decreasing precipitation is yet another common concern, which usually when occurring in severe intensity bursts does an impression of pricking on human skin. Water conservation is the need of the hour, to avoid runoff of excess rainwater in a short period of time. Farmers believe that it has great potential in addressing the impacts of climate change. Incidence of pests and diseases on crops complement with varying humidity levels in the atmosphere deserves attention. Until now minor crop pests, be it on dry sorghum or castor and paddy, are becoming major is another important observation by farmers.

Adaptation/adjustments to climate change at household level by farmers which are carried single handedly through experience and observation require greater support in terms of continuance with or without slight modifications. Insurance, changing planting dates, and planting different crops in a staggered manner come under this household adaptation category. Construction of water-harvesting structures under MGNREGA in dry districts of the study is an encouraging sign and should be promoted wherever possible. Since crop management strategies are ad hoc and immediate, farmers show a great degree of preference to it to tide over the situation, for example, change in planting dates, intercrops, etc. However, in attaining greater resilience toward climate change, soil management concepts and practices should be instilled among farmers like conservation tillage, mulching, recycling of nutrients, etc. For floods, proper drainage system for the floodwaters to empty into the sea is lacking. Drainage systems often suffer from inadequate maintenance and need improvement works like desiltation, lining of the walls, and weed removal. There is need for imparting greater awareness, education, and training about climate change issues to farmers in supporting adaptation efforts. The challenge which remains for scientists is developing quick-maturing, drought- and lodging-resistant crop varieties to surmount the current and future climate change in agriculture.

Climate Change and Agriculture in Dry Areas

Muhammad Saqib, Javaid Akhtar, Riaz H. Qureshi, and Ghulam Murtaza

Contents

Abstract

This chapter explores the implications of climate change for agriculture in dry areas in the context of decreasing quantity and diminishing quality of water. It proposes adaptation strategies for planning national and regional responses to climate change. This chapter analyzes the impacts of climate change on agriculture in dry areas taking into consideration different adaptation efforts underway and the bottlenecks faced. On the basis of this analysis, it presents certain guidelines for responses to climate change in dryland agriculture. The findings of this chapter include an elucidation of the impacts of climate change on agriculture in dry areas and the factors which contribute to these impacts. In addition

certain adaptation guidelines are proposed. Agriculture is the most important sector of life affected by climate change. The findings of this chapter will be useful for all the stakeholders including policy makers, agricultural managers, and the farmers. Agriculture in general and in drylands in particular is vulnerable to climate change. However, the impacts of climate change on agriculture and the possible adaptations are not studied extensively. Therefore, the present chapter is expected to provide original information on the subject of climate change and agriculture in dry areas.

Introduction

According to the World Atlas of Desertification, the areas where the ratio of mean annual rainfall and mean annual potential evapotranspiration is between 0.05 and 0.20 are classified as arid areas, and the areas where this ratio is between 0.2 and 0.5 are classified as semiarid areas (UNEP 1992). About 41 % of the Earth's land surface is covered by drylands with a population of more than two billion people and more than 90 % of these are in the developing countries (IIED 2008). This makes the drylands home to about one-third of the global population. However, according to United Nations Development Programme (UNDP), the arid and semiarid regions occupy about 30 % of the total area of the world and are home to 1.10 billion people or around 20 % of the total world population. About 24 % of the total population of Africa, 17 % of the Americas and the Caribbean, 23 % of Asia, 6 % of Australia and Oceania, and 11 % of Europe live in the arid and semiarid areas (UNSO 1997). The major dryland areas of the world include West African Sahel and Dry Savannas, East and Southern Africa, North Africa and West Asia, Central Asia and the Caucasus, and South Asia.

Dry areas are home to most of the world's poor and many poorest of the poor who live on less than 1$ a day (White et al. 2002). The dry areas have high population growth with low employment rate and high number of youth population, rapid urbanization, poverty, social inequality, and poorly developed markets and institutes. The health, nutrition, and living conditions are very poor in the dry areas.

The drylands are very poor in renewable water supply (less than 8 % of the renewable water resources of the world) and have low and variable precipitation and very low organic matter (IIED 2008). Low water availability is the most important limiting factor for sustainable food production from drylands. The most water-scarce regions of the world are Middle East and North Africa. The problem of water scarcity is compounded with groundwater depletion. The dry areas are also home to the most vulnerable agricultural ecosystems which are hit hard by the climate change.

World food production is seriously affected by climate change particularly in the arid and semiarid regions. The productivity of dry areas is much less than their potential and the need of the people living in these areas. For example, wheat yields are up to 30 % lower in dry areas than the global average. Similarly, the livestock and poultry production is very low in the dry areas. This low productivity leads to food imports and price hikes which threatens the food security and livelihoods of the poor people of these areas. Drylands often witness famines and natural disasters which lead to resource damage and political unrest.

History shows that extremes of heat, cold, droughts, and floods have caused devastation to the agricultural systems in the dry areas. Climate change has added to susceptibility of these areas to poverty, hunger, famine, and dislodgment. It therefore needs time to develop strategies and policies to increase food production on sustainable basis in the drylands of the globe. The agricultural and pastoral systems in dry areas are very complex and include pastures, rangelands, forests, fish and livestock, and rainfed and irrigated production systems. The management and development of the dry areas require an approach that can integrate different cropping, pastoral, forest, and livestock systems.

Climate Change-Induced Problems of Dry Areas

Climate change is the change in the weather over a long period of time. Rising levels of greenhouse gases in the global atmosphere and increasing concentrations of aerosol particulates are considered to noticeably affect the world climate systems (Santer et al. 1996). These changes lead to a rise in the world mean temperature and sea level. The mean surface temperature of the world has increased by about 0.6 °C over the twentieth century (IPCC 2001). The data from the northern hemisphere showed that this rise in temperature during the twentieth century is the maximum during a century since 1000 A.D. According to IPCC (2013), over the period of 1880–2012, the global average temperature has increased by 0.85 (0.65–1.06) °C. Agriculture is very sensitive to climate change-induced long-term trends and short-term variability of rainfall and temperature and of the occurrence of droughts, floods, heat waves, frosts, and other extreme events (IPCC 2012). Climate change is increasing threats to food safety and post-harvest losses and danger from invasive species, pests, and diseases (Vermeulen et al. 2012). The incidence and geographic spread of diseases of the human beings, animals, and plants is also likely to increase in a warming climate. Climate change particularly challenges the sustainability of food production systems and the natural resources in the areas of widespread or intense water stress and environments prone to degradation and desertification and where the poor people cannot take the needed preventive steps (IPCC 2012). Almost all the global circulation models predict that the dry areas will be hit hard by the climate change. The agroecosystems of dry areas are challenged with drought, floods, salinity, extreme temperatures, biodiversity loss, and land degradation. The farmers of the dry areas often have smallholdings and practice a mixed

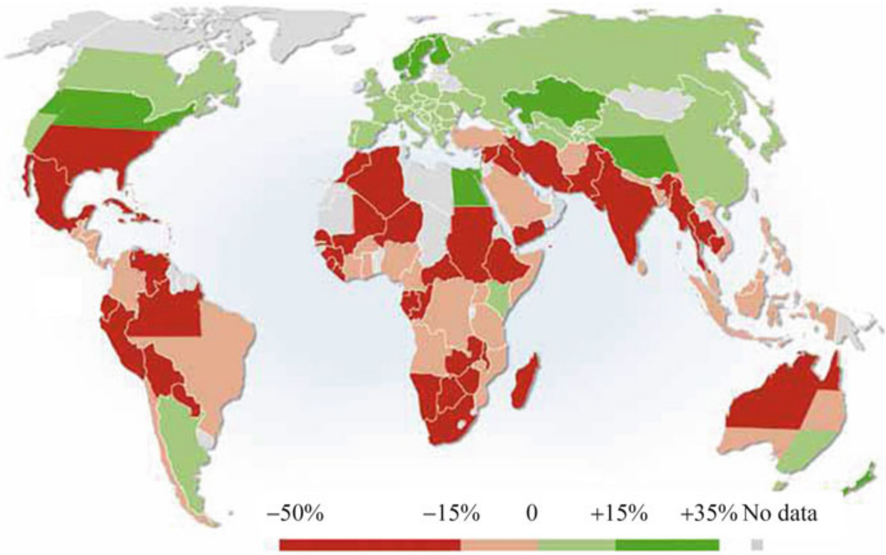

Fig. 1 **Projected changes in agricultural production in 2080 due to climate change**. Projections assume a uniform 15 % increase in yields due to the fertilization effect of rising carbon dioxide in the atmosphere on some plant species (Note that this coarse-grain analysis does not project local-scale impacts which require geographically specific analysis) (Cline 2007)

farming system comprising of rainfed cropping and livestock. These activities are mostly vulnerable to climate change that results in loss of biological potential and desertification of these areas. Climate change results in demographic changes in the agricultural areas. People migrate from one place to the other along with their livestock and enhance the load on water and soil resources of an already stressed area. This leads to poor resource management and conflicts between the nomads and the farmers of a particular area.

The food security, life quality, poverty, agriculture, and climate change are strongly linked with agriculture playing a key role in the linkage. Climate change is intensifying the problems of drylands, and the situation is predicted to get worse with time, and the drylands will have to rely more and more on the unreliable food imports. Agriculture in drylands is highly vulnerable to climate change (Fig. 1). The crop and livestock yields in the dry areas are reduced or crop failure occurs due to unreliable precipitation pattern. The overall rainfall levels have declined with climate change, and the drought events have become frequent and more intense. A change in global temperature is causing a shift in the climatic zones. The length of growing seasons is decreasing, and the pests and diseases are increasing and spreading in the areas where they were not prevalent in the past. New pests and diseases are also emerging under these conditions. A decrease in food production in the dry areas has occurred under the changing climatic conditions, and the situation is expected to get worse. This lowers the farm income, spikes the commodity prices, and increases the import of food commodities. These developments as a result of climate change are going to affect the sociopolitical stability of already geopolitically volatile dryland countries.

Climate Change Adaptation and Mitigation Strategies for Agriculture in Dry Areas

Agriculture, food security, and environmental resilience in dry areas essentially need widespread adoption of sustainable agricultural practices. The global burden of hunger is bound to increase as the frequency of extreme weather events like droughts and floods is predicted to increase (Beddington et al. 2012). Therefore, future global agriculture needs to produce more food for the growing population while adapting to changing climate (Foresight 2011; Lobell et al. 2011).

Agriculture can enhance as well as decrease the climate change and its impacts. Greenhouse gas emissions from agriculture include emissions from ruminant digestion (sheep, goat, and cattle), rice fields, and fuel use. Methane, nitrous oxide, and carbon dioxide emitted by livestock activities (i.e., enteric fermentation and manure management) and land-use changes make a substantial contribution to anthropogenic greenhouse gas emissions (Steinfeld et al. 2006). Deforestation for land clearing for agriculture also significantly contributes to greenhouse emissions (Smith et al. 2007). These greenhouse gas emissions enhance climate change. On the other hand, agriculture provides a major sink of carbon in vegetation and soil that contributes to adaptation and mitigation of climate change. Therefore, better and improved agricultural activities can reduce risk and may create a win-win situation for agriculture in dry areas. These activities may include better resource management, genetic improvement, and socioeconomic institutional support for these areas (Anonymous 2012, 2013). This section describes these activities for sustainable dryland agriculture systems.

Prioritization of Resource Utilization

Land and water resources are under tremendous pressure in dry areas and need to be used very wisely and judicially. Producing more with little is the major challenge for agriculture in the dry areas. To meet this challenge, it is very important to prioritize the resource utilization on high potential lands and marginal lands. The high potential lands and marginal lands need different strategies to maximize returns from these lands. There are drylands with good production potential, relatively friendly environmental conditions, better access to markets, and institutional support. These areas should be targeted for intensive food production using high-yielding, resource-efficient, and stress-resistant crop varieties and livestock breeds. There are the dry areas with poor/marginal land and water resources with poor access to markets and poor institutions. The major focus in these areas should be to reduce their vulnerability to climate change and avoid resource degradation. Therefore, the aim here is to decrease risk and vulnerability of these rural communities and to increase their resilience to climate change. These areas may support only very hardy plants and animal species. Rearing goats and sheep is a good option in these areas as different fodder species are hard enough to be grown in these areas. Awassi sheep is a good example as it supports the livelihood of many people in the dry areas of Middle East through providing milk, meat, and wool. This may also be used in other dryland areas.

Diversification and Integration of Crop-Livestock Systems

Land and environment suitability of crops and livestock should be extensively studied and explored. Diversification of crops, livestock species, vegetables, and trees is needed in the dry areas. A shift from high water-using crops and animals to low water-using crops and animals should also be encouraged. The diversification of agricultural systems can mitigate risk and improve income in dryland areas. Introduction of innovative uses of the arable land resources, introduction of new plants, and value addition to the existing food production in the existing agricultural systems can improve economic returns and mitigate risks.

Genetic Improvement of Crop and Livestock

Genetic improvement of crops and livestock is a key toward sustainable agriculture and food security in the dry areas. This can improve the efficiency and resilience of the food production systems in the dry areas under changing climatic conditions. The breeding programs need to be more site specific toward the environmental conditions, pests and diseases at a particular area. The genotypes developed for a particular situation may be more resource efficient under these conditions. The "Gokce," a drought-tolerant variety of chickpea introduced in Turkey, is a good example (Anonymous 2012). Biotechnology is applied in the development of varieties with superior traits including resilience to climate change and low input requirements. Some crops have been genetically engineered to reduce GHG emissions from agriculture and therefore contribute to climate change mitigation. Genetic improvement in the livestock sector also helps the farmers to adapt to climate change and reduce greenhouse gas emissions. Crops and livestock with low greenhouse gas production should be selected and promoted.

Seed has become a very costly input in agriculture. Therefore, seed development and seed-keeping are very important for a better harvest. The farmers of the dry areas may be trained in seed-keeping to reduce crop raising costs and increase farm income. The women of the Matigsalog tribe in Davao City, Philippines, were trained for selection of suitable rice varieties for different conditions which helped them to select and preserve right seeds and improved their resilience to climate change-induced problems in rice production (APEC 2012).

Conservation Agriculture

Conservation agriculture and site-specific management have found to be suitable for farming in the dry areas. Conservation agriculture involves reduced soil disturbance, retaining crop residues and conserving water and crop nutrients. It follows zero till or no-till system of cultivation. It reduces costs and improves soil health, nutrient cycling, and crop yields. It increases carbon sequestration and decreases greenhouse gas emission from agricultural land and contributes to climate change mitigation. Efficient input utilization in agriculture minimizes input use and carbon emission. Fertilizer application may be reduced by nutrient recycling through the decomposition of plant residues. When used with other improved crop management practices, conservation agriculture has given good results for wheat, barley, chickpea, and lentil. A change in animal feed, improvement in animal housing, and better waste and manure management in livestock can reduce CH_4 emissions. Alternative agricultural practices, suitable for a particular region, can reduce the emission of greenhouse gases and hence will help to maintain or improve yields and to adapt to extreme weather events (Pretty et al. 2011). However, the farmers are reluctant to follow conservation agriculture at many places as it may involve initial costs and the initial benefits are gained after some time. The policy makers are also afraid that not as much food can be produced from conservation agriculture as from the conventional ways. Similarly, limited availability of resources is a hindrance toward changing to a more conservative approach (FAO 2006).

Water Conservation and Management

Water is the most important but limited and endangered entity in dry areas. It is the single most important factor controlling the sustainability of dryland agriculture systems and dryland communities. Therefore, efforts at all levels are needed to increase its utilization efficiency. Improved water use efficiency is also needed to reduce fresh water use in agriculture which is up to 90 % in some countries. Water resources management is complicated as the key physical water bodies like rivers, lakes, and watersheds cut across the political borders. These water resources and their management provide the basis of agricultural development in dry areas. The related problems like flooding, drought, and rise in sea level also go across the political boundaries. Therefore, a cost-efficient and environment-friendly water management requires integration at farm, ecosystem, and policy levels. A successful integrated water resources management requires "top-down" as well as "bottom-up" approach including policy, funding, and institutional support and farm-level activities. Irrigation systems giving high water use efficiencies should be introduced in the dry area.

Agricultural Research, Education, and Extension

Climate change adaptation and mitigation and sustainable food production from the dry areas need modernization of agriculture. Introduction of new technologies has improved wheat yields of the dryland farmers by 22 % in Egypt and 58 % in Sudan. Agricultural adaptation to climate change is very costly and needs to be supported financially from different climate change adaptation funds. Climate smart initiatives and climate smart technologies can be helpful in sustaining and increasing food production and protecting the natural resources of the dry areas. The improved adaptation and mitigation measures will not only improve food security but will also reduce the agriculture-induced climate change by reducing greenhouse gas emissions from agriculture.

International and National Policies and Agreements

There is a strong need to increase human capacity to benefit from current and future trade-offs and to capitalize on synergies between food security and climate change adaptation and mitigation options. A strong leadership is needed at international institutes and policy processes for this purpose. It is the dire need of the dryland countries that agriculture and food security should get an important place in the discussions in the global bodies including the United Nations Framework Convention on Climate Change (UNFCCC), the Group of 20 nations (G20), and the United Nations Convention on Sustainable Development (the organizing body of the Rio + 20 Earth Summit). These bodies should be persuaded to adopt appropriate actions including policy and financial measures to improve implementation of sustainable solutions to climate change in drylands on a global level. All the dryland countries essentially need agriculture-friendly policies in this era of climate change. COP-17 in Durban has been good as the agriculture has been specifically mentioned for the first time in the text of UNFCCC. Long-term investment and funding is needed to finance the new technologies. Climate change adaptation and mitigation are costly, and a considerable funding from international agencies is required, if the dryland communities are to be sustained and further developed. A number of technologies are available today to overcome the problems of the drylands; however, these need to be taken to the field through financing, training, and advocacy to the governments as well as to the farmers.

Climate change will continue to challenge the livelihoods of the people of dryland areas. These areas are difficult to manage but need more attention of the policy makers and donors as these areas have received less investment in the past. In the twenty-first century, agricultural development is important for achieving food security and adaptation to and mitigation of climate change. Agriculture is a key sector for climate change resilience particularly in the drylands as it is accepted that climate change will severely affect the development and life in the rural areas. A concentration on the dry areas is very important for improving food security, nutrition and health, conservation of natural resources, and decreasing social inequality.

Dryland Development Beyond 2015: Beijing Statement

Dryland Development Beyond 2015: Beijing Statement of the 11th International Drylands Development Conference of the International Dryland Development Commission (18–21 March, 2013, Beijing, China) summarizes the issues, options, and solutions related to the drylands (ICDD 2013). The statement narrates as:

> Drylands – comprising deserts, rangelands, rainfed croplands, wastelands, and some savanna woodlands – cover about 41 % of Earth's land surface and are inhabited by more than 2 billion people. More than 50 % of the poor and malnourished of the world live in the dry areas and suffer from food insecurity, and socio-economic and socio-political instability. Many of these areas face severe land degradation, potentially undermining the productivity of these important ecosystems. Natural and semi-natural ecosystems are being degraded by the mismanagement of water resources, inappropriate land use practices and overgrazing. Increasing fuel prices are making agricultural inputs and operations more costly, reducing agricultural productivity, and increasing food prices. The impact of global climate change would worsen the situation. Therefore, there is **an urgent need to pay attention to improving coping capacity of the people in the dry areas and minimizing vulnerability by** developing knowledge-based adaptation and mitigation modalities through global cooperation. Hence, it is imperative that the **post-2015 development agenda** by the international community takes account of the challenges faced by over 2 billion people living in these drylands. Consolidated responses must undertake drylands development in a manner that adequately addresses water, food, feed, and energy security concerns and offer opportunities for economic development while respecting the rich and varied social and cultural heritages.
>
> The **Participants of the Conference**, representing research and development community from **29 countries** and **14 regional and international organizations**, have come to the conclusion that this can be achieved in two ways:
>
> **First**, the sustainable development goals (SDGs) should maintain a sharp focus on issues that are of relevance to drylands: reducing poverty through sustainable land management, protecting livelihoods and ensuring human wellbeing, adequate management of scarce water resources, and providing incentives to governments for initiating proactive responses to land degradation. The notion of green economy may provide us a useful starting point for formulating such SDGs. In this new paradigm of sustainability, the notions of carbon footprint and water footprint must figure centrally within green economy policies. However, this must be balanced to become globally equitable.
>
> **Second**, countries and people must be resourced to meet with new and emerging challenges, the awareness of which has to be enhanced amongst all stakeholders. As climate change exposes us to unprecedented water stress and impacts on biodiversity, no region is more adversely impacted than drylands – and we must therefore work on building societal resilience against such new challenges. This can be achieved by: (a) developing scientific and technological resources and making them available to governments and other stakeholders in drylands developing countries; (b) mobilizing and further developing human and institutional capacity in developing countries, ensuring gender equity and empowerment, particularly around sustainable land, water and genetic resource management, adopting an agro-ecosystem approach; (c) mobilizing new capital, both in the public and private sectors, to develop institutions and infrastructure and sustainable renewable energy sources; and (d) introducing specific enabling policies and legislation.

Conclusions

Climate change is a reality and no more a speculation. The occurrence of extreme weather events has become a routine around the globe particularly in the dryland regions. Drylands are home to a significant human population who has no other option except to earn their livelihoods from these vulnerable areas. They are already living in the poorest living conditions which are faced with increasing challenges and problems with time. Agriculture is the only sector which can ensure the sustainability, food security, and improvement of life quality of dryland communities. Therefore, agricultural research should emphasize to develop new resource-efficient genetic materials and technologies which can tolerate the extreme climatic events under dryland conditions. It is not possible without financial and policy support from national and international institutions, governing bodies, and commissions.

Climate Change and Water Issues in Mesopotamia: A Framework for Fostering Transboundary Cooperation in Euphrates-Tigris Basin

Vakur Sümer

Contents

Abstract

This chapter starts with presenting an overview of the current situation in Mesopotamia in terms of both water resources and increasing impacts of climate change over water resources. The existing literature on potential problems of climate change in Euphrates-Tigris region will also be discussed. Then the chapter turns to the question of how countries of the region may come together around the theme of water and increase their adaptive capacities in the face of climate-related threats.

Keywords

Mesopotamia • Euphrates • Tigris • Iraq • Syria • Turkey • Climate change • Water resources • Macro-region

Introduction

The two significant rivers in the Middle East, Euphrates and Tigris (ET), characterize the area which was historically known as Mesopotamia. The Mesopotamia region constitutes a single basin ending in the Persian Gulf. The area witnessed the earliest urban civilization in Sumerian times and is called as the "Cradle of Civilization." It also historically is part of the greater "Fertile Crescent" stretching from the Nile Delta through Jordan River and through Euphrates-Tigris into the Persian Gulf. Food production in the region continues to be vital not only for the population living in the basin but for the entire populations of the riparians. The water-dependent area of Mesopotamia now faces with the threats of climate change which could turn out to be disastrous if adaptation strategies are not implemented in timely manner.

There is a growing literature on the possible impacts of climate change on Mesopotamia.[1] However, little has been done in order to improve the adaptive capacity in the face of climate change in the region. Moreover, despite this recent literature, there is a lack of reliable historical data which renders it difficult to develop robust models of changes in time (Rifai 2008; Voss et al. 2013). Adaptation to climate change, certainly, entails a wide range of issues (Moser and Dilling 2004). One significant part of climate change adaptation is to develop the transboundary cooperation since the basin is shared by a number of countries, and as it is already known, climate change knows no boundaries.

Within this framework, this chapter aims to present a model for transboundary cooperation, particularly with regard to transboundary water resources in the region. Building upon a recent EU model and taking water as a common ground for action, this chapter tries to propose a coherent and holistic perspective for an ever climate-adaptive Mesopotamia. The chapter starts with presenting an overview of the current situation in Mesopotamia in terms of both water resources and increasing impacts of climate change over water resources. The existing literature on potential problems of climate change in Euphrates-Tigris region will also be discussed. Then the chapter turns to the question of how countries of the region may come together around the theme of water and increase their adaptive capacities in the face of climate-related threats.

Climate Change Impacts on Water Resources in Mesopotamia

Euphrates and Tigris are two significant rivers in the southwest Asia. They are important not only because of their length which makes them "transboundary" rivers but also because of their water volume which makes the region of

[1]See, for instance, Voss et al. (2013), Yilmaz and Imteaz (2011), Topcu et al. (2010), Sowers et al. (2011), Kitoh et al. (2008).

Mesopotamia as one of the most fertile agricultural regions in the world as well as their potential in terms of hydroelectricity.

Euphrates is the longest river of the region (approx. 2,700 km). The Kara Su and the Murat are two main tributaries of Euphrates in the headwaters. These two tributaries, along with the Balikh and Khabur tributaries which join Euphrates downstream, drain the heavy winter/spring precipitation in the form of runoff from the southeastern Taurus Mountains. The Tigris River, the second longest river in southwest Asia (1,840 km), originates in eastern Turkey near Lake Hazar and flows southeast where it forms the border with Syria for approximately 40 km and then enters into Iraq. Several tributaries contribute to the Tigris including the Greater Zab, the Lesser Zab, the Adhaim, and the Diyala. The Tigris and Euphrates converge near the Iraqi city of Qurna and continue as the Shatt al Arab, and finally, they drain into the Persian Gulf (Kolars and Mitchell 1991).

There are three major riparians of the Euphrates-Tigris River basin: Turkey, Syria, and Iraq.[2] Euphrates annual mean flow is 32 billion cubic meters per year (bcm/year). Ninety percent of the mean annual flow of the Euphrates originates from Turkey, and the 10 % originates from Syria. Tigris, on the other hand, has 52 bcm/year of annual average flow. While 40 % of the total discharge originates from Turkey, 51 % originates from Iraq and 9 % from Iran (Kibaroglu) (Fig. 1).

There was not a serious water issue in the region – at least in the political arena – until the second half of the twentieth century. Until then rivers were utilized by the populations living nearby. The water question emerged as a significant political – as well as a societal – issue when the three riparians initiated major water development projects in 1960s. The main reason for this was the decreasing sufficiency of water resources of the basin for the local communities in the basin and, more importantly, the need for supplying water and energy (hydroelectricity) for the rapidly increasing populations of urban agglomerations whether close by or distant from the source (Elhance 1999). Therefore, the rapid demographic changes in Mesopotamia could be seen as one of the reasons for making water resources more critical.

The increase in Turkey's population could be a good example. The total population of Turkey was 13.5 million in 1927. It increased to 31.2 million by 1965. This means a 2.5-fold increase in less than 40 years. Syria's and Iraq's populations demonstrate similar trends during these times.

And despite the decreasing rates of population increase in Turkey, Syria and Iraq continued to increase at higher percentages.[3] Iraq's population, for instance, grew from 6 to 32 million in the last six decades. Syria's population, likewise, grew from 3.5 to 22.5 million during the last 60 years. Aymenn Jawad Al-Tamimi and Oskar Svadkovsky summarize the official population policy in Syria in the last 60 years:

---

[2]It should be noted, however, that some territories of Iran and Saudi Arabia belong to the ET basin geographically and that Iran contbitutes 5–8 % of the river flow of Tigris.

[3]Note that the population of Turkey increased less than four times of its 1950 number, while Syria grew more than six times, and Iraq grew nearly six times during the last six decades.

Fig. 1 Map of Mesopotamia (Source: Heston et al. (2012))

> The seeds of the current disaster were planted as far back as 1956, when Youssef Helbaoui – head of economic analysis in Syria's Planning Department – famously declared: "A birth control policy has no reason for being in this country. Malthus could not find any followers among us." Since then Syria has been living in a state of one uninterrupted demographic cataclysm. The regime was so obsessively pro-natalist that in the early 1970s, the trade and use of contraceptives in Syria were officially banned. By 1975, the birth rate reached 50 live births per 1,000 people, with Hafez al-Assad asserting that a "high population growth rate and internal migration" were responsible for stimulating "proper socio-economic improvements" within the development framework.
>
> Even when other nations in the Middle East began to take measures to curb their population growth as the danger of demographic collapse started to loom over the region, the regime in Syria was struggling to make up its mind on the issue." (Al-Tamimi and Svadkovsky 2012)

Now, there are more than 100 million additional people living in these three basin countries when compared with 1950 numbers. This huge increase in the basin countries' population largely remained dependent to water resources of Euphrates and Tigris and, when taken in conjunction with climate change-induced decreasing levels of available water in the rivers, resulted in a water crisis, which is still surmounting (see Figs. 2, 3, and 4).

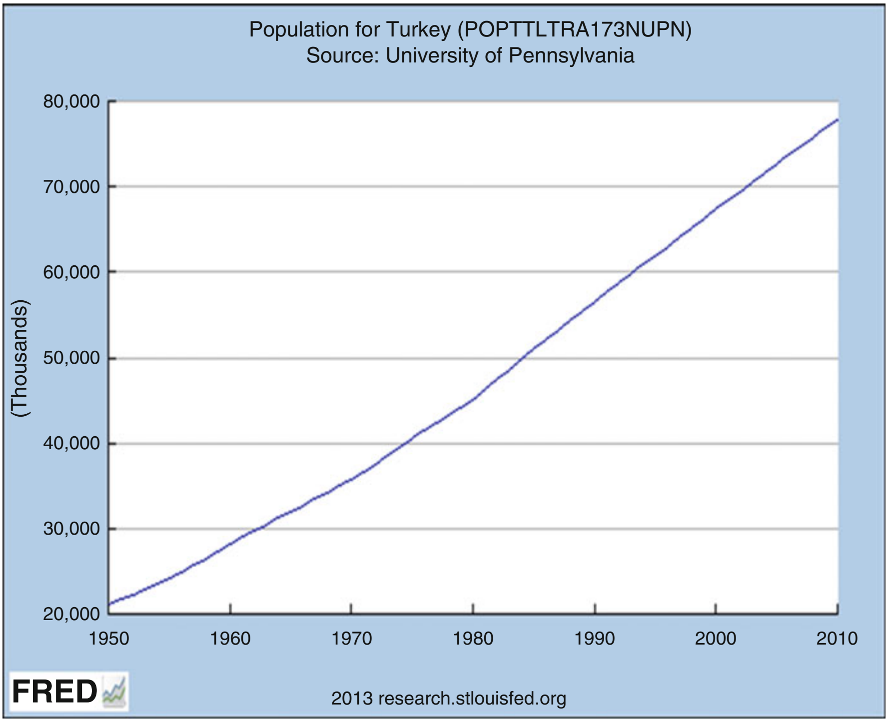

Fig. 2 Population of Turkey (Source: Heston et al. (2012))

Combinations of these push factors with a pull factor, i.e., the advent of new construction technologies enabling huge dams to be built which characterized the “hydraulic mission”[4] era, resulted in huge infrastructure plannings throughout the region countries (see Table 1). In other words, countries of the region hitherto dealt with these decreasing levels of per capita water with supply-side measures. They constructed a considerable number of reservoirs in order to continue to supply water for irrigation during dry seasons. Among these, Southeastern Anatolia Project (Turkish acronym GAP) of Turkey appears to be the biggest water-related infrastructure project undertaken in the basin.[5] Construction of additional water supplies did contribute to the water management in the basin in several aspects. Built reservoirs provide water supply guarantee throughout the year. They also appeared

[4]Hydraulic mission is a concept within a modernist world view, meaning “the strong conviction that every drop of water flowing to the ocean is a waste and that the state should develop hydraulic infrastructure to capture as much water as possible for human uses” (Wester et al. (2009). The hydraulic mission and the Mexican hydrocracy: Regulating and reforming the flows of water and power. Water Alternatives 2(3): 395–415).

[5]GAP consisted of 22 big dams and 19 hydropower plants in Turkish parts of Euphrates and Tigris basin.

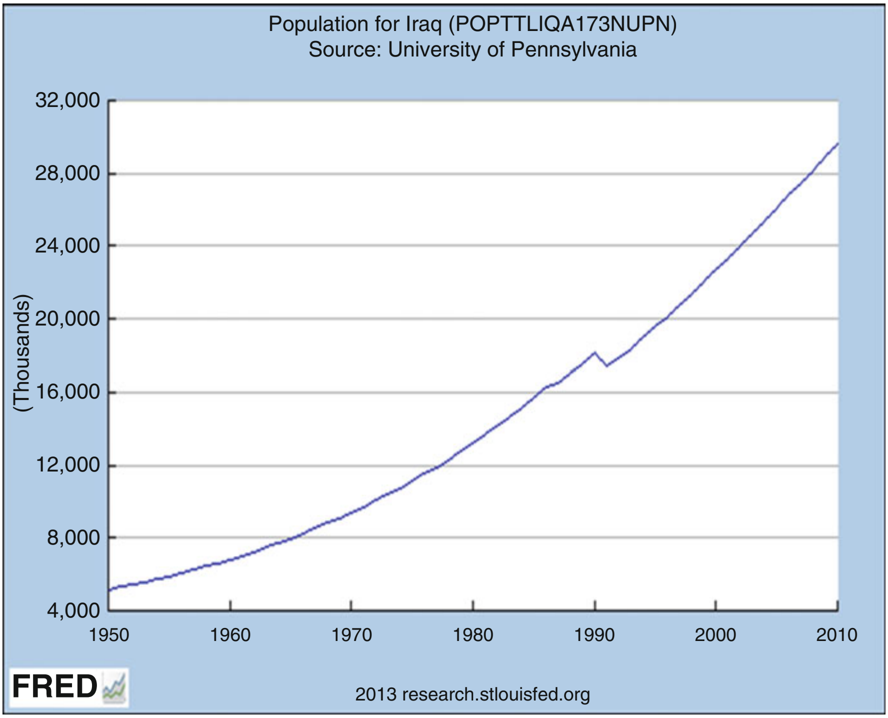

Fig. 3 Population of Iraq (Source: Heston et al. (2012))

to be useful when recurring floods are considered. Since they regulated the water flow, floods became unusual events. However, despite these contributions, huge reservoirs in the basin bear a number of potential harms, particularly in the face of climate change. For instance, huge surface area of these man-made lakes (or canals) has a problem of evaporation. Evaporation losses amount to be huge in shallow water bodies in downstream like Thartar canal in Iraq. Therefore, countries in the region might need to focus also on better management of reservoirs in the basin. If countries could agree, in accordance with the topographic and climatic imperatives, reserving much of the water in upstream could be a solution.

Thus, since the 1960s, not only Turkey and Syria began developing the potential of Euphrates-Tigris River system for basically energy production and irrigation, but also Iraq initiated new schemes for irrigation. The culmination of all these unaligned efforts was an increased water imbalance in the region and, not to mention, a patchwork approach to climate change-related threats. As FAO noted, it is clear that water resources in the semiarid or arid zones like the Middle East are already stressed, independent of climate change, and any additional stress from climate change or increased variability will only intensify the competition for water resources. The Middle East, being the world’s most water-stressed region, climate change – which is projected to cause sea-level rise, more extreme weather events

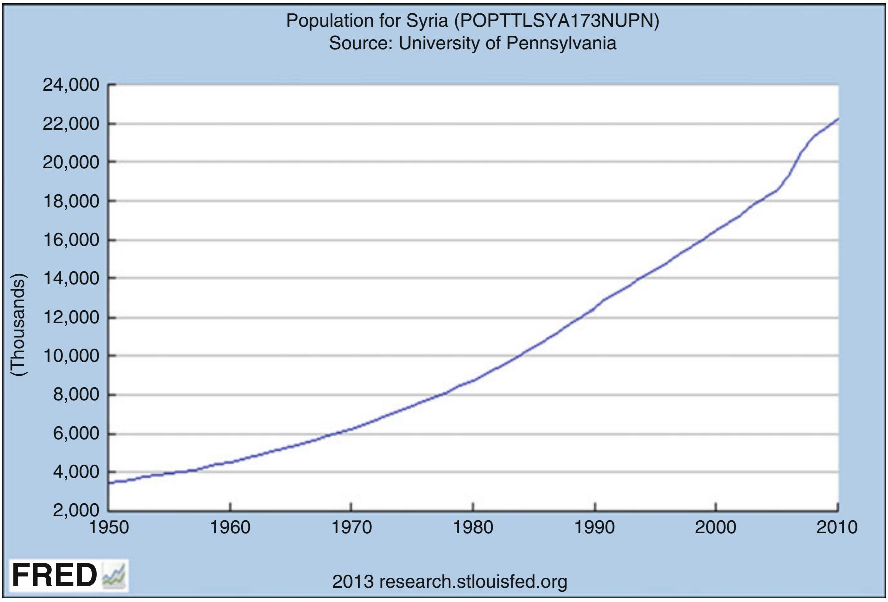

Fig. 4 Population of Syria (Source: Heston et al. (2012))

such as droughts and floods, and less precipitation – will contribute to even greater water stress in the region (Freimuth et al. 2007). Within this context, "future vulnerability depends not only on climate change but also on development plans, so that appropriate strategies followed for sustainable development can reduce vulnerability to climate change" (Topcu et al. 2010).

To date, most governments in the wider Middle East have concentrated largely on large-scale supply-side measure including desalination, dam construction, interbasin water transfers, tapping fossil groundwater aquifers, and importing virtual water. According to Sowers et al. (2011), societal involvement is one of the keys in a successful climate adaption strategy, where it lacks in the Middle East region. Sowers et al. (2011) conclude that "the key capacities for adaptive governance to water scarcity in MENA remains to be underdeveloped." What is more, all intended solutions remain to be uncoordinated and single-country solutions, lacking the transboundary dimension which needs to be taken seriously for a working climate adaptation strategy.

Climate Change and Increasing Pressures on Water Resources

The Mediterranean basin and its surrounding area, which includes Mesopotamia, are regarded as among the most climate-vulnerable regions in the world. Climate change is already underway in the ET region. The increasing impacts of climate change in the Euphrates-Tigris region have been experienced by a number of indications.

Voss et al. (2013) analyzed the changes in overall freshwater storage in the Euphrates-Tigris basin from January 2003 to December 2009. Their study indicated alarming rate of decrease in total water storage of approximately -27.2 ± 0.6 mm yr^{-1} equivalent water height, equal to a volume of 143.6 km^3 during the course of the study period. The Euphrates also has been widely reported to have become very narrow and shallow.[6] Indeed, a decreasing trend in lower Euphrates streamflows based on historical flow data analysis has already been demonstrated (Yilmaz and Imteaz 2011, p. 1277). Moreover, despite the decrease in overall precipitation, flood intensity and frequency have a tendency to rise (IPCC 2007).

Shifts in rain patterns have led to prolonged droughts all around the Middle East in recent years. As pointed out by Shetty (2006), for instance, "dramatic changes in climatic and hydrologic features in recent years have affected the economies of the region and specifically those of the dry areas where rainfed agriculture is the dominant activity and the only source of income for a majority of the rural population." The drought in Iraq in 2008, a case in point, was one of the harshest ones in the country's history which forced the country to enter into new negotiations which then culminated in signing of a memorandum of understanding in September 2009. Climate change-induced impact was particularly devastating in Syria, as al-Tamimi and Svadkovsky (2012) note, "agriculture remains a major part of the economy and the lifestyle of a large section of the population, some 20 % of Syria's GDP being generated by this sector." It was reported that "aggravation of water scarcity led to the abandonment of around 160 villages in northern Syria in the period 2007–2008. In eastern Syria, the Inezi tribe saw some 85 % of its livestock killed between 2005 and 2010 because of prolonged drought. In 2010 the United Nations estimated that more than a million people have left the northeast of the country" (Al-Tamimi and Svadkovsky 2012).

Apart from these experienced changes, recent scientific studies also warn about the expected magnitude and threats of future climate change. Therefore, the recent trends of climate change seem to continue in the upcoming years and decades. In a widely cited paper, Chenoweth et al. (2011), on the other hand, found that the average annual Euphrates-Tigris River discharge could decline by 9.5 % by 2040–2069 with the greatest decline (12 %) in Turkey.[7]

Another study suggests that climate change has the potential to severely reduce (between 10 % and 60 %) the amount of this water source and place increased stress on the water-dependent societies of the region[8]. The decrease in the Euphrates

---

[6]Faisal Rifai, Impact of Collaboration in the Euphrates Tigris Region, http://www.inbo-news.org/IMG/pdf/rifai.pdf

[7]It should be noted at this point that both Euphrates and Tigris are largely snow-fed rivers which are dependent on winter precipitation, particularly in Turkey. The Taurus Mountains and the Anatolian Highlands of eastern Turkey are the headwater regions for the Tigris and Euphrates Rivers, whose waters are shared primarily between Turkey and, downstream riparians, Syria and Iraq. In other words, the runoff from the Taurus Mountains of Turkey supplies water to 2/3 of the Arabic-speaking population of the Middle East (Cullen and deMenocal 2000).

[8]Ozdogan (2011).

basin, in particular, appears to be more alarming: "Discharge of the Euphrates River is projected to decrease between 29–73 percent by the end of the 21st century" (Kitoh et al. 2008; Granit and Joyce 2012).

Dai (2011), reviewing recent literature on drought of the last millennium, concludes that most of the Middle East will experience an increased aridity in the twenty-first century. In light of the above, although there is a remarkable variance in study findings, nearly all of studies agree on the prospect that there will be less water in the Euphrates-Tigris basin in the future. Bozkurt and Şen provide a synopsis of what could be expected in the twenty-first century in the Euphrates basin which is worth quoting:

> Temperature: All scenario simulations indicate surface temperature increases across the entire Euphrates-Tigris bsin. Projected increase in annual surface temperature in the highlands ranges between 2.1 °C and 4.1 °C for 2041–2070, and between 2.6 °C and 6.1 °C for 2071–2099.
>
> Precipitation: Projected precipitation decrease in the highlands by the end of the present century in 33 % under the higher emissions scenario (A1F1) and 6–24 % under the A2 scenario. Snow water equivalent precipitation in the highlands is projected to decrease by 55 % for B1 scenario, 77–85 % for A2 scenario and 87 % for A1F1 scenario.
>
> River discharge: The territory of Turkey will likely experience more adverse direct effects of the climate change compared to the territories of the other countries in the basin. The annual surface runoff is projected to decrease by 26–57 % in the territory of Turkey by the end of the present century. (Bozkurt and Şen)

Then, the question, is not whether or how the climate will change in Mesopotamia, but the questions that experts and decision-makers should be dealing with are, first, what these adaptive strategies are and, perhaps more importantly, how these adaptive strategies that are necessary for mitigating climate change could be implemented in the region as a whole, because climate change is such a phenomenon that renders national or regional boundaries obsolete and that necessitates a holistic approach, including spatial integration among other "integrations." In other words, in order to succeed in designing and implementing basin-wide measures aiming a successful climate adaptation, we need to transcend national boundaries and integrate the climate-vulnerable zones of the region into a unified whole. Within this context, a successful climate adaptation strategy necessarily means a transboundary cooperation.

A number of measures are hitherto taken from the supply-side thinking. One key element of adaptation is diversification of water management strategies; another is ensuring equitable access for vulnerable populations. Most MENA countries already employ a variety of supply-side measures, including dams, water transfer schemes, desalination, reuse of treated wastewater, and procuring "virtual water" (Allan 2001) through imports. Water experts in the region, in concert with international institutions, increasingly advocate demand management to promote conservation and increase efficiency.

Any cooperation attempt in the Euphrates-Tigris basin should aim at improving the water use in agriculture, because the greatest consumer of water, by far, in the Middle East is irrigation/agriculture. On average, more than 70 % of water in the region is used in agriculture. As pointed out by Shetty (2006), countries in the region now face with "increasing pressure to allocate water away from agricultural to industrial and municipal uses, as well as to increase water efficiency within the agricultural sector."

On the other hand, rapid population increases put the region in a difficult dilemma. Improving agricultural water use appears to be difficult with the continuing trends of population increases in the basin. Recent climatic models for eastern Mediterranean and Turkey predict a significant reduction in precipitation (Gao and Giorgi 2008) that would require additional water withdrawals from the Tigris and Euphrates Rivers to meet agricultural demand throughout the basin. This "could have devastating effects on the water availability" in the whole basin. As Voss et al. (2013) conclude, "the decline in agricultural output significantly influences economic stability in the region and will continue to be a threat owing to perennial limitations on water availability and the emerging threats of climate change, including more prolonged drought." Thus, whereas better climate mitigation requires water savings particularly in agriculture (this means countries of the region must focus their efforts in reallocating water towards nonagricultural water uses and use water more efficiently in agriculture[9]), this is not straightforward because of the fact that water is an indispensable element in food production in these countries and also farmers comprise big constituencies in all three countries.

One possible way out of this deadlock seems to be utilization of "virtual water," which is already in place to some extent. Both Iraq and Syria are increasingly importing foods. This is partly because of the recent warlike situation in these countries. In other words, if opportunity appears, these countries will opt for growing their own food instead. Therefore, there is a limit for virtual water: "food security." Countries of the region do not want to rely on foods from international market.

Adaptation to Climate Change in Mesopotamia Through Transboundary Water Cooperation

Steps necessary for climate adaptation need a holistic perspective in terms of national or regional boundaries. Therefore, intrastate solutions may not yield optimum outcomes when the question is about a phenomenon that does not know borders (Solomon et al. 2007). However, it appears to be quite difficult to realize a "transboundary" approach to climate change-related threats, particularly since it is mostly interconnected with the sensitive issue of water.

A number of studies have long focused on methods of how to foster the cooperation in the Euphrates-Tigris region.[10] Nevertheless, given a number of

[9]This strategy is also known as "more crop per every drop."

[10]For discussions on ET cooperation, inter alia, see Asit Biswas (ed.), *International waters of the Middle East from Euphrates-Tigris to Nile*, Oxford University Press, Oxford, 1994; Ayşegül Kibaroğlu, *Building a regime for the waters of the Euphrates-Tigris river system*. Westview Press, Boulder, 1984; Scheumann W, Schiffler M (eds) *Water in the Middle East: potential for conflicts and prospects for cooperation*. Springer, Berlin; Gün Kut Burning Waters: Hydropolitics of the Euphrates and the Tigris. In New Perspectives on Turkey, (9) (Fall), 1993.

factors limiting the construction of trust among countries, a workable solution for cooperation in this region of the world could not be easily implemented. Any attempt towards cooperation needs to take into account of the past experiences and long-lasting clashes of views and try not to cause additional problems instead of resolving them. In the past, several concepts and proposals were found "hegemonic" or "biased" and did not find ways of implementation.[11] Therefore, there is the need for a neutral approach which would not create antagonisms. The "macro-region strategy" could be treated such an unbiased concept.

Instead of facing the multifaceted and complex "water sharing" problem bluntly and as a single case for solution, the macro-region concept proposes an "issue-based" and "project-oriented" cooperation with an aim of making cooperation a habit in the region through working together around the priorities of all. Deconstructing the bigger problem of "lack of water cooperation" into smaller projects for attainable goals could work better. Within this context, climate change-related threats could be more easily dealt with.

Box 1. The EU Model of Macro-Region: Lessons from Neighborhood (Excerpts from INTERACT 2009)

Definition of macro-region: "an area including territory from a number of different countries or regions associated with one or more common features or challenges."

"An area covering a number of administrative regions but with sufficient issues in common to justify a single strategic approach."

"Its borders are not delimited once and for all, but their 'extent depends on the topic: for example, on economic issues it would involve all the countries in the region, on water quality issues it would involve the whole catchment area'. The macro-region is thus presented as a *functional* region, sharing challenges, opportunities and solutions.

The antecedents of the EU's currently-promoted macro-regional conceptualization can be traced back to the Brussels European Council of 14 December 2007, with the Council's 'invitation to the Commission to present an EU strategy for the Baltic Sea Region'.

"Macro-regional strategy requires no new ad hoc legislation. The main content is the preparation and implementation of a Plan of Action that derives from a strategic paper mostly drafted by national governments and the European Commission through a consultative approach. It is an endogenous 'bottom up' process: contrary to policies that descend from a communitarian strategic approach, the macro-region establishes its strategy through the involvement of local actors. Furthermore, the Plan of Action is *concrete* and contains tangible effects thanks to the identification of *flagship projects*."

(continued)

[11] See Warner (2008).

> "In all cases, the principle will be to add value to interventions, whether by the EU, national or regional authorities or the third or private sectors, in a way that significantly strengthens the functioning of the macro-region. Moreover, by resolving issues in a relatively small group of countries and regions the way may be cleared for better cohesion at the level of the Union."
>
> "Working together can become a habit and a skill. In addition, overall coordination of actions across policy areas will very likely result in better results than individual initiatives."
>
> "Concreteness: The one indispensable element in a macro-regional strategy is the resulting action. Strategies that consist of words in documents, and nothing more, will not achieve their objectives. An action plan, or something comparable, is therefore the sine qua non of an effective strategy. However, an action plan that stands alone risks being little more than a wish list. There is a need for an organising approach that explains and justifies the selection, prioritisation and sequencing of selected actions."

Risks and Opportunities for the Mesopotamia

EU's functional model of macro-regions (Dubois et al. 2009; Stocchiero 2010) is a relatively novel approach which needs to be carefully studied and adapted to the conditions of the Middle East. When the Euphrates-Tigris basin is concerned, there are a number of certain risks and opportunities associated with this proposed scheme. It could be summarized as follows:

Opportunities:

(a) New and neutral concept (it is easier to build trust in the region with an unbiased concept).
(b) Possible EU support and possible UN support (as well as other donors may contribute funding for establishing a secretariat, educational aid, training aid for relevant personnel).
(c) The issue of water is common to many problems of all three countries of the region (gathering around common conflicts).
(d) Establishment of a governing commission could be a starting point for further cooperation.
(e) There are a clear model (EU) and a clear timetable to follow.

Challenges:

(a) Lack of political will for such a framework of action (two countries of the region, Iraq and Syria, are presumably in flux, and water cooperation has not been given due attention).

(b) Lack of accountability and the problem of democratic deficit.
(c) Capacity (technical, personnel) and funding is problematic in war-torn countries of Syria and Iraq.
(d) There is no EU Commission-like body for acting as a guardian of the agreed projects.

Building upon the opportunities and challenges listed above, the third stage would be composed of drawing up a "roadmap" for initializing and sustaining the cooperative framework of macro-region. One of the most significant parts of this roadmap would be the discussion of different scenarios of the institutional setup. For instance, creating a working commission (like the one in the EU) would be conducive to cooperation, but it could be easily abused and become a way of limiting the cooperation. Therefore, the institutional design of the new cooperative scheme should be meticulously analyzed with its far-reaching implications.

In the fourth stage, designation of a number of flagship projects will be designed. These will be the beacons of cooperation for particularly the initial phases of the macro-region strategy. Anchoring in these flagship projects would have a likelihood to create a path-dependent attitude towards cooperation.

The success of such a cooperative action framework will largely depend on the level of political commitment of the countries concerned rather than the foreign support. Therefore, the bulk of the needed investments are to be covered by the countries of the region, which renders this project difficult since both Iraq and Syria would not like to initiate and financially contribute to this framework. And Turkey, on the other hand, has not much to gain with this cooperative scheme given its dominant position in terms of geographic position (upstream) and water resources utilization.

Conclusions

This chapter aims to analyze water-related implications of climate change in Euphrates-Tigris (ET) transboundary river basin and create a framework for advancing the international level of cooperation in order to better deal with common challenges that countries of the region began to face. The chapter began with a discussion of the possible undesirable water-related implications of climate change in ET basin countries (namely, Iraq, Syria, and Turkey) through utilization of existing scientific literature, then presents the current level of cooperation among three riparians and the gap between these challenges and existing transboundary water cooperation, and finally proposes a framework and an action plan for deepening water-based cooperation in the basin in order to tackle with the climate change-related challenges.

Reports originating from the Intergovernmental Panel on Climate Change (IPCC) conclude that freshwater systems are among the most vulnerable to climate change. In snow-dominated basins (such as the ET), hydrologic studies have long agreed that warming will result in earlier peak flows, greater winter flows, and lower summer flows. Also, climate models suggest that warmer temperatures will very likely lead to greater climate variability and an increase in the risk of extreme hydrologic events such as floods and droughts. The existing level of cooperation among three riparians does not allow for successful management of the impacts of climate change, because there is hitherto no multilateral and comprehensive agreement involving all three riparians and all water-relevant issues.

The chapter attempts to provide a detailed framework for addressing the water-related risks of climate change in ET basin and discuss the applicability and effectiveness of possible solutions. Climate change-related impacts of desertification and water scarcity which could worsen the prevailing poverty in vast areas of the region necessitate systematic action by all countries of the region. In order to open up underexplored venues for target-oriented cooperation, the neutral concept of "macro-region" – which would be a project-driven process (Bialasiewicz et al. 2012; Medeiros 2011) – has been presented. Successful implementation of flagship projects in priority areas would become a basic trust-building measure for strengthening the development of a common understanding for regional problems, which appears to be one of the prerequisites for mitigating climate change-related problems.

According to various scenarios, the climate change will be one of the most challenging phenomena in the Middle East, including the ET basin. Common challenges of this magnitude could only be dealt with collaborative action. To this end, this chapter proposed a neutral concept not only for advancing the practical cooperation among basin countries in the face of climate change but for also promoting the trust between three countries, which appears to be one of the prerequisites for strengthening cooperative ties. The chapter adopted a novel approach and focused on issue-based and attainable targets and project-driven solutions for lessening the adverse impacts of climate change in the region.

Abstract

Water quality is deteriorating and its availability is decreasing with time. This chapter presents the implications of climate change for water in agriculture and environment in dry areas. Further adaptation strategies for sustainable use of water resources under changing climatic conditions is proposed.

This chapter analyzes the impacts of climate change on water availability and its quality. It considers the ongoing adaptation efforts and the problems faced in implementing these strategies. Certain guidelines and recommendations for addressing climate change in the water sector are also proposed.

This chapter elucidates the impacts of climate change on water quality and availability. Factors that govern these impacts are highlighted and certain adaptation guidelines are proposed.

Water is a nonrenewable resource directly affected by climate change. All stakeholders, including policy makers, water managers, and water users will benefit from this chapter.

Climate change has significant impact on water quality and availability. However, not many studies have been devoted to exploring the impacts of climate change and the possible measures to mitigate these impacts on water resources. Thus, the management of original and valuable work on the subject is presented.

The Climate System and the Hydrological Cycle

The cryosphere (snow, ice, and frozen ground) on land stores about 75 % of the world's freshwater. In the climate system, the ice cover and its changes are intricately linked to the surface energy budget, the water cycle, and sea level change. More than one-sixth of the world's population lives in glacier or snowmelt-fed river basins (Stern 2007). Satellite data show that there have been decreases of about 10 % in the extent of snow cover since the late 1960s (Rangwala and Miller 2012).

The water reservoir such as ice caps, glaciers, and permanent snow are among the most sensitive indicators of climate change (Seiz and Foppa 2007), advancing when climate cools (e.g., during the Little Ice Age) and retreating when climate warms. Glaciers grow and shrink, both contributing to natural variability and amplifying externally forced changes. There are 5.773×10^6 cubic miles of water in ice caps, glaciers, and permanent snow. According to the National Snow and Ice Data Center, if all glaciers melt today, the seas would raise $\approx$ 230 ft. Luckily, that is not going to happen all in one go, but sea levels will rise. Initially, based mainly on aerial photographs and maps, this compilation has resulted in a detailed inventory of more than 100,000 glaciers covering a total area of 2.4×10^5 km^2. In preliminary estimates, based on the records, the remaining ice cover was estimated to be $\approx 4.45 \times 10^5$ km^2. The World Glacier Monitoring Service collects data annually on glacier retreat and mass balance. Mass balance data indicate 17 consecutive years of negative glacier mass balance.

Retreating mountain glaciers cover 680 km^2 of the earth surface, that is, 4 % of the total surface area of land covered by ice on earth. Mountain glaciers make 1 % of land ice; however, 99 % of mountain glaciers have been retreating since the mid-nineteenth century. The changes in sea level, snow cover, ice extent, and rainfall are consistent with warming climate near the earth surface.

The appearance of ice on lake, river, and sea surfaces requires prolonged periods with air temperatures below 0 °C. High air temperatures and warmer winds will affect the duration of ice cover, the freezing and thawing times, and the thickness of ice cover. Climatic conditions not only influence the timing and duration of the ice cover but also the thickness of the ice cover and the nature of breakup (Beltaos and Prowse 2009).

Driven by solar energy, the climate system is complex and interactive, comprising of the atmosphere, land surface, snow and ice, oceans and other bodies of water, and living things (Parry 2007). The climate system evolves over time under the influence of its own internal dynamics and due to changes in external factors that affect climate. External factors include natural phenomena (e.g., volcanic eruptions, solar variations, etc.) as well as anthropogenic activities that alter atmospheric composition and land cover and land-use change. Alterations in any of these factors can modify the balance between incoming short-wave sun radiation and outgoing long-wave radiation. The climate system responds both directly and indirectly to such changes.

The hydrological cycle designates a continuous movement of water through oceans, atmosphere, and land surface. Powered by solar radiation, the hydrological cycle begins with the evaporation of water from the surface of the ocean, transported around the globe, and returns to the surface as precipitation (rain, snow, sleet, hail, etc.). Once water reaches the ground, one of two processes may occur: (i) water evaporates or transpires back into the atmosphere or (ii) water penetrates the surface and becomes groundwater. Groundwater seeps into oceans, rivers, and streams. The balance of water that remains on the earth's surface is runoff, which empties into lakes, rivers, and streams and is carried back to the oceans, where the cycle begins again (Várallyay 2010). Any variability in climate affects the hydrological cycle on earth which directly affects the water resources.

Climatic Change and its Drivers

Factors that can shape climate are often called climate forcing. These include such processes as variations in solar radiation, deviations in earth orbit, mountain-building, as well as continental drift and changes in concentrations of greenhouse gases. These are a variety of climate change feedbacks that can either amplify or diminish the initial forcing. Some parts of the climate system, like oceans and ice caps, react slowly to climate forcing because of their large mass. Therefore, the climate system can take centuries or longer to fully respond to new external forcing.

Climate change is a significant and lasting change in the statistical distribution of weather patterns over periods ranging from decades to millions of years. Climate change is caused by factors that include oceanic processes (such as oceanic circulation), biotic processes, variations in solar radiation received by the earth, plate tectonics and volcanic eruptions, and human-induced alterations of the biosphere equilibrium; these latter effects are currently causing global warming, and "climate change" is often used to describe human-specific impacts.

Globally, the 1990s was the warmest decade and 1998 the warmest year in the instrumental record since 1861. New analyses of proxy data for the Northern Hemisphere indicate that an increase in temperature in the twentieth century is likely to have been the largest of any century during the past 1,000 years. Because fewer data are available, less is known about annual averages prior to 1,000 years.

On an average between 1950 and 1993, nighttime daily minimum air temperatures over land increased by about 0.2 °C per decade. This is twice the rate of increase in daytime daily maximum air temperatures (0.1 °C per decade). This has lengthened the freeze-free season in many mid- and high-latitude regions. The increase in sea-surface temperature over this period was about half that of the mean land surface air temperature. Arctic sea ice has decreased since 1973, when satellite measurements began. Since the start of the satellite record in 1979, both satellite and weather balloon measurements show that the global average temperature of the lowest 8 km of the atmosphere has changed by +0.10 °C $\pm$ 0.05 per decade, but the global average surface temperature has increased by +0.15 $\pm$ 0.05 °C per decade. The record shows a great deal of variability, for example, most of the warming occurred during the twentieth century, during two periods, 1910–1945 and 1976–2000.

The Earth may have warmed by an average of more than 1.7 °C over the past 150 years according to an analysis of the University of Wisconsin study of the freeze and thaw records for lakes and rivers in the Northern Hemisphere. Researchers found that the annual freeze of 26 bodies of water in North America, Asia, and Europe shifted later by about 8.7 days over the last one and a half century, while the spring ice breakup came about 9.8 days earlier. The study reported very strong evidence of a general warming from 1845 to 1995 in areas where there is ice cover. The change in the ice-on and ice-off days found in the study corresponds to an air temperature warming of about 1.8 °C over the past 150 years.

However, over the last century, a decrease of nearly 10 % snow cover and a 10–15 % decrease in spring and summer sea ice in the Northern Hemisphere have been witnessed. Other changes linked to climate include longer growing seasons, increases in rainfall and rainfall intensity in the Northern Hemisphere, and shifts when ice freezes and breaks up on rivers and lakes. The IPCC has projected that global average surface temperatures could increase by 1.4–5.8 °C by 2100. Daily minimum temperatures as well as the number of hot days, with less cold and frosty days will increase (Parry 2007).

The primary driver of climate change impacts on water resources is temperature. Current climate models suggest that effects of temperature increases are felt throughout the climatic regime leading to hydrological changes (e.g., seasonal redistribution and duration of rainfall) and other related impacts. These hydrological changes are manifested as periods of increased rainfall or floods as well as periods of drought. In addition to precipitation effects, increased temperatures are impacting glacier and snowmelt patterns, while also creating more extreme hurricane or typhoon conditions with associated high winds.

The global average precipitation and evaporation are also expected to increase by about 1–9 %. The precipitation changes are expected to vary from region to region, with increases over the northern mid- to high latitudes and in Antarctica during the winter. The intensity of extreme weather events is also likely to increase with greater extremes of both flooding and drought. Precipitation, temperature, and carbon dioxide levels can affect the demand for water as well as the supply.

Relationship and Degree of Elasticity Between Climate Change and Water Resources

Water resources are important to both the society and the ecosystems. The biology depends on a reliable supply of clean drinking water to sustain the health. We also need water for agriculture, energy production, navigation, recreation, and manufacturing. Many of these uses put pressure on water resources, stresses that are likely to be exacerbated by climate change. So, as temperatures rise, people and animals need more water to maintain their health and thrive. Many important economic activities, like producing energy, raising livestock, and growing food crops, also require water. The amount of water available for these activities may be decreased as the Earth warms and if the competition for water resources increases.

In many areas, climate change could increase water demands while shrinking water supplies. This shifting balance would challenge water managers to simultaneously meet the needs of growing communities, sensitive ecosystems, farmers, ranchers, energy producers, and manufacturers. In some areas, water shortages will be less of a problem than increases in runoff, flooding, or sea level rise. These effects can deteriorate the quality of water and can damage the infrastructure that is used to transport and deliver water.

Hydrological Variables

The water cycle is a delicate balance of precipitation, evaporation, and all of the steps in between. Warmer temperatures promote evaporation of water into the atmosphere, thus increasing the atmosphere capacity to "hold" water. Increased evaporation may dry out some areas and cause excess precipitation on other areas.

Climate warming observed over the past several decades is consistently associated with changes in a number of components of the hydrological cycle and hydrological systems such as changing precipitation patterns, intensity and extremes, widespread melting of snow and ice, increasing atmospheric water vapor, increasing evaporation, and changes in soil moisture and runoff. There is significant natural variability on interannual to decadal timescales – in all the components of hydrological cycle, often masking long-term trends. There is still substantial uncertainty in trends of hydrological variables because of large regional differences and because of limitations in the spatial and temporal coverage of monitoring networks (Huntington 2006).

The hydrology of arid and semiarid areas is particularly sensitive to climate variations. Relatively small changes in temperature and rainfall in these areas could result in large changes in runoff, increasing the likelihood and severity of droughts and/or floods.

Precipitation

Here the word precipitation includes rainfall, snowfall, dews, etc. There is a direct influence of climate change and global warming on precipitation. Increased temperature leads to greater evaporation and thus surface drying, thereby increasing the intensity and duration of drought as well as precipitation elsewhere. However, the water-holding capacity of air increases by about 7 % per 1 °C warming, which leads to increased water vapor in the atmosphere. Hence, storms (individual thunderstorms, extratropical rain or snowstorms, tropical cyclones) supplied with increased moisture could produce more intense precipitation events. Such events are observed widely occurring, even where total precipitation is decreasing. This increases the risk of flooding. The atmospheric and surface energy budget plays a critical role in the hydrological cycle and also in the slower rate of change that occurs in total precipitation than total column water vapor. With modest changes in winds, patterns of precipitation do not change much but result in dry areas becoming drier (generally throughout the subtropics) and wet areas becoming wetter, especially in the mid- to high latitudes: the "rich get richer and the poor get poorer."

This pattern is simulated by climate models and is projected to continue into the future. With warming, more precipitation occurs as rain instead of snow, and snow melts earlier; there is increased runoff and risk of flooding in early spring but increased risk of drought in summer, especially over continental areas. However, with more precipitation per unit of upward motion in the atmosphere, the atmospheric circulation weakens that results monsoons to falter. In the tropics and subtropics, precipitation patterns are dominated by shifts as sea-surface temperatures change (El Niño is a good example).

Although the precipitation has increased by 0.5–1 % per decade during the twentieth century, over most mid- and high latitudes of the Northern Hemisphere continents, and the rainfall has increased by 0.2–0.3 % per decade over the tropical (10°N to 10°S) land areas, rainfall has decreased over much of the Northern Hemisphere subtropical (10°N to 30°N) land areas during the twentieth century by about 0.3 % per decade (this is the region in which most of Pakistan is situated) (Imtiaz 2002; Rangwala and Miller 2012).

Most models simulate precipitation that occurs prematurely and too often and with insufficient intensity, resulting in recycling that is too large and a lifetime of moisture in the atmosphere that is too short, which affects runoff and soil moisture (Trenberth et al. 2007).

Evapotranspiration

There are very limited direct measurements of actual evapotranspiration over global land areas (Fig. 1). Decreasing trends during recent decades are found in sparse records of pan evaporation (measured evaporation from an open water surface in a pan, a proxy for potential evapotranspiration) over the entire globe. Using observations of precipitation, temperature, cloudiness-based surface solar radiation, and a comprehensive land surface model, Qian et al. (2006) found that global land evapotranspiration closely follows variations in land precipitation. Changes in evapotranspiration depend not only on moisture supply but also on energy availability and surface wind. Other factors affecting actual evapotranspiration include the direct effects of atmospheric CO_2 enrichment on plant physiology.

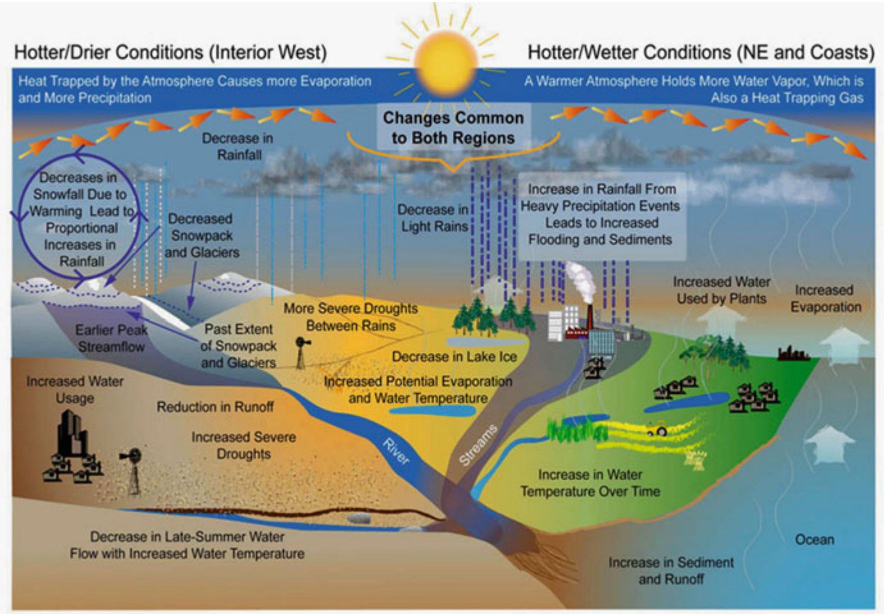

Fig. 1 Projected impacts of climate change on the hydrological cycle (Source: Karl et al. 2009)

Evaporative demand or "potential evaporation" is projected to increase almost everywhere. This is because the water-holding capacity of the atmosphere increases with higher temperatures, but relative humidity is not projected to change markedly. Resultantly, water vapor deficit in the atmosphere increases as does the evaporation rate (Trenberth et al. 2003).

Runoff

With an increase in precipitation (rain, snow, dew, etc.) and more snow melts earlier, there is increased runoff and risk of flooding in early spring with increased risk of drought in summer in dry areas. Climate change could cause more and intense precipitation but sporadic which is likely to be offset by the increased evaporative demand in many regions of South Asia and the world, i.e., where intense rainfall events with high runoff are interspersed with long dry periods of increased evaporation and transpiration.

Soil Moisture

Soil moisture is a source of thermal inertia due to its heat capacity and the latent heat required for evaporation. Soil moisture has been proposed as an important control on summer temperature and precipitation. Surface water balances reflect the availability of both water and energy. In regions where water availability is high, evapotranspiration is controlled by properties of both the atmospheric boundary layer and surface vegetation cover. Changes in the surface water balance can feed back on the climate system by recycling water into the boundary layer (instead of allowing it to run off or penetrate to deep soil levels). Changes in soil moisture depend on alterations in volume and timing not only of precipitation but also of evaporation which indirectly is affected by vegetation. The sign and magnitude of such effects are often highly variable depending on the details of the local environment (Bates et al. 2008).

Impacts of Climate Change on Surface Water Resources: Water Quantity and Availability

Excessive water uses put pressure on water resources, stresses that are likely to be exacerbated by climate change. In many areas particularly dry areas, climate change is likely to increase water demand while shrinking water supplies. This shifting balance would challenge water managers to simultaneously meet the needs of growing communities, sensitive ecosystems, farmers, ranchers, energy producers, and manufacturers. Climate change impacts on surface water (quantity and availability) vary greatly as discussed in the following sections.

Floods

Floods depend on a number of non-climatic factors like existence of dams or dikes. However, there are indications that climate change impacts their intensity and frequency. These flood-producing processes include intense and/or long-lasting precipitation, snowmelt, dam break, and decreased conveyance due to ice jams or landslides or by storm. Floods depend on precipitation intensity, volume, timing, phase (rain or snow), antecedent conditions of rivers, and their drainage basins (e.g., presence of snow and ice, soil characters, wetness, rate and timing of snow/ice melt, urbanization, existence of dikes, dams, and reservoirs). Human encroachment into recent and subrecent flood plains and lack of flood response plans increase their damage potential.

Globally, the number of great inland flood catastrophes during 1996–2005 is twice as large per decade as between 1950 and 1980. Based on climate models, the area flooded in Bangladesh is projected to increase by at least 23–29 % with a global temperature rise of 2 °C (Bates et al. 2008). This has been associated with an increasing frequency of heavy precipitation events; no ubiquitous increase is visible in trends in high river flows. With increased intensity and irregularity of rainfall, the interannular variability of river flows is likely to increase, such that rivers will become increasingly "flashy" and seasonal. As a result, flood events will be more common, and an increased proportion of the available surface water will lost in peak discharges, decreasing the quantity of accessible water (Parry 2007).

Drought

Drought is a normal, recurrent climatic feature which has caused distress since the known history of mankind. The term drought may refer to a meteorological drought, hydrological drought (low river flows and low water levels in rivers, lakes, and groundwater), agricultural drought (low soil moisture), and environmental drought (a combination of the above). The socioeconomic impacts of droughts may arise from the interaction between natural conditions and human factors such as changes in land use, land cover, and the demand for and use of water. Excessive water withdrawals can exacerbate the impact of drought.

Droughts have become more common, especially in the tropics and subtropics, since the 1970s. Pakistan has been suffering serious droughts periodically due to below normal rainfall. Although drought affects nearly all the climatic regimes and has pronounced consequences in both developed and developing countries, its effects are noticeably devastating in developing nations like Pakistan where rain-fed farming covers considerable area. Assessing the onset of drought, extent, intensity, and duration can limit drought-induced impacts and can provide a base to develop an effective drought mitigation response. Previous drought events in dry areas and the magnitude of drought losses indicate the continuing vulnerability of dry areas to drought due to lack of contingency planning. The integration of existing drought monitoring tools for dry areas is essential to decrease the vulnerability of drought in these regions. In order to reduce vulnerability to drought event in Pakistan, it is inevitable to assess relevant effects and identify their potential reasons. Due to spatial and temporal variability, it is imperative to enhance the data availability for mapping and monitoring this phenomenon. Drought-related multidisciplinary information can be handled by using geographic information system (GIS). Government institutions look after potential drought-stricken victims and others living in potential drought areas by using spatial analysis in GIS that can lead to a decision support system (Anjum et al. 2012).

Surface Water Runoff and River Discharge

The most dominant climatic drivers for runoff and river discharge are precipitation, temperature, and evaporative demand (Parry 2007). More precipitation brought about by more intense but sporadic rainfall events is likely to be offset by the increased evaporative demand in many regions of South Asia and the world, particularly where intense rainfall events with high runoff are interspersed with long dry periods of increased evapotranspiration. These conditions may lead to a greater risk of drying, land degradation, low groundwater recharge, and a significant decrease in the amount of available surface water, which are already seasonal (Meehl et al. 2007). Changes in river flows as well as lake and wetland levels will also depend crucially on whether precipitation as snow or rain. By the end of this century, rivers in South Asia are likely to exhibit decreased summer flows (after an initial increase) and increased winter flows resulting from recession of the Himalayan ice mass in a warmer condition. Glacial melt water presently contributes up to 70 % of the dry season flow of the Indus, so glacial recession will have significant impacts on water availability in South Asia climate (Kundzewicz et al. 2007).

At the global scale, there is evidence of a broadly coherent pattern of change in annual runoff, with some regions experiencing an increase in runoff and others experiencing a decrease in runoff.

Sea Level Rise

Global mean sea level is rising and the rate of rise has increased between the mid-nineteenth and the mid-twentieth centuries. The sea level increased about 18 cm (7 in.) during the past century. The most recent IPCC results suggest sea level might rise another 15–95 cm (6–37 in.) by the year 2100 owing to rise in temperature by 0.06 °C in the Atlantic, Pacific, and Indian Oceans (Parry 2007).

High sea levels and increased storm surges could adversely affect freshwater supplies to coastal areas. Saltwater in river mouths and deltas would advance inland and coastal aquifers and could induce threat of saltwater intrusion, jeopardizing the quality water for many domestic, industrial, and agricultural users. As the sea rises, saltwater will also move into freshwater areas. In addition, as more freshwater is removed from rivers for human use, saltwater will move farther upstream. Drought can cause coastal water resources to become more saline as freshwater supplies from rivers are decreased. Water infrastructure in coastal cities, including sewer systems and wastewater treatment facilities, faces risks from rising sea levels and the damaging impacts of storm surges.

Wildfire

Wildfire is a primary disturbance agent affecting the structure and composition of many forest ecosystems and hydrological cycle. The complex role that wildfire plays in shaping forests has been described in terms of vegetation responses as dependent on, sensitive to, independent of, or influenced by fire (Myers 2006). For example, fire is largely absent where cold, wet, or moist conditions prevail (e.g., tundra, some rain forests, and desert). At the other extreme, fire is essential where species have evolved to withstand burning and facilitate fire spread. Notable fire-dependent ecosystems include many coniferous boreal, temperate and tropical forests, eucalyptus forests, grasslands, savannas and marshes, and palm forests.

The specific weather conditions during a fire event greatly influence how the fire burns. It follows that long-term climate variability can influence fire behavior by affecting site-specific fuel conditions (fuel moisture, type and arrangement, and water availability). The fires we see today in some forest landscapes are of a much higher intensity than those at the turn of the twentieth century due to decades of fire suppression, an increase in biomass due to the post-1976 increase in southwestern rainfall (Swetnam et al. 1999) and warming temperatures coupled with intermittent drought conditions.

Climate change that results in drier, warmer climates has the potential to increase fire occurrence and may be affected due to the greenhouse effect. It is shown that future wildfire potential increases significantly in the United States, South America, Central Asia, Southern Europe, Southern Africa, and Australia. Fire potential moves up by one level in these regions, from currently low to future moderate potential or from moderate to high potential. It is suggested that dramatic increases in wildfire potential will require increased future resources and management efforts for disaster prevention and recovery (Liu et al. 2010).

Deforestation

The impacts of deforestation on climate illustrate this complexity. Some studies indicate that deforestation could lead to decreased daytime temperatures and increases in boundary layer cloud as a consequence of rising albedo, transpiration, and latent heat loss. However, these effects are dependent on properties of both the replacement vegetation and the underlying soil/snow surface. In some cases the opposite effects have been suggested.

Forests contribute to the regional water cycle, with large potential effects of land-use changes on local and regional climates. On the other hand, forest protection can have drought and flood mitigation benefits, especially in the tropics. The effects of deforestation on precipitation are likewise complex and could be both negative and positive, dependent on land surface and vegetation characteristics.

Impacts of Climate Change on Groundwaters

Up to 80 % of rural water supplies are dependent on groundwater, providing safe water for 400 million people. This dependence is likely to increase as surface water sources become increasingly seasonal and demands from domestic, agricultural, and industrial users for reliable water increase. Groundwater storage comprises approximately 100 times the surface water storage and provides an important buffer against climate variability and change (MacDonald et al. 2011).

Groundwater and soil moisture collectively account for over 98 % of the available global freshwater resources. Groundwater levels correlate more strongly with precipitation than with temperature, but temperature becomes more important for shallow aquifers and during warm periods (Kundzewicz et al. 2007). Although groundwater systems are likely to respond more slowly to climate change than surface water systems, the impact of climate change on recharge, and hence long-term availability, remains unclear.

Climate change could modify groundwater recharge patterns as changes in precipitation and evaporation translate directly to shifts in soil moisture deficits and surface water runoff. Increases in rainfall intensity and evaporative demand would result in increased irregularity of groundwater recharge (Kundzewicz et al. 2007). However, groundwater recharge will also be affected by soil degradation and vegetation changes, both of which may be affected by climate and human drivers.

Limited information is available on groundwater conditions and trends, and present quantities and patterns of recharge of groundwater are uncertain. Moreover, long-term projections of rainfall and temperature reveal little about how groundwater recharge may change. Hydraulically effective rainfall contributing to groundwater recharge is affected as much by annual rainfall variation, the timing, intensity, and duration of rainfall events, as by total seasonal or annual amounts (Kundzewicz et al. 2007).

Impacts of Climate Change on Water Quality

Climate change affects water quality through both increased temperature and hydrological changes in rainfall affecting runoff and mobilization of nutrients and other pollutants. Heavy downpours increase the amount of runoff into rivers and lakes, washing sediment, nutrients, pollutants, trash, animal waste, and other materials into water supplies, making them unusable and unsafe. The increased water temperature will affect ice cover and circulation patterns in lakes and rivers as well as the rate of biogeochemical and ecological processes that determine water quality. In areas where river flow and groundwater recharge will decrease, water quality could deteriorate due to less dilution of pollutants. High intensity and frequency of floods and frequent extreme rainfall events increase the load of pollutants (organic matter, nutrients, etc.) washed from soils and overflows of sewage systems to water bodies. For example, in the northeast and midwest, increases in heavy rainfall events caused problems for the water infrastructure, as sewer systems and water treatment plants were overwhelmed by the increased volumes of water (Grimalt et al. 2001). This may results in:

(i) **Increased water temperature**: Since water temperature is mainly determined by heat exchange with the atmosphere, high air temperatures lead to high water temperatures. Water temperature may also be affected by other factors than air temperature. Especially in larger rivers, flow regulation, hot or cooling water from power plants, groundwater flow, extreme hydrological events, and high wind speed may be important (Moatar and Gailhard 2006).

(ii) **Water color:** Due to increased input of humic substances as dissolved organic carbon (DOC) from the catchment and through water runoff, the coloring is induced.

(iii) **Dissolved organic carbon (DOC):** Climatic factors may affect both concentrations and fluxes of DOC. These affect production of DOC in the terrestrial systems and thereby changing DOC concentration without changes in runoff. However, increased runoff may also affect DOC concentration through changing the degree of dilution and by altering water flow paths through soil. Drought and soil frost may also stimulate DOC production through increased fine root and microbial mortality, increased fragmentation of soil organic matter (SOM) and fresh litter, and increased aggregate instability, directly releasing DOC or increased microbial activity (Beltaos and Prowse 2009).

(iv) **Oxygen content:** Increased biological respiration results in low DOC, particularly in summer low-flow periods and in the bottom layers of lakes. High temperature and low oxygen concentration will cause stress and may decrease the habitats of cold-water species like salmonid fish in lakes and rivers. The DOC concentration decreases as a direct result of temperature rise but also as an effect of increased respiration, either as a direct response to increased temperature or due to increased nutrient levels (Bloomfield et al. 2006).

(v) **Increased nutrients:** Elevated mineralization and releases of nitrogen (N), phosphorus (P), and carbon (C) from SOM and increased runoff and erosion will result in increased nutrient loads. Release of P from bottom sediments in stratified lakes may increase due to declining oxygen concentrations in the bottom waters. A warmer climate can enhance the pollution load of nutrients to lakes and rivers to induce eutrophication. Changes in rainfall and resulting discharge patterns will also affect nutrient concentrations. Low summer flow will give less dilution of nutrients that affects higher nutrient concentration. High intensity and frequency of floods and more frequent extreme rainfall events will give increased surface runoff and erosion, increasing the nutrient load to the surface water. Heavy rainfall may account for a significant proportion of annual P transfer from agricultural soils under arable crops (Jeppesen et al. 2009).

(vi) **Underwater light conditions**: These are mainly affected by three factors: turbidity, DOC concentration, and phytoplankton density. Climate may change the underwater light conditions through changes in erosion, affecting both turbidity and background input of nutrients, and through changes in the carbon cycling processes in the catchment affecting the input of humic substances. Moreover, if the stratification pattern of lakes are changed, the depth of the circulating water column will be affected and thereby also the mean underwater light for phytoplankton.

(vii) **Salinization:** Increased erosion, runoff, and sewage discharge into water bodies could increase the concentration of salts in water which is highly hazardous to its inhabitants and users.

(viii) **Pathogenic microbes:** Sewage overflows upon heavy rains combined with high water temperatures and long ice-free season may increase the number of pathogenic microbes in water. High intensity rainfall may also give increased input of pathogens from pastures, rangelands, grasslands, drains, and treatment plants. Statistically significant correlations have been observed between rainfall and outbreaks of waterborne disease in both plants and animals including human beings.

(ix) **Hazardous substances:** Direct temperature effects will largely be limited to compounds which are volatile (organic pollutants, mercury) and/or subject to degradation processes. Climate change may affect future use of pesticides. It is not likely that changes in cropping patterns will affect the use of pesticides to a large extent. However, increased prevalence of existing pests, weeds, and diseases and increased pest resistance may lead to wider and more frequent application of pesticides and introduction of new products. On the other hand, in areas severely affected by drought, the decline in agriculture will lessen the use of pesticides. Increased temperature will increase the rate of dispersal and give wider distribution of pesticides (Bloomfield et al. 2006).

Climate change will also affect mineralization of previously released hazardous substances of soil and sediment. Increased frequency of intense rainfall events and floods will increase soil and sediment erosion and increase the pollutant concentration in aquatic systems (Bloomfield et al. 2006). More intense rainfall can also give more bypass flow and more rapid movement of pesticides from agricultural soils to surface water duly promoted by the negative change on soils. Loading of hazardous substances may increase due to sewage overflow and increased leaching of hazardous substances from urban surfaces resulting from increased rainfall.

Impacts of Climate Change on Water Resources of Pakistan

Pakistan is predominantly an arid and semiarid country. Pakistan is an agricultural country mainly dependent on surface irrigation through the Indus river system. The country has developed the world's largest contagious canal network. According to the climate change scenario, the warming is reflected in the river-flow data of

Pakistan, especially during the 1990s. In the post-Tarbela era, water diverted from rivers to the canal system has remained constant around 104 MAF per year. The freshwater outflow to sea may, therefore, be considered a good indication of the total river flow for this period. From the year 1975–1990, average flow into the sea has been 34.13 MAF per year. However from the year 1990 to 2000, this flow has been 47.88 MAF a year, i.e., about 40 % greater. For the winter season for the same period, average flow into the sea from the year 1975 to 1990 was 1.86 MAF a year. However from the year 1990 to 2000, this flow was 3.28 MAF a year, i.e., about 76 % higher. Although other factors may also be contributing, nevertheless the change visible in this time frame is quite large which is partially due to climate change. The global warming initially caused the river flow to increase as glaciers melt, then decrease as these recede. One more fact that emerges from the data is that when there is an excessive amount of water in summer, the succeeding winter also has more water than usual; this increased water availability in winter seems due to increased rains because of local effect of greater moisture in the soils and atmosphere.

An overall increase in rainfall of 50–150 mm has been recorded in summer monsoon belt for the period 1931–1990. But a decrease in rainfall was witnessed in the rest of country. Such decrease is 50–100 mm in western and northern mountains, whereas it is 25–50 mm in the southeastern and central parts. These variations are in line with the predictions of global warming which is expected to cause drier south and wetter north.

Naheed and Rasul (2011) used rainfall variability coefficient to analyze the past time situation from 1960 to 2009. The results of the decadal analysis showed high value of the variability coefficient in Balochistan (251 %), Sindh (247 %), and Punjab (208 %) provinces of Pakistan. However the annual analysis showed the increasing trend of variability coefficient from north to south. According to the inter-seasonal analysis, variation in the coefficient of variability was higher in post-monsoon and pre-monsoon seasons compared to the winter and monsoon seasons. This analysis showed that forecasting is a challenging job where the variability is prominently high (Naheed and Rasul 2011).

Droughts in one country or region also affect neighboring regions that otherwise are supposed to make surplus water available for interbasin transfers during the flood seasons. Increase in persistency of drought requires a reexamination of our assumptions, operating norms, and contingency measures for existing and planned water management measures. Droughts produce additional burden of migration of population from neighboring regions into lands that are already stretched to the maximum. Besides the social disruptions, there is the cost of the degradation of the natural resources due to their over-exploitation.

Adaptation Measures and Recommendations

Adaptation refers to the adjustments in natural or human systems in response to actual or expected climatic stimuli or their effects to reduce the vulnerability and build the resilience of ecological and social systems and economic sectors to present and future adverse effects of climate change, which moderates harm or exploits beneficial opportunities (Parry 2007).

The relationship between adaptation and "normal" development is a subject of debate. Adaptation interventions often mirror ongoing efforts to promote sustainable development, making it hard to draw neat distinctions or, in terms of financing, to identify their incremental and/or additional cost over and above "development as usual."

Decreasing the Vulnerability of Water Resources

Development of human societies has involved a continuous process of adapting to changing stresses and opportunities. While climate change is seen as a relatively recent phenomenon, individuals and societies are adapting to a range of environmental and socioeconomic stresses. Adaptation aims at decreasing unavoidable adverse impacts in the shorter term, lowering vulnerability to present climate variability, and exploiting opportunities provided by climate change. Adaptation includes proactive and reactive measures, which relate mainly to planned adaptation as well as autonomous actions. Mitigation aims at avoiding the unmanageable impacts, while adaptation aims at managing the unavoidable impacts. In many parts of the world, especially in semiarid lands, there is good experience with phenomenon such as drought. As climate extremes are predicted to increase the frequency and intensity in future, it is important to understand and learn from relevant past adaptations and indigenous knowledge. The criteria to select adaptation measures and options for water are presented in Tables 1 and 2, respectively.

Adaptation Measures for Water Sector

Climate change poses a challenge to water managers by introducing uncertainty in future hydrological conditions. It may also be very difficult to detect an underlying trend, i.e., adaptation decisions may have to be made before it is clear how hydrological regimes may actually be changing. Water management in the face of climate change, therefore, needs to adapt a scenario-based approach.

Water Management Measures

These efforts include a wide variety of activities based on current and anticipated climate change impacts. Specific adaptation approaches include:

(i) Using water barrels that capture excess rainfall to minimize flooding and maintain a constant supply of water through dry spells
(ii) Improving irrigation systems and their efficiency
(iii) Protecting valuable resources and infrastructure from flood damage
(iv) Managing rainfall on-site to limit contamination and protect water quality
(v) Limiting development within vulnerable watersheds

Table 1 Criteria to select adaptation measures

Criterion	Sub-criterion	Guiding questions
Effectiveness of adaptation	Adaptation function	Does the measure provide adaptation in terms of decreasing impacts and exposure, enhancing resilience, or enhancing opportunities?
	Robustness to uncertainty	Is the measure effective under different climate scenarios and different socioeconomic scenarios?
	Flexibility	Can adjustments be made later if conditions change again or if changes are different from those expected today?
Side effects	No regret	Does the measure contribute to more sustainable water management and bring benefits in terms of alleviating the already existing problems?
	Win-win (or win-lose)?	Does the measure entail side benefits for other social, environmental, or economic objectives?
	Spillover effects	Does the measure affect other sectors or agents in terms of their adaptive capacity? Does the measure cause or exacerbate other environmental pressures?
Efficiency, costs, and benefits	Low regret	Are adaptation measures will bring high benefits relative to costs? (If possible, consider also distributional effects (e.g., balance between public and private costs) as well as nonmarket values and adverse impacts on other policy goals)
Framework conditions for decision-making	Equity and legitimacy	Who wins and who loses from adaptation? Who decides about adaptation? Are decision-making procedures accepted by those affected and do they involve stakeholders? Are there any distributional impacts of the climate change or of the adaptation measures?
	Feasibility of Implementation	What barriers are there to implementation?
		Technical
		Social (number of stakeholders, diversity of values and interests, level of resistance)
		Institutional (conflicts between regulations, degree of cooperation, necessary changes to current administrative arrangements)
	Alternatives	Are there alternatives to the envisaged adaptation measures that would be less costly or would have fewer negative side effects?
	Priority and urgency	How severe are the climate change impacts the adaptation measure would address relative to other impacts expected in the area/river basin/country? When are the climate change impacts expected to occur? At what timescales does action need to be taken?

Table 2 Some adaptation options for water supply and demand

Supply side	Demand side
Prospecting and extraction of groundwater	Improvement of water-use efficiency by recycling water
Increasing storage capacity by building reservoirs and dams	Reduction in water demand for irrigation by changing the cropping pattern, crop mix, irrigation methods, and area planted
Desalination of seawater	Reduction in water demand for irrigation by importing agricultural products
Expansion of rainwater storage	Promotion of indigenous practices for sustainable water use
Removal of invasive nonnative vegetation from riparian areas	Expanded use of water markets to reallocate water to high value uses
Water transfer	Expanded use of economic incentives including metering and pricing to encourage water conservation

Source: Parry (2007)

(vi) Precise weather forecasting and information network for farmers
(vii) Information exchange on new technologies at national and international levels
(viii) Managing aquifer recharge (MAR) is a technique for arid regions to replenish aquifers and allow subsequent recovery of water for urban, agricultural, and environmental benefit

Water Conservation Measures

Water conservation is an integral part of managing water resources. For regions experiencing population growth, water conservation can adjust current water use patterns to maximize existing water supplies. Water conservation can be achieved in several ways, varying greatly in terms of complexity, cost, and water quantity such as:

(i) Ensuring water conservation, lowering irrigation system losses, and providing incentives for adoption of more efficient irrigation techniques
(ii) Conserving water and minimizing runoff with climate-appropriate landscaping, such as xeriscaping
(iii) Promoting local watershed management systems
(iv) Expand floodplain areas, emergency flood reservoirs
(v) Introducing local rainwater harvesting measures
(vi) Efficient urban and industrial wastewater reuse

Upgrading Infrastructure

Upgrades and maintenance of water distribution and storage systems are among the most effective methods those can be employed for water conservation. Increase the capacity of existing water reservoirs (dams) and develop new ones for increasing water storage. Infrastructure upgrades consist of identifying and repairing leakages, conducting pressure adjustments, replacing aging infrastructure, and developing new ones within the existing urban water distribution system.

Exploring Alternative Water Resources

Desalination could provide an unlimited source of water. Saltwater desalination is a process of stripping salt, minerals, or other chemical entities from seawater to produce potable water. While the possibility of an unlimited supply is appealing, there are also various downsides associated with desalination. Though there are other desalinating technologies, we considered reverse osmosis (RO) desalination due to its increasing dominance worldwide. Recycling and reuse of municipal wastewater is also an effective source. Due to low precipitation and lack of perennial streams in dry areas, the most reliable water source for irrigation and industries is recycled wastewater.

Domestic Fixtures

Kitchens, toilets, sinks, and showers account for approximately 60 % of domestic water use on an average, so installation of water saving fixtures can significantly lower household water consumption. Therefore, for future generations implementation of water-efficient fixtures should be taken into account in new construction projects. We should also focus on water saving from a combination of fixtures at domestic level through public awareness.

Measures for Water Quality Control

All possible adaptive measures should be focused to prevent water pollution. All water management and conservation measures concentrated on decreasing runoff and floods should be adopted to minimize the entry of sediments, nutrients, pollutants, contaminants, trash, animal waste, sewage effluent, and other materials into water bodies and supplies; these could make waters unusable, unsafe, or in need of water treatment. Since higher intensity and frequency of floods and more frequent extreme rainfall events are expected to increase, the load of pollutants (organic matter, nutrients, and hazardous substances) washed from soils and overflows of sewage systems to water bodies (Grimalt et al. 2001). Four concrete water quality control aspects can be explained as:

(i) Measures for point source pollution control
(ii) Wastewater treatment and recycling
(iii) Measures for nonpoint source (agricultural) pollution control
(iv) Ecological restoration and eco-hydrology

(i) **Measures for Point Source Pollution Control**
Sewage treatment plants are one of the main sources of control. The main pollution problems associated with point pollution discharges are high temperature, organic and inorganic pollutants, and nutrients (nitrate, P, etc.). Uncontrolled or accidental discharge of untreated wastewaters into water bodies is particularly problematic from an environmental perspective, due to

its high levels of nutrients. The risk of this kind of discharge is particularly high in sewerage systems which combine storm water and wastewater; overflows of the system into water bodies, due to flash floods, for instance, can contain important amounts of untreated wastewater and several pollutants.

The decrease in point source pollution in view of these discharge pollutants is an effective adaptation measure. These types of measures are also recommended for limiting the risk of eutrophication in lakes, specifically targeting nutrient loading from point sources. In addition to environmental benefits, the measure has clear additional benefits for human health.

These include:

(a) **Nitrate and phosphate load in wastewaters**
The N and P present in wastewaters can lead to eutrophication of surface waters. Climate change increases this risk due to low river flows and increased frequency of flash floods – with increased storm and sewage overflow – predicted for some regions. One measure addressing this is banning or minimizing of phosphate in relevant domestic products and industrial processes. Phosphorus reclamation is considered an effective solution for maintaining high water quality in a changing climate and delivering economic benefits at the same time.

(b) **Separation of rainwater and sewage**
Untreated wastewater reaching surface waters constitute a serious pollution problem. A possibility, both when building new canalization and renovating existing drainage, is to separate wastewater and storm water. This is a comparatively expensive option, but it will strongly lower the risk of untreated wastewater entering the water systems.

(c) **Improvement of wastewater infrastructure capacity**
In many regions, the frequency of flash floods is expected to increase due to climate change. Improvements in the capacity of treatment plants or in storage capacity can address this problem.

(d) **Incorporating climate change considerations into discharge licensing schemes**
New forms of discharge license agreements include provisions that address uncertainty due to climate change. Licenses from point source discharges should be reviewed periodically; changes related to climate change impacts as well as in other parameters such as population behavior and available technology can thus be reflected in the revised agreements. In the United Kingdom, discharge licenses of wastewater treatment plants are reviewed every 5 years to this purpose. Changes to the system's carrying capacity to address climate change will be reflected in the pollution load the system is allowed to take up.

(ii) **Wastewater Treatment and Recycling**
Sewage treatment plants are one of the main control measures of point pollution. Uncontrolled or accidental discharge of untreated wastewaters into water streams is particularly problematic from an environmental

perspective due to its high levels of nutrients and other toxic substances. Such discharge is particularly high in sewerage systems which combine storm water and wastewater. They also overflow system into water bodies due to flash floods and can contain significant amounts of untreated wastewater and pollutants. Both domestic and industrial wastewater treatment and agricultural wastewater treatment and seawater treatment are effective measures for pollution control. The treated water reuse for drinking, irrigation, or industrial processes is also a potential adaptive practice.

(iii) **Measures for Diffuse Pollution Source Control**
Agriculture is the main source of diffuse pollution affecting water bodies. Conventional agriculture implies a certain level of leaching or washout of nutrients and pesticides, either to surface waters or to groundwater. Some pollutants (P, metals) adhere to soil particles and could reach surface water bodies as soil particles are transported due to erosion. Vegetated and unfertilized buffer zones alongside water courses act as a shield against overland flow from agricultural fields and decrease runoff from reaching the water course, thus decreasing erosion and the movement of pollutants into water courses.

Agricultural measures that limit erosion and leaching and aim at water conservation decrease the input of solid and suspended particles into water bodies and consequently the input of diffuse agricultural pollutants. These measures also have the potential of lowering the runoff from agricultural fields. Some of these measures are discussed in section "Adaptation Measures for Agriculture Sector."

(iv) **Ecological Restoration and Eco-hydrology**
Identify the ecosystems that are most vulnerable to climate risk and then the best available measure on climate-induced impacts to engage with vulnerable groups including assessment hazards, vulnerabilities, and capacities that can support adaptation planning (Reid and Huq 2007). Adapt appropriate measures to preserve the ecology of risk areas.

Policy Measures

(a) Assess and address the needs for additional water storage and distribution of infrastructure.
(b) Ensure early rehabilitation, remodeling, and upgrading of the existing irrigation infrastructure in the country to make it resilient to climate change-related extreme events.
(c) Identify new potential dam sites to keep the option open to develop new dams, should they be needed.
(d) Develop necessary infrastructure to harness the potential of hill torrents.
(e) Enforce measures to enhance the life of existing storage facilities.
(f) Thus, policy coherence with the agricultural policy's provisions should be ensured with regard to adaptation objectives in water management.

Integrated Water Resource Management

(a) Ensure that, in making water allocations (within gross national availability) to various sectors in the medium to long term, due consideration is given to changes in sectoral demands caused by climate change.
(b) Protect groundwater through management and technical measures such as regulatory frameworks, water licensing, slow action dams, artificial recharge especially for threatened aquifers, and adoption of integrated water resource management concepts.
(c) Ensure rational groundwater exploitation by avoiding excessive pumping.
(d) Ensure recycling of wastewater through proper treatment and its reuse, for example, in agriculture, artificial wetlands, and groundwater recharge.
(e) Protect and preserve water catchment areas and reservoirs against degradation, silting, and irrigation system contamination.
(f) Encourage active participation of farmers in water management along with line departments by accelerating implementation of participatory irrigation management reforms.
(g) Ensure water distribution among provinces as far as possible in accordance with crop sowing timings.
(h) Address seawater intrusion into the coastal region by allocating the requisite water flow downstream.
(i) Take appropriate measures to preserve the ecology of dry river reaches.
(j) Develop contingency plans for short-term measures to adapt to water shortages that could help mitigate drought.
(k) Explore the possibility of joint watershed management of trans-boundary catchment areas with neighboring countries.
(l) Safeguard Pakistan’s rights on trans-boundary water inflows according to international norms and conventions.
(m) Promote integrated watershed management including ecological conservation practices in uphill watersheds.

Legislative Framework

(a) Legislate and enforce industrial and domestic waste management practices to protect the environment, in particular water resources, from further degradation.
(b) Enact and enforce laws and regulations required for efficient water resource management and a groundwater regulatory framework.
(c) Protect the Hindu Kush-Himalayan (HKH) glaciers, considered the world’s water tower, by declaring them as “protected areas” through agreements among countries sharing the Himalayan region.

Adaptation Measures for Forests

(i) Pest control: The biological control of forest pests is a very important adaptation measure.
(ii) Promote farm forestry.
(iii) Special attention should be given to those tree species which have poor seed production and dispersal, occupy ecological niches, have small populations and restricted ranges, and are peripheral.
(iv) Preservation of watersheds to control sediments downstream.
(v) Control of wastage as the use of waste wood to produce composite wood (Joseph and Tretsiakova-McNally 2010).

Adaptation Measures for Agriculture Sector

Agriculture is a sector that can make large contributions to adaptation to climate change and water quantity as well as quality. The following measures should be promoted:

(i) **Support for switching to organic farming**
Organic farming strongly limits the possibility of agriculture-related pollution entering groundwater or surface water bodies. In addition to restrictions typically prohibiting the use of pesticides and fertilizers and regulating the use of natural fertilizers, requirements also typically include rules for improved soil structure and functioning, thus reducing the risk of soil erosion and unwanted sediment transport.
(ii) **Precision farming**
Precision farming is based on the principle of meeting crop requirements as precisely as possible, using high technology (Global Positioning System yield mapping, variable rate delivery of seed, pesticides, and fertilizers) at a very fine scale (a few square meters) and aiming for application at the best possible moment in time. This results in maximization of efficiency of all inputs and reduces the risk of nutrient and pesticide runoff to surface water, leaching to groundwater, etc.
(iii) **Erosion reduction measures**
  (a) **Continuous plant cover (catch crops, intercrops)/winter plant cover:** A cover crop will take up residual nitrate (NO_3^-) and other nutrients from soils and help stabilize soil thus decreasing soil erosion and the mobilization of associated pollutants.
  (b) **Green stripes between fields:** Establishment of green stripes of some meters wide between agricultural fields, either with permanent or with temporary (yearly) cover crops, could decrease the erosion of field soil and surface runoff, thus the input of nutrients and pesticides into surface waters.

(c) **Mulch sowing:** Maintaining plant parts after removing seed within the soil and abstaining from the use of ploughs naturally creates a protective layer of mulch while new plants are sowed directly into the soil. This helps maintain organic matter and preserve good soil structure, thus improving infiltration and retention of water and thereby decrease erosion and pollutant concentrations in surface runoff.

(d) **Preventing soil compaction:** Soil compaction lowers water infiltration into soils, thus favoring surface runoff and erosion; compaction-free soils are also more drought resistant for crops. Options for preventing compaction include use of low ground pressure tires or tracks on vehicles, avoiding wet soils, and adding organic matter to soil.

Agricultural measures that decrease erosion and/or aim at soil conservation lower the input of solid and suspended particles and pollutants into water bodies. Some of these measures (e.g., winter plant cover) also absorb soil nutrients, reducing the nutrient load available for leaching. The measures also have the potential of strongly limiting the runoff from agricultural fields.

(iv) **Fertilizer, manure, and slurry management measures**

A rational and planned application of fertilizers/manure/slurry, which is well timed and which takes account of local parameters such as soil type and structure, is a widespread tool for reducing nutrient leaching and can have an enormous impact on water quality. These management measures include:

Nutrient balance: Nutrient balance spreadsheets inform farmers on the efficiency of nutrient utilization and help identify the cropping phases in which nutrients are lost. These help to accurately account for fertilizer use and decrease unnecessary nutrient inputs. The reductions have positive effects on both surface and groundwaters.

Manure application techniques: These involve, for instance, cutting slots in soil, injecting slurry, and then closing these slots after application. These lower groundwater and surface water pollution from NO_3^- leaching and phosphate runoff.

Integration of fertilizer and manure nutrient supply: Determining the amount of nutrients supplied to soils during manure application helps farmers judge the amount and ideal timing of additional fertilizers required by the crop. Taking better account of the nutrients contained in manure can reduce the need for fertilizer inputs, which in turn minimizes NO_3^- and P losses.

(v) **Risk-based fertilizer and manure restrictions**

Risk areas include areas with flushes draining to a nearby water course, cracked soils over field drains, or fields with a high P index. By avoiding the spreading of mineral fertilizers or manure at high-risk times, the NO_3^- leaching and loss of P through surface runoff is diminished. High-risk times include when there is a high risk of surface flow and rapid movement to field drains from wet soils or when there is little or no crop uptake.

(vi) **Precision techniques**
Additional options include the adoption of improved precision techniques such as soil analysis, manure analysis, adaptation of fertilizer and pesticide application on demand, matching fertilizer to seasonal conditions, and slow- and controlled-release fertilizers.

Cash Crops

Cash crops are usually sown after the harvest of one crop and before the sowing of the next. They offer forage or green manure (providing fertility for the soil thereby reducing N applications for the next crop) potential and are usually based on quick growing plants that will establish before winter. Their mitigation benefits include reducing N_2O emissions or leakage, improving N-use efficiency and carbon sequestration in the soil (Lal 2008).

Cropping Patterns

- Adjusting cropping pattern with water availability and water conservation
- More share of cropped area under oil seed crops and crops having less water requirement
- Improving productivity and production management
- Promoting farm forestry

Effective Irrigation Systems

Ensure water conservation, decrease irrigation system losses, and provide incentives for adoption of more efficient irrigation techniques:

Conserving water and minimizing runoff with climate-appropriate landscaping, such as xeriscaping, striping, or contouring
Improving irrigation systems and their efficiency
Improving water-use efficiency by recycling water

Strategies for Implementing Adaptation Measures

To maintain water supply and conservation as well as successful adaptation programs, the main strategies could be:

(i) Research initiatives
(ii) Planning and policies
(iii) Public awareness
(iv) Enhancing capacity
(v) Technology transfer
(vi) Follow-up programs after field demonstration by experts

The following measures should be adopted regarding this aspect:

(a) Develop and extend water-efficient technologies and techniques for seawater utilization, water recycling, and avoiding wasteful use of domestic and drinking water.
(b) Ensure measurement and monitoring of irrigation water delivery at various points of the supply system for effective planning and management.
(c) Enhance national capacities in remote sensing and GIS techniques for monitoring temporal changes in glaciers and snow cover.
(d) Enhance national capacities for making seasonal hydrometeorological forecasts, particularly for monsoon rainfall.
(e) Prepare a comprehensive inventory of all water resources, including surface and groundwater, in order to support an efficient water management system in the country.
(f) Strengthen the current hydrological network to monitor river flows and flood warning systems.
(g) Devise and strengthen coordination mechanisms among national and international water sector institutions.
(h) Promote public awareness campaigns to underscore the importance of conservation and sustainable use of water resources.
(i) Enhance research activities and facilities regarding these aspects to accelerate adaptation.
(j) Linking science, management, and policy in climate change and water resources.
(k) Cost-effective, adaptive water management and technology transfer to all stakeholders.
(l) Capacity building and institutional strengthening.
(m) International and regional cooperation.

Mechanisms to Achieve Solutions

(i) **Education and awareness:** Goals of education and awareness building efforts, connecting people to water quality impacts, documenting the problem, engaging the community, working with the media, and advocacy with policy makers and agencies.
(ii) **Monitoring/data collection:** Problems with water quality data.
(iii) **Governance and regulation:** Water reforms, policies, laws, and regulations; establishing water quality standards; international water quality guidelines; international governance and law; managing trans-boundary waters; financing water quality; institutional capacity building; and strengthening enforcement.
(iv) **National strategies:** Provide the framework for adaptation actions, many of which have to be implemented at subnational and local levels. The relevance of adaptation at the national level is primarily concerned with coordinating information sharing and encouraging an appropriate, proportionate, and

integrated implementation of adaptation measures at different levels. The integration of adaptation into national sectoral policies and structural/cohesion funds together with fostering research and involving stakeholders are key instruments in this respect (Shardul and Samuel 2008).

Implications for Adaptation Process

It is possible to define five different types of limits on adaptation to the effects of climate change (Parry 2007):

(i) Physical or ecological: It may not be possible to prevent adverse effects of climate change through technical means/institutional changes, e.g., it may be impossible to adapt where rivers dry up completely.
(ii) Technical, political, or social: It may be difficult to find acceptable sites for new reservoirs or water users to consume less.
(iii) Economic: An adaptation strategy may simply be too costly in relation to the benefits achieved by its implementation.
(iv) Cultural and institutional: These may include institutional context within which water management operates, the low priority given to water management, lack of coordination between agencies, tensions between different scales, ineffective governance, and uncertainty over future climate change; all act as institutional constraints on adaptation.
(v) Cognitive and informational: Water managers may not recognize the challenge of climate change or may give it low priority compared with other challenges. A key informational barrier is the lack of access to methodologies to cope consistently and rigorously with climate change.

Feedbacks from Adaptations to the Global Environment

In attempting to adapt implementation systems to cope with climate and other environmental changes, it will be important to ensure that changes proposed do not exacerbate climate change or other aspects of environmental degradation. Past intensification (land cover change, especially the removal of trees) has made a large contribution to CO_2 emissions. Hence one means of mitigating further greenhouse gas emissions is to intensify vegetation production on existing cleared areas and leave forests intact.

A series of adaptation measures are under way to counteract these negative impacts, such as improved point source control and measures to decrease nonpoint pollution especially agricultural measures, change of industrial processes to lessen effluents, banning P in detergents, and restoration measures in rivers and lakes. The uncertainty is whether these will be sufficient and be implemented soon enough to prevent these negative impacts on the inland waters of globe.

Conclusions

The aim of this chapter was to provide an overview of the climate change impacts on water resources in dry regions and propose possible adaptation measures to mitigate these impacts. Climate change drivers directly or indirectly affect water availability by altering precipitation patterns, increasing evaporation and atmospheric water vapor, melting glacier snow and ice, raising sea level, and causing changes in soil moisture, groundwater recharge patterns, surface runoff, and river discharge.

Climate change also result in significant deterioration of water quality by altering physical, chemical, and biological characteristics of water, thereby leading to a load of pollutants including sediments, salts, organic matter, nutrients, hazardous substances, and pathogens. Changes in the water resources lead to impacts on all the socioeconomic features such as energy production, infrastructure, food availability, health, agriculture, and environment.

A number of approaches, including water management and conservation, infrastructure upgrading, exploring alternate resources, and recycling wastewater, have been proposed to facilitate the adaptation planning and implementation process. In terms of water quality, all potential management, conservation, and control measures for both point and nonpoint sources should be adopted to minimize the entry of pollutants and contaminants into water bodies and supplies.

Extending access to reliable and affordable water in terms of quantity and quality remains key to strengthening livelihoods and building resilience to climate change. Therefore, it is need of the hour that an effective adaptation program through all potential integrated measures at local, national, and global scales should be initiated or enhanced under current and future water scarcity circumstances.

Abstract

This chapter presents the recent vulnerability assessment project on a rice paddy production and climate change in Indonesia and attempts to demonstrate a practical framework and methodology for a vulnerability and adaptation assessment in the agricultural sector. This chapter applies the outcome vulnerability framework, which is defined by the IPCC. The framework is applied into a practical methodology using multidisciplinary approaches such as statistical modeling, GIS and remote sensing, as well as participatory research, focus group discussion, and policy assessment. The chapter produces vulnerability maps illustrating how climate change affects rice paddy production in Indonesia especially Bali island. In Bali island, the suitability for rice paddy production has been decreased 20 % in the last 20 years because of changes in climate, and climate change will continue in the future. On the other hand, the chapter suggests that actual damages will be based on rice paddy location and the adaptive capacity of farmers. The chapter demonstrates the impacts of climate change on rice paddy production, which is a staple food for many developing countries including Indonesia. It is important to understand the impacts of climate change in agriculture sector that is the most vulnerable to adverse changes in climate. The chapter successfully demonstrates a multidisciplinary approach, which can be applied in other agricultural products in different countries.

Keywords

Vulnerability assessment • Climate change • Agriculture • Rice production • Multidisciplinary approach • Indonesia

Introduction

This chapter assesses the vulnerability of rice paddy production on Bali island, Indonesia, and creates a climate change vulnerability map. The present assessment includes the three subcomponents that are required for climate change vulnerability: exposure, sensitivity, and adaptive capacity. The assessments of exposure are based on climate data from BMKG, such as annual rainfall, temperature, and humidity. The data regarding paddy location are used as an element of sensitivity. Adaptive capacity assessment employs a normative approach to determine paddy production, such as mixed qualitative and quantitative techniques.

The devastating impact of climate change has already been evident in Indonesia. The country's combination of high population density, high levels of biodiversity, having more than 15,000 islands, and having a coastline that stretches over staggering tens of thousands of kilometers makes Indonesia one of the most vulnerable countries to the impact of climate change. Bali, a small island of Indonesia, is likely to suffer from rising sea levels, droughts, and floods, which will impact the island's rice production. In general, the production of paddy has decreased since year 2000. Decline in paddy's production is in line with the shrinking of harvested areas for paddy. In contrast, the production rate has been increased; therefore, it negates the reduction of total yield level. From years 2000 to 2008, the harvested area has been reduced 7.1 %, productivity rate increased 8 %, and production size increased 1.6 %. The paddy production may not be able to rise or may even shrink in the future if paddy areas, production rate, or production cycle is reduced by climate change (Takama et al. 2012). Rice is one of the most important agricultural crops in Indonesia, and it can be affected by climate change just as other agricultural products can be (Centennial Group International 2012).

This chapter demonstrates the approach and the results of a vulnerability assessment for climate change and rice paddy production. This approach uses qualitative and quantitative assessment methods and relevant maps of the assessment. It also helps researchers to make policy recommendations based on the assessment. The approach will be transferable to other regions of Indonesia as well as many developing countries.

Background

Vulnerability Assessment

The IPCC (Intergovernmental Panel on Climate Change) gives the most frequently quoted definition of vulnerability: "Vulnerability is the degree to which a system is susceptible to, and unable to cope with, adverse effects of climate change, including climate variability and extremes" (2007, p 883). Extensive climatic and socioeconomic vulnerability may worsen the plight of poor farmers who comprise the majority of rural populations in developing countries such as Indonesia, and farmers will continue to be vulnerable to social and weather changes in the immediate future. It is believed that the earth is warming, and climate change on a global scale has already been observed. As a result, disasters, especially drought, hurricanes, and floods, occur more often and hinder agricultural activities. According to a report created by the Asian Development Bank, weather-related disasters in Southeast Asia will increase (Yusuf and Francisco 2009). However, "rise in disaster" does not mean "rise in vulnerability," because the concept of vulnerability is often defined based on exposure, sensitivity, and adaptive capacity. Exposure is the likelihood that climate-related disasters will happen to a target group (i.e., an exposure unit), including droughts and floods. Sensitivity can be defined as an exposure unit's susceptibility and is represented by rice paddy field density, population density, etc. Adaptive capacity is defined by the IPCC as "the ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences" (IPCC 2007) and is usually estimated by social factors, financial resources, and climate-proof infrastructures.

The social factors that are included in assessments of adaptive capacity are not related to climate, but they are closely related to the climatic impacts on rice paddy production. For example, a meteorological drought can occur in a rice paddy location, but the rice paddy will not be damaged if the farmers know how to cope with the impact, if they understand how to apply seed variety choice, and if they enforce policies adequately (Liverman 1990; Meze-Hausken 2004; Ifejika Speranza et al. 2008). In other words, when farmers possess high adaptive capacity, they can minimize the impacts of droughts. Therefore, it is important to include adaptive capacity based on social factors in a vulnerability assessment.

This report assesses separately the three components of the vulnerability assessment, because the natures and the measures of these three components (i.e., exposure, sensitivity, and adaptive capacity) differ. For example, exposure is climate stresses or potential climate-related disasters, so exposure is difficult for humans to reduce and might even be impossible for them to eliminate. Some reports mention terms like "reducing exposure through building a dike in the case of sea level rise" (Know Climate Change 2004). However, building a dike is not reducing exposure, but is, instead, improving adaptive capacity, because it is not possible to stop the sea level from rising beyond mitigation measures, such as the reduction of greenhouse gasses. Although it is not possible to tackle exposure directly, information about exposure is important. Without exposure information, it is not possible to know where potential disasters will happen or at what magnitude. It would be a waste of resources to build an irrigation system in an area where drought is unlikely to occur or to construct a dam where there will be no flood. Exposure indicates the areas of potential disasters and thus helps policymakers and stakeholders to decide how to prepare for climate change.

Normative Index Development Process

Some analysts expect vulnerability assessments of climate change to be objective (Nagel 1989). However, it is neither possible nor desirable to be purely objective when each assessment includes social issues and the desires of a number of stakeholders (Schwandt 2000; Johnson and Onwuegbuzie 2004). Therefore, a vulnerability assessment needs a normative approach so that the researchers can work with the local stakeholders.

Climate change is about the future, so the vulnerability problems in question have not occurred in most cases. In addition, developing a vulnerability map requires quantitative information, because it compares factors and locations. Quantitative techniques are neither appropriate nor outperform qualitative methodologies in terms of exploring normative questions, such as "What kind of issues usually concern farmers and policymakers?" or "What are the key factors that might affect paddy production in a particular area?" Therefore, it is important to conduct further exploratory research to answer these normative "what" questions before working on quantitative assessments. Similarly, to calibrate the quantitative results so that they fit the needs of the users and to make the results transplantable, discussions with key stakeholders are necessary.

Moreover, the process is bound to be politically sensitive to policymakers and stakeholders. Fortunately, constructing the indicators through an objective and scientific process results in fewer arguments. A normative index development involves subjective judgments, because vulnerability assessment must include judgments, such as which weather conditions would be "good" or "bad" for paddy production (Takama et al. 2012; Adger et al. 2004; Harvey et al. 2009). In the normative process, stakeholders can discuss their thoughts and priorities to develop the index collaboratively. Another advantage of the normative index is that it is more likely to be accepted by its users because they have contributed to the process of indicator development (Giovannini 2008).

Methods

Weighting Between Exposure, Sensitivity, and Adaptive Capacity

Many vulnerability assessments use three components to express vulnerability, and they are usually exposure, sensitivity, and adaptive capacity. Among16 recent vulnerability assessments conducted by the ADB, UN, World Bank, etc., almost all of them used equal weighting among the three major components, i.e., 1/3, 1/3, and 1/3 (e.g., Yusuf and Francisco 2009; Heltberg and Bonch-Osmolovskiy 2011; WHO 2011). The equal weighting may not produce the optimal end result, but assessing with equal weights is a reasonable starting point. Weighting factors within each component can be assessed with a scientific or a social scientific method. However, weighting among the three components can be too complicated or too political to be determined scientifically. The three components are organized in terms of similarities in their characteristics. Therefore, it is easier to apply the same domain of science and social science techniques to estimate weight within a component. For example, agriculture's exposure to potential disasters can be defined by the FAO's soil suitability assessment or other agricultural drought assessment techniques (FAO 1976; FAO and UNESCO 1990). In many cases, sensitivity can be defined as a statistical proportion, namely, the density of a target exposure unit, including human settlements, rice paddy density, and protected ecosystems (Yusuf and Francisco 2009). Social science assessment techniques are usually applied to estimate the weight within adaptive capacity (Ziervogel et al. 2006; Takama et al. 2012). In contrast, the characteristics of these three components are significantly different, so it is difficult to implement well-defined science or social science techniques. As a result, the weighting among the three components is evaluated in a less scientific way, such as with expert opinions and stakeholder meetings (Vincent 2004; Vincent 2007).

Equal weighting has significant biases. Heltberg and Bonch-Osmolovskiy (2011) and Eakin and Bojorquez-Tapia (2008) mentioned that equal weighting makes an implicit judgment about the degree of influence of each indicator and that it is normative and not as objective as other approaches. Therefore, the researchers of this report initialized the weighting of the three subcomponents as equal and then calibrated the weighting while discussing the results with experts and stakeholders (Savonis et al. 2008).

An index within each component is composed of a unique number of factors and weights that are estimated with approaches that are more scientific and social scientific in nature. The three components use different units and scales. For example, when a paddy area density is used as sensitivity, the unit is a percentage between 0 and 1, and the adaptive capacity is the production gain in kg/acre. Therefore, it is necessary to normalize and standardize these subindexes into a common unit such as [0, 1] for the final integration. The project tested multiple scientific techniques such as z-score normalization and minimax standardization (see more in Giovannini (2008) and CARE International (2009)) ranking based that was used by WFP (2009) were implemented for the standardization and color categorization. Moreover, values for adaptive capacity should be inversed, because the vector/direction of adaptive capacity is the opposite of the other two components. High exposure and high sensitivity mean high vulnerability, whereas high adaptive capacity means low vulnerability.

A weighting factor development starts with a prototype that is developed through qualitative stakeholder meetings (Takama et al. 2012). After the appropriate stakeholders were identified for the present study, the prototype was updated to reflect the users' needs and the non-captured reality from the stakeholders' and experts' viewpoints. For example, a stakeholder workshop was conducted with provincial and district agriculture agencies, a cultural agency, a public work agency, Udayana University, Technology Research on Agriculture, head of subak (*pekaseh*), and Indonesian Met Office (BMKG) in Denpasar. This workshop helped to finalize the components and the weight of the vulnerability and to make the models more useful and more accessible to nonexperts and stakeholders.

Livelihood Zone Map

Before the social surveys were conducted, the livelihood zones were assessed to understand the characteristics of farmers and livelihoods in Bali and to determine the survey locations (Food Economy Group 2006; Selvaraju and A.D.P. Center 2006). A livelihood is a means of living through assets (e.g., livestock, land, forest, and ships), activities (e.g., grazing land, fishing, and wage labor), and capabilities, which is the product of assets and activities. Livelihoods vary by location due to the fact that the livelihoods of many Indonesian farmers are determined by geography, agricultural potential, and market access.

Geography affects production through climate, soil, and topography and dictates marketing/trade activities through roads and proximity to urban centers. The household production of food and other items may either be directly consumed or may be traded/exchanged for other items in the market. Market access determines the ability of people to trade their goods, such as crops, livestock, or other items, to sell their labor and to obtain the prices that they desire. Factors that do not determine livelihood zones are man-made factors, such as poverty, wealth, conflict, healthcare, education, and other governmental and nongovernmental services (USAID 2009). In this study, more weight was placed on geographical characteristics, including precipitation, topology, and types of agricultural production. A complete step-by-step guide was developed by the Food Economy Group (2006), and an assessment with climate variability has also been implemented by FAO (Selvaraju and A.D.P. Center 2006).

Exposure

Exposure was measured with FAO's soil-climate suitability index (FAO 1976; FAO and UNESCO 1990; FAO 2001). The suitability method indicates the potential damages related to climate factors; therefore, it is appropriate for measuring exposure factors. Simplicity is not necessarily inaccurate. Izumi et al. (2013) predicted the global rice yield from only estimated soil moisture and the temperature of cultivation areas. The verification revealed that the model predicted good results in 20 % of the rice growing regions in the world from 1982 to 2006. The categorization is based on a report from the Indonesia Ministry of Agriculture (Subagyono et al. 2003) and is summarized in Table 1. In short, lowland rice can be grown at an altitude of 0–2,500 m above sea level, and the physical and chemical properties of acceptable soil can vary greatly from a sandy to clay soil texture, a pH of 3–10,and an organic matter content of 1–50 %. The soils can also include different levels of available nutrients. Rice needs enough radiation intensity during the reproductive and ripening phases.

Sensitivity

In this case, sensitivity was defined as paddy field density. This approach is similar to what ADB did for their South East Asia vulnerability assessment project (Yusuf and Francisco 2009). ADB's report defined human sensitivity and ecological sensitivity as the population density and the percentage of protected ecological areas, respectively. Areas with more human settlements and more biodiversity are more vulnerable to the same level of exposure than areas with fewer humans and less biodiversity. Sensitivity indicates the general likelihood that an area will be affected. Climate change is often believed to impact areas with high exposure and high sensitivity. For example, if drought is expected in a large area, policymakers should focus on the places with more rice paddies or more people rather than the places with few rice paddy fields or people. Therefore, sensitivity information is very valuable.

The paddy areas were defined with remote-sensing techniques that acquire information by utilizing devices that have no physical contact with observed objects, regions, or phenomena (Boschetti et al. 2009; Gumma et al. 2011; Wayan and Nishio 2007, Nuarsa et al. 2010, 2011, 2012; Sari et al. 2010; Shao et al. 2001; Uchida 2010; Xiao et al. 2005). The sensitivity as paddy field density was defined by dividing the rice paddy area by total land areas in each kecamatan (subdistrict). There are 39 kecamatan in the Bali province.

Table 1 Suitability of land for rice (Oryza sativa) commodity (Subagyono et al. 2003)

Land requirements/characteristics	Class of land suitability			
	S1: high suitability	S2: mild suitability	S3: low suitability	N: not suitable
Average temperature (°C)	24–29	22–24	18–22	<18
		29–32	32–35	>35
Rainfall (mm):				
First month	175–500	125–175	100–125	<100

Thickness (cm) if there is insertion of mineral material	<140	140–200	200–400	>400

Adaptive Capacity

Adaptive capacities include the functions of socioeconomic factors, technology, and infrastructure. To obtain factors that can be used for adaptive capacity, the researchers conducted a stakeholder meeting, expert discussion, and a survey of rice farming in Bali. Issues, objectives, and potential impacts were explored beforehand, as explained by Takama et al. (2012). Based on these identified issues and the livelihood zone analysis, a survey was designed to model adaptive capacity. Secondary data were also collected after distinguishing significant factors. A model was developed with a normative approach, which is the combination of the statistical assessment, expert opinions, and stakeholder meetings. The purpose of the survey and statistical analysis is to quantify the importance of the factors that influence the productivity of paddies. The factors are used as the elements of adaptive capacity. The potential factors identified by a statistical assessment were justified during stakeholder meetings and expert judgment.

A household survey was conducted to learn the farmers' adaptive capacities and perceptions of climate change. The questionnaire is mainly based on WFP's household questionnaire, which they used in their pilot food security and nutrition monitoring system project in Indonesia as well as in other similar studies (WFP, Ministry of Agriculture (Kemtan) 2009). A field survey was conducted in July and August 2012 by visiting 490 farmers at 70 subaks that are located at 81 villages in seven livelihood zones. The survey locations were chosen based on a clustered stratified random sampling method. Ten subaks in each livelihood zone were selected to represent upper, middle, and downstream areas. An ordinal least square regression model was implemented for the preliminary parameter identification, and other statistical tests were conducted on the survey data. The regression model for adaptive capacity, which is used to estimate the weighting factor, was finalized with the preferences approach, including expert interviews and a stakeholder discussion (Hinkel 2011; Harvey et al. 2009, p 17).

Results

Exposure

Bali is one of the leading rice-producing areas in Indonesia. With East Java, Bali produces 22 % of the rice produced in Indonesia (Naylor et al. 2007). Compared with other regions of rice cultivation, Bali is characterized by a short rainy season. For example, a typical rainy season in North Sumatra starts in early September and lasts until early June, but Bali's rainy season begins in late November and ends in late April. Thus, Bali is more likely to face water shortages, which is unfortunate, because it is an important region for rice production in Indonesia. It is said that the northern and eastern parts of Bali are particularly susceptible to drought (Fig. 1).

Impact of Climate Change on Rice Production

Based on a policy assessment with 10 governmental reports, including the National Action Plan and the Medium-Term Development Plan, there are 23 sets of adaptation policies in relation to agriculture (Takama et al. 2012). This is the largest number in the five major sectors, which also include water resources, coastal, ecosystems, and health. For example, the National Action Plan (2007) mentions the importance of developing an early warning system for drought. The fifth Presidential Decree in 2011 is also about climate change impacts on paddy production. As a result, examining the vulnerability of climate change on rice production is a priority in Indonesia.

Because of the warm climate, two or three cropping cycles in a year is possible in Indonesia. From the beginning of the rainy season until the beginning of the dry season, Balinese farmers usually cultivate rice twice. Then, they harvest vegetables

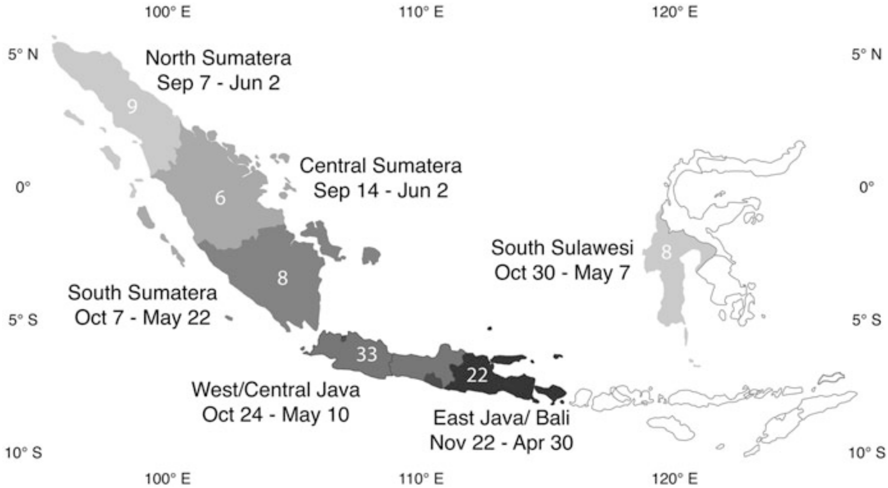

Fig. 1 Periods of a wet season and the proportion of paddy production in Indonesia. Numbers in the figure indicate the percentage of rice paddy production in Indonesia. The dates indicate the wet season periods. For example, East Java and Bali produce 22 percents of rice in Indonesia and a wet season starts from 22 November and ends 30 April on average

once before the rainy season begins. If there is not enough water, then farmers cannot do double cropping in the paddy. Rice production must be ensured in order to sustain food supplies, because rice is a staple food, and Indonesia's current population of 240 million is expected to rise to 300 million by the year 2045. Bali is expected to undergo similar growth. In the past 10 years, paddy areas have decreased by 7 %, but because the production rate has increased by 8 %, rice production in Bali has not changed much (Table 2). In other words, the increase in the rate of production due to technological innovation must keep up with the decline in paddy areas; otherwise, the production volume would fall.

Nevertheless, a sign of production decline has already been seen. A spatial analysis revealed rain pattern changes of 46 % and 54 % in Bali during wet and dry seasons, respectively, between the 1970s and the 2000s (Fig. 2). A soil and climate suitability assessment for paddy production on the basis of a method from FAO shows that the land's suitability for rice production has decreased by 20 % in the past 20 years because of a decrease in precipitation (Prasetya and Novianti 2011). In other words, there is a possibility that rice production will decrease eventually as the productivity lowers. In fact, when the project team interviewed farmers in Bali, some responded that "as there is not enough water, paddy production forced to cut."

The research outcomes reconfirmed the likelihood of climate change in Bali as well as the strong possibility of paddy insecurity following the climate change. The reduction of suitability is mainly due to the decline in precipitation. The north and northeast regions of Bali have been getting drier. Therefore, drought is potentially the number one concern among the weather-related disasters that could harm paddy production.

Table 2 Paddy harvested area, production rate, and production in Bali. In the past 10 years, paddy areas have decreased by 7 %, but because the production rate has increased 8 %, so rice production in Bali is reserved

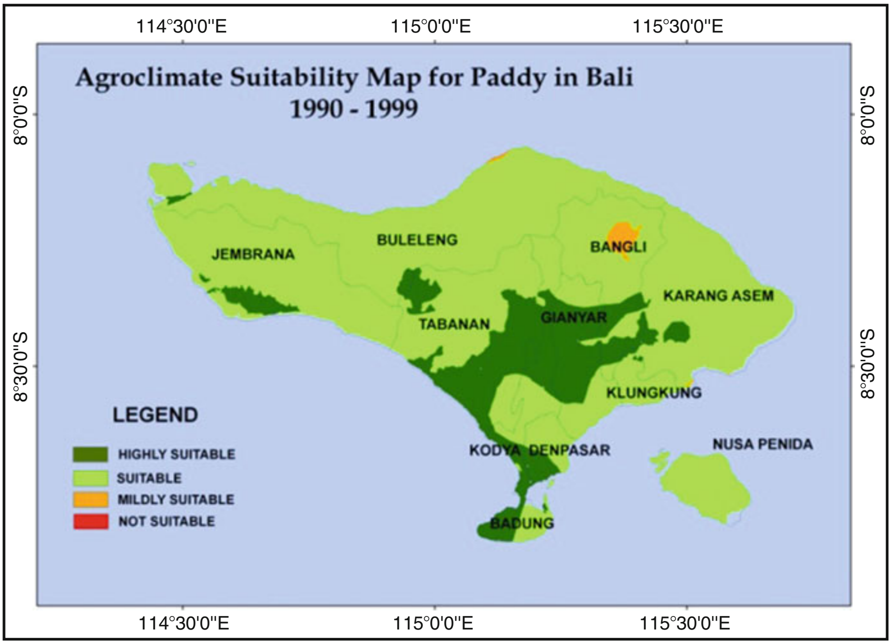
Year	Paddy harvested area (ha)		Production rate (quintal/ha)		Production (ton)
2000	155,049		53.33		826,838
2001	147,942		53.35		789,232
2002	148,025	7%	54.70		809,688
2003	145,294		54.60	8%	793,260
2004	142,663		55.00		788,361
2005	141,577		55.00		785,481
2006	150,557		56.00		840,891
2007	145,030		58.00		839,775
2008	143,999		58.37		840,465

In detail, 1.3 % of Bali's land is highly suitable (S1) for rice production (72,110 ha). Land with middle suitability (S2) covers 31.9 % of Bali (175,650 ha), and land with low suitability (S3) covers 56.9 % of Bali (313,226 ha), while land that is not suitable for paddies (N) covers as much as 9.9 % (54,235 ha). Areas and percentages of land suitability for paddies in each regency are presented in Table 3. For example, "high suitability" areas (S1) cover parts of eastern Tabanan and parts of western Karangasem, and "not suitability" areas (N) cover parts of western Buleleng, parts of northern Tabanan, parts of northern Bangli, parts of northern and eastern Karangasem, and parts of Nusa Penida Island. The soil-climate suitability map in Fig. 2 is used as an exposure map in this vulnerability assessment.

Sensitivity

If no paddies exist in a location where severe drought is expected, then a drought in this location would cause no damage to paddy production, although the drought might cause other problems due to the climatic disaster. Paddy locations as sensitivity are not directly connected to the exposure of climate change; however, in paddy production, these factors cannot be ignored. Sensitivity is spatially determined by the proportion of rice paddy areas in each kecamatan. For example, the paddy fields in the south and central regions, including Gianyar, Tabanan, Badung, and Denpasar, cover more than 20 % of the total area (Fig. 3). Experts on rice paddy production in Bali mentioned that the impact of agriculture on climate needs to be considered seriously for areas with more than 20 % of their land dedicated to agriculture (per com 2012). Therefore, these regions are perceived as areas that will be sensitive to climate impacts on rice production.

As a simple demonstration of the relationship between exposure and sensitivity, the top two maps in Fig. 4 show the change in the soil-climate suitability of paddy production. Areas circled with blue experienced reduced suitability when the precipitation has decreased. The map on the bottom shows the location of the



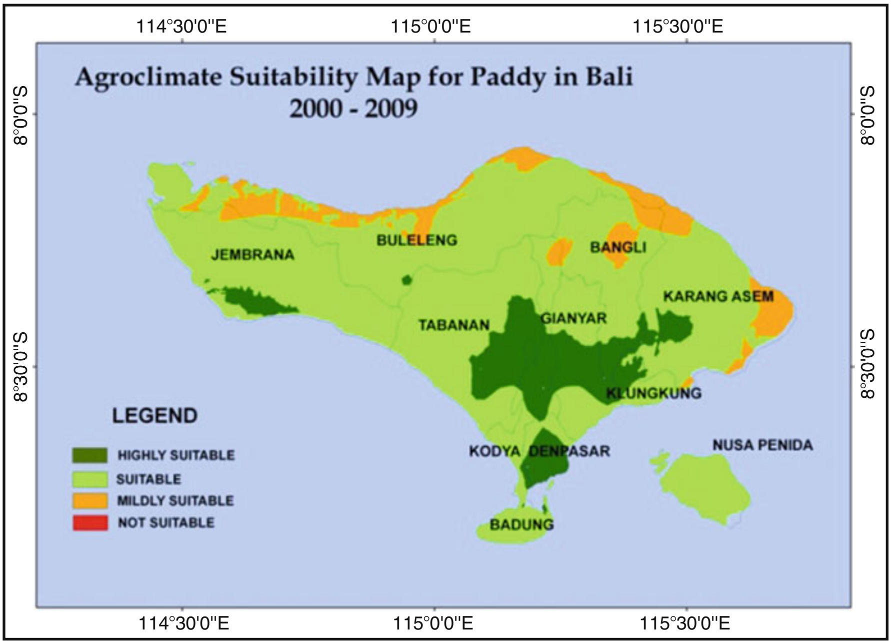


Fig. 2 Reduction of crop suitability: the dark green indicates the suitable areas and orange color indicates the less suitable areas for for rice production in Bali. The areas of dark green has decreased and the area of orange has increased in 20 years

Table 3 Total area and percentage of land suitability for paddy in Bali province

		S1: high suitability		S2: moderate suitability		S3: low suitability		N: not suitable	
	Regency	Total area (Ha)	%	(Ha)	%	(Ha)	%	(Ha)	%
1	Badung	392.6	1.1	10,346.2	27.9	26,046.6	70.4	234.9	0.6
2	Bangli	6.4	0.0	17,853.4	33.6	34,733.5	65.4	505.8	1.0
3	Buleleng			28,768.5	21.9	73,310.2	55.9	29,179.6	22.2
4	Gianyar	40.4	0.1	26,321.4	72.8	9,813.7	27.1		
5	Jembrana			18,675.2	22.7	58,355.0	70.9	5,308.7	6.4

9	Tabanan	5,239.5	6.0	49,248.5	56.6	30,595.5	35.1	1,994.3	2.3

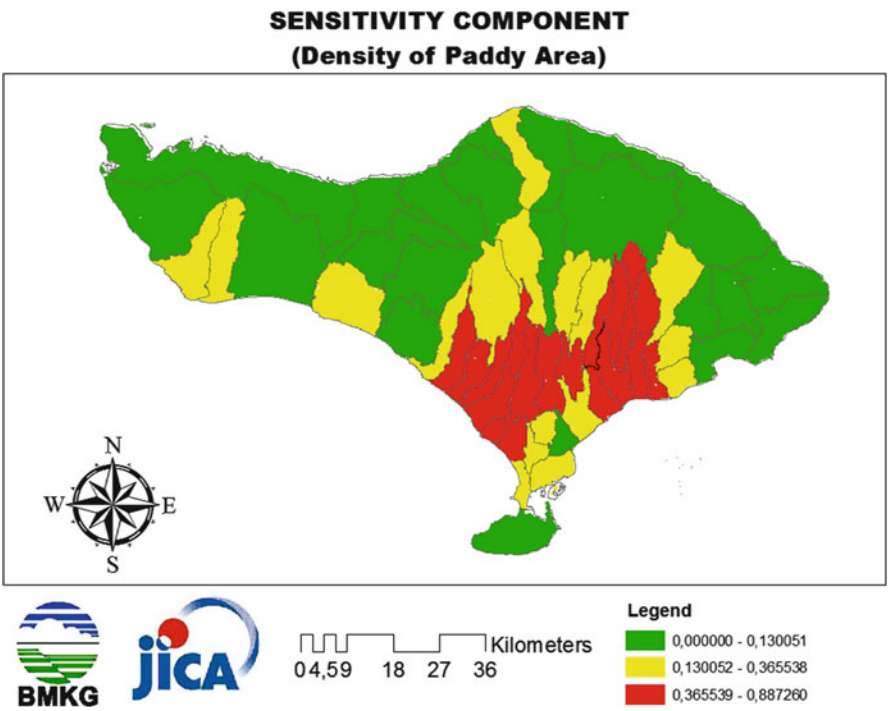

Fig. 3 Proportion paddy areas based on data from BPS-Statistics Indonesia. The red indicates the top 33 percent and green indicates the bottom 33 percent of sensitive areas for rice paddy production in Bali

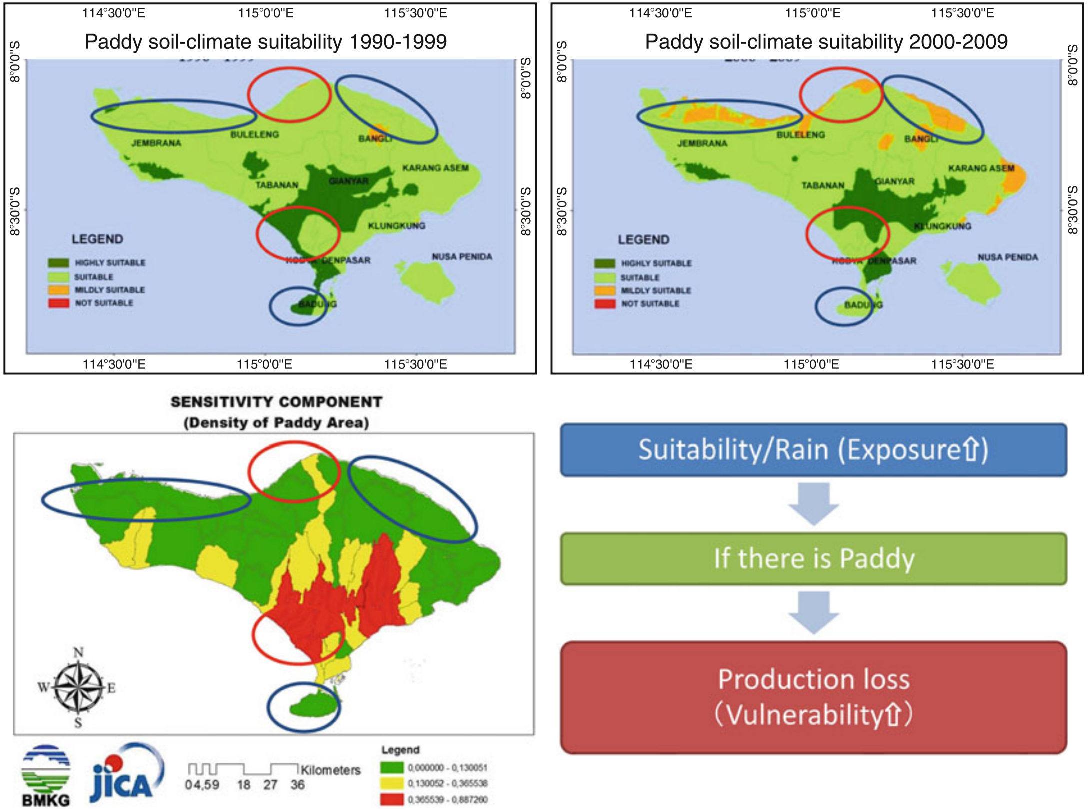

Fig. 4 Demonstration of spatial sensitivity on paddy production. Red circles indicate the areas the suitability has decreased and sensitivity (existing of rice paddy) is high. Blue circles indicate the areas suitability has decreased, but sensitivity is low

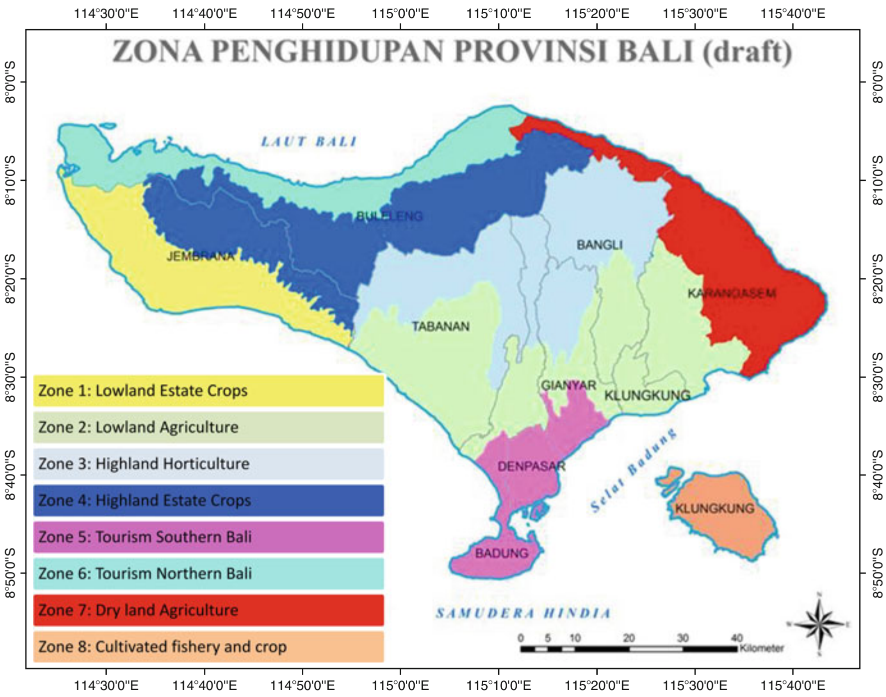

Fig. 5 Livelihood zone map in Bali: Livelihoods are categorized into eight zones based on a means of living through assets, activities, and capabilities

paddy fields. In the areas enclosed by blue circles, there are very few paddies, so the sensitivity in these areas is not high. Therefore, the "vulnerability" of rice production may not necessarily be high. However, the areas with red circles have experienced decreased suitability, and they have many paddy fields. Therefore, vulnerability is higher in these areas.

Adaptive Capacity

To determine adaptive capacity, livelihood zones were first estimated as shown in Fig. 5 after a development workshop and discussion during a stakeholder meeting. The zones explain the overall characteristics of the social activities and geographical features in Bali. The central part is the highland, and the south and southwestern regions are the lowlands. The northeastern region is drier. Typically, the northern and southern regions are more tourism-oriented, and agricultural activities are more important to the rest of the regions.

The survey showed that Zone 1 has the highest rice paddy productivity (74.72 kg/acre) followed by Zones 5, 6, 3, 4, and 2. Zone 7 has the lowest productivity (36.85 kg/acre). The high productivity in Zone 1 may come from the lowland farming. However, Zone 1 and Zone 5 are not paddy-intensive areas. That is, less productive farmers may have already quit rice farming, and only the highly productive farmers may have remained in the two zones. The type of farmers can explain why the survey showed such high productivity in Zones 1 and 5, although rice production is not as popular in these two zones as it is in some other zones. The correlation between farmers' formal education and the productivity of their paddies indicated that formal education does not affect rice paddy productivity. However, farmers with agricultural training produce 54.70 kg/acre, which is 2.65 kg/acre higher than that of farmers who have not had the training. Farmers who use only inorganic fertilizers have higher productivity (60.09 kg/acre) than farmers who use only organic fertilizers (55.21 kg/acre) or farmers who use both organic and nonorganic fertilizers (59.33 kg/acre). In any case, the use of fertilizer seems to affect the productivity of a paddy.

Regression Analysis and Normative Approach for Weighting Value Estimation

The project team is expecting to develop the vulnerability assessment to cover the whole of Indonesia in the future; therefore, scalability was an important consideration during the model construction. The microlevel quantitative data are difficult to access or are likely to be inaccurate in Indonesia. Therefore, the project focused on a model with only mesoscale and macroscale qualitative/categorical data. Regression analyses were carried out with ordinary least square, and the best fitted model is as follows:

$$\begin{aligned}\text{normhvst} = \alpha &+ \beta_1\text{two.cycle} + \beta_2\text{lowland} + \beta_3\text{infari} + \beta_4\text{only.inorganic}\\ &+ \beta_5\text{cooperative} + \beta_6\text{agritrain} + \beta_7\text{owner}\end{aligned}$$

Where:

- normhvst: KGs of unfilled grains per acre under normal conditions
- two.cycle: Dummy variable for cropping two cycles
- lowland: Dummy variable for a lowland paddy field
- infari: Dummy variable for a good variety, i.e., infari 13
- only.inorganic: Dummy variable for using only inorganic fertilizer
- cooperative: Dummy variable for a cooperative in their village
- agritrain: Dummy variable for agricultural training
- owner: Dummy variable for ownership

The coefficients for these variables are shown in Table 4. All coefficients are statistically significant at least to the 99.8 % level. All independent variables are dummy variables; therefore, the results are the same as those of the ANOVA model. Estimates indicate that all seven variables contribute to paddy production. It can also be explained logically the role of each variable in supporting paddy production. Farmers who grow paddy only once a year if their farmlands are not suitable for paddy farming due to lacking water have low productivity, while farmers who grow

Table 4 Coefficients of a paddy production OLS model

	Estimate	Std. error	t value	Pr(>|t|)
(Intercept)	35.15	1.79	19.69	0.00
two.cycle	9.35	1.38	6.75	0.00
lowland	9.27	1.33	6.98	0.00
infari	6.84	2.40	2.85	0.00
only.inorganic	6.11	2.00	3.06	0.00
cooperative	5.11	1.36	3.75	0.00
agritrain	4.14	1.42	2.91	0.00
owner	3.30	1.36	2.43	0.02

paddy three times a year also have low productivity due to decreasing soil nutrient. According to lapse rate, the temperature usually decreases with increasing altitude, and Luh (1991) mentions that the temperature greatly affects grain filling. Low temperature and high humidity during flowering will interfere with a fertilization process resulting in grains becoming empty and causing decreased paddy production, so paddy cultivation in lowland is likely to produce better than that in highland. Inpari13 is a superior variety with potential yield around 8.0 tons/ha; it is resistant to brown plant hopper and some diseases such as blass and "virus kerdil rumput"; grain of inpari 13 does not easily fall off so it can prevent yield loss at harvesting process by 1.34 % and 0.73 % at threshing process (BPTP Indonesia 2010). The advantage of inorganic fertilizers is that nutrients can be tailored to the needs of the plant. Most required nutrients for the growth and yield of the rice crop are N (nitrogen), P (phosphorus), and K (potassium), and these three nutrients are found in inorganic fertilizers. Within a cooperative, farmers share resources and it is easy to access the resources including fertilizer, seed, capital, and insecticide. Through agricultural training, farmers can improve their farming knowledge such as determining the appropriate planting time and choosing the appropriate variety. It is also proved by Suprapto (2010) that a farmer who has been taught by an extension worker has higher production than other farmers who has not been taught. According to Suprapto (2010), there is a correlation between a land ownership and the principal occupation as a farmer, so that those who have the ownership will focus more on running the farm and produce more than other farmers who rent a land.

If none of the variables are available, a farmer produces an average of 35.15 KGs/acre per paddy. The effect is largest with the usage of a two-cycle cropping pattern and is the smallest with the ownership. For example, if a farmer cultivates rice twice per year or owns the paddy field, the farmer can produce an extra 9.35 KGs/acre or 3.30 KGs/acre, respectively. In other words, two-cycle cropping and land ownership, respectively, improve production by 27 % and 9 % (Table 5). The set of percentage improvement was used as the starting point to determine the index for the adaptive capacity for paddy production.

Based on the regression analysis, an index for adaptive capacity was developed normatively via stakeholder meetings and a discussion with experts. In addition to the factors already included in the regression model, other factors might affect

Table 5 Marginal willingness to pay for intercept

(Intercept)	two. cycle	lowland	infari	only. inorganic	cooperative	agritrain	owner
1	0.27	0.26	0.19	0.17	0.15	0.12	0.09

production, including fertilizer types, excess water levels, dams, and land size. These factors are outside of the 10 % significant range; however, they are close enough to be significant to the level and are therefore logical to include.

Using inorganic fertilizer in a limited period can improve the productivity of paddy due to the composition of nutrient contained in the fertilizer. However, Syam'un (2001) states that the continual use of inorganic fertilizers can damage soil's physical properties, resulting a decrease in land productivity. Organic fertilizers provide a low impact on the growth and yield components. This can be overcome by a combination of organic and inorganic fertilizers (Syam and Sariubang 2001). Organic fertilizer can increase the paddy production when combined with a low dose of inorganic fertilizer. The area with an excess water level would ensure the water need of paddy so the plants will grow optimally and have better production. Similarly, the existence of dam will also guarantee the sufficient water for paddy, and water from dam is more stable. All four factors will help the rice production.

Therefore, the project team discussed key stakeholders the possibility of adding these factors. As a result, the project decided to include inorganic and organic mixed fertilizer in the model. The level was decided based on literature reviews and expert opinions (Table 6). Three studies estimating the advantage of the mixed fertilizer compared with inorganic fertilizer were used for the source of the discussion. The productivities rose between 77.3 % and 21 % in these studies, and the stakeholder meeting decided to take the middle value of 50 %. With the additional inorganic and organic mixed fertilizer effect (inorganic. organic), the weighting factor for adaptive capacity was settled as Table 7.

Characteristics of the Most and the Least Productive Subaks

The characteristics of the five most productive and the five least productive subaks were compared to understand the magnitude of the given impacts in extreme situations. Subaks in which less than four farmers were sampled were omitted from this assessment. The five most productive subaks are Baluk, Lanyahan, Berawan Tangi, Pangkung Jajang, and Pangkung Liplip. A total of 29 farmers were sampled from these five subaks, and, on average, they produce rice at 84.97 kg/acre. The five least productive subaks are Datah, Lebah, Penaban, Tegakin, and Pajegan. A total of 35 farmers were sampled from these five subaks, and they produce rice at an average of 30.86 kg/acre.

When the most and least productive subaks are compared (Fig. 6), the difference clearly reflects the factors affecting rice paddy production in the regression model. For example, in the five most productive subaks, 62.86 % of the farmers own their paddy field; in the five least productive subaks, only 34.48 % of farmers own their

Table 6 Literature review for inorganic and organic fertilizers

		Inorganic and organic fertilizer = 4.45 tons/ha	Inorganic and organic fertilizer = 5.28 tons/ha	
		Inorganic fertilizer = 2.51 tons/ha (increasing 77.3 %)	Inorganic fertilizer = 3.52 tons/ha (increasing 50 %)	Grain productivity was enhanced by 21 % and 24 % under CFM and CFS compared to CF, respectively

Table 7 Weighting factor for adaptive capacity before normalization

(Intercept)	two. cycle	lowland	inorganic. organic	infari	only. inorganic	cooperative	agritrain	owner
1	0.27	0.26	2.6	0.19	0.17	0.15	0.12	0.09

land. In terms of location, all farmers in the five most productive subaks are located in lowlands, whereas only 24.24 % of the farmers are located in the lowlands in the five least productive subaks. 71.42 % of the farmers crop twice in a year in the most productive subaks, and only 6.90 % farmers crop twice in the least productive subaks. Moreover, 80 % and 20 % of the most productive farmers/subaks are, respectively, located in Zones 1 and 3. In contrast, all of the least productive farmers/subaks are located in Zone 7.

The adaptive capacity scores in each livelihood zone are shown in Table 8. The score of adaptive capacity is an index, so meaning arises only through comparisons. On average, Zone 5 has the highest adaptive capacity score followed by Zones 1, 6, 2, 3, 4, and 7. The index for the adaptive capacity of the livelihood zones is mapped in Fig. 5. Generally, the southern and southwestern regions, which have excellent paddy production, have higher adaptive capacity scores, and the central and northeastern regions have lower adaptive capacity scores (Fig. 7).

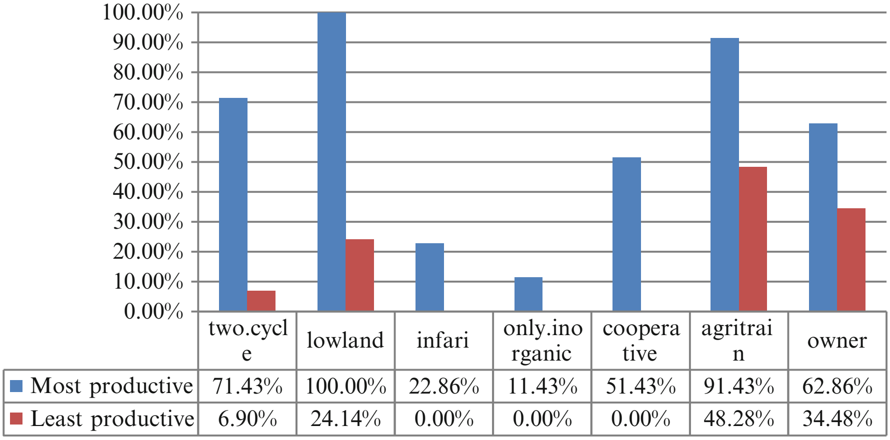

Fig. 6 Comparison between the most and least productive subaks based on seven factors used by the adaptive capacity model

Table 8 Adaptive capacity index for livelihood zones

Livelihood Zones	Min.	1st Qu.	Median	Mean	3rd Qu.	Max.	Sample no.

Zone 7	0.2606	4.401	9.529	10.76	15.05	26.32	67

Vulnerability Assessment Maps

Several versions of vulnerability maps and indexes were developed. Combining the three components changes the characteristics of the maps and indexes. For example, the maps were developed according to the livelihood zones, so the results are closely related to the actual activities of local people. If the maps had been developed based on political boundaries, such as kabupaten, then they might not have reflected the activities on the ground; nevertheless, political maps can be easier for public officers to interpret and use. Similarly, sensitivity can be defined as an exact rice paddy location or as a density/percentage in a given rice paddy area, such as kabupaten (district) or a livelihood zone. Giving a binomial value to an exact location (1 = exist, 0 = not) produces results that are easier to interpret. For example, one can conclude, "If there is no rice paddy field in the area, then the area will not sustain any damages to rice production." However, it can be harder to get a general overview of each political boundary or zone with binomial values.

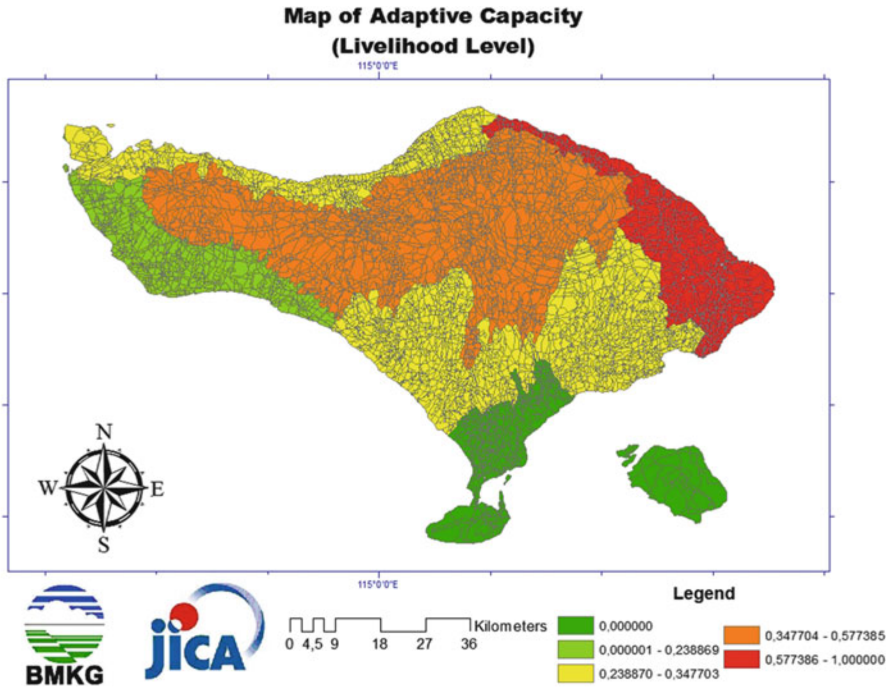

Fig. 7 Adaptive capacity for livelihood zone: green means high adaptive capacity and red means low adaptive capacity. Colors divide the adaptive capacity by 25 percents based on the ranking

As there is no universal agreement on how to make a vulnerability map, the project team verified their maps with stakeholders and local experts. Thus, the vulnerability map is based on a soil-climate suitability map as exposure, a paddy proportion at kecamatan as sensitivity, and rice paddy productivity with socioeconomic factors at livelihood zones as adaptive capacity. The combination was selected according to the needs and purpose of this vulnerability assessment.

After a discussion about the components with local experts, the weighting between the three components were determined as exposure = 0.3, sensitivity = 0.2, and adaptive capacity = 0.5 (Fig. 8). This figure describes all three characteristics of vulnerability in rice paddy production in Bali. The northeastern regions are vulnerable because of lower suitability which comes from drier climate and lower adaptive capacity. The central regions are vulnerable because of lower adaptive capacity. Tabanan is vulnerable because of its high density of paddy areas. The southern region is less vulnerable than Tabanan, because the region enjoys good climatic conditions and high adaptive capacity. Also, comparing the two maps in Fig. 8, there are changes in vulnerabilities in paddy production in Bali. The vulnerability has increased in northwest region and southeast region. The Tabanan area also has some rise in vulnerability.

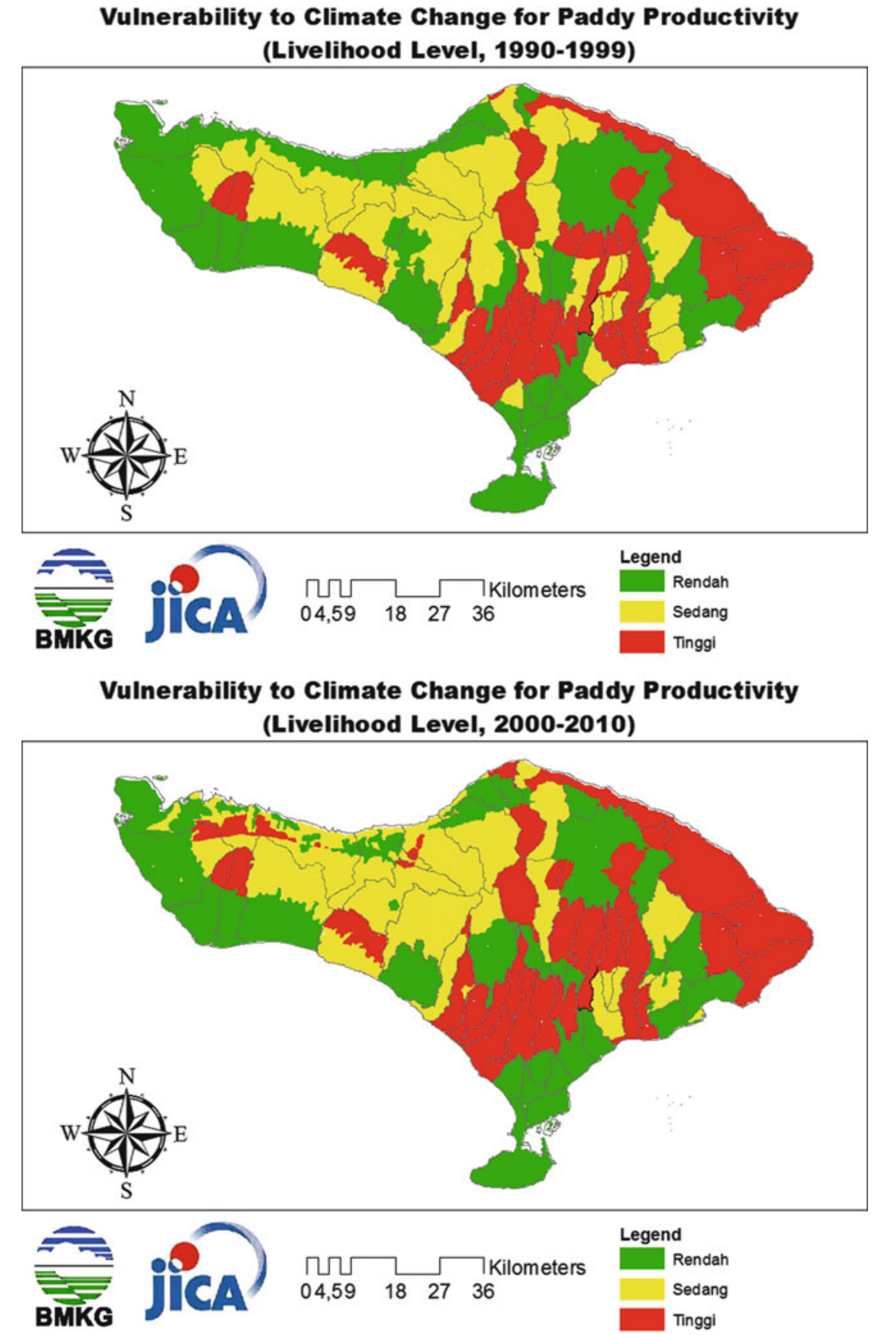

Fig. 8 Vulnerability map for rice paddy production: The *red color* indicates the higher indicate high vulnerability and the *green color* indicates low vulnerability. The *top figure* is the vulnerability based on 1990s climate and the *bottom figure* is based on 2000s climate

Discussion

A vulnerability index gives the overall picture of a vulnerability assessment. However, a vulnerability index will not give policymakers an entry point to plan adaptation measures, because they do not provide enough details about each component's unique characteristics. It is necessary to check the index of each component to understand the starting points for policy actions. An exposure index shows potential disasters, a sensitivity index shows the existence of exposure units, and an adaptive capacity index shows where abilities to handle the potential disasters are weak. For example, if policymakers need to know the location where potential disasters will happen, they need to check an exposure index and map. However, they also need to see a sensitivity map to check whether disaster-prone area has an exposure unit, and they must consult an adaptive capacity map to verify whether the exposure unit and related livelihood and stakeholders have enough adaptive capacities. The point is that checking each component is more practical than checking the weight of three components. Therefore, normative and abstract weighting between the three components is enough when a vulnerability assessment is implemented.

For example, the vulnerability map indicates high vulnerability in the northeastern region, and this vulnerability exists because of high exposure and low adaptive capacity. In this case, it is important to have proper policy actions to support the rice farmers in this region. Agricultural extension is one of policy tools that is used by a local government to encourage the development of agriculture, where agriculture extension workers have a significant role in helping farmers offering the information related to climate change and climate impacts and teaching new technologies to cope with the climatic impacts. It can be done among others through agricultural training. Our preliminary results show that a farmer who has received training from an agricultural extension worker is likely to increase their rice paddy production by 4 kg per acre, which is a 12 % gain in productivity. Strengthening the current extension system is one approach. If that is difficult due to the change in institution and management, other players such as universities, agrobusinesses, NGOs, and farmers' organizations may need to play a greater role. BMKG's climate field school is a successful example. Another way to strengthen the adaptive capacity is supporting the cooperative that can help the people to prepare for the high exposure in the region, because adaptive capacity is low there. Tabanan is a vulnerable area, but that is mainly due to high sensitivity. Therefore, policy actions will be different in Tabanan than they will be for the northeastern region. In Tabanan, the gravest concern will be catastrophic disasters and diseases, because the majority of land and farmers are engaged with rice paddy production. Therefore, the support for Tabanan can be ad hoc. For example, when a heavy drought is likely to come, the local authority may provide drought-resilient seeds and fertilizers to the farmers in Tabanan. Both climate and adaptive capacity are generally in good condition in Tabanan, so policymakers might not need to focus on training and cooperatives in this region.

If an area's productivity is low because of low adaptive capacity, policies on agricultural training and cooperatives can help adaptive capacity significantly and directly, and eventually, capacity development works will raise rice productivity. For adaptation planning based on a vulnerability assessment, the information from the three components is likely to be more useful than the final vulnerability value. Having said that, the vulnerability value is still useful for gaining a big picture of a region or a sector, but, to plan a policy, it is necessary to get information from the component level.

Moreover, Fig. 8 shows there are some changes in the vulnerability in the two periods between 1990s and 2000s. The assessment did not change sensitivity and adaptive capacity; therefore, the changes are all based on exposure such as climatic factors. Some parts of Bali have gotten drier, if the vulnerability increased. The final vulnerability map indicated not only climate change but also a vulnerability change in rice paddy production in Bali.

Perceptions of Climate Change and Impacts

Correlation and causation have to be carefully distinguished in the vulnerability assessment. In the survey result of adaptive capacity, farmers who do not perceive extreme events like flooding and their effects on paddy qualities and quantities as related to climate change have better production than other farmers, with a 95 % statistical significance. For example, farmers who do not consider the adverse effects of climate change generally produce about 5 kg of rice paddy per acre more than farmers who consider the effects. However, this does not mean that "no perception of climate change" results in better rice paddy production. Instead, these farmers already have better rice paddy production; therefore, they are likely to "not care about climate change." In other words, "good rice paddy production" can make these farmers ignorant of climate change and its potential impact. Thus, the ignorance factor should not be included to set up a paddy production function or vulnerability factors, because the causation from these factors to paddy production cannot be explained.

The climate-ignorant farmers enjoy good productivity now, but if impacts from climate change worsen and farmers continue to ignore them, then these farmers may not cope well with the adverse effects of climate change in the future. This is the definition of vulnerability from IPCC. The farmers who do not perceive climate change and its potential impact can be more vulnerable than other farmers, as the actual paddy qualities and quantities are affected by the change in climate. Moreover, the climate change assessment in the current project suggests that climate change seems to be happening in Bali. Ignoring these changes may affect future rice paddy production significantly for these uninformed farmers.

Roles of Agencies to Disseminate Climatic Information

Results show that farmers who have received training from an agricultural extension worker are likely to increase their rice paddy production by 4 kg per acre, which is a 12 % gain in productivity. Centennial Group International (2012) mentioned that the agricultural extension worker system has been weakened due to institutional and management changes, such as funding responsibility and provision of services. Therefore, at the present time, the agricultural extension system is not uniform. For example, only 2,560 extension workers, or 6 % of the total number, hold bachelor's degrees, and the rest hold lower qualifications. The agricultural extension system has a significant role to play in rice paddy production, and if the system declines, then productivity may also decline.

Conclusion

This report demonstrated how to develop a vulnerability index and maps with a quantitative and normative qualitative approach. Exposure as a potential disaster was presented by a soil-climate suitability map, and the map indicates climate change in Bali. Sensitivity was displayed as rice paddy production. Adaptive capacity was estimated by a regression model of social factors related to rice paddy production. The final map successfully indicated the regions that are vulnerable to reductions in rice paddy production due to climate change, which are, namely, the northeast, central west, and Tabanan regions.

The results of this assessment can be used for policy implementation, such as agricultural training. Since agricultural training will improve the production of rice more than 4 kg per acre, policymakers can improve the adaptive capacity of rice farmers by reinforcing agricultural training programs, which have been degrading. In addition, the results of the adaptive capacity assessment will be used to assess the vulnerability of rice paddy production. This assessment requires two more components: exposure to climatic impacts and sensitivity to such impacts. To utilize the vulnerability assessment in the future, continuous assessment and engagement with stakeholders will be necessary. Usually, less-capable farmers should receive higher attention in the vulnerability assessment, because the results indicate that they are vulnerable to the current climate and that the adverse effects of climate change will hit them harder. It is important to provide correct climate information to farmers, and developing vulnerability maps that are matched to the needs of users will help to support farmers and policymakers by providing comprehensive vulnerability information.

Abstract

Climate is one of the main determinants of agricultural productivity in Sri Lanka. Of the major climatic parameters, temperature, rainfall, and humidity are of special significance, as these cause a substantial impact on the agricultural productivity of the country. Consequently, farming systems and agronomic practices in most agricultural regions of Sri Lanka have evolved in close harmony with the prevailing climatic conditions of respective climatic regions of the island. The overwhelming scientific research has provided evidence of two general trends in Sri Lankan climate, i.e., increasing ambient temperatures resulting in more heat stress, and more frequent and severe occurrence of extreme rainfall anomalies such as droughts and floods. Both of these conditions strongly affect the crop and animal production and thus the food security in the country. The National Climate Change Policy of Sri Lanka, which was adopted in 2012, clearly endorses the need of appropriate adaptation strategies to reduce the impacts on crop and animal production so as to ensure national-level food security. While some of the strategies and actions have already been implemented as an effort to address the emerging negative impacts of climate change, scope still exists for new entry points for adaptation with a view to reduce the climate vulnerability of the agricultural sector in Sri Lanka while increasing the resilience of the entire community. One example of these actions is the development of seasonal climate forecasts that could assist farmers, business across the value chain, and the policy makers to develop improved climate risk management strategies leading to ensuring food security.

This chapter provides a comprehensive overview of the climate and climate-related risks faced by the agriculture sector of Sri Lanka and highlights the need to strengthen adaptation options to ensure national-level food security.

Introduction

Sri Lanka is an island in the Indian Ocean located at the tip of the Indian subcontinent. The country has a total land area of 65,610 km^2 including 2,905 km^2 of inland water bodies. The maximum width from east to west is 240 km and the length in north-south direction is 435 km. Sri Lanka is located between 5°55–9°5′ North latitudes and 79°42–81°53′ East longitudes and hence has an equatorial climate. Extensive faulting and erosion over time have produced a wide range of topographical features with three distinguishable elevation zones within the island: the Central Highlands, the plains, and the coastal belt. In the south-central part of Sri Lanka, the rugged Central Highlands spans around 65 km in north-south direction with peak elevation at 2,524 m. The Central Highlands is the hydrological heart of the country as almost all major perennial rivers originate here, spreading radially from the highlands to the coast. Most of the island's surface consists of plains between 30 and 200 m above sea level. In the southwest, ridges and valleys rise gradually to merge with the Central Highlands, giving a dissected appearance to the plain. A coastal belt about 30 m above sea level consists of scenic sandy beaches indented by bays and lagoons.

Despite its relatively small extent, Sri Lankan landmass exemplifies a variety of climatic conditions. There are four important geographical and topographical features in Sri Lanka, which considerably influence the climate over the island, in particular the rainfall regime. The first is the fact that Sri Lanka is a small island situated in the warm tropical Indian Ocean with associated warm, humid air. The second is its proximity to the equator, which results in solar radiation rarely being a limitation to crop growth under general weather conditions of the island. The third is the existence of a large mass of hills at the center of the island, which is perpendicular to two approaching moisture-laden monsoon wind streams (the southwest monsoon in the middle of the calendar year and the northeast monsoon towards the end of the year). The fourth factor is the presence of a vast landmass of the Indian subcontinent to the immediate north and northwest of Sri Lanka, which has a large effect in driving the monsoon. These four factors directly or indirectly influence the rainfall regime of the island. In general, the climate of Sri Lanka is considered as tropical monsoonal with a marked seasonal variation of rainfall. Of the major climatic parameters, temperature, rainfall, humidity, and evaporation are of special significance to Sri Lankan agriculture, impacting substantially on the agricultural productivity of the country.

This chapter focuses on the general climate of Sri Lanka, climate-induced risk factors that influence agriculture production (considering both crop and animal production), and the relationship of these to the food security of the nation.

Rainfall

Rainfall in Sri Lanka has multiple origins. Monsoonal and convectional rainfall, and the formation of synoptic weather especially in the Bay of Bengal, account for the majority of the annual rainfall. The average annual rainfall of the island (Fig. 1) varies from about 900 mm at the southeastern part of the Dry Zone (*Maha Lewaya* at Hambantota) to over 5,500 mm on the southwestern slopes of the Central Highlands (Kenilworth Estate at Ginigathhena) (Punyawardena et al. 2013a).

The rainfall experienced during a 12-month period in Sri Lanka can be characterized into four rainfall seasons, namely, first inter-monsoon (March–April; FIM), southwest monsoon (May–September; SWM), second inter-monsoon (October–November; SIM), and northeast monsoon (December–February; NEM).

First Inter-monsoon Season (March–April)

Warm, humid, and uncomfortable conditions, with thunderstorm-type rain, particularly during the afternoon or evening, are the typical weather conditions during the first inter-monsoon (FIM) season. The distribution of rainfall during this period shows that the entire Southwestern sector of the hill country receives 250 mm of rainfall, with some localized areas on the Southwestern slopes experiencing rainfall in excess of 700 mm (e.g., 771 mm at the Keeragala Estate). Over most part of the island, the amount of rainfall varies between 100 and 250 mm, the notable exception being the Jaffna Peninsula in the Northern Province, which has lower rainfall in the FIM season (e.g., Jaffna, 78 mm; Elephant Pass, 83 mm; Fig. 2).

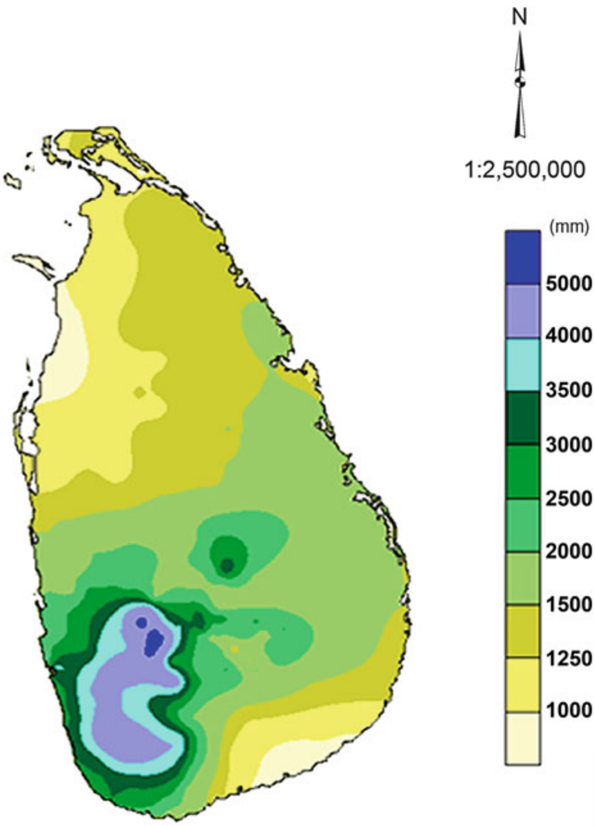
Southwest Monsoon Season (May–September)

Windy weather during the southwest monsoon (SWM) results in lower temperatures than those prevailed during the FIM season. The SWM rain totals vary from about 100 mm to over 3,000 mm (Fig. 3). The highest rainfall is received in the mid-elevations of the Western slopes (e.g., Ginigathhena, 3,267 mm; Watawala, 3,252 mm; Norton, 3,121 mm). Rainfall decreases rapidly from these maximum regions toward the higher elevation, as in Nuwara Eliya, it drops to 853 mm. The lowest rainfall is recorded from the Northern and Southeastern regions.

Second Inter-monsoon Season (October–November)

The second inter-monsoon (SIM) season is characterized by convective weather systems that typically generate thunderstorm-type of rain, particularly during the afternoon or evening (Fig. 4). However, unlike in the FIM season, the influence of weather systems such as low-level atmospheric disturbances, depressions, and

Fig. 1 Spatial distribution of the average annual rainfall in Sri Lanka (Source: Department of Meteorology, Sri Lanka)



cyclonic storms in the Bay of Bengal are common during this period. Under such conditions, the whole country can experience strong winds with a widespread, intense rain, which could lead to floods and landslides. The SIM period of October–November experiences the most evenly geographic distribution of rainfall in Sri Lanka. Almost the entire island receives in excess of 400 mm of rain during this season, with Southwestern slopes receiving higher rainfall in the range 750–1,200 mm (e.g., Weweltalawa, 1,219 mm).

Northeast Monsoon Season (December–February)

The dry and cold wind blowing from the Indian landmass will result in a comparatively cool but dry weather over many parts of Sri Lanka during the northeast monsoon (NEM) season, creating a pleasant and comfortable weather except for some rather cold morning hours in January. Cloud-free skies in January often provide days full of sunshine and pleasant and cool nights. During the NEM period, the highest rainfall amounts are recorded in the Eastern slopes of the Knuckles Range of the central hills (Fig. 5). The maximum rainfall is experienced at the

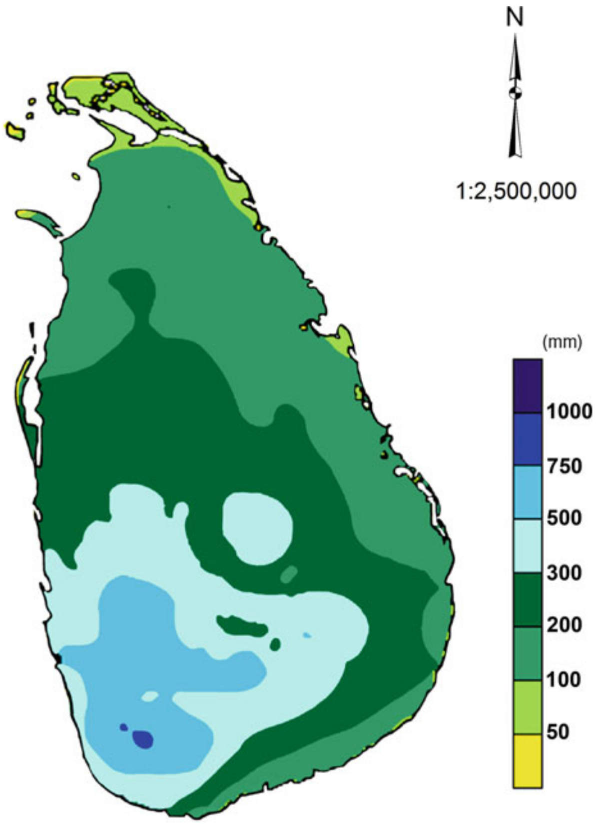


Fig. 2 Spatial distribution of the average rainfall in the first inter-monsoon in Sri Lanka (Source: Department of Meteorology, Sri Lanka)

Koboneela estate (1,281 mm), and the minimum is in the Western coastal area around Puttalam (e.g., Chilaw, 177 mm) during this period. There can be high interannual variability.

As depicted in Figs. 2, 3, 4, and 5, the four rainfall seasons do not bring homogeneous rainfall regimes over the whole island, thus leading to a high agro-ecological diversity in the country despite its relatively small extent. Out of the four rainfall seasons, two consecutive rainy seasons make up the major growing seasons of Sri Lanka, namely, *Yala* and *Maha* seasons. Generally, *Yala* season is the combination of FIM and SWM rains. As SWM rains are the highest over the country's Southwestern sector, the length (effectiveness) of this season in the rest of the country is generally confined only to 2 months (mid-March to early May), and hence, the *Yala* season is considered as the minor growing season of the country. The major growing season of the island, i.e., *Maha* season, begins with the arrival of SIM rains in October and continues up to late January/February with the NEM rains. Being mainly convective in nature, rains during the two inter-monsoon periods are usually associated with thunder and lightning along with short-duration high-intensity rains, especially during the FIM period.

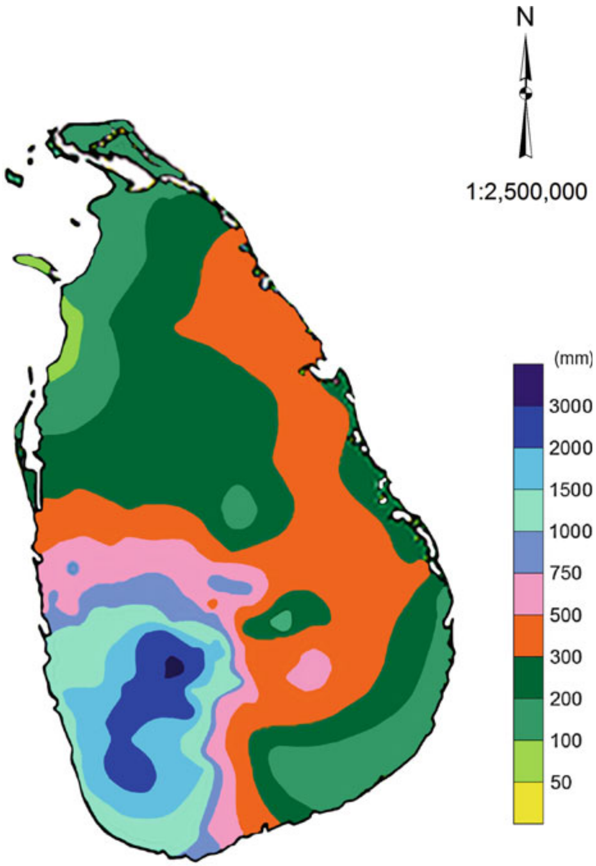

Fig. 3 Spatial distribution of the average rainfall in the southwest monsoon in Sri Lanka (Source: Department of Meteorology, Sri Lanka)

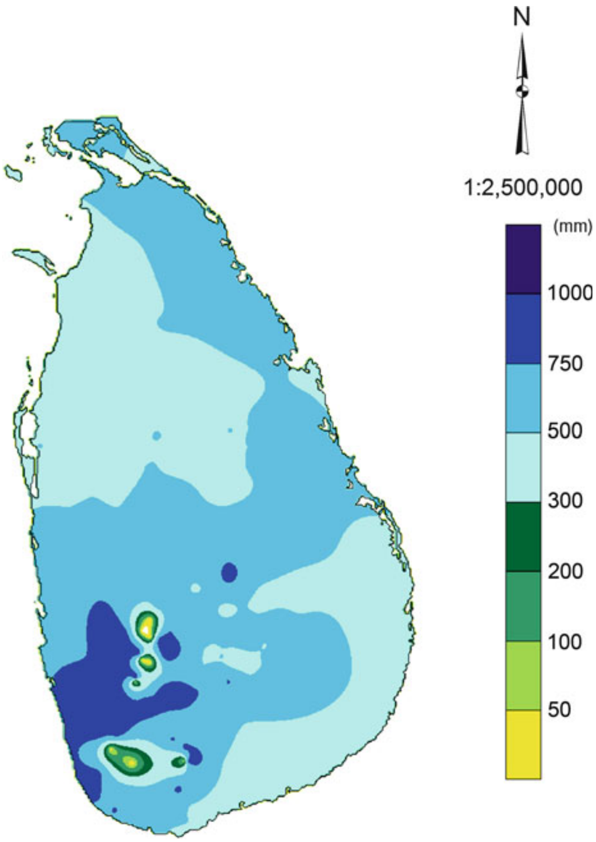
Temperature

The mean annual temperature in Sri Lanka manifests largely homogeneous temperatures in the lowlands and rapidly decreasing temperatures in the highlands. In the lowlands, up to an altitude of 100–150 m, the mean annual average temperature is 27 °C. In the highlands, the temperature falls quickly as the altitude increases. The mean annual temperature of Nuwara Eliya at an altitude of about 1,800 m is 15 °C. However, during the period of January to mid-February, the diurnal temperature variation around Nuwara Eliya is large, and thus, ground frost can be observed for about 3–7 days early in the mornings or nights when the temperature closer to the ground falls below the freezing point. However, during the period of May to September, if the westerly winds are strong, the leeward area in the east of the Central Highlands and the relatively flat terrain extending to the east coast experience warm, dry, and gusty winds. Such foehn-like winds are locally known as the *Kachchan* or *Yal-hulang*. In foehn conditions, the relative humidity

Fig. 4 Spatial distribution of the average in rainfall in the second inter-monsoon in Sri Lanka (Source: Department of Meteorology, Sri Lanka)



may fall to less than 50 %, causing vegetation and soil to dry out with possible bushfire disasters in Badulla and Moneragala districts. The coldest month with respect to the mean monthly temperature is January and the warmest months are April and August.

Relative Humidity

The relative humidity (RH) in Sri Lanka generally ranges from 70–90 % during mornings to 55–80 % during late afternoons depending on the geographical location. Relatively low humidity values (from 40–60 %) are reported in dry lowlands during June to August where the foehn-like wind (*Kachchan* wind) is often prominent. Comparatively high humidity condition that prevails during winter months (December to January) is one of the predisposing factors for plant disease outbreaks during the *Maha* season.

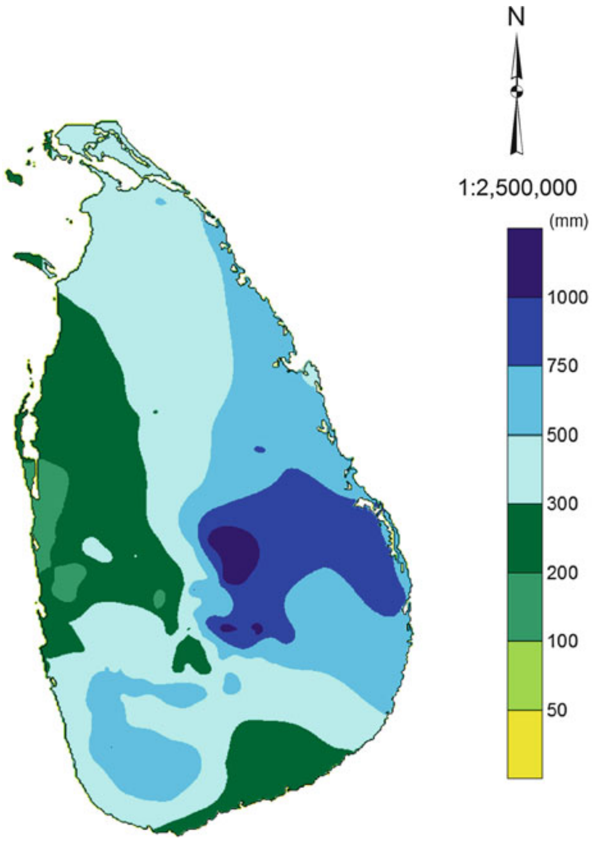


Fig. 5 Spatial distribution of the average rainfall in the northeast monsoon in Sri Lanka (Source: Department of Meteorology, Sri Lanka)

Evaporation

During the *Yala* season, pan evaporation is likely to range between 3 and 8 mm per day depending on geographical region. Higher values over 7 mm per day are often experienced in the dry lowland areas during this period. Meanwhile, a range of 2–5 mm per day is generally observed during the *Maha* season across different localities of the island.

Climatic Zones of Sri Lanka

Sri Lanka has traditionally been generalized into three climatic zones, namely, "Wet Zone" in the Southwestern region including central hill country, "Dry Zone" covering predominantly the Northern and Eastern parts of the country, and "Intermediate Zone," skirting the central hills except in the South and the West (Fig. 6).

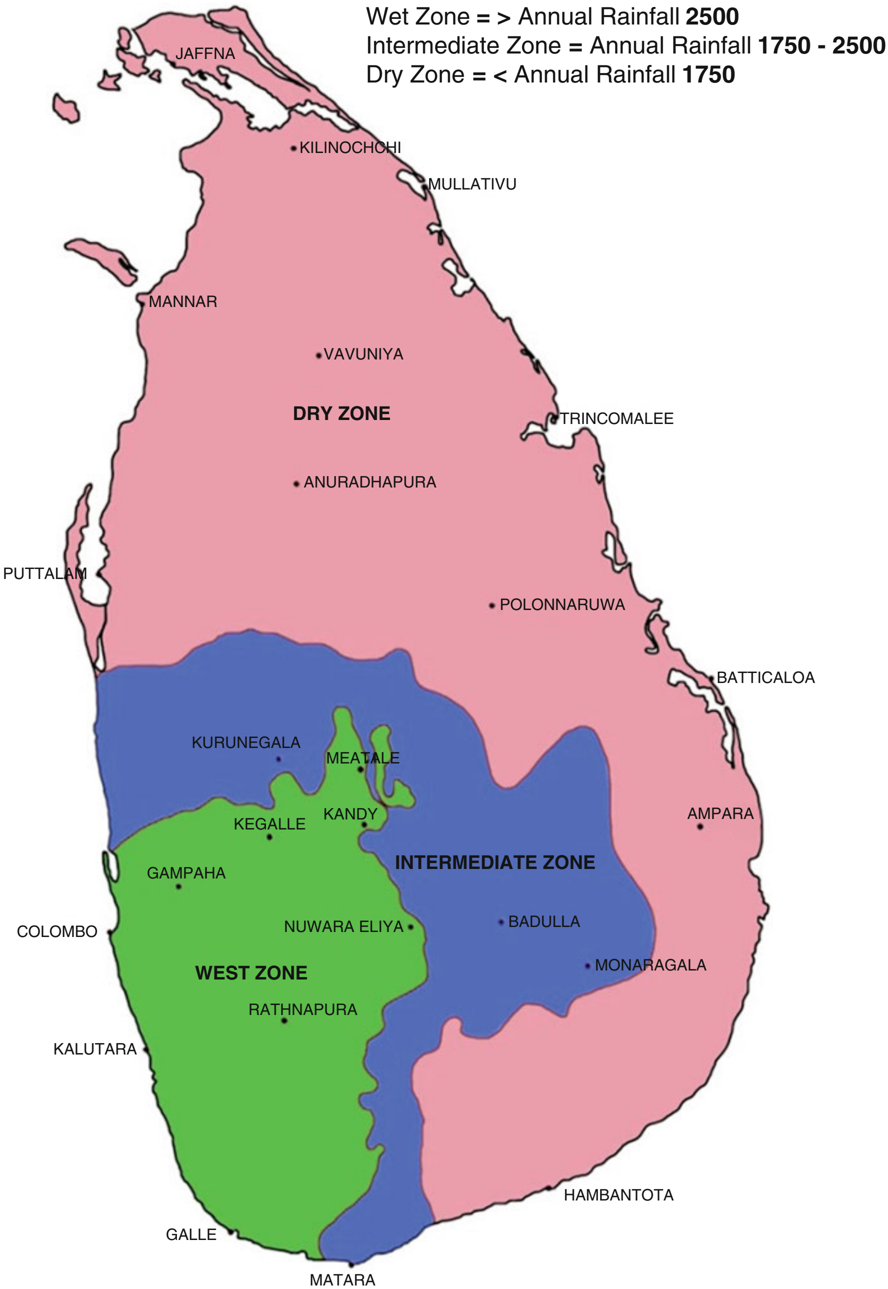

Fig. 6 Climate zones of Sri Lanka (Source: Punyawardena 2007)

In differentiating these three climatic zones, annual rainfall, contribution of southwest monsoon rains, soil type, land use, and vegetation have been widely used (Punyawardena 2007). The Wet Zone receives a relatively high mean annual rainfall over 2,500 mm without pronounced dry periods. The Dry Zone receives a mean annual rainfall of less than 1,750 mm with a distinct dry season from May to September. The Intermediate Zone receives a mean annual rainfall between 1,750 and 2,500 mm with a short and less prominent dry season. Sri Lanka has been further divided into 46 agroecological regions (Punyawardena 2007) that take into account the monthly rainfall amount (at 75 % probability) and distribution in addition to the parameters considered for identifying climate zones.

Climate Change in Sri Lanka

Sri Lanka possesses a long series of historical climatic data, especially rainfall and temperature records, which started from the 1860s in some locations. A recent analysis of these data has shown that the country's average temperature is significantly increasing at a rate of 0.01–0.03 °C per year (Fernando and Chandrapala 1995; Nissanka et al. 2011; Premalal and Punyawardena 2013). The increase is more pronounced in nighttime minimum temperature than that of the daytime maximum temperature (Marambe et al. 2012). However, due to high interannual variability, there are no discernible significant trends in seasonal and annual rainfall (Nissanka et al. 2011; Marambe et al. 2012), except a few locations among over 400 rain gauging stations of the country as has been found in many other locations across the globe. The same is true in terms of variability of cumulative and seasonal rainfall. However, it was evident that variability of seasonal rainfall during the most recent decade (2001–2010) has increased compared to the previous decade (1991–2000) in most places of the island across all three climatic zones with occurrence of more frequent drought and flood conditions.

A recent study focused on the occurrence of extreme positive rainfall anomalies in the central hills of the country has shown that in contrary to common belief, there is no significant increase of "heavy and very heavy" events in the region (daily rainfall values that exceeded the 95th and 99th percentile values, respectively, in each station from 1961 to 2010), but an apparent increase of such events during the period of 2006–2010 has been evident (Punyawardena and Premalal 2013). The temperature and rainfall projections in Sri Lanka under A2 and B2 scenarios using ECHAM4 general circulation model (GCM) for downscaling have revealed that the average annual temperature of Sri Lanka will increase with a range of 2.5–4.5 °C by the year 2080 under the A2 scenario and with a possible average annual temperature increase of 2.5–3.25 °C under the B2 scenario (Punyawardena et al. 2013a). Both these projections are analogous with the IPCC global projections of temperature changes at the turn of the century. In terms of the future rainfall climatology of Sri Lanka, projections with A2 scenario have revealed that Dry Zone will become drier while Wet and Intermediate Zones may become wetter than at present. In recent studies carried out in Sri Lanka, Marambe et al. (2012) and

Premalal and Punyawardena (2013) reported that climate change may be manifesting in changed conditions of the monsoons, with change in the date of onset and high variability, resulting in drier dry areas and wetter wet areas. Meanwhile, the B2 scenario uncovers a relatively complex situation of both Dry Zone and the Central Highlands of Sri Lanka to become drier than today as time progresses while the wetter parts of Sri Lanka to become further wet but at a lesser rate compared to the A2 scenario (Punyawardena et al. 2013b).

Vulnerability of Sri Lanka to Climate Change

Climate change is a cross-cutting issue and it is increasingly recognized as a necessary component of development-oriented decision-making process. In order for development investments to become resilient to anticipated climate change, it is important to understand the nature of vulnerability from a subnational perspective and reflect this variance in development strategies that are formulated at different administrative levels such as province, district, and divisional secretariat (DS) levels.

Punyawardena et al. (2013a), using 22 physical and socioeconomic parameters, which directly related to all three components of climate change vulnerability, namely, exposure, sensitivity, and adaptive capacity, have revealed that spatial variations of vulnerability of Sri Lanka to climate change varies according to socioeconomic, environmental, and institutional conditions of respective administrative districts in ways that do not necessarily follow the most exposed and geographically sensitive districts (Fig. 7).

The urban areas in the low-country Wet Zone except Ratnapura district are by far the least vulnerable to climate change in Sri Lanka, despite some exposure to climatic hazards such as floods. Communities in the Northern Province (excluding Jaffna Peninsula) and Puttalam and Ratnapura districts are confronted with very high degree of vulnerability due to high exposure, high sensitivity of livelihoods, and lower socioeconomic development. The major rice-producing districts of the island, namely, Anuradhapura, Polonnaruwa, Batticaloa, Hambantota, Monaragala, and Kurunegala (Trincomalee and Ampara in the Eastern Province are the exceptions), are located in the Dry and Intermediate Zones and are highly vulnerable to climate change. The mountainous districts of the Western and Eastern flanks of the central hills of Sri Lanka, namely, Kandy, Matale, Nuwara Eliya, and Badulla, along with Trincomalee and Ampara districts in the Eastern Province, show a moderate degree of vulnerability to climate change.

Food Security in Sri Lanka: Present Status

Food security (FAO 2009) in Sri Lanka is determined by several factors including diverse food systems and farming systems. Food systems in Sri Lanka are affected to different degrees by natural disasters induced by the climate change with a larger

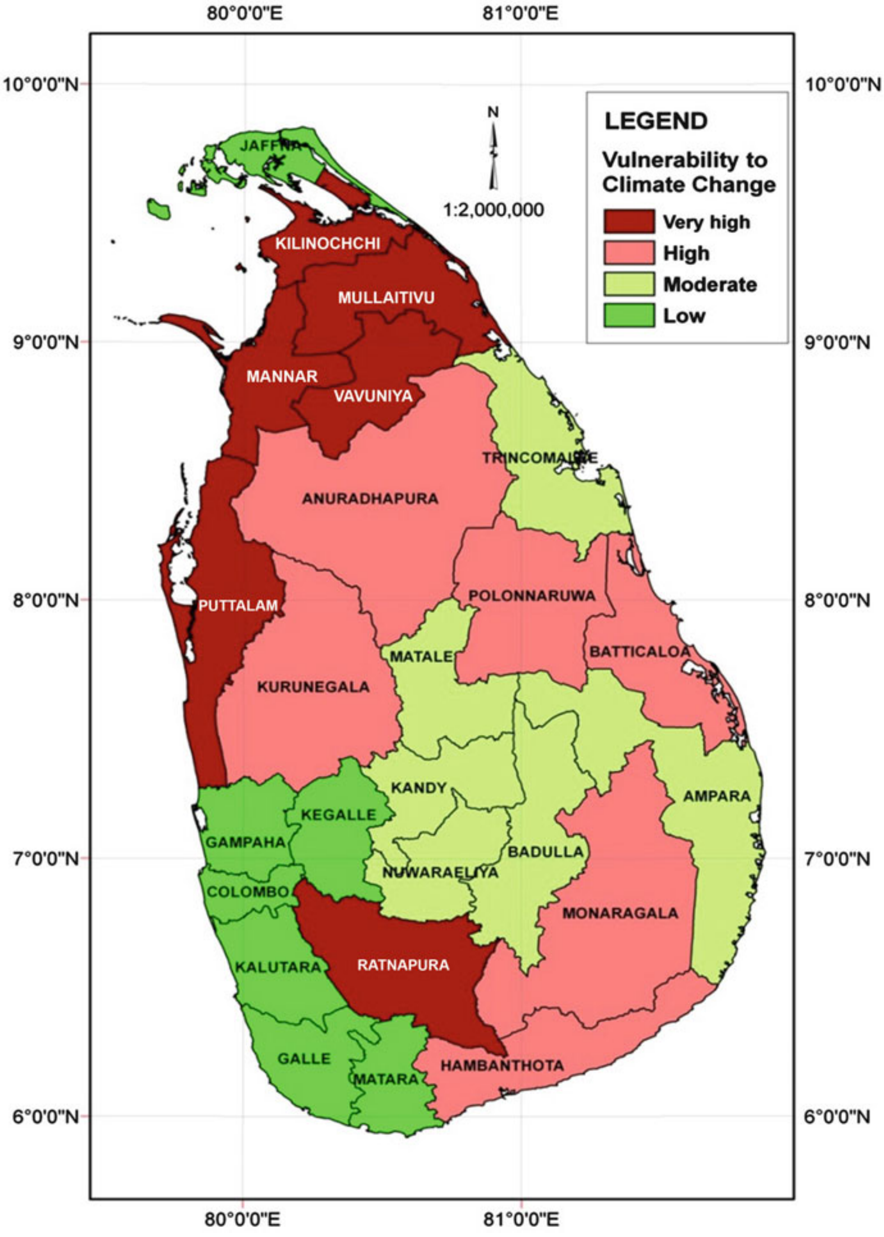

Fig. 7 Regional vulnerability of Sri Lanka to climate change (Source: Punyawardena et al. 2013a)

spatial variation. Sri Lanka's traditional farming systems have developed over hundreds of years with farmers managing production systems in the agroecological regions to best suit local environmental conditions. This has led to a rich agro-biodiversity in the island in terms food crops such as rice, cereals, pulses, vegetables, root and tuber crops, spices, and fruits. Changes in climatic conditions may, however, change the conditions that define the agroecological regions and reduce the productivity of crops and animals that are adapted to them. Conversely, they may allow new options in some areas. Currently, more than two million hectares are under some form of agriculture in Sri Lanka. However, much of the agricultural lands are located in the water-deficient Dry Zone where increased productivity of crops (other than paddy) depends almost entirely on rainfall.

In terms of food security, self-sufficiency in rice production has been the major strategy of agricultural policy since Sri Lanka gained independence in 1948. This has supported generation of employment and elimination of rural poverty. Sri Lanka reached the stated goal of self-sufficiency in rice in the year 2010 mainly due to the investments on research and development. The rice research outputs in Sri Lanka in the last half century further corroborate this contention in that on an average, for every 1 % increase in rice research investment, rice production increased by 0.37 % with an internal rate of return of 174 % in a tariff-protected regime and a benefit/cost ratio of over 2,300 (Niranjan 2004).

Poverty, climate change, decreasing arable agricultural land, and increasing population pressure are the main issues that render achieving the national-level food and nutrition security more challenging in Sri Lanka (Marambe 2012; Weerakoon 2013). The World Food Programme (2011) reported that out of the total population of Sri Lanka, 12 % are severely food insecure, of which 82 % are in the Northern and Eastern Provinces. Extreme climate events, such as the severe drought that prevailed over a period of 5–6 months in the year 2012, will provide its own challenges to food security in the near future. The Global Food Security Index 2013 (www.eiu.com/public/topical_report.aspx?campaignid=FoodSecurity2013) has ranked Sri Lanka 60th out of 107 countries. This index assists to identify and compare the core issues of food affordability, availability, access, and quality across countries.

Main Climate Risks for Food Security in Sri Lanka

The climate changes in recent decades in the forms of natural calamities like drought, flood, cyclone, accelerated land degradation, and sea-level rise pose serious threats to agricultural productivity and food security. Additional pressure coming from ever-increasing population, poor terms of trade, weak infrastructure, and limited access to modern technology and market restrict the options available for people to cope with the negative consequences of climate change. The main food-related agricultural products in Sri Lanka are crops such as rice and other field crops, fruits and vegetables, and animal products such as milk, meat, eggs, and fish. Sri Lanka has experienced frequent natural disasters in the wake of drought, flood, landslide, and cyclone events threatening its agricultural production. Coastal hazards such as coastal erosion and salinity intrusion to soils and aquifers are a common feature that affects agricultural production, especially in the drier parts along the Eastern coast of the country. Decreasing arable agricultural land, together with increasing population, renders these challenges more difficult to tackle. In Sri Lanka, most crops, e.g., coarse grains, legumes, vegetables, and potato, are likely to be adversely affected due to climate change (Titumil and Basak 2010).

The varied climatic conditions in the farming systems of Sri Lanka have given rise to a wide range of crop species and land races that are suited for different conditions of soils, rainfall, and altitude as well as to diseases and insect pests. Genetic diversity is particularly high among rice, other cereals, cucurbits, and vegetables such as tomato and eggplant, indicating the potential for crop improvement in the face of natural disasters such as climate change, as an adaptation measure. The genetic diversity of crop plants is the foundation for the sustainable development of new varieties for present and future challenges. Resource-poor farmers have been using genetic diversity intelligently over centuries to develop varieties adapted to their own environmental stress conditions. Systematic crop comparison programs under different agroecological regions of Sri Lanka through farmer participatory programs, strengthening the crop germplasm collection programs conducted by the Department of Agriculture with special focus on climate change, and creating access to and drawing in new genetic materials through intergovernmental programs to enhance food production would strengthen the strategic approaches for adaptation in Sri Lanka, thus minimizing the climate risk on food security.

In spite of the technological advances made on improved crop management, irrigation, plant protection, and fertilization, weather and climate are still key factors in agricultural value chain in Sri Lanka. Farming systems and agronomic practices in most agricultural regions of Sri Lanka have evolved in a close harmony with the prevailing climatic conditions of respective climatic regions of the island. However, it has been evident during recent decades that heritage of farming experiences and accumulated weather lore of centuries have become ineffective in agricultural planning process at all levels. The climate of the island has undergone a change to such an extent that correct amount of rainfall does not come at the correct time of the growing season.

Variability of both summer and winter monsoon rains and rains of convectional origin has increased significantly during recent decades in the world. As a result, both extremes, i.e., water scarcity and excess water, have become a recurrent problem in crop production and its entire value chain in Sri Lanka. More flexible farming approaches with water-efficient farming methods and crops to improve water productivity, construction of new reservoirs and trans-basin diversions to meet the demand, and management of water resource systems that respond to existing soil moisture and water storage levels are thus essential adaptation strategies to be used coupled with an improved climate forecast system.

Increasing ambient temperature is also inflicting several direct and indirect negative impacts on the crop growth. Urgent coping-up strategies such as identification of new areas for crop production, introduction of new climate-resilient crop varieties, organic agriculture, cropping systems including agroforestry, rainwater harvesting systems, and micro-irrigation techniques would assist in overcoming the negative impacts of higher environmental temperatures.

The intensively managed animal production sector is hardly vulnerable to the climate compared to impacts on the food crops sector. Nevertheless, the situation is obviously different for the extensively managed animal production sector where it is purely dependent on the rainfed pastoral systems and subjected to direct influence of climatic conditions. The animal production sector of Sri Lanka is signified mostly by smallholders spread across varying climatic regimes. The localized impacts of climate change are more visible in the areas where smallholder and subsistence farming are practiced as they are highly vulnerable to the localized trends of climate change. However, the high genetic variability that exists, especially among indigenous animal categories, and their adaptability to the diverse and localized climatic regimes in the country render a positive influence in building up resilience in smallholder sector by balancing the impacts of climate variability within the system of farming. Despite the importance of smallholder systems to the animal production sector of Sri Lanka, an understanding on the interaction of climate change and animals in the country is not effective enough to face the future development challenges of the sector.

Irrespective of the sectoral characteristics, the impact of climate change on any sector depends on how and what intensity the rainfall regime in a given area is variable along with the increasing environmental temperature of the same area. In addition, if the area lies in a coastal environment, the sea-level rise and the risk of increased storm surge would bring in more additive negative effects.

Impacts of Changes in Rainfall and Soil Regimes on Food Security

Increased occurrence of extreme rainfall events due to climate change, droughts, and floods has become a common feature of the climate of Sri Lanka during recent decades. It is clear until the mid-1980s that any within- or between-season variation in rainfall could be statistically accommodated within a 95 % confidence interval. However, weather aberrations that have taken place after the late 1980s could be considered as unprecedented because they fall outside even the 90 % confidence limits. Under such situations, crop losses due to decreased soil moisture and excess water, both in terms of quantitative and qualitative, are inevitable.

In Sri Lanka, more than the temperature regime, the amount and distribution of seasonal rainfall have a profound impact on the productivity and food security in different agroecological environments. Out of the 46 agroecological regions of the country, 31 of them spreading across both Dry and Intermediate Zones are more delicately poised than those of the Wet Zone in relation to rainfall seasonality and variability. Aberrations or change in rainfall pattern will therefore have a major impact on food security in the Dry and Intermediate Zones. These two climatic zones have four major great soil groups of agricultural significance, namely, reddish brown earths (RBE), non-calcic brown soils (NCB), red-yellow latosols (RYL), and regosols, that will be affected at varying degrees under variable and changing climate, thus affecting food security of the country, as described below.

Reddish-Brown Earth Region

Reddish-brown earth (RBE) is the most widespread great soil group of Sri Lanka, and it occupies mainly in DL_{1a}, DL_{1b}, DL_{1c}, DL_{1d}, DL_{1e}, DL_{1f}, DL_5, and IL_2 agroecological regions covering an aerial extent of 1.61 million hectares. The soil moisture relationships of this soil are characterized by a low water holding capacity with a rapid release of soil moisture at tensions lower than one atmosphere. It is also characterized by having a gravel layer in the sub-horizon. The depth to this gravel layer is quite variable, depending on the agroecological region. Due to the aforesaid soil moisture characteristics of this soil group, negative anomalies of seasonal rainfall that may arise frequently under a changing climate will manifest as drought injuries in upland crops at varying degrees. It is equally true that the positive anomalies of seasonal rains could lead to excess soil moisture conditions with drainage problems in upland crops due to impervious gravel layer in the subsoil of this soil group.

About 80 % of the country's coarse grains (i.e., maize and millet) and grain legumes (green gram, cowpea, black gram, and soybean) are grown on this soil group during the *Maha* season in the above-stated agroecological regions. Thus, it is likely that climate change would exacerbate the crop losses and severe instability in a year-to-year production in those farming systems due to drought and excess soil moisture conditions.

The other most dominant farming system associated with this soil group is rice cultivation in irrigable lowland during the *Maha* season and perhaps during the *Yala* season depending upon the availability of water in the tank system (irrigation reservoirs). These tanks have been constructed as a cascade system by blocking the natural drainage ways in a watershed by means of earthen dams to collect the rain and runoff at appropriate places to form a series of small tanks along the drainage way. More importantly, these tanks, known as the "minor tanks" (reservoirs with an irrigable area of less than 80 ha), provide the livelihood of a large section of the rural population in the RBE region. An estimated number of 8,500 working minor tanks are reported to provide water for 43 % of the total irrigated area in the country. These estimates suggest the great importance of minor tanks in Sri Lanka, especially for the RBE region. Generally, the catchment of these tanks is relatively small, owing to the undulating landscape of the region.

Shifting cultivation or chena cultivation is the common land use practice in these catchments for decades by the villagers, and as a result catchment yield has been declining gradually over the years. Apart from reduced inflow to the reservoirs, chena cultivation has also led to soil erosion and subsequent sedimentation of tanks, leading to reduced storage and increased surface/depth ratio.

Rainfall regime in this region has become highly erratic during the recent times due to climate change, resulting in below-average storage conditions even during

Maha seasons. Meanwhile, increasing ambient temperature regime, coupled with high surface/depth ratio of tanks in this region, has resulted in rapid drying out of these tanks to make the situation become worse. All these have led the farmers who find their livelihood from these tanks to look for other livelihood alternatives or migrate to urban areas for nonagricultural livelihood options.

Non-calcic Brown Region

The non-calcic brown (NCB) soil group is mainly confined to DL_{2a} and DL_{2b} agroecological regions in Ampara and Batticaloa districts along with the IL_3 region in the northern part of Kurunegala district, covering a total area of about 165,000 ha. This is a coarse-textured soil with very poor chemical properties. Due to the unimodal nature of rainfall pattern in the DL_{2a} and DL_{2b} agroecological regions, only a single crop is possible in those regions during the *Maha* seasons.

During the recent times, the variability of NEM has been increased dramatically due to climate change, and as a result a significant instability in season-to-season rainfed agriculture production is inevitable in this region. Nevertheless, wetland rice cultivation in valley bottoms, where NCB occurs in a complex association with relatively fertile old alluvium soils, may manage to give good yields even under a changing climate unless extreme positive rainfall anomalies cause flood damages in these regions. The IL_3 agroecological region in Kurunegala district is frequently subjected to moisture stress due to its own rainfall pattern and coarse texture of the underlying soil. Thus, negative anomalies of rainfall may aggravate the drought injuries in this region even with the dominant tree crop of coconut.

Red-Yellow Latosol Region

The great soil group red-yellow latosol (RYL) mainly occurs in the DL_3 agroecological region in the Northern Province with an aerial extent of 320,000 ha. It generally overlies a very porous limestone substrate, which provides a stable groundwater source throughout the year. Cultivation of high-value crops such as chili, onion, and vegetables under lift irrigation is the common cropping system in this region. Even though it was used to be a sustainable land use system with traditional lifting devices (*Thula Kinnaru*), the use of motor-powered lifting pumps has exponentially increased the rate of groundwater extraction, which could increase the vulnerability of the farming system to climate change.

Regosol Region

The regosol soils are located mainly on the elevated beach plains with a flat topography in the Batticaloa and Puttalam districts. Despite the dry environment that prevails in these regions, the soil supports very productive coconut plantations and cashew cultivations by underlying freshwater supplies found at a shallow depth. In some places (Kalpitiya peninsula), these soils have been widely used for intensive cultivation of high-value crops such as chili, onion, and vegetables under lift irrigation from shallow wells. However, extraction of water extensively from the shallow water supply would make the entire farming system in these regions highly vulnerable to climate change, even posing threats to drinking water supplies of the community.

Generally, rice cultivation in the Dry and Intermediate Zones possesses a considerable resilience to climate change compared to other cropping systems in those regions due to the availability of irrigation water. The animal component of the widespread mixed (crop-animal) systems across all the above regions will have an indirect influence of the rainfall pattern and soil regime due to the changes in feed availability. A recent study has shown that even the Wet Zone of Sri Lanka is undergoing significant changes in its rainfall rhythm (Premalal and Punyawardena 2013). Some years have become "years of extremes" where within a shorter time period (i.e., 1 month), a flood-stricken area of the Wet Zone could turn into a drought-affected area.

Impact of Floods and Drought on Food Security

In the food crop sector, the occurrence of floods has affected paddy production in Sri Lanka significantly compared to other crops, with heavy damages being recorded during *Maha* season 2008/2009, resulting from a peak of flood incidences in December and March. Kilinochchi and Ampara districts in the Dry Zone of Sri Lanka have reported the highest losses of paddy due to flooding during the 6-year period from 2005 to 2010 (Fig. 8).

Poultry industry was highly affected by flood incidences during the period 2005–2008 when compared to the rest of the animal production sector. Losses in the animal production sector were high during the *Maha* season, as in the case of crops, and the month of December has recorded the peak of animal losses due to floods. Kilinochchi, Jaffna, and Ampara districts have shown higher levels of animal losses due to the occurrence of floods during the period 2005–2010 (Fig. 9).

The continuous occurrence of drought over the years has resulted in a consistent pattern of crop damage, with a severe impact recorded in 2009. Crop losses were higher at the onset of the *Yala* season and at the end of the *Maha* season. The highest crop losses were observed in Kurunegala (Intermediate Zone) and Matale (Wet Zone) districts during the period 2005–2010 (Fig. 10).

Drought has also affected the poultry and cattle industries over the period 2005–2010. The cattle industry was significantly affected by drought especially during 2006 and 2007, while the poultry industry was badly hit in 2009. The highest animal loss was observed in Kilinochchi and Batticaloa districts in the Dry Zone during the period 2005–2010 (Fig. 11).

Impacts of Increased Temperature Regime on Food Security

Being a tropical island with a uniformly high-temperature regime, most of the cultivated crops in Sri Lanka operate near the maximum of the optimum temperature range of respective crops. This phenomenon is true for animal production, too. Thus, crop injuries and animal production losses due to high temperatures are inevitable in Sri Lankan agriculture with increasing temperatures. This is of particular importance for the country's major staple food, rice. It is a well-established fact that high-temperature injuries in rice are inevitable if the plant is exposed to an ambient temperature that exceeds 33 °C just for 60–90 min at the anthesis stage (flowering; Punyawardena 2011). It was used to be a rare event to experience such high values of daytime temperature in major rice-growing regions of the country; however, recent agro-meteorological observations have confirmed that the frequency of such temperature events has increased significantly in both Dry and Intermediate Zones, especially during *Yala* seasons, resulting in high rates of unfilled grains due to increased spikelet sterility (known as *Ehela Pussa*). Higher temperature regimes will also increase the evapotranspiration losses, leading to frequent soil moisture stress conditions in upland crops. Recent investigations have clearly shown that the nighttime minimum temperature in many locations of the country has been increasing during recent decades, resulting in diurnal temperature range to become increasingly narrower.

Even though root and tuber crops are more resilient to temporal variations of rainfall, a decreasing trend of diurnal temperature range is likely to cause negative impacts on the root and tuber crop production in the country. This will be highly reflected in potato production in the central hills as the existing environmental temperature regime is suboptimal for the crop even in the up-country region where the crop is mainly concentrated. The quality of the harvestable parts of crops is also to be affected negatively due to several reasons, which may arise due to climate change.

Increased temperature, especially the nighttime minimum temperature, tends to decrease the sugar translocations to harvestable fruits and thus reduce the quality by increasing sour taste in fruit crops. Meanwhile, the fiber content of the harvestable parts of crops is also likely to increase under increased temperature regimes, thereby reducing the palatability of them.

The heat stress conditions in animals under increased ambient temperature reduce the fertility and productivity of all categories of livestock and poultry, especially in high-yielding exotic breeds. This has a direct influence on production losses in the case of dairy and egg production. As the heat load accumulation inside the animal body has a profound adverse effect on the rate of growth, the meat production also gets affected significantly irrespective to the system of operation, intensive or extensive.

The yield of almost all crops grown and animals reared in the country would also be negatively affected due to increased insect pest damages and infestation by all kind of pathogens such as bacteria, virus, and fungi especially under humid conditions. Even though higher yield losses due to increased weed infestation are likely to occur with increasing temperature, recent studies have shown that there is no such trend under local conditions. However, it is too early to generalize that such threats would not occur in the future.

Apart from the direct impact of increased variability of rainfall and rise of ambient temperature, indirect effects of increased rainfall intensities are of special significance in terms of land degradation, which has a significant bearing on the crop production in Sri Lanka. Increased temperature is likely to enhance the local-scale convection and thereby to form more cumulonimbus clouds, giving rise to high-intensity rains (>25 mm/h). Such rains invariably will wash away the fertile top soil of arable lands and will lead to subsequent siltation and eutrophication of downstream reservoirs and any other surface water bodies. Moreover, increased temperature and frequent and negative rainfall anomalies are also likely to cause high evaporative demand of the atmosphere. This can cause salinization of agricultural lands in the semiarid parts of the country.

Impacts of Sea-Level Rise on Food Security

Being an island, Sri Lanka is highly vulnerable to sea-level rise with varying degrees of sectoral impacts. It is highly confident that seawater intrusion to agricultural lands will be an inevitable event under a changing climate, which will lead to further reduction of land available for agriculture.

Increased sea-level rise will also exacerbate the coastal erosion, giving rise to some additional pressure on land available for agriculture, directly and indirectly. Also, it may reduce the quality of both drinking and irrigation water in coastal regions by disturbing the interface between freshwater and brackish water. It is highly likely that sea-level rise will disturb the Ghyben-Herzberg lens of freshwater found underneath of regosol in coastal regions. These freshwater lenses provide the irrigation water for intensive agriculture in those areas.

Adapting to Climate Change Aiming at Food Security

Being cognizant of the importance of adapting to climate change, the government of Sri Lanka has taken several initiatives at the policy level by developing the National Climate Change Policy (NCCP) of 2012 (Ministry of Environment 2012) and the National Climate Change Adaptation Strategy (NCCAS) 2010–2016 (Ministry of Environment and Natural Resources 2010). While the three main policies that deal with the agriculture sector related to food security, namely, the National Agriculture Policy of 2007 (Ministry of Agriculture and Agrarian Development 2007), National Livestock Development Policy of 2007 (Ministry of Livestock and Rural Community Development 2007), and the National Fisheries and Aquatic Resources Policy of 2006 (Ministry of Fisheries and Aquatic Resources 2006), are in operation, the NCCP and NCCAS are expected to mainstream climate change adaptation into the national planning and development process.

Rice

Rice being the major staple of Sri Lankans, more efforts have been made by the scientific community to provide suitable materials resilient to changing and variable climatic scenarios. A recent study has indicated that rice farmers in the Kurunegala district of Sri Lanka (Intermediate Zone) have lost 44 % of the agriculture income every season due to drought (Chandrasiri 2013). Chandrasiri (2013) also reported that the awareness of climate change among the farmers is high, but the adaptation is poor due to the lack of knowledge on adaptation methods, unavailability of prior information on climate change, absence of suitable cultivars, and lack of funding. A recent study (Herath and Kawasaki 2012) also reported that the variability of rice yield under the future climate conditions in the Kurunegala district of Sri Lanka shows small increasing trends, averagely 1.7 % and 2.4 % under the A2 and B2 scenarios, respectively. More yield-improving techniques are required to achieve the future rice requirement of the country under the impacts of climate change.

Several successful attempts have been made in the rice production sector in the technological front to meet the challenges of climate change. The development of rice varieties, which are of short duration and suitable for short growing seasons (Harris and Shatheeswaran 2005) and high CO_2 concentration (De Costa et al. 2007), is in the forefront of technological innovations. The recent release of ultrashort-duration rice varieties by the Sri Lanka Department of Agriculture such as Bg250 maturing in 75–80 days is a positive response by the government of Sri Lanka to cope up with climatic changes. Gunawardana et al. (2013) reported on the potential for adoption of aerobic growing conditions for rice varieties minimizing the water use under changing climatic conditions while assessing the competition for weeds.

Studies carried out in Sri Lanka to identify the role of traditional paddy varieties and organic practices in adapting to climate change especially in the coastal belt have indicated that farmers have perceived climate change in rainfall patterns, intensity and timings, changes in the cloud formations, and other indicators such as the behavior of animals. As the sustainability of food production through traditional farming patterns is being challenged, farmers have been following water-conserving agronomic practices such as *Kekulama* or *Manawari* system and *Nava Kekulama* (dry-sowing systems; Upawansa 2013) and the System of Rice Intensification (SRI) (Somaratne 2010) and are also making informed choices in species selection by combining local knowledge on species and varieties under the guidance of several NGOs (Berger et al. 2009). Jayawardena et al. (2010) reported that paddy cultivation in the Dry and Intermediate Zones in Sri Lanka under zero-tillage condition has enabled a reduction in cost of production and enhanced water conservation without significantly affecting the yield. Breeding of salt-tolerant rice varieties is also a primary adaptation measure to maintain national rice production levels and ensure food security in the face of expanding salinity due to sea-level rise. In this regard, the salt-tolerant rice variety At354 (3½ month age class) has been developed by the Sri Lanka Department of Agriculture to meet food production challenges under saline conditions. Salinity in paddy fields could also be overcome by a combination of agronomic measures including improved field drainage, application of organic manure, rice straw and burnt paddy husk, and transplanting rice instead of direct seeding.

With more frequent extreme rainfall events, the area under major irrigation reservoir schemes (reservoirs with an irrigable area of more than 200 ha) in the Wet and Intermediate Zones that practice rice + rice annual cropping pattern would not be able to claim the usual share from the trans-basin diversion structures. This has forced the farming community to reduce the extent under cultivation or explore other adaptation options such as “shared cultivation” (*Bethma* system) but at the expense of the productivity of the system. Moreover, increased occurrence of extreme positive rainfall anomalies is likely to cause severe damages to existing irrigation infrastructure of major irrigation schemes, thus limiting the water availability for crop production systems under these reservoirs.

Traditional agriculture practices coupled with endogenous paddy varieties have proven to be more successful in facing climate change events such as droughts and floods (Sharma and Rai 2010). There are many traditional paddy varieties in existence today in Sri Lanka, which have strong characteristics that help them survive climate change impacts such as droughts, heavy rains, and floods compared to newer varieties used in chemical-intensive paddy cultivation (Rathnabharathi 2009). This vigor is based on certain characteristics unique to traditional paddy varieties. The traditional varieties are capable of surviving in the nursery until the field conditions are favorable for planting. Traditional varieties are tall with a strong stem compared to the new improved varieties, thus helping them to withstand heavy rains, winds, and droughts. The husk of the paddy seed of traditional varieties can withstand waterlogged as well as drought conditions (Rathnabharathi 2009). Traditional rice varieties such as *Hata da vee* that survives long dry spells are being cultivated in selected areas in the Dry and Intermediate Zones of the country. Farmers are being assisted by several NGOs to identify traditional paddy varieties such as *Pokkali*, *Kaluheenati*, and *Madathawalu*, which can be grown in sandy and saline soils with appropriate management practices. To cope with shifting seasons due to unpredictable fluctuations in rain and temperature, long- and short-age traditional varieties such as *Hata da vee* (maturing in 70 days) and the *Maha ma vee* (maturing in 6 months) are cultivated by farming communities in different localities of Sri Lanka. Paddy farmers under the minor tank systems in the Dry Zone of Sri Lanka are aligning farming activities with the recognized seasonal pattern of rainfall and managing rainwater harvested in the commonly owned village tanks (Senaratne and Wickramasinghe 2010). Amarasingha et al. (2014) reported that changing planting date of rice according to the onset of rainfall can reduce the irrigation water requirement and risk of rice cultivation. Early onset of rainfall coupled with early planting has resulted in higher yield and water productivity across different irrigation management options, while a higher variability has been observed in both water productivity and yield at a late onset and planting with subsistence irrigation. Dharmarathna et al. (2014) also reported that advancing the rice planting date by 1 month would be a non-cost climate change adaptation strategy for rice production in the Kurunegala district of Sri Lanka.

Coconut

Analysis of coconut production data from 1971 to 2001 has shown that the foregone income to the economy due to crop shortages from unfavorable climate has varied around US$ 32–73 million (Fernando et al. 2007), and the additional income to the economy from favorable climate years producing a crop glut was US$ 42–87 million. This implies the potential for significant economic benefits from investments in adaptation that would reduce the variability in coconut production, caused by variation in climate. Some varieties such as Tall x Tall and Tall x San Ramon have been recommended for drought-prone areas in Sri Lanka to meet the challenges of climate change. Furthermore, the variety Dwarf Brown appears promising for plant breeders as an ideal parent material due to some characteristics such as nonseasonality, high-yielding capacity (higher number of nuts per bunch and higher number of inflorescences per palm per year), and relatively higher tolerance to water stress conditions compared to those of other dwarf varieties (Ministry of Environment 2010).

Other Food Crops

Several strategies have been adopted in the other food crops sector (excluding rice), covering many food crops at the national and household level to cope up with the changes in climate, such as (a) soil moisture conservation with mulching, soil erosion control under intensive rainy conditions to minimize surface runoff and improve the water-retention capacity of soil; (b) growing low water-demanding crops such as mung bean (green gram), finger millet, and sesame and short-age crops for mid-season cultivation with appropriate agronomic management practices; and (c) adjusting the cropping calendar according to changes in the rainfall pattern (Howden et al. 2007).

Animal Production

Livestock and poultry form an important subsector in the social and economic context of the country, and hence strategies for adaptation and risk aversion to face the challenges brought by the changing and variable climatic conditions are crucial. Strategies for climate change adaptation have not been specifically highlighted in the National Livestock Development Plan – 2010 (Ministry of Livestock and Rural Community Development 2010), which is implemented at present. The animal production sector implements a strategic approach in animal breeding activities since 1994 according to the climatic regions by using different animal breeds and their crossbreds.

A greater emphasis has been given for the dairy subsector in the implementation of breeding strategies as the country's main strategy in terms of food security in relation to animal production is to bring self-sufficiency in milk and milk products. The interim target has been set to achieve 50 % self-sufficiency by the year 2015. However, there are no pasture development strategies or recommendation in place according to the climatic conditions due to various limitations that exist in the field level. Given the fact that Sri Lanka possesses a diverse climate as well as production environments, the benefit of development of climate-resilient systems for feed improvement is still pending.

The subsectors other than dairy have breeding strategies specified for each sector, considering the adaptability of different genotypes. In addition, sustainable utilization of indigenous animals has been specifically identified in the animal breeding guidelines (Ministry of Livestock and Rural Community Development 2010). Many efforts have been taken in the past in developing locally adopted breeds suitable for different climatic regimes in the country. Kottukachchiya goat breed (Silva et al. 2010) developed as a dual-purpose breed suitable for the Dry Zone in Sri Lanka and CPRS poultry breed (Gamage et al. 2013) developed for local climatic conditions and feeding regimes are few examples of such attempts.

Homegardens

"Homegarden" (HG) is a complex but sustainable land use system that combines multiple farming components in the homestead and provides environmental services, household needs, employment, and income-generation opportunities to the households (Weerahewa et al. 2012). A study conducted to assess the vulnerability of HGs to climate change and its impact on household food security in Sri Lanka (Marambe et al. 2013) has identified four categories of climate change adaptation strategies adopted by homegardeners, namely, (1) changing planting date, (2) changing agronomic practices, (3) changing technology such as the use of new varieties and irrigation equipment, and (4) the use of soil and water conservation measures. Family size and perceptions on climate change have positively affected the likelihood of adoption of new technologies in Sri Lanka. Male-headed households also tend to adapt more than that of the female-headed households. The factors that negatively affect adaptation in Sri Lankan HGs included ownership of animals, HG size, age of the head of the household, and plant diversity of the HG (Marambe et al. 2012). Commercial orientation, perceptions on climate changes, years of experience of the homegardeners, and location of farming have significantly influenced the probability of adoption of adaptation strategies (Daulagala et al. 2012).

Conclusions and Way Forward

The sustainable development challenge remains urgent and acute, where poverty and food insecurity impact the lives of a sizable population in developing countries including Sri Lanka. Climate change renders achieving the national-level food security more challenging, thus making sustainable development a daunting task. The United Nation's Rio+20 summit in 2012 has thus committed governments to create six Sustainable Development Goals (SDGs) to be integrated to the follow-up of Millennium Development Goals (MDGs) after the 2015 deadline. A new approach for long-term sustenance in food security is a necessity by effectively drawing in ecological principles to improve the productivity and efficiency of agriculture and food systems while reducing negative environmental impacts. Substantial gains in productivity in agriculture and food systems can be realized through investment, innovation, policy, and other improvements.

Agriculture and food systems face many challenges, making it more difficult to achieve the primary objective of meeting the world food demand. An intimidating set of unprecedented challenges and risks including the increasing competition for land, water, and other natural resources by nonagricultural sectors affect the food security of the current and future inhabitants of the world. Food security is multidimensional, and the population growth and changes in consumption patterns associated with rising incomes drive greater demand for food and other agricultural products. Advancements in the productivity frontier, transformations in production systems, and enhanced food and environmental safety are three goals to achieve by countries, and Sri Lanka is not an exception.

Climate change has continued to affect agricultural productivity (crops and animals) through shifts in rainfall patterns, changing temperature regimes, and increased climate variability as well as climatic extremes. Farmers in Sri Lanka have observed these changes, but their historic weather knowledge and experience are progressively becoming less useful in the agricultural planning process due to the rapid changes in the climate. The existing short-term (3–10 day) weather forecasts have provided limited assistance for planning in the agricultural sector, and hence, access to reliable intra-seasonal to seasonal climate forecasts (1 month to multi-month time frames) could provide farmers with a complementary set of response options, which can further help reduce production risks and ensure food security. Such mid-range forecasts could assist farmers and the policy makers to develop improved climate risk management strategies such as which crop to be planted and when, fertilizer application rates, and timing of irrigation activity and harvest. While seasonal climate forecasts in the tropical systems have been a challenge for modelers globally, valuing existing or even marginally improved forecasts could effectively be included in decision making in agriculture.

Effective intra-seasonal to seasonal management responses to short-term climate variability are key means to progressively adapt to climate change (McKeon et al. 1993).

Climate-resilient food production approaches would be the path to sustain food security for sustainable development in Sri Lanka. A research agenda closely tied to sharing of information across research, i.e., discovery, development, and deployment, is an imperative. Advancements in productivity frontier, transformations in production systems, and enhanced food and environmental safety are three priority research themes in this regard in the attempt to adapt to climate change scenarios while ensuring food security. The purpose-driven research in sustaining food security should address: (1) seasonal climate forecasting with appropriate statistical models and numerical weather predictions, crop/animal growth modeling with appropriately parameterized models, and assessment of adaptation and resilience levels of different crops and animals; (2) judicious use of wild relatives and natives for breeding/propagation for quality products and biotic and abiotic stresses, reengineering crop photosynthesis, and reverse phenology; (3) introduction and promotion of the use of precision agriculture, smart fertilizers, agroforestry, climate-smart agriculture, watershed management to minimize soil erosion and environmental contamination, and water-saving irrigation techniques; and (4) reduction in waste related to agriculture and food aiming at food safety, improved food and nutrient use efficiency, recycling and reuse, value addition, and value chain management. Realizing these goals will require an exceptional level of collaboration among stakeholders in the agriculture value chain including the government, private sector, civil society groups, academia/scientists, farmers, and consumers. Science and technological progression will make it possible for sustainable agriculture to become the new global standard, but the main factors resisting this change are political will, lack of policy coherence at many levels, financing, governance, and human behavior.

Climate Variability and Climate Change Impacts on Smallholder Farmers in the Akuapem North District, Ghana

Kwadwo Owusu, Peter Bilson Obour, and Selina Asare-Baffour

Contents

Abstract

Climate change is unequivocal and these changes have increased over the past few years. The recent vulnerability and prospect of climate variability and change impact, thus, warrants measures now to reduce the adverse impacts. This is especially important in relation to smallholder farmers whose activities provide large proportion of the food consumed in the developing world, especially in sub-Saharan Africa. A qualitative approach was used to collect data on the perceptions of smallholder farmers from three communities in the Akuapem North District in Ghana. The perceptions of the farmers about rainfall changes were compared with the empirical daily rainfall total data from the Ghana

Meteorological Agency to corroborate changes in rainfall. By comparing the perceived changes in the rainfall of the district with the empirical data, it was identified that shifts in the rainfall regime was the main cause of crop failures in the study area but not decline in the annual rainfall total. Farmers being aware of changes in the rainfall have employed new stresses to improve their productivity. However, it was observed that non-climatic stresses such as low capital and absence of institutional support in the district have increased smallholder farmers' vulnerability.

Introduction

Climate change is unequivocal according to the Intergovernmental Panel on Climate Change (IPCC), as there is now ample evidence that the earth's climate system is warming at an unprecedented rate leading to ice melting and sea-level rise (IPCC 2007). No wonder the impact of climate variability and change has taken a center stage in many scientific research worldwide (Hulme et al. 1999; Tauli-Corpuz and Lynge 2008). In the coming decades, global climate change will have an impact on all sectors of the global economy. But most impacts will fall on the agricultural sector, creating food insecurity and heightened water stress, most especially in the developing world (Ringler 2008; Nelson et al. 2009). Poor farmers who are (referred to as subsistence or smallholder farmers) and predominantly in the low-latitude developing countries living in remote and fragile environments are expected to become the most vulnerable (Altieri and Koohafkan 2008; IFAD 2008). According to IFAD (2010), by 2050 food production needs to increase by 70 % but the total arable area in developing countries may increase no more than 12 % mostly in sub-Saharan Africa and Latin America. This implies that the burden of increasing food production rests on the shoulders of these farmers whose occupation would be most affected and who are also poor and technologically deficient to master effective adaptation. Morton (2007) describes smallholder farmers as rural producers, predominantly in the developing countries, who farm using mainly family labor and for whom the farm provides a principal source of income. Their activities depend directly on climatic factors while climate also indirectly affects the terrain and the environment on which they depend.

Smallholder farmers are the backbone of the rural economy but bear the brunt of climate change impacts (IFAD 2009). Worldwide, there are 500 million smallholder farms supporting some 2 billion people. Smallholders provide up to 80 % of food consumed in Asia and sub-Saharan Africa. Although it is held that some regions in the world will enjoy increase in agricultural production as a result of climate change (a slight increase in temperature could increase crop production in higher-latitude regions), the net impact of climate change on sub-Saharan Africa would be negative (Boko et al. 2007; Vermeulen 2011).

Khamis (2006) stated that smallholders in Malawi have been exposed to tremendous drought and flood affecting food security and their livelihood. In Ghana, food security and rural incomes are under threat from unpredictable changes in rainfall and shifts in the rainfall regime (Owusu and Waylen 2009, 2013). The smallholder farmer in Ghana is facing the negative impacts also as a result of many non-climatic stresses that make him or her vulnerable. In developing countries in general, vulnerability of smallholder farmers to climate change impacts has been exacerbated by non-climatic stresses like population increase, low capitalization, rural–urban migration, health problems like HIV/AIDS and malnutrition, government policies, and market shocks (Morton 2007; Osbahr et al. 2008; Francis 2002). In Ghana in particular, lack of credit, lack of storage facilities, low levels of technology, lack of access to market, and land tenure complications which occasionally result in conflicts have heightened the smallholder farmer's vulnerability to climate variability and change (Kunateh 2011). Such stresses have been exacerbated by the fact that smallholder activities in the country are mainly rain-fed. For example, the total arable land under irrigation in Ghana was reported to be less than 3 % (GIDA 2010; MOFA 2011).

Climate change poses serious problems for these farmers to deal with since their main source of livelihood is being threatened through "crop failures and livestock death leading to economic losses, high food prices thereby undermining food security" (IFAD 2009). It is thus very important to assess how climate variability and change affect the living conditions of smallholder farmers since they are responsible for cultivating a greater chunk of arable lands in Ghana. Over the years, smallholders have learned to adjust to climate variability and change to increase agricultural sustainability (AAFRD 2005). However, the current speed and intensity of climate change and associated extremes are posing problems for smallholders and their capacity to adapt. This is more so as the prospect of adverse climate variability and change is not going to diminish in the very near future (Downing et al. 1997). This chapter investigates the impacts of climate change and its effects on the incomes and food security of the smallholder farmers in the Akuapem North District of the Eastern Region of Ghana. The adaptation strategies used by the smallholder farmers are also examined. The objectives are to assess smallholder farmers' perception and knowledge on climate change and the related risks, to account for the factors other than climate which make smallholders vulnerable to climate variability and change, and, finally, to assess the various mechanisms used to reduce the effect of climate variability and change on their system of farming.

Conceptual Framework for Smallholder Farmers' Vulnerability to Climate Change

In this study, the conceptual framework proposed by Morton (2007) was adapted to understand the various ways in which climate change impacts on the livelihoods of subsistence farmers and how such impacts heighten their vulnerability.

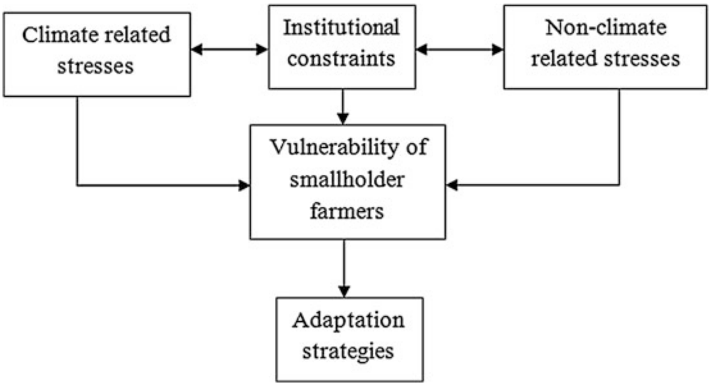

Fig. 1 Conceptual framework for climate change impacts on smallholder farmers (Source: Adapted from Morton 2007)

The framework distinguished between climatic and non-climatic stresses which integrate together to impact on smallholder farmers. Climate-related stresses such as droughts and floods affect farmers in diverse ways such as constraints on soil quality and inducing crops and animal diseases (Scoones et al. 1996; Lal 2000). The non-climatic stresses on the other hand include land fragmentation due to population growth, market failures, and prevalence of diseases affecting the health of farmers (Morton 2007).

However, as indicated in Fig. 1, unlike Morton's originally proposed framework, another impact propeller "institutional constraints" (such as public, private, and civil society support) was introduced. The reason for distinguishing between institutional constraints from non-climatic stresses is that, if well managed, institutional supports are able to cushion the impacts of both climatic and non-climatic stresses and vice versa (Agrawal and Perrin 2008).

It must be pointed that the effects of the three (3) distinguishing stresses on smallholder farmers' vulnerability depend on their sensitivity and resilience capacities (IPCC 2007). But in order to reduce such vulnerabilities, this study will examine the different livelihood adaptive and coping strategies that smallholder farmers adopt in order to reduce the risks and shocks of the stresses. The study also outlines the roles of institutions in climate change adaptation in the Akuapem North District of Ghana.

Study Area

The Akuapem North District is one of the administrative districts in the Eastern Region of Ghana and is located in the southeastern part of the region. Akropong, the district capital, is roughly 58 km from Accra. The district lies between latitude 5° 5′ North and 6° 8′ North and longitude 0° 4′ West and 0° 19′ West. It shares boundaries to the northeast with Yilo Krobo, north with New Juaben Municipal, southwest with Akuapem South Municipal, and in the west with Suhum-Kraboa-Coaltar District. The Akuapem North District covers a land area of about 450 km^2, representing 2.3 % of the total land area of the Eastern Region (Ghana Districts.com 2006) (see map of district in Fig. 2).

The vegetation of the district is made up of a mixture of forest and shrub. Geologically, the district is dominated by rocks of the Precambrian era, the Togo and Birimian series. Its terrain is mountainous and hilly ranging between 381 and 488 meters but the highest peak reaches 500 m above sea level.

It has mean daytime temperature ranging between 24 and 30 °C and night temperature between 13 °C and 24 °C. Rainfall in the district is bimodal (with a mean value of 1,270 mm). The major rainy season usually comes between May and August and the minor peaks in October. The physical factors, especially geology and climate, have greatly influenced the demographic and economic activities in the district. According to the 2010 Population and Housing Census, Akuapem North District has a population of 136,483 (Ghana Statistical Service 2012). The population is composed of different ethnic groups dominated by the Twi- and Guan-speaking people as well as Ewes and Krobos settlers.

The less rocky nature of soils in the district and the relatively high annual rainfall totals (compared to the dry Accra plains) make farming very conducive. This might account for why majority of the inhabitants, especially those who live in rural communities within the district, are smallholder farmers. The main crops grown in the area are maize (*Zea mays*), yam (*Dioscorea* spp.), cassava (*Manihot esculenta*), plantain (*Musa species*), vegetables, and fruits. Few of the people are also engaged in the production of cocoa on small-scale basis. Nontraditional products such as mushrooms and snails are also produced to serve the nearby urban markets in Accra.

Methodology

Sixty (60) structured and open-ended questionnaires were directly administered to smallholder farmers from three communities in the Akuapem North District, namely, Adukrom, Akropong, and Bipoase. The questionnaires were structured into themes to capture respondents' background information (age, educational attainment, and sources of household income), knowledge and perception about climate variability and change, climatic and non-climatic factors that increase farmers' vulnerability, adaptive strategies, and the roles of public and private institutions in supporting climate change adaptation in the district.

The farmers who were interviewed were selected purposively and this was based on the size of their farms and long period of at least 10 more years of farming. A farm size of less than 0.4 ha (1 acre) to a little above 1.2 ha (3 acres) was established as a measure of a smallholder farmer. The technique was achieved by seeking advice from the local agriculture extension officers in the study communities who helped to identify smallholder farmers in their respective communities. Appointment was sought with each of the farmers who consented to participate in the survey.

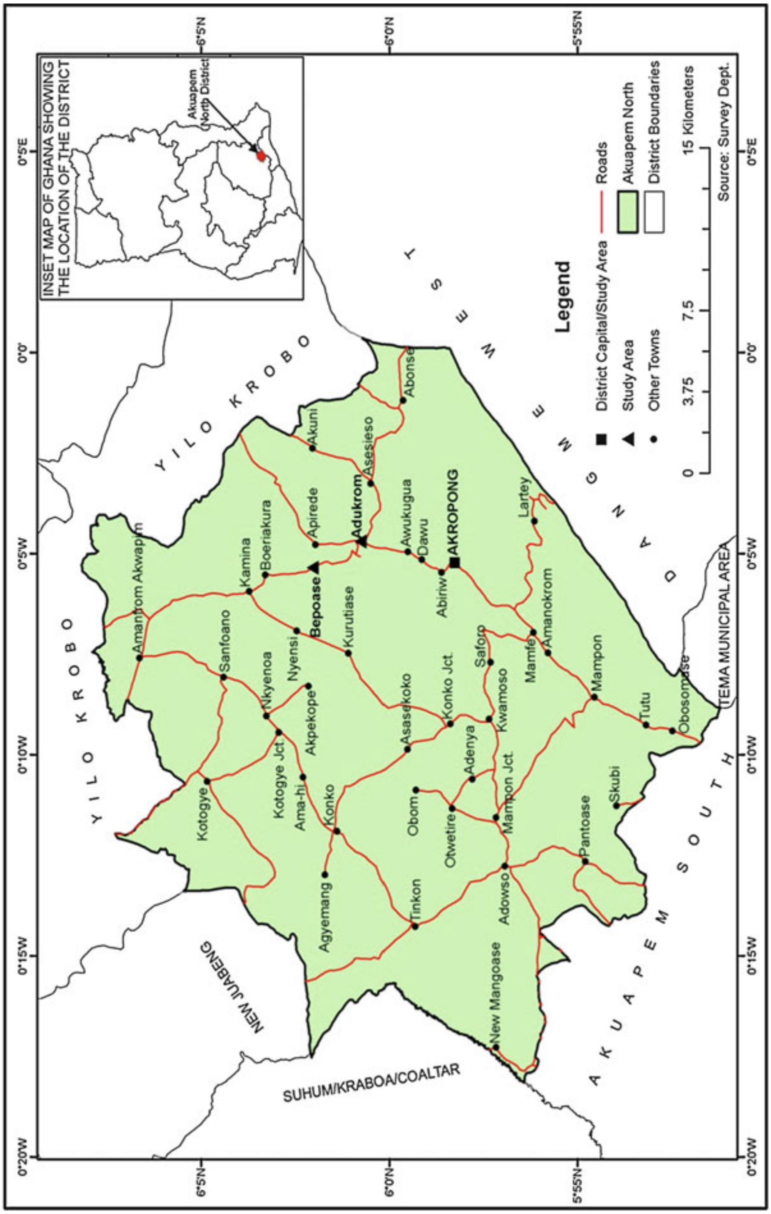

Fig. 2 Administrative map of Akuapem North District

Home visits were made to the farmers during which the questionnaires were administered. The researchers also visited few farms within the vicinities of the communities which provided them the opportunity to observe and understand some of the effects of climate change and adaptation practices of the farmers discussed in the interviews. The fieldwork lasted for a period of three (3) months. In all, twenty (20) respondents were interviewed from each of the three communities, adding up to a total of sixty (60) participants. Deliberate efforts were made to ensure that participants of different gender, age, and educational backgrounds were reached. Chi-square (χ^2) goodness of fit test was used to test the hypothesis that respondents' perceptions about causes of climate change differed across their socioeconomic characteristics. A significant level of 0.05 was used for the computation.

Daily rainfall data from 1965 to 2011 was obtained from the Ghana Meteorological Agency (GMet) for the Koforidua station to facilitate the analysis on the spatial pattern of rainfall amount and distribution in the district. The data were of high quality with only 3 years (1976, 1998, and 2005) having missing values and were therefore excluded from the analyses.

Data of total annual rainfall covering the 44 years between 1965 and 2011 were utilized. The 44 years were then divided into two 22-year periods as P1 (1965–1987) and P2 (1988–2011). The division was based on the acceptable notion that the pre-1980s were wetter periods than the post-1980s in West Africa (Owusu and Waylen 2009). The means and standard deviations were calculated for P1 and P2. In addition to the mean and standard deviation, changes in the variances and means of rainfall distribution for P1 and P2 were computed using F- and *t*-tests. The F-test was first performed to determine the appropriate type of *t*-test to be performed. From the F-test, it was indicated that the difference in variance between P1 and P2 was not statistically significant, shown by F $>$ F critical (2.23 $>$ 2.08). Based on the results, a *t*-test of two samples assuming equal variance at α value of 0.05 was tested using the formula:

$$\frac{T = \overline{\boldsymbol{Y}}_{\boldsymbol{1}} - \overline{\boldsymbol{Y}}_{\boldsymbol{2}}}{s_p\sqrt{1/\boldsymbol{N}_{\boldsymbol{1}} + 1/\boldsymbol{N}_{\boldsymbol{2}}}}$$

where N_1 and N_2 are the sample sizes for P1 and P2, $\overline{\boldsymbol{Y}}_{\boldsymbol{1}}$ and $\overline{\boldsymbol{Y}}_{\boldsymbol{2}}$ are the sample means, and ***sp*** is the pooled standard deviation.

Results and Discussion

General Characteristics of Respondents

In total, equal numbers of male and female smallholder farmers were interviewed. The average age of respondents from Bipoase was the highest (58 years) and the lowest occurred in Akropong (47 years). All the respondents have lived in their respective communities for more than 20 years and have at least 10 years of farming experience. Educational attainment of respondents in all the three communities is generally low and this reflects the general pattern of low education in rural Ghana

Table 1 Socioeconomic characteristics of respondents

Background characteristics	Percentage of respondents Adukrom (n = 20)	Akropong (n = 20)	Bipoase (n = 20)
Gender			
Male	55	45	50
Female	45	55	50
Total	100	100	100
Average age (years)	55	47	58
Average number of years of farming	15	17	23
Highest level of education			
No formal education	35	25	45
Primary	25	15	30
Middle school/JHS	15	30	10
Secondary school	15	25	5
Tertiary	10	5	10
Total	100	100	100
Household income (**source**)			
Average annual income from farm	GH $ 1,200	GH $ 1,500	GH $ 700
Average annual income from nonfarm	GH $ 500	GH $ 250	GH $ 400
Exchange rate 18 June, 2014: US$ 1 = GH $ 3			

(Ghana Statistical Service 2012). As already mentioned, the farmers interviewed practice subsistence system of agriculture. The farms serve two important roles: provide household source of food and income. The average annual household income from farm among respondents from Adukrom and Akropong was relatively higher (GH $ 1,200 and GH $ 1,500, respectively) than those from Bipoase because these communities have access to large market centers which enable farmers to sell some of their farm products. The respondents also get some proportion of their incomes from nonfarm sources, namely, petty trading, craftsmanship, and remittances (details shown in Table 1).

Farm Sizes and Type of Crops Cultivated

Farm sizes in the Akuapem North District are generally small with majority ranging between 0.4 ha (1 acre) and 1.2 ha (3 acres). This is attributed to many factors including the subsistence nature of farming and the complexities of land tenure system in the area as described by a cross section of the farmers who were interviewed. It was highlighted that farmlands are family owned and distributed among family members which results in land fragmentation. This does not promote mechanization or commercial farming. Table 2 shows the distribution of farm sizes of farmers interviewed during the survey.

Table 2 Average farm sizes of respondents interviewed from the three communities

Farm size (in hectares)	Location			Total ($N = 60$)
	Adukrom ($n = 20$)	Akropong ($n = 20$)	Bipoase ($n = 20$)	
Small (<0.4)	7 (35 %)	7 (35 %)	10 (50 %)	24 (40 %)
Average (0.8–1.2)	4 (20 %)	9 (45 %)	5 (25 %)	18 (30 %)
Large (>1.2)	9 (45 %)	4 (20 %)	5 (25 %)	18 (30 %)
Total	20 (100 %)	20(100 %)	20 (100 %)	60 (100 %)

A large proportion of farmers (40 %) had their farm sizes averaging less than 0.4 ha as against 30 % who also had their farm sizes ranging between 0.8 and 1.2 ha. Another 30 % of the farmers cultivate above 1.2 ha. These statistics on farm sizes of respondents give an indication of the subsistence nature of farming as alluded to earlier. In view of this, farmers within the three study communities are largely engaged in crop production as the main preoccupation is to feed themselves and their families. The findings indicate that maize (*Zea mays*), cassava (*Manihot esculenta*), plantain (*Musa species*), and vegetables like okra (*Abelmoschus esculentus*), tomatoes (*Lycopersicon esculentum*), and pepper (*Capsicum* spp.) dominate the type of crops cultivated by the farmers. It is, however, worth noting that majority of the farmers cultivated about two or three crops simultaneously between cassava, maize, plantain, and tomatoes. Also, all farming activities are rain-fed, meaning that any anomaly in rainfall amount or distribution could have significant impact on agricultural production in the district.

Smallholder Perception of Climate Variability and Change

The survey also shows that the participants have different knowledge and understanding about climate change. Respondents' knowledge, however, did not vary significantly ($p < 0.5$) across their age, level of education, and the number of years of farming experience. Some of the common attributes of climate change outlined by the respondents were excessive heat, drought conditions, irregular onset and cessation of rainfall, and too much rainfall. In terms of causes of climate change, wide variations of explanations were given by the respondents. According to 20 % of the respondents, climate change is due to deforestation and bushfires. Another 15 % believed that climate change is a sign of the end of the world. The majority of the respondents (50 %) associated climate change to the anger of ancestors. According to them, this is a vivid signal that "our ancestors do not like our modern way of life." The rest of 15 % attributed climate change to anthropogenic emission of greenhouse gases.

The responses of the farmers differed significantly ($p > 0.5$) according to their level of educational attainment and number of years of farming. All the farmers appreciated that the climate is really changing and this has affected agriculture. However, 85 % of the farmers who have long period of farming experience

(10 or more years) appreciated the phenomenon of climate variability and change as they were able to compare present climatic conditions with those that used to pertain over the past decades. The main climatic changes and variations these farmers stressed on were excessive heat, dryness, and too much rainfall leading to wilting of crops or even unable to till their lands. According to the farmers, beside rainfall variations and changes, temperatures have also increased, particularly, during the dry seasons in the last decade. The temperature increases perceived by the farmers are consistent with observations by Minia (2004) and Agyeman-Bonsu et al. (2008). According to Agyeman-Bonsu et al. (2008), temperature in Ghana has increased by 1 °C since 1960.

Realization of changes in rainfall was as a result of its unpredictable patterns during these few years, leading to high incidence of crop failures. The rain either delays than the expected time, lasts within a very short period during the planting season, or falls in torrent. All these have negative effects on agriculture production. To this end, it was necessary to compare the changes in rainfall over the years as recorded in the memories of the participants to the empirical rainfall data obtained from the GMet.

Statistical Analysis of Annual Rainfall Variability and Changes

The mean and standard deviation of annual rainfall totals were calculated for the two periods. P1 has mean of 1,373.9 and standard deviation of 256.6. And for P2, the mean and standard deviation are 1,340.7 and 171.8, respectively. It was determined that there has been a slight reduction in mean annual rainfall from P1 to P2. The 22-year average for P1 was 1,373.9 mm, while that of P2 was 1,340.9 mm. The standard deviation had, however, decreased from 256.6 in P1 to 171.8 in P2. This seems to imply that the rainfall in P2, even though low, is less variable on the year to year basis.

In order to confirm the observation made by the farmers that the frequency of dry spells has increased in the last two decades, the length of dry-spell days during the major rainy season from 1965 to 2011 was calculated using the statistical software Instat Plus version 3.36. Dry spells were defined as the number of consecutive non-rainy days after the start of the rainy season (Tadross et al. 2009; Ratan and Venugopal 2013).

Figure 3 shows that dry spell of 10 days or more are more frequent in P2 (1988–2011) as compared to P1 (1965–1987) which confirmed the observations made by the older farmers that rainfall frequency has slightly decreased in the last decades. The implications of these findings also support the long-known fact that annual rainfall totals have less agronomic significance than intra-seasonal variability. Before probing further into monthly analysis of the rainfall distribution, a test for statistical significances in the differences in means and standard deviation of the mean annual rainfall totals was made. The *t*-test indicates that the means of rainfall between P1 and P2 in Akuapem North District are not significantly different, shown by $t_{calc} < t_{table}$ (0.50 < 2.02) as illustrated by the means for the two periods although P2 shows a slight decline.

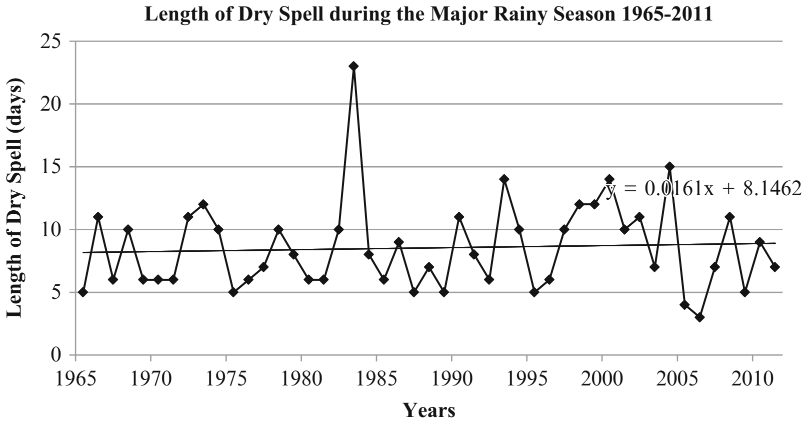

Fig. 3 Length of dry spell during the major rainy season

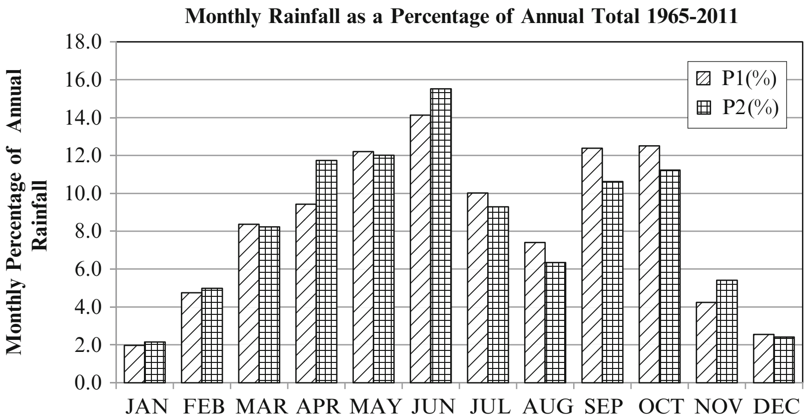

Fig. 4 Monthly rainfall total as percentages of the annual rainfall totals in P1 and P2

Guided by the farmers' assertion that rainfall has changed in the district resulting in crop failures and the fact that the annual rainfall total was not significantly different for the two periods, further probe was made to ascertain the rainfall distribution at the monthly level. The monthly rainfall total as percentages of the annual rainfall totals was calculated for the two 22-year periods as shown Fig. 4.

Figure 4 shows that rainfall distribution and amount in the district for P1 and P2 have mostly increased for the major rainy season, March to June in P2. The decrease in rains appears to occur in the minor season, July to August for P2. This pattern of minor season rainfall declines has been observed by Owusu and Waylen (2012) and by a cross section of the respondents who were interviewed from the three communities. Although the reduction has been very slight, the effects could be very crucial for agronomical activities by increasing crop failures during the minor rainy season in the district. This is because, unlike the major rainy season that spans a period of about 5 months, the bulk of rain in the minor rainy season only occurs in 2 months (September and October). The results of the monthly analysis seem to be in tandem with the views of older farmers in the study area that tie the high risk of crop failure in recent decades to changes in the rainfall regime rather than declines in the mean annual totals. The implication is that because produce from farms serves as the main source of household food and income, crop failure has significant adverse impacts on food security and household poverty in the study communities.

Non-climatic Factors That Make Smallholder Farmers Vulnerable

Apart from climatic factors of increasing temperatures and variation in the rainfall pattern, non-climatic but socioeconomic factors were also identified as major challenges impacting negatively on the smallholder farmers and making them vulnerable to climate variability and change. Notable among these factors are poverty and inadequate funds. According to the farmers, the most important constraint to their activities is inadequate capital to enable them pay for hired labor and buy fertilizers, pesticides, and other farming equipment. There are no banks or government agencies ready to loan money to the smallholder farmers in the district. As a result, they are unable to expand the sizes of their farms to increase production for home consumption and for the market due to land fragmentation and tenure complications. Another constraint they mentioned was scarcity of labor. According to the district migration data, emigration predominantly of the youth from the district has increased to more than 10 % since the past decades (Assan 2007; Akuapem North District Assembly 2012). The participants explained that most of the youth in the communities keep emigrating in search of greener pastures elsewhere in response to increased crop failure and loss.

A low price of farm products is another constraint that increases farmers' vulnerability to climate change and variability in the district. Sixty (60) percent of the farmers interviewed, predominantly those from Bipoase, explained that they do not have direct access to large market to sell their produce because of poor road transportation network and the higher cost they have to incur to convey their goods to the market. Instead, they trade directly with middlemen who come to them to do the buying, usually on the farm. These middlemen come with their own prices, which are very low, but since the farmers have no other alternatives, they accept the prices to prevent their products from going bad. The middlemen then sell the produce at very high prices in the urban markets. According to the farmers, although they do the hard work, they are the least profit beneficiaries. Less profit means they are unable to save some of their earning against unforeseen events. This problem together with those already discussed makes farmers less resilient and more vulnerable to climate change impacts, especially during prolonged drought or excessive rains leading to crop failures.

Strategies for Adaptation to Climate Change

The effects of climate change are likely to increase risk among smallholder farmers in Akuapem North District. According to the farmers interviewed, because climate change is a phenomenon that may persist for a long time, they have over the years put into place some measures that enable them cope and adapt to both adverse climatic and non-climatic stresses which increase their vulnerability. The adaptation practices are summarized in Table 3.

The most common adaptation practices are using indigenous planting techniques predominantly, doing watering, planting more resistant varieties of crops, and adjusting to rainfall variability, especially during the minor season. The farmers also engaged in on-farm activities like rearing of animals to supplement their household income, particularly during climate failures. Thirteen percent (13 %) of the farmers who have friends and relatives living outside the local community receive remittances to pay for labor and save some as a form of collateral against unexpected events. They, however, mentioned that such supports are sometimes unreliable because the amount and frequency of remittance depend on conditions in the source region.

Table 3 Frequency distribution of main adaptation strategies ($N = 60$)

Class of adaptation strategy	Specific adaptation practice	Frequency
Small-scale businesses	(i) Rearing of farm animals	10
	(ii) Sale of bushmeat and fruits	
	(iii) Making of gari, cassava dough, and palm oil	
	(iv) Engage in driving and carpentry work to supplement farm income	
Adjustment to variations in rains	(i) Diverting from farming activities and resuming when farming conditions become favorable	20
	(ii) Waiting for the rains to come before planting begins (late planting)	
	(iii) Early planting of seeds before rains	
Family support/ remittances	(i) Depending on family labor to carry out farm activities	8
	(ii) Depending on financial support of family members in the urban areas	
Indigenous methods	(i) Watering of plants such as tomatoes	22
	(ii) Planting of crop varieties more resistant to drought conditions	
	(iii) Rainfall harvesting for watering vegetables	
Total		**60**

Institutional Support for Climate Change Adaptation

In a typical rural setting like Akuapem North District, three major forms of institutions could be identified, namely, public, private, and civic institutions (Agrawal and Perrin 2008). In terms of public or government support, it was found out that although there are national climate adaptation strategies and programs, these have not trickled down to rural communities like Akropong, Adukrom, and Bipoase where the research was conducted. This is evident from the fact that there is presently no government policy intervention like sensitization and education program on climate change adaptation that can guide farmers to know what and when to plant in order to reduce the risk of climate failures. For instance, there are no seasonal forecasts given to the farmers during the cropping seasons. Farmers who were interviewed were ignorant of the existence of any national climate change adaptation program in the country. The farmers indicated that about a decade ago, the government used to distribute farm implements like cutlasses, hoes, and small funds for farmers in the district. However, these were not specifically to support climate change adaptation, but rather it was to help expand and sustain the breadbasket to reduce the risk of food insecurity in the district.

Also the farm materials and funds were not for free but have to be repaid in installment. For instance, at Akropong it was reported that some years ago, they received loans from the government in aid to boost up their production levels. Unfortunately, most farmers were unable to honor their debt because that year happened to be one of the most unfavorable farming years (high temperatures and low and sporadic rainfall). With such bitter memories, when respondents were asked if they will like to receive loans in the future, the majority were reluctant because of the fear of going through the same sour experience which will end them and their families up in jails because of inability to repay such loans.

At present, there is no private or civil society organization in the district that is into climate change adaptation to help the smallholder farmers. Similarly, none of the study communities has a civic institution like smallholder farmers' cooperatives that is focused on assisting members to cope in the event of crop failures due to variability and climate change.

Conclusion and Recommendations

In general, climate variability and change have adverse effects on smallholder farmers in Akuapem North District. Vulnerability and low resilience of farmers to climate variability and change impacts has been exacerbated by multiple non-climatic factors. Autonomous and reactive types of adaptation are the major strategies for adapting to the impacts of climate variability and change. So far, there have not been any planned and anticipatory types of adaptation assistance such as institutional support from the government, private businesses, and civil society organizations to help farmers in the district. The following are recommended to help reduce farmers' vulnerability and increase their resilience to the impacts of climate variability and change.

There is the need to strengthen their adaptation capacities mainly through institutional assistance in the form of government, NGOs, and cooperative bodies. These could help provide financial support to smallholder farmers to enable them adapt and increase output. The study, however, revealed that provision of loans for farmers to boost farming may not be successful because the farmers expressed their unwillingness to receive loans, citing past experiences and the possibility that crop failures could prevent them from paying back the loans.

Educating the farmers through outreach extension programs about climate change and its effects and cost-effective adaptive strategies such as water management would enable farmers cope with long periods of droughts and early rainfall cessations.

Also, there is the need to improve farmers' access to certain farming equipment like pumping machines, tractors, and spraying machines among others to help them increase their output within a short period of time. This will ensure that the scarcity and high cost of labor is substituted for by the farming equipment. A key strategy in achieving this goal will be through the formation of smallholder association.

Dealing with Rainfall Variability for Food Production in the Nigerian Savannah

Grace Oloukoi, Mayowa Fasona, Felix Olorunfemi, Peter Elias, and Vide Adedayo

Contents

Abstract

The chapter investigates the observed and perceived trends and effects of rainfall on food production and identifies options that are adopted by farmers in dealing with the impacts in the Nigerian savannah. Data were sourced via community engagement, key informant interviews, and a survey of 191 farming households from 11 farm settlements in the region. Arithmetic monthly means of rainfall and temperature data from six meteorological stations within the ecological zones were used to generate the past and long-term trends of local climate. The study shows no significant variation of monthly mean rainfall

across three decades of the observed data. However, there were similarities between the observed long-term averages of the station data and local perception that the amount of annual rainfall is decreasing, with delay in the onset of rain and increased trend of temperature. The variability impacts land-related livelihoods activities which are substantially tied to rain feeding. Annual planting seasons for cereals is changing from double to single, while harvest of tubers and nuts are gradually reducing. There are no organized adaptation frameworks, but when impacts are perceived by the farmers, coping ensued in the form of crop switch as on-farm modification and charcoal production as a form of off-farm livelihoods diversification. Available coping mechanisms are not adequate because they are leading to the ecosystem degradation. Local capacities need to be enhanced for improved food security and protection of ecosystems in the study area.

Introduction

Global environmental change has the potential to alter water system in most regions of the world posing the challenges of water variability (IPCC 2008; 2012). Water variability is a phenomenon in which the available water supply is dwindling in terms of space, time, and quantity (IPCC 2007). It is often been influenced by precipitation, river runoff, other hydrological formation, population pressure, land-use and land-cover changes, and inadequate infrastructure (UNEP 2009; Easterling et al. 2007; MacDonald et al. 2009). Climate change and water variability, such as periods of drought and flood as well as longer-term change, may either directly or indirectly impact on all these three components in shaping food security: food availability, food access, and access to sufficient nutrients (Ziervogel et al. 2006).

African countries are probably worse off not only because of the reduction or mean variation in precipitation (MacDonald et al. 2009; Vörösmarty et al. 2005) but as a result of high poverty rates (Ellis 2000; Kurukulasuriya et al. 2006), disproportionate dependence on natural resource-based livelihoods, economies being highly dependent on rainfed agriculture, and significant limited adaptive capacity in terms of access to development resources (Adger 2006; van de Steeg et al. 2009). The population at risk of increased water stress in Africa is projected to be on an increase trend (Ashton 2002; FAO 2005) with about 75–250 million and 350–600 million people by the 2020s and 2050s, respectively (Arnell 2004; Nyong et al. 2007).

Coping refers to strategies that have evolved over time through peoples' long experience in dealing with known and understood natural variation that they expect in seasons combined with their specific responses to the season as it unfolds (IPCC 2001; Tompkins and Adger 2004). Coping with water shortages usually connotes temporary measures designed to maintain or return to the status quo (Wisner et al. 2004) which enables a society to function during changing circumstances (Kelly and Adger 2000). Coping also includes resilience development and flexibility (Fussel and Klein 2006), in terms of mobility, storage, diversification, and communal pooling (Halstead and O'Shea 1989).

In contrast, adaptive strategies refer to long-term (beyond a single season) techniques that are needed for people to respond to a new set of evolving conditions (biophysical, social, and economic) that they have not previously experienced (Adger 2006; Bigsten 1996). Adaptation is the process through which people reduce the adverse effects of climate and take advantage of the opportunities that their climatic environment provides, including all adjustments in behavior or economic structure that reduce the society's vulnerability. Adaptation options for farming livelihoods are subdivided into policy instruments; technological and structural measures; risk, sharing, and spreading; and change of land use (DWC 2006). Burton (1996) identified financial re-budgeting, behavioral change, on-site operation, market-based process, research, and education as elements necessary for adaptive capacity building.

In the sub-Saharan Africa, available coping strategies ensue as risks are perceived by local farmers. For example, off-farm diversification (Forum for Food Security in Southern Africa 2004; O'Laughlin 2002; Agrawal and Perrin 2008; Barrett et al. 2001), institutional architecture including rules and norms of governance (Osbahr et al. 2008), adjustments in farming operations (Bryceson 2004; Benhin 2006; Osman-Elasha et al. 2006), and social and economic capital networking (Rockström 2003 cited in Boko et al. 2007) are already identified.

In this chapter, emphasis is laid on precipitation as a key factor that affects water variability in the study area, because farming is basically rainfed. Coping and adaptation options are considered as strategies for dealing with water variability because some actions are based on long-term experiences while some evolved temporarily when water risks are perceived. Following the introduction, an overview of water variability and food production in Nigeria is presented. Then, a contextual analysis of coping and adaptation mechanisms that are adopted for food production in the Nigerian savannah as a case study is presented. Basic research questions include the following: What are the observed and perceived trends of local climate and how are these impact accesses to water for farming purposes? What types of coping and adaptation options are available and how are they being implemented by various actors? How may the adaptive capacity of the farmers be strengthened for improved food security?

Water Variability and Food Production in Nigeria

In Nigeria, rainfall pattern is based on the climatic and ecological grouping (Table 1). For instance, northeast Nigeria (a Sahel ecological zone) traditionally receives less than 400 mm total annual rainfall (Ayuba et al. 2007), southwest Nigeria (Guinea savannah) has had 1602.8 mm (Adeniji-Oloukoi et al. 2013), and

Table 1 Surveyed communities and household respondents

[a]NPC, 1991; [b]Estimates based on 2.83 annual growth rate

southeast and south-south (rainforest and fresh water swamp, the Deltas) receive 1,800 mm (Gbuyiro and Adefisan 2007). Ayoade (1995) and Adejuwon (2008, 2012) also indicate that rainfall is more variable during the dry season from November to April than during wet season which runs from May to October over most parts of Nigeria. Precipitation variations in the distribution of annual and seasonal rainfall are accounted for mainly by the Inter-tropical Discontinuity (ITD) (Ayoade 2003; Fasona et al 2011). Annual rainfall variability is highest in the north and least in the southeastern parts of the country and moderately high in the southwest (Mehrotra et al. 2009).

In relation to temperature, Adejuwon (2006a) indicates that across the various climatic and ecological zones in Nigeria, maximum temperature varies between 28 °C and 40 °C. In coastal locations, maximum temperatures are lowest in August at about 28°and highest in March to May (MAM) at around 34 °C. In the subhumid Guinea zones, maximum temperatures are also lowest in August at about 30 °C and highest in the MAM season averaging 38 °C. In the semiarid zone, the highest maximum temperature as high as 40 °C is also recorded during the MAM season. On the other hand, the lowest maximum temperatures of around 28 °C are experienced in December or January.

A recent assessment of the vulnerability of agriculture to climate change in Nigeria using different General Circulation Models (GCMs) indicated that temperature changes will adversely affect sorghum production in the north. Reduction of rainfall in the southern parts of the country could adversely affect the rainforests and the yields of tree crops such as palm oil, cocoa, and rubber. Given the likely shift in vegetation patterns, the areas of concentration of the production of livestock, especially cattle, sheep, and goats, may be particularly affected by the increase in rainfall shown by the CNRM-CM3 and the MIROC 3.2 medium-resolution GCMs. In the same assessment, increasing rainfall could support the production of fodder crops but could also create favorable conditions for the proliferation of animal diseases and pests (Shuaib et al. 2013).

In Nigeria, societies have adapted to water variability in an evolutionary way through the development and use of systems; mechanisms by individuals, households, and communities to move on with their lives; and getting used to existing water variability and stress (Adejuwon 2006b, 2008; Adejuwon et al. 2007; Nyong and Kanaroglou 2001). In the Sudano-Sahel region in Nigeria, Adesina and Odekunle (2011) identify socio-reengineering (behavioral shifts) and recharging of wetlands. In the southwest, expansion of irrigation infrastructure and adoption of indigenous conservation of water resources are common (Gbadegesin and Olorunfemi 2011). Shifting towards more heat-tolerant or water-loving crops as seasons change is mostly adopted in all regions (Adejuwon 2012). In terms of policy design, some arrays of adaptation are mainstreamed into agricultural and environmental policies at the national level. The challenge is that most of the policies are generalized models which had not taken cognizes of specific local context especially in marginalized arable farming communities.

In Nigeria, coping with water variability for food production is also mostly autonomous because actions are implemented by individual farmers, rural communities, and/or farmers' organizations, depending on perceived or real climate change and without external intervention. In essence, coping strategies ensue as risks to farming activities are perceived by local farmers. It is therefore important to identify specific coping mechanisms that are already in use in local communities of the Nigerian savannah where the primary livelihoods activities are tied to rainfed farming.

Dealing with Water Variability: Case Study of the Nigerian Savannah

Data and Methods

The Study Area

The study area is located within latitudes 8–9°15′ north and longitudes 3°50′–5°50′ east, covering an estimated 40,000 km^2 in parts of Oyo, Kwara, Kogi, and Niger States in west-central Nigeria (Fig. 1). Soils consist of deep, well-drained, sandy loam soils in large areas and poorly drained sandy clay loam subsoil along the Niger floodplain. It lies within the vegetation belt described as the wooded savannah, a transitional zone between the southern rainforest and the tropical guinea savannah vegetation belts in Nigeria. In recent time, the region experiences environmental degradation as a result of population pressure, decreasing of woodlands, deforestation activities, and land-use and land-cover change (Akinbami et al. 2003).

The climate is characterized by a subhumid (*e*quatorial savannah with dry winter) where minimum precipitation is less than 60 mm in winter (Kottek et al. 2006). Annual rainfall lies between 900 mm and 1,300 mm. The area experienced a slightly bimodal rainfall pattern. The highest monthly rainfall occurs in September as opposed to July for the southern rainforest belt. Maximum temperature range is between 28 °C and 36 °C with February/March being the hottest months and the lowest maximum temperature experienced in August. Rainfall is the most important climatic factor critical to human survival. Both the mesoscale and large-scale processes define about 75 % of factors of rainfall characteristics of the savannah (Omotosho and Abiodun 2007) with impacts on regional water footprint and local livelihoods because of the prevalence of rainfed farming system (Fasona et al. 2011). Other anomalies that have been studied indicated the occurrence of double peak periods within the wooded savannah region (Adeniji-Oloukoi et al. 2013; Gbuyiro and Adefisan 2007). The future climate projection suggests an increase in temperature and decrease in the annual rainfall amount in the area (Abiodun et al. 2012).

In terms of livelihoods, human activities are agro-based in the form of rainfed farming, forestry, hunting, herbs and seeds collection, and food processing because the region is dominated with rural communities. The region's rich and large pasture undergrowth has made the area an important extensive grazing area for migrating agropastoralists from the drier Sahel and Sudan zones of the savannah (Fasona and Omojola 2005; Adisa and Adekunle 2010).

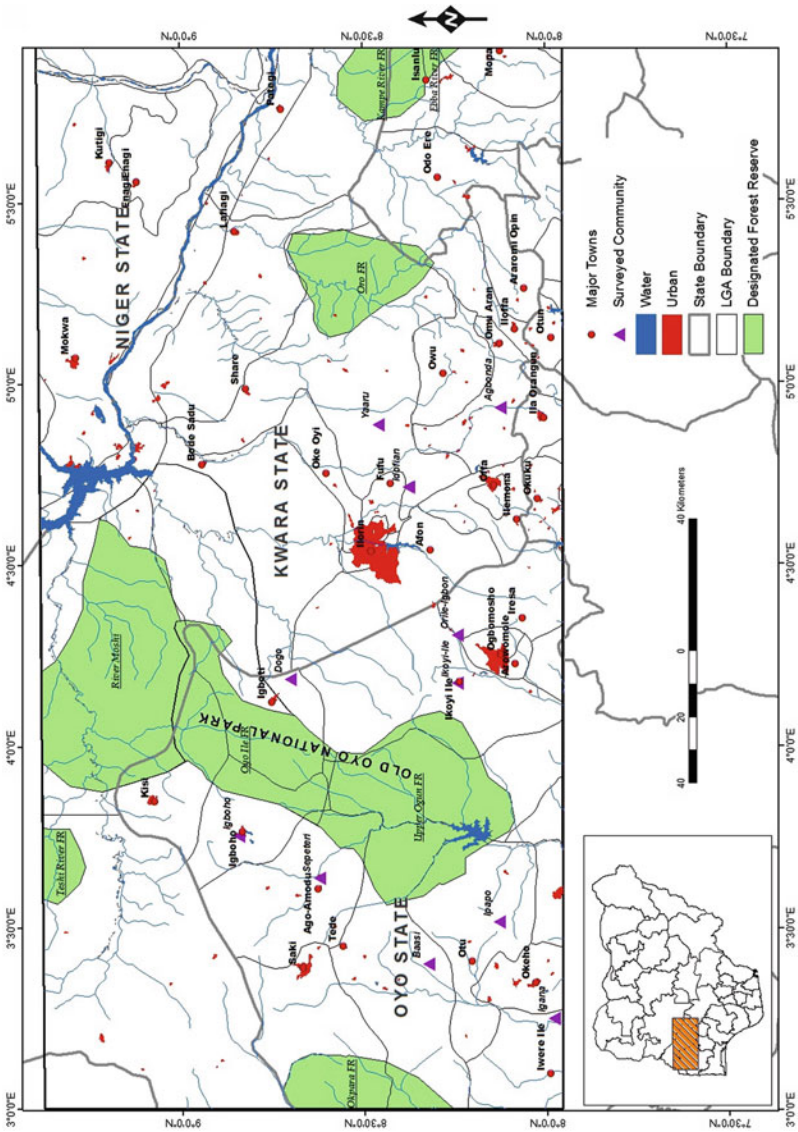

Fig. 1 Study area

Data Sources

This chapter captures a part of the project on “community-based management of ecosystem and natural resources for improved food security in the Nigerian savannah” with a research framework and procedure for data capturing, analysis, and synthesis of observation were thus followed:

Document Review and Development of Conceptual Framework

Various documents including policies, programs and projects were reviewed with a view to familiarizing with what the situation with regard to ecosystem management, livelihood, agriculture and food security, and climate change and the nexus or interconnections among them.

Climate Data

Recent rainfall and maximum temperature data were obtained from the archive of the Nigerian Meteorological Agency (NIMET) to cover the six stations around the study area. The arithmetic monthly means from the six stations were analyzed for decadal trend with the view to examine if there has been any significant shift in the temporal pattern over the three-decade period (1982–2011).

Base Maps

The spatial databases acquired include the following:

- Analogue 1:50,000 topographical map sheets were used as the guide to extract place names and location of communities. Information extracted was compared and updated with other existing sources of place names.
- Digital version of the vegetation and land use maps was produced by the then Forestry Management, Evaluation and Coordination Unit (FORMECU) of the Federal Ministry of Agriculture and Natural Resources for 1976 and 1995 at 1:250,000 scale.

These maps were used for the reconnaissance work estimate hot spots of vegetal changes and to select communities that are within 5 km radius of any forested area for fieldwork.

Pilot Surveys

There are over 2000 communities within the study area. The multistage stratified random sampling was adopted. The first stage was to set certain criteria that a candidate community must satisfy. The conditions are:

- The community must not be more than 5 km away from a forested land – this makes it easy to connect livelihood to forest and farm land.
- The community must be a rural or semi-urban – this is based on the assumption that the natural resource capital is more important to livelihood and food security in rural and semi-urban areas than urban areas.
- Two communities to be selected from each local government area (LGA).

Two states (Oyo and Kwara) constitute about 80 % of the entire study area. Then, a list of all the LGAs and communities in the two states was made. Using data generated from preliminary Geographic Information System (GIS) assessment, 44 communities across 21 LGAs in 2 States were selected and the tentative sample size was to be 25 households in each community.

The purpose of the pilot fieldwork was basically to:

- Conduct a reconnaissance of the general and specific ecologies
- Test the field instruments
- Establish a contact with community and opinion leaders and other stakeholders

From this preliminary list, the study area was stratified into three longitudinal zones; communities selected in each zone about 80 km to 100 km apart were covered in the pilot survey. The pilot survey was carried on the 28th and 29th of December 2011.

The pilot survey reveals that the general ecology and socioeconomic and demographic profile including livelihoods in all the communities are very similar. Based on these considerations, the number of communities where the final survey was done was narrowed to 11 which were drawn across the three stratified zones. Other consideration include possible past or present engagement or involvement with any state government poverty reduction and sustainable food production initiatives and nongovernmental projects such as the Local Empowerment and Environmental Management Project (LEEMP) and the Fadama were taken into consideration in selecting the communities for the final survey.

Designing the Survey Instruments

The primary data were collected using field observations, administration of questionnaires, and structured interviews. Three sets of questionnaires were designed for selected households, key informants/focused groups, and government (local and state government) offices in charge of natural resources, environment, agriculture, forestry, and other related agencies. The questionnaires were designed to include questions on livelihood and access to resources, perception on trends and impacts of climate change and water variability, adaptation options, and adaptive capacity.

Household Survey

Eleven communities spread across nine LGAs in two states (six in Oyo and three in Kwara) participated in the final survey (Table 1). The sample size for the study was further refined after the pilot survey with the total number of community narrowed to 11 communities with 191 households. The final survey was completed in February 2012. An adult member of selected households was the respondent for the household survey. Based on the established criteria for the selection of the sampled communities for the social survey, it should be noted that these communities were not the same with the local areas with meteorological stations whose climate data were used in this study.

Focus Group and Key Informants

The investigators engaged community leaders, i.e., traditional rulers and opinion leaders (who are traditional title holders) in key informant interview. Leaders and members of community association and groups were engaged in focus group discussion. Investigators also engaged with officers in charge of agriculture, forestry, and other related agencies at the LGA and state levels. Information elicited include the capacity and resources available for coping during water variability, reports on food insecurity, and willingness to partner and encourage local community participation in adaptation and mitigation planning.

Another engagement with the stakeholders was done in May 2012, during a workshop in which the major findings of the research project were discussed. This activity in particular provided opportunity for feedbacks and inauguration of a network named, ECOVANGUARD NIGERIA (www.ecovanguardnigeria.com).

Analysis of Social Survey Data

The questionnaire for household and LGAs was coded and analyzed to descriptive information. FGD and key informant interviews were transcribed from audio and video which were discussed under thematic issues.

Result and Discussion

Sociodemographic Profile of Study Population

The demographic analysis suggests that 78.3 % of the respondents were married, 15.5 % were single, and 6.2 % were widowed/or separated. The survey captured the ages of the active group (83.7 %) of the population in which ages between 31 and 45 accounted for 40.3 %, ages 18–30 accounted for 20.9 %, and ages 46–60 accounted for 22.55 %. The study area is characterized by large household sizes. Household size of between 4 and 7 persons accounted for 38 %, and those between 8 and 11 persons were 29 %. Only 17 % had household smaller than 4. One reason for preference large household might be the large number of children. It is a general assumption that children are expected to help their parents on the farm. Although the people are predominantly of the Yoruba tribe of southwestern Nigeria, labor migrant population from other ethnic groups including Agatu from Benue State across the Niger (9.9 %), Ibo from the southeastern states (1.6 %), and the Hausa/ Fulani from the northern Nigeria (2.6 %).

Livelihoods and Income Profile

Primary livelihood activities in the study area are substantially tied to farming and other natural resource systems (Fig. 2). From the survey, 62.2 % of the respondents indicated that male plays the most prominent role in farm produce, compared to only 3.9 % female. This result is contextual, because within the western region of Nigeria, activities such as small-holder farming, cutting of tree for firewood, or charcoal processing are physically tedious; hence, they are male dominated. The agroecological characteristics of the area considerably favor root and tuber crop cultivation.

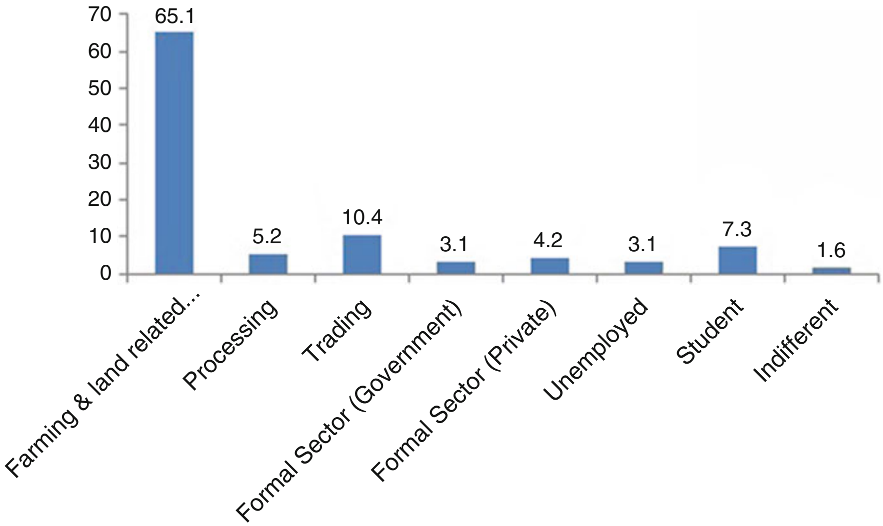

Fig. 2 Primary livelihoods in the study communities

Farming methods include mixed farming, rotation of crops, and shifting cultivation. A key issue from observation from the field individual acreage holding is small, and the yield per acre is often very low because modern farming inputs are not used, not available, or cannot be accessed by these peasant farmers. Women are also engaged in livestock keeping, vegetable farming, and water and firewood collection basically for households' nutritional needs and not for commercial purpose. Both the focus group discussion (FGD) and the key informant interview (KII) with the LGA officials and traditional rulers indicated that men and women have equal right to land ownership.

Other major livelihood activities are agro-based processing and woodland resource collection. Most (48 %) women do forest and woodland resources collection (e.g., orange, mango, wore nuts, and seed gathering (e.g., palm kernel, cashew), fuel wood and leaf collection for sale, and petty trading of basic daily needs and food items. Small scale agro-based processing includes cassava processing to *garri* (cassava flour (*sun-dried and ground* cassava) which is the commonest staple food in Nigeria. *Igba* seeds were processed from *Parkia biglobosa* to *Iru* (locust bean), *Emi* seeds from *Vitellaria paradoxa* to *Ori* (shea butter), yam to *elubo (*yam flour), and wood ash to local (black) soap.

Secondary livelihood activities are the short-term off-season activities which the rural communities engaged in for supplementary income generation. A significant number (48 %) of people (especially the youth) work at construction sites as casual laborers for charcoal production and commercial cycling especially during dry season.

The income profile shows that over 70 % earn or generate a maximum of N30,000 (less than $200) every month from their primary livelihood activities. This suggests that majority of the population are peasant farmers who can be classified as poor. It was also observed that no books are kept for income and

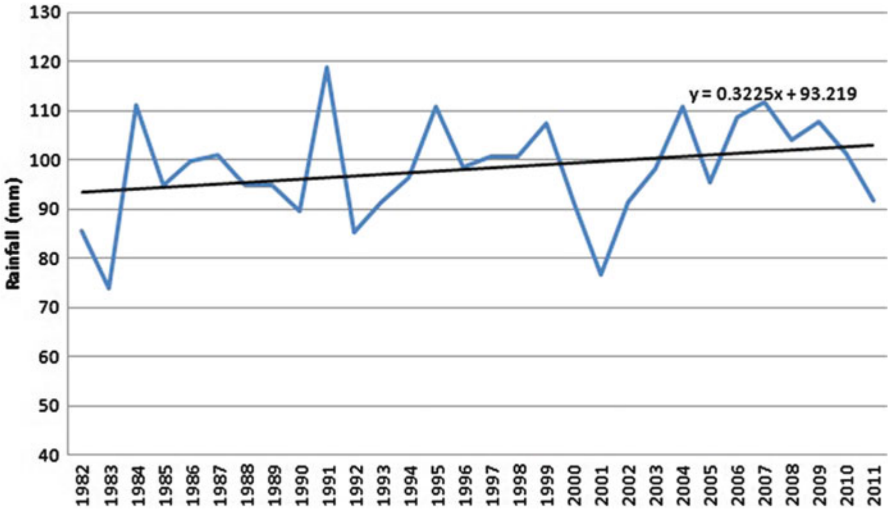

Fig. 3 Trend of annual mean rainfall (1982–2011)

expenditure (at least by majority of the farmers). This makes it extremely difficult for them to actually know how much they make as income from the farm.

Climate Variability in the Nigerian Savannah

Observed Rainfall Trends

The long-term trend in the monthly mean rainfall data (averages from the six stations) suggests that rainfall amount is increasing marginally (about 3.2 mm per decade). This is in contrast to the belief of the local people that the amount of rainfall has been declining. Figure 3 shows the observed trend of annual mean rainfall across the study area.

However, since about 75 % of rainfall in the savannah depends on mesoscale processes, the station data may not have adequately captured the true situation in the communities. This may be so because these stations are more than 100 km from each other and may not effectively capture the effect of local climate processes around the communities.

To determine the rainfall variability in the study area during the three decades (30 years series), the paired sample *t* test was used. Based on the paired *t test*, the result in Table 2 suggests that there are no statistical significant variations in the monthly mean rainfall between the three decades (i.e., 1982–1991, 1992–2001, and 2002–2011) in the study area. Even though the statistical test does not reveal a significant variation, comparisons of the trend in each decade compared with the long-term mean (Fig. 4) suggest a shift in the temporal pattern of rainfall that is consistent with the beliefs of the people in the study area. For example, the decade 1980–1990 was a drought one, while the decade 1990–2000 displays a clear dual peak pattern with peaks in June and

Table 2 Comparison of the mean (paired sample test) for the three decades monthly mean rainfall trend

		Paired differences							
					95 % Confidence interval of the difference				
		Mean	Std. deviation	Std. error mean	Lower	Upper	t	df	Sig. (2-tailed)
Pair 1	Decades 1982–1991 and 1992–2001	−3.7684E0	1.2332E1	3.5601E0	−1.1604E1	4.0673E0	−1.059	11	.313
Pair 2	Decades 1992–2001 and 2002–2011	−1.15646E0	1.1793E1	3.4046E0	−8.6499E0	6.3370E0	−.340	11	.740
Pair 3	Decades 1982–1991 and 2002–2011	−4.9249E0	1.4341E1	4.1400E0	−1.4037E1	4.1871E0	−1.190	11	.259

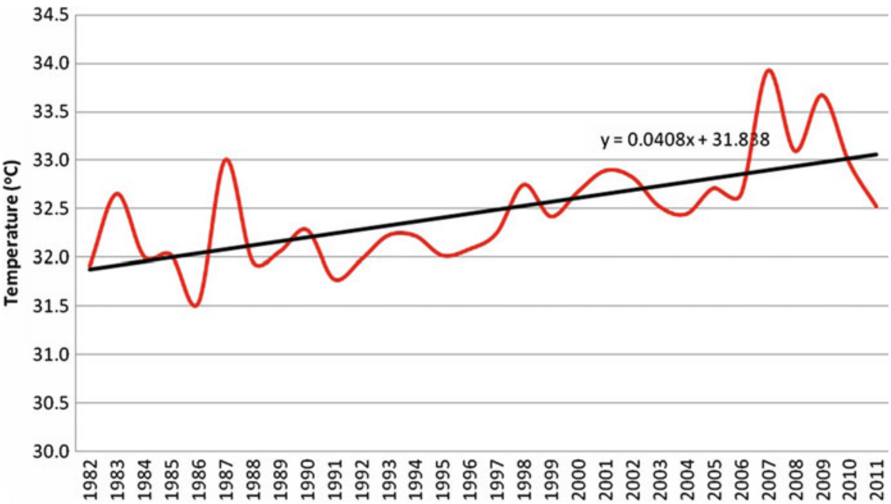

Fig. 4 Monthly mean temporal pattern of rainfall over three decades compared with the long-term mean

September, and the decade 2000–2011 displays only one clear peak that occurs in September. The gradient of rainfall in the decade 2000–2011 was also higher than normal distribution which suggests later onset of the rains and early cessation that is consistent with the perceptions on rainfall by the people.

Observed Temperature Trend

The observed trend of the mean maximum temperature is positive which suggests warming trend (Fig. 5). In all the stations in the study area, the mean decadal temperature has been rising from 1982–1992 to 2001–2011 decades (Fig. 6). Two stations (Bida and Lokoja) indicated higher temperature than the other four stations during the three decades.

Perceived Rainfall Trends

Perceptions are often used for vulnerability assessment in order to integrate social dimension of risks impacts through local engagement. It is not only the participants' responses that are important but also how they respond, what they affirm, and the tones of their affirmation (Sullivan 2010). In the study area, perceptions based on social survey suggest that the populations are aware of variability of climate parameters and its implications on farming livelihoods. Analysis of the households' survey shows that 94 % believes that there have been changes in the patterns of rainfall. Comparing the present rainfall trends with that of the last 10 years (decade before 2002–2011), majority (60 %) believes that rainfall has been decreasing (Fig. 7).

Generally, higher percentages of the sampled farming households in the study area were of the opinion that annual rainfall trends in terms of onset, cessation, and length of growing season are decreasing (Table 3). The perception of annual

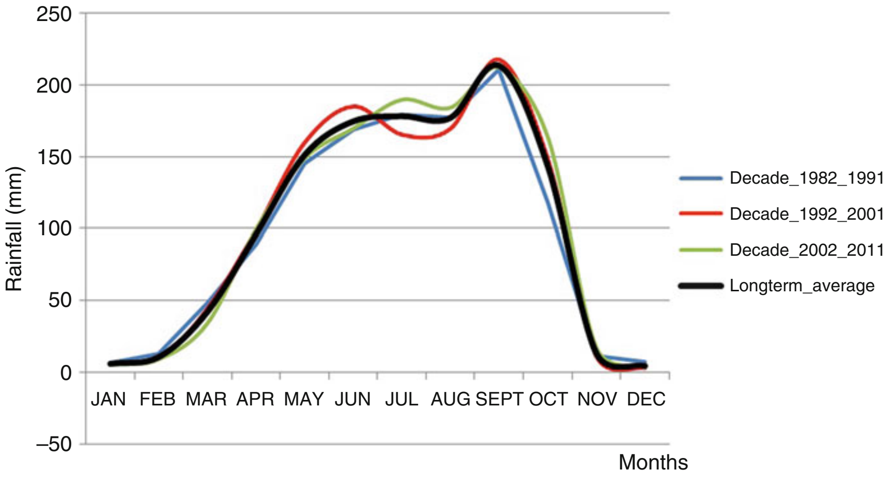

Fig. 5 Trend of mean monthly maximum temperature (1982–2011)

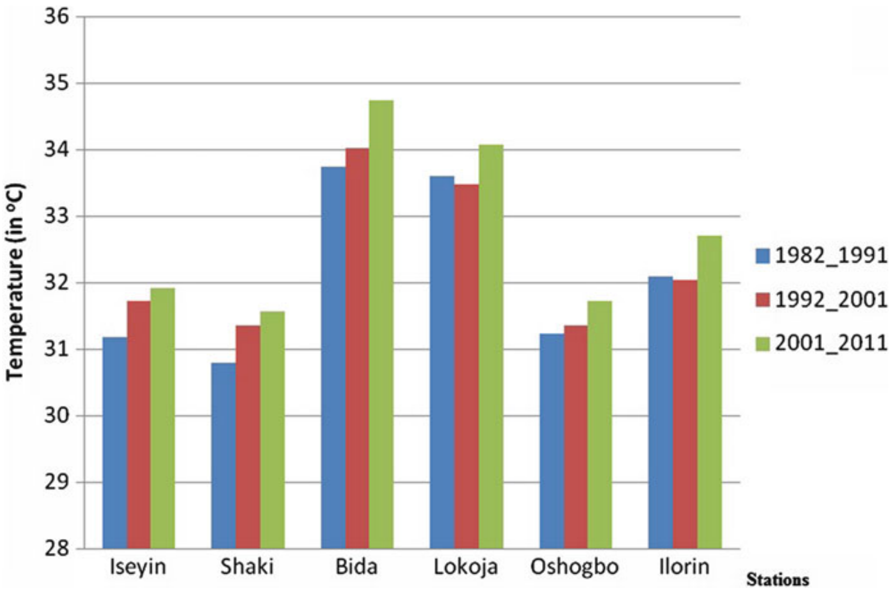

Fig. 6 Mean decadal maximum temperature for selected stations in the Nigerian wooded savanna

rainfall across the communities is shown on Fig. 8. In all the communities except Orile-Igbon, the overwhelming response is that annual rainfall amount has been decreasing compared to some 10 years ago (decade before 2002–2011). Perception on number of rainy days, onset and cessation of the rains, onset of the growing season, and length of the growing season in recent time compared to 10 years ago indicate that over one-third of the population perceived that there has been a

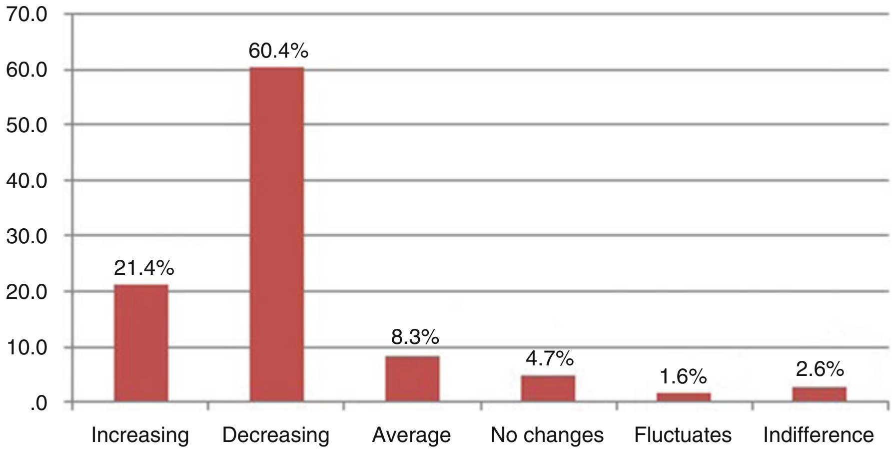

Fig. 7 Farmers' perception (in percentage) of annual rainfall compared to 10 years ago (before 2002–2011)

Table 3 Farmers' perception on number of rainy days and onset and cessation of the rains (in percent)

Number of rainy days	Rainy days $N = 191$	Onset of rain $N = 191$	Cessation of rain $N = 191$	Onset on growing season $N = 191$	Length of the growing season $N = 191$
Increasing	13	3.6	4.2	1.6	0.5
Decreasing	37.5	37.5	33.9	34.9	39.5
Average	16.1	26.0	24.9	21.4	18.8
Below average	0.5	3.6	2.6	2.1	1.6
Above average	1.6	0.5	1.6	1.0	1.0
No changes	7.8	7.3	9.9	14.1	12.0
Fluctuates	6.3	10.9	10.4	11.5	12.0
Indifferent	17.2	9.4	12.0	12.5	13.6

decline in all these variables. This has implications for small-holder rainfed agriculture on which rural livelihood thrives.

In terms of the number of hot days in recent times compared to 10 years ago (i.e., decade before 2002–2011), 42.7 % believes hot days are increasing, and 14 % thinks it is decreasing (especially as regards implication for farming). Correspondingly, 27.1 % believes cold days (i.e., days of lowest daytime temperature normally experienced during the rainy season in June–October with August being the coldest month) and during the harmattan season (December–January) are decreasing. 15.1 % believes it has been increasing, while 18.2 % thinks there has been no considerable change and 8.9 % thinks there has been fluctuation. Figure 9 shows the perception of temperature compared to 10 years ago across the communities.

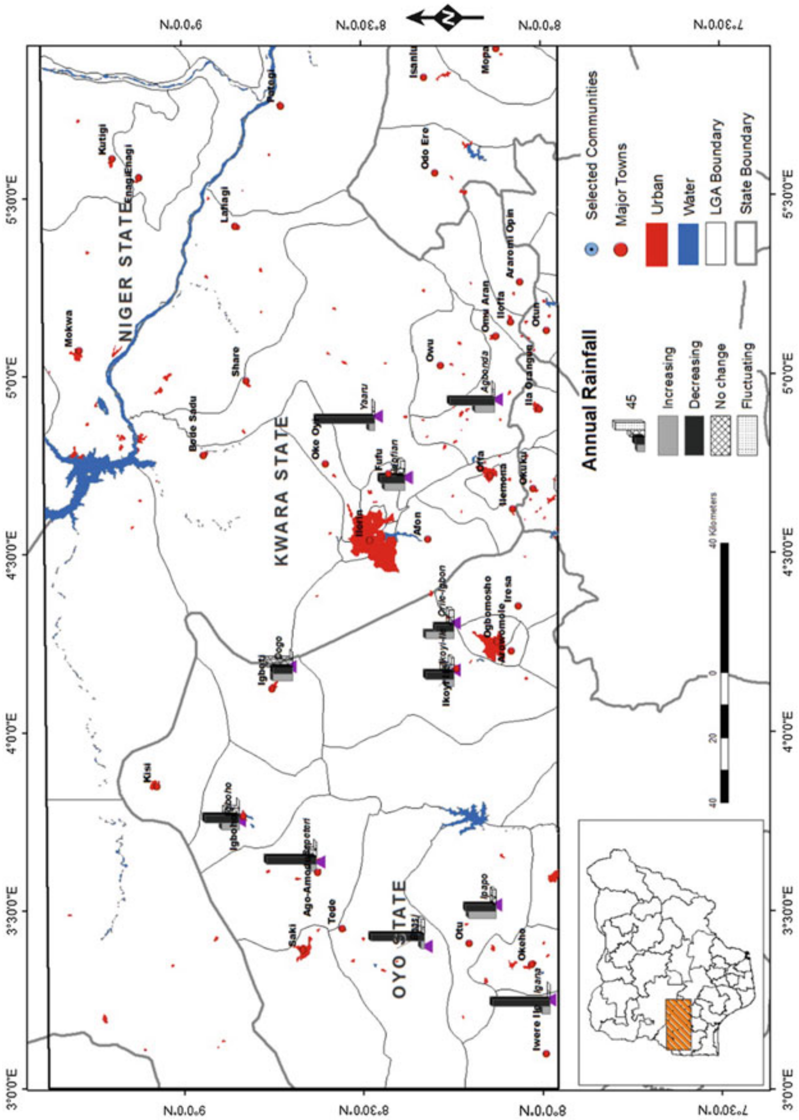

Fig. 8 Farmers' perception on the trend of annual rainfall across communities

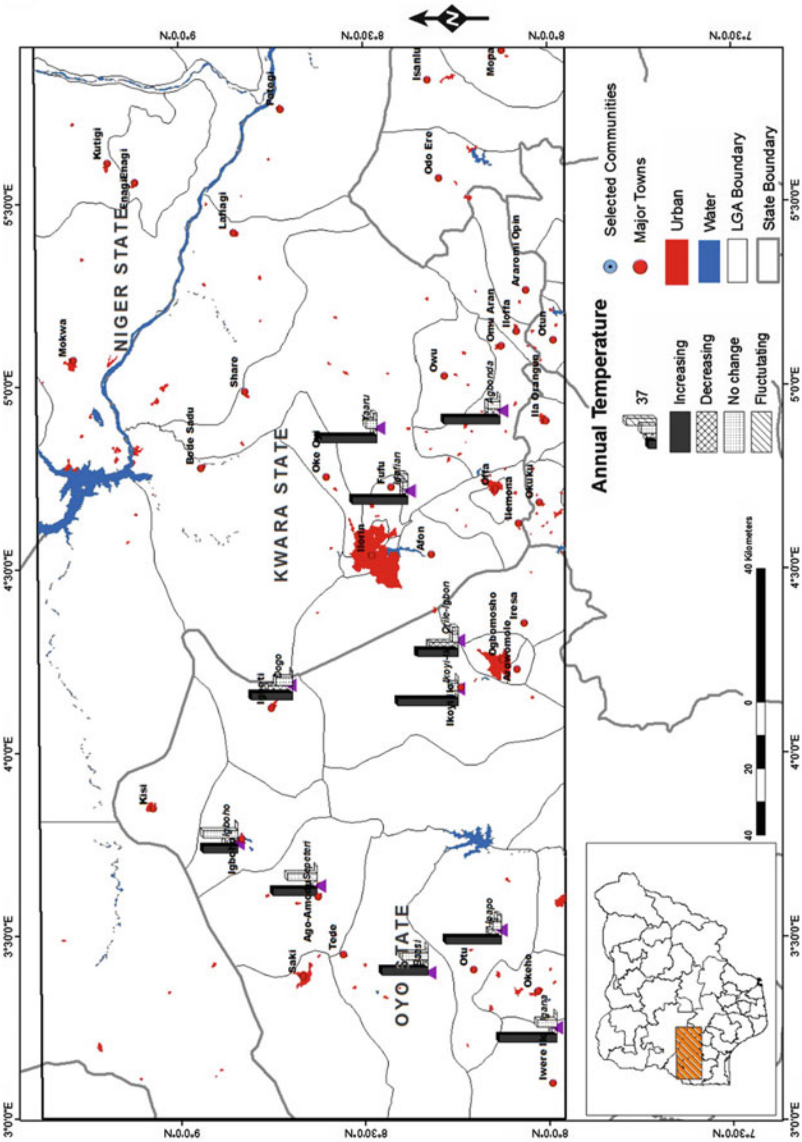

Fig. 9 Farmers' perception of annual temperature compared to 10 years ago across the communities

Voices of Community Leaders on Trends and Impact of Rainfall Variability

Engagement with traditional rulers and other key informants in selected communities affirms that there has been a reduction in the number of rainy days and the frequency and intensity rains during the wet season. Although there are no existing agricultural data to compare with perceptions on onset and cessation of the growing periods, perception related by the community leaders (Box 1) suggests that farming livelihoods are already being impacted.

Box 1: Voices of Community Leaders on Impacts of Rainfall Trends on Farming Livelihoods

The pattern (of climate) has changed. The climatic factors and elements have changed. Rainfall pattern has also changed. One thing that I know is that the local cause here is the falling of trees, and that is why we want to stop them from cutting our trees.

Last year, rain started in March and stopped in April at the time we were preparing for planting. We eventually had late planting. By the end of October, the rain ceased. This occurrence led to a massive crop failure that most farmers complained bitterly. In case we had much rain and crops are not yet ripe for harvest, it will bring crop failure. So the effect is that our planting period is changing as the weather condition changes which is not easy to adjust to.

– The traditional ruler of Iganna

So far, the weather condition has changed compared to the previous years. Back then, we grow our maize in the third month, and by the fifth cassava will be on our farms, but now we usually see rain in the fifth month and it will not last a long period before it ceases.

– The chairman of Community Development Association of Sepeteri

Since I moved into my town from Lagos, the rains have been reducing in the past 6 years. Some of the flowing rivers are drying up. If you look at this part of Kwara Stat, our rainy season is not like the other parts that receive more rainfall during the wet season.

– The Yaaru community leader

Last year was not too good for us in terms of rainfall. We expect rain in its the normal period but it failed. In fact, some of us had the problem of crop failure. Then, we pray that the following year be better than the previous year in which our target will be to make all the likely profits.

– The Aare-Ago (High Chief) of Igboho

When onset of rain is delayed, it affects our crops. About 8 years ago, the rain stopped too early; we were unable to make ridges for the yam. The heat is too much now. Last year, rain started very early and it stopped very early. We normally change the type of crops we plant once the season is altered. We used to have two planting seasons in a year, but now it is once in a year.

– The community head of Baasi

Coping Strategies

Coping strategies being adopted by local farmers towards improved food production are categorized based on on-farm and off-farm options. The on-farm options are activities carried out directly on the farm plots during the growing seasons: preplanting, planting and post planting, while off-farm deals with activities that are done outside the farm plot including behavioral shifts and livelihood diversification (Table 4).

On-Farm Modification Activities

Preplanting Season

Farmers know the implication of timely planting. The dry season is used to prepare the land for cultivation before the onset of rain. The method of land preparation for farming is one of those means through which forests and woodlands are removed, usually in December, January, and February (DJF). The study shows that about 80 % adopt forest burning system as the traditional practice for land rejuvenation. The explanations for choosing this method are as follows: the method is better than any other method (27 %) and it is traditional (11.5 %) with an assumption that the ash produced by burning goes back to the soil as a form of (organic) manure to enrich the soil and improve soil fertility. Additionally, 38 % believes these farming practices have no negative effect on the environment, while 22 % are indifferent.

This land preparation has implication for early crop production especially if there is no delay in the onset of rain. Farmers that are favored with early planting might also enjoy higher productivity and better market price especially during new crop harvest as in the case of maize, vegetables, and yam. In case of false onset of rain, such early planting might result into crop failure. While bush burning may serve as land preparation, it also destroys soil organisms, specific habitats, and plant communities. In several instances, the fire often extends beyond the original intended lands and spreads into other areas thereby causing several ecosystem perturbation that may take several years to recover.

Planting Season

The study suggests that during planting season, at least one of or all of irrigation, application organic manure, and rain harvesting are adopted by at least 60 % of the farmers. About 17.7 % also now hire laborers to assist them in farm works. Evidences from the field show that in majority of the farmers rely on inland wetlands (Fadama) along seasonal streams. Some farmers adopt application of fertilizer to grow crops during the dry season especially in Iganna and Idofian communities. In relation to cropping system, most farmers adopt mixed cropping and shift cultivation.

Mulching: this practice helps to protect seedlings against dry spells during the earlier parts of the growing season. This is usually applicable to tubers such as yam and cocoyam. During planting, the yam seeds are first covered with top soil, and then the green or dry leaves are arranged to cover the top soil against

Table 4 Categories of coping and adaptation strategies in dealing with water variability

Location	Period/season	Strategies
On-farm	Preplanting	Land preparation: bush clearing and burning
		Shift cultivation
	Planting	Delay tactics by watching false onset of rain
		Mixed cropping
		Mixed farming (crop and livestock keeping)
		Crop rotation
		Crop shifting and modification
		Mulching
		Application of fertilizers
		Use of laborers to assist with hand pump irrigation
		Use watershed for irrigation (e.g., Fadama)
	Post planting	Late harvest (harvest period is delayed)
Off-farm	All seasons and especially during crop failure	Livelihood modification: engagement in alternative income-generating activities such as farming plus trading, vegetable gardening, food processing, etc.
		Livelihood diversification: charcoal production, collection of firewood, leaves, herbs, and other woodland resources
		Migration to cities for paid labor
		Engagement in other sources of income like commercial motor cycle transportation (*Okada*)
	Dry season	Protection of watersheds
		Demarcation of different water sources for different uses
		Water reuse especially during food processing (e.g., cassava flour)
		Behavioral shift by reducing volume of water used for some activities
		Rainwater harvest and storage especially for domestic uses
	Long dryness/drought	Appealing to farm goddess (*Orisa Oko*)

the scorch of the sun. This is important to further reduce evapotranspiration of water that yam planting is usually done around October to December (at the cessation of rain).

Mixed cropping system: more than one crop is planted at a time or at intervals throughout the growing season, and it is the most preferred farming system. To do this, most farmers plant legumes and cereals or tuber and cereal together on the same plot with the aim to maximize and at the same time rejuvenate the ecological nutrients. This method is also useful to achieve food production succession in the Nigerian savannah. For example, some farmers indicated that the planting of local vegetable *Corchorus* (*Ewedu*), maize, and yam together on the same plot will provide a continuous income generation. The vegetable will be harvested after 3 or 4 weeks; maize will last for 10–12 months, while yam will last for 9 months.

Rotation of crops and shifting cultivation is traditional and does not require much technicality. Crop rotation is done by alternating crops that are planted on different plots at every planting season. For example, a farmer with three plots will arrange crop planting in a way that yam, maize, and okra are interchanged on the plots at the next planting season. To do shifting cultivation, farmers abandon a plot of land after a successive planting season and shift to another plot in the following year. The "abandoned" plot is allowed to rejuvenate for a period of one or more planting season and will be occupied again. For farmers who have large hectares of land, this agricultural method might be appropriate.

Crop switch/substitution: the strategy involves planting of crop species that have short growing periods and are more tolerant to rainfall shortages. During the KIIs, the traditional ruler in Iganna indicated that water yam, which has 3 months maturity period, is usually planted instead of white yam which would last for 9 months. Yellow yam which is more tolerant to drier period is also substituted with white yam. Yellow yam is largely cultivated for yam flour production because the by-product also last longer in storage especially when the flour is produced for exportation.

Post Planting

For most women who are engaged in collection of fruits, seeds, nuts and leaves (especially herbal leaves), delineation of harvest zone are evolving in some communities. Part of the activities to address the threats to the forest as suggested by the respondents includes replanting of trees after harvesting as being practiced by 31 % of the respondents, while 56 % did not replant any trees after harvest. Meanwhile, 13 % of the respondents are unconcerned or indifferent about tree planting perhaps due to lack of awareness or local capacity. Most farmers believed that trees and other woodland resources are reproduced by nature itself. About 70 % of the people had no formal training about farming, forestry, and ecosystem management nor participate in training on any forest management program. Only 17 % indicated that they have participated in forest management training. This says a lot about the capacity of the people to manage their ecosystem and associated resources beyond their local knowledge. Majority of those who claimed they had training on forest management did not put it into practice because they could not afford the implementation cost.

Off-Farm Coping Strategies

These are activities that farmers engaged in outside farm plots in order to maintain status quo during dry season when water supply shortages hinder effective farming.

Livelihood Diversification

This is the most common option which is manifested in the following ways:

Firewood harvesting: Collection of firewood is a common diversification as a form of coping strategy and alternative income generation especially during dry season when there is shortages of water supply to support cultivation of land for planting. This activity is done in large scale around the study area. Apart from exportation of the fire wood to urban centers, domestically, about 84 % of the people depend on firewood for cooking and heating (Fig. 5). It is also the most preferred source of fuel by 59 % either because it is readily available (42 %), freely accessible (14.6 %), and affordable (13.5 %). The implication of this form of livelihood on ecosystem is destroying because of the fact that trees that are harvested for fuel wood are never replanted except the effort of natural regeneration as confirmed by 56 % of the participating farmers.

Charcoal production: As a result of land degradation and shortage of water to support farming livelihoods, another major off-farm diversification is charcoal production. The conversion of wood into charcoal is done by the majority (68 %) of the population (youth in particular) because it generates income faster than crop planting that may wait until the planting and harvesting cycle is completed. Charcoal is on high demand as a main cooking energy source for both local and export to big cities. Engagement with some charcoal producers shows that they target some species of wood, especially the *Vitellaria paradoxa*, which are believed to be excellent for charcoal making. A matured tree (about 15 m high) will produce about ten bags of charcoal. Our investigations also reveal that the farm gate price for a bag of charcoal is between N700 and N800 (about USD5). This means that a matured tree which may have been more than 25–30 years old is sold for between N7000 and N8000 (about USD50).

Youths and adult age groups who are engaged in charcoal and firewood making will be affected if tree logging and deforestation are totally banned. When the short-term gain is compared to the ecosystem services provided by the same tree and more importantly by the regulating function such as carbon sequestration, the need to plan for alternative livelihoods and trade-offs if the ecosystem must be protected and if the active population will remain in the rural communities is inevitable.

Institutional Architecture

There is virtually no institutional collaboration work to promote ecosystem management and food security around the study area except for the Fadama project. A form of partnership is working in Kwara (one of the states covered in this study) among the Zimbabwean farmers in Shonga (located in Edu LGA in the rich River Niger alluvial floodplain). The project was supported by a public-private partnership strategy in which the state government provided the finance and other infrastructure.

Protection of Watershed and Water Storage

Most farmlands have watersheds which are thriving during wet season. During dry season, some of these watersheds are demarcated purely for certain farming activities. For instance, spring waters (*Seleru*) around some rocky areas (*ada*) in some localities are purely used for food processing such as cassava flour and yam flour because such water resource is very close to where the farmers will spread their product for solar heating.

In relation to water storage, most farming households have big water pots, each having at least 200 l capacity. Water harvest is usually done during the wet season and stored in these pots. Basically, the stored water is used for domestic purposes and irrigation of vegetable gardens at the back of house in the farm (“eyin abule”) when the rainy period ceased. In achieving some results from this option, most farmers indicated that they try to reduce the volume of water for some uses. This is a form of behavioral shift. Discussion with some farmers during the fieldwork indicated that the storage capacity is not adequate to sustain farming households throughout the dry season. In recent times, some farmers are now drilling wells which can serve them for food processing and domestic needs.

Appealing to the Goddess

During the interaction with some of the community leaders in the study area, it was revealed that another indigenous way of dealing with water supply shortages especially during extreme dryness (drought or sudden cessation of rain) is to appeal to the farm goddess (*Orisa Oko*). To do this, the community leaders and the goddess priests are principally involved to make rituals. When this is adequately done, it is believed that rain will start mostly 3 days (*ita*) post the appealing.

Conclusions

This chapter has shown that water variability in the Nigerian savannah is as a result of seasonal rainfall variation. The analysis of the farmers’ perceptions of climate change and water variability indicates that most of the farmers in the study area were aware that temperature is increasing, and the level of rainfall is declining. Observed station data and community perception indicates the delay in the onset of rain, earlier cessation of rain, and reduction in the number of raining days during wet season. These anomalies had implication for food production in the region because farming activities are basically rainfed. Planting seasons are already altered, while most participating farming households and community leaders revealed that the shortage in water supply and land degradation have impacts on their farm produce.

In the midst of these challenges, on-farm and off-farm coping options which are used during preplanting, planting, and post-planting seasons are available. Generally, the coping capacity of the study communities is very weak. However, engagement with the stakeholders during the feedback workshop shows that there is a general willingness to participate in ecosystem management and adopt new farming techniques. In the light of the above, the following suggestions are recommended as viable road map to sustainable food production and rural livelihoods in the Nigerian savannah:

- Reviving the old partnership practices: people and community leaders recalled with nostalgia the late 1970s and early 1980s when agricultural extension officers were regular and farming advice and inputs were provided through agencies such the Ogun-Osun River Basin Development Authority (OORBDA) and Oyo State Agricultural Development Programme (OYSADEP). Some of these organizations used to have offices within the community, and they hold regular meeting with the communities and advise them on climate, agriculture, forestry, food production, and rural livelihoods.

- Pro-food production agenda in poverty reduction programs: improving on the implementation of the existing poverty-focused policies and programs meant to transform the currently low-productivity agricultural sector where significant proportion of the population currently makes its livelihood. It is therefore important that programs such as Fadama should be more strengthened to allow more participation of rural farmers.
- Mainstreaming climate adaptation into food security policies: food security and adaptation to climate change are mutually supportive approaches. Design of food security programs must therefore take climate variability since farming is basically rainfed. In doing this, it is important that most of the national policies relating to agriculture and water resources are integrated climate change scenarios, downscaled and implemented locally.
- Water harvest: given the amount of total annual rainfall in the region and the availability of some watersheds, it is important that mechanisms for water collection are looked into both at the household and community levels. When this is done properly, it might salvage the challenge of irrigation.
- Institutional radicalization: it is observed that there is a need to rearchitect most institutions within the water and agricultural sectors in Nigeria. Since farming is mostly done by private individuals, this reality must be built into the institutional structures.
- Climate services: the forecasting tools currently deployed are regional in approach and general in perspective. This means a densification of existing meteorological network as well as arrangement to present end users (local farmers) with seasonal forecasts in a clear and simple language. More importantly, the Agricultural Meteorology Department of NIMET must be equipped in terms of capacity development on local climate forecasts.

Acknowledgment This study is part of the research on community-based management of ecosystems and natural resources for the improvement of rural livelihoods and food security in the Nigerian savannah, funded by the International START Secretariat through the grant for the Global Environmental Change (GEC) Africa Project for 2011–2012 from CDKN, NSF, and CCAFS.

Integrated Biophysical and Socioeconomic Model for Adaptation to Climate Change for Agriculture and Water in the Koshi Basin

Nilhari Neupane, Manchiraju Sri Ramachandra Murthy, Golam Rasul, Shahriar M Wahid, Arun B. Shrestha, and Kabir Uddin

Contents

Abstract

Water vulnerability is one of the major challenges facing people in the Himalayan river basins and is expected to increase with climate and other change. In order to develop appropriate and effective adaptation strategies, it is necessary to understand the level and spatial distribution of water vulnerability and the underlying factors contributing to it, both biophysical and socioeconomic. The development and application of a water vulnerability assessment model at district level, and its use in adaptation planning, is described using the

transboundary Koshi River basin as an example. The whole basin showed a relatively high degree of water vulnerability, with mountain districts the most vulnerable followed by the mid-hills and the plains. The mountain and mid-hill areas were more vulnerable in terms of resource stress and ecological security, whereas the plains areas were more vulnerable in terms of development pressure; all parts of the basin were vulnerable in terms of management capacity. Significant correlation among the four components indicated that improvements in resource availability, ecological security, and management capacity would reduce development pressure and overall vulnerability. Adaptation plans need to be based on district-specific vulnerability characteristics; some suggestions and recommendations for adaptation plans are made.

Introduction

Water is a multidimensional resource used for industrial, domestic, agricultural, and recreational purposes. In the majority of developing countries, a significant proportion of the total water withdrawal is for agricultural purposes, and there is a very strong linkage between water availability and peoples' livelihoods, as most livelihoods depend on agriculture. Water availability is mainly influenced by climatic parameters, such as rainfall, temperature, and snowfall, and anthropogenic changes, such as changes in the human and livestock populations, economic development, and urbanization (Kundzewicz and Somlyody 1997). The anthropogenic changes can in turn affect the climatic parameters leading to further change. Many drivers of change impact on current and future water availability, and water is considered to be a vulnerable resource to different degrees globally (Rosenzweig et al. 2004; Bates et al. 2008) increasing the challenges to water resource management (Kojiri 2008). The vulnerability of water resources directly affects peoples' livelihoods leading to increased poverty and problems of food and energy insecurity (Rasul 2012, 2014). Normally, poorer people in developing countries are more, and more rapidly, affected (Sullivan and Meigh 2005) because they are less resilient and have limited options for coping.

A water vulnerability assessment is a key entry point for suggesting suitable policy options for the sustainable utilization of water resources and plans for adaptation (Kelly and Adger 2000). The concept of vulnerability is complex and context specific, and different assessment tools have been developed for different purposes at different scales. The study described here focused on developing a water-based vulnerability assessment that could be used to develop adaptation strategies based directly on the parameter and linked indirectly with water resources specific to the study area. The study used UNEP water vulnerability assessment tools

(Babel and Wahid 2009a, b; UNEP 2011) as a framework, with some modifications and additional context-specific water-related variables so that it can be replicated in transboundary river basins of the Hindu Kush Himalayas. The strength of the approach is that it treats the biophysical and socioeconomic aspects of the river basin equally, in contrast to other studies which have tended to ignore the socioeconomic component. The water issues of the Koshi basin were used as a case study for transboundary river basins of the Hindu Kush Himalayan region; districts were taken as the smallest unit to allow empirical estimates of the current vulnerability scenarios of the basin at district level, identify basin specific vulnerability factors, and suggest suitable policy options. The study contributes to the conceptualization and methodological advance of water vulnerability assessment tools and demonstrates the applicability of the model and its contribution to adaptation planning using the Koshi basin as an example.

Notable studies on water vulnerability assessment in South Asian river basins include one for the lower Brahmaputra river basin (Gain et al. 2012) and one for the Ganges-Brahmaputra-Meghna river basin (Babel and Wahid 2011), both at macrolevels. Microlevel water vulnerability assessments have been conducted for the Bagmati River basin (Babel et al. 2011; Pandey et al. 2011) and medium-sized river basins in Nepal (Pandey et al. 2010, 2012), and a water poverty analysis for the Kali Gandaki river basin (Manandhar et al. 2012). Until now, no vulnerability assessments have been carried out at a transnational scale using district-level data (third-level administrative unit) to bridge the scales. The Koshi River is one of the major tributaries of the Ganges, and the river basin is characterized by a high level of poverty and food insecurity and thus offers a useful example for developing and testing the assessment approach.

The development of the water vulnerability assessment model, and application in planning for adaptation to climate change, is described in the following: the framework is presented in the first section; the second section describes the application of the model in a vulnerability assessment of a transboundary river basin at district level and its use in adaptation planning using the Koshi River basin as an example; and finally the approach and results are discussed and conclusions drawn.

Framework for a Vulnerability Assessment

Vulnerability is a complex concept; it differs from one discipline to another and is highly context specific (Young et al. 2010). The most widely used definition of vulnerability is that given by the IPCC (Intergovernmental Panel on Climate Change): “Vulnerability is the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes” (McCarthy et al. 2001). Vulnerability (V) can be expressed as

$$\mathrm{V} = \mathrm{f}\ (\text{exposure}, \text{sensitivity}, \text{adaptive capacity})$$

The exposure and sensitivity of a system are related to hazards and cause the vulnerability, while the adaptive capacity is a “shock absorber” and has an inverse relationship to exposure and sensitivity (Brooks et al. 2005; Hamouda et al. 2009). Biophysical forces are responsible for the exposure and sensitivity of the system, while sociocultural, political, and economic forces contribute to the adaptive capacity (Adger 2006; Smit and Wandel 2006).

Why Use an Integrated Modeling Approach for Water Vulnerability Assessment?

Most vulnerability assessments have been based on physical or biological disciplines (Sullivan and Meigh 2005) which view vulnerability in terms of the likelihood of occurrence of climate-related events (Adger 2006). This conventional approach is a top-down or end-point approach and does not look at adaptation options to cope with the vulnerability (Young et al. 2010). In contrast, social scientists view vulnerability as a set of socioeconomic and institutional factors that determine people’s ability to cope with stress or change (Kelly and Adger 2000; Brooks 2003). According to Sen, socioeconomic parameters such as access to essential resources like forest, land, and water should also be reflected in the vulnerability analysis (Sen 1981, 1990). Similarly, Adger et al. (2005) strongly emphasized the importance of incorporating socioeconomic systems with biophysical systems at varied spatial and social scales in the vulnerability assessment. O’ Brien et al. defined vulnerability to climate change as a function of a range of biophysical and socioeconomic factors (O’ Brien et al. 2004). Incorporating socioeconomic parameters into a vulnerability assessment is called a bottom-up or starting-point approach and has direct application in adaptation planning (Young et al. 2010). In the past, the vulnerability created by socioeconomic factors was largely ignored (Adger and Kelly 1999), in part because of the quantification and indexing problems for qualitative and quantitative data (Cutter et al. 2003; Plummer et al. 2012).

Water-based vulnerability assessments should also incorporate socioeconomic factors (Sullivan 2011) because people constantly interact with water resources for their livelihoods, and social factors make a significant contribution to water vulnerability (Sullivan and Meigh 2005). Incorporating socioeconomic factors in water vulnerability assessments will enable more effective adaptation strategies to be developed (Vorosmarty et al. 2000; Sullivan and Meigh 2005) and provide a holistic approach along the lines of integrated water resources management (IWRM) (Vorosmarty et al. 2000; Babel and Wahid 2011; Plummer et al. 2012).

Two of the earliest studies using biophysical and socioeconomic parameters in water vulnerability assessments are those by Boruff et al. (2005), who combined physical and socioeconomic factors in a model used to determine county-level vulnerability caused by coastal erosion in the USA, and by Sullivan and Meigh

(2005), who developed a climate vulnerability index (CVI) focused on water-related variables which considered a wide range of socioeconomic and physical parameters at different spatial scales. In the UNEP methodologies guideline for vulnerability assessment of freshwater resources (Huang and Cai 2009), water resource vulnerability is decomposed into resources stress (RS), development pressure (DP), ecological security (ES), and management challenges (MC). The first three are linked to the parameters of exposure and sensitivity in the conventional definition of vulnerability, while the last is linked to adaptive capacity. Sullivan (2011) considered the resource stress component to be the supply-driven aspect of water vulnerability, and the other three components to be the demand-driven aspect of water vulnerability.

Steps in Vulnerability Assessment

Figure 1 shows a schematic outline of the water vulnerability assessment framework (modified from Hamouda et al. 2009; Gain et al. 2012).

The first step is to define the water resource system that defines the biophysical and socioeconomic components. The second step is to define the problems in the system and choose the scale. Major water-related problems include the degree of water scarcity for different sectors, water pollution, erosion, upstream deforestation, land degradation, upstream and downstream conflicts, food insecurity, and incidence of poverty. Spatial scales can range from the whole basin or sub-basin to watershed, community, or individual levels; temporal scales decide whether the study is a monthly, seasonal, annual, or long-term assessment. The selection of spatial and temporal scales depends on the nature and scope of the work.

The third step is to select an appropriate analytical tool or model. There are more than 50 models available for water vulnerability analysis (Plummer et al. 2012). The most suitable model for the study should be selected and modified based on the nature of the problem to be addressed. The next step – identifying and defining the indicators of vulnerability – is a very important part of the analysis. Vulnerability is a complex concept and cannot be measured directly. It has to be represented using a combination of proxy indicators and variables, even though this does not represent it fully (Brenkert and Malone 2005). Sullivan and Meigh (2005) defined an indicator as a statistical concept that provides an indirect way of measuring a given quantity and state and allows for current assessment and comparison over time. According to Vorosmarty et al. (2000), the indicators should be relevant to the issues, policy relevant, analytically and statistically sound, understandable, and easy to interpret. There are two approaches to indicator selection: firstly, from the literature, using inductive or deductive approaches, and secondly, from expert judgment (Hinkel 2011).

After the list of indicators and subindicators has been developed, the data collection can proceed. Stakeholder's participation and field visits are important for triangulation.

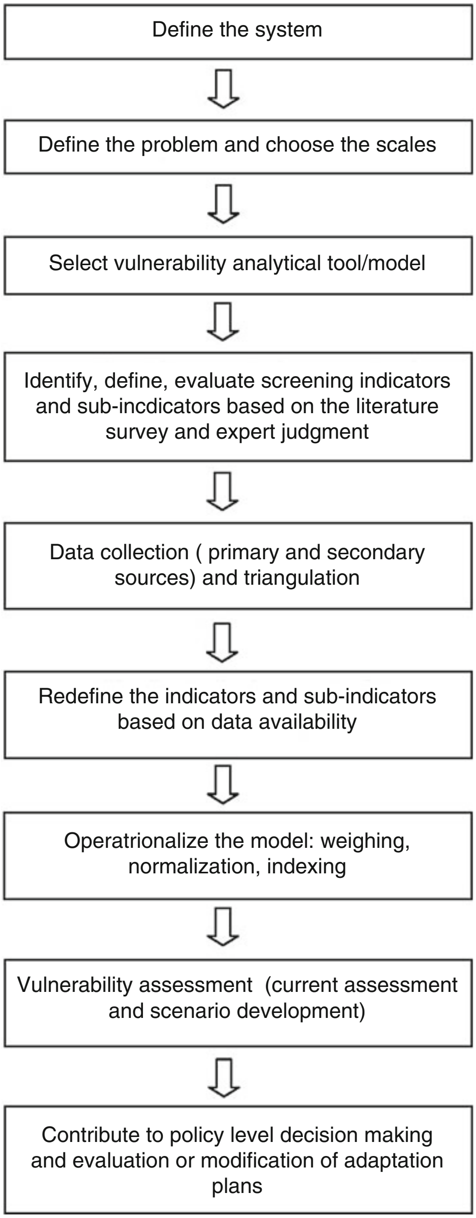

Fig. 1 Framework for water vulnerability assessment

After the data has been compiled, the indicators should be redefined based on the data availability. The indicators are then normalized and entered into the vulnerability model. Finally, the model is run, the results are interpreted, and policy recommendations are made.

Application of the Vulnerability Framework to the Koshi River Basin

The water vulnerability assessment framework (Fig. 1) was applied to the Koshi River basin at district scale. The aim was to identify the vulnerable districts and the biophysical and socioeconomic factors contributing to basin vulnerability and to use this to recommend location-specific adaptation strategies that can help policy makers to evaluate or modify existing policy options for adaptation management strategies for water resources (Babel et al. 2011). The individual steps in the assessment are described in the following.

Defining the Koshi System and the Problem

The Koshi River basin is a transboundary basin which originates in the southern area of the Tibetan Plateau in China, passes through Nepal from north to south, and then crosses the northern part of Bihar in India before joining the Ganges. The basin can be broadly divided into four geographical regions (Fig. 2): the Transhimalayan region, which consists of six counties in Tibet Autonomous Region of China (>3,500 masl); the mountains, comprising five mountain districts in eastern Nepal (3,500–8,000 masl); the mid-hills, comprising 11 mid-hill districts in Nepal (1,000–3,500 masl); and the Terai (plains area), comprising 11 Terai districts in Nepal and 16 districts in Bihar state in India (<1,000 masl). For the purposes of the study, the first three were taken as the upstream and the Terai districts as the downstream.

The Koshi is a major tributary of the Ganges and the third largest river in the Himalayas after the Brahmaputra and Indus (Sharma et al. 2000). The river basin covers an area of 90,404 km^2, 22 % in India, 33 % in China, and 45 % in Nepal. It is home to more than 50 million people, most with livelihoods based on agriculture. Both the socioeconomic and the biophysical gradients of the basin change with elevation, resulting in differences in water availability and accessibility in different parts of the basin and thus differences in water vulnerability. The upper part of the basin has problems associated with snowmelt, water runoff, soil erosion, and land degradation, while the lower part has problems associated with waterlogging, population growth, expansion of agricultural land, and urbanization.

Rainfall in the basin is highly variable in time and space. The annual rainfall ranges from 207 mm in the Transhimalaya to more than 3,000 mm in the eastern mountains and mid-hills of Nepal (Fig. 3). More than 80 % of the rainfall is from the downstream monsoon, which occurs from July to September. Climate change is expected to increase water scarcity, and this together with socioeconomic changes is expected to decrease the per capita water availability for domestic and agricultural use, which will ultimately influence the agro-based livelihoods of the people in the basin and threaten food security. The per capita water availability per annum in the countries that share the basin (2,060, 1,784, and 6,895 m^3 per

capita for China, India, and Nepal, respectively) is higher than the water poverty threshold of 1,700 m^3 (Falkenmark and Widstrand 1992) but lower than the world average of 7,243 m^3; and actual water withdrawal is considerably lower than the availability (584, 805, and 966 m^3 per capita per annum for China, India, and Nepal, respectively) (Rosegrant et al. 2002; Babel and Wahid 2011; FAO AQUASTAT 2013).

Selection of the Vulnerability Assessment Model

The UNEP water vulnerability assessment model (Babel and Wahid 2009a, b; UNEP 2011) was selected for the Koshi basin assessment. The advantages of this method are first that it offers a flexible and holistic approach that combines biophysical and socioeconomic indicators and second that it has been widely used for determining water vulnerability at basin level and is simple to calculate and the results easy to interpret. In this model, vulnerability is decomposed into resource stress (RS), development pressure (DP), ecological security (ES), and management challenges (MC). Resource stress is defined as the pressure on the water resources resulting from socioeconomic and environmental change (Babel et al. 2011); development pressure refers to the main socioeconomic development activities in the basin; ecological security refers to the ecological health of the basin, because the quality of the environment is an essential factor for sustainable use of water resources and coping with water stress (Manandhar et al. 2012); and management capacity (also called social vulnerability) refers to people's ability to manage water and is directly linked with the adaptive capacity of the basin. Mathematically, water vulnerability can be expressed as water vulnerability = f [resource stress (RS), development pressure (DP), ecological security (ES), management challenges (MC)].

The vulnerability index (*VI*) is calculated by aggregating and assigning weights to the four vulnerability components. The water vulnerability equation can be presented as

$$VI = \left[\sum\nolimits_{i=1}^{n}\left(\sum\nolimits_{j=1}^{m_i} X_{ij} \times w_{ij}\right) \times W_{ij}\right] \tag{1}$$

where

VI is the vulnerability index

n is the number of vulnerability components

m_i is the number of parameters in the ith component

X_{ij} is the jth parameter in the ith component

w_{ij} is the weight to the jth parameter in the ith component

W_{ij} is the weight given to the ith component

VI has a value between 0 and 1, with higher values representing higher vulnerability.

Preliminary and Final Identification of Indicators, Subindicators, and Variables

A list of potential socioeconomic and biophysical variables closely linked with water vulnerability was prepared using an intensive literature survey and intuitive understanding of society-water interactions (Sullivan 2002; Lawrence et al. 2002; Brooks et al. 2005; Pandey et al. 2012). Expert opinion was also solicited from an interdisciplinary team. The variables were then grouped broadly under the four components of water vulnerability proposed by UNEP. In all 88 biophysical and socioeconomic variables were identified as potential variables in the preliminary list, 19 related to resource stress, 24 to development pressure, 16 to ecological security, and 29 to management capacity.

After listing potential indicators and variables, data were collected from secondary sources including the Central Bureau of Statistics (2001, 2003, 2004, 2011), Census of India (2001, 2011), Central Bureau of Statistics and International Centre for Integrated Mountain Development (2003), Central Bureau of Statistics, World Food Programme, and World Bank (2006), Chaudhuri and Gupta (2009), Nepal Living Standards Survey (NLSS 2011), and Ministry of Agricultural Development/Government of Nepal (2012). Where possible, long-term data were collected for the individual variables; where these were unavailable, multiple year data were collected, or data from a single year was used as a proxy for long-term data as suggested by Brooks et al. (2005). The list of potential indicators and variables was then evaluated. Some variables were removed, either because a high level of colinearity was identified between two variables within the same component or because the data could not be accessed through secondary sources for all the basin districts. For example, the number of households that belong to an irrigation management group, an important indicator of management capacity, was available for Nepal but not for India. The final list contained 34 variables, five for resource stress, six for development pressure, seven for ecological security, and 16 for management challenges. Table 1 shows the list of variables and their functional relationship with vulnerability.

Operationalizing the Model

This integrated approach to vulnerability assessment uses a wide range of biophysical and socioeconomic variables at different scales and with different units. The indicators were normalized to a value between 0 and 1 using UNDP's normalization approach, as used, for example, in calculating the Human Development Index (HDI) (UNDP 2006). The functional relationship was taken into account while normalizing. The equations used are shown below, Eq. 2 was used for positive functional relationships and Eq. 3 for inverse relationships (modified from Turvey 2007; Hamouda et al. 2009; Islam et al. 2013):

Table 1 Indicators and variables used in the vulnerability assessment of the Koshi River basin and their functional relationship with vulnerability

Variable (year)	Unit	Functional relationship
Resource stress		
Rainfall variability (1950–2000)	Coefficient of variation	Increase
Temperature variability (1950–2000)	Coefficient of variation	Increase
Water availability	km^3	Decrease
Water withdrawal	km^3	Increase
Distance to water source	km	Increase
Development pressure		
Population density	$Persons/km^2$	Increase
Population growth	%	Increase
Arable land	%	Increase
Irrigated area	%	Increase
Livestock density/ha	Livestock units/ha	Increase
GDP per capita	USD	Increase
Ecological security		
Fertilizer use	%	Increase
Crop intensity	%	Increase
Households that use conventional energy for cooking	%	Increase
Households that use conventional energy for lighting	%	Increase
Forest area	%	Decrease
Slope	%	Increase
Erosion	%	Increase
Management capacity		
Literacy rate	%	Decrease
Permanent house	%	Decrease
Family size	Number/hh	Increase
Farm size	ha/hh	Decrease
Herd size	Number/hh	Decrease
Economically active population	% (15–59 years)	Decrease
Yield of food grain (rice yield as a proxy)	kg/ha	Decrease
Milk production	Metric t	Decrease
Irrigation coverage	%	Decrease
Drinking water coverage	%	Decrease
Sanitation (toilet facilities)	%	Decrease
Access to electricity	%	Decrease
Access to bank	%	Decrease
Households with TV	%	Decrease
Access to forest	%	Decrease
Poverty incidence	%	Increase

Table 2 Reference sheet for interpretation of the vulnerability index

Vulnerability index	Interpretation
Low (<0.2)	Healthy basin
Moderate (0.2–0.4)	Basin generally in good condition but facing issues in management capacity, needs strong policy intervention to improve the situation
Relatively high (0.4–0.5)	High stresses in the basin, needs long-term river basin plan to improve the situation
High (0.5–0.6)	
Very high (0.6–0.7)	
Severe (0.7–1.0)	Highly degraded basin, needs long-term integrated plan to improve the situation

Modified from Huang and Cai (2009)

$$X_{ij(\text{normalized})} = \left[\frac{X_{ij} - \min\left(X_{ij}\right)}{\max\left(X_{ij}\right) - \min\left(X_{ij}\right)}\right] \tag{2}$$

$$X_{ij(\text{normalized})} = \left[\frac{\max X_{ij} - X_{ij}}{\max\left(X_{ij}\right) - \min\left(X_{ij}\right)}\right] \tag{3}$$

where

Index $X_{ij\ (\text{normalized})}$ is the normalized value of an indicator

X_{ij} is the actual value of the indicator

$\max(X_{ij})$ and $\min(X_{ij})$ are the maximum and minimum values of the indicator, respectively

After normalization, the normalized values were entered into Eq. 1 to determine the vulnerability index per component and overall. According to UNEP (2011), assigning relative weights to individual indicators can be biased and will lead to problems with comparisons; thus, parameters should be assigned equal weights. For this reason, a balanced weighted average approach was used (Schulze 2007; Pandey et al. 2012; Manandhar et al. 2012) in which each of the four components contributed equally to the total vulnerability. The resulting composite score described the water vulnerability of the Koshi basin. The UNEP reference sheet shown in Table 2 was used to interpret the results.

Results

The results of the water vulnerability assessment were limited to the part of the basin in India and Nepal; this consists of 43 districts and three broad geographical zones.

Basin-Scale Vulnerability

The overall vulnerability index for the whole Koshi basin was 0.401, with a range of 0.327–0.482, which indicates a relatively high level of water vulnerability in the basin (Table 3). Of the basin districts analyzed, 51 % were moderately vulnerable and 49 % highly vulnerable (Table 4). None of the basin districts was either healthy or highly degraded. The low SD value indicates that there is little variation in the degree of vulnerability within the basin, but the sources of variation within the basin may differ.

The whole basin is moderately vulnerable in terms of resource stress and development pressure (0.35 and 0.30), but the relatively higher standard deviations of these components indicate that the degree of vulnerability varies significantly within the basin (Table 3). In both cases, more than 70 % of the districts were moderately vulnerable and only a few highly or severely vulnerable (Table 4). The index values for ecological security and management capacity for the whole basin were higher (0.46 and 0.48) and with a relatively small SD, showing a higher degree of vulnerability with smaller variation within the basin (Table 3); more than 80 % of districts were highly vulnerable in terms of ecological security and management capacity (Table 4).

Mapping Vulnerability Across Geographical and District Scales

Table 5 shows the 12 most vulnerable and 12 least vulnerable districts based on the aggregate vulnerability index. Comparison of the most and least vulnerable districts within a basin can help in designing policy options for the improvement of problematic districts by learning from less vulnerable districts. Figure 4 shows the geographical distribution of different levels of aggregate vulnerability. Overall, vulnerability tends to be higher in the mountains and mid-hills and moderate in the plains areas, with some exceptions. All five mountain districts were in the top 12 vulnerable districts (Table 5), as were 4 of 11 mid-hill districts, but only 3 of 27 plains districts. Nine plains districts and 3 mid-hill districts were among the 12 least vulnerable districts.

The aggregate vulnerability score provides a general indication of water vulnerability but does not explain the underlying causes. The component-wise values provide more indication of the causes and thus of areas of focus in developing relevant adaptation policies and strategies. Figure 5 shows the component-wise vulnerability of the Koshi basin districts from upstream to downstream; Table 6 shows the 12 most vulnerable districts for each component; and Figs. 6, 7, 8, and 9 show the geographical distribution of levels of vulnerability for the individual components.

Resource stress was generally higher in the mountains and some of the mid-hills and much lower in the plains districts (Figs. 5 and 6). The 12 most vulnerable districts in terms of resource stress included all five mountain districts, two districts from the mid-hills, and five in the plains (Table 6).

Development pressure vulnerability was generally higher in the mid-hills and plains areas (Figs. 5 and 7). The 12 most vulnerable districts included three

Table 3 Vulnerability of the Koshi basin

Vulnerability component	Minimum	Maximum	Mean	[a]SD
Resource stress	0.220	0.731	0.350	0.110

from the mid-hills (Kathmandu, Bhaktapur, and Lalitpur) and nine from the densely populated plains area in India (Table 6).

Ecological vulnerability extended over the whole basin, but was more pronounced in the hills and mountains than in the plains (Figs. 5 and 8). All 12 of the most vulnerable districts from an ecological perspective were from mountain and mid-hill areas, and all had a relatively high index value (>0.5) (Table 6).

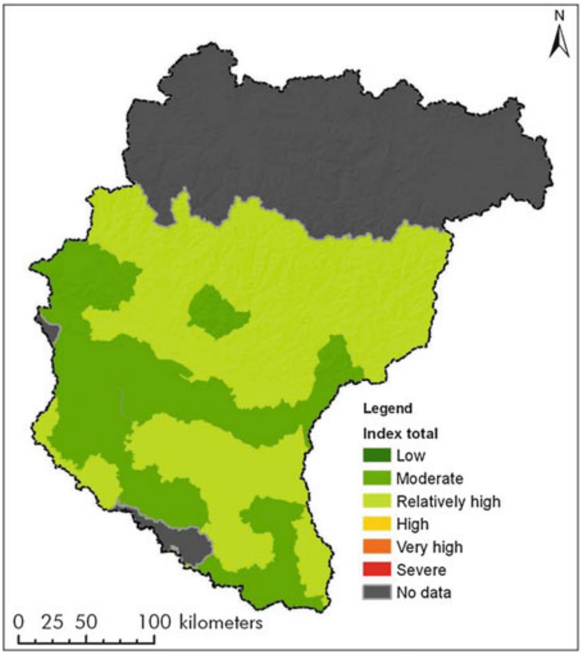

Fig. 4 Aggregate vulnerability at district level in the Koshi basin

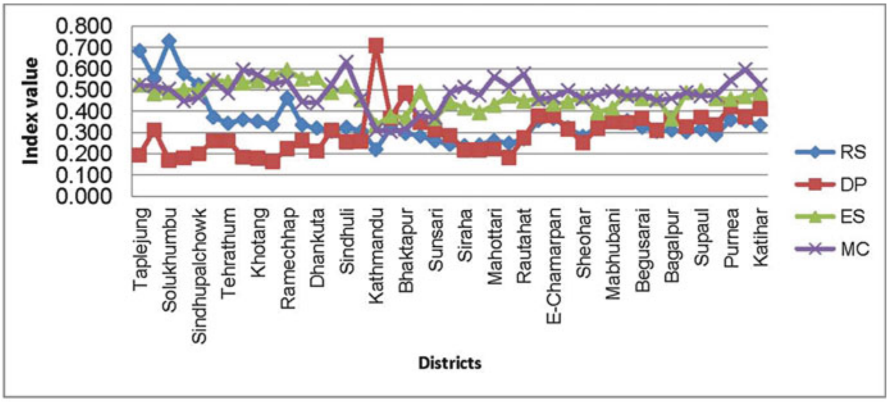

RS= Resource stress, DP = Developmental pressure, ES = Ecological security and MC = Management capacity

Fig. 5 Component-wise vulnerability of districts in the Koshi basin from upstream to downstream

Vulnerability due to low management capacity was high in most of the basin (Figs. 5 and 9), and the 12 most vulnerable districts included districts in all three geographical regions.

Five districts (Taplejung, Ramechhap, Panchthar, Bhojpur, and Purnea) were among the 12 most vulnerable districts for three of the four components (Table 6).

The Relationship Among the Vulnerability Components

The results of correlation analysis among the four components of water vulnerability are shown in Table 7. Resource stress, ecological security, and management capacity have a positive and linear relationship with each other and a negative relationship with development pressure. In other words, improvement in any of the first three components will improve the others and reduce development pressure and the overall vulnerability index; conversely, any deterioration in these components will generate adverse effects.

Table 7 Correlation analysis among the components

Component	Resource availability	Development pressure	Ecological security	Management capacity
Resource availability	X	Significant (at 5 %) and negative relationship	Significant (at 1 %) and positive relationship	Not significant but coefficient is positive
Development pressure		X	Significant (at 1 %) and negative relationship	Significant (at 1 %) and negative relationship
Ecological security			X	Significant (at 1 %) and positive relationship
Management capacity				X

Discussion

There was a higher incidence of overall vulnerability in the mountain and mid-hill areas. This can be linked to the mountain specificities (Jodha 1990; Rasul and Karki 2007) and the policy bias affecting mountain areas (Rasul and Karki 2007). The variation in vulnerability among districts within each geographical region is a result of the district-specific socioeconomic and biophysical characteristics, which can be looked at using the component-wise vulnerability results and their interrelationships.

Resource stress was not a major issue in most of the districts in the plains; water in this area is generally abundant and underutilized (Shah et al. 2006). However, it was critical in the mountain districts and some mid-hills districts, such as Bhojpur and Dhankuta, where most people have to rely on rainfall as their main or only source of water. The high resource stress in these areas may be related to the problems of higher slope gradient, high runoff, and greater variability in rainfall (ICIMOD 2009). Resource stress is expected to intensify with climate change. Resource stress was negligible in the plains area of Nepal and most of Bihar. Many reports suggest that the major problems in Bihar relate to waterlogging and flooding rather than water stress (Government of Bihar 2012). The somewhat higher incidence of resource vulnerability in some Bihar districts (Table 6) is mainly due to lower and variable rainfall, drought is prominent in these districts (Government of Bihar 2012).

In contrast to resource stress, development pressure had a higher incidence in the plains areas as well as in a few urban hubs in the mid-hills. This results from higher population growth and more economic activities in comparison to the mountains and most of the mid-hills.

Ecological vulnerability was higher in the mountains and mid-hills as a result of higher rates of deforestation, higher livestock pressure, and slope farming, consistent with the findings of Jodha (1990). Babel and Wahid (2011) also observed more ecological problems in the (higher) Nepal part of the Ganges-Brahmaputra-Meghna basin than in the (lower) Indian part. However, the ecological problems upstream have a negative impact downstream. The lower ecological vulnerability in a few mid-hills districts may be due to the recent increase in community forestry in those areas in comparison with other parts of the Koshi basin (Sharma et al. 2000). The higher vulnerability in a few districts in the plains area might be due to relatively higher fertilizer use, lower forest coverage, and more use of conventional sources of energy.

Vulnerability due to a lack of management capacity was widespread in the basin irrespective of geographical zone and was particularly high in districts with higher poverty and illiteracy rates and poor performance of other socioeconomic variables. Here the problem is not so much lack of the resource but more lack of capacity to manage what is available. The low index values in the three mid-hill districts of Kathmandu, Lalitpur, and Bhaktapur (which together form Kathmandu Metropolitan City) are due to the higher socioeconomic indicators in those districts and are consistent with the findings of Pandey et al. (2012) on the Bagmati River basin.

Five districts – Taplejung (mountains), Ramechhap, Panchthar, and Bhojpur (mid-hills), and Purnea (plains) – were among the 12 most vulnerable districts for three of the four vulnerability components and can thus be considered as hot spots of vulnerability. The nature of vulnerability in these districts is more multidimensional and widespread than elsewhere and thus requires immediate intervention for recovery.

The strong positive relationship between resource availability and ecological security indicates that an increase in resource availability will also increase the ecological security, for example, an increase in moisture in the Koshi basin will result in an increase in biomass. Equally, improving the ecological security will enhance resource availability, for example, by improving the water retention capacity of the watershed. The reverse is also true, a decrease in resource availability will reduce ecological security and vice versa. The positive, but not significant, relationship between resource availability and management capacity indicates that improved management capacity cannot significantly increase the resource availability, this may be the result of the high levels of poverty. Unlike other basins, the Koshi has abundant water but people cannot use it due to the lack of economic investment.

The strong negative correlation between development pressure and ecological security indicates that an increase in development pressure will lead to a decrease in ecological security. For example, an increase in agricultural land will decrease forest cover, and cultivation of cereals on sloping land will increase soil erosion. The strong negative correlation between development pressure and management capacity indicates that increasing the management capacity will decrease the development pressure. For example, if people's management capacity is strengthened, they will switch to more efficient methods of farming, use water in more profitable sectors, and use more efficient methods of irrigation, all of which decrease the development pressure.

Finally, the strong positive relationship between ecological security and management capacity indicates that when people's management capacity is strengthened, they will switch to more ecologically appropriate practices, for example, agroforestry in place of cereal cultivation, which will increase ecological security by reducing erosion and land degradation.

The extent and causes of vulnerability within the Koshi basin differ from one geographical zone to another and from one district to another. Some districts are stronger in one aspect and weaker in others. Therefore, any adaptation plan must be based on the district-specific vulnerability characteristics and the relationship among the vulnerability components.

Conclusions and Policy Implications

The results describe the development of a water vulnerability assessment tool based on a modification of the UNEP model and its use to assess water vulnerability in the Koshi basin at district level. The overall vulnerability of the Koshi basin was relatively high, with mountain districts the most vulnerable followed by the mid-hills and the plains. The 43 districts were mapped using a biophysical and socioeconomic modeling approach based on four components of vulnerability, and the results converted into GIS interfaces. The component-wise vulnerability assessment showed that mountain and mid-hill areas (upstream) are more vulnerable in terms of resource stress and ecological security, whereas the plains areas are more vulnerable in terms of development pressure, while all parts of the basin were vulnerable in terms of management capacity. Five districts were identified as hot spots of water vulnerability that need immediate attention to improve the situation.

Significant correlation among the four components indicated that improvements in resource availability, ecological security, and management capacity would reduce development pressure and overall vulnerability, while deterioration in any of the three components would have the reverse effect.

The validity of the model could be increased in further studies by adding important parameters like water quality and using field surveys to obtain data. Assessment of smaller areas, for example, at VDC or ward level, would also improve the assessment of vulnerability.

This study shows clearly that adaptation plans should be based on location-specific vulnerability characteristics rather than using a blanket approach. The findings will help policy makers to identify the water vulnerable geographical zones and districts and to frame policy plans for these particular locations.

Recommended adaptation options to reduce the resource stress upstream include construction of storage structures like rainwater storage tanks and reservoirs and rehabilitation of old infrastructure (ICIMOD 2009; Bartlett et al. 2010). These measures would also help provide a continuous water supply to the downstream during the dry season.

Recommended adaptation strategies to reduce development pressure without compromising the net social benefit include incorporating improved crop varieties and reducing cropping intensity; introducing water demand management strategies such as increasing water productivity and water use efficiency by diverting water to more profitable crops, and using more efficient irrigation methods; and replacing low yielding cattle with higher yielding cattle.

Recommended adaptation strategies to reduce ecological vulnerability include afforestation of barren land, replacement of cereal crops on sloping land by agroforestry practices and hedgerows (White and Bhuchar 2006), increasing access to electricity in the basin from the present low rates to help lower the deforestation rate, and using balanced amounts of fertilizer (downstream) and/or green manure to maintain soil fertility. Introduction of adaptation strategies upstream will also help improve ecological vulnerability downstream.

Finally, it is essential to increase management capacity, which is mostly governed by socioeconomic factors, across the basin. Management capacity should be improved through government capacity building programs in such areas as food security, literacy, and rural electrification.

The significant interrelationships among the vulnerability components suggest that adaptation plans designed to improve one component will automatically result in improvements in the other components. Similarly, the Koshi basin has strong upstream downstream linkages. If suitable adaptation plans are adopted upstream, this will bring positive benefits downstream, while maladaptations upstream will have a negative effect downstream. This study recommends the need for a mountain-specific policy focus as suggested in Rasul and Karki (2007).

Finally, the study recommends carrying out a comprehensive vulnerability assessment at community or household level using field data in order to clearly identify the vulnerable sections of society, since it is people, not administrative units, who are vulnerable (Brooks et al. 2005). This study acts as an entry point for such studies by identifying the vulnerable locations within the Koshi basin.

Nationally Appropriate Mitigation Actions for the Dairy Sector in Malawi: Needs and Opportunities

Irina Arakelyan and Dominic Moran

Contents

Abstract

Developing country agriculture makes a significant contribution to climate change, and the sector offers considerable potential for exploring synergies and trade-offs between mitigation, food security, and poverty reduction. But few developing countries will adopt unfunded measures to reduce greenhouse gas emissions if they compromise development and growth. Nationally appropriate mitigation actions (NAMAs) have been mooted as a means to develop possible funding modalities either within the United Nations Framework Convention for Climate Change (UNFCCC), from aid donors, or other parties seeking to fund emissions offsets in low-income countries. This chapter explores the identification of climate-smart practices that might be included under the

definition of agricultural NAMAs. It outlines elements relevant to the development of triple-win agricultural NAMAs in the smallholder dairy sector in Malawi and offers survey evidence identifying pro-poor mitigation practices, technologies, and policies for the dairy sector by assessing the current baseline and analyzing barriers to growth.

Keywords
Mitigation • Greenhouse gas emissions • Nationally appropriate mitigation actions (NAMAs)

Introduction

Climate change seriously compromises food security in some of the least developed countries, and there is an urgent need to enhance local adaptive capacity to minimize impacts and to maintain the required levels of food production (Rosenzweig and Tubiello 2007). Agriculture is also a significant source of greenhouse gas emissions, estimated to be around 10–14 % of the global total (Smith et al. 2007a), and it is the largest source of non-CO_2 greenhouse gas (GHG) emissions (De Pinto et al. 2013). To meet the demands of a growing world population, agricultural production also needs to grow, and in the absence of a step-change in the emissions intensity per unit product, this will almost inevitably lead to an increase in GHG emissions and in the sector's contribution to climate change (The Meridian Institute 2011). Assuming the sector can adapt, one of the most important areas where trade-offs might occur in coming decades is between GHG mitigation and food security.

Recent research has shown that agriculture offers significant mitigation opportunities. Smith et al. (2007b) estimate the global technical GHG mitigation potential for agriculture by 2030 to be about 5,500–6,600 Mt CO_2-eq. per year, with around 70 % of this potential thought to be in developing countries (CCAFS 2012b) and much of it potentially achievable at low cost. But realizing this potential will be challenging since under UNFCCC, non-Annex 1 (including most developing) countries do not have to subscribe to binding emissions targets, and even if they did, agricultural emissions are a particularly complex source to regulate in all contexts. Some countries such as Brazil have identified potential business opportunities in undertaking mitigation actions as part of an agenda to maintain a business edge in important livestock export sectors (BMA 2010). But the mitigation agenda also opens the potential for global aid transfers to affect low-cost mitigation in lower-income countries that could be convergent with development objectives. Agriculture is a conduit for affecting the well-being of a large proportion of the world's poorest. But it is also biophysically heterogeneous and institutionally diverse between countries and regions, conditions that complicate the definition of climate-smart interventions. Nevertheless, agricultural systems can be better designed to include farm management measures that combine complementary mitigation, adaptation, and food security or poverty alleviation outcomes. These can build on practices and technologies that are already available but need to be tailored to specific contexts including smallholder systems that characterize the sector in many developing countries. A key point is that these actions must offer a net benefit to farmers and be easily incorporated within farm practice. But mitigation actions are also likely to require incentives to help farmers adapt their practices. These incentives should provide demonstrable benefits in order to be successful.

Agriculture is the main economic activity in Malawi (Malawi Government 2011a). Food security has been a government strategic priority for the last few decades, and sectoral policy has been strongly focused on increasing food security at the household level, via improving access to essential inputs (Malawi Government GoM 2011b). Rain-fed agriculture practiced by the majority of smallholders is particularly vulnerable to climate change and the increasing incidence of droughts and erratic rainfall (99 % of 3 million ha of agricultural land in Malawi are rain dependent; FAO 2011).

Changing weather patterns have led to an increase in food security risks (Global Facility for Disaster Reduction and Recovery 2011), with the country applying for an emergency food relief as a result of the droughts in 2001 and 2005.

With the climate threat, Malawian farmers need to diversify their agricultural practices in order to have access to a reliable income stream and to maintain food security. The dairy sector is ideal for this, since it is less weather dependent than arable cropping. Assisting the development of the dairy industry in Malawi could have a positive impact on the livelihoods of the rural population which is the poorest in the country.

Despite the present danger of climate change in Malawi, there is concern that the policies and measures needed to reduce greenhouse gas emissions may impede the country's economic growth. The main challenge therefore is to control greenhouse gas emissions without negative impacts on the economy (van Asselt et al. 2010). Agricultural adaptation and (pro-poor) mitigation agendas are thus convergent in a country like Malawi, which offers a context to explore so-called climate-smart interventions. These can be defined to encompass actions that will help implement these technologies on the ground, or via, for example, policy interventions at the national level or via regional projects (e.g., supply chains) that can nevertheless deliver local benefits. The remainder of this chapter reviews issues of mitigation in the dairy sector and reflects on synergies with increasing food security and adaptation. It considers the development of a potential financing mechanism – agricultural nationally appropriate mitigation actions (NAMAs) – in the dairy sector. The chapter is structured as follows. Section "Background" provides background on the links between animal agriculture and climate change. It describes the current situation in the Malawian dairy sector and outlines potential opportunities for the development of dairy sector NAMAs. Section "Materials and Methods" provides information on survey data collected to understand farming practices and attitudes to climate change and presents results and discussion. Conclusions and implications are discussed in section "Results and Discussion."

Background

The Role of Livestock in Climate Change

Livestock are a significant source of GHG emissions including the largest source of global methane emissions from manure and enteric fermentation and N_2O from manure. Both gases have global warming potentials considerably higher than CO_2. In a comprehensive life cycle assessment (LCA), the Food and Agriculture Organization of the United Nations (FAO) has estimated that the sector contributes approximately 18 % (7.1 billion tons of CO_2 equivalent) of total GHG emissions (FAO 2006). A growing world population, predicted to reach 9 billion by 2050, will lead to an increase in the demand for livestock products with the corresponding increase in GHG emissions (Gerber 2010). The increase in livestock populations is predicted to happen mainly in the developing world, where there are currently fewer opportunities for emissions mitigation. The impacts of the increase in food production on climate change are likely to be significant. Adopting mitigation and adaptation strategies that simultaneously reduce the worst impacts of climate change on the livestock-based systems, while reducing the contribution of these systems to climate change, is therefore essential.

Within the livestock sector, rapid growth in dairy production is significant in terms of its impact on climate change and the environment. FAO estimated that in 2007, the contribution of global milk production, processing, and transportation to total anthropogenic emissions (excluding meat) was estimated at 2.7 % of total anthropogenic GHG emissions reported by IPCC (FAO 2010). The study shows that emissions per unit of milk product vary greatly across regions, with the highest emissions estimated for sub-Saharan Africa (SSA) with an average of 9.0 kg CO_2-eq per kg fat and protein-corrected milk (FPCM) at the farm gate. This compares to a global average estimated at 2.8 kg CO_2-eq (FAO 2013c). This disparity exists because of low protein production in SSA – ruminants have a very high emission intensity and low protein output (i.e., low milk production) leading to higher emissions per kg of milk in SSA than in North America or Western Europe (FAO 2013c).

But there are challenges in terms of designing interventions to redress this difference. Firstly, relative to other sectors (e.g., transport and energy), emission mitigation in agriculture is biophysically more complex and dependent on specific farm conditions. Moreover, trying to address the actions of millions of smallholders confronts behavioral and socioeconomic barriers that need to be understood in order to facilitate monitoring and verification of emission reductions.

Smallholders and Climate-Smart Practices

Smallholder agriculture is still the main economic activity in much of SSA, the livelihoods of millions being closely linked to farming (Pye-Smith 2011). Economic vulnerability is influenced by the quality of the natural resource base.

But smallholders are often unable to practice sustainable land management, either due to a lack of resources or know-how (Havemann and Muccione 2011).

Smallholder systems can potentially play an important role in both mitigation and adaptation to climate change. Whereas they may be inclined to perceive private benefits to adaptation, smallholders are unlikely to be motivated to reduce emissions without demonstrable net benefit or an incentive (Havemann and Muccione 2011). This is particularly so if such action requires a change from current practices. Net benefits can be tangible, for example, an increased profit from their agricultural activities achievable in a relatively short time frame, risk reduction, or payment for environmental services (PES), the latter involving cash payments to the smallholder to take part in conservation activities. Benefits linked to mitigation can also be indirect, such as access to training programs and institutional support, for example, through cooperative organization, extension services, and increased tenure security (Havemann and Muccione 2011).

Further, even though a failure to reduce agricultural GHG emissions would put future food security at risk, no government will adopt measures to reduce greenhouse gas emissions if they threaten a nation's current ability to feed its population (Pye-Smith 2011). The main challenge is to increase food production without increasing (or even reducing) greenhouse gas emissions from agricultural activities. Thus, the recent focus on climate-smart agriculture (CSA), a relatively new term that describes a range of practices that could increase food production, helps farmers to become more resilient to climate change and reduce emissions of greenhouse gases (Pye-Smith 2011). FAO (2012) define "climate-smart" technologies as those delivering multiple benefits, specifically, "food security and development benefits together with climate change adaptation and mitigation co-benefits."

The implementation of CSA does not presuppose a unique role for smallholders, and the challenges of monitoring actions on thousands of holdings add substance to arguments about the relative inefficiency of small-scale production (Collier and Dercon 2009). But smallholdings occupy large areas of land offering potentially cost-effective mitigation potential, and associated financing offers the potential for poverty alleviation. Unlocking this through climate-smart practices will require considerable investment, institutional and financial support, and capacity building. In many countries, these climate-smart practices can potentially be developed under NAMAs.

NAMAs as a Financing Mechanism for Mitigating Climate Change

To date, agricultural mitigation has not been a focus of international negotiation in developed or developing countries. The costs related to the adoption of mitigation practices, as well as potential difficulties associated with the monitoring, reporting, and verification (MRV) of mitigation measures all contribute to maintaining agriculture's position as a non-priority sector for climate change mitigation (FAO 2013b).

Recognizing the mitigation potential available in non-Annex 1, the Bali Action Plan (UNFCCC 2008) following COP 13 introduced a funding modality that potentially allows developing countries to propose voluntary mitigation actions termed NAMAs, which may be verified for potential bilateral or multilateral funding. NAMAs can be described as actions that contribute to the economic development of the country without contributing further to climate change or, indeed, reducing GHG emissions from a given sector (Wang-Helmreich et al. 2011). UNFCCC (2010) describe NAMAs as voluntary mitigation actions undertaken by developing countries "in the context of sustainable development, supported and enabled by technology, financing and capacity building, in a measurable, reportable and verifiable manner, aimed at achieving a deviation in emissions relative to "business as usual" emissions in 2020" (CCAFS 2012b).

Three main types of NAMAs have been described: unilateral NAMAs involving actions that a country plans to pursue for reasons other than reductions in GHG emissions; conditional/supported NAMAs that would only be agreed by a developing country if developed countries provide financial or technological support; and credited/market-oriented NAMAs that can generate credits that will be sold on the global carbon market (CCAP 2009). Each of these three types of NAMAs can be project based, sector based, or at a national scale.

NAMAs are expected to be assessed based on the performance and to be linked to real and measurable emission reductions. Apart from unilateral NAMAs, the other two types involve high costs and stringent MRV requirements. Where NAMAs are implemented with international support, they are subject to both national and international measurement, reporting, and verification (CCAFS 2012a). There are no defined rules for international support to NAMAs, but it is clear that public sector finance alone will not be able to fully finance NAMAs in developing countries, and private sector involvement will be necessary (CCAFS 2012a).

Although NAMAs are expected to contribute towards mitigation, they should not be independent of a developing country's national priorities, such as poverty alleviation and economic growth (Upadhyaya 2012). This raises an obvious question about the definition of potential agricultural sector NAMAs that can be anticipated as a promising instrument for advancing climate change abatement policies (FAO 2012).

Agricultural NAMAs can provide additional resources for agriculture with multiple benefits, including adaptation, food security, and sustainable development, i.e., they should not be considered in isolation as a stand-alone mitigation tool. Adding further to the related nomenclature, some commentators suggest that NAMAs may become Nationally Appropriate Climate-Smart Actions (NACSAs) and, potentially, be incorporated in the country's National Adaptation Plans (NAPs). The question is how to ensure that these multiple objectives are achieved simultaneously (Upadhyaya 2012).

Some countries have been proactive in proposing agricultural NAMAs, motives of which vary. NAMAs are regarded as an entry point for a transition to a low-carbon development or green growth path, or they are seen as an opportunity to access new sources of finance for sustainable development; in some cases agricultural mitigation is needed to meet voluntary national emission reduction. To date, mitigation actions in the agricultural sector are mentioned in 40 % of NAMA submissions (21 out of 55 country submissions) to the UNFCCC Secretariat, mainly by African countries (CCAFS 2012b; FAO 2013b). These focus on agricultural technologies and practices, including the restoration of degraded grazing land, the use of improved seed varieties, agroforestry, application of composts, and minimum or no-tillage, all of which provide some ancillary adaptation benefits. Increasing agricultural productivity is at the center of the majority of proposed NAMAs.

Malawi has been active in exploring the potential for agricultural NAMAs, with a 2012 UNFCCC submission proposing actions on biogas for energy and manure waste management (Malawi Government 2011b, 2012a, b). As yet, there is no specific analysis to guide the potential inclusion of the dairy sector though its mitigation potential is recognized.

The Development of the Dairy Sector in Malawi

The Malawian dairy sector is still in its infancy and makes a small contribution to the livestock subsector (livestock accounts for approximately 10 % of the country's agricultural gross domestic product (GDP) (National Statistical Office of Malawi 2012); but the exact contribution of the dairy sector to the GDP has not been estimated). The sector mainly relies for milk supply on smallholder farmers who normally own between one and four dairy cows (Chitika 2008). Most dairy farmers are situated around the three large cities in Malawi: Blantyre (the Southern Region), Lilongwe (Central Region), and Mzuzu (the Northern Region), where they are organized into milk bulking groups (MBGs) (see Fig. 1). These groups are local farmer associations with cooling centers where milk is centrally collected from farmers within a radius of 8–10 km.

Recent data suggest that there are currently around 16,000 smallholder dairy farmers in the milk-producing regions (CISANET 2013). In 2012 these smallholders produced around 13.5 million liters of milk marketed through the formal channel (data received from three main milk-producing associations in Malawi), 91 % of which was produced in the Southern region. A further 16.5 million liters is estimated to be produced in the informal sector, which is currently the dominant marketing channel (Imani Development Consultants 2004). The two channels differ in the way milk reaches the final consumer. In the formal sector, milk is processed and sold to the consumer via retail outlets; informal sector milk is sold raw (and often diluted) to either vendors or direct to consumers (Chitika 2008).

Official estimates show an increasing trend in the number of dairy cattle in the country partly through import of animals into the country (see Fig. 2). Banda et al. (2012) estimate that there has been a 65 % increase in dairy cattle between 2004 and 2010, mainly as a result of government and aid donor support.

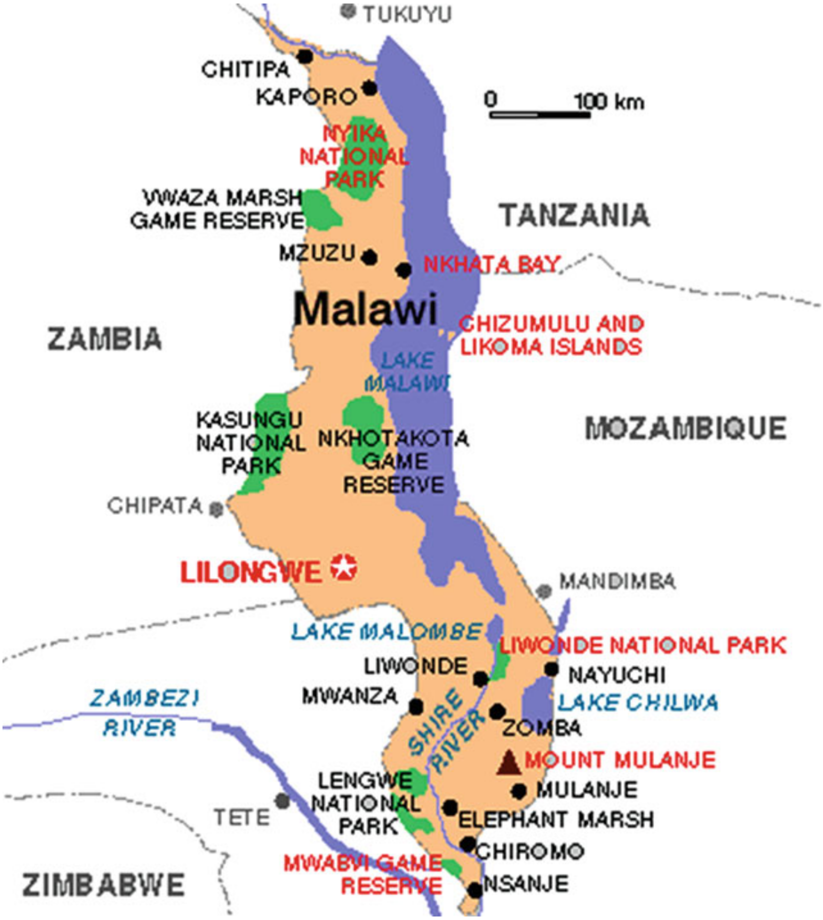

Fig. 1 Dairy production regions (Source: FAO, http://www.fao.org/ag/AGP/AGPC/doc/counprof/malawi/Malawi.htm)

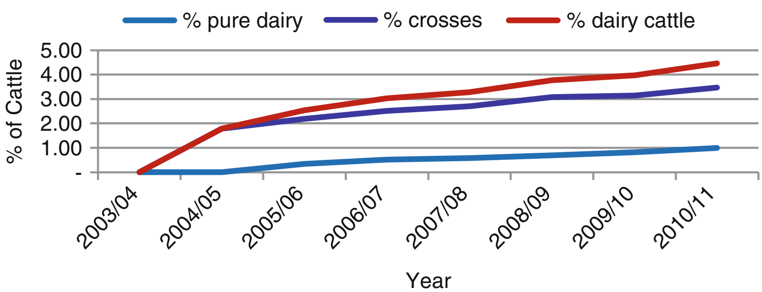

Fig. 2 Increasing trend in dairy cattle numbers in Malawi since 2003 (Source: USAID 2012)

Data provided by the Ministry of Agriculture and Food Security of Malawi shows that milk production has been steadily increasing in recent years (FAO 2011). This can be attributed to increasing cattle numbers, a result of development efforts, and a desire of many smallholders to diversify out of standard agricultural practices and to earn a reliable income.

Despite the growth in dairy cattle numbers (currently comprising about 5 % of the national cattle population), only 13 % of smallholder farmers in Malawi own cattle (CISANET 2013), reflecting a lack of emphasis on livestock in official agricultural strategies and policies. Moreover, poor performance in the arable sector has caused many farming families to expand their arable cultivation into areas traditionally grazed by livestock (CYE Consult 2009).

Diary productivity (i.e., milk output per cow) is generally low. Nakagava (2009) estimates the average production per day between 5.7 and 9 l per cow, mainly produced by the local Zebu breed. This is mainly due to the lack of good husbandry practices, long calving intervals, lack of good quality feed, and insufficient veterinary and artificial insemination (AI) and extension services (CISANET 2013). Productivity depends on breed choice with nonnative Friesians being most productive but also on the management quality (Chagunda et al. 2010). Zimba et al. (2010) estimate that even though individual farmers produce about 7 l of milk a day on average, there is a potential to produce up to 40 l by changing current management practices.

Milk consumption in Malawi is low, estimated at 4–6 kg/capita/year (Tebug 2012). This is much lower than the Africa average of 15 kg/capita/year and significantly lower than 200 kg/capita/year recommended by the World Health Organization (WHO) and FAO (Banda 2008). In other sub-Saharan countries, such as Kenya, milk consumption is 95 kg/capita/year with smallholder dairy farming playing a key role (Tebug 2012). Low consumption is partly explained by the limited supply of milk (CYE Consult 2009), leading to some of the highest consumer prices for milk products in Africa (The Dairy Task Team 2010; USAID 2012).

Tebug et al. (2012a) suggest that factors like population and income growth, plus dietary change and urbanization, have led to increased milk demand in Malawi in the recent years, consumption increasing by 40 % between 1980 and 2002 (FAO 2011). Malawi's population is predicted to grow from 15.4 million to 37 million by 2050 from its current level (Malawi Government 2012a, b; The World Bank 2012), meaning that the demand for dairy products is likely to increase further. There is thus a clear need to address barriers to sector development. But increasing milk production by increased herd size in the smallholder sector or via increasing the number of smallholder farmers diversifying into the dairy farming, while in the national interest, will almost inevitably lead to an absolute increase in GHG emissions. Introducing good farm management strategies to help reduce GHG emissions is therefore a potential entry point for climate-smart NAMA support that moves the country onto an emissions trajectory without compromising its development goals.

Opportunities and Challenges for Developing Dairy Sector NAMAs

Dairy is considered a key investment sector within agriculture for the Government of Malawi (MIPA 2011), and dairy development has become a government priority and a flagship of the livestock sector aimed at enhancing household livelihoods. Most recently, the dairy sector in Malawi has also been widely supported and promoted by international donors and NGOs that have developed business models for upscaling breeding, livestock management, value chain, and risk insurance support.

In capitalizing on the synergies in dairy sector development, it is important to recognize and reconcile the key policy drivers and extant constraints affecting sector development. Economic development and livelihoods are the key objectives of agricultural development. Malawi's National Dairy Development Programme (NDDP) aims to contribute to improved livelihoods of both producers and consumers, as well as provide economic benefits for the national economy. NDDP aims to increase the total milk production in Malawi from around 30,000 metric tons to 61,000 t per annum by 2017 (Malawi Government 2011b). As a result, it has been calculated that with current farm levels emissions will double with doubling total milk production (Wilkes et al. 2012).

Like any non-Annex 1 country, Malawi is unlikely to adopt mitigation measures if they compromise food security and unless there is some form of international compensation. Further, current lack of economic incentives for livestock farmers in Malawi to reduce GHG emissions means that any mitigation which lowers emissions at the expense of productivity is certain to be nonviable (CCAFS 2012a). These conflicting objectives can potentially be reconciled in the dairy sector by a focus on smarter production practices and sector development.

A number of constraints have been reported to the development of the dairy sector in Malawi at the farm level (Tebug et al. 2012b). These include poor farm management practices, including inadequate feed and feeding technologies often leading to low production of milk, and poor manure management, as well as poor animal health and high mortality rates of the dairy cattle (Sindani 2012). Addressing these barriers offers opportunities for pro-poor development in the sector, through improving food security (i.e., availability of safe and affordable dairy products) and smallholder incomes.

Dairying can provide a regular income with monthly payments and relatively easy work often undertaken by women. Smallholders can earn on average more than \$300/year from milk sales (USAID 2008), providing regular and relatively high income, as well as a diversification of household risk.[1] This is because income from dairying is less affected by the change in weather patterns compared to maize and tobacco. Dairying has an added advantage of being successfully practiced in

[1]According to CYE Consult (2009), one cow gives a monthly profit that is three times the minimum wage (MK317 per day as of 1 July 2012).

areas with limited land, less labor supply, and even in poor rainfall environments (CISANET 2013).

Dairy sector NAMAs can potentially be an important option for accessing climate finance opportunities directed at scaling up best practices in agriculture. Compared to other sectors, agriculture has an advantage in that many mitigation technologies and practices are already relatively well understood and available (CCAFS 2012b; Ogle et al. 2013). But important knowledge gaps persist in terms of the technical applicability of measures at significant scale across smallholdings. Furthermore, there is currently little information on the acceptability of measure implementation by low-income householders. The remainder of this chapter provides survey evidence exploring these elements.

Materials and Methods

To explore NAMA options, an extensive survey of 460 smallholder dairying households in all three milk-producing regions in Malawi was carried out in February 2013. The survey sought insights into the relationship between climate change and smallholder dairying in Malawi. A more specific aim was to explore mitigation and adaptation practices that can inform national policies and potential NAMA development.

The questionnaire contained 165 questions and included elements on dairy farm management and milk production, the dairy marketing chain and market access, and access to animal health and livestock extension services. Further sections sought information on household structure, animal numbers and breeds kept, milk sales, and feeding methods and constraints faced in production. In essence, the aim was to explore both on-farm and post farm gate issues that influenced production and could become potential entry points for NAMA design.

A sampling strategy was developed using information provided by the MBGs and the University of Malawi and covered selected MBGs in the three milk-producing regions – Mzuzu Milk Shed Area in the Northern region, Lilongwe Milk Shed Area in the Central region, and Blantyre Milk Shed Area in the Southern region.

It considered only smallholder farmers who were members of a MBG, the majority of the farmers in Malawi. Inactive MBGs (those no longer actively involved in marketing milk) were excluded from the sample. Stratified random sampling was used for the survey, based on the available farmer lists, with the number of female farmers in the milk shed areas taken into account to ensure the gender balance. Surveys were administered over a period of 3 weeks by trained enumerators and supervisors split into three groups. The team ensured quality of the data through a regular review of all questionnaires by the supervisors and research assistants after each data collection day. Further data were collected through direct observation and key informant interviews.

In terms of mitigation options, the survey focused on baseline practices related to practical measures identified in the IPCC Fourth Assessment Report

(Smith et al. 2007b), specifically livestock feed practices, including grazing management, pasture improvement, manure management, and biogas production from manure.

Results and Discussion

NAMA Development: Baseline Survey Evidence from Smallholder Agriculture

Key response data on relevant survey questions are summarized in Table 1.

The survey observations point to a number of key observations relevant to NAMA design.

Pasture Production and Feed Management

Feeding practices are clearly relevant to animal productivity and hence emissions, but current inefficiencies have much to do with limited plot sizes and the use of cut and carry forage of low digestibility and customary tenure systems working against any improvement incentive. Pasture improvement and hay making are not often practiced.

Even though supplemental feeding is becoming more common among dairy farmers, with maize bran being the most common supplement, the price of dairy mash and other supplements as well as the availability of minerals and molasses constrain regular use. A very small proportion of the households use minerals or molasses.

Increased use of crop by-products and feed supplements has been suggested as an economical way of ensuring access to adequate supplies of nutrients (Mtimuni 2012). Capacity building of farmers on locally available and potential feed resources and the importance of these in improving production efficiency will be essential.

Size of Herd and Milk Production

A revealing survey finding is that a high percentage – >80 % – own pure breed cattle rather than cross or local Zebu cattle. The latter breed is better adapted to local conditions, but milk production from Zebu is lower than from crossbreed or pure breed cows, which largely explains farmer breed preferences. Around 80 % of the sample also own only one animal, thus limiting production with obvious implications for the types of cattle-related investments they can be expected to make.

The majority of respondents think there are significant constraints on production; the most important being low milk yield and market prices, high price of concentrate feed, as well as animal disease including infertility.

Manure Management and Biogas Production

Manure is an important source of methane, whereas manure excreted during grazing, as well as emissions from livestock sheds is one of the most important

Table 1 Main survey questions and summary observations

Question	Proportion of respondents	Observations on current constraints and barriers
Pasture *production and feed management*		
Pasture size	50 % of surveyed farmers do not own pasture land, and 90.9 % of those who do own areas of less than 1 ha	Absence of established pastures leading to common feed shortages
What type of grazing do you practice?	95.4 % of respondents practice zero grazing (or cut and carry) feeding regime	Low digestibility grass/forage leading to high methane emissions
Do you make conserved feeds (e.g., hay)?	59.5 % do not make conserved feeds	Feed is not efficiently utilized as feed conservation practices such as hay making are not often practiced leading to frequent feed shortages
Do you regularly experience a shortage of feed?	50.0 % of respondents regularly experience shortage of feed	Feed shortages are a significant limitation to increasing animal productivity
Do you have enough fodder for your animals for the whole year?	53.4 % of respondents do not have enough fodder for their animals	Lack of fodder can have a significant impact on animal productivity
Do you purchase crop by-products during the year (as feed for the dairy animals)?	78.1 % do not purchase crop by-products	Crop by-products contribute to the higher yields in dairy cows leading to reduced emissions per kg of milk
Do you use concentrated feed?	Only 35.6 % of farmers use concentrated feed	Concentrated feed improves yields and thus reduces emissions per kg of milk
Milk production		
Do you plan to increase the amount of milk you produce?	89.5 % of respondents plan to increase milk production, the majority via producing or buying more feed	Farmers appreciate the importance of improved feeding practices for increasing milk production
Do you think there are significant constraints to dairy production on the farm?	94.5 % of respondents think there are significant constraints on production, the most important being low market prices of milk, low milk yield, high price of concentrate feed, and prevalence of animal disease or infertility	High price of concentrates and supplements reduce productivity and contribute to higher emissions as animals then rely on less easily digestible grass from pastures or *dambos* (*hydromorphic areas owned by the whole community*). Low milk prices indicate how supply chain structure (i.e., post farm gate) also influences production decisions

(*continued*)

Table 1 (continued)

Question	Proportion of respondents	Observations on current constraints and barriers
Manure management		
Most common manure storage system?	Dry lot/heap storage used by 54.7 % of farmers; pit storage – by 37.7 %	Uncovered manure heaps are a source of CH_4 emissions that can be reduced by changing manure management system
Biogas production from manure?	The majority of farmers do not produce biogas	The technology requires high up-front costs but can be greatly beneficial to farmers and help reduce emissions
Agroforestry		
Are you involved in any agroforestry work?	59.5 % of all respondents are not involved in any agroforestry work	Lack of know-how and lack of awareness of the benefits of agroforestry (such as providing fuel and feed for the animals) are the main reasons for farmers not practicing
Animal health		
Did you see any diseased animals on your farm in the past 12 months?	43.8 % have seen diseased animals on their farm in the past 12 months. 12 % of the respondents have experienced dairy cattle deaths	Poor animal health is a major issue, mainly associated with lack of knowledge and training in animal health
Supply chain		
Do you have difficulties selling your milk?	91.2 % of farmers experience difficulties when selling their milk; 70 % of these – due to the poor quality and low price of milk	Poor quality milk often leading to milk wastage is mainly due to the lack of the refrigeration facilities at dairy farms, milk souring while being delivered to the MBG, because of the distances and fresh milk souring after having been delivered to the MBG as a result of frequent power cuts. This, coupled with the low milk prices offered by the dairy processors irrespective of the season, does not provide incentives for farmers to produce more milk
Do you have your milk rejected by an MBG?	66.1 % of respondents regularly experience their milk being rejected by the MBGs	Even though farmers might deliver good quality milk to the MBG and milk is initially accepted, it may later be rejected by the processors if it gets sour due to frequent power outages and generator break downs. This wastage encourages some farmers to sell outside the formal market

(*continued*)

Table 1 (continued)

Question	Proportion of respondents	Observations on current constraints and barriers
Do you experience delays in getting paid for the milk sold?	88.6 % experience delays in getting paid for the milk, with 48.5 % experiencing delays of up to 1 month	Delays in payments often lead to farmers turning to the informal market for selling their milk, as the price is paid up-front. This leads to a significant amount of milk being sold outside the formal channels
Are there any incentives in your local MBG for delivering milk in low season?	93 % of all MBGs do not have any incentives in place to reward farmers delivering milk in low season or producing higher amounts of milk	The absence of incentives often makes farmers sell in the informal market, where the price paid per liter is higher
Are there any dairy cooperatives (apart from MBGs) that you are a member of?	More than 99 % of farmers do not belong to any dairy cooperatives	Lack of farmer organizations makes farmers more vulnerable and unable to negotiate better payment conditions with the dairy processors

sources of the N_2O. The most common manure storage system is dry lot – followed by pit storage. More than 80 % of this manure is produced when the cattle are housed.

CH_4 emissions from manure management greatly depend on the time manure is stored inside sheds or *kholas* or in outdoor manure stores (Chadwick et al. 2011). The majority of surveyed farmers store manure between 6 and 8 months before use or disposal. Removal of manure from animal housing into outside storage is infrequent, and the storage areas are normally not covered. More than 90 % of farmers do not cover manure with any material, and more than 40 % mix it with other material. It has been shown that emissions from cattle housing can be reduced through a more frequent removal of manure to a closed storage system (Monteny et al. 2006).

Unsurprisingly for this sample, the majority of surveyed farmers do not produce biogas on their farms, even though only 19 % of surveyed farming households have access to electricity (including solar power), and biogas production can generate energy (heat or electricity) and produce residual fertilizer. However, digesters involve significant capital costs, and finance and farmer cooperation are barriers that would need to be overcome.

Agroforestry Practices

Agroforestry is important both for both mitigation (carbon sequestration, improved feed, and consequently reduced enteric methane) and for adaptation (improving the resilience of agricultural production to climate variability by using trees to intensify and diversify production and buffer farming systems against hazards; FAO 2013a). Shade trees reduce heat stress on animals and help increase productivity.

Trees also improve the supply and quality of forage, which can help reduce overgrazing and curb land degradation (Thornton and Herrero 2010). Furthermore, crop by-products and co-products from agroforestry can be used as low-emission feeds for cattle.

More than half of respondents were not involved in any agroforestry work; the majority of these mention lack of knowledge/training or know-how as the main reason for not practicing agroforestry.

Animal Health

The survey revealed that nearly half of all respondents had detected diseased animals on their farm in the previous 12 months leading to cattle deaths on 12 % of farms.

Better nutrition, improved animal husbandry, regular animal inspection, and the use of antibiotics can improve reproduction rates and reduce mortality (Tebug 2012). All of these measures can therefore increase animal productivity at relatively low cost.

Supply Chain Efficiency

Some of the most revealing survey responses related to supply chain relationships. The survey revealed that low milk procurement prices and quality requirements are a considerable barrier to participation in formal milk marketing by smallholders. The current supply chain structure means that smallholders are reliant on conditions for quality and prices set by the MBGs. Since the latter do not return milk that fails a quality threshold, there is a risk for small producers who lack the equipment and expertise to reach these thresholds. On the other hand, reliance on informal marketing does not always guarantee higher prices or a more regular outlet for produce. An added disadvantage is that smallholders involved in the informal marketing are unable to access credit as a basis for livestock improvement (Sindani 2012).

There is also a lack of farmer organizations/cooperatives at the level below Milk Bulking Groups (CISANET 2013). Survey results show that the majority of all respondents are not part of any dairy or farmer cooperative, mostly due to the lack of these. The establishment and participation of effective and representative farmer organizations that are able and willing to communicate on behalf of their members are essential. But establishing such groups requires support and capacity development.

Overall, the survey indicates that supply chain efficiency is as important as on-farm measures for increasing productivity, hence reducing emissions. A NAMA approach that considers the entire dairy supply chain is essential.

Potential Dairy Sector NAMAs

Findings summarized in the previous section indicate considerable scope for NAMA design, with mitigation options available along the entire supply chain. The most immediate and low-cost options are likely to be targeted to feed production, enteric fermentation and adopting composting, improved manure handling and storage, as well as adoption of different application techniques. Most of these will not require any capital costs, but farmer training and knowledge dissemination will be essential.

Most on-farm interventions aim to improve basic farm productivity and resource use. For example, the use of improved feeding technologies, manure management (e.g., composting), and agroforestry are readily available for implementation and have been successfully trialed in other parts of sub-Saharan Africa (FAO 2013b).

It has been shown that a relatively small change in the efficiency of dairy feeding can have a major effect on animal productivity and farm profitability (Gerber et al. 2011). A feeding intervention NAMA will need to focus on capacity building for farmers on the benefits of introducing improved feeding techniques.

Improved manure management via deployment of technology for biogas-based electricity generation is also a promising basis for a NAMA helping to reduce CH_4 emissions from manure and provide smallholder households with much needed energy. Introduction of this technology would require credit agencies or donors to cover costs for purchasing bio-digesters, as well as training of farmers on biogas production. In this regard the NAMA objective overlaps with that of the Clean Development Mechanism (CDM), which is a longer established financing mechanism that can be used for biogas energy. Most recently CDM funding was used, for example, in the Nepal Biogas support programs (Doyle 2013). Experience with biogas CDM projects has demonstrated practical MRV approaches that can clearly facilitate NAMA development (FAO 2013b).

An agroforestry NAMA will need to focus on knowledge dissemination, awareness raising and training of farmers on the benefits of agroforestry for the productivity of the farm and income generation, provision of seeds to farmers, and follow-up work with farmers to achieve returns in terms of improved resilience and increased household incomes. Again, because of overlapping objectives, payment for environmental services mechanisms could also be explored to encourage farmers to participate in agroforestry practices. But like PES mechanisms, institutional (e.g., legal and policy) reforms would be necessary to foster the development of agroforestry and recognize its contribution to national development and mainstreaming of agroforestry in national policies.

Animal health intervention NAMA should focus on farmer training on animal health-related issues and provision of higher-quality extension advice and artificial insemination and veterinary services. Poor farm management practices may be partly addressed by improved access to information including breeding and veterinary services; the latter could have a significant impact on reducing animal mortality.

Overall, improving the efficiency of the dairy supply chain is an explicit barrier emerging from the survey, since one of the most important constraints to increasing productivity is low price paid for milk, which is an underlying reason for the lack of investment in animal productivity, thus locking farmers into a downward spiral that ultimately retards investment in animals as a capital asset. These barriers can be

Table 2 Proposed NAMAs for the smallholder dairy systems in Malawi

Sector	Proposed NAMA	Benefits to farmers	Constraints
Feeding practices	Use of improved feed and feeding technologies, increased use of crop by-products, supplements and concentrated feed	Higher yields, improved animal health	High cost for purchasing concentrates, supplements, and vitamins. Lack of established pastures to grow feed with a low-carbon output
Manure management	Activities aimed at composting, improved manure handling and storage	Higher crop yield if using manure as a fertilizer	Lack of knowledge and incentives
Biogas production	Provision of grants to farmers to purchase biogas digesters, training and follow-up support	Improved farmer livelihoods through access to energy	High capital costs, lack of knowledge and incentives
Animal health	Targeted farmer training on maintenance of animal health and improved animal husbandry	Improved reproduction rates, reduced mortality, increased productivity	Lack of knowledge and know-how, poor animal management practices, limited access to extension and veterinary advice
Agroforestry	Provision of training on agroforestry practices targeted at dairy farmers, provision of seeds and follow-up support	Improved feed and resilience, increased animal productivity	Limited land, lack of knowledge and know-how
Supply chain	Organizing dairy cooperatives/farmer organizations at a level below MBG level	Empowering farmers to negotiate higher milk prices, access to credit to purchase more animals or feed, accessing high-quality extension advice as a group	Lack of knowledge and know-how, inertia

overcome with specially targeted supply chain and policy interventions, such as extension work, farmer training, and financing mechanisms, including improving access to credit and payment for environmental services. Supply chain interventions can offer verifiable interventions that may be amenable to coordinated government and donor interventions. This is paramount for sector development and increasing production as current oligopolistic structure of bulking groups is a potential target for concerted intervention between government and donors.

The initial supply chain NAMA could focus on organizing the dairy cooperatives where dairy farmers will have a stronger collective voice and can negotiate with the MBGs and, directly, with the dairy processors regarding the prices paid per unit of milk and reducing wastage, access to feed and feeding supplements, and negotiate with the credit organizations with regard to obtaining credit for dairy farming. Higher prices paid for milk will encourage farmers to increase investment in dairy farming and to improve their knowledge of dairy farming and management practices. Furthermore, it is important for any supply chain NAMA to focus on improving links between multiple stakeholders within the supply chain and providing greater coordination among the different stakeholders.

It is important to stress that from both national and international funders' perspectives, a robust system of measuring, reporting, and verifying is essential for effective monitoring of the NAMA implementation and for assessing its impact in terms of greenhouse gas emissions reductions, cost-effectiveness, and other co-benefits (UNEP 2013).

Proposed NAMAs are summarized in Table 2 below. At the current time, it is important to improve the evidence base to demonstrate that measure implementation can reduce emissions and improve or maintain smallholder livelihoods. This might require specific farm-scale modeling of identified options. Even then some of the identified options, such as using more concentrated feed or biogas production from manure will require financial assistance to implement, and capacity building will be necessary to make farmers more aware of the potential benefits of these strategies.

Conclusions

Current farm management practices in the smallholder dairy sector in Malawi offer significant options for agricultural-based NAMAs that could potentially reduce emissions and improve livelihoods. The smallholder survey found a number of farm management practices that could be modified to be climate smart and potentially funded under a NAMA modality. These options can initially be implemented as pilot project-based NAMAs, a climate change mitigation modality that has the potential to dovetail with a range of existing development aid objectives.

But development of agricultural NAMAs requires further analysis. Specifically, the adoption of measures by farmers must be locally appropriate and clearly beneficial before behavioral change can be expected. At present, the evidence on the farm-scale profitability of measures is unproven in all cases.

Many of the available options could build on, or scale up, current practice; however, in some cases (such as biogas production), technical innovations may be required. Even though a diversity of mitigation options provides flexibility, it creates extra challenges in measuring, reporting, and verification.

Furthermore, the potential mitigation strategies need to be thoroughly assessed in terms of their emission reduction, additionality, and cost-effectiveness. Specific interventions might only make sense and achieve a net mitigation effect if greater on-farm efficiency does not instead displace emissions to other parts of the food chain.

Finally, the proximity of NAMA and climate-smart agendas suggest that the former need to be designed with clear reference to the ongoing agenda on climate change adaptation. This places emphasis on combinations of mitigation and adaptation practices adapted to specific production systems and environments (e.g., interventions addressing the management of feed, genetic resources, and manure). The potential aggregated effects that changes in farming systems may have on food security and the use of natural resources at the regional level also need to be better understood. It will be essential for the NAMA interventions to take into consideration whole production systems and supply chains, as addressing mitigation or adaptation issues requires paying attention to spillover and feedback effects along the chain.

Prospects and Challenges of Local Community Adaptation to Climate Change in Developing Countries: The Case Study of Malawi

Sane Pashane Zuka

Contents

Abstract

In response to global climatic change and variability, adaptation to climate change has become a widespread global policy goal. It is currently seen as a solution to the likely negative effects of climate change, especially in developing countries. However, adaptation to climate change largely depends on the socioeconomic system's adaptive capacity. In the urgency to achieve adaptation to climate change, this question has hardly been adequately explored. This chapter fills this gap by examining the prospects and challenges of community adaptation to climate change in developing countries through the case study of Malawi. The study findings demonstrate that community adaptation to climate change has the potential to stimulate and build productive local livelihood systems.

W. Leal Filho (ed.), *Handbook of Climate Change Adaptation*,
DOI 10.1007/978-3-642-38670-1_62

However, its success is currently hampered by two things. First, there is lack of clear climate adaptation policy framework to guide community adaptation initiatives. Secondly, the existence of rampant household poverty and low institutional capacity makes it difficult to support community adaptation initiatives. This situation is exacerbated by unstable donor funding toward climate change adaptations. This chapter, therefore, argues that sustainable community adaptation to climate change in developing countries requires improving their social, economic, and institutional capacities.

Keywords

Malawi • Climate change • Local community adaptation • Sustainable livelihoods

Introduction

This chapter undertakes a critical assessment of the developing countries' prospects and challenges of adapting to climate change through the case study of Malawi. The chapter is motivated by the fact that in response to global climatic change and variability, adaptation to climate change has become a widespread global policy goal (UNFCCC 2007; Rohr 2007; UNDP 2007). Simply defined, adaptation is the process of deliberate adjustment in ecological, social, and economic systems in anticipation of, or in response to, actual or expected climate stimuli and effects or stresses (Stringer et al. 2009; Smit and Pilifosova 2001). It is advanced because of its potential to substantially reduce negative climate change impact and stress. Empirical evidence, however, reveals that adaptation to climate change is not automatic. It depends on systems' adaptive capacity and varies among regions, countries, and socioeconomic groups depending on their resource, technology, information, and climate change-related institutional endowments (Burton et al. 1998; Rohr 2007). Equally important, though natural and human systems have spontaneously adapted to climate change for a long time, current climatic change and variability conditions have grossly strained the coping range of the systems leading to greater physical, social, and economic losses (Huq et al. 2003). Thus, current scholarship has highlighted the need for prioritizing planned adaptation to climate change, especially in developing countries. There is increasing evidence that developing countries will bear the most effects of climate change despite contributing less to its causation (Huq et al. 2003; Bie et al. 2008; Burton et al. 1998). Current community climate change adaptation efforts are, therefore, to a greater extent designed and financed by a network of local and international governments and agencies. This trend is largely premised on the argument that local people have low adaptive capacity to climate change and variation (Action Aid 2012; ICIMOD 2012; Smit and Wandel 2006).

However, empirical evidence from a variety of climate change adaptation projects suggests mixed outcomes. While there is on the overall net gains on national level, net gains on specific local communities and groups are debatable (Actionaid 2006; Labaris 2012; Bie et al. 2008). In particular, studies have highlighted lack of clear understanding of challenges facing local communities in adapting to climate change as a major cause for unimpressive outcomes. This chapter is set to fill in this gap. This study uses Malawi, one of the least developed countries, as a case study to explore this question. Specifically, this study explores Malawi's policy and institutional framework guiding its climate change adaptation initiatives, documents and assesses the effectiveness of major climate change adaptation strategies, and explores challenges for local community adaptation to climate change. More generally, the study highlights the dilemmas of climate change adaptation strategies in achieving sustainable community adaptation to climate change. Three insights emerge: (1) there is unclear policy and institutional framework for the implementation of climate change resulting in ad hoc designing and implementation of community adaptation strategies; (2) although current climate change adaptation strategies help to build community resilience for a short time, failure to correspond the design of climate change adaptation strategies to social, economic, and institutional capacity building results in unsustainable adaptation initiatives and ushers in a community that perpetually depends on external assistance; (3) externally designed climate change adaptation strategies should not be expected to improve livelihood situations among communities of developing countries without improving their social and economic conditions.

Themes in Adaptation to Climate Change in Developing Countries

Climate change adaptation debate in developing countries can be summarized into four major themes. First, though developing countries contribute less to global climate change, they will bear the most impacts due to fewer social, technological, and financial resources (UNFCCC 2007; UNDP 2007; IIED 2011). Second, though external aid is important in climate change adaptation, placement of climate change issues affecting developing countries at a periphery of international climate change forums affects nature and intensity of climate change response (UNDP 2009; Rohr 2007). This is worsened by contested agrarian trajectory for achieving sustainable economic development in developing countries. In particular, the polarized debate on small-scale versus large-scale investment, subsistence versus commercial farming, and diversity versus intensity remain unsettled (Matondi et al. 2011). For instance, the extent to which western-based agricultural innovations can equitably benefit local community members is challenged by historical empirical evidences of bias of such innovations against the poor community groups such as women (Booth et al. 2006; Mkandawire 2009). Another important theme in climate change adaptation relates to the role of local institutions in climate change adaptation. There is a growing literature that argues that local institutions affect climate change impact by, inter alia, influencing how households are affected by climate change impacts, shaping household response to climate change, and mediating the flow of external intervention to climate change adaptation (ICIMOD 2012; Agrawal 2008). However, several academicians have criticized local institutions as being responsible for perpetuating bias and discrimination against weak and poor groups of people in the community. In line with this view, there is also increasing call for a gendered approach to climate change adaptation in order to have a sustainable impact (Rohr 2007).

Conceptual Framework

It is not debatable that the question of climate change adaptation is more serious in developing countries. A number of scholars describe developing countries, especially those in Africa, as likely to bear the most impact of climate change leading to a number of social, economic, and environmental problems (Burton et al. 1998; Kelly and Adger 1999; Smit and Wandel 2006). This view is founded on the countries' low capability to positively adjust to the changing environmental conditions. Thus, this study adopts the concept of adaptive capacity, which is defined as the potential, capacity, or ability of a system to adapt to climate change stimuli or their effects or impacts. In general, there are six major variables that determine the ability of individuals, countries, and regions to adapt to climate change, namely:

- *Economic resources* – economic assets, capital resources, financial wealth, and poverty situation
- *Technology* – the type, level, and extent of use of technology in the community
- *Information and skills* – knowledge about adaptation options, capacity to access them, and capacity to implement the suitable ones
- *Infrastructure* – the recognition and contribution of social infrastructure to adaptive capacity
- *Institutions* – the institutional environment in which adaptation takes place, including institutions of holding society together, giving it sense and purpose and enabling it to adapt
- *Equity* – the allocation and distribution of resources within society

These variables influence the adaptive capacity of a local community to positively respond to climate change by presenting or altering an enabling environment in which adaptation takes place.

Methodology

This chapter is based on data collected through four main methods, namely, household surveys, key informant interviews, focus group discussions, and extensive literature review of community adaptation to climate change in Malawi and developing countries. Key informant interviews were conducted with government officers in the Ministry of Agriculture and Food Security, academicians, nongovernmental organization (NGO) staff working in the area of community livelihoods, and local leaders such as chiefs and members of the local development committees. Household surveys were carried in three districts of Mzimba, Salima, and, while key informant interviews were conducted in seven districts, namely,, Ntcheu, Nkhata Bay, Nkhotakota, Mzimba, Karonga, and Blantyre. Thus, the study covered all the three administrative regions of the country. Secondary data involved review of government policy documents, NGO reports, international donor reports, and academic literature on climate change. The study administered a total of 120 questionnaires in three districts, namely, Mzimba, Salima, and, which were sampled based on their vulnerability to climate risks. In these districts, the study randomly sampled three extension planning areas (EPAs), one EPA from each district, namely, Luwerezi, Chipoka, and Ngabu. Simple random sampling was then used to select 40 respondents in each EPA. In addition to household survey, literature review of existing secondary data in the study area was used to complement missing socioeconomic data.

A total of 35 key informant interviews and 16 focus group discussions were conducted. Use of both quantitative and qualitative study approaches allowed triangulation of issues coming out from each approach.

Socioeconomic Characteristics of Respondents in the Study Areas

The general socioeconomic characteristics of respondents in the districts of Mzimba, Salima, and are not different from the national trends in the rural areas of Malawi. Household surveys conducted in the areas reveal that over 90 % of households predominantly depend on rain-fed subsistence farming for their livelihood. The main food crops grown in these areas include maize, cassava, groundnuts, beans, sweet potatoes, and rice. In addition to farming, about 65 % of the household in all the districts raise livestock especially cattle, goats, chicken, and pigs. Thus, local communities' livelihood platforms are highly susceptible to climate change risks due to increased incidences of drought, floods, pests, and diseases. This situation is aggravated by declining household land size across the nation. In the study areas, the average household land holding size is less than 0.5 ha. Declining household land size, driven by high population growth of between 3.2 % (Salima) and 2 % (Chikhwawa), increases poverty levels because of the strong link between poverty and landholding size in the rural areas of the country (World Bank and GoM 2006). According to NSO (2010), incidence of rural poverty in Malawi is as high as 43 %. In the sampled areas, between 79 % and 82 % of the households live below $1.25 a day. The implication of this situation is that high poverty levels make it difficult for most rural communities to access modern farming techniques available on the market. This situation is worsened by relatively low literacy levels in the rural areas of Malawi, including Mzimba (75.3 %), Salima (56.9 %), Chikhwawa (53.1 %), and high HIV and AIDS prevalence rate of 9 % (NSO 2008, 2010). Generally, high levels of illiteracy and HIV and AIDS prevalence reduce the adaptive capacity of the local communities.

Climate Change Trends, Effects, and Adaptation Question in Malawi

Malawi is ranked as one of the twelve least developed countries most vulnerable to the adverse effects of climate change (World Bank 2010). This is so as the country's economy is heavily reliant on agricultural exports and subsistence farming, which are highly vulnerable to climate change. The country has a tropical continental climate characterized by wet/rainy and warm/dry seasons. The rainy season used to start in November and end in April, while dry season used to start in May and end in October. However, these seasons have not only become unpredictable but also display increased frequency and intensity of droughts and floods. Though it is difficult to predict long-term climate change scenarios, climate change pattern in Malawi mirrors climate change scenarios for Africa (Labaris 2012). Climate-related hazards such as prolonged dry spells, droughts, floods, and erratic rains have become more frequent, intense, and unpredictable. According to Oxfam (2009), Malawi's mean annual temperature has increased by 0.9 °C between 1960 and 2006, an average rate of 0.21 °C per decade. This figure is slightly higher than the global temperature increase of 0.18 °C per decade (AMCEN 2011). The average number of hot days per year has also increased by 30.5 between 1960 and 2003. The Global Climate Models project that mean annual temperature for Malawi is expected to increase by 1.0 °C to 3.0 °C by 2060 (World Bank 2011).

In the past 50 years, the country has experienced two major droughts in 1948/1949 and 1991/1992 and a number of floods related to cyclonic weather patterns in 1946, 1956, 1989, 1991, 1997, 2001, 2003, and early 2008. Prolonged periods of drought and floods were also registered between 2001 and 2005 (Action Aid 2012; UNDP 2007). According to Action Aid (2012), Malawi experienced 40 weather-related disasters between 1970 and 2006, but 16 of these occurred after 1990. In the south of the country, floods cause annual losses of about 12% of maize production, while drought destroys on average 4.6% of national maize production each year (World Bank 2011). Dry spells and heavy rains also resulted in an estimated 1.3 % economic growth slowed in 2010 (ADB 2011). Equally important, an increase in temperature has the potential to increase prevalence of malaria as its transmission and distribution is mainly determined by climatic conditions of temperature, humidity, and rainfall. In Malawi, malaria is an endemic public health problem and a leading cause of morbidity and mortality in children under age five and among pregnant women. It is estimated that Malawi experiences about six million episodes of malaria annually (GoM 2012a). All this shows that climate change and variability is real in Malawi. Despite these climate change and variability trends and effects, Malawi's contribution to global emission of green gases that are regarded as main drivers of climate change was estimated at only 29 M tons in 1990 (Mkwambisi and Gomani 2008).

Strategies of Climate Change Adaptation Employed in Malawi

Community adaptation to climate change is not a new phenomenon in Malawi. For several years local communities have protected and responded to periods of extreme climatic conditions by, inter alia, practicing crop diversification, informal irrigation, use of organic manure, mixed crop and animal farming, gathering edible fruits and tubers, and practicing seasonal migration from flood plains to upland areas (Kambewa 2005; Magombo et al. 2011). It should, however, be pointed out that autonomous adaptation to climate change and variability has become extremely costly and less rewarding to local communities over the years. Thus, planned adaptation, defined as anticipatory and government-undertaken or government-influenced adaptations, has become the option.

Malawi's climate change adaptation focus is primarily aimed at building the rural community's capacity to cope with changing climate change and making them resilient to extreme weather conditions. This focus is out of the realization that the country's economy is predominantly agro-based and 85% of its population depends on rain-fed farming for their livelihood. The agricultural sector contributes over 90 % to the country's export earnings, about 39 % of the country's gross domestic product (GDP), and accounts for 85 % of total employment (Chinsinga 2008; World Bank 2011). Over 84 % of Malawians eke their livelihoods directly out of rain-fed subsistence agriculture where women are responsible for a larger proportion of subsistence farming activities (Action Aid 2012). The effect of climate change in Malawi is aggravated by the country's heavy dependency on rain-fed farming and natural resources. It is estimated that 80 % of Malawi's food production and 65 % of the agricultural contribution to the country's GDP come from the smallholder farmers who predominantly depend on rain-fed farming (Chinsinga et al. 2012). Against this background, Malawi's National Adaptation Programmes of Action (NAPA) identified thirty-one adaptation options, and out of these options, fifteen were categorized as urgent. The following is a list of NAPA's fifteen urgent climate change adaptation options, which were further classified into high, medium, and low adaptation ranks as indicated:

- Sustaining life and livelihoods for the most vulnerable communities (high)
- Enhancing food security and developing community-based storage systems for seed and food (medium)
- Increasing crop production through the use of appropriate technologies (medium)
- Increasing resilience of food production systems to erratic rains by promoting production of maize and vegetables in dambos (river banks that have water throughout the year to support cultivation of arable crops), wetlands, and along rivers (high)
- Targeting afforestation and reafforestation programs to control siltation and provision of fuel wood for their benefits, such as sources of alternative cash income (high)

- Improving energy access and security in rural areas (e.g., through extension of rural electrification program, improved stoves, and development of ethanol-based stoves) (medium)
- Improving rural nutrition (e.g., through the promotion of fish farming, rearing of small stock, and nutritional supplements for children and the sick) (medium)
- Disseminating bed nets to high malaria incidence areas (medium)
- Developing food and water reserves for disaster preparedness and response (medium)
- Developing community-based wildlife ranching and a breeding program for Nyala (medium)
- Developing and implementing strategies for drought preparedness, flood zoning, and mitigation (medium)
- Developing technologies to mitigate climate change (medium)
- Providing standby power generation (low)
- Managing forest fires in collaboration with the community (low)
- Developing small dams and other storage facilities to mitigate flooding, to harvest water, and to initiate community fish farming and breeding (high)

Within these priorities, major community adaptation strategies to climate change practiced in Malawi include practicing conservation agriculture, growing drought-resistant and high-productivity varieties of seeds, practicing agroforestry and planting tree crops, and increased irrigation farming (GoM 2006; Chinsinga 2012). Conservation agriculture is a way of managing agroecosystems to achieve higher, sustained productivity, increased profits, and food security while enhancing the environment (Mkwambisi 2012). Specific strategies within this strategy include soil conservation agricultural practices such as terracing, crop rotation, intercropping, afforestation and reforestation, micro-irrigation, and natural resources management. The basic aim of conservation agriculture is to conserve soil condition that supports plant life by reducing soil erosion and runoff.

Growing of drought-tolerant and high-productivity crops involves use of improved seeds that mature early and are resistant to increased pests and diseases that are likely to accompany climate change (GoM 2006). Most smallholder farmers in Malawi have adopted these improved varieties through Fertilizer Input Subsidy Programme (FISP) in which poor farmers access inorganic fertilizer and seeds at a subsidized price. Agroforestry and planting tree crops involve planting of soil fertility-enhancing subsistence crops and cash crops such as *Jatropha*. Besides providing food and income, it is seen as a way of enhancing the livelihoods of farmers and mitigating the effects of climate change through carbon sequestration. However, there is reluctance of smallholder farmers to adopt agroforestry in Malawi because farmers do not see immediate benefits as trees take long to mature (Chinsinga et al. 2012). Decline per capital land size is another challenge facing agroforestry.

Prospects and Challenges of Community Adaptation to Climate Change in Malawi

Unclear Policy and Institutional Framework for Climate Change Adaptation

The Malawi government is a party to the United Nations Framework Convention on Climate Change having ratified it on 21 April 1994 as an operational tool for Agenda 21. However, apart from the 2006 NAPA document, the country does not have a coherent national policy framework on climate change. The National Climate Change Policy is still being drafted. The NAPA has identified thirty-three priority interventions across eight different sectors, and fifteen of these priorities aim at reducing the vulnerability of rural communities to climate change (GoM 2006). Climate change issues are also contained in a number of government policy documents such as Malawi Growth and Development Strategy II (2011–2016), National Environmental Policy (1996), National Environmental Action Plan (1996), National Land Policy (2002), Energy Policy (2003), Forestry Policy (1996), Fisheries Policy (2001), Water Policy (2005), National Irrigation Policy and Development Strategy (1998), and the National Biodiversity and Action Plan (2005).

However, these sectoral policy frameworks exist in isolation and are at times contradictory. For instance, while conservation agriculture is highly esteemed in climate change adaptation, its implementation has been placed at the periphery because it is not prioritized by the Ministry of Agriculture and Food Security. Driven by the primacy of food security in national politics, the government has increased nominal funding toward Fertilizer Input Subsidy Programme (FISP) since 2005/2006 growing season. Thus, climate change adaptation initiatives are caught in a political dilemma as legitimacy of the Malawian government is intimately connected to food security forcing the government to target achieving food security at all costs and placing other development priorities at the periphery (Chinsinga et al. 2012). For instance, in the 2013/2014 national budget, the government has allocated almost 50% of the Ministry of Agriculture's budget to FISP (US$187.2 million) and just over US$9.3 million to the Ministry of Environment and Climate Change (GoM 2013). This chapter, therefore, argues that sustainable community adaptation to climate is caught up in unclear policy environment. Currently, sustainable community adaptation to climate change is not a short-term objective of the government as it greatly wants to meet the immediate food security needs of the populace. Generally, climate change adaptation policies in developing countries are engineered toward meeting the immediate needs of a large proportion of poor people. In this process, it is not the government sustainable strategy that matters but the one that brings quick political rewards. Notwithstanding its positive contribution, the contribution of government-supported FISP through the subsidization of hybrid seeds and fertilizer to food security remains very debatable. For instance, when the subsidized farm input program collapsed in 1994, the share of land allocated to maize cultivation fell by 12 % (Action Aid 2006). This is so as most smallholder farmers cannot successfully grow hybrid maize as it is capital intensive.

Equally important, there is unclear institutional structure for managing climate change adaptation in Malawi. Currently, climate change issues are being handled by the Ministry of Environment and Climate Change, which was created in 2012. However, climate change adaptation issues are also implemented through a number of ministries and departments such as the Ministries of Agriculture and Food Security, Economic Planning, and Irrigation and Water Development. These ministries are, however, loosely coordinated resulting into duplication and at times conflicting policy objectives. This problem is aggravated by the ministries and departments' competition over the control of potential funding for climate change activities (Chinsinga et al. 2012). The lack of institutional coordination has resulted in local communities receiving contradictory messages from ministries and departments. For instance, while the Ministry of Agriculture and Food Security emphasizes the use of improved varieties of seeds in micro-irrigation projects, the Ministry of Environment and Climate Change prioritizes use of organic manure. Generally, the use of improved varieties of seeds is preferred with the objective of increasing national crop production and not really expanding local communities' livelihood platforms. The contentious issue concerning community adaptation to climate change, therefore, originates from policy stipulations of food security. In the present context, the government is significantly promoting maize production at the expense of other crops that favor specific agroecological regions. This direction mirrors the quantitative than the qualitative emphasis on community adaptation to climate change.

Local community adaptation to climate change in Malawi and many other developing countries in Africa has also to grasp with the recent government policy moves toward promotion of large-scale agriculture. Generally, policy moves toward large-scale farming are premised on two arguments, namely, the availability of large parcels of unutilized land and the contribution of large-scale agriculture to the welfare of local communities (Fisher et al. 2002). However, both justifications have been questioned by empirical experiences of large-scale investments in Malawi and other developing countries (Chinsinga et al. 2013). In the present context, large-scale agriculture is grabbing priceless land resource from local communities and makes them more vulnerable to economic shocks.

Inadequate Financial and Human Resources

One of the major challenges of local community adaptation to climate change in Malawi is limited financial and human capacity to implement adaptation programs. Generally, financial resources enhance adaptive capacity by enabling local communities to invest in environmental management and have freedom to choose appropriate climate change options. Human resource on the other hand affects the quality of implementation of adaptation strategies. Currently, Malawi will require

US$ 22.93 million to implement five identified priority areas concerned with community adaptation to climate change (GoM 2006). Most of this financial resource is assumed to come from the donor community, which hinges on the goodwill of the donor community. Thus, global climate change adaptation initiatives present development opportunities for local communities to access government and international funding toward climate change-related investment such as adoption of fast-maturing and drought-resistant varieties.

However, international financial support toward climate change adaptation has been far below expectations. The problem is that extreme poverty among most smallholder farmers in Malawi means that they can hardly meet the costs of improved seeds, fertilizer, and chemicals. Malawi is one of least developed countries with over 39 % of the country's population estimated living below the poverty line. Among rural households, the incidence of poverty is as high as 43 % (ADB 2012). The poverty situation in the country is also exacerbated by high population growth rates of about 2.8 %, which compounds the problem of pressure on agricultural land and forests. Discussions with local communities revealed that most farmers prefer local varieties because improved varieties of seeds are costly in terms of their price and inorganic fertilizers that they require. One bag of 50 kg inorganic fertilizer costs almost US$50, which translates to more than half of the rural population unable to buy a bag of fertilizer. According to one agricultural extension officer, "the main problem with use of improved varieties is that they require application of inorganic fertilizers and strict observations of modern farming methods." This requirement means a lot of people cannot manage to buy inorganic fertilizer (World Bank 2013). Ironically, current rainfall patterns make the growing of local varieties difficult. Equally important, while the Ministry of Agriculture prioritizes the scientific approach to adaptation, it does not have the needed human resource capacity in terms of agriculture extension workers to ensure that farmers are trained in the use of the scientific farming methods. Likewise, effective implementation of conservation agriculture demands the availability of adequate and well-trained labor force, something that is missing among rural farmers because of two conditions. Firstly, high HIV and AIDS prevalence of about 10.6 % (GoM 2012b) means that adults, especially women, spend a lot of time caring for the sick than concentrating on farming. For instance, three households reported during field interviews that they have not cultivated because they were caring for the sick during planting period. Secondly, low education levels among local communities make it very difficult for them to comprehend and adopt modern agricultural technology and practices. According to NSO (2010), 20.7 % and 13.0 % of rural women and men in Malawi, respectively, do not have any education.

Limited Information, Knowledge, and Technology on Climate Change

Community adaptation to climate change demands that communities should have and use adequate and correct information to estimate potential effects of climate change, map vulnerable communities, and design strategies to respond to climate change effects. Thus, predictions and availability of future climate change scenarios are an important step to community adaptation to climate change. One of the greatest constraints for local communities to adapt to climate change in Malawi is limited information on expected climatic patterns due to weak technical capacity to predict weather and climatic patterns. The result is that communities are not provided with adequate climate change and variation scenarios to base their adaptation decisions on. Farmers specifically are uncertain of when to plant. The failure of the country's Department of Meteorology to provide comprehensive and long-term data on climate change and changing weather patterns does not only constrain policy making regarding climate change but is also a major source of anxiety among farmers as it increases their losses and vulnerability to climate change. According to one government official report:

> We (government) do not have adequate capacity in terms of structures like data storage capacity and computers, and we lack required expertise in some areas. We also have a general shortage of staff. Lack of a Meteorological Act also affects our work because now we use the Civil Aviation Act. The draft of the Meteorological Act had to be withdrawn from Cabinet because it did not include climate change issues. (AFIDEP, 2012:27)

Lack of required technology by the Department of Meteorology means that there is inadequate up-to-date data to guide community adaptation to climate change in Malawi. This challenge is worsened by the fact that climate change research is mainly done on a global level and there is little contextualization of global data at national and subnational levels. In most developing countries such as Malawi, reversing this trend will not be achieved in the near future due to inadequate government funding channeled to capacity development of institutions dealing with issues of climate change. In general, there is overdependence on donors for funding of climate change work (Chinsinga 2012; UN OHRLLS 2009). Given the increasing social and economic needs of the population in developing countries, it is doubtful that the state will allocate adequate resources to long-term climate adaptation needs such as recruiting adequate staff dealing with climate change and buying modern equipments for climate prediction. For instance, the Department of Meteorology is operating with less than half required human capacity. Thus, donor support will for a time remain the country's sure hope of accessing modern technology in climate change human capacity development. This hope is, however, grossly threatened by the general failure of developed countries to honor their climate change adaptation promises to developing countries. According to the IIED (2011), developed countries have made little progress toward their overall fast-start adaptation target currently pegged at 19–25 % of total fast-start finance.

Currently, there is a lot of confusion about the best strategy to climate change adaptation among the local communities and even among the educated group. For instance, over half of interviewed academicians outside the agriculture specialization argued that most modern farming techniques such as use of chemicals are not good as they reduce soil fertility. According to one academician who usually designs farmers' radio programs, chemicals require following strict procedures as they may make the soil completely unproductive. Another academician interviewed reported that his relatives refused to use improved varieties and chemicals in their farm because they do not trust modern seeds and chemical. They argued that "these seeds will make us poor because we cannot use them again next year, what are we going to do if we fail to find money to buy new seeds." These sentiments were also common among local farmers, which show that there is a lot of mistrust toward new farming technologies. Thus, the battle for local community adaptation to climate change will be easy unless farmers have adequate information on the subject.

Social Infrastructure and Equity

Successful community adaptation to climate change requires that local resources be equitably allocated and distributed among local community members. Equitable allocation of resources within the community largely depends on the extent to which individuals are able to participate in adaptation activities without social, economic, or political barriers. This is one of the challenges facing local communities in the effort to adapt to climate change in Malawi. Generally, there are three main climate change adaptation strategies being practiced in Malawi, namely, conservation agriculture, use of drought-resistant seed varieties, and agroforestry. The Least Developed Countries Fund (LDCF), for instance, funded Malawi US$3 million to implement rural livelihood and agriculture which largely included use of improved crop seeds, improved crop sequencing, and irrigation. However, such strategies have the potential of increasing income inequality among local communities by favoring the haves in society. The benefits of improved crop sequencing are premised on growing of two crops in one growing season through following strict growing calendars. Lessons from many irrigation initiatives in the country such as Mpemba irrigation scheme in Ntcheu, however, reveal that crop sequencing may not be a panacea for climate change adaptation to the powerless and landless groups of people in a community. This is so as land parcels belonging to individual households are compulsorily subdivided to willing households during dry season, thereby creating two land right arrangements, namely, individual land user rights during rainy season and collective land user rights during dry season. The expectation is that two strict crop-growing seasons are going to be followed and that crops for each growing season are going to mature strictly within the specified growing season.

However, this assumption may not be the case with increasing unpredictable rainfall pattern in the area (see UNDP 2007). Again, the designed strict growing arrangement restricts the types of crops grown during rain-fed and dry season as crops have different maturing periods. Some crops such as maize mature within 4 months, while some crops mature late but are also consumed for a long time while in the field. According to the interviews conducted with the communities in the area, only maize and vegetables are allowed to be grown under this arrangement and crops which are grown late into rainy season and mature late such as sweet potatoes are not allowed. The problem is that some of the crops not allowed to be grown under this arrangement form a major part of the local community food nutrient. This situation calls into question the extent to which local people will benefit from the climate change adaptation strategies. As earlier explained, crops grown in the irrigation scheme are preferred with the objective of increasing national crop production and not really expanding local livelihood platforms. The contentious issue concerning community adaptation to climate change, therefore, originates from the capitalistic conceptualization of food security. In the context of Malawi, increased production has emphasized the quantitative aspect and disregarded the qualitative aspects of diversified livelihood. Analysis of climate change adaptation debate supports this trend by emphasizing increased production of crops widely involved in market economy at the expense of local crops which form a major part of local livelihoods.

Conclusion

Community adaptation to climate change in developing countries is vital, taking into account the negative effects of climatic change. There is widespread agreement that external assistance is necessary if this process is to be achieved. To this end, there is generally real and expected global assistance toward climate change adaptation. However, analysis of local community adaptation to climate in Malawi has revealed that communities face a number of challenges to adapt. Firstly, there is no clear policy and institutional framework guiding climate change adaptation initiatives. Secondly, local communities lack the necessary monetary resources to effectively engage in adaptation initiatives. In particular, high poverty and illiteracy levels make it difficult for the communities to adopt new farming technologies. These observations suggest one critical point to consider; although climate change adaptation is a sure way of escaping negative effects of climate change, its success heavily depends on a number of development-related variables. Thus, arising from this observation, climate change is unlikely to be successful if it is implemented in isolation of other economic development variables especially poverty, literacy, and governance.

Responding to Climate Change: Ecological Modernization in Bangladesh's Agriculture

Saleh Ahmed

Contents

Abstract

Climate change is one of the biggest humanitarian challenges in many parts of the world. Unfortunately, low-income developing countries in the Global South will be the major victims, even though they are not the major driver of this global environmental change. It is not very uncommon that the people, community, and the country in the Global South are putting efforts to develop their own resiliency strategies to confront this challenge. With a regional focus on southwest Bangladesh, which is one of the major climate hot spots in the world, this chapter tries to explain climate resilient efforts particularly in agriculture sector with a lens of ecological modernization theory. The findings of this chapter highlight the importance of understanding ecological modernization as well as required process and mechanisms for climate resilient agriculture practice. Even though

the findings are theoretically grounded, the focus is on how the theory can be translated with further modifications, if necessary, into local communities. It is expected that this chapter will have larger implications by generating further theoretical and empirical discourse focusing on low-income developing countries in the Global South.

Keywords

Bangladesh • Climate change adaptation • Climate change • Ecological modernization theory

Background

Changing climate and associated impacts are among the major humanitarian crises of our contemporary society. It can obviously make changes to our economy, society, politics, and environment at large. It will have influence on our food supply and the patterns of livelihoods. However, the impacts of changing global environment will not be homogenous. People in the low-income developing nations will face larger exposure and vulnerability. Even though in most cases poor people are not the major driving forces for environmental or climate change, unfortunately they will be the major victims of this changing environment.

Climate policy, or more generally nation's environmental policy, is increasingly intertwined with the logic of ecological modernization (Curran 2009). While in Bangladesh the term "ecological modernization" is not officially adopted or widely used, the nation's climate policy or climate adaptation debate increasingly takes place within the larger domain of ecological modernization. In the present context of climate vulnerability and risks, the logics and promises of ecological modernization have never been so compelling. Like many other social sciences theories, this is also not an exception from criticisms and proposals for refinements.

This particular chapter reviews the perspectives of ecological modernization with a regional focus on southwest Bangladesh. Climate resilient agriculture is at the core of this discussion. As the major share of population are predominantly engaged in agriculture-related activities, changing pattern of agriculture has large implications on society and economy. Bangladesh is one of the most densely populated and poorest countries in the world (Streatfield and Karar 2008; Clayton 2013). One in every three Bangladeshis is poor and the ratio is slightly more in the rural areas (Clayton 2013). Despite huge population and pervasive poverty, the country has demonstrated progressive trajectories towards growth and development, based on a number of development indicators, such as the Human Development Index (BBS 2007). On the contrary, the global environmental change, e.g., climate change, can jeopardize the country's current trend with social and economic progresses.

It is one of the most vulnerable countries due to extreme climate events. Low-lying topography of the southwest coastal landforms of Bangladesh suggests that minimal increase in sea level can have catastrophic impacts on the coastal communities and the country at large (Abedin and Shaw 2013). One meter rise in sea level can be the reason for landlessness of 14.8 million people. That can also make 40 million people internally displaced due to the loss of 29,846 km^2 of land area in largely coastal areas (Brown 2011). The majority of the affected people will be poor that are dependent on local and regional natural resources such as fisheries, forestry, agriculture, etc.

In this changing situations of climate, agriculture, the major economic base in the country, can be affected severely followed by damages to many other livelihood opportunities (Brown 2011; Madhu and Jahid 2010). In Bangladesh, agriculture is a climate-sensitive sector. It is dependent on seasonal weather variability (Abedin and Shaw 2013). Due to the changing pattern of climate, rice production in Bangladesh is predicted to fall by 8 % and wheat production by 32 % until 2050 (Climate Change Cell 2009).

Southwest Bangladesh is often treated as the most disaster-prone region in the country due to its exposure to extreme climate events in coastal areas, such as salinity intrusion, increased intensity and frequency of tropical cyclones, tidal surges, floods, repeated water logging, etc. Approximately ten million people live in this region. Apart from this, the region is treated as one of the poorest regions in the country. Often the regional poverty dynamics is shaped by the ecological conditions and entitlements. The Sundarbans, world's largest mangrove forest, is one of the major suppliers of livelihood opportunities to majority of the coastal population, illustrating people's interactions and dependencies on nature and natural resource as a whole (Pravda Bangladesh 2009). Extreme climate events will eventually have adverse impacts on this regional resource base and at the end will disrupt this coupled human and natural system in local and regional scale.

To confront climate challenge, now Bangladesh is also focusing on climate resilient agriculture to feed its burgeoning population. Often this comes with different forms of ecological modernization such as agriculture intensification. The available lands for agriculture are not abundant in Bangladesh. This illustrates that there are not many options available for horizontal expansion of agriculture; rather vertical expansion is often treated as the most affordable option. Vertical expansion of agriculture, a form of intensification, can be perceived within the larger framework of ecological modernization. Bangladesh is a cosigner country with the Kyoto protocol along with other major environmental treaties, and therefore, the country is legally bonded for its improvements towards ecological efficiency.

In a low-income developing country like Bangladesh, there usually exists a huge vacuum to conceptualize the ecological modernization theory with implications. People often strive for sustainability without any substantial theoretical focus. As a consequence, society experiences the malpractices and implications of innovations and technological advancement. The theoretical development of ecological modernization was largely taken in the western European countries. Till to date, there is little to no research discussing the Global South and its connection to climate change adaptation mechanisms.

This chapter is an attempt to contribute to the discourse of ecological modernization focusing on the Global South, where the majority of the world population resides. This chapter discusses how climate resilient agriculture can be discussed within the larger framework of ecological modernization theory in the context of southwest Bangladesh. Even though the findings in this chapter are largely theoretically grounded, however, it is intended to focus on how the theory can be translated with further modifications, where necessary, into local communities of the Global South.

Local Environmental Challenges

Bangladesh is often characterized by her yearly monsoon patterns. Therefore, in Bangladesh, agriculture is largely treated as a weather-sensitive sector. Even though local agriculture is heavily dependent on monsoon rains, excessive monsoon rains can cause substantial crop damages. Therefore, delay of plantation and damage of produced crops are among the most significant losses due to the unpredictable pattern of monsoon rains. Often it creates massive flash floods. The flood in 1988 caused the reduction of agriculture production by forty-five percent. In a resource-constrained country like Bangladesh, it was a big national security challenge. The country became heavily dependent on food exports and aid for meeting the local consumption demands. However, flood in this extent is not rare in Bangladesh. In the recent years, the frequency and the extent of floods have substantially increased (Fig. 1).

Apart from floods, tropical cyclones and storm surges can also make damages to agriculture. The Cyclone Sidr struck the coastal Bangladesh on November 15, 2007. The total damage of crops was approximately Bangladesh Taka 28.4 billion (76 BDT = 1 US$), and the total loss of production in all crops was 1.3 million metric tons (Madhu and Jahid 2010). Natural hazards like floods, droughts, cyclones, etc. are likely to increase in frequency and in intensity due to the changing nature of climate (Abedin and Shaw 2013; IPCC 2007), and it is not a surprise that these disasters will generate further challenges for agriculture in Bangladesh (Abedin and Shaw 2013). Salinity intrusion is another major environmental challenge in the region. If it generates regional humanitarian crisis due to the lack of drinkable water and cultivable land, then southwest coastal Bangladesh will be treated as one of the major climate hot spots in human history. A migration from coastal Bangladesh to other parts of the country is already an increasing phenomenon. Lack of drinking water and salinity intrusion in land and water are shaping this migration dynamics. This process with salinity intrusion can be further increased by the reduced dry-season freshwater supply from upstream sources resulting from climate change (IPCC 1998) as well as by the increasing salinity intrusion due to sea-level rise (Abedin and Shaw 2013). These mentioned environmental challenges, heightened mostly due to climate change, will gradually contribute to the fact of decreasing amount of available agriculture lands.

In addition to that, population growth and unplanned and uncontrolled urbanization also contribute to the declining trends with prime agriculture land.

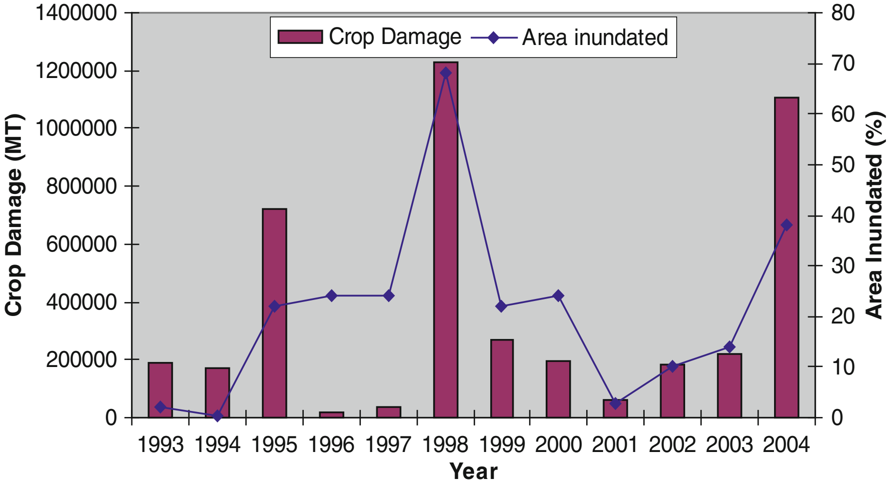

Fig. 1 Crop damage (in metric ton) due to historical flood (Source: Madhu and Jahid 2010)

Right now the declining rate of agriculture land is approximately 1 % per annum (Ahmed 2010). The land use change from farm to nonfarm activities is another phenomenon in this land-constrained country. The loss of agricultural lands and the adverse impacts on overall agriculture warn us about the possible future food shortage for the country's growing population. An emerging middle-class population will likely consume more and that will eventually increase the demand for consumption in the entire country. The conflict or mismatch between demand and supply of agriculture products will most likely increase the country's vulnerability to further social, economic, and political chaos (Fig. 2).

The national picture of agriculture challenges is not very different in southwest coastal Bangladesh. The region is the home of 35.1 million people (Bangladesh Bureau of Statistics 2011). The majority of populations are poor, mostly marginalized farmers and fishermen, or dependent on other natural resources. The net cultivable lands are 1.95 million hectares. This average landholding per household is half of national average (Abedin and Shaw 2013).

Possible Solution: Climate Resilient Agriculture

As the climate change is not any more a theoretical or abstract concept, rather very much visible in regional context, the southwest Bangladesh is in urgency to focus on different climate resilient agricultural practices (Mahmood 2006). However, evidence shows that in the southwest coastal areas, the evaluation and demonstration of climate resilient high-yielding rice varieties have been neglected until recently (Clayton 2013). Fewer farmers adopted the modern agricultural practices and mostly remained lock with traditional agriculture practice (Clayton 2013).

Fig. 2 Southwest coastal area of Bangladesh (Source: CoastalCare 2011)

It is important to reinforce that climate resilient agriculture practice will reduce substantially the risks and vulnerabilities associated with climate change (Abedin and Shaw 2013) and that is particularly relevant and have larger implications in the low-income developing countries where the adaptive capacities are extremely limited. Climate resilient agriculture can contribute to four strategic objectives: it can contribute to ensure the production of adequate food for the bourgeoning population; alleviation of poverty particularly among the poor and marginalized farmers can be promoted; access to food will help to achieve better health and nutrition; and finally, it contribute to conserve the local natural resource base, which is not only helpful for the environment, but can also contribute to the local productivity, economy, and long-term sustainability (CGIAR 2011).

Even though the climate resilient agriculture has a paramount importance, the implications of modernization and associated consequences are not very clear to the local policy makers and also to the farmers. This makes the situation complicated, because without understanding the process of (ecological) modernization, the local society might end up by generating further negative impacts on nature, such as loss of biodiversity.

Business-as-usual can no longer any effective mechanism to understand the context and challenges. Innovative concepts and practices are required therefore for a region’s sustainability. Evidence shows in the southwest coastal regions, improving water efficiency and crop diversification should be at the core of local adaptation efforts (Abedin and Shaw 2013; Fig. 3).

Apart from environmental dimension, climate resilient agriculture has social dimensions. In some situations, it is primarily driven by social forces like local consumption pattern or profit-oriented production systems. Changing agricultural

Fig. 3 Floating agriculture practice (Source: Rahman 2013)

pattern can alter this conventional trajectory. The entire process of climate resilient agriculture should be conceived as a coupled interaction between human and nature. One-dimensional approach of climate resiliency can disrupt the entire systems of sustainability. Agricultural modernization (or ecological modernization) largely depends on how the people can link their eco-efficiency of production system with the market force. It is not an easy process; rather it involves farmers' awareness and engagement with climate resilient farming practice along with the state and policy supports for coupled understanding of modernization and long-term impacts.

Theoretical Framework: Ecological Modernization

Core Arguments

Joseph Huber was among the first group of ecological modernization theorists who put substantial importance on the role of technological innovations in environmental reform. Even though the theory of ecological modernization presents a complex array and understanding of postindustrial modern society, however, the core argument involves contemporary technological innovation. Therefore, the proponents of ecological modernization see continued industrial development as the best possible option for escaping from the advanced societies' ecological crises (Fisher and Freudenburg 2001).

Ecological modernization can be one of the major reference points in contemporary social sciences disciplines for analyzing society-environment interactions (Mol and Sonnenfeld 2000). A large share of ecological modernization literature has been developed by the sociologists, and therefore, the theory or the perspective has become influential within the subdiscipline of environmental sociology (Buttel 2000).

Initially ecological modernization perspective emerged as the hegemonic environmental discourse focusing on the advanced developed societies. Gradually, it shows its prospective neoliberal solution to the global environmental crisis, such as climate change (Lippert 2010). The core argument of the ecological modernization is to reach a balanced and synergistic relationship between industrialized societies and their environment. Therefore, these developed societies need to engage with nature more techno-scientifically efforts. At the same time, the market economy should mediate the process (Lippert 2010). In summary, the core arguments of ecological modernization could be as follows:

> An ecological modernization perspective hypothesizes that while the most challenging environmental problems of this century and the next have (or will have) been caused by modernization and industrialization, their solutions must necessary lie in more – rather than less – modernization and 'superindustrialization.' (Buttel 2000, p. 61)

The logic of ecological modernization entails a postmodernist perspective. The ideological development surrounded on the perceived inadequacy of neo-Marxist interpretation schemes. Ecological modernization perspective challenges the core ideas of de-modernization (Mol and Spaargaren 2000). The core of ecological modernization illustrates that increasing industrialization can solve contemporary environmental problems. An ecologically modernized society should adopt the core principles of environmentalism in the design of locally available institutions to regulate human interactions with nature (Mol and Spaargaren 2005). Therefore, a vibrant local market economy and democratically elected government, along with constitutionally guaranteed rights and freedoms, are basic prerequisites for realizing ecological modernization. It is clearly evident that ecological modernization theorists highlight the process of structural change in economic, political, and cultural institutions that can directly influence the environmental outcomes. These propositions are closely aligned with the contemporary sustainable development agenda and initiatives where substantial importance on institutions and institutional capacity is clearly evident (Mol and Spaargaren 2005). Proponents of ecological modernization believe that currently we are exposed to ecological modernization and, to tackle global environmental challenge, we need more modernized efforts in terms of eco-efficiency (Lippert 2010). So far the empirical evidences of ecological modernization are largely from advanced industrial societies. One of the major reasons is that ecological modernization requires advanced technological development, a state regulated economy, and widespread environmental consciousness and behavior for the desired green industrial restructuring.

Criticisms

The logic of ecological modernization is not beyond criticisms. It argues that eco-efficiency can be achieved without radical structural changes in state and civil society (Buttel 2000). A majority of criticisms are surrounding to this argument. Therefore, if we really need to understand the theoretical arguments of ecological modernization and its implications on some specific geographical context, it is also important to discuss the counterarguments of ecological modernization.

Firstly, the perspectives of ecological modernization differ from neo-Marxist social theories in paying little attention to changing relations of production or to altering the capitalist mode of production altogether. Therefore, ecological modernization perspective misses the point, how modernization exploits labor and resource base for the sake of increasing profits. In addition to that, the proponents of ecological modernization also believe that some institutions and/or organizations will become more "ecologically rational" at the later stages of development or modernization. However, developing countries might respond to this differently. Even though at the later stage of modernization it can be ecologically rational, that process of development already can make substantial damages of resource base with the exploitation of labor and production interaction, where the working class usually get exploited by the capital class. This process of development can actually generate increasing phenomenon with the treadmill of production. Apart from that, evidence shows that ecological modernization efforts were mostly successful to produce solutions to "conventional" environmental problems such as surface water pollution and solid waste management; however, high-consequence risks like climate change can only be explained with more rational integration of social and natural systems.

Neo-Marxist perspective also criticizes ecological modernization because it overlooks the effect of modernization by additions to and withdrawals from nature (Schnaiberg 1980). For example, modern production systems require greater material inputs, e.g., fertilizers. It is capital intensive, and hence, more energy is needed to run the system. It is intended to increase the production levels, thus requiring far more raw materials. Usually agricultural intensification (modernization) can lead substantial chemical additions to the nature. It can generate environmental problems, such as natural resource depletion and pollution of land and water. This can adversely impact the land's productive capacity.

From the very beginning the major critique of ecological modernization theory is the technological optimism as well as perceived technocratic character (Mol and Spaargaren 2000). It is mostly based on the invention, innovation, and diffusion of newer technologies and associated techniques of operating industrial processes (Murphy 2000). This is clearly evident that ecological modernization advocates for super-industrialization. It will generate substantial pressure on economy, nature, and society, and at the same time, not all developing countries in the Global South can follow this modernistic trajectory with ecological modernization due to its own social, economic, and political situations. Without having some levels of economic efficiency, it is very hard to generate and/or promote ecological modernization. It can generate extra burden to the economy as well as to the society. More elaborately, even if the low-income developing countries follow the trajectory with ecological modernization, it will be interesting to explore at what cost and what would be the implications for labor and production relationship. Will the modernization generate profits for the large corporates or continue to marginalize the working class people? Still the proponents of ecological modernization are not very clear on these questions focusing on Global South.

If we summarize the major critics of ecological modernization, we can see that there is no compelling evidence available from where see can see that the ecological sphere has been detached from the economic sphere in decision-making criteria. In addition to that, ecological modernization has focused narrowly on ecological issues by neglecting or overlooking other equally important components of social processes, such as social equity (Pellow et al. 2000).

Without considering these challenges, modernization can generate even further pollution by increasing environmental and economic loads to the working class people, who will be the major victims of adverse impacts of changing climate. Apart from that, in many of the developing countries, the quality of governance and political and social institutions is very weak to support the country's endeavor towards ecological modernization. It is a concern that might derail the ecological modernization efforts in low-income developing countries.

Perspectives on Bangladesh

In Bangladesh, ecological modernization is at the very early stage of conceptualization and implementation. The process is going through restructuring in the local sociopolitical context and challenges. Not only in developing countries like in Bangladesh but also in developed societies it is not very uncommon that agricultural modernization or intensification as part of ecological modernization without proper supervision can cause the loss of fertility of prime agriculture lands. By modernizing agriculture sector in Bangladesh, there is a big chance that the farmers will not be the ultimate beneficiary groups. Big corporates might consume the major share of profits. Apart from that, as the ecological modernization process is technology driven, it might disrupt the local community structure and practice.

Therefore, it is a critical issue for Bangladesh how the country can follow the trajectory of growth and modernization within the larger framework of ecological modernization. Even though the agricultural vulnerability is high and adaptation needs are paramount, very little efforts have made so far to understand the potentials of agricultural adaptation (Abedin and Shaw 2013) and more particularly from the theoretical point of view.

Since the very beginning of ecological modernization discourse, scholars identified two distinct patterns within this framework: weak ecological modernization and strong ecological modernization (developed by Christoff 1996, but also discussed in Blowers 1997; Mol 2001; Dryzek et al. 2002). Weak ecological modernization can be characterized for its sole focus on efficiency and technological solutions by promoting technocratic and corporatist patterns of decision-making. It is treated as an initiative to introduce a single, focused, nondemocratic, and closed-ended framework and initiatives on political and economic structures and development.

The core ideology of weak ecological modernization is to maintain both the political legitimacy and market competitiveness, because the state and market emphasize on environmental benefits through technological advancements (Schlosberg and Rinfret 2008). However, this narrowly defined ecological modernization reflects no significant changes to corporate or political structures and often provides minimal ecological outcomes (Christoff 1996). However in contrast, a stronger ecological modernization considers broad ranging changes to the society's institutional structures and economic systems (Schlosberg and Rinfret 2008). The process often involves open democratic decision-making by using precautionary principles of modernization, and in addition to that it involves opportunities for political development (Schlosberg and Rinfret 2008).

Within the discourse of ecological modernization, we can see that even if Bangladesh adopt ecological modernization perspective, the process entails the components of weak ecological modernization, because its framework narrowly focuses on how alternative technological advancement can enhance the agriculture productivity as well as local economy. This narrowly focused conceptualization of ecological modernization does not involve opportunities for broader societal change in response to changing climate. The current trajectory of ecological modernization in Bangladesh clearly misses the opportunity for conceptualizing the situation from a holistic perspective, and it argues on more importance for broader change with enhanced democratic governance on crucial issues (Schlosberg and Rinfret 2008).

Summary

Agriculture is the major defining factor for food security and social development in Bangladesh. The associated problems of agriculture are multifaceted. Therefore, responding to climate change is complex and interdependent. The local society needs to understand the coupled relationships of human and natural systems prior to any specific modernization efforts.

Ecological modernization is a relatively new concept, and in many ways it is an improved perspective towards sustainable development. It is obviously an attractive concept of modernization, because it provides us an alternative to the pessimistic connotations of development frameworks such as the treadmill of production and growth machine (Buttel 2000).

Considering the local economy, society and political structure ensuring "strong" ecological modernization is a challenging task in Bangladesh. It is important to mention that ecological modernization is not necessarily a uniform prescription for all sectors. It can work better in some particular sectors than others. Advanced developed countries with mature governance are in advantageous position for ensuring ecological modernization. Low-income developing countries have contrasting scenarios.

In Bangladesh, climate adaptation strategy particularly the climate resilient agriculture practice is very much aligned with the concept of "weak" ecological modernization.

To avoid further distress, it would be important for the local society to focus more on the "community-based" side of the process; that means, the process should be led by the local community. The technocratic approach of ecological modernization can generate further disarray in the system and society.

In general, the farmers of the southwest Bangladesh are now interested on innovation and adaptation of climate resilient agriculture practice, such as floating-bed cultivation system. It is a good sign for eco-efficiency responding to climate change. However, it is important to mention that to speedup the process, the market and state should continue further research and development on new varieties of saline- and flood-tolerant crops and strive to disseminate new information and skills among the farmers and local community to create locally conducive environment and precondition for "strong" ecological modernization in southwest Bangladesh.

Security Implication of Climate Change Between Farmers and Cattle Rearers in Northern Nigeria: A Case Study of Three Communities in Kura Local Government of Kano State

Salisu Lawal Halliru

Contents

Abstract

This study focused on the implication of climate change between cattle rearers and farmers in the desert-prone line in northern Nigeria which led to unavoidable crisis and insecurity in Nigeria and Africa in general. The consequence of climate change has untold security implications on the life of Nigerians; attacks in the country have been traced to the doorsteps of two strange groups that are forced to live together as a result of unfavorable climatic conditions in the Northern part of the country. The conflict between Fulani and farming communities linked to disputes over grazing land has become frequent in parts of central and northern Nigeria in recent years. The method of purposive random sampling was employed to select the local government and communities where data was

DOI 10.1007/978-3-642-38670-1_6

collected for this study. The measures for selecting the communities include the following: community with a sizable number of cattle rearers with at least ten (10) heads of cattle and above, community with more than one communal clash which involves the farmers and the Fulani, community with both permanent cattle rearers' settlement and transit Fulani that are always on the move, and agricultural economy-based community. Interviews were also conducted, and 60 respondents were purposively selected: fifteen (15) Fulani, six (6) traditional rulers, and 39 farmers. A qualitative method of data collection was used to gather information, and in-depth interviews were chosen as an appropriate data collection tool; the interview was drafted in Fulfulde language and was later translated into English and the Hausa language was translated into English as well. Multiple data were collected from February to April 2010 and July to September 2010. The study revealed population increase also takes over grazing land as a result of development, paths of animals (Burtali) in the past are now taken over by farmers, desert encroachment has taken over vast farmland, and the quest for a greener pasture usually brings the Fulani crisis among others. These researches also join others before it to call for more research on climate change and insecurity in Africa generally. Finally, this paper recommended ways on how to address immense challenges of adaptation, through educating farmers and the Fulani on the implication of climate change, and reduce human activities which further aggravate and cause climate change – planting of Jatropha plants to prevent animals from going into farms to destroy crops and creating grazing land.

Climate change • Security • Fulani • Farmers • Conflicts

Introduction

A clash over land ownership and grazing land for animals has continued to grow in the few years. The growing pressure for land these past few years has been described by many experts and onlookers as a clear manifestation of the impact of climate change across Nigeria with most states in the far North being the worst affected by these changes. Security has been a major issue in Nigeria's development crisis. Climate change is one of such problems that are globally identified but the effects of which are more pronounced in developing countries. Recurrent droughts, in conjunction with other social and economic factors, have led to conflicts among farmers and cattle rearers. These conflicts are a constant threat to the security of those in the community affected.

Sudano-Sahelian zones of northern Nigeria have suffered environmental degradation caused by successive years of poor rainfall and recurrent droughts, exacerbated by the combined effects of natural population growth and in-migration with the growing population; more land is being cultivated and less is available for pasture and traditional land use systems that rely on mobility. As average rainfall decreases, pastoralists have migrated south into land occupied by sedentary farmers

Fig 1 Map of Nigeria

(Nyong 2009). It is predicted that the majority of Nigerian and all African countries inclusive will have novel climates over at least half of their current crop year by 2050 (IPCC 2007). Already climate change rate is gradually exceeding the adaptive capacity of a broad range of crop and forage varieties, animal breeds, and tree populations in Nigeria, ten years earlier than the IPCC climate model prediction of 2020 (IPCC 2007).

The descriptions of the climate of Nigeria and northwest Nigeria have been rather simplistic due to paucity of data, but with the availability of data manipulation techniques, it is possible to discuss more fundamental features of the climate. Such is necessary at this point in time as recent droughts, water shortages, and fauna and flora depletion have highlighted how important it is to understand weather phenomena (Oguntoyimbo, 1982 in Obioha 2005) and how they affect human security. Nigeria is one of the countries in the West African subregion; it has an estimated population of 140,003,542 people (NPC 2006) spread over a land area of 932,768 km^2 (Fig. 1).

Disasters such as cyclone Nargis and the China earthquake claimed thousands of lives, ruined millions of livelihoods, and caused billions of pounds worth of damage. Disasters have always been with us, but they are becoming more frequent and more severe. As global warming increases the frequency and severity of climate extremes, there are more weather-related disasters. It can leave people without access to food and water, without incomes as crops fail, and displaced from home by flooding or drought (DFID 2009).

Climate changes have forced some cattle rearers (Fulani) to leave their region and migrate to the southwest where the effects of climate change have not been so severe. If the harmattan is not well pronounced in a particular month/season, the hot condition often takes over, creating a strong heat stress in the atmosphere. The stress so created is highest in the region of convergence between the two air masses often referred to as ITD (Inter Tropical Discontinuenity) – the zone of meeting between the dry northeast harmattan wind and wet southwest wind (Michael 2010).

The intercommunal crises have been traced to the aftermath of the effects of climate change in Nigeria. People that have been affected by the consequences of climate change move to other communities where the effects of climate change are less severe or that have not experienced disaster occasioned by the effects of climate change. The rate at which intercommunal clashes occur between the Fulani herdsmen and their host communities is recurrent event in Nigeria. Most of these crises have been traced to pressure on land and destruction of farmland by the Fulani herdsmen during cattle grazing (Michael 2010).

Aim and Objective

The main aim of the study is to examine the security implication of climate change between farmers and cattle rearers that led to communal conflicts in Kura, Kano state (Fig. 2). From which the following objectives were derived:

1. To examine the communal conflicts resulting from climate change and agriculture
2. To observe the physical exposure and the immense challenges of adaptation in northern Nigeria where the study area falls
3. To highlight the potential impacts of climate change on security and the strategies for addressing these challenges

Statement of the Research Problem

Conflicts between cattle rearers and farming communities linked to disputes over grazing land have become frequent in parts of central and northern Nigeria in recent years. Some analysts have blamed the trend on increasing desertification which is pushing cattle rearers southward in their search for pasture, often putting them in conflict with farmers (Olabode and Ajibade 2010). In view of the above, there is a serious need to answer the regular question "what have been the causes of the conflict?" so that we can draw a line and come up with a solution.

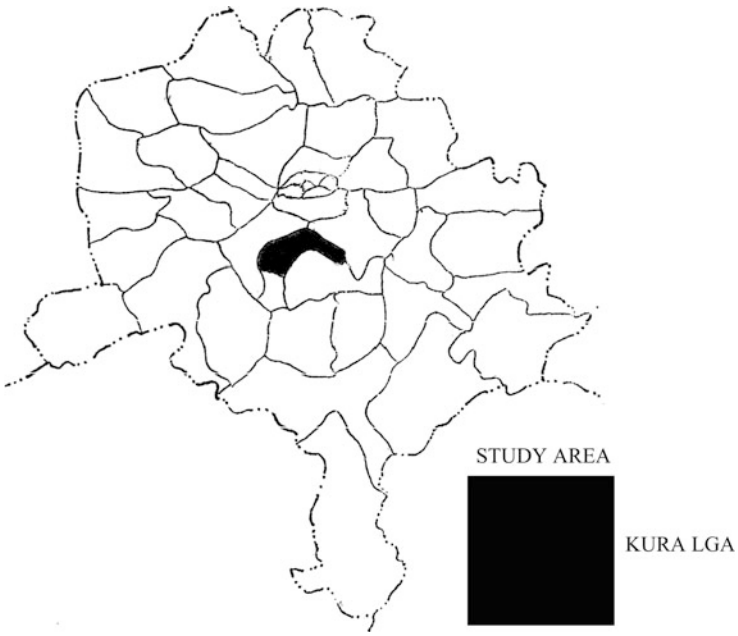

Fig 2 Map of Kano state showing the study area

Justification and Importance of the Study

In the world, generally, conflicts have led to grave consequences like starvation, death, social unrest, poverty, and unquantifiable losses among the citizens of different nations. There is therefore a need to study and understand the causes and processes of conflict and find appropriate strategies for addressing these challenges. The intensity of the conflict between cattle rearers known as BAKWALOGI or BORO, herdsmen with red cows and sheep migrating from Niger every year to enter Kano state, where the study location is, call for timely mitigation and adaptation measures of reducing the frequent conflict occurrence that displaces local farmers and claims lives and crops as well.

Study Area

This study was carried out in Kura local government area of Kano state, Nigeria. The area was selected because agriculture is the bedrock of its economy and it has been victim of the Bakwalogi–farmer conflict for a long time. The study area is located at the southern part of Kano state with a population of 144,601 million people (NPC 2006) with a land mass of 206 km^2, located between 11° 46′12.84″N and

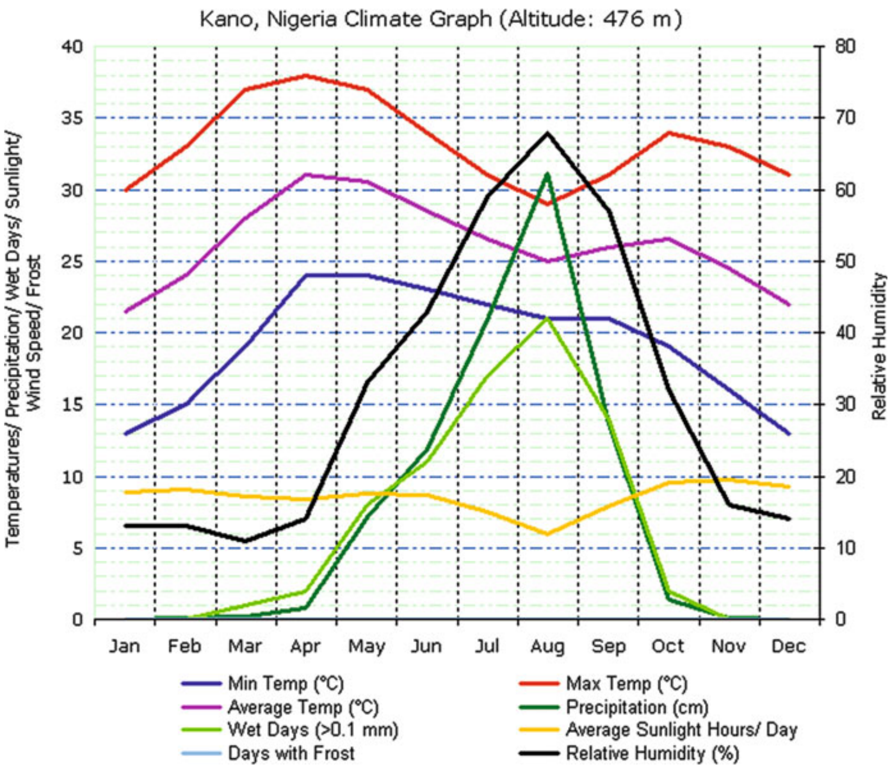

Fig 3 Climate of Kano state (Source: Field study 2010)

longitude 8°35′29.02″E; it is about 900 km from the edge of the Sahara desert and 1,140 km away from the Atlantic Ocean approximately.

The study area shares a boundary in the north and the east with Kumbotso local government; west to south, it boarders with Madobi and Garun Malan local government areas, respectively, and extreme south to east, it boarders with Bunkure local government area (Fig. 2). The area has three marked temperature regimes (warm, hot, and cold) with mean annual temperature of 26°C and 21°C main monthly range of maximum temperature in December/January and over 35°C which is hottest (April/May); wet season starts in May and ends in October, while November to February is a dry cool season with harmattan haze. Vegetation is savanna (grassland) of Sahel–Sudan Guinea type (Salisu 2009; Fig. 3).

Methodology

Three communities were selected from this local government; purposive random sampling was employed to select the local government and communities where data was collected for this study. Three communities were chosen to represent

Table 1 Totality of the respondents

S/no	Respondent	Number
1	Cattle rearers	15
2	Traditional rulers	06
3	Farmers	39
Total	Respondent	60

Source: Field study 2010

the local government purposively selected. The measures for selecting the communities include the following:

1. Community with a sizable number of cattle rearers with at least ten (10) heads of cattle
2. Community with more than one communal clash which involves the farmers and cattle rearers
3. Community with permanent cattle rearers' settlement and transit Fulani that are always on the move
4. Agricultural economy-based community

On the above criteria, Karfi, Dukawa, and rigar-gundutse were selected as the study location. Sixty respondents were also purposively selected (twenty from each community). The following distribution of respondents was obtained: cattle rearers (5), traditional rulers (2), and farmers (13) from each of the three communities selected for this study (Table 1).

A qualitative method of data collection was used to gather information from the respondents, because majority of the respondents are not formally educated and cannot fill in questionnaires adequately. In-depth interviews were chosen as an appropriate data collection tool. The interview guide was wholly structured but also contained open-ended questions to allow a free-flow discussion and unedited information from respondents.

The cattle rearers' interview was drafted in *Fulfulde*; the data collected was later translated into English for the purpose of analysis. Also, the traditional rulers' and farmers' interviews were prepared in Hausa language for data collection. The data collected was also translated into English language for data interpretation.

Data Collection

Multiple data were collected over six months, three months during the dry season (February to April 2010) and the three months during the rainy season (July to September 2010). Data were collected during the dry season since this is the critical period when there is no pasture for grazing and farmers are busy during irrigation activities.

Findings and Discussion

The study revealed that in the past, people were very few and there was enough land for grazing, but now the population has increased so there are fewer lands to farm on. Desert encroachment has not eaten deeper to the southern Kano. Cattle rearers are nomads who move from one location to another to find pasture for their cattle. Changing climate forces them to move where they can get a greener pasture, water, and a friendly environment for their cattle and families. Variability in climate has altered the environment with unbearable effects which are significant in severe desert encroachment, drought, etc.

The place with high cattle population lament for the highest cases of conflict between cattle rearers and farmers due to limited dry season grazing resources (Table 2).

Another observable and major thing that brings clashes between the ***Fulani*** and farmers in the study area is paths for animals in the past (Burtali) are now taken over by the farmers and other developments; hence, the paths are taken over in the process of searching their way to available grazing land and they end up destroying crops in the farmland that is why there are always clashes between the cattle herders and farmers.

The cattle come in droves, invading most farmlands in search of better grazing land as desert encroachment seems to have taken over vast farmlands in the far north, while the farmers who are already feeling the impact of the changes, especially delayed and interrupted rainfall, are protesting the invasion of their farms by the cattle rearers.

The above are conflicts where actors rationally calculated their interest in a zero-sum or negative-sum situation such as might arise from resource scarcity. Table 3 shows that there is a positive feedback relationship between the northwest as it is in the northeastern Nigeria and quest by competing interests to control the available scarce resource in the area (Obioha 2005). The need for more food has led to a serious conflict over land. Violent conflicts involving different typologies that were identified in the study area are very recurrent. Another agent of conflict which we identified arises from large-scale movements of (Bakwalogi/Baroroji) Fulani herdsmen from neighboring countries (Niger and Chad axis) as a result of environmental change.

Security Implications of Violent Conflict

Human security involves the protection of individuals from a sudden violent attack on one person or property, the security being described as having two principal aspects: the freedom from chronic threats such as hunger, disease, and repression, coupled with the protection from sudden calamities, and a number of significant harms that go unmitigated. The seven components of human security are economic, food, health, environmental, personal, community, and political security (United Nations Development Programme 1994). In a more analytically useful manner, Owens (2004) and Obioha (2005) defined human security as protection of

the “vital core” of all human lives from “critical and pervasive” environmental, economic, food, health, and personal threats due to climate change. A drop in agricultural output may weaken rural communities.

Identified Security Implication at the Study Area

- Decreased agricultural production
- Hunger, disease, and malnutrition
- Destruction of farmland/farm crops
- Killing of livestock owned by the herdsmen
- Economic decline
- Population displacement
- Fighting between cattle rearers and farmers which results in loss of lives and injuries every year

Table 4 Factors that attract the cattle rearers

Push factors	Pull factors
Drought and desert storm	Green vegetation
Poor weather condition	Moderate weather
Strange diseases	Hope and aspiration
No water for animals	Market opportunity
Lake Chad is dried up	Forage

Source: Field study 2010

The consequence of climate change has untold security implications on the life of Nigerians. A series of interethnic, interreligious, and reprisal attacks in the country have been traced to the doorsteps of two strange groups that are forced to live together as a result of unfavorable climatic conditions in the northern part of the country (Adediran 2010; Table 4).

The above are pushes and pull factors that attracted the cattle rearers which eventually led to unavoidable crisis, conflict, and insecurity. The following are the extracts from the interview conducted with the cattle rearers and farmers in the three communities selected for this study:

> We travel from far away to find grass for our cows to feed on and how ever we get a Small area to graze on, the farmers come and tell us to go away, where do they want Us to go and feed our cows. (Musa/cattle rearer)

> We travel to far away state close to the border of Niger Republic to feed our cows but Now the weather has changed and the place is full of dry ground and sand which why We came here as we used to do before but now we are always fighting with the Farmers

> Before we can feed our animals we are not allowed to let our animals drink even water In the river. (Bello/cattle rearer)

> Farm lands are no longer as fertile as they use to be in the past so it is really painful For farmers to struggle and spend so much money buying fertilizer and then watch As cattle herders drive their animals to feed on the crops. (Yawale/farmer)

> It is difficult to avoid confrontation with cattle rearers these days because more of them are coming into our farms more especially in the night to destroyed our crops their animals and runaway. (Abdulmumini/farmer)

Conclusion

The devastating impact of climate change is expected to force more people into the north central except if mitigation and adaptation strategies are put in place immediately; most farmers interviewed in Kura local government were not aware of the impacts of climate change, but they said they noticed the gradual changes in the weather and the environment but are not aware of what is causing the changes.

The quests for greener pasture by the (Fulani) herdsmen usually bring them in contact with farmers involved in crop production. In most cases, this contact results to invasion of the cropland of the farmers by the livestock of the migratory group. Conflicts that usually arise in this process are usually violent and long lasting, which may have some internal repercussion around neighboring states and borders.

From all observations, the human security implication of the conflict is enormous, because other areas of human needs are usually in danger wherever there is conflict. This study also found that climate change has and still is affecting farmers and the people in northern Nigeria economically, socially, and otherwise.

Recommendation

- People must be educated on the need to reduce human activities such as tree felling, burning of carbon fuel and biomass, as well as gas flaring which further aggravate and cause climate change.
- Farmers are to demarcate areas of the farms by planting Jatropha plants around it to prevent animals from going into the farms to destroy crops. Animals do not feed on Jatropha nor do they go near the plant because it emits an odor that repels animals.
- Reforestation in the drought-prone areas of northern Nigeria needs to be boosted.
- Nigeria as a country should invest more in combating climate change; agricultural and climatological research should be enhanced to combat desert encroachment.
- Creation of grazing land in each state, local government and communities with standard ranching method that can bring reduction of seasonal in- regional movement of the Fulani, periodic orientation for the Fulani at the grazing point, viable economic value both on the animals and herdsmen.

Acknowledgments I am very grateful to Dr. (Mrs.) R. J. Muhammad (provost FCE, Kano) for her support and encouragements all the time directly or indirectly; Mohammed A. Mohammed; Sani Danladi; Musa Sule; Haruna Abdulhamid; all academic staff of the Department of Geography, FCE, Kano; and the entire management and staff of the Federal College of Education, Kano, who have in one way or the other contributed to the success I have achieved nationally and internationally. I am greatly indebted to the Education Trust Fund (ETF) for funding my attendance at an international conference in Cairo and FCE, Kano, in Nairobi to mention but a few. Thanks also to Associate Professor A. I. Tanko, Department of Geography, Bayero University Kano, Nigeria; Professor S. U. Abdullahi (former VC ABU, Zaria), Brig. Gen. Ibrahim Attahiru, General H. M. Lai, Ibrahim Ahmad Gundutse, and Dr. M. L. Mayanchi. All errors and omissions, and all views expressed, remain solely my responsibility.

Social Capital and Local Institutions: A Perspective to Assess Communities Adaptation Potential to Climate Change

Bhaskar Padigala

Contents

Abstract

Communities residing in Himalayan mountain environment are particularly at risk to climate changes externalities owing to their high dependence on natural resources, relatively high contact to severe climatic events, and prevalent economic and infrastructural marginalization. The present article tries to explore the nature of local society-environment interactions, particularly the role of social institutions and social capital in adaptive capacity to possible climate change impacts in Miyar watershed situated in the northeastern part of Lahaul and Spiti district of Himachal Pradesh, India. The first part of the article deals with climate change perception among local communities and the following part deals with identification and evaluation of adaptive capacities and prevailing institutional mechanisms.

W. Leal Filho (ed.), *Handbook of Climate Change Adaptation*,
DOI 10.1007/978-3-642-38670-1_114

Study findings indicate that local community in Miyar valley, over the time, has developed variety of efficient resource (natural and human) management strategies and institutions (like *Jowari* system and *Kuhl* Committee, etc.) formed as a result of social cohesiveness (social capital), collective action, and common motivation to deal with both environmental and nonenvironmental changes. These aspects of local institutions and social capital are directly related to resource management and community development, but it also provides a buffer zone for the communities to adapt against any future changes (climatic variability, social or economic, etc.) up to some extent.

Keywords
Climate change • Social capital • Adaptation • Local institutions • Collective action

Introduction

Vast amount of scientific literature suggests that the climate is gradually altering and that anthropogenic activities like GHG emissions and ecosystem degradation have resulted in accelerating these climatic variability's and its associated disastrous impacts (Aizebeokhai 2009; Hansen et al. 2000). Alarming projections by IPCC 2001 indicate that the global temperature is on rising trend, and by the end of twenty-first century and depending on the emissions, these raise in the global mean temperatures likely varies anything between 1.4 °C and 5.8 °C (Lal 2002).

These increases in climate variability are likely to have wide range of impacts, ranging from sea level rise (Hallegatte et al. 2011; Galbraith et al. 2002), forest degradation (Watson 2000), glaciers melting (Barnett et al. 2005; Singh and Kumar 1997), and many more (Parmesan and Yohe 2003; Thomas et al. 2004; Watson et al. 1998). Even though, the probability, intensity, and geographical distribution of these impacts are still a lot unclear (Schneider 2001). But, the fact remains that despite the type and location of these impacts, marginalized communities (both economically and socially) are likely to be the most vulnerable sections in the society (Furgal and Seguin 2006; Raleigh 2010; Downing 2003).

Similarly, communities inhabiting Himalayan mountain ecosystem are likely to be more vulnerable and impacted to climate variability owning to fragile environment, lack of proper infrastructure, livelihood instability, and their high dependence on local natural resources (Macchi 2011). But, care must be taken not to attribute all these impacts to environmental and climatic availabilities, since communities and their interactions are very complex and there are many other factors or drivers that also influence communities' actions and responses like social, political, and economic factors.

Mountain communities have always been at risk due to limited natural resources and fragile ecosystem they live in, but at the same time, these communities have also developed a great potential resilience to these limitations by incorporating interventions at different scale like traditional land and water management practices

(Gadgil et al. 2003; Friedman and Rangan 1993; Padigala 2013), village institutions and resource governance (Agrawal 2001; Ostrom 2005), etc. Still, very limited studies have been carried out to understand impacts of climate variability on Himalayan communities and their resilience capacities to the same (Eriksson et al. 2009; Ensor and Berger 2009). Thus, it is imperative to understand these local adaptive capacities and assess their potential for climate change.

Understanding Human Adaptive Potential and Social Capital

Wide-ranging discussions revolving around the topic of climate variability deal with vulnerability and impacts on the natural ecosystem and especially on human systems (Smith et al. 2000). As a consequence, assessment of community vulnerability and its adaptation capacity is garnering rising interest among wide range of stakeholders like grassroot organizations, policymakers, researchers, etc. (Burton et al. 2005; Thomas and Twyman 2005; Moser and Ekstrom 2010). However, measuring adaptation capacities is difficult to ascertain, as it involves predicting the adaptive capacity for potential crisis periods. Even more, the adaptive capacity to climate variability is also influenced by other dependent aspects like social, political, economic, technological, and institutional factors, thus making assessment of adaptation potential all the way more uncertain (Van Aalst et al. 2008).

Throughout the literature many researchers through their research have tried to define a complex aspect, i.e., adaptive capacity (Folke et al. 2002; Grothmann and Patt 2005). Brooks (2003) in his work define adaptive capacity as “reductions in social vulnerability as arising from the realization of adaptive capacity as adaptation. The term adaptation means adjustments in a system’s behaviour and characteristics that enhance its ability to cope with external stresses.” This hereby means that, a system over the time will cultivate capacity of adaptation to reduce its vulnerability with consistent levels of risks. Adaptive capacity is many times used as an indicator for climate change adaption potential of a society (Grothmann and Patt 2005; Adger and Vincent 2005; Adger 2003; Kelly and Adger 2000). However, it is important to understand that this potential is based on various interconnected asset bases like financial capital, human capital, social capital, etc. Thus, cumulative vulnerability and adaptive capacity of a society can be estimated by understanding resource management strategies and these assets.

The one element which is common to all the five forms of capital is that there is a stock associated with each capital, which can be channelized into a flow of benefits. The stock of financial capital, for example, is associated with a flow of benefit, which is the interest. Similarly, social capital is associated with a benefit which has been termed as “Mutually Beneficial Collective Action” or MBCA (Krishna and Uphoff 2002).

Adaptive capacity is a multivariate idea, not only it is interconnected with different assets but this interrelationship also runs across different scales. At the national level, adaptive capacity is represented by the accessibility of financial resources and institutional and governance capability for resource management thereby reducing the vulnerability of marginalized sections of the society. At the household level, this capacity is more dependent on the livelihood and knowledge base of the individual. Thus, assessing adaptive capacity based on different assets and across different scales is very important for building up successful adaption model for future climatic as well as non-climatic variability's (Vincent 2007). Thus, it is therefore very difficult to create a universal set of indicators to determine adaptive capacity hence these indicators need to be devised and modified suiting to individual cases (Adger et al. 2004).

Speaking of adaption strategies and models, their success largely depends on the identification of the indicators or assets and also on the willingness of the vulnerable community. Thus, adaptive potential of a community primarily depends upon local institutions, governance aspects, and the social capital.

Communities have innate capability to acclimatize to environmental variability's. These capacities are outcome of society's capability to work cooperatively. These choices of adaptation strategies are taken by institutions formed by individuals from within the community. Hence, one of the key elements of this article has been to explore the nature of these society-environment interactions, particularly the role of social institutions and social capital in adaptation processes and capacity.

Social capital and its role in adaptation have been getting lot of interest among researchers and practitioners alike (Pretty 2003; Katz 2000; Pretty and Ward 2001; Adger 2003; Pretty and Smith 2004; Adger 2001). Social capital can be understood as a system of networks, concurrence, and information flow that is integrated into the fabric of society. The scope of the concept of social capital varies considerably in the literature. Putnam provides a more narrow theory of social capital. According to Putnam (1993), social capital can be viewed as *a set of* "horizontal associations" *between people: social capital consists of social networks* ("networks of civic engagement") *and associated norms that have an effect on the productivity of the community*. Defining social capital in two-way process, Coleman (1988) defines it as a network of vertical and horizontal associations, wherein social capital encompasses both the positive and negative aspects of the associations. Lastly, defining it in more border sense, North (1990) suggests that social capital embraces the social and political situations and transforms the social arrangements and interactions thereby helping the society to develop. Adger (1999, 2000) in his studies has indicated economic and political processes in Vietnam that have led to reviving of resilience of informal networks against the risks of sea-flooding. This argument directly indicates the role of institutions and networks among the society and its significance in economic and social development.

It should be understood that social capital is a system of institutions governing a society, but it is also an aspect that encompasses relations and interactions among the individuals which are facilitated and governed by institutions, norms, values, and extent of the capital (economic, human, and natural) commanded by these connected individuals.

Social capital is more than a theoretical notion, and it does provide variety of social benefits like increased collective actions among individuals (Knack and Keefer 1997) and efficient functioning of local governmental and civic institutions (Bebbington 1997). But, understanding and measuring social capital is fraught with uncertainties and probabilities. However, over the years many researchers across the globe have attempted to understand this aspect, in rural Tanzania (Narayan and Pritchett 1999) using Social Capital and Poverty Survey (SCPS) found that at village level, increasing income levels have direct correlation with the extent of social capital. Similarly, Knack and Keefer (1997) in their research used the indicators of trust and civic norms to understand the correlation between economic development and social capital.

Traditional notion of community development is based on the four capitals or assets, i.e., financial, natural, physical, and human capitals, but with predicated impacts due to climatic variability and urgent need for inclusive sustainable development, it is imperative that the social capital needs to be also brought into the mainstream planning and decision making (Grootaert 1998). Since, social capital is the crucial link that governs the nature and extent of interactions between different societal entities to generate growth and development.

Local Institutions and Climate Adaptation

As discussed in previous sections, communities have inherent capacity to reduce vulnerability to climatic variability owning to many adaptation strategies developed over the time. But the effectiveness of these adaptations largely depends on the structure and operation of the institutions. According to Agarwal (2010) these institutions can be classified into three categories, namely, (1) public or state (local agencies & local governments), (2) private or market (service organizations & private businesses), and (3) civic (membership organizations, cooperatives). And these organizations through its range of activities like capacity building, resource mobilization, information channelling, etc., reduce the community's vulnerability and increases resilience.

Undeniably, the role of institutions at multiple scales, including household level, has been identified; Eakin (2005) in his study across three communities in Mexico observed that resource management strategies applied in these communities are largely successful due to presence of local institutions. Similarly in Trinidad and Tobago, formation of informal institution has led to successful coastal management thereby highlighting the role of local institutions, social capital, and information flow in natural resource management (Tompkins and Adger 2004). Related studies on various themes like water conservation (Padigala 2013; Mosse 1995; Cleaver 1998), agricultural management (Uphoff 1992; Little and Brokensha 1987), pastoral management (Niamir-Fuller 2005), and forest governance (Gibson et al. 2000; Hayes 2006) have all indicated the significant role of institutions in the management of resources. But relatively limited studies have been carried out to assess the institutions role in climate change adaptation (Naess et al. 2005; Berkes and Jolly 2002), especially in Himalayan ecosystem.

From the above discourse it is evident that local institutions are vital component in community's resilience and adaptation to climate change. However, there is still information gap on measuring the effectiveness of these local institutions and social capital against climate change impacts and ways to mainstream these "bottom up" aspects in the traditional climate change adaptation planning and decision-making process, which follow a "top-to-bottom" approach. The following section would shed light on these very issues of community-based natural resource management strategies and social capital and role local institutions in Miyar valley and asses effectiveness of these interventions against likely climate change impacts on the communities.

Introduction to Miyar Valley

The Miyar watershed lies in the northeastern part of Lahaul and Spiti district of Himachal Pradesh extending between 32°42′36″ N – 33°15′24″N – 33°15′24″N latitude to 76°40′12″E – 77°1′15″ E longitude (Fig. 1). The community living in the area is exclusively dependent on the climate, natural resources, and social collective action for their survival. The study area included five villages (Tingrit, Ghumpa, Urgos, Sukto, and Khanjar) (Table 1) which were taken to learn the socioeconomic aspects, land use dynamics, and community adaptive capacity of the area. The site was selected considering the two circumstances (viz., climate dependency and changing economic pattern) and how these situations and community will behave in the light of current global environmental change.

The main livelihood source in the valley is agriculture; being a rain shadow area, the only source of irrigation water is snow meltwater along with some amount of glacial water. Also the area receives heavy snowfall during winters from October to March causing complete halt to agricultural activities and hindrance to the normal life; this means that people get only the remaining six months to do agriculture and gather food and fodder for themselves and for their livestocks.

From the last few years, the area is witnessing change in the economic and land use pattern due to the introduction of cash crops like peas, seed potato, etc., which has lead to increased economic stability in community and also change in the land use of the area like conversion of small patches of forest and grazing lands into agricultural fields by villagers.

However, Sen et al. (2011) indicate that the major recent economic transformation in Miyar valley has been diversification of traditional agricultural practice towards cash crops like peas, which is a perishable commodity. The possibility of better income thus is connected to transportation of the commodity to the market in time. Thus, road or transport seems to be the single major reason for diversification. Majority of small farmers report higher income as the driving force; a large section of larger farmers feel that the road is what makes commercialization possible. The major conclusion that comes out from this study is that the recent changes in the valley cannot be directly related to climate change only.

Though there is a lack of benchmark data, there is no doubt that the current trend of commercialization has uplifted the livelihood status of the valley which has been primarily driven by increased connectivity of sthe region. Thus, it becomes important to inquire as to whether the community sees commercialization as a risky proposition and, subsequently, to identify the major risk variables (climatic as well as non-climatic) as perceived by the communities.

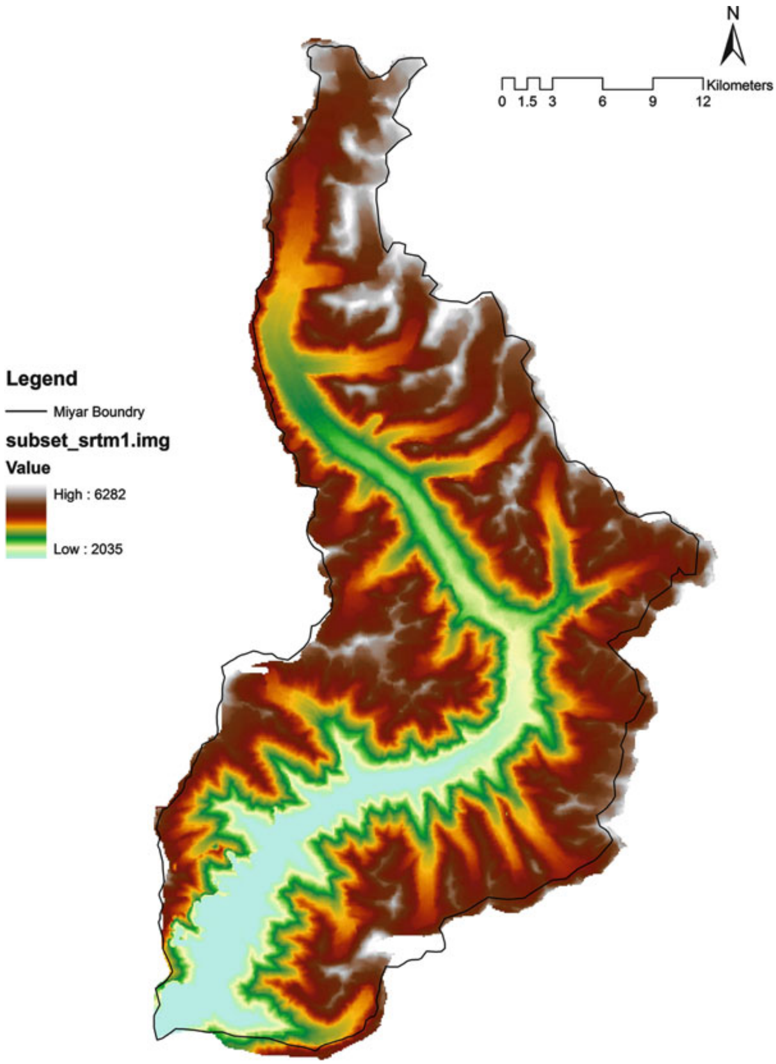

Fig. 1 Figure showing a digital elevation model of Miyar valley

Methodology

In this study the adaptive capacity of the communities were assessed using the model of sustainable livelihoods approach (SLA). The SLA was employed to create an understanding of the livelihood patterns among the inhabitants, since the livelihood assets are important parameters to assess the vulnerability and capacity of the communities to adapt against environmental and socioeconomic changes.

Table 1 Showing population growth in the area

Village	Total population 1999		Total population 2001		Total population 2010	
	Male	Female	Male	Female	Male	Female
Khanjar	25	26	29	32	25	23
Sukto	Data not available				20	17
Urgos	Data not available				114	112
Ghumpa	Data not available				21	24
Tingrit	154	123	167	144	93	78

Source: District Census Handbook 1991, 2001, Lahaul & Spiti, Registrar General and Census Commissioner, Ministry of Home Affairs, Govt. of India

Livelihood can be defined as "the capabilities, assets (including both material and social resources), and activities required for a means of living. A livelihood is sustainable when it can cope with and recover from stresses and shocks and maintain or enhance its capabilities and assets both now and in the future, while not undermining the natural resource base" (DFID 1999).

Being geographically located in fragile and extreme ecosystem, these communities have already developed livelihood assets to adapt to environmental and socioeconomic changes. Thus, sustainable livelihoods approach (SLA) also provides crucial impetus on strongly and weakly developed assets in the community. This in turn is crucial to strengthen these weakly developed assets, so as to increase community's adaptive capacity.

The sustainable livelihoods approach (SLA) exhibits the primary issues that have impact on people's livelihoods and their different assets. SLA categorizes these assets into five types: human capital, financial capital, physical asset, environmental capital, and lastly, social capital (Fig. 2). Table 2 shows the various proxy indicators used during the study to assess the adaptive capacity of the communities inhabiting Miyar valley.

Study involved the collection of primary data (field verification and mapping, household surveys with sample size of 80 households out of 120 houses in the selected five villages) from the field. This primary data was supported by a wide-ranging study and examination of secondary literature and other region specific documents like census data, topographic sheets and satellite data, and climatic data of the study area.

Primary data from the study area was collected according to the community-based vulnerability and capacity assessment approach (CBVCA) framework. This framework was modified to suit the site conditions.

In a community-based vulnerability and capacity assessment approach (CBVCA), primary informations are collected using different quantitative and qualitative research techniques including focus group discussions (FGDs), key informant interviews and participatory rural appraisal (PRA) methods at the community and household levels. While conducting the evaluation to the household residents and the community members or the representatives of different institutions, it was made sure that the idea "climate change" and its aspects and impacts were not directly incorporated or mentioned. This was done so as to forbid any predisposition in their answers.

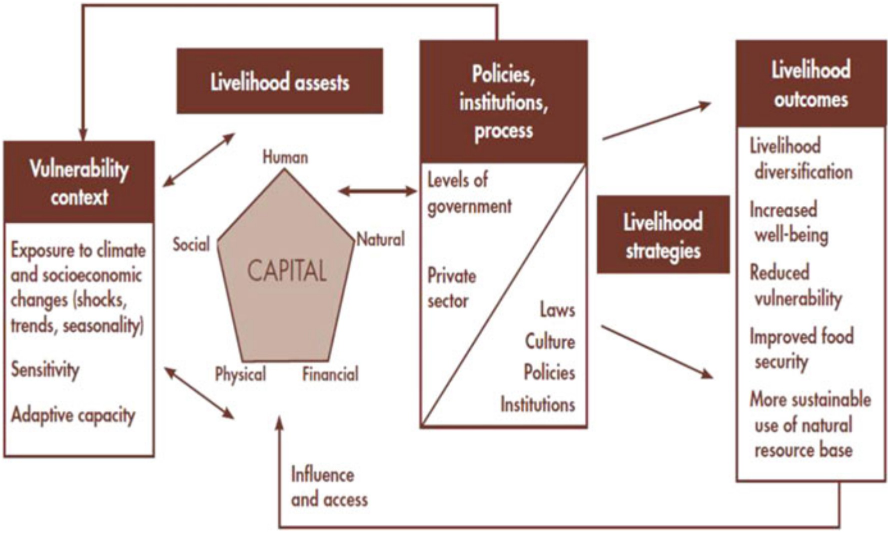

Fig. 2 Figure showing sustainable livelihoods framework (Source Macchi 2011)

Table 2 Showing sectors/capacities and proxy indicators applied to measure adaptive capacity of community for the study

Adaptive capacity	
Sectors/resources	Proxy indicators
Human capital	Family size, education, knowledge, and skills
Financial capital	Income sources, savings, credits and loans
Physical capital	House structure and materials, road connectivity, local technologies and equipments
Environment (resources) capital	Natural resources (pasture land, forest, fresh water resources), land holding per family
Social capital	Social structure and relationships, local governance, community support, trust, bonding, and network

Principally, apart from collecting primary data, to gather data on community-based VCAs, qualitative research methods were undertaken since qualitative research techniques provides an achievable scenario to study the history of that community and its different crucial aspects like gender, culture, ethnicity, etc. These factors are essential in observing and understanding the source reasons for social and economic susceptibility to transformations, environmental, as well as other aspects (Birkmann and Wisner 2006).

Statistical Package for Social Science (SPSS) and Excel computer software were used to analyze the collected quantitative data. From a researcher's perspective, it was taken care that there are also other factors or drivers of change in the Miyar valley like infrastructure development, change in land use, agricultural patterns, and outmigration, etc., apart from climate change, thereby not attributing every change (both externalities as well as opportunities) to climate change. Furthermore, to validate the collected data, during the study the communities' perception on climate change aspects were authenticated using information gathered from secondary literature and sources. This was done so that the conclusions coming out from this study were realistic and in turn facilitates future policy and developmental interventions that ensures enhanced resilience of the communities.

Results and Discussions

Environmental Change Perception

Miyar region is heavily dependent on the temperature variability and water availability, because the main source of livelihood for the community in the area is agriculture. With increasing temperature the cropping season might increase, and also the availability of irrigation water will fluctuate. A variety of literature on climatic variability and climatic modelling on Himalayan region suggests an increasing trend in temperature in the near future (Bhutiyani et al. 2007; Ageta and Kadota 1992; IPCC 2007).

More than 65 % of the respondents from across the villages perceived that there has been change in the temperature of the valley and the change has been on the higher side, i.e., villagers felt that the temperature has increased a little since the past 10–30 years. Along with temperature respondents also perceived a slight increase in the duration of the summer season (Table 3).

Correlating to the temperature change, villagers were asked about change in the agriculture practices due to increased duration of the summer season, and it was found that more than 90 % farmers from all villages (up to 100 % in Sukto and Tingrit) have not increased the cropping numbers. Likewise, 100 % of the respondents from all villages replied that they have not adapted to any new variety of crop. However, respondents do feel that the cropping season has extended a little.

It was very interesting to know that, despite perceiving increase in temperature and extension in the cropping season, farmers were not taking advantage of it. This could be attributed to two reasons: first that though there seem to be some change in temperature but the change is small and not that significant to which they should adapt in agricultural practices and secondly, farmers experienced that the annual snowfall is increasing and its season is getting erratic, due to which there is a great risk if people try to harvest a second crop. Since the first crop harvesting lasts up to October the month for potatoes and August the month for peas, if they try to harvest the second crop after the peas, the crop will require 2–3 months time before it could yield and thus the harvesting time overlaps with the commencement of the winter season with snowfall that could pose a huge threat to standing crop if the snowfall occurs little early that year.

With rain almost unknown and erratic, the amount and availability of the irrigation water greatly depends on the yearly snowfall. For the year with scanty

Table 3 Respondents perception to changes

	Parameters											
	Change in temperature		Change in cropping number		Change in cropping type		Change in cropping time		Change in snowfall		Change in drinking water availability	
	Yes (%)	No (%)	Yes (%)	No (%)	Yes (%)	No (%)	Yes (%)	No (%)	Yes (%)	No (%)	Yes (%)	No (%)
Village												
Thingrit	80.0	20.0	0	100.0	0	100	15.0	85.0	55.0	45.0	10.0	90.0
Ghumpa	70.0	30.0	10.0	90.0	0	100	40.0	60.0	60.0	40.0	10.0	90.0
Urgos	84.8	15.2	6.1	93.9	0	100	18.2	81.8	72.7	27.3	15.2	84.8
Sukto	66.7	33.3	0	100.0	0	100	16.7	83.3	50.0	50.0	16.7	83.3
Khanjar	72.7	27.3	9.1	90.9	0	100	9.1	90.9	45.5	54.5	18.2	81.8

snowfall, streams dwindle quickly and dry up in the beginning of August and hence crops suffer. Thus, during this study it became important to understand the observation of the community with respect to snowfall variability in the area.

During the survey it was found out that all villages expect village Khanjar to display above 50 % agreement to the phenomenon of increased snowfall in the area. Villagers also feel that duration of onset and the season of snowfall have reduced slightly. Moreover when inquired about water-related hazards to the area such as cloud burst-induced floods or GLOFs (glacial lake outburst floods), villagers felt positive risk about it, though the occurrence of the floods in the area has been very sporadic, like the only recent case of flood was back in year 2000, where only one small village (Changut) was partially affected by the flood.

One of the most observable changes of global warming in the Himalayan region is the withdrawal of the glaciers, at advanced rates than glaciers in other regions (Pathak 2010). This continued deglaciation could have an intense impact on the hydrology and water flows in the river basins starting off in the NW Himalayan region (Rao et al. 2008; Jianchu et al. 2009). Owing to this increased speed of glacier melting, water discharges in the glacial-fed rivers are more expected to rise for some time, before decreasing as the ice storage of the glaciers gradually decreases (Karki et al. 2009).

With several literature predicting scarcity of drinking water in it was surprising to find that majority of the local community did not recognize any change in the drinking water availability (more than 80 % respondents across all villages). The major source for drinking water for the village in the study area is spring water; occasionally following the year with less snowfall few spring sources got dried up. To which villagers have no problem in adjusting and finding a new source for water supply.

But these predicted changes in water regime due to likely future environmental variability will no doubt change and up to some extent disturb the local economy and natural resource availability and accessibility. It can also be believed that these changes will certainly transform the functioning of local institutions and governance along with social capital and communal actions in the region.

Local Adaptations and Institutions for Resource Management

From the above sections it is evident that climatic variability has been also perceived by the locals, yet they do not feel any risk associated with it (Table 4). Following section tries to explore what are the different resources available to the community, what strategies are being employed to manage these resources for their development, and whether these adaptive mechanisms can be seen as indicators for adaptive potential to climate change.

The valley has almost unrestrained source of water supply for both irrigation and drinking purposes. The majority of the villages which lie on the plateaux on both sides of the main river get water from the streams which trickle down from the cliffs (Saini 2008). The amount and availability of the irrigation water greatly depends on

Table 4 Coping and adaptation mechanisms implemented by the communities

S. No.	Parameter	Communities perception of change	Impact on livelihood	Communities perception of risk to change	Coping and adaptation
1.	Temperature change	Slight increase	No significant impact	No risk	No coping and adaptation
2.	Snowfall	Increased	Little impact	No risk (risk is there if, they try to take two crops in a season)	No coping and adaptation
3.	Drinking water availability	No significant change		No risk (risk is there if, following year after less snowfall spring dries up)	Diversion of the spring water system to the new source

the yearly snowfall and glacier meltwater. Drinking water is obtained from the springs. The gravity-type water supply schemes have been installed in every village to provide drinking water.

Vegetation cover of the Miyar watershed is of central Asian or Siberia type with dry alpine character at lower elevation. Low precipitation is another reason for scanty vegetation in the area. Vegetation distribution of the region has been divided into three zones. First zone extends from 2,590 to 3,350 m.s.l and contains maximum vegetation with nearly all the trees that exist in the watershed, viz., juniper, blue pine; and birch. Second region ranges from 3,350 to 4,875 m.s.l where most characteristic plant *Rheum moorcroftiana* is which does not thrive below that height.

Total number of species recorded from the study area is 142, from which 17 are trees, 18 shrubs, 85 herbs, and 22 lichens. *Asteraceae* and *Fabaceae* are the dominant family in the area with 15 and 12 species, respectively. In trees *Salicaceae* and *Pinaceae* are represented by 5 and 4 species, respectively; *Asteraceae* and *Fabaceae* are also dominant families in the herbaceous layer (Forest Working Plan 1996–2006).

Quite a few patches of juniper tree (*Juniperus semiglobosa*) can be seen here, which represents subalpine forests in the region. This is one of the featured species of high conservation and religious importance in the valley.

Glaciers are devoid of any vegetation while a narrow belt below glacier contains lichen, mosses, and few other grasses. The forest patches are very sparse and were depleting before 1980 because forest wood was the only material available for house construction and fuel wood. This led to rapid reduction in forest area; to this with this situation *Mahila Mandal* was formed and it has proven successful in its mission.

Miyar valley is also endowed with large areas of grasslands with nutritive grasses (*Poa* sp and *Agropyron* sp) which attract many heads of sheep and goats with transhumance.

The valley due to its climatic and geographical condition and various other reasons lacks the luxury of abundance of natural resource (except for water resource), and also the valley people cannot undertake large scale developmental interventions because of various constraints like only limited season to grow crops, loss of physical contact with the outer world during winters due to avalanches and road blockages, etc.

But people in the Miyar valley, over the ages, have adapted to manage and sustainably utilize resources like forest resources, pasture, water resources, manpower, etc., for their development. Mentioned below are the few fine examples of the collective action, awareness, resilience, and excellent social bonding to adapt community against resource scarcity and to attain overall community development.

Jowari: Labor Exchange (Resource Management)

One of the best examples of efficient resource management and collective community action is reciprocal labor exchanges in agriculture. There is no class of landless agricultural labors in the villages; even the poorest owns a small patch.

The short season between snowfalls for cultivation creates an immense time constraint on production along with shortage of casual labors (usually Nepali migrants). People have adapted to this by pooling their labor. A labor pool will usually include 4–5 families who share manpower, bullocks, and plow; weed; and harvest the fields in rotation. Generally women are the ones who work in labor exchange (Fig. 3).

Community Livestock Grazing

Due to short season of summer season, farmers have to deal with maintaining duel economic task of farming and livestock rearing to keep their financial condition stabilized. Now due to greater financial gains, villagers are more involved in farming and hence they have adopted an innovative way to tackle the problem of livestock rearing by practicing community livestock grazing.

Fig. 3 *Jowari*: Labor Exchange (Resource Management)

Each village has extensive private irrigated grasslands, usually on slopes which are too steep for cultivation or on large bunds between fields. These areas are opened as commons to the cattle in April and closed when the fields are put under cultivation. The livestock are then taken to alpine pastures by a grazier who receives payment from all households in the village (e.g., village Tingrit has employed two grazier for a sum of INR 50,000 to look after village livestock and to graze them in pasture for a period of 6 months). The alpine pastures are managed as a common property by the villages. The decision on when to open and close the fields for grazing, and when to start plowing, is taken jointly by *Yuva Mandal* (representative from every household is part of this institution) and is based on a commitment to collective action.

Mahila Mandal **(Local Women's Group)**

Mahila Mandal is a community-based rural women organization. Generally it has about 20 members. It has an elected executive body consisting of a president, vice president, secretary, and treasurer. In all of the five villages surveyed, the *Mahila Mandal* has been in existence since the early 1980s. Total of three *mandals* have been observed in the area. Each household of the village has one representation in the *Mahila Mandal*. The mandals has INR 12 to INR 50 per month as membership fee and INR 1000 to INR 1500 as joining fees. This amount is then deposited into a bank account which is opened under the name of the *Mahila Mandal* of the respective village.

The main functions and activities of the *Mahila Mandal* are:

- Mobilization, networking with community groups especially *Yuva Mandals* and Panchayat, to strengthen participation and interlinkages, and participation in *Yuva Mandals* and Panchayat meetings.
- Addressing issues affecting women and village as a whole such as gender, social injustice, alcohol abuse awareness, women's role in Panchayat, cleanliness drives, clean water sources, and tree plantation.
- Efforts in organizing work for the village, such as fixing the walkways through the village, or putting in a water system, labor exchange in fields for *mandal* members.
- Acts as a nodal agency along with Panchayat between block office and village for release and utilization of development funds.
- Mahila Mandal also provides loans between 10,000 and 15,000 Rs to the members with interest rates of 2 %.
- Lastly, one of main function of the *Mahila Mandal* in the area is forest and natural resource conservation. However, the flexibility in terms of the purpose and objectives of *Mahila Mandals* has meant that in some cases it has been adapted to the local needs of the village. Almost all *Mahila Mandals* of the five villages surveyed during field study indicated that they were active to a large degree in forest protection.

Yuva Mandal (Youth Group)

Yuva Mandal is a community-based organization and is a good example of informal institution working parallel with formal local institution such as village Panchayat. The formation of the *Yuva Mandal* in Miyar valley was around 1985–1986 mostly after the formation of the *Mahila Mandals* in the area. Generally the number of members depends on the number of households in the village as it is mandatory for each family in the village to have one representative in the mandal. In the study area, size of the mandals ranges between 16 and 45. It has an elected executive body of *Pardhan* (head), *Up-pardhan* (deputy head), secretary, and treasurer. The term for an executive body is 1 year, and after the completion of the term, a new body is selected within the members unanimously. The main objective or motivation for formation of the mandals was to discuss and agree on village requirements (infrastructure, education, health, etc.) and to put it forward through village *Pardhan* (head) during village meetings for the approval and grants.

The main functions and activities of the mandals are to:

- Lead construction activities: Yuva Mandals constructed internal roads, temples, Kuhls (irrigation channels).
- Provide loans between 10,000 and 15,000 Rs to the members without any interest rates.
- Work also as a *Kuhl* committee (construction and maintenance of *Kuhls*, distribution of water rights, etc.)
- Decide on working and payment-related community livestock grazing.

Kuhl Committee (Water Institution)

Irrigation in the Miyar valley is done by *Kuhls* (Fig. 4), channels which harness water from snow meltwater glaciers. These *Kuhls* are built with the collective labor of the village, and the water is distributed according to the share of labor contributed by a family; the distribution of the water rights is done in impartial lottery system, where each house name is written on a chit and sequence of water rights is decided by lottery system. The labor contribution is annual process as avalanches often destroy the *kuhls* during the winter. Failure to contribute family labor can lead to a withdrawal of water rights and penalties. The decision related to *kuhls* construction, maintenance, and water rights distribution is taken by *Kuhl* committee (Fig. 5), and this committee represents whole village as each house has to nominate one member from house who will represent house in committee meeting and also will provide money and manpower for construction for the maintenance of *kuhls* (Padigala 2013).

From the above examples of both the resource management efforts and the functioning of the institutions, it is observed that there are internal capabilities within the communities in Miyar valley to deal with various kinds of shocks and uncertainties. Thus, this existing adaptive potential will be very crucial in case any transformation related to climate change occurs in near future. Another important characteristic of these strategies is that they are tailor made to suit the community need at utmost local level and are dynamic in themselves to modify according to the

Fig. 4 Kuhl Head, Village Tingrit

Fig. 5 *Kuhl* Committee (Water Institution) Village Tingrit

changing need and requirements of the village. A good example is of the water right distribution in upstream villages like Tingrit and downstream village like Shansha in the Chamba valley, where in upstream village water for irrigation is in plenty due to which the water right distribution rules are less stringent, but in the downstream village where water availability is little less, local institution has modified the water distribution rules and has made it strict so that there must be equity and no fights over water distribution.

Assessment of Existing Adaptive Capacity in the Local Communities

The study has incorporated the sustainable livelihood (SLA) framework which advocates the classification of the assets or capitals into five classes (Table 2). According to the framework adaptive potential of a person or community can be

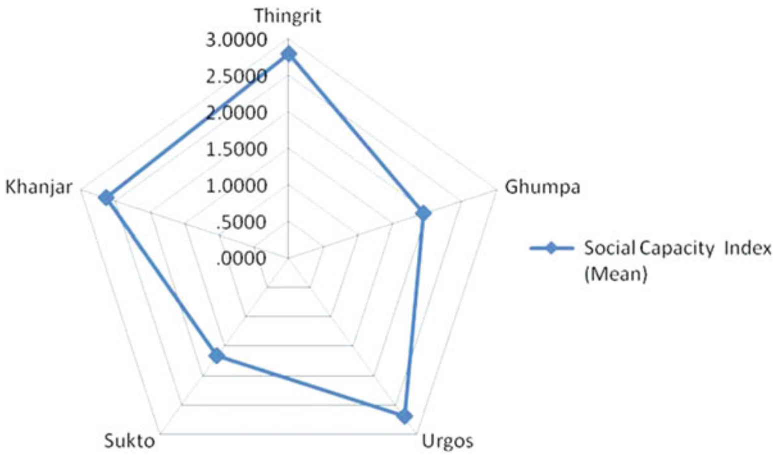

Fig. 6 Village wise social capital index

Table 5 Showing village wise institutional setup

Village	Mahila mandal	Yuva mandal	Community grazing	Gram panchayat representation
Tingrit	Yes	Yes	Yes	Yes
Ghumpa	No	No	Combined with Urgos village	Yes
Urgos	Yes	Yes	Yes	Yes
Sukto	Combined with Khanjar village			Yes
Khanjar	Yes	Yes	Yes	Yes

evaluated by using these capitals (or indicators). Present capacity assessment encapsulates evaluation of the five capital indexes based on the proxy indicators (Table 2) by using graded codes, summation, and simple averaging.

Figure 6 shows the status of the social capital in the five villages studied. It was found that two villages Sukto and Ghumpa have low social capital index (SCI) compared to the rest of the villages. This can be attributed to lack of local institutions (Table 5) like Yuva Mandal and Mahila Mandal in these villages, as these institutions help in keeping community bonded and generate mutual trust. These institutions have crucial significance in initiating and managing resource management interventions like *Jowari*, *Kuhl* works, and community grazing, etc., which leads to formation of social capital since these works involve collective action and management of common village property resources (Table 6).

Based on the social capital index and remaining four capital all the five indexes a cumulative capacity index (Figs. 7 and 8) was generated along final adaptability index ranking was created. In this ranking exercise, it was found that Ghumpa village scored better than Khanjar village despite having low index score in SCI;

Table 6 Table showing village wise social capital index

Rank	Village	Social capital index (mean)	N
1	Tingrit	2.80	20
2	Urgos	2.69	33
3	Khanjar	2.63	11
4	Ghumpa	1.95	10
5	Sukto	1.66	6
	Total	2.54	80

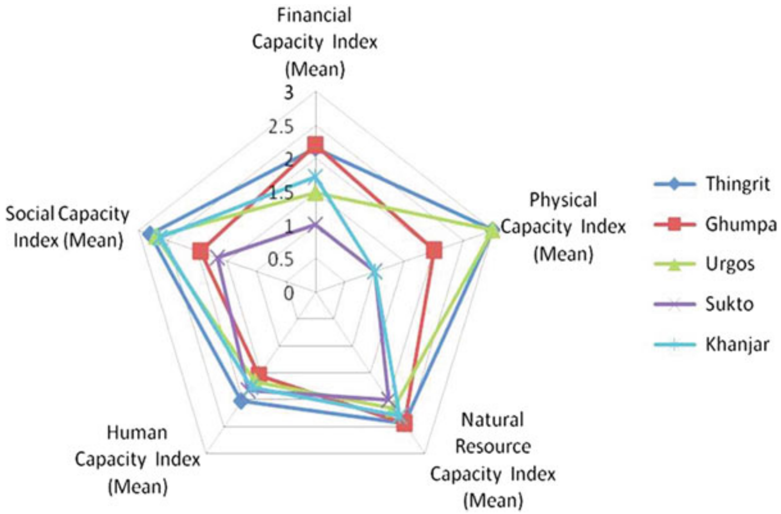

Fig. 7 Village wise capacity index

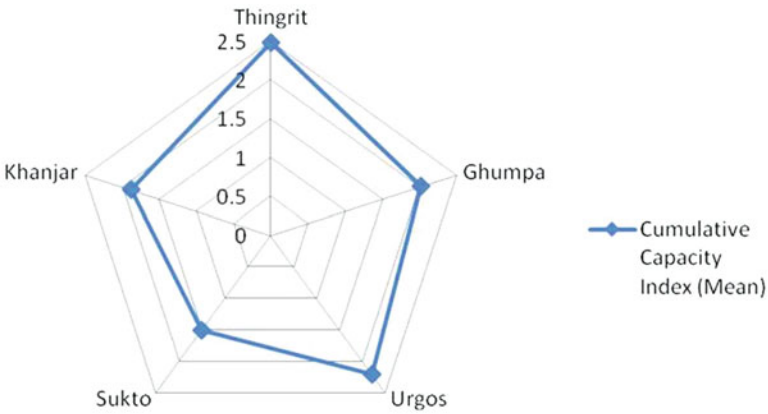

Fig. 8 Village wise cumulative capacity index

Table 7 Table showing Village wise capacity index

Village	Financial capacity index	Physical capacity index	Natural resource capacity index	Human capacity index	Social capacity index
Tingrit	2.15	3	2.43	2.02	2.80
Ghumpa	2.20	2	2.43	1.55	1.95
Urgos	1.48	3	2.15	1.66	2.69
Sukto	1.00	1	2.00	1.83	1.66
Khanjar	1.72	1	2.30	1.77	2.63

Table 8 Land holding and it's relation to adaptive potential

Land holdings	Human capacity index	Financial capacity index	Natural capacity index	Physical capacity index	Social capacity index	Cumulative capacity index
Small	1.42	1.00	2.00	2.31	2.70	1.88
Medium	1.73	2.00	2.33	2.46	2.69	2.25
Large	2.15	2.19	2.46	2.58	2.23	2.32
Total	1.77	1.74	2.27	2.45	2.54	2.15

Source: Sen et al. (2011)

this could be ascribed to higher financial capacity index and natural capital index. Khanjar village has a healthy landholding to family ratio; hence it has scored more points and ultimately exceeded in the ranking scale (Table 7).

Table 8 shows that villagers with low land holdings are weak in terms of financial and natural capital compared to large land holders. Comparing SCI with land holdings, it can be said that small land owners tend to have more social capital as a compensatory mechanism to counter low financial and natural capital. Alternatively it can be stated that with increasing financial capital there is a decreasing trend in SCI, which can be related to changing economic pattern (cash crops and high returns) in the valley.

Social capital and collective action can be used as an indicator to assess the adaptive capacity, and when faced with considerable environmental and economic risks, the ability of these societies to mitigate these risks relies heavily on intersocietal networks and social capital (Adger 2003).

In case of the Miyar valley, the villages which did not have any local institution (*Yuva Mandal* and *Mahila Mandal*) had less social capital than the other villages which have the institutions in place. Since during crisis situations, these very institutions play a crucial role (like providing intercommunity loans and food/fodder etc.) and create a bond of trust, cohesiveness, and network which motivates community to work collectively to any issue and problem among the community. And as already discussed previously, the key to adaptability against environmental variability or any other resource scarcity is the community's collective actions, trust, and social bonding. The more the social capital, the greater will be the chance of successful adaptation by the community to the changes.

Conclusion

The communities in Miyar valley have long been fighting with the harsh environments of the mountain region for survival, not only they have succeeded in it but ongoing economic trade, education, institutional mechanisms, and overall village development despite various limiting factors (such as lacking infrastructure, short cropping season) represents communities' superior resilience, adaptive capacity, and high level of social capital. The community has developed various village level adaptations strategies and institutions to manage and sustainably make use of natural resource and avoid resource scarcity in future. These adaptations strategies and institutions provide a buffer zone for the community to adapt against any change (environmental, social, or economic, etc.) up to some degree.

From the study it can be concluded that local institutions, governance, social capital, and collective actions are directly related to development, resilience, and increased adaptive capacity of the society and of the whole region. But with the predicted future, environmental changes coupled with changing economic and infrastructure scenario will defiantly alter and transform the current functioning of local institutions and governance.

It can be assumed that with increased uncertainty, climate risk and resource scarcity communities will have no other option but to adapt to the situation and work collectively to sustainably consume scarce and declining natural resources. This may lead to increased social interaction, bonding, and trust which will be a crucial factor for the community to adapt to environmental changes.

Acknowledgement The author would like to gratefully acknowledge the contribution of Prof. Milap Chand Sharma and Prof. Sucharita Sen for providing valuable inputs and guidance throughout the project work. The author would also like to thank Mr. Sunil Kraleti for his support in field survey and documentation exercise. Lastly, the author would like to thank the locals of Miyar valley for their helpful participation in this project and warm hospitality.

Abstract

The focus of this paper is on a small water harvesting system that collects excess water runoff during the rainy season, and stores it for agricultural purposes during dry periods. Technical and institutional options and case studies are presented as strategic information for climate change adaptation in drought-prone rainfed areas. The paper provides a technical as well as an institutional analysis of small water harvesting system as strategic adaptation measure for climate change in drought-prone community watersheds. Through modeling studies of weather and runoff, information on the annual water yield for small water harvesting projects was estimated. To assess socioeconomic impact, ten (10) water harvesting systems were surveyed in drought-prone communities. Harvestable water from a small catchment was determined including the amount of soil erosion under various farm management practice and rainfall patterns. Case studies of ten (10) small water harvesting systems show positive results of socioeconomic impacts. Water harvesting for agricultural purposes in this era of climate change is a crucial adaptive strategy to ensure food security and alleviate poverty in the rural areas. Climate change has the most immediate impacts to be felt by rainfed agriculture.

Keywords

Climate change • Small farm reservoir • Rainfed agriculture • Upland areas

Introduction

In the upland agricultural areas, rainfall variability is a key constraint to agricultural production and economic growth in many developing countries. This is likely to be exacerbated in many places as rainfall variability is amplified as a result of climate change. Changes in rainfall will also increase variability in groundwater recharge and river flow, thus affecting all water sources. Thus, water harvesting, in its various technological forms, provides a mechanism for dealing with variability which, if planned and managed correctly, increases water security, agricultural productivity, and adaptive capacity to climate change. As such, water storage can make an important contribution to safeguarding livelihoods and reducing rural poverty.

For many millions of smallholder farmers, reliable access to water defines the difference between drought and water sufficiency. The classic response is to store water behind dams or in tanks or ponds when it is abundant and where it can be conserved in times of crisis. Water harvesting for agricultural purposes in this era of climate change is a crucial adaptive strategy to ensure food security and alleviate poverty in the rural areas.

The upland areas of many developing countries are where the vast open public areas lie, where many landless and poor peasants rush in and strive to make a living from already degraded resource. Generally, people living in these areas live below subsistence level and are locked in the vicious cycle of poverty and environmental degradation.

In the Philippines, emerging issues on climate change and dryland agriculture has been at the center of discussions and interests among top policy makers as manifested by the recently concluded conference on National Dryland Conference and the eventual creation of the Philippine Dryland Institute (PhilDri) (Dar and Obien 2007). One important research and development component of PhilDri is the institutionalization of community watershed development efforts through the introduction and optimum utilization of water harvesting technologies (Dar 2010).

General Classifications of Different Water Harvesting/Storage Options

1. Natural wetlands. Lakes, swamps, and other wetland types have provided water for agriculture for millennia both directly as sources of surface water and shallow groundwater and indirectly through soil moisture. Consequently, wetlands span the surface/subsurface interface and provide water in many different ways. As a result of their important role in the provision of water, wetlands are increasingly perceived as "natural infrastructure" (Emerton and Bos 2004).
2. Soil moisture. Globally, the total volumes of water stored within the soil are huge, but at any given locality, they are relatively small and quickly depleted through evapotranspiration. Because of this, in recent decades, there has been increased interest in various in situ rainwater management techniques that enhance infiltration and water retention in the soil profile. Widely referred to as soil and water conservation (SWC) measures, examples vary from place to place, but the most promising include deep tillage, reduced tillage, zero tillage, and various types of planting basin. The effectiveness of different measures depends a lot on soil characteristics and, particularly, on water holding capacity (Gregory et al. 2000).
3. Groundwater. Water stored beneath the surface of the earth in aquifers. A major advantage of groundwater is that there is little or no evaporation, and total volumes are often much greater than annual recharge. The amount of water that can be abstracted from a well in an aquifer is a function of the characteristics (particularly the permeability) of the rock. Some aquifers will yield only a few liters per day, while others can yield as much as several million liters. Methods for increasing groundwater recharge include pumping surface water directly into an aquifer and/or enhancing infiltration by spreading water in infiltration basins.
4. Ponds and tanks. Ponds and tanks are cisterns or cavities (covered or uncovered, lined or unlined) built by individuals or communities to store water. They are often linked with rainwater harvesting and store relatively small (but often vitally important) volumes of water. Ponds and tanks fill either by surface runoff or through groundwater and differ from reservoirs by the absence of a dam. A common limitation is that they are usually shallow, with a relatively large surface area, so that often a significant proportion of the water is "lost" through evaporation.

5. Reservoirs. Water is impounded behind small and large dams constructed across streams and rivers. Small dams (often built simply by mounding earth) store relatively small amounts of water (a few 100 to a few 1,000 m^3) and often empty every year. Many small dams do not have outlets, and water is simply removed by livestock drinking and pumping and as consequence of spilling and evaporation. They tend to be shallow with relatively large surface areas so that, in common with many ponds/tanks, a significant proportion (sometimes more than 90 %) of the water may be lost through evaporation. Large dams (often rock-filled or concrete) store millions, sometimes billions, of cubic meters of water. The water may be used for multiple purposes. Sometimes they are also used for flood control. Because they tend to be deeper with a relatively smaller surface area, in comparison to small reservoirs, they often have a higher yield relative to the inflow. Furthermore, some large reservoirs provide storage that is greater than the mean annual runoff and thus provide multiyear carryover of water.

General Advantages and Benefits of Water Harvesting Systems

The Food and Agriculture Organization of the United Nations has identified better management of soil moisture and investment in small water storage as promising interventions for poverty alleviation (FAO 2008). Under the right circumstances, small-scale water storage interventions can contribute to both food security and increased economic prosperity at a local level. For example, field studies in various semiarid environments have shown that crop yields can be stabilized and increased when seeds are sown not in furrows but in small planting basins which harvest water in situ (Twomlow and Hove 2006; Fatondji et al. 2007). Small tanks, ponds, and reservoirs can also make important contributions to livelihoods and peoples' well-being with significant potential in both Africa and Asia (Vohland and Barry 2009; Wisser et al. 2010). However, each storage type needs to be considered carefully within the context of its geographic, cultural, and political location. With the exception of large dams, past agricultural water storage development has mostly occurred in an ad hoc fashion, largely through private, community, and local initiatives, with minimal planning. In some cases (e.g., where reservoirs have silted, wells are dry and ponds have aggravated negative health impacts), it is likely that it is the lack of planning that has resulted in less than optimal investments.

Reported failures were attributed to a range of factors, including poor site selection, design and technical problems (e.g., failure of lining materials leading to seepage), and lack of commitment by communities for maintenance (Balderama 1998). In many places, there is a dearth of information on existing storage, the benefits that they provide, and their costs, including the impacts of scaling up. This is despite it being a recognized fact that though they may increase the reliability of water supplies at the local level, the cumulative effect of large numbers of small reservoirs can be to reduce river flows, with potentially serious implications for downstream reservoirs (Meigh 1995; Liebe et al. 2009).

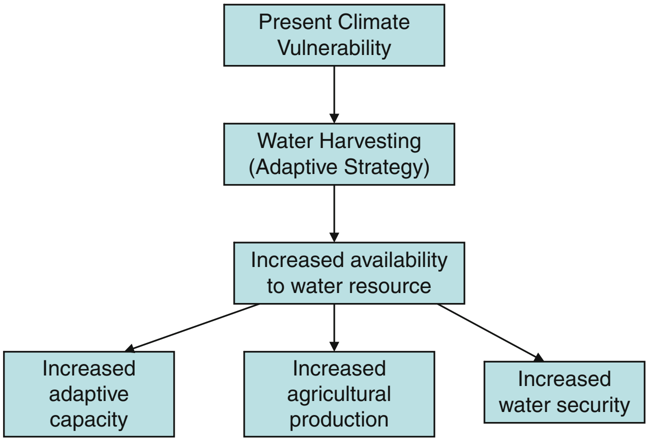

Fig. 1 Water harvesting as an adaptation strategy to reduce climate vulnerability

Even where data are available, they are often dispersed and difficult to access. Furthermore, basic scientific knowledge required for planning is also often inadequate.

Contribution to Climate Change Adaptation

As the challenges posed by global warming are increasingly understood, it is widely accepted that water is the principal medium through which the societal stresses of climate change will be manifested. Although the exact impacts remain uncertain, in many places, even where total rainfall increases, climate change will most likely increase rainfall variability. Without doubt, those who will be most adversely affected are the poor, who already struggle to cope with existing variability. They will find it increasingly difficult to protect their families, livelihoods, and food supply from the negative impacts of seasonal rainfall and droughts and floods, all of which will be exacerbated by climate change. Water storage (in all its forms) has a key role to play for both sustainable development and adaptation to climate change. By providing a buffer, water storage reduces risk and offsets some of the potential negative impacts of climate change, thereby reducing the vulnerability of people. Water storage can enhance both water security and agricultural productivity (Fig. 1).

Philippines' Program for Water Harvesting in Agriculture

General definition of water harvesting is the collection of runoff water for its productive use (Balderama 1998). Runoff can be harvested from roofs and ground surfaces as well as from intermittent or ephemeral water courses. Storage may include soil storage, groundwater storage, or surface ponding.

Water harvesting would be beneficial in the following cases:

- To supplement existing and limited irrigation water sources
- To counteract the low reliability and high variability of rainfall for rainfed agriculture
- To meet the increasing demand on agricultural food products and the increased pressure on existing cultivated land and water resources
- To increase the production and productivity of existing rainfed agriculture
- To make more efficient use of available unused agricultural resources, soil, and water

In the Philippines, the Bureau of Soils and Water Management of the Department of Agriculture serves as the governments' lead agency in the development and implementation of water harvesting and small-scale irrigation program aimed at increasing agricultural productivity in the upland and rainfed areas (Bureau of Soils and Water Management 2003). At present, there are two (2) water harvesting technologies being introduced to communities, farmer's groups, and local government units for adoption and commercialization:

Small Water Impounding Project (SWIP)

A SWIP is an earth dam structure built across a narrow depression or valley to harvest and store rainfall and run off for multiple uses (Fig. 2). Its structural height is not more than 30 m and a volume storage not exceeding 50 million cubic meters. The average service area of SWIP is about 60 ha (25–150 ha). Investment cost ranges from P1,500 USD to P4,000 USD per hectare of service area. At present,

Fig. 2 Reservoir area of small water impounding project

there are now 350 units of SWIP in the country with a service area of 21,000 ha and 16,000 farmer beneficiaries. Important functions of the project are:

- For supplemental irrigation
- Provide water for livestock
- Inland fish production
- For domestic purposes
- As a recreational facility

Irrigation System Operation of the Project

Management of the system rests on the Irrigators' Association (IA) right after project construction. The government irrigation agency, however, continues to provide guidance and technical and institutional assistance at various degrees, depending on the extent of assistance requested by the beneficiaries within the bounds of their memorandum of agreement. An engineer, an agricultural extension worker, and other specialists are tasked to strengthen the IA's periodic visits to the system to provide this assistance. Officials of the association, the President, the Vice President, the Treasurer, the Secretary, etc., are involved in order in the system management to attain the desired success. The duties and responsibilities as well as penalties/sanctions for certain infractions that pertain to system operation, drainage, and other aspects are generally spilled out in the bylaws of the association.

Basic Water Management/Distribution Plan

The basic water management plan is provided by the planned system cropping calendars, and the date of start of the cropping calendar dictates the start of water delivery/distribution. If simultaneous land soaking throughout the whole system is planned, simultaneous irrigation covering the whole system will be employed. The activity starts at the downstream sectors and moves to the upstream sectors to assure the water is not monopolized by farmers in the upstream areas.

Principles in Basic Water Distribution Planning (Cruz 2002)

(a) The basic water distribution plan is dictated by the planned system cropping calendar. The start of water deliver/distribution corresponds to the start of farming activities as articulated in the planned cropping calendar. The stages of farming activities and types of crops dictate the amounts of water to be delivered.
(b) For rice crops, high irrigation requirement is needed during land soaking. Because of this big demand, some planned cropping calendars provide for sequential start of this activity within a sector. In such a case, water delivery would, correspondingly, be planned to jibe with the planned sequence.
(c) Diversified crops require less amount of water compared to rice. The scheme usually applied is intermittent irrigation. For diversified crops planted in the uplands, e.g., beans, sweet peas, and crucifers (broccoli, cauliflower, etc.), where the plants' water requirement is low, sprinkler type of irrigation is normally adopted.

(d) During the wet season, water supply is usually abundant. It would be convenient therefore to adopt simultaneous distribution of water, system-wide.
(e) During the dry season, it oftentimes becomes necessary to plan for rotational method of water allocation.
(f) It may become necessary to shift from one method of water allocation to another. The decision to shift must be based upon an objective, established, and verifiable such as presence of farmer complaints. The complaints are to be monitored by the President preferably with the sector leader/s. Some questions will have to be answered:
    (i) How many farmers are complaining?
    (ii) Are all the complaints unbiased and verified?
    (iii) Who verified the complaints?

    If these questions have been satisfactorily answered, the President will declare the change in the method of water allocation.

    When there is low level of water supply in the reservoir before water distribution has started, common agreement are established by the Irrigator's Association as to what method of water distribution is to be adopted. A method of informing the farmers about the shift in method of allocation is developed. These procedures approved by the IA aimed at minimizing if not entirely eliminating any suspicions that the President is exercising his or her discretion in favor of any farmer, sector, or group of farmers.
(g) Adopted method of water distribution are properly disseminated. There are meeting of minds among farmers on a fixed signal that a certain scheme of water distribution is to be enforced. For small systems, it would be convenient to just pass on the information to each sector leaders who would assume the responsibility of informing the farmers within the area. There is also meeting of minds to a certain method of distribution. A flag will be raised at designated and conspicuous place, say, the IA's meeting hut area or the canal's turnout. These signals or information dissemination would invalidate any farmer's claim that he or she was not aware that such a scheme is being enforced.
(h) The water distribution scheme are evolved, tried, modified, and improved by the farmers themselves, if necessary, through several trials until an acceptable one is developed adaptable to the system.
(i) Sanction against erring members must be strictly enforced. Strict adherence to the rules and regulations promulgated for the implementation of the plan must be enforced, and any violations thereof must be dealt with accordingly. Sanction can be of different ways and of varying degrees of severity as in the following:
    (i) During imposition of sequential start for land soaking, the farmer who cannot follow the schedule will not be given irrigation water.
    (ii) During simultaneous irrigation for all sectors, sector taking in water more than what is prescribe will be deprived of irrigation water for (1) day.
    (iii) During rotational irrigation, farmers stealing water will not be given water for one rotation.

(iv) During rotation, farmers taking in water out of turn will deprive of water for one rotation or a cash fine. Violation for three times within the season will deprive the farmer of water for whole season.

Methods of Water Distribution

(a) Simultaneous irrigation – for rice cultivation, during the wet season cropping, reservoir is expected to be always at full capacity. The usual plan of distribution is simultaneous delivery to the canals and to all sectors and individual farms. This method of water delivery had the widest acceptance among the farmers, and there is less labor input in the control of gates and in apportioning water at the turnouts. Even during the dry season cropping, if the cropping calendar had made an early start, with a minimum of turnaround time, in most localities the reservoir would still be at peak storage when planting activities start and land soaking may be done simultaneously system-wide requiring simultaneous water delivery. However, it may be prudent to conserve water and employ other schemes when simultaneous delivery may be done only to some extent.

(b) Rotational irrigation – generally, rotational irrigation method of water distribution is employed when there is some shortage in irrigation supply. However, even during the dry season, where there is ample supply at the start of farming activities to satisfy the water demand for the programmed area, it might be advantageous to practice water rotation. Rotating the delivery is a judicious scheme to ensure equitable distribution of the available irrigation water. It will correct the usual pernicious practice of the upstream farmers drawing more than their needs as the water passes throughout their fields.

Small Farm Reservoir (SFR)

A small farm reservoir is a water impounding structure with a maximum height of embankment of 4 m and average pond area of 1,500 m^2. It serves limited areas no more than 2 ha and is designed to become an integral part of individual rainfed farms with catchment area not exceeding 10 ha. Its advantages are as follows: (1) less capital intensive, (2) easy to construct and maintain, and (3) empower farmer cooperation and production capability (Fig. 3).

In 1989, the Philippine Government embarked on a national program called the Small Farm Reservoir (SFR) project. This program aimed to accelerate rural development through the adoption of on-farm reservoir technology and to boost farm income by intensifying land use in rainfed areas (Maglinao 1994).

Design of Small Farm Reservoir

The reservoir is owned and managed by individual farmers and is typically built using a bulldozer. It consists of an earthen dam that traps harvests and stores rainfall and runoff. The embankment is not more than 4 m high, the surface area averages about 1,000 m^2, the depth is 2–3 m, and the storage capacity is some 2,000 m^3.

Fig. 3 Picture of a small farm reservoir

Design Conditions

Prior to design, an intensive physical assessment of the proposed area is completed. The following design conditions are considered most important for successful reservoir use:

(a) Topography – the most suitable topography is undulating with a slope of 2–15 %.
(b) Soil texture – embankments are normally constructed from soil at the reservoir site as transporting embankment materials are expensive. Ideal soil types for an SFR embankment are loam, sandy loam, clay loam, and sandy clay loam. These types of soil should be present at the site within a depth of 1.5 m. Peat soils, heavy clays, and saline, alkaline, or sodic soils should be avoided.
(c) Rainfall pattern – while the SFR system is suitable for all climate types, greater benefits are derived if the rainfall is unimodal with 5 wet months (>200 mm/month) and a total annual rainfall of 1,500 mm or more.
(d) Watershed and service areas – SFRs are best suited for areas with undulating topography where the shortest embankment spans across the valley. The size of the watershed must be adequate and compatible with the proposed reservoir size, and a service area should be included to ensure full use of the SFR. For sites with ample rainfall, a minimum catchment area of 0.2–0.5 ha of terraced rice land is adequate to store a water volume of 1,000 m^3. Using sound water management practices in conjunction with this volume of water stored in the reservoir at the beginning of dry season, 0.33 ha of rice land can be supported (Guerra et al. 1990). It is assumed that planting is performed early in the season and that rainfall occurs during the growing season.

Embankment Design

An SFR should ideally have a storage capacity that is adequate to supply water to the intended service area. Moreover, in terms of cost, there must be a sufficiently high storage ratio, i.e., the ratio of maximum volume of water stored in the reservoir to the volume of earth moved to construct it. The average storage ratio for completed SFRs ranges from 2.6 to 3.5.

Being designed to hold water and resist pressure, the reservoir embankment must be stable and easy to maintain. A maximum top width of 2 m is recommended for a dam height of less than 4 m. The recommended side slopes fro clayey soils are 2.5–3 horizontal to 1 vertical at the pond side and 2 horizontal to vertical 1 at the downstream side, while for silty or sandy soils, it is recommended that both slopes be 3–4 horizontal to 1 vertical.

Hydrological Characteristics

For the sound operation and management of SFRs, it is essential to gain a quantitative understanding of the following hydrological characteristics:

(a) Water collection: SFR field studies indicate that direct interception of rainfall accounts for about 36 % of SFR inflow, with the remaining 64 % coming from runoff collection. Moreover, due to the dynamic nature of inflow and water used for irrigation, the total annual water flow into an SFR is two to three times higher than the storage capacity.
(b) Water loss: seepage and percolation (S&P) account for about 45 % of the total volume of water outflow from the SFRs. Minimum and maximum S&P losses are typically 4 and 5 mm/day, respectively, with average evaporation loss accounting for 25 % of total outflow volume. The relationship between S&P loss and SFR water depth varies with the square of water depth.
(c) Water use: water use for land preparation and irrigation accounts for 30 % of total outflow volume, while the volume of water available for irrigation during the dry season crop is approximately equal to 65 % of reservoir capacity.

Utilization of Reservoir Water

The rain and surface runoff from three heavy rainfalls occurring in June, July, and August are normally sufficient to fill an SFR. Important factors regarding water utilization are:

(a) Irrigation practice: SFRs provide supplemental irrigation during the wet season, with the accumulated water enabling farmers to prepare the nurseries and land earlier than would be possible without reservoirs. During short periods with limited or no rainfall, SFR water can also be released by furrow or hand watering.
(b) Freshwater fish culture: for SFRs designed for dual use as both an irrigation and a fish culture resource, either organic or inorganic fertilizer can be added to enhance growth of plankton at the reservoir filling stage. Once the water turns bluish green, fingerlings can then be seeded in the pond at the recommended rate.

(c) Rice-based cropping systems: for SFRs used in rice-based cropping systems. Farmers must plant early in the main season in order to allow for an early start of the next drops in the dry season. The common cropping patterns adopted are rice + fish, rice (+fish) – rice, rice (+fish) – watermelon, rice (+fish) – vegetable, and rice (+fish) – rice – watermelon.

Water Management Practices

Water from the reservoir is released through flexible siphon hoses. This simple method has distinct merits as the education system in many rural areas is insufficient to effectively implement more technical methods without major help from government. Vegetable and fruit trees can even be irrigated using a bucket or watering container. Such crops are important as they supply a ready source of cash and food on a daily basis. Depending on the market demand and availability of capital and labor, this method could control the periods when a portion of the service area is planted with vegetable, watermelon, and/or other cash crops.

Financial Viability of SFRs

The adoption of SFRs at an annual interest rate of 18 % and 15-year life span with a periodic 3-year maintenance cycle provides a high value benefit-cost ratio of 5.1 and an internal rate of return of 177 %. Indeed, this is why such an overwhelming majority of SFRs are a lucrative capital investment.

Even with a life span of only 5 years, an SFR investment pays for itself in 3 years with rice and fish alone, whereas with rice + fish + rice combination in which 2 and 0.5 ha of rice are irrigated during the wet and dry seasons, respectively, with tilapia being grown at the same time, the payback period is reduced to 2 years. Such a return is considerable in that properly maintained SFRs would naturally provide irrigation service for much longer than 5 years. A summary of the features and technical specification of an SFR is presented in Table 1.

Government Support and Program Impact

Even for highly suitable areas, the initial cost of an SFR is too high for an average farmer to afford. Accordingly, the Philippine Government has implemented a financing scheme in which farmers use a government loan to construct their own SFR. While the repayment period is 5 years, a hardworking farmer can repay the loan in less than 2 years. To ensure technical assistance is provided in every aspect of the technology transfer, government technicians are regularly dispatched for this purpose.

Socioeconomic Impacts of Water Harvesting Systems for Agriculture: Case Studies of 10 Water Harvesting Projects

This section presents results of case studies on the socioeconomic impact of ten (10) small reservoir irrigation projects located in the northern region of the Philippines. The irrigation systems studied were small, low cost, communally

Table 1 SFR features and technical specification

Typical features and technical specification of SFR	
1. Watershed	
Area (ha)	3 ha
Proposed land use	Vegetable and trees
Soil type	Clayey loam
2. Reservoir area (m^2)	1,000
3. Project facilities	
(a) Dam	
Type	Straight embankment
Height, m	3 m
Crest width	2 m
Upstream slope	1:3
Downstream slope	1:2
(b) Spillway	
Width, m	1.5
Depth, m	1.0
4. Design service area	1 ha
Components	Fish + vegetables + animal + mushroom + grasses
5. Water use	Irrigation, livestock watering, fish culture
6. Conservation showcases	Water harvesting, contour farming
	Crop-animal-fish integration
	Micro-irrigation
7. Project cost construction	P900 USD

owned and managed, and located in vulnerable areas with slope greater than 20 % (Balderama et al. 2006). Operated by an Irrigator' Association, the purpose of the irrigation project is to increase production through increasing water supply and protect the environment that supports the project with the community as the main actors in the development process. The study area covers a total of 267 ha planted into rice, a combination of rice and vegetables and vegetables only.

System Performance

As a whole, the systems had an increased cropping intensity of 21 %, a distribution efficiency of 40 %, and a fair satisfaction rating given by the members interviewed. One notable problem is a poor collection of Irrigation Service Fee (ISF) in 70 % of the project area. However, all the projects are believed to be functioning efficiently with minimal conveyance losses because of the use of pipes and canal lining.

Overall Benefits Derived from the Project

(a) Economic impact – results show that most of the impact was due to increases in productivity and increases in cropping intensity. Across all crops, average productivity per hectare was highest in vegetable-producing areas. The average aggregate annual benefit per project was P5,150.00 USD. Considering the total construction cost as the initial investment of the various projects and the increases in the value of benefits due to increases in productivity, cropping intensity, and area as the project benefits, the average payback period is 1.95 years. This payback period for investment projects is quite fast. This result implies that the investment cost in these projects can be recouped very quickly. Also, this implies that the direct benefits from the projects are high.

(b) Social impact – the project created positive impact at three levels: community, organization (IA), and households. The positive impact at the community level included increased access to resources like the construction of water bridges out of collected service fees and external sources for microfinancing. At the organization level, the IAs generally learned to cope up with maintenance problems especially when their livelihood security was threatened with inadequate irrigation water. These enhanced the cooperation among farmers and ness in others, leadership development, market integration among vegetable growers, and more cohesive relationship of the IAs and the local government units.

Impact of Participatory Approach in Project Development

Participatory development in the communities was legally established through Republic Act 7160 signed in 1992. The law provides decentralized decision-making at the lowest local government unit – the barangay or village level. Projects were established based on needs of the community. Through the representation of their officials, the community decides on what type of projects will be established. Each barangay is granted Internal Revenue Allocation (IRA) from the national government based on their population, land area, and revenue collections for development projects. In the implementation of the communal irrigation projects, the participatory development strategies employed are as follows (ERP-CASCADE 1998; CASCADE 1998, 2000):

(a) Involvement of the local government officials from the provincial to the community in the planning and operation of the projects. This strategy gave the local government a firsthand look on the economic and environmental conditions in the project sites.

(b) Facilitating the integration of various government services and programs into the community.

(c) Formulation of “Rules-in-Use” by the members of the IAs.

(d) “Counterparting Scheme” for various stakeholders (i.e., IAs contributing labor in the construction and operation and maintenance of the irrigation projects).

(e) Trainings on capability building not only on maintenance and operation of the projects but also on negotiations, decision-making, resource generation, and communications strategies.

Evidences of Participation

(a) Contribution to the construction of the project – participation is in itself shown primarily in the construction of the facilities. On the average, the beneficiaries contributed more than 22 % of the total project cost in the form of labor and food.
(b) Indicative increase in organizational control – the level of organizational control increased in most of the projects. Maintenance and operation have become easier to implement in IAs with high to medium level of organizational control.
(c) Development of new leaders – in some IAs, new sets of leaders were regularly elected to manage the projects. This is one of the offshoots of participatory approach.

Characteristics of Sustainable and Stable Irrigators Associations

From the case studies conducted, several characteristics of the Irrigators Association found to be good measure for their long-term sustainability are as follows:

(a) The members are involved in the planning, operation, and maintenance of the irrigation systems.
(b) Support services were broadened and integrated into the project operations.
(c) Rules formulated were tied up with water distribution criteria.
(d) The members and young leaders are mentored on how to make rational decisions

Water Harvesting as Adaptive Strategy for Climate Change

Evaluation of seasonal climate impacts on crop production as well as on crop growth and development will enable agricultural managers and researchers to formulate strategies and mitigation techniques to counter such impacts. Figure 4 shows the result of data analysis at Echague climate station at different levels of rain probability using dependable rainfall approach. Eighty percent probability represents a dry year that approximates the 2009 actual record which was an El Nino year. As presented, the figure conforms to climate agency's estimate that the El Nino phenomenon causes rainfall to be 60 % lower than the historical average.

A simulation study was conducted to establish a relationship between reservoir volume and rain probabilities and their effect on income. Important result of the simulation for selected crop combination planted after rice is presented in Table 2.

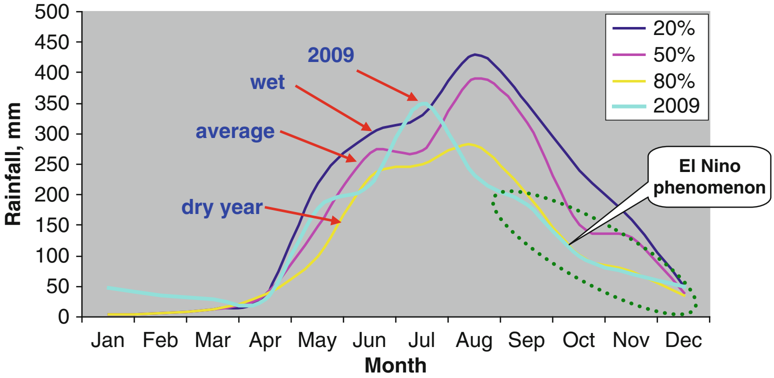

Fig. 4 Rainfall at different probabilities compared to 2009 data

Table 2 Effect of varying volume of reservoir and rainfall probability to gross income

Selected cropping pattern	Income (US dollars)			
		Rainfall probability (%)		
	Volume of reservoir (cubic meters)	*20*	*50*	*80*
Garlic-mungo	1,000	1,714	1,657	1,429
	1,500	1,857	1,829	1,800
	2,000	1,971	1,943	1,914
Garlic-soybean	1,000	1,714	1,657	1,429
	1,500	1,829	1,800	1,771
	2,000	1,914	1,886	1,857
Garlic-peanut	1,000	1,717	1,657	1,143
	1,500	1,800	1,786	1,771
	2,000	1,857	1,829	1,800
Tomato-mungo	1,000	1,229	1,200	1,143
	1,500	1,371	1,314	1,286
	2,000	1,457	1,429	1,371
Tomato-soybean	1,000	1,200	1,171	1,143
	1,500	1,286	1,229	1,171
	2,000	1,371	1,343	1,286

From the sample result and analysis, important finding reveals that increasing reservoir volume will have significant effect on income of non-rice crops during normal (50 % probability) and dry (80 % probability) years. If a wet year (20 % probability) is expected, optimum yield and cropping intensity will be realized provided that a minimum of 2,000 cubic meters of reservoir water is available for supplemental irrigation.

Model Institutional Framework on Successful Implementation of Community Water Harvesting Irrigation System

From lessons learned in the past, Balderama et al. 2006 developed a framework on implementation of communal irrigation projects as a guide to planners and managers.

Process Framework on Planning and Implementation

The process framework on planning and implementation of a community reservoir irrigation project is described below. The principal actors in the planning stage are the community and municipal local government units. There are three important milestones to attain in this process: (1) formal request for funding by the proponent group, (2) decision to implement by all stakeholders, and (3) forging of construction agreements by concerned parties including a contractor, if there is any.

Formal Request

The first activity is the issuance of formal request by the village local government or farmer organization to the funding agency with accompanying proposal that contains basic data and information pertaining to engineering and agro-socioeconomic aspects of the proposed irrigation project.

The engineering data/informations are the following:

(a) Service area
(b) Soil suitability
(c) Water availability
(d) Existing farming systems

The agro-socioeconomic data/informations are the following:

(a) No. of households to be impacted
(b) Existing land tenure arrangement
(c) Projected benefits
(d) Market opportunities

The time frame is about 2 weeks for the engineering survey and up to 6 weeks for the agro-socioeconomic data gathering. At this stage, the role of the municipal local government is very crucial in the packaging and endorsement of the proposal considering that farmer groups usually lack skills on this kind of work.

Decision to Implement

The "decision to implement" would depend on the results of more detailed investigation by the agency-commissioned multidisciplinary team of evaluators.

Data/Information to be gathered and activities to be undertaken are as follows:

(a) Environmental impact assessment.
(b) Organization of water users group.
(c) Agreement on management scheme.
(d) Counterparts' agreements of the different stakeholder are finalized.

This process may take up to 4 months to complete.

Construction Agreement

The third phase, "construction agreement," should require the following documents:

(a) Detailed intake and canal design
(b) General layout design and view
(c) Mitigation works design
(d) Agreement of future maintenance and development cum water fee
(e) Agreement on sharing of works (i.e., agency provides engineers and materials, LGU with equipments, and members free labor)

Preparation of engineering designs shall be the responsibility of local government and project engineers in close consultation with the water users group. The final agreement may require 2–3 months.

Framework on Sustainable Management of Communal Irrigation Project

Figure 5 presents a framework on successful operation and management of a communal irrigation system. Main consideration is to address major factors causing inefficient operation and poor maintenance of an irrigation system such as the following:

1. Lack of systematic operation and maintenance procedure
2. Inadequate training of the O&M staff
3. Insufficient fund for O&M works
4. Lack of farmer participation
5. Lack of farmer education

Considering the abovementioned factors, it is evident that the success and sustainability of any communal project would largely depend on the strength of the association that runs and manages the system.

The framework shows the indicative output of a successful communal irrigation system and the input parameters that cause its successful performance. The improved management factors contributing to its performance are systematized O + M, adequate funding and training, regular dialog of stakeholders, and good water management philosophy. The social factor that is equally important is the participation

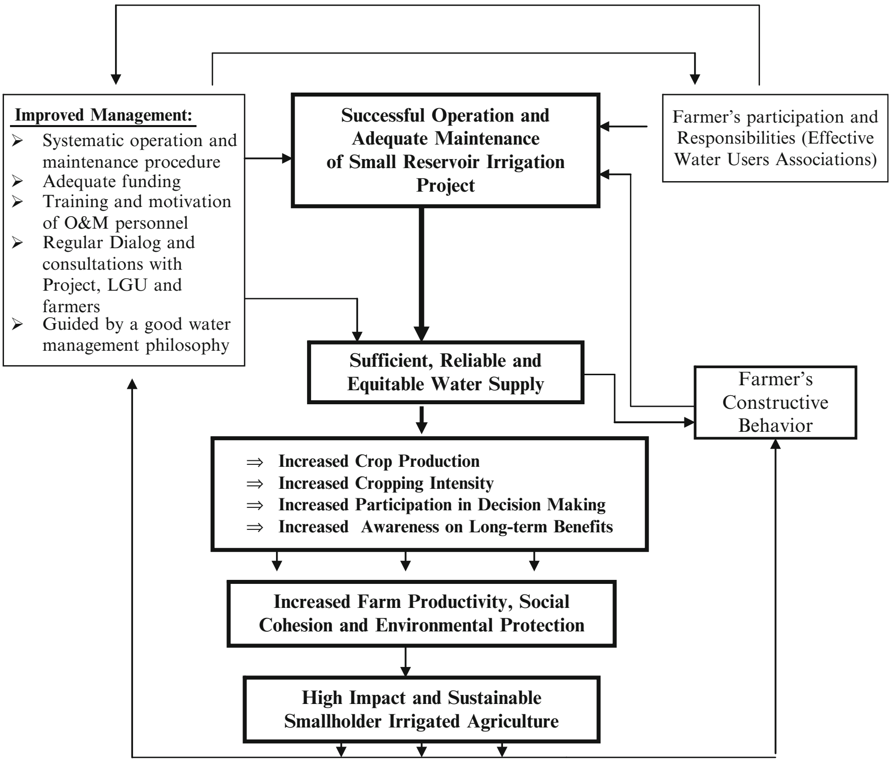

Fig. 5 Framework on the management of communal irrigation system

and responsibility of the water users. Strengthening the individual farmer's constructive behavior strengthens the farmers group.

The strengthening of the water users group will provide them enough skill to do the routine O + M in a systematic way, generate their own resources for O + M funds, and mobilize enough manpower at the right time for O + M. In addition, core values (i.e., responsibility, accountability, and resourcefulness) are instilled to every member through regular seminars and dialogs. The sufficiency, reliability, and equitability of water supply across the system should be a water management philosophy every single member should adhere to.

The dynamic interplay of improved management and good social behavior will result to efficient, reliable, and equitable delivery system of irrigation water to farmers. These result to positive impact due to increase in crop production with environmental protection, increase in cropping intensity using different crops, and increase in participation in any decision-making process and increase in awareness on long-term benefits.

The attainment of improved water management in a system will also have positive impact on the constructive behavior of members who will in turn become more responsible members and better assets of the group.

Perceived Constraints in Linking Water Harvesting Technologies to Agricultural Development and Suggested Research Topics

1. Dissemination of water harvesting techniques to other areas has never been explicitly a subject of research. The socioeconomic and environmental conditions should be the key criteria for selecting the most suitable techniques.
2. Lack of adequate hydrological, soil, and land use data which often results in applying design criteria for water harvesting structures which have been designed from questionable assumptions.
3. Soil erosion in the cultivated areas resulting from poor farming practices.
4. Lack of technical advice, training, and other services including incentives for farmers.
5. Lack of documentation and analysis of existing indigenous water harvesting system.
6. The lack of risk analysis studies of crop failure due to low reliability of rainfall.
7. Lack of large-scale demonstration projects.

To generate information to address the above constraints, research and development topics are suggested:

1. Detailed hydrometeorological analysis of rainfall data (daily and storm by storm) is needed, including probability and risk analysis of intra-storm drought periods, rainfall intensities, and duration of single rainfall events.
2. Analysis of the effect of different water harvesting and farming techniques on soil erosion and on soil and water conservation.
3. Establishment of rainfall and surface runoff measurement networks to obtain basic data for project planning and design. Community watersheds would provide realistic data on surface runoff from measured rainfall events and would thus facilitate the use and calibration of simulation models.
4. Use of geographic information system(GIS) and other IT-based tools for the identification of potential areas for water harvesting and planning for community watershed development.
5. More attention must be given to socioeconomic aspects in project planning, implementation, and maintenance such as viability of indigenous systems and local experience, people's priorities and participation, land tenure, subsidies and incentives, and the role of women.
6. Development of a package of appropriate and cost-effective technologies to optimize soil and water management and to intensify agricultural production.

Conclusion

In the rainfed and upland areas which are also considered as fragile ecosystems, rainfall variability is an important factor in development and translates directly into a need for water storage and harvesting system. In areas of developing and underdeveloped societies, existing variability and insufficient capacity to manage rainfall will exacerbate the already prevailing poverty and food insecurity. Thus, these places are predicted to experience the greatest negative impacts of climate change.

Successful undertakings show that by making water available at times when it would not be naturally available, water harvesting can significantly increase agricultural and economic productivity and enhance the well-being of the environment and the people.

Future population growth, in conjunction with climate change, will increase the importance of putting in place water harvesting technologies and systems especially in the rural communities. However, as water resources are increasingly utilized and climate variability increases, planning will become even more difficult. Without greater understanding of which types of storage are best utilized under specific agroecological and social conditions and in the absence of much more systematic planning, there is the risk that many water harvesting investments will fail to deliver the intended benefits.

Current research and development activities are aimed to better understand water resources and storage under different social and ecological conditions. This will provide insights into potential climate change impacts on water supply and demand, the social and environmental impacts of different storage options, the implications of scaling up small-scale interventions, and the reasons for success/failure of past storage schemes. Systematic methods for evaluating the suitability and effectiveness of different storage options are being developed to assist planning and facilitate comparison of storage options, individually and within systems.

Abstract

This chapter presents the contribution of "chakra," a traditional agroforestry system, to climate change adaptation and biodiversity conservation in Ecuador's Amazonian communities. IPCC's methodology was used for the estimation of carbon sequestration in soil, biomass, and cacao plantations. Carbon levels in multiple systems of land use were measured through temporary plots. Chakra is efficient to adapt to climate change due to higher levels of carbon sequestration and tree diversity in comparison to other forms of land use. Chakra allows for sustainable use of forests by combining cultivation of the Ecuadorian finest aromatic cacao, controlled timber extraction, production of staple food, and conservation of medicinal plants. Chakra enables Amazonian communities to contribute to both food security and well-being and conservation of the region's high biodiversity. The chapter informs policy makers and communities about the importance of strengthening traditional agroforestry to achieve environmental and social sustainability. The Amazon region is a vulnerable ecosystem, where adaptation to climate change depends on the extent to which the options for land use are compatible with the conservation of biodiversity and the provision of the ecosystem services that sustain local communities' livelihoods. The chapter provides solid evidence that this might be possible through traditional agroforestry.

Keywords

Ecuadorian Amazon • Climate change • Traditional agroforestry • Sustainability • Cacao

Introduction

Traditional systems of agricultural production, particularly agroforestry, have been recognized worldwide as an integrated approach to sustainable land use. More recently, agroforestry systems are believed to have a high potential to contribute to climate change mitigation through carbon sequestration. This has brought a renewed interest in research both on the biophysical conditions under which efficient carbon sequestration can happen and the factors that can enable positive gains for farmers. Yet, the evidence found in this recent literature is not conclusive and generalizations tend to become unrealistic, often because several interrelated and site-specific factors influence the rate and extent to which agroforestry can sequester carbon (Noponen et al. 2013; Oelbermann et al. 2004).

Agroforestry, generally referred as the practice of growing of trees and crops in interacting combinations, is based on the premise that complex land-use systems result in greater efficiency of resource (nutrients, light, and water) capture and utilization and greater structural diversity that enables tighter nutrient cycles, therefore, more system stability and resilience at site level and connectivity between forests and other landscape features at landscape and watershed levels (Nair et al. 2008). The advantage of agroforestry as a mechanism for climate change mitigation is that, compared with other terrestrial options, agroforestry has other environmental benefits such as restoring and maintaining above-ground and below-ground biodiversity, corridors between protected forests, and reduction of pressure on natural forests and maintaining watershed hydrology. These ecological foundations of agroforestry systems have been associated with a potential for the provision of ecosystem services worldwide and contribution to food security and poverty alleviation in developing countries (c.f. Lal 2001; Pandey 2002).

In large-scale studies of regions where data is available and reliable, the potential of agroforestry to increase carbon sequestration is promising. For example, in European agriculture it has been estimated to reach near 35 % of all CO_2-equivalent emissions in the EU in 2007, which at prices of 2012 would have a value of 282 euro/ha (Aertsens et al. 2013). Freibauer et al. (2004) analyzed the potential for carbon sequestration and economic viability of agricultural soils in Europe (EU-15) and concluded that efficient carbon sequestration in agricultural soils demands a permanent management change and implementation concepts adjusted to local soil, climate, and management features. In tropical agroforestry systems, Albrecht and Kandji (2003) estimated the carbon sequestration potential in a range of 1.1–2.2 pc carbon in the terrestrial ecosystems over the next 50 years. However, there are shortcomings of these estimates associated with the uncertainties related to future shifts in global climate, land use, and land cover and the poor performance of trees and crops on substandard soils and dry environments, pests, and diseases. Also, research in the Appalachian agriculture (López-Bellido et al. 2010) shows that current practices do not allow for contribution to C sequestration; hence, improved agricultural practices are needed in order to increase soil organic carbon sequestration.

In developing countries, where reliable environmental and economic data are less available c.f. (Claessens et al. 2012), there is increasing expectation about the economic impact of agricultural carbon sequestration. In the Andean region, the fragile nature of agroecosystems and limited capacity of resource-poor farmers to adopt the large-scale use of fertilizers and pesticides suggest the need for agroecological intensification to restore soil functioning and ensure long-term sustainability (Fonte et al. 2012). However, Antle et al. (2007) used a model to simulate the effects of adopting agroforestry practices in the Peruvian Andes and showed that the economic potential is relatively low at carbon prices below $50 per MgC. The price would need to rise significantly (100 %) to make the adoption of agroforestry in terraces attractive; if that happens, carbon sequestration could raise per capita incomes by up to 15 % and reduce poverty by 9 %. In Central America, Somarriba et al. (2013) suggest that, among the agroforestry crops that have the greater potential to mitigate climate change, the cacao tree is credited for stocking significant amounts of carbon.

Research on sub-Saharan Africa, where climate change is predicted to have considerable negative impacts, shows also that carbon sequestration in agricultural soil can make only modest contributions, in a range of 3–6 of fossil-fuel contributions, to mitigation of overall greenhouse gas emissions (Hutchinson et al. 2007). Palmer and Silber (2012) showed that, in order to make the potential of traditional land use effective for improving the farmers' income of Mozambique, systems that combine sequestration and cash crop production have higher net benefits, although they have less carbon-sequestration potential. In West African Sahel as in sub-Saharan Africa, carbon sequestration is a promising incentive for introducing agroforestry practices and contributing to sustainable land use (Takimoto et al. 2008; Thangata and Hildebrand 2012); therefore, countries that incentive this practice can benefit from REDD+ and other global environmental policies for climate change mitigation. Additionally, as it has been demonstrated in traditional societies like in many parts of rural China (Xu et al 2007), the economic impact of environmental policies that promote carbon sequestration through agroforestry can also have social implications in terms of participation, increased mobility, and less subsistence agriculture-based livelihoods.

This brief review suggests that research is not conclusive and more is needed, especially for the tropics, to more accurately capture the impact of region-specific interactions between climate, soil, and management of resources on carbon sequestration, which are lost in global-level assessments. In the recent global context of climate uncertainty, many productive ecosystems are endangered. Diversified farming systems are an example of complex systems which are able to adapt and resist the effects of climate change. These systems have a high structural complexity which enables them to act as a buffer against temperature fluctuations (Nicholls 2013) and, as Ríos et al. (2007) suggest, there is increasing interest in understanding how local population's traditional practices can generate a path for sustainable use of plant diversity and adaptation to climate change. The purpose of this chapter is to present the contribution of "chakra," a traditional agroforestry system developed in Ecuador's Amazonian communities, to climate change adaptation and biodiversity conservation. Given that the Amazon region is a vulnerable ecosystem, where adaptation to climate change depends on the extent to which the options for land use are compatible with the conservation of biodiversity and the provision of the ecosystem services that sustain local communities' livelihoods, we argue that the chakra system is efficient to adapt to climate change due to higher levels of carbon sequestration in comparison to other forms of land use. Chakra also allows for sustainable use of forests by combining cultivation of the Ecuadorian finest aromatic cacao, controlled timber extraction, production of staple food, and conservation of medicinal plants. The local governance system established around chakra enables Amazonian communities to improve their chances for food security, increasing income, and conservation of the region's high biodiversity. In the remaining sections, we develop this argument, preceded by a description of the methodology used in the study and a contextual description of the Ecuadorian Amazon.

Chakra in the Context of the Ecuadorian Amazon

Characteristics of the Ecuadorian Amazon

Ecuador represents only 0.2 % of the earth's surface; it is positioned in the 6th place among the most mega-diverse countries in the world (Mittermeier 1988), hosting around 10 % of the world's plant species (CAAM 1995). In this epicenter of biodiversity, the Andean-Amazonian space is considered as a "leading hotspot" (Myers et al. 2000) with a great potential to provide the ecosystem services needed to sustain local livelihoods and global goods such as carbon forest.

However, one of the major problems facing this area is deforestation mainly due to the increase of the agricultural frontier (Pichón 1997; Bilsborrow 2004; Pan and Carr 2010). The forest clearing started in the early 1960s, when the emergent oil industry induced the formation of human settlements in the rainforest, and continued at a rapid pace during the land reform, from 1964 to 1973, when a process of agricultural colonization (Murphy et al. 1997; Sierra 2000; Mena et al. 2006) changed significantly the pattern of land use from forests to agricultural crops and livestock grasslands (Carr and Bilsborrow 2001; Torres et al. 2005; Pan and Carr 2010). Farmers from coastal and highland areas of Ecuador settled in the Amazon and introduced practices of monoculture (Pichón 1997), unsuitable for the fragile Amazonian soils. The expansion of agriculture and the introduction of livestock induced significant levels of immigration and the construction of road infrastructure, which severely impacted the Amazon ecosystems and landscape (Pichón 1997; Wunder 2000; Pan et al. 2005).

The challenges of biodiversity conservation and recovery of cultural patrimony associated with traditional land use led to design a strategy based on spatial planning, supported by the UNESCO. As part of this strategy, the "Man and Biosphere" program delimitated an area located in northeastern Ecuador to be the Sumaco Biosphere Reserve (SBR), covering 931,930 ha, i.e., 8 % of the Ecuadorian Amazon (MAE 2002). The core of this strategy is the conservation of the Sumaco Napo-Galeras National Park in an area of 205751.11 ha (MAE 2013; see, Fig. 1).

The native Kichwa population inhabiting the Ecuadorian Amazon is concentrated in Napo province, representing 60 % of Napo's total population (Irvine 2000; INEC 2010). However, since the 1980s, Napo has become one of the main attractive centers for migration (Arévalo 2009), particularly to the SBR, for its potential for economic activity. The new human settlements have located in the SBR transition and buffer areas.

Traditional Agroforestry in the Ecuadorian Amazon: The Chakra System

Cultivation of small plots within the rainforest is a traditional practice that, over the centuries, the Kichwa population from the Ecuadorian Amazon has developed in order to sustain their livelihoods. Such a pattern of land use, locally known as "chakra,"

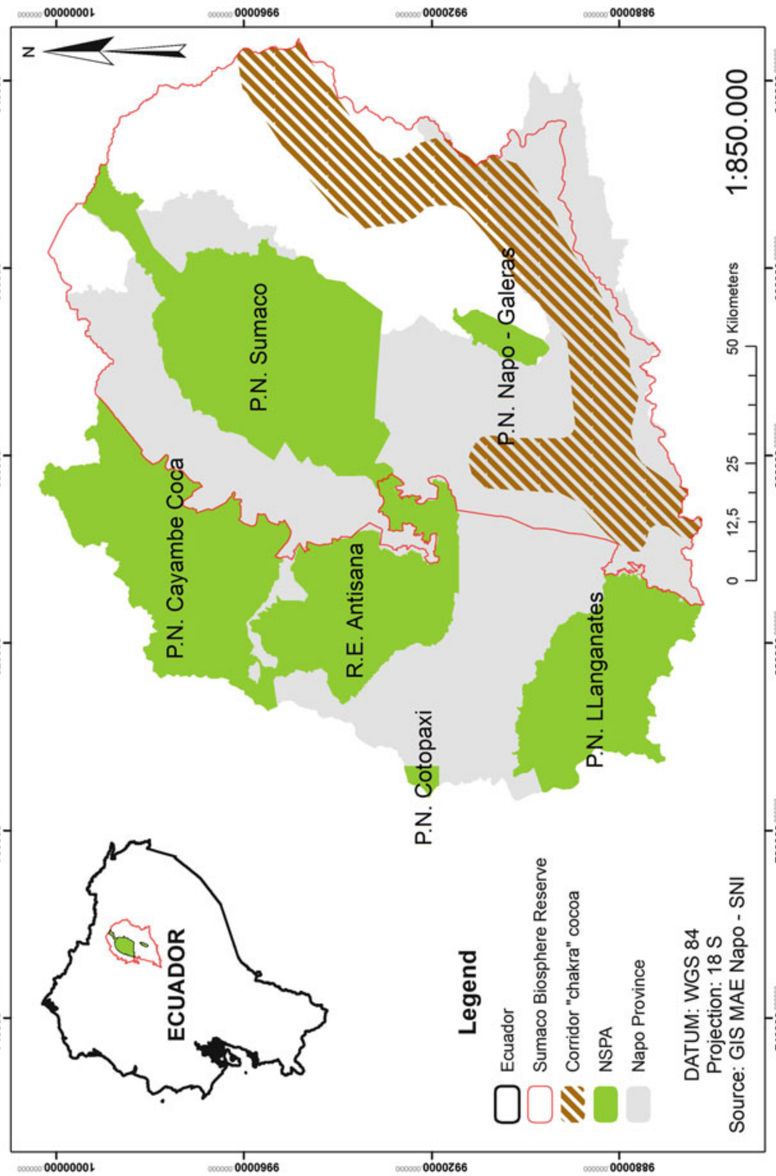

Fig. 1 Sumaco Biosphere Reserve and the chakra cacao corridor in Napo, Ecuador

integrates cultivation of staple food and medicinal plants, including manioc (*Manihot esculenta* Crantz), banana (*Musa paradisiaca* L.), peach palm (*Bactris gasipaes* Kunth), and other edible and medicinal plants that enable food and health security (Irvine 2000; Lu et al. 2004; Whitten and Whitten 2008). Over time, other agricultural species with commercial value have been integrated into this traditional agroforestry system, which is the case of the fine-flavored cacao (*Theobroma cacao* L.) and robusta coffee (*Coffea canephora* Pierre ex A. Froehner). The size of cultivation plots of cacao within an Amazonian chakra is in a range of 0.5–4 ha (Gizb 2011); these plots are generally located in remaining areas of primary and secondary forests and fallow land. This forms a landscape that resembles a mosaic economically productive and ecologically friendly to the biodiversity of the area.

The SBR contains near 12,500 ha of cacao cultivated in the chakra system, which are managed by 9,200 farmers, approximately (Gizb 2011). Most of it is located in buffer and transition areas of the SBR and Yasuní, within the so-called cacao corridor (see, Fig. 1), and belongs to indigenous Kichwa communities which, since the 1970s, had to adapt to the process of agricultural colonization and relocated their settlements in areas surrounding the Sumaco and Yasuni reserves. While the state has guaranteed the property rights of these communities through land titles and facilitated their access to agricultural credit (Irvine 1989, 2000; Perreault 2003), the intensive migration to the area observed in the last 40 years (Bilsborrow et al. 2004) has also implied diversification of local population and new forms of land use oriented not only to subsistence but also to the market. From an economic perspective, the integration of subsistence and commercial agriculture specialized in the market niche of fine cacao has implied the improvement of households' income. Ecologically, it has produced the effect of redrawing the northern Amazon landscape, pictured now as a multifunctional rainforest with productive plots of cacao or coffee, patches of primary and secondary forest, and stubble and non-used areas, all of which are needed for the soils' resilience in their multiple strata.

The cultural meaning of the chakra system for local population is directly related to the conservation of the Amazon landscape. Cultural practices among the SBR and Yasuní reserve include: selective classification of crops and identification of fertile or unfertile time periods based on the moon's phases, a particular local calendar, the fluorescence of some trees, the birds' incubation period or flight style, and/or some insects' behavior (Avilés and Sarmiento 1997). As suggested by Irvine (2000) and GIZ (2013), these practices have enabled indigenous local population to achieve a certain harmony between food security, income generation, and the preservation of traditional medicine and spiritual values.

Recently, new challenges that climate change presents to local population in the SBR have motivated research both on the capacity of the chakra system to facilitate the adaptation of local population and the rainforest ecosystems to climatic conditions and their capacity to contribute to climate change mitigation. While the former goes beyond the scope of this chapter, the latter is developed in detail in the following chapters.

Methodology

The research project "Diversification of land use and carbon assessment for biodiversity preservation," in its initial phase, studies changes in carbon storage, biodiversity preservation, and productivity in various land-use systems. The investigation was implemented in 2011 in the buffer and transition zone of the Sumaco Biosphere Reserve and aims at examining the potential for carbon storage by the chakra system, therefore assessing their potential for climate change mitigation. The project is located in the so-called cacao corridor in the province of Napo in the northeastern part of the Ecuadorian Amazon region. The research was performed as results of an international collaboration of universities including the Amazon State University (Universidad Estatal Amazónica) in Ecuador, the Tropical Agricultural Research and Higher Education Center (Centro Agronómico Tropical de Investigación y Enseñanza) in Costa Rica, and the Technical University of Munich in Germany.

The criteria used to select cultivation plots where traditional agroforestry practices are implemented (i.e., classification of plots under the chakra system) were percentage of shadow $\geq$10 %, net area of chakras $\geq$0.5 ha, and the farmers' willingness to support the system. Fifteen circular temporary plots of 1,600 m^2 under the chakra system were selected to measure the numbers and diversity of tree species and the amount of carbon captured in each plot and to assess the diversity of tree species and practices that produce food and medicinal plants. Similarly, 8 circular temporary plots under the monoculture system were also selected for the purpose of comparison. The cacao chakras included in the sample are, on average, 7 years old, have diversified shading systems in multiple strata and growth periods, and have the potential to store carbon efficiently each year. Table 1 summarizes the cultivation plots' characteristics.

In all temporary plots of 1,600 m^2, diameter at breast height (DBH) was measured (taken at 1.30 m) from all trees and palm with DBH $\geq$ 10 cm, and the total height was also measured. The floristic diversity of species was identified in situ, by using common and scientific names at the level of family, genus, and species. Species that were not recognized in situ were collected and identified in a national herbarium with the help of expert botanists.

Multiple systems of land use were selected in the lower area of the Sumaco Biosphere Reserve (Fig. 1), specifically in Tena and Archidona cantons within the Napo province. All sites are located below 700 m above sea level. The plots selected belong to farmers from the Kallari and Wiñak producer organizations, both members of the Cacao Dialog Table (MCFA in Spanish) in the SBR. Plots chosen for comparison in native forests were located in the Jatun Sacha Biological Station (EBJS).

Research on the contribution of the chakra system to climate change mitigation adopted the IPCC methodology for assessing the capacity of traditional agroforestry for carbon sequestration. This includes methods to estimate the amount of biomass and carbon in each one of the land-use systems.

According to the methodology used by Jadán et al. (2012), ground biomass was estimated using algometric equations formulated for primary rainforest species.

Table 1 Cultivation plots studied to assess the capacity of the chakra agroforestry system to conserve tree species diversity and carbon sequestration

Land-use system	Forest cover (%)	Years of agricultural use (average)	Sample (number of plots)	Surface (hectares)
Traditional agroforestry system (cacao chakra)	40.6	7	15	2.4
Cacao monoculture	4	5	8	1.3

Table 2 Algometric equations used to estimate the air biomass of trees in the shade areas of cacao plantations in the Sumaco Biosphere Reserve, Napo Province

Ecosystem or species	Equation	Range (dap, age)	R^2	Source
Tropical forests	$\text{Ln (Bt)} = -1.864 + 2.608 \times \text{Ln (dap)} + \text{Ln} (d)$	5–150	0.99	Chave et al. (2005)
Bactris gasipaes	$\text{Bt} = 0.74 \times \text{h}^2$		0.95	Szott et al. (1993)
Cacao	$\text{Bt} = 1.0408 \exp^{0.0736} \times {}^{(\text{d}_{30})}$		0.97	Ordóñez et al. (2011)
Low latizales (1–5 cm dap)	$\text{Bt} = 10^{(-1.27+2.2} \times {}^{\text{Log (dap))}}$	0.3–9.3	0.88	Andrade et al. (2008)
Musaceae	$\text{Bt} = (185.1209 + 881.9471 \times (\text{Log(h)/h}^2))/1000$			ANACAFE (2008)
Palmas in general	$\text{Bt} = 7.7 \times \text{h} + 4.5$		0.90	Frangi and Lugo (1984)
Roots	$\text{Br} = \exp(-1.0587 + 0.8836 \times \text{Ln Bt})$		0.84	Penman et al. (2003)

Notes: R^2 ajustado; *Bt* total biomass area (kg arbol^{-1}), *Br* underground biomass, *dap* diameter of breast length (cm), *d* basic density of the wood, d_{30} diameter taken from the bass at 30 cm, *h* total height (m), *exp* strength of the base e, *Ln* natural logarithm (base e).
Source: Based on Jadán et al. (2012)

These equations were also used to calculate low-latizal sapling biomass and necromass (Table 2). The underground biomass was calculated using the equation recommended by the IPCC (2003). The biomass of dead wood was calculated based on volumes obtained via the Smalian formula taken in different decomposition categories (Table 3).

The estimated biomass was converted into units of C by multiplying by the 0.5 factor of conversion, as indicated in IPCC (2003). The values obtained were expressed as MgCha^{-1} (mega grams of C per hectare).

The organic carbon in the soil was estimated using the percentage of organic C and the apparent density and deepness of the sample. The total amount of C that is stored was calculated, adding the C to each of the components of the ecosystem (biomass, necromass, and soils) in each one of the evaluated systems (Table 3).

Table 3 Equations used to calculate the underground biomass of different components evaluated in the Sumaco Biosphere Reserve, Napo Province

Component	Equation	Variable meaning	Source
Necromass		S1 = initial section	
Volume of dead wood	V = (S1 + S2)/2 *L	S2 = final section	
		L = length timber log	Schlegel et al. (2001)
Biomass of dead wood	B = V × Db	B = biomass (Mg)	
		V = volume (m^3)	
		Db = wood basic density (Mg m^{-3}) in the several decomposition categories proposed by IPCC (2003).	
Soil organic carbon	SC = CC × AD × P	SC = soil carbon (Mg C ha^{-1})	Schlegel et al. (2001)
		CC = content of carbon percentage	
		AD = apparent density (Mg cm^{-3}).	
		P = soil thickness in the sample (cm)	
Total carbon stored	TCS = CTB + CN + OCS	TCS = total stored carbon (Mg C ha^{-1})	
		CTB = carbon stored in the biomass (above and under the soil)	
		CN = carbon stored in the necromass	
		OCS = organic carbon in the soil	

Source: From Jadán et al. (2012)

The air biomass in tropical forests was estimated based on the wood density (d) of tree species with a DAP (diameter of breast length) greater than 10 cm through the equation formulated by the Global Wood Density Database (Zanne et al. 2009), i.e., Ln (Bt) = $-1.864 + 2.608 \times \text{Ln (DAP)} \times \text{Ln}\ (d)$.

Contribution of the Chakra Agroforestry System to Climate Change Mitigation

As reviewed in the Introduction, the benefits of agroforestry systems for carbon sequestration and climate change mitigation are nowadays widely recognized. Adequate management of these systems increases their potential for recovering part of the carbon released into the atmosphere due to deforestation in the world (Montagnini and Nair 2004). Therefore, agricultural production has the potential to be less a problem and more part of the solution to problems related to climate change and development (Hoffmann 2011).

Table 4 Average ± standard error for C stored in the traditional chakra cacao agroforestry system and in cacao monoculture, compared with carbon stored in primary rainforests evaluated in the cantons of Tena and Archidona, Sumaco Biosphere Reserve, Napo Province, 2011

Storage components (Mg C ha-1)	Primary rainforest	Cacao chakra agroforestry system	Cacao monoculture
C air biomass	206.2	52.8	5.7
	±29 a	±8.1 b	±2.5 e
C root biomass	58	15.3	1.8
	±7 a	±2 b	±0.8 d
C total biomass	**264.2**	**68**	**7.6**
	±36 a	±10.3 b	±3.2 de
C necromass	4	4.1	2.8
	±0.8 ab	±0.4 a	±0.6 abc
C organic soil	65.9	69.2	74.9
	±9.2 ab	±4.9 a	±6.8 a
Total carbon	**334.2**	**141.4**	**85.2**
	±41.7 a	±11.9 b	±7.9 c

Source: From Jadán et al. 2012

The initial findings of the project, reported in Table 4, show that, in comparison with primary rainforest, traditional agroforestry systems based on cacao farming store 42 % of C (334 Mg C ha^{-1}) and 56 Mg C ha^{-1} more than cacao monocultures (see, also, Torres et al. 2013).

The carbon content in air and root biomass shows that the cacao chakra system contains 896 % more C than cacao monocultures (68.1 Mg C ha-1 and 7.6 Mg C ha^{-1}, respectively). This high percentage of carbon storage in the chakra system corresponds to the diversity of trees used for timber, most of which have a high commercial value, for example, chuncho [C*edrelinga cateniformis* (Ducke) Ducke], cedro (*Cedrela odorata* L.), caoba (*Swietenia macrophylla* King), aguacatillo (*Persea* spp.), canelos (*Ocotea* spp.), guayacán [*Tabebuia chrysantha* (Jacq.) G. Nicholson], laurel [*Cordia alliodora* (Ruiz and Pav.) Oken], and pigüe [*Pollalesta discolor* (Kunth) Aristeg] (see Table 6). There is also a diversity of fruit trees, bushes, and palm trees that form part of the local population gastronomic culture.

These findings on stored carbon in air and root biomass in cacao chakras are similar to those obtained by Ordoñez et al. (2011) in locations near the area of our study within the SBR. They register (68.6 Mg C ha^{-1}) in chakra agroforestry systems with cacao trees that are 8 years old, on average (Table 5).

These results show that, given the amount of carbon stored both in air biomass and in root biomass in cacao, fruit, and timber trees, the potential of the traditional cacao chakra system to enter into the carbon market is important. Also, participation in the carbon market could help to maintain other components of the chakra system, which produce ecosystem services with no market value.

Table 5 Average C stored in cacao plantations using the traditional chakra agroforestry system with 2-, 4-, 8-, and 12-year-old trees, evaluated in the cantons of Tena and Archidona, Sumaco Biosphere Reserve, Napo Province

	Cacao plantations using the chakra system (age in years)			
Storage components (Mg C ha-1)	2	4	8	12
C air biomass in the cacao	2.15	5.00	14.63	27.17
C root biomass in the cacao	0.67	1.42	3.67	6.53
C total biomass in the cacao	**2.83**	**6.43**	**18.30**	**34.71**
C biomass in fruit and timber-yielding trees[a]	50.34	50.34	50.34	50.34
C total biomass in the cacao plus fruit and timber-yielding trees	**53.7**	**56.77**	**68.64**	**85.05**

Contribution to the Conservation of Plant Species Diversity and the Amazon Landscape

One of the main characteristics of the chakra system is the floral diversity and density of timber-yielding species, which mostly regenerate naturally.

With regard to the floristic diversity at family, genus, and species levels, we found an average of eight families, nine genus, and nine species in the chakra system. Meanwhile, in cocoa monoculture farms, only one family, one gender, and two species were found (in average). These demonstrate the contribution of the chakra with cocoa production system to the conservation of floristic diversity of fruit and timber trees. In addition, having a variety of species, commonly used for food, medicine, energy drink, craft, spiritual rituals, and multipurpose materials (Table 7), also shows its potential to adapt to climate change.

In relation to density, the chakra system with cacao was found to have on average 170 timber and fruit trees with a diameter greater than or equal to 10 cm at breast height (DBH). Figure 2 shows the number of trees identified in line with the DAP ranking.

A particular pattern of spatial distribution of timber tree species and fruit trees could not be identified due to the absence of systematic practices for planting timber or fruit trees. These trees grow in a process of natural regeneration from the dispersion of seeds caused by wind or from the diversity of the fauna present in the system. As a general observation, it can be mentioned that timber-yielding trees can be found in distances between 15 and 20 m apart (Figs. 3, 4, and 5).

However, it is important to highlight that, at the time when producers engage in crop management, timber species of commercial value are generally carefully managed. The management of tree diversity in the chakra system (Table 6) shows how the Amazonian Kichwa population maintains crucial information about plant resources from a solid popular knowledge of plant species and their uses. Thus, it can be said that chakras are a model of biodiversity conservation; at the same time, they provide ecosystem services for the livelihoods of local population.

systems with high diversity of plants and animals is a means to address climate change (Kotschi and von Lossau 2012).

In the Sumaco Biosphere Reserve, chakras are based on the cultivation of cacao, combined with fruit trees and food plants, which also have the function to store carbon during their growth process. This is the case of guabos (*Inga* spp.), grape tree (*Pourouma cecropiifolia* Mart.), hard chonta (*Bactris gasipaes* Kunth), white cacao (*Theobroma bicolor* Bonpl.), and introduced fruit trees such as achotillo (*Nephelium lappaceum*), cherimoya [*Rollinia mucosa* (Jacq.) Baill.], among others. Given that, at 2010, there were about 12,500 ha of cacao-based chakra farms in the SBR, managed by approximately 9,200 producers (Giza 2011), it can be said that the contribution of traditional agroforestry to climate change mitigation is important (see, also, section "Methodology").

Noteworthy, research supported by the German Development Cooperation (GIZ) on the contribution of traditional agroforestry to local economies suggests that the chakra system substantially supports rural livelihoods. Indeed, for producers from the Kallari Association in the SBR, it was found that 42 % of the household monetary income comes from the sale of cacao and 37 % corresponds to produce that contributes to food security, i.e., staple food produced and consumed in chakras (GIZb 2011).

Table 7 shows the main species of fruit trees, shrubs, and palms that are commonly found in a chakra. These species contribute both to carbon sequestration and storage and the preservation of local food culture. All species listed in the table correspond to the cacao-based chakras. Their botanical identification and most popular use were verified through two sources: de la Torre et al. (2008) and Ríos et al. (2007).

Edible plants found in chakras with cacao in the Sumaco Biosphere Reserve like banana (*Musa* spp.), cassava (*Manihot esculenta* Crantz), pineapple [*Ananas comosus* (L.) Merr.], corn (*Zea mays* L.), peanuts (*Arachis hypogaea* L.), lemongrass [*Cymbopogon citratus* (DC.) stapf], chili (*Capsicum annuum* L.), star peanut (*Plukenetia volubilis* L.), Chinese potato [*Colocasia esculenta* (L.) Schott], wild coriander (*Eryngium foetidum* L.), naranjilla (*Solanum quitoense* Lam.), and lemon (*Citrus* spp.) are among the 25 food species most consumed by 10 indigenous nationalities and one mestizo population, according to Ríos et al. (2007). This highlights that the chakra system, associated with a cash crop such as cacao, can be an option for carbon sequestration and climate change mitigation; it also contributes to food security. Chakras with cacao also can be integrated into wildlife corridors, connecting patches of primary or secondary forests while generating household income (Torres et al. 2013). Therefore, they potentially contribute to local populations' lifestyle in harmony with nature. However, more quantitative approaches are needed in order to develop concrete strategies for climate change adaptation.

Local Governance for Climate Change Management by Promoting Chakra System with Cacao

The Ecuadorian Constitution of 2008 includes two specific articles for climate change management: Article 413 ("The State shall promote energy efficiency, development and use of environmentally clean technologies, practices and policies as well as diversified renewable energy of low impact on and no risk for food

Table 7 Main species of fruit trees, bushes, and palms that store carbon and are used for consumption in chakras with cacao in the Sumaco Biosphere Reserve

sovereignty, ecological balance of ecosystems and the right to water") and Article 414 ("The State shall take appropriate and transverse measures to mitigate climate change by limiting emissions of greenhouse gases, deforestation and air pollution"). This mandate is implemented through the National Development Plan for Good Living (2009–2013), in which objective 4 includes a policy to "promote the adaptation to and mitigation of climate variability with focus on climate change."

In 2008, both legal instruments set up a framework for the First Forum of Cacao, established in the city of Tena. This started an innovative process of land management of cacao fields based on strengthening a space of coordination (the cacao round table – MCFA) in the SBR (GIZa 2011). Such a public space includes participatory governance principles for issues regarding mitigation of and adaptation to climate change.

The SBR MCFA promotes the production of cacao on the basis of the chakra system. At the time this chapter was finished (August 2013), the MCFA had 41 actors representing the social, public, private, and cooperative sectors. Remarkably, 16 of them are representatives of local producers. The MCFA works with a concerted strategy called "faces of cacao"; this includes (Chacón et al 2012) (a) the agro-productive face, (b) the ecological face, (c) culture and tourism, and (d) flavors and smells. In this strategy, the ecological face addresses issues of climate change in chakras with cacao.

The MCFA is a local governance mechanism that helps to coordinate actions to mitigate climate change through the cultivation of cacao. It has achieved to promote participatory processes that address and guide a local agenda, where stakeholders, from public and private sectors, put in practice their ideas and interests in local action plans. These are implemented on the basis of a single driving scheme where all actors have the same rights to evaluate and decide on the principle of horizontality.

This model of management allows for particular and transparent contribution from each member of the MCFA platform to collective action. Participation draws on the principles of inclusion and interacting planning becomes practical action on the principle of complementarity. All these consolidate, in practice, the implementation of climate-smart, socially, and ecologically sustainable production systems.

Revival of the Amazonian traditional chakra system, adapted to a commercial produce that adds value such as cacao, has facilitated the political understanding of sustainability both on productive and climate change grounds. As a land management system, the Amazonian chakra is an example that shows how adaptation of production systems based on traditional knowledge can contribute to mitigate and adapt to climate change; therefore, it is useful for the promotion of sustainable production patterns in other areas where traditional systems also exist.

Conclusion

This chapter reports findings on the capacity of a traditional agroforestry system, called chakra, to contribute to climate change mitigation and adaptation. The focus was particularly on the integrative characteristic of such a system to harmoniously pursue the achievement of multiple goals. The findings suggest that chakras can be taken as examples of sustainable production that must be preserved in order to tackle climate change effects in tropical zones. Chakras with cacao in the Ecuadorian Amazon region provide diversified ecosystem services that can only be recuperated through the recognition of local knowledge. Furthermore, it is within the chakra system where decisions concerning harmonized landscapes, territory, and locally constructed processes of adaptation to climate change are made every day.

The findings can guide policy makers and other stakeholders in their decisions on land-use policy and measures to tackle poverty and climate change. In this way, the intention is to contribute to making future policies more effective, thus better enabling local population to strengthen their organizational capacity for climate change adaptation. Yet, encouraging dialogue platforms to support local governance mechanisms, based on sustainable production systems, requires transdisciplinary research focused on issues of sustainable climate change adaptation, that is, combining climatic concerns with "good living" goals. Further, it requires a development strategy that has the sustainable conservation of the rainforest as a main pillar and integrates local population in the Amazon region territorial planning.

Climate Change Adaptation Technologies

Build Sponge Eco-cities to Adapt Hydroclimatic Hazards

Chung-Ming Liu, Jui-Wen Chen, Ying-Shih Hsieh, Ming-Lone Liou, and Ting-Hao Chen

Contents

Abstract

Global population increases steadily and the majority are moving into cities. In the meantime, fast-growing cities are suffering with intensified hydroclimatic hazards. In this chapter, the authors propose to transform cities to sponge eco-cities so as to enhance their capacity on flood prevention, water resources replenishment, heat-island mitigation, biodiversity development, and air and water quality improvement. The strategy proposed is to replace all urban pavements with load-bearing, permeable, breathable, and sustainable pavements, so that rainwater will be stored underneath on raining days and water vapor will be released on sunny days. With water and air reaching soil underneath, underground ecosystem will flourish to enrich urban biodiversity. The JW eco-technology meets the seven criteria specified in this chapter to construct

desired pavements. JW refers to the initials of the first name of the inventor, Jui-Wen Chen. These criteria are load-bearing capability, permeability, water storage capacity, breathability, underground ecosystem enrichability, affordability, and sustainability. In Taiwan, this JW eco-technology has been tested successfully for 10 years and is recommended by the official agency responsible for the green building certification. Certainly, it is not a trivial task to replace all man-made pavements of any city within a short period of time. A "Build Sponge Taiwan Initiative" has been launched by environmental groups in Taiwan to promote the idea to the general public and to hopefully build sponge eco-communities island-wide in the nearest future.

Keywords
Sponge eco-city • JW eco-technology • Urban-hydrological hazards

Introduction

Global population converges steadily into cities, and cities are expanding fast (UN 2012). Challenged by abnormal climatic events, record-breaking rainfall easily results in widespread floods in cities (Hibbs and Sharp 2012). A typical example was the devastating flood happened on July 21, 2012, in Beijing. Within a short period of time, many areas were buried in water with depths up to 2 m. Losses were severe. People are pondering how to avoid similar disasters in the future (Olesen 2012). Some experts on flood control suggest lifting the storm drainage standard from the current 1–3 years' recurrence period to a higher interval. However, with more extreme rainfall events are expected to occur (IPCC 2012), how much higher the recurrence interval should be raised? Besides, such strategy may not be affordable to all other cities (Searle 2004).

In the meantime, Beijing, with a population of 20 million living in a semiarid region, is hungry for more water resources. Overexploiting of groundwater with a yearly volume of 10 million is blamed for local land subsidence (Wang 2004). Therefore, storing record-breaking rainfalls for later usage may be more beneficial than diverting rainwater downstream for flood prevention. Such dilemma poses a profound challenge to all city governments. In addition, accelerated urban growth leads to intensified urban heat island (Lin and Yu 2005; Liu et al. 2007). Shortage of green zones and water worsen the condition and put stress on elderlies when unexpected heat waves prevail (Jenerette and Larsen 2006; Kovats 2008). Clearly, for a modern city, a balance between stormwater drainage (Butler and Davies 2010) and rainwater harvesting (Pandey et al. 2003) must be tackled respectably.

In this report, the authors propose to transform each city to a sponge eco-city, which is supposed to store rainwater during each rainfall event and to release water vapor on sunny days. Ideally, it is like a sponge absorbing and releasing water spontaneously. No mechanical or chemical or electrical energy is needed.

With enhanced detention capacity and extra water storage, a sponge eco-city can prevent flood and mitigate urban heat island smoothly.

How to create a sponge eco-city? The approach is to replace all man-made pavements with high load-bearing, high permeable, and high breathable pavements and to store rainwater within a gravel layer right below. With water and air reaching to the underground soil layer, tree roots and microorganisms will flourish underneath and pollutants captured will be decomposed and become nutrients to the ecological system (Liu et al. 2012; Fan et al. 2013).

Seven criteria are specified to select desired technique for paving the high load-bearing, high permeable, and high breathable pavement. Only the JW eco-technology (Chen 2004) meets these criteria and the completed pavement is named as the JW pavement. In the following, ideas about a sponge eco-city, the JW eco-technology, and the benefits accompanying with a sponge eco-city are explored.

Sponge Eco-city

The term "sponge city" was used by demographers in population studies to describe the fact that urban cities concentrate and absorb the surrounding rural populations like a sponge, resulting in a continuous, steady decrease in rural populations and a simultaneous expansion of urban areas (Budge 2006). However, urban development results in compactly built buildings, congested roads, traffic, pollutant accumulation, and the pooled consumption of a variety of materials, such as electricity, oil, food, water, and medicines (Van Rooijen et al. 2005; Grimm et al. 2008). Thus, while cities are very important for the development of modern human civilization, they also produce many problems, especially when they encounter hydroclimatic hazards (Hibbs and Sharp 2012).

In this report, a sponge city represents a city with all man-made pavements being replaced by permeable and breathable pavements which will store rainwater underneath and let water evaporate on sunny days. Since ecological system will flourish underneath, the authors name this kind of city as a sponge eco-city.

The idea of reducing effective impervious area in city so as to reduce surface runoff, thus reducing the amount of water directly entering the drainage system and increasing the retention time of rainwater in natural ecosystems to filter the surface impurities carried by rainwater, is proposed in the low-impact development (LID) strategy (Dietz 2007; USEPA 2000, 2006) and the sustainable urban drainage systems (SUDS) in UK (Ellis et al. 2002) and the water-sensitive urban design (WSUD) in Australia (Donofrio et al. 2009). In principle, concepts outlined in LID, SUDS, and WSUD are sound, but they are difficult to make an impact on either an ancient or a fast-growing city, such as Beijing. The key problem is lacking an innovative technology to pave a permeable, breathable, load-bearing, and sustainable pavement to replace all impervious man-made pavements with limited resources.

In the following, seven criteria are specified for identifying a qualified pavement technology:

1. Load-bearing capability: The compressive strength of the constructed pavement should reach 600 kg f/cm^2; that is, the pavement is with strength greater than 8,000 lb f/in^2 and is able to withstand the pressure from grinding by a heavy tank (Papagiannakis and Masad 2008).
2. Permeability: The pavement must be permeable to 10,000 mm/h of water under clean conditions and 1,000 mm/h when covered with leaves and dust (Scholz and Grabowiecki 2007). One advantage of such pavement is that no matter how strong a rainfall occurs, the surface runoff would be close to zero (Wu 2005). Thus, the construction of drainage ditches around the pavement may be unnecessary.
3. Water storage capacity: In many areas, it is specified that permeable pavements must be accompanied with gravel layers underneath (Krueger and Smitha 2012). The purposes are for stormwater detention and pollutant filtering (Sansalone et al. 2008). Since the environmental condition of each city is different, the designated water detention amount can be different. In this chapter, an effective 10-cm water storage layer is proposed, which can be achieved with a 33.4-cm-depth gravel layer of porosity 0.3 or in any other combinations of gravels and water-storing materials. Then, as the road area in Beijing is 62.7 Mm^2 (BSIN 2013), thus 6.27 Mm^3 of water, or 6.27 MT of water, could be stored underneath.
4. Breathability: Detectable movement of air flowing freely up and down through the pavement is specified. The purpose is to cool the ambient air through vaporing the underground water and to absorb air pollutants substantially into layers below the pavement (Liu et al. 2012). Also, the air provides necessary nutrients and active agents to the ecosystem underneath (Paul 2007).
5. Underground ecosystem enrichability: With air and water flowing freely into layers below the pavement, tree roots and microorganisms will flourish. Such underground ecosystem development is not detectable with eyes, which is in contrast to the ecosystem linked with the urban green landscape, but will function similarly, i.e., to decompose pollutants absorbed and clean the environment (Chapelle 2000; Liu et al. 2012). Such system may be named as an underground wetland (Mitsch and Gosselink 2007).
6. Affordability: This is an important factor to consider when transforming an ancient city in the third world to a sponge eco-city. The construction cost should not be a burden; the maintenance spending must be negligible; and, most importantly, there are minimized needs to repair or replace the pavement for a long period of time, such as more than 30 years. Therefore, when estimating the total budget for a period of 30 years or more, the cost will be affordable to almost all cities in the world.
7. Sustainability: With suitable maintenance being applied, major characteristics of the pavement, such as smoothness, evenness, load-bearing, permeability, water storage, breathability, and underground ecosystem development, must be kept for a period of 30 years or more. Thus, a considerable amount of resources and funding involved in replacing the pavement could be saved in the long run. These all meet the specification as a sustainable pavement (Gopalakrishnan 2011).

The JW Eco-technology

To every place explored by man, there must be a road. Under every road built by man, there must be an interruption of soil linking with nature. Therefore, all man-made pavements, such as walkways, road, etc., can be viewed as the first act of destruction by humans to the environment. Taking human skin as an example, if covered by paints, the skin would be deteriorated to a deceased condition. Hence, humans are practically living above deceased Earth surface with man-made pavements extending widely all over a city and are wishing that all urban-hydrological problems can be managed through engineering measures, which is clearly an impossible mission. To sustain urban environment, pores of all man-made pavements must be opened up so as to cooperate with Earth while facing the challenge of long-lasting heat waves, severe droughts, devastating floods, etc.

The pavement paved with the JW eco-technology (Fig. 1) is characterized with a specific thickness of gravels under a concrete pavement, which uses structured plastic frames with hydraulic conductivity (Liu et al. 2012), named as the JW aqueduct frame (Fig. 2), to replace traditional reinforced steels to ensure the compressive strength and flexural strength of the concrete pavement (Chen 2004). The JW aqueduct frame has a covering stripe which is removed after the solidification of concrete, so as to reveal holes of water pipes. These holes are named as pores of the JW pavement.

Since reinforced steels would oxidize, rust, and expand upon contact with water, efforts are needed to block water entry below the conventional reinforced concrete

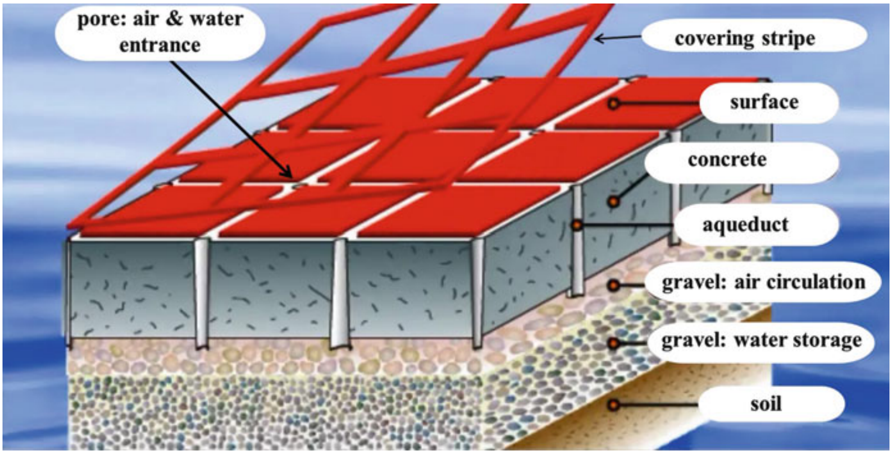

Fig. 1 Illustration of the JW pavement. The upper section is a rigid concrete block with the concrete being reinforced by the JW aqueduct frame (Fig. 2). Covering stripe of the aqueduct frame is removed after the solidification of concrete, so as to reveal holes of all aqueducts. These holes are named as pores of the JW pavement. Water and air are flowing freely through aqueducts. Below, gravels function as pillars to maintain the stability of the upper solid block, while the upper gravel layer facilitates air circulation and the lower gravel layer is for water storage

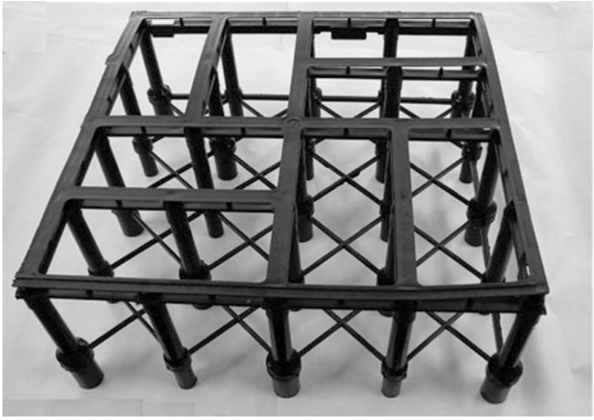

Fig. 2 The JW aqueduct frame

pavement (Papagiannakis and Masad 2008). In contrast, with the JW aqueduct frame, water is welcomed to flow freely into layers below. Furthermore, a conventional rigid pavement would crack with rainwater seeping underneath or tree roots extending below (Papagiannakis and Masad 2008). This is not the case with the JW pavement.

In Taiwan, a 50-meter length JW road was constructed within the campus of the Taipei National University of Technology (TNUT) since 2003, with tree roots unblocked along the pavement. Until now, the road maintains similar functions with no crack or bumps (Tsai JH, 2010, Long-term monitoring of the pervious pavements in front of the architecture building of the National Taipei University of Technology, personal communication. (in Chinese)). Liu et al. (2012) and Fan et al. (2013) opened up portion of this pavement and revealed that tree roots were growing widely underneath. In Taiwan, a 10-year guarantee for the evenness and smoothness of the JW pavement is provided by the inventor. Theoretically, if damages caused by earthquake would not happen, the JW pavement could last for more than 30 years and hence qualify as a sustainable concrete pavement (Van Dam et al. 2012).

The JW plastic frame composes of many air-cycle aqueducts (Fig. 2). On the surface, it is about 100 pores per square of meter, acting as skin holes for allowing the flow of rainwater and air circulation. In comparison to the conventional porous asphalt pavement, grass bricks, and permeable tiles, negligible surface runoff can be measured over the JW pavement during each rainfall event (Wu 2005), for the rainwater penetrates directly through each aqueduct into the lower gravel layer (Fig. 1) rather than slowly seeping through the pavement as most other permeable materials.

Tests done by Li (2004) showed that when all the aqueduct entrances were free from dusts and leafs, the pavement had an average infiltration rate of 12,557 mm/h; if occupied thoroughly by dusts and leafs, it still recorded an average infiltration rate of 1,487 mm/h. Still, routine maintenance is recommended to keep the aqueducts free from clogs and maintain a good condition. In Taiwan, the Architecture and Building Research Institute recommends the usage of the JW pavement in the green building evaluation manual and specifies the porosity below the JW pavement as 0.3, which is about six times of those conventional permeable tiles sold in Taiwan (Lin et al. 2012).

The mission and bearing load of each man-made pavement is designed differently; therefore, the underlying depth of the gravel layer, the thickness of the concrete pavement (i.e., the length of the air-cycle aqueduct), the artistic surface treatment, etc., can all be different. For instance, the thickness of a road pavement must be larger than that of a walkway. In short, the thicker the concrete pavement, the more weight the pavement can bear.

Li (2004) measured the vertical point load on a JW concrete block with a thickness of $60 \times 60 \times 7.5$ cm by the test specifications for flat-panel concrete given by the European Federation for Specialist Construction Chemicals and Concrete Systems (EFNARC). The authors found that the block could withstand 20–30 kg/cm^2 (equivalent to 300–420 psi), while the standard load of a general large vehicle is 90 psi. Pavements with thicknesses of 10 cm and 15 cm could withstand 30–40 kg/cm^2 and 40–60 kg/cm^2, respectively. Acceptable ductility, malleability, and toughness of the JW concrete block were also noted. In addition, according to the standard specification CNS1232 of Taiwan, the compressive strength of JW pavement could reach 1,980 kg f/cm^2; according to the standard specification CNS1011 of Taiwan, the tensile strength of JW pavement reached 74 kg f/cm^2; according to the standard specification CNS10757 of Taiwan, the wear resistance of JW pavement reached 0.51–1.22 %; according to the standard specification CNS6471 of Taiwan, soluble sulfate only affected the JW pavement by 0.38 ± 0.01; according to the standard specification ASTMC979 of Taiwan, alkaline substances would not affect the surface characteristics of the pavement.

Meanwhile, the gravel layer can be specified with a longer depth for regions wishing to store more water. Or permeable pipes can be placed within the gravel layer to direct rainwater into the underground stormwater drainage system, as shown in Fig. 3.

In Taiwan, a 4×120 m JW road was recently constructed in Xizhi, New Taipei City, with two parallel underground water tanks capable of storing 70 t of rainwater. Measurements on April 18, 2013 show that around noontime the ambient temperature was about 33 °C, while the surface temperature of the JW road and the nearby asphalt road was about 26.2 °C and 38.2 °C, respectively. On August 12, 2013, the noontime air temperature was about 38.3 °C, while the surface temperature of the JW road and the nearby asphalt road was about 41.8 °C and 63 °C, respectively. With the pavement breathability, the surface temperature of the JW road is clearly much lower than that of the asphalt road. Furthermore, it is due to a significant amount of rainwater stored underneath in spring that the surface temperature of the JW pavement was lower than that of the ambient air (Chen et al. 2013).

Fan et al. (2013) compared the ecological activities below the JW pavement installed in TNUT with those under three other adjacent permeable pavements by collecting samples in the gravel and soil layers underneath and concluded that the microbial compositions and their activities under the JW pavement were both

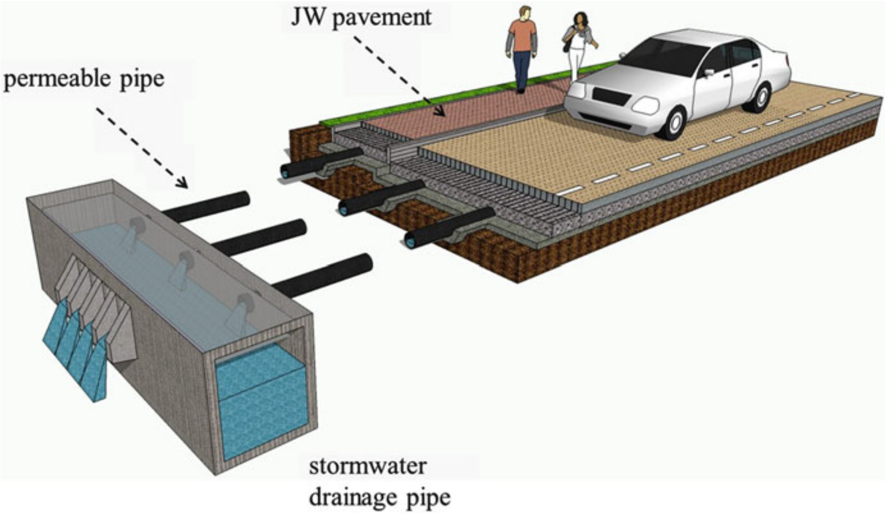

Fig. 3 Underneath the JW pavement, permeable pipes within the gravel layer can direct rainwater into the stormwater drainage system

superior to those under other pervious pavements. Bacterial communities under the JW pavement were more abundant and diverse. The soil under the JW pavement also reflected more activated and versatile microbial activities in all substrates and for specific types of functional guilds.

Liu et al. (2012) also studied the function of the JW pavement in TNUT and designed experiments to compare the variation of the air pollutants concentrations within a fenced area over the JW pavement with one vehicle emissions discharging into with results from similar experiments over a non-JW pavement. Under stagnant condition, it was found that the JW pavement diluted vehicle pollutant emissions near the ground surface by 40–87 % within 5 min of emission, while the data at 2 m height suggested that about 58–97 % of pollutants were trapped underneath the pavement 20 min after emission. Those quantitative estimations may be off by ± 10 %, if errors in emissions and measurements were considered. SO_2 and CO_2 underwent the most significant reduction. Very likely, pollutants were forced to move underneath due to the special design of the JW pavement. In order to track the fate of pollutants, parts of the pavement were removed to reveal a micro-version of wetland underneath (Fan et al. 2013), which could possibly hold the responsibility of absorbing and decomposing pollutants to forms harmless to the environment and human health.

According to the "2012 Yearly Parliamentary Validation of the Budget Price for Engineering Projects" of the Taipei City Government (TCG 2012), the JW permeable pavement has a unit installation price close to that of highly compressed bricks which is about 30 % lower than that of permeable tiles. But the compressed bricks require 21 times more than the JW pavement for the maintenance cost, which is mostly for replacing broken bricks every year. Also, the former is officially recommended to be replaced in every 5 years, while the latter has a life expectancy more than 30 years. In reality, local government would replace the former in every 10 years and pay more on the yearly maintenance. Therefore, with the JW pavement, the total budget would be at least 3–7 times lower than that using the highly compressed within a 30-year time span or 5–10 times lower than that of permeable tiles.

To all cities in the world, the JW aqueduct frame can be manufactured locally, while materials such as concrete and gravels are from local origin and the construction workers are trained local labors. Under the principle of "everything local" and with a sustainable nature, paving of the JW pavement is absolutely affordable to all cities in the world.

In all, this section explains how the JW eco-technology meets the seven criteria specified for constructing a sponge eco-city: load-bearing, permeable, water-storing, breathable, underground ecosystem friendly, affordable, and sustainable.

Benefits of a Sponge Eco-city

What are the benefits of a sponge eco-city? In the following, a few cities are selected for illustration.

Using Beijing as an example, given that 10 % of the 3,377 km^2 of the developed areas (337.7 million m^2) (BSIN 2012) are sidewalks, squares, and parking lots with 62.7 million m^2 of road areas, there are approximately a total of 400 million m^2 of man-made pavement that can be changed to the JW pavement. If the space under the pavement is designed to store 10-cm effective thickness of rainwater, approximately 40 MT of water can be stored, which is equivalent to 80 streams of the Cheonggyecheon in Seoul, Korea. Here the Cheonggyecheon is selected for comparison due to it being a successful urban renovation project. The Cheonggyecheon was once covered with an intra-urban double-deck highway and the ambient air temperature of the area was about 5° higher than that of the central area. In early 2000s, a nature restoration project was executed and the stream with approximately 500 KT of water storage was restored (Cho 2010). The ambient temperature of the area is now about 3.6° lower than that of the central area (RESTORE 2013).

If one restored Cheonggyecheon-type stream is enough to cool the nearby area by 8.6° with respect to the previous covered condition, a weakened urban heat island could be expected in Beijing with 80 streams of Cheonggyecheon flowing underneath. With such detention capacity, the chance to observe serious flooding in Beijing would be lowered. Moreover, future record-breaking rainfalls will be kept to replenish local water resources. There are other unexpected benefits: every degree of the ambient temperature lowered will lead to less air-conditioning demands and hence less energy consumed and less carbon dioxide and air pollutants emitted from power plants (Kan and Tien 2004). Also, at least 50 % of carbon dioxide and air pollutants emitted by vehicles will be captured by the JW road to become nutrients for the underground ecological system (Liu et al. 2012). Clearly, reduction of ambient PM2.5 level and haze could be expected and hence the public health risk would be lowered considerably (Liu et al. 2013).

The benefits to create a sponge eco-city are impressive. If 10 % of the following urban areas, London (1,623 km^2), Paris (2,844 km^2), Berlin (1,347 km^2), Moscow (4,403 km^2), Warsaw (544 km^2), Cairo (1,709 km^2), Istanbul (1,399 km^2), Delhi (1,943 km^2), Bangkok (2,331 km^2), Shanghai (3,497 km^2), Tokyo (8,547 km^2), Los Angeles (6,299 km^2), Houston (4,644 km^2), Rio de Janeiro (2,020 km^2), Buenos Aires (2,642 km^2), and Sydney (2,031 km^2) (DEMOGRAPHIA 2013), are man-made pavements and can be converted to the JW pavements with a designated 10-cm effective depth of rainwater storage, then about 16, 28, 14, 44, 5.4, 17, 14, 19, 23, 35, 86, 63, 46, 20, 26, and 20 MT of water can be stored, respectively, which is equivalent to 32, 56, 28, 88, 10, 34, 28, 38, 46, 70, 172, 126, 92, 40, 52, and 40 Cheonggyecheon streams, respectively. The benefits to all these cities with such a tremendous amount of detention capacity are astonishing. Although the exercise here only provides a rough idea of the potential in changing these cities to sponge eco-cities, it gives a hope to sustain these cities and other expanding urban areas to adapt hydroclimatic hazards under the ongoing climate change.

Discussion and Conclusion

This chapter proposes a daring and innovative idea: transform urban cities to sponge eco-cities by replacing all man-made pavements to load-bearing, permeable, water-storing, breathable, underground ecosystem flourishing, and sustainable pavements. The goal is to store rainwater below the urban pavements on raining days and to release water vapor on sunny days. It will function as a sponge spontaneously with no extra efforts needed. Benefits include enhancing the detention capacity and hence strengthening local flood prevention capability, storing rainwater to replenish local water resources, cooling pavement temperature and mitigating urban heat island, nursing the development of the underground ecosystem, capturing vehicle-emitted pollutants and CO_2 to clean the ambient environment, filtering stormwater pollutants, reducing haze and public health risks, saving long-term costs on pavement replacement, and adapting hydroclimatic hazards and climate change.

As global population is growing steadily and congesting restlessly into cities, they are becoming the most vulnerable areas in facing hydroclimatic hazards (Mitchell 1999; Pelling 2003). Transforming cities to sponge eco-cities will lower this risk and, therefore, is the most favorable approach toward sustainability. It is worthwhile to note that the transformation toward sponge eco-cities has no conflict with the installation of the current urban stormwater drainage system (Butler and Davies 2010). Rather, the combination will surely enhance the local water storage and the detention and drainage capacity (Sansalone et al. 2008), as shown in Fig. 2. The idea has already been exercised in Taiwan (Chen et al. 2013).

In this chapter, seven criteria are specified for identifying the suitable technology: load-bearing capability, permeability, water storage capacity, breathability, underground ecosystem enrichability, affordability, and sustainability. Among them, affordability is the most important factor for cities in the third world, i.e., low costs in installation, maintenance, and replacement for at least 30 years or more. In this chapter, the JW eco-technology is recommended for fulfilling those seven criteria with supporting experimental data outlined. This technology has been tested in Taiwan for 10 years and is now recommended in the Taiwan green building evaluation manual (Lin et al. 2012) and is certainly ready to be tested and implemented in any place in the world.

Certainly, it is not a trivial task to replace all man-made pavements to the JW pavements within a short period of time; but for reducing the urban vulnerability and for sustaining nature and human population, it is better to start the task as early as possible. In Taiwan, a "Build Sponge Taiwan Initiative" (Liu and Hsieh 2013) has been launched by environmental groups to promote the idea to the general public. To create JW sponge eco-cities may be a dream difficult to fulfill, but it is possible to construct sponge eco-communities at every place in the nearest future. Hopefully, similar activities will be launched soon all over the world.

Climate Change Adaptation Through Grassroots Responses: Learning from the "Aila" Affected Coastal Settlement of Gabura, Bangladesh

A. F. M. Ashraful Alam, Rumana Asad, and Afroza Parvin

Contents

Abstract

The southwestern coastal region of Bangladesh has faced thirty large- and moderate-scale natural disasters since the last two decades. Aila, the extreme disaster event, has unveiled major shortfall in the approach of conventional disaster preparedness. Gap between planned intervention and the way coastal inhabitants respond to climatic exposures has widened due to lack of understanding of the grassroots risk perception and effectiveness of associated responses

from them. The research examines locally adopted measures taken for disaster risk mitigation in the coastal settlements of Gabura, Bangladesh, and recommends future directions for climate change adaptation. As grassroots responses, firstly, the age-old spontaneous coping mechanisms of the individual households with particular emphasis on their baseline vulnerability were explored. Secondly, the nonphysical and physical responses before, during, and after disaster were categorized. Finally, with a strength and weakness matrix, the effectiveness and limitations of grassroots responses related to typical exposures and extremes were pinpointed. The study concludes that grassroots responses are mostly effective as adaptive measures during typical hazards; however, they have limitations in extreme events. Most importantly, adequate recognition of grassroots responses will not only inform better adaptation but also contribute to broader regional development planning and climate change policy context.

Keywords

Climate change adaptation • Grassroots responses • Baseline vulnerability • Coastal settlements

Introduction

Bangladesh is globally considered one of the most vulnerable countries to sea level rise.[1] This is obvious for its very low elevation geographical setting with a flat deltaic topography exposed to extreme climate variability. The coastal settlements comprise 32 % of the country's total area.[2] Nearly seven million households are exposed to frequent storm surge and cyclones.[3] According to (Parry et al. 2007), with a one meter sea level rise, about 20 % of the country will be not only inundated with saline water but also the poor and marginal groups will be critically affected (Rahman et al. 2007). Apart from the anticipations concerning climate change, the region remains vulnerable due to large population size, low economic strength, inadequate infrastructure, and chronic inefficiency with institutional capacity (MoEF 2005, 2009 World Bank 2010).

Post-disaster experience[4] in recent years unveiled shortfalls in the approach of government-led disaster preparedness. NAPA (MoEF 2005) and BCCSAP (MoEF 2009) have been criticized as top-down and unable to recognize the role of community in the process. Gap between the conventionally advocated adaptation strategies and the way coastal grassroots respond to hazard consequences has

[1]World Bank (2010, 2013) recognizes Bangladesh the third most vulnerable country to sea level rise and it will be worsening with an expected 2 °C rise in the world's average temperature in the next decades.

[2]The coastal settlements cover an area of 47,211 km^2.

[3]Coastal settlements in Bangladesh receive 40 % of the impact of total storm surges in the world (Dasgupta et al. 2010).

[4]Category-1 cyclone "Sidr" in 2007 and "Aila" in 2009

widened due to inadequate knowledge of associated risks and vulnerability. To date, attempts to recognize the role of grassroots responses in climate change adaptation of coastal settlements are scanty and, therefore, could not be effectively included in government's policy responses, except Parvin and Cassidy (2012), who recently examined the role of indigenous knowledge towards resilient coastal settlement planning.

This chapter investigates in Gabura, one of the most disaster-prone settlements in the southwestern coastal region of Bangladesh that was hit by the deadly cyclone "Aila" in 2009. The research explores the individuals' survival responses inherent in grassroots lifestyle before, during, and after disaster. Underpinned with an analytical framework for vulnerability, grassroots responses, and adaptation, it examines the effectiveness of individuals' responses during typical and extreme hazard events. Finally, insights on how to mainstream grassroots responses into the process of climate change adaptation have been given.

Analytical Framework for Vulnerability, Grassroots Responses, and Adaptation

During exposure to a given hazard, individual responds in various degrees. Based on the severity of disaster, the effectiveness of responses is quantified. As the human being's responses to a hazard are based on his social, political, and economic conditions, there is an increasing recognition that disasters including the components of vulnerability, adaptation, and resilience are socially constructed (Cannon and Müller-Mahn 2010). To understand the effectiveness of grassroots responses in the coastal settlements of Gabura, which is the aim of this chapter, an analytical framework has been proposed. The framework defines baseline vulnerability of the coastal grassroots instigating responses.

Climatic and Non-climatic Vulnerability of the Coastal Settlement

The coastal settlements of Bangladesh are witnessing a number of climatic impacts, i.e., frequent flood, erosion of the coastline, rising water tables, long-term inundation, saltwater intrusion, and other biophysical effects.[5] These are proxy for social vulnerability in sectors concerning water resources, agriculture, human health, fisheries, tourism, and above all the human settlements of the coast itself (Klein and Nicholls 1999). On top of the anticipated and observed climate change-induced

[5]In Bangladesh, the floodplains of the lower Ganges and the Surma basins became exceedingly vulnerable (Alam et al. 1999). Elevated riverbeds due to continued sedimentation induced backwater effect, which eventually increased both the frequency and severity of floods (Huq et al. 1996). Increased magnitude of cyclonic storm surges inundated the coastal unprotected lands with saline water (Islam et al. 1998). The forest ecosystem of the resourceful Sundarbans has been disturbed by floods in monsoon and moisture stress in winter (Ahmed et al. 1999).

risks, the settlements face high level of threats caused by various non-climatic factors. The coastal grassroots suffer from unequal distribution of resources and welfare incentives compared to those in the rest of the country. Even the existing institutional structures are not favorable to ease the hardship of people through providing minimum level of support, which translates into accelerated economic difficulties and social deprivation. Interestingly, the coastal settlements contain twofold characteristics in themselves, because, at one hand, they possess visible disparities triggered by the formal institutional channel coupled with climatic impacts and, all at once, are affluent in natural resources and biodiversity to offer varying livelihood opportunities, which assist people to adapt and retain there for centuries.

Scholars claim that deprivation of resources induces non-climatic vulnerability to individuals and societies in the form of poverty and marginalization (Adger and Kelly 1999; Hewitt 1983, 1997; Watts and Bohle 1993). These may refer to economic resources, technology, information, skills, infrastructure, institutions, and equity. They are often termed "generic determinants" of adaptive capacity of the social system (Brooks et al. 2005, p. 153), often specified by the political economy of the context that determine the sensitivity of the system to climate change. They constrain endogenous factors (i.e., the characteristics and behavior of the community) of coping responses (Cannon 1994). In this sense, vulnerability of the grassroots in coastal settlements is likely to have climatic and non-climatic differentiations and they are mutually inclusive. Irrespective of hazard circumstances, individual's accessibility and reliance on resources determine the first layer of vulnerability. In fact, the degree of accessibility determines the baseline status of the individual.

Baseline Vulnerability

The most widely accepted meaning of vulnerability has been defined as the "susceptibility of exposure to harmful stresses" and "the ability to respond" to those stresses (Adger 2006; Adger et al. 2007; Bohle et al. 1994; Kelman and Lewis 2005; Lewis 1999). Vulnerability, according to the IPCC definition (Houghton et al. 2001; McCarthy et al. 2001), includes "exposure" of a system as an external dimension to climate variations (Few 2003), as well as an internal dimension of its "sensitivity" and its "adaptive capacity." The two sets of definitions have some commonality within them – where "susceptibility" counterparts "sensitivity" of the later definition and "the ability to respond" resembles to the "adaptive capacity." It is to be noted that sensitivity is reliant on the baseline characteristics (climatic and non-climatic) induced by the whole (natural and social) system as discussed in the preceding segment, whereas adaptive capacity links more to the individual's willingness, understanding of priorities, and ability to perform in the system.

As exposure and climatic variability vary across contexts, vulnerability has geographical dimension (Lewis and Kelman 2010) and links to specific hazards and the likely exposure to hazard impacts (Brooks et al. 2005). A settlement having shelters made of permanent materials may not be that much susceptible to windstorm compared to those with temporary structures. Along this line, Lewis (1999) and Wisner et al. (2004) suggested that any kind of vulnerability assessment would focus on the susceptibility of concerned variables that characterize the well-being of people and, in other words, the root causes of sensitivity to a specific disaster and setting. While the social interpretations of disaster are not new (Burton 1993; O'Keefe et al. 1976), whatever their cause, their effects are perpetually rooted in societal processes that render certain groups or individuals particularly vulnerable to the impacts (Wisner et al. 2004) and over time (Uitto 1998).

However, the term vulnerability has become highly contested due to lack of precision (Cannon 2008b). It is often confused with poverty, marginalization, or any other conceptualizations that recognize sections of the disadvantaged population (Wisner et al. 2004). In order to comprehend vulnerability, it is clearly not adequate to understand only the types of hazards and the natural system themselves, but the hazard impacts on groups of people who are at different level of preparedness with varying capacities to recover. Therefore, the research employed a simple working definition from Wisner et al. (2004, p. 11), where vulnerability was meant as the "characteristics of a person or group and their situation that influence their capacity to anticipate, cope with, resist and recover from the impact of a natural hazard." The definition implies that in order to understand the grassroots responses, it is important to identify the characteristics and condition of individuals in the community.

Cannon demonstrated conditions of social vulnerability as root causes of an individual that include one's initial well-being, livelihood and resilience, self-protection, social protection, and social and political networks including institutions (Cannon 2008a; Cannon et al. 2003). Others identify factors that hinder capacity of individuals as economic imbalances, disparity in power and knowledge among social groups, and inequality in welfare and social protection (Adger and Kelly 1999; Blaikie et al. 1994; Dow 1992). However, individuals' vulnerabilities change over time through changes in one's institutional and economic position (direct) and condition of shelter, food, and health (indirect); and these changes are affected by environmental changes (Adger 1999). In the present research, they have been termed as baseline parameters of vulnerability. Together they determine individual's instinct, relying on which one starts to respond to a given disaster event either normal or extreme. These parameters have been further illustrated as livelihood, food and health, education, kinship, and shelter as being considered the basic survival tectonics for an individual to constitute his/her household.

Among the five parameters, livelihood (diversity of jobs, income and savings, assets), education (access to knowledge), and kinship (at neighborhood level, family and community) are independent although some may defy that livelihood and education depend on each other. It is true that certain livelihood opportunities are quasi-independent due to educational qualification remains as prerequisite to access them. However, in an underdeveloped and natural resource-based setting, livelihood opportunities are naturally in place. The component of access to education may not only rely on income than willingness and awareness to be literate based on the level of subsidy from government, whereas livelihood opportunity is central to establish individual's command over economic performances and resources to satisfy fundamental needs. Security of food and health (sources and supply of basic nutrients including safe drinking water) and decision of shelter (settlement, built environment, build form, natural resources/vegetation) are dependent variables as they are highly relied on individual's income, educational attainment, and network of kinship.

Nevertheless, it is to be noted that the parameters of baseline vulnerability do not necessarily constitute resilience, but determine the capacity to some extent to adapt to climate change scenarios. An important point also to be noted is that the main difference between baseline vulnerability and vulnerability definition is therefore the first one is a more intimate assessment of individual's ability than the society as a whole. Therefore, the parameters remain as the first-stage manual to assist individual households to analyze risk and prioritize allocation of resources to reduce immediate vulnerability arising from the household core.

Grassroots Responses in Climate Change Adaptation Process

Recognition of grassroots responses, the aim of this research, requires a clear understanding of the grassroots first. The verbatim "grassroots" encompasses the common and ordinary people at a local level rather than at the center of any major political affiliation or social organizations. Grassroots responses in this chapter limit themselves to those simple individual household-level coping strategies in face of continuing hazard exposures and are not subject to any planned intervention except from the grassroots community itself. Obviously, the grassroots coping strategies are hereditary in nature and central to the assumption that "an event will follow a familiar pattern and that previous coping actions are a reasonable guide for similar events" (Wisner et al. 2004, p. 320). It is the "learning by doing" evolution which makes use of indigenous knowledge gained over centuries. The indigenous knowledge is constituted through gathering of social memory of past weather extremes (Harley 2003). Strauss and Orlove (2003) refer to such practices as use of "intuitive data" derived from individual perception of recent experience of weather guided by historical weather data. Since data are always context specific, grassroots responses are highly localized, generating community-wide ownership and commitment (Jabeen et al. 2010, p. 418).

Parvin and Johnson (2012) identified that indigenous knowledge-based responses occur through stages of anticipation, coping, adaptation, and recovery. Based on their timing, grassroots responses can also be referred to craft passive (concurrent), reactive (responsive or ex post), and anticipatory (proactive or ex ante) (Fankhauser et al. 1999; Smit et al. 2000) "adjustments" (Brooks 2003; Carter 1996; Smit 1993; Stakhiv 1993; Watson et al. 1996), in response to the expected or real-time climatic consequences. Such adjustments take place in the social, economic, and ecological spheres (Smit et al. 2000). According to Cannon (2008b), people, when faced with crisis, would behave "culturally" to respond in ways so unique that sometimes they seem to be quite irrational from outside. However, by virtue of the very notion of culture as unique to a system, grassroots responses as processes of cultural adjustments are spontaneous; hence, the grassroots own full autonomy on their actions (Carter et al. 1994). As Smithers and Smit (1997) claim that spontaneous adaptation is the activity of an individual, his decision making of autonomous responses is embedded in social processes that reflect the relationship with other individuals, his networks, capabilities, and social capital where unmanaged natural systems often are hotbed to stimulate them.

The Analytical Framework

To develop the analytical framework of this chapter, vulnerability has been scaled down to baseline vulnerability. Exposure is the key stimulus against which vulnerability can be traced. Scale of analysis is highly important to understand the layers of changes in the vulnerability condition against a given exposure. When exposed to a hazard, individual responds selectively according to the level of basic vulnerability one withstands and sets the priority areas of response. The ability of one to control the parameters that determine vulnerability might be translated into one's capacity to adapt. As for a fisherman, his livelihood depends on the workable condition of a fishing boat. Therefore, during disaster securing the boat is his first priority than saving his own life. It is the spontaneous responses of that particular individual the framework of this present research identifies as "grassroots." In contrast, a poor day laborer who lives in a comparatively unsafe shelter in a risky location and has nothing much to lose materially would migrate to a safer place at the first instance leaving everything behind. Although the fisherman is wealthier than the poor day laborer in terms of their respective asset share, the first one is more vulnerable according to the differences in the priorities. In these sense, the scope of this analytical framework has tended to consider baseline vulnerability of individuals as the most important aspect to examine the effectiveness of grassroots responses.

Figure 1 shows the range of climate variability and on the eve of exposure how sensitivity of the individual is determined based on his access to resources. Priorities of responses are set depending on the baseline vulnerability. The individual then starts to respond in the adaptation process through bringing changes to the physical and nonphysical attributes of vulnerability parameters. This is the boundary of autonomous adaptation as long as there is no external intervention involved (such as planned government intervention). The baseline condition and associated responses together constitute residual impact towards the next layer of vulnerability. This is the point where planned adaptation starts to operate and determines total vulnerability of the system to climate change. It further trickles back and suggests change of state to the sensitivity of individual. Future alteration in planned intervention also takes place based on the changed situation.

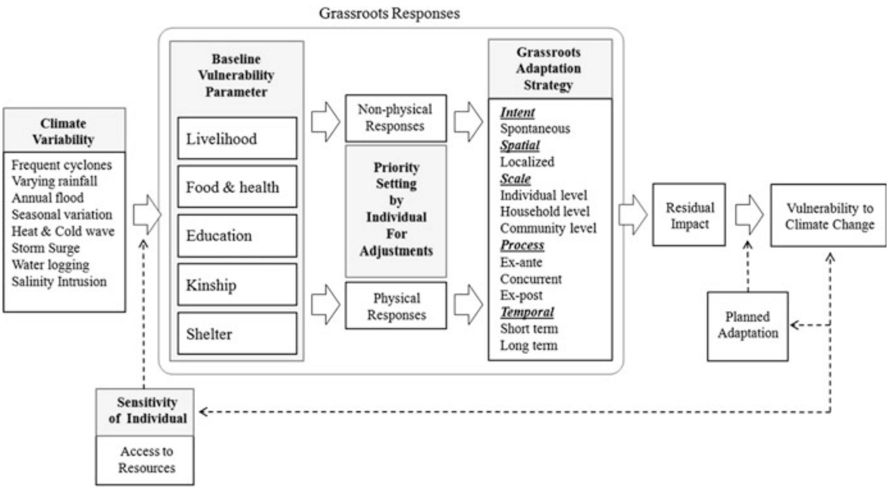

Fig. 1 Analytical framework for vulnerability, adaptation, and grassroots responses

Climate Change Adaptation and Grassroots Responses: The Case of Gabura

Profile of Gabura

Gabura[6] is in the eastern part of Shyamnagar Upazila in Satkhira district of Khulna division in Bangladesh. It is a small island, bounded by Kholpetua and Kopotakhsa rivers, which are subject to year-round strong wind and tidal interactions. It was once part of the Sundarbans.[7] More than a century ago, people cleared this part of the forest for shelter and livelihood opportunities. However, in recent period, excessive reliance on forests is being controlled by restrictions to protect loss of biodiversity.[8] Recently, during the aftermath of extreme disaster, significant portion of inhabitants was forced to retreat from their hereditary occupations of agriculture. At present, 80 % of the economically active population is involved in fishing or activities related to marketing and processing of fish.

[6]Gabura union covers an area of 10,195 acres, with an estimated population of more than 31,115. Most inhabitants (about 96 %) are Muslim. The male–female ratio is 49:51 and literacy rate of this region is 35.9 %. The union consists of 9 wards and 15 villages. 75 % people are involved in fisheries and 20 % rely on crop farming. The rest lives on occupations like industrial labors, rickshaw, and boat puller. The average income is 4000 BDT (BBS 2012).

[7]Sundarbans, the largest mangrove forest in the world, was declared UNESCO World Heritage Site in 1999.

[8]The forest department introduced a “pass” system to restrict the abuse of forest resources.

Most inhabitants, particularly the fishermen, now live along the embankment[9] and on the highlands near the water interface, while farmers live in the middle part.

The way people of Gabura perceive disaster is unique. They are used to typical climate-induced hazards of heat, storm, cyclone, heavy rainfall, and flood. Disaster is part of their daily life as normal as seasonal variation. They are skilled to predict the timing and type of disaster by applying indigenous techniques of observing the weather condition. According to the inhabitants, Gabura is relatively protected, firstly, by the vast natural barrier of the Sundarbans and, secondly, by the embankment. However, "Aila" was the most sudden catastrophe of an unprecedented scale. Within less than an hour, the tidal waves leaped up as high as it could overflow the embankment and rolled into inland washing out every man-made and natural element along its path.[10] Seawater, once entered the inland, could not return to the river and retained for 3 months. The whole island went "green to gray." In addition to physical impacts, vulnerability increased through disrupted livelihoods, long-term displacement of people from their homesteads, and increased health risks due to shortage of drinking water and food supply. Schools remained closed for as long as 2 years. Although the massive momentary shock of Aila had exhausted every possible means to cope with the event at that time, significance of the grassroots responses started to show its upshot at a more profound pace during the 4 years' recovery stage.

Study Approach and Methodology of Field Investigation

An interpretive analysis was done to explain the everyday life in Gabura in relation to climate variability. Qualitative survey was conducted in depth among 20 households to identify their demographic characteristics and perception of hazards, risks, and responses to disaster. Family history of households and their tenure of association with Gabura were critical for selection of interviewees. Afterwards, the unique grassroots responses attributed to their baseline vulnerability were explored through semi-structured interviews. Sample households were selected based on their dwelling location and occupation. Ten households were fishermen with few having business stakes relating to fish marketing and processing, eight were involved in multiple jobs as available and suitable across different season, and

[9]In early 1960 the then East Pakistan Power and Water Development Authority (after independence it is named WAPDA) surrounded the coastal cropland with embankment to protect it from saline water flooding. Apparently, it ensured good cropping in the coastal area, however, from the ecosystem perspective; it has badly altered the natural water–coast interaction, barring the natural siltation process. Consequently the area has gone lower than the sea level and has become subject to water logging and saline water intrusion (Parvin and Johnson 2012).

[10]According to Upazila Nirbahi office, Shyamnagar (local authority) around 41.11 km^2 area of Gabura union was undulated where 4324.97 ha of shrimp land was destroyed, 12,280 households were destroyed, 28 people were dead, 467 people were injured, and more than 30,034 people were affected. More than 3,000 people took shelter in nearby cyclone center and 13,000 people on embankments (Kumar et al. 2010).

the rest two were farmers. Except the fact that the farmers only lived in the middle part of the island, where farmlands got sizeable recovery during last 4 years after Aila, the rest lived in clusters within proximity of the water edge along the peripheral high embankment. Households with firsthand experience in Aila incident were only included in the sample.

In addition, physical features of homesteads including landscape elements, organization, and distribution of homesteads were observed carefully. It helped to understand the spatial manifestation of grassroots responses. Focus group discussion was conducted primarily to unveil the history of community in general and the nature of collective responses. Moreover, cross-checking the authenticity of the household interviews was a secondary concern. Based on the analytical framework, grassroots responses were analyzed in terms of physical and nonphysical key attributes. An effectiveness matrix of grassroots responses was built to understand the level of resilience.

Priority Setting for Grassroots Responses in the Adaptation Process

Neither the buzzword "climate change" nor the issue of "sea level rise" is familiar among the inhabitants of Gabura, except those who received formal education. Nevertheless, they were found highly sensitive to those climate-created stimuli, which would influence to identify their adaptation responses. However, responses vary not only for climatic stimuli but also for the non-climatic conditions (Smit et al. 2000, p. 235). Together they determine the sensitivity of the social system and assist in setting priority towards adjustments. Table 1 depicts a relationship among climate variability, disaster, their impacts, and perception of risk by the grassroots.

Most respondents feel that after the year 2000, nature has been extreme and frequency of disaster intensified. They recognized changes in seasonal variations including increased heat, cold wave in summer nights, untimely rainfall, or no rain however, they impose low to moderate risk on livelihood, food, and health status. There has been increased frequency of cyclones during monsoon, however, they impose low risk on the livelihood and education sectors and cause minor damage to shelter. Typical annual flooding causes short-term displacement and sometimes interruption in education. Increased water logging condition due to heavy rainfall and storm surge including saline retention in the subsoil pose high risk and destabilize most of the baseline vulnerability parameters. These are caused by extreme climatic hazards and eventually they push grassroots responses to the thresholds of limit.

Grassroots Responses Before, During, and After the Disaster

Given the fact that Gabura is incessantly exposed to different degree of climatic hazards, grassroots responses are the inbuilt elements of the daily life of the islanders. It is hard to differentiate from one another as they are overlapping.

Table 1 Perceived climate change impacts by households in Gabura

Climate change stimulus	Climate variability	Disaster impact	Effects	Level of perceived risk
Sea level rise	Untimely rainfall	Disturbed cropping pattern	Loss of livelihood	Medium
	Less rainfall	Disturbed fish farming	Insecurity of food	
	Less seasonal variation	Scarcity of natural fish in rivers and canals		
	Frequent cyclone	Loss of working days	Loss of livelihood	Low
		Temporary interruption of communication	Interrupted education	
		Temporary interruption of schooling		
	Increased heat	Heat stress	Deterioration of health	Low
	Cold wave during summer nights	Chronic fever		
		Pneumonia to children		
	Annual flooding	Short-term displacement	Loss of kinship	Medium
		Medium-term interruption of schooling	Interrupted education	
	Heavy rainfall for short time period	Damage to homestead	Loss of life	High
	Storm surge that crossed over the embankment	Medium- and long-term displacement	Loss of farmland	
	Prolonged water logging	Damage to household assets	Loss of traditional and other livelihood	
		Damage to water supply system		
		Scarcity of food and drinking water	Insecurity of food and water	
		Increased waterborne diseases	Interrupted education	
		Damage to livelihood assets	Loss of kinship	
		Damage to fish ponds	Loss of shelter	
		Long-term interruption of schooling	Deterioration of health	
		Increased salinity of soil and water		
		Scarcity of drinking water		
		Salt in air during summer		

Source: Field Survey, 2013

The interview unveiled the nonphysical and physical grassroots responses before, during, and after disaster that have been categorized in Tables 2 and 3. Aila is the major disaster event in recent years. Therefore, responses after Aila have been considered ex post responses. The key findings are as follows:

Before Disaster

Historically, the geographical setting of Gabura has provided spontaneous choices of cropping, fishing, and other livelihood opportunities. While the fishermen have inherited unique time-bound fishing techniques[11] from the river system of the Sundarbans, farmers held intimate knowledge of soil, water, and seeds that are resistant to flood and saline water. It is the harsh reality that, throughout the year, all have to maintain rationing of drinking water through rainwater harvesting system. The bountiful forest and water system has ensured supply of high-carbohydrate and high-protein daily food.[12] Previous experiences have taught them to store dry food, matchbox, cooker, and cooking fuel (enough for couple of days) on a relatively higher place – a preparedness strategy based on anticipation. They usually maintain extended family networks inside and outside of village through marriage and kinship to secure assistance (usually in monetary form with unconditional loan) during disaster. Timing of schools is scheduled based on the changing time of high tide and low tide. Children take plastic bags to carry books for protection from unwanted rain.

They chose higher land for homesteads along the embankment or internal high-water edges in proximity to their working place. Plantation of mangrove trees[13] along the embankment as well as the periphery of homesteads helps to withstand soil erosion, gusty wind, and wave. Supply of food, fuel, and building materials comes as by-product. Families within blood relation build house around courtyard and share services (e.g., toilet, vegetable gardens, and animal rearing spaces) except cooking. Houses are built on raised earthen plinth.[14] Height of the plinth is determined based on previous mean level of flooding observed. Mud for the plinth is collected through excavating ponds. These ponds are used to retain rainwater[15] for cooking and fish culture. False ceiling with local materials is used to store valuables and insulation from heat. To protect the roof from hauling, they tie bamboo frame or net on the roof and maintain the roof slope less than 40°. Anticipating storm, they tie the roof with nearby trees or ground with strong rope, so that it may not waft away.

[11]They follow a cycle of three "*Gone*"– "*Omabossha*," "*Purnima*," and "*Bosa*" – according to the behavioral pattern of fishes with tidal variation.

[12]The Sundarbans and its streams are source of honey, fruits, edible shoots of trees, fishes, and crabs.

[13]"*Keora*," "*Goran*," "*Golpata*," "*Geoa*," "*Sundari*," Coconut, *Tal*, etc.

[14]Locally called "vita"

[15]Salinity of pond water reduces if the ponds can be retained for at least two seasons, as the salt sediments. The rainwater also helps to reduce the salt content. Water with reduced saline in this way is called "Dudh–Pani" (milk–water).

Table 2 Nonphysical responses of the grassroots in Gabura Island

Attributes of responses	Ex ante (before)	Concurrent (during)	Ex post (after)
Livelihood	Majority involved in crop farming and fishing, few in fish farming	Occupation sectors, i.e., farming, fishing, boat-pulling practices are disrupted	Adoption of alternative sources of income gets priority during recovery stage
	Time-bound fishing strategies[a] based on the lunar calendar		Fishing from the river becomes predominant occupation
	Cropping pattern based on the quality and classification of soil		Male members from poorest families travel to nearby towns for jobs
			Forced to enter into the Sundarbans and narrow canals for collection of honey, wood, and fishes
Food and Health	Sufficient consumption of locally available foods with high carbohydrate and protein on daily basis across all classes	Less consumption as norms impeded by food shortage	Less consumption as norms impeded by food shortage during recovery stage
		Consumption of wild fruits (i.e., Keora) and seeds from the Sundarbans during extreme events	
Education	Setting up school hours according to the timing of high tide and low tide	Receipt of education disrupted	An increased number of children receive education with the belief that they may change family hardship in the future through jobs in government sector
Kinship	Extended family structure for shared assistance	Immediate assistance comes from family members and neighbors within village level during disaster	Financial assistance from relatives living in town in the reconstruction phase
	Safeguarding strong kinship networks within the same community		
	Female children of the family receive early marriage and usually sent out of the island as long-term strategy of extending kinship beyond Gabura		
Shelter	Few literate people save money for shelter	Immediate response during extreme condition includes securing educational certificates, legal documents of land ownership than the physical shelter itself	Increased interest in saving money for shelter repairing and construction

[a]Locally called “*Gone*”

Table 3 Physical responses of the grassroots in Gabura Island

Attributes of responses	Ex ante (before)	Concurrent (during)	Ex post (after)
Livelihood	Selection of agricultural land in relatively higher part of island	Relocating livelihood assets (i.e., poultry, livestock, fish net, boat) in higher place near roadside/embankment or temporary elevated structure or even on the rooftop	Increased engagement in shrimp farming due to salinity intrusion during Aila
	Shrimp farming in the lower part		
	Narrow canals to control saline water for fish farming		
Food and Health	Storage of dry food, matchbox, cooker, cooking fuel in relatively higher place	Clay pots sealed to secure drinking water during storm surge	Underground storage of foods, matchbox, cooker, cooking fuel after experience from Aila
	Rainwater harvesting through use of plastic sheet on roof surface to collect water and preservation in clay pots	Temporary latrine on stilt above water closed to embankment	Increased protection measures for homestead ponds
	Homestead ponds for sweet water fish culture and water with reduced saline content[a] for cooking	Temporary cooking facilities on top of bed or any higher place available	Homestead/kitchen garden as source of vegetable for daily consumption
Education	Use of plastic shopping bag to protect dry clothes and books during extreme weather	Primary schools and mosques used for cyclone shelters during disaster	
Kinship		Use of temporary boats either made of banana tree or large cooking pots to maintain connection with relatives and rescue effort	
Shelter	Appropriate mix of mangrove plants to withstand soil erosion in river banks	Children moved to elevated structure or even on the rooftop	Compact and organic distribution of homesteads during the four years' recovery phase after Aila
	Raised earthen mound for plinth of house or use of stilt	Construction of makeshift shelter along the roadside and embankment	Selection of high land to build shelter along both sides of the embankment

(*continued*)

Table 3 (continued)

Attributes of responses	Ex ante (before)	Concurrent (during)	Ex post (after)
	Use of locally available materials for construction of shelter	Bracings made with chords and bamboo to avoid upward hauling of the roof during cyclone	Homestead forest in the periphery to protect from gusty wind and source of wood for shelter repair/ construction
	Construction of smaller false ceiling for storage and shelter		Increased height of the plinth based on the flooding experience in Aila
	Roof slope less than 40°, use of bamboo frame bracing and fishing net on roof surface to protect from gusty wind		Roofing material changed from thatched roof to CI sheet and preferably asbestos
	Annual maintenance of weaker parts of built structure

[a]Water with reduced saline content is locally called "Dudh-Pani." The literal translation in English should be "milk–water"

During Disaster

During disaster, the most preferable option is to stay at homestead as long as possible. During regular flooding and storm surge, people keep on waiting in the house observing how high the water gets in and build elevated structures[16] for storing foods, valuables, and livestock. The flood hinders livelihood activity and they pass lazy time on furniture above flood level, and use moveable cooker for food preparation. Children move to a higher place, such as on false ceiling and sometimes even on rooftop. During long-standing inundation, people move to makeshift shelters on embankments or nearby cyclone shelter, usually schools. However, such makeshift shelters are inadequate in numbers. Temporary shelter consists of one single room to accommodate the whole family. Shortage of food supply leads to consumption of wild fruits and seeds. Immediate assistance comes from family members and neighbors within village level during disaster. Handmade boats[17] or large water pots as substitute of boats are used for communication. Interestingly, both the higher- and lower-income population travel to nearby city centers for social safety by choice and livelihood by need, respectively. It is hard for

[16]Locally termed "Matcha"

[17]Locally called "Vela," made of bamboo or banana trunk

the middle class to opt for migration. Neither the job opportunity in cities suits their class, nor can they risk on their last piece of land to be illegally grabbed.

After "Aila"

By nature, the people of Gabura did not learn to save money for the future; rather, they followed a day-to-day livelihood path. Therefore, during recovery stage after a major disaster like Aila, search for alternative sources of income gets priority as the regular job options are disturbed. As farmland goes under long-term inundation, fishing from rivers becomes a predominant response. Shift to large-scale shrimp farming was limited to powerful elites as it was never a labor-intensive sector. Consequently, some male members from poorer families migrated to town centers for jobs. Many (including females) were forced to enter into the Sundarbans to collect honey, wood, and fishes. Less consumption was established as norms impeded by food shortage after Aila.

Nevertheless, during the 4 years' recovery period after Aila, the grayed landscape is showing signs to get greener. Homestead level ponds, vegetable gardens, and forests are being reinstated with cautions (increased plinth level, high trees in the windward direction of homestead, raised embankment for the pond to withstand flood, roofing materials changed from CI sheet to asbestos, etc.) that are learned from Aila experience. The number of children receiving education has increased with the belief that they may change family hardship in the future through better jobs. Financial assistance in the form of unconditional loan from relatives living in town has contributed immensely in the reconstruction phase. However, it is limited to the well-off families only. Increasing awareness to save money for future survival responses is evident. More dense and organic distribution of homesteads is taking place along the embankment. Briefly, with many creative interventions, grassroots responses are being evident as ex post measures after Aila. However, confusion remains among them, whether these adaptations, although improved from the past, would withstand a next disaster as extreme as Aila.

Effectiveness of Grassroots Responses

Analysis of grassroots responses in relation to the effects of disaster reveals their effectiveness, which has been presented in Table 4. The evaluation in terms of strengths and weaknesses suggests that most responses are quite effective in relation to the typical hazard condition including minor weaknesses. However, the analysis also reveals that some of the grassroots responses did not succeed during extreme event of Aila, which was too unpredictable in nature. During typical hazards, the indigenous knowledge base helps better adaptation through decisions to change cropping and fishing pattern and optimum utilization of time in different livelihood sectors. Usually, the natural weather indicators help better preparedness on the eve of any exposure. Yet during extreme event, it failed to anticipate the severity and timing of hazard. Field survey revealed that most interviewees could hardly perceive the extremity of "Aila." Although the resourceful natural system

Table 4 Effectiveness of grassroots responses

Grassroots responses	Typical hazard		Extreme event
	Strength	Weakness	
Nonphysical responses			
Adoption of new livelihood strategies	Multiple livelihood options and income opportunities	Loss of traditional occupation	×
	Adaptation to changed environment	New land use distribution detrimental to ecology	
	Male–female equal participation		
Increased interest in receiving education	New job opportunity	Loss of labor force in traditional occupations	×
	Increased self-dependency and awareness	Displacement	
	Increased tendency of savings		
Indigenous knowledge-based weather forecasting	Better adaptation with mother nature		×
	Productive cropping and fishing pattern		
	Optimum utilization of time		
	Better preparedness to fight with disaster		
Short-, medium-, and long-term displacement	Alternative skill for livelihood	Displaced from the hereditary land	√
	New networks	Declination of community bondage	
		Destruction of traditional lifestyle and settlement	
High level of kinship and social capital	Strong social ties irrespective of occupation, religion, ethnicity, or economic status	Increased social liabilities	√
	Mutual trust		
	Cooperating attitude		
	High human value		
Physical response			
Life safety measures and protection of livelihood asset	Initial preparedness for the recovery stage		×
Increased dependency on natural resources from surroundings and the Sundarbans	Alternative source of income	Detrimental to natural biodiversity	○
	Source of local and organic construction material		
	Source of high-nutrient food supply		
	Protection from cyclone and storm surge

has offered an array of livelihood opportunities, traditional occupations could not sustain the aftermath of the extreme event. The settlement has undergone a slow process of deterioration in ecology. Growing literacy among the inhabitants has been opening new avenues for livelihood and enhanced preparedness. In contrast, the traditional skills are diminishing and stimulating displacement to make way for the formal scientific knowledge. However, after extreme event like Aila, education system terminated as long as 2 years. Most interestingly, the nonphysical responses of migration and safeguarding kinship were powerful coping strategies during extremes.

Among the physical responses, the typical life safety measures have been proven useful during both the normal and extreme hazard conditions. However, they lost their usefulness as the impact of “Aila” had lasted for a longer period. Even after extreme events, the natural system of the Sundarbans requires time to get back to its earlier state. Yet excessive dependency on the Sundarbans for livelihood and food supply is exhausting the natural setting. Cyclone shelters and schools, although very limited in number, play positive role through providing alternative shelter during all events including extremes. Physical responses like rainwater harvesting and homestead vegetable gardens are critical to meet requirement of safe drinking water, supply of nutrition, and other cost-saving household income during and after disaster. They are highly vulnerable during extreme events as whichever falls in the direction of storm surge gets wiped out.

Terminologies such as "community-based adaptation," "participatory adaptation," "climate change adaptation from below," and even "grassroots responses" bear romanticism within them because of their inherent "people-centered" notion. There is a wider belief in theory and practice that grassroots can solve everything. However, in reality, during disasters in coastal settlements, grassroots remain handicapped due to limitation of adequate resources and institutional support. In extreme event, livelihood options and education system are severely disrupted. As it is an independent parameter of baseline vulnerability, the command on other dependent parameters like food, health, and shelter naturally are invalidated. During the aftershock of extreme events, even the bountiful resource base of the Sundarbans enters into a crisis state and fails to meet the demand side with its disrupted supply side for a while. Recalling from the history, people know that there has been an extreme event in every 5–10 years or so. The gap between extreme events has been decreasing over last two decades. Nevertheless, successive improvements in grassroots responses are pushed to the "critical thresholds" (Adger et al. 2003) as every time new hazards hit with higher extremities.

Climate Change Adaptation Through Grassroots Responses: Future Direction

It is somewhat unanticipated that people often become vulnerable because they are excluded from safer places due to their structural inequality and forced to choose locations that are exposed to extreme events; at the same time, the vulnerable locations have provided them with livelihood options (Kelman and Mather 2008; Lewis and Kelman 2010). In this sense, the natural system of the coastal settlements is not to be blamed but the governance system that has set up unequal access to resources resulting into deprivation. Cannon (2008b) argued that culture plays a powerful role for people willing to live in peril where livelihood is able to connect to well-being. Hence, willingness for self-protection comes naturally with livelihood and well-being. This is the limit of an individual's response without any external intervention (Cannon 2008a). Beyond this point, external incentives should be required either in the form of societal protection or through a favorable government that would facilitate grassroots responses more effectively through optimum allocation of resources. The empirical findings of this chapter have an important implication suggesting insights to facilitate grassroots responses in the process of climate change adaptation.

Evidence from this study suggests that the first step to reduce the baseline vulnerability is to facilitate livelihood options and ensure their long-term sustenance. The study undoubtedly revealed storm surges that overflowed the embankment causing long-term inundation of inland pose highest level of risk through disrupting livelihood and other parameters of baseline vulnerability. It is of extreme necessity to scrutinize the existing settlement morphology and identify what is problematic towards long-term inundation. Therefore, more sustainable settlement-planning strategies have to be formulated which would not only reduce the risk but also offer scope to nurture traditional livelihood practices. One of the major challenges should be to upkeep the delivery of education, which can be an escape route for many in the future through better livelihood opportunity and scientific knowledge base. Therefore, disaster adaptive schooling system (physical design or policy support) has to be ensured, so that delivery of education may not be stopped under any circumstances. The number of schools has to be increased in strategic locations, so that they may cater adaptive utilization during disasters and overcome the present supply shortage of cyclone shelters.

Contrary to the expectations, as the indigenous way of anticipating weather events fails to predict extreme event, awareness should be created among the grassroots, which would result in increased reliance on scientific warning systems. Individual’s life safety measures are not that useful in the end until one’s livelihood assets are secured during disaster. New policy and planning responses are needed towards a comprehensive safety net. Biodiversity of the Sundarbans should be protected at any cost. However, an equitable policy support is necessary to establish a sustainable baseline supply chain of food and fuel for the indigenous people. Strong social ties of mutual trust and kinship have to be properly utilized for both individual and collective disaster responses. In this regard, some of the individual level responses (i.e., rainwater harvesting and gardening in homesteads) can be scaled up to community-level practice to build on collective resilience. Responses to the improvement of shelter are piecemeal. Research-led design interventions are needed to combine traditional building technologies and science of building to cater resilience and shelter’s sustainability.

Nevertheless, strength–weakness matrix of grassroots responses demonstrated that “displacement” either temporary or permanent has been a common phenomenon during all disasters. Gabura is a disaster-prone island and disaster extremities will increase year on year due to unavoidable consequences of sea level rise. Long-term strategies may be adopted through creating diversified job opportunities in nearby safer locations, so that people may respond through trading off their risky living place with better livelihood options. The process of planned gradual relocation over a decade or so would eventually leave less people exposed to future extremes in places like Gabura. The resulting settlement initiative would provide reasonable setback for both the Sundarbans and Gabura Island to recover back to their earlier state of resourcefulness. This strategic intervention should be integrated into the regional planning strategy for the central government to redistribute and decentralize resource base. As a result, it would ensure equitable scope of resource share for the vulnerable communities of the coastal settlements to build up nationwide resilience.

Conclusion

Climate change is a reality and cannot be denied. Living with disaster is part of everyday life for millions of people dwelling in the disaster-prone areas of Bangladesh and in other places of the world. However, the baseline vulnerability arisen from the root causes of this large population's socioeconomic strata is yet intimately embedded in the mainstream understanding of disaster preparedness through either risk reduction or adaptation. This is probably because preparedness has been still enclosed around the dimensions of broader hazard-centric paradigm than considering as an active socioeconomic development process (Gaillard 2010; Kelman and Gaillard 2008). Neither has been many attempts visible to place adaptation scholarship within the paradigm of disaster risk reduction (Kelman and Gaillard 2010).

The present study confirms that adaptation starts at local level as part of the individual's fundamental urge for survival. Grassroots responses are spontaneous and they facilitate community to adapt to climate variability respective of their socioeconomic status. Yet the responses are inadequate during extreme event. Mismatch is evident among the increasing level of extremities in disasters from climatic hazards and the improvement of grassroots responses over time. Integration of grassroots response with relevant policies and development mechanisms of the existing developmental programs to cater the needs of climate variability can be a first step. Integrated policy to address the baseline vulnerability of the community is important. Interventions compatible to the coastal settlements system itself may significantly reduce its vulnerabilities and create opportunities for the country's large coastal population. Experiences from the category one cyclone "Aila" revealed weakness of existing grassroots responses. However, the importance of community-led adaptation can never be ignored. Rather, they need to be adequately equipped with reasonable climate change adaptation planning and policy responses. Failure in doing so may pose a threat to extinction of indigenous knowledge base climate change responses and lead the large coastal population to an uncertain future.

Abstract

By outlining the central role of water in the global warming process, the necessity of international collaboration in terms of tertiary education in hydraulics and hydrology is being derived. In this chapter an integrated approach of knowledge exchange in the framework of a descriptive education concept and applied university research projects is being elaborated. The focus is placed on descriptive teaching of fundamental flow physics, the application of a sophisticated but open-source software tool for the prediction of flood areas, and a small hydropower project plant which was designed to enhance the living quality of indigenous people in the middle of Ecuador's rainforest. These projects were mutually realized with committed and open-minded local partners.

Keywords

Water • International knowledge exchange • Descriptive education concept • Hands-on projects • Flood prediction • Small-scale decentralized renewable energy systems

Introduction

Over the past and the current century, the so-called developed part of the world has almost entirely exploited the Earth's resources which have been built up over billions of years. And it was only in 1972 when the so-called civilized part of the world realized "the limits to growth" which were formulated by the Club of Rome. The irreversible consumption of fossil fuels satisfies the quenchless hunger of an exponentially increasing living standard. This process goes in line with (a) a rapidly growing world population and (b) a continuously growing percentage of people benefitting from technical progress. The latter fact is truly a great achievement but nevertheless still a few percent of the people live on the cost of the majority.

With the UN millennium goals (United Nations 2013), the gap between the rich and the poor should be reduced which means to significantly enhance the living quality in developing and emerging countries. However, one has to learn from the mistakes mankind has made and support the erection of a sustainable infrastructure in such regions. Therefore, one does not only have to set an example but also to put effort in developing smart and peripheral renewable energy supply units and to implement them in collaboration with the local people. It is needless to mention the imperative of curtailing the impact of global warming on the Earth's ecosystems.

Climate Change: Greenhouse Effect

Global warming is a highly complex physical phenomenon; it is a consequence of solar energy entering the Earth's atmosphere as shortwave radiation, whereas its longwave reflection is captured to a certain percentage by the so-called greenhouse gases. Without the natural greenhouse effect, the world would look differently – and a lot (32 °C) colder (Roedel 2000). However, there is a quite instable equilibrium between the planet's temperature and the greenhouse gas content of the atmosphere.

When the shortwave radiation from the sun enters the atmosphere, only a negligible fraction is being reflected at the outer atmosphere and the rest reaches to the ground. There, dependent on the material, parts of the rays are directly (same wavelength) reflected. This process is called albedo effect; glaciers, e.g., directly reflect 30–75 % of the sun's radiation, whereas liquid water only mirrors 5–22 % and clouds 60–90 %. The rest of the energy is absorbed by the Earth's surface which radiates heat waves back to the atmosphere. So-called greenhouse gases act membrane-like and reflect these longwaves back to the Earth whereupon a gradual temperature rise ensues. Greenhouse gases are mainly water vapor (H_2O, CO_2 equivalent due to strong temperature dependency not allocated), carbon dioxide (CO_2), methane (CH_4, 25 times CO_2 equivalent), and nitrous oxide (N_2O, 298 times CO_2 equivalent), which is produced by nitrification and denitrification (Sloss 1992). Water vapor in the atmosphere contributes, for instance, 36–66 % to the natural greenhouse effect; carbon dioxide and methane come up to 9–26 % and 4–9 %, respectively. While the CO_2 content increased from the preindustrial era from 280 ppm to 390 ppm in 2011, it is responsible for 60 % of the anthropogenic greenhouse effect. Methane increased from 730 ppbV in 1750 to 1,741 ppbV in 1998. Nitrous oxide (N_2O) emissions arise mainly from cropland (69 %) and grew from about 270 to 323 ppbV and account for 6 % of anthropogenic global warming (Blasing 2013).

It can be concluded that 50 % of the anthropogenic impact on climate change can be traced back to the energy sector where mainly CO_2 is being emitted (Schabbach and Wesselak 2012). The cement industry, deforestation, and mainly agriculture, particularly livestock farming and rice cultivation, add up to the other half (IPCC 2007).

According to the Intergovernmental Panel on Climate Change (IPCC), the anthropogenic impact on global warming is in all probability. Between 1906 and 2006, the spatial average close-to-ground air temperature has risen globally for about 0.74 K $\pm$ 0.18 K (IPCC 2007). The oceans, with a much greater specific heat capacity, heated up by 0.037 K from 1955 (surface temperatures increased by 0.6 K) which corresponds to an atmospheric temperature rise of 11 °C (NOAA 2007). The risky issue is that ocean streams are density driven so that they react very sensitively on changes in temperature or salt contents. The Gulf Stream, e.g., carries northwards twice the heat every day that is produced annually by all the thermal power plants worldwide at a velocity of 1.8 m/s at Florida's coast (Ball 2001). However, according to the IPCC (2007), there is a probability smaller than 10 % that a transition of the streams takes place before 2100.

Depending on the future emissions, the IPCC predicts an atmospheric temperature rise with respect to the preindustrial era (1750 CE) of 1.1–6.4 K in 2100 (IPCC 2007). For comparison, the greatest warming after the last ice age was 1 °C within a millennium (Leggett 2005). It is important to mention that local impacts show greater amplitudes than global mean values do. A global 4° warming means, for instance, a temperature rise of 8 °C in the Mediterranean (Wicke 2013).

Water: Global Warming's Central Element

Water as life's central element plays an important role in the global warming context. Water in its three phases – gaseous (0.001 % water vapor), liquid (97 % saltwater and 0.7 % freshwater), and solid (2.3 % ice) – has got a significant impact on the Earth's climate. The oceans absorb CO_2, water vapor is the number one greenhouse gas, and the ice-albedo is the most substantial rebound effect (see below). Even more important rising temperatures affect the hydrologic circle immensely. On the one hand, greater water vapor contents will lead to a greater probability and more severe thunderstorms with subsequently following flood events, and on the other hand, water shortage will increase dramatically. According to Hare, a temperature rise of 1 °C with respect to the preindustrial era will imply 400–800 million people living in water-shortage areas by the 2020s; at 1–2 °C rise, a peak risk of 1.5 billion by the 2050s follows and a rise of 2.5 °C makes 2.4–3.5 billion people suffer from water shortage (Hare 2005).

Katrina 2005, Rita 2005, Ike 2008, 243 hurricanes only in April 2011 in the USA, Irene 2011, Sandy 2012, and the latest striking storm in Oklahoma in 2013 underline that the recurrence interval of such events becomes shorter and shorter. In Germany, for instance, historical floods were recorded in the years 1342, 1501, 1787, 1899, and 1954. Devastating floods then occurred in 1991, 1999, 2002, 2005, and 2013 which makes global warming effects obvious, while there are regions on Earth much more prone to flood fortification.

Hydrology and hydraulics are therefore the basis of climate change adaptation.

Attenuating and Cumulative Effects on Global Warming

Aerosols in higher layers, e.g., reduce the planet's temperature; in lower layers or even on snow or ice, they increase global warming immensely. Particles in the atmosphere reflect the incident sunlight back to outer space, whereas on snow, for instance, they absorb the energy and warm the planet's surface. Especially sulfate aerosols are said to have a cooling effect as the particles in the atmosphere shield the sun's radiation. It seems bizarre that sulfate filters of coal-fired power plants have a negative effect on the climate. The reduction of the ozone layer actually cools the planet, too. The radiation is not absorbed by the ozone in the stratosphere anymore yet in the troposphere as it reaches there more likely (-0.15 ± 0.10 W/m^2). However, the outer layer, the stratosphere, is cooler and therefore cools the troposphere more pronounced than the absorption takes place.

The so-called ice-albedo rebound effect, in contrary, enhances warming. While glaciers melt their surfaces shrink which leads to less reflection and therefore more absorption of sun radiation. The hydrogen-vapor feedback is yet another self-reinforcing factor which, however, cannot be traced back to industrialization. At greater temperatures air can hold more hydrogen vapor, which is yet another greenhouse gas that boosts global warming (Rahmstorf and Schellnhuber 2007). Taking the impact of water vapor on the natural greenhouse effect into account a not negligible fraction of global warming will result from its rebound effect.

Greenhouse gas molecules do have different life spans. In average CO_2 is being dissolved in the oceans after 5 years, although it is released again so that 30 % of the anthropogenic CO_2 will stay in the atmosphere for a couple of centuries and 20 % for a couple of millennia. Methane has a life span of 12 years (IPCC 2007) and nitrous oxide even 114 years.

Consequences of Global Warming

The consequences of global warming are versatile. Melting glaciers lead to a greater sea level (0.19–0.58 m (IPCC 2007)); the vegetation will change; deserts will grow. These issues will have a direct impact on habitats of flora and fauna. Regionally, an increase of 1–2 °C carries substantial, above 2 °C serious dangers (Hare 2005), whereas the total collapse of ecosystems is feared at 3 °C ascent. But it has also got a crucial impact on mankind, mainly through food production (although plant growth increased by 6 % between 1982 and 1999 due to a greater CO_2 content (Nemani et al. 2003), the agricultural production will develop locally different; however, a global reduction of 3–16 % is assumed by the World Health Organization). Higher temperatures lead to greater evaporation which enhances the probability of hurricanes or massive floods threatening animals and people, destroying the harvest. Geopolitical problems, e.g., due to lack of water or food impend and lead to more environmental migration. The financial damage of global warming was assessed by the German Institute for Economic Research to sum up to US$200 billion; the Stern review emanates from 5 % to 20 % loss of the global economic performance. Every region of the world will be affected by global warming, but the poorest that are not able to protect themselves against extreme conditions will be hit hardest (PICIRCA 2012). According to Hare “Africa seems to be consistently amongst the regions with high to very high projected damages” (Hare 2005). Global warming is the first man-made global threat; however, the ones suffering most from it are not its major contributors.

Adaptation to Global Warming

People had to adapt to their environment ever since. All over the place, they suffered from thunderstorms and the subsequently following flood events. Our ancestors had to learn how to cope with extreme climate or weather conditions and drought periods. The major step of mankind to civilization was the control of natural runoff that in some areas even made settlements possible. Freshwater needed to be held back in times of over capacities and released when the crops required it. That process marked the end of the Neolithic Age which took place in the so-called Fertile Crescent (Pleticha 1995). Although a bit later, one of the most impressive monuments that document the effort that has been made to protect people from floods has been erected in Egypt during the Cheops dynasty (approx. 2620–2580 BCE, when hydrologists were worshipped as high priests):

Sadd-El-Kafara, a 10 m high, 45–82 m wide and 61–112 m long dam. There are numerous examples for adaptation technologies in terms of protection from natural hazards worldwide.

Flood control became even more important during the industrial revolution when the risk potential grew enormously as almost all crafts needed water and settled close to rivers. And nowadays, imagine the economic threat of a flooded subway network. As elaborated above, the risk of such hazardous floods increases dramatically due to global warming. Even in Central Europe which is a region not prone to an enhanced thunderstorm probability, extreme flood events occurred more often in recent times. To cope with the challenge, Bavaria's (Germany) adaptation method is a 15 % supplement on the previous design discharge which induces an extensive enlargement of retention potential and embankment strengthening (KLIWA 2012).

International Knowledge Exchange About Water

Academic Education

In this heavily interconnected world knowledge can be exchanged easily (e.g., through wikipedia.org). And it is evident that knowledge exchange has always been the base of development. The permanent gains of cognition and perception, however, convey complexity which requires specialists to handle certain responsible duties. The word exchange means mutual give and take. Thus, international and intercultural knowledge exchange is essential for the solving of regional and global current and future troubles. Primary education, which is aimed to be made accessible to every child (United Nations 2013), is the first step only. Fundamental tertiary education for an appropriate fraction of people (for the smartest not for the richest) is essential for the sustainment and development of good living conditions. The universities and academies have to make sure that knowledge which is accessible at all hours all over the world is being prepared, shared, explained, and set into the right context. Enthusiastic knowledge imparting which is important for the learning success can be handled by passionate pedagogues only. At Technische Universität München (TUM), a concept for fundamental hydraulic education has been developed and conducted over several years. It is based on the train of thought that education has to follow the same path research does (Rapp 2012):

Observe → comprehend → deduce → challenge → apply

This descriptive method has been quite successfully implemented in conjunction with the von Humboldt principle (bond between research and education) and hands-on projects. To share the knowledge and the lecturing experiences internationally, the "Association for International Knowledge Exchange" (German: Verein zur Förderung des internationalen Wissensaustauschs e.V.) has been founded in Munich. In the following some of the experiences gathered in Mozambique are being described. A hands-on project where students from Ecuador and Germany applied their knowledge will be described in the section "Renewable Energies in Developing and Emerging Countries".

Experiences from Mozambique: Flood Protection

Collaboration TUM-UEM

In developing and emerging countries, the protection standard is still very poor. Ever since, Mozambicans, e.g., have suffered from disastrous floods. A tragic example is the year 2000 Limpopo flood which caused some hundred deaths and hundreds of thousands who have lost their homes (650,000 according to GIZ). Only 1 year later, a flood devastated the Zambezi banks. The reasons are on the one hand geographical and topographical and on the other political and socioeconomic. The great African streams Zambezi and Limpopo flow through Mozambique before they discharge into the Indian Ocean at Africa's east coast. After centuries of colonial suppression, Mozambique gained independence only in the mid-1970s. A bloody civil war followed which was aggravated by the Cold War claiming approx. 5 % of the population dead and countless injured. Africa typical threats, e.g., poor educational standard or diseases like malaria or AIDS, contribute to prevent Mozambique from developing. Since the end of the militant actions in the mid-1990s, a gradual improvement, especially in the education sector, can be noticed. Academic structures are being established in the framework of ambitious policies, although the country depends on massive support from international institutions.

To enhance the education of Mozambican engineers, collaboration has been established between Universidade Eduardo Mondlane (UEM) in Maputo and TUM, Germany, and is based on a Memorandum of Understanding between the two federal states. Several courses have been given so far by German lecturers and the hydraulic laboratory of UEM has been assessed and improved through provision of measuring techniques as well as training of the staff (see Fig. 1). Special software has been developed to evaluate these experiments but also to predict, e.g., transient flow phenomena such as water hammer in penstocks. The codes have been written in Octave – a MatLAB substitution which is free to use and to modify (www.octave.org).

Hydrodynamical Approach of Flood Area Prediction

Fluid flows are generally three dimensional and time dependent what makes the partial differential equations that were derived independently by Claude Navier and Gabriel Stokes almost 200 years ago solvable for a handful laminar problems only (e.g., very low velocities like in veins or groundwater flow). The default flow condition, however, is turbulent where a chaotic behavior can be noticed. To predict such flows, the so-called Navier–Stokes Equations have to be solved at discrete points in space and at certain time steps. The more turbulent a flow is, the finer the computational grid has to be and the time step shorter which makes the solution of a relevant industrial or environmental problem computationally unaffordable or even physically impossible. Therefore, different strategies have been developed to cope with this challenge.

Fig. 1 Practical courses and digital transient pressure measurements in the Laboratório Hydraulico of Universidade Eduardo Mondlane, Maputo, Mozambique

For the prediction of flood areas, the state-of-the-art method is to solve the 2D shallow water equations numerically. Deriving the shallow water equations from the three-dimensional Navier–Stokes Equations, the vertical momentum is being neglected and the velocity in the horizontal direction is depth-averaged (Beffa 1994). The momentum balance in the z direction becomes the description of hydrostatic pressure distribution. Integration of mass conservation over the flow depth leads to a transport equation of the flow depth.

For these reasons, the Navier–Stokes Equations can be simplified in such way that they can be applied to solve even great domains, though the preconditions, hydrostatic pressure distribution, and a comparatively small vertical velocity component have to be met. These assumptions generally hold very nicely in natural waters where exact specifications of the bounding geometry are lacking so that the simulation strategy provides significant information.

At TUM's Chair for Hydromechanics, a shallow water equation solver based on the open-source software package OpenFOAM (www.openfoam.org) has been developed to approach such problems efficiently. The solver called shallowFoam and the underlying software package OpenFOAM have been developed under the GNU license agreement so that it is free to use and to customize for any purpose. For the post-processing step, the freely available software ParaView is applied.

Especially in developing countries, this approach has got manifold advantages. Firstly, open-source code licenses are free of charge and the code can be adapted to whichever problem. Secondly, there is comprehensive support available on the Internet because of countless OpenFOAM users worldwide. Thirdly, this software package belongs to the most powerful tools for the solving of partial differential equations like the shallow water equations. Fourthly, the program is massively parallelized and with the solver shallowFoam flood scenarios of even great computational domains can be simulated on servers all over the world in an acceptable timespan. Finally, a link has been programmed to convert GIS data to be OpenFOAM standard (e.g., Jud et al. 2011).

A crucial drawback of the method is that – except for ParaView – graphical user interfaces (GUIs) are lacking which makes the application not easy to handle or even inconvenient for beginners. However, additional university courses on numerical river hydraulics form the integrated approach that the Association for International Knowledge Exchange follows.

Flood Area Prediction

Simulation of flood events requires input data such as the topography (underlying the computational grid, roughness, and discharge). Worldwide topographical data can be downloaded for free – at least at a resolution of 25 m × 25 m – from http://eoweb.dlr.de:8080. Depending on the assignment, finer resolutions are available at different websites. Roughness of the ground depends mainly on the land use and can be gained from aerial photos (e.g., Google Earth).

As profound hydrologic data are mostly not available in developing or emerging countries, extreme flood event discharges can be reconstructed by so-called inverse simulations (Motzet 2003) or they can be reconstructed from the Global Runoff Data Centre (German Federal Institute of Hydrology 2013). By modifying the inflow into and rainfall onto the surveyed region, the different simulation results are being compared with observed data. At the best match, the required parameters can be identified. The procedure has to be done for different events which will help to derive flood probabilities. Future events with certain occurrence probabilities can be subsequently investigated. Safety margins to account for increasing precipitation intensities due to global warming can be considered in the computations (KLIWA 2012). Figure 2 exemplarily depicts a flood risk plan gathered through shallowFoam simulations and illustrated in ParaView (blue = low risk, red = high risk).

The consideration of global warming effects, thus increasing peak discharges, in these numerical simulations leads to appropriate flood risk plans which are the basis for adaptation means.

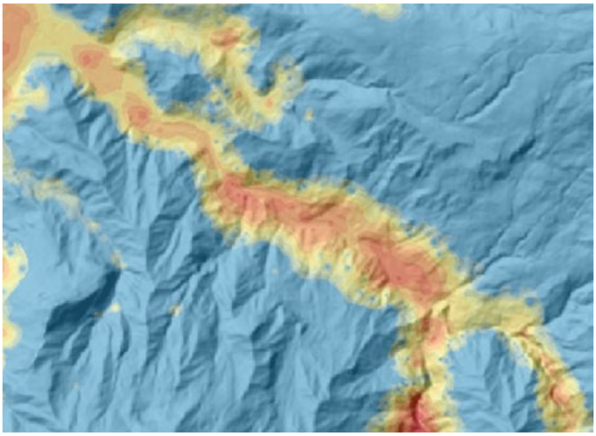

Fig. 2 Risk potential: example for a design flood in an arbitrary domain (From Schäffler et al. 2011)

Remarks on the Academic Concept

This integrated approach – fundamental and depictive hydraulic education, provision of free-to-use software, computer training, and enabling of discrete modification and application – helps to cope with the water-based challenges arising from climate change. The fundamentals in hydraulics are needed for the planning of drinking water supply, wastewater discharge, flood protection, irrigation, and many more.

In the example in the section "Flood Area Prediction," a certain approach to identify areas prone to damage and to ascertain the protection of the people has been elaborated.

Renewable Energies in Developing and Emerging Countries

Energy has become an essential livelihood. What energy means to people can best be assessed where it is not accessible to everyone. William Kamkwamba, an uneducated engineer from Malawi, is a renowned genius. He has built a wind turbine from scrap supplying his family shack with electric light and even being able to charge other people's mobile phones (Kamkwamba and Mealer 2009). Access to power changes life completely and makes development possible.

However, providing the global population with Western European standard will soon lead to a total environmental collapse which thwarts Millennium Goal 7 (ensure environmental sustainability). Despite the additional warming effects and general availability of resources (even for uranium which is by far no alternative), their accessibility is limited (Schabbach and Wesselak 2012). The so-called energy turnaround implies renunciation from a centralized and grand-scale electricity generation to communal renewable energy plants with high harvesting factors (energy gain over energy need for erection and operation).

Conventional plants receive the fuel from remote point sources mainly in Asia, America, Australia, or Africa. The plants are not where the sources are. The combustion of fuels in grand plants and the ensuing delivery to the end user are physically and economically more efficient rather than the resource distribution to the end user with local generation. Renewable energy sources are being used where they appear. For example, it is hardly imaginable that wind is taken from all over the world to a central spot where one huge turbine generates power for a whole city. Hence, where development takes place, the focus has to be placed on small-scale decentralized renewable energy systems.

Hands-on projects based on these principles collaboratively realized with the local population create acceptance enable them to understand the technique and maintain the facilities on their own while rural areas are ecologically friendly empowered (Rapp et al. 2012). And a not negligible side effect is that the added value stays local. One project that has been realized in a smaller scale only is being presented in the following.

Overview of the Project

In 2010 a group of students of Technische Universität München had the opportunity to conduct their final theses within a hands-on project in the Ecuadorian rainforest. Focus was put on fresh and wastewater as well as electricity supply. The latter will be specified by a feasibility study on micro hydropower that was done during a 2-week stay in the village of Yuwientsa. The results were presented and discussed with students from Quito in the framework of a "seminario transatlántico" at Ecuador's oldest and greatest University – Universidad Central del Ecuador.

Yuwientsa is situated in the rainforest about 1 h distance by small aircraft to the nearest town of Puyo in east Ecuador. Up to now, it only had sparse access to electricity although there is an urgent need, i.e., for medication cooling, education, and lighting. There are some PV cells installed and diesel (has to be flown in) generators but by far not enough to cover all basic needs.

The region with an almost closed rainforest area possesses an overwhelming biodiversity and a vivid culture of local indigenous tribes who struggle to preserve their identity and livelihood for their future generations. As this region is also blessed with different kinds of natural resources, there are various commercial ambitions for exploitation. International companies try to get access to believed oil fields or the huge potential of precious tropical wood.

UNESCO declared the region a biosphere reserve to support the sustainable development of the indigenous population. As energy forms the basis for it, a special focus needs to be placed on renewable supply. The goal is to share simple but effective technical solutions in order to enable locals to implement and spread the technology on their own. This can also form an appeal for the young indigenous generation not to leave for the cities but to stay in their communities to protect their forest and therefore play an essential role in global climate preservation. With the implementation of rainforest academies, designed by German artist Markus Heinsdorff, UNESCO provides secondary and tertiary education for the indígenas of the Shuar tribe.

Electricity in the Middle of the Rainforest

The assignment was to find a solution in collaboration with the indígenas to provide sustainable energy supply that is exactly customized to the local needs and on-site conditions. This demands special requirements as robustness and low-maintenance effort of the technology as well as minor ecological impact. External dependencies regarding technical support or fuel supply should be abstained from and low construction and operation cost guaranteed.

Scope of the Project

In order to assess the impact on the local society of the 250 inhabitants of Yuwientsa but also further upcoming project regions, a "social impact assessment" has been conducted according to the suggestions of the UN Centre for Good Governance (2006). The result of the assessed electrification was in overall positive under the constraint of close cooperation and involvement of the local population. The provided electricity demand of approx. 10 kW is mainly needed to illuminate the classrooms and housings. Furthermore, a computer with satellite-based Internet access and a refrigerator for medication need to be supplied. The abundant and reliable availability of water in this region proves the reasonable application of micro hydropower.

During a 2-week stay in the village of Yuwientsa, appropriate installation sites were searched for. It turned out that several layout possibilities are conceivable. A fundamentally important factor was the assurance of flood protection of the installed technical appliances. Several sites were excluded because of spiritual relevance. Finally two preferred sites were identified and surveyed in detail. The first one gave the opportunity of installing an overshot water wheel. The second would use a conventional, i.e., Pelton or crossflow turbine.

Close cooperation and information exchange with the local decision makers as well as with surrounding residents formed the basis of a successful joint project.

Hydrology

The conditions in Yuwientsa are determined by tropical daytime climate with an almost constant mean temperature of more than 20 °C. There is daily cloud cover with convective precipitation. Furthermore, there are distinguished dry (August until November) and rainy seasons (December, January, and May to July).

Surveillance of the hydrological conditions was the first step to assess the feasibility. As there was almost no information on the characteristic water discharges in and around Yuwientsa, the most important fact sources were the experiences and observations of the locals. Nevertheless, some short-term measurements were conducted to get a first impression. After a number of interrogations with people living in the surroundings of the streams, a first insight over long-term hydrological discharges could be gained. Important to mention are the very quick discharge reactions after heavy rainfall as a result of the hilly topography and rather small catchment areas.

In order to assess the seasonal deviations, a measuring gauge was installed at a close river together with the indígenas who check the level daily. But even with all the collected data, the hydrology can only be estimated basically. Through constructional measures, a minimization of negative impact was aspired.

On-Site Approach

The equipment was rather basic and aimed to be flexibly applied in rough terrain. GPS, altimeter, and measuring tape were used for spatial localization; bucket and stopwatch or yardstick for the cross section and leaves as tracers for the flow velocity were the low-tech but sufficient discharge measuring gears. Clear documentation with photos and sketches made later assessment and construction planning possible. Installation potentials were approximated by Eq. 1 with discharge Q and geodetic head H_{geo}:

$$P_{\mathrm{Turbine}} = 8 \cdot Q \cdot H_{\mathrm{geo}}\ [\mathrm{kW}] \tag{1}$$

Using a water wheel, the result will be reduced due to lower efficiency.

Eleven potential installation sites were identified around the village with a power range of 5–35 kW. After a detailed evaluation regarding energy demand, ecological impact, and flood safety, two preferred options were finally chosen.

Water Wheel

First option considered the use of an overshot water wheel at the river Yuwints close to the settlement. A small river drop with a head difference of 2.2 m ends in a bigger basin. The constant (according to the indígenas) discharge of 1.2 m^3/s (measured with tracer yardstick and stopwatch) will therefore offer a permanent hydropower potential of approx. 18 kW. The water wheel with 3.5 m width and 2 m of diameter can be constructed using mainly locally available material (Nuernbergk 2007). The foundation needs to be handled with special caution as it was not possible to further examine the underground conditions. Flood protection forms the most important challenge as an open water wheel is very prone to floating refuse. Therefore, the wheel will be installed in a protected recess with a separately controllable channel inlet. The powerhouse will be placed on an elevated position and driven by a V-belt (see Fig. 3).

Conventional Turbine

The second installation option uses a conventional water turbine with penstock. Best choices are constant pressure turbines like Pelton or crossflow. The latter are especially beneficial with unknown discharge changes and unknown water quality conditions. They possess a sturdy design and low maintenance effort in combination with flexible operation.

The considered site is located at the small river Río Yangunts close to the village center. With a penstock length of approx. 600 m a head of 82 m can be used. The water discharge of around 25 l/s would result in 10–13 kW of electrical power. According to the residents, the water yield is a little fluctuating but constantly available. The penstock alignment is best done along the brook – also in order to avoid air entrapments. The natural water reservoir with a volume of approx. 20 m^3 can easily be used as inlet structure.

Due to logistic but also economic reasons, a PVC penstock is the preferred option. The use of a pipe with 0.125 m diameter – as it is available in Ecuador – will result in a usable net head of $H_n = 58.3$ m and therefore 11 kW of electrical output. The maximum pressure according to hydraulic hammer calculations (Joukowsky equation) is $p_{\max} = 15.3$ bar (Giesecke and Mosonyi 2009).

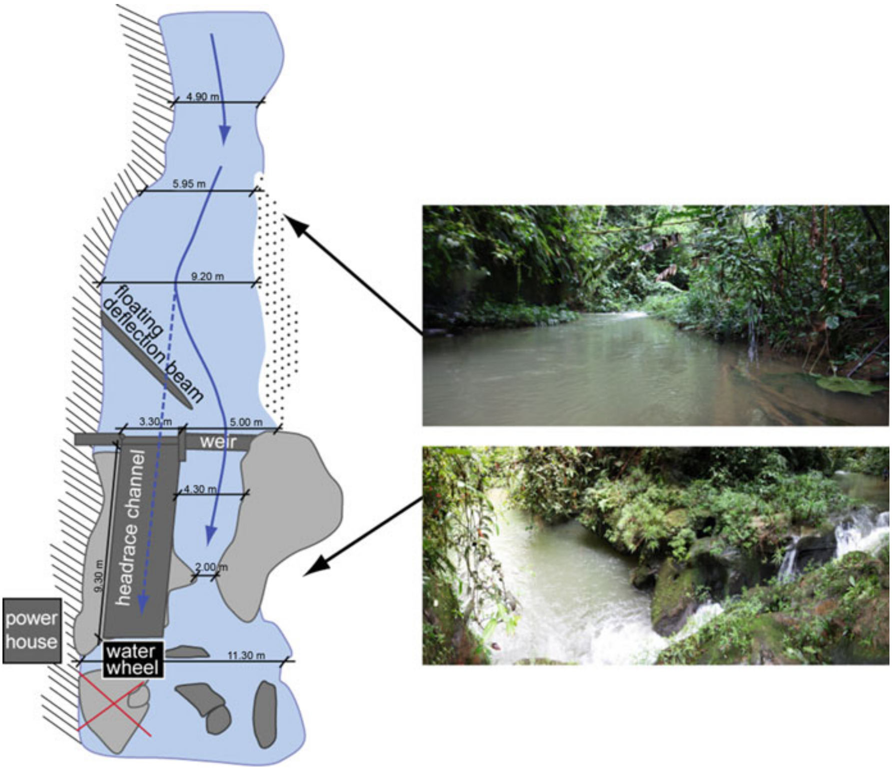

Fig. 3 Plot of the water wheel layout

Electrical Installation

For both installation options, the electricity is distributed through an island grid. For economic reasons as well as the lower freight weight, an asynchronous generator is recommended – even though it has a higher control demand (Williams and Simpson 2009). Basically the produced electrical energy needs to be stored and buffered in batteries.

Outlook

The choice between the suggested options will finally be done by the community of Yuwientsa – also with regard to financing options. Therefore, the results of this study were translated to Spanish and handed over to the village elders. It forms the basis for financial aid requests. Costs are approximated at 30,000 € for the water wheel option and around 50,000 € for the conventional turbine layout (not including labor).

The central concern of the project was and still is knowledge exchange. This is accompanied by the training of hydropower specialists. Close cooperation during

Fig. 4 Indigenous hydropower specialist Tibi with water wheel model (*left*) and in operation (*right*)

the whole stay, permanent consultation, and inclusion of the indígenas made a vivid exchange of experience and knowledge possible for both sites. This formed the foundation of a better understanding of the other's lives (Fig. 4).

Conclusion

Climate change happens. A mean temperature rise of 2 °C is said to be severe but somehow controllable. So if mankind succeeds to limit warming to acceptable temperatures, still any effort has to be taken to adapt to the changing conditions. Any effort means to integrally collaborate worldwide.

Here, a fairly minor approach has been presented. From the reflections that (a) water is global warming's central element, (b) the poorest will be hit hardest, and (c) higher education is the basis of development, an integrated concept of hydraulic knowledge exchange with emerging and developing countries has been elaborated. The importance of the bond between research and higher education – the von Humboldt ideal – has been noticed, and a teaching concept from descriptive fundamental hydraulics to state-of-the-art open-source research and application software for the hydrodynamic determination of flood risk areas has been illustrated.

Finally, the electrification of a village and a rainforest academy in Ecuador using hydropower has been shown. With UNESCO's support the living quality of the indigenous people is improved by satisfying their basic needs and offering higher education; they abstain from moving to cities and protecting their precious land from international timber and mineral oil enterprises. Unfortunately, the hydropower project was only realized in a much smaller scale.

Climate Change Knowledge Platforms Targeted at West Africa: A Review and a Focus on the New CILSS Platform

T. Ourbak and A. Bilgo

Contents

Abstract

Climate change in West Africa has important impacts due to the low resilience capacity of the majority of the population in these territories. However, on the contrary, in most regions of the world, data and informations on climate change and particularly adaptation are sparse and sometimes difficult to obtain. Nonetheless, scientific state of the arts, policies, as well as tools and funding opportunities and agenda on climate change initiatives are a great challenge for West African stakeholders.

To fill the gap, in November 2012, CILSS/AGRHYMET launched their climate change and sustainable land management platform to allow for easy access to informations targeted at West Africa.

The goal of this chapter is to propose an overview of existing platforms, analyzing assets and differences, and to present CILSS/AGRHYMET platform in this context. Details are given on the platform structure, the "opportunity," "agenda," and "news" parts. A rapid focus on CILSS past and present projects is also presented. Thematic articles concerning essentially agriculture and water, the heart of AGRHYMET's actions, are presented then in the resources part:

documents, tolls (to challenge vulnerability), and database (AGRHYMET master's students, institutional and individuals, etc.). A presentation of different tools available for download or access on the Web, adapted to a West African use to study vulnerability to climate change and other aspects like mitigation, is made.

Introduction

Sahel is often designated as the territory in the south of the Saharan border. It is characterized by low precipitation rates, sparse vegetation, and a rain-fed agriculture mainly based on crops and livestock breeding. Although indigenous knowledge has proved to facilitate adaptation (e.g., Waha et al. 2013), Sahelian countries, among the poorest of the world and also the ones that are the most vulnerable (Niasse et al. 2004), are subjected to drought periods such as the 1973–1974 one or more recently in 1983 (Sarr 2007). Recently, flooding events have been recorded, with important societal impacts (thousands of deaths, Sarr 2010). After the 1973 drought, a few governments decided to create an institution to fight against drought: the Interstate Committee for Drought Control in the Sahel (CILSS). This organization is working to lower the vulnerability of Sahelian countries, this vulnerability being exacerbated by climate change-related phenomena such as temperature increase (Sarr 2012), precipitation variability (Ali and Lebel 2009), and sea level rise.

More and more focus is given to climate change impacts: sea level rise, temperature warming, droughts, extreme events, etc. (IPCC 2007). However, there is a gap between scientific data, research activities, operational needs on the ground, and political action. It has been reckoned that capacity building was necessary to help stakeholders to tackle climate change issues: the way the information is transmitted, popularization processes, and stakeholder empowerment need to be reinforced. The webscape is growing in West Africa, and a lot of UN organizations, NGOs, and institutions are willing to make the information available; but if a myriad opportunities exist for Web users, most of the websites are very specific or, on the contrary, with a large geographical scale with a proliferation of "global" websites not specifically adapted to local West African needs.

In the context of raising attention toward climate change and sustainable development, Africa has around 14 % of the population, but release less than 4 % of greenhouse gases. Thus, although mitigation (i.e., emission reduction with renewable energy or forestry practices), is receiving more and more attention, the main concern for the African population is to be able to be resilient to climate changes (adaptation).

The following text will focus on adaptation, specifically to West Africa, where 13 out 17 of ECOWAS (Economic Community of West African States)/CILSS countries are part of the 49 least developed countries according to UN classification (see http://www.unohrlls.org/en/ldc/25/). It is important to note that adaptation, especially in West Africa, is a transversal topic covering both climate change and desertification under the United Nations negotiations. The CILSS/AGRHYMET website presented here is unique in the sense that it addresses topics related to both UNFCCC (United Nations Framework Convention on Climate Change) and UNCCD (United Nations Convention to Combat Desertification).

The Climate Information Knowledge Gap

Since 1992 and the Rio conferences, environmental issues have raised more and more attention. In particular, climate change has drawn a lot of attention, notably because of IPCC's successive reports, alerting the world on the potential impacts and effects of a changing climate on various sectors (health, economy, environment, etc.).

Most attention has been recently focused on the lack of information available for both policymakers and nonspecialists (media, civil society). The latter is particularly effective when looking at Sahel and West Africa. For instance, the 1970s and 1980s presented noticeable drought periods, which had impacts on the population (food security, livestock issues, water shortages, etc.).

Sahelian governments (up to 13 countries are part of the CILSS in 2013) joined efforts in order to work for food security and sustainable environment. Although data do exist on climate and also on land management, there is a gap between stakeholders and data users.

Overview of Existing Informations

The World Wide Web had been a revolution for the diffusion and access to information. Nowadays, a lot of websites are focused on climate change and particularly, in the context of this chapter, climate change adaptation.

Table 1 summarizes some of the major available websites.

The main feature concerning Table 1, which is not an exhaustive and complete panel of existing efforts available, is that a lot of websites have a global approach. The first website is the only one targeted at West Africa. The West African Science Service Center on Climate Change and Adapted Land Use (WASCAL) is very specific, as it is dedicated to training and research, with PhD and master's programs. The next 5 first platforms presented in Table 1 are dedicated to the whole African continent, and the Web user could find a lot of very useful informations such as updated newsletters and detailed documentation on specific topics. The other websites presented have a worldwide view and, again, bring to the table several crucial informations (the World Bank website presents climate situation nationally, for instance); many specific tools are presented that could be used by policymakers as well as development practitioners on the ground (e.g., methods to mainstream

Table 1 Snapshot of existing platforms

Name and website link	Principal organization/institution/program	Geography	Thematic	Plus	Minus
WASCAL (West African science service center on climate change and adapted land use) https://icg4wascal.icg.kfa-juelich.de/	Federal Ministry of Education and research. Center for Development research (Univ. Bonn)	Ten West African countries	Climate and weather, landscape dynamics, agricultural systems, markets and livelihoods, risk management	Focus on research	Site under construction, English only
Réseau AfricaAdapt (consortium) http://www.africa-adapt.net/	ENDA (Environnement et Développement du Tiers-Monde), FARA (Forum for Agricultural Research in Africa), ICPAC (IGAD Climate Prediction and Applications Centre), IISD (Institute of Development Studies)	Africa	Adaptation (thematic or geographical entries)	A real network of people, sharing ideas	Portal could be more dynamic
AAKNet: Africa adaptation knowledge network (UN) www.africa.ganadapt.org	UNEP (consortium of 9 partners)	Africa	Thematic, geographic, projects, knowledge base entries	Dynamic, lot of documents	Difficulties to download in African places, mix of languages (mainly English but sometimes in French)
*Afri*CAN climate (EU) http://www.africanclimate.net/	Funded by UE, coordinated by **WIP Renewable Energies (Germany) with 5 European and 5 African organizations**	Africa	Research, policy, good practices, indigenous knowledge, finance and geographical entries	Filtered parts, practical (e.g., financing guidebook)	Program will end in 2014, not specific to Africa

ACCRA (African climate change resilience alliance) http://community.eldis.org/.59d66929/	Consortium of NGOs	Africa	blogs	Files not regularly updated	Growing community (less than 600 members in May 2013)

Adaptation learning mechanism http://www.adaptationlearning.net/	Joint effort from main UN agencies + UNFCCC	Global	Based on communities	Interactive map, very diverse entries (from agriculture to workshop materials)	Difficulties in accessing the website (download elements from the map)
Community adaptation based adaptation exchange http://community.eldis.org/cbax/	Community (more than 1,000 in May 2013), launched by NGOs	Global			
The knowledge resources page of UNFCCC adaptation http://unfccc.int/adaptation/knowledge_resources/items/6994.php	UNFCCC (different work streams: Nairobi Work Programme, NAPs, NAPAs, loss and damages)	Global	Databases, publications, LDC portal, newsletters	A complete website from the international climate change negotiations	Portal could be more dynamic and focus on user needs and user friendliness

climate change into policies to climate proofing tools). Most of the websites are user friendly and easy to discover for the nonspecialist while containing targeted documents or informations.

One notes that most of the websites are from international organizations, such as United Nations websites, or NGOs (nongovernmental organizations). It is important to note the United Nations Framework Convention on Climate Change website, very complete, which addresses the outcomes and presents the material of the negotiations. Some websites are project related, such as the Africa Adaptation Programme, which could lead to a potential problem of durability and dynamism once the funding is over. Most of them contain a lot of informations that are user friendly.

A lot of different languages are used in Africa. In Table 1, all the websites are accessible in English and 7 out of 12 in French, and other languages such as Spanish, Portuguese, Arabic, or Deutsch are also available. It is to note that two websites propose translation in numerous languages such as Afrikaans or Swahili. However, some websites propose only the translations of titles and rubrics. Most of the sites are aimed at disseminating information to professionals and not to producers and politicies makers. The forum is a way for users to ask specific questions. The CILSS/AGRHYMET website is doing an effort to adapt the knowledge and science presented, for instance, thematic pages, with simple figures helping the reader to have a better understanding of complex topics.

However, not a lot of governmental websites such as the ones you could find in most of the developed countries exist in Africa. This could bring the issue of the validity of information found for policymakers and governmental stakeholders. For instance, a politician working in health issues could be interested to have access to several informations such as climatology of flooding events or heat waves. This specific example could be translated to many sectors where the information could be very difficult to obtain. We already have had feedbacks from local and national West African agricultural organizations using technical informations provided on the platform. Moreover, although the number of platforms is important, most of them are not specifically targeted at West Africa, although recognized as a very vulnerable region, and bring a large amount of general considerations on climate change.

Presentation of the CILSS Platform

When creating the CILSS climate change and sustainable land management platform, the idea was to create a unique site where one can find diverse informations targeted at West African needs. Figure 1 presents a snapshot of the CILSS/AGRHYMET platform (www.agrhymet.ne/portailCC).

Six parts have been created:

- The NEWS part is the most consulted one so far. It is regularly an updated source for opportunities of training and funding, for example, but also news and agenda.

Fig. 1 Snapshot of CILSS/AGRHYMET platform (July 14, 2013)

For instance, call for grants and application for projects or programs are recorded. Any stakeholder could find a peculiar call for grants and a researcher could have information on a specialized workshop as well as general conference and could find an updated intergovernmental negotiations process; the three rubrics are the unique entry to keep up with what is ongoing for the West Africa Adaptation world.

- The MENU part is a more classical package, with a presentation, informations on teaching activities from the AGRHYMET Regional Center, useful links to navigate the Web, and a presentation of the platform, contact, and a research tool.
- The PROJECTS part presents emblematic ongoing or achieved CILSS projects. This is a unique way to capitalize a multi-project database and to make sure the information is still available even after the end of funding (e.g., the “Projet d’appui aux capacités d’adaptation des pays du CILSS au changement climatique” project was a pioneer and innovative project tackling climate change issues in West Africa, and some of the most important documents produced are made available).
- The THEMATICAL part presents popularized, easy-to-understand access to the following areas of CILSS expertise: climate science, adaptation, mitigation, climate governance, and water management. The climate science part describes

West African climatology, monsoon system, and hydrology regimes and presents the climate change context. The adaptation part describes some generalities that focus on agricultural practices adapted to climate change in a rain-fed context, an irrigated context, and finally a pastoral context. The mitigation part presents several aspects of the mitigation issues for West African countries, such as financing processes and CILSS actions. The climate governance presents the Intergovernmental Panel on Climate Change process, as well as the negotiations under UNFCCC, and focuses on the regional as well as national level of political documents. Finally, the water sector is presented with a special attention drawn on impacts of climate change on water and a few adaptation strategies.

- The RESOURCES part presents several documents such as CILSS documents, national and regional documents (National Adaptation Programmes of Action (NAPAs) (under UNFCCC) but also national action programs (under UNCCD) as well as West African organizations such as ECOWAS policy papers), synthesis documents and also tools and products (mitigation, impacts and vulnerability, sustainable land management, etc.), database on CILSS students, and finally scientific publications. It is sometimes a unique way to have access to such documents.
- The FORUM part is a very new part and is trying to bring experts to discuss various topics. As an example, the first topic is the cost of adaptation in rain-fed West African agricultural systems.

This site has been launched at the end of 2012. So far, 7 months after launching the report, it has received more than 30,000 views. The question of language is crucial to reach a maximum of users. At the beginning, we have produced only a French version. However, noting that around 15 % of our users are connected from English-speaking countries, we have added an English translation to reach more users. However, CILSS is willing to translate the website in Portuguese to cover the official languages of the CILSS/ECOWAS region. It is important to note that a mean of 5 min is spent by every user and that around 40 % are regular users (i.e., which come back regularly to the website) visiting 3 pages on average.

Concerning the geographical origin of the Web users, the vast majority are connected from African countries, namely, Niger, Burkina Faso, Senegal, Togo, Benin, Ivory Coast, and Mali, whereas less than 15 % originated from developed countries (France and the United States).

Conclusions

While climate change impacts are widespread all over the planet, a lot of attention has been given in order to make information accessible to Web users. However, although very vulnerable, the West African region has not received a lot of attention specifically focused on West African regional circumstances. After reviewing the existing platform, the chapter has presented detailed informations related to the CILSS climate change and sustainable land management platform. The next step to improve the platform is to work with more focus on user needs. The CILSS is willing to start a dialogue with different types of stakeholders in order to publish informations useful for the most part. A fine analysis of the utility actual users are making of individual pages is in progress and should flourish the development of new informations. It is expected to produce a questionnaire and to send it to Web users, to produce more demand-driven information. The forum part should be more active, and a work is also under progress by CILSS experts in order to determine the most effective way to make experts react to posted articles. Finally, the network should be strengthened inside and outside West Africa in order to transfer knowledge and to spread out good practices and tools, for example, by presenting the platform to international fora, such as the Conferences of the Parties of the United Nations Framework on Climate Change Convention (UNFCCC) or other relevant fora, but also by having a communication strategy to "spread the word," by e-mail lists, newsletters, and interaction with other platforms.

The lesson learned is that the strong demand for information posted on the platform is a real challenge. While climate change issues are getting more and more attention, there is room for information sharing and dissemination of all kinds of informations to those who need it; however, there is a lot of overlapping and much attention is done to specific topics or areas. Although not directly linked to it, this website is part of a broader Nairobi Work Programme on impacts, vulnerability, and adaptation to climate change ongoing under UNFCCC. An incoming challenge will be to make this platform more interactive, with a discussion forum, and the possibility for the Web users to ask for specific questions to the community and for specific topics to be treated in the website. The first feedbacks we had are encouraging, and counting methods teach us that the vast majority of users are coming back regularly. The next step is to better understand their needs (so far, the majority looks for opportunity) as well as attracting new users. This website is one of the milestones in building a common response to climate change and building a more resilient Africa.

Acknowledgment This work is funded by the Fonds Français pour l'Environnement Mondial and the French Ministry of Foreign Affairs.

Climate Resilience in Natural Ecosystems in India: Technology Adoption and the Use of Local Knowledge Processes and Systems

Prakash Rao and Yogesh Patil

Contents

Abstract

Excess water and energy consumption, unplanned urbanization, and consumption patterns may form the key indicators of future climate mitigation. Entrepreneurship-based ventures in energy and agribusiness with strong community focus coupled with traditional knowledge processes can go a long way in strengthening community systems. The chapter proposes an approach to enhance

the coping capacity of the community, and vulnerability reduction is proposed through use of technologies and local knowledge systems. Combining traditional knowledge systems with new research ideas and development of innovative technologies can provide a suitable adaptation response in the face of adverse climate impacts. The use of innovative technologies like geographical information systems, software-based weather systems, low-cost and decentralized technologies, as well as industrial symbiosis as a concept is therefore proposed. The chapter proposes a paradigm shift in the way government programs are conceptualized and implemented through innovative technology diffusion and industry action. The solutions suggested in the chapter have significant benefits for rural communities and ecosystem-dependent stakeholders with a focus on integration of natural resource base and socioeconomic concerns of local communities.

Introduction

In recent times, at least in the last 200 years, humanity has made rapid strides in economic growth across the world. While an agrarian economy might have remained a major base and perhaps so even today in many parts of the world, the desire to expand horizons and explore vast frontiers has led to creation of an industrialized economy. Such an economy which brought about huge economic progress to millions of people through better living standards, access to communications, transport, health care, education, etc. also meant that there were significant impacts to the local environment over several decades.

The past few decades have perhaps been one of the most tumultuous phases in the development of humanity in the context of three important sectors, namely, industrialization, sociocultural values, and the environment. While the first two sectors have seen phenomenal increase in intellectual thought process leading to innovation and creative desire to excel, the third sector, namely, the environment, has perhaps borne the brunt of the rapid progress made by industrialization.

In the 1900s most of the developed group of nations moved ahead rapidly, through rapid industrial growth to create a welfare system within their polity. The European Union and United States formed the largest group of nations where rapid industry growth was an indicator of progress and growth. However in the Asia Pacific region and in particular countries like India which were under the rule of foreign nations or were just about emerging from colonialism in the early half of the 1900s were seen to lag far behind in terms of industrialization. In India this could be divided as preindependence era and postindependence era. This chapter, while tracing the overall historical perspective of environmental issues, a factor in corporate and societal governances, focuses on some of the rapid stride and changes made in the last few decades in postindependence India.

The postindependence India has also been the period when much of the world's efforts have gone into building institutions of governance across the world ranging from political, economic, social, and environmental paradigms. Education has played a key part in driving the paradigm of growth across these sectors in the past 50 years or so. Since 1947, independent India has had a major thrust towards industrialization, and building the country's granaries to fulfill the needs of its citizens was a key priority.

Climate Change: A Global Environmental Threat

Changes in precipitation, temperature, glacial melt patterns, and sea level rise are being seen as increasingly affecting the world's ecosystems and natural resource base. The Intergovernmental Panel on Climate Change (IPCC) has provided clear evidence of the impacts of climate change on biodiversity and the increasing vulnerability of some critical ecosystems and consequences for livelihoods of people. The recent erratic weather and monsoon patterns in the Indian subcontinent coupled with climate variability and rise in the incidences of extreme events like cyclones are major threats to the ecosystem, e.g., low-lying islands, some of which are already facing partial submergence resulting in shoreline changes (Dinesh Kumar et al. 2007). In places with high human density and dependent on an agro-economy, such changes have often led to adverse impacts on the local eco-diversity. Ecosystem-dependent communities are particularly vulnerable where single-crop agriculture, fishing, and harvesting of other local resources are practiced. These in turn could be adversely affected by changes such as sea level rise, increase in salination, changing patterns of rainfall, and increase in moisture content in the atmosphere leading to increasing incidences of vector-borne diseases, e.g., fishing communities along the coastal region are at increased risk due to reduced fish catch as a consequence of warmer seas.

The Decade of Sustainable Development

The early 1990s perhaps can be termed as a landmark decade in the history of humanity as it was the realization of some of the most important global environmental threats which were reviewed by the United Nations. It was also one of the decades when the entire issue of sustainability as a tool of corporate business practice became a reality with the involvement of major industry players, civil society, academic bodies, and the United Nations. In 1992, the United Nations Conference in Rio de Janeiro, Brazil, also popularly known as the Earth Summit (www.un.org) established three major international conventions namely:

- The Convention on Biological Diversity (CBD)
- The United Nations Framework Convention on Climate Change (UNFCCC)
- The United Nations Convention to Combat Desertification (UNCCD)

The UNFCCC was considered one of the most important conventions established to fight the global threat of climate change through mitigation and adaptation efforts. While corporate social responsibility as an ethical business practice was in prevalence for a few years, it was only after the establishment of the UNFCCC and other industry bodies that environmental management and sustainability practices began to be seen by business and industry leaders (Adams et al. 2011) as an important part of their business operations. The mitigation efforts under the UNFCCC also provided for various market mechanisms like the Clean Development Mechanism (CDM) and Joint Implementation (JI) and emissions trading as a means to get the corporate world into meaningful involvement on sustainable development activities (www.unfccc.int).

Impacts of Climate Change on Ecosystems and Processes

Climate change is expected to have a series of impacts on India's natural ecosystems like water, agriculture, coasts, mountains, and forests. According to the Fourth Assessment Report of the IPCC (2007), some of these impacts are likely to be felt across a range of systems causing severity of damage for most vulnerable ecosystems.

Water

Climate change is likely to have impacts on the hydrological cycle with underlying impacts on rainfall, increased precipitation, river flows, increased glacial melt runoffs, decreased groundwater, rise in flood-related events, etc. Field initiatives have shown the rapid changes occurring in the Himalayas in retreat of key glaciers by various agencies (WWF 2005; Rao et al. 2009). The scientific community has developed models linking temperature rise and glacial retreat to changing river flows. Future scenarios addressing subsequent impacts on freshwater availability for agriculture, hydropower generation, etc. are of critical concern. This has implications for regional water, food, and energy security in the South Asian region.

Agriculture

The Indian agriculture economy has been typically weather and monsoon dependent and therefore is vulnerable to climatic variability each year. The presence of several agroclimatic zones with a diverse range of crops and grains has resulted in severe dependence with impacts on soil and crop processes. Changes in freshwater supply in the perennial rivers will affect agriculture productivity across different zones. Increases in temperature and water stress are expected to lead to decline in crop yields up to 30 % and changes in phenology and time of growth. For the Indian economy, this could lead to increasing demand for food production, increased competition for land resources, deterioration of agri-environments, scarcity of water resources, and changes in weather conditions. Recent simulation studies on crops indicate a decrease in yield of crops as temperature increases in different parts of India, e.g., for a 2 °C increase, rice yields could decrease by about 0.75 t/ha in the high yield areas. The loss in farm-level net revenue will range between 9 % and 25 % for a temperature rise of 2–3.5 °C. The total food grains production in the country rose from 50 million tonnes – 1950s – to 210 million tonnes by the turn of the century. Food security is under stress largely due to increase in population and demands for energy and freshwater.

New management practices are seen as an adaptation response (Rao 2010). Complex agroclimatic conditions make such practices difficult with low technological and financial adaptability of the community. At existing rate of growth, increasing temperature and more variability of precipitation will put 50–120 million more people at risk of hunger and food prices likely to show an upward trend throughout the global economy. In India, combined effects of poverty, water scarcity, less predictable harvests, and climatic changes are most likely lead to increased conflicts. The rate of growth of agricultural production has been the lowest since India gained independence, from after 1991 till the present. In such a circumstance under severe climate stress, there could be reduced food grain and agricultural production with low per capita availability of food grains.

Adaptation responses and strategies to tackle climate-related stresses could take the shape of climate-smart knowledge processes like:

- Educating farmers in appropriate energy-conserving farming techniques
- Provisioning of seeds of crops that could withstand variable weather conditions
- Use of drip irrigation in place of flow irrigation and enhanced water use efficiency
- Practicing participatory integrated watershed development programs
- Facilitating farmers in developing suitable markets for their produce, and getting a remunerative price
- Concessions or special market outlets or price support
- Production management and practices

At policy level, linkages to the National Mission on Sustainable Agriculture, the National Water Mission, the Integrated Energy Policy, the National Horticulture Mission, and the National Rainfed Area Authority could be explored to address adaptation responses.

Benefits of Developing Localized Knowledge Processes for Society

While there are many facets to developing solutions for climate change in the area of agriculture and coastal ecosystems, there are clearly incremental benefits to society and ecosystem-dependent communities in using technology-based knowledge processes. This could include both individuals and enterprises whose core business is dependent on climate factors. The use of ICT-based solutions also has shown that developmental issues can be addressed on an equitable and sustainable basis where economic, social, and environmental parameters are considered as central to the economic prosperity of society. The role of ICT and agri-retail innovation in rural Indian markets can be seen as a form of climate adaptation for the agribusiness sector.

Apart from agri-related interventions, climate-smart knowledge processes also play a key role in watershed management and the involvement of civil society. The sustainability practices followed by the Indian business conglomerate ITC Ltd. is a case in point where several watershed initiatives have been implemented across arid and semiarid regions of India through collaborative initiatives between industry and civil society groups. Along with water, the role played in the use of efficient energy systems is equally important in developing a sustainable business operation. The importance of decentralized energy generation technologies like biomass power in agricultural markets and wind energy in coastal systems are of great significance.

Information and Communication Technologies for Building Knowledge Processes

In recent times, many global environmental changes have increased the vulnerability of its ecosystems and people. Two of the most sensitive ecosystems in the Indian subcontinent, namely, the coastal region and the Himalayas, are under tremendous pressure from a wide range of biotic and abiotic pressures leading to increased stress to the natural ecosystem and livelihood of people. The increased pressure from resource scarcity in such critical ecosystems often causes a severe imbalance to the economic growth and livelihood patterns of local people and regions. This has long-term implications for sustainability of a region's diversity from environmental, social, economic, and technological perspective. The use of information and knowledge-based systems is a step in understanding some of the dynamics of such complex ecosystems and can greatly contribute to the mitigation efforts of environmental stress (Rao and Patil 2011). Increasing use of technology also means that there needs to be a holistic approach to building capacity of all levels of stakeholders to understand some of the techniques for adapting to changing environmental conditions. This included recent advances in developing sciences like industrial ecology which are shaping the development of integrated industrial centers with high levels of interdependence, thereby providing an alternate adaptation action plan to climate change and low carbon development.

Coastal Systems

The use of information and communication technologies has greatly enhanced the resilience and adaptive capacity of the coastal ecosystem. Studies by researchers in the low-lying coastal region of the east coast of India have tried to introduce various state-of-the-art technologies to understand the local systems better. A comparison of satellite data from 1998 to 1999 showed that some of the islands in the Sundarbans delta in West Bengal, India, have undergone severe erosion of about 3.26 km^2 (Kumar et al. 2007). International conservation organizations like the World Wide Fund for Nature (WWF) have helped bring technology closer to the needs of local communities in order to ensure that the tools and technologies can act as an aid to quantify the extent and nature of the development change to develop sound and sustainable land-use practices. Deltaic regions, like the Sundarbans, experience repeated occurrence of cyclonic storms and depression, and communication tools like early warning systems need to be strengthened to increase adaptive capacity. The WWF Climate Adaptation Centre at Mousuni Island in the Sundarbans is an example of building local knowledge for local communities. This is being achieved by integrating academic, industry, and civil society involvement in helping to bring out natural solutions and helping local communities towards sustainable development against adverse impact of climate stresses. Setting up of these early warning systems is an excellent example of addressing disaster risk reduction from a short-term and a long-term perspective. The use of high-resolution remote-sensing technologies has also helped to get a better understanding of coastal zone dynamics and developing response mechanisms. A recent study using high-resolution digital elevation model data and importing more than 80,000 GPS point data sets (Loucks et al. 2010) in Bangladesh Sundarbans suggests that an expected sea level rise of 28 cm above 2000 levels is likely to severely impact the remaining resident population of the Bengal tigers in the Sundarbans ecosystem.

Agriculture Systems

One of the major sectors which drives the economic activity of a large developing nation like India is agriculture. Much of India's agriculture economy is monsoon dependent, and rural poor and farmers living in the rainfed regions are vulnerable to the variability of the monsoon leading to either excess rainfall or drought-like conditions. The limited resources at the disposal of the rural communities coupled with high level of climate risks identified are a threat to food security, livelihood, and economic prosperity of local communities. Scientific institutions and civil society organizations have therefore been trying to design appropriate coping strategies and mechanism aimed at building a sound adaptation framework to meet some of the threats.

While technology-driven processes like low-cost water-harvesting solutions have their benefits, it is important to first understand the needs and perception of the farming community on the importance on climate change and its impacts on agricultural productivity as well as current adaptation measures being taken up. Under the Government of India's All India Coordinated Research Project on Agrometeorology, a recent survey found that about 70–100 % of farmers had prior knowledge about climate change-related issues. Enhancing rural livelihoods option in rainfed regions in remote and inaccessible terrain like the Himalayas requires innovative technology interventions to enable rural farming communities to address future impacts of climate-related stress. Institutions like the MS Swaminathan Research Foundation, Chennai, India, have pioneered the concept of a village knowledge center in several states across India. These act as resource centers which provide information on local weather forecasting through weather-based agro-meteorological observatory services and crop management practices through Internet kiosks.

Local Knowledge Centers of Farmers

In the state of Andhra Pradesh, India, village-based knowledge centers have been developed where science-based ICT tools have been used to predict the variability of drought-like conditions and micro-level preparedness against drought. The International Crops Research Institute for Semi-Arid Tropics (ICRISAT) with assistance from the Government of Andhra Pradesh have developed a low-cost ICT tool in eight villages aimed at providing detailed queries about local agricultural and weather patterns to village communities through the use of a desktop-based system connected through an Internet hub. A local NGO coordinates these rural knowledge centers through maintenance of the records of responses and solutions provided by technical experts (Sreedhar et al. 2009). The rural knowledge centers have also helped build capacity for local women to undertake their own weather measurements of rainfall temperature. Generation of local-level drought vulnerability maps using GIS-based color-coding mapping tools has helped raise awareness about drought impacts in the region. Community perception about past weather patterns and drought vulnerability assessments is a key component in developing a knowledge-based adaptation practices besides useful use of technology and communication tools. ICT tools at community level will ensure availability of critical information at the right time apart from getting a better understanding of future climate risks.

Industrial Ecology

For most developing countries, economic development has been the issue of top priority as a machine to enhance social prosperity. In the process, eventually for the sake of development, the environmental protection/conservation part was left far behind (World Bank 2000).

In the light of the above background, the present integrated program at symbiosis decided to introduce a new integrated industrial planning and management mechanism in its curriculum. “Industrial ecology/symbiosis/ecosystem” is one such emerging concept in the evolution of environmental management paradigms (Ehrenfield 1997) and springs from interests in integrating notions of sustainability into environmental and economic systems (Ehrenfield 1997). The concept of industrial ecology was first introduced by Frosch and Gallopoulos in 1989 (Heeres et al. 2004), and since then industrial development has entered a new perspective of production and process system. Industrial development thus should resemble the natural ecosystem because, in such a system, energy and resources are optimally used and wastes are absent. In contrast to the earlier viewpoint, industrial ecology considers industrial waste or any other waste (both hazardous and nonhazardous) as an "economic resource" (Ehrenfeld and Gertler 1997; Itankar et al. 2013), which, upon reducing, reusing, and recycling, and recovering means greater profit to the industries/companies in that ecosystem. Industrial symbiosis is designed such that industrial areas are developed mimicking a natural ecosystem (Garner and Keoleian 1995). Natural ecosystems are self-contained and self-sustained and generate zero waste through complex interactions of food chains. Industries are visualized as interacting systems rather than isolated components in a system of linear flows. Waste materials and energy emanated from one source are used as feedstock by other (life cycle approach – cradle to reincarnation). Thus, the model of industrial symbiosis or eco-industrial park (EIP) in developing and underdeveloped countries would have an opportunity to manage their waste to become sources without much investment in the technology of waste management (Bhat et al. 2012; Patil 2012). It will also (a) help industries to improve their environmental performance and strategic planning and will become more competitive; (b) help local communities develop and maintain a sound industrial base and infrastructure without sacrificing the quality of their environments; and (c) help local, regional, and national government to formulate policies and regulations in order to improve environmental protection with simultaneous building of business competitiveness.

One example of industrial symbiosis/ecosystem being practiced in India is at Naroda Industrial Estate (NIE), Gujarat, which was established in 1966 by the Gujarat Industrial Development Corporation (Hauff and Wilderer 2000). This estate is spread across 30 km^2 and consists of 700 companies, which mainly include chemical, pharmaceutical, dye and dye intermediate, engineering, textile, and food production units. Naroda Industrial Association (NIA), which was formed by 80 % of the companies, has founded a charitable hospital and a bank, has constructed a common effluent treatment plant (CETP), and has also planted more than 30,000 trees. NIA and the local bureau of the Confederation of Indian Industry (CII) took up the leadership role by creating the industrial ecology networking in NIE. This began with a baseline survey of NIA members by identifying common environmental problems and focusing primarily on materials, water, and energy usage. NIA convened open meetings in which the companies explored their needs, using a broad eco-industrial network framework as proposed by Rosenthal and Musnikow (2003). This exercise resulted into four priority projects – namely, recycling of spent acid, recycling of chemical gypsum, recycling of chemical iron sludge, and reuse/recycling of biodegradable waste. These projects after its successful implementation resulted into several benefits like conversion of waste products into value-added products for its possible recycling in industries, reduction in transportation cost (logistics), provision of new jobs, reduction in waste disposal cost, reduced demand for natural resources, saved landfill areas, improved profit margin of the industries, energy savings, and several others. Immense success in the first four projects triggered the development of the fifth project in the later stages, wherein 15 ceramic firms came together and invested in ceramic testing laboratory, thereby assuring cleaner production. Thus, the industrial ecology initiative at NIE had clearly demonstrated over the years that the collaborative approach of all isolated companies can effectively improve their environmental and financial performances (Hauff and Wilderer 2000). Other than NIE, there are few other examples of industrial symbiosis happening in India like Tirupur textile sector, Tamil Nadu tanneries, Tamil Nadu paper-sugar complex (all three in the state of Tamil Nadu), and Calcutta foundries, West Bengal (Bain et al. 2010; Erkman and Ramaswamy 2000). It has not escaped the authors' attention that an excellent example of agro-based industrial symbiosis does exist at Warananagar, District Kolhapur, located in the southern part of Maharashtra. This industrial symbiosis has a networking of sugar, distillery, pulp and paper, and dairy industries along with the process like aerobic composting, biogas generation, and agriculture system. However, the Warananagar industrial symbiosis has not been documented so far.

Future Trends

The need for continuous monitoring of ecosystems necessitates the availability of state-of-the-art technology and tools apart from regular capacity building of manpower to use the technologies (Rao 2010, Rao and Patil 2011). Various ecosystems have their own inherent limitations for use of ICT-based tools. It can be said that though there have been many studies conducted on most of the agro- and coastal ecosystems, the lack of baseline data poses as a major limitation in documenting continuous records of climate characteristics and meteorological observations. These are particularly relevant when agribusiness and coastal industries like aquaculture are heavily dependent on adverse climatic conditions. Also, complex interaction of spatial scales in weather and climate phenomena in mountains is not given sufficient importance at most of the times. Therefore, future content development in management education should incorporate knowledge processes that combine emerging technological tools and their role in assessments of climate risk from a business angle. Course curriculum could include:

- Information (improved regional forecasting, local community ICT-based knowledge networks)
- Insurance (innovations in micro finance, weather risk insurance products)
- Technology innovation and diffusion (improving efficiencies for agri-energy linkages), e.g., efficient pump sets in irrigation, captive power generation from agriculture waste, biogas, biodiesel, etc.

In agro-based ecosystems, the use of ICT tools is relatively less complex as it does not entail large investments, and monitoring of weather parameters can be undertaken with low-cost methods and solutions.

The need of the hour is to make use of modern tools such as satellite technology and weather stations and use the results for policy formulation on adaptation issues for the different ecosystem regions as well as catchment or watershed areas which are dependent on them. A multidisciplinary approach is required to integrate the ecosystem research in various sectors and across different stakeholders in order to promote sustainable growth models.

Technology interventions require a paradigm shift in bringing societal benefits in the face of environmental stresses. While there have been some good examples of technology-academia-civil society interface in this direction, a series of action-oriented policies and plans needs to be developed towards creating low-cost technology models in the area of solar power, LED lighting systems, water technologies and distribution services, etc. These could be embedded in the policymaking processes of local governments with the support of various technology providers and inputs from grassroot agencies and NGOs. The concept of providing efficient, reliable, and affordable technology-based services will eventually bring the state-of-the-art tools at the doorstep of large sections of society.

The tremendous growth in telecommunication technologies has seen an increased economic growth and prosperity across many parts of the world. In countries like Bangladesh, the concept of Grameenphone has helped empower some of the rural populace to enable them to move into the mainstream of society. In India, such a model could possibly be tested in key rural districts where access to communications and related services is often a major barrier for development and economic growth. Although the advent of mobile telephony has been seen as a game changer across many parts of India with a subscriber base of over 900 million, the lack of Internet-related services as a tool for social progress is still a problem.

Future research trends are likely to focus at developing and implementing low carbon technologies particularly in the renewable energy sector. Decentralized rural energy generation from solar and biomass power is being seen as solutions to a sustainable future. The recent National Action Plan on Climate Change by the Government of India released in 2008 provides clear focus towards sectors like solar energy, energy-efficient technologies, and increasing capacity of all levels of stakeholders by strengthening their knowledge domain.

The decades of the 1990s and 2000s are perhaps seen as a turning point not only in India's economic growth curve but also heralded a change in global understanding of business growth through increased market-based investment across several regions. In the context of business and industry involvement in sustainability and environmental standards and compliances, this can perhaps be termed as a transition economy considering that many technologies and regulatory structures are yet to be developed across these regions particularly in emerging economies. The opportunity of setting up sunrise industries in renewable energy, hybrid transport and mass public transport systems, waste to energy technologies, water distribution systems and services, low-cost technology diffusion across rural markets, and ICT-based innovation can be major markets for businesses to penetrate. However, it is important to note here that much of these industries are likely to expand only if there are adequate safeguards and incentives provided by regulatory institutions to commercialize technologies and services from just a drawing broad stage in research and development laboratories.

Conclusion

The coastal and agro-ecosystems are known to be one of the most productive ecosystems across the world, harboring a diverse range of floral and faunal elements. The range of ecological services generated by these ecosystems has tremendous implications for the well-being of communities and businesses in sustaining local livelihood and strengthening sustainable development of the region. The increasing developmental pressure being brought upon these regions as a consequence of unplanned development and urbanization (Mukhopadhyay and Revi 2009) have already resulted in severe pressures for both local ecology, business and dependent communities.

Future efforts in building the resilience of the local community and the ecosystems through technology-based knowledge processes should take into account a concerted and integrated approach. There is an urgent need by communities, business and industry, academic institutions, scientists, and policymakers to take a closer look at the linkages between local impacts, scientific research, policy interventions, and the larger understanding of using resource conservation technologies and practices for:

Technology and knowledge processes**:**
- Building local and traditional knowledge systems
- Development of resource conserving technologies
- Improved understanding of regional and local climate models
- Build capacity within management institutions, student community on strengthening technology innovation, and community-level practices

Policy level**:**
- Inter-sectoral collaboration
- Improved natural resource management policies and institutions
- Water and energy demand management
- Improved risk management through early warning systems and insurance schemes

A vision-based approach therefore needs to be adopted as a sustainable growth model for society. Ecosystem-dependent communities and local economies need to be adapted for environmental impacts and supporting mitigation advocacy. As part of this process, various stakeholders at multiple levels need to come together to address the issue of climate change and environment security.

- Local – community-level site-specific measures could be developed.
- National – consensus among stakeholders like industry, policy makers and citizen’s groups for national adaptation and knowledge management strategies.
- Regional – synergies among regional associations, networks, and policymakers.
- Global – supporting intergovernmental processes.

In the context of vulnerable ecosystems, some of the stakeholder groups could include:

- Poor and vulnerable
- Ecosystem-dependent communities (agriculture, fisherfolk communities, etc.)
- Decision-making bodies at local, state, and national levels
- Urban consumers
- Technology innovation and incubation groups
- Climate-dependent businesses and groups
- Regulatory groups
- Scientists and academic bodies

The stakeholder groups should also be fully inclusive, such as all genders, all castes, people with physical and mental disabilities, and minorities. A multidisciplinary approach involving several stakeholders on a common platform can stimulate integration of environmental concerns in overall development planning process. Empowering stakeholders through collaboration could take the shape of establishing institutional processes like Gyan Choupals with local civil society organizations and other stakeholders (MSSRF Report 2009). Environmental stress and impacts are still relatively less understood and strengthening capacity through awareness generation is an important part of building resilience (Report of 5th Convention of Grameen Gyan Abhiyan 2008)

Coupled with other activities this involves promoting the role of grassroots-level civil societies through the development of resource centers and creating local knowledge networks to raise the level of local development planning.

Technology development and technology enabled services play a major role in enhancing the resilience and capacity of society to prosper and achieve sustainable economic growth. Much of the future growth of society is likely to be centered on the ability to adapt to these tools and services to the benefit of humanity. The Internet revolution has already seen a tremendous change in shaping global economies, and perhaps the world is now at the crossroads of using other innovative technologies for creating a sustainable society.

The importance of environment as a compulsory element of primary and secondary school curriculum has already been implemented by the Government of India. Strengthening regulatory frameworks and framing policy guidelines across resource-dependent industries and inclusion of new governance paradigms which focus on sustainability will drive the future efforts to develop sound adaptation policies and processes. This will help in developing a governance model and value systems that is driven by sound social, environmental, and economic performance of societal operations.

by causing environmental pollution. Enterprises of small- to medium-scale (SMEs) in South Asian regions are one such highly polluting sector. Toxic and hazardous wastes emanated from this sector have the potential to cause negative and irreversible impact on human health and ecology. It is, therefore, necessary to take appropriate environmental management contemplations to deal with these wastes. Since the problems associated with physicochemical management practices are a manifold, the use of biomass (biological)-mediated mitigation measures seems to be a promising step, and many ideas, concepts, and research are floating around it across the world. The authors in this present chapter discuss two biomass-based case studies from their previous research work and glide over an emerging management thought/concept for green practices in South Asia for a sustainable tomorrow.

Introduction

An industrial sector of any developed and underdeveloped nation plays a critical role in the overall economic development by way of providing employment opportunities, poverty alleviation, and refining quality of life. The world, in the recent times, perceives region-wide structural shift toward increased industrialization. Emerging economies and many other developing economies are gradually shifting their dependence from the agricultural to the industrial sector, whereas highly industrialized nations are shifting from the industrial to the service sector. Ghani and Ahmed (2009) have reported that in South Asian countries, the share of industrial sector in the last 5 years has increased from 21 % to 26 % of the total output and is expected to grow swiftly in the years to come. Structural shift coupled with substantial growth of the industrial sector in South Asian countries during the last two to three decades has taken its toll by instigating environmental pollution. Environmental problems include those caused by widespread poverty, industrialization, and a change in consumption patterns. The cumulative impact of these two causes has serious effects on urban dwellers; noise, overcrowding, inappropriate design, and stress contribute to the growing psychosocial health problems of many urban dwellers in developing countries (South Asia Environment Outlook 2009). In order to address these environmental problems, in an emerging economy like India, many universities, institutions, and business schools have introduced energy and environmental management-related programs after post-liberalization (Rao et al. 2013).

Pollution of various environmental segments, viz., air, soil, and water, due to the release of hazardous and toxic pollutants has all the potential to cause deleterious impact to human health, ecology, and climate change. If appropriate environmental contemplations are not integrated with the industrial systems, implications could be manifold. It has been reported that the industrial sector, in general, consumes 37 % of the world's energy and emanates 50 % of the world's carbon dioxide (GHG) and 90 % of the world's sulfur dioxide and nearly all of its toxic chemicals. In South Asia, the carbon dioxide emission was estimated to be about 437 million tons by the end of 2000 and is expected to double by the year 2012–2013 (Ghani and Ahmed 2009). SAARC countries together contribute to 6.59 % of the world's total carbon emissions. Current efforts for global environmental protection are mainly confined around large- to medium-scale development projects. However, small-scale operations have been left unnoticed in spite of their high resource intensity, inefficiency, and high levels of pollution load per unit of production. This has created severe environmental problems and pressures at the local level on industries to manage the waste emanated by them. However, high cost of remediating waste is becoming an increasingly sensitive issue in the current scenario. It is reported that around 125 million people are at risk from toxic pollution across 49 low- to middle-income countries (Blacksmith Report 2012). The report for the first time estimates the total global burden of disease attributed to toxic pollution from industrial sites in these countries. It establishes the global burden of disease from toxic pollution as on par with better-known public health problems such as malaria and tuberculosis. Very interestingly, the report has made the first attempt at creating a widespread estimate of disease burden attributable to toxic pollution from industrial sources (Blacksmith Report 2012). This could be attributed to weak policy and regulations, oversight of industries using hazardous substances and thereby emanating it, mismanagement of waste management, poor technology for management, location of industries in populated areas, the lack of skilled operators, human exposure to hazardous and toxic substances, role of SMEs in emitting toxic and hazardous chemicals, limitation of space, financial resources to incorporate best practices, and many more (Blacksmith Report 2012; Patil 1999).

SMEs and Environmental Pollution

There are more than 6 million small-scale industrial (SSI) units in South Asia, and this sector contributes to about 40 % of the total industrial output, besides having a 35 % share in direct exports (Ghani and Ahmed 2009). SSIs also provide major employability and with reasonable equity benefits in terms of distribution of income. A strong SME sector is critical in terms of the goods and services it provides to large enterprises and to informal microenterprises. However, the flip side of SSIs is that they have a lot of adverse effects on the environment (State of Environment, South Asia 2001). Considering the overall growth rate in developing countries, there is a growing need to address the problems of pollution, energy efficiency, GHG emissions, raw material utilization, and health and safety hazards these industries pose. Furthermore, enactment of stricter regulations across the world demands for effective waste management practices. However, SMEs are facing enormous constraints on using eco-friendly technology due to the shortage of capital, technical know-how, underdeveloped infrastructure, weak research and development, and the lack of awareness of the options for pollution control and prevention. Moreover, smaller industrial units have added burden of using age-old and inefficient production processes, thereby resulting into more pollution. A lack of capital investment, skilled human resource, and limited access to pollution control and prevention systems are some of the other problems being faced by these companies.

Some of the heavy-metal-user industries that come under SME sector are electroplating, jewelry units, steel hardening, printed circuit board (PCB) manufacturing, and automobile industries. These industries emanate large volume of wastewaters containing cyanide and metal cyanide complexes and are one of the pressing environmental issues since long time. Cyanide is well known for its inhibition of sensitive enzyme cytochrome oxidase in all living cells (Solomonson 1981). Despite toxicity, cyanide finds large applications in industrial processes as mentioned above. It has also been listed among priority environmental pollutant by US Environmental Protection Agency (EPA). Therefore, statutory agencies across the world demand for its complete removal from wastes prior to their discharge in environment. The total cyanide and metal content in these effluents ranges from 1 to 250 and 1 to 180 mg/l, respectively. In India, the statutory limit for discharge of total cyanide and metals in the inland water body is 0.2 and 0.1–5.0 mg/l, respectively (Santra 2006). Undoubtedly, metal cyanide bearing effluents cannot be discharged in the environment without proper management and treatment.

Conventional Technologies and Their Problems in the Era of Climate Change

There are several physicochemical technologies known for the treatment of cyanide and metal cyanides from the effluents emanated from SMEs like electroplating, jewelry units, PCB manufacturing, etc. One of the most commonly adopted technologies for the removal of cyanide and metal cyanides is alkaline chlorination, and oxidation process is one of the most adopted technologies (Ganczarczyk et al. 1985; Patil and Paknikar 2000). This method of treatment, although effective on free cyanide waste, is not effective in the treatment of metal-bound cyanide complexes (Eckenfelder 1989). There are several known disadvantages which include production of toxic sludge, relatively expensive due to the quantity of chlorine required (Kenfield et al. 1988), increases TDS (total dissolved solids) content of water, and formation of hazardous chlorinated organics like trihalomethanes (THMs) (APHA-AWWA-WEF 1998). In order to keep operational costs as low as possible, frequently effluents are only partially treated to the cyanate phase (Teo and Tan 1987), or in many cases the undecomposed metal cyanides containing effluents are directly discharged without treatment. Other methods for managing cyanide containing wastes include hydrogen peroxide oxidation, ozonation, electrolytic decomposition, etc. However, these technologies are beset with problems like cost-effectiveness and efficacy and require special equipments and maintenance. Therefore, scientists and technologists across the world are focusing on developing novel technologies and strategies for the treatment of such industrial wastes.

Biomass-Mediated Mitigation

In the last couple of decades, use of biomass-based technologies has emerged as one such effective alternative due to its cost-effectiveness, better efficacy, and eco-friendly nature. However, most of the biological management technologies employ bacterial (Patil 1999, 2008) or fungal (Barclay et al. 1998) organisms, which require high nutrient supplementation and moreover emanate carbon dioxide during treatment process resulting to global climate change. Finding an alternative sustainable biological method and strategy for environmental cleanup is the pressing need of time. Numerous research papers are published concerning biodegradation of free cyanide, metal cyanides, and thiocyanate using bacterial (Patil and Paknikar 2000) and fungal species (Barclay et al. 1998); scanty information is available on employing biomass (i.e., microalgae) for the mitigation of cyanide and metal cyanides (Gurbuz, et al. 2004). Microalgae are photosynthetic in nature and have the potential of utilizing smaller quantity of nutrients. Nevertheless, it has an advantage of energy conservation and mitigation of global warming by way of absorbing carbon dioxide. This fact can certainly lead to a paradigm shift in the near future in regard to the implementation of biotechnological solutions to mitigate environmental pollution.

Secondly, most of the South Asian nations being an agricultural countries, easy availability and accessibility of biomass exist on a large scale. Biomass may be broadly classified into live or active biomass and dead or passive biomass which will include plants and plant materials, animals and their parts, bacteria, fungi, algae, organic fraction of municipal solid waste, agricultural waste biomass, etc. There is a huge potential of converting waste biomass into usable energy. However, till date, approximately 1.5–2.75 % of the biomass energy has only been tapped from India (Global Energy Network Institute 2006; Energy Alternatives India 2013). Waste biomass also has large number of applications in pollution control by virtue of their surface charges and being exploited worldwide for the removal of various contaminants from water and wastewater. Moreover, biomass can be used as animal feed once its entire capacity of recovering the target contaminant from waste is over. Another important aspect of biomass is that it is renewable in nature and is capable of growing on diverse range of waste. Since all the countries in South Asia are tropical, biomass production holds the key for its effective utilization and applications. Saini et al. (2012) have also reported the city-based analysis of MSW to energy generation in India.

There has been extensive literature on the GHG emissions of livestock at regional as well as global levels (Bellarby et al. 2013). It is well known that food production and consumption contribute significantly to the anthropogenic GHG emissions, with livestock being a major source (Steinfeld et al. 2006). It has been reported that contributions from livestock is 18 % of the total GHG emissions (Steinfeld et al. 2006). If the entire global emissions are consumed, then these estimates decrease to 16 % (O'Mara 2011). From the futuristic viewpoint, food security and energy supply are the matter of great concerns. It has been documented that livestock (ruminants) occupy 80 % of anthropogenic land use and consume

35 % of agricultural crops (Bellarby et al. 2013). Because of this, such livestock are directly competing with the agricultural crop production for human consumption and the potential alternative land uses, such as bioenergy crop production and nature conservation (Smith et al. 2010). Managing livestock in the future is, therefore, a very critical issue in the debate of food security and land competition.

While the problems associated with physicochemical technologies are manifold, the use of biomass (biological)-mediated mitigation measure seems to be a promising step from the climate change point of view, and many ideas, concepts, and research work are floating around it across the world. The authors in the present chapter discuss two biomass-based feasibility studies from their previous research work and glide over an emerging technological and management thought/concept for green practices in South Asia for a sustainable tomorrow.

Case Study 1

Research Objectives

To employ low-cost waste biomass for the removal of precious metals like gold and silver cyanide from solutions and e-waste (Bhat et al. 2012; Gaddi and Patil 2011; Patil 2012).

Methodology

While majority of the South Asian countries are agricultural countries, the waste biomass from agricultural systems and agro-based industries is abundantly available. Considering this fact, the researchers in their studies employed a variety of low-cost biomaterials procured from diverse source and habitats for the removal of precious heavy metals from waste solutions and electronics. A diverse range of waste biomass was used in the present study and is reported by Patil (2012). These included agricultural by-products, industrial wastes and by-products, solid waste, waste fungal cultures, mixed algal biomass, photosynthetic plants, and activated charcoal as reference materials (Gaddi and Patil 2011). Primary processing of the biomass samples (collection, transportation, washing, drying, grinding) and experimental protocols was carried out as prescribed by Gaddi and Patil (2011). A biosorption study on silver cyanide was conducted by batch equilibration method as prescribed by Patil (1999). The amount of silver cyanide (henceforth referred as DCAG) sorbed at equilibrium, Q (mol/g), which represents the DCAG uptake, was calculated from the difference in DCAG concentration in the aqueous phase before and after adsorption, according to the following equation:

$$Q = V\ (C_i - C_f)/1,000\ m$$

where Q is the DCAG uptake (mol per gram biomass), V is the volume of DCAG solution (ml), C_i is the initial concentration of DCAG (mol/l), C_f is the final concentration of DCAG (mol/l), and m is the mass of sorbent (g).

Results, Interpretation, and Model Development

Detailed results obtained by the researchers during their studies are well documented (Bhat et al. 2012; Gaddi and Patil 2011; Patil 2012). The researchers observed that the optimum Q (i.e., μmol DCAG sorbed per gram waste biomass) of 0.1 mmol DCAG for most of the waste biomass tested were at pH 6.0. Biosorption was significantly decreased above pH 7.0 and increased in acidic conditions. Waste biomass of *Eichhornia* roots (water hyacinth) and tea powder waste were the most efficient biomaterials for DCAG among all the biomass screened. The Q values obtained for efficient biomass were highly competitive and marginally below the Q value of activated charcoal. The optimum pH for maximum DCAG biosorption by *Eichhornia* root biomass and tea powder waste biomass was in the range of 6.0–9.0 and 5.0–9.0, respectively. It is well documented that the process of biosorption is influenced by the solution pH (Paknikar et al. 2003). Experimental controls run simultaneously proved that biosorption was the only operating mechanism for the removal of DCAG from solutions. On the basis of maximum DCAG uptake, *Eichhornia* root and tea powder waste biomass were shortlisted for further experiment of loading capacity. Loading capacity of biomass could be taken as an equivalent measure of binding sites present. Loading capacity value of *Eichhornia* root biomass (9.74 μmol/g) was highly competitive and comparable with activated charcoal (9.95 μmol/g), which was used as reference material. This opens up new possibilities of developing an efficient biosorption technology for the recovery of anionic species like silver cyanide, gold cyanide, and similar other species. The researchers also observed that biomass pretreated with L-cysteine chemical enhances the biosorption capacity. Uptake of DCAG by *Eichhornia* root biomass conformed to the Langmuir and Freundlich isotherm models. Continuous mode study in fixed bed column showed that the service time (breakthrough point) obtained for silver cyanide was 40 h. Thus, it could be concluded from our screening/feasibility studies that *Eichhornia* root biomass was an efficient low-cost biomaterial for the sorption/removal of silver cyanide from solutions.

In view of the above experimental results, Bhat et al. (2012) have attempted to propose a sound strategic model for the recovery of gold/silver using a combination of hydrometallurgical (chemical) and biometallurgical (biosorption) processes. Figure 1 shows the broad strategic framework for recovery of precious metals from waste electronics and industrial wastes. As per this model, the segregated electronic scrap material consisting of gold/silver should first be subjected to hydrometallurgical process using cyanide as a leaching agent. The gold/silver cyanide (leachate) thus formed could then be subjected to biometallurgical (biosorption) process using a low-cost biomass (like *Eichhornia* root biomass), wherein the biomass will adsorb the gold/silver cyanide within an hour's time.

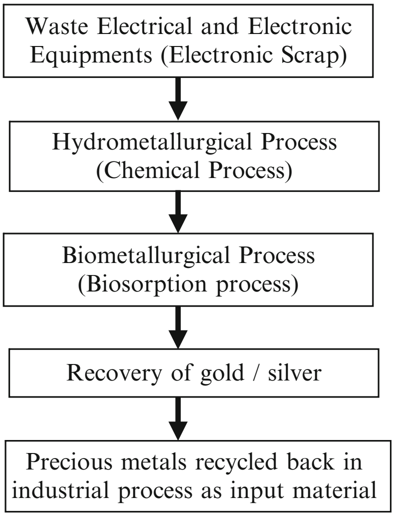

Fig. 1 Proposed broad strategic framework for the recovery of precious metals from industrial waste and waste electronics (Bhat et al. 2012)

Recovery of gold/silver cyanide could be accomplished using a suitable leaching agent. The recovered precious metals then could be recycled back to the industry as an input material, thereby reducing the demand for natural nonrenewable resource. Comprehensive information about the model can be obtained from Bhat et al. (2012).

Case Study 2

Research Objectives

To test the feasibility of treating cyanide and copper cyanide containing electroplating effluent by employing live photosynthetic biomass (microalgae) and development of sustainable waste management model with concurrent mitigation of climate change (Patil et al. 2012).

Methodology

Scenedesmus, a microalga, capable of removing free cyanide and copper cyanide from aqueous solutions was isolated by enrichment technique under alkaline conditions (pH 9.0–10.0). The source of obtaining mixture of algae was the Rankala Lake located in Kolhapur city. *Scenedesmus* sp. was grown in Chu-10 medium for 72–96 h containing 25 mg/l of free cyanide. Downstream processing of the culture was carried out in order to obtain suspension containing 10^6 cells/ml and subsequently used for further experiments. Detailed experimental procedure could be obtained from Patil et al. (2012). The different variables used in this study were as follows: pH (7.0–11.0), temperature (20–45 °C), initial population size (10^3–10^6 cells/ml), and initial cyanide concentration (10–50 mg/l, as cyanide). In all the experiments, one parameter was varied while keeping the others constant. All the analytical methods used in the study were carried out as per the method prescribed by Patil and Paknikar (2000) and Standard Methods (APHA-AWWA-WEF 1998).

Results, Interpretation, and Model Development

Bioremoval of cyanide and copper cyanide by *Scenedesmus* sp. as a function of pH, temperature, and inoculum size is shown in Table 1. It was revealed that degradation of both the cyanide species was significantly affected by the pH of the medium. Optimum pH values observed for free cyanide biodegradation (>99 %) was in the range of 7.0–9.5. In case of copper cyanide, the optimum pH for degradation was 9.5–10. There was no auto-oxidation of copper cyanide above pH 8.0.

It is well known that the cyanide bearing effluents emanated from various metal-user industries have pH in alkaline range (7.5–11.0) (Patil 1999). Biodegradation of free cyanide and copper cyanide in the present study occurred at pH 9.5–10.0. This was because *Scenedesmus* sp. was isolated by carrying out enrichment at alkaline pH in the presence of free cyanide. This result is conducive for the practical use of the process, as very little or no pH adjustment of the effluents may be required. The higher

Table 1 Biodegradation of free cyanide and copper cyanide by *Scenedesmus* sp. as a function of pH, temperature, and inoculum size

	% Biodegradation			
pH	Free cyanide (control)	Free cyanide (experimental)	Copper cyanide (control)	Copper cyanide (experimental)
7.0	>99.0	>99.0	11.2	78.1
7.5	–	–	–	–
8.0	>99.0	>99.0	1.9	81.0
8.5	–	–	–	–
9.0	96.8	>99.0	0.3	95.9
9.5	50.4	>99.0	0	>99.0
10.0	38.9	87.6	0	>99.0
10.5	19.0	78.3	0	59.8
11.0	4.7	39.9	0	5.1

	% Biodegradation			% Biodegradation	
Temperature (°C)	Free cyanide	Copper cyanide	Inoculum size (cells/ml)	Free cyanide	Copper cyanide
20	82.9	73.6	10^3	21.2	18.8
30	>99.0	>99.0	10^4	52.4	28.6
35	86.4	84.7	10^5	76.0	57.1
45	20.7	7.5	10^6	>99.0	>99.0

All the values indicated in the table are the average of two readings; above data is obtained from Patil et al. (2012)

and negligible auto-oxidation of free cyanide and copper cyanide, respectively, in control flasks from pH 7.0 to 9.0 was due to the significant variation of logK value of free cyanide (logK 9.2) and copper cyanide (logK 25.0) (Dawson et al. 1986).

It could be also observed from Table 1 that with increase in incubation temperature from 20 to 30 °C, a concomitant increase in the waste mitigation of free cyanide and copper cyanide occurred. Optimum temperature for maximum biodegradation of both cyanide types occurred at 30 °C. These results were highly significant from the point of view of actual use of the process in tropical countries like India and others, where the average ambient temperature varies between 20 °C and 40 °C. These research findings showed that the *Scenedesmus* sp. used in the present study was alkaliphilic and mesophilic in nature. As far as inoculum size was concerned, complete degradation (>99 %) of free cyanide and copper cyanide occurred with initial population cell density of 10^6 cells/ml within 24–36 h. Therefore, from the process development point of view, it is mandatory to retain maximum biomass in the bioreactor to accelerate the mitigation process.

The researchers observed that biodegradation (>99 % efficiency) of free cyanide occurred within 72 h at initial concentration of 5 and 10 mg/l. As initial concentration increased, longer periods were required. It was revealed that copper cyanide was completely degraded by *Scenedesmus* in 48, 72, and 96 h when the initial cyanide concentration was 5, 10, and 25 mg/l, respectively. These results clearly pointed that the photosynthetic *Scenedesmus* biomass could tackle cyanide up to 25–50 mg/l. This is very crucial as the process developed using this biomass could be immune to shock loads, which are highly prevalent under field conditions in most of the South Asian countries. Presence of the contaminants greater than the normal concentrations in the industrial effluents is normally regarded as shock loads. These shock loads might occur during industrial activities like cleaning, sudden spillages, transfers, decanting, and the presence of acids, alkalis, organic loads, and other toxic substances (Sipma et al. 2010) thereby resulting into sudden increase in concentration.

In further experiments, the authors elucidated the fate of copper from waste solutions during mitigation of copper cyanide using *Scenedesmus* biomass. It was found that S*cenedesmus* sp. utilizes cyanide of the copper cyanide complex resulting in the release of free copper ions. Part of copper gets adhered to the biomass, while the other fraction gets accumulated inside the biomass. The above study clearly points out the fact that heavy metals that are associated with toxic chemical species (like cyanide) are very precious and finite resource (nonrenewable) and therefore could be recovered using biomass (alive or dead) in their suitable speciated form.

Interpretation

From the above results and foregoing experimental evidences, the authors propose a novel biotechnological model from the climate change point of view using *Scenedesmus* sp. as shown in Fig. 2, now summarized.

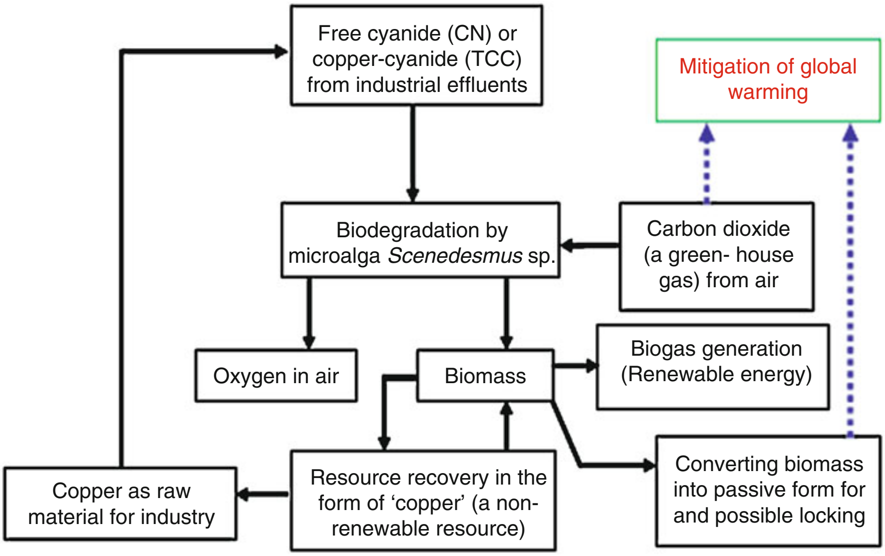

Fig. 2 Integrated sustainable biotechnological strategy using microalgae (Patil et al. 2012)

Inorganic cyanide and metal-bound cyanide (copper cyanide in this case) could be utilized and managed by *Scenedesmus* sp. as the sole source of carbon and nitrogen in the presence of air (oxygen). In turn, carbon dioxide (GHG) from air will be absorbed by alga along with cyanide to build up the biomass with simultaneous generation of oxygen. Surface charges and inherent capacity of biomass will ensure removal of metal from waste solutions (recovery of nonrenewable resource). After metal recovery by a suitable process, biomass free of metal could be employed for biogas generation (energy recovery) or as poultry feed. Moreover, photosynthetic biomass could also be converted into passive form for possible burying in the Earth's crust, thereby reducing carbon dioxide from atmosphere (for this, end-of-life mines can be used). This would ensure mitigation of global warming. Table 2 shows some rough estimates as far as the carbon dioxide capture from atmosphere by *Scenedesmus* species in concerned.

These theoretical calculations are based on the biomass data obtained from the studies carried out by Maraskolhe et al. (2012) and Toledo-Cervantes et al. (2013). From the calculations, it could be seen that the amount of carbon dioxide that would be captured by one large-sized mine would be 0.005495 Gt (i.e., 0.0015 Gt of carbon). In the year 2012, the total global carbon emission from the fossil fuels burning, cement, and land-use changes was 9.7 Gt, i.e., 35.6 Gt of CO_2 (www.co2now.org). Therefore, the amount of carbon locked in the form of microalgae *Scenedesmus* sp. by one mine would be 0.0155 %. Although this figure is only for one mine and small as compared to the total carbon emissions per year, but the authors firmly believe that this could be one of the several ways to combat climate change.

Table 2 Some theoretical calculations of capturing atmospheric CO_2 by *Scenedesmus* species

Parameter	Amount	Comments, if any
Rate of biomass production (dried) per liter	4 g	–
Amount of carbon dioxide fixation per liter	1.4 g	Approx. 35 % of the total biomass production
So for every 1,000 kg of biomass, amount of CO_2 captured would be	350 kg	–
Volume of an end-of-life mine of large size	19,625,000 m^3	Assumption: 100 m depth and 500 m diameter (a cylindrical mine)
Dried algal biomass that could be accommodated in mine (80 % of total capacity)	15,700,000 m^3	Assumption: 1 m^3 = 1,000 kg of dried algal biomass
Therefore, total CO_2 that could be captured by one mine of large size	5,495,000 m^3 (i.e., 5,495,000000 kg or 0.005495 Gt[a])	Algae can be locked in mines after suitable alkali treatment (to raise the pH) to cease biological action
So total carbon locked in one mine	0.0015 Gt	Carbon dioxide converted to Carbon by dividing with 3.67 (i.e., 0.005495/3.67)

Source: Maraskolhe et al. (2012); Toledo-Cervantes et al. (2013); [a]*Gt* gigatons

Recovered metal can further be recycled back to the industry, thereby reducing the demand for the natural nonrenewable resource. Thus, the integrated biotechnological strategy using microalgae suffices the problem of pollution control, resource recovery, and energy conservation with simultaneous mitigation of global warming. In view of the above, the present case study certainly adds to the advancement of knowledge in the field of bioremediation. Furthermore, this novel management thought after further studies could readily be practiced in most of South Asian countries where right environmental conditions do exist in considerable amount.

Conclusion

Both the case studies mentioned above explicitly point out the fact that photosynthetic biomass (like microalga) and the waste biomass from different sources have got immense potential to remediate the industrial effluents containing toxic chemicals with simultaneous recovery of heavy metals (nonrenewable resource). The authors firmly believe that concurrently, the biomass-mediated treatment technologies can also mitigate the climate change by way of using carbon dioxide from atmosphere and utilization of waste biomass which are recyclable in nature. Low-cost treatment technologies also have the advantage of energy efficiency and savings thereby indirectly mitigating climate change. The authors therefore strongly recommend that this emerging and novel management concept could certainly put into practice in most of emerging economies of South Asia for a better sustainable tomorrow.

Although there are several advantages, employing microalgae does have some disadvantages as well. Microalgae require light for its growth which in normal circumstances is only available for 10–12 h during day. Energy inputs are required during night in order to speed up the growth and biodegradation process which might lead to cost escalation. Secondly, alga requires huge space which normally is the constraint, and thirdly, it is a slow grower compared to the other microorganisms (viz., bacteria) in order to accomplish biochemical reactions. At this moment, culturing algae is not economically viable. Drying of algae is also a challenge, which consumes substantial energy and lowers overall efficiency. Currently, algal technology is in its infant stage and not used on a large scale. Despite several limitations, the authors firmly believe that microalgae will certainly play a key role forward to combat climate change.

Abstract

Comparison between the EU's 2020 energy efficiency targets and the forecasted energy savings clearly indicates a gap for expected energy savings in 2020. One of the reasons lies in the lack of specific policies for low-income households, which represent about 40 % of Mediterranean households and are considered as *far to reach* through traditional public policies. Due to their complexity, low-income households require innovative financial approaches for implementation of energy efficiency measures. Smart metering has been identified as one of the climate change adaptation technologies which can be used to encourage people in low-income households to become more aware of their energy consumption and stimulate them to change their energy-related behavior. Activities presented in this paper have been evaluated within the EU-funded project ELIH-Med with the objective to identify innovative energy efficiency measures and financial instruments for low-income households in the Mediterranean area. Also, this paper evaluates the impact of customized and adaptive consumption feedback on energy behavior patterns and energy savings in low-income households. Energy and cost saving prediction and verification flowchart are outlined to yield different combinations of suggested smart metering services, which would enable the minimization of households' environmental impacts.

Keywords

Energy efficiency • Smart metering • Consumption feedback • Behavior • Low-income housing • Mediterranean

Introduction

The European Union (EU) has set a primary energy saving target of 20 % below the 2007 projections for 2020 (European Commission 2007). The success in achieving this goal will largely depend on promoting efficient energy end use in households. Many studies have confirmed that decisions and concrete actions of individuals have greater power and effects than capability of municipal administration to interfere in their actions. End-user's (consumer) behavior is a very important parameter for the success of each national energy efficiency policy and related programs. It is necessary that the government efforts on the state level address not only what state or city can do directly to improve energy efficiency but also how the state can promote greater adoption of new and efficient technologies by consumers. According to (Birnera and Martinot 2005), this can come through changes in regulation, taxes, subsidies, access to capital, and provision of trusted information, as well as marketing and campaigning to raise the awareness and encourage consumers to make choices that are both economically and environmentally sustainable. In the present moment in the framework of sustainable and climate-friendly development of urban areas, the most often highlighted problems are efficient spatial planning, efficient and secure energy supply, and efficient public transport. Energy efficiency is a red line, which connects all abovementioned areas.

However, many contemporary policies and instruments for reaching energy saving potential are mainly oriented on technical systems (building envelope, heating systems, electrical appliances), while behavioral changes are addressed only by improved information availability through awareness campaigns. As presented by Gram-Hanssen (2013), user behavior is at least equally important as building physics when it comes to energy consumption for heating, while electricity consumption for lighting and appliances is more dependent on the user behavior than on energy-efficient appliances. Interactions between different parameters that have the effect on households' energy consumption are presented in (Haas 1997). In general, energy consumption in households depends on many different parameters, namely, household structure (dwelling area, number of occupants, etc.), occupant's behavior, technical efficiency of the installed equipment, and climate variables.

In the present economic and financial crisis, the costs for energy and related challenges become even more important, and new and innovative approaches need to be considered in the residential sector where low-income households (LIH) must be specially targeted. Energy efficiency in low-income housing in the Mediterranean (ELIH-Med) project (strategic project within the MED Program, started in 2011) focuses on energy efficiency in the context of EU climate and energy targets for 2020. The LIH represent about 40 % of Mediterranean households and are considered as *far to reach* through traditional public policies (ELIH-Med 2010). Smart metering and its consumption feedback approach can be used for encouraging improvement of end-use energy efficiency and environmentally sustainable behavior in the targeted sector. As pointed out by European Smart Metering Alliance (2010), smart metering adds value to the ordinary utility service, giving better information to consumers and optimizing the use of the demanded power and consumed energy. Smart metering is widely used as a synonym for a system that records energy consumption and other parameters with bidirectional communication between utility and its clients. It implies a new relation model between the utility and its clients, using Information and Communication Technologies (ICT) to interchange information between the utility and the devices installed at consumer's premises.

The majority of people tend not to see or feel the link between their actions (behavior) and the households' energy performance and impact on the environment. Households' behavior has been of great interest to social and psychological scientists as presented in (Abrahamse et al. 2005; McCaley 2006; Faiers et al. 2007; Steg 2008). Also, in many empirical studies, it can be found that individualized energy use information in the form of more informative bills, periodic feedback, and continuous feedback can lead to reductions in energy use. However, from the scientific point of view, it is not clear whether feedback needs to be more frequent to be effective and the sophisticated real-time monitors are more effective than simpler versions (Allen and Janda 2006). On the other hand, as pointed out by Fischer (2008), relevant features of consumption feedback that may determine its effectiveness are frequency, duration, content, breakdown, medium and way of presentation, comparisons, and combination with other instruments. In spite of considerable data restraints and research gaps, there are some indications that the most successful feedback combines the following features: it is given frequently and over a long time, it provides an appliance-specific consumption breakdown, it is presented in a clear and appealing way, and it uses computerized and interactive tools (Fischer 2008). Considering the socioeconomic factors, household income has been found to be a significant determinant of baseline energy use, but not of energy conservation behavior in reaction to feedback (Heslop et al. 1981; Brandon and Lewis 1999; Matsukawa 2004). On the other hand, it is undeniable that human behavior impacts energy consumption and varies from culture to culture (Wang 2011). To evaluate the social dimensions of energy use, initiatives that combine society, energy, and technology in various permutations are needed (Janda 2009).

This paper evaluates the impact of customized and adaptive consumption feedback on energy behavior patterns and energy savings in LIH. Activities presented in this paper have been evaluated within the EU-funded project, ELIH-Med. Several pilot project locations were selected for the installation of different smart metering and advanced consumption monitoring systems with the objective to identify innovative energy efficiency measures and financial instruments for low-income households in the Mediterranean area. Participating Mediterranean countries are Spain, France, Italy, Greece, Cyprus, Malta, and Slovenia. Besides analysis of consumption feedback, supported by different smart metering solutions, the ELIH-Med project also focuses on identifying and demonstrating the feasibility of other innovative energy efficiency measures and financial instruments with the deployment potential relevant to Mediterranean territories and supported by European Regional Development Funds (ERDF).

Reaching EU 2020 Objectives in the Mediterranean Area

In 2008, the share of energy consumption in households was 25.3 % of the total EU final energy consumption (European Environment Agency 2011). While space heating and cooling remains the most significant component of households' energy consumption in EU, electricity consumption associated with the use of electrical appliances increased the most rapidly in percentage terms during the recent years – increase of more than 21 % per dwelling comparing with 1990 (European Environment Agency 2011). According to the requirements of directive on energy end-use efficiency and energy services (Directive 2006/32/EC), each EU Member State had to adopt and achieve an indicative energy saving target of 9 % by 2016 in the framework of the first National Energy Efficiency Action Plan (NEEAP). Despite the commitment and huge policy efforts to boost energy efficiency improvements by EU Member States, the EU is far from reaching its 2020 energy saving target as shown in Fig. 1 (European Commission 2009).

In 2010, after a large and long-lasting consultation with the public, the European Commission presented the *Energy 2020 – A strategy for competitive, sustainable, and secure energy* (European Commission 2010). Within the strategy for competitive, sustainable, and secure energy, the European Commission defines the energy

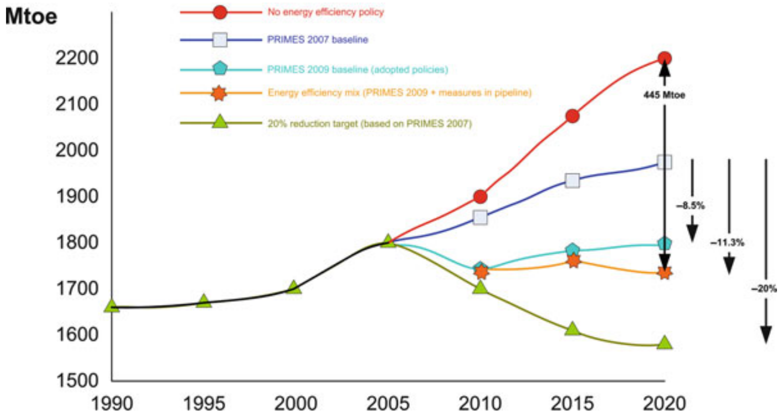

Fig. 1 Energy saving policy gap in the EU countries: development and projection of gross inland energy consumption for EU by 2020 (European Commission 2009)

priorities for the next 10 years and sets the actions to be taken in order to tackle the challenges of saving energy, achieve a market with competitive prizes and secure supplies, boost technological leadership, and effectively negotiate with EU's international partners. The objectives presented in the European Commission (2010) are part of the EU's 2020 strategy and in 2011 posted Resource-Efficient Europe initiative (European Commission 2011a). The aim of both documents is to make far-reaching changes to the way in which Europe produces and consumes energy, while building on what has already been achieved in the area of energy policy. Also, the European Commission recognizes the importance of the energy cooperation in the Mediterranean region and suggests improvements to the regulatory framework and stresses that an integrated regional market in the Maghreb would facilitate large-scale investments in the region and enable Europe to import renewable electricity.

According to the European Commission (2011b), the EU needs to act immediately to get on track to achieve its targets, and a two-step approach was proposed for energy efficiency target setting. In the first step, Member States should set their own national efficiency targets, and in the second step, if the review of the set targets and programs shows that EU is not on track to reach 20 % target, the European Commission will propose legally binding national targets. This is formally laid down in the Energy Efficiency Directive from 2012 (Directive 2012/27/EU). Unfortunately, forecasted energy savings may be rather optimistic if the measures (according to the first and second NEEAPs) will not be implemented successfully and in that case, the expected gap by 2020 will be even larger.

Unfortunately, there are many causes for the projected gap in the residential sector by 2020, and the most of them are associated with symptomatic unbalance between efforts for preparing polices and preparations for policy implementation. A major policy barrier is the absence of the implementation program follow-up and the clear definition of responsibilities of the management bodies on the state, regional, and local level. Almost all Mediterranean countries have defined long-term objectives in their energy strategies, but lack of clear definition of responsibilities with deadlines for the implementation was the crucial reason why many goals have not been achieved. As long as there is no clear definition of responsibilities of the management on the state, regional, and local level and consequences in the case of not fulfilling its obligations, there is no basis for involvement of other stakeholders. This reveals another key barrier for the successful implementation of the energy efficiency programs: *lack of implementation capacity!* Current situation is characterized by the fact that more people are working on planning of the energy efficiency measures than on its actual implementation. With the aim to make any energy efficiency action plan or strategy alive in the real terms, comprehensive and adaptive implementation and follow-up mechanisms have to be developed. The vast majority of policymakers are focused on transposition of common EU energy policies and requirements into national strategic and legislative framework, without in-depth evaluation of the energy efficiency developments in their countries. Unfortunately, in many Mediterranean countries, energy efficiency is not perceived as the most proper instrument for the future sustainable growth. Proper energy and growth policy can play an important role in overcoming these transition challenges, especially by providing financial incentives that lead to accelerated energy efficiency technology development and deployment. Having in mind high percentage of LIH in residential sector and scarce financing resources hardly accessible to LIH, each Mediterranean country will have to revise its energy policy and introduce effective and innovative energy saving mechanisms available for LIH. In the majority of cases, the private-public financing sources are not enough for all the LIH end users. Even the scheme of tax incentives for energy efficiency investment is not followed by the most of LIH due to lack of information and awareness of economic and environmental benefits in terms of the energy and money savings. Therefore, energy-efficient end-user behavior can be an important parameter for the success of national energy policy and programs, especially in LIH residential sector. Correctly navigating the interface between policymaking and human behavior is the key for achieving sustainable energy consumption (European Environment Agency 2013).

As demand for electricity from appliances is increasing, one of the effective and innovative measures includes installation of smart metering. Smart metering can provide desired and necessary link between end-user behavior and energy consumption. Introduction of smart metering, besides the benefits for the utilities, suppliers, and distributions, in its essence has the goal to help consumers to understand their energy consumption. Only a consumer who understands its energy consumption is capable to systematically and sustainably decrease it. On the other hand, utilities are already well aware of their total energy balancing, but with the additional amount of consumption information provided by smart metering, they will be able to better understand and anticipate the end-user behavior and explore this knowledge in synergy of utility measures for optimizing its overall energy performance.

Consumption Feedback Influence on Behavior

According to (Darby 2006), improved feedback may help consumer to reduce its energy consumption by up to 20 %. However, to properly understand the consumption feedback influence on behavioral change, it is necessary to define and understand what is the relation between environmentally and energy-relevant behavior. According to Markowitz and Malle (2012), the environmentally relevant behavior refers to any behavior that can be identified as having a significant direct or indirect impact, negative or positive, on the health and stability of natural (eco)systems. Energy-relevant behavior refers to any behavior that can be identified as having a significant direct or indirect impact, negative or positive, on the energy consumption in selected object or energy system. Since there is a direct link between energy consumption and environmental impact of that consumption, it can be concluded that the energy-relevant behavior is the subset of the environmentally relevant behavior.

Integrative influence model of environmentally relevant behavior (influence model) has been introduced by Matthies (2005) (see Fig. 2). These kinds of models are necessary to understand what consumers do and why they do so. Also, a model proposed by Matthies (2005) can be used for explaining why and how feedback on electricity consumption can reduce consumption (Fischer 2008).

According to (Fischer 2008), the influence model distinguishes between two types of environmentally relevant behavior. The first is habitual behavior or routine, called *environmentally detrimental habits*. The second and above the habits are *conscious decisions*. Habitual behavior or routine is the behavior performed regularly in the same way, and it is not reflected upon. Day-to-day household activities can be classified as such, and many of them are related to household's environmental footprint, mostly through energy consumption activities

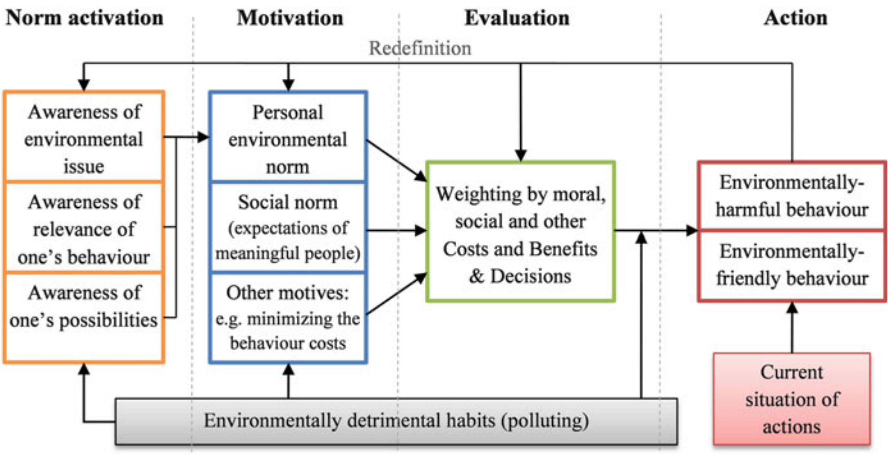

Fig. 2 Integrative influence model of environmentally relevant behavior

(such as cooking, washing, turning on the lights, etc.). Once the routine is established, it may spiral into suboptimal way of doing things because majority of people never really think about an optimum way of doing it anymore. In the field of environmentally relevant behavior, many habits are environmentally detrimental because the environment or energy was not a relevant issue to consider at the time the habit was formed, or because beliefs about environmental effects held at that time have been shown to be wrong, or because the situation has changed so that a once beneficial behavior is not useful anymore (Fischer 2008).

On the other hand, a conscious decision needs to be taken for new norms and considerations to enter the established behavior patterns and break the habits. To do this, a person has to be aware of various options to choose from and to establish proper norms and criteria to evaluate his/her own decisions. The influence model describes this process as *norm activation* and includes three stages of awareness:

- Awareness of an environmental issue which is not solved or tackled by established habits
- Awareness of relevance of one's behavior to the environmental issue
- Awareness of one's possibilities to influence personal behavior to have sense of control.

This process can be illustrated by correlating electricity consumption and electricity bill. One can improperly attribute the high electricity bill to electricity prices and not to one's consumption behavior; therefore, no decision on behavior change will be made. If consumption costs are correctly linked to one's behavior, a person has to realize how to control it. This can only be achieved if a person has sufficient information (i.e., consumption feedback on appliance-specific consumption).

After successful norm activation, a person faces different motives (*motivation*) in order to reach a decision on how to act. Firstly, one is confronted with his/her personal norms and evaluates his/her personal ideas of how to act. Secondly, one is confronted with social norms and what one may consider as socially appropriate or desired behavior. People may sometimes make decisions based on the beliefs and values they perceive to be prevalent in their culture instead of their personal beliefs and values (Chiu et al. 2010). Lastly, there are also other motives not specifically defined in the influence model. In the case of energy consumption in households, these motives may comprise the need or desire for the services associated with electricity consumption on one side and a desire for comfort on the other. When norms and motives conflict with each other, a person has to go through *evaluation or decision-making process*, where moral, social, and other costs and benefits are weighed. During the decision-making process, the persons' norms and motives may be influenced and redefined by available information. According to the model, the final stage is a decision for an environmentally friendly *action*. Under specific conditions, such an action may be performed regularly and develop into a new habit or routine (Fischer 2008).

Four processes described in this model (*norm activation*, *motivation*, *evaluation*, and *action*) can be used for detecting the ways on how consumption feedback can be used to stimulate the conscious decision and development of new energy-efficient habits. In general, consumption feedback gives clear and comprehensive information about energy consumption and can direct consumers' attention toward energy consumption of everyday household activities. Concerning the energy consumption, feedback may focus on two consumption-related problems, problem of consumption costs and problem of pollution (environmental or sustainability issue). With the help of consumption feedback, these issues can influence reasoning process and motivate the consumer for cost savings or for minimizing environmental footprint. Past studies have shown that combining real-time consumption feedback with competition can additionally motivate consumers to reduce their energy consumption and stimulate behavioral change (Petersen et al. 2005). According to Fischer (2008), consumption feedback is most effective if it:

- Successfully captures the consumers' attention
- Draws a close link between specific actions and their effects
- Activates various motives that may appeal to different consumer groups, such as cost savings, resource conservation, emissions reduction, competition, and others.

Smart Metering in LIH

In the light of EU energy saving efforts, the ELIH-Med pilot projects try to identify the most effective smart metering functionalities and services to increase energy efficiency in LIH and achieve measurable energy savings. Within the ELIH-Med project, analysis of twelve multi-energy smart metering projects in the Mediterranean area was performed. Performed analysis confirms that electricity has the leading role in the smart metering projects. Also, electricity smart grids are foreseen to be the backbone of the future energy grids, and smart electricity meters are expected to have the *data concentrator* role for other sources (heat, cold, natural gas, and water). EU Member States are obliged to roll out smart electricity meters for at least 80 % of their end consumers by 2020 and to achieve full coverage by 2022 (European Commission 2011b). In spite of this, smart grid concept cannot be taken for granted as the universal solution for all problems. It is a powerful framework which can assure that the full potential of concrete energy efficiency measure is systematically utilized and verified.

Evaluated smart metering projects were sorted according to nine topics representing different benefits of smart metering for the end consumers on one side and suppliers and utilities on the other, as shown in Table 1. Evaluation confirms that the majority of benefits are at the supply side, indicating the need to put bigger emphasis on exploring consumer benefits in upcoming smart electricity meter rollout.

Unfortunately, in the current situation of economic crisis and cheap electricity available on the market, there is little interest in demand side management, and each Member State is facing the problem of funding the smart metering implementation. Rollout of smart electricity meters should be set in the development plans of

Table 1 Benefits allocation of evaluated smart metering projects

	Topic	No. of projects	Final beneficiary
1	Customer feedback / change of behavior	8	
2	Advanced tariff systems	3	Consumer
3	Other / new customer services (energy service companies)	4

7	Interoperability	7	Suppliers utilities
8	Equipment testing	11	
9	System services (distribution, supplier)	8	

individual distribution network operator(s) in each Member State. It is assumed that the necessary funds for implementation would be allocated from the grid fee and distribution network operator(s) would be the equipment owners. In many states, the current practice is that costs of implementing additional services and additional smart metering equipment (i.e., in-home display or individual appliance consumption metering) are charged separately and directly to the consumer. Such practice limits the availability of these services. In the case of LIH, it is crucial that electricity suppliers offer innovative ways of funding for additional services and the equipment. Due to the specific structure of this customer group, one of the options is to stimulate the implementation of additional energy services for energy efficiency by awarding the achieved energy savings in LIH and all in the framework of energy efficiency obligation scheme (Directive 2012/27/EU) where the energy suppliers are obliged to report about achieved energy savings at the end consumers. In this way, suppliers will be more interested in the preparation of suitable energy efficiency programs for the LIH.

Smart Metering and Energy Efficiency Benefits

The use of electrical appliances within households varies significantly in time. The most common measurement interval for load profile analysis in today's electricity grids is 15-min interval. This resolution is satisfactory to show variations in electricity consumption, and it is used for billing purposes. Considering the climate change mitigation activities, smart metering represents technology with the potential for encouraging sustainable change toward the energy-efficient behavior. Smart metering introduces real-time automated meter reading, enables two-way communication, and is suitable for dynamic pricing. Also, the availability of accurate and almost online data for the evaluation of energy consumption has the potential to transform demand forecasting and detection of consumption patterns from a passive historical data-based activity to an active real-time data-driven process. However, smart metering without consumer participation and additional services will, by itself, do nothing to change behavioral pattern and save energy since the meter is simply an *enabler*. Energy savings will be achieved only if the installation of meters is connected with the comprehensive informational campaign which will help consumers to actually understand their energy consumption and stimulate them to move toward sustainable behavioral changes (European Smart Metering Alliance 2010). Also, traditional approaches that focus just on instrumentation and tend to ignore social characteristic of the target group are not suitable for the LIH. In order for energy savings to be realized, problem-oriented approach and customized financial incentives have to be introduced to make energy saving measures more attractive to LIH in economic terms (European Smart Metering Alliance 2010). According to the analysis performed within the ELIH-Med project, these incentives are usually in the form of demand response services and dynamic pricing, introduced by energy utilities.

Demand Response

The target of demand response is to enable active participation of consumers in the market through the provision of consumption flexibility services to different players in the power system. Particularly challenging is the integration of households in the demand response programs due to almost stochastic nature of domestic electricity consumption and available load flexibilities. Therefore, the typical demand response of household consumers is a voluntary reaction to a price signal (Joint Research Centre 2011). Typical response is load shifting where electricity demand is delayed. Although the deployment of smart meters can enable active participation of consumers in the market (i.e., purchase of home energy sources), it is the energy savings and cost reduction which are of interest to LIH consumers and can potentially range up to 15 % (Joint Research Centre 2011). Understanding the relationship between consumption feedback measures, demand response measures, and energy efficiency programs is important to avoid potential conflicts and ultimately failure to capture the full energy saving potential available (European Environment Agency 2013).

Dynamic Pricing

Dynamic pricing encourages consumers to shift consumption away from the peak consumption periods to lower consumption periods, lowering distribution and supply costs. This is achieved through dynamic pricing mechanisms which reflect the cost of supplying electricity. Dynamic pricing is suitable for LIH as it reflects immediately in the lower consumption costs. This mechanism can also utilize the characteristics of Mediterranean environment with high potential for solar electricity generation within certain time of day. In practice, there are several methods and degrees of dynamic pricing, but due to its simplicity Time-Of-Use (TOU), pricing scheme was recognized as the most appropriate for the LIH consumers. TOU tariffs stimulate people to switch their electricity consumption from peak to off-peak hours. The peak hours are known in advance and properly communicated to consumers. The prices may also vary according to the season. Potential for consumer financial savings using TOU tariffs is estimated up to 5 % (Stromback et al. 2011). Dynamic pricing enables energy savings only on the supply side by comprising intelligent integration of centralized and distributed energy generation resources and lowering transmission and distribution losses during peak hours.

Tariff Use Planning and Home Automation

Advanced tariffs are pointless if consumers do not have a proper understanding of its time frames, possible money savings, and environmental benefits due to energy savings on the supply side. For this reason, the consumption feedback introduced in ELIH-Med project (through informative billing and interactive web page) includes additional explanation of implemented tariff systems and proposed the use of home appliances with high intensity of consumption (space heating and cooling systems, electrical boilers for domestic hot water preparation, appliances with adjustable time of operation) according to the implemented tariff system. The home automation in LIH concentrates on installation of electronic plug timers for demand shifting of energy-intensive appliances according to optimal tariffs and programming appliances with integrated time controllers for use in low or off-peak tariff. Proposed concept follows the rules of the simple home automation since the advanced home automation with remote load controllers is out of scope for LIH.

Consumption Feedback Services

The role of consumption feedback is to make the consumption of energy/electricity visible. Feedback can also provide a more direct, detailed, comparable, and comprehensive information about households' energy consumption pattern. Indirect or direct consumption feedback can be provided to consumers utilizing smart metering and its services.

Indirect Feedback

According to (Darby 2006), the indirect feedback is more suitable for demonstrating longer term effects on the energy consumption as the consequence of behavioral changes and applied energy efficiency measures. Through indirect feedback, the consumer has no direct access to the real-time consumption data and is therefore responding to previous consumption behavior and has to rely on processed information. Examples of indirect feedback appropriate for use in LIH are through informative billing and interactive web page. These types of feedback are based on smart meter readings with a combination of appropriate and tailor-made energy efficiency indicators, disaggregated consumption data, detailed energy reports, and other forms of presenting the energy consumption patterns.

Informative Billing and Interactive Web Page

As indicated by *Saving Energy in Social Housing with ICT* project (eSESH deliverable 2010), from the consumers' point of view, one of the biggest advantages of the smart metering implementation is accurate and informative billing. Informative billing includes explanations of the energy saving options regarding the received monthly bill, and it is the favorable feedback option for tenants in social housings (eSESH deliverable 2010). Even though that informative billing provides real and accurate energy consumption data to domestic consumer, the biggest challenge is making this data understandable to all consumers including tenants in LIH. From the ELIH-Med perspective, the informative billing should have the following features:

- Monthly billing based on actual consumption
- Interpretation of monthly consumption in kWh and local currency (EUR)
- Graphic representation of monthly consumption (load profile) with appliance-specific consumption breakdown (where utility provides individual appliance metering). Additionally, a graphic representation must include monthly consumption for at least past 3 months or more (up to 12 months)
- Comparative and normative feedback (efficiency indicators) – e.g., graphic representation of billing consumption compared to consumption in comparable past periods, to average consumption in the past year, correlated to inside and outside temperature difference, etc.
- Common bill for all on-site utility meters (electricity, natural gas, heat, cold, and water).

Interactive web page with the secured personal access can also be utilized as indirect consumption feedback service in LIH. Similar to online banking, energy utilities should provide an option of e-billing (same characteristics as for the classical informative billing) and some degree of energy management (e.g., planning the use of home appliances with high intensity of consumption according to implemented tariff system). As indicated by eSESH project (2010), web services can reach a wider group of tenants also in social housings, and according to eSESH project survey, 85 % of tenants own a PC, and 77 % have access to the Internet.

Direct Feedback

The main characteristic of the direct feedback is that consumers have an immediate and easily accessible display either directly on the smart meter or associated to the smart meter. The primary role of the smart meter is to provide a clear, concise, and understandable information or point of reference for improved feedback, preferably in combination with a separate in-house display (IHD) and individual appliance consumption metering. Using only smart meters, display for direct consumption feedback has its advantages in LIH as it does not bring additional costs for separate IHD.

According to the ELIH-Med project, the direct feedback provided to LIH should include:

- Appropriate indication that allows consumers to easily distinguish between high and low levels of electricity consumption (intensity of consumption)
- Appropriate indication that allows consumers to easily distinguish between peak and off-peak times (indication and price of active tariff) and clear overview of billing consumption (in kWh and currency), broken down by tariff.

Besides meter's display and potential use of IHD, direct feedback allows alarm notification of tenants in the events when abnormal or extensive electricity consumption occurs. Such *alarms* may prove to be the most influential on behavior changes. Due to already available communication channels (SMS or smartphone applications, e-mail), this way of communication is very simple to implement in LIH. According to ELIH-Med, possible triggering events are:

- Tariff switch.
- Steep deviation from average hourly consumption.
- Monthly threshold (average monthly consumption) has been reached.

Pilot Households

Selection of ELIH-Med pilot households, participating in ELIH-Med smart metering experimentation, was based on the household matrix according to which each participating household was categorized.

Required data was gathered with the comprehensive survey which was also used to establish the baseline energy consumption for each observed household/tenants and energy-related behavior. One of the purposes for thorough household categorization was to enable long-term comparisons with an average normalized or benchmarked consumer in the same user category. The need for this comparison is specified in the new Energy Efficiency Directive (Directive 2012/27/EU).

Economic characteristics define the dwellings in LIH category where *low income* refers to households who usually do not have sufficient resources to have an easy access to credit or capital in order to invest in energy efficiency. Social characteristics define the target groups by social and behavior aspects. They are further divided into three subgroups:

- Dwellings size and typology
- Social structure of tenants in household
- Usage of social media.

Table 2 Groups of representative cases

Category	Included cases
Mediterranean space	Cyprus and Malta; Mediterranean region of France, Greece, and Spain
Tenants income	Retired
	Employed
	Unemployed
	Scholarship
Household	Family with children
	Family without children
	Single occupant
	Students
Dwelling typology	Single house
	Semidetached house
	Apartment in multiple dwelling building
	Student dorm
Ownership	Private property
	Rent
	Social housing

Technical characteristics define the technical features of LIH. They are further divided into five subgroups:

- Type of appliances used and their typical usage
- Use of home automation
- Use of lightning
- Heating, cooling, and domestic hot water (DHW)
- Historical data on energy consumption (past energy consumption).

During the pilot households' selection, a special care has been taken to include all envisioned use cases, as defined in groups of representative cases (Table 2).

Surveys of pilot households have highlighted some of the LIH and Mediterranean characteristics which were considered during the use cases development.

LIH characteristics:

- Moderate electricity consumption (reaching national average or below average).
- Energy costs present significant part of household income.
- Use of old and inefficient household appliances.
- Use of passive ventilation is more common than use of advanced cooling or air-conditioning systems.
- Frequently suboptimal living conditions due to inadequate maintenance of living quarters.

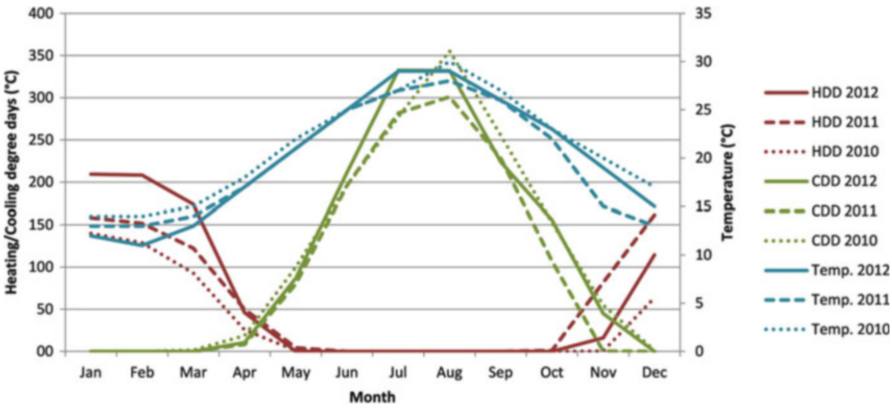

Fig. 3 Cooling and heating degree days for Larnaca, Cyprus

Mediterranean:

- Higher demand for cooling
  Cooling degree days (CDD) exceed heating degree days (HDD) as show in Fig. 3 *for one of the pilot locations (Larnaca, Cyprus) in years 2010 through 2012*
- Low penetration of efficient heating systems (i.e., central heating)
- Low penetration of natural gas grids and district heating
- Electricity as main energy source for cooking

It was noticed that even in cases where natural gas is used for DHW, electricity is usually used for cooking. Also, there is a noticeable rise of electricity consumption during summer months (direct consequence of higher cooling than heading demand) as shown in the case of pilot dwellings in Larnaca, Cyprus (Fig. 4).

Implementation of Consumption Feedback Services

Different types and forms of consumption feedback can be used to influence the reasoning process as described in integrative influence model of environmentally relevant behavior. Three types of consumption feedback presentation were used in selected pilots to target the desired action of the consumer:

- Presentation as environment/pollution problem – equivalent of energy used in CO_2 emissions
- Presentation as family budget problem – costs of energy consumption
- Presentation as consumption problem – consumption in kWh.

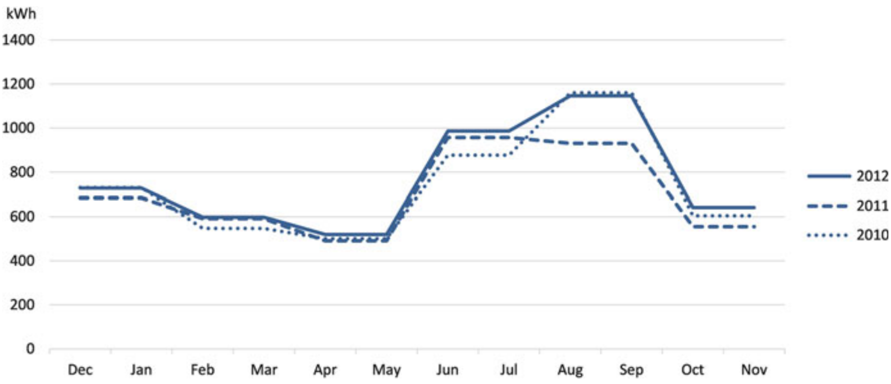

Fig. 4 Sample household electricity consumption

To maximize the consumption feedback impact on the consumer's behavior, ELIH-Med project follows the previously suggested feedback types and include four forms of implementation as shown in Table 3. The first three forms are targeting the behavior of single households, and the last one is targeting the change of behavior on a group of residents. All forms can use several types of presentation. The focus can be either on environment (CO_2 emissions) or energy (consumption in kWh) or on the costs related to consumption. Reduction of costs is particularly important for LIH as even small energy cost savings can have significant impact on the household budget.

Smart Metering Experimentation Plan

Smart metering experimentation plan of the ELIH-Med project was divided into four phases, preinstallation, installation, monitoring, and evaluation (Fig. 5). Phases were designed to follow the integrative influence model of environmentally relevant behavior. Also, the first three phases had an important role in helping LIH consumers to understand how they can use the information provided by smart metering to manage their energy consumption effectively and to save energy.

Preinstallation

Main purpose of preinstallation phase was to assure that selected dwellings comply with LIH criteria and to additionally motivate households participating in experiment (norm activation). Awareness campaign included information concerning all renovation (other ELIH-Med project initiatives) and installation works which were carried out through the experiment. Within the preinstallation phase, the baseline consumption data and past behavioral patterns through survey of participating LIH were obtained. Figure 6 shows the main activities and scope of preinstallation phase.

Table 3 Forms of smart metering implementation

	Form	Type of presentation (in the order of focus)	Target	Number of cases
1.	Appliance-specific consumption breakdown with simple kWh, CO_2, and costs presentation of energy consumption on IHD. Web access with additional consumption breakdown is also available. The pilot projects without web access or in cases where tenants are not customized or willing to use the Internet and monthly reports provided by installed metering equipment are printed by equipment maintainers and distributed to tenants. The form of report is suited to the tenant's needs in each case	Consumption Budget Environment	Behavior of single household	60 households
2.	Sophisticated environmental feedback including consumption and environmental parameters in the form of advanced consumption and environment monitoring system, where energy consumption, temperature, humidity, and other parameters are monitored and presented in individualized web page	Environment Consumption Budget	Behavior of single household	40 households
3.	Utility smart meters are used as main focus point of consumption monitoring, and informative billing is used as main consumption feedback medium. Installation of smart meters is coupled with installation of photovoltaic system as complementary utilizing Mediterranean-specific climate conditions	Budget Consumption Environment	Behavior of single household	60 households
4.	Comparative consumption feedback between several buildings (student dorms) in the form of public dashboards to initiate and stimulate the competition	Environment Consumption	Behavior of a group of residents	5 buildings 144 rooms

Fig. 5 Four phases of interactions in smart metering experimentation

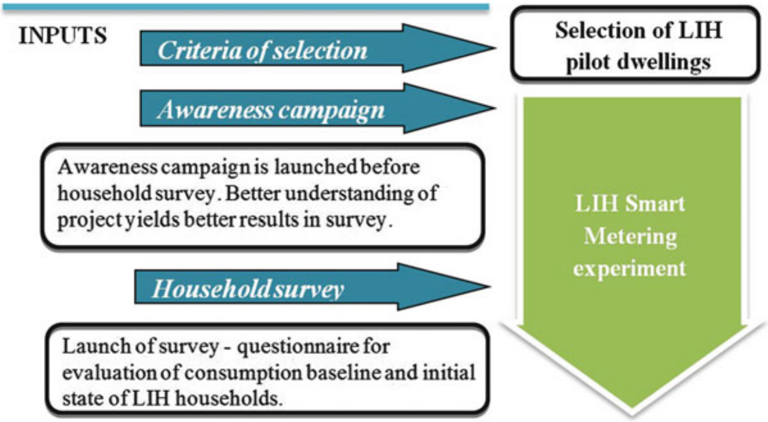

Fig. 6 Preinstallation phase

Experiences from this phase clearly confirm that people welcome the works and changes in their premises when actions are previously well explained. Following a presentation of the project objectives, tenants were in favor of installing smart metering systems into their premises.

The second and equally important finding from this phase was related with the importance of community involvement. The best way of motivating households for installation works and other initial activities is to designate the local representative who coordinates the building activities (organization of education and awareness sessions, coordination of installation process between installers and tenants, etc.). Including the representatives of the local community (neighborhood or building representative) in the preparations and awareness campaigns has proved to be a crucial point in the transfer of sustainable ideas. Initial skepticism, which was particularly present in LIH, has turned into enthusiasm and a desire to cooperate.

Installation of Smart Metering Equipment

During equipment installation phase, it was essential to assure that all LIH participating in the experiment are familiar with installed smart metering equipment. Figure 7 shows the main inputs of the installation phase.

This phase has highlighted the poor condition of LIH living premises. In several cases, due to safety reasons, old wiring needs to be replaced before the installation of new equipment.

Monitoring

Main purpose of this phase was to monitor the effects of implemented consumption feedback services on behavior of the LIH and adjustment of individual smart

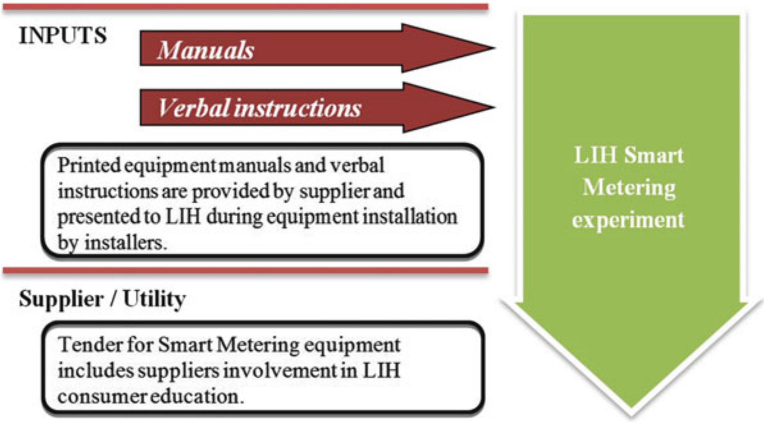

Fig. 7 Smart metering equipment installation phase

metering services according to the survey feedback from households, facilitating the living lab approach to fine-tune different smart metering services to different households (impact of social, cultural, and regional differences). Survey feedback from the tenants on their experience regarding available services was collected and evaluated. Based on these results, the additional adjustment of consumption feedback was done during the monitoring phase:

- Adjustment of monthly report with consumption indicators (printed report or interactive web page).
- In the cases of individual appliance monitoring, it was enabled that the monitored appliances might be changed.

During this phase, three main findings of recognizable benefits have been recorded:

- Tenants have become aware of individual appliance consumption and expressed the surprise of their effects on the monthly electricity bill. In some cases, tenants turn down the heating/cooling when prompted on excess consumption.
- Awareness of current consumption and households' environmental footprint has initiated clear interest about additional energy efficiency measures to be implemented in the households.
- Multiplying the effect of complementary energy efficiency measures. When other energy efficiency measures are implemented (i.e., thermal insulation, double-glazed windows, etc.), the consumption feedback additionally motivates the tenants to adapt behavior to implemented technical updates and modifications.

Figure 8 shows the main characteristics of the monitoring phase.

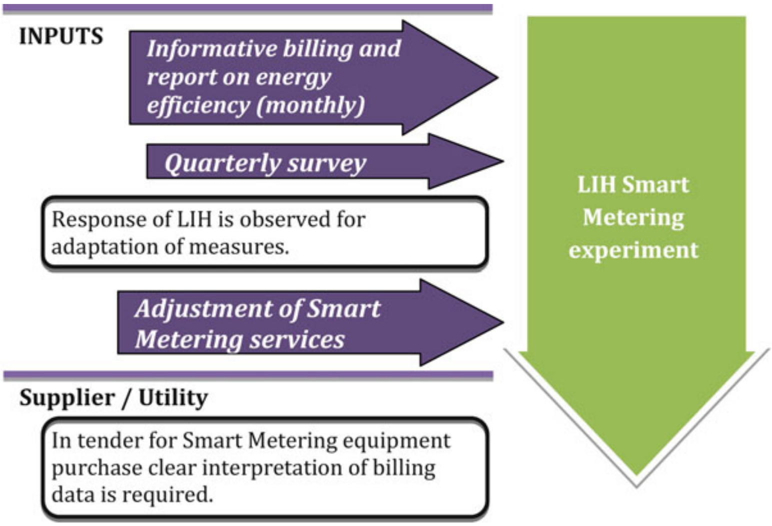

Fig. 8 Monitoring phase

Evaluation

Within this phase, household consumptions as a result of smart metering experiment and induced behavioral changes are to be analyzed. Monitoring and review of the experimentation progress include the consumer experience of the process, new smart metering functionalities, and identified services. Results of the analysis will be used as input in the process of the development of the Energy Savings Verification Model.

The preliminary analysis of LIH electricity consumption within the ELIH-Med project has clearly confirmed electricity saving potential with employment of smart meters and described functionalities. In all cases, principles of demand response and sustainable behavior changes have provided up to 5 % of electricity savings. In the cases where LIH consumers have applied additional load optimization techniques (economical usage of household appliances) stimulated by consumption feedback, up to 7 % savings have been achieved.

Future Research Challenges

Smart metering is primarily intended as an active element of utilities' energy distribution operations in smart grid infrastructure, but it has also shown potential as climate change mitigation tool through two additional *side effects*. The first is a support for the energy efficiency services and measures as an independent and customizable tool providing a more direct, comparable, and comprehensive information about households' energy consumption pattern. Secondly, smart metering infrastructure enables proper energy saving verification and validation. Based on the preliminary results from the ELIH-Med project, electricity utilities have the vital role in the smart metering implementation and must be involved in providing LIH with new customized services. Also, multi-energy metering must be established when other energy utilities are present (water, natural gas, district heating, and cooling), and the advantage of existing electricity grid infrastructure has to be explored. If smart meters are used for all utilities on-site, communication with these meters can be done via a smart electricity meter since the electricity meter can always provide the power supply for the communication. Sharing the remote communication channel can also greatly reduce the combined costs of communication and therefore costs for the consumer, which is vitally important for LIH. Even though that electricity is the most dominant energy carrier in the Mediterranean area, only a complete overview of household energy balance from all utilities (electricity, water, natural gas, district heating, and cooling) can induce proper consumer behavior changes as savings in one energy form may be replaced by increased consumption in the others.

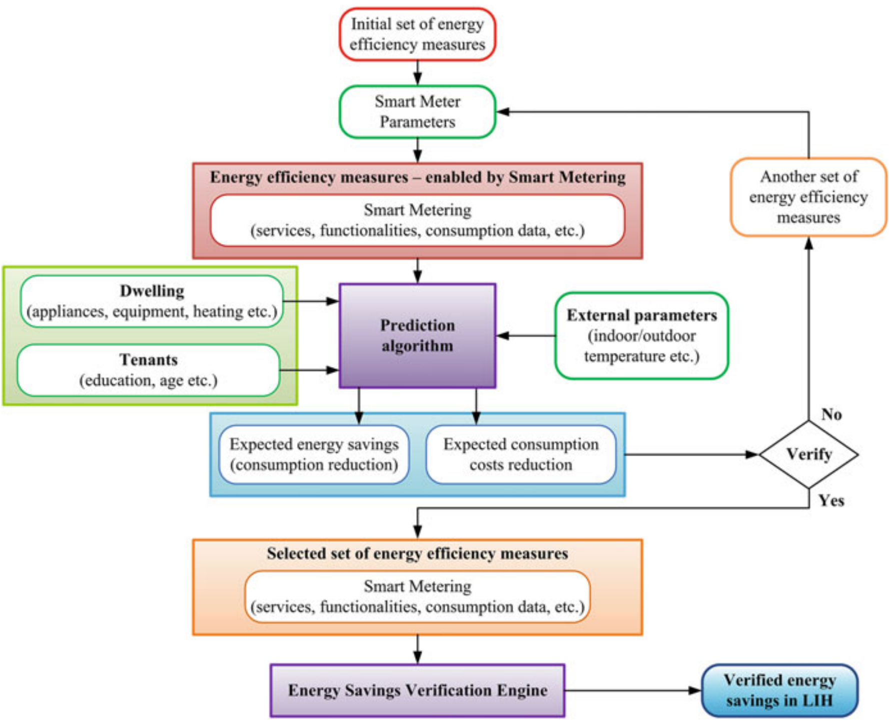

Fig. 9 Energy and cost saving prediction and verification flowchart

Energy Saving Verification

Results of the ELIH-Med smart metering experimentation process will be used to build an algorithm for the verification of energy savings considering different functionalities of smart meters in combination with the behavioral changes, implemented energy efficiency measures, and other influential factors. The experimental results enabled contextualization of the energy consumption where the notion of context refers to (actual) characteristics of the household and its environment, typology, social status, appliances, and devices. Database of performance results will also enable energy performance benchmarking, where a selected and comparable LIH can be benchmarked based on the input data gathered by household survey. Finally, the prediction algorithm based on the results of smart metering experiment will enable the forecast of energy savings and energy consumption cost reductions as shown in Fig. 9.

The outcome of validation model should also help Member States to decide which energy efficiency objectives and which benefits to the end consumers are taken into account when obliging market participants and setting minimum functionalities for smart meters. This obligation is established in the new directive on energy efficiency (Directive 2012/27/EU), which in Article 9(2)(a) states that Member States must ensure that "*objectives of energy efficiency and benefits for final customers are fully taken into account when establishing the minimum functionalities of the meters and the obligations imposed on market participants*."

Conclusion

Successful energy efficiency policy must be adaptive and must rely on the empirical data. Smart metering is a powerful tool for monitoring and verification and must be part of the comprehensive energy efficiency and climate change mitigation policy. Implementation of energy efficiency measures and utilization of the smart metering and its consumption feedback services in LIH may prove to be quite challenging introduction of changes in a very complex environment. However, energy-efficient behavior is a critical parameter for the success of each national energy policy and programs.

The ELIH-Med project clearly confirmed the importance of community involvement before and during the smart metering implementation. Also, in the case of LIH, it has been confirmed that proper and tailor-made consumption feedback has a potential to influence on the established behavioral patterns, break the habits, and initiate environmentally friendly actions. To make such feedback available, energy suppliers should offer innovative ways of covering the costs of additional smart metering services and equipment in LIH. Although individual consumption registration of energy-intensive household appliances may prove to have big influence on consumer behavior, it is the notification about relevant and extraordinary events in energy consumption that proved to have the biggest impact to behavioral changes in LIH. Also, it has been noticed that the awareness about energy consumption and households' environmental footprint has raised the interest for additional energy efficiency measures. In cases where other energy efficiency measures were implemented, the consumption feedback additionally motivated the tenants to adapt their behavior and achieve even bigger savings. Internet access has proved to be available for the majority of LIH and should be used for enriched consumption feedback. As consumption feedback will be specific to LIH, this is also an opportunity for different social programs to act through energy efficiency awareness campaigns in providing additional information and programs utilizing smart metering communication channels.

Transition to Low-Carbon Future in Nigeria: The Role of Pro-Environmental Behaviors

Oluwatosin E. Ilevbare, Maruf Sanni, Femi M. Ilevbare, and Godwin A. Ali

Contents

Abstract

Various environmental challenges pose a lot of threats to sustainable development, among which are global warming, air pollution, and loss of biodiversity. Many of the causes of these challenges are rooted in unsustainable human behaviors and thus can be managed by changing the relevant behavior so as to reduce its ecological and detrimental impacts. This chapter explores the potential for discouraging behavior that contributes to greenhouse gas emission into the atmosphere. It also suggests alternatives to fossil fuel-dependent pathways,

giving attention to the behavioral and social drivers of change in Nigeria. The chapter further prescribes behavioral and social changes into the roles played by households, business sector, and government policies. Strategic framework and initiatives for energy saving and adoption of low-carbon pathways in the medium- to long-term were suggested. The chapter concludes that to move toward a low-carbon economy in Nigeria, there is the need to institutionalize appropriate behavioral and social changes in the society as well as developing technological capabilities in the area of clean technologies.

Keywords

Low-carbon future • Nigeria • Greenhouse gas emissions • Climate change • Pro-environmental behaviors

Introduction

Global warming caused by climate change has been regarded by many scholars to be the most severe environmental challenge of the present time. Metz et al. (2007) estimated that the average global temperature has increased by approximately 0.6 °C over the past 150 years and projected to increase between 1.4 °C and 5.8 °C by 2100 if greenhouse gas emissions are not significantly reduced. Many developed and developing countries are faced with the dilemma of reducing the emissions of greenhouse gases into the atmosphere or face the considerable risks associated with global warming such as drought, excessive flood, sea level rise, food insecurity, increasing number of extreme events, etc. A lot of evidences in the literature support the fact that human activities are contributing immensely to global warming and that our failure to act now could lead to disasters such as increase mortality, disease, injury, heat waves, storms, and floods (Anderegg et al. 2009). Consequences of extreme climatic changes as a result of global warming are severe, and there has been considerable and disturbing concern among various environmental scientists and policy makers in various countries of the world. According to the World Health Organization (2002), it was estimated that global warming is responsible for 154,000 deaths worldwide by creating conditions more favorable for the spread of diseases such as malaria, dengue fever, and diarrhea.

Although the total greenhouse gas (GHG) emissions in Nigeria is minimal compared with the global average, nonetheless the carbon footprint in the country is on the increase due to her large population and fossil fuel-dependent economy. The major contributors of CO_2 in Nigeria include land use, land use change and forestry (LULUCF), energy consumptions, industry, solvents use, agriculture, and waste management (see Fig. 1). In 1994, the gross carbon emission was 52.5 Tg–CO_2–C, while the net uptake, principally from land use change, was 10.4 Tg–CO_2–C. This gives a net carbon emission of 42.1 Tg CO_2–C (FME 2003). The summary of national emissions of GHG is 192 Tg CO_2, 17.0 Tg CO, 5.9 Tg CH_4, and 2.2 Tg NMVOC. Others include 660 Gg of NO_X and 12 Gg of N_2O. Meanwhile, the total GHG emissions (in CO_2 equivalent) for the three main

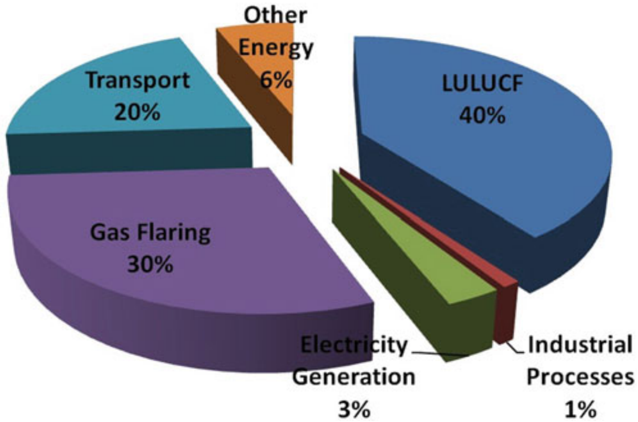

Fig. 1 Major sources of CO_2 emissions in 1994

greenhouse gases (CO_2, CH_4, andN_2O) and from the five main sectors (energy, industry, agriculture, land use change and forestry (LUCF), and waste) were about 330,946 Gg CO_2e in 2000. The net CO_2 was 214,523 Gg, representing 65 % of the national GHG emissions, methane (CH_4) was109,319 Gg CO_2e or 33 %, and nitrous oxide (N_2O) totaled 7,104 Gg (CO_2e) or 2 % (FME 2010).

Climate Change Impacts in Nigeria

Over the years, the conditions of human and capital developments remain challenging. Out of 187 countries ranked on the United Nations Development Programme (UNDP) Human Development Report (2013), Nigeria's position is 153. Average life expectancy is 52.3 years compared with 64.6 years in Ghana. Today, the maternal mortality ratio (deaths per 100,000 live births) is 630. The country's Multidimensional Poverty Index (MPI) value (the share of the population that is multidimensionally poor adjusted by the intensity of the deprivations) is 0.31, while the adult literacy rate stands at around 61.3. Climate change impacts are bound to add to some of these challenges. Climate change occurs when there is a change in the steady state of equilibrium in the climate system causing changes in one or more of the components making up the system (Metz et al. 2001; Kak'mena et al. 2012). Climate change is anticipated to impact across ecosystem, societies, human livelihoods, food security, human health, and well-being. This could be changes in temperature, changes in seasonal occurrences of rainfall, etc. According to the Intergovernmental Panel on Climate Change (Metz et al. 2001), a rise in temperature of between 1.4 °C and 5.8 °C by 2100 will have serious negative effects on the socioeconomic well-being of the people. Some of these effects in Nigeria include the following, among others: increase in amount of rains and number of rainy days, flooding in the coastal areas, and higher risk of 100-year flood occurring at shorter intervals. Africa is believed to be one of the most vulnerable continents to the effects of climate change (Obasi 2000; Metz et al. 2007). Nigeria, like other African nations which are at the receiving end of the effect of global climate change, is counting its losses from the impact of the phenomenon. From desertification and drought in the north to gully erosion and flooding in the south, the Nigerian citizens are directly feeling the effect of climate change on their socioeconomic life. There are many indications in the literature that the climate has not just changed, it has affected the way people conduct *business* in Nigeria. For instance, there has been increasing incidence of health risk (Eke and Onafalujo 2013), reduction in agricultural productivity (Dinar et al. 2006; Ayinde et al. 2010), reduced access to quality education, reduction in rainfall in already desert-prone areas of northern Nigeria (Medugu 2011), and increase in conflict occurrence and insecurity. All these have serious effects on the standard of living of the Nigerian populace and hence on their quality of life.

Over the past few decades, Nigeria like many other parts of the world is not immune to the adverse effects of climate change. For instance, studies have predicted that there is a possible sea level rise from1990 levels to 0.3 m by 2020 and 1 m by 2050 and rise in temperature of up to 3.2 °C by 2050 under a high climate change scenario (IFAD 2001). Under a low climate change scenario, however, there is possibility for a sea level rise of 0.1 m and 0.2 m by 2020 and 2050, respectively, and a temperature increase of 0.4–1 °C over the same period (IFAD 2001). The study also stated that a sea level rise of 1 m could result in loss of 75 % of the Niger Delta.

The negative impacts of climate change such as temperature rise, ill-health, erratic rainfall, sand storms, desertification, low agricultural yield, drying up of water bodies, and excessive floods are already being experienced most especially in the semiarid parts of Nigeria (Medugu 2011). Environmental degradation and attendant desertification are major threats to the livelihoods of the inhabitants of these dryland states of Nigeria. Also the increasing population pressure has led to intensive agricultural land use, overgrazing, bush burning, and high rate of extraction of fuel wood.

Nigeria's strategy has been to reduce greenhouse gas emissions while promoting sustainable economic development. Some of the ways proposed to achieve this include the passing into law the climate change policy and use of clean natural gas for productive uses in the power sector and in homes for cooking and in transport as compressed natural gas (CNG), among others. Few attempts have however been made by the government to explore behavioral approach to environmental sustainability in Nigeria.

Environmental Sustainability and Low-Carbon Development in Nigeria

Environment has been defined as the totality of the places and surroundings in which we live, work, and interact with other people in our cultural, religious, political, and socioeconomic activities for self-fulfillment and advancement of our communities, societies, or nations (Akinbode et al. 2003). Sustainability is a development that meets the need of the present without compromising the ability of the future generations to meet their needs (WCED 1987). Sustainable development stands on three pillars: social, economic, and environmental development. Sustainability in the area of environmental development is a policy by which the environment can be protected from pollution and dilapidation and replaced or restituted after degradation. In other words, environmental sustainability involves making decisions and taking action that can contribute to low-carbon economy in the interests of protecting the natural environment, with emphasis on preserving the capability of the environment to regenerate and ensure good quality of life.

Public perceptions and attitudes are critically important to both the supply and the demand side of the transition to a low-carbon economy (Poortinga et al. 2004). The reluctance of the public to accept new energy development in their community has been highlighted by the UK government as one of the main challenges to the transition to a low-carbon economy. On the demand side, perceptions of the need to take mitigating action against climate change, and of the ability to act on this, can be key precursors to personal behavior change and compliance with wider policies aimed at modifying behavior (Spence and Pidgeon 2009).

As Nigeria firms up strategies to promote environmental sustainability and improve quality of livelihood of the populace, there is the need to promote a low-carbon society through changing or modifying what people buy and how they work and travel. A low-carbon society has been described as the one that uses less energy and fewer resources through greater energy efficiency, which can also mean reduced costs for households and businesses (Scottish Government 2010). Such society consciously incorporates renewable sources such as wind, water, wave, and solar power in the energy mix. In all, a society such as this will be able to realize the economic opportunities that come from developing clean technologies, creating low-carbon manufacturing industries, and building more sustainable infrastructures and creating thousands of green jobs. In essence, people will be able to live healthier and more sustainable lifestyles. There are clear benefits in moving toward a low-carbon society. For instance, in the analysis of options for low-carbon development in the oil and gas sector of Nigeria, the low-carbon scenario reduced emissions by 750 $MtCO_2e$ (million metric tonnes of carbon dioxide equivalent emissions) or 34 % of the reference emissions. The revenues from sale of the additional gas and associated liquid petroleum gas (LPG) generated a positive net present value (NPV) of $7.5 billion at a 10 % real discount rate. It was concluded that the low-carbon scenario not only significantly reduces emissions but also generates higher economic returns from Nigeria's gas resources (Raffaello et al. 2013). However, there are challenges in trying to transition to low-carbon economy. For example, the capital cost of implementing the emission reduction options included in the low-carbon scenario is estimated at US$17 billion (Raffaello et al. 2013), but it is generally believed that the benefits of low-carbon economy generally outweigh the challenges in the long run.

Understanding how to change people's behavior toward more pro-environmental actions is thus a critical part of these processes. This study examines the evidence currently available on changing attitudes to sustainability and offers views on a number of different ways in which behavioral change could be encouraged among the key stakeholders in the country. In order to be able to achieve this, these critical questions are raised: Why do we consume in the ways that we do? What factors shape and constrain our choices and actions? Why (and when) do people behave in pro-environmental ways? And how can we encourage, motivate, and facilitate more sustainable attitudes, behaviors, and lifestyles?

Climate Change Response in Nigeria

Responding to climate change from both mitigation and adaptation perspectives involves strategic approaches from policy, regulatory, and institutional frameworks as well as technological point of views (FMENV 2010). It requires that all sectors of the economy be comprehensively addressed because of the multifaceted nature of the expected impacts of climate change. Another key aspect of these strategies is that of mobilization of financial resources to implement the programs. All these activities would only be possible with the establishment of a sustainable national climate change policy framework.

However, Nigeria's response to climate change threats in the context of policy development framework remains a major challenge. Despite its high dependence on fossil fuel and high vulnerability to climate change, Nigeria has just passed into law the climate change policy. This policy has a response strategy that could address the issues of mitigation and adaptation measures and financial requirements and mobilization. As a signatory to the Kyoto Protocol, the country has come up with this policy to address the impacts as well as maximize the opportunities there in. The policy focuses on adaptation, mitigation, finance, and technology. Presently, there are a number of existing policies that could be adapted and implemented in anticipation of climate change to reduce its potential adverse effects (FMENV 2010). Some of them include the first national communication to the United Nations Framework for Climate Change (UNFCCC), National Adaptation Strategy and Plan of Action on Climate Change for Nigeria, Greenhouse Gases Mitigation Options Assessments for Nigeria (2000–2040), National Energy Policy, Renewable Energy Master Plan, Natural Gas Flare Out Policy, etc.

National Policy Efforts to Combat Climate Change in Nigeria

The Federal Ministry of Environment (FMENV) is in charge of addressing issues related to climate change in Nigeria. The ministry has mandates to address the challenges of key environmental issues such as that of land degradation (deforestation, desertification, and coastal and marine environment erosion), air and water pollution, urban decay and municipal waste, as well as hazards of drought, coastal surges, floods, and erosion. The Nigerian government elaborated a National Environmental Policy in 1989. The policy was revised in 1999 to accommodate new and emerging environmental concerns. The goal of the revised policy is to achieve sustainable development in Nigeria and, in particular, to (i) secure a quality environment adequate for good health and well-being, (ii) promote the sustainable use of natural resources, (iii) restore and maintain the ecosystem and ecological processes and preserve biodiversity, (iv) raise public awareness and promote understanding of linkages between the environment and development, and (v) cooperate with government bodies and other countries and international organizations on environment matters (FMENV 2010).

In order to coordinate activities related to climate change matters, the FMENV created a Special Climate Change Department (SCCU). It was established in recognition of the importance attached to the issue of climate change and global warming and in view of the enormity of activities required for the implementation of the Climate Change Convention and the Kyoto Protocol (FMENV 2010). This unit has since been upgraded to the status of a substantive department in the ministry. The department has been the driver of the ministry's policy and programs on climate change. In addition to responding to international obligations, the Climate Change Department has been coordinating the activities of the Inter-ministerial Committee on Climate Change. It also oversees the activities of the Presidential Implementation Committee on the Clean Development Mechanism (CDM) in Nigeria. The Nigerian government also upgraded the Department of Meteorology in the Ministry of Civil Aviation to a full-fledged Nigerian Meteorological Agency (NIMET) in 2003. This was carried out so as to improve the national capacity to generate observational climate data and climate monitoring systems. The Federal Government has also enacted quite a few number of specific policies and action plans that could be adapted to support national climate change mitigation and adaptation response. Some of these initiatives include (i) National Policy on Drought and Desertification; (ii) Drought Preparedness Plan; (iii) National Policy on Erosion, Flood Control and Coastal Zone Management; (iv) National Forest Policy; and (v) National Biodiversity Strategy and Action Plan.

Other initiatives include the creation of the House Committee on Climate Change. This committee is mandated to promote sustainable behavior across the civil society, private sector, and government. Many states across the country are also taking a proactive stance with regard to climate change issues. For instance, Lagos State created a Climate Change Department and raised awareness through the Lagos State Public Schools Climate Change Club. Lagos State is also the only state in Nigeria that has a functional climate change policy. However, Niger State was the first state to convene a climate change dialogue and has harmonized legislation and restructured institutions to promote sustainable development and respond to climate change issues (FMENV 2010). Nigeria's First National Communication (FNC) was produced in 2003. This communication presented Nigeria's gross national emissions of GHGs by sources and by sinks as well as impacts, vulnerability, and adaptation measures against climate change impacts. The draft report of the Second National Communication (SNC) to the United Framework Convention for Climate Change has been finalized and the country is in the process starting the Third National Communication. The government of Nigeria has finalized a 10-year plan for stimulating Nigeria's economic growth (Vision 20:2020). The plans aim, among others, to reduce the impact of climate change on socioeconomic development processes in the overall context of preserving the environment for socioeconomic development. Other initiatives along this line include National Economic Empowerment and Development Strategy (NEEDS) I and II, 7-Point Agenda, etc. It is envisaged that these economic initiatives will strengthen environmental governance and optimize economic benefits from sustainable environmental management (FMENV 2010).

Many local and international development partners have also intervened with a lot of activities to raise awareness on climate change impacts in Nigeria. For instance, the British High Commission, with ICED and Christian Aid, supported advocacy programs to raise awareness in the National Assembly through the Nigeria Climate Action Network. A working document on adaptation strategies of actions which identifies interventions across 11 different sectors in which adaptation will be crucial for Nigeria has also been developed by the Climate Change Department and the Heinrich Böll Stiftung (HBS) Foundation. The Canadian International Development Agency (CIDA) supported the Building Nigeria's Response to Climate Change (BNRCC) program in a bid to explore the ecological problems and perceived impacts in certain ecological zones in Nigeria. The study covers the assessment of vulnerability, impacts, and adaptation to climate change in two sectors: agricultural production and food security and water resources (marine, freshwater/underground, rain) and water quality change. FAO has also carried out the assessment of potential impacts of climate change on agriculture, food security, and the environment in Nigeria.

Low-Carbon Society and Behavioral Strategies: The Conceptual Framework

A global treaty which encouraged action to reduce/stabilize greenhouse gas emissions was agreed upon in 1992. This treaty led to the establishment of the UNFCCC. The treaty was later strengthened by committing the signatories to agree to take action to cut their greenhouse gas emissions through the Kyoto Protocol. In 2005, the Kyoto Protocol entered into force and later ended in 2012 (UNESCO 2010). At COP 17 in Durban, the EU agreed to a second commitment period for the Kyoto Protocol (KP2), but there was no time to finalize all the rules. In Doha, at COP 18 the rules for that second commitment period were finally agreed upon, allowing it to move forward for another 8-year period (2013–2020). It is however surprising that most of the international agreements failed to incorporate human dimension which is key to the analysis of climate change issues. Rather most of the discussions rationalize human behavior and assume that they can be guided by just the economic tools (Kloeckner and Blobaum 2010). As such, the effects of climate change on humans' experiences and behavior as well as the psychological explanations behind humans' climate-related behaviors have not been adequately reflected in many of these agreements (Kloeckner and Blobaum 2010). As a result of this, many of the approaches to the issue of climate change have fallen short of addressing the average human's pro-environmental behaviors.

Climate change adaptation and mitigation is a multidimensional issue that demands integration across various key elements of the society such as household, business sector, and government. This multi-stakeholder dimension and approach is one of the best ways to successfully guide the process of changing human attitudes, perceptions, and behavior toward climate change impacts. Kloeckner and Blobaum (2010) and UNFCCC (2007) substantiated this fact by reiterating that understanding people's behavior related to climate change (mitigation and adaptation) is crucial for successfully dealing with the future challenges. The conceptual framework in Fig. 2 underscores the need for attitudinal change and energy-efficient behaviors among key stakeholders: household, business sector, and government. It is believed that the highlighted activities under these key stakeholders could contribute substantially to effective low-carbon economy.

Thinking Forward: Reducing Nigeria's Carbon Footprints

There are many interventions that can be used to generate desirable pro-environmental behavior changes. These varieties of strategies can be broadly categorized into two: regulatory and nonregulatory or voluntary (see Fig. 3) measures. Regulatory interventions involve making and changing laws or establishing rules that eliminate or restrict choice. A good example of this type of initiative is the fiscal measures which are financial incentives and disincentives that can encourage behavior change. Other examples of regulatory measures include performance and technology standards. Within the category of nonregulatory or voluntary interventions (Fig. 3), examples include nudges (see Table 1), labeling, negotiated agreements, training, and awareness. A mix of these policies has the capacity to provide better information, enabling emitters (both consumers and producers) to make better decisions to reduce their carbon footprints.

With regard to climate change impacts, it has now become a common knowledge in the private, public, and policy arenas that in order to secure more sustainable future, current patterns of behavior have to be modified. Although modifying behavior can be beneficial to the environment, change often does not occur among individuals on their own accord (Cervigni et al. 2013). It has been discovered that people still choose to act in an environmentally unfriendly manner even when they are aware of the benefits attached to acting differently. The reasons for such behavior fall into a number of categories that include financial cost (Stern 2000), lack of alternatives, anticipated regret, inconvenience (Stern 2000), ignorance, lack of concern, laziness or habits, the common dilemmas (Cervigni et al. 2013), and perceptions that their contribution can make no difference, i.e., powerlessness (Jackson 2005). Klockner and Blobaum (2009) proposed a model named Comprehensive Action Determination Model (CADM). This model conceives behavior to be predicted directly by three different motivational paths: The first is that "what people intend to do has an impact on their behavior," i.e., part of a person's

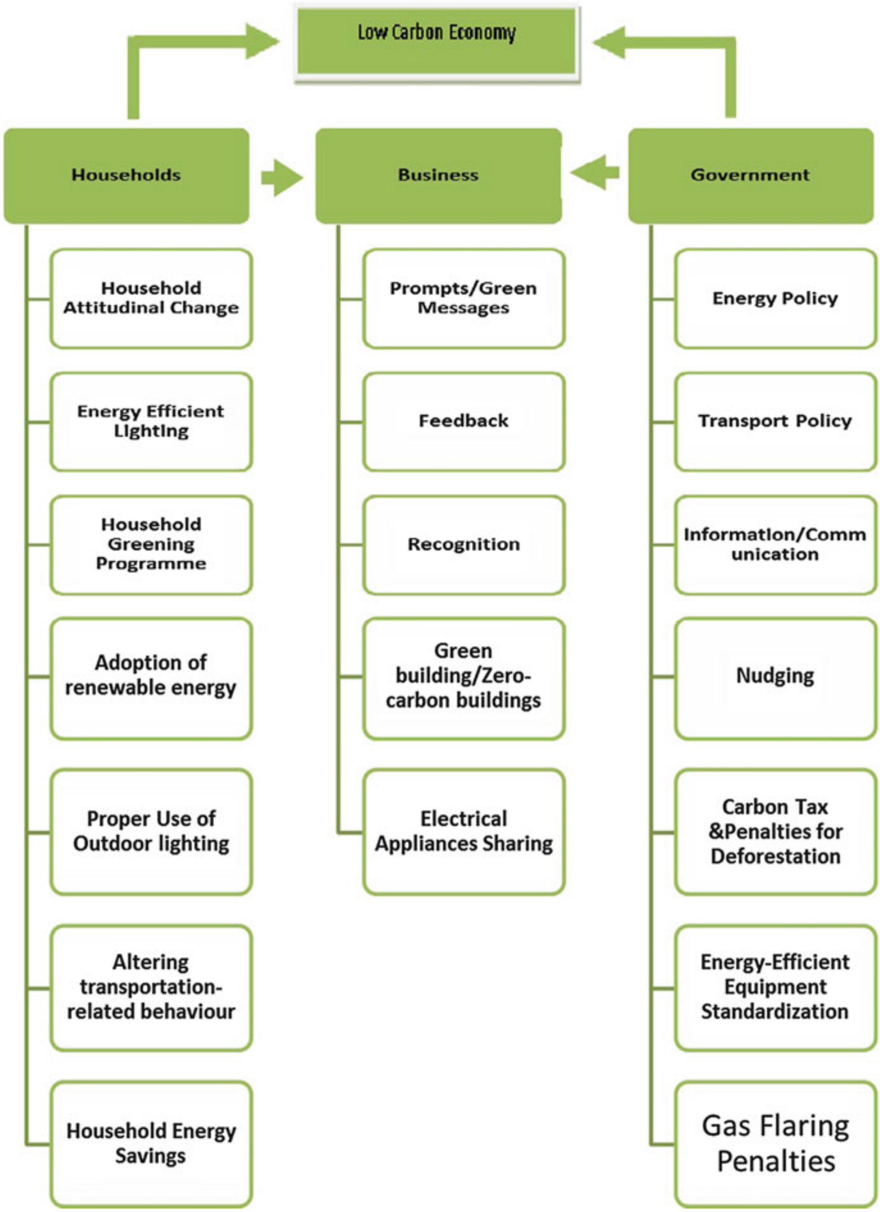

Fig. 2 The conceptual framework of action for the key stakeholders

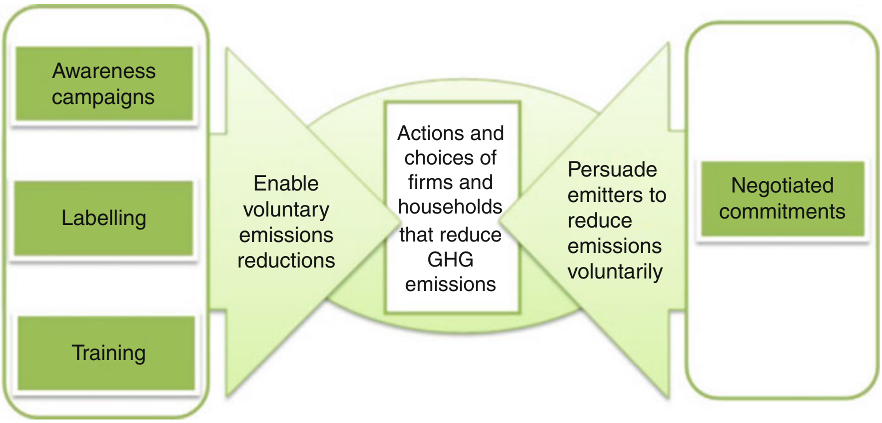

Fig. 3 Voluntary and information-based programs

behavior is assumed to be under the control of intentional decision-making processes. Secondly, “a person’s behaviour is under the control of the objective situational conditions and their subjective perception,” for example, when there is no mode of transportation that prevents carbon emission, an individual will not be able to enact the desired behavior even if they intended to do so. The third motivational path is “If people perform an action repeatedly, they start building routines and habits that over time, take control over their actions.” That is, habitual processes have the power to moderate the relations between intentions and behavior.

These factors have contributed significantly to the understanding of environmental behaviors among consumers such as individual households, governmental and nongovernmental organizations, etc. Meanwhile, studies have shown that one of the best determinants of future behavior is past behavior: people tend to be regimented in carrying out their tasks and stick with the old habits (Ouellette and Wood 1998). As a result of this, to change from undesirable old habits, there is the need for deliberate intention. In view of this, interventions that motivate or nudge (see Table 1) people toward pro-environmental behaviors should be targeted at their behavioral choices. It has been noted that such guided interventions enhance an individual’s capacity to change (Verplanken et al. 1998). Meanwhile, pro-environmental behavior has been described as action that reduces harm to the environment or even benefits it (Steg and Vlek 2009). However, it should also be noted that there are certain barriers to pro-environmental behaviors most especially as it relates to energy use (see Box 1). Examples of pro-environmental behaviors include recycling household wastes, purchasing “sustainable” products, using energy-efficient appliances, choosing green electricity tariffs, composting garden and kitchen waste, conserving water or energy, buying organic food, returning electrical goods for reuse or recycling, switching transport mode to more

Table 1 Types of interventions

		Interventions	Illustrative examples to encourage energy-saving light bulbs
Regulation		Eliminate choice	Prevent the use of conventional, inefficient light bulbs
		Restrict choice	Stop selling conventional light bulbs
Fiscal measures		Guide through financial disincentives	Increase tax on conventional light bulbs
		Guide choice through financial incentives	Reduce tax or subsidize energy-saving light bulbs
Nonregulatory and non-fiscal measures		Guide choice through nonfinancial incentives or coerce through nonfinancial disincentives	Offer a reward, e.g., entry into a prize draw, for buying energy-saving light bulbs
		Persuade individuals using argument and coercion	Persuade people that improving energy efficiency is important and that energy-saving light bulbs help save energy while reducing bills
	Nudges	Guide choices through changing the default policy	Supply energy-saving light bulbs in new light fittings and lamps
		Enable choice by designing or controlling the physical or social environment	Make energy-saving light bulbs the most prominent type at the point of sale
		Use social norms and salience, provide information about what others are doing	Use advertisements to show how many people are buying energy-saving light bulbs
		Provide information to educate and increase knowledge and understanding	Explain how energy-saving light bulbs work and how they save energy
		Do nothing or monitor the current situation	Track sales in different types of light bulb

sustainable ones, buying remanufactured or reused goods, reducing material consumption, etc. (Jackson 2005). Failure of several interventions has been linked to the complexity involved in changing behaviors. For instance, have argued that many interventions to promote sustainable behaviors do not take into consideration the rich mixture of cultural practices, social interactions, and human feelings that influence the behavior of individuals, social groups, and institutions. It is within this context that this chapter examines the roles of households, business sector, and the government in engraining low-carbon future in the country.

Box 1: Barriers to Energy Behavior Change

There are many barriers to energy behavior change to be considered when designing policy:

Low prominence of energy efficiency – energy is "invisible" and saving energy is often a low priority.

Low cost of energy – efficiency measures can be, or are perceived to be, relatively expensive.

Availability of energy-efficient technology.

Lack of knowledge and understanding of energy-saving behavior and efficiency measures available.

Hassle factor of installing efficiency measures, such as the need to clear out the loft before insulation.

Aesthetics, for example, where people are concerned about the attractiveness of energy-saving alterations.

Social norms (what other people are doing around you) – norms influence people's behavior and can prevent them from adopting a new efficiency measure.

Policy acceptability – for example, the government is unlikely to heavily regulate energy use because of a lack of acceptability within the electorate.

Households

Households are vital to delivering pro-environmental change, not just for themselves but also within organizations and networks as "agents of change." Everyday choices can make a difference from household travel, to use of electrical appliances, to cutting down of trees, to shopping choices. Households could engage in behavior geared at restoring and conserving the environment such as the use of energy-efficient lighting, household greening program, adoption of renewable energy, avoidance of forest deforestation, proper use of outdoor lighting, planting of appropriate tree species, use of energy-efficient stove at home, and planting of drought-resistant crops.

Household Attitudinal Change

Perceptions of the need to take mitigating action against climate change and capacity to take action are key determinants to personal behavioral or attitudinal change toward compliance with policies aimed at motivating such behavioral changes. Attitudes are the evaluations and associated beliefs and behavior toward some object or new experience. Attitudinal change most often precedes behavior. Explained that the idea behind attitude-behavior relationship is that the more people know about and understand the connections between their own behavior and a range of environmental threats, the more likely they will adjust their behavior accordingly. In essence, this requires households to logically consider incoming information and apply this new knowledge to their own behavior. Public perception and attitudes play a vital role in the transition to low-carbon emissions. However, it has been argued that attitudes are mainly context dependent and therefore not stable over time; thus they are not really suitable as a stable predictor of behavior. It has been suggested that the causal relation between attitude and behavior can also be bidirectional. For instance, Dwyer et al. (1993) and Leiserowitz et al. (2010a) found that in examining attitudes toward climate change, behavior influences attitudes more strongly than the other way around. In spite of this, whichever way we choose to look at it, it is clear that there is a strong link between attitude and behavior, and as such pro-environmental interventions targeted at households should take cognizance of this connection.

Energy-Efficient Lighting

Energy efficiency means using less energy to provide the same service. For instance, a compact fluorescent bulb or energy-efficient bulb is more efficient than a traditional incandescent bulb as it uses much less electrical energy to produce the same amount of light. Similarly, an efficient refrigerator takes less fuel to cool the items in it than a less efficient model. It has been reported that Nigeria's energy consumption can be reduced drastically if households use energy-efficient fluorescent bulbs. GEF reported that households could save up to 67 % of the energy they use if the use of traditional fluorescent tubes and incandescent bulbs are discouraged. Compact fluorescents consume an average of 75 % less electricity than conventional incandescent lights, thereby reducing the overall demand for electricity and the resulting greenhouse gas emissions and environmental impacts. Energy-efficient bulbs may be more expensive at the point of purchase but help save more in the long run because they last longer than the incandescent bulbs. Household should be encouraged and supported to use energy-saving lighting and appliances.

Household Greening Program

This is a concept that suggests the need for households to green the environment. This concept suggests that each building could be built in such a way that there is room for green plantation within the surrounding so as to allow the plant to absorb carbon dioxide in the environment as well as reduce excessive flood by increased infiltration rate. Household greening program contributes to the mitigation of climate change impacts. In addition to storing carbon, trees planted in and around our environment especially urban areas and residences can provide much-needed shade in the hot season, reducing energy bills and fossil fuel use. It could also serve as resistance during severe rainstorm as well as reduce air pollution.

Adoption of Renewable Energy

Energy plays a leading role in any economy. It supports practically every other sector. Renewable energy comes from natural resources such as sunlight, wind, rain, tides, and geothermal heat, which are naturally replenished. This is an important area for intervention, since burning fossil fuels accounts for nearly 70 % of all electricity

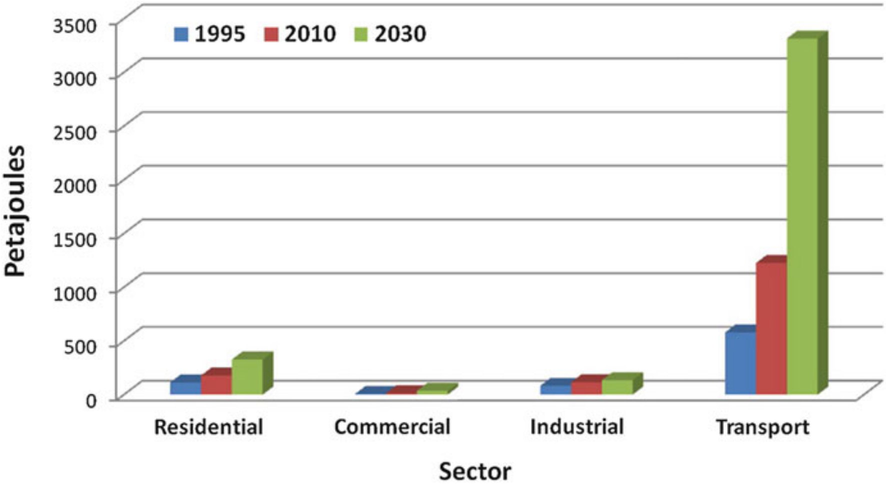

Fig. 4 Useful energy projections for Nigeria

generation (Energy Information Administration 2003a). With the abundance of renewable energy sources in Nigeria, the country could effectively mitigate the impacts of climate change. Individual household reliance on alternative sources of energy instead of relying solely on fossil fuel will likely contribute to climate change mitigation. Some of these alternatives include biogas, solar, and wind which are more environmentally friendly for cooking, heating, lighting, refrigerating, etc. It has been projected that residential energy demand for cooking and lighting will increase rapidly in the next decades, and as such integrating renewable energy into the energy mix at this level will be very important in the country (see Fig. 4). Education and awareness may, however, be needed to sensitize and orientate households toward the benefits of these renewable energy technologies.

Proper Use of Outdoor Lighting

Outdoor lighting is used at night to illuminate the surroundings. In Nigeria, however, most outdoor lights are often left on during the day. The proper use of outdoor lighting needs to be instilled among the populace. Lighting needs to be switched off when areas are unoccupied such as toilets, corridors, or even office areas out of hours. Outdoor lighting should only be on when needed. In Nigeria, where energy is generated mostly by burning of fossil fuel, leaving outdoor lights on when not needed increases consumption of fossil fuel and emission of carbon into the atmosphere. However, deployment of smart-metered electricity is expected to curb this behavior.

Altering Transportation-Related Behavior

Reducing vehicle emissions is often thought of as a technological challenge, with efforts going into the development of more efficient cars or fuels that produce fewer greenhouse gases per unit energy. Vehicles account for most of the carbon monoxide (CO) and a large share of the hydrocarbons (HC), nitrogen oxides (NO x), and particulates in major urban areas (ICCT 2013). In Nigeria, most automobiles imported into the country are old cars with inefficient fuel combustion system. It has been estimated that the export of used cars to developing countries and emerging markets worldwide will create additional pollution of 1.8 million tonnes of carbon dioxide (Bertinelli et al. 2005).

However, behavioral change could contribute to a low-carbon future by altering transportation-related behavior (Kollmuss and Agyeman 2002). Individuals could reduce travelling with personal cars, use video conferencing to attend meetings instead of travelling, join mass transit buses to office instead of taking personal car, etc. The proper maintenance and use of automobiles can help increase fuel efficiency and reduce energy consumption as well as pollution.

Household Energy Savings

Energy use at home contributes immensely to the total energy consumption of a country. The major energy-consuming activities in many homes in Nigeria are cooking, lighting, and use of electrical appliances (ECN 2005). Cooking accounts for a staggering 91 % of household energy consumption, lighting uses up 6 %, and the remaining 3 % can be attributed to the use of basic electrical appliances such as televisions and electrical irons (ECN 2005). Household activities can be tuned toward a low-carbon emission by encouraging individuals and households to turn off appliances instead of using standby mode and supporting the use of renewable energy, such as solar and wind energy. These activities will lead to low energy consumption at home and as such could help mitigate climate change impacts. Smart metering system that shows the amount of energy consumed daily could also be used to nudge household toward pro-environmental behavior.

The Business Sector

Climate change is affecting the ecosystems, marketplaces, and stakeholder needs in a remarkable way. This has created strategic new risks and opportunities for the business sector of the economy. For instance, many companies are now adopting pro-environmental innovative strategies so as to make them competitive in the global market. There is a large body of opinion that believes that an organization's culture plays an essential role in shaping the workplace behavior of employees in making them a low-carbon employee and hence widely considered to be crucial to an organization's performance. Organizations have roles to play in mitigating and adapting to the impacts of climate change in Nigeria. Industry and organizations use large amount of energy to power diverse range of manufacturing and resource extraction processes. Many industrial processes require large amounts of heat and mechanical power, most of which is delivered as natural gas, fuels, thermal, etc. In the past, most businesses in Nigeria have acted with little regard or concern for the negative impacts their production processes have on the environment. Many oil and gas companies in Nigeria were guilty of significantly flaring gas into the atmosphere until recently when the government has put some regulations in place to curb these activities. Subsequently, there are now an increasing number of businesses that are committed to reducing their damaging impact and even working toward having a positive influence on the environment. Below are suggested ways organizations can contribute to ensuring low-carbon future in Nigeria through the adoption of pro-environmental behavior.

Prompts/Green Messages

Prompting strategies are verbal or written antecedent messages that designate desirable target behaviors. Prompts are short messages used to elicit desirable behaviors. The message should be stated politely to avoid negative reaction. Geller et al. (1982) identified several conditions under which prompting strategies are most effective. Messages such as "Please, don't step on the Lawn," "Plant a TREE today," and "Switch off the Light" are simple messages that can remind people to mitigate climate change and as such preserve the environment. Prompt reminds people to make change again and again, until it becomes habitual. Prompts are most effective if specific and close to where and when the desired behavior occurs. Staats et al. (2000) found that office workers improved their energy-conserving behaviors (keeping thermostat settings consistent and putting off electrical appliances when not in use) immediately after an informational brochure was delivered. Later, other intervention components (posters and feedback) were added to maintain these energy-conserving practices.

Feedback

Feedback is vital to driving and sustaining change. Instead of understanding the changed behavior to be the end of the process, interventions should build in "feedback loops," i.e., opportunities to feed learning from the change process back into subsequent behaviors (Metz et al. 2007). Feedback should also be accounted for between individuals and organizations in networks and across society as a whole. A feedback strategy could involve providing information to staffs about their environment-relevant behaviors. Such data make the consequences of behavior (e.g., money spent, environmental degradation, or protection) more relevant and increase the likelihood of behavior change corresponding with the consequences. Some environment protection research that employed feedback strategy focused on household energy use and revealed that there was a modest and consistent reduction in energy consumption (Geller et al. 1982; Dwyer et al. 1993). Feedback reduces anxiety, encourages repetition of desirable behavior, and helps people know that they are making a difference. Feedback on energy use has been shown to have created savings of up to 20 % (Darby 2006).

Recognition

Organizations could engage in activities with the intention of reorienting the behavior of staff members toward reducing their carbon footprints. For instance, a form of recognition through monthly appraisal could help staff members in an organization to adopt energy-saving attitude. This could be in the form of award such as the "Most environment-friendly staff of the month." Also, offices can install a smart metering system which informs individual occupants how much they have consumed for the week and at what cost. Through this, individuals would become conscious of putting on appliances when they are not ready to use them.

Green Building/Zero-Carbon Buildings

Green building is defined as a structure that is environmentally responsible and resource efficient throughout a building's life cycle: from citing to design, construction, operation, maintenance, renovation, and demolition (World Bank Institute 2013). A green building is designed through architecture, materials, and fixtures to have a minimal impact on the environment. Improving the energy efficiency of organizational buildings through architectural building design will likely have the potential to reduce energy bills and building maintenance costs and more productive workers and increased building value. Organizations can adopt energy-efficient housing design principles with the aim of reducing the amount of energy consumed within the building. For instance, when the structure of a building adopts the use of fewer walls, it allows for reflection from outside, thereby reducing the need for artificial lighting during the day and access to ventilation resulting in less need of air conditioners.

Electrical Appliances Sharing

The concurrent use of electrical appliances in shared offices is a common sight in Nigerian offices. Appliances such as refrigerators, air conditioners, photocopy machines, fans, etc., can be shared among common-office occupants to reduce energy consumption. Organizations could inculcate in their employees the culture of putting appliances off especially when not in use, and they should encourage sharing of appliances among congruent office occupants.

The Role of Government

The government has a major role to play in the transition toward low-carbon economy. Government interventions in fostering human activities toward low-carbon emission can be of great benefit in terms of policy making, subsidizing the cost of energy-saving appliances, carbon tax on high emission appliance, ensuring importation of quality energy-saving appliances, and providing environmental education and regulatory guidelines.

Energy Policy

Issues such as energy crisis in the 1970s and concerns over climate change impacts have attracted the interests of policy makers in supporting incentives for electricity from renewable energy sources (Fischer and Preonas 2010). The IPCC has reported that apathy for fossil fuel could lead to the promotion of alternative sources of energy. Renewable energy technologies are being rapidly commercialized in developed countries. In 2012, about 26 % of the global final energy consumption came from renewable energy and supplied 21.7 % of global electricity (REN21 2013). During the 5 years from the end of 2004 through 2009, worldwide renewable energy capacity grew at rates of 10–60 % annually for many technologies. Nigeria is yet to harness this independent source of generating income for the economy and in solving the electricity crisis ravaging the country. However, the Energy Commission of Nigeria has developed a Renewable Energy Master Plan for the country. The main objective of the master plan is to promote clean, reliable, secure, and competitive energy supply into the national energy mix as well as meeting up with the national sustainable development agenda. The main goal of this project is to reduce projected energy use by 20 % by 2020 and meet 20 % of the country's electricity needs with renewable energy sources by 2020. This initiative combines energy efficiency, conservation, and renewable energy resources to meet future increase in energy demand while reducing its dependence on nonrenewable resources. As part of the implementation of this initiative, NNPC set up a Renewable Energy Division (RED) to develop private sector-driven investments in ethanol production as alternatives to fossil fuels. However, there is still a lot to be done in terms of national implementation, capacity building, and strong institutional framework to support this policy.

Transport Policy

In Nigeria, two main types of environmental policies could be proposed to alter or modify people's transportation behavior. These could be in the form of information and regulatory measures. In Nigeria, regulatory measures should include rebuilding and reintroducing rail transport in order to reduce the present massive use of buses for long distance travel, restructuring urban transportation to introduce car-free zones and urban mass transit system, subsidizing urban mass transportation, and improving the infrastructure for cycling and walking as well as green parks.

In addition, informational measures could be achieved through mass media by discouraging the use of personal cars or making it less desirable by raising awareness of the problems caused by carbon emissions from multiple cars on the road. Awareness should also be created on using mass transit buses, discouraging frequent travels, encouraging the purchase of eco-friendly vehicles, and changing in driving behavior (improved vehicle maintenance, fuel-efficient driving, and using telematics to provide information on traffic situations) (Jalel et al. 2011).

Role of Information/Communication

One enduring assumption of much public policy in the environmental domain claims that when provided with information, people will change their behavior toward low-carbon society. Human beings have the capacity to use information-based approaches to change significant others' behavior. Awareness creation can play a big role in changing the attitude of Nigerians on the need to develop a low-carbon economy toward mitigating and adapting to the impact of climate change.

Nudging: In recent times, many policy makers have incorporated the use of nudges on pro-environmental behavior change strategy. "Nudges" have been defined as “any aspect of the choice architecture (the context in which people make decisions) that alters people’s behaviour in a predictable way, without forbidding any options or significantly changing their economic incentives” (Thaler and Benartzi 2008). For instance, while removing incandescent bulb from the point of sale in a supermarket is a nudge, banning it or significantly raising its price is not (see Table 1).

Carbon Tax

The government can introduce environment-related tax reduction for organizations with less carbon emission during production/manufacturing in order to encourage organizations to adopt such production processes. For individuals that decide to leave their cars at home to use public transport, the government can subsidize mass transit buses and introduce congestion charges and subsidies for alternative fuel vehicles to encourage such activities. The Nigerian government could encourage businesses to reduce their carbon footprint by providing grants to invest in energy-efficient equipment and supporting the private sector for renewable and clean technology projects.

Energy-Efficient Equipment Standardization

The government has the obligation to ensure that the quality of energy-efficient appliances and equipment imported into the country is of high standard. If the standard of these appliances can be assured to be of good quality, it will encourage buyers and users to take the pain of paying more for these appliances. Also, the government can help subsidize these appliances in order to increase the willingness to buy. Government policies can be directed to encourage the importation and local production of energy-efficient light bulbs so as to reduce the cost of these bulbs.

Penalties for Deforestation

Strict penalties should be in place for the cutting down of trees unjustly. Deforestation should be discouraged as much as possible, and human activities that encourages the cutting of trees for survival and economy purposes could be diversified. Planting of trees will help increase mitigating climate change impacts. Trees are 50 % carbon. When they are felled or burned, the CO_2 they store escapes back into the air. According to the UNFAO (2006), about 13 million hectares of forests worldwide are lost every year, almost entirely in the tropics. The government can even take up the initiative of rewarding tree planting as it is done in the developed world. A nationwide program of reafforestation can also be developed. A case in point is the “Igi Iye” reafforestation initiative of the Osun State government in Nigeria.

Gas Flaring Penalties

Despite the legislative framework pegging the deadline for gas flaring of Nigeria’s petroleum sector on December 31, 2012, the Nigerian National Petroleum Corporation recently stated that gas flaring has only dropped by 15 % as of 2013 (Yakubu 2013). Nigeria flares volumes of carbon daily as part of its oil exploration activities.

Gas flaring has raised temperatures and rendered large areas uninhabitable. According to the World Bank 2012 Report on Global Gas Flaring Reduction partnership (GGFR), Nigeria is second next to Russia in terms of gas flaring and has remained so over a period of 5 years between 2007 and 2011. Nigeria, the highest producer of gas in Africa, loses about $1.789 billion or N286.24 billion to gas flaring annually (Deziani 2010). Due to the contained methane and carbon dioxide, Nigeria's gas flaring contributes more to global warming than all the other emissions in the whole sub-Saharan Africa. The Nigerian government needs to double its effort in addressing this situation by ensuring compliance with regulations and issue stiff penalties to nonadhering companies.

Conclusion

Climate change is a challenge that requires effort across individuals, organizations, and government levels. This chapter discusses the human behavioral contributions to climate change issues. It also addresses both the psychological and contextual drivers of these concerns in Nigeria. Pro-environmental behaviors are multifaceted, context specific, and affected by numerous factors, many of which need to be addressed simultaneously to facilitate the desirable change. Policies that aim to encourage pro-environmental behavior need to reflect these intricacies. As outlined above, there are a number of specific actions that key stakeholders can undertake to heal the environment and "green" their lifestyles. However, there is the urgent need to collectively focus on a more limited set of pro-environmental behavior goals for the purpose of public policy and awareness creation. This is important as it will ensure that a clearer focus would reduce some of the current confusion over conflicting information about what people can or should do as well as establishing a baseline against which progress could be assessed.

Policy Implications

In view of the issues raised above, the effectiveness of any strategic policy framework to address the effects of climate change in Nigeria both in the medium and longer term depends largely on achieving changes in behavior and attitudes among the key stakeholders. This will involve changing behavior by the households, government, and the practitioners in the business sector. In addressing these issues, some of the policy strategies should involve the widespread adoption of more sustainable options over the conventional alternatives, increased awareness about climate change, more increased support for the development of renewable energy infrastructure (such as waste to energy plants, wind farms, and related transmission infrastructure), and cumulative small-scale actions in individual homes (e.g., waste reduction, energy efficiency measures). This chapter reiterates that the specific objective of low-carbon future for the country should be the development, adoption, and implementation of sustainable policies, action plans, strategies, and regulation that promote pro-environmental behaviors as well as enhancement of increased investments in sustainable energy utilization via energy planning, nudging, regulation, enabling carbon tax, and improved public-private partnership options. These initiatives, if properly implemented, will stimulate the development of pro-environmental behaviors and implementation of environmentally sustainable policies, strategies, and regulation.

Abstract

Adaptation to climate change is increasingly supported through international financing. In contrast to mitigation, where the effectiveness of policy action can be measured through the metric "tonnes of CO_2 equivalent reduced," no universally accepted metric for assessment of adaptation effectiveness exists. Without such a metric, adaptation finance vehicles such as the Adaptation Fund or the Green Climate Fund encounter challenges when trying to compare the adaptive effect of projects in order to achieve an efficient allocation of their funds. First experiences with adaptation funding show a tendency to avoid final impact metrics. This might lead to a backlash against adaptation funding by electorates in industrialized countries if adaptation funding cannot show clear results. This report assesses two possible candidates for generic adaptation effectiveness metrics: (1) wealth saved from climate change impacts and (2) disability-adjusted life years saved (DALYs), which are widely used in public health policy analysis. Apart it is proposed to use no-harm assessments to evaluate environmental and cultural impacts of adaptation projects. The authors discuss uncertainties encountered in applying these metrics, including the uncertain link between commonly reported intermediate indicators and our metrics and ideas to handle such, e.g., the use of regularly updated methodologies and agreed climate and economic models.

Keywords

Adaptation • Climate change • Effectiveness • Metrics • DALYs • Adaptation Fund • Green Climate Fund

Introduction: Climate Change and the Emergence of Adaptation Policies

Burning of fossil fuels and other human activities have led to an increase of atmospheric CO_2 concentrations from around 280 parts per million (ppm) in the preindustrial era to more than 400 ppm in 2014. Global temperature increase from preindustrial levels has already reached more than 0.7 °C, and temperatures are expected to further rise 1.1–6.4 °C until 2100 leading to sea-level rise, melting of ice, and changes in wind and precipitation patterns (Solomon et al. 2007).

Due to these alarming trends, anthropogenic climate change has been on the agenda of the international community for the last two decades. A series of multilateral treaties tries to address the problem. The United Nations Framework Convention on Climate Change (UNFCCC) has the ultimate objective to achieve a "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner"

(Art. 2, UNFCCC 1992). The Kyoto Protocol to the UNFCCC, agreed in 1997, has introduced legally binding emission targets for industrialized countries and an array of market mechanisms to reduce the costs of reaching those targets, including the Clean Development Mechanism (CDM), which allows the generation of greenhouse gas emission credits through emission reduction projects in developing countries.

While adaptation to the adverse effects of climate change has generally taken a backseat to mitigation in international climate policy, parties to the UNFCCC and the Kyoto Protocol have increasingly realized that adaptation is vital in order to reduce the impacts of climate change that has already taken place or to which they are committed. Therefore, in 2001 the UNFCCC has set up two funds for adaptation financed by voluntary contributions of industrialized countries – the Least Developed Countries Fund (LDCF) and Special Climate Change Fund (SCCF), which are managed by the Global Environment Facility (GEF). In 2007, parties of the Kyoto Protocol established the Adaptation Fund (AF) with a creative system of financing. The AF receives 2 % of all emission credits (CERs) issued under the CDM, i.e., an in-kind tax on emission credit transactions. The CERs are then sold by the Trustee of the AF (i.e., the World Bank) in tranches. However, attempts to extend this tax to other market mechanisms have failed due to the resistance of Russia and other countries in transition.

The unexpected success of the CDM has led to a substantial inflow of finance to the AF. By 2014, 1.5 billion CERs had been issued, and the AF thus received 30 million CERs. Revenues from sales of CERs have reached about 190 million USD (Adaptation Fund 2013). This is a large sum raised in only 5 years compared to the 270 million USD the LDCF and the SCCF have raised together in 10 years (HBS/ODI 2011).

Besides these existing funds, the negotiations about a post-2012 climate policy regime have led to the commitment of industrialized countries to provide 30 billion USD of "fast start" financing to developing countries within the period 2010–2012. Around 20 % of these funds are allocated toward adaptation (analysis according to Nakhooda et al. 2013; UNFCCC 2011; VROM 2011). Additionally the Green Climate Fund (GCF) has been established as an operating entity of the financial mechanism of the UNFCCC, also being responsible for the funding of adaptation activities. It is in the implementation phase, and the GCF Board has been developing modalities and procedures since 2012.

Currently, projects financed with international adaptation funding are not assessed according to comparable metrics. The guidelines used by the AF's Project and Programme Review Committee (PPRC) entail many criteria for the assessment of projects, such as economic, social, and environmental benefits, meeting national standards, cost-effectiveness, and arrangements for management and monitoring (AFB 2010). These criteria are very general and do not allow to compare the concrete adaptation effect of project proposals. As another example, the GEF neither uses efficiency indicators nor global targets for adaptation projects (GEF 2008).

From an economic point of view, it would be desirable to maximize the adaptive benefit achieved with the available financial resources for adaptation. The limited level of these resources compared with the adaptation needs, which are three orders of magnitude higher – as calculated by Parry et al. (2009) – makes this even more urgent. This implies that funds need to be allocated to those projects/programs that bring the highest benefits to economies, people, and the environment. Clear metrics of the "adaptive benefit" and an evaluation of proposals with regard to these metrics are required.

This paper tries to identify universal metrics for adaptation benefits and test them by assessing existing adaptation projects. First attempts in the literature to use universal indicators are analyzed, and two universal metrics are proposed, which synthesize three existing approaches: saved wealth and saved health. As these metrics depend on long-term results of the projects, it is discussed how (measurable) outcome indicators can be linked with them. To illustrate and test this approach, it is applied to specific examples and conclude.

Lack of Universally Accepted Metrics: Opportunities and Challenges

For projects mitigating GHG emissions, a universal consensus has emerged that their effectiveness is to be measured in terms of tonnes of CO_2 equivalent reduced. This metric is used for all project-based mechanisms and allows calculating the efficiency of projects in terms of currency units spent to achieve 1 t CO_2 equivalent reduced.

Regarding adaptation, the situation is much more diffuse as adaptation policies just start to emerge and even basic concepts of adaptation are still contested. The 4th IPCC assessment report (Adger et al. 2007) is lamenting the lack of globally accepted and agreed indicators for vulnerability and adaptive capacity, while also noting that there is no consensus on the usefulness of such generic indicators. A 2008 workshop on adaptation metrics has not managed to identify universal metrics but only stated that good adaptation metrics should be comparable but also context specific and developed in participatory processes (IGES and World Bank 2008). The lack of universal metrics has continued until today (UNFCCC 2010b).

The skepticism against global indicators and the call for bottom-up approaches may be linked to the disciplinary background of many adaptation researchers and stakeholders: qualitative, case study-based social science. In this vein, e.g., Klein (2009) argues that vulnerability cannot just be defined by technical experts as any definitions involve value judgments. In his view, a definition rather has to evolve through a "consultative, stakeholder-driven process."

Economists have not managed to clearly specify adaptation metrics either. While there have been several influential studies on the economics of adaptation (Agrawala and Fankhauser 2008; World Bank 2010), they have concentrated on highly aggregated adaptation costs and did not assess how effectiveness of projects could be measured. In parallel to the elaboration of this study, further literature has been published that aims at universal metrification of adaptation benefits. Schultz (2012) has developed a concept on how to finance adaptation with a vulnerability reduction credit mechanism. Based on the polluter's pay principle, Schultz derived

Table 1 Opportunities and challenges of universal metrics for adaptation

	Opportunities	Challenges
Political view	Shared vision of adaptation goals	Choosing indicators will make some nations better off than others; agreement is therefore difficult (Hinkel 2008)
Ethical view	Transparent criteria for projects	Value judgments are needed (Hinkel 2008; Klein 2009)
Economic view	Ex ante identification of promising projects (Noble 2008), ex post monitoring (Noble 2008), ex post adjustment (Hallegatte et al. 2011), potentially allocation of funds (Butzengeiger et al. 2011)	Measurement of indicators is uncertain (Hallegatte et al. 2011; Hinkel 2008); important metrics are qualitative (IGES and World Bank 2008)

the idea of a universal compliance scheme that either leads to mitigation or adaptation activities. This fungible structure works with credits that quantify the vulnerability reduction through adaptation projects. These credits get monetized by annual calculation of the costs of climate change impacts per tonne of CO_2. Finally the polluter chooses if he complies through mitigation or adaptation credits. However the rudimentary model still lacks a detailed description on how both the climate change impacts and the vulnerability reduction can be quantified properly.

Baca (2010) discusses a market-based adaptation approach through a CDM-like system that allows polluters to generate emission allowances through adaptation activities. Hereby National Adaptation Plan of Actions (NAPAs) deliver a prioritization of required projects, and the mechanism tenders these projects through reverse auctioning. As reward the project developer receives emission rights (see Baca 2010, p. 10ff). However, a detailed description of the metrics to allocate emission rights to adaptation projects is missing.

A UNFCCC (2010a) review of approaches for assessing costs and benefits of adaptation options clearly shows that most approaches focus on either adaptation costs or vulnerability/risk management. Only two options clearly compare costs and impacts: cost-benefit analysis (see, e.g., ECAWG 2009; Moench et al. 2009) and cost-effectiveness analysis. This situation can be compared to the early days of assessing effectiveness of emission reduction, where the metrics to compare the effect of different greenhouse gases were contested.

What may be the reasons for the lack of global indicators, apart from disciplinary backgrounds? Table 1 shows that universal metrics bring both opportunities and challenges. On the political side, agreed adaptation metrics may help to improve the shared vision in the climate change regime. However, political agreement may be difficult as some metrics leave some nations better off than others. Ethically, universal indicators may bring transparency in assessing adaptation projects, but some scholars argue that defining universal adaptation metrics will include value judgments, which raises the question which stakeholders are involved in defining the metrics (Hinkel 2008; Klein 2009).

The largest advantages of universal indicators are on the economic side. Promising projects and programs may be identified ex ante, and monitoring may allow for ex post adjustments of projects (Hallegatte et al. 2011; Noble 2008). The main challenge here is that the prediction and measurement of indicators for adaptation is highly uncertain (Hallegatte et al. 2011; Hinkel 2008) given the missing knowledge on climate change and its impacts, as well as the development and influence of other socioeconomic variables. Hinkel (2008) argues that this makes outcome indicators for adaptation non-promising and calls for using process indicators. Hallegatte et al. (2011) are more optimistic by saying that cost-benefit analysis is a useful tool as long as uncertainty is satisfactorily addressed.

Concluding, the opportunities of universal adaptation metrics justify a closer look at possible metrics. However, the challenges should not be forgotten: while the political and ethical issues are not part of this chapter, it is explored how uncertainty could be addressed.

Synthesizing Three Approaches for the Effectiveness of Adaptation Projects

When searching for a universal metric for the effectiveness of adaptation projects, three existing approaches are particularly relevant: vulnerability assessment, cost-benefit assessment, and cost-effectiveness assessment.

Reducing vulnerability is the shared goal of many adaptation programs and is anchored in several UNFCCC documents. However, vulnerability is not universally defined, and many different vulnerability indicators and assessment exist: the Disaster Risk Index, the impact vulnerability index, the Disaster Deficit Index, UNDP's Vulnerability Reduction Assessment scorecard, and further vulnerability indicators (GEF 2008). Politically, it has never been possible to agree on a specific indicator. Therefore, vulnerability has to be incorporated in any adaptation metric system, but developing a new vulnerability (benefit) index will not solve the problem.

Another starting point for universal effectiveness metrics is cost-benefit analysis simply looking at economic benefits of adaptation projects. For example, Moench et al. (2009) discuss the appropriateness of cost-benefit analysis coupled with intense stakeholder participation and apply cost-benefit analysis for a series of case studies in India and Pakistan. In a bold study, the Economics of Climate Adaptation Working Group (ECAWG 2009) criticized the lack of a systematic way of estimating climate risks and the absence of an overarching methodology to facilitate comparisons between the risks posed by different hazards and in different geographies. It developed a methodology that gave rise to adaptation benefit-cost curves and applied it to China, Guyana, India, Mali, Samoa, Tanzania, the UK, and the USA. Such cost-benefit analysis can be criticized for neglecting nonmonetary benefits such as health, which is recognized by Moench et al. (2009).

Cost-effectiveness analysis, as the third approach, includes nonmonetary or difficult-to-monetize benefits as well: it identifies the least-cost method of reaching a prescribed target or risk reduction level. For instant, it is widely used in the literature on public health (see, e.g., Detsky and Naglie 1990). On the downside, cost-effectiveness analysis for adaptation was only applied in a sectoral context until now. Universal metrics are missing, which blocks comparison of effects between different areas.

With the indicators to be proposed, the intention is to synthesize the three approaches: while aiming to avoid the monetary-only approach of cost-benefit analysis, global comparability shall be guaranteed, currently missing in cost-effectiveness studies focusing on. Furthermore, vulnerability should be captured by the metrics as well.

Reasons for Moving Beyond a Pure Economic Approach

Theoretically, the effects of adaptation projects could be measured in monetary terms. This theoretical approach underlies the cost-benefit analysis approach of ECAWG (2009) which leads to a "benefit-cost curve" for adaptation projects. However, a substantial share of the benefits of adaptation projects is the avoidance of direct impacts on human life and health. Then the challenge arises on how to value human life and human health. Fankhauser and Tol (1998) argue that "values of a statistical life" embodying people's attitude to mortality risks should be used for that valuation. These values strongly depend on the income of the person and thus are substantially lower for a poor person than that of a rich person, varying by a factor of 15 between China and OECD countries (Fankhauser and Tol 1998). Other studies show a range of value of a statistical life of up to over 20 million USD (Viscusi and Gayer 2003; Viscusi and Aldy 2003), and the valuation is country, income, and age dependent (Aldy and Viscusi 2008; Viscusi and Aldy 2003). This approach thus became heavily contested in the elaboration of the 2nd Assessment Report of the IPCC, when developing country authors and policymakers strongly attacked what was seen as "Northern arrogance" (described condescendingly by Tol 1997). As a response to the controversy, Fearnside (1998) suggested to separate human lives and property values. In our view, Fearnside's approach should be followed to avoid endless political debates about an equitable valuation of human life and health. This is also in line with UNFCCC (2010a) which stresses that pure cost-benefit analysis "fails to account for those costs and benefits that cannot be reflected in monetary terms, such as ecological impacts and impacts on health." Thus it is differentiated between monetary and human life-/health-related benefits, in the form of two indicators.

Saved Wealth (SW)

Accumulated income not spent for consumption gives rise to wealth; this can include productive assets and other forms of property (e.g., real estate and precious metals). The indicator specifies wealth protected by an adaptation project against destruction by climate change impacts. For cross-country comparisons, purchasing power parity should be used.

When assessing the wealth benefit of an adaptation project/program, one can use two different concepts: absolute wealth and relative wealth (assessed on an aggregate or individual level).

"Absolute wealth saved" is similar to the approach of cost-benefit analysis as it measures the absolute wealth saved. The concept is straightforward but does not take into account differences of wealth, which might be crucial for overall resilience: regions with a higher wealth level would be favored. The indicator would be currency units.

In the concept of "relative wealth saved (aggregated assessment)," the absolute wealth saved by the project is divided by the total wealth of the region, city, or community. This allows accounting for differences in average wealth but does not yet cover the distribution of wealth within the project region. The indicator would be percent wealth saved times population.

In an alternative specification, "relative wealth saved (individual-level assessment)," the affected number of people and their individual wealth shares protected by the adaptation project are calculated. In contrast to the aggregate assessment of relative wealth, the relative wealth is assessed on an individual level and then summed up. Data challenges are massive as every person has to be accounted individually. This might only be possible in countries with a highly efficient tax administration and no data confidentiality restrictions regarding personal fortunes. Given data constraints, the concept is more realistic, when using a city or community as individual unit: in this case, the total relative wealth saved consists of the sum of the relative wealth saved in each city or community, rather the sum of the relative wealth saved per individual.

Advantages and disadvantages of the different approaches are described in Table 2.

The relative wealth concept (on an aggregated basis) seems to be most adequate from a vulnerability perspective, taking data availability into account. The more local the geographical scale of this relative wealth concept is, the better the concept addresses vulnerability. However, from an economic perspective, the absolute wealth concept is most appropriate as it measures the overall wealth savings. It is thus proposed to include both relative and absolute wealth savings in the saved wealth indicator in order to balance vulnerability and economic benefits.

For determining the potential of an adaptation activity to save wealth, one needs to consider autonomous developments of the wealth of the relevant region during the project duration. Demographic and/or economic developments over time will lead to changes of property and therefore wealth under a baseline scenario.

A time-related discounting of wealth in the region impacted by an adaptation activity should take place in order to reflect inflation as well as autonomous decrease of the economic value of infrastructure and hardware over time (capital consumption, standard accruals). Discounting is also important to achieve comparability of adaptation projects with different lifetimes.

Table 2 Approaches to measure saved wealth

Concept	Description	Advantages	Disadvantages
Absolute wealth saved	Wealth benefit in absolute terms	Relatively easy to measure	Benefits richer countries, does not reflect vulnerability
Relative wealth saved (assessed on an aggregate level)	Wealth benefit relative to overall assets of a nation, multiplied with population	Allocates (adaptation) funds to poorest countries (or regions, cities, communities)	Benefits not necessarily poorest or most vulnerable persons within a country
Relative wealth saved (assessed on an individual level)	Wealth % saved per person; individual percentages are summed up	Close to vulnerability	Data access difficult in case of individualized approach

Figure 1 below visualizes the effects of autonomous development of wealth in the region over time and of discounting on saved wealth.

The total wealth that can theoretically be saved by an adaptation activity is the discounted wealth that would be lost by climate change-induced events during the technical lifetime of the adaptation project/program. To calculate this, one needs a frequency distribution function of climate change impacts for the duration of the project (see Moench et al. 2009 for the first conceptualization of such frequency functions, here shown in Fig. 2).

Using the approach of the frequency distribution function, saved wealth (SW_p),[1] for a disaster risk reduction adaptation project, can then be calculated as

$$\mathrm{SW}_p = \sum_0^i \cdot \frac{\mathrm{MDP}_i}{(1+\mathrm{r})^i} \cdot \mathrm{DS}_i \cdot p_{\mathrm{occ},n,i} \tag{1}$$

where

$0\ldots i$: years of duration of adaptation project
MDP_i: maximum damage potential from climate change in year i
DS_i: share of discounted MDP damaged by event forecast in year i
$p_{\mathrm{occ},\,n,i}$: probability of occurrence of a certain damage event n (increase of risk due to climate change) in year i
r: discount rate to be applied to the project

From a purely economic perspective, total damage should be assessed and differentiated by whether it is due to baseline climatic variability or due to events that can be linked to climate change. For projects financed by third parties, only the differential damage due to climate change should be covered. However,

[1]Here, for simplicity just the absolute and not the relative wealth savings are calculated.

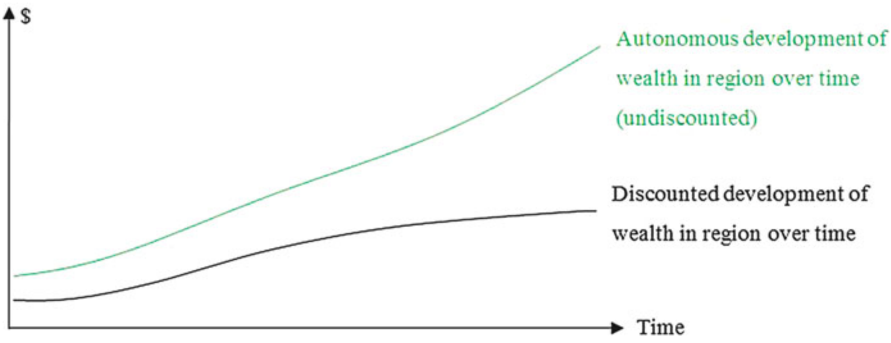

Fig. 1 Change of wealth over time and discounting

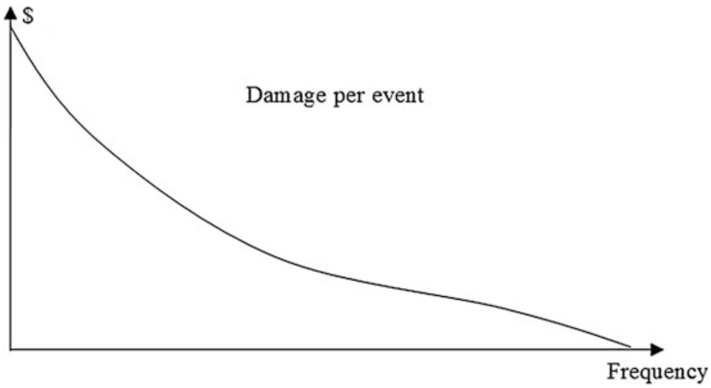

Fig. 2 Frequency distribution function of expected damage

differentiation of impacts from baseline climate variability, climate change, and autonomous adaptation is likely to be extremely difficult.

Saved Health (SH)

As discussed above, valuation of human life is fraught with ethical challenges and thus should be avoided, especially if comparing industrialized and developing countries. This section explores the concept of disability-adjusted life years saved (DALYs), which was introduced in 1993 by the World Bank (1993), and has since then been systematically utilized – inter alia by the World Health Organization (WHO) in the "Global Burden of Disease Concept" (GBD), which provides a comprehensive and comparable assessment of mortality and loss of health due to diseases, injuries, and risk factors for all regions of the world (WHO 2010a). It is a concept to quantify the burden of disability and death, expressed as the number of years lost due to disability and early death:

$$\mathrm{DALY} = N \cdot L + \sum_i I_i \cdot \mathrm{DW}_i \cdot D_i \quad (2)$$

where

N: numbers of deaths
L: standard life expectancy at age of death (in years). Here, an ethical issue is the choice of the region. From an equity viewpoint, the average global life expectancy should be chosen, whereas from a comparative economic view, the locally applicable life expectancy would be preferred:
I_i: cases of disease/injury i
DW_i: disability weight of disease/injury i
D_i: average duration of disease/injury i (years)

The weight factor DW reflects the severity of the disease or injury on a scale from 0 (perfect health) to 1 (dead) and has been estimated by WHO (2010b) for a wide range of diseases.

Taking the frequency distribution function approach described above (see Fig. 2), for assessing the saved health for a particular adaptation activity, one needs to define a health damage frequency distribution function that quantifies the typical health damages of a given event and its frequency.

Environmental and Cultural Benefits

The valuation of nonmonetary environmental and cultural benefits is fraught with conceptual difficulties (see, e.g., Bockstael and Freeman 2005). Fankhauser et al. (1998) describe the differences in willingness-to-pay and willingness-to-accept valuation approaches for such benefits. In our view, the challenges of this approach are so high that a simple “no-harm” rule should be followed for the evaluation of adaptation projects. For projects of certain minimum sizes, a qualitative evaluation system comparable, e.g., to standard environmental impact assessments (EIA) could be applied to check whether an adaptation project has negative impacts regarding biodiversity and soil, air, and water pollution. Likewise, projects should check whether cultural heritage, be it material or immaterial, would be jeopardized. Generally, an approach could be imagined where the host country of foreign-funded adaptation projects approves the ecologic and cultural sustainability, in a procedure akin to today’s approval of CDM projects.

Dealing with Uncertainty

Obviously, introduction of the impact indicators requires highly challenging data collection exercises. Given the uncertainties of future climate change and economic development, coordinated approaches are required to prevent ad hoc choices of data

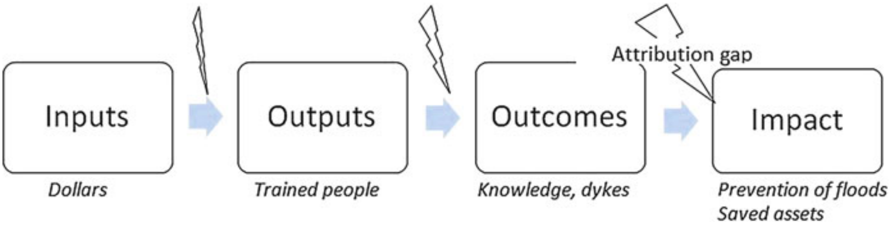

Fig. 3 Linking adaptation project outcomes with impacts (own graph)

that are favorable for the project developer. At first, a political agreement on the downscaled climate models used for derivation of the frequency curves of climate impacts is required. In a similar vein, forecasts for economic development need to be made consistent to allow a comparable wealth forecast. While the use of such indicators is certainly a non-perfect solution given data constraint, it is preferable to a situation where projects are evaluated according to a heterogeneous set of (often project-specific) indicators.

Links Between Intermediate and Final Indicators

As final metrics, such as saved wealth and health, are difficult to measure, multilateral institutions such as the GEF (2008) and the AFB (2010) use intermediate (so-called output and outcome) indicators for climate change adaptation projects, e. g., institutional capacity or awareness (see Fig. 3). How are they linked to our proposed metrics? Adger et al. (2007) emphasized the relevance of all outcomes shown in Fig. 3 for adaptation and reducing vulnerability. The only one not explicitly mentioned as factor contributing to adaptation is ecosystem resilience. Generally, the literature is not very explicit about the size of the effects, while it becomes clear that only few effects are direct such as the use of new dam technology on saving wealth. Most links are rather indirect and require an intermediate action (e.g., the climate change information provided by an early warning system has to be put into use via disaster response actions). Furthermore, several intervening factors may reduce the strength of the theoretical link, e.g., change in socioeconomic circumstances.

A key issue for output-outcome-impact links is the time horizon. The longer an adaptation intervention lasts, the higher is the risk that an adaptation, appropriate in the short and maybe medium term, turns into maladaptation. Maladaptation may be defined as "action taken ostensibly to avoid or reduce vulnerability to climate change that impacts adversely on, or increases the vulnerability of other systems, sectors or social groups" (Barnett and O'Neill 2010). For example, an adaptation project may change the design level of water supply for an irrigation system based on the estimate of the increased river flow due to glacial melting in the catchment area. As long as the glacial melting continues, the project contributes to adaptation, but once the glaciers have vanished, the irrigation system will be oversized and a water supply crisis will erupt. So in the long term, the link between outcome and impact indicators will be weakened.

A response to the risk of maladaptation could be to introduce an indicator that defines the risk of long-term maladaptation and to check this indicator periodically, triggering an adjustment in the adaptation project design. In the context of the irrigation project case, the indicator would be glacier volume in the catchment area and the probable date of glacier disappearance. If, for example, the glacier disappearance would be less than a decade in the future, a downsizing of the irrigation system would be started combined with an economic diversification strategy.

Dealing with Causal Links in the Future

The assessment of the existing knowledge and the use in practice has shown that outcome-impact links are highly uncertain and prone to risks. Furthermore, new scientific evidence may change the intensity or even direction of the expected effects. Therefore, any approach to estimate effectiveness of adaptation projects with global indicators has to apply a flexible approach allowing for permanent adaptation, as also called for by Hallegatte et al. (2011).

A four-pronged approach is proposed to guarantee flexibility. First, as start, the intermediate steps between outcome and impact indicators have to be elaborated more in detail. This idea is similar to the concept of secondary outcomes as proposed by the AFB (2010). Secondly, the intervening variables that enable or prevent an effect from taking place have to be identified and potentially measured or estimated. Third, all links and assumptions are to be seen as best assumption for the time being. As soon as new scientific evidence is available, the assumptions have to be changed. Fourth, the intermediate indicators as set out here are to be complemented or replaced by other indicators, if scientific studies show the importance of further indicators. In the end, various approaches and ways may lead to the desired results. Certainly, the current eight or nine indicators used by the GEF and the AFB are too broad if applied to specific sectors. An example of refined indicators per sector is given by Schönthaler et al. (2010).

How can this encompassing and flexible approach be achieved institutionally? One idea is to elaborate specific causal-chain methodologies for each sector or even better for each project type, similar to the methodologies in the CDM (see Michaelowa 2005). Methodologies could be elaborated by the AF itself, country program managers, international organizations, or academic experts. Each methodology would have to be approved by the AFB, and revisions can be proposed by stakeholders or the AFB itself at any time, as long as they are based on the newest scientific findings.

Application of Framework to Concrete Projects

In order to illustrate and test the applicability of the proposed impact metrics, five adaptation projects are assessed. For the assessment, information in the official project proposals downloaded from the Adaptation Fund website (AFB 2011) is

Table 3 Assessment of five adaptation projects against proposed metrics (own assessment, using project documents from AFB (2011))

Metric	Unit	Project A	Project B	Project C	Project D	Project E
Beneficiary intensity	Persons with improved livelihoods/ million USD of adaptation funding	22,600	Not reported	950	50	26,850
Wealth saved – absolute	USD saved per annum/USD	6	Not reported	0.3	0.7	Not reported
Wealth saved – relative	# of personal wealth saved/ million USD	5,000	Not reported	700	75	[530]
Health saved	DALYs/million USD	Not reported	Not reported	Not reported	Not reported	120,000
Environmental benefits	[Qualitative scale]	Positive	Positive	Positive	Slightly positive	Positive

used. No external sources were used to verify the information, which means that the following results are illustrative.

Table 3 shows the predicted benefits of the five projects when assessed against our metrics.

Relating to *absolute saved wealth* (measured in annual USD saved per USD of requested grant), project A has the highest score, followed by D and C. The other two projects did not give any information on absolute saved wealth. Where absolute wealth benefits were given, justification was mostly scarce and the assumptions were not fully specified. Projects report saved wealth not over the total project lifetime but only per year, which raises the question how long a project will last.

Relative wealth saved is measured here in number of persons whose personal income is saved per million USD of requested grant. This relative wealth number was calculated as share of average income saved multiplied with the number of beneficiaries. Therefore, aggregate wealth numbers were used, as individual wealth numbers are not available. Average income was assumed to equal the national GDP per capita using data from the World Bank (2011).

Project A scored highest before projects C, E, and D. For project B the factor could not be calculated as numbers of beneficiaries and absolute saved wealth are missing. Interestingly, project C is performing better on this relative wealth indicator than project D, whereas it is the other way round in case of absolute wealth saved. The reason is both higher number of beneficiaries and lower income in case of project C.

Finally, when assessing *health saved*, measured in DALYs saved per million USD of requested grant, no data has been identified in the project documents. For project E the number of beneficiaries with malnutrition is known, and assuming a disability weight of malnutrition of 0.3, one can estimate the number of DALYs saved.

The numbers given here would indicate that projects A and E perform highest on the adaptive benefit, before projects C and D. Deciding on the exact rating for the adaptive benefit will depend on the political weighting of different indicators. Environmental no-harm is never a critical issue, as all projects show significant positive environmental benefits.

This illustrative analysis of five adaptation projects has revealed two major problems: missing data on impact indicators and unclear assumptions. For making global metrics feasible, AF projects would have to be obliged to report on how they perform on promising impact indicators to assess their feasibility before introduction.

Conclusion

In contrast to climate change mitigation, the effectiveness of adaptation projects so far is not evaluated according to universally accepted metrics. As adaptation so far was the “step child” of the climate regime, it was mainly treated as a by-product of development assistance, and thus the evaluation procedures of development assistance projects have traditionally been used. These procedures are based on a “results chain,” with a series of indicators from input to project impacts.

To avoid a situation where adaptation funding is essentially distributed in a “first come, first serve” mode, it is imperative to agree on one or a set of indicators that allow a choice of adaptation projects according to their effectiveness per unit of money invested. A single, universal indicator is not possible due to the challenges in valuating protection of human lives and health. Therefore two main indicators are proposed: one assessing economic assets saved from destruction by climate change impacts (saved wealth) and one calculating human lives and health protected (saved health). The former indicator is a combination of two values, one of which is the absolute value of wealth saved, while the other looks at the relative wealth saved. This is done in order to better take into account vulnerability. The health indicator uses the concept of disability-adjusted life-years saved (DALYs).

The wealth indicator is calculated in a procedure that first estimates the expected wealth existing in the project area over time. Subsequently, the expected climate change damages during the lifetime of the adaptation project are calculated to set the baseline. A frequency distribution of damaging events is used for this purpose. Finally, the remaining damages after implementation or the project are assessed.

To reduce uncertainties that may make the indicator calculation irrelevant, coordinated approaches for the determination of wealth forecasts and damage frequency curves are required. A political agreement on the climate and economic models used would help. Here, the regulatory structure for the evaluation of emission mitigation projects in the context of the Clean Development Mechanism could serve as example. As an initial step, the indicator systems of adaptation funds should be oriented versus outcome indicators. Moreover, indicators should periodically assess the risk of maladaptation, especially for projects with a very long lifetime. The links between outcome and impact indicators should be studied in more detail.

Acknowledgments The authors would like to thank the Swiss Agency for Development and Cooperation for funding and participants of the Colorado Conference on Earth System Governance and the 2011 Climate Economics and Law Conference in Berne for comments and suggestions. Abstract

This chapter explores the state of the art in existing climate change risk, vulnerability, and adaptation assessment tools, with a focus on web-based tools. It then details the development and application of two online decision support tools created for climate change adaptation planning in cities – a Risk and Vulnerability Assessment Tool and Surface Temperature and Runoff (STAR) Tools. Both are freely available web-GIS tools that can be used to inform policy, strategy, and development. The Risk and Vulnerability Assessment Tool, developed through a collaborative and iterative process, follows the principles of an online public participation GIS. The Assessment Tool delivers GIS data and analysis functions online, widening the possibilities for participation in climate change adaptation planning. The STAR Tools enable assessment of the impacts of climate change on temperature and runoff in a specified urban area and evaluate the potential of green infrastructure as a climate change adaptation response. The STAR Tools can be used to develop "what if" scenarios, to illustrate how changes resulting from different land surface cover and climate change scenarios can impact upon local surface temperatures and runoff. The chapter presents the lessons learned from the development and application of these tools in municipalities across Europe and discusses key challenges for developing such tools to aid effective climate change adaptation planning in cities.

Climate change adaptation • Urban areas • Climate resilience • Vulnerability • Risk assessment • PPGIS • Web-GIS

Introduction

Climate change, causing temperatures and sea levels to rise and an increase in the frequency and intensity of extreme events such as heat waves, droughts, heavy rainfall, and storm, presents risks to human and natural systems (IPCC 2014). The IPCC assessment reports confirm that climate change should be addressed by both mitigating the greenhouse gas emissions that are causing global warming and adapting societies to a new climate context to enhance resilience to current and future climate hazards (IPCC 2013, 2014). While mitigation actions have been acknowledged as essential for some time, adaptation has more recently emerged as a central area in climate change research, in country-level planning, and in the implementation of climate change strategies (IPCC 2014).

Since around 50 % of the world's population is now urban and with further growth anticipated within cities in developing countries, increasing concern is being raised about the potential impacts of climate change on urban environments and their growing populations and valuable assets. The assessment of climate change risk can help with improving the resilience of urban areas to present climate hazards in addition to providing information to guide adaptation strategies necessary for reducing future risks associated with climate change impacts.

Risk can be conceptualized through a framework comprising hazard, vulnerability, and exposure (Crichton 2001). Thus, the assessment of climate change risks can be undertaken through detailed understanding the three components – hazard, vulnerability, and exposure – where:

- Hazard is defined as the extent, severity, and probability of the climatic hazard of interest (such as a heat wave or flood event).
- Exposure refers to the degree to which elements at risk (such as people or infrastructure) may come into contact with the hazard of interest.
- Vulnerability is defined as the susceptibility to damage of the elements at risk (such as people or infrastructure) to a particular hazard at a particular intensity (as determined by the degree of exposure which could occur) (Lindley et al. 2006).

Risk assessment with the use of the hazard–exposure–vulnerability framework is useful because it enables consideration of the inherent vulnerability of elements at risk such as infrastructure or populations, rather than focusing on impacts only (Lindley et al. 2006). Identifying where vulnerability is high is central to targeting locations which require climate change adaptation strategies. Adaptation strategies act to reduce vulnerability by lowering exposure and increasing resilience of elements at risk to climate hazards. Thus, where vulnerability is reduced, the risk associated with impacts of climate hazards is significantly reduced (Lindley et al. 2006).

Appropriate data, knowledge, and information are vitally important to enable the assessment of climate change-related risks and a prerequisite to identifying city-scale adaptation responses. Spatial data and information in particular can provide the knowledge needed to identify context-specific vulnerability, thereby enabling spatially targeted assessments of risk and implementing appropriate adaptation responses across cities. A web-GIS (or Internet GIS) approach enables delivery of GIS data and analysis functions on the Web through the Internet (Peng 2001). Web-GIS tools therefore enable spatial information to be integrated and readily accessible to a wide range of stakeholders, creating a participatory environment and facilitating collaboration in climate change adaptation planning.

This chapter focuses on the development and application of two web-GIS tools to aid climate change adaptation planning, produced as part of the GRaBS Project (see section "The GRaBS Project"). A review of the state of the art in existing online vulnerability, risk, and climate adaptation decision tools was undertaken before the development of the GRaBS Tools began. This review is presented in section "Review of Online Tools for Climate Change Vulnerability, Risk, and Adaptation Assessment." Sections "The GRaBS Climate Change Risk and Vulnerability Assessment Tool" and "The Surface Temperature and Runoff (STAR)

Tools" discuss the development and application of the two GRaBS Tools created. Section "Conclusions: Lessons Learned and Key Challenges" concludes the chapter with a discussion of the lessons learned and key challenges for developing and implementing such tools for climate change adaptation planning in cities.

The GRaBS Project

The Green and Blue Space Adaptation for Urban Areas and Eco Towns (GRaBS) project (2008–2011) was a network of 14 leading pan-European organizations involved in integrating climate change adaptation into regional planning and development (Table 1). A key emphasis of the project was upon much needed exchange of knowledge and experience and the actual transfer of good practice on climate change adaptation strategies to local and regional authorities. The ten European municipalities involved represented a broad spectrum of authorities and climate change challenges, all with varying degrees of strategic policy and experience. These authorities were required to develop Adaptation Action Plans (AAPs) – documents to help guide adaptation decision-making within their organizations. The AAPs were informed by exchanges of knowledge and experience, together with evidence tools delivered by the research institutions to support policymaking, which included a database of case studies (Kazmierczak and Carter 2010) and online climate change risk and vulnerability assessment tools.

Review of Online Tools for Climate Change Vulnerability, Risk, and Adaptation Assessment

Prior to designing a web-based GIS tool for urban climate change adaptation assessment, a review was undertaken in 2009 to explore existing vulnerability, risk, and adaptation assessment tools. This review has been updated here to include some more recent examples of tools. A "tool" was interpreted as anything which identified itself as such within the broad climate and adaptation field, found through literature search terms and selected online search engines. Although tools are emerging which attempt to integrate mitigation and adaptation goals, tools focused on mitigation tend not to include strong adaptation elements.

There are widely different views on what constitutes a tool for vulnerability and risk assessment and for risk management in relation to climate adaptation. Certain key criteria used in past reviews were applied here in order to ensure that similar tools were assessed. A review conducted for the United Nations Framework Convention on Climate Change (UNFCCC) refined the definition of an adaptation decision tool, specifying that it must have a clear user dimension and the possibility for users to be assisted in the process of evaluating options (Stratus Consulting Inc 1999). In particular it required tools to be able to link adaptation options to impacts and allow an assessment of trade-offs. Tools were also required to have a clear user group, have available documentation, and be applicable at the national, regional, or local scale (Stratus Consulting Inc 1999). While this is a useful definition of an adaptation decision tool, it is also very specific and, subsequently, may be restrictive. For example, applying this definition may exclude some of the useful models or methods subsequently developed, such as the UKCIP Adaptation Wizard (UKCIP 2008). More recent reviews such as Scholze and Wahl (2009) and Garg et al. (2007) apply broader criteria and definitions to adaptation decision tools, allowing inclusion of the most recent developments in adaptation decision tools. For example, Garg et al. (2007) considered tools which tackle both risk and adaptation themes in keeping with the IPCC's definition of vulnerability: "the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude, and rate of climate variation to which a system is exposed, its sensitivity, and its adaptive capacity" (IPCC 2007, p. 883).

Garg et al. (2007) analyzed the specific aims and requirements of climate change-related decision support tools for the US Global Change Research Program. The analysis revealed that three core elements were required, as follows:

- Climate change policy development should be supported by providing mechanisms through which methods can be evaluated (such as scenario evaluations, integrated analyses, and alternative analytical approaches). These methods should be demonstrated using case studies.
- Successful climate change adaptive management and planning requires the development of information and other resources. Resources need to be clearly transferred from a research-based environment to an operational environment.

- Assistance is required to help stakeholders prepare appropriate scientific assessments and summaries of information to be used within the decision-making process and as a means to inform other relevant stakeholders as well as the media and the general public. In this context, the IPCC (2007) Fourth Assessment Report indicates that assessments need to be consistent, comparable, and transparent, allow integration, and represent reality as accurately as possible.

Given the huge variation in types of tools which could now be considered a form of climate change vulnerability and risk assessment tool, this review attempts a broad categorization of tools and provides indicative examples of each. Tools can be grouped into five key types. A brief introduction to each of these types is presented below, together with a number of exemplars of each type. It is notable that some tools may cut across one or more of these groups (Garg et al. 2007). Integrated Assessment Models are designed to look at a range of impacts and feedbacks in related sectors. However, no models directly dealing with urban climate risk and adaptation themes were found during the research for this review.

The five key groups of tools are as follows:

1. Risk and adaptation decision-making frameworks (process orientated): These tools are guidelines to completing risk assessments for the purposes of risk management: they do not actually provide the means to conduct risk assessments themselves. These tools guide users through the decision-making framework by using the questions that decision-makers would want to have answered as prompts and provide links to other sources to assist with collecting data to answer questions. Examples include the UKCIP Adaptation Wizard and UKCIP Risk Framework, Climate-ADAPT Adaptation Support Tool, and the Quality Standards for the Integration of Adaptation to Climate Change into Development Programming (CCA QS, UNDP's structural framework) (Table 2). Although many of these frameworks are generic and valid for all climate-related risks, some are specific to a single-risk theme and provide guidance and examples pertinent to that theme only.
2. Portals or "platforms": These provide a gateway to direct users to a set of more specific tools where information and/or guidance for risk and adaptation decision-making can be obtained. Some include the functionality to support limited manipulation or visualization of data from other sources. In general, they do not enable the creation of new data in response to specific user inputs. Examples include the World Bank Climate Change Data Portal and weADAPT (Table 2). The World Bank Portal includes additional tools for visualizing climate data, specifically the Climate Mapper (also a tool in its own right due to not being fully integrated within the host website). Other portals are much more independent from the tools to which they link, as is the case with the Adaptation Learning Mechanism (ALM) as the tools here are provided as links in a separate resource area.
3. General vulnerability, risk, or impact assessment techniques and approaches which can be applied to climate change risk and adaptation assessment: These

Table 2 Examples of climate change vulnerability, risk, and adaptation assessment tools

Name/type of tool	Purpose	Web link
Risk and adaptation decision-making frameworks (process orientated)		
UKCIP Adaptation Wizard	A guided five-step process to aid organizations to assess their vulnerability to climate change and aid adaptation planning	http://www.ukcip.org.uk/wizard/
UKCIP Risk Framework	A process based on standard decision-making and risk principles to identify risks, adaptation options and make decisions	http://www.ukcip.org.uk/wizard/about-the-wizard/ukcip-risk-framework/
Quality Standards for the Integration of Adaptation to Climate Change into Development Programming (CCA QS)	A framework for best practices to facilitate successful incorporation of climate change adaptation concerns in development projects	https://unfccc.int/adaptation/nairobi_work_programme/knowledge_resources_and_publications/items/5467.php
Adaptation support tool from Climate-ADAPT	Assists users in developing climate change adaptation policies by providing guidance and links to relevant sources and tools. Based on the UKCIP Adaptation Wizard and other risk assessment frameworks	http://climate-adapt.eea.europa.eu/web/guest/adaptation-support-tool/
Portals or platforms		
World Bank Climate Change Data Portal	"One stop shop" for climate-related data and tools. Produces map output, online summaries and links to additional tools	http://www.worldbank.org/climateportal
weADAPT	Portal to a range of tools for assisting climate change adaptation	http://www.weadapt.org/
Climate Mapper	Maps and visualizes climate model data for onward use by a wider user community to improve vulnerability assessments	http://www.iagt.org/focusareas/envmon/climatechg.aspx
Adaptation Learning Mechanism (ALM)	A knowledge-sharing platform providing an information database of resources on adaptation knowledge	http://www.adaptationlearning.net/
Climate-ADAPT	The European Climate Adaptation Platform is a portal to a large amount of information and includes tools such as the adaptation support tool, case study search and map viewer	http://climate-adapt.eea.europa.eu/

(*continued*)

Table 2 (continued)

Name/type of tool	Purpose	Web link
General vulnerability, risk, or impact assessment techniques		
Social Vulnerability Index for the USA	A comparative metric that facilitates the examination of geographic variation in social vulnerability and an indicator of disaster recovery	http://webra.cas.sc.edu/hvri/products/sovi_32.aspx
Severe Weather Impacts Monitoring System (SWIMS)	Online data capture tool enabling users to record impacts and responses to assess vulnerability to severe weather events	http://www.kent.gov.uk/business/Business-and-the-environment/severe-weather-impacts-monitoring-system-swims
High-level or screening models		
Climate Wizard	Shows historical and future climate projections for technical and nontechnical audiences and enables spatial data download	http://www.climatewizard.org/
MIST (Mitigation Impact Screening Tool)	Determines potential impacts of different Urban Heat Island (UHI) mitigation strategies on average temperatures	http://www.heatislandmitigationtool.com
Detailed models		
PRECIS (Providing Regional Climates for Impacts Studies)	Enables experimentation with The Hadley regional climate modeling system, including various data output options	http://precis.metoffice.com/index.html
AUSSSM	A numerical model that simulates the urban microclimate and enables analysis of the impact of changes in design parameters on the urban heat island effect	http://ktlabo.cm.kyushu-u.ac.jp/e/UHI/ausssm_tool/ausssm_top_e.htm
ENVI-met	Stand-alone fine-scale model which allows the impacts of different types of urban greening on buildings to be quantified	http://www.envi-met.com/

are more generic methods, including cost–benefit analysis, expert judgment, and scenario analysis (Willows and Connell 2003; Stratus Consulting Inc 1999). Additional tools useful to spatial planners include identifying constraint (or sieve mapping), tipping points/threshold analysis, high-level risk assessments, and decision pathway tools (ESPACE 2008). For vulnerability assessment a range of indicators, methods, and datasets have been produced, for example, the Social Vulnerability Index for the USA (SoVI). Individual computer-based tools usually incorporate one or more of these approaches, e.g., cost–benefit in addition to other assessment elements.

4. High-level or screening models where new data are created based on input datasets from one or more offline models: These would usually provide functionality to allow data to be manipulated and analyzed to provide new information which may be in real time. Examples include the Climate Wizard (Table 2). Given the challenges for hosting very complex tools on the Internet, online tools are usually of this form rather than very detailed models. These high-level models tend to be at national or regional level, with data at relatively coarse scale. Examples include the MIST tool (Table 2). There are few screening tools available below city scale.
5. Detailed models (usually for individual risk themes or sectors) which require considerable data and resource input and often a high level of technical competence: Such sophisticated models take a long time to run and are therefore less suited to online deployment, though they may run on intranet sites. An example is the Met Office PRECIS tool, a scaled-down climate model which takes days or months to process simulations. These tools have an important role to play, since once processing has completed offline, data outputs can be integrated into high-level models or portals. The AUSSSM and ENVI-met are detailed models for understanding urban heat island mitigation options.

Recommendations for a New Climate Adaptation Decision-Making Tool

Scholze and Wahl (2009) analyzed the Strengths, Weaknesses, Opportunities, and Threats (SWOT) of existing adaptation decision-making tools (Table 3), which are particularly valuable to reflect upon before developing a new tool, both to establish technical and functional requirements and to assist with developing the general "look and feel" of the tool. The opportunities highlighted in Table 3, including awareness raising, stakeholder interest to use and apply, customization to local settings, and developing a toolbox of all tools, are useful ideas to progress. Identified threats to be avoided include the challenge of making tools sufficiently reliable yet easy to use for a wide audience. Further, while online tools enhance access to evidence to support climate change adaptation and decision-making, a key weakness identified is the dependence on good Internet connectivity. Internet connection speeds and coverage have greatly improved in the last 20 years. However, detailed climate change information may by necessity be data intensive, and therefore models over the Internet may be prone to slow down.

Drawing upon this SWOT analysis, recommendations for new tools include to place the tool within a clear risk management and adaptation assessment framework/process, to house the tool within a website which acts as a data/tool portal, to ensure that terminology is clear and full documentation is provided for users, to ensure that the functions include those provided in existing tools, and to consider the possibility of a data upload element in the tool.

Table 3 Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis of adaptation decision-making tools (after Scholze and Wahl 2009)

Strengths	Weaknesses
Capacity-building elements	Lack of tools designed for the national level
Improved access to climate change information	Lack of consideration of cross-sectoral interactions
Evidence of entrepreneurial spirit in the tool developer community	Lack of consideration of financial implications (e.g., cost–benefit analysis)
Good handling of physical aspects very well (but are not as good on socioeconomic factors)	Lack of linkage to disaster risk management
Provision of data for nonexperts in an easy to understand format	Lack of communication of limits and constraints
Free, simple to use and open-source tools	Tools are not always developed with partners and can be donor-centric
Assistance with open and transparent decision-making process	Lack of monitoring and evaluation
Assistance with decision-making process	Tools do not handle implementation issues
Richness in the diversity of tools serving different needs; all are useful in some way	Online tools depend on good Internet connectivity
	Need more engagement with soft solutions
Opportunities	Threats
Customization to local settings	Resources could be wasted if there is too much overlap and poor coordination
Stakeholder interest to use and apply tools	Oversimplistic tools
Creation of a toolbox of all tools	Overshadowing of existing tools and policies and creation of “climate bias”
Cataloging all tools to see whether new tools are necessary to fill gaps	Competing tools
Greater coordination/collaboration needed	
Creation of high-quality tools through links to research and the scientific community	
Awareness raising (public and data needs)	
Business opportunities	
Development of peer review mechanisms	
Including adaptation and mitigation	
Capturing of local knowledge	
Handling trade-offs	
Identification of tools useful in particular settings and for particular tasks	
Integration of disaster risk management ideas to ensure valuable knowledge not missed	
Data quantity/quality transparency and assessment	

This review identified that there was no existing tool specifically for vulnerability assessment and that there was scarcity of tools specifically focused on cities and associated themes of interest. Furthermore, the use of a web-GIS approach is an accepted format for the development of tools in climate change adaptation planning. A web-GIS (or Internet GIS) approach enables delivery of GIS data and analysis functions on the Web through the Internet (Peng 2001). Spatial representations are important in the planning process, and web-GIS can enhance the traditional planning process through its interactive map exploration features (Dragicevic and Balram 2004). Dragicevic (2004) identifies three main ways that web-based GIS has enhanced the open use of GIS: spatial data access and dissemination; spatial data exploration and geovisualization; and, spatial data processing, analysis, and modeling. Web-GIS can effectively support the task of integrating data from disparate sources, making these available through the whole planning process, thereby enabling open and transparent decision-making (Dragicevic and Balram 2004).

The GRaBS Climate Change Risk and Vulnerability Assessment Tool

The GRaBS Climate Change Risk and Vulnerability Assessment Tool (hereafter, Assessment Tool) follows the principles of an online Public Participation GIS (Kingston et al 2000; Kingston 2007). The main aim was to develop web-based Geographical Information Systems (GIS) to enhance public involvement and participation in environmental planning and decision-making. These systems are referred to as PPGIS and are a form of Planning Support System. The main objective is based on the belief that by providing all stakeholders, including citizens, with access to information and data in the form of maps and visualizations, they can make better informed decisions about the natural and built environment around them.

Development of the GRaBS Assessment Tool

Development of the Assessment Tool followed an explicit methodology (Fig. 1). Following the review of existing state-of-the-art risk and adaptation tools, the project team embarked on a collaborative process of tool development with all the GRaBS partners (Table 1), in order to shape the exact form and function of the final Assessment Tool (Fig. 1). This process involved using Checkland's (1999) soft systems methodology to inform system development. Firstly, a user needs and requirements analysis of all partners was carried out via an online questionnaire to inform the writing of the functional specification which fed into the building of the beta version of the tools. This was piloted at a user workshop to test functionality and usability. Feedback from this workshop then led to numerous refinements to the

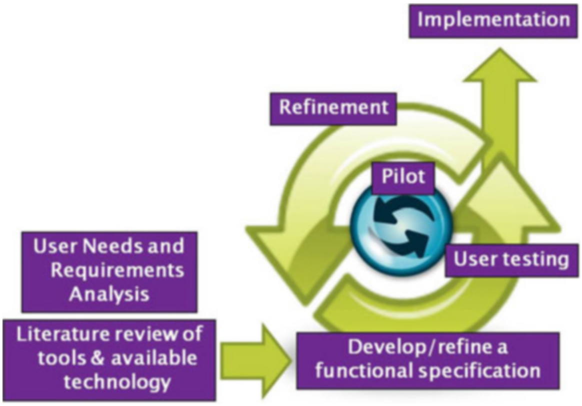

Fig. 1 The GRaBS Risk and Vulnerability Assessment Tool development process (Cavan and Kingston 2012)

tool followed by further user testing and refinement before the tools were fully deployed. This process is reported in detail in Cavan and Kingston (2012).

The nature of the GRaBS project with a pan-European user-base meant that the tool had to be built using a common map base for all partners. Using Google Maps' Application Programming Interface (API) which is free, generic, highly customizable, and probably, most importantly from a user perspective, very simple to use and navigate, meant that a single generic tool could be built for all partners. The GIS data is served over the top of Google Maps using MapServer, which converts proprietary spatial GIS data into an image format (in this case png) which speeds up the map rendering process for the user. This also means that the user of the Assessment Tool does not have access to the source GIS data, overcoming data access restrictions which might apply to some of the datasets depending upon their source of origin. The tool can therefore be categorized as a high-level or screening tool because the data used in the model is processed offline and the tool does not involve real-time processing of models (Scholze and Wahl 2009).

The Assessment Tool adopts a spatial screening risk assessment framework (Lindley et al. 2006, 2007), whereby an explicit set of spatial data layers are created in order to represent each component of risk (including separate layers representing hazard, vulnerability, and exposure). GIS overlay is used to represent the spatial coincidence that would be required in order for risk to be realized at a particular location. Thus, the online Assessment Tool presents climate change risks and vulnerabilities at a range of spatial scales from EU-wide to the neighborhood. The Assessment Tool allows decision-makers to overlay different raster, point, and polygon data layers to visually assess their spatial relationships and examine appropriate attribute information (Fig. 2b). For example, the user can investigate the spatial incidence of flood hazard, together with the distribution of vulnerable people, social and critical infrastructure.

There are over 350 different spatial layers in the Assessment Tool, with 32 EU-wide layers, and individual partner level data ranging from 7 to over 60 layers. This includes geospatial data from the following categories:

a

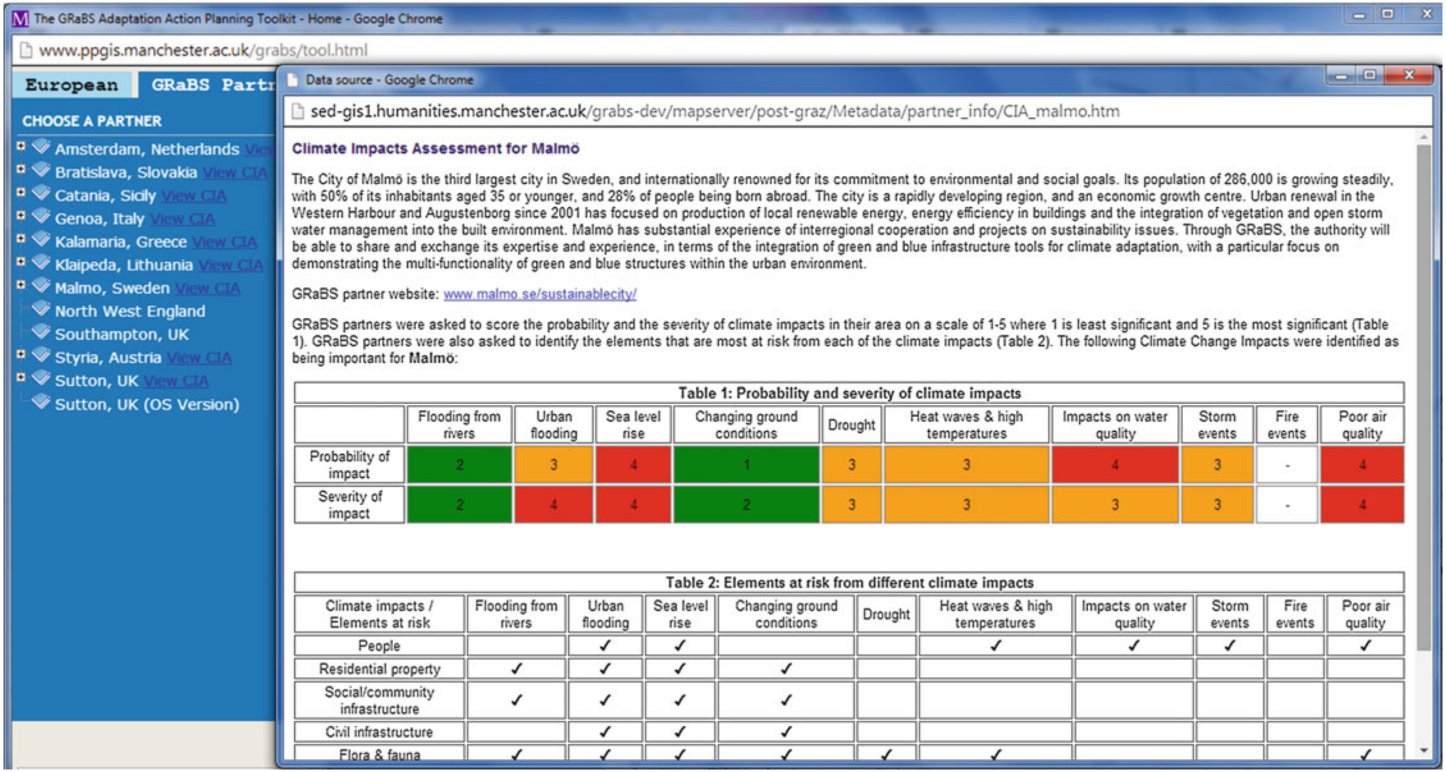

Fig. 2 (continued)

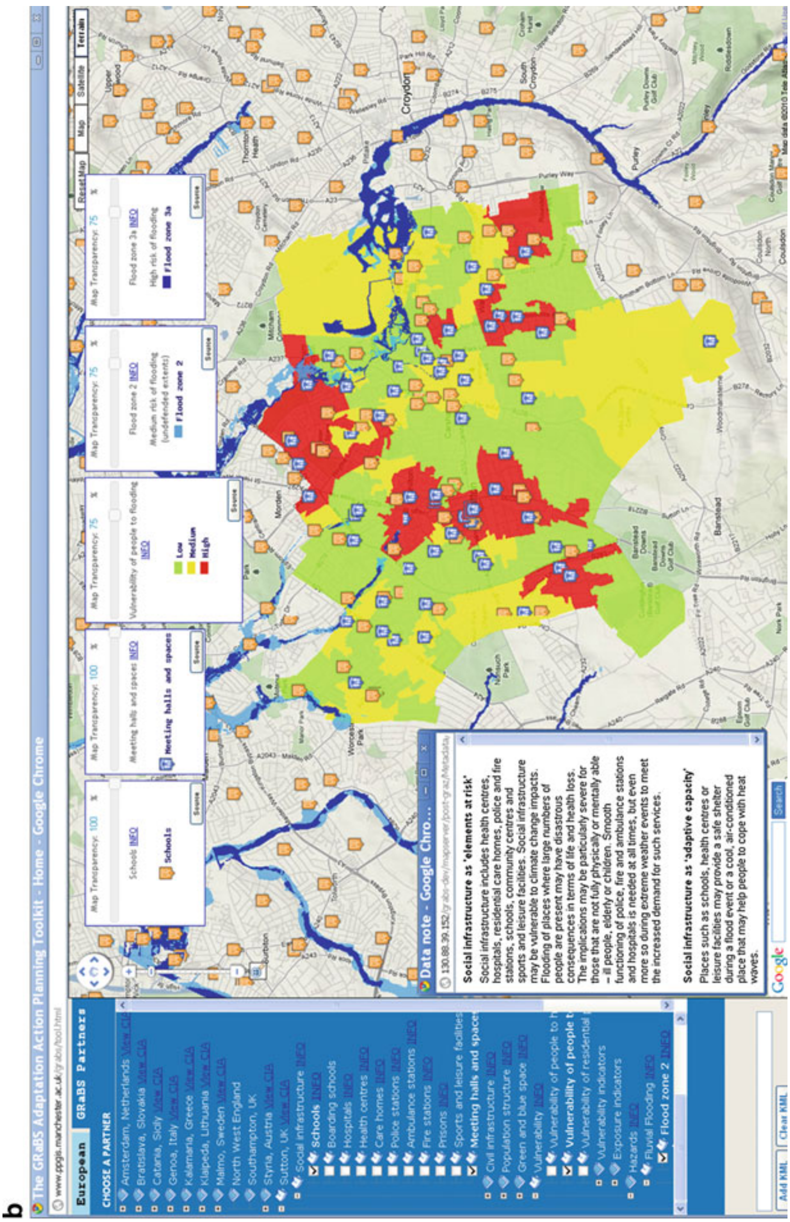

Fig. 2 The Risk and Vulnerability Assessment Tool: partner level interface (**a**) Climate Impacts Assessment and (**b**) vulnerability map

- Green and blue space, e.g., parks, public open space, rivers, canals, and lakes
- Vulnerability indicator, e.g., people aged over 75 years, people living on a low income
- Social infrastructure, e.g., schools, hospitals, fire stations, and public buildings
- Civil infrastructure, e.g., power stations, water treatment works, and railway stations
- Hazard, e.g. river, surface water, and sewer flood risk areas
- Vulnerability index, e.g., people vulnerable to flooding and high temperatures
- Population structure, e.g., population density and deprivation
- Urban development, e.g., building types and residential areas

The variability in the amount of local level data reflects both the extent to which different municipalities have been collecting relevant geospatial data and their ability to work across departmental boundaries to obtain necessary information. Additionally, qualitative information provided in hundreds of *data notes* offers important background information on the issues of climate change, vulnerability, and adaptation, including an explanation of key terms and why each layer may be important to consider in climate change adaptation planning. A summary of the key elements and functions of the Assessment Tool is provided in Fig. 3.

ELEMENTS	EXPLANATION
Portal	The tool is housed in a website which acts as a portal and provides other tools and guidance for risk and adaptation decision-making
Risk management framework	The tool is structured around a risk framework, including the themes of vulnerability, hazard, exposure, risk and elements at risk
EU and case study levels	The tool has two levels of operation – European and case study level, which includes the GRaBS project partners' study areas
Climate impact assessment (case study level only)	A pop-out window provides an assessment of the climate hazards and elements at risk of key importance within the GRaBS partners' area
FUNCTIONS	
Visualisation	Real-time display of point, polygon and raster geospatial data layers
Overlay	Overlay of up to five geospatial data layers
Transparency	A slider bar enables the user to adjust the transparency of the colour of a theme to enable the base map to be viewed more easily or to enhance the overlay function
Zoom, pan	Map navigation functions
Data note	Pop-up window providing clear terminology and interpretation of the data
Data source	Pop-up window providing metadata information
Data query	Enables querying of the attribute information of the geospatial data
Add kml	Enables upload of local data - particularly useful for sensitive or restricted information
Basemap	The user can view satellite, terrain or map modes

Fig. 3 Key elements and functions of the Risk and Vulnerability Assessment Tool (Cavan and Kingston 2012)

User guidance included the creation of three storylines or use cases (Cockburn 2000), which offer typical examples of how an individual or organization might use the Assessment Tool to support climate change adaptation policy and decision-making within their organization.

Application of the Risk and Vulnerability Assessment Tool Across Europe

Adaptation Action Plans (AAPs) were the key output of the GRaBS project from 11 of the partners – the municipal or regional planning authorities and partners that provide a planning support function. The AAPs were developed via a six-stage cyclical process, as follows:

1. Baseline review and process launch
2. Raise awareness and explore adaptation responses
3. Agree high-level aim and objectives
4. Agree delivery program
5. Implementation and monitoring
6. Evaluation and reporting

The AAPs represent a potentially significant influence over adaptation issues in the areas that they cover and support the partner urban areas and regions in developing responses to climate change and extreme weather. The key role of the Assessment Tool in supporting the GRaBS AAPs was identified through better understanding the connections between the Assessment Tool and three interlinked issues – the objectives of AAP development, the stages of AAP development, and the generic barriers constraining effective adaptation (Carter et al. 2010; Fig. 4). Taking these issues collectively, the Assessment Tool was identified as able to support adaptation planning and decision-making in four key areas: (1) raising awareness of climate change impacts and adaptation responses, (2) encouraging participation in adaptation planning, (3) enhancing data availability and use, and (4) supporting decision-making.

A questionnaire sent to GRaBS partners (Table 1) in January 2011 allowed an evaluation of how the Assessment Tool had been applied, the identification of lessons learned, and suggestions for future development. The following sections present an analysis of this information in the context of the key areas identified above.

Raising Awareness of Climate Change Impacts and Adaptation Responses

Raising awareness of climate change is an important early stage in the process of developing adaptation responses and can help to improve the adaptive capacity of individuals and stakeholders who have an important role in responding to associated impacts (Carter et al. 2010).

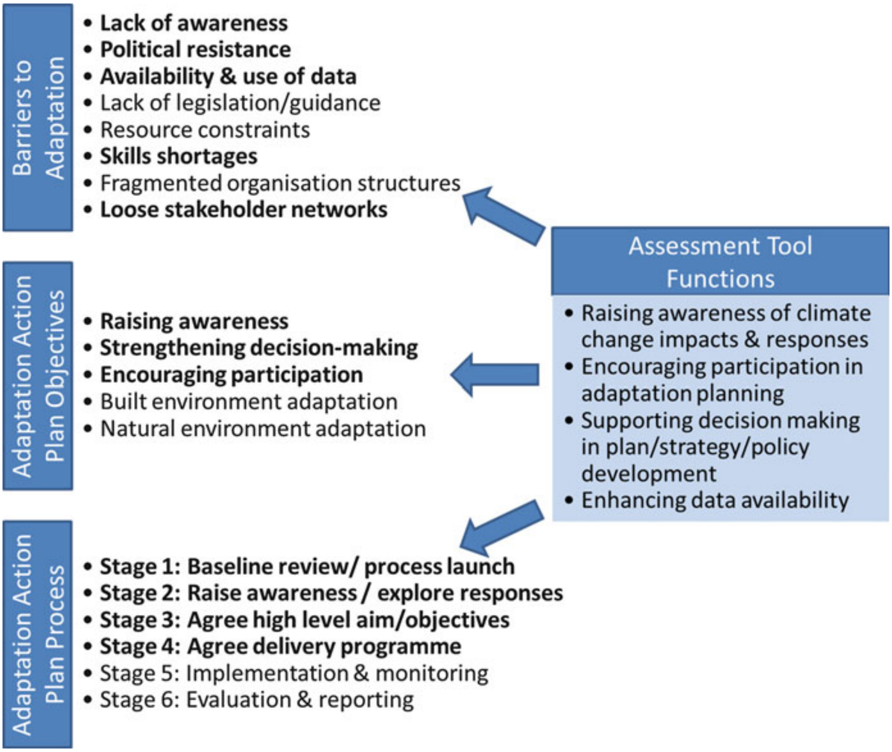

Fig. 4 The role of the Risk and Vulnerability Assessment Tool in supporting the GRaBS Adaptation Action Plans (After Carter et al. 2010)

The Assessment Tool was an excellent means of raising awareness of climate hazards and vulnerability among the public and decision-makers and a way to visualize "what can happen and what we need to take action on" (Cavan and Kingston 2012, p. 265). The Assessment Tool was demonstrated at many awareness raising events held for both internal and external stakeholders focused upon climate change impacts and local adaptation responses. A common structure to these events involved providing an introduction to climate change adaptation issues, the GRaBS project and Assessment Tool, a live demonstration of the Assessment Tool, and/or hands-on workshop session, questions, and discussion. The feedback from workshops was positive, with an emphasis on its user-friendly interface and useful spatial and contextual information provided in data notes.

It was noted that specific discussion at awareness-raising events depended upon the audience. When the Assessment Tool was presented to the public or private sector stakeholders with greater adaptation expertise, discussions often stimulated more questions than answers, for example:

- Regarding the capability (or limitations) of the Assessment Tool
- How to plan for future scenarios

- Its transferability to local authorities beyond the GRaBS partnership and the accessibility of relevant data
- Its principle use for awareness raising among local councilors or communities
- Conflicts with existing GIS tools in terms of building an evidence base for planning

Encouraging Participation in Adaptation Planning

Developing adaptation responses in urban areas is complex due to the ubiquitous nature of climate change impacts occurring across different sectors and spatial scales. Bringing stakeholders together in stakeholder workshops and community events can facilitate establishment of collaborative networks and generate consensus and a shared vision toward adaptation issues and responses, which will enhance the effectiveness of the AAP implementation process.

The Assessment Tool was valuable in encouraging participation in adaptation planning at stakeholder workshops and community events. For example, the London Borough of Sutton held a stakeholder workshop which incorporated a practical computer session for around 35 participants, including representatives of statutory bodies such as the Environment Agency, Natural England, and utilities (e.g., Thames Water), in addition to officers from a range of local authority departments. After an introduction to the GRaBS project, a hands-on workshop session enabled participants to explore the Assessment Tool. The discussion and feedback sessions were particularly valuable for the development of Sutton's "Community Map" (see section "Enhancing Data Availability and Use").

The Northwest England partner (NWDA and Community Forest Northwest) connected the Assessment Tool to other resources and tools aimed at encouraging participation in adaptation planning. The Community Forest Northwest website "Green Infrastructure to Combat Climate Change"[1] includes a wealth of resources developed through the GRaBS project including action guidance, an evidence base, an evidence report, and a link to the Assessment Tool. Specifically, the Community Forest Northwest encouraged stakeholders and community groups to apply the Assessment Tool through two key mechanisms:

- The "Framework for Action" – an action guidance document that can be used to aid issues concerning policy development and delivery.
- "Community Adaptation Training" – whereby the Assessment Tool is provided as one activity for community groups in the training materials. The training is intended for use by professionals with community groups to engage them on the need for climate change adaptation and/or how their local green infrastructure helps to adapt their neighborhood to climate change.

[1]Green Infrastructure to Combat Climate Change:http://www.greeninfrastructurenw.co.uk/climatechange/

Enhancing Data Availability and Use

Data availability was highlighted as a key barrier to climate change adaptation planning. The process of developing the Assessment Tool raised significant issues regarding data accessibility and availability within planning authorities, which need addressing if adaptation action is to be delivered successfully. A key function of the Assessment Tool is that it required the collation of spatial data in a consistent format to support adaptation planning. For the Municipality of Kalamaria, a lack of access to relevant data in relation to climate change vulnerability was a pertinent issue, and the AT's role also included identification of the gaps in necessary data:

> Awareness raising may be the most important use. The general lack of data on our behalf grabbed the attention of the attendees… Vulnerabilities have not been recorded for the climate change impacts at a local level in Greece so there is a need for them for proper estimation of risk.

Using a consistent framework throughout the Assessment Tool added significant value and allowed partners to investigate each other's local datasets, to assist in the development of their own tool. For example, the Amsterdam City District of Nieuw-West revealed that:

> We used other partner tools to demonstrate that there are still crucial data layers missing in our tool. By showing the value of these layers we hope that in the future, we can still gather these data and add them to the tool.

The Assessment Tool development process required the collation of data across different departments, thereby facilitating cross-departmental working and awareness raising among local authority staff. A key finding of the project was the need to break down silos between departments in order to gather evidence on the need to act on adaptation and to support adaptation planning.

The development of the Assessment Tool also stimulated GRaBS partners to develop local online GIS tools and portals. This includes the Province of Genoa's ADAPTO Adaptation Action Planning Toolkit, which enables visualization of local indicators for the assessment of the vulnerability of environmental parameters (Provincia di Genova 2013). In addition, the London Borough of Sutton developed their own web-GIS to facilitate community engagement and feedback on climate change and flooding issues at the neighborhood scale. The London Borough of Sutton (2013) online "Community Map" incorporates a comprehensive range of environmental issues relating to the delivery of council services, in addition to adopting the conceptual risk framework and relevant geospatial information from the Assessment Tool.

Supporting Decision-Making

The Assessment Tool supported decision-making in three ways: within Adaptation Action Plans, internal strategies, and through guidance documentation. The role of the Assessment Tool in the GRaBS AAP process differed between partners according to the form and function of the AAP, the stage of the AAP process that the Assessment Tool was applied, and the local information available to each partner (Carter et al. 2010). Thus, the application of the Assessment Tool within

AAPs also differed between partners, which ranged from explicit inclusion in high-level policy statements and delivery programs to use for gathering material to inform the development of the AAP, e.g., through analysis of the spatial data, to stakeholder workshops and meetings. Within the time frame of the GRaBS project, the Assessment Tool was applied at the first two stages of the AAP process by all of the GRaBS partners responsible for producing AAPs, where stage 1 is a baseline review and process launch and stage 2 is raise awareness and explore adaptation responses (Fig. 4).

Additionally, the Province of Genoa, Southampton City Council, and London Borough of Sutton incorporated the Assessment Tool into stages 4 and 5 (agree high-level aim and objectives and agree delivery program; Fig. 4). For example, Action 4 of the Province of Genoa's high-level policy statement states that

> Vulnerability to climate change risks, and adaption measures should be evaluated through a reliable, updated and flexible tool, able to answer specific local issues; then, the GRaBS assessment tool should be used both for building programmes and Provincial level, both for delivering green and blue infrastructure projects in homogenous physical contexts. (Provincia di Genova 2011)

Priority 4 of Southampton City Council's AAP "we will minimise the impact from flooding for the city" stated that it should implement the Assessment Tool in the Council's delivery program (Fig. 5). Additionally, Southampton City Council applied the Assessment Tool in internal strategies, specifically, strategic decision-making for climate change adaptation planning:

> It has been used internally by officers, already familiar with climate related risks, to help inform strategy work that is currently underway. In particular, it has been used to test the validity of assumptions about areas of the city that were believed to experience problems.

Suggestions for Future Tool Development

The final part of the questionnaire aimed to gather comments about future tool development, specifically, if there was a future version of the tool, what would users want it to do? Many of the GRaBS partners expressed the desire for the Assessment Tool to include future modeling scenarios, e.g., for land use, development, and climate, over various time horizons, including the "possibility to show a "before and after" situation about climate change adaptation effects in the region," and "the tool should also include the information on vulnerable objects (not only existing ones, but also planned developments)." The flexible spatial screening risk assessment framework adopted does allow assessing scenarios of different adaptation options, by adding new layers representing each component of risk according to potential future changes. However, such scenario development requires significant scientific research to be conducted at case study level before such spatial data layers can be included. The Assessment Tool therefore can at present only deal with current vulnerability to climate change. The Surface Temperature and Runoff (STAR) Tools were later developed to address this limitation and provide some modeling capabilities, which is the focus of the next section.

4. We will minimise the impact from flooding for the city
Southampton will be a city that is resilient to all but the most extreme floods and has robust emergency plans to respond to, and recover from, flooding.

Ref	Aim	Action	Measure of Success	Timescale	Progress	Lead	Resources
4.3	Raise individual and community level awareness of flooding and the measures they can undertake to reduce risks to become more 'adaptation aware' and able to manage the consequences of flooding	CCATCH project implementation of engagement strategies in Hampshire 2012-13	To be confirmed	2013	Amber	Rob Crighton, Special Projects Team Leader, Planning and Sustainability	✓
4.5	Market the key development assets in the city and reassure investors that Southampton is a safe place to invest	Develop an urban design showcase in partnership with the EA and the University which demonstrates managed adaptive approach to flooding in the city attracting prospective developers	A suitable site in Southampton is identified by 2011	2011	Green	Kay Brown, City Design Manager, Corporate Policy and Economic Development	✓
			Number of stakeholders signed up to attend the event	2013	Green		✓
4.6	Reduce flood risk to the city's most critical assets and vulnerable communities	Identify and map existing vulnerabilities to flooding and climate impacts in terms of the potentially adverse health and other consequences on people, property and essential infrastructure, taking critical thresholds and the extent of resilience into account	Climate Change Risks and Vulnerabilities Assessment Tool finalised and implemented through the city council emergency planning unit	2011	Amber	Sustainability Team and Emergency Planning Unit	✓

Fig. 5 Southampton City Council's Low Carbon City Strategy 2011–2020. A section of the delivery program for priority 4 (Southampton City Council 2011)

The Surface Temperature and Runoff (STAR) Tools

There is an increasing body of literature that emphasizes the multifunctional benefits of green infrastructure and its important role in adapting urban areas to climate change through, for example, flood alleviation and temperature regulation (Gill et al. 2007; Bowler et al. 2010). However, it is important to be able to quantify such benefits in order to illustrate the importance of green infrastructure and to highlight how changes to the built environment at a local level can affect the delivery of important ecosystem services it provides.

The STAR Tools is an online toolkit that enables users to assess the potential of green infrastructure in adapting urban areas to climate change (Fig. 6a). It includes two modeling tools – a Surface Temperature (ST) and a Surface Runoff (SR) Tool – both of which are underpinned by scientific models (see Gill 2006 for full details):

- Surface Temperature Tool: developed from an urban climate model (Tso et al. 1990, 1991; Whitford et al. 2001) and produces outputs of maximum surface temperature expected during the two hottest days in summer for a specified study area (98th percentile). Since the mix of different land surfaces (such as proportion of green cover, water, and buildings) is an important determinant of the land surface temperature, these parameters are also accounted for in the model.
- Surface Runoff Tool: based upon the US Soil Conservation Service approach (SCS 1972), this tool outputs the percentage of the rainfall that becomes surface runoff and the volume of the surface runoff for a given amount of daily rainfall. The Surface Runoff Tool thus calculates how much rainfall from a given event will not be converted to surface runoff; this could be because this rainfall is intercepted (e.g., by plants and vegetation), infiltrated (e.g., into the soil), or stored (e.g., on surfaces). The remaining rainfall is converted to surface runoff. Again, the land surface cover type is an important determinant of rainfall runoff and is accounted for in the model, as is soil type.

The STAR Tools are applicable for the “neighborhood” scale (recommended between 0.4 ha and 4 km^2), though they can be run for more than one neighborhood or study area at a time. The STAR Tools have few input requirements and are straightforward to use. The key benefit of the STAR Tools is that they allow the role of urban vegetation to be explored. This is possible through creating “what if” scenarios for both climate and land surface cover, for example, running the STAR Tools with the “business as usual” or current climate and land surface cover, compared to adding 10 % green cover and comparing the resulting output surface temperature or runoff. If several neighborhoods are run, the results can be mapped using GIS (see section Application of the STAR Tools to inform the Mersey Forest Plan), although this functionality is not available in the tool itself.

The STAR Tools enable assessment of how surface temperatures and runoff may vary under future climate projections and as the proportion of green space is increased or decreased. Thus, it can help to answer important questions such as: given the changing climate, how much greening do we need in particular areas to

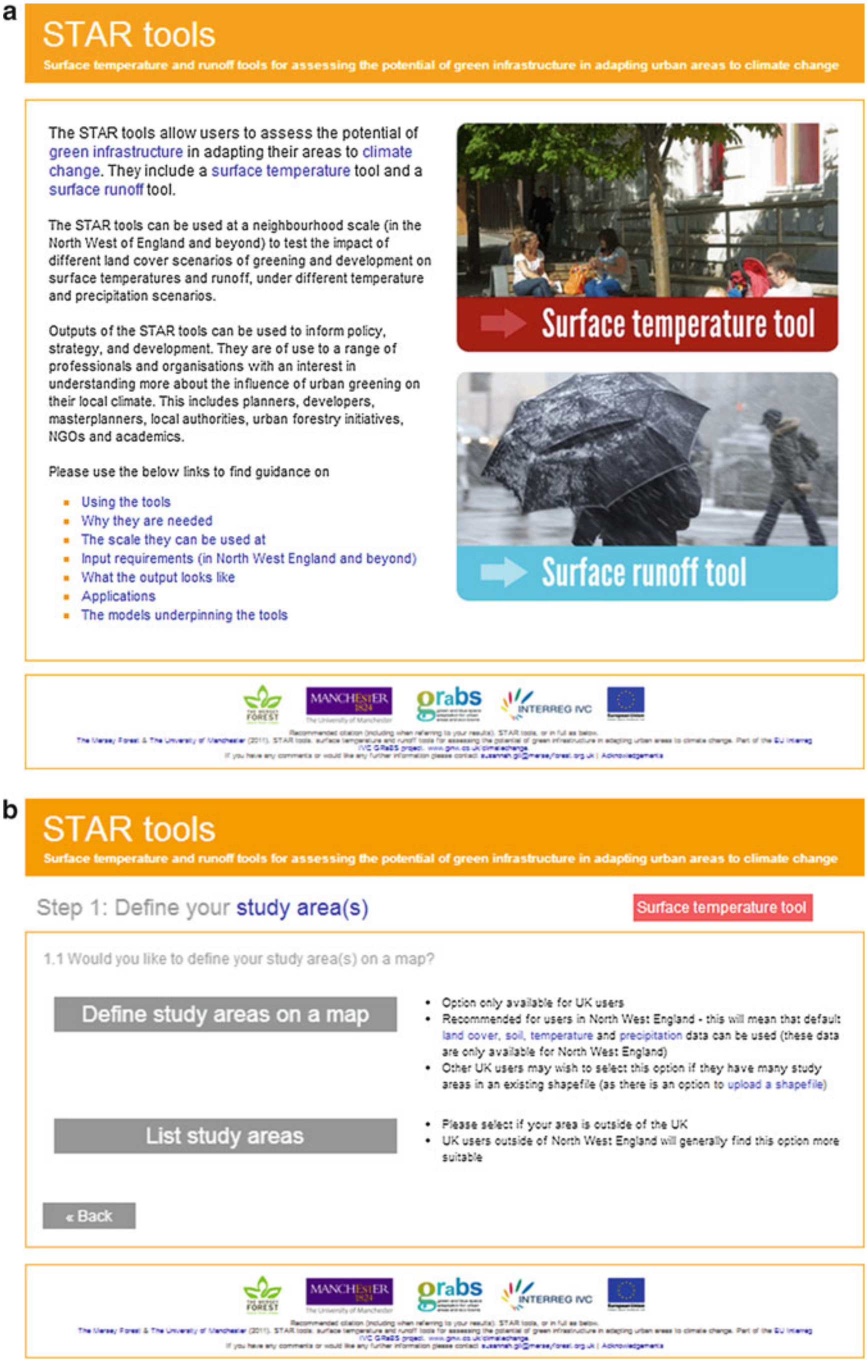

Fig. 6 The STAR Tools interface, (**a**) homepage, (**b**) defining a case study area, http://maps.merseyforest.org.uk/grabs/

achieve certain reductions in temperatures or runoff in the future? What impact would a proposed development have upon temperature or runoff at the neighborhood scale? Such information could also be used to set targets for green infrastructure provision within new developments or in existing neighborhoods. In this way, the information could be used to guide policy and strategy development – both urban development and green infrastructure policies. The outputs of the STAR Tools are thus potentially of use to a range of professionals including planners, developers, master planners, local authority officers, NGOs, urban forestry initiatives, and academics.

Developing the STAR Tools

The STAR Tools were developed as an addition to the Assessment Tool, in response to feedback regarding the desire to project future land use scenarios and their potential impact. While the development of the STAR Tools was focused upon North West England (one of the GRaBS case study locations), it was important that users outside of this area could also apply the STAR Tools to investigate the potential of green infrastructure in adapting their specific urban neighborhood to climate change. Therefore, users enter the Tools in two ways (Fig. 6b). If the study area is located in the UK, users can define their study area(s) on an interactive map, driven by OpenLayers and Ordnance Survey's OpenSpace. All default input values are automatically provided for the Mersey Belt within North West England, including climate projections, land surface cover, and soil data, together with detailed information about data sources and model assumptions. Users also have the option to simply list their study areas. At the next stage, the user is then able to both insert their own input values (including climate projections, land surface cover, and soils) and modify the default model parameter values (set to North West England climate and environment context) to adapt the STAR Tools to their particular case study area. While this option may be more suited to academic or more technical users, it ensures that the STAR Tools can potentially be used for any location, and full guidance is provided regarding the default parameters and model assumptions.

The technical development of the STAR Tools involved representing the two underpinning models as web-based tools. Server side, the processing is carried out in PHP running on an Apache server with MapServer. Spatial processing is carried out using GDAL/OGR and MapScript. Data is stored in a MySQL database. AJAX techniques are used to communicate between the client- and server-side scripts. Web Map Services and Web Feature Services are used to serve spatial data to the front end.

Since the STAR Tools were launched in early 2012, they have had 1,100 unique visitors, with over 200 progressing to the results page.[2] Regarding the origin of users, 64 % of visitors are from the UK, 5 % from the USA, and smaller numbers

[2]Unique visitors are defined as an individual user (or computer). Statistics were taken in December 2013.

were from Brazil, Spain, Belgium, and other countries. Information captured by the optional online questionnaire reveal that the STAR Tools have been used by policymakers, researchers, and green infrastructure professionals to guide policy and for academic research purposes.

Application of the STAR Tools to Inform The Mersey Forest Plan

The Mersey Forest is a community forest in North West England, covering 1,370 km^2. Established in 1991, it is a partnership of local authorities, national government agencies, land owners, businesses, and local communities. Its vision is to get "more from trees" to help make Merseyside and North Cheshire one of the best places to live in the country. The partnership has planted over nine million trees and doubled woodland cover since 1991, with three times more trees planted than the England average. This has attracted investment, boosted health and well-being, and improved the local environment.

The Mersey Forest Plan is the long-term and strategic guide to the work of The Mersey Forest team and partners. While it is not a statutory planning document in its own right, under the National Planning Policy Framework "an approved community forest plan may be a material consideration in preparing development plans and in deciding planning applications" (DCLG 2012). The Mersey Forest Plan was first written in 1994, updated in 2001, and has been refreshed again in 2014.

Since the earlier versions of the plan, climate change has risen up the policy agenda. In the early versions there is a brief acknowledgement of the "local and global atmospheric benefits" of trees and woodlands. In addition, reference is made to what we would now recognize as both the mitigation and adaptation benefits of trees and woodlands; specifically, "forestry locks up carbon and offsets other carbon dioxide emissions, helping to reduce global warming. Forests also have more local benefits in filtering out air pollutants, especially dust, reducing noise and acting as windbreaks. The shelter they provide will also improve the local climate of open spaces and has been shown to reduce the cost of heating buildings" (The Mersey Forest 1994, p. 16).

There was a clear need, which was recognized by The Mersey Forest partners, for climate change to have greater prominence in the refreshed plan. As such, it features as one of 20 policies set out under the headings "Who, What, How and Why" and is also cross-referenced in many of the other policies. The specific policy on climate change states, "We will safeguard, plant and manage trees and woodlands for their role in climate change mitigation, adaptation, and resilience – such as providing urban cooling, carbon storage, flood alleviation and water management, helping wildlife adapt, low carbon fuels and products, sustainable travel routes, and outdoor recreation opportunities. We will design, plant and manage them to increase their resilience to potential climate change impacts, such as changing pests and diseases" (The Mersey Forest 2014, p. 52).

The STAR Tools and the Surface Temperature Tool in particular provided evidence to support this policy. The Surface Temperature Tool was run for the

210 wards within The Mersey Forest for the baseline climate (1961–1990) and for the 2050s high emissions scenario (at the 10 %, 50 %, and 90 % probability levels). The default temperature scenarios supplied with the tool (available for North West England) were used. It was also run for the current land cover scenario (again, using the default values supplied) and for two further scenarios where 10 % green cover was either added or removed. When green cover was added, the same percentage was removed firstly from other impervious surfaces and then, if this did not meet the full 10 %, sequentially from major roads, buildings, and bare soil or gravel (and vice versa for when green cover was removed). In a few instances, in wards where either green cover was already above 90 % or below 10 %, it was not possible to add or remove the full 10 % green cover, and therefore, green cover was only added or removed to the maximum amount possible.

Since the Surface Temperature Tool was run for 210 case study areas (wards), the output was mapped using GIS and features within the plan (Fig. 7). The results found the hottest ward to be Liverpool Central, with a maximum surface temperature of 31.7 °C, whereas the coolest ward is Tilston in Cheshire West and Chester at 18.3 °C. There is a surface temperature difference of 13.4 °C between the hottest and coolest wards. These are also the wards with the lowest and highest green cover

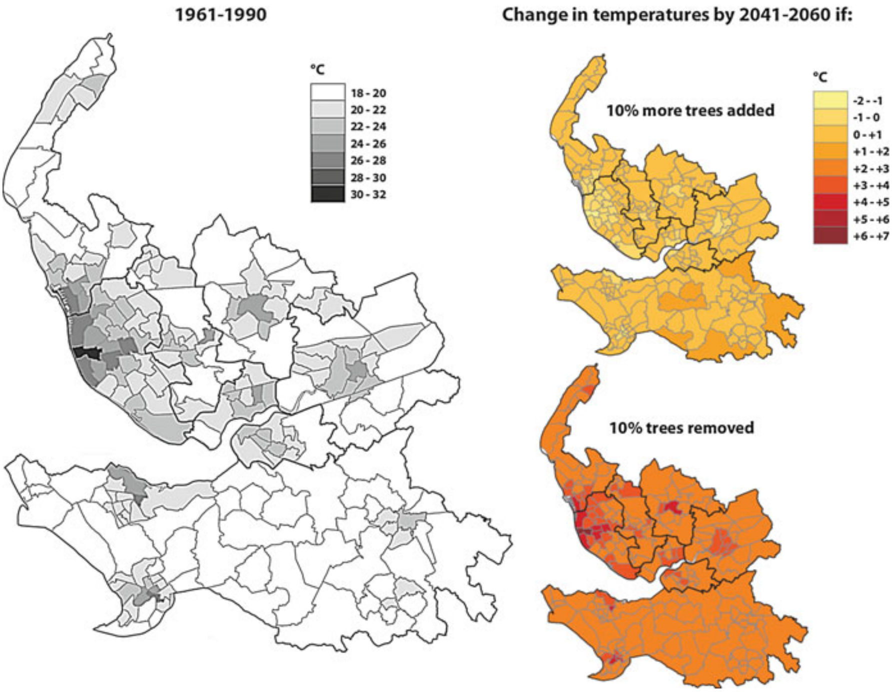

Fig. 7 Maximum surface temperatures on a hot summer's day (98th percentile summers day) (Mapped at the ward level; the 2041–2060 mapping used is for the 2050s high emission scenario, at a 50 % probability level) (© Crown copyright and database right 2012 Ordnance Survey 100031461)

(Liverpool Central is 16.7 % green, whereas Tilston is 97.7 % green). By the 2050s (at a 50 % probability level), the maximum surface temperature in Liverpool Central increases to 33.9 °C (2.2 °C hotter than in 1961–1990). Removing green cover from this ward would further exacerbate the situation; if 10 % green cover is removed, then the maximum surface temperature in the 2050s would be 38.5 °C (6.8 °C hotter than the maximum surface temperature in 1961–1990 with current land cover). However, adding green cover can help to ameliorate the situation; if 10 % green cover is added, then the maximum surface temperature in the 2050s would be 30.6 °C (1.1 °C cooler than the maximum surface temperature in 1961–1990 with current land cover).

The Surface Temperature Tool output was used to support the argument in The Mersey Forest Plan that increased tree planting will provide shade and evaporative cooling that help keep neighborhoods cooler and ensure that towns and cities continue to be healthy, comfortable, and attractive places to live, work, visit, and invest. The results can also be analyzed further by The Mersey Forest team in order to support ongoing activities in delivering the plan.

Conclusions: Lessons Learned and Key Challenges

The overall aim of the GRaBS project was to enhance local and regional planning policy in respect of climate change adaptation. The Assessment Tool is a useful decision-aiding tool, enabling support of the sharing of knowledge and expertise and helping to build the evidence base available to decision-makers and other stakeholders when developing adaptation plans and strategies. Similarly, the STAR Tools can be used to inform climate adaptation plans, green infrastructure plans and strategies, as well as local plans and developments.

Since planning is an integrative data-driven activity to enable effective decisions (Stillwell et al. 1999 cited in Dragicevic and Balram 2004), data availability, quality, and scale are key issues. It is notable that the GRaBS Assessment Tool local partner level tools vary in their comprehensiveness to assess risk and vulnerability based upon the existing spatial data that has been collected. The experience of developing the tools has highlighted the need for a common framework to help identify, collect, distribute, share, and prioritize the data that is required to inform the evidence base and enable a more harmonized approach to spatial planning for adaptation to climate change. This would need to be flexible to enable modification to the user's particular location, specifically in terms of context-specific vulnerability and climatic hazards.

The process of developing the Assessment Tool was invaluable for the GRaBS partners, particularly in helping to build bridges between departments (both internally and externally) during collation of spatial data. A key finding of the project was the need to break down silos between departments in order to gather holistic evidence of the need to act on adaptation. A key lesson is the importance to invest in a collaborative development process with the user, not only because the user can benefit significantly from this process, but also to ensure that resulting tools are not donor-centric, and the end product is provided in an accessible format for the intended user.

Generic challenges have been raised previously in relation to applying a PPGIS approach and are applicable to the GRaBS web-GIS tools – firstly, the cost and time involved in maintaining the currency of tools, including updating the spatial data and information. When developed, the STAR Tools included input data for the complete region of North West England; however, the ongoing data license for the soils input data remained too excessive, and this area was thus reduced to the Mersey Belt area. Further, while the importance of ensuring that the development and maintenance of the Assessment Tool continued beyond the GRaBS project was identified at an early stage, a funding stream through which this could be supported was not secured. The Assessment Tool is hosted as an open-source project at the University of Manchester and is available for use in other case study areas by changing the spatial data and associated metadata – although this requires knowledge of the Google Maps' API and JavaScript programming. Further work in the future could investigate how the Assessment Tool could be easily updated and edited by nonspecialists, to keep it up to speed with changing knowledge and the underlying spatial data.

Secondly, restrictions due to license agreements and confidentiality of sensitive data are a challenge to optimize access to information for the public. Free and open-source tools may conflict with the license agreements of many geospatial datasets (both public and private sectors), constraining the amount of data that can be included in the tool, thereby limiting its effectiveness. The Assessment Tool included a function to add data locally, thereby addressing this issue to some extent. The STAR Tools provide a modeling environment and were designed to enable application in any location, relying more upon user input data and thus minimizing the problem of license restrictions.

A third challenge in developing web-GIS tools is balancing the performance with data resolution. The Assessment Tool achieved fast performance by outputting spatial GIS data into an image format to speed up the map rendering process for the user. However, this approach meant that other useful web-GIS functionalities were restricted, such as changing data classifications or color schemes. Balancing user-friendliness with flexibility was also important in the STAR Tools development. Since the STAR Tools are complex scientific models, it was important that casual users were able to produce their outputs without having to consider or understand the full complexities of the model while also allowing more comprehensive users to interact with all underlying model parameters if they so desired.

A fourth challenge is providing enough information for the user to be able to apply the tool and interpret the data or output effectively. Detailed notes and guidance materials (including storylines) provided for the GRaBS Tools go some way to aiding this issue, but training events may also be beneficial, both to enhance understanding of the tools and ensure greater application. A more recent review of tools by Climate UK (2012), which included review of the Assessment Tool and

STAR Tools, suggested that there is little demand from UK stakeholders for new tools but more demand in terms of awareness raising and use of existing tools, including clear guidance on how the tools can be best applied. As the STAR Tools were released toward the end of the GRaBS project, buy-in from GRaBS partners was limited, and encouraging stakeholders to use the tool is challenging. Despite efforts to publicize the STAR Tools, usage remains low relative to the investment in developing the tools. Creation of a "toolbox of tools" by national and cross-sectoral organizations would therefore be useful to signpost stakeholders to the tools.

A final challenge for web-GIS tools is the fast pace of change in technology. When the Assessment Tool was envisaged, Google Maps was the only viable mapping Application Programming Interface (API). Since then, a number of other APIs, including Bing and OS OpenSpace have arisen, with functionality advancing at an unchecked rate. Additionally, post-GRaBS, a significant change in Web Map Services (WMS) in the UK in particular has occurred, with national organizations shifting to deliver their spatial data via WMS. Linking to the spatial data via WMS means there is no need to keep a local copy of the data that becomes outdated. While challenging, these fast changes are also very encouraging for the development of web-GIS tools and enhancing public participation in planning.

In terms of the future development of tools for climate change adaptation planning in cities, it is clear that the Public Participatory ("PP" in PPGIS) element could be advanced much further. Additional functions for the Assessment Tool such as push pins (to enable highlighting of locations of interest) and comment boxes could be applied to enable a more interactive facility, which could be extremely effective when utilizing the tool for community participation events. Gathering of user experiences and evidence could be particularly beneficial for climate change adaptation planning. For example, crowdsourcing local flooding evidence may be very useful to verify modeled flooding hazard outputs and official flood records utilizing the geo-referencing capabilities within social media applications.

Finally, Climate UK (2012) highlights that the greatest demand from existing tools is to help with prioritizing clear next steps and actions. Many tools, including the Assessment Tool and STAR Tools, are very effective in their ability to raise awareness about climate impacts and the need for adaptation responses, though they do not necessarily aid prioritization of risks and opportunities. This is an area that should be considered in future developments.

Acknowledgments The GRaBS project was funded under Interreg IVC, project number 0108R1. The authors would like to thank the GRaBS project partners in addition to Dr Stephen Lynch, from Manchester Metropolitan University, for assistance with the mathematics of the ST Tool. The Mersey Forest Plan was part funded by the EU Interreg IVB GIFT-T! (Green Infrastructure For Tomorrow – Together!) project. The GRaBS Tools build on research from the EPSRC-funded project Adaptation Strategies for Climate Change in the Urban Environment (ASCCUE), EPSRC GR/S19233/01.
