## CHAPTER 16

# Amenorrhea

NORMAL MENSTRUAL CYCLE . . . . .	369
CLASSIFICATION SYSTEM . . . . .	370
ANATOMIC DISORDERS . . . . .	370
HYPERGONADOTROPIC HYPOGONADISM . . . . .	373
HYPOGONADOTROPIC HYPOGONADISM . . . . .	375
EUGONADOTROPIC AMENORRHEA . . . . .	378
EVALUATION . . . . .	379
TREATMENT . . . . .	383
REFERENCES . . . . .	384

Evaluation and management of a patient with amenorrhea is common in gynecology. Specifically, the prevalence of pathologic amenorrhea ranges from 3 to 4 percent in reproductive-aged populations (Bachmann, 1982; Pettersson, 1973). Amenorrhea has classically been defined as primary (no prior menses) or secondary (cessation of menses). Although this distinction does suggest a relative likelihood of finding a particular diagnosis, the approach to diagnosis and treatment is similar for either presentation (Tables 16-1 and 16-2). Of course, amenorrhea is a normal state prior to puberty, during pregnancy and lactation, with certain hormonal medications such as continuous administration of combination oral contraceptives (COCs), and following menopause. Evaluation is considered for an adolescent: (1) who by age 13 has not menstruated or shown other evidence of pubertal development, or (2) who has reached other pubertal milestones but has not menstruated by age 15 or within 3 years of thelarche (American College of Obstetrician and Gynecologists, 2009). Secondary amenorrhea for 3 months or oligomenorrhea involving fewer than nine cycles a year is also investigated (American Society for Reproductive Medicine, 2008). In some circumstances, testing reasonably may be initiated despite the absence of these strict criteria. Examples include a patient with the stigmata of Turner syndrome, obvious virilization, or a history of uterine curettage. An evaluation for delayed puberty is also considered before the ages listed above if the patient or her parents are concerned.

## NORMAL MENSTRUAL CYCLE

A differential diagnosis for amenorrhea can be constructed based on requirements for normal menses. Ovarian function in a normal menstrual cycle is divided into the follicular phase (preovulatory), ovulation, and luteal phase (postovulatory). Endometrial characteristics are partitioned into the proliferative phase (preovulatory) and secretory phase (postovulatory). Generation of a cyclic, controlled pattern of uterine bleeding requires precise temporal and quantitative regulation of several reproductive hormones (Chap. 15, p. 346).

First, the hypothalamic-pituitary-ovarian axis must be functional. The hypothalamus releases pulses of gonadotropin-releasing hormone (GnRH) into the hypophyseal portal circulation at defined frequencies and amplitude. GnRH stimulates the synthesis and secretion of the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by the gonadotrope cells of the anterior pituitary gland. These gonadotropins enter the peripheral circulation and act on the ovary to stimulate both follicular development and ovarian hormone production. These ovarian hormones include estrogens, progesterones, and androgens. Gonadal steroids are typically inhibitory at both the pituitary and the hypothalamus. Development of a mature follicle, however, creates a rapid rise in estrogen levels, which instead act positively to generate an LH surge. This surge is essential for ovulation.

Following ovulation, LH stimulates luteinization of the granulosa and theca cells, which had surrounded the mature oocyte, to form the corpus luteum. The corpus luteum continues to produce estrogen but also secretes high levels of progesterone. The thickened, proliferative endometrial lining produced by high circulating estrogen levels during the follicular phase is now converted to a secretory pattern by this luteal progesterone. If pregnancy occurs, the corpus luteum is “rescued” by human chorionic gonadotropin (hCG) secreted from early placental trophoblast. hCG is similar structurally to LH, shares the same receptor as LH, and assumes the role of corpus luteum support during early pregnancy. If pregnancy does not occur, then progesterone and estrogen secretion ceases, the corpus luteum regresses, and the endometrium sloughs. The pattern of this “progesterone withdrawal bleed” varies in duration and amount among women but is relatively constant across cycles for a given individual.

Amenorrhea may follow disruption of this choreographed communication. However, even with normal hormonal cycling, altered anatomy may prevent menses. The endometrium must

TABLE 16-1. Primary Amenorrhea: Frequency of Etiologies

Presentation	Frequency (%)
<b>Hypergonadotropic hypogonadism</b>	<u>43</u>
45,X and variants	27
46,XX	14
46,XY	2
<b>Eugonadism</b>	<u>30</u>
Müllerian agenesis	15
Vaginal septum	3
Imperforate hymen	1
Androgen insensitivity syndrome	1
Polycystic ovarian syndrome	7
Congenital adrenal hyperplasia	1
Cushing and thyroid disease	2
<b>Low FSH without breast development</b>	<u>27</u>
Constitutional delay	14
GnRH deficiency	5
Other CNS disease	1
Pituitary disease	5
Eating disorders, stress, excess exercise	2

CNS = central nervous system;  
FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone.  
Data from Reindollar RH, Byrd JR, McDonough PG: Delayed sexual development: a study of 252 patients, Am J Obstet Gynecol 1981 Jun 15;140(4):371–380.

TABLE 16-2. Secondary Amenorrhea: Frequency of Etiologies<sup>a</sup>

Etiology	Frequency (%)
<b>Low or normal FSH level: various</b>	<u>67.5</u>
Eating disorders, stress, excess exercise	15.5
Nonspecific hypothalamic	18
Chronic anovulation (PCOS)	28
Hypothyroidism	1.5
Cushing syndrome	1
Pituitary tumor/empty sella	2
Sheehan syndrome	1.5
<b>High FSH level: gonadal failure</b>	<u>10.5</u>
46,XX	10
Abnormal karyotype	0.5
<b>High prolactin level</b>	13
<b>Anatomic</b>	<u>7</u>
Asherman syndrome	7
<b>Hyperandrogenic states</b>	<u>2</u>
Nonclassic CAH	0.5
Ovarian tumor	1
Undiagnosed	0.5

<sup>a</sup>Excluding pregnancy diagnoses.  
CAH = congenital adrenal hyperplasia; FSH = follicle-stimulating hormone; PCOS = polycystic ovarian syndrome.  
Adapted with permission from Reindollar RH, Novak M, Tho SP, et al: Adult-onset amenorrhea: a study of 262 patients, Am J Obstet Gynecol 1986 Sep;155(3):531–543.

be able to respond normally to hormonal stimulation, and the cervix, vagina, and introitus must be present and patent.

CLASSIFICATION SYSTEM

Numerous classification systems for the diagnosis of amenorrhea have been developed, and all have their strengths and weaknesses. One useful scheme is outlined in Table 16-3. This system divides causes of amenorrhea into anatomic versus hormonal etiologies, with further division into congenital versus acquired disorders.

As described above, normal menses require adequate ovarian production of steroid hormones. Decreased ovarian function (hypogonadism) may result either from a lack of stimulation by the gonadotropins (*hypogonadotropic hypogonadism*) or from primary failure of the ovary (*hypergonadotropic hypogonadism*) (Table 16-4). Several disorders are associated with relatively normal LH and FSH levels (*eugonadotropic*), however, appropriate cyclicity is lost.

ANATOMIC DISORDERS

Inherited Disorders

Anatomic abnormalities causing amenorrhea can broadly be viewed as either inherited or acquired disorders of the outflow tract (uterus, cervix, vagina, and introitus). Of these two, an inherited cause is frequent in adolescents, and pelvic anatomy is abnormal

in approximately 15 percent of women with primary amenorrhea (American Society for Reproductive Medicine, 2008). Figure 16-1 depicts the range of anatomic defects that may present with amenorrhea. These are additionally discussed in Chapter 18 (p. 404).

Lower Outflow Tract Obstruction

Amenorrhea is associated with imperforate hymen (1 in 2000 women), a complete transverse vaginal septum (1 in 70,000 women), or isolated vaginal atresia (Banerjee, 1998; Parazzini, 1990). Also, although structurally normal, labia in some girls may be severely agglutinated and can lead to obstruction. Most with agglutination are treated early with topical estrogen and/or manual separation, and outflow obstruction is thereby avoided.

Patients with outflow obstruction have a 46,XX karyotype, female secondary sexual characteristics, and normal ovarian function. Thus, the amount of uterine bleeding is normal, but its normal path for egress is obstructed or absent. Patients may note miminal symptoms, such as breast tenderness, food cravings, and mood changes, which are attributable to elevated progesterone levels. With inherited or acquired outflow obstruction, accumulation of blood behind the blockage frequently results in cyclic abdominal pain. Intrauterine trapping of fluid (hydrometra), pus (pyometra), or blood (hematometra) creates a soft, enlarged uterus. Similarly, the terms hydrocolpos, pyocolpos, and hematocolpos describe distention of the vagina and are seen with distal obstructions. Moreover, in women

TABLE 16-3. Classification Scheme for Amenorrhea

ANATOMIC	
Congenital	Acquired
Müllerian agenesis (partial or complete)	Intrauterine synechiae (Asherman syndrome)
Cervical atresia	Dilation and curettage
Transverse vaginal septum	Infection (tuberculosis)
Imperforate hymen	Cervical stenosis
HORMONAL/ENDOCRINOLOGIC	
<b>Hypergonadotropic hypogonadism (pOF)</b>	<b>Hypogonadotropic hypogonadism</b>
Inherited/congenital	Disorders of the hypothalamus
Chromosomal (gonadal dysgenesis)	Inherited/congenital
Single gene disorders	Idiopathic hypogonadotropic hypogonadism (IHH)
Acquired	Kallmann syndrome
Infectious	Acquired
Autoimmune	Hypothalamic amenorrhea (“functional”)
Iatrogenic	Eating disorders
Environmental	Excessive exercise
Idiopathic	Stress
<b>Eugonadotropic amenorrhea</b>	Destructive processes
Inherited	Tumor
Polycystic ovarian syndrome	Radiation
Adult-onset congenital adrenal hyperplasia	Trauma
Acquired	Infection
Hyperprolactinemia	Infiltrative disease
Thyroid disease	Pseudocyesis
Cushing syndrome	Disorders of the anterior pituitary gland
Acromegaly	Inherited/congenital
Ovarian tumors (steroid producing)	Pituitary hypoplasia
<b>Other</b>	Acquired
End-stage kidney disease	Macroadenoma
Liver disease	Metastases
Malignancy	Radiation
Malabsorption syndromes	Trauma
Acquired immunodeficiency syndrome	Infarction (Sheehan syndrome)
	Infiltrative disease

with outflow blockage, an increase in retrograde menstruation may lead to endometriosis development.

Müllerian Defects

During embryonic development, the müllerian ducts give rise to the upper vagina, cervix, uterine corpus, and fallopian tubes.

Agenesis during these ducts’ development may be partial or complete. Accordingly, amenorrhea may result from outflow obstruction or from a lack of endometrium in cases involving uterine agenesis. In complete müllerian agenesis, often called Mayer-Rokitansky-Kuster-Hauser syndrome, patients fail to develop any müllerian structures, and examination reveals

TABLE 16-4. Categories of Amenorrhea Based on Gonadotropin and Estrogen Levels

Type of Hypogonadism	LH/FSH	Estrogen	Primary Defect
Hypergonadotropic	High	Low	Ovary
Hypogonadotropic	Low	Low	Hypothalamus/pituitary
Eugonadotropic	Normal <sup>a</sup>	Normal <sup>a</sup>	Varied

<sup>a</sup>Generally in normal range, but lack cyclicality.  
FSH = follicle-stimulating hormone; LH = luteinizing hormone.

only a vaginal dimple (Chap. 18, p. 420). It ranks second only to gonadal dysgenesis as a cause of primary amenorrhea (Aittomaki, 2001; Reindollar, 1981).

Similar to patients with lower outflow tract obstruction, patients with müllerian anomalies have a 46,XX karyotype and normal ovarian function. Research has begun to identify candidate gene mutations that may contribute to this disorder, but details are lacking. Importantly, complete müllerian agenesis may be confused with complete androgen insensitivity syndrome. In the latter condition, the patient has a 46,XY karyotype and functioning testes. However, underlying androgen receptor mutations prevent normal testosterone binding, normal male ductal system development, and virilization. These two syndromes are compared in Table 16-5 and discussed further in Chapter 18 (p. pp. 412 and 420).

■ **Acquired Disorders**

**Cervical Stenosis**

Other abnormalities of the uterus that cause amenorrhea include cervical stenosis and extensive intrauterine adhesions. With stenosis, postoperative scarring and cervical os narrowing may follow dilatation and curettage (D & C), cervical conization, loop electrosurgical excision procedures, infection,

and neoplasia. Severe atrophic or radiation changes are other sources. Stenosis most commonly involves the internal os, and symptoms in menstruating women include amenorrhea or abnormal bleeding, dysmenorrhea, and infertility. Management seeks to reopen the os and is discussed in Chapter 4 (p. 102).

**Intrauterine Adhesions**

Also known as uterine synechiae and, when symptomatic, as Asherman syndrome, the spectrum of scarring includes filmy adhesions, dense bands, or complete obliteration of the uterine cavity (Fig. 16-2). Normally, the endometrium is divided into a functional layer, which lines the endometrial cavity, and a basal layer, which regenerates the functional layer with each menstrual cycle. Destruction of the basal endometrium prevents endometrial thickening in response to ovarian steroids. Thus, no tissue is produced or subsequently sloughed when steroid hormone levels fall at the end of the luteal phase.

Endometrial damage may follow vigorous curettage, usually in association with postpartum hemorrhage, miscarriage, or elective abortion complicated by infection. In a series of 1856 women with Asherman syndrome, 88 percent followed postabortal or postpartum uterine curettage (Schenker, 1982). Damage may also result from other uterine surgery, including metroplasty, myomectomy, or cesarean delivery, or from infection related to an intrauterine device. Although rare in the United States, tuberculous endometritis is a relatively common cause of Asherman syndrome in developing countries (Sharma, 2009). Of course, Asherman syndrome may also be an intentional outcome following uterine ablation for heavy menstrual bleeding.

Depending on the degree of scarring, patients may describe amenorrhea; in less severe cases, hypomenorrhea; or recurrent pregnancy loss due to inadequate placentation (March, 2011).

**TABLE 16-5.** Comparison of Müllerian Agenesis and Androgen Insensitivity Syndrome

Presentation	Müllerian Agenesis	Androgen Insensitivity
Inheritance pattern	Sporadic	X-linked recessive
Karyotype	46,XX	46,XY
Breast development	Yes	Yes
Axillary and pubic hair	Yes	No
Uterus	No	No
Gonad	Ovary	Testis
Testosterone	Female levels	Male levels
Associated anomalies	Yes	No

In their evaluation of 292 women with intrauterine adhesions, Schenker and Margalioth (1982) noted delivery of term pregnancies in only 30 percent of 165 pregnancies. The remaining pregnancies either were spontaneously aborted (40 percent) or delivered prematurely.

If intrauterine adhesions are suspected, radiologic evaluation of the uterine cavity is performed. If information regarding tubal patency is needed, then hysterosalpingography (HSG) offers information regarding both uterine cavity and fallopian tube patency. Otherwise, saline infusion sonography (SIS) provides an excellent alternative. Intrauterine adhesions characteristically appear as irregular, angulated filling defects within the cavity (Fig. 19-6, p. 439 and Fig. 2-23, p. 34). At times, uterine polyps, leiomyomas, air bubbles, and blood clots may masquerade as adhesions. Definitive diagnosis requires hysteroscopy. To improve fertility rates or to relieve symptomatic hematometra, hysteroscopic lysis of adhesions is the preferred surgical treatment. The procedure is described in Section 44-19 (p. 1052), and fertility advantages are discussed in Chapter 20 (p. 460).

**HYPERGONADOTROPIC HYPOGONADISM**

The term *hypergonadotropic hypogonadism* describes any process in which: (1) ovarian function is decreased or absent (hypogonadism) and (2) due to absent negative sex-steroid feedback, the gonadotropins, LH and FSH, have increased serum levels (hypergonadotropic). This category of disorders implies primary dysfunction within the ovary rather than hypothalamic or pituitary dysfunction (Table 16-6). This process can also be termed *premature menopause* or *premature ovarian failure (POF)*, with a current trend toward the term *premature ovarian insufficiency* or *primary ovarian insufficiency (POI)*. The term ovarian insufficiency conveys the fact that ovarian function may fluctuate before complete oocyte depletion and may lead to occasional

transient menses resumption or even pregnancy (Bidet, 2011). For our purposes, the term premature ovarian failure, implying permanent cessation of menses, will be used.

POF is defined as loss of oocytes and the surrounding support cells prior to age 40 years. The diagnosis is determined by two serum FSH levels that measure greater than a threshold range of 30 to 40 mIU/mL and are obtained at least 1 month apart. This definition distinguishes POF from the physiologic loss of ovarian function, which occurs with normal menopause. The incidence of POF has been estimated at 1 in 1000 women younger than 30 years and at 1 in 100 women younger than 40 (Coulam, 1986).

Careful evaluation is mandatory as the diagnosis and effective treatment may have significant implications for the patient's psychologic, cardiovascular, bone, and sexual health. The finding of a genetic disorder may also require evaluation of family members. Nevertheless, in most cases, an etiology for POF is not determined (American College of Obstetricians and Gynecologists, 2014).

**Heritable Disorders**

**Gonadal Dysgenesis**

Gonadal dysgenesis is the most frequent cause of POF. In this disorder, a normal complement of germ cells is present in the early fetal ovary. However, oocytes undergo accelerated atresia, and the ovary is replaced by a fibrous streak—termed a streak gonad (Figs. 16-3 and 16-4)(Simpson, 1975; Singh, 1966). Individuals with gonadal dysgenesis may present with various clinical features and can be divided into two broad groups based on whether their karyotype is normal or abnormal (Schlessinger, 2002). These are all discussed further in Chapter 18 (p. 409).

Those with normal karyotype (46,XX or 46,XY) are described as having “pure” gonadal dysgenesis. Patients with a 46,XY genotype and gonadal dysgenesis (Swyer syndrome) are phenotypically female due to absent testosterone and absent antimüllerian hormone (AMH) secretion by the dysgenetic testes. The etiology of the gonadal failure in both genetically male and female patients is poorly understood but is likely due to single gene defects or destruction of gonadal tissue in utero, perhaps by infection or toxins (Hutson, 2014).

Those with abnormal karyotype include Turner syndrome (45,X) and chromosomal mosaics such as 45,X/46,XX or 45,X/46,XY. In general, approximately 90 percent of individuals with gonadal dysgenesis from a loss of X genetic material never menstruate. The remaining 10 percent have sufficient residual follicles to experience menses and rarely may achieve pregnancy. However, the menstrual and reproductive lives of such individuals are invariably brief (Kaneko, 1990; Simpson, 1975; To, 1981).

As noted, in some cases of gonadal dysgenesis, a Y chromosome is present. If Y chromosomal material is found, the streak gonads are removed because nearly 25 percent of these patients will develop a malignant germ cell tumor (Chap. 36, p. 762) (Manuel, 1976). Thus, chromosomal analysis is performed in all cases of amenorrhea associated with POF, particularly before age 30. The presence of a Y chromosome cannot be determined

clinically, as only a few patients will demonstrate signs of androgen excess.

### Specific Genetic Defects

In addition to chromosomal abnormalities, patients may experience POF due to single gene mutations (Cordts, 2011; Goswami, 2005). First, a significant relationship is noted between fragile X syndrome and POF (American College of Obstetricians and Gynecologists, 2010). This syndrome is caused by a triple repeat sequence mutation in the X-linked *FMR1* (fragile X mental retardation) gene. This gene is unstable, and its size can expand during parent-to-child transmission. The fully expanded mutation (> 200 CGG repeats) becomes hypermethylated, resulting in silencing of gene expression. As such, this fully expanded mutation is the most common known inherited genetic cause of mental retardation and of autism. Males with the so-called premutation (50 to 200 CGG repeats) are at risk for fragile-X associated tremor/ataxia syn-

drome (FXTAS). Females with the premutation have a 13- to 26-percent risk of developing POF, although the mechanism is unclear. An estimated 0.8 to 7.5 percent of sporadic POF and 13 percent of familial POF cases are due to premutations in this gene. The prevalence of premutations in women approximates 1 in 129 to 300 (Wittenberger, 2007).

Less common gene defects are *CYP17* mutations. These decrease 17 $\alpha$ -hydroxylase and 17,20-lyase activity and thereby prevent production of cortisol, androgens, and estrogens (Fig. 15-5, p. 337). Affected patients have sexual infantilism and primary amenorrhea due to absent estrogen secretion. *Sexual infantilism* describes patients with a lack of breast development, absent pubic and axillary hair, and a small uterus. Mutations in *CYP17* also increase adrenocorticotropin hormone (ACTH) release, thereby stimulating mineralocorticoid secretion. This, in turn, leads to hypokalemia and hypertension (Goldsmith, 1967).

Mutations in genes that encode LH and FSH receptors have also been reported. These defects prevent normal responses to circulating gonadotropins, a condition termed *resistant ovary syndrome* (Aittomaki, 1995; Latronico, 2013). Identification of other single gene mutations that can cause POF is an area of active investigation. The list of implicated genes now includes those that encode both estrogen receptors (ER $\alpha$  and ER $\beta$ ), extracellular signaling proteins (specifically, BMP15), and transcription factors FOXL2, FOXP3, and SF-1 (Cordts, 2011; Goswami, 2005). The importance of these factors in maintaining ovarian function is providing further insights into normal ovarian physiology and may lead to new infertility treatments and contraceptive options.

Although frequently cited, galactosemia is a rare cause of POF. Classic galactosemia affects 1 in 30,000 to 60,000 live births. Inherited as an autosomal recessive disorder, this condition leads to abnormal galactose metabolism due to a deficiency of galactose-1-phosphate uridyl transferase, encoded by the *GALT* gene (Rubio-Gozalbo, 2010). Galactose metabolites are believed to have a direct toxic effect on many cell types, including germ cells. Potential complications include neonatal

**FIGURE 16-4** Photograph taken during laparoscopy of a streak gonad (dotted line). IP = infundibulopelvic. (Used with permission from Dr. Victor Beshay.)

death, ataxic neurologic disease, cognitive disabilities, and cataracts. POF will develop in almost 85 percent of females if left untreated. Treatment is lifelong dietary restriction of galactose, which is present in milk-based foods. Galactosemia is frequently diagnosed during newborn screening programs or during pediatric evaluation of impaired growth and development and long before a patient would present to a gynecologist (Kaufman, 1981; Levy, 1984).

### ■ Acquired Abnormalities

Hypergonadotropic hypogonadism can be acquired from infection, environmental exposures, autoimmune disease, or medical treatments. Of these, infectious causes of POF are relatively rare and poorly understood, with mumps oophoritis being the most frequently reported (Morrison, 1975). Various environmental toxins have a clear detrimental effect on follicular health. These include cigarette smoking, heavy metals, solvents, pesticides, and industrial chemicals (Jick, 1977; Mlynarcikova, 2005; Sharara, 1998).

Autoimmune disorders account for an estimated 40 percent of POF cases (Hoek, 1997; LaBarbera, 1988). Ovarian failure may be one component of autoimmune pituitary polyglandular failure and accompanied by hypothyroidism and adrenal insufficiency, or it may follow other autoimmune disorders such as systemic lupus erythematosus. POF has also been associated with myasthenia gravis, idiopathic thrombocytopenic purpura, rheumatoid arthritis, vitiligo, and autoimmune hemolytic anemia (de Moraes, 1972; Jones, 1969; Kim, 1974). Although several antiovarian antibodies have been characterized, there is currently no validated serum antibody marker to assist in the diagnosis of autoimmune POF (American Society for Reproductive Medicine, 2008).

Iatrogenic ovarian failure is relatively common. This group includes patients who have undergone surgical removal of the ovaries or cystectomy due to recurrent ovarian cysts, endometriosis, or severe pelvic inflammatory disease. Alternatively, a woman may experience amenorrhea following pelvic radiation for cancer or following chemotherapy for treatment of malignancies or severe autoimmune disease.

With the latter two, the chance of developing POF is correlated with increasing radiation and chemotherapeutic dose. Patient age is also a significant factor, with younger patients less likely to develop failure and more likely to regain ovarian function over time (Gradishar, 1989). With radiotherapy, ovaries are preventively repositioned using surgery (oophoropexy), if possible, out of the anticipated radiation field prior to therapy (Terenziani, 2009). Of chemotherapeutic drugs, alkylating agents are believed to be particularly damaging to ovarian function. As discussed in Chapter 27 (p. 598), preventive adjuvant GnRH analogues may lower rates of chemotherapy-induced POF, although the efficacy of this approach remains controversial. Importantly, recent advances in oocyte and ovarian tissue cryopreservation make it likely that oocyte harvest prior to treatment will become the preferred approach when feasible. Of interest, persistent chemotherapy-induced amenorrhea appears to confer a decreased risk of breast cancer recurrence, possibly beyond that attributable to the low estrogen

levels (Swain, 2010; Zhao, 2014). Nevertheless, a substantial menopause-specific decrease in quality of life is observed in these patients (Yoo, 2013).

## HYpOGONADOTROPIC HYpOGONADISM

The term *hypogonadotropic hypogonadism* implies that the primary abnormality lies in the hypothalamic-pituitary axis. As a result, poor gonadotropin stimulation of the ovaries leads to impaired follicular development. Generally in these patients, LH and FSH levels, although low, will still be in the detectable range ( $< 5$  mIU/mL). However, levels may be undetectable in patients with complete absence of hypothalamic stimulation, such as occurs in Kallmann syndrome. In addition, absent pituitary function due to abnormal development or severe pituitary damage may lead to similarly low levels. Thus, the group of hypogonadotropic hypogonadism disorders may be viewed as a continuum with perturbations leading to luteal dysfunction, oligomenorrhea, and, in the most severe presentation, amenorrhea.

### ■ Hypothalamic Disorders

#### Inherited Hypothalamic Abnormalities

Inherited hypothalamic abnormalities primarily consist of those patients with idiopathic hypogonadotropic hypogonadism (IHH). A subset has associated defects in the ability to smell (hyposmia or anosmia) and are said to have Kallmann syndrome. This syndrome can be inherited as an X-linked, autosomal dominant, or autosomal recessive disorder (Cadman, 2007; Waldstreicher, 1996). The X-linked form was the first to be characterized and follows mutation in the *KAL1* gene on the short arm of the X chromosome. Expressed during fetal development, this gene encodes an adhesion protein, named anosmin-1. As this protein is critical for normal migration of both GnRH and olfactory neurons, loss of normal anosmin-1 expression results in both reproductive and olfactory deficits (Fig. 16-5) (Franco, 1991; Soussi-Yanicostas, 1996). Kallmann patients have a normal complement of GnRH neurons, however, these neurons fail to migrate and instead remain near the nasal epithelium (Quinton, 1997). As a result, locally secreted GnRH is unable to stimulate gonadotropes in the anterior pituitary gland to release LH and FSH. In turn, marked decreases in ovarian estrogen production result in absence of breast development and menstrual cycles.

Kallmann syndrome is also associated with midline facial anomalies such as cleft palate, unilateral renal agenesis, cerebellar ataxia, epilepsy, neurosensory hearing loss, and synkinesis (mirror movements of the hands) (Winters, 1992; Zenaty, 2006). Kallmann syndrome can be distinguished from IHH by olfactory testing. This is performed easily in the office with strong odorants such as ground coffee or perfume. Interestingly, many of these patients are unaware of their deficit.

During the past 10 years, an array of autosomal genes has been identified that contribute to normal development, migration, and secretion by GnRH neurons (Caronia, 2011; Layman, 2013). Mutations in several of these genes have been described in patients with hypothalamic amenorrhea. Genes

**FIGURE 16-5** Normal GnRH neuron migration and the pathogenesis of Kallmann syndrome. **A.** During normal development, olfactory neurons arising in the olfactory epithelium extend their axons through the cribriform plate of the ethmoid bone to reach the olfactory bulb. Here, these axons synapse with dendrites of mitral cells, whose axons form the olfactory tract. Mitral cells secrete anosmin-1, which is the protein product of the *KALI* gene. This protein is necessary to direct the olfactory axons to their correct location in the olfactory bulb. The GnRH-secreting neurons use this axonal path to migrate from the olfactory placode to the hypothalamus. **B.** Patients with Kallmann syndrome due to a *KALI* mutation lack anosmin-1 expression. As a result, the axons of the olfactory neurons cannot interact properly with mitral cells, and their migration ends between the cribriform plate and olfactory bulb. As GnRH neuronal migration is dependent on this axonal trail, the GnRH secretion pathway likewise ends at this location. (Reproduced with permission from Rugarli E, Ballabio A: Kallmann syndrome. From genetics to neurobiology, JAMA 1993 Dec 8;270(22):2713–2716.)

include *FGF8*, *KALI*, *NELF*, *PROK2*, *PROKR2*, and *CHD7*. As a result, the percentage of patients in whom this disorder need be considered idiopathic is gradually decreasing. Of note, mutation in the *CHD7* gene may cause either normosmic IHH or Kallmann syndrome, thereby blurring the distinction between these disorders.

### Acquired Hypothalamic Dysfunction

Acquired hypothalamic abnormalities are much more frequent than inherited deficiencies. Most commonly, gonadotropin deficiency leading to chronic anovulation is believed to arise from functional disorders of the hypothalamus or higher brain centers. Also called “hypothalamic amenorrhea,” this diagnosis encompasses three main categories: eating disorders, excessive exercise, and stress. From a teleologic perspective, amenorrhea in time of starvation or extreme stress can be seen as a mechanism to prevent pregnancy at a time in which resources are suboptimal for raising a child. Each woman appears to have her own hypothalamic “setpoint” or sensitivity to environmental factors. For example, individual women can tolerate markedly different amounts of stress without developing amenorrhea.

**Eating Disorders.** Anorexia nervosa and bulimia, both described in Chapter 13 (p. 301), can lead to amenorrhea. Hypothalamic dysfunction is severe in anorexia and may affect other hypothalamic-pituitary axes in addition to the reproductive axis. Amenorrhea in anorexia nervosa can precede, follow, or appear coincidentally with weight loss. In addition, even with return to normal weight, not all women with anorexia will regain normal menstrual function. Patients with premenarchal onset of anorexia are at particular risk for protracted amenorrhea (Dempfle, 2013).

**Exercise-induced Amenorrhea.** This is most common in women whose exercise regimen is associated with significant

loss of fat, including ballet, gymnastics, and long-distance running (De Souza, 1991; Frisch, 1980). In those women who continue to menstruate, cycles are notable for their variability in cycle interval and length due to reduced hormonal function (De Souza, 1998). Puberty may be delayed in girls who begin training before menarche (Frisch, 1981).

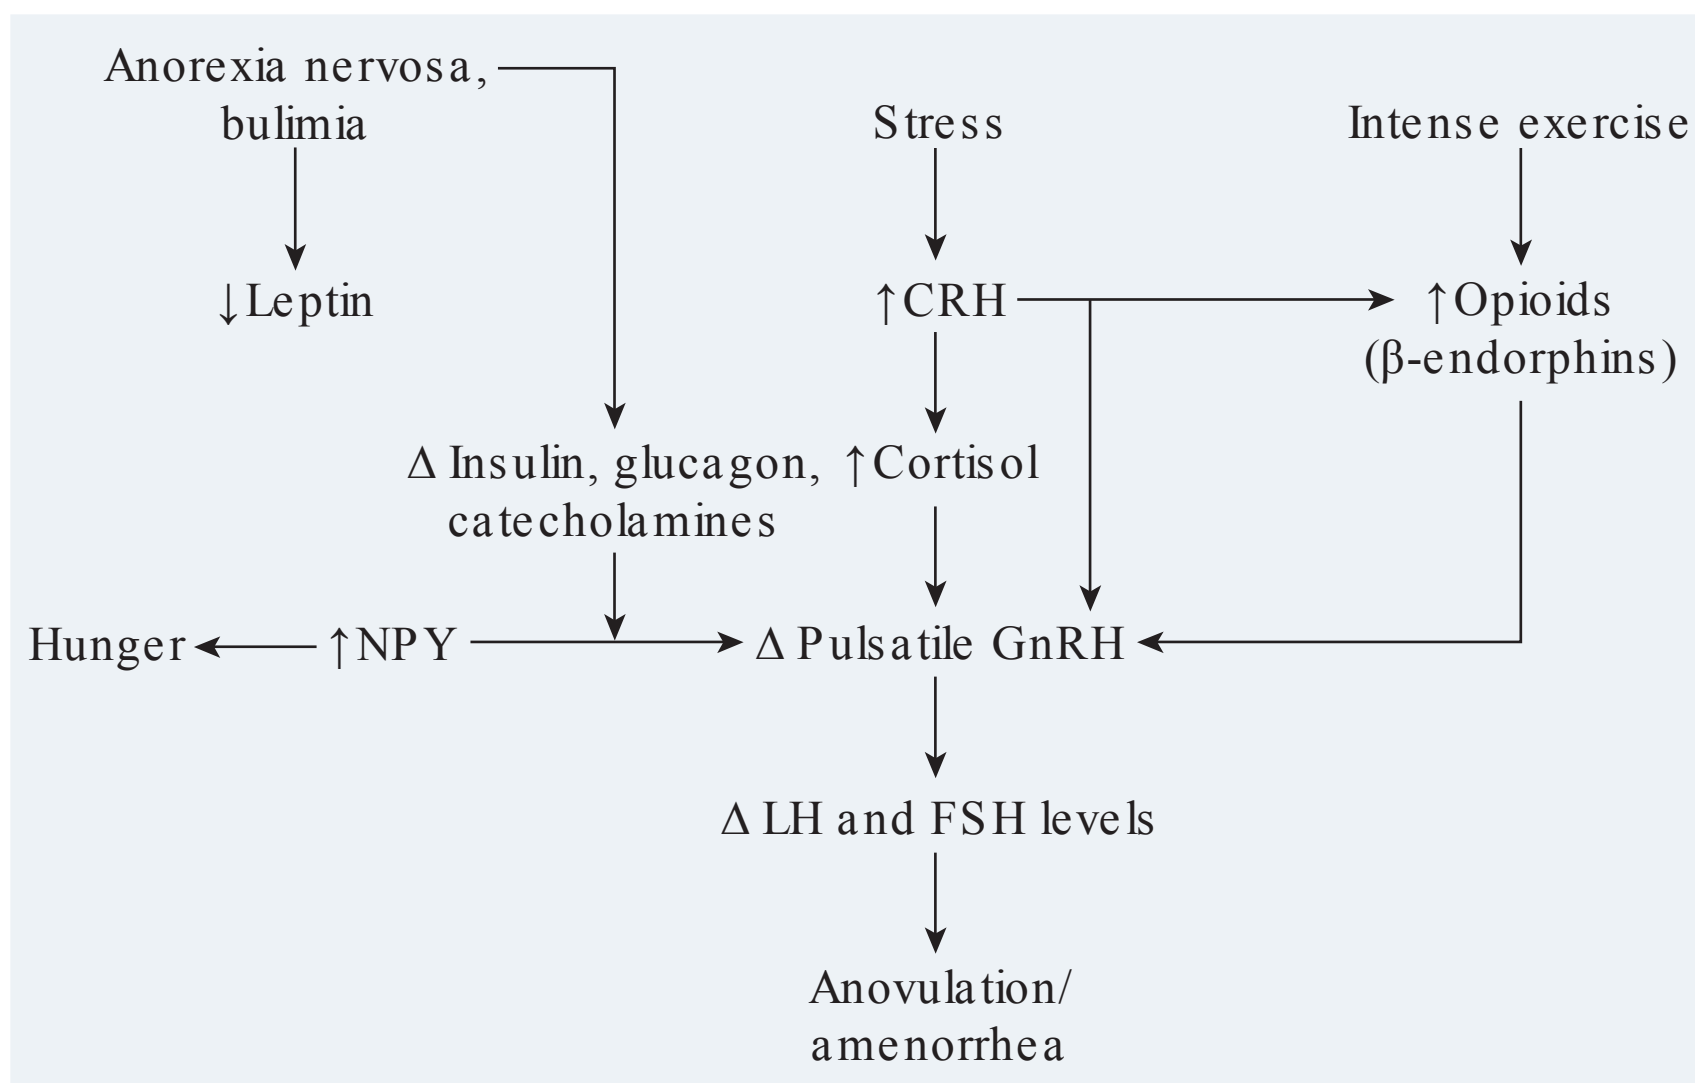

An appreciation for the link between exercise and reproductive health has led to the concept of the *female athlete triad*, which consists of menstrual dysfunction, low energy availability with or without disordered eating, and low bone mineral density in extreme athletes. Two international symposia held in this field have begun to develop risk stratification and recommendations for this population (Duckham, 2012; Joy, 2014).

In 1970, Frisch and Revelle proposed that an adolescent girl needed to achieve a critical body weight to begin menstruating (Frisch, 1970). This mass was initially postulated to approximate 48 kilograms and was subsequently refined to a minimal body mass index (BMI) approaching normal, which is  $\geq 19$ . Subsequent studies suggest that, although there is a clear correlation between body fat and reproductive function at both ends of the weight spectrum, overall energy balance better predicts the onset and maintenance of menstrual cycles (Billewicz, 1976; Johnston, 1975). For example, many elite athletes regain menstrual cyclicity following a decrease in exercise intensity prior to any gain in weight (Abraham, 1982).

**Stress-induced Amenorrhea.** This may be associated with clearly traumatic life events. Nevertheless, less severe life events and even positive events may be associated with stress. For example, stress-related amenorrhea is frequently associated with leaving for college, test taking, or wedding planning.

**Functional Hypothalamic Amenorrhea pathophysiology.** Eating disorders, exercise, and stress may disturb menstrual

**FIGURE 16-6** Diagram depicting a simplified model for the development of amenorrhea in women with eating disorders, high stress levels, or rigorous exercise. CRH= corticotropin-releasing hormone; FSH= follicle-stimulating hormone; GnRH= gonadotropin-releasing hormone; LH= luteinizing hormone; NPY= neuropeptide Y.

function through overlapping mechanisms. This observation may be in part because these problems are often concurrent. For example, women with eating disorders frequently exercise excessively and are undoubtedly under stress as they attempt to control their eating patterns. Figure 16-6 depicts a simplified model for the development of amenorrhea in these patients. It must be emphasized that each cause of functional hypothalamic amenorrhea may act via one or all of these pathways. Furthermore, in many cases, the factors known to affect reproductive function are likely acting indirectly on GnRH neurons through various neuronal subtypes that have synaptic connections to GnRH neurons.

Exercise in particular has been associated with an increase in levels of endogenous opioids ( $\beta$ -endorphins), producing the so-called runner's high. Opioids alter GnRH pulsatility.

As part of the stress response, each of these conditions may lead to an increase in corticotropin-releasing hormone (CRH) release by the hypothalamus, which in turn results in cortisol secretion by the adrenal gland. CRH alters the pattern of pulsatile GnRH secretion, whereas cortisol may act directly or indirectly to disrupt GnRH neuronal function.

Eating disorders are thought to disturb ovulatory function through several hormonal factors including insulin, insulin-like growth factor-1, cortisol, adiponectin, ghrelin, and leptin (Misra, 2014). First identified in 1994, leptin is a 167-amino-acid protein encoded by the *ob* gene and produced in white adipose tissue (Zhang, 1994). Leptin receptors have been identified in the central nervous system (CNS) and a wide range of peripheral tissues (Chen, 1996; Tartaglia, 1995).

Primarily produced in adipose tissue, leptin provides an important link between energy balance and reproduction, albeit one of many mechanisms (Chou, 2014; Schneider, 2004). Leptin has been termed a "satiety factor" as human leptin gene mutation results in morbid obesity, diabetes mellitus, and hypogonadism. This trio of abnormalities can be successfully

reversed with recombinant human leptin treatment (Licinio, 2004).

Patients with anorexia nervosa have been found to have low circulating leptin levels (Mantzoros, 1997). It has been hypothesized that a decrease in leptin production due to weight loss could secondarily stimulate neuropeptide Y, which is known to stimulate hunger and alter GnRH pulsatility. Leptin likely acts through various additional neurotransmitters and neuropeptides including the  $\beta$ -endorphins and  $\alpha$ -melanocyte-stimulating hormone (Tartaglia, 1995).

**pseudocyesis.** Although rare, pseudocyesis is considered in any woman with amenorrhea and pregnancy symptoms. Pseudocyesis exemplifies the ability of the mind to control physiologic processes. More than 500 cases of pseudocyesis have been reported in the medical literature in women ranging from ages 6 to 79 years.

These patients fervently believe that they are pregnant and subsequently demonstrate several pregnancy signs and symptoms, including amenorrhea.

Endocrine evaluation in a limited number of patients has suggested a pattern of hormonal derangements. These include alterations in LH pulse frequency concurrent with elevated serum androgen levels, which may explain the observed amenorrhea. Elevated serum prolactin levels and resultant galactorrhea have been noted in a subset of patients. Nocturnal growth hormone secretion also appears blunted (Tarin, 2013).

A common link in these patients is a history of severe grief, such as recent miscarriage, infant death, or longstanding infertility. Pseudocyesis may be more common in developing countries, where societal pressure to produce children may be strong (Seeman, 2014). Psychiatric treatment is generally required to treat the associated depression, which is often exacerbated when the patient is informed that she is not pregnant (Whelan, 1990).

**Anatomic Destruction.** Any process that destroys the hypothalamus can impair GnRH secretion and lead to hypogonadotropic hypogonadism and amenorrhea. Due to the complex neurohormonal input to the GnRH neurons, abnormalities do not need to directly interact with GnRH neurons but may operate indirectly by altering the activity of modulatory neurons.

The tumors most often associated with amenorrhea include craniopharyngiomas, germinomas, endodermal sinus tumors, eosinophilic granuloma (Hand-Schuller-Christian syndrome), gliomas, and metastatic lesions. The most common of these tumors, craniopharyngiomas, are located in the suprasellar region and frequently present with headaches and visual changes. Alternatively, impaired GnRH secretion may follow trauma, radiation, infections such as tuberculosis, or infiltrative diseases such as sarcoidosis.

## ■ Anterior pituitary Gland Disorders

The anterior pituitary gland consists of gonadotropes (producing LH and FSH), lactotropes (prolactin), thyrotropes (thyroid-stimulating hormone), corticotropes (adrenocorticotropic hormone), and somatotropes (growth hormone) (Chap. 15, p. 343). Although various disorders may directly affect gonadotropes, many causes of pituitary-derived amenorrhea may also follow abnormalities in other pituitary cell types, which in turn alter gonadotrope function.

### Inherited Abnormalities

In addition to mutations that underlie hypothalamic dysfunction, our understanding of genetic mechanisms that regulate normal pituitary development and function is rapidly advancing. First, patient cohorts have been described that have pituitary hormone deficiency combined with central facial and/or neurologic defects due to a failed midline fusion, a syndrome known as septo-optic dysplasia. Many of these patients carry mutations in the *PROPI* gene (Cadman, 2007). Second, mutations in genes that encode the LH or FSH  $\beta$ -subunits or the GnRH receptor have also been identified as rare causes of hypogonadotropic hypogonadism. Last, mutations in genes encoding the nuclear hormone receptors SF-1 and DAX1 (NR0B1) as well as genes encoding the G-protein-coupled receptor 54 (GPR54) for kisspeptin-1 are associated with hypothalamic and pituitary dysfunction (Matthews, 1993; Pallais, 2006; Seminara, 2006; Weiss, 1992).

### Acquired Pituitary Dysfunction

Most pituitary dysfunction is acquired after menarche and therefore presents with normal pubertal development followed by secondary amenorrhea. Nevertheless, in rare cases, these disorders may begin prior to puberty, resulting in delayed puberty and primary amenorrhea (Howlett, 1989).

Pituitary adenomas are the most frequent cause of acquired pituitary dysfunction (Chap. 15, p. 359). These most commonly secrete prolactin, but excessive secretion of any pituitary-derived hormone can result in amenorrhea. For example, excessive ACTH secretion results in Cushing disease, which is associated with menstrual abnormalities and signs of cortisol excess. Significantly elevated serum prolactin levels ( $> 100$  ng/mL) are almost always due to a pituitary mass.

Increased serum prolactin levels are found in as many as one-tenth of amenorrheic women, and more than half of women with both galactorrhea and amenorrhea have elevated prolactin levels (the “galactorrhea-amenorrhea syndrome”). Mechanistically, dopamine is released by the hypothalamus and acts on the anterior pituitary. Dopamine is the primary regulator of prolactin biosynthesis and secretion and plays an inhibitory role. Thus, elevated prolactin levels feed back to the hypothalamus and are associated with a reflex increase in central dopamine production to lower prolactin concentrations. This rise in central dopamine levels alters GnRH neuronal function.

Pituitary tumors also may indirectly alter gonadotrope function by a mass effect. First, tumor growth may compress neighboring gonadotropes. Second, damage to the pituitary stalk can disrupt dopamine’s pathway to inhibit prolactin secretion. In this latter case, resulting elevated prolactin levels lead to ele-

vated central dopamine levels that presumably interfere with menstrual function through the same mechanisms described in the previous paragraph.

As in the hypothalamus, pituitary function may also be diminished by inflammation, infiltrative disease, metastatic lesions, surgery, or radiation treatment. Although a rare condition, peripartum lymphocytic hypophysitis can be a dangerous cause of pituitary failure. Infiltrative diseases include sarcoidosis and hemochromatosis. Spontaneous hemorrhage into a pituitary adenoma, termed pituitary apoplexy, also may result in acute loss of pituitary function (Chap. 15, p. 360).

Sheehan syndrome refers to panhypopituitarism. It classically follows massive postpartum hemorrhage and associated hypotension. The abrupt, severe hypotension leads to pituitary ischemia and necrosis (Kelestimur, 2003). Patients with the most severe form develop shock due to pituitary apoplexy. Pituitary apoplexy is characterized by a sudden onset of headache, nausea, visual deficits, and hormonal dysfunction due to acute hemorrhage or infarction within the pituitary. In less severe forms, loss of gonadotrope activity in the pituitary leads to anovulation and subsequent amenorrhea. Damage to the other specific pituitary cell types lead to a failure to lactate, loss of sexual and axillary hair, and hypothyroidism or adrenal insufficiency symptoms. Pituitary cell types are differentially sensitive to damage. For this reason, prolactin secretion deficiency is the most common, followed by loss of gonadotropin and growth hormone release, loss of ACTH production, and least commonly, by decreases in thyroid-stimulating hormone (TSH) secretion (Veldhuis, 1980).

## ■ Other Causes of Hypogonadotropic Hypogonadism

Hypogonadotropic amenorrhea may be observed in various chronic diseases including end-stage kidney disease, liver disease, malignancies, acquired immunodeficiency syndrome, and malabsorption syndromes. The mechanisms by which these disorders result in menstrual dysfunction are poorly understood. End-stage kidney disease is associated with increased serum prolactin and altered leptin levels, both of which may disrupt normal GnRH pulsatility (Ghazizadeh, 2007). Of patients with nonalcoholic chronic liver disease, the cause of the low gonadotropin levels is unknown and is observed only in a subset of amenorrheic women (Cundy, 1991). Chronic diseases may produce amenorrhea through common mechanisms, such as stress and nutritional deficiencies. For example, patients with malabsorption due to celiac disease may have delayed menarche, secondary amenorrhea, and early menopause, which have been attributed to deficiencies in trace elements such as zinc and selenium. These are required for normal gonadotropin biosynthesis and secretion (Özgör, 2010).

## EUGONADOTROPIC AMENORRHEA

Several disorders that produce amenorrhea are not associated with significantly abnormal gonadotropin levels, at least as measured at a single point in time, as is done in clinical settings. Even so, gonadotropin amplitude or pulse frequency is likely disturbed

in these patients. As a result, chronic sustained sex-steroid secretion interferes with the normal feedback between the ovary and the hypothalamic-pituitary axis. Normal oocyte maturation and ovulation are impaired, and menstruation fails to occur.

Due to relatively normal gonadotropin levels, these patients will secrete estrogen and therefore can also be said to have *chronic anovulation with estrogen present*. This is in contrast to patients with ovarian failure or hypothalamic-pituitary failure, in whom estrogen levels are low or absent. This distinction may be useful during evaluation and treatment.

### ■ polycystic Ovarian Syndrome

This syndrome is by far the most common cause of chronic anovulation with estrogen present and is discussed fully in Chapter 17 (p. 386). Patients with PCOS may have various menstrual presentations. First, complete amenorrhea may follow anovulation. Without ovulation, progesterone is lacking, and an absent progesterone withdrawal fails to prompt menses. In some women with PCOS, however, amenorrhea may be attributable to the ability of androgens, which are elevated in PCOS patients, to atrophy the endometrium. Alternatively, heavy menstrual or intermenstrual bleeding can result from unopposed estrogen stimulation of the endometrium. Within this unstable, thickened proliferative-phase endometrium, episodic stromal breakdown and shedding leads to irregular bleeding. Vessels may be abnormally dilated in anovulatory endometria, and bleeding may be severe. Last, women with PCOS may experience occasional ovulatory cycles, and normal withdrawal menses or pregnancy may occur.

### ■ Nonclassic Congenital Adrenal Hyperplasia

This condition closely mimics the presentation of PCOS with hyperandrogenism and irregular menstrual cycles. Most commonly, nonclassic congenital adrenal hyperplasia (CAH), also termed adult-onset CAH or late-onset CAH, is due to a mutation in the *CYP21A2* gene, which encodes the 21-hydroxylase enzyme. With a mild mutation, patients are asymptomatic until adrenarche, a time that requires increased adrenal steroidogenesis. Patients with CAH are unable to convert an adequate percentage of progesterone to cortisol and aldosterone, thus increasing the production of androgens (Fig. 15-5, p. 337). As in PCOS, chronically elevated androgen levels blunt follicular maturation and prevent normal cyclic feedback at the hypothalamus and pituitary gland, and thereby result in anovulation and amenorrhea.

### ■ Ovarian Tumor

Although uncommon, chronic anovulation with estrogen present can also be observed with ovarian tumors producing either estrogens or androgens. As discussed in Chapter 36, examples include granulosa cell tumors, theca cell tumors, and mature cystic teratomas (Aiman, 1977; Pectasides, 2008; Tommas, 2012).

### ■ Hyperprolactinemia and Thyroid Disorders

Although hyperprolactinemia can cause hypogonadotropic hypogonadism, as described on page 378, many hyperprolactinemic

women may instead have relatively normal gonadotropin levels. As a group, however, their estrogen levels will be mildly depressed. Aside from pituitary adenomas, other circumstances significantly raise prolactin levels. First, many medications and herbs have been associated with hyperprolactinemia, galactorrhea, and disrupted menstrual cycling (Table 12-2, p. 281). The antipsychotic group of medications is a frequent cause.

Second, primary hypothyroidism may result in mildly elevated prolactin levels. One example is Hashimoto thyroiditis. In this disorder, the decrease in circulating thyroid hormone levels results in a compensatory increase in hypothalamic thyrotropin-releasing hormone (TRH) secretion. TRH prompts pituitary gland thyrotropes to produce TSH. In addition, TRH also binds to pituitary lactotropes, increasing prolactin secretion. This tight link between thyroid function and prolactin levels justifies measurement of a TSH with prolactin levels when initiating evaluation for galactorrhea or amenorrhea.

Whether due to adenoma, medications, or hypothyroidism, prolactin elevation creates a compensatory rise in central levels of dopamine, the primary inhibitor of prolactin secretion. Increased central dopamine levels alter GnRH secretion, thereby disrupting normal cyclic gonadotropin secretion and preventing ovulation. With thyroid disease, additional proposed mechanisms include direct effects of thyroid hormone and prolactin on peripheral cells as thyroid receptors are found in most cell types. Specifically, prolactin receptors have been identified in the ovary and in the endometrium. Moreover, thyroid hormone increases sex hormone-binding globulin levels, altering the levels of unbound, and thereby active, ovarian steroids.

These potentially discordant effects are reflected in the various bleeding patterns seen with thyroid disease (Krassas, 2010). Classically, hypothyroidism is stated to cause anovulation and subsequent heavy menstrual bleeding (Chap. 8, p. 192). Hyperthyroidism is implicated in amenorrhea. Nevertheless, these patterns are not strictly observed. As might be expected, the likelihood of menstrual abnormality correlates with the severity of the thyroid function disturbance (Kakuno, 2010).

## EVALUATION

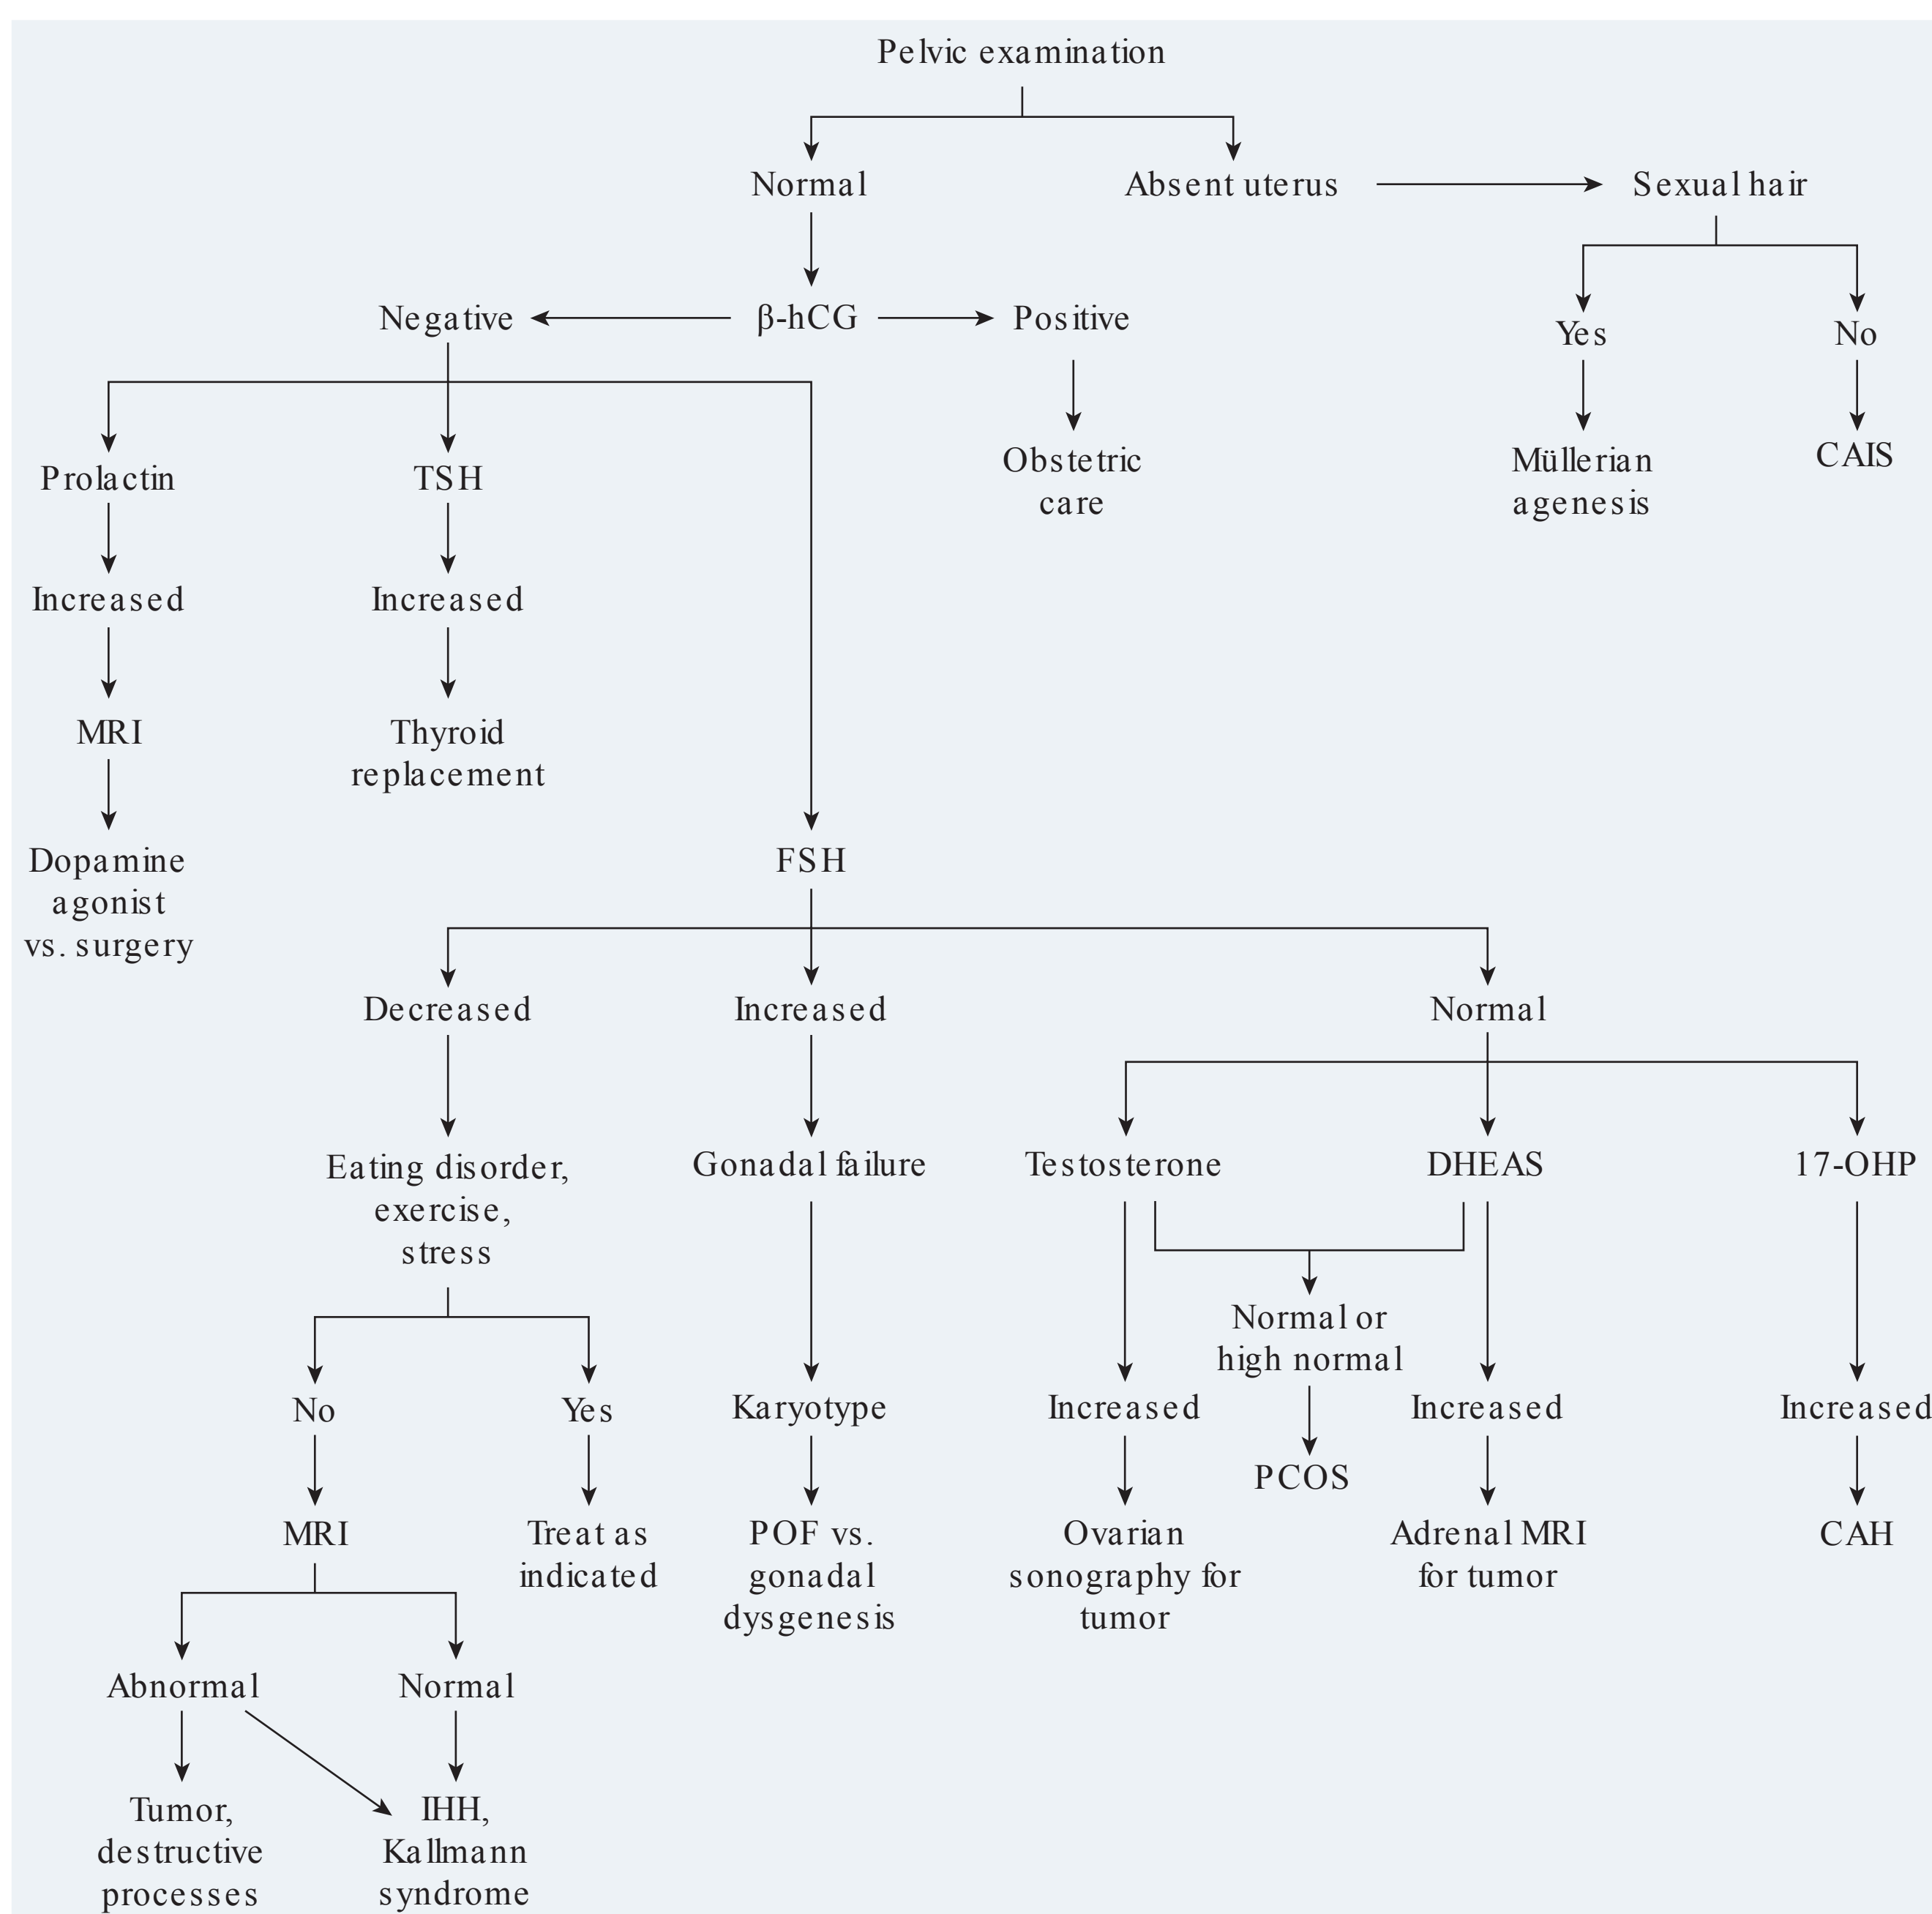

### ■ History

Figure 16-7 offers an algorithm for approaching the patient with amenorrhea. Initial questions investigate whether pubertal Tanner stages have been reached and whether menses have begun (Chap. 14, p. 319). The cycle interval, duration, and amount of menstrual flow are also characterized. Menstrual pattern changes and a description of these changes are sought. Also, the development of amenorrhea may be temporally correlated with pelvic infection, surgery, radiation therapy, chemotherapy, or other illnesses.

Surgical history focuses on prior pelvic surgery, especially intrauterine or ovarian surgery. Patients are questioned regarding postoperative infection or other surgical complications.

A review of symptoms can also be helpful. For example, new-onset headaches or visual changes may suggest a tumor of the CNS or pituitary gland. Pituitary tumors may impinge on the optic chiasm, resulting in bitemporal hemianopsia, that

**FIGURE 16-7** Diagnostic algorithm to evaluate amenorrhea. CAH = congenital adrenal hyperplasia; CAIS = complete androgen insensitivity syndrome; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; IHH = idiopathic hypogonadotropic hypogonadism; MRI = magnetic resonance imaging; 17-OHP = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POF = premature ovarian failure; TSH = thyroid-stimulating hormone.

is, the loss of both right and left outer visual fields. Bilateral milky breast discharge may reflect hyperprolactinemia. Thyroid disease can be associated with heat or cold intolerance, weight changes, and sleep or bowel motility abnormalities. Hirsutism and acne are often seen with PCOS or with nonclassic CAH. Cyclic pelvic pain would suggest a reproductive tract outlet obstruction. Hot flashes and vaginal dryness point to hypergonadotropic hypogonadism, that is, POF. Of note, the range, severity, and persistence of symptoms observed in women with POF appear to exceed those experienced by women with age-appropriate menopause (Allshouse, 2015).

Important questions regarding family history include premature cessation of menses or a history of autoimmune disease, including thyroid disease, which would suggest an increased risk for POF. A history of irregular menses, infertility, or signs of excess androgen production is often noted with PCOS. Sudden neonatal death may have occurred in family members carrying mutations in the *CYP21A2* gene responsible for CAH.

The social history investigates exposure to environmental toxins, including cigarettes. Any medications are inventoried, especially those such as antipsychotics that increase prolactin levels.

## ■ physical Examination

General appearance can be helpful in the evaluation of amenorrhea. A low BMI, perhaps in conjunction with tooth enamel erosion from recurrent vomiting, is highly suggestive of an eating disorder. Signs of Turner syndrome are evaluated, including short stature, webbed neck, shield-shaped chest, and others listed in Table 18-3 (p. 411) (Turner, 1972). Midline facial defects, such as cleft palate, are consistent with a developmental defect of the anterior pituitary gland. Hypertension in a prepubertal girl may reflect mutation in the *CYP17* gene and shunting of the steroidogenic pathway toward aldosterone.

Visual field defects, particularly bitemporal hemianopsia, may indicate a pituitary gland or CNS tumor. Skin is inspected for acanthosis nigricans, hirsutism, or acne, which may indicate PCOS or other hyperandrogenism causes. Supraclavicular fat, abdominal striae, and hypertension may be noted in those with Cushing syndrome. Hypothyroidism can present with an abnormally enlarged thyroid gland, delayed reflexes, and bradycardia. During breast examination, bilateral spontaneous galactorrhea implies hyperprolactinemia.

Examination of the genitalia starts by noting hair pattern. Sparse or absent axillary or pubic hair may reflect either lack of adrenarche or androgen insensitivity syndrome. Conversely, elevated androgen levels will result in a male pattern of genital hair growth. Markedly elevated levels of androgens can produce signs of virilization, most noticeably clitoromegaly (Chap. 17, p. 395). These women may also note voice deepening and male pattern balding.

Evidence of estrogen production includes a pink, moist vagina and cervical mucus. With estrogen present, vaginal smears demonstrate mostly superficial epithelial cells, whereas with atrophy, parabasal cell numbers increase (Fig. 21-9, p. 488). Low estrogen levels also manifest with a pale, thin, unrugated vagina.

Determination of reproductive tract anomalies by physical examination is described in Chapter 18 (p. 415). Rectal and digital vaginal examination may help identify a uterus above an obstruction at the level of the introitus or in the vagina. Hematocolpos suggests normal ovarian and endometrial function.

## ■ Testing

The differential diagnosis of amenorrhea is extensive, but evaluation of most women is relatively straightforward. For all disorders, testing may be modified by patient history and physical examination. All reproductive-aged women with amenorrhea are assumed pregnant until proven otherwise. Thus, a urinary or serum  $\beta$ -hCG level is almost always obtained.

### Progesterone Withdrawal

Classically, patients are given exogenous progesterone and monitored for a progesterone withdrawal bleed, which follows a few days after progesterone completion (the progesterone challenge test). One regimen is medroxyprogesterone acetate (Provera) given as a 10-mg daily oral dose for 10 days. If bleeding ensues, then a woman is assumed to produce estrogen and to have a developed endometrium and patent outflow tract. If

bleeding does not follow, then a patient is given estrogen followed by progesterone treatment. A single pack of COCs works nicely for this. If a woman again fails to bleed several days after completing the 21 hormone-containing pills, then an anatomic abnormality is diagnosed.

Several factors can lead to an incorrect test interpretation. First, estrogen levels may fluctuate both in hypothalamic amenorrhea and in the early stages of ovarian failure. As a result, patients with these disorders may have at least some bleeding after progesterone withdrawal. Furthermore, women with high androgen levels, such as occurs with PCOS and CAH, may have an atrophic endometrium and fail to bleed. Specifically, up to 20 percent of women in whom estrogen is present will fail to bleed following progesterone withdrawal (Rarick, 1990). Conversely, menses may be observed after progesterone administration in up to 40 percent of women with hypothalamic amenorrhea due to stress, weight loss, or exercise and in up to 50 percent of women with POF (Nakamura, 1996; Rebar, 1990). This bleeding derives from endometrium that grew prior to amenorrhea onset.

### Serum Hormone Levels

As suggested by the American Society for Reproductive Medicine (2008), it may be more reasonable to begin with hormonal evaluation in any woman found to have a normal pelvic examination (Table 16-7). First, *serum FSH levels* are typically assessed, and levels that are low suggest hypothalamic-pituitary dysfunction. An elevated FSH level is consistent with POF. FSH levels in the normal range suggest an anatomic defect or eugonadotropic hypogonadism, such as occurs in PCOS, hyperprolactinemia, or thyroid disease. Although many patients with PCOS have elevated LH to FSH level ratios  $> 2$ , testing for this relationship is unnecessary as a normal ratio does not exclude this diagnosis.

If an FSH value is low, repeating this measurement and adding an LH level, which will also be low, can help confirm hypogonadotropic hypogonadism. Additional testing may include a GnRH stimulation test. Several different protocols can be employed, but one common approach provides 100  $\mu$ g of GnRH as an intravenous bolus and then measures LH and FSH levels at 0, 15, 30, 45, and 60 minutes. In patients with hypogonadotropic hypogonadism or delayed puberty, although both LH and FSH levels will be blunted, FSH levels will be high relative to LH ratios during the test (Job, 1977; Yen, 1973). Although informative, use of this test has been constrained by the lack of consistently available clinical grade GnRH. More recently, providers have begun to use GnRH agonist protocols.

In contrast, an elevated FSH level strongly suggests the presence of hypergonadotropic hypogonadism, namely, POF. This diagnosis requires two FSH levels greater than a threshold range of 30 to 40 mIU/mL and obtained at least 1 month apart. At least two elevated values are required because the course of POF may fluctuate over time. This variation likely explains the occasional pregnancy that has been reported in these women. Patients keep a menstrual calendar while testing is completed because bleeding 2 weeks following an elevated serum FSH level may simply indicate that the sample was obtained during a normal midcycle gonadotropin surge.

**TABLE 16-7.** Tests Commonly Used in the Evaluation of Amenorrhea

primary Laboratory Tests	Diagnosis
β-hCG	Pregnancy
FSH	Hypogonadotropic versus hypergonadotropic hypogonadism <sup>a</sup>
Estradiol	Hypogonadotropic versus hypergonadotropic hypogonadism
Prolactin	Hyperprolactinemia
TSH, ± ft4	Thyroid disease
Secondary Laboratory Tests	
Testosterone	PCOS and exclude ovarian tumor
DHEAS	Exclude adrenal tumor
17-OHP	Nonclassic CAH
2-hour glucose tolerance test	PCOS
Fasting lipid panel	PCOS
Autoimmune testing	POF
Adrenal antibodies (CYP21A2)	POF
Fragile X(FMR1 premutation)	POF
Karyotype	POF < 35 years
Radiologic Evaluation	
Sonography	PCOS, uterine agenesis, or ovarian tumor
HSG or SIS	Müllerian anomaly or intrauterine synechiae
MR imaging	Müllerian anomaly or hypothalamic-pituitary disease

<sup>a</sup>Hypogonadotropic hypogonadism includes functional causes of hypothalamic amenorrhea (excessive exercise, eating disorders, and stress). Hypergonadotropic hypogonadism refers primarily to premature ovarian failure (POF). CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; ft4 = free thyroxine; hCG = human chorionic gonadotropin; HSG = hysterosalpingography; MR = magnetic resonance; 17-OHP = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; SIS = saline infusion sonography; TSH = thyroid-stimulating hormone.

As adjuncts to FSH testing, ancillary markers that will increase the sensitivity and specificity of ovarian reserve testing have been investigated. Many clinicians obtain measurements for estradiol in addition to FSH, although this has not been consistently shown to increase diagnostic accuracy. Attention has turned more recently to the use of circulating serum AMH levels (Chap. 19, p. 436) (Visser, 2012).

*Prolactin* and *thyroid-stimulating hormone* levels are tested in most patients with amenorrhea as prolactin-secreting adenomas and thyroid disease are relatively common and require specific treatment. Because of the relationship between hypothyroidism and prolactin levels, both hormones are measured simultaneously. If present, treatment for hypothyroidism will also normalize prolactin levels. If a TSH level is elevated, an unbound thyroxine (T<sub>4</sub>) level is drawn to confirm clinical hypothyroidism.

*Serum testosterone* levels are measured in women with suspected PCOS or with clinical signs of androgen excess. Hormonal evaluation includes measurement of serum total testosterone levels. Measurement of free testosterone levels is generally unwarranted as these assays are more expensive and less reliable unless sent to a specialized laboratory. Mild elevations in testosterone levels are consistent with the diagnosis of PCOS. However, values > 200 ng/dL may suggest an ovarian tumor and warrant pelvic sonography.

*Serum dehydroepiandrosterone sulfate (DHEAS)* production is essentially limited to the adrenal gland. Levels in high-normal

range or mildly above are consistent with PCOS. Adrenal adenomas may produce circulating DHEAS levels above 700 μg/dL and merit investigation with magnetic resonance (MR) imaging or computed tomography (CT) scanning of the adrenals. Measurement of 17-hydroxyprogesterone (17-OHP) aims to identify patients with nonclassic CAH. However, confirmation of this diagnosis can be difficult due to the overlapping values among normal patients and heterozygote and homozygote carriers of mutations in the 21-hydroxylase (*CYP21A2*) gene. Accordingly, adrenal stimulation with ACTH, often colloquially termed the *cort stim test*, may be required as described in Chapter 17 (p. 395).

Other Serum Testing

At times, other serum testing may be prudent. If an eating disorder is suspected, an immediate assessment of serum electrolytes is warranted as imbalances can be life-threatening. An electrocardiogram is also considered in those patients perceived to have more severe disease. A reverse triiodothyronine (T<sub>3</sub>) level is often elevated in patients with functional hypothalamic amenorrhea. Women with PCOS are screened for insulin resistance and lipid abnormalities as these are often found in affected patients and increase risks for diabetes and cardiovascular disease (Chap. 17, p. 391). Although no consensus exists, repeating these tests every few years is sensible.

Many patients with POF will not have a clear etiology for their disorder based on medical history or genetic testing and

may reasonably be assumed to have an autoimmune cause. Recommendations for testing vary among experts, but the current recommendations focus on measurement of antiadrenal antibodies, specifically antibodies directed against 21-hydroxylase. Addition of antithyroid antibodies such as antimicrosomal/thyroid peroxidase antibodies (TPO Ab) is also logical if thyroid dysfunction is suspected.

### Chromosomal Analysis

Patients with gonadal dysgenesis, such as Turner syndrome, are considered for karyotyping. Classic teaching suggests that this test is unnecessary after age 30. However, consideration is given to testing patients up to age 35 because a rare individual mosaicism may retain functional oocytes and thus sustain cyclic menses longer than expected. As previously indicated, a Y-containing cell line requires bilateral oophorectomy because of the increased risk for ovarian germ cell tumors. Due to the close association between stature and abnormalities in the X-chromosome, many specialists advise karyotyping all women with POF who are shorter than 60 inches (Saenger, 2001). Chromosomal studies are also considered in any woman with a family history of POF.

### Radiologic Evaluation

Any patient with hypogonadotropic hypogonadism is assumed to have an anatomic CNS or pituitary gland abnormality until proven otherwise by MR imaging or CT scanning. Thus, functional hypothalamic amenorrhea due to stress, exercise, or eating disorder is a diagnosis of exclusion. Imaging is highly sensitive for identification of destructive disorders such as tumors or infiltrative diseases of the hypothalamus or pituitary gland. Although fundamentally normal, a subset of patients with genetic causes for Kallmann syndrome or IHH will demonstrate developmental defects of the hypothalamus, olfactory bulbs, or pituitary gland during MR imaging (Klingmuller, 1987).

Reproductive tract anatomic disorders can be evaluated with several modalities depending on the suspected cause. Sonographic examination is frequently useful as a first screen for a uterus deemed grossly normal by physical examination. HSG or SIS is excellent for the detection of intrauterine synechiae or developmental anomalies. Changing trends favor SIS unless information on tubal patency is also required. Three-dimensional (3-D) sonography and 3-D SIS can also add information. MR imaging is frequently used for delineation of more complex uterine structures, such as a noncommunicating or hypoplastic uterine horn. Imaging of congenital reproductive tract anomalies is discussed further in Chapter 18 (p. 416).

## TREATMENT

Treatment of amenorrhea depends on its etiology and patient goals such as a desire to treat hirsutism or seek pregnancy. Anatomic abnormalities often require surgical correction, if possible, and are discussed in Chapter 18 (p. 415). Hypothyroidism is treated with thyroid replacement, and a suggested dosage of levothyroxine is 1.6  $\mu\text{g/kg}$  of body weight per day (Baskin, 2002). For most, a suitable starting dose is 50 to 100  $\mu\text{g}$  of levothyroxine orally daily. TSH response is

slow and levels are rechecked 6 to 8 weeks following initiation. A TSH level in the lower range of normal is the therapeutic goal. If needed, the dose may be increased by an increment of 12.5 or 25  $\mu\text{g}$  (Jameson, 2012). Women with hyperprolactinemia receive a dopamine agonist, such as bromocriptine or cabergoline. Macroadenomas may require surgery if secondary deficits such as visual changes are observed. Both medical and surgical specifics of pituitary disease treatment are found in Chapter 15 (p. 360).

### Estrogen Replacement

Therapy is instituted in essentially every patient with hypogonadism to avoid osteoporosis. Exceptions include patients with an estrogen-sensitive tumor. As in postmenopausal women, bone loss is accelerated in the first few years following estrogen deprivation. Thus, treatment is instituted quickly. Women with a uterus also require continuous or intermittent progesterone administration to protect against endometrial hyperplasia or cancer (Chap. 22, p. 494). There is no consensus, however, on an optimal regimen in these patients. Some experts recommend that women in their 20s receive higher doses of estrogen than is routinely given to postmenopausal women as this is a time of ongoing bone deposition. Frequently, it is easiest to prescribe COCs. Younger women may prefer this treatment as their friends may also use these pills, and in their minds, hormone replacement therapy may be associated with aging. Additionally, consensus is lacking on treatment duration in this patient population. For most individuals, continuation until approximately age 50, the usual age of menopause, seems reasonable.

Patients who have eating disorders or who exercise excessively will require behavior modification. In a patient with an eating disorder, psychiatric intervention is imperative due to the significant morbidity and mortality associated with this diagnosis (American Psychiatric Association, 2013; Michopoulos, 2013). Elite athletes may choose not to alter their exercise regimens and will therefore require estrogen treatment.

### polycystic Ovarian Syndrome

Treatment of women with PCOS may include cyclic or chronic progesterone treatment as outlined in Chapter 17 (p. 398). Insulin-sensitizing agents such as metformin (Glucophage) may be indicated in those with diabetes mellitus. In women with hyperandrogenism due to PCOS, COCs and/or spironolactone are often helpful.

Depending on its severity, nonclassic CAH in some women may be treated with low-dose corticosteroids. This partially blocks ACTH stimulation of adrenal function and thereby decreases adrenal androgen overproduction.

### Infertility

Alternative approaches may be required in a patient who desires conception. Adequate treatment of hyperprolactinemia and thyroid disease typically results in ovulation and in normal fertility for most women. If clearly linked to infertility, anatomic abnormalities are surgically corrected whenever possible. However, depending on the type and severity of the abnormality, a surrogate to carry a gestation may be needed. POF is

not reversible, and affected individuals can be offered in vitro fertilization using a donor oocyte to conceive. Assuming that behavioral modification is not successful, women with hypogonadotropic hypogonadism are referred to an infertility specialist for treatment with pulsatile GnRH or with gonadotropins. Most patients will receive gonadotropin therapy because pulsatile GnRH is more complex to administer, and GnRH is not reliably available. Women with PCOS will frequently ovulate following treatment with the selective estrogen-receptor modulator clomiphene citrate, or with an aromatase inhibitor such as letrozole. Clomiphene citrate is believed to act by transient inhibition of estrogen feedback at the hypothalamus and pituitary gland (Fig. 20-1, p. 451). Treatment, however, is not effective in those with hypogonadotropic hypogonadism as they lack significant levels of circulating estrogen.

## ■ patient Education

Patients are adequately counseled regarding their diagnosis, its long-term implications, and treatment options. All women with an intact endometrium must understand the risks of unopposed estrogen action, whether the estrogen is exogenous, such as through hormone therapy, or endogenous, such as in PCOS. For hypoestrogenic women, clinicians explain the importance of estrogen replacement to protect against bone loss. As described in Chapter 22 (p. 494), estrogen may have additional benefits, which are also detailed. Last, even if not raised by the patient, the potential or lack of potential for future child-bearing is discussed.

CHAPTER 17

Polycystic Ovarian Syndrome and Hyperandrogenism

DEFINITION . . . . . 386

INCIDENCE AND ETIOLOGY . . . . . 386

PATHOPHYSIOLOGY . . . . . 387

SIGNS AND SYMPTOMS . . . . . 389

DIAGNOSIS . . . . . 393

TREATMENT . . . . . 397

REFERENCES . . . . . 400

Polycystic ovarian syndrome (PCOS) is a common endocrinopathy typified by oligoovulation or anovulation, signs of androgen excess, and multiple small ovarian cysts. These signs and symptoms vary widely between women and within individuals over time. Women with this endocrine disorder also have higher rates of dyslipidemia and insulin resistance, which increase long-term health risks. As a result, women with PCOS may first present to various medical specialists, including pediatricians, gynecologists, internists, endocrinologists, or dermatologists.

DEFINITION

■ Polycystic Ovarian Syndrome

In Rotterdam, The Netherlands, PCOS was redefined in a consensus meeting between the European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine (ESHRE/ASRM)—The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004. As shown in Table 17-1, affected individuals must meet two out of three criteria. Importantly, because other etiologies, such as congenital adrenal hyperplasia, androgen-secreting tumors, and hyperprolactinemia, may also lead to oligoovulation and/or androgen excess, these must be excluded. Thus, PCOS currently is a diagnosis of exclusion.

The Rotterdam criteria constitute a broader spectrum than that formerly put forward by the National Institutes of Health (NIH) Conference in 1990 (Zawadzki, 1990). The prominent difference is that the NIH Conference defined PCOS without regard to ovarian sonographic appearance. Last, a third organization—The Androgen Excess and PCOS Society (AE-PCOS)—has also defined criteria for PCOS (Azziz, 2006). As is shown in Table 17-1, criteria are similar among these three groups, and controversy exists as to which is most appropriate.

■ Ovarian Hyperthecosis and HAIRAN Syndrome

*Ovarian hyperthecosis*, often considered a more severe form of PCOS, is a rare condition characterized by nests of luteinized theca cells distributed throughout the ovarian stroma. Affected women exhibit severe hyperandrogenism and may occasionally display frank virilization signs such as clitoromegaly, temporal balding, and voice deepening (Culiner, 1949). In addition, a much greater degree of insulin resistance and acanthosis nigricans typically is found (Nagamani, 1986).

The *hyperandrogenic-insulin resistant-acanthosis nigricans (HAIRAN)* syndrome is also uncommon and consists of marked hyperandrogenism, severe insulin resistance, and acanthosis nigricans (Barbieri, 1983). The etiology of this disorder is unclear, and HAIRAN syndrome may represent either a PCOS variant or a distinct genetic syndrome. Both ovarian hyperthecosis and HAIRAN are exaggerated phenotypes of PCOS, and their treatment mirrors that for PCOS described later in this chapter.

INCIDENCE AND ETIOLOGY

PCOS is the most common endocrine disorder of reproductive-aged women and affects approximately 4 to 12 percent in general population studies (Asunción, 2000; Knochenhauer, 1998; Lauritsen, 2014). Although symptoms of androgen excess may vary among ethnicities, PCOS appears to affect all races and nationalities equally.

The underlying cause of PCOS is unknown. However, a genetic basis that is both multifactorial and polygenic is suspected, as there is a well-documented aggregation of the syndrome within families (Franks, 1997). Specifically, an increased prevalence is noted between affected individuals and their sisters (32 to 66 percent) and mothers (24 to 52 percent) (Govind, 1999; Kahsar-Miller, 2001; Yildiz, 2003). Twin studies also suggest a prominent heritable influence (Vink, 2006).

Some have suggested an autosomal dominant inheritance with expression in both females and males. For example, first-degree male relatives of women with PCOS have been shown to have significantly higher rates of elevated circulating dehydroepiandrosterone sulfate (DHEAS) levels, early balding, and insulin resistance compared with male controls (Legro, 2000, 2002).

Identification of candidate genes linked to PCOS is a major research focus, given the large potential benefit for both diagnosis and management. In general, putative genes include those involved in androgen synthesis and those associated with insulin resistance. Genome-wide association studies in Chinese women have identified variants in 11 genomic regions as potential risk factors for PCOS (Chen, 2011; Shi, 2012).

**TABLE 17-1.** Definition of Polycystic Ovarian Syndrome

**ESHRE/ASRM (Rotterdam) 2003**

Clinical and/or biochemical hyperandrogenism  
Oligo-/anovulation

**AE-PCOS (2006)**

To include both:  
Clinical and/or biochemical hyperandrogenism  
Oligo-/anovulation and/or polycystic ovaries

AE-PCOS = Androgen Excess and PCOS Society; ASRM = American Society for Reproductive Medicine; ESHRE = European Society of Human Reproduction and Embryology; NIH = National Institutes of Health. PCOS = polycystic ovarian syndrome.  
Data from Azziz, 2006; The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004; Zawadzki, 1990.

In addition, epigenetic modification of genetic susceptibility within the maternal-fetal environment may influence adult PCOS development (Dumesic, 2014). Further investigation, however, is needed to determine the roles of these gene products in PCOS pathogenesis.

## PATHOPHYSIOLOGY

### ■ Gonadotropins

Anovulation in women with PCOS is characterized by inappropriate gonadotropin secretion (Fig. 17-1). Specifically, altered gonadotropin-releasing hormone (GnRH) pulsatility leads to preferential production of luteinizing hormone (LH) compared with follicle-stimulating hormone (FSH) (Hayes, 1998; Waldstreicher, 1988). It is currently unknown whether hypothalamic dysfunction is a primary cause of PCOS or is secondary to abnormal steroid feedback. In either case, serum LH levels rise, and increased levels are observed clinically in approximately 50 percent of affected women (van Santbrink, 1997). Similarly, LH:FSH ratios are elevated and rise above 2:1 in approximately 60 percent of patients (Rebar, 1976).

### ■ Insulin Resistance

Women with PCOS also display greater degrees of insulin resistance and compensatory hyperinsulinemia than nonaffected women. Insulin resistance is defined as a reduced glucose-uptake response to a given amount of insulin. The decreased insulin sensitivity appears to stem from a postbinding abnormality in insulin receptor-mediated signal transduction (Dunaif, 1997). Both lean and obese women with PCOS are found to be more

**TABLE 17-2.** Consequences of Polycystic Ovarian Syndrome

**Short-term consequences**

Obesity  
Infertility  
Depression  
Sleep apnea  
Irregular menses  
Abnormal lipid levels  
Non-alcoholic fatty liver disease  
Hirsutism/acne/androgenic alopecia  
Insulin resistance/acanthosis nigricans

**Long-term consequences**

Diabetes mellitus  
Endometrial cancer  
Cardiovascular disease

insulin resistant than nonaffected weight-matched controls (Dunaif, 1989, 1992).

Insulin resistance has been associated with an increase in several disorders including type 2 diabetes mellitus (DM), hypertension, dyslipidemia, and cardiovascular disease. Therefore, PCOS is not simply a disorder of short-term consequences such as irregular periods and hirsutism, but also one of potential long-term health consequences (Table 17-2).

### ■ Androgens

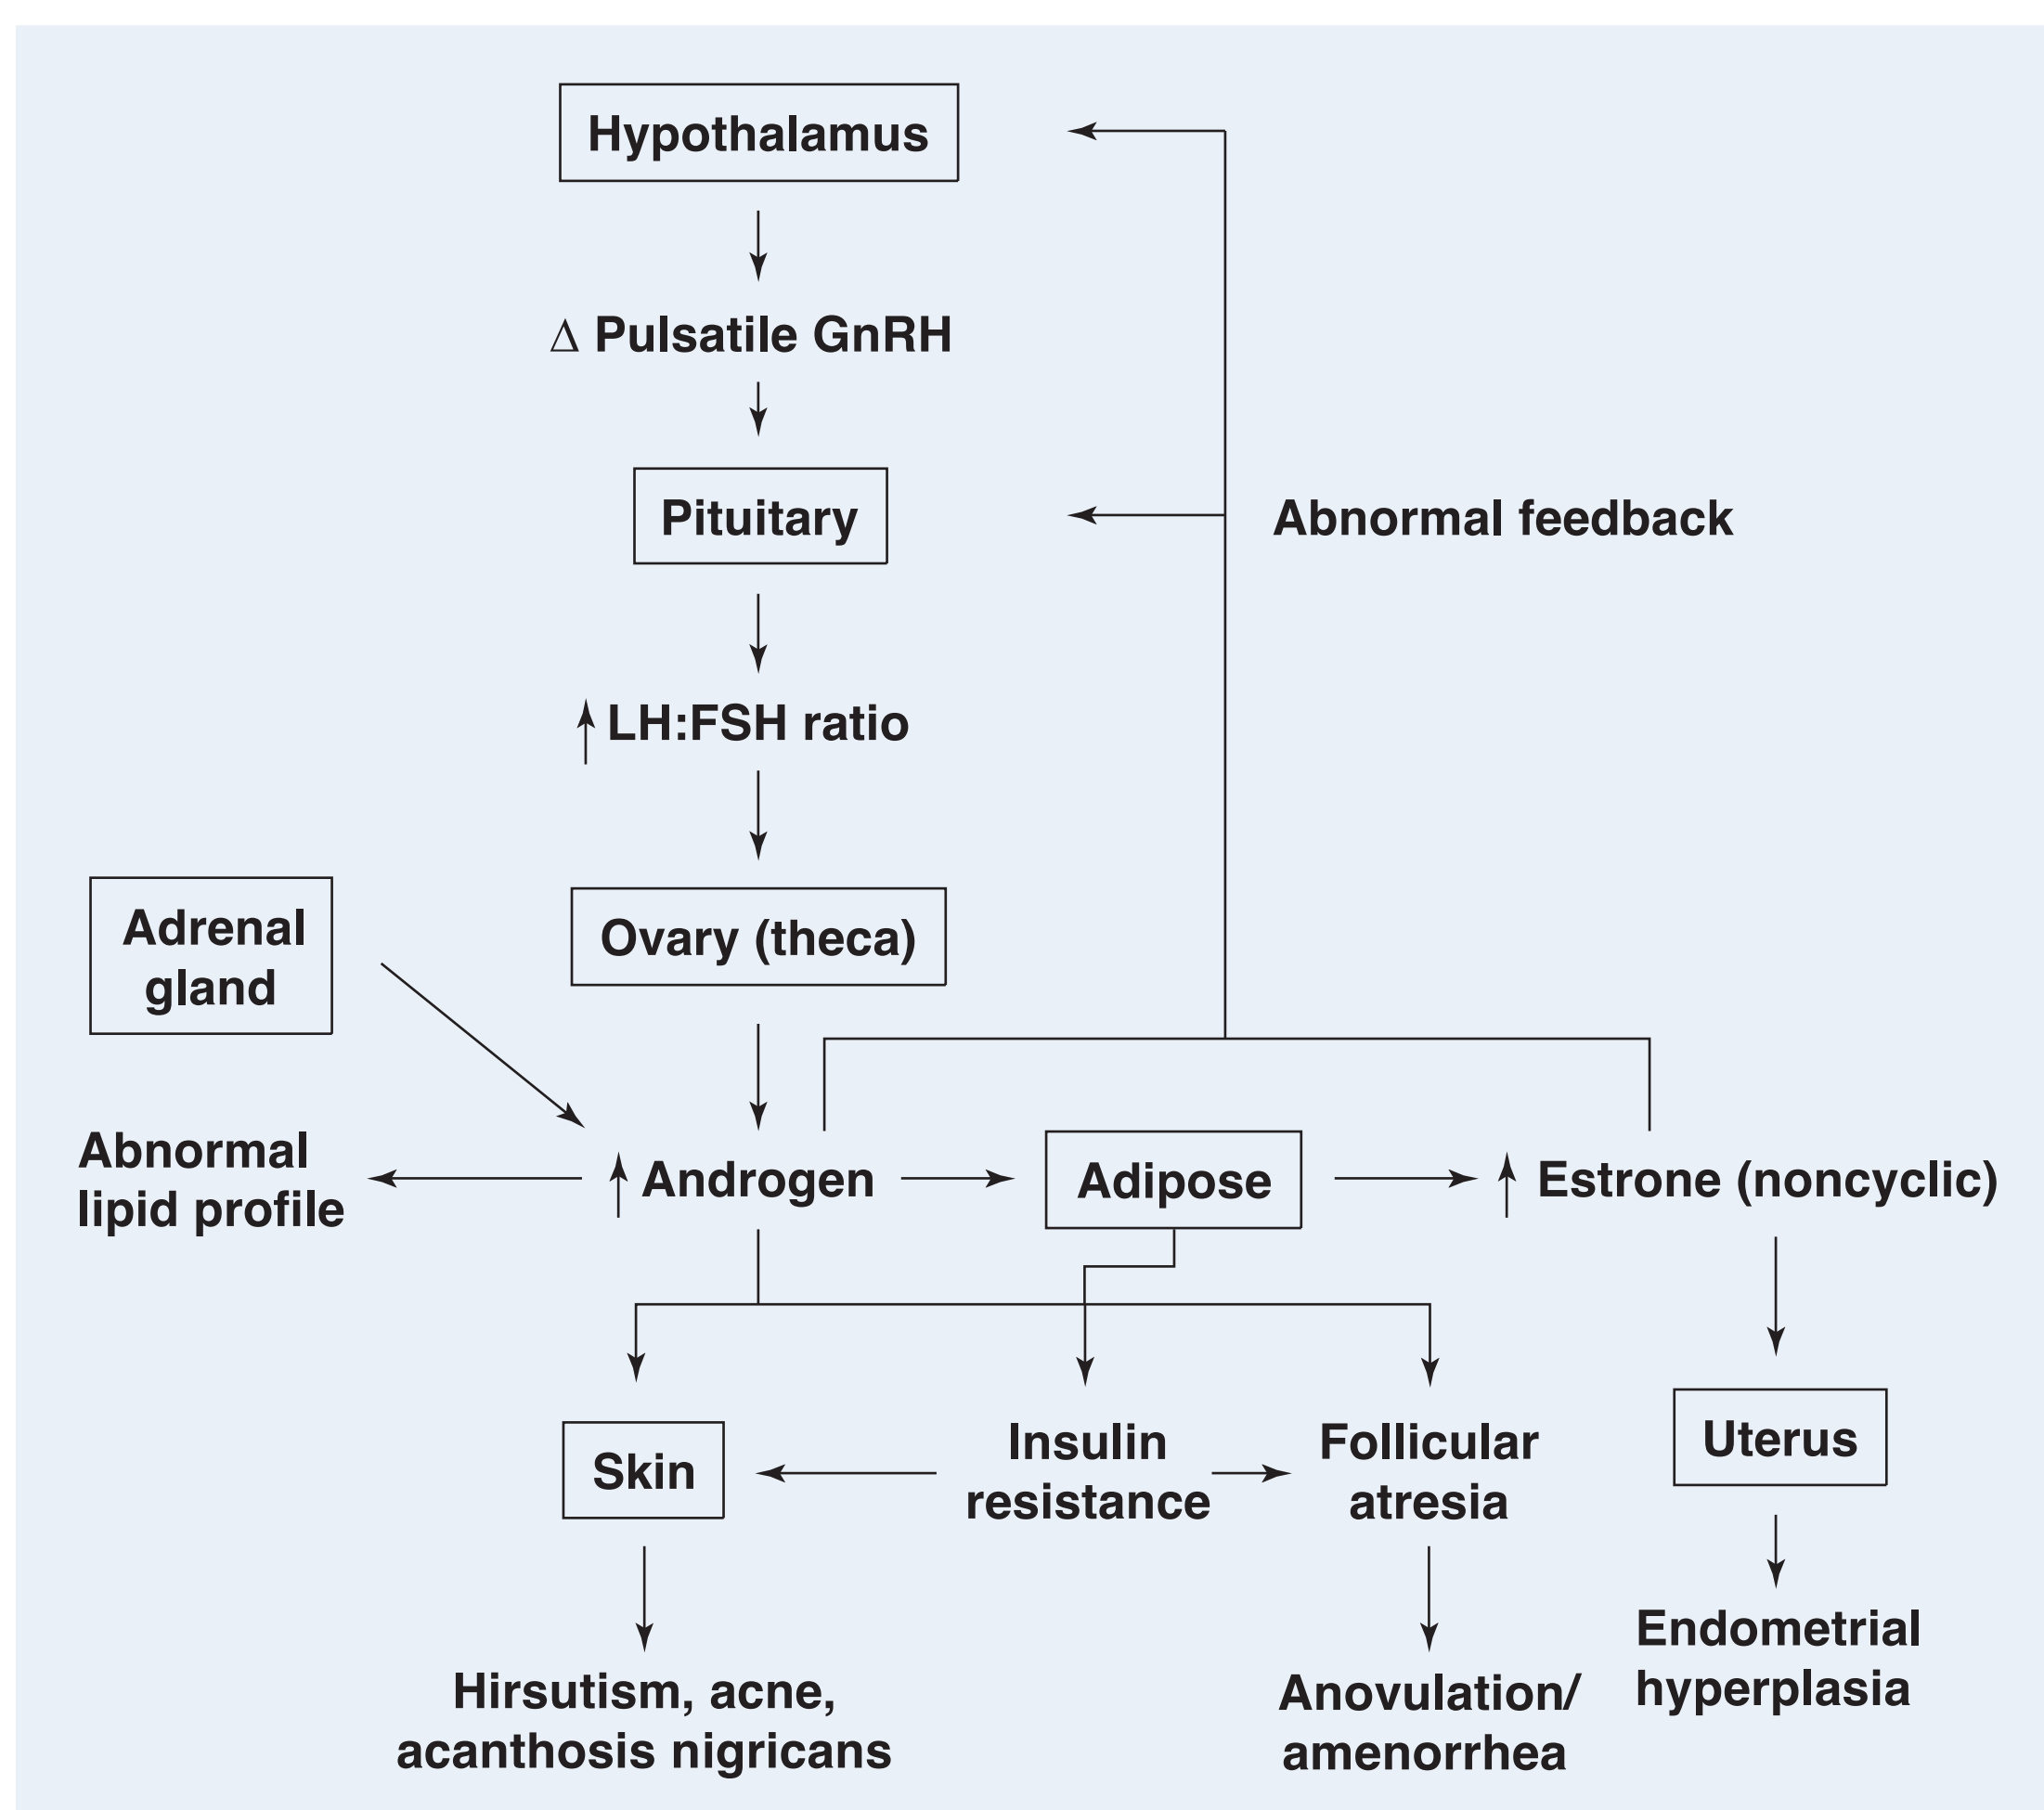

Both insulin and LH stimulate androgen production by the ovarian theca cell (Dunaif, 1992). As a result, affected ovaries secrete elevated levels of testosterone and androstenedione. Specifically, elevated free testosterone levels are noted in 70 to 80 percent of women with PCOS, and 25 to 65 percent exhibit elevated levels of DHEAS (Moran, 1994, 1999; O’Driscoll, 1994). In turn, elevated androstenedione levels contribute to an increase in estrone levels through peripheral conversion of androgens to estrogens by aromatase.

### ■ Sex Hormone-binding Globulin

Women with PCOS display decreased levels of sex hormone-binding globulin (SHBG). This glycoprotein, produced in the liver, binds most sex steroids. Only approximately 1 percent of these steroids are unbound and thus free and bioavailable. The synthesis of SHBG is suppressed by insulin as well as androgens, corticoids, progestins, and growth hormone (Bergh, 1993). Because of suppressed SHBG production, less circulating androgen is bound and thus more remains available to bind with end-organ receptors. Accordingly, some women with PCOS will have total testosterone levels in the normal range, but will be clinically hyperandrogenic due to elevated free testosterone levels.

In addition to hyperandrogenism, low SHBG levels have also been linked to impaired glucose control and a risk for developing type 2 DM (Ding, 2009). The mechanism of this association is not fully understood and may reflect a role for SHBG in glucose homeostasis. For example, Veltman-Verhulst

**FIGURE 17-1** Model for the initiation and maintenance of polycystic ovarian syndrome (PCOS). Alterations in pulsatile gonadotropin-releasing hormone (GnRH) release may lead to a relative increase in luteinizing hormone (LH) versus follicle-stimulating hormone (FSH) biosynthesis and secretion. LH stimulates ovarian androgen production, while the relative paucity of FSH prevents adequate stimulation of aromatase activity within the granulosa cells, thereby decreasing androgen conversion to the potent estrogen estradiol.

Increased intrafollicular androgen levels result in follicular atresia. Increased circulating androgen levels contribute to abnormalities in patient lipid profiles and the development of hirsutism and acne. Increased circulating androgens can also be derived from the adrenal gland.

Elevated serum androgens (primarily androstenedione) are converted in the periphery to estrogens (primarily estrone). As conversion occurs primarily in the stromal cells of adipose tissue, estrogen production will be augmented in obese PCOS patients. This conversion results in chronic feedback at the hypothalamus and pituitary gland, in contrast to the normal fluctuations in feedback observed in the presence of a growing follicle and rapidly changing levels of estradiol. Unopposed estrogen stimulation of the endometrium may lead to endometrial hyperplasia.

Insulin resistance due to genetic abnormalities and/or increased adipose tissue contributes to follicular atresia in the ovaries as well as the development of acanthosis nigricans in the skin.

Lack of follicular development results in anovulation and subsequent oligo- or amenorrhea.

Note that this syndrome may develop from primary dysfunction of any one of a number of organ systems. For example, elevated ovarian androgen production may be due to either an intrinsic abnormality in enzymatic function and/or abnormal hypothalamic-pituitary stimulation with LH and FSH.

The common denominator is development of a self-perpetuating noncyclic hormonal pattern.

(2010) evaluated SHBG levels in women with PCOS and found an association between low SHBG levels and subsequent development of gestational diabetes mellitus.

## ■ Anovulation

The precise mechanism leading to anovulation is unclear, but altered GnRH pulsatility and inappropriate gonadotropin secretion have been implicated in menstrual irregularity.

Moreover, anovulation may result from insulin resistance, as a substantial number of anovulatory patients with PCOS may

resume ovulatory cycles when treated with metformin, an insulin sensitizer (Nestler, 1998). It has been suggested that oligoovulatory women with PCOS exhibit a milder phenotype of ovarian dysfunction than anovulatory PCOS patients and have a more favorable response to ovulation induction agents (Burgers, 2010).

Finally, the large antral follicle cohort with increased intra-ovarian androgens seen in PCOS may contribute to anovulation. This is supported by the fact that some patients who have undergone ovarian wedge resection or laparoscopic ovarian drilling have improved menstrual regularity. One study demonstrated

that 67 percent of PCOS patients developed regular menses following such surgery compared with only 8 percent prior to surgery (Amer, 2002).

## SIGNS AND SYMPTOMS

In women with PCOS, symptoms may include menstrual irregularities, infertility, manifestations of androgen excess, or other endocrine dysfunction. Symptoms classically become apparent within a few years of puberty.

### ■ Menstrual Dysfunction

In women with PCOS, menstrual dysfunction may range from amenorrhea to oligomenorrhea to episodic menometrorrhagia with associated iron-deficiency anemia. In most cases, amenorrhea and oligomenorrhea result from anovulation. Namely, without ovulation and endogenous progesterone production from the corpus luteum, a normal menstrual period is not triggered. Alternatively, amenorrhea can stem from elevated androgen levels. Specifically, androgens can counteract estrogen to produce an atrophic endometrium. Thus, with markedly elevated androgen levels, amenorrhea and a thin endometrial stripe can be seen.

In contrast to amenorrhea, women with PCOS may have heavy and unpredictable bleeding. In these cases, progesterone is absent due to anovulation, and chronic estrogen exposure results. This produces constant mitogenic stimulation of the endometrium. The instability of the thickened endometrium leads to unpredictable bleeding.

Characteristically, oligomenorrhea (fewer than eight menstrual periods in 1 year) or amenorrhea (absence of menses for 3 or more consecutive months) with PCOS begins with menarche. Those with PCOS fail to establish monthly ovulatory menstrual cycles by midadolescence, and they often continue to have irregularity. However, approximately 50 percent of all postmenarchal girls have irregular periods for up to 2 to 4 years because of hypothalamic-pituitary-ovarian axis immaturity. Thus, due to the frequency of both irregular cycles and acne in unaffected adolescents, some advocate delaying the diagnosis of PCOS until after age 18 (Shayya, 2011).

**TABLE 17-3.** Medications That May Cause Hirsutism and/or Hypertrichosis

Hirsutism	Hypertrichosis
Anabolic steroids	Cyclosporine
Danazol	Diazoxide
Metoclopramide	Hydrocortisone
Methyldopa	Minoxidil
Phenothiazines	Penicillamine
Progestins	Phenytoin
Reserpine	Psoralens
Testosterone	Streptomycin

Last, some evidence suggests that PCOS patients with prior irregular cycle intervals may develop regular cycle patterns as they age. A decreasing antral follicle cohort as women enter their 30s and 40s may lead to a concurrent decrease in androgen production (Elting, 2000).

### ■ Hyperandrogenism

This condition is usually manifested clinically by hirsutism, acne, and/or androgenic alopecia. In contrast, signs of virilization such as increased muscle mass, voice deepening, and clitoromegaly are not typical of PCOS. Virilization reflects higher androgen levels and should prompt investigation for an androgen-producing tumor of the ovary or adrenal gland.

#### Hirsutism

In a female, hirsutism is defined as coarse, dark, terminal hairs distributed in a male pattern (Fig. 17-2). This is distinguished from hypertrichosis, which is a generalized increase in lanugo, that is, the soft, lightly pigmented hair associated with some medications and malignancies. PCOS accounts for 70 to 80 percent of cases of hirsutism, which typically begins in late adolescence or the early 20s. Idiopathic hirsutism is the second most frequent cause (Azziz, 2003). Additionally, various drugs may also lead to hirsutism, and their use should be investigated (Table 17-3).

**FIGURE 17-2** A. Facial hirsutism. (Used with permission from Dr. Tamara Chao.) B. Male pattern escutcheon.

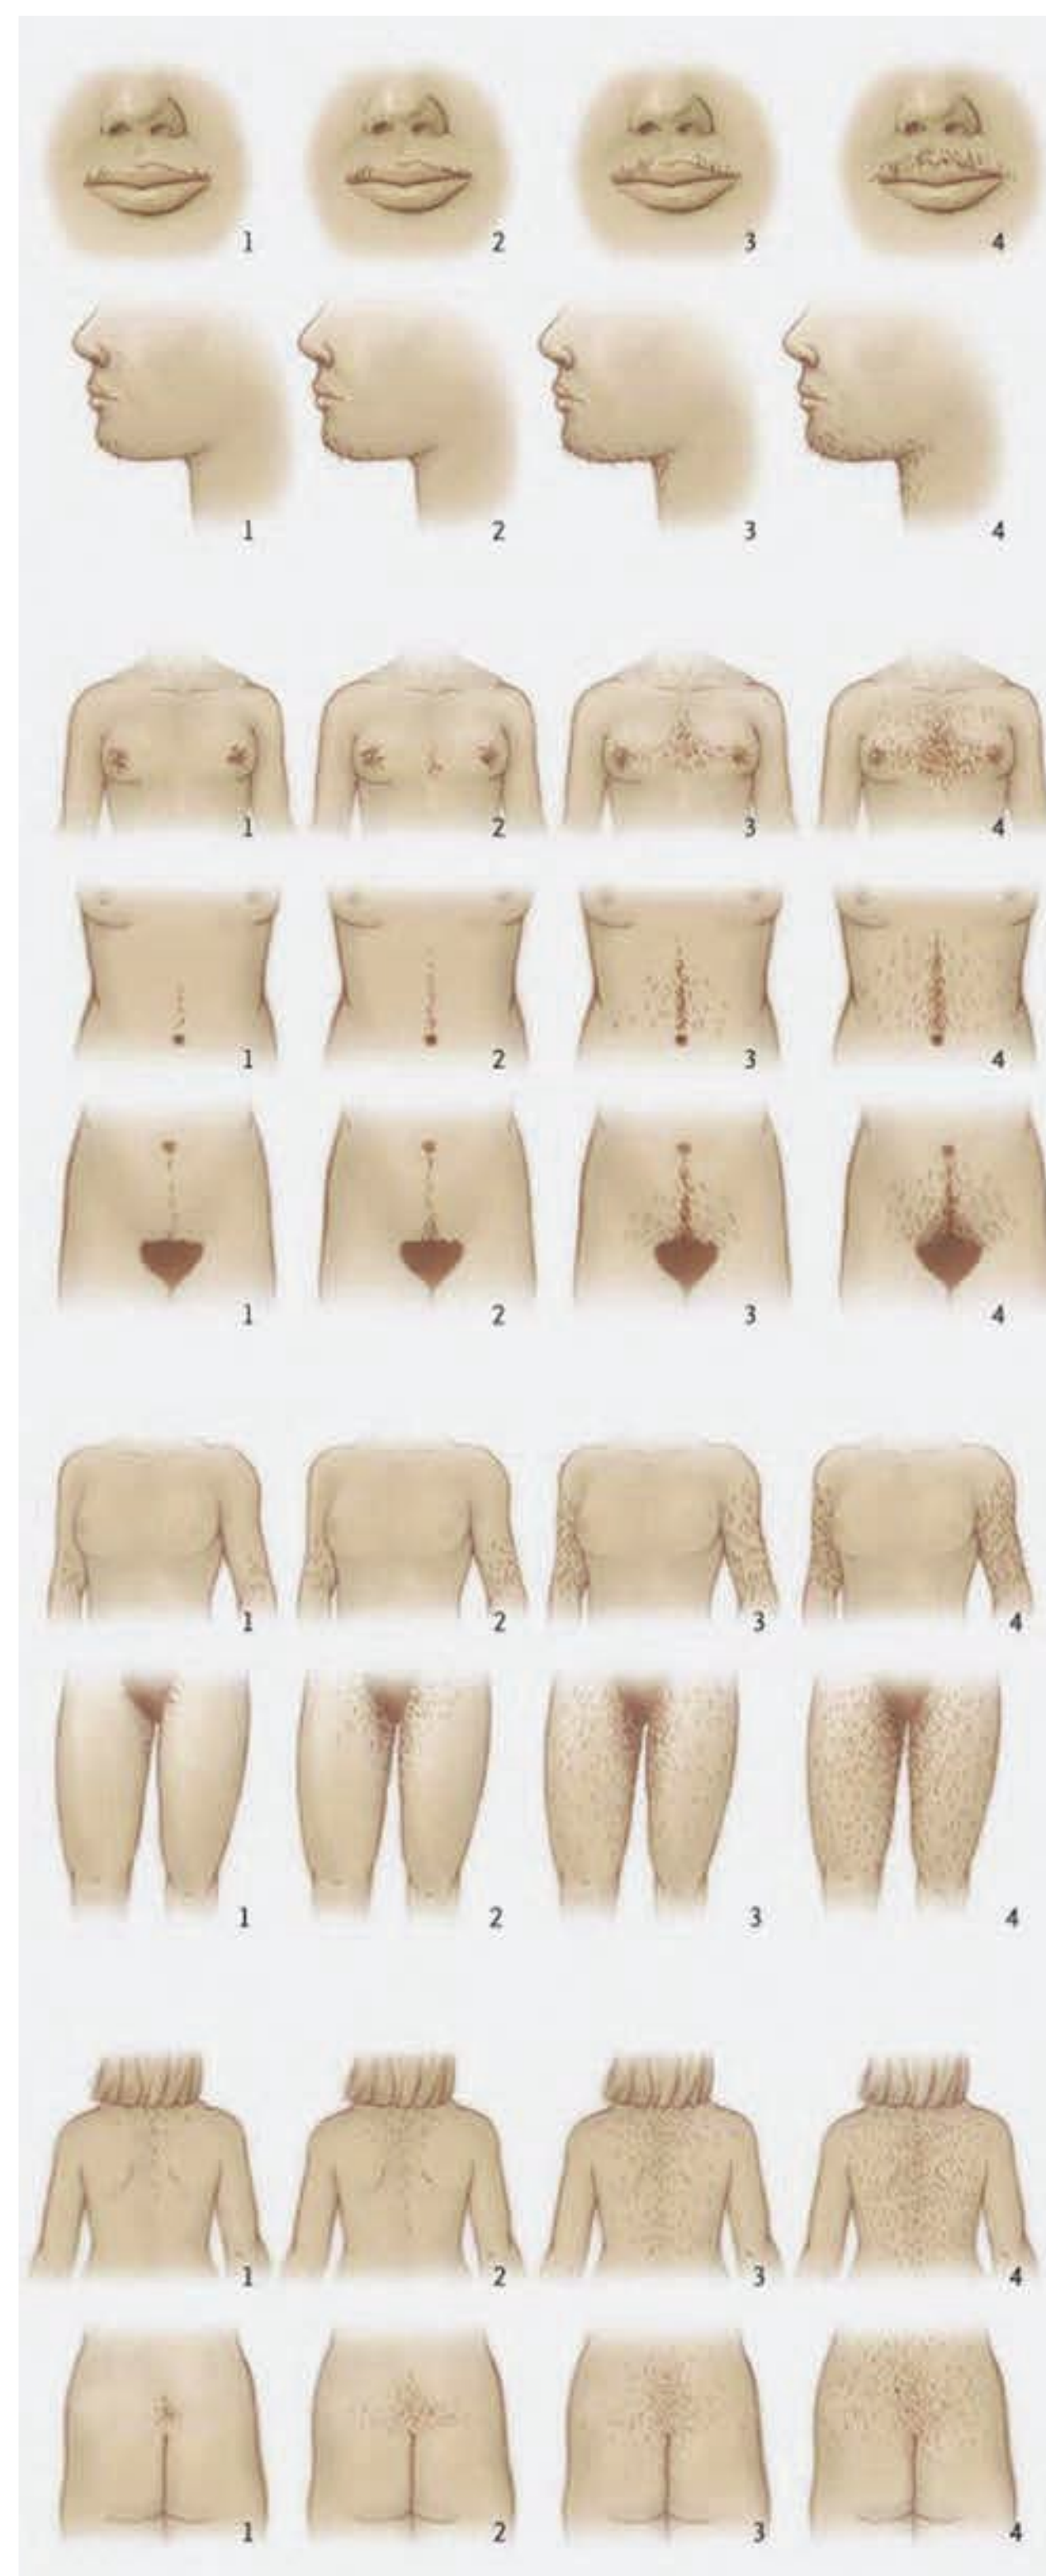

**FIGURE 17-3** Androgenic effects on the pilosebaceous unit. In some hair-bearing areas, androgens stimulate sebaceous glands, and vellus follicles (A) are converted to terminal follicles (B), leading to hirsutism. Under the influence of androgens, terminal hairs that were not previously dependent on androgens (C) revert to a vellus form and balding results (D).

**Pathophysiology of Hirsutism.** Elevated androgen levels play a major role in determining the type and distribution of hair. Within a hair follicle, testosterone is converted by the enzyme  $5\alpha$ -reductase to dihydrotestosterone (DHT) (Fig. 17-3). Although both testosterone and DHT convert short, soft vellus hair to coarse terminal hair, DHT is markedly more effective than testosterone. Conversion is irreversible, and only hairs in androgen-sensitive areas are changed in this manner to terminal hairs. As a result the most common areas affected with excess hair growth include the upper lip, chin, sideburns, chest, and linea alba of the lower abdomen. Specifically, *escutcheon* is the term used to describe the hair pattern of the lower abdomen. In women, this pattern is triangular and overlies the mons pubis, whereas in men it extends up the linea alba to form a diamond shape.

The concentration of hair follicles per unit area does not differ between men and women, however, racial and ethnic differences do exist. Individuals of Mediterranean descent have a higher concentration of hair follicles than Northern Europeans, and a much higher concentration than Asians. For this reason, Asians with PCOS are much less likely to present with overt hirsutism than other ethnic groups. Additionally, the familial tendency for the hirsutism development is strong and stems from genetic differences in  $5\alpha$ -reductase activity and in target tissue sensitivity to androgens.

**Ferriman-Gallwey Scoring System.** To quantify the degree of hirsutism for research purposes, the Ferriman-Gallwey scoring

system was developed in 1961 and later modified in 1981 (Ferriman, 1961; Hatch, 1981). Within this system, abnormal hair distribution is assessed in nine body areas and scored from 0 to 4 (Fig. 17-4). Increasing numeric scores correspond to greater hair density within a given area. Many investigators define hirsutism as a score  $\geq 8$  using the modified scoring. Because of the

**FIGURE 17-4** Depiction of the Ferriman-Gallwey system for scoring hirsutism.

lower follicle concentration in Far East Asians, the AE-PCOS Society suggests a threshold value  $\geq 3$  for this group (Escobar-Morreale, 2011).

The Ferriman-Gallwey scoring system is cumbersome and thus is not used frequently in clinical settings. Nevertheless, it may be useful for following treatment responses in individual patients. Alternatively, an abbreviated score that combines only the upper and lower abdomen and chin scores may be a suitable surrogate (Cook, 2011). Also, many specialists choose to classify hirsutism more generally as mild, moderate, or severe depending on the location and density of hair growth.

## Acne

Acne vulgaris is a frequent clinical finding in adolescents. However, acne that is particularly persistent or late onset suggests PCOS (Homburg, 2004). The prevalence of acne in women with PCOS is unknown, although one study found that 50 percent of adolescents with PCOS have moderate acne (Dramusic, 1997). In addition, androgen level elevation has been reported in 80 percent of women with severe acne, 50 percent with moderate acne, and 33 percent with mild acne (Bunker, 1989). Women with moderate to severe acne have an increased prevalence (52 to 83 percent) of polycystic ovaries identified during sonographic examination (Betti, 1990; Bunker, 1989).

The pathogenesis of acne vulgaris involves four factors: blockage of the follicular opening by hyperkeratosis, sebum overproduction, proliferation of commensal *Propionibacterium acnes*, and inflammation. As in the hair follicle, testosterone is converted within sebaceous glands to its more active metabolite, DHT, by 5 $\alpha$ -reductase. In women with androgen excess, overstimulation of androgen receptors in the pilosebaceous unit increases sebum production that eventually leads to inflammation and comedone formation (see Fig. 17-3). Inflammation leads to the main long-term side effect of acne—scarring. Accordingly, treatment is directed at minimizing inflammation, decreasing keratin production, lowering colonization of *P. acnes*, and reducing androgen levels to diminish sebum production.

## Alopecia

Female androgenic alopecia is a less common finding in women with PCOS. Hair loss progresses slowly and is characterized by diffuse thinning at the crown with preservation of the frontal hairline (Quinn, 2014). Its pathogenesis involves an excess of 5 $\alpha$ -reductase activity in the hair follicle leading to a rise in DHT levels. Moreover, androgen receptor expression in these individuals is increased (Chen, 2002).

Alopecia, however, may reflect other serious disease. For this reason, affected women are also evaluated to exclude thyroid dysfunction, anemia, or other chronic illness.

## Other Endocrine Dysfunction

### Insulin Resistance

Although not well characterized, the association among insulin resistance, hyperandrogenism, and PCOS has long been recognized. The precise incidence of insulin resistance in women with PCOS has been difficult to ascertain for lack of a simple method to determine insulin sensitivity in an office setting. Although obesity is known to exacerbate insulin resistance, one

**FIGURE 17-5** Insulin sensitivity is decreased in obese women with polycystic ovarian syndrome. NL= normal (those without PCOS); PCOS= polycystic ovarian syndrome. (Reproduced with permission from Dunaif A, Segal KR, Futterweit W, et al: Profound peripheral insulin resistance, independent of obesity, in polycystic ovary syndrome, *Diabetes* 1989 Sep;38(9):1165–1174.)

classic study demonstrated that both lean and obese women with PCOS have increased rates of insulin resistance and type 2 DM compared with weight-matched controls without PCOS (Fig. 17-5) (Dunaif, 1989, 1992).

**Acanthosis Nigricans.** This skin condition is characterized by thickened, gray-brown velvety plaques seen in flexure areas such as the back of the neck, axillae, inframammary creases, waist, and groin (Fig. 17-6) (Panidis, 1995). Thought to be a cutaneous marker of insulin resistance, acanthosis nigricans may be found in individuals with or without PCOS. Insulin resistance leads to hyperinsulinemia, which is believed to stimulate keratinocyte and dermal fibroblast growth, producing the characteristic skin changes (Cruz, 1992). Acanthosis nigricans develops more frequently in obese women with PCOS (50 percent incidence) than in those with PCOS and normal weight (5 to 10 percent).

As part of its differential diagnosis, acanthosis nigricans rarely can be seen with genetic syndromes or gastrointestinal tract malignancy, such as adenocarcinoma of the stomach or pancreas. To differentiate, acanthosis nigricans associated with malignancy usually has a more abrupt onset, and skin involvement is more extensive (Moore, 2008).

**FIGURE 17-6** Acanthosis nigricans and multiple small pedunculated acrochordons (skin tags) in the neck crease. Both are dermatologic signs of insulin resistance.

### Impaired Glucose Tolerance and Type 2 Diabetes Mellitus.

Women with PCOS are at increased risk for impaired glucose tolerance (IGT) and type 2 DM. Based on oral glucose tolerance testing of obese women with PCOS, the prevalence of IGT and DM is approximately 30 percent and 7 percent, respectively (Legro, 1999). Even after adjusting for body mass index (BMI), women with PCOS remained more likely to have DM (Lo, 2006). Specifically,  $\beta$ -cell dysfunction that is independent of obesity has been reported in patients with PCOS (Dunaif, 1996a). Similar findings are reported in groups of obese and normal-weight adolescent girls with PCOS (Flannery, 2013; Palmert, 2002).

### Dyslipidemia

The classic atherogenic lipoprotein profile seen in PCOS shows increased low-density lipoprotein (LDL) and triglyceride levels, elevated total cholesterol:high-density lipoprotein (HDL) ratios, but depressed HDL levels (Banaszewska, 2006). Independent of total cholesterol levels, these changes may increase the cardiovascular disease risk in women with PCOS. The prevalence of dyslipidemia in PCOS approaches 70 percent (Legro, 2001; Talbott, 1998).

### Obesity

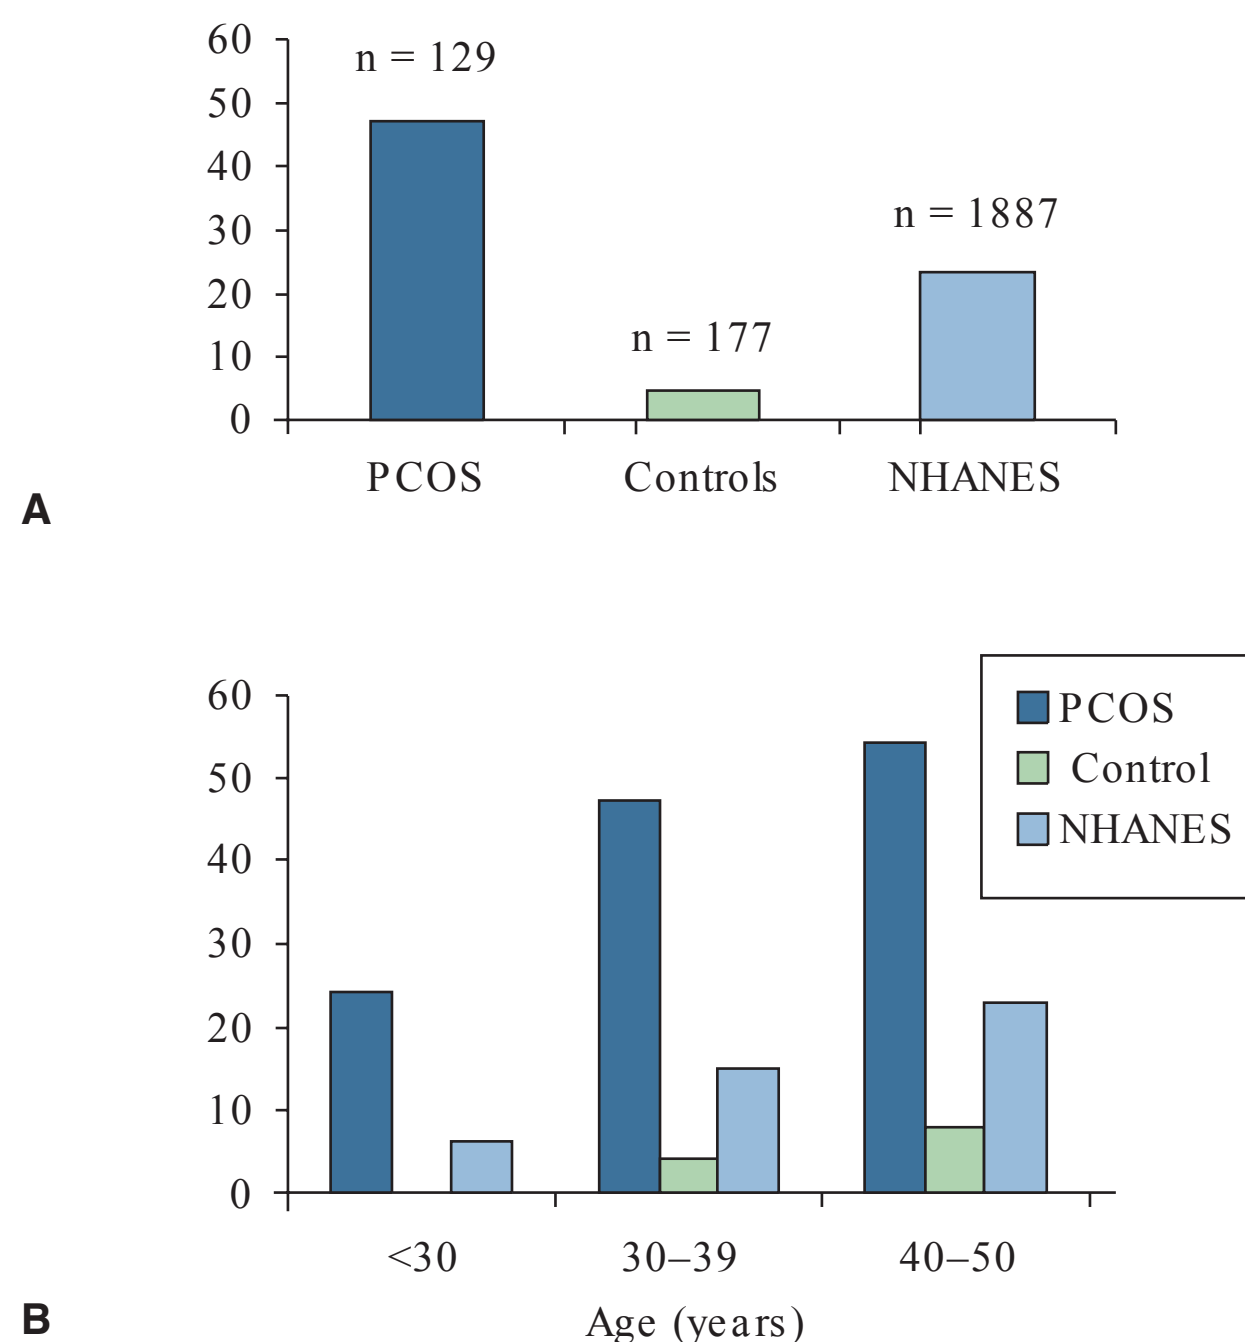

Compared with age-matched controls, women with PCOS are more likely to be obese, as reflected by elevated BMIs and waist:hip ratios (Talbott, 1995). This ratio reflects an android or central pattern of obesity, which itself is an independent risk factor for cardiovascular disease and predicts insulin resistance. As noted earlier, insulin resistance is believed to play a large role in the pathogenesis of PCOS and is often exacerbated by obesity (Dunaif, 1989). For example, obesity can worsen hyperandrogenism by lowering SHBG and therefore increasing bioavailable testosterone (Lim, 2013). Thus, obesity can have a synergistic effect on PCOS and can worsen ovulatory dysfunction, hyperandrogenism, and acanthosis nigricans.

### ■ Obstructive Sleep Apnea

This disorder is likely related to central obesity and insulin resistance (Fogel, 2001; Vgontzas, 2001). Women with PCOS have a 30- to 40-fold higher risk of sleep apnea compared with weight-matched controls. This suggests a link between obstructive sleep apnea and the metabolic and hormonal abnormalities associated with PCOS. Moreover, some theorize two subtypes of PCOS, that is, PCOS with or without obstructive sleep apnea. PCOS patients with this condition may be at much higher risk for DM and cardiovascular disease than women with PCOS but without obstructive sleep apnea (Nitsche, 2010).

### ■ Metabolic Syndrome and Cardiovascular Disease

The metabolic syndrome is characterized by insulin resistance, obesity, atherogenic dyslipidemia, and hypertension. It is associated with an increased risk of cardiovascular disease (CVD) and type 2 DM (Schneider, 2006). The prevalence of metabolic syndrome approximates 45 percent in women with PCOS compared with 4 percent in age-adjusted controls (Fig. 17-7)

**FIGURE 17-7** **A.** Women with polycystic ovarian syndrome (PCOS) have an increased risk of metabolic syndrome compared with age-adjusted controls and with women from the Third National Health and Nutrition Survey (NHANES III). **B.** In women with PCOS, the risk of metabolic syndrome begins earlier than in controls or those from NHANES III. NHANES III collected data from a representative sample of the noninstitutionalized civilian U.S. population from 1988 through 1994. (Reproduced with permission from Dokras A, Bochner M, Hollinrake E. Screening women with polycystic ovary syndrome for metabolic syndrome. *Obstet Gynecol* 2005 Jul;106(1):131-137.)

(Dokras, 2005). PCOS shares several endocrine features with the metabolic syndrome, although definitive evidence for an increased incidence of CVD in women with PCOS is lacking (Legro, 1999; Rebuffe-Scrive, 1989; Talbott, 1998). However, in a small group of women with PCOS, Dahlgren and colleagues (1992) predicted a relative risk of 7.4 for myocardial infarction. Another 10-year surveillance study showed an odds ratio of 5.91 for CVD in overweight white women with PCOS (Talbott, 1995). Thus, evidence suggests that women with PCOS should have CVD factors identified and treated (Table 1-8, p. 14) (Wild, 2010).

In addition to components of the metabolic syndrome, other markers of subclinical disease link PCOS and CVD. Women with PCOS have been found to have a greater incidence of left ventricular diastolic dysfunction and increased internal and external carotid artery stiffness (Lakhani, 2000; Tiras, 1999). Moreover, in affected women, studies have found greater endothelial dysfunction, which is described as an early event in the evolution of atherosclerosis (Orio, 2004; Tarkun, 2004).

### ■ Endometrial Neoplasia

In women with PCOS, the risk of endometrial cancer is increased threefold. Endometrial hyperplasia and endometrial cancer are long-term risks of chronic anovulation, and neoplastic changes in the endometrium are felt to arise from chronic

unopposed estrogen (Chap. 33, p. 702) (Coulam, 1983). Moreover, the effects of hyperandrogenism, hyperinsulinemia, and obesity to lower SHBG levels and increase circulating estrogen levels may add to this risk.

Few women who develop endometrial cancer are younger than 40 years, and most of these premenopausal women are obese or have chronic anovulation or both (National Cancer Institute, 2014; Peterson, 1968). Thus, the American College of Obstetricians and Gynecologists (2012) recommends endometrial assessment in any woman older than 45 years with abnormal bleeding, and in those younger than 45 years with a history of unopposed estrogen exposure such as seen in obesity or PCOS, failed medical management, and persistent bleeding.

### ■ Infertility

Infertility or subfertility is a frequent complaint in women with PCOS and results from anovulatory cycles. Moreover, in women with infertility secondary to anovulation, PCOS is the most common cause (Hull, 1987). Infertility evaluation and treatment in women with PCOS is described in more detail in Chapter 20 (p. 449).

### ■ Pregnancy Loss

Women with PCOS who become pregnant experience an increased rate (30 to 50 percent) of early miscarriage compared with a baseline rate of approximately 15 percent in the general population (Homburg, 1998b; Regan, 1990; Sagle, 1988). The etiology of early miscarriage in women with PCOS is unclear. Initially, retrospective and observational studies showed an association between LH hypersecretion and miscarriage (Homburg, 1998a; Howles, 1987). However, one prospective study showed that lowering LH levels with GnRH agonists failed to improve outcome (Clifford, 1996).

Others have suggested that insulin resistance is related to miscarriage in these women. To lower loss rates, an insulin level lowering drug, metformin (Glucophage), has been investigated. Metformin, a biguanide, lowers serum insulin levels by reducing hepatic glucose production and increasing the sensitivity of liver, muscle, fat, and other tissues to the uptake and effects of insulin.

Some retrospective studies have indicated that women with PCOS taking metformin during pregnancy have a lower incidence of miscarriage (Glueck, 2001; Jakubowicz, 2002). In addition, a prospective study demonstrated a lower miscarriage rate for women conceiving while taking metformin compared with those using clomiphene citrate (Palomba, 2005). However, a metaanalysis of 17 studies failed to show an effect of metformin administration on miscarriage risk in women with PCOS (Palomba, 2009). Until further randomized controlled trials are performed studying the effects of metformin (a category B drug) on pregnancy outcome, the use of this medication in gestation for miscarriage prevention is not recommended.

### ■ Complications in Pregnancy

Several pregnancy and neonatal complications have been associated with PCOS. One large metaanalysis found that

women with PCOS have a two- to threefold higher risk of gestational diabetes, pregnancy-induced hypertension, preterm birth, and perinatal mortality, unrelated to multifetal gestations (Boomsma, 2006). Metformin has been studied as a tool to mitigate these complications in those with PCOS but without DM. However, investigators in one study found that metformin treatment during pregnancy did not reduce rates of these complications (Vanky, 2010).

Many women with PCOS require the use of ovulation induction medications or in vitro fertilization to conceive. These practices substantially increase the risk of multifetal gestations, which are associated with increased rates of maternal and neonatal complications (Chap. 20, p. 466).

### ■ Psychologic Health

Women with PCOS may present with various psychosocial problems such as anxiety, depression, low self-esteem, reduced quality of life, and negative body image (Deeks, 2010; Dokras, 2011, 2012). If depression is suspected, screening tools such as those found in Chapter 13 (p. 298) are implemented.

## DIAGNOSIS

Other potentially serious disorders may clinically appear similar to PCOS and are excluded during patient evaluation (Table 17-4). For women, who present with complaints of hirsutism, the algorithm in Figure 17-8 can be used.

### ■ Thyroid-stimulating Hormone and Prolactin

Thyroid disease may frequently lead to menstrual dysfunction. Thus, a serum thyroid-stimulating hormone level is typically measured during evaluation, and treatment is discussed in Chapter 16 (p. 383). Similarly, hyperprolactinemia is a well-known cause of menstrual irregularities and occasionally amenorrhea. Elevated prolactin levels lead to anovulation through inhibition of GnRH pulsatile secretion. A list of potential causes of hyperprolactinemia is found in Table 12-2 (p. 281), and treatments are described in Chapter 15 (p. 360).

### ■ Testosterone

Tumors of the ovary or adrenal are a rare but serious cause of androgen excess. Various ovarian neoplasms, both benign and malignant, may produce testosterone and lead to virilization. Among others, these include the stromal tumors (Chap. 36, p. 767). Importantly, an abrupt onset or sudden worsening of virilizing signs should prompt concern for a hormone-producing ovarian or adrenal tumor. Symptoms may include those in Table 17-5. Of these, hirsutism is quantified with the Ferriman-Gallwey score, whereas clitoromegaly is assessed using the clitoral index (Fig. 17-9). For the latter, clitoral length (mm) and width (mm) values are multiplied. Values greater than 35 mm<sup>2</sup> are abnormal (Tagatz, 1979; Verkauf, 1992).

Diagnostically, serum testosterone levels can aid ovarian tumor exclusion. Free testosterone levels are more sensitive than total testosterone levels as an indicator of hyperandrogenism. Although improving, however, current free testosterone

**TABLE 17-4.** Differential Diagnoses of Ovulatory Dysfunction and Hyperandrogenism

	Evaluation	Indicative Results <sup>a</sup>
<b>Causes of oligo- or anovulation</b>		
PCOS	Total T level	Mildly increased
	DHEAS level	May be mildly increased
	LH:FSH ratio	Typically > 2:1
	AMH level	Increased
Hyperthyroidism	TSH level	Decreased
Hypothyroidism	TSH level	Increased
Hyperprolactinemia	PRL level	Increased
Hypogonadotropic hypogonadism	FSH, LH, E <sub>2</sub> levels	All decreased
POI	FSH, LH levels	Increased
	E <sub>2</sub> levels	Decreased
<b>Causes of hyperandrogenism</b>		
PCOS		
Late-onset CAH	17-OH-P level	> 200 ng/dL
Androgen-secreting ovarian tumor	Total T level	> 200 ng/dL
Androgen-secreting adrenal tumor	DHEAS level	> 700 μg/dL
Cushing syndrome	Cortisol level	Increased
Exogenous androgen use	Toxicology screen	Increased
<b>Summary of PCOS testing</b>		
Serum levels of FSH, LH, TSH, Total T, PRL, DHEAS, 17-OH-P		
2hr-GTT, HbA1c, lipid profile		
Measurement of BMI, waist circumference, BP		

<sup>a</sup>Based on reference laboratory ranges of normal.  
AMH = antimüllerian hormone; BMI = body mass index; BP = blood pressure; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; E<sub>2</sub> = estradiol; FSH = follicle-stimulating hormone; GTT = glucose tolerance test; LH = luteinizing hormone; 17-OH-P = 17-hydroxyprogesterone; PCOS = polycystic ovarian syndrome; POI = premature ovarian insufficiency; PRL = prolactin; T = testosterone; TSH = thyroid-stimulating hormone.

assays lack a uniform laboratory standard (Faix, 2013). For this reason, total testosterone levels remain the best approach for identifying a possible tumor. T reshold values > 200 ng/dL of total testosterone warrant evaluation for an ovarian lesion (Derksen, 1994).

Pelvic sonography is the preferred method to exclude an ovarian neoplasm in a female with very high androgen levels. Alternatively, computed tomography (CT) or magnetic resonance (MR) imaging may also be used.

■ **Dehydroepiandrosterone Sulfate**

T is hormone is essentially produced exclusively by the adrenal gland. T erefore, serum DHEAS levels > 700 μg/dL are highly suggestive of an adrenal neoplasm, and adrenal imaging with abdominal CT or MR imaging is warranted.

■ **Gonadotropins**

During evaluation of amenorrhea, FSH, LH, and estradiol levels are typically measured to exclude premature ovarian failure and hypogonadotropic hypogonadism (see Table 17-4). Although LH levels classically measure at least twofold higher than FSH levels, this is not found in all women with PCOS. Specifically,

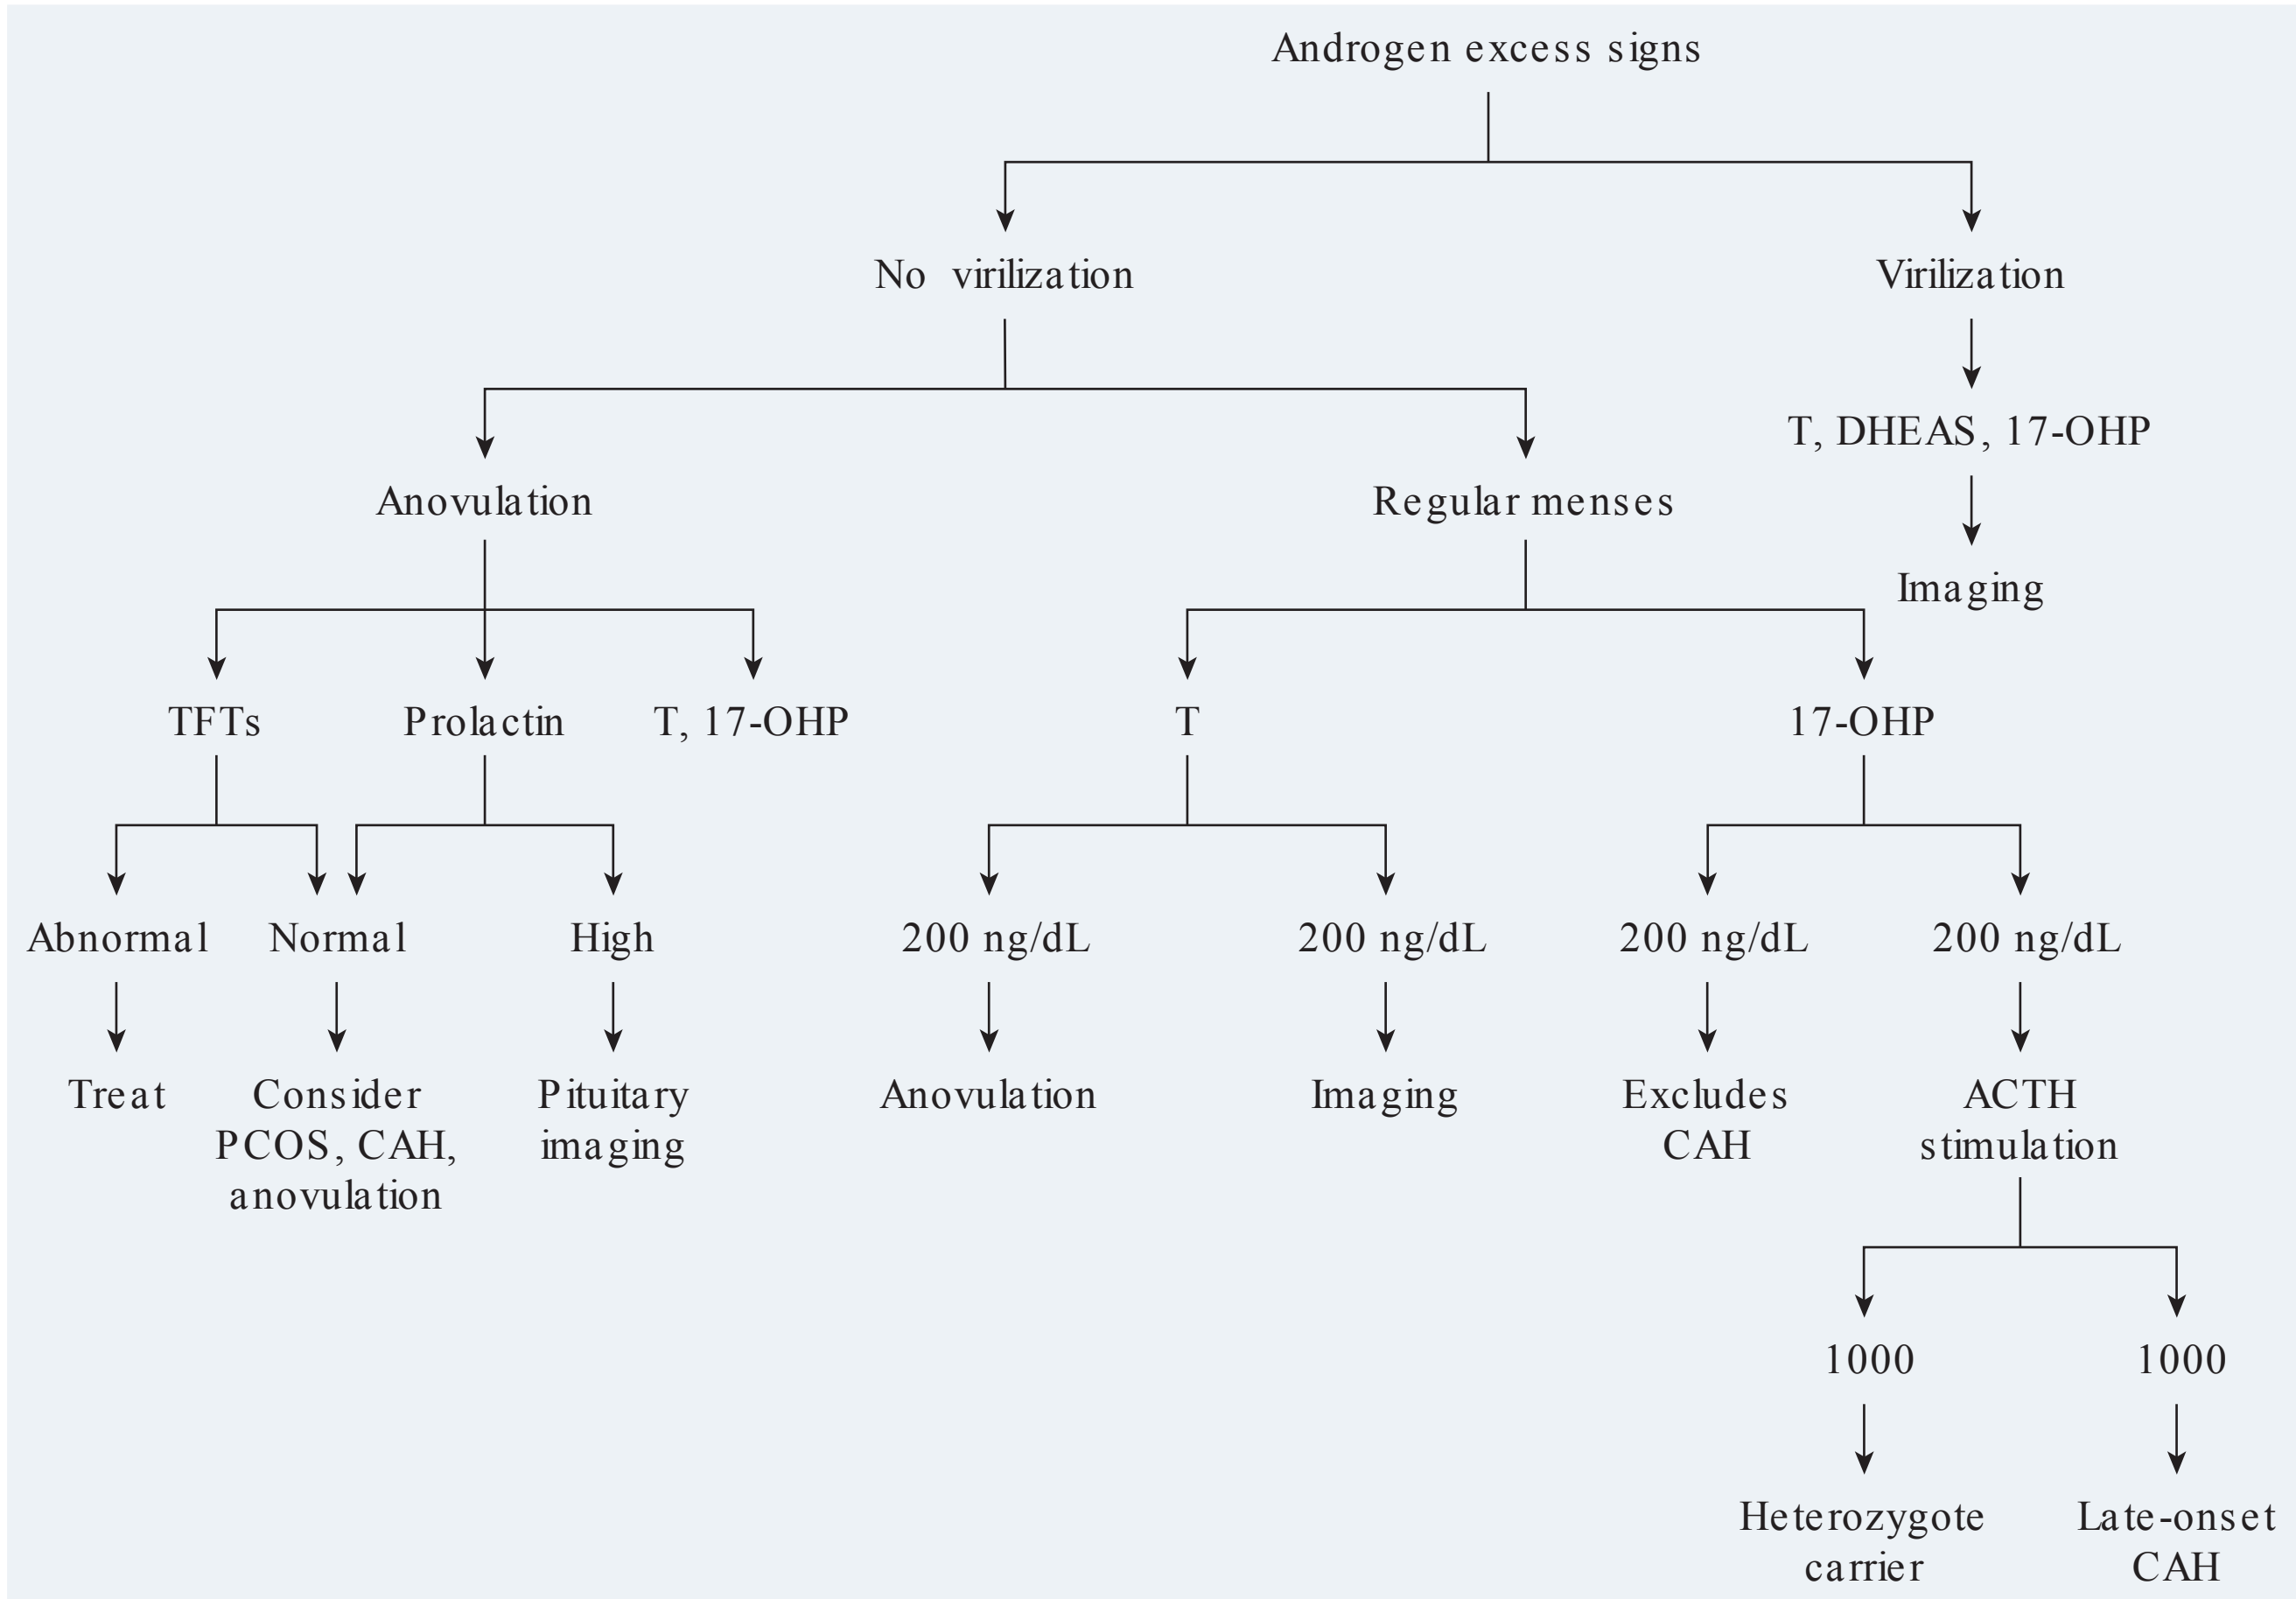

one third of women with PCOS have circulating LH levels in the normal range, a finding more common in obese patients (Arroyo, 1997; Taylor, 1997). Moreover, serum LH levels are affected by sample timing within a menstrual cycle, use of oral contraceptive pills, and BMI.

■ **17-alpha Hydroxyprogesterone**

T e term congenital adrenal hyperplasia (CAH) describes several autosomal recessive disorders that result from complete or partial deficiency of an enzyme involved in cortisol and aldosterone synthesis, usually 21-hydroxylase or less frequently 11-hydroxylase (Fig. 15-5, p. 337). As a result of these defects, precursors are shunted into pathways leading to androgen production. T us, depending on the enzyme affected, symptoms of CAH vary. It may present in the neonate with ambiguous genitalia and life-threatening hypotension (Chap. 18, p. 413). Alternatively, symptoms may be milder and delayed until adolescence or adulthood.

In this late-onset form of CAH, the enzyme deficiency leads to a relative cortisol deficiency. In response, adrenocorticotrophic hormone (ACTH) levels are increased to normalize cortisol production. Consequent to this accommodation, adrenal gland hyperplasia and elevated androgen levels develop. T erefore,

**FIGURE 17-8** Algorithm for evaluation of androgen excess. 17-OHP = 17-hydroxyprogesterone; ACTH = adrenocorticotropin hormone; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; PCOS = polycystic ovarian syndrome; T = testosterone; TFTs = thyroid function tests.

symptoms of late-onset CAH reflect accumulation of precursor C19 steroid hormones. These precursors are converted to dehydroepiandrosterone, androstenedione, and testosterone. Thus, signs of hyperandrogenism predominate.

**FIGURE 17-9** Photograph of woman with virilization manifest by clitoromegaly. (Reproduced with permission from Hoffman BL, Schorge JO, Schaffer JJ, et al (eds): Williams Gynecology Clinical Pearls: Clitoromegaly, 2nd edition. New York: McGraw-Hill; 2014.)

With late-onset CAH, the most commonly affected enzyme is 21-hydroxylase, and deficiency leads to accumulation of its substrate, 17-hydroxyprogesterone. Serum values are drawn in the morning from a fasting patient. Threshold values of 17-hydroxyprogesterone that measure > 200 ng/dL should prompt an ACTH stimulation test. With this test, synthetic ACTH, 250 µg, is injected intravenously, and a serum 17-hydroxyprogesterone level is measured 1 hour later.

To explain this test, the ACTH given during testing stimulates uptake of cholesterol and synthesis of pregnenolone. If 21-hydroxylase activity is ineffective, steroid precursors up to and including progesterone, 17-hydroxypregnenolone, and especially 17-hydroxyprogesterone accumulate in the adrenal cortex and in circulating blood. Thus in affected individuals, serum levels of 17-hydroxyprogesterone can reach many times their normal concentrations. Levels > 1000 ng/dL from blood drawn after synthetic ACTH is given are indicative of late-onset CAH.

TABLE 17-5. Clinical Features of Virilization	
Acne	Androgenic alopecia
Hirsutism	Decreased breast size
Amenorrhea	Deepening of the voice
Clitoromegaly	Increased muscle mass

■ Antimüllerian Hormone

The classic polycystic ovary contains two- to threefold more growing preantral and antral follicles than normal ovaries (Hughesdon, 1982). Within the granulosa cells of these developing follicles, the dimeric glycoprotein antimüllerian hormone (AMH) is produced, and serum AMH levels correlate closely with the number of antral follicles. Not surprisingly, AMH levels are two- to threefold higher in women with PCOS compared with nonaffected age-matched controls (Cui, 2014; Homburg, 2013). For this reason, some view AMH as a potentially useful diagnostic marker for PCOS (Pigny, 2006). That said, data regarding this marker in both PCOS and controls are incomplete and require further investigation before it can be adopted as a formal diagnostic criterion (Dewailly, 2014).

■ Cortisol

*Cushing syndrome* results from prolonged exposure to elevated levels of either endogenous or exogenous glucocorticoids. Of these, the syndrome is most frequently caused by administration of exogenous glucocorticoids. Alternatively, the term *Cushing disease* is reserved for cases stemming from increased adrenocorticotropin hormone (ACTH) secretion by a pituitary tumor. Cushing syndrome shares many symptoms with PCOS such as menstrual dysfunction, signs of androgen excess, truncal obesity, dyslipidemia, and glucose intolerance. Classically, moon facies and purple abdominal striae are also noted. Cushing syndrome is rare, and routine screening in all women with oligomenorrhea is not indicated. However, in those with classic Cushing findings, proximal muscle weakness, and easy bruising, screening is strongly considered (Nieman, 2008).

Initial laboratory testing investigates excessive glucocorticoid production, and three are endorsed by the Endocrine Society (Nieman, 2008). Of these, a 24-hour urine collection for urinary free cortisol excretion can be obtained. Alternatively, a dexamethasone suppression test administers 1 mg of dexamethasone orally at 11 PM, and a plasma cortisol level is measured at 8 AM the following morning. In women with a normal functioning feedback loop, administration of the corticosteroid dexamethasone lowers ACTH secretion and thus diminishes adrenal cortisol production. Normal testing values are < 5 µg/dL (Crapo, 1979). However, if a woman has an exogenous or an ectopic endogenous source of cortisol, then cortisol levels during suppression testing will remain elevated. Last, using a late-night salivary cortisol level measurement, patients collect saliva

samples between 11 PM and midnight on two separate evenings. Once identified, Cushing syndrome is treated based on the underlying source of excess glucocorticosteroids.

■ Measurements of Insulin Resistance and Dyslipidemia

Many women with PCOS have insulin resistance and compensatory hyperinsulinemia. Although the consensus meeting in Rotterdam suggested that tests of insulin resistance are *not* required to diagnose or treat PCOS, these tests are often used to evaluate glucose metabolism and impaired insulin secretion in these women (The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004).

The “gold standard” for evaluating insulin resistance has been the hyperinsulinemic euglycemic clamp. Unfortunately, this test as well as the intravenous glucose tolerance test (IV GTT) requires an intravenous line and frequent sampling, are labor and time intensive, and are not practical in a clinical setting. Accordingly, other less sensitive surrogate markers that evaluate insulin resistance are used and include: (1) 2-hour glucose tolerance test (2-hr GTT), (2) fasting serum insulin level, (3) homeostasis model assessment of insulin resistance (HOMA IR), (4) quantitative insulin sensitivity check (QUICKI), and (5) calculation of serum glucose:insulin ratios.

Of these, a 2-hr GTT is frequently used to exclude impaired glucose tolerance (IGT) and type 2 DM (Table 17-6). This test is particularly important in obese PCOS patients who are at higher risk for both. According to several organizations, women with PCOS should undergo such screening (American Diabetes Association, 2014; Conway, 2014; Fauser, 2012; Legro, 2013; Wild, 2010). Their recommendations vary as to whether all women or only specific PCOS subgroups are screened and as to the screening interval. The Amsterdam ESHRE/ASRM-Sponsored 3rd PCOS Consensus Workshop Group promotes evaluation in the following circumstances: hyperandrogenism with anovulation, acanthosis nigricans, obesity (BMI > 30 kg/m<sup>2</sup> or > 25 in Asian women), and a family history of DM or gestational DM. Women with PCOS may demonstrate a worsening of IGT over time, with a reported conversion rate of approximately 2 percent per year to type 2 DM. This affirms the importance of periodic assessment of glucose tolerance with a 2-hr GTT in women with PCOS (Legro, 1999, 2005). The AE-PCOS Society recommends that those with normal glucose tolerance be rescreened at least once every 2 years or more frequently if additional risks exist. Those with impaired glucose tolerance are tested annually. These

TABLE 17-6. Diagnosis of Impaired Glucose Tolerance and Diabetes Mellitus			
	Normal Range	Impaired Glucose Tolerance	Diabetes Mellitus
HbA <sub>1c</sub>	< 5.7%	5.7–6.4%	≥ 6.5%
Fasting blood glucose level	< 100 mg/dL	100–125 mg/dL	≥ 126 mg/dL
2-hr GTT	< 140 mg/dL	140–199 mg/dL	≥ 200 mg/dL
2-hr GTT = 2-hour oral glucose tolerance test; HbA <sub>1c</sub> = hemoglobin A <sub>1c</sub> . Data from American Diabetes Association: Standards of medical care in diabetes—2014. Diabetes Care 2014 Jan;37 Suppl 1: S14–80.			

same organizations counsel against use of a fasting glucose level and note that a surrogate HbA<sub>1c</sub> level can be considered.

In addition to assessment of insulin resistance, a fasting lipid profile is used to evaluate dyslipidemia. Evaluation and treatment of dyslipidemia are further described in Chapter 1 (p. 15).

## ■ Endometrial Biopsy

An endometrial biopsy is recommended for abnormal bleeding in any woman older than 45 years and in those younger than this with a history of unopposed estrogen exposure such as seen in obesity or PCOS, failed medical management, and persistent bleeding (American College of Obstetricians and Gynecologists, 2012). Steps of this procedure are found in Chapter 8 (p. 185).

## ■ Sonography

Histologically, a polycystic ovary (PCO) displays increases in the number of ripening and atretic follicles, cortical stromal thickness, and number of hilar cell nests (Hughesdon, 1982). Many of these tissue changes can be seen sonographically, and pelvic sonography is commonly used to evaluate the ovaries in women with suspected PCOS. In the NIH criteria for PCOS, sonographic evaluation is not required. However, sonography is particularly important for women with PCOS seeking fertility and in women with signs of virilization to exclude an androgen-producing ovarian cancer. A high-definition transvaginal approach is superior and has a higher detection rate of PCO than the transabdominal route. However, a transabdominal route is preferred for virginal adolescents.

Sonographic criteria for polycystic ovaries from the 2003 Rotterdam conference include  $\geq 12$  small cysts (2 to 9 mm in diameter) or an increased ovarian volume ( $> 10$  mL) or both (Fig. 17-10). Only one ovary with these findings is sufficient to define PCOS. However, criteria do not apply to women taking combination oral contraceptive pills (The Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2004).

Remarkably, studies using sonography have shown that at least 23 percent of young women have ovaries that exhibit PCO

morphology, yet many of these women have no other PCOS symptoms (Clayton, 1992; Polson, 1988). In addition, a polycystic appearance of the ovaries can often be found in other conditions of androgen excess, such as congenital adrenal hyperplasia, Cushing syndrome, and exogenous use of androgenic medications. For this reason, PCO morphology found during sonographic examination is not used solely for PCOS diagnosis.

## ■ PCOS Diagnosis in Adolescence

Several independent *prepubertal* risk factors for PCOS have been identified. These include above-average or low birthweight for gestational age, premature adrenarche, atypical sexual precocity, and obesity with acanthosis nigricans (Rosenfield, 2007). The diagnosis of PCOS in adolescence is challenging because many symptoms of PCOS mimic the normal physiologic responses of puberty. As noted, adolescents frequently have irregular menses, and acne is common. Moreover, in adolescence, transabdominal rather than transvaginal pelvic sonography is generally performed, and image resolution is poorer. In adolescents with incomplete criteria for a firm diagnosis of PCOS, careful surveillance is warranted as they may be diagnosed at a later time (Carmina, 2010).

## TREATMENT

The treatment choice for each symptom of PCOS depends on a woman's goals and the severity of endocrine dysfunction. Thus, anovulatory women desiring pregnancy will undergo significantly different treatment than adolescents with menstrual irregularity and acne. Patients often seek treatment for a singular complaint and may see various specialists such as dermatologists, nutritionists, aestheticians, and endocrinologists prior to evaluation by a gynecologist.

## ■ Conservative Treatment

Women with PCOS who have fairly regular cycle intervals (8 to 12 menses per year) and mild hyperandrogenism may choose not to be treated. In these women, however, periodic screening for dyslipidemia, diabetes mellitus, and metabolic syndrome is prudent.

For obese women with PCOS, important lifestyle changes focus on diet and exercise. Even modest weight loss (5 percent of body weight) can result in restoration of normal ovulatory cycles in some women. This improvement results from reductions in insulin and androgen levels, the latter mediated through increases in SHBG levels (Huber-Buchholz, 1999; Kiddy, 1992; Pasquali, 1989).

The optimal diet that best improves insulin sensitivity is not known. Diets high in carbohydrates increase insulin secretion rates, whereas diets high in protein and fat lower those rates (Bass, 1993; Nuttall, 1985). However, very-high-protein diets are concerning with respect to stresses on kidney function. Moreover, they afford only short-term weight loss initially with lesser benefits over time (Legro, 1999; Skov, 1999). Thus, it appears that a well-balanced hypocaloric diet offers the most benefit in treating obese women with PCOS.

**FIGURE 17-10** Transvaginal sonography displays multiple small hypoechoic cysts. (Used with permission from Dr. Elysia Moschos.)

Exercise is known to have a beneficial effect in treating patients with type 2 DM (Nestler, 1998). The most dramatic effect of lifestyle intervention was published in 2002 as the Diabetes Prevention Program. Women and men at risk for diabetes were asked to lose at least 7 percent of their weight and to exercise for 150 minutes each week. This group had a twofold greater benefit in delaying the onset of diabetes compared with a group given metformin alone. Both groups fared better than a placebo group (Knowler, 2002). Few studies, however, have looked specifically at the effect of exercise on insulin action in women with PCOS (Jaatinen, 1993). In addition to DM, women with PCOS may have comorbid risk factors for CVD. In patients with PCOS, exercise has been shown to improve cardiovascular capacity (Vigorito, 2007).

## ■ Treatment of Oligo- and Anovulation Hormonal Agents

Women with oligo- or anovulation typically have fewer than eight menses per year, often skip menses for several months at a time, or simply have amenorrhea. Flow may be scanty or may be very long and heavy, resulting in iron-deficiency anemia.

A first-line treatment for menstrual irregularities is combination oral contraceptive pills (COCs), which induce regular menstrual cycles, lower androgen levels, and thin the endometrium. Specifically, COCs suppress gonadotropin release, which results in decreased ovarian androgen production. Moreover, the estrogen component increases levels of SHBG, which binds free androgen. Last, the progestin component antagonizes the endometrial proliferative effect of unopposed estrogen from PCOS, thus reducing the endometrial hyperplasia risk.

Theoretically, COCs that contain progestins with fewer androgenic properties are preferred. Such progestins include norethindrone; a third-generation progestin, such as norgestimate or desogestrel; or the newer progestin, drospirenone. However, no COC pill has shown superiority compared with another in reducing hirsutism (Sobbrio, 1990). Alternative combination hormonal contraceptive options include the contraceptive patch and vaginal ring. Before COC initiation, if a woman's last menses was more than 4 weeks prior, a pregnancy test is indicated.

In patients who are not candidates for combination hormonal contraception, progesterone withdrawal is recommended every 1 to 3 months. Examples of regimens used include: medroxyprogesterone acetate (MPA), 5 to 10 mg orally daily for 12 days, or micronized progesterone, 200 mg orally each evening for 12 days. Patients are counseled that intermittent progestins will not reduce symptoms of acne or hirsutism, nor do they provide contraception. For those requiring birth control, a continuous progestin-only contraceptive pill, depot medroxyprogesterone acetate, or a progestin-releasing implant or intrauterine device may be used and will act to thin the endometrium.

## Insulin Sensitizing Agents

Although use of insulin sensitizers for PCOS has not been approved by the Food and Drug Administration (FDA), they have been found to improve both metabolic and gynecologic issues. Of these agents, metformin is the most commonly prescribed, particularly in women with impaired glucose tolerance

and insulin resistance. In clinical studies, 1500 to 2000 mg in divided doses daily with meals is typically used. More common side effects are gastrointestinal, and these can be minimized by starting at a low dose and gradually increasing the dose over several weeks to an optimal level.

Metformin decreases androgen levels in both lean and obese women with PCOS, leading to increased rates of spontaneous ovulation (Essah, 2006; Haas, 2003; Lord, 2003). Several studies demonstrate that up to 40 percent of anovulatory women with PCOS will ovulate, and many will achieve pregnancy with metformin alone (Diamanti-Kandarakis, 1998; Fleming, 2002; Neveu, 2007). Metformin is a category B drug and is safe to use as an ovulatory induction agent. As such, it may be used alone or in concert with other medications such as clomiphene citrate (Chap. 20, p. 452). Specifically, metformin has been shown to increase the ovulatory response to clomiphene citrate in patients who were previously clomiphene-resistant (Nestler, 1998). Despite these positive findings regarding metformin and ovulation induction, Legro and colleagues (2007) in a randomized prospective study of 626 women found higher live-birth rates with clomiphene citrate alone (22 percent) than with metformin alone (7 percent). Based on data, the Thessaloniki ESHRE/ASRM Sponsored PCOS Consensus Workshop Group (2008) recommends against the routine use of metformin for ovulation induction, and first-line treatment remains clomiphene citrate. They note that the addition of metformin to clomiphene citrate may be indicated for women with PCOS and glucose intolerance.

The thiazolidinediones are another class of medications also used for patients with diabetes mellitus. Similar to metformin, rosiglitazone and pioglitazone improve ovulation rates in some patients (Azziz, 2001; Dunaif, 1996b; Ehrmann, 1997). However, the glitazones are category C drugs and should be discontinued if pregnancy is achieved.

## ■ Hirsutism

With hirsutism treatment, a primary goal is lowering androgen levels to halt further conversion of vellus hairs to terminal ones. However, medical therapies will not eliminate hair already present. Moreover, treatments may require 6 to 12 months before clinical improvement is apparent. For this reason, clinicians should be familiar with temporary hair removal methods that may be used in the interim. Permanent cosmetic therapies can then be implemented once medications have reached maximal therapeutic effect.

## Lowered Effective Androgen Levels

Several options are available to decrease androgen levels affecting hair follicles. First, as described earlier, COCs are effective in establishing regular menses and lowering ovarian androgen production.

Second, GnRH agonists lower gonadotropin levels over time, and in turn subsequently lower androgen levels. Despite their effectiveness in treating hirsutism, long-term administration of GnRH agonists is not ideal due to associated bone loss, high cost, and menopausal side effects.

Last, 5 $\alpha$ -reductase inhibitors block conversion of testosterone to DHT. Of these, finasteride is available as a 5-mg tablet for prostate cancer (Proscar) and a 1-mg tablet for the treatment

of male alopecia (Propecia). Most studies have used 5-mg daily doses for women and have found finasteride to be modestly effective for hirsutism treatment (Fruzzetti, 1994; Moghetti, 1994). Side effects are low with finasteride, although decreased libido has been noted. However, as with other antiandrogens, the risk of male fetal teratogenicity is present, and effective contraception must be used concurrently.

### Eflornithine Hydrochloride

T is antimetabolite topical cream is applied twice daily to affected areas and is an irreversible inhibitor of ornithine decarboxylase. T is enzyme is necessary for hair follicle cell division and function, and its inhibition results in slower hair growth. It does not permanently remove hair, and thus women must continue routine methods of hair removal while using this medicine.

Eflornithine hydrochloride (Vaniqa) may require 4 to 8 weeks of use before changes are noticed. However, approximately one third of patients have marked improvement after 24 weeks of eflornithine use compared with placebo, and 58 percent showed some overall improvement in hirsutism scores (Balfour, 2001).

### Androgen-receptor Antagonists

Antiandrogens are competitive inhibitors of androgen binding to the androgen receptor (Brown, 2009; Moghetti, 2000; Venturoli, 1999). Although these agents effectively treat hirsutism, they carry a risk for several side effects. Metrorrhagia may frequently develop. In addition, as antiandrogens, these drugs bear a theoretical risk of interfering with external genitalia development in male fetuses of women using such medications in early pregnancy. Accordingly, these drugs are commonly used in conjunction with oral contraceptive pills, which prompt regular menses and provide effective contraception. None of the antiandrogen agents are FDA-approved for treatment of hyperandrogenism and thus are used off-label.

*Spironolactone* (Aldactone), in a dosage of 50 to 100 mg orally twice daily, is the primary antiandrogen used currently in the United States. In addition to its antiandrogen effects, this drug also affects hair conversion from vellus to terminal by its direct inhibition of  $5\alpha$ -reductase. Spironolactone is also a potassium-sparing diuretic. As such, it is not prescribed for chronic use in combination with agents that can also raise blood potassium levels, such as potassium supplements, angiotensin-converting enzyme (ACE) inhibitors, nonsteroidal antiinflammatory drugs such as indomethacin, or other potassium-sparing diuretics.

Of less prescribed alternatives, in Europe, Canada, and Mexico, the antiandrogen cyproterone acetate is used in an oral contraceptive pill. However, this agent is not FDA-approved largely based on its potential for liver injury. Flutamide is another nonsteroidal antiandrogen marketed for the treatment of prostate cancer. It is rarely used for hirsutism, again due to its potential hepatotoxicity.

### Hair Removal

Hirsutism is often treated by mechanical means, and these include both depilation and epilation techniques. In addition to hair removal, lightening hair color with bleach is a cosmetic option.

*Depilation* describes hair removal above the skin surface. Shaving is the most common form and does not exacerbate

hirsutism, contrary to the myth that it will increase hair follicle density. Alternatively, topical chemical depilatories are also effective. Available in gel, cream, lotion, aerosol, and roll-on forms, these agents contain calcium thioglycolate. T is agent breaks disulfide bonds between hair protein chains, causing hair to break down and separate easily from the skin surface.

*Epilation* removes the entire hair shaft and root and includes techniques such as plucking, waxing, threading, electrolysis, and laser treatment. T reading, also known as “khite” in Arabic, is a fast method for removing entire hairs and is commonly used in the Middle East and India. Hairs are snared within an outstretched strand of twisted cotton thread and pulled out.

Although waxing and plucking allow effective temporary hair removal, permanent epilation may be achieved with thermal destruction of the hair follicle. Electrolysis, performed by a trained individual, involves placement of a fine electrode and passage of electric current to destroy individual follicles. It requires repetitive treatments over several weeks to months, can be painful, and can result in scarring.

Alternatively, laser therapy directs specific laser wavelengths to also permanently destroy follicles. During this process, termed *selective photothermolysis*, only target tissues absorb laser light and are heated. Surrounding tissues fail to absorb the selective wavelength and receive minimal thermal damage. For this reason, light-skinned women with dark hairs are better candidates for laser treatment due to the selective wavelength absorption by their hair. Advantageously, laser treatment can cover a wider surface area than electrolysis and therefore requires fewer treatments. It causes less pain, but is expensive and can result in dyspigmentation.

Prior to any epilation technique, topical anesthetics may be prescribed. Specifically, a topical cream combination of 2.5-percent lidocaine and 2.5-percent prilocaine (EMLA cream) can be applied as a thick layer that remains for 1 hour and is removed just prior to epilation. Recommended adult dosing is 1.5 g for each  $2 \times 2$ -inch area of skin treated.

### ■ Acne

One part of acne treatment is similar to that for hirsutism and involves lowering of androgen levels. As such, therapy may include: (1) COC pills, (2) an antiandrogen such as spironolactone, or (3)  $5\alpha$ -reductase inhibitors. In addition to lowering androgen levels, other therapies may be added.

In general, mild noninflammatory comedonal acne may be treated with topical retinoid monotherapy. If mild inflammatory pustules are present, topical retinoids are combined with topical antimicrobial therapy or benzoyl peroxide. Moderate to severe acne may require triple therapy with the above agents or use of oral retinoids or oral antibiotics. For this reason, women with moderate to severe acne may benefit from consultation with a dermatologist.

*Topical retinoids* regulate the follicular keratinocyte and normalize its desquamation. In addition, these agents also have direct antiinflammatory properties and thereby target two factors linked to acne vulgaris (Zaenglein, 2006). T e most commonly used of these is tretinoin (Retin-A, Renova, others). Adapalene and tazarotene are also effective (Gold, 2006; Leyden,

2006). Initially, a pea-sized dab sufficient to cover the entire face is applied every third night and progressively increased as tolerated to nightly application (Krowchuk, 2005). Tretinoin may cause a transient worsening of acne during the first weeks of treatment. Concerning teratogenicity, tretinoin and adapalene are category C drugs and thus are not recommended for use during pregnancy or breast feeding. However, epidemiologic studies currently do not support a link between topical retinoids and birth defects (Jick, 1993; Loureiro, 2005). Tazarotene is category X and similarly is not used during these times or without highly effective contraception.

*Topical benzoyl peroxide* is bactericidal to *P. acnes* by generating reactive oxygen species within the follicle. It also has weak comedolytic and antiinflammatory properties. Although it is the active ingredient in many over-the-counter acne products, some prescription preparations also combine benzoyl peroxide with topical clindamycin or erythromycin.

*Topical antibiotics* typically include erythromycin and clindamycin, whereas oral antibiotics most often used for acne include doxycycline, minocycline, and erythromycin. Oral antibiotics are more effective than topical therapies but can have various side effects such as sun sensitivity and gastrointestinal upset.

*Oral isotretinoin* (Accutane) successfully treats severe recalcitrant acne. Despite its efficacy, oral isotretinoin is teratogenic if taken during the first trimester of pregnancy. Malformations typically involve the cranium, face, heart, central nervous system, and thymus. Therefore, isotretinoin administration is limited to women using a highly effective method of contraception. Moreover, the iPLEDGE program is an FDA-mandated risk evaluation and mitigation strategy for isotretinoin that requires participation by involved patients, physicians, and pharmacies to eliminate embryofetal exposure.

## ■ Acanthosis Nigricans

Optimal treatment for acanthosis nigricans is directed toward decreasing insulin resistance and hyperinsulinemia (Field, 1961). Specifically, a few studies have shown an improvement in acanthosis nigricans with insulin sensitizers (Walling, 2003). Other methods, including topical antibiotics, topical and systemic retinoids, keratolytics, and topical corticosteroids, have been tried with limited success (Schwartz, 1994).

## ■ Surgical Therapy

Although ovarian wedge resection is now rarely performed, laparoscopic ovarian drilling restores ovulation in many women with PCOS that is resistant to clomiphene citrate (Section 44-7, p. 1021) (Farquhar, 2012). Rarely, oophorectomy is a viable option for women not seeking fertility who exhibit signs and symptoms of ovarian hyperthecosis and accompanying severe hyperandrogenism.

Early in life, embryos of male and female sex are indistinguishable from one another (Table 18-1). At critical stages of embryonic development, insults can lead to congenital anatomic disorders

of the reproductive tract. Influences include genetic mutation, epigenetic factors, developmental arrest, or abnormal hormonal exposures. Disorders range from congenital absence of the vagina and uterus, to lateral or vertical fusion defects of the müllerian ducts, to external genitalia that are ambiguous. Sexual differentiation is complex and requires both hormonal pathways and morphologic development to be normal and correctly integrated. Thus, it is not surprising that neonates with genital anomalies often have multiple other malformations. Associated urinary tract defects are especially frequent and are linked to the concurrent embryonic development of both reproductive and urinary tracts (Hutson, 2014).

NORMAL EMBRYOLOGY

The urogenital tract is functionally divided into the urinary system and genital system. The urinary organs include the kidney, ureters, bladder, and urethra. The reproductive organs are the gonads, ductal system, and external genitalia. Like most organ systems, the female urogenital tract develops from multiple cell types that undergo important spatial growth and differentiation. These develop during relatively narrow time windows and are governed by time-linked patterns of gene expression (Park, 2005).

Both the urinary and genital systems develop from intermediate mesoderm, which extends along the entire embryo

TABLE 18-1. Embryonic Urogenital Structures and Their Adult Homologues

Indifferent Structure	Female	Male
Genital ridge	Ovary	Testis
Primordial germ cells	Ova	Spermatozoa
Sex cords	Granulosa cells	Seminiferous tubules, Sertoli cells
Gubernaculum	Uteroovarian and round ligaments	Gubernaculum testis
Mesonephric tubules	Epoophoron, paroophoron	Efferent ductules, paradidymis
Mesonephric ducts	Gartner duct	Epididymis, ductus deferens, ejaculatory duct
Paramesonephric ducts	Uterus, fallopian tubes, upper vagina	Prostatic utricle, appendix of testis
Urogenital sinus	Bladder, urethra Vagina Paraurethral glands Greater (Bartholin) and lesser vestibular glands	Bladder, urethra Prostatic utricle Prostate glands Bulbourethral glands
Genital tubercle	Clitoris	Glans penis
Urogenital folds	Labia minora	Floor of penile urethra
Labioscrotal swellings	Labia majora	Scrotum

**FIGURE 18-1** Early development of the embryonic genitourinary tract. **A.** In the developing embryo, the urogenital ridge forms from intermediate mesoderm lateral to the primitive aorta. The dotted line reflects the level from which part B is taken. **B.** Cross section through the embryo shows division of the urogenital ridges into the genital ridge (future gonad) and nephrogenic ridge, which contains the mesonephros and mesonephric (wolffian) ducts. The mesonephros is the primitive kidney and is connected by the mesonephric ducts to the cloaca. Primordial germ cells migrate along the dorsal mesentery of the hindgut to reach the genital ridge. Paramesonephric (müllerian) ducts develop lateral to the mesonephric ducts. (Used with permission from Kim Hoggatt-Krumwiede, MA.)

length. During initial embryo folding, a longitudinal ridge of this intermediate mesoderm develops along each side of the primitive abdominal aorta and is called the urogenital ridge. Subsequently, the urogenital ridge divides into the nephrogenic ridge and the genital ridge, also called the gonadal ridge (Fig. 18-1).

At approximately 60 days of gestation, the nephrogenic ridges develop into the mesonephric kidneys and paired mesonephric ducts, also termed wolffian ducts. These mesonephric ducts connect the mesonephric kidneys (destined for resorption) to the cloaca, which is a common opening into which the embryonic urinary, genital, and alimentary tracts join (Fig. 18-2A). Recall that evolution of the renal system passes sequentially through the pronephric and mesonephric stages to reach the permanent metanephric system. The ureteric bud arises from the mesonephric duct at approximately the fifth week of fetal life. It lengthens to become the metanephric duct (ureter) and induces differentiation of the metanephros, which will eventually become the final functional kidney.

The paired paramesonephric ducts, also termed the müllerian ducts, develop from invagination of the intermediate mesoderm at approximately the sixth week and grow alongside the

mesonephric ducts (Figs. 18-1B and 18-2B). The caudal portions of the müllerian ducts approximate one another in the midline and end behind the cloaca (Fig. 18-2C). The cloaca is divided by formation of the urorectal septum by the seventh week and is separated to create the rectum and the urogenital sinus (Fig. 18-2D). The urogenital sinus is considered in three parts: (1) the cephalad or vesicle portion, which will form the urinary bladder; (2) the middle or pelvic portion, which creates the female urethra; and (3) the caudal or phallic part, which will give rise to the distal vagina and the greater vestibular (Bartholin), urethral, and paraurethral (Skene) glands. During differentiation of the urinary bladder, the caudal portion of the mesonephric ducts is incorporated into the trigone of the bladder wall. Consequently, the caudal portion of the metanephric ducts (ureters) penetrates the bladder with distinct and separate orifices (see Fig. 18-2D).

The close association between the mesonephric (wolffian) and paramesonephric (müllerian) ducts has important clinical relevance because developmental insult to either system is often associated with anomalies that involve the kidney, ureter, and reproductive tract. For example, Kenney and colleagues (1984) noted that up to 50 percent of females with uterovaginal malformations have associated urinary tract anomalies.

**FIGURE 18-2** Embryonic development of the female genitourinary tract. (Reproduced with permission from Shatzkes DR, Haller JO, Velcek FT: Imaging of uterovaginal anomalies in the pediatric patient. *Urol Radiol* 1991;13(1):58–66.)

### ■ Gonadal Determination

Mammalian sex is determined genetically. Individuals with X and Y chromosomes normally develop as males, whereas those with two X chromosomes develop as females. Before 7 weeks of embryonic development, embryos of male and female sex are indistinguishable from one another.

During this indeterminate time, the genital ridge begins as coelomic epithelium with underlying mesenchyme. The epithelium proliferates, and cords of epithelium invaginate into the mesenchyme to create primitive sex cords. In both 46,XX and 46,XY embryos, the primordial germ cells are first identified as large polyhedral cells in the yolk sac. These germ cells migrate by amoeboid motion along the hindgut dorsal mesentery to populate the undifferentiated genital ridge (see Fig. 18-1). Thus, the major cellular components of the early genital ridge include primordial germ cells and somatic cells.

At this point, the presence or absence of gonadal determinant genes directs fetal gender development (Taylor, 2000). *Sexual determination* is the development of the genital ridge into either an ovary or testis. This depends on the genetic sex produced at fertilization, when the X-bearing oocyte is penetrated by either an X- or Y-chromosome-bearing sperm. In

humans, the gene named the *sex-determining region of the Y (SRY)* is the testis-determining factor. In the presence of *SRY*, gonads develop as testes. Other genes are important for normal gonad development and include *SOX9*, *SF-1*, *DMRT1*, *GATA4*, *WNT4*, *WT1*, *DAX1*, and *RSPO1* (Arboleda, 2014; Blaschko, 2012). Not surprisingly, mutations in any of these genes may lead to abnormal sexual determination. Moreover, gene dosage and relative expression levels play an important role (Ocal, 2011).

In males, cells in the medullary region of the primitive sex cords differentiate into Sertoli cells, and these cells organize to form the testicular cords (Fig. 18-3A). Testicular cords are identifiable at 6 weeks and consist of these Sertoli cells and tightly packed germ cells. Early in the second trimester, the cords develop a lumen and become seminiferous tubules. Development of a testis-specific vasculature is crucial for normal testicular development (Ross, 2005).

During this early development, Sertoli cells begin secreting antimüllerian hormone (AMH), also called müllerian inhibitory substance (MIS). This gonadal hormone causes regression of the ipsilateral paramesonephric (müllerian duct) system, and this involution is completed by 9 to 10 weeks' gestation (Marshall, 1978). AMH also controls the rapid gubernacular

**FIGURE 18-3** Development of the gonads and ductal systems in male (A) and female (B) embryos. SRY= sex-determining region of the Y.

growth necessary for the transabdominal descent of the testis. Serum AMH levels remain elevated in boys during childhood and then decline at puberty to the low levels seen in adult men. In contrast, girls have undetectable AMH levels until puberty, when serum levels become measurable. Clinically, AMH levels in mature women reflect ovarian follicle reserve and are used in fertility aspects of reproductive medicine (Chap. 19, p. 436).

In the testes, Leydig cells arise from the original mesoderm of the genital ridge and lie between the testicular cords. Their differentiation begins approximately 1 week after Sertoli cell development. The Leydig cells begin to secrete testosterone by 8 weeks' gestation due to stimulation of the testes by human chorionic gonadotropin (hCG). Testosterone acts in a paracrine manner on the ipsilateral mesonephric

(wolffian) duct to promote virilization of the duct into the epididymis, vas deferens, and seminal vesicle. In addition, the androgens testosterone and dihydrotestosterone (DHT) are essential for male phenotype development. These androgens control differentiation and growth of the internal ducts and external genitalia and also prime male differentiation of the brain.

In the female embryo, without the influence of the *SRY* gene, the bipotential gonad develops into the ovary. The pathways regulating female sex determination have remained incompletely defined, but *WNT4*, *WT1*, *FoxL2*, and *DAX1* genes are important for normal development (Arboleda, 2014; MacLaughlin, 2004). Compared with testicular development, ovarian determination is delayed by approximately 2 weeks. Development is first characterized by the absence of testicular

cords in the gonad. The primitive sex cords degenerate, and the mesothelium of the genital ridge forms secondary sex cords (Fig. 18-3B). These secondary cords become the granulosa cells that band together to form the cell layer that surrounds the germ cells. Oocytes and the surrounding granulosa cells begin communication when the resting primordial follicles are stimulated to grow under the influence of follicle-stimulating hormone (FSH) at puberty. The medullary portion of the gonad regresses and forms the rete ovarii within the ovarian hilum.

Germ cells that carry two X chromosomes undergo mitosis during their initial migration to the female genital ridge. They reach a peak number of 5 to 7 million by 20 weeks' gestation. At this time, the fetal ovary demonstrates mature organization of stroma and primordial follicles containing oocytes. During the third trimester, oocytes begin meiosis but arrest during meiosis I until the oocyte undergoes ovulation after menarche. Atresia of the oocytes starts in utero, leading to a reduced number of germ cells at birth.

### ■ Ductal System Development

Sexual differentiation of the mesonephric (wolffian) and paramesonephric (müllerian) ducts begins in week 7 from the influence of gonadal hormones (testosterone and AMH) and other factors. In the male, AMH forces paramesonephric regression, and testosterone prompts mesonephric duct differentiation into the epididymis, vas deferens, and seminal vesicles.

In the female, a lack of AMH allows müllerian ducts to persist. Early, these ducts grow caudally along with the mesoneph-

ric ducts. During paramesonephric duct elongation, homeobox (Hox) genes, specifically in groups 9–13, play a role in determining positional identity along the long axis of the developing duct. For example, *HoxA9* is one such gene that is expressed at high levels in areas destined to become the fallopian tube (Park, 2005). *HoxA10* and *HoxA11* are expressed in the developing uterus and in the adult uterus. These and other ovarian determinant genes play an active role in gonadal and reproductive tract morphogenesis, but mechanisms are yet to be elucidated fully (Massé, 2009; Taylor, 2000).

During their elongation, both mesonephric and paramesonephric duct systems become enclosed in peritoneal folds that later give rise to the broad ligaments of the uterus. At approximately 10 weeks' gestation and during their caudal migration, the two distal portions of the müllerian ducts approach each other in the midline and fuse even before they reach the urogenital sinus. The fused ducts form a tube called the utero-vaginal canal. This tube then inserts into the urogenital sinus at Müller tubercle (Fig. 18-4).

By 12 weeks, mesonephric ducts regress from lack of testosterone. The uterine corpus and cervix differentiate, and the uterine wall thickens. Initially, the upper pole of the uterus contains a thick midline septum that undergoes dissolution to create the uterine cavity. Dissolution of the uterine septum is usually completed by 20 weeks. The unfused cephalad portions of the müllerian ducts become the fallopian tubes (Fig. 18-2F). Any failure of lateral fusion of the two müllerian ducts or failure to reabsorb the septum between them results in separate uterine horns or some degree of persistent midline uterine septum.

**FIGURE 18-4** Development of the lower female reproductive tract. **A.** The fused müllerian ducts join the urogenital sinus at Müller tubercle (**B**). **C.** From the urogenital sinus, the sinovaginal bulbs evaginate and proliferate cranially to create the vaginal plate. **D.** Lengthening of the vaginal plate and canalization leads to development of the lower vagina. The upper vagina develops from the caudal end of the fused müllerian ducts. (Used with permission from Kim Hoggatt-Krumwiede, MA)

Most investigators suggest that the vagina develops under influence from the müllerian ducts and estrogenic stimulation. The vagina forms partly from the müllerian ducts and partly from the urogenital sinus (Massé, 2009). Specifically, the upper two thirds of the vagina derive from the fused müllerian ducts. The distal third of the vagina develops from the bilateral sinovaginal bulbs, which are cranial evaginations of the urogenital sinus.

During vaginal development, the müllerian ducts reach the urogenital sinus at Müller tubercle (Fig. 18-4A). Here, cells in the sinovaginal bulbs proliferate cranially to lengthen the vagina and create a solid vaginal plate (Fig. 18-4B). During the second trimester, these cells desquamate, allowing full canalization of the vaginal lumen (Fig. 18-4C). The hymen is the partition that remains to a varying degree between the dilated, canalized, fused sinovaginal bulbs and the urogenital sinus. The hymen usually perforates shortly before or after birth. An imperforate hymen represents persistence of this membrane.

## ■ External Genitalia

Early development of the external genitalia is similar in both sexes. By 6 weeks' gestation, three external protuberances have developed surrounding the cloacal membrane. These are the left and right cloacal folds, which meet ventrally to form the genital tubercle (Fig. 18-5A). With division of the cloacal membrane into anal and urogenital membranes, the cloacal folds become the anal and urethral folds, respectively. Lateral to the urethral folds, genital swellings arise, and these become the labioscrotal folds. Between the urethral folds, the urogenital sinus extends onto the surface of the enlarging genital tubercle to form the urethral groove. By week 7, the urogenital membrane ruptures, exposing the cavity of the urogenital sinus to amniotic fluid.

The genital tubercle elongates to form the phallus in males and the clitoris in females. However, one is not able to visually differentiate between male and female external genitalia until week 12. In the male fetus, dihydrotestosterone (DHT) forms locally by the  $5\alpha$  reduction of testosterone. DHT prompts the anogenital distance to lengthen, the phallus to enlarge, and the labioscrotal folds to fuse and form the scrotum. Sonic hedgehog (*SHH*) is a gene that regulates urethral tubularization in males at 14 weeks' gestation (Shehata, 2011). Specifically, DHT and *SHH* expression promote the urethral folds to merge and enclose the penile urethra (Fig. 18-5B). In the female fetus, without DHT, the anogenital distance does not lengthen, and the labioscrotal and urethral folds do not fuse (Fig. 18-5C). The genital tubercle bends caudally to become the clitoris, and the urogenital sinus becomes the vestibule of the vagina. The labioscrotal folds create the labia majora, whereas the urethral folds persist as the labia minora.

## DISORDERS OF SEX DEVELOPMENT

### ■ Definitions

As evident from the prior discussion, abnormal sex development may involve the gonads, internal duct system, or external genitalia. Rates vary and approximate 1 in every 1000 to 4500 births (Murphy, 2011; Ocal, 2011).

Formerly, intersex disorders were subdivided as those: (1) associated with gonadal dysgenesis, (2) associated with under-virilization of 46,XY individuals, and (3) associated with pre-natal virilization of 46,XX subjects. The nomenclature used to describe atypical sexual differentiation has evolved. Instead of the terms “intersex,” “hermaphroditism,” and “sex reversal,” consensus recommends a new taxonomy based on the umbrella term, *disorder of sex development (DSD)* (Lee, 2006). Proposed classification of DSDs are: (1) sex chromosome DSDs, (2) 46,XY DSDs, and (3) 46,XX DSDs (Table 18-2) (Hughes, 2006).

Other terms describe the abnormal phenotypic findings that can be found. First, some DSDs are associated with abnormal, underdeveloped gonads, that is, *gonadal dysgenesis*. With this, if a testis is poorly formed, it is called a *dysgenetic testis*, and if an ovary is poorly formed, it is called a *streak gonad*. In affected patients, the underdeveloped gonad ultimately fails, which is indicated by elevated gonadotropin levels. Another important clinical sequela is that patients bearing a Y chromosome are at high risk of developing a germ cell tumor in the dysgenetic gonad.

A second term, *ambiguous genitalia*, describes genitalia that do not appear clearly male or female. Abnormalities may include

**FIGURE 18-5** Development of the external genitalia. **A.** Indifferent stage. **B.** Virilization of external genitalia. **C.** Feminization.

hypospadias, undescended testes, micropenis or enlarged clitoris, labial fusion, and labial mass.

Last, *ovotesticular* defines conditions characterized by ovarian and testicular tissue in the same individual. It was formerly termed true hermaphroditism. In these cases, the morphology of the paired gonads can vary, and options that may be paired include a normal testis, a normal ovary, a streak gonad, a dysgenetic testis, or an ovotestis. In the last, both ovarian and testicular elements are combined within the same gonad. The gonadal location varies from abdominal to inguinal to scrotal. With ovotesticular DSDs, the internal ductal system structure depends on the ipsilateral gonad and its degree of determination. Specifically, the amount of AMH and testosterone determines the degree to which the internal ductal system is masculinized or feminized. External genitalia are usually ambiguous and undermasculinized due to inadequate testosterone.

## ■ Sex Chromosome Disorders of Sex Development

### Turner and Klinefelter Syndromes

Sex chromosome DSDs typically arise from an abnormal number of sex chromosomes. Of these, Turner and Klinefelter syndromes are most frequently encountered. *Turner syndrome* is caused by de novo loss or severe structural abnormality of one X chromosome in a phenotypic female. It is the most common form of gonadal dysgenesis that leads to primary ovarian failure.

Most affected fetuses are spontaneously aborted. However, in girls with Turner syndrome who survive, phenotype varies widely, but nearly all affected patients have short stature. This results from lack of one copy of the *SHOX* gene, which resides on the short arm of the X chromosome (Hutson, 2014). The classic stigmata of Turner syndrome are listed in Table 18-3. Of these, cubitus valgus is an elbow deformity that deviates the forearm greater than 15 degrees when the arm is extended at the side. Associated problems include cardiac anomalies (especially coarctation of the aorta), renal anomalies, hearing impairment, otitis media and mastoiditis, and an increased incidence of hypertension, achlorhydria, diabetes mellitus, and Hashimoto thyroiditis. This syndrome may be recognized in childhood. However, some patients are not diagnosed until adolescence, when they present with prepubertal female genitalia and primary amenorrhea, both stemming from gonadal failure, and with short stature. The uterus and vagina are normal and capable of responding to exogenous hormones.

**TABLE 18-3.** Characteristic Findings of Turner Syndrome

Height 142–147 cm	High-arched palate
Micrognathia	Hearing loss
Epicanthal folds	Webbed neck
Low-set ears	Absent breast development
Shield-like chest	Widely spaced areolae
Cubitus valgus	Short fourth metacarpal
Renal abnormalities	Autoimmune disorders
Aorta coarctation	Autoimmune thyroiditis
Diabetes mellitus	

Those with a Turner variant have a structural abnormality of the second X chromosome or have a mosaic karyotype, such as 45,X/46,XX. Indeed, more than half of the girls with this syndrome have chromosomal mosaicism. Those with a Turner variant may exhibit some or all of the syndrome signs. Patients with mosaicism are more likely to have some pubertal maturation.

For patients with 45,X DSD, hormone treatment is needed to effect breast development. Our protocol uses estradiol, 0.25 mg orally daily for approximately 6 months. This begins near age 12 or at the time of delayed puberty diagnosis. The daily estradiol dose is sequentially increased each 6 months to 0.5 mg, 0.75 mg, 1 mg, and then 2 mg daily. We colloquially term this the “start low and go slow” protocol. Progesterone is begun after approximately 1 year of unopposed estrogen treatment. Each month, micronized progesterone, 200 mg orally nightly, is given for 12 nights and then stopped to permit withdrawal bleeding. This method mimics normal pubertal hormonal stimulation of breast tissue. The patient is then maintained on 2 mg of oral estradiol and monthly withdrawal to progesterone. Alternatively, a low-dose combination oral contraceptive would also be acceptable maintenance after adequate breast development has been effected.

Another sex chromosome DSD is *Klinefelter syndrome* (47,XXY), which occurs in one in 600 births or in 1 to 2 percent of all males. These individuals tend to be tall, undervirilized males with gynecomastia and small, firm testes. They have significantly reduced fertility from hypogonadism due to gradual testicular cell loss that begins shortly after testis determination (Nistal, 2014). These men are at increased risk for germ cell tumors, osteoporosis, hypothyroidism, diabetes mellitus, breast cancer, and cognitive and psychosocial problems (Aksela, 2013). The most common genotype of Klinefelter syndrome is XXY, although variants exist with differing numbers of X chromosomes.

### Chromosomal Ovotesticular DSD

Several karyotypes can create a coexistent ovary and testis, and thus ovotesticular DSD is found in all three DSD categories (see Table 18-2). In the sex chromosome DSD group, ovotesticular DSD may arise from a 46,XX/46,XY karyotype. Here, an ovary, testis, or ovotestis may be paired. The phenotype mirrors that for ovotesticular DSDs in general described earlier on this page.

For others in the sex chromosome DSD group, ovotesticular DSD arises from a chromosomal mosaic such as 45,X/46,XY. With this karyotype, a picture of *mixed gonadal dysgenesis* shows a streak gonad on one side and a dysgenetic or normal testis on the other. The phenotypic appearance ranges from undervirilized male to ambiguous genitalia to Turner stigmata.

## ■ 46,XY Disorders of Sex Development

Insufficient androgen exposure of a fetus destined to be a male leads to 46,XY DSD, formerly called male pseudohermaphroditism. The karyotype is 46,XY, and testes are frequently present. The uterus is generally absent as a result of normal embryonic AMH production by Sertoli cells. These patients are most often

sterile from abnormal spermatogenesis and have a small phallus that is inadequate for sexual function. As seen in Table 18-2, etiology of 46,XY DSD may stem from abnormal testis development or from abnormal androgen production or action.

### 46,XY Gonadal Dysgenesis

This spectrum of abnormal gonad underdevelopment includes pure or complete, partial, or mixed 46,XY gonadal dysgenesis (see Table 18-2). These are defined by the amount of normal testicular tissue and by karyotype.

Of these, *pure gonadal dysgenesis* results from a mutation in *SRY* or in another gene with testis-determining effects (*DAX1*, *SF-1*, *CBX2*) (Hutson, 2014). This leads to underdeveloped dysgenetic gonads that fail to produce androgens or AMH. Formerly named Swyer syndrome, the condition creates a normal prepubertal female phenotype and a normal müllerian system due to absent AMH.

*Partial gonadal dysgenesis* defines those with gonad development intermediate between normal and dysgenetic testes. Depending on the percentage of underdeveloped testis, wolffian and müllerian structures and genital ambiguity are variably expressed.

*Mixed gonadal dysgenesis* is one type of ovotesticular DSD. As discussed, with mixed gonadal dysgenesis, one gonad is streak and the other is a normal or a dysgenetic testis. Of affected individuals, a 46,XY karyotype is found in 15 percent (Nistal, 2015). The phenotypic appearance is wide ranging as with partial gonadal dysgenesis.

Last, *testicular regression* can follow initial testis development. A broad phenotypic spectrum is possible and depends on the timing of testis failure.

Because of the potential for germ cell tumors in dysgenetic gonads and intraabdominal testes, affected patients are advised to undergo gonadectomy (Chap. 36, p. 762).

### Abnormal Androgen Production or Action

In some cases, 46,XY DSD may stem from abnormalities in: (1) testosterone biosynthesis, (2) luteinizing hormone (LH) receptor function, (3) AMH function, or (4) androgen receptor action. First, as evident from Table 15-5, (p. 337), the sex steroid biosynthesis pathway can suffer enzymatic defects that block testosterone production. Depending on the timing and degree of blockade, undervirilized males or phenotypic females may result. Potential defective enzymes include steroid acute regulatory protein (StAR), cholesterol side-chain cleavage enzyme (P450<sub>scc</sub>), 3 $\beta$ -hydroxysteroid dehydrogenase type II, 17 $\alpha$ -hydroxylase/17,20 desmolase (P450<sub>c17a</sub>), and 17 $\beta$ -hydroxysteroid dehydrogenase. The last two enzyme deficiencies can also cause congenital adrenal hyperplasia, and hypertension is a common feature in P450<sub>c17a</sub> deficiency. In addition to these central enzymatic defects, peripherally, abnormal 5 $\alpha$ -reductase type 2 enzyme action leads to impaired conversion of testosterone to DHT. DHT is the active androgen in peripheral tissues, and undervirilization results.

Second, hCG/LH receptor abnormalities within the testes can lead to Leydig cell aplasia/hypoplasia and impaired testosterone production. In contrast, disorders of AMH and AMH

receptors result in persistent müllerian duct syndrome (PMDS). Affected patients appear as males but have a persistent uterus and fallopian tubes due to failed AMH action.

Finally, the androgen receptor may be defective and result in androgen insensitivity syndrome (AIS). The estimated incidence of AIS ranges from 1 in 13,000 to 1 in 41,000 live births (Bangsbo, 1992; Blackless, 2000). Mutations produce a non-functional receptor that will not bind androgen or is unable to initiate full transcription once bound. As a result, resistance to androgens may be complete and female external genitalia are found. Alternatively, an incomplete form is associated with varying degrees of virilization and genital ambiguity. Milder forms of AIS have been described in men with severe male factor infertility and poor virilization. For those with male gender assignment, testosterone therapy via patch or injection may be needed for continued masculine response.

Patients with complete androgen-insensitivity syndrome (CAIS) appear as phenotypically normal females at birth. They often present at puberty with primary amenorrhea. External genitalia appear normal; scant or absent pubic and axillary hair is noted; the vagina is shortened or blind ending; and the uterus and fallopian tubes are absent. However, these girls develop breasts during pubertal maturation due to abundant androgen-to-estrogen conversion. Testes may be palpable in the labia or inguinal area or may be found intraabdominally.

In CAIS patients, surgical excision of the testes after puberty is recommended to decrease the associated risk of germ cell tumors, which may be as high as 20 to 30 percent (Chap. 36, p. 762) (Chavhan, 2008). Additionally, estrogen is replaced to reach physiologic levels, and a functional vagina is created either by dilation or by surgical vaginoplasty. Adequate estrogen replacement in these patients is important to maintain breast development and bone mass and to provide relief from vasomotor symptoms.

## ■ 46,XX Disorders of Sex Development

As seen in Table 18-2, etiology of 46,XX DSD may stem from abnormal ovarian development or from excess androgen exposure.

### Abnormal Ovarian Development

Disorders of ovarian development in those with a 46,XX complement include: (1) gonadal dysgenesis, (2) testicular DSD, and (3) ovotesticular DSD.

With *46,XX gonadal dysgenesis*, similar to Turner syndrome, streak gonads develop. These lead to hypogonadism, prepubertal normal female genitalia, and normal müllerian structures, but other Turner stigmata are absent.

With *46,XX testicular DSD*, several possible genetic mutations lead to testis-like formation within the ovary (streak gonad, dysgenetic testis, or ovotestis). Defects may stem from *SRY* translocation onto one X chromosome. In individuals without *SRY* translocation, other genes with testis-determining effects are most likely present or activated. These include *WNT4*, *RSPO1*, or *CTNNB1* gene defects or *SOX9* gene duplication (Ocal, 2011). *SRY* guides the gonad to develop along testicular lines, and testicular hormone function is near normal.

Production of AMH prompts müllerian system regression, and androgens promote development of the wolffian system and external genitalia masculinization. Spermatogenesis, however, is absent due to a lack of certain genes on the long arm of the Y chromosome. These individuals are not usually diagnosed until puberty or during infertility evaluation.

With *46,XX ovotesticular DSD*, individuals possess a unilateral ovotestis with a contralateral ovary or testis, or bilateral ovotestes. Phenotypic findings depend on the degree of androgen exposures and mirror those for other ovotesticular DSDs (p. 411).

### Androgen Excess

Discordance between gonadal sex (46,XX) and the phenotypic appearance of external genitalia (masculinized) may result from excessive fetal androgen exposure. This was previously termed female pseudohermaphroditism. In affected individuals, the ovaries and female internal ductal structures such as the uterus, cervix, and upper vagina are present. Thus, patients are potentially fertile. The external genitalia, however, are virilized to a varying degree depending on the amount and timing of androgen exposure. The three embryonic structures that are commonly affected by elevated androgen levels or ovarian development disorders are the clitoris, labioscrotal folds, and urogenital sinus. As a result, virilization may range from modest clitoromegaly to posterior labial fusion and development of a phallus with a penile urethra. Degrees of virilization can be described by the Prader score, which ranges from 0 for a normal-appearing female to 5 for a normal, virilized male.

Fetal, placental, or maternal sources may provide the excessive androgen levels. Maternally derived androgen excess may come from virilizing ovarian tumors such as luteoma and Sertoli-Leydig cell tumor or from virilizing adrenal tumors. Fortunately, these neoplasms infrequently cause fetal effects because of the tremendous ability of placental syncytiotrophoblast to convert C19 steroids (androstenedione and testosterone) to estradiol via the enzyme aromatase (Cunningham, 2014c). As another source, drugs such as testosterone, danazol, norethindrone, and other androgen derivatives may cause fetal virilization.

Of fetal sources, exposure can also arise from fetal congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency from *CYP21* mutation. This is a frequent cause of virilization and has an incidence approximating 1 in 14,000 live births (White, 2000). In many cases, CAH can be diagnosed antenatally, and early maternal dexamethasone therapy can ameliorate the masculine phenotype (New, 2012). In addition, androgen excess and ambiguous genitalia can also be seen with fetal 11-beta hydroxylase and 3β-hydroxysteroid dehydrogenase deficiencies, from *CYP11B1* and *HSD3B2* gene mutations, respectively (Fig. 15-5, p. 337). Mutations of *POR* gene can also disorder steroidogenesis. Cytochrome POR is a protein that transfers electrons to important cytochrome P450 enzymes and steroidogenic enzymes. Severely affected female neonates with *POR* gene mutations are virilized because of defective aromatase activity and because of the diversion of 17-hydroxyprogesterone to DHT by a “backdoor” androgen pathway (Fukami, 2013).

Of placental sources, placental aromatase deficiency from fetal *CYP19* gene mutation causes an accumulation of placental androgen and underproduction of placental estrogens. Consequently, both the mother and the 46,XX fetus are virilized (Murphy, 2011).

### Gender Assignment

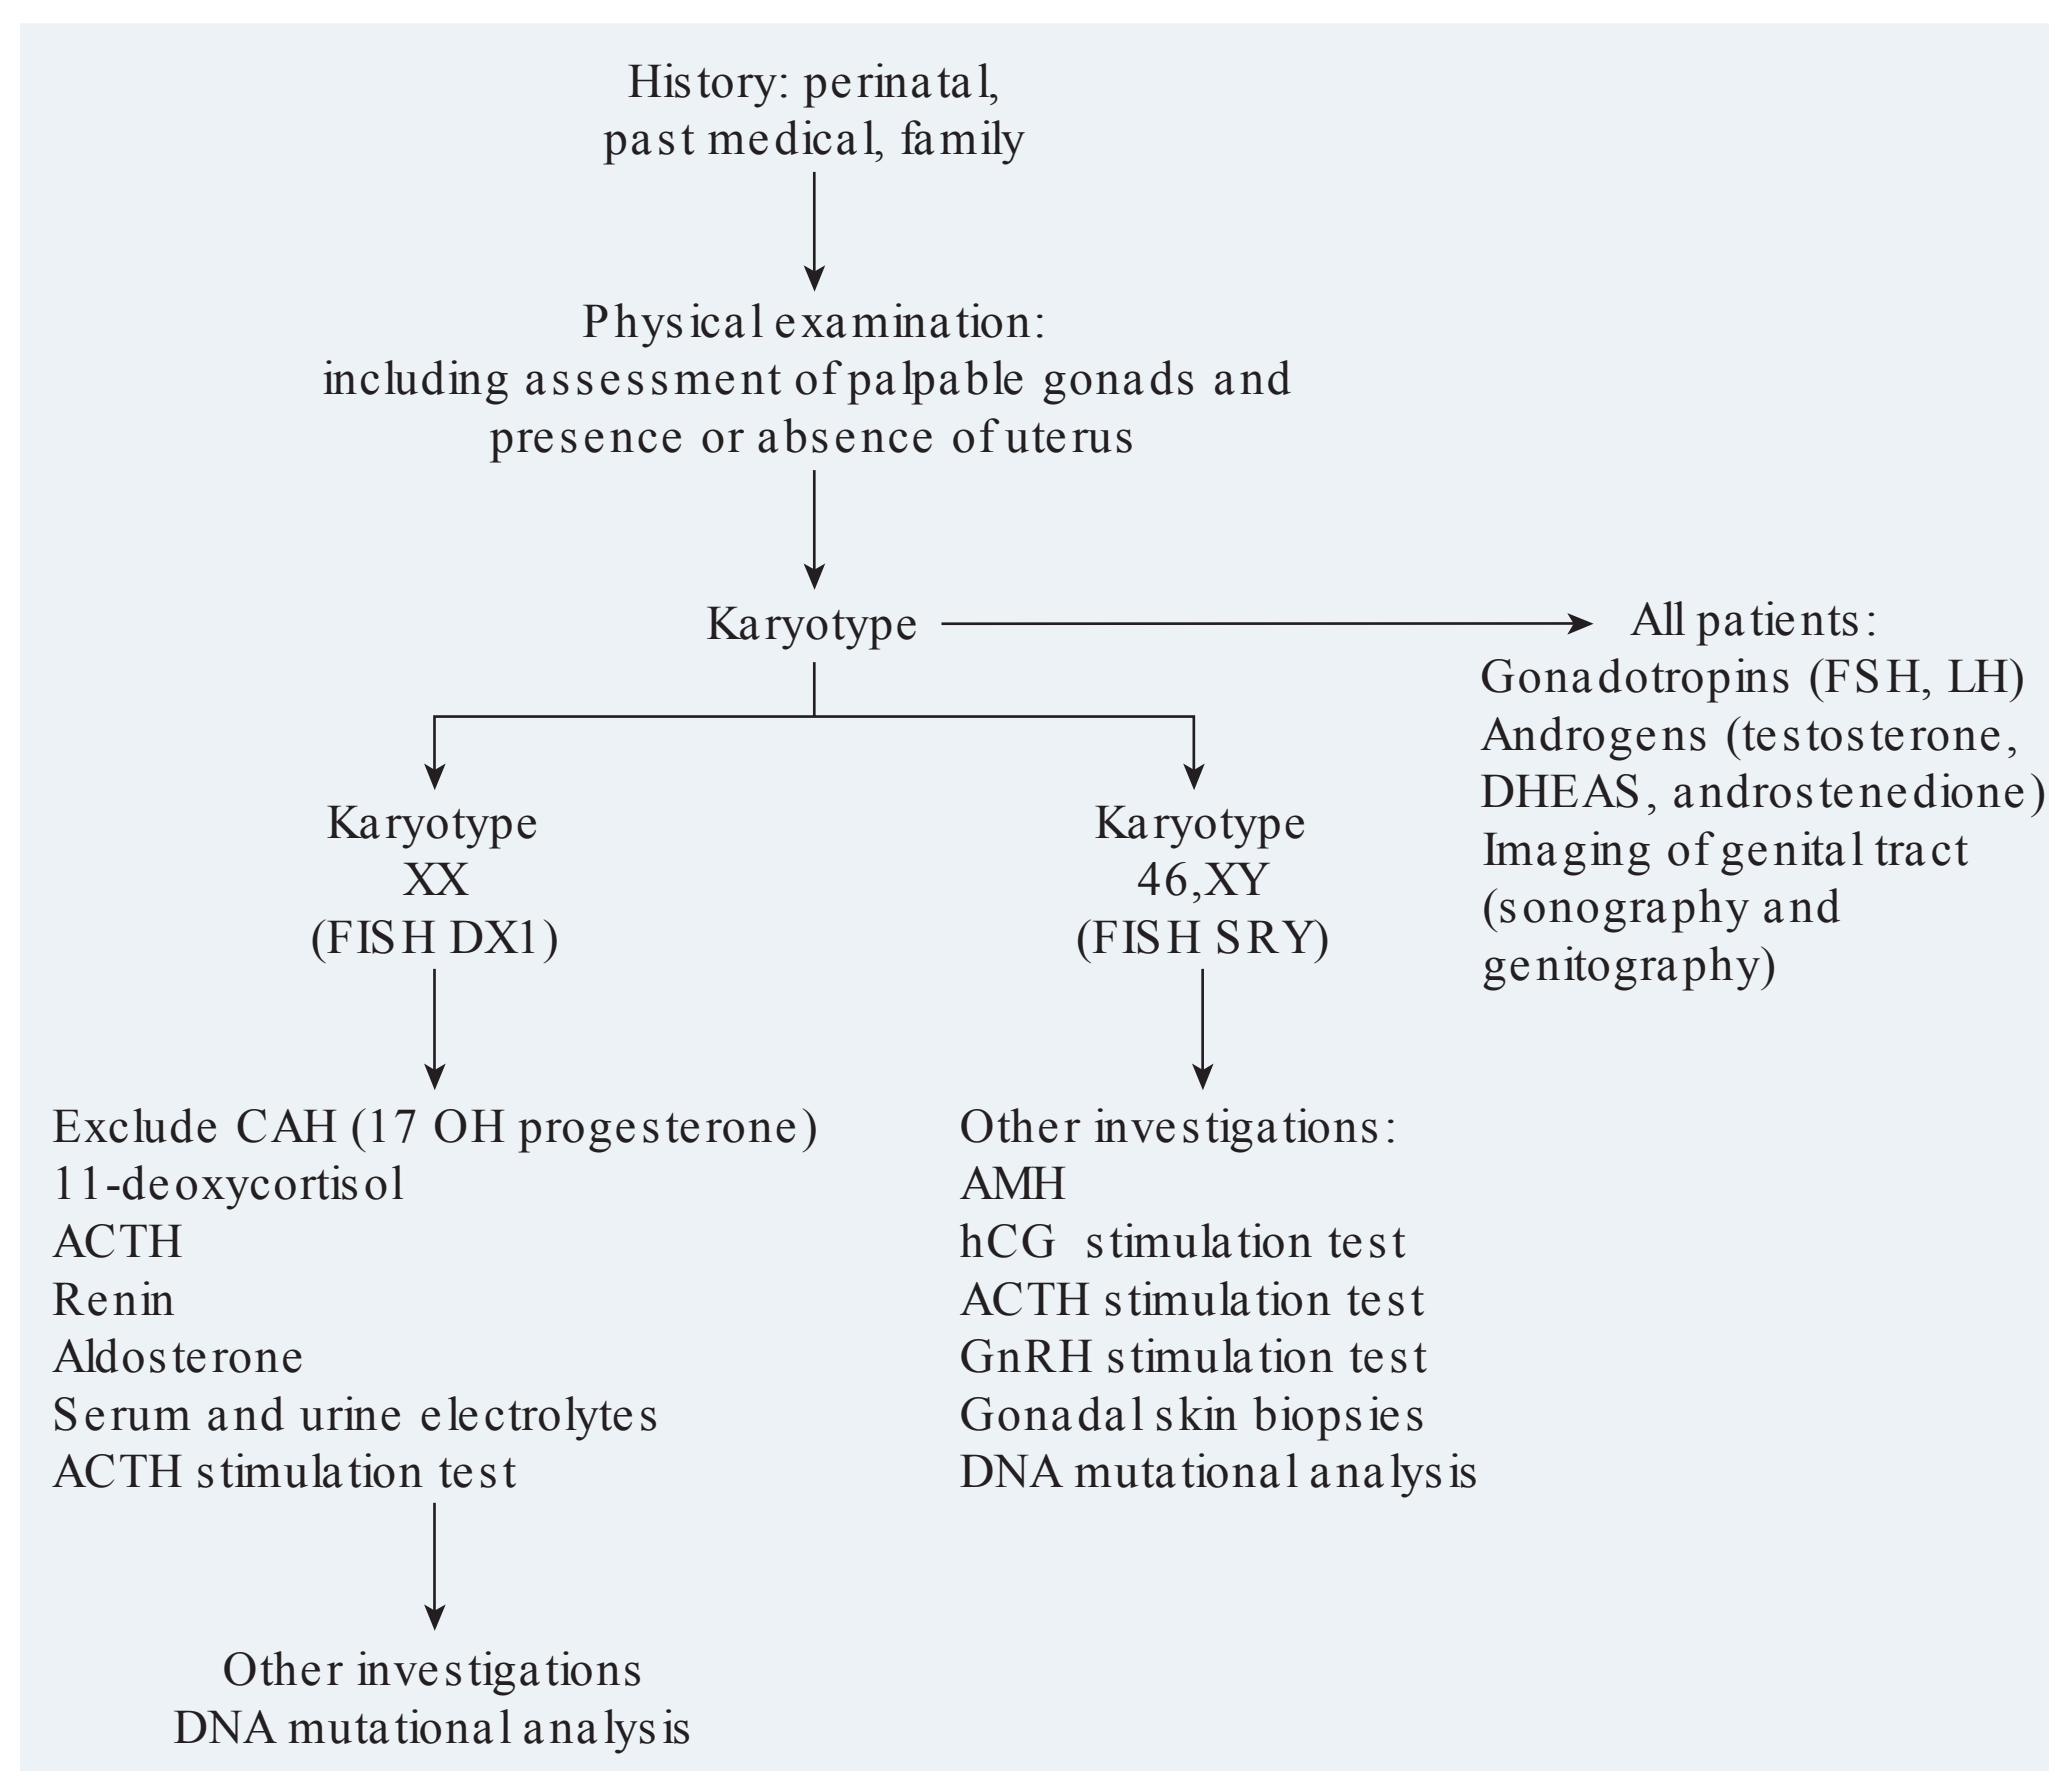

At birth, gender assignment to the normal newborn usually involves a simple assessment of the external genitalia and a straightforward joyful declaration of male or female by the obstetrician. Delivery of a newborn with DSD is a potential medical emergency and presents a serious psychosocial, diagnostic, medical, and possibly surgical challenge for a multispecialty medical team. For the unprepared obstetrician in the labor room, ambiguous external genitalia in a newborn can create possible long-lasting psychosexual and social ramifications for the individual and family. Ideally, as soon as the neonate with ambiguous genitalia is stable, parents are encouraged to hold the child. The newborn is referred to as “your baby” and not as “it” or “he/she.” When discussing ambiguous development, other suggested terms used include “phallus,” “gonads,” “folds,” and “urogenital sinus” to reference underdeveloped structures. The obstetrician explains that the genitalia are incompletely formed and emphasizes the seriousness of the situation and the need for rapid consultation and laboratory testing (see Fig. 18-6). During family education, the need for accurate determination of gender and sex of rearing is emphasized.

Because similar or identical phenotypes may have several etiologies, diagnosis of a specific DSD may require several diagnostic tools (Ocal, 2011). Relevant neonatal physical examination evaluates: (1) ability to palpate gonads in the labioscrotal or inguinal regions, (2) ability to palpate uterus during rectal examination, (3) phallus size, (3) genitalia pigmentation, and (4) presence of other syndromic features. The newborn’s metabolic condition is assessed, as hyperkalemia, hyponatremia, and hypoglycemia may indicate congenital adrenal hyperplasia. The mother is examined for signs of hyperandrogenism (T Yen, 2006).

Pediatric endocrinologists and reproductive endocrinologists are consulted as soon as possible. The diagnostic evaluation of DSD includes hormone measurements, imaging, cytogenetic studies, and in some cases endoscopic, laparoscopic, and gonadal biopsy. Sonography shows the presence or absence of müllerian/wolffian structures and can locate the gonads. Sonography also can identify associated malformation such as renal abnormalities. The genetic evaluation includes karyotype, fluorescent in situ hybridization (FISH), and more recently, specific molecular studies to screen for mutations or gene dosage imbalance.

The psychologic and social implications of gender assignment and those relating to treatment are important and require a multidisciplinary approach. The current intense debate on the management of patients with DSD focuses on four major issues, namely, etiologic diagnosis, gender assignment, indications for and timing of genital surgery, and disclosure of medical information to the patient (Daaboul, 2001; de Vries, 2007). Discussions include the possible need for hormonal stimulation at puberty and potential later surgical reconstruction.

**FIGURE 18-6** One algorithm for investigating disorders of sexual development. ACTH = adrenocorticotrophic hormone; AMH = antimüllerian hormone; CAH = congenital adrenal hyperplasia; DHEAS = dehydroepiandrosterone sulfate; FISH = fluorescent in situ hybridization; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone; SRY = sex-determining region of the Y.

## DEFECTS OF THE BLADDER AND PERINEUM

The bilaminar cloacal membrane lies at the caudal end of the germinal disc and forms the infraumbilical abdominal wall. Normally, an ingrowth of mesoderm between the ectodermal and endodermal layers of the cloacal membrane leads to formation of the lower abdominal musculature and the pelvic bones. Without reinforcement, the cloacal membrane may prematurely rupture. Bladder exstrophy is a complex and severe pelvic malformation due to premature rupture of this cloacal membrane and subsequent failure of the membrane to be reinforced by an ingrowth of mesoderm. Depending on the infraumbilical defect size and developmental stage at rupture, bladder exstrophy, cloacal exstrophy, or epispadias results.

Of these, bladder exstrophy has an estimated incidence of 1 in 50,000 newborns and is equally prevalent in males and females (Lloyd, 2013). Exstrophy is characterized by an exposed bladder lying outside the abdomen. Associated findings commonly include abnormal external genitalia and a widened symphysis pubis, caused by the outward rotation of the innominate bones. Stanton (1974) noted that 43 percent of 70 females with bladder exstrophy had associated reproductive tract anomalies. The urethra and vagina are typically short, and the vaginal

orifice is frequently stenotic and displaced anteriorly. The clitoris is duplicated or bifid, and the labia, mons pubis, and clitoris are divergent. The uterus, fallopian tubes, and ovaries are typically normal except for occasional müllerian duct fusion defects.

A complex approach is required to achieve acceptable urinary continence and external genitalia reconstruction (Laterza, 2011). Surgical closure of the exstrophy is currently performed in the first 4 years of life in stages (Massanyi, 2013). Vaginal dilatation or vaginoplasty may be required to allow satisfactory intercourse in mature females (Jones, 1973). Long term, the defective pelvic floor may predispose women to uterine prolapse (Nakhal, 2012).

## DEFECTS OF THE CLITORIS

Congenital abnormalities of the clitoris are unusual but include clitoral duplication, clitoral cysts, and clitoral enlargement from excess androgen exposure. Clitoral duplication, also known as bifid clitoris, usually develops in association with bladder exstrophy or epispadias. The disorder is rare, and the incidence approximates 1 in 480,000 females (Elder, 1992).

In those with epispadias but without bladder exstrophy, visibly apparent anomalies include a widened, patulous urethra;

absent or bifid clitoris; flattened mons pubis; and labia that do not fuse anteriorly. Vertebral abnormalities and diastases of the pubic symphysis are also commonly associated. Female epispadias can be divided into three types—vestibular, subsymphyseal, and retrosymphyseal—which are differentiated by the type of urethral involvement (Schey, 1980).

Female phallic urethra is another clitoral anomaly, and the phallic urethra opens at the clitoral tip (Sotolongo, 1983). This anomaly affects 4 to 8 percent of girls with persistent cloaca and has been associated with embryonic exposure to cocaine (Karlin, 1989).

Epidermal cysts may be found on the clitoris, and inversion of epidermal cells beneath the dermis or subcutaneous tissue is the presumed pathogenesis. Cysts can reach 1 to 5 cm in diameter. Surgical removal of the cyst is the preferred treatment. Vascularity and nerve supply preservation during this procedure is important to sexual health (Johnson, 2013).

Clitoromegaly noted at birth is suggestive of fetal exposure to excessive androgens. Clitoromegaly is defined as a clitoral index greater than  $10 \text{ mm}^2$ . This index is determined by the glans length times the width. Moreover, early androgen exposure may lead to fusion of the labioscrotal folds and findings of a single perineal opening, the urogenital sinus. Labia are rugated and scrotum-like. A gonad found in the groin or labia majora, however, raises concern for 46,XY DSD.

Frequently in premature neonates, the clitoris may appear large, but it does not change size and appears to regress as the infant grows. Other causes of newborn clitoromegaly include breech presentation with vulvar swelling, chronic severe

vulvovaginitis, and neurofibromatosis (Dershwitz, 1984; Greer, 1981). Clitoral reduction surgery is done typically by skilled pediatric urologists, and preservation of vascularity and nerve supply is essential.

## HYMENEALE DEFECTS

The hymen is the membranous vestige of the junction between the sinovaginal bulbs and the urogenital sinus (see Fig. 18-4). It generally perforates during fetal life to establish a connection between the vaginal lumen and the perineum. Various hymeneal abnormalities include imperforate, microperforate, annular, septate, cribriform (sievelike), naviculate (boatlike), or septate types (Fig. 18-7) (Breech, 1999). Imperforate hymen follows failure of the inferior end of the vaginal plate to canalize, and its incidence approximates 1 in 1000 to 2000 females (Parazzini, 1990). Although typically sporadic, imperforate hymen in multiple family members has been reported (Stelling, 2000; Usta, 1993).

If the hymen is imperforate, blood from endometrial sloughing or mucus accumulates in the vagina. During the neonatal period, significant amounts of mucus can be secreted secondary to maternal estradiol stimulation. The newborn may have a bulging, translucent yellow-gray mass at the vaginal introitus. This condition is termed hydro/mucocolpos. Most cases are asymptomatic and resolve as the mucus is reabsorbed and estrogen levels decline. However, large hydro/mucocolpos may cause respiratory distress or may obstruct the ureters, resulting in hydronephrosis or life-threatening acute renal failure (Breech, 2009; Nagai, 2012).

**FIGURE 18-7** Types of hymens.

After menarche, adolescents with imperforate hymen present with trapped menstrual blood behind the hymen, which creates a bluish bulge at the introitus (Fig. 14-5B, p. 321). With cyclic menstruation, the vaginal canal greatly distends, and the cervix may dilate and allow formation of a hematometra and hematosalpinx. Cyclic pain, amenorrhea, abdominal pain mimicking acute abdomen, and difficulty with urination or defecation may be presenting symptoms (Bakos, 1999). Moreover, retrograde menstruation can lead to development of endometriosis. Other obstructive reproductive tract anomalies that are located more cephalad, such as transverse vaginal septum, may present similarly.

Patients with microperforate, cribriform, or septate hymen will typically complain of menstrual irregularities or difficulty with tampon placement or intercourse. Microperforate or imperforate hymen may be corrected when diagnosed and is illustrated in Section 43-17 (p. 969). Breech and Laufer (1999) advocate repair when estrogen is present to improve tissue healing, either in infancy or after thelarche, but before menarche. Timing avoids the formation of hematocolpos and possible hematometra. Laparoscopy is often performed concurrently with hymenectomy to exclude endometriosis. Importantly, clinicians should avoid needle aspiration of a hematocolpos for diagnosis or treatment. Aspiration may seed the retained blood with bacteria and increase infection risks. Moreover, recurrent hematocolpos secondary to inadequate drainage is common following needle aspiration alone.

Hymeneal cysts in the newborn must be differentiated from an imperforate hymen with hydro/mucocolpos (Nazir, 2006). These cysts typically have an opening and may regress spontaneously (Berkman, 2004). They may also be treated by incision and drainage. Simple puncture without anesthesia has also been successfully performed.

### TRANSVERSE VAGINAL SEPTUM

Transverse vaginal septa are believed to arise from failed müllerian duct fusion or failed canalization of the vaginal plate (Fig. 18-8). The anomaly is uncommon, and Banerjee (1998) reported an incidence of 1 in 70,000 females. A septum may be obstructive, with mucus or menstrual blood accumulation, or nonobstructive, with mucus and blood egress.

Transverse vaginal septum can develop at any level within the vagina (Williams, 2014). Those in the upper vagina correspond to the junction between the vaginal plate and the caudal end of the fused müllerian ducts (see Fig. 18-4). Septal thickness may vary but typically is thin (1 cm). Thicker septa can measure 5 to 6 cm, and these tend to lie nearer the cervix (Rock, 1982).

In neonates and infants, obstructive transverse vaginal septum has been associated with fluid and mucus collection in the upper vagina. The resulting mass may be large enough to compress abdominal or pelvic organs. In addition, pyomucocolpos, pyometria, and pyosalpinges may develop from ascension of vaginal or perineal bacteria through small perforations within a septum (Breech, 1999). In contrast to other müllerian duct defects, transverse vaginal septum is associated with few urologic abnormalities.

Patients with transverse vaginal septum usually present with symptoms similar to those of imperforate hymen. The diagnosis

**FIGURE 18-8** Potential locations of transverse vaginal septa are indicated and marked (A–C). (Reproduced with permission from Rock JA, Zaccaro HA, Dlugi AM, et al: Pregnancy success following surgical correction of imperforate hymen and complete transverse vaginal septum, *Obstet Gynecol* 1982 Apr;59(4):448–451.)

is suspected when an abdominal or pelvic mass is palpated or when a foreshortened vagina and inability to identify the cervix is encountered. Diagnosis is confirmed by either sonography or magnetic resonance (MR) imaging. MR imaging is most helpful prior to surgery to determine the septal thickness and depth (Fig. 18-9). In addition, MR imaging may identify whether a cervix is present, and thereby allow differentiation of a high vaginal septum from cervical agenesis.

Surgical repair technique is dependent on septal thickness, and skin grafts or buccal mucosal grafts may occasionally be necessary to cover the defect left by excision of very thick septa. Smaller septa may be removed by excision followed by end-to-end anastomosis of the upper and lower vagina as described in Section 43-24 (p. 983). Sanfilippo (1986) recommends laparoscopy concurrently with transverse vaginal septum excision because of the high rate of endometriosis due to retrograde menstruation from outflow tract obstruction.

### LONGITUDINAL VAGINAL SEPTUM

A longitudinal vaginal septum results from defective lateral fusion or incomplete reabsorption of the caudal central portion of the müllerian ducts. These septa may be partial or extend the complete vaginal length. Longitudinal septa are generally seen with partial or complete duplication of the cervix and uterus. They may also accompany anorectal malformations, and renal abnormalities are common.

Affected individuals complain of difficulty with intercourse. Vaginal bleeding may occur despite placement of a tampon, because the tampon is placed in only one of the duplicated

**FIGURE 18-9** Magnetic resonance image of complete low transverse septum with obstruction. Marked hematocolpos is identified (arrows) in this 13-year-old female. The relatively low signal intensity on the T2-weighted images is consistent with subacute blood. The uterus is seen above the hematocolpos. (Used with permission from Dr. Doug Sims.)

vaginas. Nonobstructed forms can be managed conservatively unless dyspareunia develops. However, there are obstructive longitudinal vaginal septa (Fig. 18-10). Typically, the patient presents in adolescence with normal menarche, but reports worsening, monthly unilateral vaginal and pelvic pain from outflow obstruction (Carlson, 1992). During examination, a patent vagina and cervix are noted, but a unilateral vaginal and pelvic mass can be palpated. Obstructed hemivagina is almost universally associated with ipsilateral renal agenesis. The triad of uterine didelphys, obstructed hemivagina, and ipsilateral renal anomaly is the OHVIRA syndrome, also known as Herlyn-Werner-Wunderlich syndrome.

Surgical correction of a longitudinal vaginal septum consists of excision of the obstructing septum, taking precautions to avoid the urethra/bladder and rectum. With obstructive cases, sonographic guidance during excision can help in identifying the distended upper vagina (Breech, 2009). Joki-Erkila and Heinonen (2003) followed 26 females after surgical repair of obstructive outflow tract anomalies. They found a high rate

of vaginal stricture requiring reoperation, as well as abnormal uterine bleeding, dyspareunia, and dysmenorrhea.

## CONGENITAL VAGINAL CYSTS

Although in each sex the müllerian or wolffian ducts marked for degeneration normally do regress, vestigial remnants can be found and may become clinically apparent. Thus, laterally located cysts may be mesonephric (wolffian) duct remnants. The lowermost portion of the vagina derives from the urogenital sinus, which may give rise to congenital vestibular cysts (Heller, 2012).

Remnant cysts are typically located in the anterolateral wall of the vagina, although they may be found at various locations along its length. Most are asymptomatic and benign, measure 1 to 7 cm in diameter, and do not require surgical excision. Deppisch (1975) described 25 cases of symptomatic vaginal cysts and reported a wide range of symptoms. These included dyspareunia, vaginal pain, difficulty with tampon use, urinary symptoms, and palpable mass. If these cysts become infected and intervention is required during the acute phase, cyst marsupialization is preferred.

Occasionally, a remnant cyst may cause chronic symptoms and warrant excision. Pelvic MR imaging can assist prior to surgery to determine the extent of the cyst and its anatomic relationship to the ureter or bladder base (Hwang, 2009). Of note, complete vaginal cyst excision may be more difficult than anticipated, as some may extend up into the broad ligament and anatomically approximate the distal course of the ureter.

## MÜLLERIAN ANOMALIES

Abnormalities of the uterus may be congenital or acquired and typically present with menstrual dysfunction, pelvic pain, infertility, or pregnancy wastage. Congenital anomalies have a heterogeneous genetic basis, and *WT1*, *Pax2*, *WNT2*, *PBX1*, and *HOX* genes are potentially involved (Hutson, 2014).

Various classification schemes for female reproductive tract anomalies exist, but the most commonly used system was proposed by Buttram and Gibbons (1979) and adapted by the American Society for Reproductive Medicine (former American Fertility Society, 1988). Within this system, six categories organize similar embryonic developmental defects

**FIGURE 18-10** Uterine didelphys with obstructed hemivagina. **A.** Complete obstruction. **B.** Partial vaginal communication. **C.** Partial uterine communication. **TABLE 18-4.** Classification of Müllerian Anomalies

- I. Segmental müllerian hypoplasia or agenesis**
  - a. Vaginal
  - b. Cervical
  - c. Uterine
  - d. Tubal
  - e. Combined
- II. Unicornuate uterus**
  - a. Rudimentary horn with cavity, communicating to unicornuate uterus
  - b. Rudimentary horn with cavity, not communicating to unicornuate uterus
  - c. Rudimentary horn with no cavity
  - d. Unicornuate uterus without a rudimentary horn
- III. Uterine didelphys**
- IV. Bicornuate uterus**
  - a. Complete bifurcation (bicollis)
  - b. Partial bifurcation (unicollis)
- V. Septate uterus**
  - a. Complete septation
  - b. Partial septation
- VI. Arcuate uterus**
- VII. Diethylstilbestrol-related anomalies**

Data from American Fertility Society: The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions, *Fertil Steril* 1988 Jun;49(6):944–55.

(Table 18-4). Acien (2009) and Rock (2010) have described types of uterovaginal and cervical malformations that do not adapt to the usual classification systems. Such anomalies are best described and drawn in detail in a patient’s medical record for future reference.

Most cases are diagnosed during evaluation for obstetric or gynecologic problems, but in the absence of symptoms, most anomalies remain undiagnosed. Because nearly 57 percent of women with uterine defects have successful fertility and pregnancy, the true incidence of congenital müllerian defects may be significantly understated. Nahum (1998) found that the prevalence of uterine anomalies in the general population was 1 in 201 women or 0.5 percent. Dreisler and colleagues (2014) found uterine anomalies in nearly 10 percent of 622 women from the general population undergoing saline infusion sonography.

Anatomic uterine defects have long been recognized as a cause of obstetric complications. Recurrent pregnancy loss, preterm labor, abnormal fetal presentation, and prematurity constitute the major reproductive problems encountered. Cunningham and colleagues (2014a) provide a full discussion of specific müllerian abnormalities and their obstetric importance. Müllerian defects are also associated with renal anomalies in 30 to 50 percent of cases, and defects include unilateral renal agenesis, severe renal hypoplasia, horseshoe kidney, pelvic kidney, and ectopic or duplicate ureters (Sharara, 1998). Spinal anomalies have been reported in 10 to 12 percent of cases and

include wedge, supernumerary, or asymmetric and rudimentary vertebral bodies (Kimberley, 2011). The combination of müllerian and renal aplasia and cervicothoracic somite dysplasia has been described as MURCS association (Duncan, 1979). An association with Klippel-Feil syndrome has also been reported. Other anomalies associated with vaginal agenesis include ear anomalies and hearing loss, with the latter reported to be as high as 25 percent. The pattern of associated anomalies suggests an embryologic link (Kimberley, 2011).

Müllerian anomalies may be discovered during routine pelvic examinations, infertility evaluation, or surgery for other indications. Depending on clinical presentation, diagnostic tools may include hysterosalpingography (HSG), sonography, MR imaging, laparoscopy, and hysteroscopy. Each tool has limitations, but they may be used in combination to completely define anatomy. In women undergoing fertility evaluation, HSG is commonly selected for uterine cavity and tubal patency assessment. That said, HSG poorly defines the external uterine contour and can delineate only patent cavities. In other clinical settings, sonography is initially performed. Transabdominal views may help to maximize the viewing field, but transvaginal sonography (TVS) provides better image resolution. Saline infusion sonography (SIS) improves delineation of the endometrium and internal uterine morphology, but only with a patent endometrial cavity. Three-dimensional (3-D) sonography can provide uterine images from virtually any angle. Thus, coronal images can be constructed and are essential in evaluating both internal and external uterine contours. Sonography is ideally completed during the luteal phase when the secretory endometrium provides contrast from increased thickness and echogenicity (Caliskan, 2010). Several investigators have reported good concordance between 3-D TVS and MR imaging of müllerian anomalies, but MR imaging is currently preferred for imaging complex defects (Bermejo, 2010; Ghi, 2009). MR imaging provides clear delineation of both the internal and external uterine anatomy and has a reported accuracy of up to 100 percent in the evaluation of müllerian anomalies (Fedele, 1989; Pellerito, 1992). Moreover, complex anomalies and commonly associated secondary diagnoses such as renal or skeletal anomalies can be concurrently evaluated. In some women undergoing an infertility evaluation, hysteroscopy and laparoscopy may be selected to assess for müllerian anomalies; screen for endometriosis, which is often coexistent; and exclude other tubal or uterine cavity pathologies (Puscheck, 2008; Saravelos, 2008).

■ **Segmental Müllerian hypoplasia or Agenesis**

Some form of müllerian aplasia, hypoplasia, or agenesis affects 1 in every 4000 to 10,000 females and is a common cause of primary amenorrhea (American College of Obstetricians and Gynecologists, 2009). Uterine agenesis follows failed development of the lower portion of the müllerian ducts during embryogenesis and usually leads to absence of the uterus, cervix, and upper part of the vagina (Oppelt, 2006). Variants may display absence of the upper vagina but presence of the uterus. Normal ovaries are found, and affected individuals otherwise develop as phenotypically normal females and present with primary amenorrhea.

**FIGURE 18-11** Classification of müllerian anomalies. (Modified with permission from American Fertility Society: The American Fertility Society classifications of adnexal adhesions, distal tubal occlusion, tubal occlusion secondary to tubal ligation, tubal pregnancies, müllerian anomalies and intrauterine adhesions, *Fertil Steril* 1988 Jun;49(6):944–55.)

### Vaginal Atresia

Females with vaginal atresia lack the lower portion of the vagina, but otherwise have normal pubertal maturation and external genitalia (Fig. 18-11). Embryologically, the urogenital sinus fails to contribute its expected caudal portion of the vagina (Simpson, 1999). As a result, the lower portion of the vagina, usually one-fifth to one-third of the total length, is replaced by 2 to 3 cm of fibrous tissue. In some individuals, however, vaginal atresia may extend to near the cervix.

Since most affected women have normal external genitalia and upper reproductive tract organs, vaginal atresia does not often become apparent until menarche. Adolescents generally present shortly after physiologic menarche with cyclic pelvic pain due to hematocolpos or hematometra. On physical examination, the hymeneal ring is normal. But proximal to the ring, only a vaginal dimple or small pouch is found. A rectoabdominal examination confirms midline organs. Additionally, sonographic or MR imaging will display upper reproductive tract organs. Of these, MR imaging is the most accurate diagnostic tool, as the length of the atresia, the amount of upper vaginal dilatation, and the presence of the cervix can be identified. Presence of the cervix in such cases distinguishes vaginal atresia

from müllerian agenesis. Laparoscopy, however, is often necessary when anatomy cannot be fully evaluated with radiographic studies. Treatment follows that for müllerian agenesis (p. 420).

### Cervical Agenesis

Because of the common müllerian source, women with congenital absence of the cervix typically also lack the upper vagina. The uterus, however, usually develops normally (see Fig. 18-11). In addition to agenesis, Rock (2010) has described various forms of cervical dysgenesis.

Women with cervical agenesis initially present similarly to patients with other reproductive tract obstructive anomalies, that is, with primary amenorrhea and cyclic abdominal or pelvic pain. If a functional endometrium is present, a patient may have a distended uterus, and endometriosis may have developed secondary to retrograde menstrual flow. A single midline uterine fundus is the norm, although bilateral hemiuteri have also been described (Dillon, 1979).

Radiographic studies, sonography, and MR imaging aid anatomy delineation. If imaging demonstrates an obstructed uterus, hysterectomy has been recommended by some (Rock, 1984). In contrast, Niver (1980) and others report creation of

an epithelialized endocervical tract and vagina. Significant morbidity, including infection, recurrent obstruction requiring hysterectomy, and death due to sepsis, however, has been reported with establishment of such a vaginal-uterine connection (Casey, 1997; Rock, 2010). Alternatively, conservative management with GnRH antagonists or agonists or with combination oral contraceptive pills may be used to suppress retrograde menses and possible endometriosis until a patient is ready for reproduction options (Doyle, 2009). Thus, the uterus may be retained for possible reproductive potential. Tjissen and associates (1990) reported a successful pregnancy using zygote intrafallopian tube transfer in a patient with cervical agenesis. Gestational surrogacy offers another viable option for these women.

### Müllerian Agenesis

Congenital absence of both the uterus and vagina is termed müllerian aplasia, müllerian agenesis, or Mayer-Rokitansky-Küster-Hauser syndrome (MRKHS). In classic müllerian agenesis, patients have a shallow vaginal pouch, measuring only 1 to 2 inches deep. In addition, the uterus, cervix, and upper part of the vagina are absent. Typically, normal ovaries persist, given their separate embryonic source, and a portion of the distal fallopian tubes is present. Most patients with müllerian agenesis have only small rudimentary müllerian bulbs without endometrial activity. However, in 2 to 7 percent of women with this condition, active endometrium develops and patients typically present with cyclic abdominal pain (American College of Obstetricians and Gynecologists, 2009). Surgical excision of symptomatic rudimentary bulbs is required. With müllerian agenesis, traditional conception is impossible, but pregnancy may be achieved using oocyte retrieval, fertilization, and gestational surrogacy.

Evaluation for associated congenital renal or other skeletal anomalies is essential in individuals with müllerian hypoplasia or agenesis. As noted, approximately 15 to 36 percent of women with uterine agenesis also have defects of the urinary system, and 12 percent may have scoliosis. Skeletal malformations observed include spina bifida, sacralization (partial fusion of L5 to the sacrum), sacral bone lumbarization (nonfusion of the first and second sacral segments), and cervical vertebral anomalies. As noted earlier, MURCS syndrome displays müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia (Oppelt, 2006). Cardiac malformations and neurologic disturbances play a lesser role and include ventricular septal defects and unilateral hearing problems. Fifty to 60 percent of women with müllerian agenesis have secondary malformations and thus are regarded as having a complex multiorgan and multisystem syndrome.

**Treatment.** One treatment goal for most of these women is creation of a functional vagina. This may be accomplished conservatively or surgically. There are several conservative approaches, and each attempts to progressively invaginate the vaginal dimple to create a canal of adequate size. Graduated hard glass dilators were initially recommended by Frank (1938). Ingram (1981) modified the Frank method by affixing the dilators to a bicycle seat mounted upon a stool. This affords patients hand mobility for other activities during the 30 minutes to 2 hours spent each day for passive dilation (American

College of Obstetricians and Gynecologists, 2009). Currently, firm silicon dilators are available through several medical vendors. A vagina may also be created with repeated coitus. Overall, vaginal dilatation techniques are successful in forming a functional vagina in as many as 90 percent of cases (Croak, 2003; Roberts, 2001).

Surgical procedures are seen by many as a more immediate solution to creation of a neovagina, and several methods have been reported. The method used most commonly by gynecologists is the McIndoe vaginoplasty (McIndoe, 1950). As illustrated in Section 43-25 (p. 985), a canal is created within the connective tissue between the bladder and rectum. A split-thickness skin graft obtained from the patient's buttocks or thigh is then used to line the neovagina.

Modifications of the McIndoe procedure include substitution of buccal mucosa, human amnion, or absorbable adhesion barriers as the neovaginal lining (Ashworth, 1986; Lin, 2003; Motoyama, 2003). Similarly, cutaneous or musculocutaneous flaps have been employed to line the neovagina (Williams, 1964). Also, the Davydov procedure pulls pelvic peritoneum from the pelvis into the newly created vaginal space and then to the introitus. However, bladder and ureteric injuries and vesicovaginal fistula are potential complications (Davydov, 1969).

All of these methods require a commitment to scheduled postoperative dilatation to avoid significant vaginal stricture (Breech, 1999). Accordingly, these procedures should be considered only if the patient is mature and willing to adhere to a postoperative regimen of regular intercourse or manual dilatation with dilators.

To avoid these postoperative requirements, pediatric surgeons more frequently use a segment of bowel to create the vagina. These colpoplasties most commonly use sigmoidal or ileal segments and require abdominal entry and bowel anastomosis. Many patients complain of a persistent vaginal discharge from the gastrointestinal mucosa. Kapoor (2006) reported on 14 such sigmoid vaginoplasties and noted good cosmetic results and no cases of colitis, stenosis, or excessive mucus.

Alternatively, the Vecchietti procedure uses an initial abdominal surgery to create an apparatus for passive vaginal dilatation. A synthetic sphere, attached to two wires, is placed in the vaginal dimple. The wires are guided through the potential neovaginal space and into the peritoneal cavity, and then exit onto the anterior abdominal wall. The wires are placed on continuous tension, which is increased daily to stretch the blind vaginal pouch (Vecchietti, 1965).

To address uterine agenesis, uterine transplantation from a deceased donor has been described and entailed uterine harvest and revascularization. The donor uterus was supplied by its uterine and internal iliac vessels, which were anastomosed to the recipient's external iliac vessels (Ozkan, 2013). This patient with MRKH syndrome resumed menses, conceived following in vitro fertilization, but failed to sustain the gestation (Erman Akar, 2013). More work is likely to come in this area of research.

### ■ Unicornuate Uterus

Failure of one müllerian duct to develop and elongate results in a unicornuate uterus. This anomaly is common, and Zanetti

(1978) found an incidence of 14 percent in a series of 1160 uterine anomalies. With unicornuate uterus, a functional uterus, normal cervix, and normal round ligament and fallopian tube are found on one side. On the contralateral side, müllerian structures develop abnormally, and agenesis or more frequently a rudimentary uterine horn is identified. A rudimentary horn may communicate or more commonly not communicate with the unicornuate uterus. In addition, the endometrial cavity of the rudimentary horn may be obliterated or may contain some functioning endometrium. Active endometrium in a noncommunicating horn will eventually be symptomatic with cyclic unilateral pain and possibly with hematometra.

Women with a unicornuate uterus have an increased incidence of infertility, endometriosis, and dysmenorrhea (Fedele, 1987, 1994; Heinonen, 1983). On physical examination, the uterus is often markedly deviated, but imaging is frequently needed to further define horn anatomy (p. 418). In addition, renal sonography is performed, as 40 percent of women with a unicornuate uterus also have some degree of renal agenesis, usually ipsilateral to the anomalous side (Rackow, 2007). If anatomy is unclear, then MR imaging is selected to add information.

Women with unicornuate uterus have impaired pregnancy outcomes. A review of studies reveals a spontaneous abortion rate of 36 percent, a preterm delivery rate of 16 percent, and a live birth rate of 54 percent (Rackow, 2007). Other obstetric risks include malpresentation, fetal-growth restriction, fetal demise, and prematurely ruptured membranes (Chan, 2011; Reichman, 2009).

The pathogenesis of pregnancy loss associated with unicornuate uterus is incompletely understood, but reduced uterine capacity or anomalous distribution of the uterine artery has been suggested (Burchell, 1978). Moreover, cervical incompetence may contribute to the risk for premature delivery and second-trimester abortion. Accordingly, a unicornuate uterus is suspected in any woman with a history of pregnancy loss, premature delivery, or abnormal fetal lie.

No surgeries are currently available to enlarge the unicornuate uterus cavity. Some obstetricians recommend prophylactic cervical cerclage, but adequate trials assessing outcome are lacking. Selection of a gestational surrogate may circumvent these anatomic limitations. Other patients, however, seem to carry their pregnancies longer with each subsequent gestation and may eventually reach fetal viability prior to labor.

Pregnancy may also occur in the rudimentary horn. In noncommunicating horns, this is thought to result from the intraabdominal transit of sperm from the contralateral fallopian tube. Pregnancy in a cavitary horn regardless of communication is associated with a high rate of uterine rupture, typically prior to 20 weeks (Rolen, 1966). Because of the high maternal morbidity secondary to intraperitoneal hemorrhage, preconceptual excision of a cavitary rudimentary horn is reasonable (Heinonen, 1997; Nahum, 2002). With a rudimentary horn pregnancy, excision is indicated. Laparotomy is typical, but laparoscopy is feasible with suitable skills and well-selected cases (Kadan, 2008; Spitzer, 2009).

If the rudimentary horn is obliterated, removal is not routinely recommended. Salpingectomy or salpingo-oophorectomy on the side with the rudimentary horn, however, has been

suggested to prevent ectopic pregnancy in women with a unicornuate uterus, although the ectopic pregnancy risk is low.

## ■ Uterine Didelphys

A didelphic uterus results from failed fusion of the paired müllerian ducts. This anomaly is characterized by two separated uterine horns, each with an endometrial cavity and uterine cervix. A longitudinal vaginal septum runs between the two cervices in most cases. Heinonen (1984) reported that all 26 women with uterine didelphys in his series had a longitudinal vaginal septum. Occasionally, one hemivagina is obstructed by an oblique or transverse vaginal septum (see Fig. 18-10) (Hinckley, 2003).

Uterine didelphys should be suspected if a longitudinal vaginal septum or if two separate cervices are discovered. Imaging is recommended to confirm the diagnosis as outlined on page 418.

Pregnancies develop in one of the two horns, and of the major uterine malformations, the didelphic uterus has a good reproductive prognosis. Compared with the unicornuate uterus, although the potential for uterine growth and capacity appears similar, uterine didelphys probably has an improved blood supply from collateral connections between the two horns. Alternatively, improved fetal survival may be secondary to earlier diagnosis, which favors earlier and more intensive prenatal care (Patton, 1994). Heinonen (2000) followed 36 women with uterus didelphys long term and found that 34 of 36 women (94 percent) who wanted to conceive had at least one pregnancy, and they produced 71 pregnancies. Of these pregnancies, 21 percent were spontaneously aborted, and 2 percent were ectopic. The rate for fetal survival was 75 percent; for prematurity, 24 percent; for fetal-growth restriction, 11 percent; for perinatal mortality, 5 percent; and for cesarean delivery, 84 percent. In this series, pregnancy located more often (76 percent) in the right horn than in the left. Because the spontaneous abortion rate mirrors that of women with normal uterine cavities, surgical procedures in response to pregnancy loss are rarely indicated. Thus, surgery should be reserved and only considered for highly selected patients in whom repeated late-trimester losses or premature delivery has occurred with no other apparent etiology.

## ■ Bicornuate Uterus

This anomaly is caused by incomplete fusion of the müllerian ducts. It is characterized by two separate but communicating endometrial cavities and a single uterine cervix. Failed fusion may extend to the cervix, resulting in a complete bicornuate uterus, or may be partial, causing a milder abnormality. Women with a bicornuate uterus can expect reasonable success—approximately 60 percent—in delivering a living child. As with many uterine anomalies, premature delivery is a substantial obstetric risk. Heinonen and colleagues (1982) reported a 28-percent abortion rate and a 20-percent incidence of premature labor in women with a partial bicornuate uterus. Women with a complete bicornuate uterus had a 66-percent incidence of preterm delivery and a lower fetal survival rate.

Radiologic discrimination of bicornuate uterus from the septate uterus can be challenging, however, it is important

**FIGURE 18-12** Strassman metroplasty is one of several techniques of bicornuate uterus repair. **A.** Excision of intervening uterine wall. **B.** Reapproximation of posterior uterine wall with a layer of myometrial sutures. **C.** Reapproximation of the anterior wall is closed similarly. Following placement of myometrial sutures, a layer of subserosal sutures is placed in the anterior and posterior walls.

because septate uterus is easily treated with hysteroscopic septal resection. Widely diverging horns seen on HSG may suggest a bicornuate uterus. An intercornual angle  $> 105$  degrees suggests bicornuate uterus, whereas one  $< 75$  degrees indicates a septate uterus. However, MR imaging is necessary to define fundal contour. With this, an intrafundal downward cleft measuring  $\geq 1$  cm is indicative of bicornuate uterus, whereas a cleft depth  $< 1$  cm indicates a septate uterus. Use of 3-D sonography also allows internal and external uterine assessment. Thus, sonography and HSG seem acceptable imaging techniques in the initial investigation. When the presumptive diagnosis is a septate uterus, laparoscopy may be performed for a definitive diagnosis and before hysteroscopic resection of the septum is initiated.

Surgical reconstruction of the bicornuate uterus is infrequently done but has been advocated in women with multiple spontaneous abortions in whom no other causative factors are identified. Strassman (1952) described the surgical technique that unified equal-sized endometrial cavities (Fig. 18-12). Reproductive outcome after unification generally has been good. In 289 women, preoperative pregnancy loss was more than 70 percent. Following surgery, more than 85 percent of pregnancies resulted in delivery of a viable infant. The actual benefit of metroplasty for a bicornuate uterus, however, has not been tested in a controlled clinical series. As in surgery for uterine didelphys, metroplasty is reserved for women in whom recurrent pregnancy loss occurs with no other identifiable cause.

### ■ Septate Uterus

Following fusion of the müllerian ducts, failure of their medial segments to regress can create a permanent septum within the uterine cavity. Its contours can vary widely and depend on the amount of persistent midline tissue. The septum can project minimally from the uterine fundus or can extend completely to the cervical os. Moreover, septa can develop segmentally, resulting in partial communications of the partitioned uterus (Patton, 1994). The histologic structure of septa ranges from fibrous to fibromuscular.

The true incidence of these anomalies is not known because they are usually detected only in women with obstetric complications. Although this defect does not predispose to increase rates of preterm labor or cesarean delivery, septate uterus is associated

with a marked increase in spontaneous abortion rates (Heinonen, 2006). Woelfer and associates (2001) reported a first-trimester spontaneous abortion rate for septate uterus of 42 percent. Moreover, early pregnancy loss is significantly more common with a septate than with a bicornuate uterus (Proctor, 2003).

The extraordinarily high pregnancy wastage likely results from partial or complete implantation on a largely avascular septum, from distortion of the uterine cavity, and from associated cervical or endometrial abnormalities. Based on operative experience for septal defects, the blood supply to the fibromuscular septum appears markedly reduced compared with normal myometrium. In addition to spontaneous abortion, septate uterus may rarely cause fetal malformation, and Heinonen (1999) described three newborns with a limb-reduction defect born to women with septate uterus.

Diagnosis of the septate uterus follows guidelines established for the bicornuate uterus and includes HSG and/or sonography. Historically, abdominal metroplasty for septate uterus was shown to dramatically decrease fetal wastage and ultimately improve fetal survival rates (Rock, 1977; Blum, 1977). Two main disadvantages to metroplasty include the requirement of cesarean delivery to prevent uterine rupture in subsequent pregnancy and the high rate of postoperative pelvic adhesion formation and subsequent infertility.

Currently, hysteroscopic septum resection is an effective and safe alternative to treat women with septate uterus (Section 44-17, p. 1048). Typically, operative hysteroscopy is combined with concurrent laparoscopic surveillance to reduce the risk of uterine perforation. After the initial case reports by Chervenak and Neuwirth (1981), many investigators have confirmed satisfactory live birth rates with the procedure (Daly, 1983; DeCherney, 1983; Israel, 1984). In a retrospective review, Faye (1986) evaluated reproductive outcome in women who had either an abdominal metroplasty or hysteroscopic septoplasty. They noted an 87-percent live birth rate in the hysteroscopic group compared with a 70-percent rate in the abdominal group. Similarly, Daly and associates (1989) reported impressive results after hysteroscopic surgery. Proponents of hysteroscopic resection describe reduced rates of pelvic adhesions, shortened postoperative convalescence, lowered operative morbidity, and avoidance of mandatory cesarean delivery (Patton, 1994).

## ■ Arcuate Uterus

An arcuate uterus displays only mild deviation from normal uterine development. Anatomic hallmarks include a slight mid-line septum within a broad fundus, sometimes with minimal fundal cavity indentation. Most clinicians report no impact on reproductive outcomes. Conversely, Woelfer and colleagues (2001) found excessive second-trimester losses and preterm labor. Surgical resection is indicated only if excessive rates of pregnancy loss are encountered and other etiologies for recurrent spontaneous abortion have been excluded.

## ■ Diethylstilbestrol-Induced Reproductive Tract Abnormalities

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed to an estimated 3 million pregnant women in the United States from the late 1940s through the early 1960s. Early reports claimed the drug was useful in treating abortion, preeclampsia, diabetes, hot flushes, and preterm labor (Massé, 2009). It was ineffective for these indications. Almost 20 years later, Herbst and coworkers (1971) found that DES exposure in utero was linked to the development of a “T-shaped” uterus and an increased incidence of clear cell adenocarcinomas of the vagina and cervix. The risk of this vaginal malignancy approximates 1 in 1000 exposed daughters. Daughters also have increased risks of developing vaginal and cervical intraepithelial neoplasia, suggesting that DES exposure could affect gene regulation (Herbst, 2000). DES has also been shown to suppress the *WNT4* gene and alter *Hox* gene expression in mouse müllerian ducts. This provides a plausible molecular mechanism for the uterine abnormalities, vaginal adenosis, and rarely, carcinoma observed in exposed patients (Massé, 2009).

During normal development, the vagina is originally lined by a glandular epithelium derived from the müllerian ducts. By the end of the second trimester, this layer is replaced by squamous epithelium extending up from the urogenital sinus. Failure of the squamous epithelium to completely line the vagina is termed adenosis. Although variable, it typically appears red, punctate, and granular. Common symptoms include vaginal irritation, discharge, and metrorrhagia—in particular, postcoital bleeding. Moreover, adenosis is frequently associated with vaginal clear cell adenocarcinoma.

Genitourinary malformations following DES exposure in utero have also been noted and include those of the cervix, vagina, uterine cavity, and fallopian tubes. Transverse septa, circumferential ridges involving the vagina and cervix, and cervical collars (“cockscomb cervix”) have been found. Women with cervicovaginal abnormalities are more likely to have uterine anomalies, such as smaller uterine cavities, shortened upper uterine segments, and “T-shaped” and irregular cavities (Barranger, 2002). Fallopian tube abnormalities include shortened and narrowed dimensions and absent fimbria.

Males exposed to DES in utero also have structural abnormalities. Cryptorchidism, testicular hypoplasia, microphallus, and hypospadias have been reported (Hernandez-Diaz, 2002).

Women exposed to DES, in general, have impaired conception rates (Senekjian, 1988). Reduced fertility in these women is poorly understood but is associated with cervical hypoplasia

and atresia. Of those who do conceive, the incidences of spontaneous pregnancy loss, ectopic pregnancy, and preterm delivery are increased, again particularly in those with associated structural abnormalities (Goldberg, 1999). Now, more than 50 years after DES use was proscribed, most affected women are past childbearing age, but higher rates of earlier menopause and breast cancer have been reported (Hatch, 2006; Hoover, 2011).

## FALLOPIAN TUBE ANOMALIES

The fallopian tubes develop from the unpaired cephalad ends of the müllerian ducts. Congenital anomalies of the fallopian tube include accessory ostia, complete or segmental absence of the fallopian tube, and several embryonic cystic remnants. The remnants of the mesonephric duct in the female include a few blind tubules, the *epoophoron*, in the mesovarium, and similar ones, collectively called the *paroophoron*, adjacent to the uterus (see Fig. 18-2F) (Moore, 2013). The epoophoron or paroophoron may develop into clinically identifiable cysts.

Remnants of the müllerian duct may be found along its embryologic course. The most common is a small, blind cystic structure attached by a pedicle to the distal end of the fallopian tube, the hydatid of Morgagni (Zheng, 2009).

Paratubal cysts are frequent incidental discoveries during gynecologic operations for other abnormalities or are found on sonographic examination (Chap. 9, p. 223). They may be of mesonephric, paramesonephric, or mesothelial origin. Most cysts are asymptomatic and slow growing and are discovered during the third and fourth decades of life.

In utero exposure to DES has been associated with various tubal abnormalities. Short, tortuous tubes or ones with shriveled fimbria and small ostia have been linked to infertility (DeCherney, 1981).

## OVARIAN ANOMALIES

A *supernumerary ovary* is an ectopic ovary that has no connection with the broad, uteroovarian, or infundibulopelvic ligaments (Wharton, 1959). This rare gynecologic anomaly may be located in the pelvis, retroperitoneum, paraaortic area, colonic mesentery, or omentum. Aberrant migration of part of the genital ridge after incorporation of germ cells describes one theory (Printz, 1973).

In contrast, the term *accessory ovary* describes excess ovarian tissue nearby and connected to a normally placed ovary. Wharton (1959) estimated that both accessory ovary and supernumerary ovary were rare, finding approximately 1 case of accessory ovary in 93,000 patients and 1 case of supernumerary ovary in 29,000 autopsies. In Wharton’s review, 3 of 4 patients with supernumerary ovary and 5 of 19 patients with accessory ovary had additional congenital defects, most frequently involving the genitourinary tract.

An absent ovary, with or without an associated tube, may result from congenital agenesis or from ovarian torsion with necrosis and reabsorption (Eustace, 1992; James, 1970). The incidence has been suggested to be approximately 1 in 11,240 women (Sivanesaratnam, 1986).

## CHAPTER 19

# Evaluation of the Infertile Couple

ETIOLOGY OF INFERTILITY.....	428
MEDICAL HISTORY.....	428
PHYSICAL EXAMINATION.....	433
EVALUATION FOR ANOVULATION.....	433
EVALUATION FOR DIMINISHED OVARIAN RESERVE.....	435
EVALUATION FOR FEMALE ANATOMIC ABNORMALITIES.....	437
EVALUATION OF MALE INFERTILITY.....	442
CONCLUSION.....	445
REFERENCES.....	446

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse of reasonable frequency. It can be subdivided into *primary infertility*, that is, no prior pregnancies, and *secondary infertility*, referring to infertility following at least one prior conception.

Conversely, fecundability is the ability to conceive, and data from large population studies show that the monthly probability of conceiving is 20 to 25 percent. In those attempting conception, approximately 50 percent of women will be pregnant at 3 months, 75 percent will be pregnant at 6 months, and more than 85 percent will be pregnant by 1 year (Fig. 19-1) (Guttmacher, 1956; Mosher, 1991).

Infertility is common and affects 10 to 15 percent of reproductive-aged couples. Of note, even without treatment, approximately half of women will conceive in the second year of attempting. According to the National Survey of Family Growth, the percentage of married women who reported infertility fell from 8.5 percent in 1982 to 6.0 percent in 2006 to 2010. In comparison, the percentage of women aged 15 to 44 years who had ever used infertility services increased from 9 percent in 1982 to 12 percent in 2002, with a peak of 15 percent in 1995 (Chandra, 2013, 2014). Interpretation of these data is complicated by ongoing changes in marriage rates, intentional delays in childbearing, and socioeconomic and educational status changes in a growing immigrant community. Nevertheless, well-publicized successes in infertility treatment now give patients greater hope that medical intervention will help them achieve their goal.

Most couples are more correctly considered to be *subfertile*, rather than infertile, as they will ultimately conceive if given enough time. The concept of subfertility can be reassuring to couples. However, there are obvious exceptions, such as the woman with bilaterally obstructed fallopian tubes or the azoospermic male. In general, infertility evaluation is for any couple that has failed to conceive in 1 year. But, several scenarios may prompt earlier intervention. For example, to delay assessment in an anovulatory woman or a woman with a history of severe pelvic inflammatory disease (PID) may not be appropriate. Of particular note, fecundability is highly age-related, with a significant decrease beginning at approximately 32 years of age and more rapid decline after age 37 (American Society for Reproductive Medicine, 2014a). The decline in conception rates is associated with an increase in poor pregnancy outcomes, primarily due to increased aneuploidy rates. Thus, most experts agree that evaluation is considered after only 6 months in women older than 35 years.

Prior to initiating infertility treatment, a patient's health status must be optimized for an anticipated pregnancy. Ideally, these issues are addressed prior to referral to an infertility specialist whenever possible. Topics include appropriate vaccination; screening for diabetes, infectious diseases, or genetic disorders; folic acid supplementation; weight reduction; and cessation of cigarette smoking or illicit drug use. Additional information is provided later in this chapter and in Table 1-17 (p. 18).

**FIGURE 19-1** Time required for conception.

ETIOLOGY OF INFERTILITY

Successful pregnancy requires a complex sequence that includes ovulation, ovum pick-up by a fallopian tube, fertilization, transport of a fertilized ovum into the uterus, and implantation into a receptive uterine cavity. In the male system, sperm of adequate number and quality must be deposited at the cervix near the time of ovulation. Remembering these critical events can aid in developing an appropriate evaluation and treatment strategy.

In general, infertility can be attributed to the female partner one third of the time, the male partner one third of the time, and both partners in the remaining one third. This approximation emphasizes the value of assessing both partners before instituting therapy. Although a complete investigation may not be required before instituting therapy if a clear etiology is present, strong consideration is given to finishing testing if pregnancy is not rapidly achieved. Estimates of the incidence of various causes of infertility are shown in Table 19-1 (Abma, 1997; American Society for Reproductive Medicine, 2006).

Both partners are urged to attend the initial consultation. This time provides an excellent opportunity to educate regarding the normal conception process and methods to optimize their natural fertility. Such efforts may obviate the need for expensive and time-consuming interventions (American Society for Reproductive Medicine, 2013a). Couples are informed of the concept of a fertile window for conception. The chance of conception is increased from the 5 days preceding ovulation through the day of ovulation (Wilcox, 1995). If the male partner has normal semen characteristics, a couple ideally has daily intercourse during this period to maximize the chance of conception. Although sperm concentrations will drop with increasing coital frequency, this decrease is generally too small to significantly lower the chance of fertilization (Stanford, 2002). Couples are also reminded to avoid oil-based lubricants, which are harmful to sperm. Many myths surround the ability to conceive. Examples, such as the importance of coital position and the need to remain horizontal following ejaculation, can add undue stress to an already stressful situation and should be dispelled.

MEDICAL HISTORY

Female History

Gynecologic

As with any medical condition, a thorough history and physical examination is critical (American Society for Reproductive

Medicine, 2012a). Specifically, questions cover menstruation (frequency, duration, recent change in interval or duration, hot flushes, dysmenorrhea), prior contraceptive use, coital frequency, and infertility duration. Previous endometriosis, recurrent ovarian cysts, leiomyomas, sexually transmitted diseases, or PID is also pertinent. Because prior conception indicates ovulation and a patent fallopian tube in the patient's past, this history is sought. A prolonged time to conception may suggest borderline fertility and may increase the chance of determining an etiology. Pregnancy complications such as miscarriage, preterm delivery, retained placenta, postpartum dilatation and curettage, chorioamnionitis, or fetal anomalies are also recorded. Prior abnormal Pap testing may be relevant, particularly if a woman underwent cervical conization, which can diminish cervical mucus and cervical competence. A coital history, including frequency and timing of intercourse, is also obtained. Symptoms such as dyspareunia may point to endometriosis and a need for earlier diagnostic laparoscopy for the female partner.

Medical and Surgical

During medical history inventory, symptoms of hyperprolactinemia or thyroid disease are sought. Symptoms of androgen excess such as acne or hirsutism may point to polycystic ovarian syndrome (PCOS) or much less commonly, congenital adrenal hyperplasia. Prior chemotherapy or pelvic irradiation may suggest ovarian failure. This is also an excellent opportunity to ensure that all indicated vaccinations are current, as several are contraindicated once pregnancy is achieved (American Society for Reproductive Medicine, 2013d). Vaccine indications and schedules are found in Table 1-2 (p. 8).

Questions regarding medications include over-the-counter agents, such as nonsteroidal antiinflammatory drugs, that may adversely affect ovulation. In most instances, herbal remedies are discouraged. Women are encouraged to take a daily vitamin with at least 400 µg of folic acid to decrease the chance of neural-tube defects. In those with a previously affected child, 4 g is taken orally daily (American College of Obstetricians and Gynecologists, 2014b).

Previous pelvic and abdominal surgeries, especially if linked to endometriosis or adhesion formation, can lower fertility. As examples, operations for ruptured appendicitis or diverticulitis raise suspicion for pelvic adhesive disease or tubal obstruction or both. Prior uterine surgery can predispose to pain, bowel obstruction, or extra- or intrauterine adhesions with resultant infertility. When planning surgery, reducing adhesion formation is a priority, and meticulous surgical technique and minimally invasive surgical approaches are favored. Surgical adhesion barriers, described in Chapter 11 (p. 261), lower postoperative adhesion rates. However, no strong evidence exists that their use improves fertility, decreases pain, or lowers bowel obstruction rates (American Society for Reproductive Medicine, 2013b).

Social

A social history focuses on lifestyle factors such as eating habits. Abnormalities in gonadotropin-releasing hormone (GnRH) and gonadotropin secretion are clearly related to body mass

TABLE 19-1. Etiology of Infertility

Male	25%
Ovulatory	27%
Tubal/uterine	22%

indices > 25 or < 17 (Grodstein, 1994a). An estimated 30 to 50 percent of women, depending on race and ethnicity, are overweight or obese. Most agree that this incidence is increasing (American Society for Reproductive Medicine, 2008c; Hedley, 2004). In these women, infertility is primarily related to an increased incidence of ovulatory dysfunction, but data also suggest that fecundity is lower among ovulatory obese women. Although difficult to achieve, even modest weight reduction in overweight women is correlated with normalized menstrual cycles and subsequent pregnancies (Table 19-2).

Accumulating data also suggest that cigarette smoking lowers fertility rates (American Society for Reproductive Medicine, 2012d). At least one fifth of reproductive-aged men and women in the United States smoke cigarettes (Centers for Disease Control and Prevention, 2014). The prevalence of infertility is higher, and the time to conception is longer in women who smoke, or even those exposed passively to cigarette smoke. Moreover, smoking's negative effects on female fecundity do not appear to be overcome by assisted reproductive technologies (ART). A 5-year prospective study of 221 couples found that the risk of failing to conceive with ART was more than doubled in smokers. Each year that a woman smoked was associated with a 9-percent increase in the risk of unsuccessful ART cycles (Klonoff-Cohen, 2001).

Toxins in the smoke can accelerate follicular depletion and increase genetic mutations in gametes or early embryos (Zenzes, 2000). Smoking is associated with an increased miscarriage rate in both natural and assisted conception cycles. The mechanism for this is unclear, but the vasoconstrictive and antimetabolic properties of some cigarette smoke components such as nicotine, carbon dioxide, and cyanide may lead to placental insufficiency. Specifically, smoking has been linked to higher rates of abortion, fetal growth restriction, and preterm labor (Cunningham, 2014). In addition, smoking in pregnant women is associated with an increased risk of trisomy 21 that results from maternal meiotic nondisjunction (Yang, 1999). Admittedly, current data do not prove causation, but only correlation, between smoking and infertility or adverse pregnancy outcomes.

The effect of smoking on male fertility is more difficult to discern. Although smokers often have comparatively reduced

**TABLE 19-3.** Women's Awareness of Health Risks Associated with Smoking

Smoking Risk	Percentage Aware of Risk
Respiratory disease	99%
Heart disease	96%
Pregnancy complications	91%

sperm concentrations and motility, these often remain within the normal range.

Smoking is discouraged for both male and female partners planning pregnancy. The desire for pregnancy can be a powerful motivator toward cessation (Augood, 1998). Education is the most important first step (Table 19-3). If behavioral approaches fail, use of medical adjuncts such as nicotine replacement therapy, bupropion (Zyban), or varenicline (Chantix) may prove effective (Table 1-4, p. 11). Nicotine preparations are designated as category D. Bupropion and varenicline are non-nicotine Food and Drug Administration (FDA)-approved agents and carry a category C designation (Fiore, 2008). Ideally pharmacological smoking cessation therapies are best used prior to conception.

Alcohol consumption also should be limited. Heavy alcohol intake decreases fertility in women, and in men has been associated with a decrease in sperm counts and increase in sexual dysfunction (Klonoff-Cohen, 2003; Nagy, 1986). A standardized alcoholic drink is typically defined as 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of hard alcohol. Based on several studies, five to eight drinks per week negatively affects female fertility (Grodstein, 1994b; Tolstrup, 2003). As alcohol is also detrimental to early pregnancy, it is prudent to advise patients to avoid excessive alcohol consumption while trying to conceive.

Caffeine is one of the most widely used pharmacologically active substances in the world. Studies evaluating a potential relationship between caffeine and impaired fertility have varied in design and resulted in conflicting findings. One large prospective trial found no association between either total caffeine intake or coffee consumption and fecundability (Hatch, 2012). Despite this, recommendations of caffeine intake moderation in infertile women seem prudent.

Illicit drugs may also affect fecundability. Marijuana suppresses the hypothalamic-pituitary-gonadal axis in both men and women, and cocaine can impair spermatogenesis (Bracken, 1990; Smith, 1987).

### Environmental Factors

Increasing information suggests that some male and female infertility may result from environmental contaminants or toxins

(Giudice, 2006). Endocrine-disrupting chemicals (EDCs) have been shown to be reproductive toxicants. Examples are dioxins and polychlorinated biphenyls, as well as agricultural pesticides and herbicides, phthalates (used in making plastic materials), lead, and bisphenol A (used in the manufacture of polycarbonate plastic and resins) (Hauser, 2008; Mendola, 2008). EDC exposure is implicated to underlie a broad range of women's reproductive disorders. Lower fecundability and lower birthweight show the most solid evidence for this correlation (Caserta, 2011). Although direct links to infertility in humans are not conclusive, clinicians should counsel patients that environmental exposures to toxic substances should be avoided if possible. Currently, these cautions should be discussed carefully to avoid alarm.

### Ethnicity and Family History

The ethnic background and family history of both partners influences the need for preconceptional testing. A family history of infertility, recurrent miscarriage, or fetal anomalies may point to a genetic etiology. Although the inheritance pattern is complex, data suggest that both PCOS and endometriosis occur in familial clusters. For example, a woman carries an estimated sevenfold increased risk of endometriosis over that of the general population if a single first-degree family member has the disease (Moen, 1993).

Genetic carrier screening can be offered preconceptionally or following conception. Testing before conception is often more straightforward and less stressful for the couple than delaying until pregnancy has been achieved. However, insurance carriers may decline to reimburse for this evaluation (American Academy of Pediatrics and American College of Obstetricians and Gynecologists, 2012). Preconception carrier screening also allows a couple to consider the most complete range of reproductive options. Knowing the risk of having an affected child, a couple may consider preimplantation genetic diagnosis, prenatal genetic testing, or the use of donor gametes (American College of Obstetricians and Gynecologists, 2014e). In the absence of known family history of genetic disease, it is reasonable to offer genetic carrier screening to the woman first and test the male partner only if the mother has positive results.

Specific recommendations for genetic carrier screening have been published by the American College of Obstetricians and Gynecologists (2009, 2014a,c,d), by the American College of Medical Genetics and Genomics, and by other advocacy groups and societies (Grody, 2013; Gross, 2013; Pletcher, 2006). These opinions have changed over time and continue to vary across organizations. No doubt, screening guidelines will continue to evolve as technology advances and the costs and benefits of obtaining this information become more evident. Certain disorders are more common in specific ethnic groups, although it is essential to note that there are no disorders found uniquely in a certain ethnic or racial group. Many families may be interracial and ethnic background may be unknown. For example, cystic fibrosis screening was initially recommended only for the non-Hispanic white population and those of Ashkenazi Jewish descent. However, this recommendation now extends to all individuals to account for increased numbers of

individuals with mixed ethnicity and inaccuracies based on personal reporting (Ross, 2011; Tanner, 2014).

Traditional genotyping methods detect a limited number of mutations, and these tests have been developed to be specific for the more common mutations found in the ethnic group most at risk. Expanded genotyping panels have been developed but are costly and remain limited. More recently, the cost of DNA sequencing has been greatly reduced due to the emergence of next-generation sequencing (NGS) techniques (Hallam, 2014). This allows rapid and efficient testing of many genes and thousands of mutations concurrently. Panethnic population screening by NGS for numerous genetic disorders is now technically feasible. Given that a large number of sequence variants might be identified by NGS that are not disease causing, rigorous analytic and clinical validation is required before widespread clinical application is begun (Prior, 2014).

### Male History

Similar attention is paid to assessing the male partner's potential contribution to infertility (American Society for Reproductive Medicine, 2012b). Questions include abnormalities in pubertal development and sexual function. Erectile dysfunction, particularly in conjunction with decreased beard growth, may suggest decreased testosterone levels. Ejaculatory problems are also evaluated, including a search for developmental anomalies such as hypospadias, which could result in suboptimal semen deposition (Benson, 1997).

Sexually transmitted diseases or frequent genitourinary infections, including epididymitis or prostatitis, may lead to vas deferens inflammation and obstruction. Similarly, mumps in an adult can create testicular inflammation and damage spermatogenic stem cells (Beard, 1977). Prior cryptorchidism, testicular torsion, or testicular trauma may suggest abnormal spermatogenesis (Anderson, 1990; Cobellis, 2014). Compared with fertile males, males with unilateral or bilateral cryptorchidism have fertility rates of 80 percent and 50 percent, respectively (Lee, 1993). The reason for poor semen characteristics in these patients is unclear. The relatively warm intraabdominal temperature may cause permanent stem cell damage. Alternatively, genetic abnormalities that led to the abnormal testis location may also affect sperm production.

A history of varicocele is also obtained. A varicocele consists of dilated veins of the pampiniform plexus of the spermatic cords that drain the testes (Figs. 19-2 and 19-3). Varicoceles are believed to raise scrotal temperature, however, the negative effects of varicoceles on fertility are controversial (American Society for Reproductive Medicine, 2014b; Baazeem, 2011; Jarow, 2001). Although 30 to 40 percent of men seen in infertility clinics are diagnosed with a varicocele, nearly 20 percent of men in the general population are similarly affected. If a varicocele is suspected, it should be evaluated by a urologist, preferably one with a specific interest in infertility.

Spermatogenesis, from stem cell to mature sperm, takes nearly 90 days (Fig. 19-4). Thus, any detrimental event in the prior 3 months can adversely affect semen characteristics (Hinrichsen, 1980; Rowley, 1970). Spermatogenesis is optimal

**FIGURE 19-2** Male genitalia. (Reproduced with permission from McKinley M, O'Loughlin VD: Human Anatomy. New York: McGraw-Hill; 2006.)

at temperatures slightly below body temperature, hence the location of the testes outside of the pelvis. Illness with high fevers or chronic hot tub use can temporarily impair sperm quality. There is no definitive evidence that boxer underwear is advantageous.

Medical questions focus on prior chemotherapy or local radiation treatment that may damage spermatogonial stem cells. Hypertension, diabetes mellitus, and neurologic disorders can be associated with erectile dysfunction or retrograde ejaculation. Several medications are known to worsen semen characteristics,

including cimetidine, erythromycin, gentamicin, tetracycline, and spironolactone (Sigman, 1997). Moreover, obesity, cigarettes, alcohol, illicit drugs, and environmental toxins all adversely affect semen parameters (Muthusami, 2005; Ramlau-Hansen, 2007). The increasing use of anabolic steroids also decreases sperm production by suppressing the output of intratesticular testosterone (Gazvani, 1997). Although the effects of many medications are reversible, anabolic steroid abuse may lead to lasting or even permanent damage to testicular function.

## PHYSICAL EXAMINATION

### ■ Examination of the Female patient

A physical examination may provide many clues to the cause of infertility. Vital signs, height, and weight are recorded. A particularly short stature may reflect a genetic condition such as Turner syndrome. Hirsutism, alopecia, or acne indicates the need to measure androgen levels. Acanthosis nigricans is consistent with insulin resistance associated with PCOS or much less commonly, Cushing syndrome. Galactorrhea is often indicative of hyperprolactinemia. Additionally, thyroid abnormalities are sought. Many of these diagnoses and their management are discussed in greater detail in other chapters (Table 19-4).

A pelvic examination may be particularly informative. Inability to place a speculum through the introitus may raise doubts about coital frequency. The vagina should be moist and rugated, and the cervix should have a reasonable amount of mucus. Both indicate adequate estrogen production. An enlarged or irregularly shaped uterus may reflect leiomyomas, whereas a fixed uterus suggests pelvic scarring due to endometriosis or prior pelvic infection. Uterosacral nodularity or ovarian masses may additionally implicate endometriosis or less commonly, malignancy.

All women should have cervical cancer screening that is up-to-date prior to treatment. Negative cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are obtained to ensure that cervical manipulation during evaluation and treatment does not cause ascending infection. The breast examination must be

normal, and when indicated by age or family history, a mammogram is obtained prior to initiating hormonal treatment.

### ■ Examination of the Male patient

Most gynecologists will not feel comfortable performing a complete male physical examination. Nevertheless, parts of this evaluation are relatively easy to perform, and a gynecologist at minimum should understand the primary focus of the examination. As signs of testosterone production, normal secondary sexual characteristics such as beard growth, axillary and pubic hair, and perhaps male pattern balding should be present. Gynecomastia or eunuchoid habitus may suggest Klinefelter syndrome (47,XXY karyotype) (De Braekeleer, 1991).

The penile urethra should be at the glans tip for proper semen deposition in the vagina. Testicular length measures at least 4 cm and a minimal testicular volume is 20 mL (Charny, 1960; Hadziselimovic, 2006). Small testes are unlikely to produce normal sperm numbers. A testicular mass may indicate testicular cancer, which can present as infertility. The epididymis should be soft and nontender to exclude chronic infection. Epididymal fullness may suggest vas deferens obstruction. The prostate should be smooth, nontender, and normal size. Additionally, the pampiniform plexus of veins is palpated for varicocele (Jarow, 2001). Importantly, both vasa deferentia should be palpable. Congenital bilateral absence of the vas deferens is associated with mutation in the gene responsible for cystic fibrosis and is discussed on page 444 (Anguiano, 1992).

## EVALUATION FOR ANOVULATION

The infertility evaluation can be conceptually simplified into confirmation of: (1) ovulation, (2) normal female reproductive tract anatomy, and (3) normal semen characteristics. The specifics regarding evaluation of each of these categories are detailed in the following sections and shown in Table 19-5.

Of these, ovulation may be perturbed by abnormalities within the hypothalamus, anterior pituitary, or ovaries. Hypothalamic disorders may be acquired or inherited. Acquired disorders include those due to lifestyle, for example,

TABLE 19-5. Infertility Testing

Etiology	Evaluation
Ovulatory dysfunction	Ovulation predictor kit Early follicular FSH ± estradiol level (ovarian reserve) ± Antimüllerian hormone ± Serum measurements (TSH, prolactin, androgens) ± Ovarian sonography (antral follicle count)
Tubal/pelvic disease	Hysterosalpingography Laparoscopy + chromotubation
Uterine factors	Hysterosalpingography Transvaginal sonography/saline-infusion sonography ± Magnetic resonance imaging Hysteroscopy ± laparoscopy
Male factor	Semen analysis

FSH = follicle-stimulating hormone; TSH = thyroid-stimulating hormone.

excessive exercise, eating disorders, or stress. Alternatively, dysfunction or improper migration of the hypothalamic gonadotropin-releasing hormone neurons may be inherited, such as that which occurs in idiopathic hypogonadotropic hypogonadism (IHH) or Kallman syndrome. Thyroid disease and hyperprolactinemia may also contribute to menstrual disturbances. A full discussion of endocrine-related disorders that result in menstrual disturbances is found in Chapter 16 (p. 369).

Clinical Evaluation

A patient’s menstrual history is an excellent predictor of regular ovulation. A woman with cyclic menses at an interval of 25 to 35 days and duration of bleeding of 3 to 7 days is most likely ovulating. Although these numbers vary widely, each woman will have her own normal pattern. Therefore, these figures typically do not vary significantly across cycles for an individual woman.

Probable ovulation is also suggested by *mittelschmerz*, which is midcycle pelvic pain associated with ovulation, or by moliminal

symptoms such as breast tenderness, acne, food cravings, and mood changes. Ovulatory cycles are more likely to be associated with dysmenorrhea. Severe dysmenorrhea may suggest endometriosis.

*Basal body temperature (BBT)* charting has long been used to identify ovulation. This test requires that a woman’s morning oral temperature be graphically charted (Fig. 19-5). Oral temperatures are usually 97.0° to 98.0°F during the follicular phase. A postovulatory rise in progesterone levels increases basal temperature by approximately 0.4° to 0.8°F. This biphasic temperature pattern is strongly predictive of ovulation (Bates, 1990). Nevertheless, although this test has the advantage of being inexpensive, it is insensitive in many women. Furthermore, for a couple wishing to conceive, the temperature increase follows ovulation, and therefore the window of maximal fertility has been missed (Luciano, 1990). Although this method is discussed here for completeness, most patients are better served by the use of the sensitive and readily available urinary ovulation detection kits described in the next section.

FIGURE 19-5 Biphasic pattern seen on this basal body temperature chart suggests ovulation. (Reproduced with permission from Chang WY, Agarwal SK, Azziz R: Essential Reproductive Medicine. New York: McGraw-Hill; 2005.)

### ■ Ovulation predictor Kits

These kits measure urinary luteinizing hormone (LH) concentration by colorimetric assay. They are widely available in pharmacies, are relatively easy to use, and provide clear instructions regarding interpretation. In general, a woman begins testing 2 to 3 days prior to the predicted LH surge, and testing is continued daily. There is no clear consensus regarding the optimal time of day to test. Some specialists suggest that the concentrated first morning void is a logical time. Others are concerned that this sample may provide a false-positive result and recommend testing the second morning urine. Other clinicians reason that the serum LH peak occurs in the morning and that the greatest likelihood of detecting a urinary peak would be in the late afternoon or evening. Timing is probably not critical as long as the test is performed daily, as the LH surge spans only 48 to 50 hours. In most instances, ovulation will occur the day following the urinary LH peak (Luciano, 1990; Miller, 1996).

If equivocal results are obtained, the test can be repeated in 12 hours. In one study, urine LH surge assays were estimated to have 100-percent sensitivity and 96-percent accuracy. This is undoubtedly an overestimate of typical-use results (Grinstead, 1989; Guermandi, 2001).

### ■ Serum progesterone

Adequate progesterone levels are required for endometrial preparation prior to implantation. This has led to the concept of *luteal phase defect (LPD)*, defined as inadequate endometrial development due to suboptimal progesterone production (American Society for Reproductive Medicine, 2012f).

Midluteal phase serum progesterone levels have long been used to document ovulation, although the sensitivity of this test has been questioned. In a classic 28-day cycle, serum is obtained on cycle day number 21 following the first day of menstrual bleeding, or 7 days following ovulation. Levels during the follicular phase are generally < 2 ng/mL. Values above 4 to 6 ng/mL correlate with ovulation and progesterone production by the corpus luteum (Guermandi, 2001). Progesterone is secreted as pulses, and therefore a single measurement does not indicate overall production during the luteal phase. As a result, an absolute threshold for acceptable progesterone levels has not been clearly established. Although some clinicians empirically treat any woman with a progesterone level below approximately 10 ng/mL, the utility of this approach is unproven, and it is costly. Accordingly, the midluteal progesterone level is best regarded as an acceptable test for ovulation but not an absolute indicator of adequate luteal function.

### ■ Endometrial Biopsy

Luteal phase endometrial biopsy was hoped to reflect both corpus luteum function and endometrial response, and thereby provide more clinically relevant information than a serum progesterone level alone (Noyes, 1975). Unfortunately, the utility of this test is severely hampered by high intraobserver and interobserver variability during histologic evaluation. An out-of-phase biopsy is found nearly as frequently in fertile as in infertile women, and the overlap in incidence between the

two groups is large (Balasch, 1992; Scott, 1993). In its current form, the endometrial biopsy has little predictive value and is no longer considered a routine part of infertility evaluation.

Interestingly, the timing of protein expression in the endometrial glands and stroma is being defined. Potential markers for uterine receptivity include osteopontin, cytokines (leukemia inhibitory factor, colony-stimulating factor-1, and interleukin-1), cell adhesion molecules (the integrins), ion channels, and the L-selectin ligand (Carson, 2002; Garrido-Gomez, 2014; Kao, 2003; Lessey, 1998; Petracco, 2012; Ruan, 2014). In the future, endometrial biopsies may again become part of the diagnostic evaluation if expression patterns of these proteins prove to be predictive of endometrial receptivity.

### ■ Sonography

Serial ovarian sonographic evaluations can demonstrate the development of a mature antral follicle and its subsequent collapse during ovulation. This approach is time consuming, and ovulation can be missed. However, sonography is an excellent approach for supporting the diagnosis of PCOS. Sonographic criteria for PCOS are found in Chapter 17 (p. 397).

## EVALUATION FOR DIMINISHED OVARIAN RESERVE

Ovulatory status does not provide a complete picture of ovarian function. A woman may have regular, ovulatory menses but have reduced follicular response to ovarian stimulation compared with other women of similar age due to a decrease in ovarian follicles available for recruitment. In this situation, the woman is said to have decreased or diminished ovarian reserve (DOR) and in more severe presentations, primary ovarian insufficiency (POI). Although most often the result of advancing age, a decrease in ovarian reserve can occur for other reasons including smoking, genetic conditions, or prior ovarian surgery, chemotherapy, or pelvic irradiation (American College of Obstetricians and Gynecologists, 2015; American Society for Reproductive Medicine, 2012e). A more complete discussion of causes of accelerated follicular loss is found in Chapter 16 (p. 373).

### ■ Reproductive Aging

There is a clear inverse relationship between female age and fertility (Table 19-6) (American Society for Reproductive Medicine, 2014a). This loss is primarily attributable to a decrease in oocyte quality and quantity, although accumulating risk for the development of medical disorders or uterine and

**TABLE 19-6.** Female Aging and Infertility

Female Age (years)	Infertility
20–29	8.0%
30–34	14.6%
35–39	21.9%
40–44	28.7%

pelvic abnormalities also contributes. A classic study was performed in the Hutterites, a community that eschews contraception. After ages 34, 40, and 45, the incidence of infertility was 11 percent, 33 percent, and 87 percent, respectively. The average age at last pregnancy was 40.9 years (Menken, 1986; Tietze, 1957). Another study evaluated cumulative pregnancy rates in women using donor insemination. In women younger than 31 years, 74 percent achieved pregnancy within 1 year. These rates fell to 62 percent for women between 31 and 35 years, and further declined to 54 percent in women older than 35 (Treloar, 1998).

Ongoing atresia of nondominant follicles proceeds throughout a woman's reproductive life span (Fig. 14-1, p. 319). In addition to follicular number decline, the risks of genetic abnormalities and mitochondrial deletions in the remaining oocytes substantially increase as a woman ages (Keefe, 1995; Pellestor, 2003). These factors result in decreased pregnancy rates and increased miscarriage rates in both spontaneous and stimulated cycles. The overall miscarriage risk in women older than 40 years has been estimated to be 50 to 75 percent (Maroulis, 1991).

The follicular loss rate and age at menopause varies between women and is likely genetically determined. For example, a family history of early menopause is correlated with an increased risk of early menopause in an individual woman. In general, the age at last birth in naturally fertile populations averages 10 years prior to menopause (Nikolaou, 2003; te Velde, 2002). However, in most cases, it is impossible to predict the onset of menopause. Therefore fertility testing is ideally performed starting at age 35 in all patients desiring conception. Testing is also seriously considered in any woman with an unexplained change in menstrual cyclicity, family history of early menopause, or risk factor for POI.

An array of serum and sonographic tests has been developed to assess ovarian reserve (American Society for Reproductive Medicine, 2012e). Unfortunately, these tests lack sensitivity and positive predictive value for DOR, particularly if applied to patients at low risk for this process. In addition, these tests are more accurate as predictors of ovarian response to pharmacologic stimulation than as predictors of subsequent pregnancy. Identification of the optimal combination of tests and their appropriate interpretation continues to be refined. Currently, measurement of early follicular FSH and estradiol levels is probably the most cost-effective approach for the general practitioner. However, addition of a serum antimüllerian hormone level is moving into standard practice. Measurement of serum inhibin B levels or use of the clomiphene citrate challenge test has fallen out of favor.

Abnormal test results from any of these methods correlate with a poorer prognosis for achieving pregnancy, and referral to an infertility specialist is advisable. Conversely, a normal test does not negate the impact of a woman's age on her fertility status. This information may be useful in counseling a couple regarding prognosis. Poor results in an older woman can supply an impetus either to attempt donor oocyte in vitro fertilization (IVF) or to pursue alternatives such as adoption. Borderline results in a younger woman may suggest a need for more intensive treatment.

## ■ Follicle-stimulating Hormone and Estradiol

Measurement of serum follicle-stimulating hormone (FSH) levels in the early follicular phase is a simple and sensitive predictor of ovarian reserve (Toner, 1991). Frequently termed a "cycle day 3" FSH, this may reasonably be drawn between days 2 and 4. With declining ovarian function, the support cells (granulosa cells and luteal cells) secrete less inhibin, a peptide hormone that is responsible for inhibiting FSH secretion by the anterior pituitary gonadotropes (Chap. 15, p. 351). With loss of luteal inhibin, FSH levels rise in the early follicular phase. A value  $> 10$  mIU/mL indicates significant loss of ovarian reserve and prompts a more rapid evaluation and more intensive treatment. In a large study evaluating IVF cycles, a day-3 FSH level exceeding 15 mIU/mL predicted significantly lower pregnancy rates (Toner, 1991).

Many clinicians also measure serum estradiol levels simultaneously (Buyalos, 1997; Licciardi, 1995). Addition of an estradiol measurement may decrease the incidence of false-negative results in FSH values alone. Somewhat paradoxically, despite the overall depletion of ovarian follicles, estrogen levels in older women are elevated early in the cycle due to increased stimulation of ovarian steroidogenesis by elevated FSH levels. An early-follicular serum estradiol level  $> 60$  to  $80$  pg/mL is considered abnormal. Notably, reference levels for estradiol and FSH can vary between laboratories. Thus, every clinician should be familiar with their own laboratory's normal values.

## ■ Antimüllerian Hormone

This is the most recent circulating factor to be analyzed as an ovarian reserve predictor (La Marca, 2009). As suggested by its name, antimüllerian hormone (AMH) is expressed by the fetal testes during male differentiation to prevent development of the müllerian system (fallopian tubes, uterus, and upper vagina) (Chap. 18, p. 406). AMH is also expressed by the granulosa cells of small preantral follicles, with limited expression in larger follicles. This suggests that AMH plays a role in dominant follicle recruitment.

Because AMH is thought to vary minimally across the cycle, measurement of AMH levels provide an advantage compared with FSH testing. However, new studies demonstrate larger fluctuations than originally reported (Gnoth, 2015). In addition, recent or ongoing use of hormonal contraceptives may affect serum AMH levels (Johnson, 2014). At this point, it is reasonable to obtain an AMH level during the follicular phase coincident with measuring an FSH level. Notably, these recommendations may change in the near future.

Recent studies suggest that AMH levels correlate with ovarian primordial follicle number more strongly than do levels of FSH or inhibin (Hansen, 2010). Furthermore, AMH levels may drop prior to observable changes in FSH or estradiol levels, providing an earlier marker of waning ovarian function. Seifer and colleagues (2011) reported a steady decline in AMH serum levels across the reproductive life span. The median level approximated 3 ng/mL at age 25, and this dropped to 1 ng/mL at age 35 to 37. Several AMH assays are commercially available, and thus patient results are interpreted relative to normative data provided for the

selected assay. Interestingly, AMH levels are increased two- to threefold in women with PCOS compared with normal cycling women (Hornburg, 2014). This observation is consistent with the multiple early follicles found in these patients.

### ■ Antral Follicle Count

Sonographic evaluation of the follicular phase antral follicle count (AFC) is commonly used as a reliable predictor for subsequent response to ovulation induction (Frattarelli, 2000; Maseelall, 2009). The number of small antral follicles reflects the size of the resting follicular pool. Antral follicles between 2 and 10 mm are counted in both ovaries. The total AFC usually ranges between 10 and 20 in a reproductive-aged woman. A count < 10 predicts poor response to gonadotropin stimulation.

## EVALUATION FOR FEMALE ANATOMIC ABNORMALITIES

### ■ Tubal and pelvic Factors

Symptoms such as chronic pelvic pain or dysmenorrhea may suggest tubal obstruction, pelvic adhesions, or both. Adhesions can prevent normal tubal movement, ovum pick-up, and transport of the fertilized egg into the uterus. Etiologies include tubal disease, especially pelvic infection; endometriosis; and prior pelvic surgery.

Approximately one third to one fourth of all infertile women are diagnosed with tubal disease in developed countries (Serafini, 1989; World Health Organization, 2007). In the United States, the most common cause of tubal disease is infection with *C. trachomatis* or *N. gonorrhoeae*. With PID, tubal infertility has been estimated to follow in 12 percent, 23 percent, and 54 percent of women following one, two, or three cases of PID, respectively (Lalos, 1988). Nevertheless, an absent PID history is not overly reassuring, as nearly one half of patients who have tubal damage have no clinical history of antecedent disease (Rosenfeld, 1983).

In contrast, in developing countries, genital tuberculosis may account for 3 to 5 percent of infertility cases (Aliyu, 2004; Nezar, 2009). As a result, this diagnosis is considered in immigrant populations from countries with endemic infection. In these cases, tubal damage and endometrial adhesions are underlying causes. Genital tuberculosis typically follows hematogenous seeding of the reproductive tract from an extragenital primary infection. The likelihood of a return to fertility after antitubercular treatment is low, and IVF with embryo transfer remains the most reliable approach (Aliyu, 2004).

With endometriosis, chronic inflammation and intraperitoneal bleeding can lead to pelvic adhesions and subsequently impaired oocyte pick-up, compromised oocyte or embryonic uterotubal transport, or frank tubal obstruction. Endometriosis also is thought to diminish fertility via an increase in peritoneal fluid inflammatory factors, alterations in endometrial immunologic function, poor oocyte or embryonic quality, or impaired implantation (American Society for Reproductive Medicine, 2012c).

*Salpingitis isthmica nodosa* is an inflammatory condition of the fallopian tube, characterized by nodular thickening of its

isthmus portion. Histologically, smooth muscle proliferation and diverticula of tubal epithelium contribute to this thickening. This is an uncommon condition typically develops bilaterally and progressively leads to ultimate tubal occlusion and infertility (Saracoglu, 1992). Treatment options include those for proximal tubal occlusion, discussed in Chapter 20 (p. 458).

Of note, a prior ectopic pregnancy, even if treated medically with methotrexate, implies the likelihood of significant tubal damage. Residual adhesions are common after even the most meticulous surgery for any pelvic pathology. This is particularly true in cases with associated pelvic inflammation due to blood or infection. Irritation caused by mature cystic teratoma (dermoid) contents may be particularly damaging.

### ■ Uterine Abnormalities

Uterine abnormalities can be either inherited (congenital) or acquired. Common congenital anomalies include uterine septum, bicornuate uterus, unicornuate uterus, and uterine didelphys. With the possible exception of a large uterine septum, the fertility effects of these anomalies have been difficult to verify, although a subset are clearly associated with pregnancy complications. As a uterine septum can now be removed relatively simply and safely with hysteroscopy, most infertility specialists will proceed with surgery if this anomaly is identified. Clinical findings and management of congenital reproductive tract anomalies are fully described in Chapter 18 (p. 417).

Acquired anomalies include intrauterine leiomyomas, polyps, and Asherman syndrome. Of these, leiomyomas may diminish fertility by proposed mechanisms including endometrial cavity distortion with associated changes in blood flow and endometrial maturation; endometrial inflammation; disordered uterine contractility that may hinder sperm or embryo transport; obstruction of the proximal fallopian tubes; or interference with ovum capture (American Society for Reproductive Medicine, 2008b; Makker, 2013; Metwally, 2012; Pritts, 2001; Samejima, 2014). Thus far, no algorithm incorporating tumor number, volume, or location accurately predicts the need to remove them, either to improve implantation rates or to decrease pregnancy complications. Of these, miscarriage, placental abruption, and preterm labor are potential problems. Nevertheless, although not supported by definitive evidence, most experts suggest removal of submucosal fibroids that significantly distort the endometrial cavity. In addition, many consider surgical excision of leiomyomas larger than 4 to 5 cm or multiple smaller tumors in this range regardless of location. Importantly, surgical benefits are weighed against postoperative complications that lower subsequent fertility. These include pelvic adhesion formation, creation of Asherman syndrome following large submucous leiomyoma removal, or the need for cesarean delivery if the full myometrial thickness is transected.

*Endometrial polyps* are found in an estimated 3 to 5 percent of infertile women (Farhi, 1995; Soares, 2000). The prevalence is higher in women with symptoms such as intermenstrual or postcoital bleeding. Although these complaints typically prompt hysteroscopic removal, most data have not clearly demonstrated an indication for removing polyps in otherwise asymptomatic women (Ben-Arie, 2004; DeWaay, 2002; Jayaprakasan, 2014).

**TABLE 19-7.** Advantages and Disadvantages of Various Methods for Evaluating Pelvic Anatomy

	Tubal Patency	Uterine Cavity	Ovaries	Endometriosis or PAD	Developmental Defects
HSG	+	+	—	+ /—	+
TVS	—	+ /—	+	—	+ /—
3-D TVS	—	+	+	—	+
SIS	+ /—	+	+	—	+
MR imaging	—	+	+	—	+
Hysteroscopy	—	+	—	—	+ (with laparoscopy)
Laparoscopy	+	—	+	+	+ (with hysteroscopy)

HSG = hysterosalpingography; MR = magnetic resonance; PAD = pelvic adhesive disease; SIS = saline-infusion sonography; TVS = transvaginal sonography.

Of note, however, one study suggested that removal of even small polyps (< 1 cm) may improve pregnancy rates following intrauterine insemination (Perez-Medina, 2005).

The presence of intrauterine adhesions, also called *synechiae*, is termed *Asherman syndrome*. This diagnosis is discussed in Chapter 16 (p. 372). Asherman syndrome develops most frequently in women with prior uterine dilation and curettage, particularly in the context of infection and pregnancy (Schenker, 1996). The clinical history will often include an acute post-surgical decrease in menstrual bleeding or even amenorrhea. A woman with an intrauterine device (IUD) complicated by infection or a woman with genital tuberculosis is also at high risk for intrauterine adhesions. Treatment of Asherman syndrome involves hysteroscopic lysis of the scar tissue as described in Chapter 20 (p. 460) and Section 44-19 (p. 1052).

■ **Anatomy Evaluation**

Several approaches for evaluating pelvic anatomy are: (1) hysterosalpingography (HSG), (2) transvaginal sonography (TVS) with or without saline instillation, (3) 3-dimensional (3-D) TVS, (4) hysteroscopy, (5) laparoscopy, and (6) pelvic imaging by magnetic resonance (MR) imaging. As shown in Table 19-7, each has its own advantages and disadvantages.

**Hysterosalpingography**

This radiographic tool can display the shape and size of the uterine cavity and define tubal status. Hysterosalpingography is generally performed on cycle days 5 through 10. At this time, few intrauterine clots should remain to block tubal outflow or give the false impression of an intrauterine abnormality. Furthermore, a woman theoretically has not ovulated or possibly conceived. For this test, iodinated contrast medium is infused through a catheter placed into the uterus. With fluoroscopy, dye is visually followed as it fills the uterine cavity, then the tubal lumen, and finally spills out of the tubal fimbria into the pelvic cavity (Fig. 19-6).

In a large metaanalysis, HSG was demonstrated to have 65-percent sensitivity and 83-percent specificity for tubal obstruction (Swart, 1995). Tubal contractions, particularly cornual spasm, can give the incorrect impression of proximal

fallopian tube obstruction (a false-positive result). Much less commonly reported is a scenario in which a false-negative result is obtained when the fallopian tube is seen as patent by HSG, although subsequently it is determined to be blocked. Many causes of tubal disease affect both tubes, and thus unilateral disease is unusual. Unilateral obstruction with a normal contralateral tube is most likely due to the dye following the path of least resistance during the HSG procedure. However, laparoscopy with chromotubation is considered prior to treatment to confirm a final diagnosis.

HSG is not reliable in detecting peritubal or pelvic adhesions, although loculations of dye around the tubes may be suggestive. Thus, HSG is an excellent predictor of tubal patency but is less effective at predicting normal tubal function or the presence of pelvic adhesions. Pregnancy rates have been reported to be increased following HSG and are thought to follow flushing of intratubal debris. However, these reports described evaluation with oil-based dyes rather than water-based dyes, which are currently preferred.

HSG also provides analysis of the intrauterine cavity contour. A polyp, leiomyoma, or adhesion within the cavity will block dye diffusion and create an intrauterine “defect” in dye opacity on the radiograph (Fig. 19-7). Although false-positive results may originate from blood clots, mucus plugs, or shearing of the endometrium during placement of the intrauterine catheter, HSG accurately identifies intrauterine pathology. In one study of more than 300 women in which hysteroscopy was the gold standard, HSG was determined to be 98-percent sensitive and 35-percent specific and have a positive predictive value of 70 percent and a negative predictive value of 8 percent. Most misdiagnoses were due to an inability to distinguish polyps from submucous leiomyomas. Other studies have reported much less impressive results. For example, Soares and coworkers (2000) reported sensitivity and positive predictive values of only 50 and 30 percent, respectively, for endometrial polyp and submucous leiomyoma detection in asymptomatic patients. Nevertheless, it is clear that HSG is a helpful tool for uterine cavity evaluation.

HSG can also define developmental uterine anomalies (Fig. 19-8). A Y-shaped uterus identified during HSG may represent either a uterine septum or bicornuate uterus. In these

Normal

Asherman syndrome

Bilateral hydrosalpinges

**FIGURE 19-6** Hysterosalpingogram findings. These images are digitally reversed, causing the radiopaque contrast to appear black against a radiolucent background. **A.** Normal hysterosalpingogram. Radiopaque dye fills the uterine cavity and spills from both fallopian tubes into the peritoneal cavity. The dye catheter is seen beneath the endometrial contour. **B.** Asherman syndrome. Contrast dye fills a small and irregularly shaped endometrial cavity, often described as having a “moth-eaten” appearance. **C.** Bilateral hydrosalpinges. Note the marked tubal dilation and lack of spill of contrast medium at the fimbrial ends. (Used with permission from Dr. Kevin Doody.)

Submucous leiomyoma

Endometrial polyp

**FIGURE 19-7** Appearance of leiomyoma and endometrial polyps on hysterosalpingogram (HSG). **A.** A broad-based filling defect is formed during HSG by a submucous leiomyoma. Note distortion of the left cornu by this mass. **B.** A more irregular filling defect is created by an endometrial polyp. Note that polyps generally have a less substantial attachment to the myometrium. (Used with permission from Dr. Diane Twickler.)

Bicornuate uterus

Septate uterus

Uterine didelphys

**FIGURE 19-8** Hysterosalpingogram appearance of müllerian developmental anomalies. **A.** Bicornuate uterus, due to a failure of fusion of the müllerian ducts, produces a fundal defect with wide-spaced uterine horns. **B.** Septate uterus due to a failure of resorption. This moderate septum displaces the radiopaque dye to the level of the radiolucent injector balloon. **C.** Uterine didelphys consisting of two completely separate müllerian systems including duplication of the cervix. (Used with permission from Dr. Diane Twickler.)

cases, the external contour of the uterine fundus must be evaluated using MR imaging, high-resolution sonography, 3-D TVS, or laparoscopy. With a uterine septum, a smooth fundal contour is found, whereas with a bicornuate uterus, a cleft between the two uterine horns is seen. This is an important distinction, as a septum is often resected, but a bicornuate uterus is usually not treated. In general, uterine anomalies do not cause infertility but may be associated with miscarriage or later fetal loss. Accordingly, it may be reasonable to surgically treat a uterine anomaly to improve pregnancy outcome. However, a couple must be carefully counseled that the conception rate itself is unlikely to be affected. A further discussion of the fertility effects of congenital anomalies is found in Chapter 18 (p. 417).

### Sonography

Transvaginal pelvic sonography may be helpful in determining uterine anatomy, particularly during the luteal phase, when the thickened endometrium acts as contrast to the myometrium. Now more widely available, 3-D sonography is advancing discriminatory abilities (Chap. 2, p. 26).

Infusion of saline into the endometrial cavity during sonography performed in the follicular phase provides another approach to create contrast between the cavity and uterine walls. This procedure has many names including hysterosonography, sonohysterography, or saline infusion sonography (SIS). Details of this procedure are described in Chapter 2 (p. 24). SIS has a reported sensitivity of 75 percent and specificity of more than 90 percent for detecting endometrial defects. It has an acceptable positive predictive value of 50 percent and an

excellent negative predictive value of 95 percent, which greatly exceeds the negative predictive value of HSG (Grimbizis, 2010; Seshadri, 2015; Soares, 2000). Moreover, SIS may be more sensitive than HSG in determining whether a cavitory defect is a pedunculated leiomyoma or a polyp (Figs. 8-7 and 9-5, pp. 187 and 206). Perhaps more importantly, SIS can help determine what portion of a submucous leiomyoma lies within the cavity. Only those with more than 50-percent of their mass within the cavity are considered for hysteroscopic resection.

The primary limitation of SIS is that it does not provide information regarding the fallopian tubes, although rapid loss of saline into the pelvis is certainly consistent with at least unilateral patency. SIS is generally less painful than HSG and does not require radiation exposure. Thus, it is preferred if information about tubal patency is not required, such as in patients who are known to require IVF for other reasons such as severe oligospermia.

### Laparoscopy

Direct inspection provides the most accurate assessment of pelvic pathology, and laparoscopy is the gold standard approach. Chromotubation may be performed, and a dilute dye is injected through an acorn cannula placed against the cervix or through a balloon catheter positioned within the uterine cavity. Tubal spill is evaluated through the laparoscope (Fig. 19-9). Indigo carmine dye, if available, is preferable to methylene blue, as the methylene blue rarely may induce acute methemoglobinemia, particularly in patients with glucose-6-phosphate dehydrogenase deficiency. One 5-mL vial of indigo carmine is mixed with 50 to 100 mL of sterile saline for injection through the cervical cannula.

**FIGURE 19-9** Chromotubation seen at laparoscopy. Note the spill of blue dye from the fimbriated end of the fallopian tube. (Used with permission from Dr. Kevin Doody.)

Laparoscopy allows both diagnosis and immediate surgical treatment of abnormalities such as endometriosis or pelvic adhesions. Laparoscopic ablation of these lesions may increase subsequent pregnancy rates (Chap. 10, p. 243).

As laparoscopy is an invasive procedure, it is not advocated in place of HSG as part of the initial infertility evaluation. Exceptions include women with a history or symptoms suggestive of endometriosis or prior pelvic inflammation. However, even in these women, a preliminary HSG may be informative (De Hondt, 2005).

If laparoscopy is clearly indicated, then hysteroscopy can also be performed to evaluate the uterine cavity while the patient is under anesthesia. Moreover, in operative hysteroscopic cases, laparoscopy can help direct surgery and avoid perforation, for example, during septal incision.

Laparoscopy also may be considered in patients who fail to conceive with clomiphene or gonadotropin ovulation induction. If pelvic disease is found and treated, progression to IVF may be avoided. With improvements in IVF success rates, this latter argument is becoming less justifiable, as the cost of surgery well exceeds the cost of an IVF cycle.

## Hysteroscopy

Endoscopic evaluation of the intrauterine cavity is the preferred method to define intrauterine abnormalities. Hysteroscopy can be performed in an office or operating room. With improved instrumentation, the ability to concurrently diagnose and treat abnormalities in the office is increasing. However, substantially more extensive hysteroscopic surgery is possible in the operating room. A fuller discussion of hysteroscopy and its indications is found in Chapter 41 (p. 901).

## ■ Cervical Factors

The cervical glands secrete mucus that is normally thick and impervious to sperm and ascending infections. High estrogen levels at midcycle change the quality of this mucus. It becomes thin

**FIGURE 19-10** Ferning pattern can be seen midcycle if cervical mucus is dried on a microscope slide. A high sodium chloride concentration creates a crystalline pattern and is produced by elevated estrogen levels near ovulation.

and stretchy and has an increased sodium chloride concentration (Fig. 19-10). Estrogen-primed cervical mucus filters out non-sperm components of semen and forms channels that help direct sperm into the uterus. Midcycle mucus also creates a reservoir for sperm. This allows ongoing release during the next 24 to 72 hours and extends the potential time for fertilization (Katz, 1997).

Abnormalities in mucus production are most frequently observed in women who have undergone cryosurgery, cervical conization, or a loop electrosurgical excision procedure (LEEP) for treatment of cervical neoplasia. Cervical infection may also worsen mucus quality, but data are conflicting. Implicated agents include *C trachomatis*, *N gonorrhoeae*, *Ureaplasma urealyticum*, and *Mycoplasma hominis* (Cimino, 1993). Although there may be no advantage in terms of mucus quality, obtaining cultures for *C trachomatis* and *N gonorrhoeae* seems prudent to avoid causing ascending infection during HSG or intrauterine inseminations.

The postcoital test, also known as the Sims-Huhner test, was used historically to evaluate cervical mucus. For this test, a couple is requested to have intercourse on the day of ovulation. A subsequent sample of the cervical mucus is evaluated for elasticity (*Spinnbarkeit*) and the number of motile sperm per high-power field. This test has been hampered by a limited consensus on the definition of a normal test (Oei, 1995). Moreover, in a prospective, randomized trial, a normal postcoital test did not predict increased cumulative pregnancy rates (Oei, 1998).

Many infertility specialists recommend bypassing the cervix with intrauterine insemination (IUI) in any woman with prior cervical surgery, especially if she has noted a decrease in midcycle mucus production. The remaining utility of the postcoital test is for the rare couple who will not consider intrauterine insemination or do not have intrauterine insemination readily available. In regions of the world in which more specific testing cannot be obtained, a postcoital test will provide basic information regarding mucus production, appropriate intercourse practices, and presence of motile sperm.

EVALUATION OF MALE INFERTILITY

Causes of male infertility can roughly be categorized as abnormalities of sperm production or sperm function or obstruction of the ductal outflow tract.

■ Normal Spermatogenesis

During evaluation of a male infertility patient, the basics of male reproductive physiology should be understood. Analogous to the ovary, testes have two functions: the generation of mature germ cells (sperm) and the production of male hormones, primarily testosterone. The seminiferous tubules contain developing sperm and support cells called *Sertoli cells* or *sustentacular cells* (see Fig. 19-4). The Sertoli cells form tight junctions that produce a blood-testis barrier. This avascular space within the seminiferous tubules protects sperm from antibodies and toxins but also makes these cells dependent on diffusion for oxygen, nutrients, and metabolic precursors. Located between the seminiferous tubules are Leydig cells, also called *interstitial cells*, which are responsible for steroid hormone production. In simplistic terms, Leydig cells are similar to the theca cells of the ovary.

Unlike the ovary, testes contain stem cells that allow ongoing production of mature germ cells throughout a male's life. In a fertile male, approximately 100 to 200 million sperm are produced each day (Sigman, 1997). The process begins with a diploid (46,XY) spermatogonial cell, which grows and becomes a primary spermatocyte. The first meiotic division produces two secondary spermatocytes, and completion of meiosis results in four mature sperm with a haploid (23,X or 23,Y) karyotype. During this developmental process, most sperm cytoplasm is lost, mitochondria that provide energy are positioned in the sperm midpiece, and sperm flagella develop.

Production of sperm requires approximately 70 days. An additional 12 to 21 days is needed for sperm to be transported into the epididymis. Here, they further mature and gain motility (Heller, 1963; Hinrichsen, 1980; Rowley, 1970). Importantly, due to this prolonged developmental period, the results of a semen analysis reflect events during the past 3 months, not a single point in time.

To fertilize an oocyte, human sperm must undergo a process known as *capacitation*. Capacitation results in sperm hyperactivation (an extreme increase in movement) and the ability to release acrosomal contents, which allow penetration of the ovum's zona pellucida.

Normal spermatogenesis is dependent on high local levels of testosterone. LH from the anterior pituitary gland stimulates production of testosterone by the Leydig cells. FSH increases LH receptor density on the Leydig cells, thus indirectly contributing to testosterone production. In addition, FSH increases production of sex hormone-binding globulin, also called androgen-binding protein. Androgen-binding protein binds testosterone and maintains high concentrations of this hormone in the seminiferous tubules (Sigman, 1997).

In addition to hormone levels, testicular volume often reflects spermatogenesis, and a normal volume is between 15 and 25 mL. Most of this volume is provided by the seminiferous

tubules. Thus, decreased testicular volume is a strong indicator of abnormal spermatogenesis.

Spermatogenesis is directed by genes on the Y chromosome. Autosomal genes also provide important contributions, which continue to be elucidated. Therefore, genetic abnormalities may adversely affect this process, as discussed later.

Male fertility likely decreases modestly with increasing age. Several studies have demonstrated that pregnancy rates decline and time to conception lengthens as male age increases. Studies of semen parameters across age suggest that sperm concentration is maintained, however, sperm motility and morphology progressively worsen (Levitas, 2007). The clinical significance of this change is unclear (Kidd, 2001). In short, although advancing male age may lower fertility, it is probably insignificant compared with aging changes in women.

■ Semen Analysis Collection

This is a core test in male fertility evaluation. For this test, the male is asked to refrain from ejaculation for 2 to 3 days, and a specimen is collected by masturbation into a sterile cup. If masturbation is not an option, then a couple can use specially designed Silastic condoms without lubricants. Importantly, the sample should arrive in the laboratory within an hour of ejaculation to allow for optimal analysis.

The sample undergoes liquefaction, or thinning of the seminal fluid, due to enzymes from the liquid contribution of the prostate gland. This process takes 5 to 20 minutes and allows more accurate evaluation of the sperm contained in the seminal fluid. Ideally, two semen samples separated by at least a month are analyzed. In practice, frequently only a single sample is analyzed if parameters are normal.

Semen Analysis Results

The reference values for the semen analysis are shown in Table 19-8. A clinician should remember several critical aspects of this test. First, semen characteristics vary across time in a single individual. Second, semen analysis results, particularly morphologic interpretation, differ between laboratories. Thus, reference ranges for the laboratory being used should be known. Note that the concept of "reference" range is more appropriate than "normal" range. Although total motile sperm count correlates with fertility, not all males with "normal" semen parameters display normal fertility (Guzick, 2001). Conversely,

TABLE 19-8. Semen Analysis Reference Limits	
Volume	> 1.5 mL <sup>a</sup>
Count	> 15 million/mL <sup>a</sup>
Total Motility	> 40% <sup>a</sup>
Morphology	> 4% <sup>a</sup>
WBCs	< 1 million/mL <sup>b</sup>
Round cells	< 5 million/mL <sup>b</sup>
<sup>a</sup> Data from Cooper, 2010.	
<sup>b</sup> Data from World Health Organization, 1999.	
WBCs = white blood cells.	

patients with semen analysis results outside the reference range may achieve pregnancy. The lack of absolute predictive value for this test is likely due to the fact that it does not provide information regarding sperm function, that is, the ultimate ability to fertilize an oocyte.

Most semen analysis reports will indicate semen volume, pH, and presence or absence of fructose. Nearly 80 percent of semen volume comes from the seminal vesicles. Seminal fluid is alkaline and is thought to protect sperm from acidity in prostatic secretions and in the vagina. Seminal fluid also provides fructose as an energy source for sperm. An acidic pH or lack of fructose is consistent with obstruction of the efferent ductal system (Daudin, 2000).

Of parameters, low semen volume often simply reflects incomplete specimen collection or short abstinence interval. However, it may indicate partial vas deferens obstruction or retrograde ejaculation. Partial or complete vas deferens obstruction may be caused by infection, tumor, prior testicular or inguinal surgery, or trauma. Retrograde ejaculation follows failed closure of the bladder neck during ejaculation and allows seminal fluid to flow backward into the bladder. Retrograde ejaculation is suspected in men with diabetes mellitus, spinal cord damage, or prior prostate or other retroperitoneal surgery that may have damaged nerves (Hershlag, 1991). Medications, particularly  $\beta$ -blockers, may contribute to this problem. A postejaculatory urinalysis can detect sperm in the bladder and confirm the diagnosis. If urine is properly alkalinized, these sperm are viable and can be retrieved to achieve pregnancy.

Sperm counts may be normal, or males may have low sperm counts (oligospermia), or no sperm (azoospermia) (Sharlip, 2002). Oligospermia is defined as a concentration less than 15 million sperm per milliliter, and counts below 5 million per milliliter are considered severe. The prevalence of azoospermia is approximately 1 percent of all men. Azoospermia may result from outflow tract obstruction, termed obstructive azoospermia, such as that which occurs with congenital absence of the vas deferens, severe infection, or vasectomy. Azoospermia may also follow testicular failure (nonobstructive azoospermia). In the latter case, careful centrifugation and analysis may identify a small number of motile sperm adequate for IVF use. Alternatively, this latter group may have viable sperm obtainable through either epididymal aspiration or testicular biopsy. As described later, endocrine and genetic evaluation is indicated for men with abnormal sperm counts.

Sperm movement is also assessed, and decreased sperm motility is termed *asthenospermia*. Some laboratories will distinguish between rapid (grade 3 to 4), slow (grade 2), and nonprogressive (grade 0 to 1) movement. *Total progressive motility* is the percentage of sperm exhibiting forward movement (grades 2 to 4). Asthenospermia has been attributed to prolonged abstinence, antisperm antibodies, genital tract infections, or varicocele. To differentiate between dead and nonmotile sperm, a hypoosmotic swelling test can be performed. Unlike dead sperm, living sperm can maintain an osmotic gradient. Thus, when mixed with a hypoosmotic solution, living, nonmotile sperm with normal membrane function swell and coil as fluid is absorbed (Casper, 1996). Once identified, these viable sperm may be used for intracytoplasmic sperm injection.

Abnormal sperm morphology is termed *teratospermia* or *teratozoospermia*. Kruger and colleagues (1988) developed a detailed characterization of normal sperm morphology, which showed improved correlation with fertilization rates during IVF cycles. Their criteria require careful analysis of the shape and size of the sperm head, the relative size of the acrosome in proportion to the head, and characteristics of the tail, including length, coiling, or presence of two tails. Significantly decreased fertilization rates are seen when normal morphology of the sample falls below 4 percent.

Round cells in a sperm sample may represent either leukocytes or immature sperm. White blood cells (WBCs) can be distinguished from immature sperm using various techniques, including a myeloperoxidase stain for WBCs (Wolff, 1995). True leukocytospermia is defined as greater than 1 million WBCs per milliliter and may indicate chronic epididymitis or prostatitis. In this scenario, many andrologists consider empiric antibiotic treatment prior to obtaining a repeat semen analysis. A common protocol would include doxycycline at a dosage of 100 mg orally twice daily for 2 weeks. Alternative approaches include culture of any expressible discharge or of the semen sample.

Unless a general obstetrician-gynecologist has developed a particular interest and expertise in the area of infertility, persistent abnormal semen analysis findings are an indication for referral to an infertility specialist. Although the partner may be referred directly to a urologist, it may be more reasonable to refer the couple to a reproductive endocrinologist, as the female will also require evaluation. Treatment is likely to be more complex in these couples and will typically be directed to both partners. The reproductive specialist can determine the need for further referral of the male partner to a urologist for investigation of a genetic, anatomic, hormonal, or infectious abnormality.

## ■ DNA Fragmentation

During the past 10 years, interest in elevated sperm DNA fragmentation as a cause of male factor infertility has increased (Sakkas, 2010; Zini, 2009). Although some degree of DNA damage is likely repaired during embryogenesis, the location and extent of damage may lower fertilization and increase miscarriage rates. Increased levels of DNA damage are associated with advanced paternal age and external factors such as cigarette smoking, chemotherapy, radiation, environmental toxins, varicocele, and genital tract infections. Studies have observed increased levels of reactive oxygen species in sperm samples with abnormal DNA fragmentation rates. In response to this observation, dietary supplementation with the antioxidants vitamin C and vitamin E has been proposed. However, data are currently lacking regarding the efficacy of this approach.

Numerous tests are currently available to analyze for DNA integrity and include the Sperm Chromatin Structure Assay (SCSA), the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) assay, the single-cell gel electrophoresis assay (COMET), and the sperm chromatin dispersion test (SCD) (American Society for Reproductive Medicine, 2013c). Each of these tests provides semiquantitative

data on DNA structure. For example, the SCSA is based on the increased susceptibility of DNA with single-strand or double-strand breaks to denature in weak acid. The TUNEL assay exploits the ability of labeled nucleotides to intercalate into DNA breaks for subsequent measurement. These tests are currently hampered by a lack of consensus regarding appropriate threshold values and by conflicting data regarding their ability to predict successful pregnancy. As a result, currently evidence is insufficient to recommend the routine use of these tests in infertile couples. Nevertheless, the concept that sperm DNA integrity can be adversely affected through multiple mechanisms provides useful insight into a previously underappreciated cause of male infertility.

### ■ Additional Sperm Testing

Antisperm antibodies may be detected in as many as 10 percent of men. However, controversy exists regarding the negative fertility effects of antisperm antibodies found in semen. These antibodies may be particularly prevalent following vasectomy, testicular torsion, testicular biopsy, or other clinical situations in which the blood-testis barrier is breached (Turek, 1994). Treatment historically included corticosteroids, but it is unclear if this approach improves fertility. Moreover, significant side effects, including aseptic necrosis of the hip, have been reported in treated patients. Current data suggest that antisperm antibody assay does not need to be a routine component of infertility evaluation.

Numerous assays have been developed to test sperm function. These include the mannose fluorescence assay, hemizona assay, sperm penetration assay, and acrosome reaction test. The predictive significance of these assays is questionable, as they are based on highly nonphysiologic conditions and results vary widely from infertility center to infertility center. Most are no longer used and are not considered part of a basic infertility evaluation.

### ■ Hormonal Evaluation of the Male

Hormonal testing in the male is analogous to endocrine testing in an anovulatory female. In overview, abnormalities may be due to central defects in hypothalamic-pituitary function or due to defects within the testes. Most urologists will defer testing unless a sperm concentration is below 10 million/mL. Testing will include measurements of serum FSH and testosterone levels.

Low FSH and low testosterone levels are consistent with hypothalamic dysfunction, such as idiopathic hypogonadotropic hypogonadism or Kallman syndrome (Chap. 16, p. 375). In these patients, sperm production may be achieved with gonadotropin treatment. Although such treatment is frequently successful, at least 6 months may be required for detection of sperm production.

Elevated FSH and low testosterone levels provide evidence of testicular failure, and most men with oligospermia fall into this category. In this patient group, it is important to determine, based on testosterone levels, whether testosterone replacement is indicated. Normal spermatogenesis requires high levels of intratesticular testosterone, which cannot be achieved with

exogenous testosterone. Furthermore, many of these men will lack spermatogonial stem cells. Thus, testosterone replacement will not rescue sperm production. In fact, replacement will decrease gonadotropin stimulation of remaining testicular function through negative feedback at the hypothalamus and pituitary. Unless the couple has chosen to use donor sperm, androgen supplementation is deferred during fertility treatment. However, replacement will provide other benefits, such as improved libido and sexual function, maintenance of muscle mass and bone density, and a general sense of well-being.

Additional hormonal testing may be included as part of an evaluation of the infertile male. Elevated serum prolactin levels and thyroid dysfunction affect spermatogenesis and are the most likely endocrinopathies to be detected (Sharlip, 2002; Sigman, 1997).

### ■ Genetic Testing of the Male

Genetic abnormalities are a relatively common cause of abnormal semen characteristics (American Society for Reproductive Medicine, 2008a). Approximately 15 percent of azoospermic men and 5 percent of severely oligospermic men will have an abnormal karyotype. Although genetic abnormalities cannot be corrected, they may have implications for the health of the patient or their offspring. Therefore, karyotyping is pursued when indicated by poor semen analysis results. The lower limit in sperm concentration for such testing varies between practitioners but lies between 3 and 10 million sperm per milliliter.

Klinefelter syndrome (47,XXY) will be a frequent finding. Klinefelter syndrome is observed in approximately 1 in 500 men in the general population and accounts for 1 to 2 percent of male infertility cases. Classically, these men are tall, undervirilized, and have gynecomastia and small, firm testes (De Braekeleer, 1991). As the phenotype varies widely, lack of these characteristics does not preclude chromosomal evaluation. Conversely, a clinician may strongly consider obtaining karyotype testing in any male with these characteristics. Autosomal abnormalities will also be found in a subset of men with severe oligospermia.

A patient with severely decreased sperm counts and a normal karyotype is offered testing for microdeletion of the Y chromosome. Up to 15 percent of men with severe oligospermia or azoospermia will have small deletions in a region of the Y chromosome termed the *azoospermia factor region (AZF)*. If the deletion is within the AZFa or AZFb subregions, then it is unlikely that viable sperm can be recovered for use in IVF. Most men with an AZFc deletion will have viable sperm at biopsy. However, these deletions should be presumed to be inherited by their offspring. The clinical significance of microdeletions in the recently identified AZFd region is unknown, as these patients have apparently normal spermatogenesis (Hopps, 2003; Kent-First, 1999; Pryor, 1997).

Obstructive azoospermia may be due to congenital bilateral absence of the vas deferens (CBAVD). Approximately 70 to 85 percent of men with CBAVD will have mutations found in the cystic fibrosis transmembrane conductance regulator gene (*CFTR* gene), although not all will have clinical cystic fibrosis

(Oates, 1994; Ratbi, 2007). Conversely, essentially all men with clinical cystic fibrosis will have CBAVD. Fortunately, testicular function in these men is usually normal, and adequate sperm may be obtained by epididymal aspiration to achieve pregnancy through IVF. Careful genetic counseling and testing of the female partner for carrier status is critical in these situations.

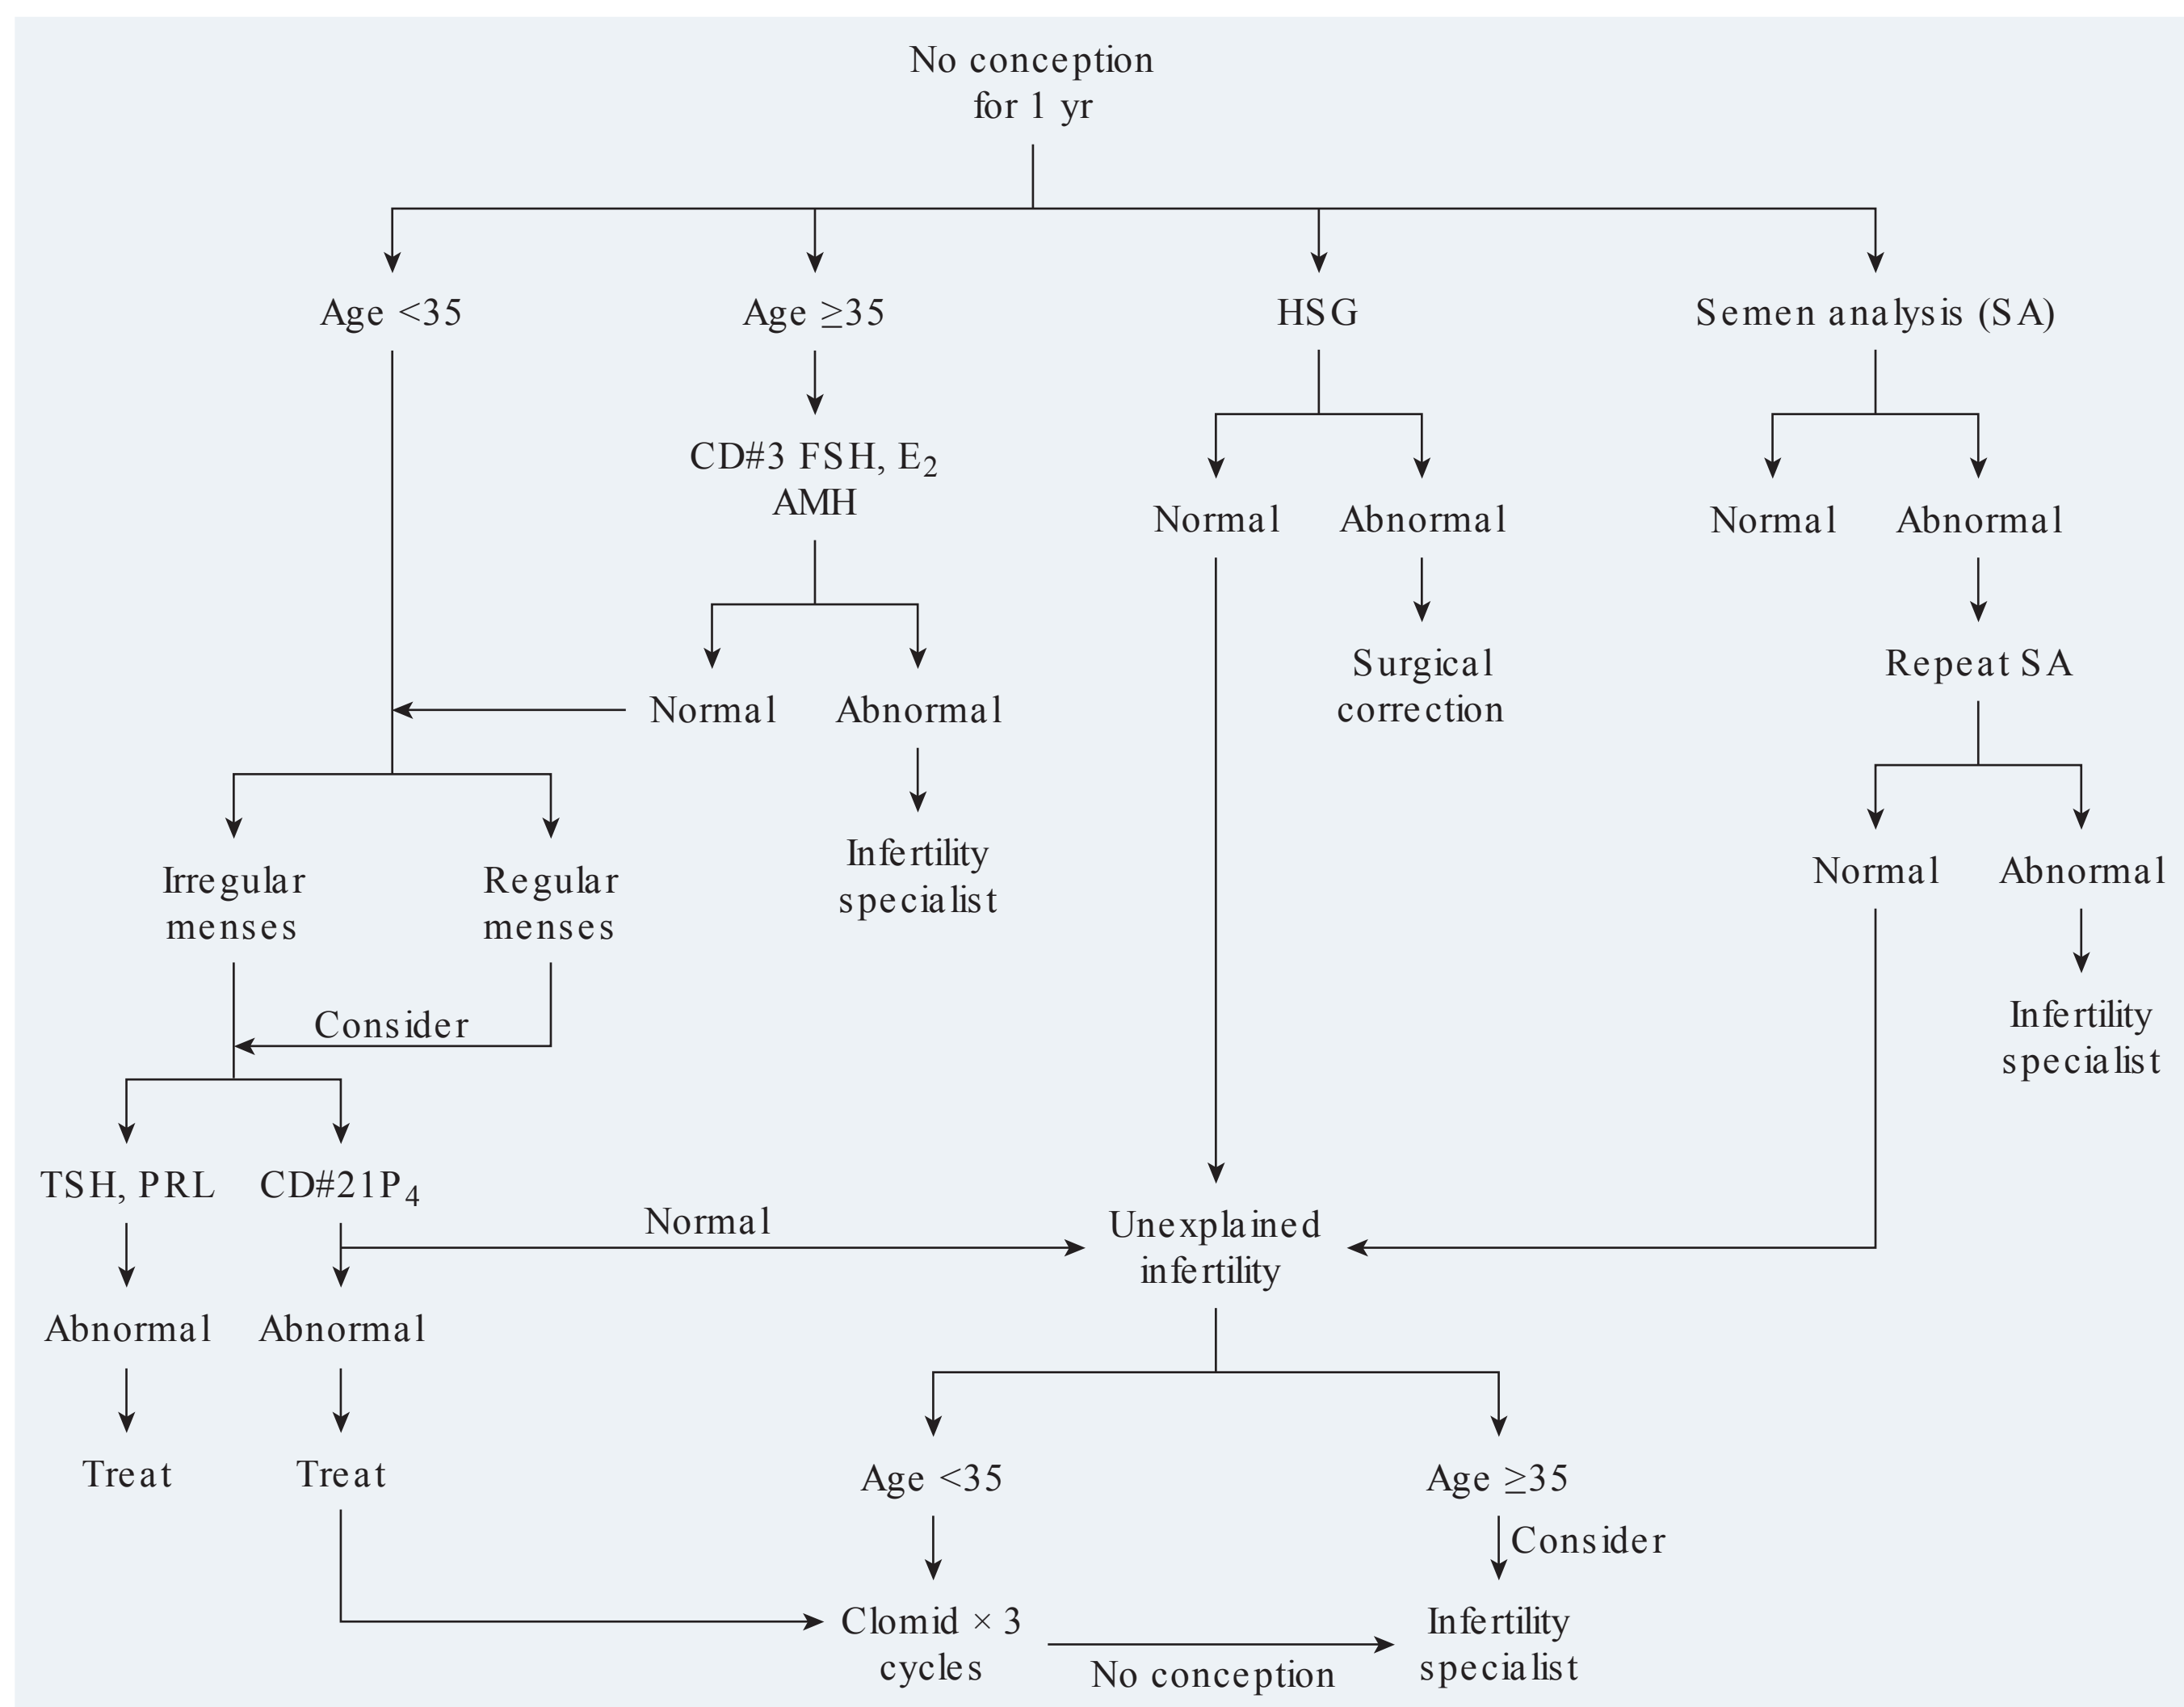

### ■ Testicular Biopsy

Evaluation of a severely oligospermic or azospermic male may include either open or percutaneous testicular biopsy to determine whether viable sperm are present in the seminiferous tubules (Sharlip, 2002). For example, even men with testicular failure diagnosed by elevated serum FSH levels may have adequate sperm on biopsy for use in intracytoplasmic sperm injection. The biopsy specimen can be cryopreserved for future extraction of sperm during an IVF cycle. However, freshly biopsied specimens are generally felt to provide higher success

rates. Thus, the biopsy may have diagnostic, prognostic, and therapeutic value.

### CONCLUSION

Figure 19-11 provides an algorithm for the evaluation of an infertile couple. Details will vary between practitioners and will be affected by patient presentation. In general, the female partner has some form of testing to confirm ovulation and undergoes HSG, whereas the male partner has semen analysis performed. In older women, evaluation of an early-follicular serum FSH level is essential to ensure adequate follicular reserves. A subset of couples will decline HSG and semen analysis if the woman has a clear ovulatory defect. These couples are reminded that there is a relatively high incidence of couples having two abnormalities, one of which would be missed by this approach. These patients may be treated, but are strongly encouraged to complete the evaluation if they do not conceive within a few months. Options for treatment are discussed in Chapter 20.

**FIGURE 19-11** Diagnostic algorithm for evaluation of the infertile couple. AMH = antimüllerian hormone; CD#3 = cycle day 3; CD#21 = cycle day 21; E<sub>2</sub> = estradiol; FSH = follicle-stimulating hormone; HSG = hysterosalpingography; P<sub>4</sub> = progesterone; PRL = prolactin; SA = semen analysis; TSH = thyroid-stimulating hormone.

Infertility results from diseases of the reproductive system that impair the body's ability to perform basic reproductive function. It is defined as the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse. Earlier evaluation and treatment may be justified based on medical history and physical findings and is warranted after 6 months for women older than 35 (American Society for Reproductive Medicine, 2012b). Ten to 15 percent of the reproductive-aged population is infertile, and men and women are equally affected.

Infertility treatment is a complex process influenced by numerous factors. Important considerations include duration of infertility, a couple's age (especially the female's), and diagnosed cause. Additionally, the level of distress experienced by a couple should be taken into account.

In general, a first step involves identification of a primary cause and contributing factors, and treatment is aimed at their direct correction. Most are treated with conventional therapies such as medication or surgery. In many cases, therapy can begin without a complete evaluation, especially if a cause is obvious. However, if pregnancy does not quickly follow, then more thorough testing is prudent.

In contrast, evaluation commonly may not yield a satisfactory explanation or may identify causes that are not amenable to direct correction. For such cases, recent advances in assisted reproduction have provided effective treatments. These approaches, however, are not without disadvantage. For example, in vitro fertilization (IVF) has been linked with higher rates of some fetal and maternal complications. Appropriate treatments may also pose ethical dilemmas for couples or their

physician. For example, selective reduction of a multifetal pregnancy may improve survival chances for some fetuses but at the cost of others. Last, infertility treatment can be a financial burden, a significant source of emotional stress, or both. During consultation, an infertility specialist does not dictate treatment but offers and explains therapy options, which may include expectant management or even adoption.

### LIFESTYLE THERAPIES

#### ■ Weight Optimization

Ovarian function is dependent on weight. Low body-fat content is associated with hypothalamic hypogonadism. In contrast, central body fat is associated with insulin resistance and contributes to ovarian dysfunction in many women with polycystic ovarian syndrome (PCOS). Lifestyle modification in overweight infertile women with PCOS leads to a reduction of central fat and improved insulin sensitivity, decreased hyperandrogenemia, lowered luteinizing hormone (LH) concentrations, and restoration of normal fertility in many cases (Hoeger, 2001; Kiddy, 1992). Even a 5 to 10 percent reduction in body weight has been shown to be successful in these women (Crosignani, 2003; Kiddy, 1992; Pasquali, 1989). Apart from diet, exercise can also improve insulin sensitivity. Weight loss and exercise are inexpensive and should be recommended as first-line management of obese women with PCOS.

Although pharmacologic options can effectively treat anovulation if weight cannot be lost, it should be noted that obesity is a significant risk factor for obstetric and perinatal complications. Some maternal risks include higher rates of gestational diabetes, cesarean delivery, preeclampsia, unexplained stillbirth, and surgical wound infection (Cunningham, 2014). Obesity also has been associated with an increased risk of birth defects (American Society for Reproductive Medicine, 2008). Therefore, strong consideration is given to delaying treatments in morbidly obese women until their body mass index (BMI) can be reduced below 40. This is especially true if treatments involve surgical risks or risk of multifetal gestation.

Weight-loss options are discussed in Chapter 1 (p. 13). If bariatric surgery is selected, conception is ideally delayed for 12 to 18 months (American College of Obstetricians and Gynecologists, 2013). This is because rapid weight loss during this time poses theoretical risks for intrauterine fetal-growth restriction and nutritional deprivation.

Undernutrition can also be a problem. The reproductive axis is closely linked to nutritional status, and inhibitory pathways suppress ovulation in subjects with significant weight loss.

Anorexia nervosa and bulimia nervosa affect up to 5 percent of reproductive-aged women and may cause amenorrhea, infertility, and in those who do conceive, an increased likelihood of miscarriage. Fortunately, recovery may follow minimal acquisition of weight because energy balance has a more important effect than body fat mass.

### ■ Exercise

Physical activity has numerous health benefits. The relationship between exercise and fertility, however, is not straightforward. Competitive female athletes often experience amenorrhea, irregular cycles or luteal dysfunction, and infertility. This may be related not specifically to physical activity itself but rather to low body-fat content or physical stress associated with competition. At this time, insufficient data exist to support or discourage physical activity in infertile women without documented ovarian dysfunction associated with obesity or low body weight.

### ■ Nutrition

In the absence of obesity or significant undernutrition, the role of diet in infertility is unclear. High-protein diets and gluten intolerance (celiac disease) have been investigated as underlying causes in women. However, studies sizes have been small, and conflicting results found (Collin, 1996; Jackson, 2008; Meloni, 1999). In men, dietary antioxidants have been proposed as a potential way to improve male reproductive outcomes by reducing oxidative damage in sperm DNA (Ross, 2010). Although the approach is promising, large well-designed studies to guide its clinical use are needed (Patel, 2008). Additionally, the nutritional supplement carnitine had been often touted as a potential benefit for male infertility. This finding, however, has not been confirmed by a randomized, prospective trial (Sigman, 2006).

Despite a lack of conclusive benefits to nutritional supplements or diet modification in infertile couples, it does seem reasonable to recommend daily multivitamin supplementation to both. Folic acid is contained in most multivitamins, and daily doses of 400 µg orally are recommended for women attempting pregnancy to reduce the incidence of neural-tube defects in their fetuses (American College of Obstetricians and Gynecologist, 2014b).

Herbal therapies including traditional Chinese medicine and acupuncture have been proposed to enhance fertility either alone or in conjunction with standard therapies including assisted reproductive technology (ART). Smith and associates (2010) found that 29 percent of infertile couples seeking pregnancy in the United States had used complementary and alternative medicine. At this time, however, current evidence does not support a benefit of herbal/botanical therapies or acupuncture for fertility as either a primary treatment modality or an adjunct to established therapies (Cheong, 2013).

### ■ Stress Management

Stress has been implicated in reproductive failure. Although severe stress can result in anovulation, less significant stress may

also play a role, but a mechanism has yet to be defined. Patients with higher stress levels have been found to have lower pregnancy rates when undergoing IVF treatments (Tiering, 1993). Accordingly, screening all infertile couples for evidence of anxiety or depression is a consideration. Although pharmacologic management of stress is not typically recommended during infertility treatments, a “mind/body” approach that combines psychological counseling and meditation may be reasonable for those patients manifesting high levels of anxiety (Domar, 1990).

## CORRECTION OF OVARIAN DYSFUNCTION

### ■ Hyperprolactinemia

Prolactin is a pituitary hormone that plays an important role in various reproductive functions, and elevated levels are commonly encountered in clinical endocrinology practice. If hyperprolactinemia is found, then physiologic, pharmacologic, or other secondary causes of hormone hypersecretion are sought (Table 12-2, p. 281).

Dopamine agonists are the primary treatment of hyperprolactinemia (Chap. 15, p. 360). Surgical therapies are only considered with prolactin-secreting adenomas resistant to medical therapy. During pregnancy, if hyperprolactinemia is not associated with a pituitary lesion or a lesion is less than 10 mm (microadenoma), then dopamine-agonist therapy is stopped because the tumor expansion risk is low (Molitch, 1999). If the tumor size is 10 mm or larger (macroadenoma), bromocriptine (Parlodel) use is advised during pregnancy to avoid significant tumor growth.

### ■ Hypothyroidism

Thyroid disorders are prevalent in reproductive-aged individuals and affect women four to five times more often than men. In women, oligomenorrhea and amenorrhea are frequent findings. Although ovulation and conception can still occur in those with mild hypothyroidism, treatment with thyroxine usually restores a normal menstrual pattern and enhances fertility.

Subclinical hypothyroidism may also be associated with ovarian dysfunction (Strickland, 1990). Lincoln and associates (1999) found a 2-percent incidence of elevated thyroid-stimulating hormone (TSH) levels in 704 asymptomatic women seeking evaluation for infertility. Correction of hypothyroidism in those with ovarian dysfunction and elevated TSH levels led to pregnancy in 64 percent of patients. In addition, subclinical hypothyroidism may also adversely affect pregnancy outcomes, but current evidence does not support that treatment of subclinical hypothyroidism during pregnancy improves these outcomes (Casey, 2014). That said, in women seeking treatment for infertility, early detection and treatment of hypothyroidism of any degree is advised.

### ■ Ovulation Induction

Ovarian dysfunction is the most common indication for the use of medications to induce ovulation. These agents can also be selected for ovulatory women to increase the likelihood of

pregnancy in couples with other causes of infertility or unexplained infertility. Use of these medications to promote follicular development and prompt ovulation is called *superovulation* or *ovulation enhancement*. If these agents are administered solely to stimulate follicles and egg harvesting is completed by ART, then the term *controlled ovarian hyperstimulation* is used. In contrast, we prefer the term *ovulation induction* to describe treatment with medications to stimulate normal ovulation in women with ovarian dysfunction.

Frequent causes of ovarian dysfunction include PCOS and diminished ovarian reserve. Less often, central (hypothalamic or pituitary) disorders or thyroid dysfunction can result in infertility (Table 16-3, p. 371). Rarely, ovarian tumors or adrenal abnormalities lead to abnormal ovarian function. Treatment of ovarian dysfunction is based on the identified cause and the results of any prior attempted therapy.

### Clomiphene Citrate

Clomiphene citrate (CC) is the initial treatment for most anovulatory infertile women. Chemically similar to tamoxifen, CC is a nonsteroidal triphenylethylene derivative that demonstrates both estrogen agonist and antagonist properties. Antagonist properties predominate except at very low estrogen levels. As a result, negative feedback that is normally produced by estrogen in the hypothalamus is reduced (Fig. 20-1). Gonadotropin-releasing hormone (GnRH) secretion is altered and stimulates pituitary gonadotropin release. The resulting increase in follicle-stimulating hormone (FSH) levels, in turn, drives ovarian follicular activity.

Tamoxifen has also been used successfully for ovulation induction. However, it is not approved by the Food and Drug Administration (FDA) for this indication and has not been demonstrated to have significant advantage compared with CC.

Clomiphene citrate is administered orally, typically starting on the third to fifth day after the onset of spontaneous or progestin-induced menses. Ovulation rates, conception rates, and pregnancy outcome are similar regardless whether treatment begins on cycle day 2, 3, 4, or 5. Prior to therapy, sonography is advisable to exclude signs of significant spontaneous follicular maturation or residual follicular cysts. In general at our institution, clomiphene can be administered if no follicle is > 20 mm and the endometrium is less than 5 mm. A pregnancy test is also indicated after spontaneous menses. Although not a proven teratogen, CC is classified as category X by the FDA and thus is contraindicated in suspected or documented pregnancy.

The dose required to achieve ovulation correlates with body weight. However, there is no reliable way to accurately predict which dose will be required in an individual woman (Lobo, 1982). Consequently, CC is titrated empirically to establish the lowest effective dose for each patient. Treatment typically begins with a single 50-mg tablet taken daily for 5 consecutive days. Doses are increased by a 50-mg increment in each subsequent cycle until ovulation is induced. The dose of CC should not be increased if normal ovulation is confirmed. Thus, lack of pregnancy alone does not justify a dose increase. The effective dose of CC ranges from 50 mg/d to 250 mg/d, although doses in excess of 100 mg/d are not approved by the FDA. Some studies have suggested that adjunctive therapy with glucocorticoids

**FIGURE 20-1** Effect of clomiphene citrate (CC) administration. **A.** Clomiphene binds to the estrogen receptor in the pituitary and hypothalamus. This causes an effective reduction in hypothalamic estrogen receptor number. Because of this reduced receptor number, the hypothalamus and pituitary are effectively blinded to true circulating estrogen levels and perceived hypoeestrogenism results. From this, estrogen's negative feedback is interrupted centrally, and follicle-stimulating hormone (FSH) secretion increases from the anterior pituitary. This leads to maturation of multiple follicles. **B.** By the late follicular phase, because of clomiphene citrate's long retention within tissues, estrogen receptor depletion continues centrally. As a result, increased estradiol ( $E_2$ ) secretion from the ovary is not capable of exerting normal negative feedback on FSH release. This leads to a growth of multiple dominant follicles and multiple ovulations.

may benefit some patients not responsive to CC alone (Elnashar, 2006; Parsanezhad, 2002). The precise mechanism is unclear, although several direct and indirect actions of dexamethasone have been suggested. This therapy may be empiric or individualized based on elevated dehydroepiandrosterone sulfate (DHEAS) levels.

In general, women failing to ovulate with 100 mg/d dosing or failing to conceive following 3 to 6 months of ovulatory response to CC should be considered candidates for alternative treatments. In a retrospective study including 428 women who received CC for ovulation induction, 84.5 percent of pregnancies achieved with treatment occurred during the first three ovulatory cycles (Gysler, 1982).

Insulin-sensitizing Agents

Although PCOS appears to be a heterogeneous disorder, many women with this condition exhibit insulin resistance (Chap. 17, p. 387). Insulin resistance leads to compensatory hyperinsulinemia and dyslipidemia. Given the strong evidence that hyperinsulinemia plays a pivotal pathogenic role in development of PCOS, it is reasonable to assume that interventions that reduce circulating insulin levels in women with PCOS may restore normal reproductive endocrine function. As discussed, weight loss, nutrition, and exercise have clearly led to reduced hyperinsulinemia, resolution of hyperandrogenism, and in some cases, resumption of ovulatory function in overweight women with PCOS. However, women may be poorly compliant, and weight loss is rarely maintained over time.

Insulin-sensitizing agents show promise in the treatment of PCOS. When administered to insulin-resistant patients, these compounds act to increase target tissue responsiveness to insulin, thereby reducing the need for compensatory hyperinsulinemia (Antonucci, 1998). Current insulin-sensitizing agents include the biguanides and thiazolidinediones (Chap. 17, p. 398).

Of these, studies suggest that metformin (Glucophage), given 500 mg orally three times daily or 850 mg twice daily with meals and administered to women with PCOS, increased the frequency of spontaneous ovulation, menstrual cyclicality, and ovulatory response to CC (Nestler, 1998; Palomba, 2005; Vandermolen, 2001). In contrast, a large, prospective, randomized, multicenter trial does not support the hypothesis that

metformin, either alone or in combination with CC, improves the live-birth rate in women with PCOS (Legro, 2007).

Gonadotropins

Clomiphene citrate is easy to use and leads to ovulation in most patients (Hammond, 1983). However, pregnancy rates are disappointing and approximate  $\leq 50$  percent (Raj, 1977; Zarate, 1971). Lower than expected pregnancy rates with CC have been attributed to its long half-life and peripheral antiestrogenic effects, mainly on the endometrium and cervical mucus. For such individuals, who are often classified as “clomiphene resistant,” the next step is traditionally the administration of exogenous gonadotropin preparations via injections.

As with CC, the goal of ovulation induction with gonadotropins is simply to normalize ovarian function. Ideally, the dose used is the minimum required to cause normal development of a single dominant follicle. Because the response to gonadotropins can vary greatly from individual to individual and even from cycle to cycle, intensive monitoring is required to adjust dosage and timing of ovulation.

Gonadotropin preparations vary in terms of their source (urinary or recombinant) and by the presence or absence of LH activity (Table 20-1). Traditional urinary-derived human menopausal gonadotropin (hMG) preparations contain both FSH and LH. These are extracted and purified from the urine of postmenopausal women, in whom FSH and LH levels are normally high. These preparations also contain human chorionic gonadotropin (hCG), which is mainly derived from normal pituitary secretion in postmenopausal women. LH and hCG both bind to the same receptor (luteinizing hormone/chorionic gonadotropin receptor [LHCGR]).

In contrast, in purified hMG, hCG serves as the primary source of the LH activity, although significant LH is also present in the older, nonhighly purified hMG products (Filicori, 2002). Highly purified urinary preparations allow for administration via subcutaneous route with minimal or no reaction at the injection site. Alternatives to hMG include highly purified urinary gonadotropin preparations and purified recombinant FSH.

Both LH and FSH activity are required for normal ovarian steroidogenesis and follicular development. In many cases, pure FSH preparations can be used because of adequate endogenous

TABLE 20-1. Injectable Gonadotropin Preparations Used for Ovulation Induction

<sup>a</sup>No longer available.  
FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; LH = luteinizing hormone.

LH production. However, for ovulation induction in patients with hypogonadotropic amenorrhea, LH activity must be provided from an exogenous source. Thus, options include hMG, recombinant LH, low-dose (diluted) urinary or recombinant hCG. Ovulation induction in women with PCOS can be performed either with FSH-only containing products or those containing both LH and FSH activity. At present, data do not support the superiority of one preparation over another.

Gonadotropin development will likely continue. A long-acting FSH is commercially available outside the United States. This recombinant molecule was created by adding a DNA sequence to the human FSH gene. This extra sequence allows for more glycosylation and hence a prolonged clearance. Low-molecular-weight molecules (nonproteins) have been identified that activate the FSH and LH receptors. However, these compounds are still in early stages of clinical development. Advantages of these nontraditional gonadotropins include oral delivery.

Most clinicians begin ovulation induction attempts at a low gonadotropin dosage of 50 to 75 IU injected daily. This is gradually increased if no ovarian response (as assessed by serum estradiol measurements) is noted after several days (Fig. 20-2). This is referred to as a “step-up” protocol. A “step-down” protocol can also be used with the advantage of a decreased duration of stimulation. However, the risk of excessive ovarian response, such as multiple follicle development or ovarian hyperstimulation syndrome, may be increased with this method. With either approach, if a patient fails to conceive, subsequent cycles may be started at higher doses based on prior response.

In general, gonadotropin stimulation in women with PCOS is less successful than in patients with hypogonadotropic amenorrhea (Balen, 1994). Women with PCOS have ovaries highly sensitive to gonadotropin stimulation. They have a higher risk of excessive ovarian response and of multifetal pregnancy than those with normal ovaries (Farhi, 1996).

### Aromatase Inhibitors

Gonadotropins are associated with more effective ovulation induction and higher pregnancy rates than CC. However, gonadotropins are expensive and carry higher risks for ovarian hyperstimulation syndrome and multifetal gestation. Accordingly, aromatase inhibitors have been investigated as ovulation-inducing agents (Fig. 20-3). These drugs were originally developed for breast cancer treatment and effectively inhibit *aromatase*, a cytochrome P450 hemoprotein that catalyzes the rate-limiting step in estrogen production. Aromatase inhibitors are orally administered, easy to use, relatively inexpensive, and associated with typically minor side effects (Chap. 10, p. 241).

The most widely used aromatase inhibitor to induce ovulation in anovulatory and ovulatory infertile women is letrozole (Femara). Compared with CC, its use is associated with higher pregnancy rates following ovulation induction (Legro, 2014). When used in combination with gonadotropins, letrozole leads to lower gonadotropin requirements and may achieve pregnancy rates comparable to gonadotropin treatment alone (Casper, 2003; Mitwally, 2004). The typical dosage used is 2.5 mg to 5 mg orally daily for 5 days.

Data suggesting that letrozole use for infertility treatment might be associated with a higher risk of congenital cardiac

and bone malformations in the newborn are contradictory (Biljan, 2005; Tulandi, 2006). However, in 2005, the manufacturer issued a statement to physicians worldwide advising that letrozole use in premenopausal women, specifically its use for ovulation induction, is contraindicated (Fontana, 2005). As a result, it is not likely that letrozole will gain FDA approval or widespread acceptance for ovulation induction in the near future. Larger, well-designed randomized prospective trials that confirm their safety are still needed (Franik, 2014).

A second aromatase inhibitor, anastrozole, is of the same compound class as letrozole and has also been approved for treatment of women with breast cancer. At this time, no concerns have been raised regarding its teratogenicity. However, experience with anastrozole (Arimidex) in ovulation induction at this time is limited, and ideal dosages are currently unknown. Two trials comparing anastrozole to clomiphene have not found it to be more effective than clomiphene (Tredway, 2011a,b).

### Complications of Fertility Drugs

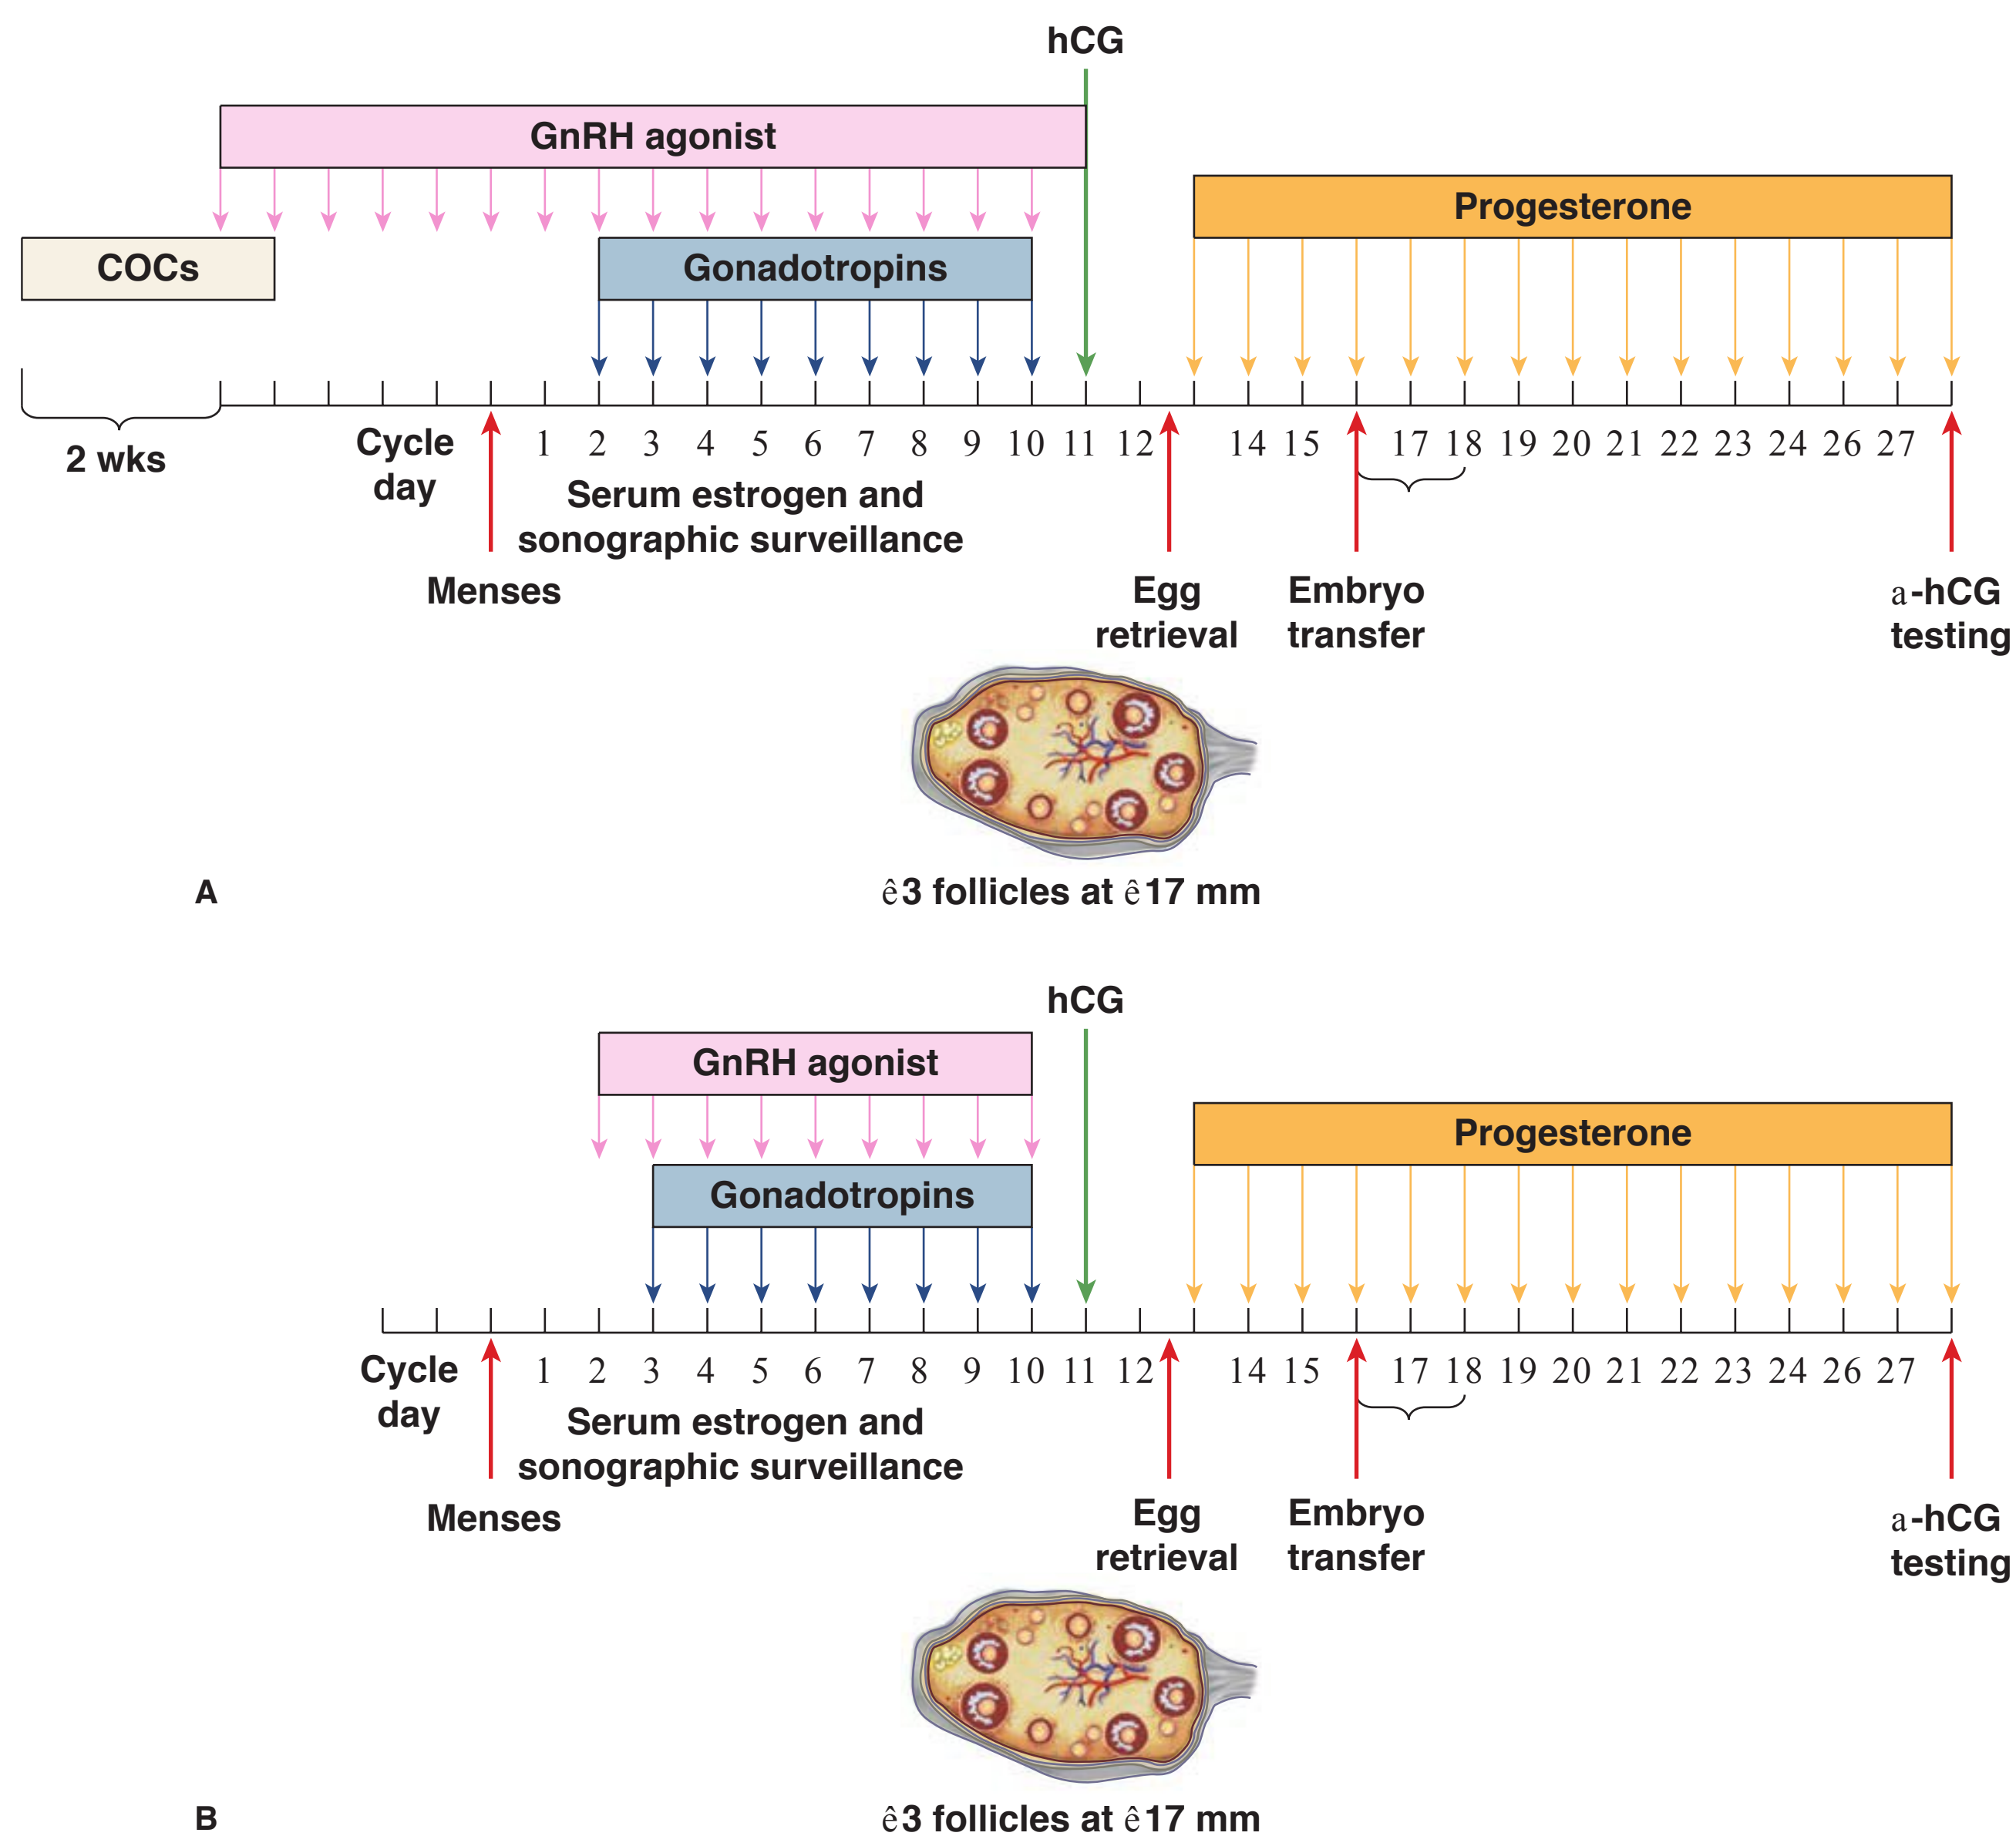

**Ovarian Hyperstimulation Syndrome.** This is a clinical symptom complex associated with ovarian enlargement resulting from exogenous gonadotropin therapy. Symptoms may include abdominal pain and distention, ascites, gastrointestinal problems, respiratory compromise, oliguria, hemoconcentration, and thromboembolism. These symptoms may develop during ovulation induction or in early pregnancies that were conceived through exogenous ovarian stimulation.

The etiology of ovarian hyperstimulation syndrome (OHSS) is complex, but hCG, either exogenous or endogenous (derived from a resulting pregnancy), is believed to be an early contributing factor. Development of OHSS involves increased vascular permeability and loss of fluid, protein, and electrolytes into the peritoneal cavity, which leads to hemoconcentration. Increased capillary permeability is felt to result from vasoactive substances produced by the corpus luteum. Vascular endothelial growth factor (VEGF) is thought to play a major role, and angiotensin II may also be involved. Hypercoagulability may be related to hyperviscosity following hemoconcentration. Alternatively, it may be secondary to the high estrogen levels present, and these high levels can increase coagulation factor production. Predisposing factors for OHSS include multifollicular ovaries such as with PCOS, young age, high estradiol levels during ovulation induction, and pregnancy.

Abdominal pain is prominent and caused by ovarian enlargement and accumulation of peritoneal fluid. Although sonographic examination of women with OHSS usually reveals enlarged ovaries with numerous follicular cysts and ascites, OHSS is a clinical diagnosis (Fig. 20-4). Several different classification schemes have been proposed to categorize the severity of this syndrome, and Table 20-2 lists one.

Treatment of OHSS is generally supportive. Paracentesis is typically performed transvaginally as an outpatient and can ameliorate abdominal discomfort and relieve respiratory distress. Reaccumulation of ascites may prompt additional paracenteses or rarely placement of a percutaneous “pigtail” catheter for continuous drainage. Untreated hypovolemia can lead to renal, hepatic, or pulmonary end-organ failure. Thus, fluid balance must be maintained by replacement with an isotonic fluid

**FIGURE 20-2** Drug protocols for ovulation induction. **A.** Downregulation of gonadotropin-releasing hormone (GnRH) agonist protocol. This is also known as the long protocol. In this diagram, the long protocol is combined with combination oral contraceptive (COC) pill pretreatment. With the long protocol, GnRH agonists are begun typically 7 days prior to gonadotropins. GnRH agonists suppress endogenous pituitary release of gonadotropins. This minimizes the risk of a premature luteinizing hormone (LH) surge and thus premature ovulation. During all protocols, serial serum estrogen levels and sonographic surveillance of follicular development accompany gonadotropin administration. Human chorionic gonadotropin (hCG) is administered to trigger ovulation when sonography shows three or more follicles measuring at least 17 mm. Eggs are retrieved 36 hours later. Embryos are transfer back to the uterus 3–5 days following retrieval. Progesterone supplementation, with either vaginal preparations or intramuscular injection, follows during the luteal phase to support the endometrium. The goal of COC pretreatment is to prevent ovarian cyst formation. One of the major drawbacks of GnRH agonist therapy is the induction of initial transient gonadotropin release or flare, which may lead to ovarian cyst formation. Functional ovarian cysts can prolong the duration of pituitary suppression required prior to gonadotropin initiation and may also exert a detrimental effect on follicular development because of their steroid production. Moreover, COC pretreatment may improve induction results by providing an entire cohort of follicles synchronized at the same developmental stage that will reach maturity at the same time once stimulated by gonadotropins. **B.** GnRH flare protocol. This is also known as the short protocol. GnRH agonists initially bind gonadotropes and stimulate follicle-stimulating hormone (FSH) and LH release. This initial flare of gonadotropes stimulates follicular development. Following this initial surge of gonadotropes, the GnRH agonist causes receptor downregulation and an ultimately hypogonadotropic state. Gonadotropin injections begin 2 days later to continue follicular growth. As with the long protocol, continued GnRH agonist therapy prevents premature ovulation. (Continued)

**FIGURE 20-2** (Continued) **C.** GnRH antagonist protocol. As with GnRH agonists, these agents are combined with gonadotropins to prevent premature LH surge and ovulation. This protocol attempts to minimize risk of ovarian hyperstimulation syndrome (OHSS) and GnRH side effects, such as hot flashes, headaches, bleeding, and mood changes.

such as normal saline. Monitoring of electrolytes is critical. Because of hypercoagulability in these women, prophylaxis for thromboembolism is strongly considered with severe OHSS.

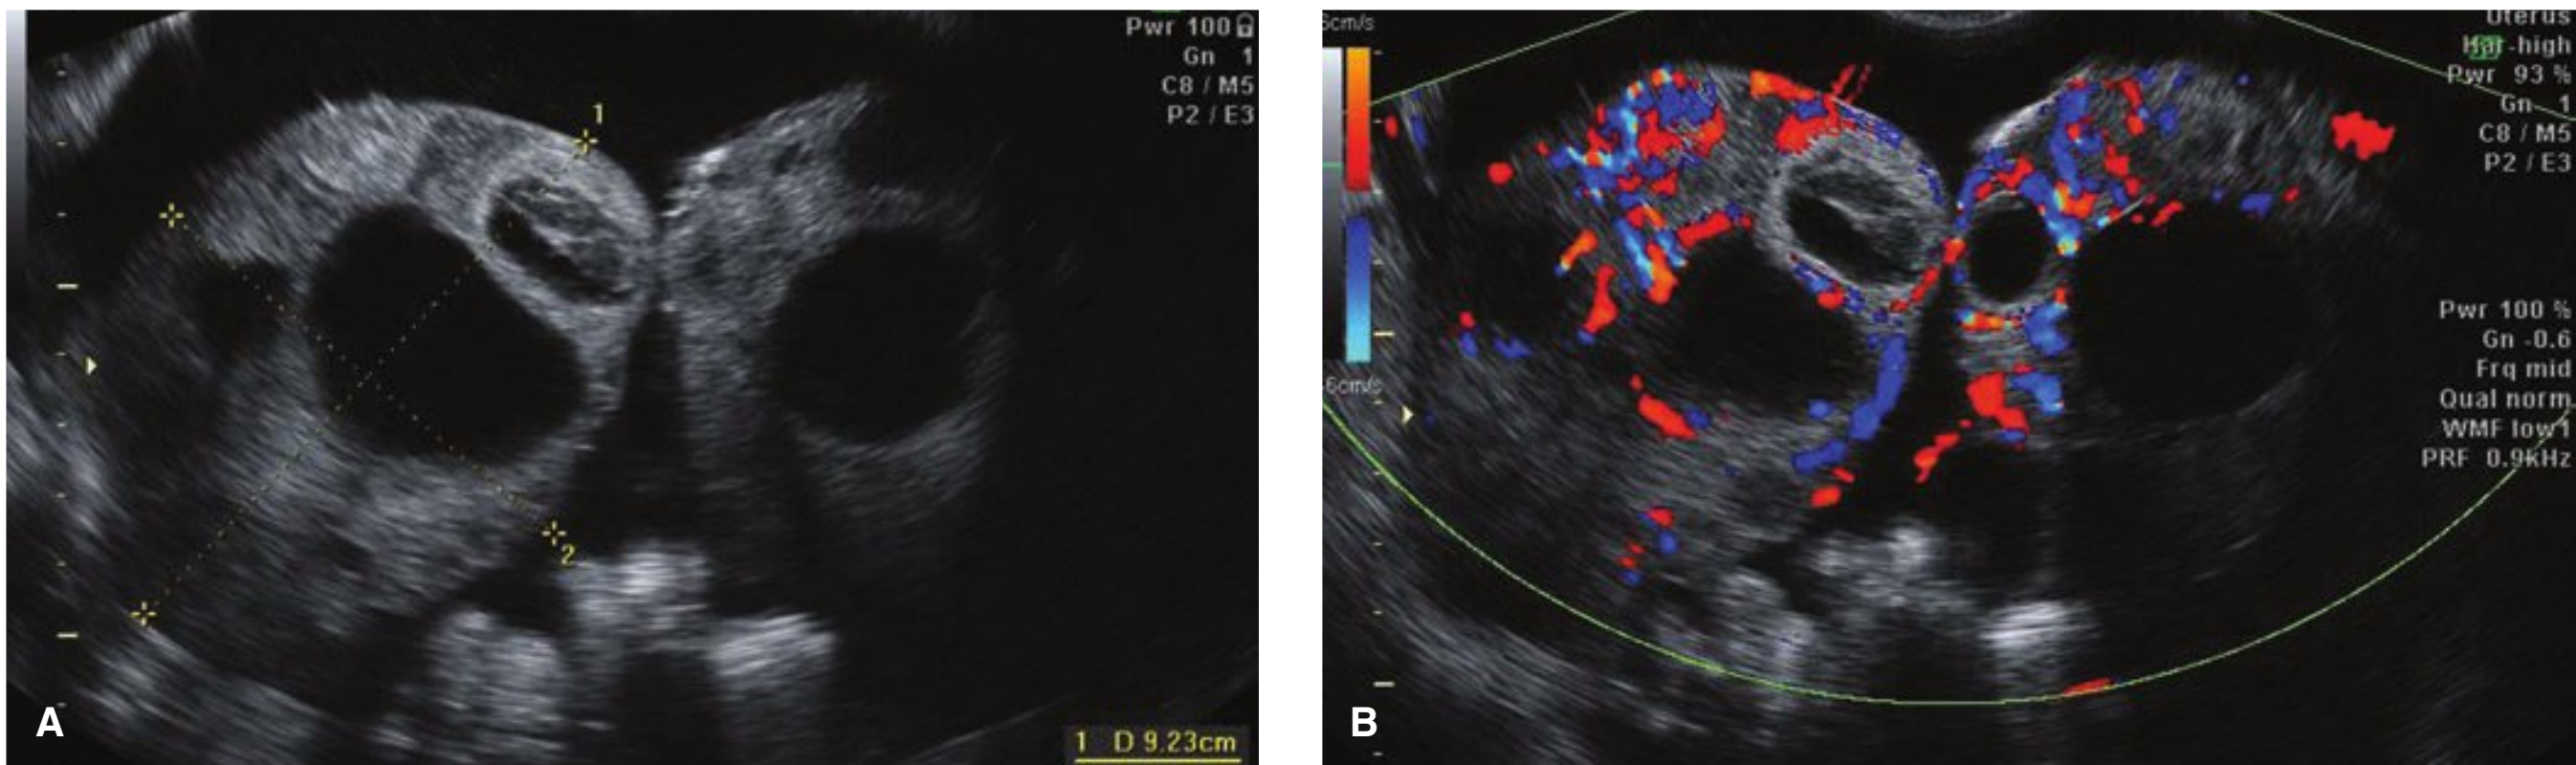

During exogenous ovulation, strategies to avoid OHSS induction include decreasing follicular stimulation (a decreased FSH dose), “coasting” (withholding FSH administration for one or more days prior to the hCG trigger injection), prophylactic

treatment with volume expanders, and substitution of hCG for FSH during the final days of ovarian stimulation. With this last strategy, low-dose hCG administration can support maturation of larger ovarian follicles but is postulated to directly or indirectly increase atresia rates of small antral follicles and thereby lower OHSS rates. However, during ovulation induction, if concern for OHSS develops, then the hCG trigger can

**FIGURE 20-3** Effect of aromatase inhibitor (AI) administration. **A.** Administration suppresses ovarian estradiol (E<sub>2</sub>) secretion and reduces estrogen negative feedback at the pituitary and hypothalamus. As a result, increased follicle-stimulating hormone (FSH) secretion from the anterior pituitary stimulates growth of multiple ovarian follicles. **B.** Later in the follicular phase, the effect of the aromatase inhibitor is reduced, and E<sub>2</sub> levels increase as a result of follicular growth. Because aromatase inhibitors do not affect estrogen receptors centrally, the increased E<sub>2</sub> levels result in normal central negative feedback on FSH secretion. Follicles smaller than the dominant follicle undergo atresia, with resultant monofollicular ovulation in most cases.

**FIGURE 20-4** **A.** Sonogram of ovaries with multiple large cysts secondary to ovarian hyperstimulation syndrome. Ovaries are enlarged and meet in the midline. Ascites surrounds these enlarged ovaries. **B.** Color Doppler transvaginal sonography is often performed to exclude ovarian torsion in these patients.

be withheld, resulting in cycle cancellation. For these patients, IVF should often be considered rather than further attempts at ovulation induction.

OHSS can also develop with ART therapy, and the risk can be substantially reduced with appropriate precautions. Predicted high responders (e.g., high numbers of antral follicles, high AMH level, or prior high response to ovulation induction) should be stimulated with a GnRH antagonist protocol. This allows a single GnRH agonist dose to be used for the “trigger” in place of hCG. The resulting endogenous LH surge can bring about the final stages of follicle and oocyte maturation without significant OHSS risk. Moreover, prevention of pregnancy does not completely eliminate the risk of OHSS but certainly serves to limit symptom duration. Thus, an additional option in ART cycles is to freeze all embryos and forgo embryo transfer that cycle.

**Multifetal Gestation.** From 1980 through 1997, the number of twin births rose by more than 50 percent, and the number of higher-order multifetal births increased by more than 400 percent (Fig. 20-5) (Martin, 1999). Using data from these years, the Centers for Disease Control and Prevention (CDC) (2000) estimated that approximately 20 percent of triplets and higher-order multifetal births were attributable to spontaneous events;

40 percent were related to ovulation-inducing drugs without ART; and 40 percent resulted from ART. However, further analysis of the same data indicates that the overwhelming majority of all multifetal births result from spontaneously conceived twin gestations and that only approximately 10 percent result from IVF and related procedures.

Higher-order multifetal pregnancy is an adverse outcome of infertility treatment. In general, increased fetal number leads to greater risk of perinatal and maternal morbidity and mortality. Prematurity leads to most adverse events in these cases, but fetal-growth restriction and discordance are other potential factors.

Monozygotic gestation is also increased in ovulation induction and ART and is associated with greater fetal risks. These include a three- to fivefold higher perinatal mortality rate compared with that of dizygotic twins. Abnormal placentation also develops at higher rates. Additionally, congenital anomalies are increased two- to threefold in monozygotic twins versus singleton neonates, with an estimated incidence of 10 percent. Initially, extended embryo culture and zona manipulation were postulated to increase the risk of monozygosity. More recent, well-designed trials have refuted this contention (Franasiak, 2015; Papanikolaou, 2010).

Patients with higher-order multifetal gestations are faced with options of continuing their pregnancy with all the risks previously described, terminating the entire pregnancy, or selecting multifetal pregnancy reduction (MFPR). MFPR reduces the number of fetuses to decrease the risk of maternal and perinatal morbidity and mortality. Although MFPR lowers the risks associated with preterm delivery, it often creates profound ethical dilemmas. Moreover, multifetal reduction lowers, but does not eliminate, the risk of fetal-growth restriction in remaining fetuses. With MFPR, pregnancy loss and prematurity are primary risks. However, current data suggest that such complications have decreased as experience with the procedure has grown (Evans, 2008).

Several issues in infertility care contribute to the increased incidence of higher-order multifetal pregnancies. An infertile couple’s sense of urgency may lead to a preference for more aggressive strategies involving gonadotropin treatment or for more embryos to be transferred in IVF cycles. Clinicians may feel competitive pressures to achieve higher pregnancy rates and may be inclined to turn to superovulation or IVF earlier in treatment or to transfer a greater number of embryos.

**TABLE 20-2.** Classification and Staging of Ovarian Hyperstimulation Syndrome

Grade 1:	Abdominal distention/discomfort
Grade 2:	Grade 1 plus nausea and vomiting or diarrhea Ovaries enlarged 5–12 cm
Grade 3:	Sonographic evidence of ascites
Grade 4:	Clinical evidence of ascites or hydrothorax or difficulty breathing
Grade 5:	All of the above plus decreased blood volume, hemoconcentration, diminished renal perfusion and function, and coagulation abnormalities

Reproduced with permission from Whelan JG III, Mahos NF: The ovarian hyperstimulation syndrome, *Fertil Steril* 2000 May;73(5):883–896.

**FIGURE 20-5** Trends in frequency of multifetal gestations. **A.** Number of twin births in the United States from 1980 to 2006. **B.** Number of triplet and higher-order multifetal births in the United States for the same time period. (Data from Martin JA, Hamilton BE, Osterman MH, et al: Births: final data for 2013. Natl Vital Stat Rep 64:1, 2015.)

There have been efforts to lower the rates of multifetal gestation in patients undergoing ovulation induction or superovulation by using serum estradiol limits and arbitrary sonographic criteria of follicular size. These, however, have been ineffective. In a multicenter randomized clinical trial involving 1255 ovulation induction cycles, hCG was withheld if the estradiol concentration rose above 3000 pg/mL or if more than six follicles greater than 18 millimeters in diameter were present (Guzick, 1999). Despite these limits on hCG administration, the multifetal gestation rate was still 30 percent. Although sonography and serum estradiol monitoring have not reduced the incidence of multifetal gestation or OHSS, the risk of multifetal pregnancy does correlate with the magnitude of follicular response as indicated by follicle number and serum estradiol levels. However, there is no consensus among centers regarding specific sonographic criteria or estradiol levels beyond which hCG should not be administered.

When the likelihood of multifetal gestation is felt to be excessive, IVF can be undertaken to reduce the risk. Because the number of embryos transferred can be strictly controlled, this strategy can minimize the risk of higher-order multifetal gestations. Guidelines set forth by the American Society for Reproductive Medicine and the Society for Assisted Reproductive Technology (2013a) have led to a significant reduction in triplet (and higher-order) gestations (Table 20-3). Efforts to reduce twin pregnancies through the increased use of elective single embryo transfer (eSET) are currently ongoing (American Society for Reproductive Medicine, 2012c).

### Ovarian Drilling

Surgical ovarian wedge resection was the first established treatment for anovulatory PCOS patients. It was largely abandoned

because of postsurgical adhesion formation, which converted endocrinologic subfertility to mechanical subfertility (Adashi, 1981; Buttram, 1975; Stein, 1939). As a result, it was replaced by medical ovulation induction with CC and gonadotropins (Franks, 1985). However, medical ovulation induction, as discussed earlier, has limitations. Accordingly, surgical therapy using laparoscopic techniques and termed *laparoscopic ovarian drilling* is an alternative in women resistant to medical therapies.

During laparoscopic ovarian drilling, electrosurgical coagulation, laser vaporization, or Harmonic scalpel may be used to create multiple perforations into the ovarian surface and stroma (Section 44-7, p. 1021). In many uncontrolled observational studies, drilling has led to temporary, higher rates of spontaneous postoperative ovulation and conception or to improved medical ovulation

induction (Armar, 1990, 1993; Farhi, 1995; Greenblatt, 1987; Kovacs, 1991).

The mechanism of action with laparoscopic ovarian drilling is thought to be similar to that of ovarian wedge resection. Both procedures destroy ovarian androgen-producing tissue

**TABLE 20-3.** Recommended Limits on the Numbers of Embryos to Transfer

Prognosis	Age			
	< 35 yr	35–37 yr	38–40 yr	41–42 yr
<b>Cleavage-stage embryos<sup>a</sup></b>				
Favorable <sup>b</sup>	1–2	2	3	5
All others	2	3	4	5
<b>Blastocysts<sup>a</sup></b>				
Favorable <sup>b</sup>	1	2	2	3
All others	2	2	3	3

<sup>a</sup>Justification for transferring one additional embryo more than the recommended limit should be clearly documented in the patient's medical record.

<sup>b</sup>Favorable = first cycle of in vitro fertilization (IVF), good embryo quality, excess embryos available for cryopreservation, or previous successful IVF cycle.

Reproduced with permission from American Society for Reproductive Medicine, Society for Assisted Reproductive Technology: Criteria for number of embryos to transfer: a committee opinion, Fertil Steril 2013 Jan;99(1):44–6.

and reduce peripheral conversion of androgens to estrogens. Specifically, a fall in serum levels of androgens and LH and an increase in FSH levels have been demonstrated after ovarian drilling (Armar, 1990; Greenblatt, 1987). The endocrine changes following surgery are thought to convert the adverse androgen-dominant intrafollicular environment to an estrogenic one and to restore the hormonal environment to normal by correcting ovarian-pituitary feedback disturbances (Aakvaag, 1985; Balen, 1993). Thus, both local and systemic effects are thought to promote follicular recruitment and maturation and subsequent ovulation.

Risks of ovarian drilling include postoperative adhesion formation and the other risks of laparoscopic surgery (Chap. 41, p. 877). Additionally, theoretical risks of diminished ovarian reserve and premature ovarian failure remain to be well investigated. As surgery is more invasive, ovarian drilling is generally not offered prior to consideration of medical therapies.

### CORRECTION OF DIMINISHED OVARIAN RESERVE

Ovarian dysfunction may result from ovarian failure or from a diminished ovarian reserve, either of which may follow normal aging, disease, cancer treatment, or ovarian surgery. Even if a woman is spontaneously menstruating, a basal (cycle day 2 or 3) FSH level above 15 IU/L predicts that medical therapies including exogenous gonadotropins will be of little benefit. For these women, the option of using donor eggs should be considered (p. 465). Expectant management may also be considered, although the likelihood of pregnancy is low. AMH can identify patients with diminished ovarian reserve prior to the elevation of basal FSH. Although patients with low AMH (< 1 ng/mL) generally respond poorly to gonadotropins, some may benefit from ART.

### CORRECTION OF ANATOMIC ABNORMALITIES

Anatomic distortions of the female reproductive tract are a major cause of infertility and may prevent ovum entry into the fallopian tube; impair transport of ova, sperm, or embryos; or interfere with implantation. The three primary types of anatomic abnormalities include tubal factors, peritoneal factors, and uterine factors. Each has differing effects and therefore may require different therapies.

#### ■ Tubal Factors

Tubal occlusion can arise from congenital abnormality, infection, or iatrogenic causes. Additionally, a small subset of tubal infertility is idiopathic. Not only the cause of tubal damage but also the anatomic abnormality is important. For example, proximal tubal occlusion, distal tubal occlusion, and tubal absence differ markedly in their treatment.

*Proximal tubal occlusion* describes obstruction proximal to the fimbria and may develop at the tubal ostium, isthmus, or ampulla. *Midtubal occlusion* is considered a subset of proximal occlusion. Proximal tubal occlusion may be secondary to tubal

resection, luminal obliteration, or simple plugging with mucus or debris. In contrast, *distal tubal occlusion* describes obstruction at the tube's fimbria. It typically results from prior pelvic infection and may be associated with concomitant adnexal adhesions.

#### Tubal Cannulation

Proximal tubal occlusion is often amenable to direct techniques. If diagnosed at the time of hysterosalpingography (HSG), consideration is given to performing concurrent selective salpingography. A catheter is placed such that it wedges within the tubal ostium. This allows significant hydrostatic pressure to be applied to the tube. Such pressure will likely overcome most instances of tubal spasm or plugging by mucus or debris. If tubal patency cannot be reestablished, an inner catheter with guide wire is used to cannulate the tube. This creates patency of isolated short segmental scarring in most instances. Scarring of a longer segment or luminal obliteration, however, is not amenable to correction with tubal cannulation. In these women, surgical segmental resection with reanastomosis or IVF may be considered.

#### Tubal Reconstruction

**Proximal Tubal Obstruction.** Tubal obstruction not amenable to treatment with selective salpingography has traditionally been treated surgically, and options include hysteroscopic cannulation, surgical reanastomosis, and neosalpingostomy. Although success rates of ART have risen considerably, reproductive surgery remains an important option or complement to ART for many couples.

Some types of tubal blockage have a much better prognosis with surgical therapy than others. For example, hysteroscopic cannulation of fallopian tubes can treat some types of proximal obstruction in a fashion similar to selective salpingography (Section 44-18, p. 1050). Hysteroscopic cannulation is best performed with concurrent laparoscopy to verify distal tubal patency.

Proximal obstruction not amenable to cannulation techniques can be treated with segmental resection and reanastomosis (Fig. 20-6). In most cases, this can be done as an outpatient procedure through a minilaparotomy incision. However, obstruction extending into the interstitial portion of the tube is more technically challenging to repair and more prone to repeated obstruction postoperatively. Therefore, proximal occlusion extending to the interstitial segment that cannot be treated with cannulation is best treated in most instances with IVF.

Options for proximal and midtubal occlusion resulting from prior sterilization are either tubal reanastomosis or IVF. From a patient perspective, outpatient tubal reanastomosis avoids ovarian stimulation and increased risk for multifetal gestation and provides an ability to conceive normally. In general, although the monthly probability of pregnancy following tubal reversal is likely lower than that for age-matched controls without prior sterilization, the cumulative chance of pregnancy is high. However, IVF is strongly considered if other fertility factors are present or the type of sterilization performed does not permit reconstruction. For example, in cases of sterilization completed by fimbriectomy, neosalpingostomy can be corrective.

**FIGURE 20-6** Surgical reanastomosis of fallopian tube segments. The scarred portion of the tube is sharply excised until nonfibrotic tubal tissues are reached. **A.** The mesosalpinx is reapproximated with interrupted stitches using 6-0 delayed-absorbable suture. **B.** The tubal muscularis is reapproximated with single stitches in each quadrant using 7-0 delayed-absorbable suture. Tubal serosa is closed with interrupted or running 6-0 delayed-absorbable suture.

However, the probability of pregnancy is lower, and IVF is considered. Importantly, the risk of subsequent ectopic pregnancy following reanastomosis for midtubal occlusion is 3 to 5 percent (Gordts, 2009).

The “reversibility” of sterilization can generally be determined by review of the operative report and also the pathology report if the procedure involved segmental resection. If operative records are unavailable or suggest that reanastomosis may not be feasible, laparoscopy is performed prior to laparotomy to assess chances of surgical success.

Outpatient reversal of sterilization is most commonly done by minilaparotomy. Incision size typically varies from 3 to 6 cm depending on a patient’s weight and anatomy. Some surgeons are able to complete some of these procedures by laparoscopy. Robotic control may be helpful for this but may increase operating time and expense.

**Distal Tubal Obstruction.** Following pelvic inflammatory disorders, normal fimbrial anatomy may be destroyed, or fimbria may be encased by adnexal adhesions. In these cases, neosalpingostomy can be performed at minilaparotomy or laparoscopy (Fig. 20-7). However, women desiring neosalpingostomy for treatment of distal occlusion are counseled that the risk of ectopic pregnancy is high, the likelihood of pregnancy is 50 percent or lower, and postoperative reocclusion

is common (Bayrak, 2006). Moreover, hydrosalpinges that are dilated more than 3 cm in diameter, that are associated with significant adnexal adhesions, or that display an obviously attenuated endosalpinx yield a poor prognosis. These tubes are best treated by salpingectomy. If both tubes are affected, bilateral salpingectomy is recommended prior to proceeding with IVF. This stems from data showing women with hydrosalpinges undergoing IVF have approximately half the pregnancy rate of other women with unaffected tubes (American Society for Reproductive Medicine, 2012a).

## ■ Uterine Factors

Three types of uterine factors have been implicated in infertility and include leiomyomas, endometrial polyps, and intrauterine adhesions. Müllerian anomalies, especially intrauterine septum or segmental agenesis, can increase infertility or pregnancy complication rates. These congenital abnormalities are described fully in Chapter 18 (p. 417). Mechanisms of infertility with these factors have not been clearly elucidated. However, the end result is decreased endometrial receptivity and reduced likelihood of embryo implantation.

## Leiomyomas

Leiomyomas are common benign tumors of the uterus and have been associated with infertility in some women (Chap. 9, p. 205). Retrospective studies have suggested a benefit from surgically removing certain tumors to increase efficacy of both natural and assisted conception (Grifths, 2006).

There are no randomized controlled trials to clearly demonstrate that myomectomy improves fertility. However, in view of the many retrospective observational studies that suggest this, it is reasonable to offer myomectomy to well-selected infertile women, especially if tumors are large or impinge on the endometrial cavity. Myomectomy can be performed using hysteroscopy, laparoscopy, or laparotomy, and selection of the approach is discussed in Chapter 9 (p. 211). Currently, no studies validate one method compared with another in terms of efficacy. Therefore, clinical judgment should determine the most appropriate technique from the standpoint of safety, restoration of normal uterine anatomy, and speed of recovery.

**FIGURE 20-7** Neosalpingostomy. **A.** The distal end of the clubbed fallopian tube is opened sharply or with electric or laser energy. **B.** The endosalpinx is everted using Cuff or Bruhat technique.

**TABLE 20-4.** Number and Percentage of Pregnancies after Hysteroscopic Polypectomy (n = 204)

	Polypectomy n = 101 (%)	Control n = 103 (%)	p-value
Subsequent pregnancy	64 (63.4)	29 (28.2)	< 0.001

RR 2.1 (95% CI 1.5–2.9).  
Reproduced with permission from Pérez-Medina T, Bajo-Arenas J, Salazar F, et al: Endometrial polyps and their implication in the pregnancy rates of patients undergoing intrauterine insemination: a prospective, randomized study. Hum Reprod 2005 Jun;20(6):1632–1635.

Endometrial Polyps

These soft, fleshy endometrial growths are commonly diagnosed during infertility evaluation. Several studies suggest good pregnancy rates following polypectomy, although the mechanism by which polyps impair fertility has not been established. The requirement to remove even small polyps in infertile women has been previously debated. However, one prospective trial of 204 women with polyps and with an additionally diagnosed cervical factor, male factor, or unexplained infertility appears to give some clear guidance.

In this trial, women were randomized to one of two groups prior to treatment with intrauterine insemination (IUI) (Pérez-Medina, 2005). The first group underwent polypectomy. The second underwent only hysteroscopic biopsy of the polyp to obtain histologic confirmation. All patients were managed expectantly for three cycles prior to proceeding with up to four cycles of IUI. The pregnancy rate in the polypectomy group was more than twice as high regardless of initial polyp size (Table 20-4). These data suggest that endometrial polyps can significantly impair infertility treatment outcome. Thus, it would seem prudent to

perform hysteroscopic polypectomy in all infertile patients if a polyp is identified (Section 44-13, p. 1038).

Intrauterine Adhesions

Adhesions within the endometrial cavity, also called *synechiae*, can range from asymptomatic small bands to complete or near complete obliteration of the endometrial cavity. If amenorrhea or hypomenorrhea result, the condition is termed *Asherman syndrome* (Chap. 16, p. 372).

Treatment involves surgical adhesiolysis to restore normal uterine cavity size and configuration. Dilatation and curettage (D & C) and abdominal approaches have previously been used. However, with the advantages of hysteroscopy, the role of these other techniques has been minimized.

Hysteroscopic adhesion resection may range from simple lysis of a small band to extensive adhesiolysis of dense intra-uterine adhesions using scissors, electrosurgical cutting, or laser energy (Section 44-19, p. 1052). However, women whose uterine fundus is completely obscured and those with a markedly narrowed, fibrotic cavity present the greatest therapeutic challenge. Several techniques have been described for these difficult cases, but outcome is far worse than in patients with small band adhesions. In those women with severe Asherman syndrome that is not amenable to reconstructive surgery, gestational carrier surrogacy is a valuable option (p. 465).

■ Peritoneal Disease

Endometriosis

This condition and its effects on infertility are extensively discussed in Chapter 10 (p. 234). In women with minimal or mild disease, evidence supporting lesion ablation is limited and use of empiric general fertility boosting procedures such as ART or superovulation combined with IUI is reasonable. These treatments have been validated to increase fecundity in women with stage I and II disease (Table 20-5) (Guzick, 1999).

**TABLE 20-5.** Cycle Fecundity with Stage I or II Endometriosis compared with Unexplained Infertility

Moderate and severe endometriosis results in distortion of anatomic relationships of reproductive organs. In many cases, surgical treatment may improve anatomy, and pregnancy can result (American Society for Reproductive Medicine, 2006). Unfortunately, advanced disease may prevent adequate restoration of pelvic anatomy. Therefore, a surgeon's operative findings and anticipated surgical results guide postoperative strategy. If satisfactory surgical outcome is achieved, it is reasonable to attempt pregnancy for 6 to 12 months prior to considering other options such as IVF. It should be remembered that endometriosis in some cases may recur quickly, and unnecessary delay in attempting pregnancy postoperatively is not advised.

In women with advanced endometriosis, several studies suggest that long-term treatment with GnRH agonists before initiation of a cycle may improve fecundity (Dicker, 1992; Surrey, 2002). Currently, however, this treatment strategy is not universally accepted.

If endometriomas are noted, surgical options include cyst drainage, drainage followed by cyst wall ablation, or cyst excision. These three procedures can be performed laparoscopically in nearly all circumstances given adequate surgeon experience. Simple drainage minimizes ovarian destruction but commonly results in rapid cyst recurrence. One histologic study demonstrated that a mean of 60 percent of the cyst wall (range of 10 to 98 percent) was lined by endometrium to a depth of 0.6 mm (Muzii, 2007). Thus, drainage and ablation may not destroy all endometrium to this depth. Moreover, this approach is associated with significant risk of cyst recurrence and thermal damage to the ovary. For these reasons, laparoscopic excision of the cyst wall by a stripping technique should be considered optimal treatment for most endometriomas (Section 44-5, p. 1015). Hart and coworkers (2008) compared ablative surgery and cyst excision. With excision, they noted more favorable rates of diminished pain, cyst recurrence, and spontaneous pregnancy. However, excision is inevitably accompanied by removal of normal ovarian tissue and often leads to decreased ovarian volume and diminished ovarian reserve (Almog, 2010; Exacoustos, 2004; Ragni, 2005).

Endometrioma recurrence is common. But, surgery for a recurrent endometrioma appears to be even more harmful to the ovarian reserve than primary surgery (Muzii, 2015). Thus, further ovarian surgery is individualized (American College of Obstetricians and Gynecologists, 2014a). If there is confidence in the diagnosis, it may be prudent in some cases to avoid surgery entirely when future fertility is desired.

### Pelvic Adhesions

Pelvic adhesions may result from endometriosis, prior surgery, or pelvic infection and often vary in their density and vascularity. Adhesions may impair fertility by distorting adnexal anatomy and by interfering with gamete and embryo transport, even in the absence of tubal disease.

Surgical lysis may restore pelvic anatomy in some cases, but adhesions may recur, especially if they are dense and vascular. Adherence to microsurgical principles and minimally invasive surgery may help decrease adhesion formation. Although numerous adjuvants, such as adhesion barriers, have been used to reduce the risk of postoperative adhesion formation, currently none have been validated to improve fecundity (American Society for Reproductive Medicine, 2013c).

Among infertile women with adnexal adhesions, pregnancy rates after adhesiolysis are 32 percent at 12 months and 45 percent at 24 months of surveillance. These rates can be compared with 11 percent at 12 months and 16 percent at 24 months in those left untreated (Tulandi, 1990). As with severe endometriosis, clinical judgment regarding operative findings and results of surgery should guide the strategy postoperatively. IVF is the best option for those with a poor prognosis for normal anatomy restoration.

### CORRECTION OF CERVICAL ABNORMALITIES

In response to follicular estradiol production, the cervix should produce abundant thin mucus. If present, this mucus acts as a conduit and functional reservoir for sperm. Accordingly, inadequate cervical mucus impairs sperm transport to the upper female reproductive tract.

Causes of abnormal or deficient mucus include infection, prior cervical surgery, use of antiestrogens (e.g., clomiphene citrate) for ovulation induction, and sperm antibodies. However, many women with decreased or hostile mucus have no history of predisposing factors.

Examination of cervical mucus may reveal gross evidence of chronic cervicitis that deserves treatment. Doxycycline, 100 mg orally twice daily for 10 days, is an appropriate therapy. In those with decreased mucus volume, treatments include short-term supplementation with exogenous estrogen, such as ethinyl estradiol, and the use of the mucolytic expectorant guaifenesin. However, the value of estrogen and guaifenesin has not been confirmed. Moreover, exogenous estrogens could have a negative effect on follicular development and ovarian function.

For these reason, most clinicians treat noninfectious, suspected cervical mucus abnormalities with IUI (Fig. 20-8). Although this approach also has not been validated with randomized prospective trials, the theoretical basis for this approach seems sound (Helmerhorst, 2005). Additionally, IUI has been

**FIGURE 20-8** Intrauterine insemination (IUI). Prior to IUI, partner or donor sperm is washed and concentrated. IUI is usually combined with superovulation, and signs of impending ovulation are monitored with transvaginal sonography. At the time of suspected ovulation, a long, thin catheter is threaded through the cervical os and into the endometrial cavity. A syringe containing the sperm concentrate is attached to the catheter's distal end, and the sperm sample is injected into the endometrial cavity.

demonstrated to be effective for treatment of unexplained infertility. As a result, many clinicians forgo cervical mucus testing and proceed directly with IUI treatments in the absence of tubal disease.

## CORRECTION OF MALE INFERTILITY

Male infertility has numerous causes and may include various sperm or semen volume abnormalities that are described subsequently. Accordingly, therapy should be planned only after thorough evaluation (Chap. 19, p. 442). In the absence of identifiable correctable cause, it is appropriate to offer IUI or ART as treatment options. The choice of whether to proceed initially with IUI therapies as opposed to the more intensive and expensive ART treatments is dependent on several factors. These include duration of infertility, age of the female, and history of prior treatments. If ART is considered for male factor, intracytoplasmic sperm injection (ICSI) is typically selected rather than traditional IVF (Fig. 20-9).

### ■ Abnormal Semen Volume

*Aspermia* is characterized by a complete lack of semen and results from failure to ejaculate. The physiology of normal ejaculation includes emission of sperm with accessory gland fluid into the urethra, simultaneous closure of the urethral sphincters, and forceful ejaculation of semen through the urethra. Emission and closure of the bladder neck are primarily alpha-adrenergically mediated thoracolumbar sympathetic reflex events with supraspinal modulation. Ejaculation is a sacral spinal reflex mediated by the pudendal nerve.

Anejaculation or anorgasmia is not rare and may stem from psychogenic factors, organic erectile dysfunction, or impaired parasympathetic sacral spinal reflex. Appropriate treatments depend on the cause and can include psychologic counseling or erectile dysfunction treatment with sildenafil citrate (Viagra) or other similar medication. Vibratory stimulation may also be effective in some instances. Electroejaculation is an invasive procedure and is generally used for men with spinal cord injuries who are unresponsive to the therapies above.

Men who always achieve orgasm but never experience prograde ejaculation or have a greatly reduced prograde volume typically have retrograde ejaculation. Therefore, administration of oral pseudoephedrine or another alpha-adrenergic agent to aid bladder neck closure is warranted. However, for many, pharmacologic methods are ineffective, and IUI may be performed using sperm processed from a voided urine specimen collected after ejaculation.

A minority of men who achieve orgasm, but not prograde ejaculation, have failure of emission. A trial of sympathomimetic agents is reasonable in these individuals as well, although pharmacologic therapies have generally provided limited success. Alternatively, testicular or epididymal extraction of sperm via aspiration or biopsy may be used in cases refractory to medication. As with electroejaculation, this technique recovers a limited number of viable sperm and is best suited for use with ICSI.

*Hypospermia*, that is, low semen volume ( $< 2$  mL), impairs sperm transport into cervical mucus and can be associated with decreased sperm density or motility. Retrograde ejaculation may underlie this condition, and treatment follows that just described for aspermia.

Alternatively, hypospermia may follow partial or complete ejaculatory duct obstruction. In these cases, transurethral excision of the obstruction and reanastomosis of the ejaculatory ducts has resulted in marked semen parameter improvement, and pregnancies have been achieved. However, couples are counseled that postoperative complete obstruction of the ejaculatory ducts is not rare. Thus, consideration is given to cryopreservation of sperm prior to surgical attempts in those individuals with partial obstruction.

### ■ Abnormal Sperm Count

*Azoospermia* is characterized by the total absence of sperm in semen. This may result from male reproductive tract obstruction or from nonobstructive causes.

Obstructive azoospermia, especially resulting from prior vasectomy or ejaculatory duct obstruction, may be amenable to surgical treatment. However, congenital bilateral absence of the vas deferens (CBAVD) is a common cause of azoospermia and

**FIGURE 20-9** Photomicrographs of intracytoplasmic sperm injection.

unfortunately is not treatable surgically. In such candidates, testicular sperm extraction (TESE) may be performed in conjunction with ICSI.

Nonobstructive azoospermia may be caused by a karyotypic abnormality such as Klinefelter syndrome (47,XXY) or balanced translocation; deletion of a small portion of the Y chromosome; testicular failure; or by unexplained causes. In many cases, TESE may be combined effectively with ICSI in those with Klinefelter syndrome and Y microdeletion of the AZFc region. However, in men with Y microdeletion in the AZFa or AZFb region, this ART combination has been ineffective (Choi, 2004).

*Oligospermia* is diagnosed if fewer than 15 million sperm are present per milliliter of semen. Causes are varied and include hormonal, genetic, environmental (including medications), and unexplained causes. Additionally, an obstructive cause, especially ejaculatory duct obstruction, should be considered if oligospermia is seen in conjunction with low semen volume. If severe oligospermia (< 5 to 10 million sperm per mL) is noted, then an evaluation similar to that for azoospermia is warranted.

Oligospermia in the absence of decreased sperm motility not uncommonly reflects hypogonadotropic hypogonadism. In general, hypogonadotropic hypogonadism is best treated with FSH and hCG administered to the male. Alternatively, clomiphene citrate and aromatase inhibitors, although not FDA-approved treatment for this indication, may be considered for some males, especially if obesity and elevated serum estradiol levels are present. Spermatogenesis is a long process lasting approximately 100 days. Thus, several months may be required to identify significant improvements in sperm density with either treatment.

Environmental factors such as excessive exposure to high temperatures should be investigated. Drug and medication history is also obtained. If an environmental factor is identified, correction may improve sperm numbers.

### ■ Abnormal Sperm Motility or Morphology

*Asthenospermia*, that is, decreased sperm motility, may be seen alone or in combination with oligospermia or other abnormal semen parameters. In general, asthenospermia does not respond to directed treatments. Expectant management may be considered especially if the duration of infertility is short and maternal age is less than 35 years. For treatment, IUI and ICSI are preferred, although IUI is generally not successful in severe cases (Centola, 1997). If fewer than 1 million motile sperm are available for insemination following semen processing or the couple has experienced more than 5 years of infertility, then ICSI is considered as initial therapy (Ludwig, 2005).

*Teratozoospermia* or abnormal sperm morphology is most often seen in conjunction with oligospermia, asthenospermia, and oligoasthenospermia. Directed treatments for teratozoospermia are not available, and therapy options include IUI and ART. Because teratozoospermia may commonly be accompanied by sperm function defects that may impair fertilization, ICSI is considered if ART is selected.

### ■ Varicocele

This results from dilatation of the pampiniform plexus of the spermatic vein and is usually left-sided (Fig. 19-3, p. 431).

Traditional treatment is surgical ligation of the internal spermatic vein. With ligation, several surgical techniques have been employed, but retroperitoneal high ligation and transinguinal ligation are the most frequently performed. More recently, interventional radiographic techniques that selectively catheterize and embolize the internal spermatic vein with sclerosing solutions, tissue adhesives, or detachable balloons or coils have been used as alternatives. Despite the widespread application of varicocele treatments, there is insufficient evidence to conclude that treatment of a clinical varicocele in couples with male subfertility improves the likelihood of conception (Evers, 2003).

## UNEXPLAINED INFERTILITY

This may represent one of the most common infertility diagnoses, and its reported prevalence has reached as high as 30 percent (Dodson, 1987). The diagnosis of unexplained infertility is highly subjective and depends on the diagnostic tests performed or omitted and on their quality. Paradoxically, a diagnosis of unexplained infertility, therefore, will more often be reached if the evaluation is incomplete or poor quality (Gleicher, 2006). Nevertheless, an unexplained infertility diagnosis can, by definition, not be directly treated. Expectant management may be considered especially with infertility of short duration and with relatively young maternal age. However, if treatment is desired, then IUI, superovulation, and ART are empiric appropriate interventions to consider.

## INTRAUTERINE INSEMINATION

This technique uses a thin flexible catheter to place a prepared semen sample into the uterine cavity. First, motile, morphologically normal spermatozoa are separated from dead sperm, leukocytes, and seminal plasma. The highly motile fraction is then inserted transcervically near the anticipated time of ovulation. Intrauterine insemination can be performed with or without superovulation and is appropriate therapy for treatment of cervical factors, mild and moderate male factors, and unexplained infertility.

If performed for cervical factors, IUI timed by urine LH surge is an initial strategy that achieves reasonable pregnancy rates of up to 11 percent per cycle (Steures, 2004). Although this rate is lower than that seen with superovulation combined with IUI, the side effects and costs of superovulation are avoided.

In contrast, for unexplained infertility and for male factors, IUI is most commonly performed in conjunction with superovulation. A combination of clomiphene citrate and IUI was evaluated by Deaton and colleagues (1990) in one randomized trial. The treatment group had a significantly higher pregnancy rate (9.5 percent) compared with controls (3.3 percent). Gonadotropin treatment (FSH or hMG) alone has been shown to increase the likelihood of pregnancy, but the benefit is markedly improved with the addition of IUI.

## ASSISTED REPRODUCTIVE TECHNOLOGY

Assisted reproductive technology describes clinical and laboratory techniques used to achieve pregnancy in infertile couples

for whom direct corrections of underlying causes are not feasible. In principle, IUI meets this definition. By convention, however, ART procedures are those that at some point require extraction and isolation of an oocyte as described in the following paragraphs.

### ■ In Vitro Fertilization

During IVF, mature oocytes from stimulated ovaries are retrieved transvaginally with sonographic guidance (Fig. 20-10). Sperm and ova are then combined in vitro to prompt fertilization (Fig. 20-11). If successful, viable embryos are transferred transcervically into the endometrial cavity using sonographic guidance (Fig. 20-12). As discussed earlier, prior to proceeding with IVF, hydrosalpinges are removed or tubal interruption performed to increase implantation rates and decrease the risk of miscarriage.

Similar to IUI, substantial benefit is achieved using controlled ovarian hyperstimulation prior to egg retrieval. Many ova are genetically or functionally abnormal. Thus, exposure of

**FIGURE 20-10** Sonogram demonstrates transvaginal oocyte retrieval. The needle is seen in the upper right portion of the image as a hyperechoic line (arrow) entering a mature follicle.

**FIGURE 20-11** In vitro fertilization (IVF). Controlled ovarian hyperstimulation is achieved with one of the protocols displayed in Figure 20-2, and follicle maturation is monitored over several days sonographically. Near ovulation, a transvaginal approach is used to harvest eggs from the ovaries. These oocytes are fertilized in vitro, and fertilized eggs develop to the blastocyst stage. Blastocysts are then drawn up into a syringe and delivered into the endometrial cavity under sonographic guidance.

**FIGURE 20-12** Embryo transfer performed using abdominal sonographic guidance for proper placement. Catheter (arrow) is seen within the endometrial cavity.

several ova to sperm results in an increased chance of a healthy embryo. Most often, a GnRH agonist is used in conjunction with gonadotropins (FSH or hMG). These agonists prevent the possibility of spontaneous LH surge and ovulation prior to egg retrieval. Optimally, 10 to 20 ova are harvested, and from these, one healthy embryo is ideally transferred back to the uterus.

Unfortunately, methods to determine embryo health are imperfect. Therefore, to maximize the probability of pregnancy, more than one embryo is typically transferred, thus resulting in increased risk of multifetal gestation. However, advances in culture conditions now permit embryos to be cultured to the blastocyst stage. This allows transfer of fewer embryos yet maintains high pregnancy rates (Langley, 2001).

### ■ Intracytoplasmic Sperm Injection

This variation of IVF is most applicable to male factor infertility. During the micromanipulation technique of ICSI, cumulus cells surrounding an ovum are enzymatically digested, and a single sperm is directly injected through the zona pellucida and oocyte cell membrane. Pregnancy rates with ICSI are comparable with those achieved with IVF for other causes of infertility. For azoospermic men, ICSI has made pregnancy in their partners possible. In these cases, sperm are mechanically extracted from the testicle or epididymis.

### ■ Gestational Carrier Surrogacy

This variation of IVF places a fertilized egg into the uterus of a surrogate rather than into the “intended mother.” Indications are varied, and this approach may be appropriate for women with uncorrectable uterine factors, for those in whom pregnancy would pose significant health risks, and for those with repetitive unexplained miscarriage.

Gestational carrier surrogacy has legal and psychosocial issues. In most states, a surrogate is the legal parent and therefore, adoption must be completed after birth to give the intended mother her parental rights. However, a few states have adopted specific laws that extend protection to the intended parents.

### ■ Egg Donation

This may be employed in cases of infertility associated with ovarian failure or diminished ovarian reserve. Additionally, the technique may also be used to achieve pregnancy in fertile women when offspring would be at risk for maternally transmitted genetic disease. Egg donors may be known to the recipient couple or more commonly are anonymous young women recruited by an agency or IVF center.

Egg donation can be performed using “fresh” oocytes or cryopreserved eggs. Fresh egg donation cycles require synchronization of the recipient’s endometrium with egg development in the donor.

To accomplish this, the egg donor completes one of the superovulation protocols outlined in Figure 20-2. Concurrently, if a recipient is not menopausal, GnRH agonists are used to suppress gonadotropin production in the receiving woman. This allows a scheduled priming of her endometrium with estrogen and progesterone. Following gonadotropin suppression, exogenous estrogen is given to the recipient. This estrogen administration begins just prior to the start of gonadotropin administration to the egg donor. After a donor receives hCG to allow the final stages of follicle and egg maturation, the recipient begins progesterone to prepare her endometrium. In the recipient, estrogen and progesterone are typically continued until late in the first trimester when placental production of these hormones is deemed to be adequate.

### ■ Gamete or Zygote Intrafallopian Transfer

Gamete intrafallopian transfer (GIFT) is similar to IVF in that egg retrieval is performed after controlled ovarian hyperstimulation. Unlike IVF, however, fertilization and early embryo development do not take place in the laboratory. Eggs and sperm are placed via catheter through the fimbria and deposited directly into the oviduct. This transfer of gametes is most commonly performed at laparoscopy. Like IUI, GIFT is most applicable for unexplained infertility and should not be considered for tubal factor causes.

This technique was most popular in the late 1980s and early 1990s. However, as laboratory techniques have improved, IVF has largely replaced GIFT. In general, GIFT is more invasive, provides less diagnostic information, and requires transfer of more than two eggs for optimal pregnancy chances, which increases the risk of higher-order multifetal gestation. Thus, the major indication for GIFT at present is to avoid the religious or ethical concerns that some patients may have with fertilization taking place outside the body.

Zygote intrafallopian transfer (ZIFT) is a variant of IVF with similarities to GIFT. Zygote transfer is not performed directly into the uterine cavity but rather into the fallopian tube at laparoscopy. If the transfer is completed after a zygote has begun to divide, the procedure is more accurately termed tubal embryo transfer (TET). Although a normal fallopian tube may provide a superior environment for the early-stage embryo, this advantage has been lessened with improvements in laboratory culture methods. Accordingly, ZIFT currently is considered most appropriately in the rare case in which transcervical transfer during IVF is technically not feasible.

## ■ Embryo, Oocyte, or Ovarian Tissue Cryopreservation

With IVF, many eggs are retrieved to ultimately produce one to three healthy embryos for transfer. This frequently leads to extra embryos. Successful freezing and thawing of embryos has been possible for two decades. Moreover, advances in cryoprotectants and techniques have allowed improved survival rates of embryos frozen at various developmental stages. With cryopreservation, these supernumerary embryos can yield pregnancies later, obviating the need for ovarian stimulation and egg retrieval. For some patients, avoidance of fresh transfer and cryopreservation of all embryos may improve the chance of pregnancy. This may be due to improve synchrony between the embryo and the endometrium (Doody, 2014).

Cryopreservation of unfertilized eggs had previously posed significant technical hurdles. These challenges have been largely overcome by the development of ultrarapid freezing techniques (vitrification). Because of this advancement and preliminary data confirming its safety, oocyte cryopreservation is no longer considered experimental. Egg freezing is useful in preserving the fertility potential of women facing gonadotoxic chemotherapy. This technique also provides greater timing flexibility to circumvent cycle synchronization during egg donation. As success improves, oocyte cryopreservation may assist women desiring to delay childbearing, although data are lacking regarding its efficacy in this patient population. Careful counseling is needed with regard to age and clinic-specific success rates (American Society for Reproductive Medicine, 2013a).

Distinct from oocyte freezing, ovarian tissue cryopreservation is an option to preserve reproductive potential. Candidates are patients who must urgently undergo aggressive chemotherapy and/or radiotherapy or who have other medical conditions requiring treatment that may threaten ovarian function and subsequent fertility. This fertility preservation strategy may be well suited for prepubertal girls or women with hormone-sensitive malignancies. One or both ovaries or ovarian cortex tissue is removed during laparoscopy or minilaparotomy. Postoperatively, the ovarian cortex is cut into small tissue slivers measuring 0.3- to 2-mm thick and cryopreserved. Successful pregnancies have been achieved following autologous transplantation of thawed cortical tissue into a pelvic site such as a contralateral ovary or pelvic sidewall. Some pregnancies have been achieved without further intervention, while others have required ART. Safety concerns include the risk for reintroducing a malignancy following transplantation. This risk may be greatest with blood-borne cancers such as leukemia. Although promising, this procedure is currently considered experimental (American Society for Reproductive Medicine, 2014).

## ■ In Vitro Maturation

This technique has been used to achieve pregnancy by aspirating antral follicles from unstimulated ovaries and culturing these immature oocytes to allow resumption and completion of meiosis in vitro. In vitro maturation (IVM) may be useful in patients with PCOS in whom stimulation poses a significant risk of OHSS. Recent data suggest that success rates with standard IVF remain superior to those with IVM (Walls, 2015).

Additionally, long-term outcomes are unknown, thus IVM is deemed experimental (American Society for Reproductive Medicine, 2013b). In the future, refinement of this technique may make possible maturation of ova from preantral follicles. This could potentially allow preservation of fertility potential but without the need for subsequent autologous transplantation for women in whom gonadotoxic chemotherapy is required.

## ■ Preimplantation Genetic Diagnosis or Screening

These laboratory techniques identify genetic abnormalities in eggs or embryos prior to their transfer. Thus, risk for transmission of heritable disease is a well-established indication for *preimplantation genetic diagnosis (PGD)*. In contrast, *preimplantation genetic screening (PGS)* aims to identify embryonic aneuploidy resulting from gamete meiotic errors. Its proposed indications include recurrent miscarriage, advanced maternal age, and multiple failed IVF cycles.

PGD is no longer considered experimental, and implementation of newly developed methods for genetic analysis will likely continue to broaden its application (Society for Assisted Reproductive Technology, 2008). During this technique, cells are removed from a developing embryo. Multiple options exist regarding biopsy timing and genetic material source. Biopsy of the first and second polar body has the advantage of avoiding cell removal from the developing embryo. However, two separate micromanipulation procedures are required, and genetic abnormalities of paternal origin are not detected. Biopsy of cleavage-stage embryos (6- to 8-cell stage) allows evaluation of both maternal and paternal contribution to the genome (Fig. 20-13). However, biopsy at this stage may only partially reflect the embryo's genetic makeup if mitotic nondisjunction has occurred and embryonic mosaicism has been created. In addition, biopsied normal embryos may have a slightly decreased implantation rate. Most recently, biopsy of the trophectoderm at the blastocyst stage has been suggested to hold several advantages (Fig. 20-14). The trophectoderm is the layer from which trophoblasts and thus the placenta develop. Biopsy from this layer allows evaluation of several cells but avoids removal of fetal cells. However, biopsy of embryos at this late stage may require embryo cryopreservation following biopsy if genetic analysis cannot be performed rapidly.

Once cells are extracted, they are tested for structural aberrations and/or aneuploidy. Common testing options include single-nucleotide polymorphism (SNP) plus comparative genomic hybridization (CGH) microarrays or quantitative polymerase chain reaction. To analyze single cells for disease-specific DNA mutations, linkage analysis and DNA sequencing are generally used. Most recently, next-generation sequencing (NGS) has been used for both PGS and PGD. NGS has the potential to improve genetic diagnosis in embryos, especially in terms of high-throughput automation (Fiorentino, 2014).

## ■ Complications of Assisted Reproductive Technology

In most cases, ART leads to successful delivery of healthy singleton pregnancies. However, some pregnancy complications

**FIGURE 20-13** Photomicrographs of embryo biopsy.

may develop more frequently in those conceived using ART. Of maternal risks, preeclampsia, placenta previa, and placental abruption are more common in IVF-conceived pregnancies ([Table 20-6](#)). Of fetal risks, multifetal gestation, discussed earlier, is the most common. In addition, perinatal mortality, preterm delivery, low birthweight, and fetal-growth restriction have been implicated in IVF singleton gestations. These trends persist even following adjustment for age and parity (Reddy, 2007). Other studies, however, have not confirmed this increased risk (Fujii, 2010). Additionally, congenital anomalies and epigenetic issues are concerns ([Table 20-7](#)).

Discussions regarding the risks for congenital anomalies began shortly after the initial success of IVF and intensified following the use of ICSI. Specifically, studies do suggest a higher incidence of congenital anomalies in infants conceived with ovulation induction, IUI, or IVF compared with those from the general population (El-Chaar, 2009; Reddy, 2007). Interpretation of most published studies, however, is complex. For example, the patient population undergoing IVF is very different from the general obstetric population with respect to age and other factors. If data are adjusted for maternal age or

duration of subfertility, the risk of congenital anomalies does not appear to be increased with ART (Shevell, 2005; Zhu, 2006). This implies that much of the risk is intrinsic to the infertile couple and not related to the procedure itself.

An increase in the risk of epigenetic issues has also been reported. Although these conditions appear to be rare, their importance cannot be overstated. For review, each autosomal gene is represented by two copies, or alleles, and one copy is inherited from each parent. For most genes, both alleles are expressed simultaneously. However, approximately 150 human genes are *imprinted*, and with these genes, only one of the alleles is expressed. Imprinted genes are under control of an imprinting center that directs embryogenesis and viability. Alteration of the cellular environment can interfere with this regulation and may follow gamete manipulation or inadequate in vitro culture conditions. As a result, accelerated embryo growth, birth complications, placental abnormalities, and polyhydramnios have been observed in nonhuman mammalian ART pregnancies.

**TABLE 20-6.** Potential Risks in Singleton IVF-conceived Pregnancies

	Absolute Risk (%) in IVF-conceived Pregnancies	Relative Risk (vs. non IVF-conceived Pregnancies)
Preeclampsia	10.3%	1.6 (1.2–2.0)
Placenta previa	2.4%	2.9 (1.5–5.4)
Placental abruption	2.2%	2.4 (1.1–5.2)
Gestational diabetes	6.8%	2.0 (1.4–3.0)
Cesarean delivery <sup>a</sup>	26.7%	2.1 (1.7–2.6)

<sup>a</sup>Please note that most experts believe the rate of cesarean delivery to be well above the 26.7% rate quoted here.

IVF = in vitro fertilization.

**FIGURE 20-14** Photomicrograph of trophoctoderm biopsy. The trophoctoderm is distinct from the embryonic inner cell mass and gives rise to trophoblastic cells of the future placenta.

TABLE 20-7. Potential Risks in Singleton IVF Pregnancies

	Absolute Risk (%) in IVF Pregnancies	Relative Risk (vs. non-IVF Pregnancies)
Preterm birth	11.5	2.0 (1.7–2.2)
Low birthweight (< 2500 g)	9.5	1.8 (1.4–2.2)
Very low birthweight (< 1500 g)	2.5	2.7 (2.3–3.1)
Small for gestational age	14.6	1.6 (1.3–2.0)
NICU admission	17.8	1.6 (1.3–2.0)
Stillbirth	1.2	2.6 (1.8–3.6)
Neonatal mortality	0.6	2.0 (1.2–3.4)
Cerebral palsy	0.4	2.8 (1.3–5.8)
Genetic risks		
imprinting disorder	0.03	17.8 (1.8–432.9)
major birth defect	4.3	1.5 (1.3–1.8)
chromosomal abnormalities (after ICSI):		
of a sex chromosome	0.6	3.0
of another chromosome	0.4	5.7

IVF = in vitro fertilization; NICU = neonatal intensive care unit.

In humans, imprinted genes may contribute to behavior and language development, alcohol dependency, schizophrenia, and bipolar affective disorders. Imprinting may also increase risks for obesity, cardiovascular disease, and for childhood and adult cancers. Of imprinting disorders, only rates of the rare Beckwith-Wiedemann syndrome are currently suggested to be increased in human ART. Additionally, causation has not been conclusively proven. However, in view of the above increased risks, it is reasonable to consider more intensive prenatal assessment in pregnancies conceived by IVF.

Studies assessing cognitive development after ART have for the most part been reassuring, although conflicting studies do exist. Many studies are suboptimal due to small sample size, choice of comparison group, and confounding and mediating factors (Carson, 2010). Fortunately, currently available data suggest that the psychomotor development of preschool children conceived by IVF does not differ from that of naturally conceived children. Similarly, the socioemotional development of children conceived by IVF appears comparable with that of naturally conceived children (Ludwig, 2006).

CONCLUSION

The treatment of infertility is typically initiated only after a thorough investigation as outlined in the previous chapter. The initial focus is to identify lifestyle or environmental issues that may contribute to or cause the reproductive impairment. Obesity, adequate nutrition, and associated stress should not be overlooked. In general, it is desirable to correct any identifiable contributors to subfertility. In many cases, no obvious cause can be detected. In other couples, the cause(s) may be identifiable but not amenable to directed corrective therapies. In these circumstances,

generalized fertility boosting strategies may be recommended. These treatments include IUI (with or without superovulation) and ART. Importantly, superovulation and ART are not without risks, and couples should be appropriately counseled. Additionally, these techniques may involve third parties (egg, sperm, or embryo donors or gestational carriers). These procedures are associated with unique psychosocial, legal, and ethical considerations. Emerging technologies such as preimplantation genetic testing bring additional ethical issues that must be confronted and resolved by both patient and practitioner.

INFLUENTIAL FACTORS . . . . . 471

PHYSIOLOGIC CHANGES . . . . . 472

PATIENT EVALUATION . . . . . 487

REFERENCES . . . . . 489

The menopausal transition is a progressive endocrinologic continuum that takes reproductive-aged women from regular, cyclic menses to a final menstrual period and ovarian senescence. With medical advancements, average life expectancy has increased, and most women can now expect to live at least one third of their lives in the menopause. Specifically, by 2020, approximately 43 million women will be aged 45 to 64 years (U.S. Census Bureau, 2014). Importantly, menopausal transition and the years of life spent in the postmenopausal state bring with them issues related to both quality of life and disease prevention and management (Lund, 2008).

DEFINITIONS

*Menopause* refers to a point in time that follows 1 year after the complete cessation of menstruation, and the *postmenopause* describes years following that point. The average age of women experiencing their final menstrual period (FMP) is 51.5 years, but a halt to menses from ovarian failure may occur at any age. Cessation before age 40, termed *premature ovarian failure*, is associated with an elevated follicle-stimulating hormone (FSH) level and variable causes described in Chapter 16 (p. 373). Of other definitions, the older words *perimenopause* and *climacteric* generally refer to the late reproductive years, usually late 40s to early 50s. These can be used with patients but less so in scientific settings. Here, the term *menopausal transition (MT)* is preferred (Harlow, 2012; Soules, 2001). Characteristically, MT begins with menstrual cycle irregularity and extends to 1 year after permanent cessation of menses. This reproductive aging with loss of follicular activity progresses within a wide age range (42 to 58 years). The average age at its onset is 47, and MT typically spans 4 to 7 years (Burger, 2008; McKinlay, 1992).

As chronological age is an unreliable indicator, guidelines for classifying reproductive aging have been proposed. The first classification of stages and nomenclature for female reproductive aging were developed in 2001 and updated in 2012 at the Stages of Reproductive Aging workshop (STRAW)

(Harlow, 2012). These staging criteria are guides rather than strictly applied diagnoses. Every stage may not manifest in all women, or a stage may occur out of the expected sequence. Also, the age range and duration of each stage varies for given individuals.

In the STRAW system, the anchor stage is the FMP (Fig. 21-1). Five stages precede and two stages follow the FMP. Stage -5 refers to the early reproductive period, stage -4 to the reproductive peak, and stage -3 to the late reproductive period. Stage -2 is the early MT, and stage -1 is the late MT. Stage + 1a is the first year after FMP, stage + 1b reflects years 2 to 5 postmenopause, and stage + 2 refers to the ensuing later postmenopausal years.

INFLUENTIAL FACTORS

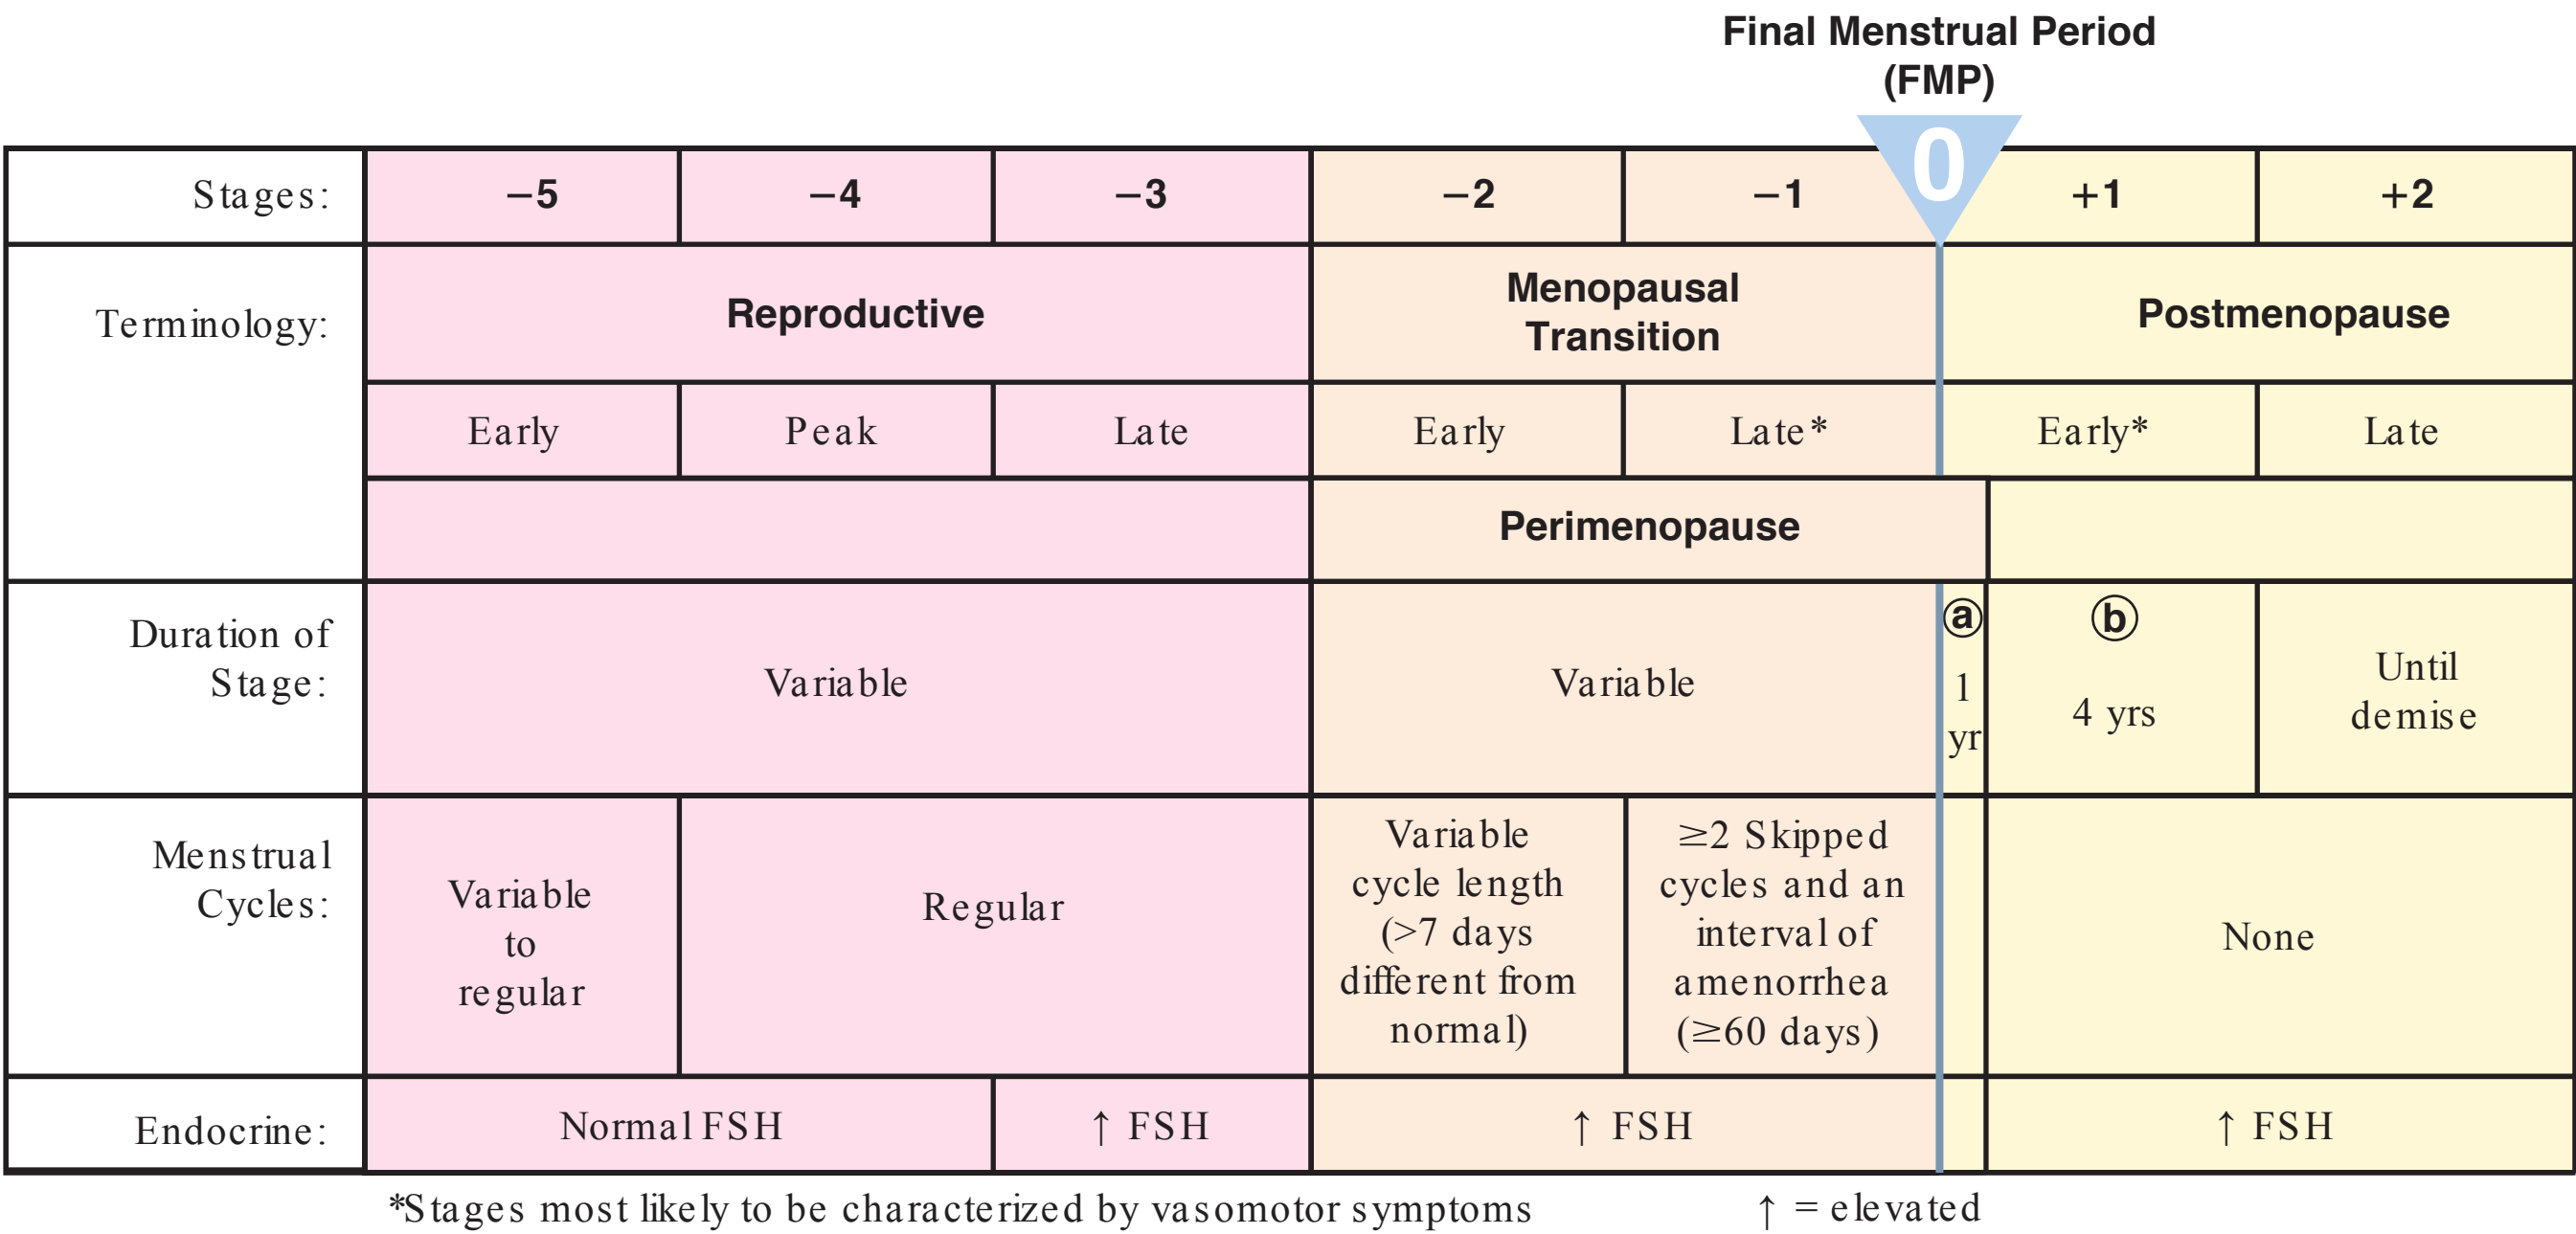

Several environmental, genetic, and surgical influences may alter ovarian aging. For example, smoking hastens the age of menopause by approximately 2 years (Gold, 2001; Wallace, 1979). Chemotherapy, pelvic radiation, and ovarian surgery may also lead to earlier menopause. During MT, more erratic fluctuations in female reproductive hormones lead to an array of physical and psychological symptoms as outlined in Table 21-1 (Bachmann, 2001; Dennerstein, 1993). Diet, exercise, reproductive history, socioeconomic status, body mass index (BMI), mood, climate, and individual or cultural attitudes toward

TABLE 21-1. Symptoms Associated with Menopausal Transition

<b>Menstrual pattern</b>	<b>Sexual dysfunction</b>
Shorter cycles (typical)	Vaginal dryness
Longer cycles (possible)	Decreased libido
Irregular bleeding	Dyspareunia
<b>Vasomotor</b>	<b>Somatic</b>
Hot flushes	Headache
Night sweats	Dizziness
Sleep disturbances	Palpitations
<b>Psychological/cognitive</b>	Breast pain/enlargement
Worsening PMS	Joint aches and back pain
Depression	<b>Others</b>
Irritability	Urinary incontinence
Mood swings	Dry, itchy skin
Poor concentration	Weight gain
Poor memory	

PMS = premenstrual syndrome.

**FIGURE 21-1** The stages of reproductive aging. (Reproduced with permission from Soules MR, Sherman S, Parrott E, et al: Executive summary: stages of reproductive aging workshop (STRAW). Fertil Steril 2001 Nov;76(5):874–878.)

menopause may explain variations in reports of menopausal symptoms (O’Neil, 2011).

PHYSIOLOGIC CHANGES

In the early MT (stage –2), a woman’s menstrual cycles remain regular, but the interval between cycles may be altered by 7 or more days. Typically, cycle lengths become shorter. Compared with younger women, FSH levels are elevated, and serum estrogen levels may be increased in the early follicular phase. Normal ovulatory cycles may be interspersed with anovulatory cycles during this transition, and conception can occur unexpectedly. The late MT (stage –1) is characterized by two or more skipped menses and at least one intermenstrual interval of 60 days or more due to longer and longer periods of anovulation (Soules, 2001). This overview of altered menstruation results from changes in several endocrine axes described next.

Hypothalamus-Pituitary-Ovarian Axis

During the reproductive years, gonadotropin-releasing hormone (GnRH) is released in a pulsatile fashion by the arcuate nucleus of the medial basal hypothalamus. It binds to GnRH receptors on the pituitary gonadotropes to stimulate cyclic luteinizing hormone (LH) and FSH release. These gonadotropins, in turn, stimulate the production of the ovarian steroids: estrogen, progesterone, and also inhibin. Estrogen and progesterone exert positive and negative feedback on pituitary gonadotropin production and on the amplitude and frequency of GnRH release. Produced by granulosa cells, inhibin also exerts an important negative influence on FSH secretion from the pituitary. This tightly regulated endocrine system leads to regular, ovulatory menstrual cycles.

Beginning in the late 40s and in early MT (stage –2), FSH levels rise slightly and bring about an increased ovarian follicular

response, which raises overall estrogen levels (Jain, 2005; Klein, 1996). The monotropic FSH rise is attributed to decreased ovarian inhibin secretion rather than diminished estradiol feedback. In perimenopausal women, estradiol production fluctuates with FSH levels and can reach higher concentrations than those observed in women younger than 35. Estradiol levels generally do not drop significantly until late in MT. Despite continuing regular cyclic menstruation, progesterone levels during the early MT are lower than in mid-reproductive aged women (Santoro, 2004). Testosterone levels do not vary appreciably during the MT. That said, sex hormone-binding globulin (SHBG) production declines after the menopause and may lead to relative increased levels of free or unbound estrogen and testosterone.

Women in late MT exhibit impaired folliculogenesis and an increasing incidence of anovulation compared with women in their mid-reproductive years. Also, during this time, ovarian follicles undergo an accelerated rate of loss until eventually, in late MT, the supply of follicles is depleted. These changes, including the earlier-described FSH level increase, reflect the reduced capability of aging follicles to secrete inhibin (Reyes, 1977; Santoro, 1996). As another indicator, antimüllerian hormone (AMH) is a glycoprotein secreted by the granulosa cells of secondary and preantral follicles and indirectly reflects the primordial follicle pool (Grynnerup, 2014). Circulating AMH concentrations remain relatively stable across the menstrual cycle in reproductive-aged women and correlate with the number of early antral follicles. AMH levels decrease markedly and progressively across MT (Hale, 2007). With ovarian failure in the menopause (stage +1b), ovarian steroid hormone release ceases, and the negative-feedback loop is opened. As a result, GnRH is released at maximal frequency and amplitude. In turn, circulating FSH and LH levels rise up to fourfold higher than those in the reproductive years (Klein, 1996).

## ■ Ovary

Ovarian senescence is a process that has been shown to actually begin in utero within the embryonic ovary due to programmed oocyte atresia. From birth onward, primordial follicles continuously are activated, mature partially, and then regress. This follicular activation continues in a constant pattern that is independent of pituitary stimulation.

A more rapid depletion of ovarian follicles starts in the late 30s and early 40s and continues until a point at which the menopausal ovary is virtually devoid of follicles (Figs. 21-2 and 21-3). An average woman may experience about 400 ovulatory events during her reproductive lifetime. This represents a very small percentage of the 6 to 7 million oocytes present at the 20th week of gestation, or even the 1 to 2 million oocytes present at birth. The process of atresia of the nondominant cohort of follicles, largely independent of menstrual cyclicity, is the prime event that leads to the eventual loss of ovarian activity and menopause.

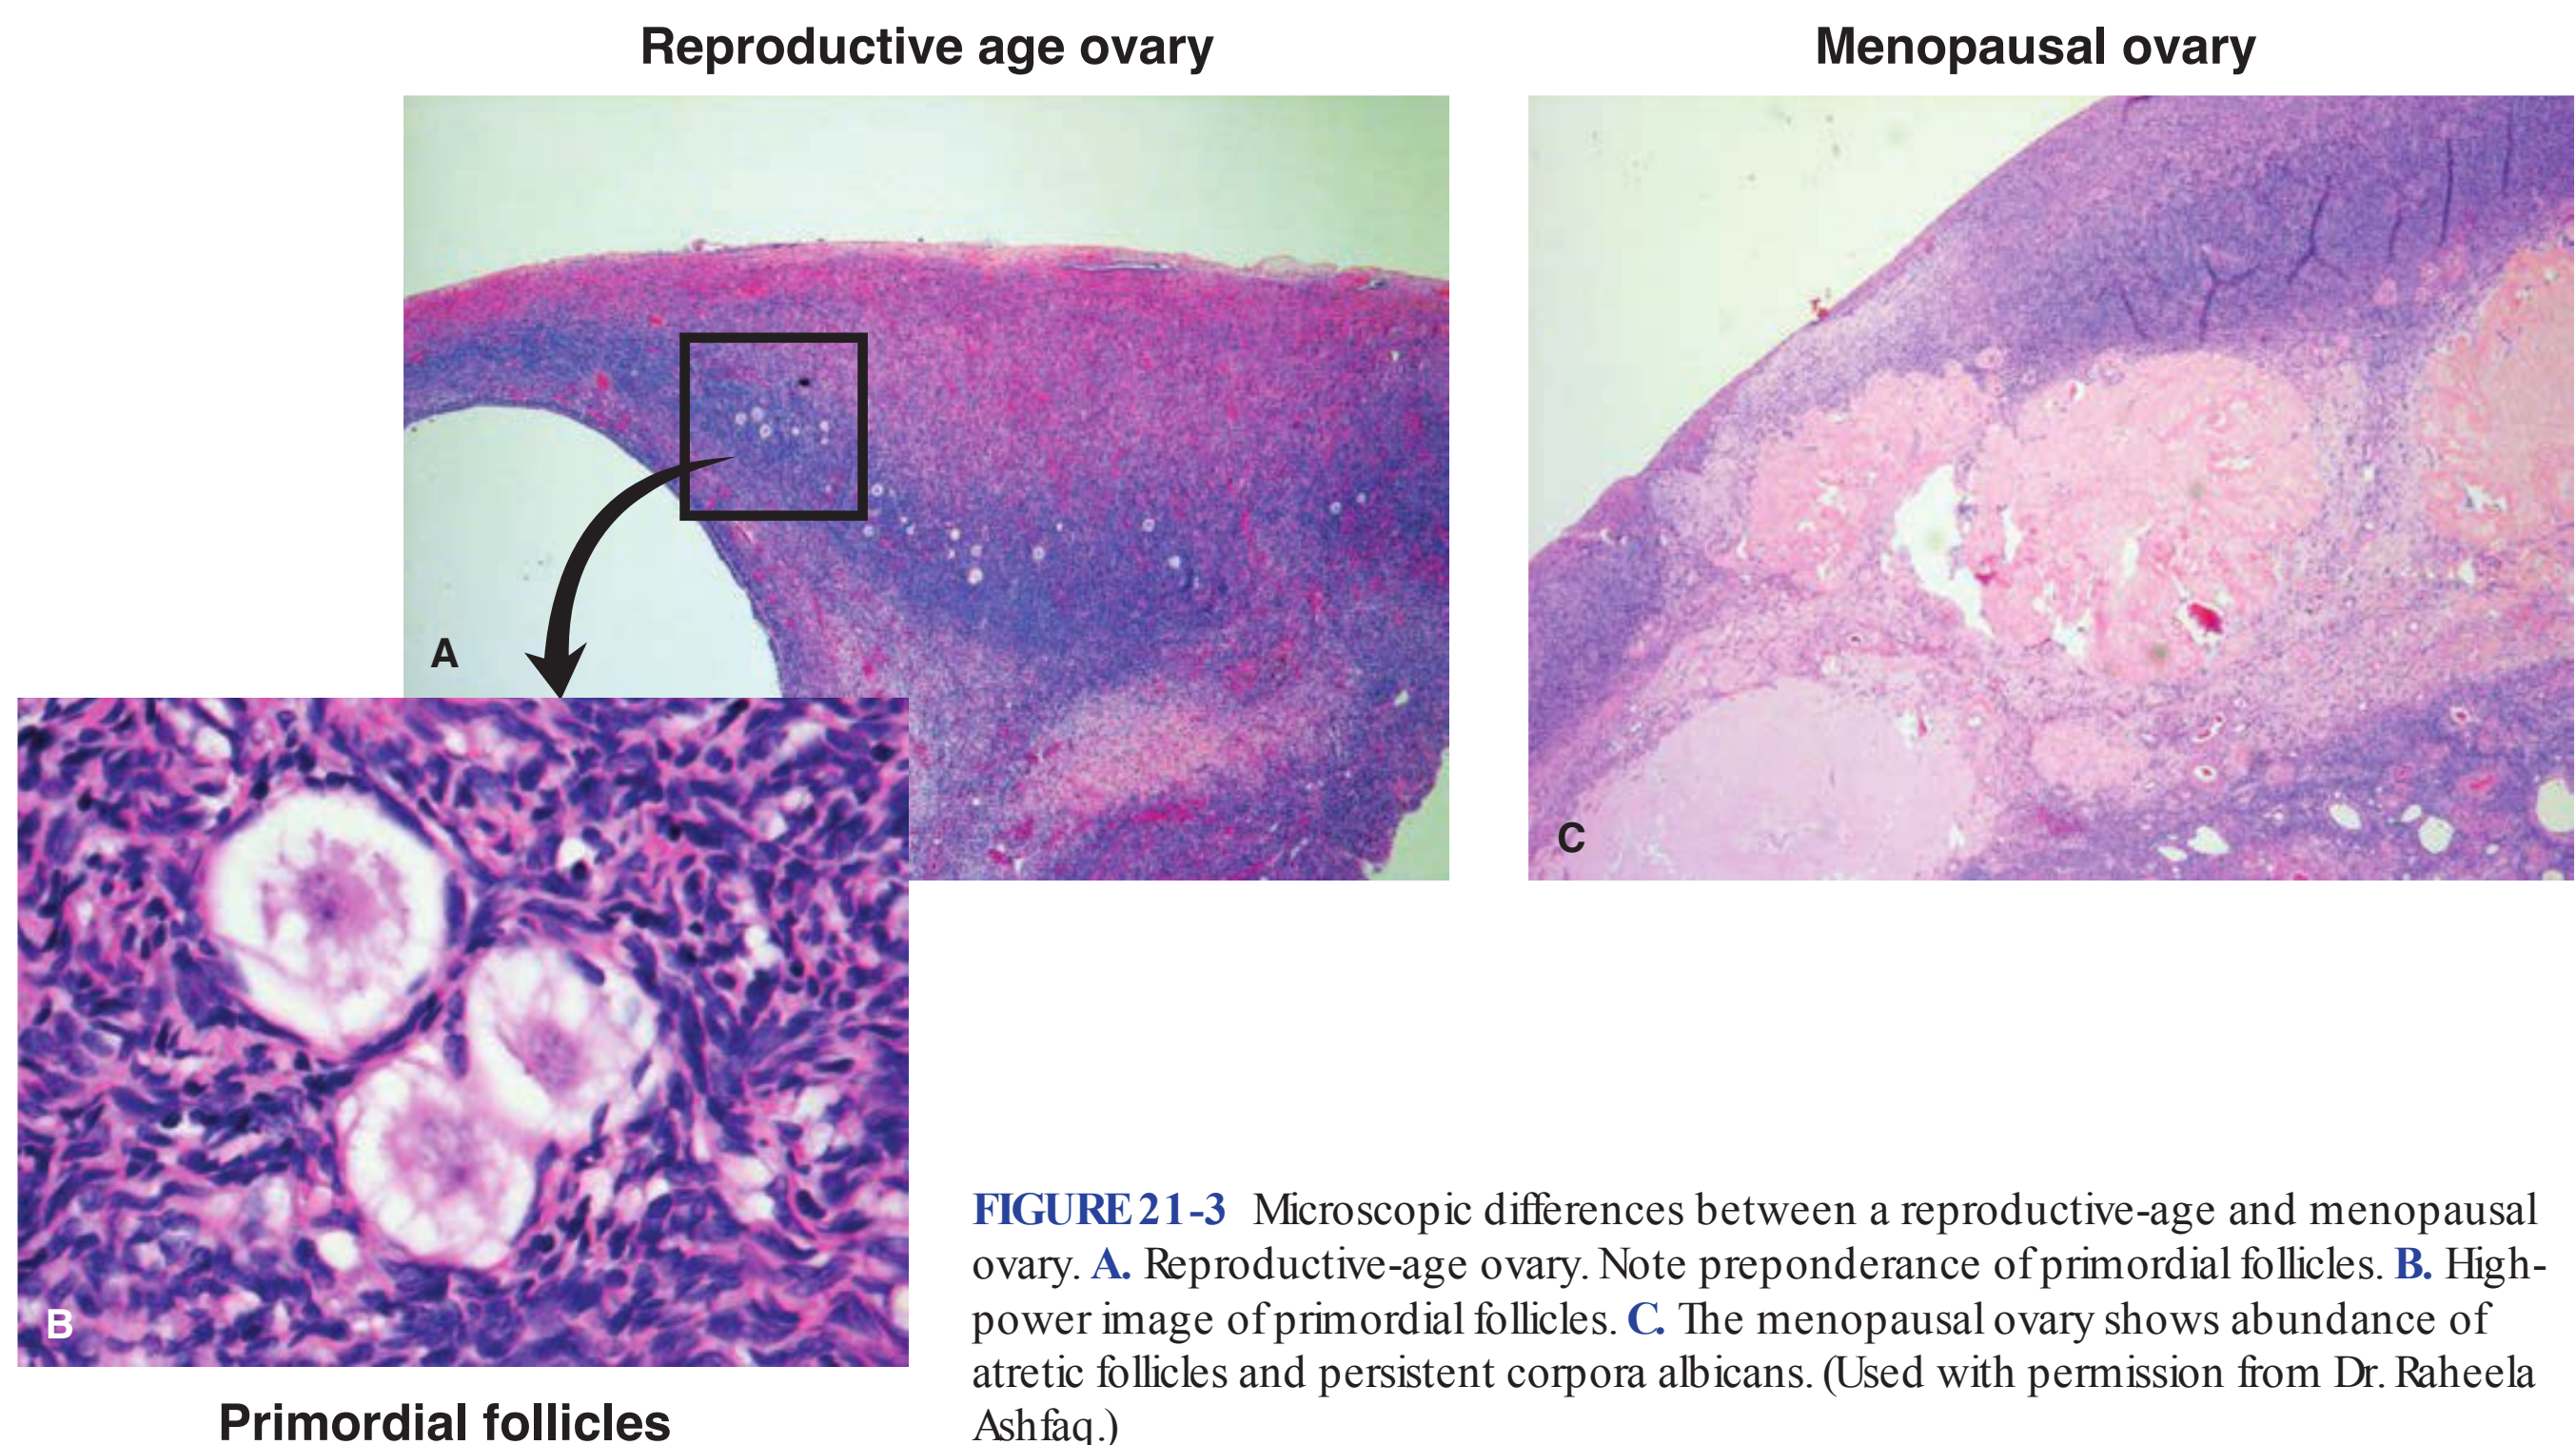

As evidence, Richardson and colleagues (1987) performed a quantitative histologic study of the endometrium and ovaries of women in MT undergoing hysterectomy for benign indications. These were coupled with a single hormonal measurement and a reproductive history from the study women aged 44 to 55 years. The women who reported regular cycles had an average of 1700 follicles in a selected ovary compared with an average of 180 follicles in the ovaries of those who reported irregular cycles.

## ■ Adrenal Steroid Levels

With advancing age, adrenal production of dehydroepiandrosterone sulfate (DHEAS) declines. In women aged 20 to

**FIGURE 21-2** Transvaginal sonographic images of a pre- and postmenopausal ovary. **A.** In general, premenopausal ovaries have greater volume and contain follicles, which are seen as multiple, small, anechoic smooth-walled cysts. **B.** In comparison, postmenopausal ovaries have smaller volume and are characteristically devoid of follicular structures. (Used with permission from Dr. Elysia Moschos.)

**FIGURE 21-3** Microscopic differences between a reproductive-age and menopausal ovary. **A.** Reproductive-age ovary. Note preponderance of primordial follicles. **B.** High-power image of primordial follicles. **C.** The menopausal ovary shows abundance of atretic follicles and persistent corpora albicans. (Used with permission from Dr. Raheela Ashfaq.)

30 years, DHEAS concentrations peak, with an average of 6.2  $\mu\text{mol/L}$ , and then decrease steadily. In women 70 to 80 years of age, DHEAS levels are diminished by 74 percent to 1.6  $\mu\text{mol/L}$ . Other adrenal hormone levels fall with aging as well (Burger, 2000; Labrie, 1997). Androstenedione levels peak at ages 20 to 30 years and then decline to 62 percent of this peak level in women aged 50 to 60 years. Pregnenolone levels diminish by 45 percent from reproductive life to menopause. The ovary contributes to the production of these hormones during the reproductive years, but after menopause, only the adrenal gland continues this hormone synthesis.

Burger and associates (2000) prospectively studied 172 women during MT as a part of the Melbourne Women's Midlife Health Project. By analyzing hormone levels longitudinally in these patients, no relationship between a woman's final menstrual period and the decline in DHEAS levels was noted. Advancing age, regardless of menopausal status, determined DHEAS level decline.

### ■ Endometrium

Microscopic changes in the endometrium directly reflect systemic estrogen and progesterone levels and thus may change dramatically depending on the stage of MT. During early MT, the endometrium may reflect ovulatory cycles, which are prevalent during this time. During later MT stages, anovulation is common, and the endometrium will display an estrogenic effect that is unopposed by progesterone. Accordingly, proliferative changes or disordered proliferative changes are frequent findings on pathologic examination of endometrial biopsy samples. After menopause, the endometrium becomes atrophic due to lack of estrogen stimulation (Fig. 15-19, p. 356).

### ■ Menstrual Disturbances

During MT, abnormal uterine bleeding (AUB) is common, and Treloar (1981) found that menses were irregular in more than one half of all women in this transition. Paramsothy (2014) reported that AUB accounted for 14 percent of all hospitalizations from 1998 to 2005 among women aged 45 to 54. Anovulation is the most common cause of erratic bleeding during MT. However, because the time interval surrounding menopause is characterized by relatively high, acyclic estrogen levels and relatively low progesterone production, women in MT are at increased risk for developing endometrial hyperplasia or carcinoma. Estrogen-sensitive neoplasms, such as endometrial polyps and uterine leiomyomas, and pregnancy-related events are also considered. Many women in their late 40s do not consider themselves fertile and will cease contraception but will still have occasional ovulatory cycles. Contraception can be discontinued by all women at age 55. No spontaneous pregnancies above that age have been reported. Some women may still have menstrual bleeding above age 55, but ovulation is rare and any oocytes are likely poor quality and not viable (Gebbie, 2010).

In all women, regardless of menopausal status, the etiology of AUB should be determined as outlined in Chapter 8 (p. 180). As noted, endometrial cancer is suspected in any woman in MT with AUB. The overall incidence of endometrial cancer is

approximately 0.1 percent of women in this group per year, but in women with AUB in MT, the risk increases to 10 percent (Lidor, 1986). Thus, endometrial biopsy is done to exclude malignancy.

Although endometrial neoplasia is the greatest concern during this time, endometrial biopsy frequently reveals a non-neoplastic endometrium displaying estrogen effects unopposed by progesterone. In premenopausal women, this results from anovulation. In postmenopausal women, unopposed estrogen may be derived from extragonadal endogenous estrogen production, which may result from increased aromatization of androgen to estrogen due to obesity. In addition, decreased SHBG levels lead to increased levels of free and therefore bioavailable estrogen (Moen, 2004). Less often, unopposed exogenous estrogen administration or an estrogen-producing ovarian tumor can also account for these effects in postmenopausal women.

### ■ Central Thermoregulation

Of the many menopausal symptoms that may affect quality of life, the most frequent are those related to thermoregulation dysfunction. Kronenberg (1990) tabulated all of the published epidemiologic studies and determined that vasomotor symptoms, also variably termed hot flashes, hot flushes, and night sweats, developed in 11 to 60 percent of menstruating women during MT. In the Massachusetts Women's Health Study, the incidence of hot flushes increased from 10 percent during the premenopausal period to approximately 50 percent after menses cessation (McKinlay, 1992). Hot flushes begin an average of 2 years before the FMP, and 85 percent of women who experience them will continue to experience them for more than 1 year. Of these women, 25 to 50 percent will have hot flushes for 5 years, and > 15 percent may experience them for > 15 years (Kronenberg, 1990). More recent studies of duration indicate that women can expect hot flushes to continue, on average, for nearly 5 years after the FMP, while more than one third of women who experience moderate/severe hot flushes will continue to have them for more than 10 years after the FMP (Freeman, 2014). Longitudinal studies show that hot flushes are associated with low exercise levels, smoking, high FSH and low estradiol levels, increasing BMI, ethnicity, lower socioeconomic status, and prior premenstrual dysphoric disorder (PMDD) or depression (Gold, 2006; Guthrie, 2005).

### Vasomotor Symptoms

Thermoregulatory and cardiovascular changes that accompany a hot flush are well documented. An individual hot flush generally lasts 1 to 5 minutes, and skin temperatures rise because of peripheral vasodilation (Kronenberg, 1990). This change is particularly marked in the fingers and toes, where skin temperature can increase 10 to 15°C. Most women sense a sudden wave of heat that spreads over the body, particularly the upper body and face. Sweating begins primarily on the upper body, and it corresponds closely in time with an increase in skin conductance (Fig. 21-4). Sweating has been observed in women during 90 percent of hot flushes (Freedman, 2001).

Increases in both awake and sleep systolic blood pressure are noted with hot flushes (Gerber, 2007). In addition, heart rate rises 7 to 15 beats per minute at approximately the same

**FIGURE 21-4** Physiologic changes (means) during a hot flush. **A.** Core body temperature. **B.** Respiratory exchange ratio. **C.** Skin temperature. **D.** Sternal skin conductance. Time 0 is the beginning of the sternal skin conductance response. (Reproduced with permission from Freedman RR: Biochemical, metabolic, and vascular mechanisms in menopausal hot flashes. *Fertil Steril* 1998 Aug;70(2):332–337.)

time as peripheral vasodilatation and sweating. Heart rate and skin blood flow usually peak within 3 minutes of the hot flush onset. Simultaneously with sweating and peripheral vasodilation, the metabolic rate also significantly rises. Hot flashes can also be accompanied by palpitations, anxiety, irritability, and panic.

Five to 9 minutes after a hot flush begins, the core temperature declines 0.1 to 0.9°C due to heat loss from perspiration and increased peripheral vasodilation (Molnar, 1981). If heat loss and sweating are significant, a woman may experience chills. Skin temperature gradually returns to normal, sometimes taking 30 minutes or longer.

## Pathophysiology of Vasomotor Symptoms

The underlying physiologic steps leading to hot flashes remain an enigma, and some dysfunction of the thermoregulatory nucleus of the hypothalamus is likely. This nucleus regulates perspiration and vasodilatation, which is the primary mechanism of heat loss in humans. If exposed to higher temperatures, the nucleus activates these heat dissipation mechanisms. This maintains core body temperature in a regulated normal range, called the *thermoregulatory zone*. It is hypothesized that women who experience more severe vasomotor symptoms have a narrower thermoregulatory zone than those without symptoms. In these women, minimal changes in core body temperature induce shivering or hot flush.

Various hormones and neurotransmitters modulate hot flush frequency. Of these, estrogens play a vital role. Although there is no clear correlation between the two, estrogen withdrawal or rapid fluctuation in levels, rather than a chronically low estrogen concentration, is suspected (Erlik, 1982; Overlie, 2002). This hypothesis is supported by the fact that women with gonadal dysgenesis (Turner syndrome), who lack normal estrogen levels, do not experience hot flashes unless first exposed to estrogen and then withdrawn from treatment.

In addition to estrogen, Freedman and colleagues (1998, 2014) hypothesized that altered neurotransmitter concentrations may create a narrow thermoregulatory zone and a lowered sweating threshold. Norepinephrine is thought to be the primary neurotransmitter responsible for lowering the thermoregulatory setpoint and triggering the heat loss mechanisms associated with hot flashes (Rapkin, 2007). Plasma levels of norepinephrine metabolites are increased before and during hot flashes. Moreover, research shows that norepinephrine injections can increase core body temperature and induce a heat loss response (Freedman, 1990). Conversely, medications that decrease norepinephrine levels, such as clonidine, may reduce vasomotor symptoms (Laufer, 1982).

Estrogens are known to modulate adrenergic receptors in many tissues. Freedman and colleagues (2001) suggested that menopause-related declines in estrogen levels lower hypothalamic  $\alpha_2$ -adrenergic receptor concentrations. In turn, a decline in presynaptic  $\alpha_2$ -adrenergic receptor levels leads to increased norepinephrine levels, thereby causing vasomotor symptoms.

Serotonin is likely another involved neurotransmitter (Slopien, 2003). Estrogen withdrawal is associated with a decreased blood serotonin level, which is followed by upregulation of serotonin receptors in the hypothalamus. Activation of specific serotonin receptors has been shown to mediate heat loss (Gonzales, 1993). However, the role of serotonin in central regulatory pathways is complex because binding at some serotonin receptors can exert negative feedback on other serotonin receptor types (Bachmann, 2005). Therefore, the effect of a change in serotonin activity depends on the type of receptor activated. Of other potential candidates,  $\beta$ -endorphins and other neurotransmitters affect the thermoregulatory center and make some women more prone to hot flashes (Pinkerton, 2009).

Genetic polymorphisms and vasomotor symptom prevalence and severity may also be linked. Some polymorphisms are variants of genes encoding estrogen receptor alpha (Crandall, 2006; Malacara, 2004). Others are single nucleotide polymorphisms

involved in the synthesis or metabolism of estradiol or in its conversion to more- or less-potent estrogens. Currently, it is unknown whether these genetic determinants exert their effects centrally or peripherally (Al-Safi, 2014).

In sum, studies suggest that reductions and significant fluctuations in estradiol levels lead to a decline in inhibitory presynaptic  $\alpha_2$ -adrenergic receptor concentrations and an increase in hypothalamic norepinephrine and serotonin release. Norepinephrine and serotonin lower the setpoint in the thermoregulatory nucleus and allows heat loss mechanisms to be triggered by subtle changes in core body temperature. T is current theory of hot flush pathogenesis underlies many of the treatment options discussed in Chapter 22 (p. 495).

Risk Factors for Vasomotor Symptoms

Several risk factors have been associated with an increased probability of hot flushes, including early menopause, surgical menopause, race/ethnicity, BMI, a sedentary lifestyle, smoking, and use of selective estrogen-receptor modulators (SERMs). Moreover, women exposed to high ambient temperatures may experience more frequent and severe hot flushes (Randolph, 2005). Of risks, surgical menopause is associated with a 90-percent probability of hot flushes during the first year after oophorectomy, and symptoms can be more abrupt and severe than those associated with natural menopause. Among racial and ethnic groups, hot flushes appear to be more common and more bothersome in African-American than in white women and are more common among white than among Asian women (Gold, 2001; Kuh, 1997; T urston, 2008). T ese racial/ethnic differences in vasomotor symptoms persisted even after controlling for key factors such as BMI, estradiol level, hormone use, smoking, education level, and economic hardship (Al-Safi, 2014). T e effect of BMI on hot flush frequency is not clear (Da Fonseca, 2013; Hunter, 2012; Wilbur, 1998).

■ Bone Structure and Metabolism

T e skeleton consists of two bone types (Fig. 21-5). Cortical bone is the bone of the peripheral skeleton (arms and legs), and trabecular bone is the bone of the axial skeleton, which includes the vertebrae, pelvis, and proximal femur. Peak bone mass is influenced by genetic and endocrine factors, and opportunity in the younger years for acquiring bone mass is brief (American College of Obstetricians and Gynecologists, 2012). Almost all bone mass in the axial skeleton will be accumulated in young women by late adolescence, so the years immediately following menarche are especially important (Sabatier, 1996; T eintz, 1992). Calcium supplementation in prepubertal and pubertal girls improves bone accrual (Bonjour, 2001; Stear, 2003). Accordingly, osteoporosis prevention with weight-bearing exercise and vitamin D and calcium intake ideally begins in adolescence (Recker, 1992). Following adolescence, bone resorption is normally coupled to bone formation such that positive bone balance is achieved when skeletal maturity is attained, typically at age 25 to 35 years. T hereafter, bone mass declines at a slow, steady rate of approximately 0.4 percent each year. During menopause, the rate increases to 2 to 5 percent per year for the first 5 to 10 years and then slows to 1 percent per year. T e

FIGURE 21-5 Photograph of bone with trabecular and cortical bone labeled. (Reproduced with permission from Saladin KS: Anatomy & Physiology, 3rd edition. New York: McGraw-Hill; 2005.)

subsequent risk of fracture from osteoporosis will depend on bone mass at the time of menopause and the rate of bone loss following menopause (Riis, 1996).

Normal bone is a dynamic, living tissue that is in a continuous process of destruction and rebuilding. T is bone remodeling, also described as bone turnover, allows adaptation to mechanical changes in weight bearing and other physical activities. T e process of bone remodeling involves a constant resorption of bone, carried out by multinucleated giant cells known as *osteoclasts*, and a concurrent process of bone formation, completed by *osteoblasts* (Fig. 21-6).

Activated osteoclasts secrete hydrochloric acid and collagen-degrading enzymes onto the bone surface, resulting in bone mineral dissolution and degradation of the organic matrix. After detaching from the organic matrix, the osteoclasts can relocate and begin resorption at another site on the bone surface or undergo apoptosis. Increased osteoclast activity in postmenopausal osteoporosis is mediated by the receptor activator of nuclear factor (RANK) ligand pathway. In this pathway, RANK, RANK ligand, and osteoprotegerin (OPG) are three major components (Table 21-2).

Of these, RANK ligand is expressed by osteoblasts (Bar-Shavit, 2007). T is ligand binds to the RANK receptor on osteoclasts and osteoclast precursors. Binding promotes osteoclast formation, function, and survival. RANK ligand is the common

TABLE 21-2. Key Components of the RANKL/RANK/OPG Pathway
<b>RANKligand (RANKL)</b> Protein expressed by osteoblasts/bone lining cells Binds to RANK on osteoclasts Activation of RANK promotes osteoclast formation, function, survival
<b>RANK</b> Expressed by osteoclasts and their precursor Activated by RANKL binding
<b>Osteoprotegerin (OPG)</b> Protein secreted by osteoblasts/bone lining cells Natural inhibitor of RANKL Blocks RANKL-mediated activation of RANK to balance bone remodeling

**FIGURE 21-6** Bone remodeling. **A.** Osteoclasts resorb matrix, whereas osteoblasts deposit new lamellar bone. Osteoblasts that are trapped in the matrix become osteocytes. Others undergo apoptosis or form new, flattened osteoblast lining cells. Osteoblasts produce the proteins RANKL and OPG. When RANKL binds to RANK, the receptor on the surface of osteoclast progenitor cells, this promotes those cells' development, activity, and survival as osteoclasts. This leads to bone resorption. OPG serves as a counterbalance. OPG binds to RANKL and thereby, RANKL is incapable of binding with RANK to promote osteoclast development. Through this mechanism, bone resorption is limited. **B.** With hypoestrogenism, RANKL production is increased. Excessive levels of RANKL outnumber those of OPG and osteoclast development and bone resorption is favored.

regulator of osteoclast activity and ultimately of bone resorption. OPG is also secreted by osteoblasts and is a natural inhibitor of RANK ligand. OPG blocks RANK ligand-mediated activation of RANK and thereby limits osteoclast resorption activity. This balances bone remodeling (Kostenuik, 2005). Many different factors can affect osteoclast activity, but RANK ligand is required to mediate their effects on bone resorption. Cytokines and certain hormones stimulate the expression of RANK ligand by osteoblasts and other cells. One negative regulator of this process is estrogen, which limits the expression of RANK ligand from osteoblasts. Another regulator is OPG, a natural inhibitor of RANK ligand that sequesters and neutralizes the effects of RANK ligand.

In healthy premenopausal women, estrogen limits osteoblast expression of RANK ligand. The OPG binds to RANK ligand to further limit its availability to stimulate osteoclasts. The remaining RANK ligand binds to osteoclast precursors, which fuse and form differentiated osteoclasts for bone resorption. This

is followed by the appearance of osteoblasts resulting in bone formation. In sum, resorption and formation are balanced in premenopausal women.

In postmenopausal women, decreased estrogen levels lead to increased RANK ligand expression, which may overwhelm the natural activity of OPG. Studies show that estrogen may indirectly inhibit RANK ligand expression and stimulate OPG expression. Thus, the reduction in estrogen levels associated with menopause may lead to increased RANK ligand and decreased OPG. Bone resorption follows, but osteoblasts can only partially fill resorption cavities. This results in a chronic imbalance of formation and resorption, which leads to ongoing bone loss over time. Thus, increased RANK ligand after menopause leads to excessive bone resorption and potentially postmenopausal osteoporosis (Sambrook, 2006).

### ■ Osteopenia and Osteoporosis Clinical Importance

Osteoporosis is a skeletal disorder that progressively reduces bone mass and strength (typically in trabecular bone) and leads to increased fracture risks. Changes to the microstructure of bone in women with postmenopausal osteoporosis include increased cortical porosity, decreased bone mass, disrupted trabecular architecture, reduced cortical thickness, and lower mineral content of bone. Osteopenia is a precursor to osteoporosis, and the National Osteoporosis Foundation (2014) estimates that more than 10 million Americans currently have osteoporosis and another 33.6 million have osteopenia of the femoral neck.

Fracture is a frequent consequence of osteoporosis. The vertebrae, femoral neck, and wrists are most commonly fractured, and epidemiologic studies estimate that the remaining lifetime risk of common fragility fractures in white women after age 50 approximates 15 percent at each of these sites (Holroyd, 2008; Kanis, 1994). Nearly 1.5 million Americans experience osteoporotic fractures each year. Worldwide, 9 million osteoporotic fractures are estimated per year (Johnell, 2006; Lund, 2008).

Fractures are associated with significant morbidity and mortality, and the risk of dying following a clinical fracture is reportedly twofold higher than for persons without fractures. The overall mortality rate from femoral neck fracture alone approximates 30 percent. In addition, only 40 percent of those who sustain a femoral neck fracture are capable of returning to their prefracture level of independence. As such, clinicians ideally educate patients regarding bone loss prevention, screen to identify bone loss early, and work with patients to implement effective management plans for osteoporosis or osteopenia.

## Pathophysiology

A major proportion of bone strength is determined by bone mineral density (BMD), which is grams of mineral per area and volume of bone. However, bone quality, bone strength, and fracture risk are also affected by bone remodeling rates, bone size and geometry, microarchitecture, mineralization, damage accumulation, and matrix quality. Unfortunately, all of these are more difficult to accurately assess (Kiebzak, 2003).

*Primary osteoporosis* refers to bone loss associated with aging and menopausal estrogen deficiency. As estrogen levels fall after menopause, its regulatory effect on bone resorption is lost. As a result, bone resorption is accelerated and is usually not balanced by compensatory bone formation. This accelerated bone loss is most rapid in the early postmenopausal years (Gallagher, 2002). If osteoporosis is caused by other diseases or medications, the term *secondary osteoporosis* is used (Stein, 2003).

The amount of bone at any point in time reflects the balance of the osteoblastic (building) and osteoclastic (resorbing) activities, which are influenced by numerous stimulating and inhibiting agents (Canalis, 2007). As noted earlier, both aging and a loss of estrogen lead to a significant increase in osteoclastic activity. Also, decreased dietary calcium intake or impaired calcium absorption from the gut lowers the serum level of ionized calcium. This stimulates parathyroid hormone (PTH) secretion to mobilize calcium from bone by stimulation of osteoclastic activity (Fig. 21-7). Increased PTH levels stimulate vitamin D production. In turn, elevated vitamin D concentrations raise serum calcium levels by several effects: (1) stimulates osteoclasts to remove calcium from bone, (2) increases intestinal calcium absorption, (3) stimulates renal calcium reabsorption, and lowers PTH production by the parathyroid glands (Molina, 2013).

**FIGURE 21-7** Vitamin D metabolism. Provitamin D (7-dehydrocholesterol) in the skin is converted to cholecalciferol by ultraviolet (UV) light. Cholecalciferol and ergocalciferol (from plants) are transported to the liver, where they undergo hydroxylation to form the major circulating form of vitamin D. A second hydroxylation step occurs in the kidney and results in the hormonally active vitamin D [1,25(OH)<sub>2</sub>D<sub>3</sub>], also known as calcitriol. This activation step is mediated by 1 $\alpha$ -hydroxylase and is regulated by parathyroid hormone (PTH), Ca<sup>2+</sup> levels, and vitamin D [1,25(OH)<sub>2</sub>D<sub>3</sub>]. The activity of 1 $\alpha$ -hydroxylase is stimulated by PTH and inhibited by sufficient levels of Ca<sup>2+</sup> and 1,25(OH)<sub>2</sub>D<sub>3</sub>. Vitamin D increases bone resorption, Ca<sup>2+</sup> absorption from the intestine, and renal Ca<sup>2+</sup> reabsorption, but it decreases PTH production by the parathyroid glands. The overall effect of vitamin D is to increase plasma Ca<sup>2+</sup> concentrations. This rise in plasma Ca<sup>2+</sup> levels inhibits 1 $\alpha$ -hydroxylase and favors hydroxylation at C-24. This leads to synthesis of an inactive vitamin D metabolite—24,25(OH)<sub>2</sub>D<sub>3</sub>. (Reproduced with permission from Molina PE: Endocrine Physiology, 4th ed. New York: McGraw-Hill; 2013.)

In normal premenopausal women, this series of events leads to increased serum calcium levels, and PTH levels return to normal. In menopausal women, estrogen deficiency creates a greater responsiveness of bone to PTH. Thus, for any given PTH level, relatively more calcium is removed from bone.

Diagnosis

BMD is the standard used for bone mass determination and is assessed with dual-energy x-ray absorptiometry (DEXA) of the lumbar vertebrae, radius, and femoral neck (Fig. 21-8) (Marshall, 1996). The lumbar vertebrae contain primarily trabecular bone, and this bone type forms 20 percent of the skeleton. Trabecular bone is less dense than cortical bone and has a faster bone remodeling rate. Therefore, early rapid bone loss can be determined by evaluation of this site. Cortical bone is denser and more compact bone and makes up 80 percent of the skeleton. It is most abundant in the long-bone shafts of the appendicular skeleton. The greater trochanter and femoral neck contain both cortical and trabecular bone, and these sites are ideal for the prediction of femoral neck fracture risk in older women (Miller, 2002).

Normative bone mineral density values for sex, age, and ethnicity have been determined. For diagnostic purposes, results of BMD testing are reported as *T-scores*. These measure in standard deviations (SDs) the variance of an individual's BMD from that expected for a person of the same sex at peak bone mass (25 to 30 years). A T-score of  $-2.0$  in a woman, for example, means that her BMD is two SDs below the average peak bone mass for a young woman. Definitions include those found in Table 21-3. The fourth category, "severe osteoporosis," describes patients who have a T-score below  $-2.5$  and who have also suffered a fragility fracture. These are fractures caused by a fall from standing height or lower.

Patients are also assigned a *Z-score*, which is the standard deviation between the patient's measurement and average bone mass for a patient with the same age and weight. Z-scores lower than  $-2.0$  (2.5 percent of the normal population of the same age) require diagnostic evaluation for *secondary osteoporosis* (Faulkner, 1999). Similarly, any patient with osteoporosis is screened for other conditions that lead to osteoporosis (Table 21-4).

The relation between BMD and fracture risk has been calculated in numerous studies. A metaanalysis by Marshall and coworkers (1996) showed that BMD is still the most readily quantifiable predictor of fracture risk for those who have not

yet suffered a fragility fracture. For each standard deviation of BMD below a baseline level (either mean peak bone mass or mean for the reference population of the person's age and sex), the fracture risk approximately doubles (National Osteoporosis Foundation, 2002).

Recognizing the difficulty in measuring bone mass and bone quality accurately, the World Health Organization (WHO) developed the Fracture Risk Assessment Tool (FRAX) to assess an individual's 10-year fracture risk. The algorithm, however, is applicable only for patients who have not received pharmacotherapy. The FRAX tool is accessible online and is available for multiple countries and in different languages (<http://www.shef.ac.uk/FRAX/>). The online tool incorporates 11 risk factors and the femoral neck raw BMD value in  $\text{g}/\text{cm}^2$  to calculate the 10-year fracture risk. The site also offers downloadable charts for calculating fracture risks using BMI or BMD. The FRAX algorithm identifies patients who might benefit from pharmacotherapy and is most useful for recognizing those with BMD in the osteopenic category.

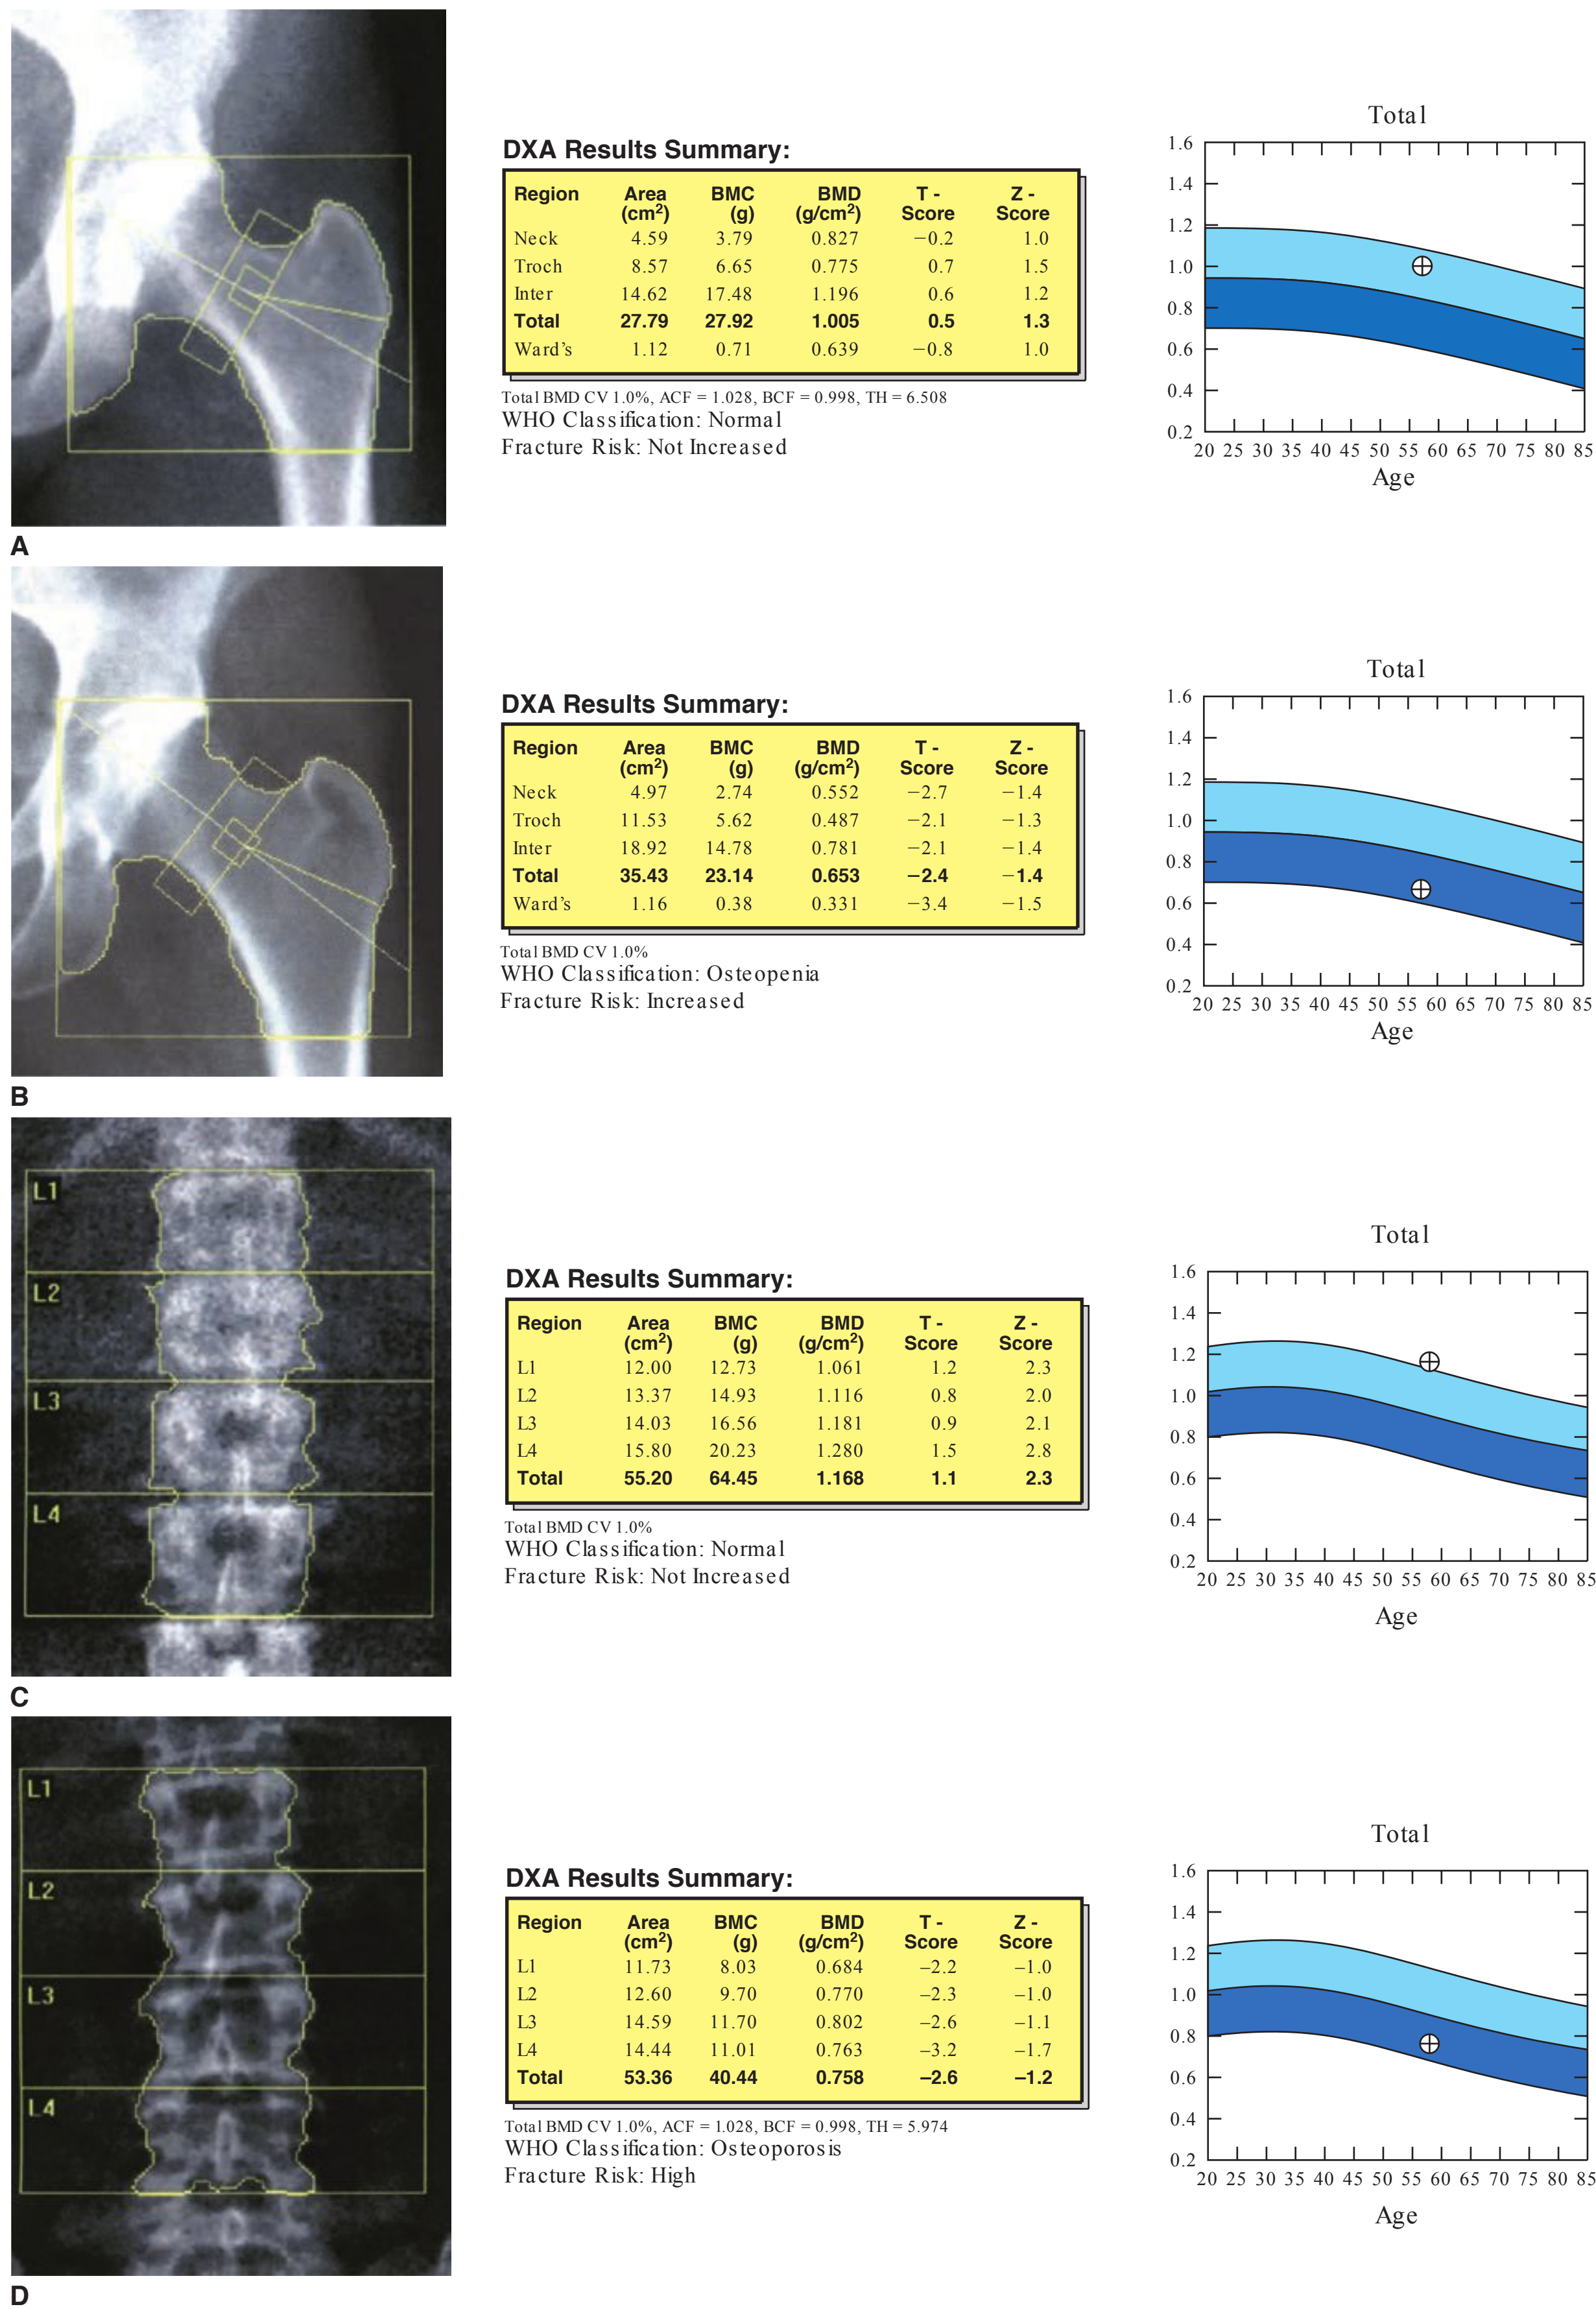

Prevention

As predictors of osteoporotic fracture, the most important factors are BMD in combination with age, fracture history, ethnicity, various drug treatments, weight loss, and physical fitness. The presence of a key risk factor alerts a clinician to the need for further assessment and possibly active intervention, such as calcium and vitamin D therapy coupled with weight-bearing exercise or pharmacologic therapy (Tables 21-5 and 21-6). Treatment options for osteoporosis are discussed in Chapter 22 (p. 499).

TABLE 21-3. WHO Criteria for Bone Disease Based on Bone Mineral Density (BMD)
Normal BMD : T-score between $+2.5$ and $-1.0$
Osteopenia: T-score between $-1.0$ and $-2.5$
Osteoporosis : T-score at or below $-2.5$
Severe or established osteoporosis: T-score at or below $-2.5$ with one or more fractures
Data from National Osteoporosis Foundation: Clinician's guide to prevention and treatment of osteoporosis. Washington, National Osteoporosis Foundation, 2014.

TABLE 21-4. Secondary Causes of Osteoporosis and Recommended Testing	
Primary hyperparathyroidism	Serum levels of: parathyroid hormone calcium phosphorus alkaline phosphatase
Secondary hyperparathyroidism from chronic renal failure	Renal function tests
Hyperthyroidism or excess thyroid hormone treatment	Thyroid function tests
Increased calcium excretion	24-hour urine collection for calcium and creatinine concentrations
Hypercortisolism, alcohol abuse, and metastatic cancer	Careful history and when indicated appropriate laboratory studies
Osteomalacia	Serum levels of: calcium phosphorus alkaline phosphatase 1,25-dihydroxyvitamin D

**FIGURE 21-8** Dual-energy x-ray absorptiometry (DEXA) scans. **A.** DEXA report describing normal hip density. **B.** DEXA report describing osteopenia of the hip. **C.** DEXA report describing normal vertebral body density. **D.** DEXA report describing vertebral body osteoporosis. BMC = bone mineral content; BMD = bone mineral density.

**TABLE 21-5.** Osteoporosis Risk Factors

Major Risk Factors	Minor Risk Factors
Age > 65 years	Rheumatoid arthritis
Vertebral compression fracture	History of clinical hyperthyroidism
Fragility fracture after age 40	Chronic anticonvulsant therapy
Family history of osteoporotic fracture	Low dietary calcium intake
Systemic glucocorticoid therapy for > 3 months	Smoker
Malabsorption syndrome	Excessive alcohol intake
Primary hyperparathyroidism	Excessive caffeine intake
Propensity to fall	Weight < 57 kg
Osteopenia apparent on radiography	> 10 percent weight loss at age 25
Hypogonadism	Chronic heparin therapy
Early menopause (before age 45)	

Risk factors for osteoporotic fracture are not independent of one another. They are additive and are considered in the context of baseline age and sex-related fracture risk. For example, a 55-year-old woman with low BMD is at significantly less risk than a 75-year-old woman with the same low BMD. Similarly, a woman with low BMD and a prior fragility fracture is at considerably greater risk than another person with the same low BMD and no prior fracture.

**Nonmodifiable Factors.** Age is one major contributor to fracture risk. As summarized by Kanis and associates (2001), the 10-year probability of experiencing a fracture of forearm, humerus, vertebra, or femoral neck increases as much as eightfold

between ages 45 and 85 years for women. Osteoporotic fractures occur most commonly in men and women older than 65 years. Medical interventions have been demonstrated to be effective only in preventing fractures in populations with an average age older than 65 years. However, most currently approved osteoporosis therapies prevent or reverse bone loss if initiated at, or soon after, age 50. Therefore, it seems prudent to begin the identification of people at high risk for osteoporosis in their 50s. As noted, BMD is currently the best quantifiable predictor of osteoporotic fracture, and screening guidelines are discussed on page 482.

As noted, a prior fragility fracture places a person at increased risk for another fracture. The increased risk is 1.5- to 9.5-fold depending on age at assessment, number of prior fractures, and site of prior fracture (Melton, 1999). Vertebral fractures are the best studied, and a vertebral fracture increases the risk of a second such fracture at least fourfold. The placebo group of a major clinical trial showed that 20 percent of those who experienced a vertebral fracture during the study period had a second vertebral fracture within 1 year (Lindsay, 2001). Vertebral fractures also indicate vulnerability at other sites, such as the femoral neck. Similarly, wrist fractures predict vertebral and femoral neck fractures.

Another nonmodifiable risk factor is race, and osteoporosis is most common in menopausal white women. In 2002, the National Osteoporosis Foundation found that 20 percent of these women have osteoporosis, and 52 percent have low BMD. Although persons of any ethnicity can develop osteoporosis, data from the Third National Health and Nutrition Examination Survey (NHANES III) show that the risk is highest among non-Hispanic white and Asian women and lowest among non-Hispanic black women. Racial and ethnic differences are important in counseling and management because fracture rates do not always correlate with BMD across ethnic groups. For example, Chinese American women typically have lower BMD than white American women, but lower rates of femoral neck and forearm fracture (Walker, 2011). It is postulated that greater cortical density and thicker trabeculae compensate for fewer trabeculae in smaller bones. Thus, both BMD and microarchitecture appear to play distinct roles in fracture vulnerability (American College of Obstetricians and Gynecologists, 2012).

**TABLE 21-6.** General Guidelines for Prevention of Osteoporosis in Postmenopausal Women

Counsel on osteoporosis risks
Check for secondary causes (see Table 21-4)
For women 51 and older, encourage diet containing calcium 1200 mg daily and vitamin D 800–1000 IU daily.
Add supplement if diet is incomplete
Recommend regular weight-bearing and muscle-strengthening exercise
Advise against tobacco smoking and excess alcohol intake
Assess for fall risks (see Table 21-7) and modify as possible
Measure height annually
In women ≥ 65 years, recommend BMD testing
In postmenopausal women aged 50–65 years, recommend BMD testing based on the risk factor profile (see Table 21-5)
In those > 50 with a new fracture, recommend BMD testing to determine degree of disease severity
For patients on pharmacotherapy, perform BMD testing 2 years after initiating therapy and every 2 years thereafter. However, testing frequency may be tailored to clinical situations

BMD = bone mineral density.  
Data from National Osteoporosis Foundation: Clinician’s guide to prevention and treatment of osteoporosis. Washington, National Osteoporosis Foundation, 2014.

Genetic influence on osteoporosis and BMD is important, and heredity is estimated to account for 50 to 80 percent of BMD variability (Ralston, 2002). The Study of Osteoporotic Fractures, for example, identified that maternal femoral neck fracture was a predictor for femoral neck fracture in a population of elderly women (Cummings, 1995). An affected maternal grandmother also raises a woman’s fracture risk. Several genes have been associated with osteoporosis, but these discoveries have yet to translate into clinical application.

**Modifiable Factors.** Of these, exercise, in the form of progressive resistance training, may result in clinically relevant benefits to femoral neck BMD and lumbar vertebral BMD in postmenopausal women (Kelly, 2012). Greater improvements in bone mass were also associated with increases in static balance. These associations may be particularly important for reducing fall risks. Exercise results in other general health benefits that are not totally realized with pharmacological and nutritional interventions. For example, investigators note that greater increases in femoral neck BMD and lumbar vertebral BMD are also associated with declines in BMI and percent body fat (Bouchard, 2013).

Fractures are frequently associated with falls. Thus, a history of falls or factors that increase fall rates are included in a risk assessment (Table 21-7). Factors include those associated with general frailty, such as reduced muscle strength, impaired balance, low body mass, and diminished visual acuity (Delaney, 2006). Alcohol and sedative drug use are other important risks.

Therapy with glucocorticoids lasting more than 2 to 3 months is a major risk factor for bone loss and fracture, particularly among postmenopausal women. The National Osteoporosis Foundation guidelines (2014) describe a chronic daily dose of prednisone that is  $\geq 5$  mg as the threshold for assessment and clinical intervention to prevent or treat glucocorticoid-induced osteoporosis.

**Osteoporosis Screening.** After assessment of all potential risk factors, BMD measurement is a prominent component of strategies to confirm osteoporosis and determine disease sever-

ity. BMD testing is recommended for all menopausal women who: (1) are aged 65 years or older, (2) have one or more risk factors for osteoporosis, or (3) sustain fractures (see Table 21-5). Additionally, screening is considered for perimenopausal women if they have a specific risk factor such as prior low-trauma fracture, have a low BMI, or are taking a medication known to accelerate bone loss. Many vertebral fractures are asymptomatic, and vertebral imaging is recommended for women aged  $\geq 70$  years with a T-score  $\leq -1.0$  or those 65 to 69 years with a score  $\leq -1.5$  (National Osteoporosis Foundation, 2014). Unfortunately, Schnatz and associates (2011) found that many women are not properly screened or treated for osteoporosis and that inappropriate screening may also lead to improper management of osteoporosis and its associated complications. If therapy to increase BMD is instituted, BMD should be monitored.

Less commonly, bone markers of resorption and formation are used as an adjunct to BMD. These can be used to assess osteoporosis risk or to monitor treatment. During remodeling, osteoblasts synthesize several cytokines, peptides, and growth factors that are released into the circulation. Their concentrations thus reflect the rate of bone formation. Serum bone formation markers include osteocalcin, bone-specific alkaline phosphatase, and procollagen I carboxy-terminal propeptide (PICP). Osteoclasts produce bone degradation products that are also released into the circulation and are eventually cleared via the kidney. Main bone resorption markers include urinary deoxypyridinoline (u-DPD), urinary collagen type I cross-linked N telopeptide (u-NTX) and serum collagen type I cross-linked C telopeptide (s-CTX).

These markers of bone formation and resorption can estimate bone-remodeling rates and may help identify fast bone losers. As evaluated by these markers, bone remodeling rates increase at menopause and remain elevated and correlate negatively with BMD.

That said, most prospective studies analyzing the relationship between bone remodeling and rates of bone loss have been short-term and have been limited by the precision error of densitometry. Garnero and colleagues (1994) prospectively evaluated over 4 years the utility of bone markers to identify fast bone losers in a large cohort of healthy menopausal women. They found that higher levels of bone formation and resorption markers were significantly associated with faster and possibly greater BMD loss.

Markers of bone resorption may also be useful predictors of fracture risk and bone loss. Elevation of these markers may be associated with an increased fracture risk in elderly women, although data are not uniform. The association of markers of bone resorption with femoral neck fracture risk is independent of BMD, but a low BMD combined with high bone resorption biomarker doubles the risk associated with either of these factors alone. However, biomarker measurements are currently limited by their high variability within individuals. Additional studies with fracture endpoints are needed to confirm the usefulness of these markers in individual patients.

Biomarkers may also have value in predicting and monitoring response to potent antiresorptive therapy in clinical trials. Normalization of bone formation and resorption marker levels following therapy has been observed in prospective trials.

TABLE 21-7. Fall Risk Factors

<b>Physiologic changes</b>	<b>Environmental</b>
Prior falls	Poor lighting
Diminished balance	Unsafe footwear
Reduced muscle mass	Telephone cords
<b>Comorbid conditions</b>	Cluttered hallways
Arthritis	Loose rugs
Arrhythmia	Slippery/damaged flooring
Alcohol abuse	No bathroom support bars
Gait disorders	<b>Medications</b>
Balance disorders	Narcotics
Visual impairment	Anticonvulsants
Cognitive impairment	Antiarrhythmic agents
Orthostatic hypotension	Psychiatric medications
	Antihypertensive agents

Reduction in biochemical marker levels appears in some studies to be correlated with a decrease in vertebral fracture incidence but is not necessarily always predictive of response to therapies.

Bone remodeling markers are not yet used for routine clinical management. Additional studies are needed to confirm their use in individual patients. However, with refinement of assay technology and better understanding of biological variability, it is likely that they will become a useful adjunct in the future for risk assessment and management.

## ■ Cardiovascular Changes

In women older than 50 years, atherosclerotic cardiovascular disease (CVD) remains the leading cause of death. CVD accounts for approximately 40 percent of deaths in women compared with about 5 percent due to breast cancer. Before menopause, women have a much lower risk for cardiovascular events compared with men their same age. Reasons for protection from CVD in premenopausal women are complex, but a significant contribution is assigned to greater high-density lipoprotein (HDL) levels in younger women, which is an effect of estrogen. However, after menopause, this benefit disappears over time such that a 70-year-old woman begins to have a CVD risk identical to that of a male of comparable age (Matthews, 1989). The risk of CVD increases exponentially for women as they enter menopause and as estrogen levels decline (Matthews, 1994; van Beresteijn, 1993). This becomes vitally important for women in MT, when preventive measures can significantly improve both life quality and quantity.

The relationship between menopause and CVD incidence was first examined in the Framingham cohort of 2873 women (Kannel, 1987). A trend showed a two- to sixfold higher incidence of CVD in postmenopausal women compared with premenopausal women in the same age range. Moreover, the increases in CVD associated with the MT are observed regardless of the age at menopause. These and other data indicate that withdrawal of estrogen may be associated with an increased CVD risk. Nonetheless, questions of whether estrogen deficiency accelerates development of CVD and whether menopausal hormone treatment can ameliorate CVD risk remain unanswered (Harman, 2014).

## Cardiovascular Disease Prevention

CVD risk factors are the same for men and women and include nonmodifiable risk factors such as age and family history of CVD. Modifiable elements are hypertension, dyslipidemia, obesity, diabetes/glucose intolerance, smoking, poor diet, and lack of physical activity. Because most CVD risk factors are modifiable, significant reductions in cardiovascular morbidity and mortality rates are feasible. Since data question the widespread use of hormone treatment to avert this common problem, other strategies must be considered (Chap. 22, p. 492). Modifying strategies are discussed fully in Chapter 1 (p. 14), and some are briefly summarized here.

Of these, physical activity and its cardiovascular benefits were studied in the Women's Health Initiative (WHI). Manson and colleagues (2002) determined that walking or vigorous exercise reduced the risk of cardiovascular events in postmenopausal

women regardless of their age, BMI, or ethnic background. As expected, a sedentary lifestyle correlated directly with an elevated risk for coronary events (McKechnie, 2001).

As another CVD risk factor, central fat distribution, also termed truncal obesity, in women correlates positively with increases in total cholesterol, triglyceride, and low-density lipoprotein (LDL) cholesterol levels, and negatively correlates with HDL levels (Haarbo, 1989). The atherogenic lipid profile associated with abdominal adiposity is at least partly mediated through interplay with insulin and estrogen. A strong correlation exists between the magnitude of the worsening in cardiovascular risk factors (lipid and lipoprotein changes, blood pressure, and insulin levels) and the amount of weight gained during MT (Wing, 1991).

Favorable lipoprotein profiles in young women are maintained in part by physiologic estrogen levels. Specifically, throughout adulthood HDL levels are approximately 10 mg/dL higher in women. Moreover, total cholesterol and LDL levels are lower in premenopausal women than in men (Jensen, 1990; Matthews, 1989). After menopause and with the subsequent declines in estrogen levels, this favorable effect on lipids is lost. HDL levels decrease and total cholesterol levels increase. After menopause, the risk of coronary heart disease doubles for women, and at approximately age 60, the atherogenic lipids reach levels higher than those in men. Despite these changes in atherogenic lipids following menopause, total cholesterol and LDL levels can be favorably reduced by dietary modifications, estrogen treatment, and lipid-lowering medications (Matthews, 1994).

Last, clotting parameters are known to change with aging. Fibrinogen, plasminogen activator inhibitor-1, and factor VII levels increase and cause a relatively hypercoagulable state. This is thought to contribute to increases in CVD and cerebrovascular disease rates in older women. Aspirin is effective in the *secondary prevention* of CVD in both men and women (Antithrombotic Trialists' Collaboration, 2002). However, as discussed in Chapter 1 (p. 15), aspirin is not recommended for *primary prevention* of heart disease in women younger than 65 unless individual health benefits are judged to outweigh risks. These counterbalancing risks primarily involve aspirin-related bleeding episodes such as hemorrhagic stroke and gastrointestinal bleeding (Lund, 2008).

## ■ Weight Gain and Fat Distribution

Weight gain is a common complaint among women during MT. With aging, a woman's metabolism slows, reducing her caloric requirements. If eating and exercise habits are not altered, weight is gained (Matthews, 2001). Specifically, Espeland and associates (1997) characterized the weight and fat distribution of 875 women in the Postmenopausal Estrogen/Progestin Interventions (PEPI) trial and correlated the effects of lifestyle, clinical, and demographic factors. Women aged 45 to 54 years had significantly greater increases in weight and in hip circumference than those aged 55 to 65 years. These investigators reported that overall baseline physical activity and baseline leisure and work activities were strongly related to weight gain in the PEPI cohort. Women who reported more activity gained less weight than less active women.

Weight gain during this period is associated with fat deposition in the abdomen, increased amounts of visceral fat, and body fat redistribution (Kim, 2014). These raise the likelihood of developing insulin resistance and subsequent diabetes mellitus and heart disease (Dallman, 2004; Wing, 1991). This stems from associated alterations in cardiometabolic risks due to hormone-related declines in energy expenditure and fat oxidation (Jull, 2014). In addition, data from the Rosetta Study and the New Mexico Aging Process Study show that older adults have higher percentages of body fat than younger adults at any age due to muscle mass loss with aging (Baumgartner, 1995).

Numerous other factors underlie weight gain and include genetic factors, neuropeptides, and adrenergic nervous system activity (Milewicz, 1996). Although many women believe that noncontraceptive estrogen therapy causes weight gain, results from clinical trials and epidemiologic studies indicate that the effect of menopausal hormone therapy on body weight and girth, if any, is to blunt slightly the rate of age-related increases.

Lifestyle interventions to minimize gains in fat mass and changes in body composition and body fat distribution during MT predominantly include exercise and healthy nutrition. As discussed in Chapter 1 (p. 13), specific interventions include encouraging individuals to set realistic lifestyle goals, referral to weight loss programs, pharmacotherapy, or surgical interventions (Jull, 2014). Women exposed to a program of combined exercise and calorie-restricting dietary interventions for 54 weeks had improved body weight and reduced abdominal adiposity compared with usual activities in the control group (Simkin-Silverman, 2007). As well, significant reductions in waist circumference and body fat were maintained beyond 4 years. Hagner and coworkers (2009) found that a Nordic walking program reduced weight gain during MT.

### ■ Dermatologic Changes

Skin changes that may develop during MT include hyperpigmentation (age spots), wrinkles, and itching. These are caused in part by skin aging, which results from the synergistic effects of intrinsic aging and photo-aging (Guinot, 2005). Hormonal aging of the skin is also thought to be responsible for many dermal changes. These include a reduced thickness due to lower collagen content, diminished sebaceous gland secretion, loss of elasticity, and decreased blood supply (Wines, 2001). Although the effect of hormone deficiency on skin aging has been widely studied, distinguishing its contribution from those of intrinsic aging, photo-aging, and other environmental insults is difficult.

### ■ Dental Changes

Dental problems may also develop as estrogen levels wane in late MT. The buccal epithelium atrophies due to estrogen deprivation, resulting in decreased saliva and sensation. A bad taste in the mouth, increased incidence of cavities, and tooth loss also may occur (Krall, 1994). Oral alveolar bone loss is strongly positively correlated with osteoporosis and can lead to tooth loss. Even in women without osteoporosis, vertebral BMD correlates positively with the number of teeth. In turn,

the beneficial effect of estrogen on skeletal bone mass is also manifested in oral bone.

### ■ Breast Changes

The breast undergoes change during MT mainly because of hormonal withdrawal. In premenopausal women, estrogen and progesterone exert proliferative effects on ductal and glandular structures, respectively. At menopause, withdrawal of estrogen and progesterone leads to a relative reduction in breast proliferation. A significant reduction in the volume and tissue density is seen during mammography as these areas become replaced with adipose tissue. Mammography is advisable for women older than age 40, and breast imaging is fully discussed in Chapter 12 (p. 288).

### ■ Central Nervous System Sleep Dysfunction and Fatigue

Sleep quality declines with age, but the menopausal transition appears to contribute to this decline in women. Women may wake several times during the night and may be drenched in sweat. The relationship between hot flashes and impaired sleep has been studied. Hollander and associates (2001) studied late reproductive-aged women and found that women with a greater incidence of hot flashes were more likely to report poor sleep than were women with fewer vasomotor symptoms. Self-reported poor sleep rates increase as women traverse MT, and it was reported in 38 percent of the 12,603 women who participated in the cross-sectional survey of the SWAN Study (Hall, 2009). As with most menopausal symptoms, severity and prevalence seem to peak during late MT, when women have prolonged amenorrhea.

Even women with few vasomotor symptoms may experience insomnia and associated menopause-related mood symptoms (Erlik, 1982; Woodward, 1994). As women age, they are more likely to experience lighter sleep and are awakened more easily by pain, sound, or bodily urges. Health issues and other chronic conditions experienced by women or by their spouse or bedmate are likely to further disrupt sleep. Arthritis, carpal tunnel syndrome, chronic lung disease, heartburn, and certain medications that are known to disrupt sleep may dramatically lower the quality and quantity of restful sleep. Nocturia, urinary frequency, and urgency, all of which are more common in menopausal women, are other notable factors.

Sleep disordered breathing (SDB), which includes various degrees of pharyngeal obstruction, is much more common in menopausal women and their mates. In women, SDB is often associated with increased BMI and declining estrogen and progesterone levels. Loud snoring can follow partial upper airway obstruction that ranges in severity from upper airway resistance to obstructive sleep apnea (Gislason, 1993).

Disturbed sleep can lead to fatigue, irritability, depressive symptoms, cognitive dysfunction, and impaired daily functioning. Commonsense education for patients during MT may prove valuable (Table 21-8). Importantly, although fatigue may stem from night sweats and poor sleep, other common potential etiologies, such as anemia or thyroid disease, among

**TABLE 21-8.** Fatigue Prevention Instructions

Obtain adequate sleep every night
Exercise regularly to reduce stress
Avoid long work hours and maintain your personal schedule
If stress is environmental, take vacations, switch jobs, or approach your company or family to help resolve sources of stress
Limit intake of alcohol, drugs, and nicotine
Eat a healthy, well-balanced diet
Drink adequate amounts water (8 to 10 glasses) during the early part of the day
Consider seeing a specialist in menopausal medicine

others, are also considered. In all these examples, treatment of underlying health conditions is the main focus to improve patient sleep. At times, short-term use of pharmacologic sleep aids is indicated, and these are listed in Table 1-16 (p. 18).

### Cognitive Dysfunction

Memory declines with advancing age. Although no direct effect of lowered estrogen levels on memory and cognition has been determined, many investigators suspect a relationship between the two. Cognitive functioning was assessed in a cohort study of reproductive-aged and postmenopausal women not using hormone replacement therapy. In postmenopausal patients, cognitive performance declined with advancing age. This was not the case for reproductive-aged women. Premenopausal women in their 40s were less likely to exhibit cognitive decline compared with postmenopausal patients in the same decade of life. These researchers concluded that deterioration of some forms of cognitive function is accelerated after menopause (Halbreich, 1995).

In another study, Henderson and coworkers (2013) studied 643 healthy postmenopausal women not using hormone therapy who were recruited as early (< 6 years after menopause) and late (> 10 years after menopause) groups. Women were administered a comprehensive neuropsychological battery. Concurrently, serum free estradiol, estrone, progesterone, free testosterone, and SHBG levels were measured. Cognitive outcomes were standardized composite measures of verbal memory, executive functions, and global cognition. Endogenous sex steroid levels were unassociated with cognitive composites, but SHBG levels were positively associated with verbal memory. Results for early and late groups did not differ significantly, although progesterone concentrations were significantly positively associated with verbal memory and global cognition in early group women. Hormone levels were not significantly related to mood.

Factors accelerating cerebral degenerative changes represent potentially modifiable risks for cognitive decline (Kuller, 2003; Meyer, 1999). Investigators have studied putative risk factors and have correlated them with measures of cerebral atrophy, computed tomography (CT) densitometry, and cognitive testing among neurologically and cognitively normal, aging volunteers. Risk factors for decreased cerebral perfusion and thinning of gray and white matter densities include prior transient ischemic attacks (TIAs), hyperlipidemia, hypertension, smoking, excess

alcohol consumption, and male gender, which would imply lack of estrogen. The authors encourage interventions to modify many of these risks.

### ■ Psychosocial Changes

Women have long been recognized as carrying a higher lifetime risk of developing depression than men. The World Health Organization has consistently ranked depression as a leading cause of disability in women. The risk of developing a major depressive disorder is 1.5 to 1.7 times higher in women than in men, particularly during reproductive years. A prior depressive episode (particularly if related to reproductive events) remains the strongest predictor of mood symptoms or depression during midlife. Vasomotor symptoms, anxiety, and other health-related issues also modulate depression risks (Soares, 2014).

Contemporary findings have dispelled myths that natural menopause itself is associated with depressed mood (Ballinger, 1990; Busch, 1994). However, an increased risk of depressive symptoms during MT has been repeatedly observed in population-based studies. In the Penn Ovarian Aging Study, the risk was nearly three times higher in women in MT compared with premenopausal women. Moreover, women with no history of depression were two and a half times more likely to report depressed mood during MT than during the premenopausal period (Freeman, 2004). Other cohort studies report similar findings (Bromberger, 2011; Cohen, 2006; Dennerstein, 2004; Woods, 2008). Moreover, there are a high percentage of subjects with recurrent depression during MT (Freeman, 2007). Thus, a screen for depression is prudent for women in this transition, and tools are described in Chapter 13 (p. 298).

It has been suggested that the hormonal fluctuations during early MT are responsible, in part, for this affective instability. Similarly, surgical menopause induces mood changes because of the rapid hormonal loss at this time. Soares (2005) hypothesizes that a major component of the reported emotional distress during MT may be causally related to high and erratic estradiol levels. For example, Ballinger and colleagues (1990) showed that increases in stress hormones (and probably symptoms that are stress related) are physiologically linked with high estrogen levels. They also reported that women with abnormal psychometric test scores early after menopause had higher estradiol levels than women with lower scores. Spinelli and associates (2005) showed that estrogen levels are correlated with the intensity of menopausal symptoms. A randomized, placebo-controlled menopause treatment study evaluated administered standard doses of conjugated equine estrogen (0.625 mg/d), which significantly improved sleep, but also showed an estrogen-related increase of inward-directed hostility (Schiff, 1980).

Importantly, the MT is a complex sociocultural as well as a hormonal event, and psychosocial factors may contribute to mood and cognitive symptoms. For example, women entering MT may face emotional stress from onset of a major illness, caring for an adolescent or aging parent, divorce or widowhood, and career change or retirement (LeBoeuf, 1996). Lock (1991) suggests that part of the stress reported by Western women is clearly culture-specific. Western culture emphasizes beauty and youth, and as women grow older, some suffer from

a perceived loss of status, function, and control (LeBoeuf, 1996). However, the end of predictable menstruation and the end of fertility may be significant to a woman simply because it is a change, no matter how aging and the end of reproductive life are viewed by that woman and by her culture (Frackiewicz, 2000). For some women, the approach of menopause may also be perceived as a significant loss, both to women who have accepted childbearing and rearing as their major life roles and those who are childless, perhaps not by choice. For these reasons, impending menopause may be perceived as a time of loss, when depression and other psychological disorders may develop (Avis, 2000).

■ Libido Changes

Although the relationship between circulating hormones and libido has been extensively investigated, definitive data are lacking. Many studies demonstrate that other factors besides menopause may account for libido changes (Gracia, 2007). Avis and associates (2000) studied sexual function in a subgroup of 200 women in the Massachusetts Women’s Health Study II who underwent natural menopause. None took hormone treatment, and all these women had sexual partners. Menopausal status was observed to be significantly related to decreased sexual interest. However, after adjustment for physical and mental health, smoking, and marital satisfaction, menopausal status no longer had a significant relationship to libido. Dennerstein (2005) prospectively evaluated 438 Australian women during 6 years of their menopausal transition. Menopause was significantly associated with dyspareunia and indirectly with sexual response. Feelings for one’s partner, stress, and other social factors also indirectly affected sexual functioning.

Other investigators have demonstrated that sexual problems are more prevalent after menopause. A longitudinal study of women during MT until at least 1 year after the final menstrual period demonstrated a significant decrease in the rate of weekly coitus. Patients reported a significant decline in the number of sexual thoughts, sexual satisfactions, and vaginal lubrication after becoming menopausal (McCoy, 1985). In a study of 100 naturally menopausal women, both sexual desire and activity decreased compared with that during the premenopausal period. Women reported loss of libido, dyspareunia, and orgasmic dysfunction, with 86 percent reporting no orgasms after menopause (Tunghaisal, 1991).

■ Lower Reproductive Tract Changes

Estrogen receptors have been identified in the vulva, vagina, bladder, urethra, pelvic floor musculature, and endopelvic tissues. These structures thus share a similar hormonal responsiveness and are susceptible to estrogen deprivation. To reflect this common link, the International Society for the Study of Women’s Sexual Health (ISSWSH) and The North American Menopause Society adopted the term *genitourinary syndrome of menopause (GSM)* to encompass the constellation of signs and symptoms that affect the genitourinary system after menopause (Table 21-9). As such, GSM is a syndrome that may include genital symptoms of dryness, burning, and irritation; sexual symptoms of absent lubrication, dyspareunia, and dysfunction;

TABLE 21-9. Genitourinary Syndrome of Menopause Characteristics	
Symptoms	Signs
Genital dryness	Labia minora resorption
Poor lubrication	Narrowed introitus
Dyspareunia	Absent hymenal tags
Postcoital bleeding	Tissue pallor or erythema
Poor arousal, orgasm, desire	Urethral eversion
Vulvovaginal:	Urethral prolapse
irritation, burning, itching	Prominent urethral meatus
Dysuria	Recurrent UTI
Urinary frequency	Absent rugae
Urinary urgency	Fragile or fissured tissue
	Petechial hemorrhages
	Scant vaginal secretions
	Poor elasticity

UTI = urinary tract infection.  
Adapted with permission from Portman DJ, Gass ML; Vulvovaginal Atrophy Terminology Consensus Conference Panel: Genitourinary syndrome of menopause: new terminology for vulvovaginal atrophy from the International Society for the Study of Women’s Sexual Health and the North American Menopause Society, Menopause 2014 Oct;21(10):1063–1068.

and urinary symptoms of urgency, dysuria, and recurrent urinary tract infections (UTIs) (Portman, 2014).

Vulvovaginal Changes

Without estrogen’s trophic influence, the vagina loses collagen, adipose tissue, and ability to retain water (Sarrel, 2000). As vaginal walls shrink, rugae flatten, and the vagina attains a smooth-walled, pale-pink appearance. The surface epithelium thins to only a few cell layers. This markedly reduces the ratio of superficial to basal cells, described on page 489. Moreover, the thin vaginal surface is friable and prone to submucosal petechial hemorrhages or bleeding with minimal trauma. The blood vessels in the vaginal walls narrow, and over time the vagina itself contracts and loses flexibility.

In addition, vaginal pH becomes more alkaline and a pH greater than 4.5 is typically observed with estrogen deficiency (Caillouette, 1997; Roy, 2004). An alkaline pH creates a vaginal environment less hospitable to lactobacilli and more susceptible to infection by urogenital and fecal pathogens. Hoffmann and colleagues (2014) found that the prevalence of bacterial vaginosis ranged from 23 to 38 percent in postmenopausal women, and rates increased with age. In contrast, *Candida* species were noted in 5 to 6 percent of these same women, and rates declined with aging.

In addition to vaginal changes, the vulvar epithelium gradually atrophies and secretions from sebaceous glands diminish. Subcutaneous fat in the labia majora is lost, which leads to shrinkage and retraction of clitoral prepuce and the urethra, fusion of the labia minora, and introital narrowing and then stenosis (Mehta, 2008).

Symptoms of vulvovaginal atrophy include vaginal dryness, itching, irritation, and dyspareunia. These are common complaints during MT, and prevalence estimates range from 10 to 50 percent (Levine, 2008). Treatment options include topical or systemic estrogen, SERMs, and vaginal moisturizers, which are all discussed in Chapter 22 (p. 505).

### Dyspareunia and Sexual Dysfunction

Menopausal patients often note dyspareunia and other forms of sexual dysfunction. In one study, 25 percent of postmenopausal women noted some degree of dyspareunia (Laumann, 1999). These same investigators found that painful intercourse correlated with sexual problems, including lack of libido, arousal disorder, and anorgasmia. Although dyspareunia in this population is generally attributed to vaginal dryness and mucosal atrophy secondary to estrogen deficiency, prevalence studies suggest that a decrement in all aspects of female sexual function is associated with midlife (Dennerstein, 2005).

Levine and associates (2008) studied 1480 sexually active postmenopausal women and found that the prevalence of vulvovaginal atrophy and of female sexual dysfunction each approximated 55 percent. They found that women with female sexual dysfunction were 3.84 times more likely to have vulvovaginal atrophy than women without such dysfunction. Estrogen deficiency diminishes vaginal lubrication, blood flow, and vasocongestion with sexual activity. These changes are coupled with the structural atrophy described in that last section. Reduced testosterone levels have been implicated in genital atrophy as well, but the relationship between testosterone and sexuality during MT remains obscure. Circulating testosterone levels decline gradually with age from the mid-reproductive years and have dropped by 50 percent by age 45. Paradoxically, studies have been unable to demonstrate that sexual dysfunction is related to decreased androgen levels in MT (O'Neil, 2011).

Urogenital conditions such as prolapse or incontinence correlate strongly with sexual dysfunction (Barber, 2002; Salonia, 2004). Patients with urinary incontinence are likely to have pelvic-floor hypotonus dysfunction, which may cause pain on deep penetration due to pelvic support instability. Hypertonic or dyssynergic pelvic-floor muscles, which are commonly seen in patients with urinary frequency, constipation, and vaginismus, are often associated with superficial pain and friction during intercourse (Handa, 2004). The presence of organ prolapse contributes to dyspareunia, as does a history of a gynecologic surgical procedure that may cause dyspareunia by shortening the vagina (Goldberg, 2001).

Menopause is also a time of life when significant psychosocial and physiological changes occur simultaneously, and concomitant illnesses arise. It is understandable that such major life changes influence sexual functioning. In the longitudinal Melbourne Midlife Study, Dennerstein and associates (1993) confirmed a significant decline in sexual functioning during MT. Sexual responsivity, libido, sexual frequency, positive feelings for a partner, and a partner's sexual performance all typically decreased, and vaginal dyspareunia rates typically increased. Other medical conditions such as arthritis, hip or lumbar joint pain, or fibromyalgia may contribute to vaginal or pelvic pain with intercourse. Pain may be due to radiation

of pain from trigger points in the trunk, buttocks, or pelvic-floor muscles, or from possible pudendal nerve entrapment. Chronic pelvic pain may also contribute to sexual dysfunction as discussed in Chapter 11 (p. 262).

### Urogenital Changes

As part of GSM, urinary symptoms can include dysuria, urgency, urethral eversion or prolapse, and recurrent UTIs (Portman, 2014; Trutnovsky, 2014). Specifically, thinning of urethral and bladder mucosa underlie these. For these complaints, vaginal estrogen, discussed in Chapter 22 (p. 505), is a reasonable first option (Rahn, 2014).

The association between declining estrogen levels and incontinence is more controversial. In support of a causal link, urethral shortening associated with menopausal atrophic changes may result in genuine stress urinary incontinence. For example, Bhatia and colleagues (1989) showed that estrogen therapy may improve or cure stress urinary incontinence in more than 50 percent of treated women, presumably by exerting a direct effect on urethral mucosa coaptation (Chap. 23, p. 530). Accordingly, a trial of hormone therapy may be considered in select patients prior to surgical correction of incontinence in women with vaginal atrophy.

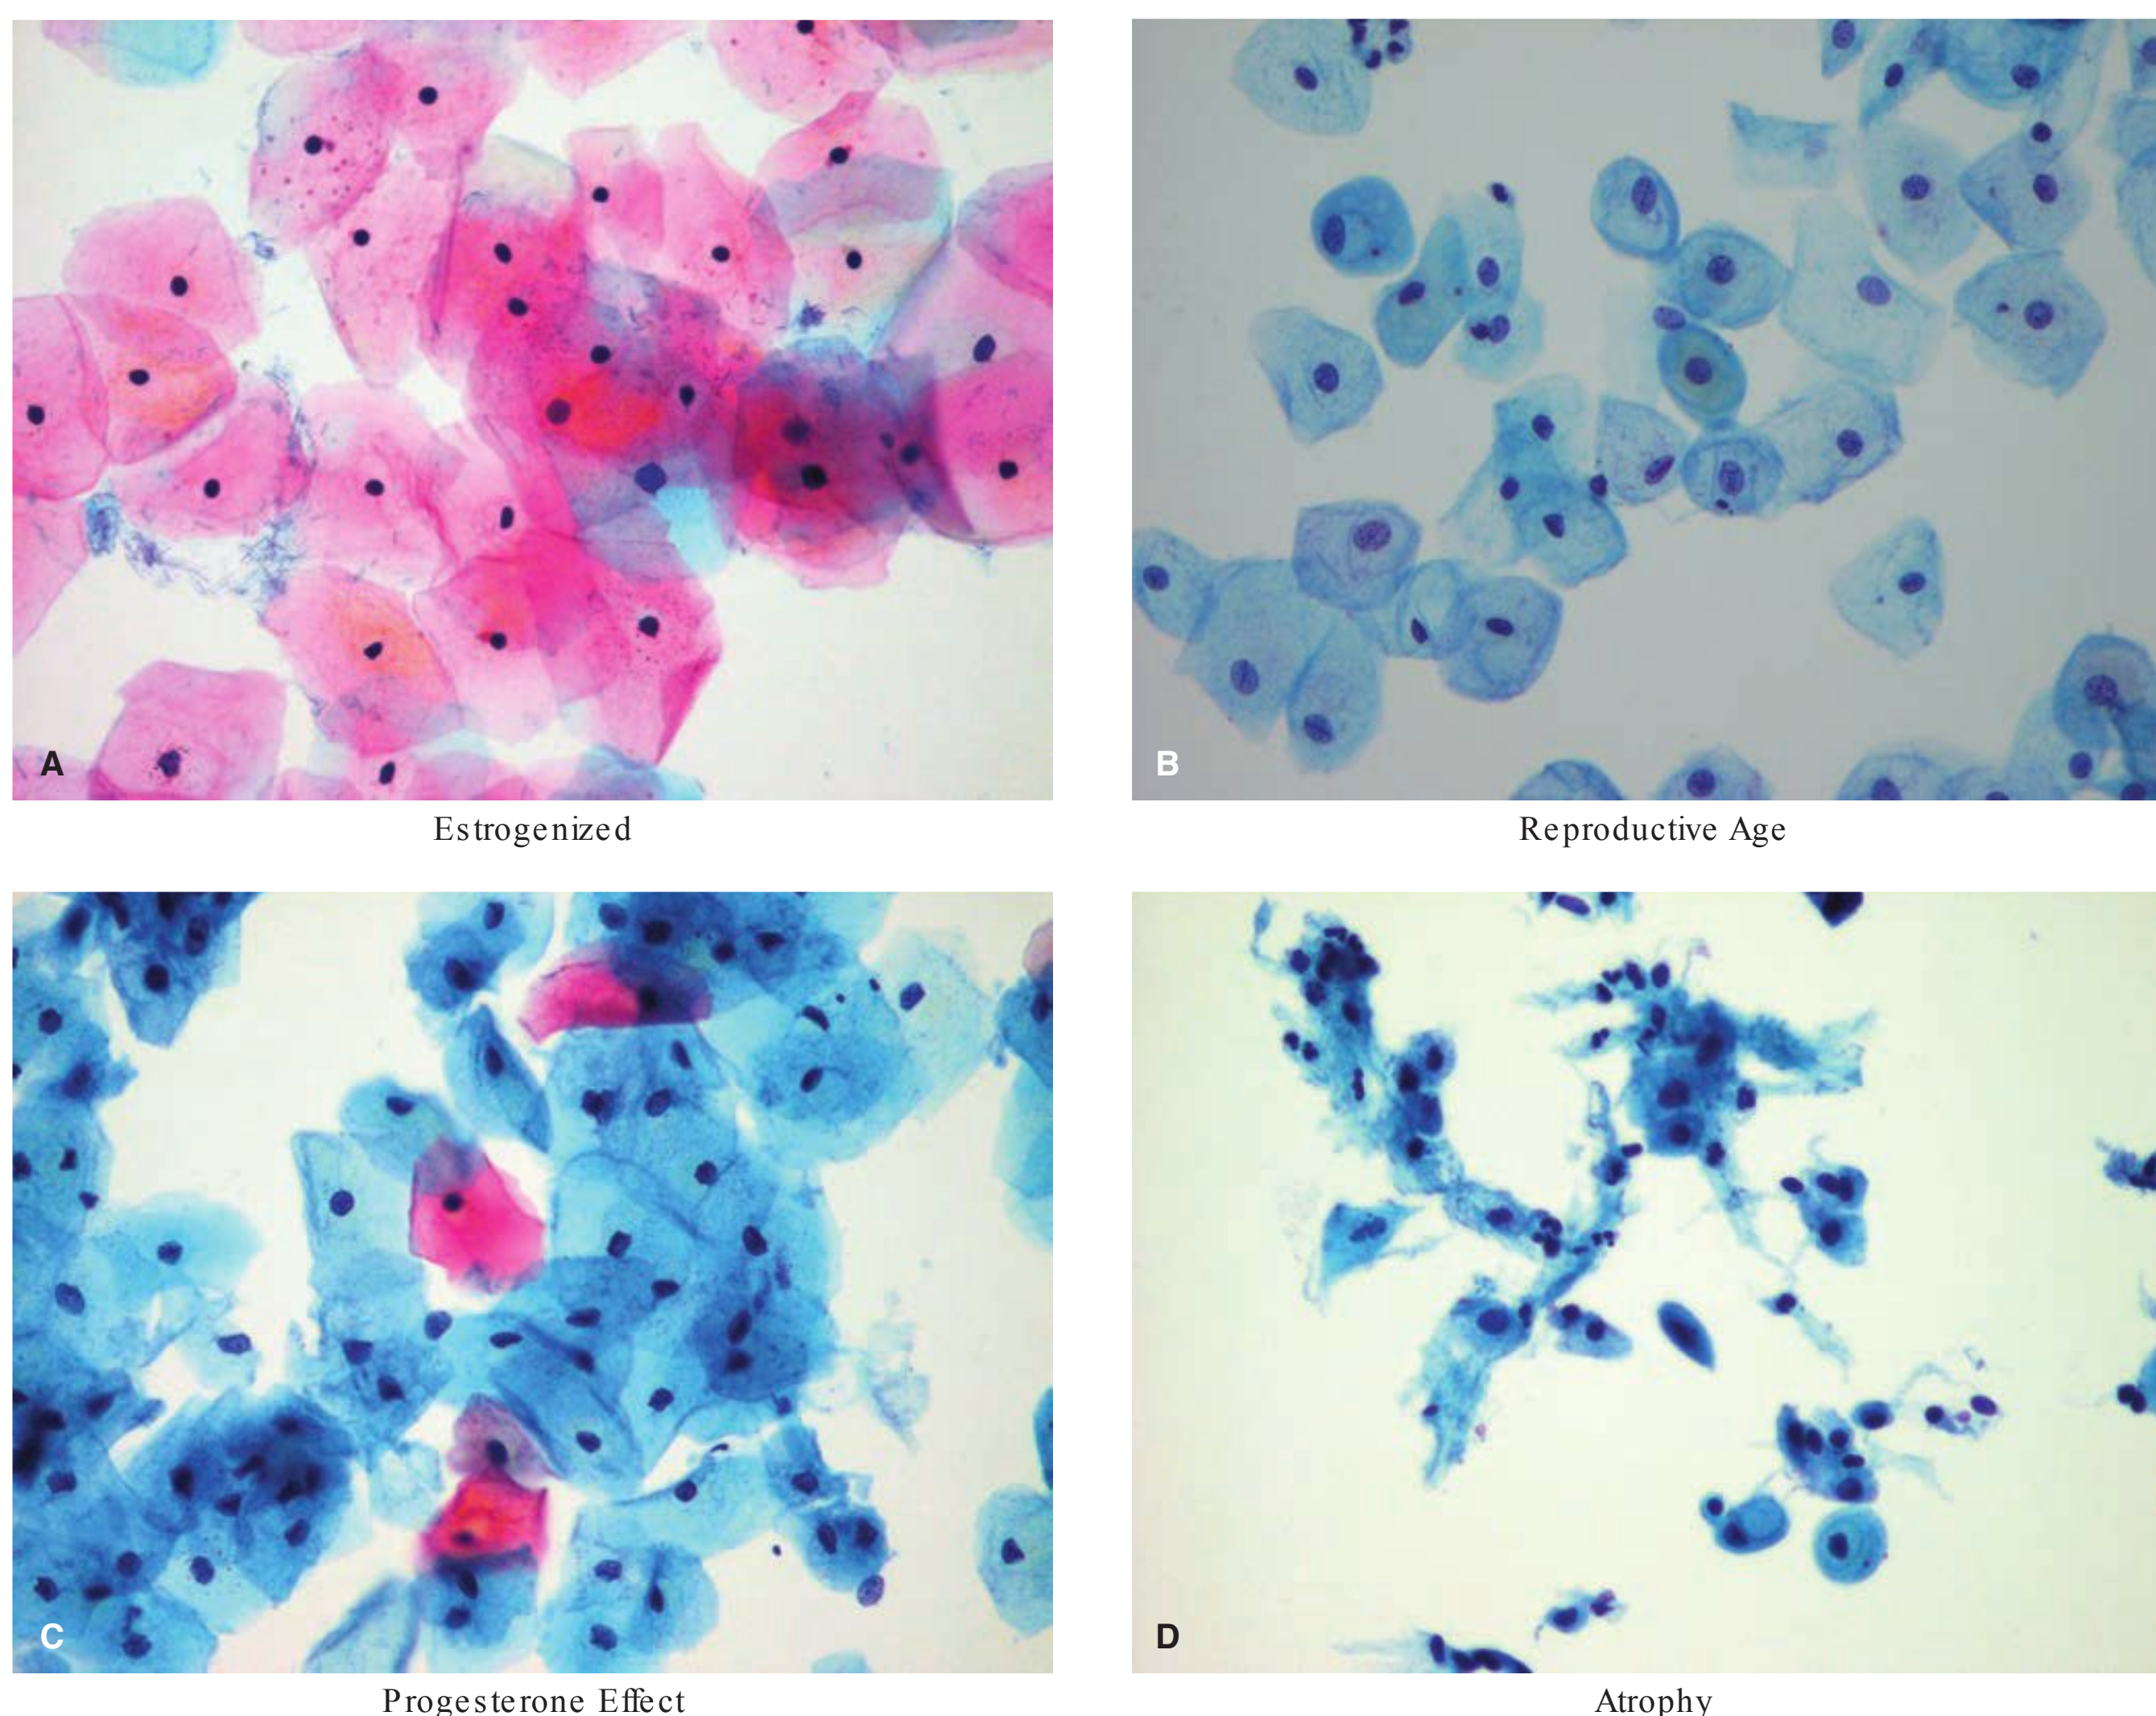

That said, Waetjen and coworkers (2009) evaluated women in MT and found a slight increase in stress and urge incontinence. They did find, however, a more robust association with worsening anxiety symptoms, a high baseline BMI, weight gain, and new-onset diabetes. Their conclusion was that from a public health standpoint, clinicians and women should focus first on these modifiable risk factors. Other studies have also failed to find links between incontinence and menopausal status. Sherburn and colleagues (2001) performed a cross-sectional study of Australian women aged 45 to 55 years. In this population, they identified a 15-percent prevalence of incontinence. Associated risk factors included gynecologic surgery, higher BMI, UTIs, constipation, and multiparity. Subsequently, these investigators studied a subset of 373 premenopausal females to determine if MT itself was associated with an increased incidence of incontinence. In this group of women, the overall incidence was 35 percent, with no increase associated with menopause. Incontinence was most closely related to hysterectomy. More recently, Trutnovsky and associates (2014) explored the effects of menopause and hormone therapy both on stress and urge urinary incontinence. In the 382 women evaluated, the length of menopause showed no significant relationship with urinary incontinence.

In addition to incontinence, pelvic organ prolapse rates increase with advancing age. Importantly, vaginal relaxation with anterior wall, posterior wall, or apical prolapse is not a direct consequence of estrogen deprivation, as many factors play a role in pelvic floor relaxation (Chap. 24, p. 538).

## PATIENT EVALUATION

Clinical goals during MT are to optimize a woman's health and well-being during and after this transition. This is an excellent time for a comprehensive health evaluation that includes a complete medical history, physical examination, and laboratory studies. Risk factors for common health problems such as obesity,

**FIGURE 21-9** Photomicrographs of cytologic specimens illustrate key points of the maturation index. This index provides insight into the cytochemical status of the patient and is based on a count of parabasal, intermediate, and superficial (P:IS) cells. Generally, a predominance of superficial or superficial and intermediate cells (**A** and **B**) is seen in reproductive-aged women. **C**. A predominance of intermediate cells is seen in the luteal phase, in pregnancy, with amenorrhea, and in newborns, premenarchal girls, and women in early menopausal transition. **D**. A predominance of parabasal cells is seen in menopausal patients with atrophy. (Used with permission from Dr. Raheela Ashfaq.)

osteoporosis, heart disease, diabetes mellitus, and certain cancers are assessed and then managed. Counseling regarding diet, exercise, alcohol moderation, and smoking cessation is imperative, if applicable. Psychosocial well-being is also assessed. Clinicians may inquire directly about depression, anxiety, and sexual functioning or may choose to administer a simple questionnaire to assess for psychosocial issues (Chap. 13, p. 299).

A thorough general physical examination is performed during patient visits to document changes associated with aging and MT. Of elements, height, weight, waist circumference, and BMI are recorded and can be used to counsel women about physical exercise and weight loss or weight gain. Height loss may be associated with osteoporosis and vertebral compression fractures and thus is recorded yearly. Blood pressure monitoring effectively screens for hypertension, which is common in this population. The remaining examination notes expected physiologic changes of MT and seeks potential pathology described in earlier sections.

The diagnosis of MT can usually be made with documentation of age-appropriate symptoms and careful physical examination. Clearly, a 50-year-old woman with menstrual irregularity, hot flashes, and vaginal dryness is considered to be in MT. Other testing such as FSH or estradiol levels, described next, can be performed to document ovarian failure. However, for those in MT, FSH levels may be normal. Even when much younger women present with similar symptoms, evaluation should also include FSH measurement. If ovarian failure develops before age 40, it is usually pathologic. Thus, chromosomal abnormalities, infections, autoimmune disorders, galactosemia, cigarette smoking, or iatrogenic causes such as radiation or chemotherapy are considered (Table 16-6, p. 373).

### ■ Gonadotropin and Estrogen Levels

Biochemical changes, of which a woman may be unaware, may be identified prior to cycle irregularity. For example, in the

early follicular phase of the menstrual cycle in many women older than 35 years, FSH levels may rise without a concurrent luteinizing hormone (LH) elevation. This finding is associated with a poor prognosis for future fertility. Specifically, a cycle day 3 FSH level greater than 10 mIU/mL is used in some in vitro fertilization (IVF) programs to route patients into donor egg programs (Chap. 20, p. 465). An FSH level greater than 40 mIU/mL has been used to document ovarian failure associated with menopause.

Estrogen levels may be normal, elevated, or low depending on the stage of MT. Only at menopause are estrogen levels extremely low or undetectable. Additionally, estrogen levels may be used to assess women's response to hormone treatment. Most clinicians prefer to reach a physiologic serum estradiol range of 50 to 100 pg/mL when selecting and adjusting replacement therapy. Women who receive estradiol pellets as replacement therapy may have elevated serum estradiol values from 300 to 500 pg/mL. These high levels are not uncommon with this replacement method but are discouraged.

## ■ Estrogen Maturation Index

The maturation index (MI) is an inexpensive, but less often used, means to evaluate hormonal influences in women. A specimen to measure the MI may be collected during a vaginal speculum examination at the same time cervical cancer screening is performed. The index report is read from left to right and refers to the percentage of parabasal, intermediate, and superficial squamous cells appearing on a smear, with the total sum of all three values equaling 100 percent (Fig. 21-9) (Randolph, 2005). For example, an MI of 0:40:60 represents 0 percent parabasal cells, 40 percent intermediate cells, and 60 percent superficial cells. This MI reflects adequate vaginal estrogen effects. A shift to the left indicates an increase in parabasal or intermediate cells, which denotes low estrogen effects. Conversely, a shift to the right reflects an increase in the superficial or intermediate cells, which is associated with higher estrogen levels.

An ideal MI vaginal specimen consists of freely exfoliating squamous cells from the upper third of the vaginal wall. Avoiding the cervix, the vaginal wall secretions are gently scraped with a spatula or saline-moistened swab. Immediately after collection, the specimen is transferred to a microscope slide. Cells are either suspended in a small amount of saline (as in a wet prep) or smeared to the slide and fixed with 95-percent ethanol spray fixative.

The typical “mature woman” is aged 40 years or older and has completed childbearing. During their late 40s, most women enter menopausal transition. Detailed in Chapter 21, this period of physiologic change due to ovarian senescence and estrogen decline is usually completed between ages 51 and 56. Menopause marks a defining point in this transition and is defined as the point in time of permanent menstruation cessation due to loss of ovarian function. Clinically, the menopause refers to a point in time that follows 1 year after cessation of menstruation.

With ovarian senescence, declining hormone estrogen levels have specific effects. Some lead to physical symptoms, such as vasomotor symptoms and vaginal dryness, whereas others are metabolic and structural changes. These include bone loss, skin thinning, fatty replacement of the breast, lipoprotein changes, and genitourinary atrophy. As a result, postmenopausal women have unique issues associated with aging and estrogen loss that may negatively affect their individual health.

For many years, menopause was seen as a “deficiency disease” of estrogen, progesterone, and testosterone. For this reason, hormone replacement therapy has been used in one form or another for more than 100 years. The history surrounding this treatment is discussed here, as are current recommendations for the treatment of menopausal symptoms.

HORMONE TREATMENT: HISTORY AND CONTROVERSIES

Clinicians ideally provide evidence-based medicine, and seldom is a single study relied on solely to guide practice (Lobo,

2008). Thus, providers should understand the weaknesses and strengths of clinical trials to accurately counsel their patients. As one example, hormone treatment (HT) was widely prescribed to menopausal women, in good faith, based on initial observational studies. The general medical consensus was that HT, in addition to its prevention and treatment of osteoporosis, could protect against cardiovascular disease, stroke, and dementia. Subsequently, prospective, randomized controlled trials (RCTs) challenged the validity of these earlier observational studies. However, in this evaluation, clinicians must appreciate the type of population studied, the ages and risk factors of participating women, and the hormone regimens tested.

■ Early Estrogen Administration Trends

Estrogen treatment (ET) for menopausal symptom relief gained popularity in the 1960s and 1970s. Proponents promoted ET for its “preservation of youth” and prevention of chronic disease. By the mid-1970s, more than 30 million prescriptions were written for estrogen each year, and half of all menopausal women were using ET for a median of 5 years. Premarin (conjugated equine estrogen) was the fifth most prescribed drug in the marketplace.

In 1975, a study revealed a connection between endometrial cancer and ET. Investigators found a 4.5 times greater risk of this cancer in those using estrogen (Smith, 1975). As a result, the Food and Drug Administration (FDA) ordered labeling changes to state this higher risk. Progestins were then added in the 1980s to therapy regimens to significantly reduce endometrial cancer risks.

During that same time, estrogens were documented by several studies to prevent bone loss (Gambrell, 1983). Additionally, an expanding literature provided a robust affirmation of the effectiveness of menopausal HT in reducing vasomotor symptoms, maintaining bone mineral density (BMD), and preventing and treating vulvovaginal atrophy (Shulman, 2010). Several observational studies also suggested that estrogens prevented development of coronary heart disease (CHD) and other conditions, such as Alzheimer disease. However, in 1985, conflicting reports from two studies were published.

First, the Framingham Heart Study, an observational study of 1234 women, showed that those who took hormones had a 50-percent elevated risk of cardiac morbidity and more than a twofold risk for cerebrovascular disease (Wilson, 1985). In the same edition of the *New England Journal of Medicine*, a much larger observational trial, The Nurses’ Health Study, with 121,964 women, found significantly lower rates of heart disease in postmenopausal women taking estrogen compared with a similar cohort not taking estrogen (Stampfer, 1985). Numerous subsequent articles reported the protective effects

that combination HT provided menopausal women against cardiovascular disease and osteoporosis.

Current thinking is that these early nonrandomized, unblinded, observational studies included samples of women who were not necessarily representative of the entire postmenopausal population. These hormone users tended to have superior access to care and to be thinner, wealthier, and healthier (Grodstein, 2003; Prentice, 2006). An additional source of confounding and possible selection bias is suggested to be the timing of HT initiation relative to the underlying state of the vasculature. Some investigators suggest that estrogen may delay the onset of the earliest stages of atherosclerosis, which are more likely to be present in younger women. However, estrogen may be ineffective or even trigger events in advanced lesions that are found in older women (Mendelsohn, 2005). This potential “window of opportunity” is supported by animal and laboratory studies (Grodstein, 2003). In sum, these study biases may have contributed to favorable outcomes attributed to estrogen in observational trials. When these biases are eliminated and the data reanalyzed, the results of earlier observational trials and later RCTs are remarkably similar.

### ■ postmenopausal Estrogen/progestin Interventions Trial

Because of data available in the late 1980s, estrogens were prescribed, not only for vasomotor symptom relief, but also for prevention of other conditions. In 1995, The Writing Group for the Postmenopausal Estrogen/Progestin Interventions (PEPI) Trial published results that suggested benefit for CHD risk. In this study, menopausal women with a mean age of 56 years were randomly allocated to one of five treatments: (1) placebo, (2) estrogen alone, (3) estrogen plus cyclic medroxyprogesterone acetate (MPA), (4) estrogen plus cyclic micronized progesterone, or (5) estrogen plus continuous MPA. Primary outcomes studied in the 875 women evaluated during 3 years included measurement of systolic blood pressure and of serum lipid, insulin, and fibrinogen levels. The PEPI trial documented that low-density lipoprotein (LDL) cholesterol levels declined and high-density lipoprotein (HDL) levels were increased in the four treatment groups receiving estrogens. Levels were most substantially improved in women solely given estrogen. An intermediate effect was noted in those prescribed conjugated equine estrogen (CEE) and micronized progesterone, whereas the smallest change followed CEE and MPA administration. Fibrinogen levels were increased in the placebo group compared with groups given hormones. However, no differences were identified in systolic blood pressure or glucose-challenged insulin levels. Clinical outcomes were also reported, and complications were few. Of these, all occurred in the HT-treated groups and included one cardiac arrest, two myocardial infarctions (MIs), and two cerebrovascular events.

### ■ Heart and Estrogen/progestin Replacement Study

With results published in 1998, the Heart and Estrogen/Progestin Replacement Study (HERS) described cardiac morbidity in 2763 women with preexisting heart disease (Hulley,

1998). These women received estrogen as secondary prevention for further cardiac disease progression. First-year findings showed an increase in MIs in women who received CEE with continuous MPA. However, after average treatment duration of 4 years, rates of cardiovascular death or nonfatal MI did not differ between treatment groups.

This trial represented the first RCT at variance with prior data and created confusion for both clinicians and their patients. Beliefs that hormones prevented heart disease persisted, but the HERS data caused many investigators to question the cardioprotective effects of hormones. Subsequent HERS II results also showed that HT was not beneficial in the secondary prevention of heart disease even after 6.8 years (Grady, 2002). One reanalysis of the Nurses' Health Study focused on early hazard among women initiating HT during the monitoring period and showed a similar time trend, with early harm (Grodstein, 2001).

### ■ Women's Health Initiative

After an unsuccessful effort in 1990 to obtain FDA approval for HT as prevention for CHD, the need for RCTs to demonstrate conclusive benefit was widely acknowledged. As a result, before the results from the PEPI trial and HERS trials were available, the National Institutes of Health (NIH) launched the Women's Health Initiative (WHI) in 1993. This major study was to evaluate the putative protective effects of HT on common chronic diseases of aging. The WHI examined the effect of a single combined CEE and MPA drug compared with placebo in 16,608 healthy postmenopausal women aged 50 to 79 years (mean of 63.3 years) who had not undergone hysterectomy (Rossouw, 2002). Specific end points were evaluated: CHD, venous thromboembolism (VTE), breast cancer, colon cancer, and bone fractures. Concurrently, the study also compared CEE with placebo in postmenopausal women without a uterus (the estrogen-only arm).

As part of the original WHI study design, investigators predetermined targets for CHD (anticipated benefit) and breast cancer (anticipated risk) as primary disease end points. This design dictated that if the incidence of an end point was exceeded within a given period, the study would be terminated. Moreover, combined end points were weighted into a “global index,” which if exceeded, would result in study termination. After a mean 5.2 years of monitoring, the estrogen and progestin arm of WHI was halted early upon recommendation of its Data and Safety Monitoring Board because overall risks exceeded the benefits. In July 2002, results were released to the media. This preceded journal publication of the data and timely education of health care providers. Chaos ensued while physicians and patients evaluated research facts and before recommendations could be made.

In a subsequent detailed analysis of cardiovascular end points, the hazard for cardiovascular death or nonfatal MI was 1.24. This translated into 188 actual cases in the hormone group and 147 in the placebo group (Anderson, 2004). However, there were no significant differences in coronary revascularization, hospitalization for angina, confirmed angina, acute coronary syndrome, or congestive heart failure.

To explore the timing of HT initiation, Rossouw and colleagues (2007) performed a secondary analysis of the WHI

data. They looked specifically at the effect of HT on stroke and CHD rates across categories of age and years since menopause in the combined trial. Women who initiated HT closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause. In women with less than 10 years since their menopause began, the hazard ratio for CHD was 0.76. In those with 10 to 20 years since menopause, the ratio was 1.10; and with 20 or more years, 1.28.

In evaluating data by age, lower risk was found for young women and higher risk for older patients. Specifically, for the age group of 50 to 59 years, the hazard ratio for CHD was 0.93, or two fewer events per 10,000 person years; for the age group 60 to 69 years, 0.98 or 1 fewer event per 10,000 person years; and for those 70 to 79 years, 1.26 or 19 extra events per 10,000 person years. HT increased the stroke risk—the hazard ratio was 1.32—and this risk did not vary significantly by age or time since menopause. Rossouw and colleagues concluded that women who initiated HT closer to menopause tended to have reduced CHD risk compared with the increase in CHD risk among women more distant from menopause. Whether CEE or combined CEE and MPA administration improves the cardiovascular health of women who recently experienced menopause remains to be determined. Presently, evidence is insufficient to suggest that either of these regimens should be initiated or continued for primary or secondary CHD prevention (American College of Obstetricians and Gynecologists, 2013). Although this was the principal analysis conclusion, the results led providers and patients to limited HT use, even for healthy women with bothersome vasomotor symptoms during menopausal transition.

Concurrent with the WHI, a similarly constructed study, the Women's International Study of Long Duration Oestrogen after Menopause (WISDOM), began enrollment in 1999. This trial was stopped following halting of the WHI. Analyzing data collected from this study, Vickers and coworkers (2007) found that HT increases cardiovascular and thromboembolic risk when started many years after the menopause.

With this background in mind, data from no single trial can be extrapolated to all women. In the North American Menopause Society's (2012) hormone therapy position statement, they note that while the WHI is, for some outcomes, the only large long-term RCT of postmenopausal women using HT, the trial has several characteristics that limit generalization to all postmenopausal women. These include the use of only one formulation of estrogen and only one progestin. Unlike most HT studies that focused on symptomatic, recently postmenopausal women, the WHI enrolled generally healthy but older postmenopausal women. These parameters should be accounted for when applying the WHI findings to clinical practice.

## CURRENT HORMONE REPLACEMENT ADMINISTRATION

### ■ Risks and Benefits

As a result of these and other studies, most clinicians agree that HT is associated with an increased risk of CHD in older menopausal women, and an increased risk of breast cancer, stroke,

VTE, and cholecystitis. Breast cancer appears only to be a risk factor with long-term use (> 5 years). Two studies have shown an increase in ovarian cancer risk with long-term use (> 10 years) but not with short-term use (< 5 years) (Danforth, 2007; Lacey, 2006). However, other studies have not confirmed this risk (Noller, 2002).

In contrast, several long-term benefits are noted with HT. These include increased BMD and decreased rates of fracture and colorectal cancer. HT's effects on mortality rates have also been examined. A metaanalysis by Salpeter and associates (2004) pooled data from 26,708 participants to reveal that the mortality rate associated with HT was 0.98. Of note, HT reduced mortality rates in women younger than 60 years but not in women older than 60. These investigators suggest that once CHD is established, HT has no effect in reversing disease progression. Moreover, the incidence of cardiovascular events can potentially increase in older groups due to an increased risk for blood clots. Similarly, Rossouw and colleagues (2007) showed a nonsignificant tendency for the effects of HT on mortality rates to be more favorable in younger than older women.

### ■ Indications and Contraindications

Based on current literature, HT is indicated only for treatment of vasomotor symptoms and vaginal atrophy and for osteoporosis prevention or treatment. Current guidelines recommend reevaluation of the need for HT at 6- to 12-month intervals. HT is prescribed in the lowest effective dose for the shortest period of time. Accordingly, bone-specific agents would likely be more appropriate in women requiring long-term osteoporosis prevention or treatment.

For women with a uterus, a progestin is combined with an estrogen to lower risks of endometrial cancer. Progestins may be prescribed daily with estrogen, and this dosing is termed continuous therapy. Another suitable continuous oral agent is the combination of CEE plus the selective estrogen-receptor modulator (SERM) bazedoxifene. This is marketed as the drug Duavee.

Instead, HT may be provided in a cyclic regimen. For this, estrogen is administered for 25 days each month and a progestin added for the final 10 days. Drugs are withdrawn for 5 days and endometrial sloughing and bleeding follows. Another common regimen includes treatment with estrogen continuously with a progestin administered for the first 10 days of each month. Such cyclic therapy is most often used in those during menopausal transition, whereas continuous therapy is usually selected for women following menopause.

Oral progestins are most commonly prescribed, although a progestin-releasing intrauterine device (Mirena) provides another promising option for localized rather than systemic progesterone administration in postmenopausal women (Peled, 2007). In addition, combined estrogen and progestin products are available for either oral or transdermal use. Low-dose combination oral contraceptives are effective in the young perimenopausal woman and have the additional benefit of pregnancy prevention.

Importantly, estrogen is contraindicated or evaluated in women who exhibit conditions found in [Table 22-1](#).

**TABLE 22-1.** Warnings and Precautions with Estrogen Administration

<b>Estrogen should not be used in women with any of the following conditions:</b>
Undiagnosed abnormal genital bleeding
Known, suspected, or history of breast cancer
Known or suspected estrogen-dependent neoplasia
Active or prior venous thromboembolism
Active or recent (e.g., within the past year) arterial thromboembolic disease (e.g., stroke or myocardial infarction)
Liver dysfunction or disease
Known hypersensitivity to the ingredients of the estrogen preparation
Known or suspected pregnancy
<b>Estrogen should be used with caution in women with the following conditions:</b>
Dementia
Gallbladder disease
Hypertriglyceridemia
Prior cholestatic jaundice
Hypothyroidism
Fluid retention plus cardiac or renal dysfunction
Severe hypocalcemia
Prior endometriosis
Hepatic hemangiomas

Data from Food and Drug Administration: Noncontraceptive estrogen drug products for the treatment of vasomotor symptoms and vulvar and vaginal atrophy symptoms—recommended prescribing information for health care providers and patient labeling, 2005.

Ultimately, the decision regarding whether or not to begin HT is a personal one, to be decided by the patient with guidance from her health care provider.

**TREATMENT OF VASOMOTOR SYMPTOMS**

Common early symptoms of menopause include hot flashes, insomnia, irritability, and mood disorders, which can be caused by vasomotor instability. Physical changes include vaginal atrophy, stress urinary incontinence, and skin atrophy. Long-term health risks that have been attributed to the hormonal changes from menopause include osteoporosis, cardiovascular disease, and, in some studies, Alzheimer disease, macular degeneration, and stroke.

Of these, the most frequent complaint of the menopausal transition is vasomotor symptoms. Also known as hot flashes or hot flashes, their physiology is discussed in Chapter 21 (p. 474). Following menopause, hot flashes are still pervasive and are experienced by 50 to 85 percent of postmenopausal women. Significant distress results for approximately 25 percent of women. Sleep disturbances can lead to lethargy and depressed mood.

The frequency of hot flashes does decrease with time. In the PEPI trial, the percentage of women taking placebo who experienced vasomotor symptoms declined from 56 percent at their entry into the study to 30 percent by their third year in the trial

(Greendale, 1998). Freeman and coworkers (2014) found that moderate to severe hot flashes more than on average of women observed for 10 years or more after menopause have these. Fifteen years after menopause, approximately 3 percent of women report frequent hot flashes, and 12 percent report moderate to severe vasomotor symptoms (Barnabei, 2002; Hays, 2003).

Several treatment options are discussed subsequently, and three have FDA approval for this indication. These are systemic estrogen, one selective serotonin-reuptake inhibitor (SSRI), and the combined CEE plus bazedoxifene agent. When deciding among the available interventions for vasomotor symptoms, the safest options are encouraged first, such as lifestyle changes, but may proceed to prescription treatments, as needed. Patient preference, symptom severity, side effects, and the presence of other comorbid conditions will influence treatment options.

■ **Hormonal Therapy**  
**Estrogen**

Systemic ET is the most effective treatment for vasomotor symptoms, and the value of such treatment has been demonstrated in numerous RCTs (Nelson, 2004). MacLennan and associates (2004) performed a systematic review of 24 RCTs involving 3329 women who had moderate to severe hot flashes. These investigators found that HT reduced the frequency of hot flashes by approximately 18 events per week, that is, approximately 75 percent compared with placebo. The severity of vasomotor symptoms also was reduced significantly. Moreover, in the PEPI trial, all treatment arms were more effective than placebo in reducing vasomotor symptoms. There were no significant differences between specific hormone regimens (Greendale, 1998).

Estrogen can be administered by oral, parenteral, topical, or transdermal routes with similar effects (Table 22-2). Within these groups, several different formulation choices are available. Continuous estrogen therapy is recommended, although doses and route of administration can be changed relative to patient preference. In the United States, oral estrogens are the most popular. Transdermal estrogen patches avoid the liver’s first-pass effect and offer the convenience of less frequent administration (once or twice weekly). The lowest effective dose and duration of therapy are unknown, but this “mantra” is cited by most major menopause organizations for ensuring safety. For treatment of vasomotor symptoms, the FDA has approved all oral estrogen formulations, most transdermal patch formulations, a topical gel, and one intravaginal estrogen product. All systemic HT products except for the ultra-low-dose estradiol transdermal patch (Menostar) have FDA approval for this indication (North American Menopause Society, 2012).

**Progestins**

These alone are somewhat effective for daily treatment of hot flashes in women for whom estrogen is contraindicated. However, adverse effects that include vaginal bleeding and weight gain may limit their use. Beyond mild reduction in number of hot flashes, progestins used as agents in combined HT offer only one additional benefit. Namely, they provide essential protection against estrogen-induced endometrial hyperplasia and endometrial cancer

**TABLE 22-2.** Selected Hormonal Preparations for the Treatment of Menopausal Vasomotor Symptoms

Preparation	Generic Name	Brand Name	Available Strengths
<b>Estrogen</b>			
Oral <sup>a</sup>	CEE	Premarin	0.3, 0.45, 0.625, 0.9, or 1.25 mg
	17β-Estradiol	Estrace <sup>b</sup>	0.5, 1.0, or 2.0 mg
	Estradiol acetate	Femtrace	0.45, 0.9, or 1.8 mg
	10 synthetic estrogens	Enjuvia	0.3, 0.45, 0.625, 0.9, or 1.25 mg
Transdermal Patch	17β-Estradiol	Alora <sup>b</sup>	0.025, 0.05, 0.075, or 0.1 mg/d (patch applied twice weekly to abdomen or buttock; 8 patches/box)
	17β-Estradiol	Climara <sup>b</sup>	0.025, 0.0375, 0.05, 0.06 0.075, or 0.1 mg/d (patch applied to abdomen or buttock weekly; 4 patches/box)
	17β-Estradiol	Menostar <sup>b</sup>	14 μg/d (patch applied to abdomen weekly; 4 patches/box)
	17β-Estradiol	Vivelle-dot <sup>b</sup>	0.025, 0.0375, 0.05, or 0.075, 0.1 mg/d (patch applied twice weekly to abdomen; 8 patches/box)
Transdermal Gel	17β-Estradiol	Estroge <sup>b</sup>	1 metered dose of gel applied daily to arm (64 doses per 93-g can)
	17β-Estradiol	Estrasorb <sup>b</sup>	Gel from 2 packets applied to legs daily (56 packets/carton)
	17β-Estradiol	Divigel <sup>b</sup>	0.25, 0.5, or 1 mg packets Gel from 1 packet applied to thigh daily (30 packets/carton)
	17β-Estradiol	Elestrin <sup>b</sup>	1 metered-dose of gel applied to arm daily (30 doses per 35-g container)
	17β-Estradiol	Evamist <sup>b</sup>	1 to 3 metered-dose sprays to forearm daily (56 doses per pump)
Vaginal	Estradiol acetate	Femring	0.05 or 0.1 mg/d (inserted for 90 days)
<b>progestin</b>			
Oral <sup>a</sup>	MPA	Provera	2.5, 5.0, or 10.0 mg
Vaginal	Micronized progesterone	Prometrium <sup>b</sup>	200 mg (in peanut oil) (1 daily for 12 days each 28-d cycle)
	Progesterone	Prochieve 4% <sup>b</sup>	45 mg
<b>Combination preparations</b>			
Oral sequential <sup>a</sup>	CEE + MPA	Premphase	0.625 mg CEE (red) plus 0.625 mg CEE/5.0 mg MPA (blue) (28 pills per pack; 14 red & 14 blue) <sup>c</sup>
Oral continuous <sup>a</sup>	CEE+ MPA	Prempro	0.3 mg CEE/1.5 mg MPA, or 0.45 mg CEE/1.5 mg MPA, or 0.625 mg CEE/2.5 mg MPA, or 0.625 mg CEE/5 mg MPA (28 pills per pack)
	17β-Estradiol + drospirenone	Angeliq	1 mg E <sub>2</sub> /0.5 mg drospirenone (28 pills per pack)
	17β-Estradiol + NETA	Activella	1 mg E <sub>2</sub> /0.5 mg NETA, or 0.5 mg E <sub>2</sub> /0.1 mg NETA (28 pills per dial pack)
Transdermal continuous	Ethinyl estradiol + NETA	femhrt	2.5 μg EE/0.5 mg NETA, or 5 μg EE/1 mg NETA
	17β-Estradiol + LNG	Climara Pro	0.045 mg/d E <sub>2</sub> + 0.015 mg/d LNG (patch applied weekly)
	17β-Estradiol + NETA	CombiPatch	0.05 mg/d E <sub>2</sub> + 0.14 mg/d NETA, or 0.05 mg/d E <sub>2</sub> /0.25 mg/d NETA (patch applied twice weekly to abdomen)
TSEC <sup>a</sup>	CEE + BZA	Duavee	0.45 mg/d CEE+ 20 mg BZA

<sup>a</sup>One pill daily.  
<sup>b</sup>Considered a bioidentical preparation.  
<sup>c</sup>The first 14 pills contain estrogen and the subsequent pills (15 through 28) contain estrogen with progestin.  
BZA = bazedoxifene; CEE = conjugated equine estrogen; LNG = levonorgestrel; MPA = medroxyprogesterone acetate; NETA = norethindrone acetate; TSEC = tissue selective estrogen complex.

in women with a uterus. Clinical trials have shown that progestins provide no meaningful increase in estrogen’s benefits to bone. Moreover, progestins may attenuate estrogen’s beneficial effects on lipids and blood flow and increase the risk for breast cancer.

Bazedoxifene

T is SERM combined with CEE was FDA-approved in 2014 for the management of menopausal vasomotor symptoms in women with an intact uterus (Lobo, 2009). As with other SERMs, bazedoxifene (BZA) acts as an estrogen agonist or antagonist, depending on the tissue affected. T is combination is called a *tissue-selective estrogen complex (TSEC)*, and its advantage is to combine the benefits of CEE with the SERM’s ability to offset estrogen stimulation of the endometrium and breast. T us, a progestin is not required. By itself, BZA reduces BMD loss, increases the number of hot flushes, and raises VTE risks. T e combination of BZA 20 mg plus CEE 0.45 mg reduces BMD loss and incidence of hot flushes but does not increase VTE rates compared with CEE and MPA. Notably, BZA acts as an antagonist in uterine tissue to prevent the endometrial hyperplasia commonly associated with unopposed estrogen (Pinkerton, 2014).

In the randomized Selective estrogens, Menopause, and Response to T erapy (SMART-2) trial, BZA plus CEE reduced hot flush frequency by 74 percent at week 12 compared with a 51-percent reduction from placebo (Pinkerton, 2009). A secondary efficacy analysis of SMART-2 data assessed sleep parameters and health-related quality of life in 318 women experiencing > 7 moderate to severe hot flushes daily. Time to fall asleep, sleep disturbance, and sleep adequacy were improved with BZA plus CEE compared with placebo. T is dose also significantly improved the vasomotor function score and the Menopause-Specific Quality of Life (MENQOL) questionnaire score compared with placebo (Utian, 2009). Overall the BZA plus CEE combined agent is well tolerated and effective in treated hot flushes, but its effectiveness relative to HT remains uncertain.

Bioidentical Hormones

Some women believe that conventional FDA-regulated pharmaceutical estrogens and progestins hold a clear and present danger. Ironically, more is known about the absolute risks and benefits of HT than almost any other class of drugs. Although prescriptions for estrogen and progesterone have declined significantly since publication of the WHI results, the use of “bioidentical hormones” has increased. T is term invented by marketers is often used to describe custom-compounded HT products but has no clear scientific meaning (Shifren, 2014). T e term now usually refers to compounds that have the same chemical and molecular structure as hormones that are produced in the body.

Custom compounding of HT may combine several hormones (e.g., estradiol, estrone, and estriol) and use nonstandard routes of administration (e.g., subdermal implants). Some of the hormones are not FDA approved (estriol) or monitored, and some compounded therapies contain nonhormonal ingredients (e.g., dyes, preservatives) that some women cannot tolerate. Moreover, custom-compounded formulations have not been tested for efficacy or safety; product information is not

consistently provided to women along with their prescription, as is required with commercially available HT; and batch standardization and purity may be uncertain. T us, these hormones cannot be assumed to be safer than conventional pharmaceutical estrogen or progestins. Several organizations note that conventional FDA-approved HT products are preferred to custom-compounded formulations (American College of Obstetricians and Gynecologists, 2014a; North American Menopause Society, 2012). In conjunction with bioidentical hormones, salivary hormone testing to assist with hormone level adjustment is inaccurate and unreliable (Lewis, 2002; Zava, 1998).

■ Central Nervous System Agents

Several nonhormonal therapies are available to treat vasomotor symptoms (Table 22-3). Alternatively, women who are principally bothered by night sweats and sleep disruption may benefit from a trial of sleep medication, and options are listed in Table 1-16 (p. 18). Of vasomotor symptom therapies, SSRIs, selective norepinephrine-reuptake inhibitors (SNRIs), clonidine, and gabapentin have demonstrated benefits compared with placebo (American College of Obstetricians and Gynecologists, 2014b). Of these, only the SSRI paroxetine mesylate (Brisdelle) is FDA-approved for vasomotor symptom treatment.

For many, the side effects or relative ineffectiveness of these agents compared with estrogen therapy can limit their routine use for this indication. Moreover, long-term studies with any of these agents for vasomotor symptom treatment are not available.

Serotonin and Norepinephrine

As noted in Chapter 21 (p. 474), both serotonin and norepinephrine are implicated in modulation of the thermoregulatory setpoint, which is integral to hot flushes. Accordingly, SSRIs have been studied, and in two RCTs, the low-dose mesylate salt of paroxetine (LDMP) was given to postmenopausal women experiencing daily, moderate to severe hot flushes. One study lasted 12 weeks, and the other 24 weeks (Simon, 2013). In

TABLE 22-3. Nonhormonal Agents Used for Vasomotor Symptoms

Prescription (brand name)	Dose <sup>a</sup>
SSRI	
Paroxetine mesylate (Brisdelle)	7.5 mg
Paroxetine (Paxil)	20 mg
Venlafaxine (Effexor XR)	75 mg
Citalopram (Celexa)	20 mg
Escitalopram (Lexapro)	10–20 mg
Sertraline (Zoloft)	50 mg
Fluoxetine (Prozac, Sarafem)	20 mg
SNRI: Desvenlafaxine (Pristiq)	100 mg
Clonidine (Catapres)	0.1 mg
Gabapentin (Neurontin)	600–900 mg

<sup>a</sup>Oral daily dosing.  
SNRI = selective norepinephrine- reuptake inhibitor;  
SSRI = selective serotonin-reuptake inhibitor.

both trials, LDMP reduced the weekly *frequency* of hot flushes compared with placebo, but persistent declines in hot flush *severity* were less consistent (Carris, 2014). Following initiation, frequency reduction begins as early as 1 week after therapy, and for severity reduction, as early as 2 weeks.

Other SSRIs have also been studied. With venlafaxine extended release (Effexor XR), Evans and coworkers (2005) noted 51-percent fewer hot flushes compared with placebo. Several other trials have compared this same SSRI with gabapentin or with clonidine in breast cancer survivors with hot flushes and also showed symptom benefit from the SSRI (Boekhout, 2011; Bordeleau, 2010; Loprinzi, 2000). Joffe and associates (2014) compared venlafaxine and low-dose estrogen and noted that estradiol reduced hot flushes by 2.3 events daily compared with 1.8 for the SSRI. Both outperformed placebo.

With paroxetine (Paxil) modest improvement in hot flushes are seen compared with placebo. In one RCT, a 20-mg dose lowered hot flush frequency by 51 percent. Stearns and coworkers (2003) evaluated paroxetine CR, 12.5 mg/d and 25 mg/d dosages, compared with placebo. At both dosages, paroxetine led to approximately three fewer hot flushes per day compared with 1.8 fewer per day with placebo.

With citalopram (Celexa), mean hot flush scores were lowered by 37 to 50 percent (Barton, 2010; Kalay, 2007). With escitalopram (Lexapro), two RCTs noted significant improvement compared with placebo (Carpenter, 2012; Freeman, 2011). Of the SSRIs, fluoxetine (Prozac, Sarafem) and sertraline (Zoloft) appear to be less effective (Gordon, 2006; Grady, 2007; Loprinzi, 2002; Suvanto-Luukkonen, 2005).

Of the SNRIs, desvenlafaxine (Pristiq) significantly reduces the number of hot flushes by approximately 60 percent and their severity by 25 percent compared with placebo (Archer, 2009a,b; Speroff, 2008). A 1-year study noted that these improvements persisted (Pinkerton, 2013).

Importantly, benefits of SSRIs are balanced against drug side effects, which can include nausea, headache, diarrhea, insomnia, jitteriness, fatigue, and sexual dysfunction. With the SNRIs, hypertension may also be aggravated (Handley, 2015).

### Clonidine

The centrally active  $\alpha_2$ -adrenergic receptor agonist clonidine (Catapres) has been effective in some clinical trials (Nagamani, 1987). Many of these RCTs specifically evaluated benefits for breast cancer survivors and showed improvement in vasomotor symptoms (Boekhout, 2011; Buijs, 2009; Loibl, 2007). Notably, hypotension, dry mouth, dizziness, constipation, and sedation may limit its use. For many women, low-dose clonidine is ineffective, and thus adequate therapy may require substantially higher doses that may magnify side effects.

### Gabapentin

Gabapentin (Neurontin) is structurally related to the neurotransmitter  $\gamma$ -aminobutyric acid (GABA), but its exact mechanism of action is unknown. Currently, gabapentin is FDA-approved to treat seizures and neuropathic pain. However, it has extensive off-label use for various other neurologic conditions.

In 2003, Guttuso and colleagues evaluated the use of gabapentin, 900 mg daily, for treatment of vasomotor symptoms.

They found a 45-percent reduction in hot flush frequency compared with a 29-percent reduction with placebo. Moreover, Reddy and coworkers (2006) conducted an RCT in which 60 postmenopausal women received gabapentin, 2400 mg/d; oral CEE, 0.625 mg/d; or placebo for 12 weeks. The reductions in the hot flush composite scores for both estrogen (72 percent) and gabapentin (71 percent) were greater than that associated with placebo (54 percent). However, headache, dizziness, and disorientation occurred in almost 25 percent of the women treated with gabapentin.

## ■ Complementary and Alternative Medicine

### Phytoestrogens

Phytoestrogens (isoflavones) are plant-derived compounds that bind to estrogen receptors and have both estrogen agonist and antagonist properties. They are found in soy products and red clover. In sum and outlined subsequently, data supporting their effectiveness for vasomotor symptom treatment show no conclusive efficacy (Lethaby, 2013).

With soy products, although the mechanisms of action are not fully understood, they appear to bind to the estrogen receptor. For this reason, one should not assume these dietary supplements are safe for women with estrogen-dependent cancers. That said, sonographic surveillance has not shown increased endometrial thickness or altered lipid profiles in women taking isoflavones (Palacios, 2010; Quaas, 2013; Ye, 2012). For treatment of hot flushes, data supporting isoflavone efficacy are mixed (Albertazzi, 1998; Cheng, 2007; Liu, 2014; Quella, 2000). Moreover, the effects of soy protein found in various food preparations are not bioequivalent. Even soy foods are not necessarily reliable sources of biologically active isoflavones.

Flaxseed or faxseed oil (*Linum usitatissimum*) is rich in  $\alpha$ -linolenic acid, a form of omega-3 fatty acid. Also known as linseed, faxseed is touted to reduce vasomotor symptoms. However, data regarding its efficacy for this indication are contradictory (Lemay, 2002; Lewis, 2006; Pruthi, 2012).

Red clover (*Trifolium pretense*) is a member of the legume family. It contains at least four estrogenic isoflavones and is therefore marketed as a phytoestrogen source. Several studies and analyses, however, have failed to demonstrate an effect over placebo in the treatment of menopausal symptoms (Geller, 2009; Nelson, 2006; Tice, 2003).

Dong quai, also translated as don kwai, dang gui, and tang kuei, is a Chinese herbal medicine derived from the root of *Angelica sinensis* and is the most commonly prescribed Chinese herbal medicine for “female problems.” Within traditional Chinese medicine practice, dong quai is suggested to exert estrogenic activity. In most studies, however, its benefit cannot be substantiated (Haines, 2008; Hirata, 1997). Notably, dong quai contains numerous coumarin-like derivatives and may cause excessive bleeding or interactions with other anticoagulants. This herbal agent also contains psoralens and is potentially photosensitizing.

Black cohosh (*Cimifuga racemosa*) is also thought to have estrogenic properties, although its mechanism of action is unknown. In their Cochrane Review, Leach and Moore (2012) found insufficient evidence to support its use for vasomotor

symptom relief. Although few adverse effects have been reported, the long-term safety of this product is unknown.

### Phytoprogestins

Extracts, tablets, and creams derived from yams are claimed to be progesterone substitutes. Specifically, claims are made that the plant sterol dioscorea is converted into progesterone in the body and alleviates “estrogen dominance.” However, there is no human biochemical pathway for bioconversion of dioscorea to progesterone *in vivo*.

In contrast, Mexican yam extract contains considerable diosgenin, an estrogen-like substance found in plants. Some estrogen effects might be expected from eating these yam species, but only if large quantities of raw yams are consumed. Yams from the grocery store generally are not the varieties known to contain significant amounts of dioscorea or diosgenin.

Based on the lack of bioavailability, the hormones in wild and Mexican yam would not be expected to have efficacy. Wild yam extracts are neither estrogenic nor progestational, and although many yam extract products contain no yam, some are laced with progestins. There are no published reports demonstrating the effectiveness of wild yam cream for postmenopausal symptoms. Moreover, oral ingestion does not produce serum levels.

### Vitamin E

In a few studies in breast cancer survivors, vitamin E provided minimal or no vasomotor symptom improvement (Biglia, 2009; Rada, 2010).

### Lifestyle Changes

Practices that lower core body temperature such as cooling the room, dressing in layers, and consuming cool drinks may temporarily help with night sweats and flushing (American College of Obstetricians and Gynecologists, 2014b). However, behavioral efforts to curb the frequency of hot flashes have no firm support in RCTs. For example, little evidence demonstrates

the efficacy of relaxation techniques, acupuncture, exercise, and yoga to control vasomotor complaints (Daley, 2014; Dodin, 2013; Newton, 2014; Saensak, 2014).

## TREATMENT OF OSTEOPOROSIS

### ■ Indications

The primary goal of osteoporosis treatment is fracture prevention in women who have low BMD or additional risk factors for fracture (Fig. 22-1). Toward this end, therapy aims to stabilize or increase BMD. Treatment includes lifestyle changes and often pharmacologic therapy. The key lifestyle modifications that can decrease fracture risks of in postmenopausal women include regular weight-bearing exercise and a balanced diet with adequate calcium and vitamin D. Factors for patients to avoid include smoking, an excessively low body weight, excessive alcohol intake, and fall risks at home (Christiansen, 2013).

With pharmacologic therapy, several organizations offer guidelines. The National Osteoporosis Foundation (NOF) (2014), American Association of Clinical Endocrinologists (AACE) (Watts, 2010), and North American Menopause Society (NAMS) (2010) recommend starting therapy for: (1) all postmenopausal women with total hip, femoral neck, or spine T-scores at or below  $-2.5$ ; (2) for those with an osteoporotic vertebral or hip fracture; and (3) all postmenopausal women with total hip or spine T-scores from  $-1.0$  to  $-2.5$  who have one or more additional risk factors for fracture, such as those in Table 21-8 (p. 480).

Drugs prescribed for fracture prevention attempt to restore and balance bone remodeling by: (1) reducing bone resorption, termed *antiresorptive agents*, or (2) stimulating bone formation, termed *anabolic agents*. Most of the bone-active agents currently available in the United States inhibit bone resorption. Estrogen, SERMs, bisphosphonates, denosumab, calcitonin, and vitamin D each have antiresorptive properties

**FIGURE 22-1** Electron micrographs of tissue obtained from iliac crest biopsy. Normal bone architecture in an individual with normal bone mineral density (left). Diminished bone architecture is seen in the biopsy from an individual with osteoporosis (right) (Reproduced with permission from Dempster DW, Shane E, Horbert W, et al: A simple method for correlative light and scanning electron microscopy of human iliac crest bone biopsies: qualitative observations in normal and osteoporotic subjects, *J Bone Miner Res* 1986 Feb;1(1):15–21.)

**TABLE 22-4.** Agents Approved in the United States for the Management of Osteoporosis<sup>a</sup>

Agent	Brand Name	Clinical Indication	
		Prevention	Treatment
<b>Bisphosphonates</b>			
Alendronate	Fosamax	5 mg pill once daily 35 mg pill once wkly	10 mg pill once daily 70 mg pill or solution once weekly
	Binosto	—	70 mg solution once weekly
Ibandronate	Boniva	2.5 mg pill once daily 150 mg pill once monthly	2.5 mg pill once daily 150 mg pill once monthly
Risedronate	Actonel	5 mg pill once daily 35 mg pill once wkly	5 mg pill once daily 35 mg pill once weekly 150 mg pill once monthly 75 mg pill on two consecutive days as a monthly dose
Risedronate (enteric coated)	Atelvia	—	35 mg pill once weekly
Zoledronate	Reclast	5 mg IV every 2 years	5 mg IV yearly
<b>Hormones</b>			
CEE	Premarin	0.3 mg pill daily	
Other estrogens	See Table 22-2		
<b>Monoclonal antibody</b>			
Denosumab	Prolia	—	60 mg SC once every 6 months
<b>Recombinant human parathyroid hormone</b>			
Teriparatide	Forteo	—	20 µg SC daily. 1 injection pen contains 28 doses
<b>Salmon calcitonin</b>			
Nasal spray	Fortical	—	1 spray = 200 IU intranasally daily (alternating nostrils daily). 1 bottle contains a 30-day supply
	Miacalcin	—	1 spray = 200 IU intranasally daily (alternating nostrils daily). 1 bottle contains a 30-day supply
Injectable	Miacalcin	—	100 units SC or IM every other day. 1 vial contains 4 doses
<b>SERM</b>			
Raloxifene	Evista	60 mg once daily	60 mg once daily
<b>TSEC</b>			
CEE/BZA	Duavee	0.45 mg/20 mg pill once daily	

<sup>a</sup>Oral agent unless route indicated.  
BZA = bazedoxifene; CEE = conjugated equine estrogen; IM = intramuscular injection; IU = international units; IV = intravenous; SC = subcutaneous injection; SERM = selective estrogen-receptor modulator; TSEC = tissue-selective estrogen complex.

(Table 22-4). All have been shown to halt bone loss, and most also increase BMD. Improvement in BMD with therapeutic intervention varies according to bone composition. Therapies that prevent bone resorption will act most quickly on bone that has high trabecular content and rapid turnover, such as the vertebrae. Alternatively, the impact of drug therapies on the hip may be delayed because the hip is composed of approximately

50 percent trabecular and 50 percent cortical bone (Fig. 21-5, p. 476). In contrast to these antiresorptive agents, recombinant parathyroid hormone (PTH 1–34), known as teriparatide, is anabolic and leads to BMD increases.

For osteoporosis, each agent differs in its indication for prevention, for treatment, or both. HT is indicated for the prevention of osteoporosis. Bisphosphonates and SERMs can be used

for prevention and for treatment. Calcitonin and teriparatide are approved for treatment. Denosumab is a monoclonal antibody to the receptor activator of nuclear factor (RANK) ligand and is approved for osteoporosis treatment.

## ■ Hormonal Therapy

### Estrogen and Progesterone Replacement

As estrogen levels decline, bone-remodeling rates increase and favor bone resorption over bone formation. In observational studies, HT reduces osteoporosis-related fractures by approximately 50 percent when started soon after menopause. Continued long term, HT significantly decreases fracture rates in women with established disease (Tosteson, 2008). Results from 57 randomized, placebo-controlled trials show that HT reduces the rate of bone resorption and results in an increase in BMD (Wells, 2002). The WHI controlled trials confirmed a significant 33-percent reduction in hip fractures in healthy postmenopausal women receiving HT after an average follow-up of 5.6 years. Notably, hip fracture reduction was not limited to women with osteoporosis, as in trials of other pharmacologic agents (The Women's Health Initiative Steering Committee, 2004). Even very low estrogen doses combined with calcium and vitamin D produce significant increases in BMD compared with placebo (Ettinger, 2004; Prestwood, 2003). Specifically, oral daily 0.2-mg doses of estradiol; 0.3-mg doses of CEE; or transdermal estradiol patch delivering 0.014 mg/d are suitable.

Unfortunately, this preventive effect is lost rapidly following HT discontinuation (Barrett-Connor, 2003). Women participating in the National Osteoporosis Risk Assessment (NORA) trial who had discontinued estrogen therapy within the 5 years preceding the study demonstrated a significantly higher hip fracture risk than did women who had never received estrogen therapy. In addition, current HT users in the NORA trial had a 40-percent reduction in hip fractures, which was lost by past users. Thus, fracture risk and the potential need for an alternative therapy is ideally assessed when women discontinue HT.

### Bazedoxifene

The drug that combines CEE with the SERM bazedoxifene is indicated to alleviate vasomotor symptoms and prevent postmenopausal bone loss. In the randomized SMART trials noted earlier (p. 497), investigators found a significantly increased adjusted mean percentage BMD change in the lumbar spine from baseline to 24 months in those taking BZA plus CEE compared with women using placebo (Lindsay, 2009). Findings were similar for total hip BMD. Moreover, the FDA-approved dose of CEE (0.45 mg) plus BZA (20 mg) does not cause a change in breast density or endometrial thickness compared with placebo (Pinkerton, 2014).

### Raloxifene

This SERM is approved for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer. It activates estrogen receptors in the bone but does not appear to activate those in the breast or uterus.

Of bone loss sites, raloxifene may be most appropriate for prevention and treatment of vertebral disease. For example,

raloxifene prevented vertebral fractures in the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, which enrolled 7705 postmenopausal women with osteoporosis. The beneficial effects of oral raloxifene, 60 mg/d, appeared rapidly, and clinical vertebral fracture risk was reduced by 68 percent following the first year of therapy. In addition, this effect was sustained over time. At 4 years of treatment, dosages of 60 mg daily led to a 36-percent reduction in fractures, and 120 mg each day produced a 43-percent decline (Delmas, 2002; Ettinger, 1999). However, in the MORE trial, Ettinger and associates (1999) reported that raloxifene therapy compared with placebo was not associated with significant reductions in nonvertebral fracture risks at 3 and 4 years. A more recent retrospective cohort study showed that patients treated with alendronate and raloxifene had similar adjusted fracture rates in up to 8 years of compliant treatment (Foster, 2013).

In 2012, Chung and colleagues showed that raloxifene, but not bisphosphonates, significantly suppressed circulating concentration of sclerostin, an inhibitor of bone formation, suggesting that sclerostin may in part mediate the action of estrogen on bone metabolism.

In addition to its bone effects, raloxifene may protect against breast cancer, as suggested by observational studies of various clinical trials (Barrett-Connor, 2006). The incidence of breast cancer was evaluated as a secondary end point in the MORE trial. Investigators found that raloxifene was associated with a 65-percent relative risk reduction in all breast cancers. Of specific breast cancer subtypes, they noted a 90-percent reduction in estrogen receptor–positive cancers, a 12-percent reduction in estrogen receptor–negative breast cancers, and a 76-percent relative risk reduction in invasive breast cancer.

Raloxifene may not have the same increased cardiovascular risk profile as estrogen. In a MORE post hoc analysis, 4 years of raloxifene therapy had no adverse effect on cardiovascular events in the overall cohort. Advantageously, it did result in a significant 40-percent reduction in the incidence of cardiovascular events among a subgroup of women with increased cardiovascular risk (Barrett-Connor, 2002).

Of side effects, hot flashes are associated with raloxifene therapy, although the incidence is low (Cohen, 2000). In addition, raloxifene, 60 mg daily for 4 years, has been associated with an increased risk of thromboembolic events. In one study, the relative risk associated with any dosage of raloxifene was 2.76 for deep-vein thrombosis, 2.76 for pulmonary embolism, and 0.50 for retinal vein thrombosis (Delmas, 2002). It is therefore contraindicated in patients with a history of VTE and is used with caution in women with hepatic or moderate to severe renal impairment.

## ■ Nonhormonal Antiresorptive Agents

### Bisphosphonates

Four bisphosphonates are currently available and include alendronate (Fosamax, Binosto), risedronate (Actonel, Atelvia), ibandronate (Boniva), and zoledronate (Reclast). The first three are taken orally, but zoledronate is an intravenous infusion. These agents chemically bind to calcium hydroxyapatite in bone (Figs. 22-2 and 22-3). They decrease bone resorption

**FIGURE 22-2** The molecular structure of bisphosphonates, with two short side chains ( $\text{R}_1$  and  $\text{R}_2$ ) attached to the C core, is similar to that of the naturally occurring pyrophosphates. Variations in side-chain structure determine the strength with which the bisphosphonate binds to bone, the distribution throughout bone, and the amount of time it remains in the bone after treatment is discontinued.

by blocking the function and survival but not the formation of osteoclasts (Diab, 2012; Russell, 2008).

The oral bisphosphonates display poor bioavailability and therefore are taken on an empty stomach with adequate water for proper dissolution and absorption. In general, these agents have a favorable overall safety profile, and adverse event rates are comparable with placebo (Black, 1996; Harris, 1999). However, bisphosphonates may cause upper gastrointestinal inflammation, ulceration, and bleeding (Lanza, 2000). Thus, to aid delivery to the stomach and reduce the risk of esophageal irritation, dosing instructions are reinforced with each patient.

**FIGURE 22-3** Bisphosphonates reduce fractures by suppressing bone resorption by osteoclasts. The molecular structure of the bisphosphonates is analogous to that of the naturally occurring pyrophosphates. **A.** Bisphosphonate concentration is increased eightfold at sites of active bone resorption. **B.** The bisphosphonates enter osteoclasts and reduce resorption through inhibition of farnesyl pyrophosphate synthase. Inhibition of this enzyme leads to disruption of osteoclast attachment to the bone surface. This halts resorption and promotes early osteoclast cell death.

First, bisphosphonates are taken in the morning with a full glass of water. During the 30 minutes following administration, no other food or beverages are consumed. Finally, women must remain upright (sitting or standing) for at least 30 minutes after ingesting the drug.

In terms of long-term safety, concerns about two uncommon adverse events have emerged: osteonecrosis of the jaw (ONJ) and atypical femur fractures (AFFs) (Diab, 2013). ONJ is defined as exposed necrotic bone in the maxillofacial region that fails to heal after 8 weeks. It can be associated with pain, paresthesia, soft tissue ulceration and swelling, and loosening of teeth. It can develop spontaneously but is generally associated with invasive dental procedures. ONJ has been described in patients receiving chronic bisphosphonate therapy for osteoporosis treatment but appears to be much more common in cancer patients receiving higher-dose bisphosphonates (Khosia, 2007).

AFFs are stress fractures that are frequently bilateral, are typically associated with minimal or no trauma, and are heralded by prodromal pain in the fracture region (Dell, 2012). One case-controlled study found that longer bisphosphonate use (5 to 9 years) was associated with a greater risk of AFFs compared with shorter use (< 2 years) (Meier, 2012). One review showed that bisphosphonate exposure was associated with an increased risk of AFF and an adjusted risk ratio of 1.70 (Gedmintas, 2013). However, in this analysis, the large variation in relative risks reported in the different studies suggests significant heterogeneity in the patient populations.

No causal relationship has been established between prolonged bisphosphonate exposure and either of these outcomes. Even though the risks of ONJ and AFF may increase after 5 years of bisphosphonate therapy, the likelihood remains low. The FDA suggests reevaluating individually the need for continuing bisphosphonate therapy beyond 3 to 5 years (Whitaker, 2012). A “drug holiday” may be considered because of the unique pharmacokinetics of bisphosphonate. These agents accumulate in the skeleton to create a reservoir that continues to be released for months or years after treatment. Although this provides some residual benefit in terms of fracture reduction after an initial 3- to 5-year course of therapy, continuing treatment for 10 years seems to be a better choice for high-risk patients. If a drug holiday is advised, risk is reevaluated sooner for drugs with lower skeletal affinity. Thus, reassessment may be prudent after 1 year for risedronate, 1 to 2 years for alendronate, and 2 to 3 years for zoledronate (Diab, 2014).

**Alendronate.** This bisphosphonate is approved for the treatment and prevention of osteoporosis. Alendronate has been shown to reduce the risk of vertebral fractures in postmenopausal women with low BMD or osteoporosis, either with or without existing vertebral fractures (Black, 1996). Alendronate also reduces nonvertebral fracture risk in women with osteoporosis. Among women with osteoporosis who participated in the Fracture Intervention Trial (FIT), the risk of nonvertebral fractures was reduced by month 24. In addition, the effects of alendronate are sustained. For example, women who used alendronate for 5 years and then discontinued use for a subsequent 5 years had nonvertebral fracture rates comparable to those of women using the drug for 10 years (Black, 2006; Bone, 2004).

**Risedronate.** This bisphosphonate is an effective agent in the prevention and treatment of postmenopausal osteoporosis. The strongest data supporting its efficacy stem from the Vertebral Efficacy with Risedronate Therapy (VERT) trials, conducted multinationally and also in North America. In the VERT multinational trial, Reginster and coworkers (2000) showed that risedronate reduced the risk of new vertebral fractures by 61 percent at 1 year and by 49 percent at 3 years of use. Moreover, both VERT trials found significant reductions in vertebral fractures as early as 6 months after initiation of risedronate therapy (Roux, 2004). Two extensions of these trials have provided evidence of sustained efficacy. The continuation of risedronate therapy for 2 additional years (5 years total) in the multinational VERT study was associated with a 59-percent reduction in new vertebral fractures compared with placebo.

**Ibandronate.** This bisphosphonate is approved for the prevention and treatment of postmenopausal osteoporosis. Ibandronate is an effective agent, and data from the Oral Ibandronate Osteoporosis Vertebral Fracture Trial in North America and Europe (BONE) trial showed that daily ibandronate lowered incident vertebral fracture risk by 62 percent (Chesnut, 2004). To improve compliance, this drug was evaluated as a once-monthly therapy. Once-monthly oral ibandronate is at least as effective and well tolerated as daily treatment (Miller, 2005; Reginster, 2006). Moreover, once-monthly administration may be more convenient and thereby improve compliance rates.

**Zoledronate.** This bisphosphonate is approved for the prevention and treatment of postmenopausal osteoporosis. Zoledronate is effective, and data from the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly (HORIZON) Pivotal Fracture Trial showed that yearly zoledronate infusion lowered incident vertebral fracture risk by 70 percent compared with placebo (Black, 2007).

### Denosumab

This is a fully human monoclonal antibody to RANK ligand, which is described and illustrated in Chapter 21 (p. 476). To summarize, denosumab's binding to RANK ligand inhibits osteoclast development and activity. This in turn decreases bone resorption and increases BMD. In a manufacturer-sponsored trial, 7868 women randomly received either denosumab or placebo subcutaneously every 6 months for 3 years (Cummings, 2009). Relative risk for new radiographically diagnosed vertebral fractures was 68-percent lower in the denosumab group. The risk for hip fractures was 40-percent lower in the denosumab group. Overall incidence of significant adverse events was similar between groups.

### Calcitonin

The polypeptide hormone calcitonin decreases the rate of bone absorption by inhibiting resorptive activity in osteoclasts. Calcitonin is a protein, and as such, oral administration leads to its digestion. For this reason, it is delivered as an injection or nasal spray (Fortical, Miacalcin). Salmon calcitonin nasal spray has been associated with a reduction in vertebral fracture risk among postmenopausal women with osteoporosis. In

the Prevent Recurrence of Osteoporotic Fractures (PROOF) study, calcitonin nasal spray, 200 IU administered daily for up to 5 years reduced the risk of vertebral fractures by 33 percent compared with placebo. However, vertebral fracture reduction was not seen at lower (100 IU/d) or higher (400 IU/d) dosages (Chesnut, 2000). Moreover, in this study, calcitonin failed to produce significant reductions in nonvertebral fracture.

Some observational data suggest that calcitonin has an analgesic effect independent of its effect on bone (Häuselmann, 2003; Ofuoglu, 2007). This analgesic effect may make this agent particularly useful as an adjunct to other therapies for osteoporosis in women with painful, symptomatic fracture (Blau, 2003). Injectable or intranasal calcitonin is associated with an 8- to 10-percent incidence of nausea or gastric discomfort and a 10-percent incidence of local site reactions. These symptoms tend to decrease in severity with continued use. Nasal symptoms such as rhinitis occur in 3 percent of patients treated with intranasal calcitonin (Cranney, 2002).

### ■ parathyroid Hormone

Recombinant parathyroid hormone (PTH 1–34), known as teriparatide, is given by daily subcutaneous injection and is approved by the FDA for the treatment of postmenopausal women with established osteoporosis, who are at high risk for fracture. Teriparatide (Forteo) increases osteoblast numbers and activity by recruiting new cells and reducing apoptosis of differentiated osteoblasts. At low daily doses of teriparatide, the anabolic effects of PTH predominate. This is in contrast to the catabolic effects generally associated with long-term, higher-dose, and chronic exposure to PTH.

Clinical studies indicate that teriparatide increases bone quality by increasing bone density, turnover, and size (Rubin, 2002). Moreover, improvements in microarchitectural elements are evident in both cancellous and cortical regions. In women with postmenopausal osteoporosis, teriparatide, 20 or 40 µg/d, administered for approximately 21 months, was associated with 65-percent and 69-percent reductions in vertebral fractures, and 35-percent and 40-percent reductions in nonvertebral fractures, respectively (Neer, 2001).

Similar findings were reported in a study of 52 women treated with concomitant teriparatide and HT compared with HT alone (Lindsay, 1997). In this study, at the end of 3 years, increases in vertebral, total hip, and total body BMD were 13.4 percent, 4.4 percent, and 3.7 percent, respectively, in the combined treatment group. The addition of alendronate to teriparatide, however, does not appear to enhance effects on BMD (Gasser, 2000). The effects of combination use of PTH with other bisphosphonates are not known.

In general, PTH is safe and well tolerated, although additional data from long-term studies are needed. The most frequent treatment-related adverse events in clinical trials of teriparatide were dizziness, leg cramps, nausea, and headache. Toxicity studies with rats have shown an increased risk of osteosarcoma. However, there are significant differences in bone metabolism between rats and humans, and the applicability of rat data to humans is unclear. That said, a black box warning has been included on the product labeling in the United States,

and teriparatide use is avoided by patients at increased risk for skeletal malignancy. Use for more than 2 years is not recommended due to the potential for side effects (Tashjian, 2002).

In sum, denosumab seems to be as effective as teriparatide and zoledronate. Osteonecrosis of the jaw and fragility fractures associated with long-term bisphosphonate use are unlikely to be linked to short-acting agents such as denosumab. Because denosumab is an antibody, its potential to affect the immune system requires scrutiny. Long-term adherence to oral bisphosphonate therapy is often poor, making the relative ease of biannual injections attractive. Although teriparatide and intravenous bisphosphonates are expensive, weekly oral alendronate is available at low cost as a generic. Clinically, cost will likely play a central role in determining how these agents are selected.

## ■ Nonpharmacologic Therapy

### Calcium

Nonpharmacologic interventions are cornerstones of osteoporosis prevention and include dietary modifications, exercise programs, fall prevention strategies, and education. Of these, adequate daily calcium intake is essential for bone maintenance. For women aged 31 to 50 years, the recommended dietary reference intake (DRI) is 1000 mg daily, and for those 51 years and older, 1200 mg is recommended daily. Ideally, these DRIs are obtained through diet alone, but supplementation is used to attain these levels if needed (Institute of Medicine, 2010; Prentice, 2013). Few women meet these goals, and calcium deficiency is widespread. For example, more than 90 percent of women fail to take in enough dietary calcium to meet DRIs put forth by the Institute of Medicine. Although poor calcium intake is observed at all ages, it appears to be most common among older individuals. Specifically, fewer than 1 percent of women 71 years or older actually meet recommended goals.

Calcium supplementation combined with vitamin D administration has been associated with reduced bone loss and decreased risk for fractures in several prospective studies (Chapuy, 1992; Dawson-Hughes, 1997; Larsen, 2004). Prentice and associates (2013) examined the health benefits and risk of calcium and vitamin D supplementation using data from the WHI. This showed a substantial reduction in hip fracture risk. Notably, supplementation must be continued long term for efficacy to be sustained.

### Vitamin D

The DRI of vitamin D is 600 IU daily for a postmenopausal woman who is not at high risk for fractures or falls. For persons who have a high risk of osteoporosis or who are older than 70, 800 IU daily is recommended (Institute of Medicine, 2010). As with calcium, the prevalence of vitamin D deficiency is high, especially in the elderly. Deficiency leads to poor calcium absorption, secondary hyperparathyroidism, increased bone turnover, increased rates of bone loss, and, if severe, impaired bone mineralization. In addition, vitamin D deficiency causes muscle weakness and is associated with an increase in rates of falls. Vitamin D supplementation can reverse many of these effects and significantly reduce falls and hip fractures (Dawson-Hughes, 1997).

The metabolite 25-hydroxyvitamin D is considered to be the best clinical measure of vitamin D stores (Rosen, 2011). Vitamin D *deficiency* is defined as a 25-hydroxyvitamin D serum level below 10 ng/mL. Vitamin D *insufficiency* is a serum level of 25-hydroxyvitamin D between 10 and 30 ng/mL.

### Diet

A relationship between protein intake and BMD has been reported, but a relationship with fractures has not been described. Using data from the Third National Health and Nutrition Examination Survey (NHANES III), Kerstetter and colleagues (2000) demonstrated a significant association between protein intake and total femur BMD among non-Hispanic white women aged 50 years and older. Moreover, protein supplementation (20 g/d) five times weekly for 6 months following hip fracture was associated with a 50-percent reduction in femoral bone loss at 1 year compared with placebo.

Although no specific recommendations regarding protein intake can be made based on the limited data available, it seems prudent for clinicians to ensure that their patients eat healthy diets that provide the daily DRI of protein. As put forth by the Institute of Medicine, diets ideally contain at least 46 g/d for women (Dawson-Hughes, 2002). There may be upper limits for desirable protein intake as well. Excess urinary calcium excretion has been observed in association with the large acid loads delivered by very-high-protein diets (Barzel, 1998).

Caffeine consumption does not appear to influence bone health in postmenopausal women who maintain an adequate daily intake of calcium and vitamin D. However, one longitudinal study showed that even moderate amounts of caffeine (two to three servings of coffee daily) may lead to bone loss in women with low calcium intake (< 800 mg/d) (Harris, 1994).

Calcium reabsorption is directly proportional to sodium reabsorption in the renal tubule. Accordingly, increases in dietary sodium have been observed to cause increases in urinary calcium excretion and corresponding increases in biochemical markers of bone turnover. Specifically, a relationship between high sodium intake (> 1768 mg/d) and lower BMD has been described (Sellmeyer, 2002). This sodium effect appears to be independent of calcium intake and activity levels. As with caffeine, sodium intake moderation is a reasonable precautionary measure until this relationship is fully understood.

### Physical Preventions

Small but statistically significant increases in BMD have been observed in postmenopausal women participating in exercise programs, including aerobic exercise and resistance training (heavy weight with few repetitions). One metaanalysis of 43 RCTs concluded that lower limb resistance exercise was most effective for femur neck BMD, and combination exercise programs were most effective for vertebral BMD (Howe, 2011). Another analysis that focused on walking as exercise showed a benefit for femur neck BMD (Ma, 2013).

Although an increase in bone density may occur, especially at the sites at which the exercise is directed, benefits of exercise may likely also be due to factors other than greater BMD (Carter, 2002). For example, an association between exercise and reduced falls has been reported. Improvements in balance,

**TABLE 22-5.** Selected Preparations for Genitourinary Symptoms of Menopause<sup>a</sup>

Preparation	Generic Name	Brand Name	Dose
Vaginal cream	Conjugated estrogens	Premarin	0.625 mg per 1 g cream (0.5 g twice weekly or 0.5 g/d for 3 wks, with 1 wk off therapy. May titrate up to 2 g per application as needed) (available as 42.5 g tube)
	17β-Estradiol	Estrace	0.1 mg per 1 g cream (2–4 g/d for 1–2 wks, then 1–2 g/d for 1–2 wks, then 1–2 g 1 to 3 times weekly) (42.5 g tube)
Vaginal tablet	Estradiol	Vagifem	0.010 mg tablet (1 tablet/d for 2 wks, then 1 tablet twice weekly)
Vaginal ring	17β-Estradiol	Estring	2 mg, remains for 90 days
	Estradiol acetate	Femring	12.4-mg or 24.8-mg ring, remains for 90 days
Oral tablet	Ospemifene	Osphena	60 mg daily

<sup>a</sup>Most estrogen-containing products listed in Table 22-2 for the treatment of menopausal hot flashes are also approved for the treatment of vaginal dryness.

stronger muscles, better muscle tone, and stronger, more flexible bone all undoubtedly contribute to fracture reduction.

Falls are responsible for more than 90 percent of hip fractures (Carter, 2002). Sideways falls appear to be the most detrimental and were independently associated with hip fracture in a study by Greenspan and associates (1998). Therefore, fall prevention is essential for women with osteopenia or osteoporosis. Living conditions are modified to minimize falls by reducing clutter and implementing nonslip tiles, rugs with nonskid backing, and night lights.

Hip protector padding was also initially thought to reduce hip fractures in elderly adults. However, one Cochrane database analysis indicates that the effect of hip protectors to lower hip fracture risk is small, and compliance is low (Santesso, 2014). Falls and fractures often occur at night, when women are likely to have taken off their hip protectors. This may result from the bulkiness of hip protectors, which are uncomfortable to wear while sleeping (van Schoor, 2003).

**TREATMENT OF SEX-RELATED ISSUES**

**■ Dyspareunia**

**Estrogen Replacement**

Low estradiol levels commonly lead to the *genitourinary syndrome of menopause*. This syndrome may include but is not limited to: (1) genital symptoms of dryness, burning, and irritation; (2) sexual symptoms of lack of lubrication, discomfort or pain, and impaired function; and (3) urinary symptoms of urgency, dysuria and recurrent urinary tract infections (Portman, 2014). Data from the Yale Midlife Study showed a close relationship between serum estradiol levels and sexual problems. In this study, significantly more women with estradiol levels less than 50 pg/mL reported vaginal dryness, dyspareunia, and pain compared with women whose estradiol levels were greater than 50 pg/mL (Sarrel, 1998). Prospective records of coital behavior and concomitant steroid analysis revealed that women with estradiol levels less than 35 pg/mL reported significant reductions in coital activity.

Estrogen replacement effectively reverses atrophic changes. Vaginal atrophy and diminished vaginal mucosal elasticity, vaginal fluid secretion levels, blood flow, and sensorimotor responses are improved by either topical or systemic estrogen (Dennerstein, 2002). In one metaanalysis evaluating RCTs from 1969 to 1995, investigators found that compared with placebo, oral or vaginal estrogens significantly improved vaginal atrophy symptoms, dyspareunia, and vaginal pH (Cardozo, 1998). If oral and vaginal estrogens were compared, vaginal products had greater patient acceptance, lower systemic estradiol concentrations, yet significant improvement of dyspareunia and pH changes.

Of vaginal topical agents, available forms include creams, continuous-release rings, and tablets (Table 22-5). In comparing types during a 12-week study period, Ayton and colleagues (1996) found that a continuous low-dose estradiol-releasing vaginal ring (Estring) provided comparable relief to CEE vaginal cream used for 12 weeks. In addition, study patients found the vaginal ring significantly more acceptable than the cream. The ring is prescribed as a single unit. Each unit contains 2 mg of estradiol and is worn vaginally for 90 days and then replaced.

Alternatively, a 10-μg 17β-estradiol tablet (Vagifem) is available for vaginal application. One tablet is inserted daily for an initial 2 weeks of treatment and is followed by twice-weekly application. These tablets and CEE vaginal cream have been found to be equivalent in relieving symptoms of atrophic vaginitis (Rioux, 2000). Advantageously, women using vaginal tablets had less endometrial proliferation or hyperplasia than those using cream. Additionally, tablets were rated significantly more favorably than the cream, and their use was associated with fewer patient withdrawals from the study.

Studies of the vaginal tablets and ring have confirmed endometrial safety at 1 year, but studies of the long-term effects of low-dose vaginal ET on the endometrium are lacking. Women using vaginal ET should report any vaginal bleeding, and this bleeding should be evaluated thoroughly. Progestins typically are not prescribed to women using only low-dose vaginal estrogen products. If a woman is at high risk of endometrial cancer or is using a higher dose of vaginal ET, transvaginal ultrasound

or intermittent progestogen therapy may be considered (North American Menopause Society, 2013).

### Ospemifene

Marketed as Osphena, this SERM is taken orally daily in a 60-mg dose to treat moderate to severe dyspareunia from menopause-associated vulvar and vaginal atrophy. In one RCT with 826 women, ospemifene was significantly superior to placebo in improving the vaginal pH, the self-assessed severity of most bothersome symptoms, and the percentage of superficial vaginal epithelial cells (Bachmann, 2010). As noted in Chapter 21 (p. 489), superficial cells are increased relative to parabasal cells in estrogen-sufficient vaginal epithelia. Ospemifene was shown to be safe and well tolerated.

Hot flushes, a common adverse event associated with SERM use, were more frequently reported in the ospemifene groups. These did not raise discontinuation rates and were generally mild. Urinary tract infections were slightly more prevalent. The endometrial effects of ospemifene were negligible. There were no cases of endometrial hyperplasia or carcinoma and no reports of vaginal bleeding/spotting in this 3-month trial.

### Vaginal Lubricants and Moisturizers

Various water-soluble vaginal lubricants are available over the counter for treatment of vaginal dryness with coitus. Most commonly used water-based lubricants include K-Y Jelly, Astroglide, and Slippery Stuff. They can be applied before intercourse to the vaginal introitus. Alternatively, a polycarbophil-based gel (Replens) offers a more sustained correction of vaginal dryness. This gel is an acidic hydrophilic insoluble polymer, which can hold water to act as a vaginal moisturizer. The polymer binds to the vaginal epithelium and is sloughed with epithelial layer turnover. In addition, the acidity of the gel helps to lower the vaginal pH to that found in premenopausal women. This vaginal moisturizer is used three times weekly, but the schedule can be individualized.

As a group, these agents are an effective first-line tool for vaginal atrophy symptoms. From their review of 44 RCTs and prospective comparative trials, Rahn and associates (2014) suggest vaginal moisturizers/lubricants or vaginal estrogen for relief in women with a sole complaint of vaginal dryness, dyspareunia, itching or burning, dysuria, or urinary urgency. For those with multiples of these, they favored vaginal estrogen therapy.

### ■ Libido

A decline in libido is common during menopause (Sarrel, 1990). As described in Chapter 21 (p. 486), the cause is no doubt multifactorial. Estrogen therapy can be helpful for GSM symptoms, as described in the last section. However, HT is not recommended as the sole treatment of other problems of sexual function, including diminished libido (North American Menopause Society, 2012).

Flibanserin (Addyi) is an agent that has both serotonin-receptor agonist and antagonist activity. In 2015, this agent was approved by the FDA to treat female hypoactive sexual desire disorder (HSDD). For postmenopausal women, data derive mainly from the SNOWDROP trial (Simon, 2014). In

this study, flibanserin, compared with placebo, provided a significant increase in the number of satisfying sexual events (1.0 versus 0.6) and in the Female Sexual Function Index (FSFI) desire domain score (0.7 versus 0.4). Notably, these gains are measured against drug side effects that can include hypotension and syncope, especially with alcohol use. To emphasize this interaction, as part of the FDA-approval, prescribing clinicians must participate in a risk evaluation and mitigation strategy (REMS) program. An additional black box warning describes hypotension and syncope when flibanserin is administered with moderate or strong CYP3A4 inhibitors or in patients with hepatic impairment (Sprout Pharmaceuticals, 2015).

Androgen replacement in women with HSDD is a controversial topic. Although some studies have documented an association between androgen replacement and improved sexual desire, large quality trials with long-term follow-up are needed (Lobo, 2003; Pauls, 2005; Shifren, 2000). Dehydroepiandrosterone (DHEA) is an androgen precursor, and reviews of RCTs show no or only slightly improved sexual functioning in supplemented postmenopausal women (Elraiyah, 2014; Scheffers, 2015).

Symptoms of androgen insufficiency include diminished sense of well-being, persistent fatigue, sexual function changes, and low levels of serum free testosterone. Women with these findings may be offered replacement. Importantly, candidates are counseled that androgen replacement therapy is off-label and not FDA-approved. Therapy should be performed under close clinician supervision. Early effects of androgen therapy include acne and hirsutism, with one study reporting a 3-percent increased rate of acne in testosterone-therapy groups (Lobo, 2003). Long-term side effects such as male pattern baldness, voice deepening, and clitoral hypertrophy are infrequent within normal androgen levels. Androgen therapy may adversely affect the lipid profile, and long-term effects on cardiovascular and breast cancer risks are unknown (Braunstein, 2007; Davis, 2012, 2013).

## TREATMENT OF DEPRESSION

Depression in women is common, with a lifetime prevalence of approximately 18 percent (Chaps. 13, p. 298). Antidepressant medications together with psychotherapy and counseling are the principal therapeutic interventions for women with depression.

HT is not considered treatment for depression, but lesser mood symptoms may be improved concurrent with resolution of hot flushes and disrupted sleep. For example, in the prospective Massachusetts Women's Health Study, hot flushes and trouble sleeping were highly related to depression and provide support for the "domino" hypothesis that menopausal symptoms are a cause of increased depressed mood at this life stage (Avis, 2001). Several controlled studies have demonstrated that HT can improve depression in *perimenopausal* women. Notably, most studies involved women with vasomotor symptoms, so it is likely that the depressed mood improvement was predominantly linked to resolution of bothersome hot flushes and sleep disruption and improved quality of life (Soares, 2001; Zweifel, 1997). Women who present with bothersome

vasomotor symptoms and associated disordered mood at the time of the menopausal transition may elect a trial of HT for symptom relief. Namely, consideration may be given to those who fail to respond to a conventional first-line intervention, those who refuse to take psychotropic agents, or those who will begin HT for other acute menopausal symptoms and who could delay antidepressant therapy until determining whether estrogen treatment is sufficient.

TREATMENT OF SKIN AGING

As people age, their skin loses elasticity, collagen fibers, vascularity, and moisture. As a result, the skin lies more loosely, and lines appear where the facial muscles attach to the skin’s undersurface. Many factors play a role in the rate and degree of aging. First and foremost is genetics. People with thin, dry, fair skin realize signs earlier. In addition, overexposure to sunlight and excessive use of tobacco and alcohol accelerate skin aging. Thus, prevention of skin aging includes protection from ultraviolet light, avoidance of tobacco, and limited alcohol intake.

Skin is a hormonally sensitive structure, and both estrogen and androgen receptors have been localized to skin (Hasselquist, 1980). However, it is difficult to separate hormonal deficiency from chronological skin aging and age-related environmental insults such as smoking or photo-aging from sun exposure.

The predominant evidence for an estrogen effect on skin has been derived from observational studies using various estrogen preparations with or without cyclic progestin. Thus, it is difficult to clearly separate the effects of estrogen from estrogen and progestin in many of the studies. Results of RCTs show improvement in certain skin parameters, but these were inconsistent among the trials (Maheux, 1994; Sator, 2007; Sauerbronn, 2000). In the largest RCT, Phillips and associates (2008) noted that low-dose HT did not significantly alter age-related facial skin changes in 320 women compared with placebo. Thus in balancing the risk and benefits, there is currently insufficient evidence to recommend HT to improve age-related skin characteristics.

PREVENTIVE HEALTH CARE

Leading causes of mortality for two age groups of women are found in Table 22-6. Testing and prevention strategies are aimed at reducing the incidence and effects of these causes. In addition to testing, illness prevention requires patient education to enable women to play an active role in maintaining their own health. Through dialogue and counseling, clinicians and their actively participating patients can reap the benefits of preventive care. Prevention recommendations for many of these causes of morbidity are reviewed in Chapter 1, but a select few found commonly in older populations are discussed below.

■ Alzheimer Senile Dementia

Dementia is defined as a progressive decline in intellectual and cognitive function. Its causes can be categorized into three broad groups: (1) cases in which the brain is the target of a systemic illness; (2) primary structural causes such as tumor; and (3) primary

TABLE 22-6. Leading Causes of Mortality in Women of Differing Age<sup>a</sup>

In those between 45 and 54 years:

- Cancer
- Heart disease
- Accidents
- Chronic liver disease
- Cerebrovascular disease
- Chronic lower respiratory disease
- Diabetes mellitus
- Suicide

In those older than 65 years:

- Heart disease
- Cancer
- Cerebrovascular disease
- Chronic lower respiratory disease
- Alzheimer disease
- Diabetes mellitus
- Influenza and pneumonia
- Chronic renal disease

<sup>a</sup>For each age group, causes are listed by their descending frequency.  
Data from Heron M: Deaths: leading causes for 2010. Natl Vital Stat Rep 62(6):1, 2013.

degenerative diseases of the nervous system, such as senile dementia of the Alzheimer type (SDAT). It is estimated that up to 50 percent of women aged 85 years or older may suffer from senile dementia or SDAT. Early signs of dementia may be subtle, and testing strategies are found in Chapter 1 (p. 17).

The role of estrogen in the prevention of dementia is controversial. Several epidemiologic studies have suggested that HT prevents development of SDAT. Moreover, metaanalyses of observational studies found that HT was associated with a decreased risk of dementia, but it does not seem to improve established disease (Yaffe, 1998; Zandi, 2002). However, data from a large RCT found negative findings for a preventive role. Women enrolled in the Women’s Health Initiative Memory Study (WHIMS), an ancillary study of the WHI, were noted to have increased rates of dementia compared with those given placebo (Shumaker, 2003, 2004). Although this increased risk was statistically significant only in the group of women > 75 years, the observation nonetheless is a cause for concern in terms of its long-term implications for HT in older postmenopausal women who are well advanced in menopause. It is unclear whether, similar to CHD, concepts of critical window and timing hypotheses or if the duration of HT have an effect in the prevention of SDAT. Unfortunately, these mixed findings leave unanswered questions regarding HT’s efficacy in preventing dementia in postmenopausal women. Currently, HT is not recommended for this indication.

■ Urogynecologic Disease

The development of pelvic organ prolapse and urinary incontinence is multifactorial. Thus, the effectiveness of preventive

measures such as cesarean delivery, pelvic floor muscle training (Kegel exercises), and estrogen therapy is unclear. Estrogen receptors are found throughout the lower urinary and reproductive tracts. In these areas, hypoestrogenism is associated with collagen changes and diminished vascularity of the urethral subepithelial plexus. However, separating the effects of hypoestrogenism from aging in the genesis of pelvic organ prolapse and urinary incontinence is problematic and discussed in Chapters 23 (p. 515) and 24 (p. 539).

For a woman with obvious lower reproductive tract atrophic changes, a trial of vaginal estrogen treatment for urinary incontinence is reasonable. Vaginal ET reduces irritative urinary symptoms, such as frequency and urgency, and has been demonstrated to reduce the likelihood of recurrent urinary tract infections in postmenopausal women (Eriksen, 1999). However, several other studies evaluating effects of estrogen have noted either de novo development or worsening of incontinence in women using HT (Hendrix, 2005; Jackson, 2006). Accordingly, there is no current indication for the use of HT for the prevention of pelvic organ prolapse or incontinence.

In sum, the body of current evidence shows that HT prescribing is complex and should be tailored to the individual woman's risk/benefit profile. The dose, type, and route of administration are carefully evaluated. While clinicians spout the mantra of "lower doses for shorter periods of time," there actually are no arbitrary time limits regarding the duration of HT use in the symptomatic woman. It can be used for as long as the woman feels the benefits outweigh the risks for her. Annual or semiannual visits to reevaluate symptoms, side effects, risks, and benefits are tailored to the individual patient.

DEFINITIONS

Urinary incontinence is defined as involuntary leakage of urine. This is in contrast to urine that leaks from extraurethral sources, such as with fistulas or congenital malformations of the lower urinary tract. Although incontinence is categorized into several forms, this chapter focuses on the evaluation and management of stress and urgency urinary incontinence. *Stress urinary incontinence (SUI)* is the involuntary leakage of urine with increases in intraabdominal pressure. *Urgency urinary incontinence* (previously “urge” urinary incontinence) is the involuntary leakage accompanied or immediately preceded by a perceived strong imminent need to void. A related condition, *overactive bladder*, describes urinary urgency with or without incontinence and usually with increased daytime urinary frequency and nocturia (Abrams, 2009).

According to International Continence Society guidelines, urinary incontinence is a symptom, a sign, and a condition (Abrams, 2002). For example, with SUI, a patient may complain of involuntary urine leakage with exercise or laughing. Concurrent with these symptoms, involuntary leakage from the urethra synchronous with cough or Valsalva may be observed during examination by a provider. And as a condition, SUI is objectively demonstrated during urodynamic testing if involuntary leakage of urine is seen with increased abdominal pressure and absence of detrusor muscle contraction. Under these circumstances, when the symptom or sign of SUI is confirmed with objective testing, the term *urodynamic stress incontinence* is preferred.

With urgency urinary incontinence, women have difficulty postponing urination urges and generally must promptly empty their bladder on cue and without delay. Common triggers are hand washing, running water, or exposure to cold. Urgency urinary incontinence is sometimes objectively demonstrated during urodynamic testing to correspond temporally with spontaneous detrusor muscle contractions—a condition

termed *detrusor overactivity*. When both stress and urgency symptoms are present, it is called *mixed urinary incontinence*.

EPIDEMIOLOGY

In Western societies, epidemiologic studies indicate a prevalence of urinary incontinence of 25 to 51 percent and even higher among nursing home patients (Buckley, 2010; Markland, 2011). This wide range is attributed to variations in research methodologies, population characteristics, and definitions of incontinence. As part of the 2005 to 2006 National Health and Nutrition Examination Survey (NHANES), a cross-sectional group of 1961 nonpregnant, noninstitutionalized women in the United States were questioned regarding pelvic floor disorders. Urinary incontinence characterized by participants as moderate to severe leakage was identified in 15.7 percent (Nygaard, 2008). However, current available data are limited by the fact that most women do not seek medical attention for this condition (Hunskar, 2000). It is estimated that only one in four women will seek medical advice for incontinence, due to embarrassment, limited health care access, or poor screening by health care providers (Hagstad, 1985).

Among ambulatory women with urinary incontinence, the most common type is SUI, which represents 29 to 75 percent of cases. Urgency urinary incontinence accounts for up to 33 percent of incontinence cases, whereas the remainder is attributable to mixed forms (Hunskar, 2000). In one review, 15 percent of 64,528 women met criteria for overactive bladder with or without incontinence, and 11 percent had urgency urinary incontinence (Hartmann, 2009).

Urinary incontinence can significantly impair quality of life and lead to disrupted social relationships, embarrassment and frustration, hospitalizations due to skin breakdown and urinary tract infection (UTI), and nursing home admission. An incontinent elderly woman is 2.5 times more likely to be admitted to a nursing home than a continent one (Langa, 2002). Moreover, population projections from the U.S. Census Bureau forecast that the number of American women with urinary incontinence will increase 55 percent from 18.3 million to 28.4 million between 2010 and 2050 (Wu, 2009).

RISKS

■ Age

The prevalence of incontinence appears to increase gradually during young adult life. For example, data from the 2005 to 2006 NHANES demonstrate a steady increase in incontinence

prevalence with age: 7 percent in those aged 20 to 40 years, 17 percent for ages 40 to 60, 23 percent for ages 60 to 80, and 32 percent for those older than 80 (Nygaard, 2008).

Incontinence should not be viewed as a normal consequence of aging. However, several physiologic age-related changes in the lower urinary tract may predispose to incontinence, overactive bladder, or other voiding difficulties. First, the prevalence of involuntary detrusor contractions increases with age, and detrusor overactivity is found in 21 percent of healthy, continent community-dwelling elderly (Resnick, 1995). Both total bladder capacity and the ability to postpone voiding decreases, and these declines may lead to urinary frequency. In addition, urinary flow rates are reduced in older women and are likely due to an age-associated decrease in detrusor contractility (Resnick, 1984). In women, postmenopausal decreases in estrogen levels result in atrophy of the urethral mucosal seal, loss of compliance, and bladder irritation, which may predispose to both stress and urgency urinary incontinence. Finally, renal filtration rate and diurnal levels of antidiuretic hormone and atrial natriuretic factor change with age. These alterations shift the diurnal-predominant pattern of fluid excretion toward one with greater urine excretion later in the day (Kirkland, 1983).

### ■ Other Factors

*Race* may influence incontinence rates, and white women are believed to have higher SUI rates than women of other races. In contrast, urgency urinary incontinence is believed to be more prevalent among African-American women. Most reports are not population-based and thus are not the best estimate of true racial differences. However, data from the Nurses' Health Study cohorts, which included more than 76,000 women, did support these racial differences (Townsend, 2010). It is not yet clear whether these differences are biologic, related to health-care access, or affected by cultural expectations and symptom tolerance thresholds.

*Body mass index (BMI)* is a significant and independent risk factor for urinary incontinence of all types (Table 23-1). Specifically, the prevalence of both urgency urinary and stress incontinence increases proportionally with BMI (Hannestad, 2003). Theoretically, the increase in intraabdominal pressure

that coincides with an increased BMI results in a higher intravesical pressure. This higher pressure overcomes urethral closing pressure and leads to incontinence (Bai, 2002). Encouragingly, weight loss for many can be an effective treatment and is considered a first-line option to reduce urinary incontinence rates (Dumoulin, 2014b). The prevalence of urinary incontinence significantly declines following weight loss achieved by behavior modification or with bariatric surgery (Burgio, 2007; Deitel, 1988; Subak, 2009). Even losses of 5 to 10 percent of body weight are sufficient for significant improvement in urinary incontinence (Wing, 2010).

*Menopause* may have a relationship with incontinence, but studies have inconsistently demonstrated an increase in urinary dysfunction rates (Bump, 1998). In those with symptoms, separating aging changes from hypoestrogenism effects is difficult. First, high-affinity estrogen receptors are found in the urethra, pubococcygeal muscle, and bladder trigone but are infrequently found elsewhere in the bladder (Iosif, 1981). Hypoestrogenic-related collagen changes and reductions in urethral vascularity and skeletal muscle volume are factors. They are thought collectively to contribute to impaired urethral function via a decreased resting urethral pressure (Carlile, 1988). Moreover, estrogen deficiency with resulting urogenital atrophy is believed to be responsible in part for urinary sensory symptoms following menopause (Raz, 1993). Despite this current evidence, it is less clear whether estrogen therapy is useful in the treatment or prevention of incontinence. Namely, systemic estrogen replacement, compared with placebo, appears to worsen incontinence, whereas topical vaginal estrogen application *may improve* incontinence (Cody, 2012; Fantl, 1994, 1996; Rahn, 2014, 2015).

*Childbirth and pregnancy* also play a role, and urinary incontinence prevalence is higher in parous women compared with nulliparas. The effects of childbirth may result from direct injury to pelvic muscles and connective tissue attachments. In addition, nerve damage from trauma or stretch injury can lead to pelvic muscle dysfunction. Specifically, rates of prolonged pudendal nerve latency after delivery are higher in women with incontinence compared with asymptomatic puerperal women (Snooks, 1986).

Of potential obstetric factors, one large study identified that fetal birthweight > 4000 g increased the risk of all urinary incontinence types (Rortveit, 2003b). These authors also noted that cesarean delivery may offer a short-term protective effect from urinary incontinence. The adjusted odds ratio for any incontinence associated with vaginal delivery compared with that with cesarean delivery was 1.7 (Rortveit, 2003a). However, the protective effect of cesarean delivery on incontinence may dissipate after additional deliveries, decreases with age, and is not present in older women (Nygaard, 2006).

*Family history* may alter incontinence risks, and the urinary incontinence rates may be increased in the daughters and sisters of incontinent women. In one large survey, daughters of incontinent women had an increased relative risk of 1.3 and an absolute risk of 23 percent of having urinary incontinence. Younger sisters of incontinent women also had a greater likelihood of having any urinary incontinence (Hannestad, 2004).

*Chronic obstructive pulmonary disease* in women older than 60 years significantly increases urinary incontinence risks

**TABLE 23-1.** Risk Factors for Urinary Incontinence

Age

Functional impairment
Chronically increased abdominal pressure
Chronic cough
Constipation
Occupational lifting

(Brown, 1996; Diokno, 1990). Similarly, cigarette smoking is identified as an independent risk factor for urinary incontinence. Both current and former smokers have a two- to three-fold risk of incontinence compared with nonsmokers (Brown, 1996; Bump, 1992; Diokno, 1990). In one study, investigators found an association between current and former smoking and incontinence, but only for those who smoked more than 20 cigarettes daily. Severe incontinence was weakly associated with smoking regardless of cigarette number (Hannestad, 2003). Theoretically, persistently increased intraabdominal pressures are generated from a smoker's chronic cough, and collagen synthesis is diminished by smoking's antiestrogenic effects.

*Hysterectomy* does not appear to increase urinary incontinence rates. Studies that include pre- and postoperative urodynamic testing reveal clinically insignificant changes in bladder function. Moreover, evidence does not support avoidance of clinically indicated hysterectomy or the selection of supracervical hysterectomy as measures to prevent urinary incontinence (Vervest, 1989; Wake, 1980).

## PATHOPHYSIOLOGY

### ■ Continence

The bladder has the capacity to accommodate large increases in volume with minimal or no increases in intravesical pressure. The ability to store urine coupled with convenient and socially acceptable voluntary emptying is *continence*. Continence requires the complex coordination of multiple components that include: muscle contraction and relaxation, appropriate connective tissue support, and integrated innervation and communication between these structures. Simplistically, during filling, urethral contraction is coordinated with bladder relaxation and urine is stored. During voiding, the urethra relaxes and the bladder contracts. These mechanisms can be challenged by uninhibited detrusor contractions, marked increases in intraabdominal pressure, and degradation or dysfunction of the various anatomic components of the continence mechanism.

### ■ Bladder Filling

#### Bladder Anatomy

The bladder wall is multilayered and contains mucosal, submucosal, muscular, and adventitial layers (Fig. 23-1). The bladder mucosa is composed of a transitional cell epithelium, supported by a lamina propria. With small bladder volumes, the mucosa appears as convoluted folds. However, with bladder filling, it is stretched and thinned. The bladder epithelium, termed *uroepithelium*, is made up of distinct cell layers. The most superficial is the umbrella cell layer, and its impermeability is thought to provide the primary urine-plasma barrier. Covering the uroepithelium is a glycosaminoglycan (GAG) layer. This GAG layer may prohibit bacterial adherence and prevents urothelial damage by acting as a protective barrier. Specifically, theories suggest that this carbohydrate polymer layer may be defective in patients with interstitial cystitis (Chap. 11, p. 263).

The muscular layer, termed the detrusor muscle, is composed of three smooth-muscle layers arranged in a plexiform

fashion. This unique arrangement allows for rapid multidimensional expansion during bladder filling and is a key component to the bladder's ability to accommodate large volumes.

### Innervation

Normal function of the lower urinary tract requires integration of peripheral and central nervous systems. The peripheral nervous system contains somatic and autonomic divisions (Fig. 23-2). Of these, the somatic component innervates striated muscle, whereas the autonomic division innervates smooth muscle.

The autonomic nervous system controls involuntary action and is categorized into sympathetic and parasympathetic divisions. The sympathetic system mediates its end-organ effects through epinephrine or norepinephrine acting on  $\alpha$ - or  $\beta$ -adrenergic receptors (Fig. 23-3). The parasympathetic division acts through acetylcholine binding to muscarinic or nicotinic receptors. In the pelvis, autonomic fibers that supply the pelvic viscera course in the superior and inferior hypogastric plexi (Fig. 23-4).

The somatic nervous system controls voluntary movement, and the portion of this system that is most relevant to lower urinary tract function originates from Onuf somatic nucleus. This nucleus is located in the ventral horn gray matter of spinal levels S2–S4 and contains the neurons that innervate the striated urogenital sphincter complex, described next. Nerves involved with that connection include branches of the pudendal and pelvic nerves.

### Urogenital Sphincter

As the bladder fills, synchronized contraction of the urogenital sphincter is integral to continence. Composed of striated muscle, this sphincter complex includes: (1) the *sphincter urethrae*, (2) the *urethrovaginal sphincter*, and (3) the *compressor urethrae*. The sphincter urethrae wraps circumferentially around the urethra. In comparison, the urethrovaginal sphincter and the compressor urethrae arch ventrally over the urethra and insert into the fibromuscular tissue of the anterior vaginal wall (Fig. 23-5).

These three muscles function as a single unit and contract to close the urethra. Contraction of these muscles circumferentially constricts the cephalad two thirds of the urethra and laterally compresses the distal one third. The sphincter urethrae is predominantly composed of slow-twitch fibers and remains tonically contracted, contributing substantially to continence at rest. In contrast, the urethrovaginal sphincter and the compressor urethrae are comprised of fast-twitch muscle fibers, which allow brisk contraction and urethra lumen closure when continence is challenged by sudden increases in intraabdominal pressure.

### Innervation Important to Storage

The urogenital sphincter receives somatic motor innervation through the pudendal and pelvic nerves (Fig. 23-6). Thus, pudendal neuropathy, which may follow obstetric injury, can affect normal sphincter functioning. Additionally, prior pelvic surgery or pelvic radiation therapy may damage nerves, vasculature, and soft tissue. Such injury can lead to ineffective urogenital sphincter action and contribute to incontinence.

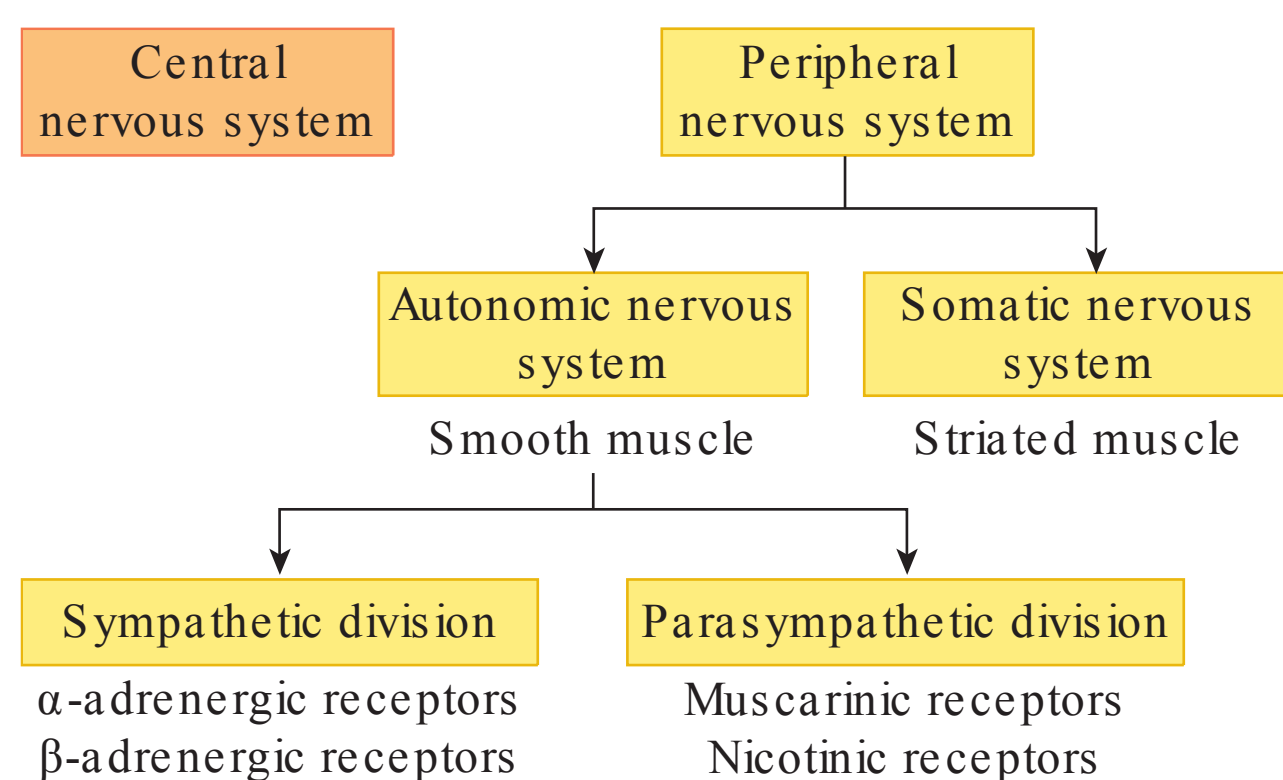

**A**

**B**

**FIGURE 23-1** Bladder anatomy. **A.** Anteroposterior view of bladder anatomy. Inset: The bladder wall contains mucosal, submucosal, muscular, and adventitial layers. **B.** Photomicrograph of the bladder wall. The mucosa of an empty bladder is thrown into convoluted folds or rugae. The plexiform arrangement of muscle fibers of the detrusor muscle cause difficulty in defining its three distinct layers. (Reproduced with permission from McKinley M, O'Loughlin VD: Human Anatomy. New York: McGraw-Hill; 2006.)

**FIGURE 23-2** Divisions of the human nervous system. The peripheral nervous system includes: (1) the somatic nervous system, which mediates voluntary movements through its actions on striated muscle and (2) the autonomic nervous system, which controls involuntary motion through its actions on smooth muscle. The autonomic nervous system is further divided into the sympathetic division, which acts through epinephrine and norepinephrine binding to adrenergic receptors and (2) the parasympathetic division, which acts through acetylcholine binding to muscarinic or nicotinic receptors.

Sympathetic fibers are carried through the superior hypogastric nerve plexus and communicate with  $\alpha$ - and  $\beta$ -adrenergic receptors within the bladder and urethra.  $\beta$ -Adrenergic receptor stimulation in the bladder dome results in smooth-muscle relaxation and assists with urine storage (Fig. 23-7).  $\beta$ -Agonist medication may improve overactive bladder symptoms through this mechanism of smooth muscle relaxation. In contrast,  $\alpha$ -adrenergic receptors predominate in the bladder base and

**FIGURE 23-3** The bladder dome is rich in parasympathetic muscarinic receptors (M) and sympathetic  $\beta$ -adrenergic receptors ( $\beta$ ). The bladder neck contains a greater density of sympathetic  $\alpha$ -adrenergic receptors ( $\alpha$ ). (Used with permission from Lindsay Oksenberg.)

urethra. These receptors are stimulated by norepinephrine, which initiates a cascade of events that preferentially leads to urethral contraction and aids urine storage and continence. These effects of  $\alpha$ -stimulation underlie the treatment of SUI with imipramine, a tricyclic antidepressant with adrenergic agonist properties.

**FIGURE 23-4** The inferior hypogastric plexus, also known as the pelvic plexus, is formed by visceral efferents from S2 to S4, which provide the parasympathetic component by way of the pelvic nerves. The superior hypogastric plexus primarily contains sympathetic fibers from the T10 to L2 cord segments and terminates by dividing into right and left hypogastric nerves. The hypogastric nerves and rami from the sacral portion of the sympathetic chain contribute the sympathetic component to the pelvic plexus. The pelvic plexus divides into three portions according to the course and distribution of its fibers: the middle rectal plexus, uterovaginal plexus, and vesical plexus. (Used with permission from Lindsay Oksenberg.)

**FIGURE 23-5** Striated urogenital sphincter anatomy. The perineal membrane is removed to show the three component muscles of the striated urogenital sphincter. This sphincter receives most of its somatic innervation through the pudendal nerve. (Used with permission from Lindsay Oksenberg.)

### Urethral Coaptation

One key to maintaining continence is adequate urethral mucosal coaptation. The uroepithelium is supported by a connective tissue layer, which is thrown into deep folds, also known as plications. A rich capillary network runs within its subepithelial layer. This vascular network aids in urethral mucosal

approximation, also termed *coaptation*, by acting like an “inflatable cushion” (Fig. 23-8). In women who are hypoestrogenic, this submucosal vasculature plexus is less prominent. In part, hormone replacement targets this diminished vascularity and in theory, enhances coaptation to improve continence.

**FIGURE 23-6** Onuf nucleus is found in the ventral horn gray matter of S2 through S4. This nucleus contains the neurons whose fibers supply the striated urogenital sphincter. The urethrovaginal sphincter and compressor urethrae are innervated by the perineal branch of the pudendal nerve. The sphincter urethrae is variably innervated by somatic efferents that travel in the pelvic nerves. (Used with permission from Lindsay Oksenberg.)

**FIGURE 23-7** Physiology of urine storage. Bladder distention from filling leads to: (1)  $\alpha$ -adrenergic contraction of the urethral smooth muscle and increased tone at the vesical neck (via the T11-L2 spinal sympathetic reflex); (2) activation of urethral motor neurons in Onuf nucleus with contraction of striated urogenital sphincter muscles (via the pudendal nerve); and (3) inhibited parasympathetic transmission with decreased detrusor pressure.  $\alpha$  = alpha adrenergic receptors;  $\beta$  = beta adrenergic; M = muscarinic (cholinergic). (Used with permission from Lindsay Oksenberg.)

**FIGURE 23-8** Drawing of urethral anatomy. **A.** Urethral anatomy in cross section. Urethral coaptation results in part from filling of the rich subepithelial vascular plexus. The urethra contains circular and longitudinal smooth muscle layers. **B.** Vesical neck and urethral anatomy. The striated urogenital sphincter lies external to the urethral smooth muscle layers. (Used with permission from Lindsay Oksenberg.)

**FIGURE 23-9** Physiology of urine evacuation. Efferent impulses from the pontine micturition center results in inhibition of somatic fibers in Onuf nucleus and voluntary relaxation of the striated urogenital sphincter muscles. These efferent impulses also result in preganglionic sympathetic inhibition with opening of the vesical neck and parasympathetic stimulation, which results in detrusor muscarinic contraction. The net result is relaxation of the striated urogenital sphincter complex causing decreased urethral pressure, followed almost immediately by detrusor contraction and voiding.  $\alpha$  = alpha adrenergic receptors;  $\beta$  = beta adrenergic; M = muscarinic (cholinergic). (Used with permission from Lindsay Oksenberg.)

## ■ Bladder Emptying

### Innervation Related to Voiding

When an appropriate time for bladder emptying arises, sympathetic stimulation is reduced and parasympathetic stimulation is triggered. Specifically, neural impulses carried in the pelvic nerves stimulate acetylcholine release and lead to detrusor muscle contraction (Fig. 23-9). Concurrent with detrusor stimulation, acetylcholine also stimulates muscarinic receptors in the urethra and leads to outlet relaxation for voiding.

Within the parasympathetic division, acetylcholine receptors are broadly defined as muscarinic and nicotinic. The bladder is densely supplied with muscarinic receptors, which when stimulated lead to detrusor contraction. Of the muscarinic receptors, five glycoproteins designated  $M_1$ – $M_5$  have been identified.  $M_2$  and  $M_3$  receptor subtypes are predominantly responsible for detrusor smooth muscle contraction. Thus, treatment with muscarinic antagonist medication blunts detrusor contraction

to improve continence. Continence drugs that target only the  $M_3$  receptor maximize drug efficacy yet minimize activation of other muscarinic receptors and drug side effects.

### Muscular Activity with Voiding

Smooth muscle cells within the detrusor fuse with one another so that a network of low-resistance electrical pathways extends from one muscle cell to the next. Thus, action potentials can spread quickly throughout the detrusor muscle to cause rapid contraction of the entire bladder. In addition, the plexiform arrangement of bladder detrusor fibers allows multidirectional contraction and is ideally suited for rapid concentric contraction during bladder emptying.

During voiding, all components of the striated urogenital sphincter relax. Importantly, bladder contraction and sphincter relaxation must be coordinated for effective voiding. Occasionally, the urethral sphincter fails to relax during contraction of the

detrusor and retention ensues. Classically, this is a possible urinary complication of spinal cord injury termed *detrusor sphincter dyssynergia* and may lead to elevated bladder pressures and vesicoureteral reflux. Women with this condition are sometimes treated with  $\alpha$ -blocking agents to help with sphincter relaxation and to lower bladder pressures during contraction, but these may aggravate hypotension. In women without known neurologic pathology but still with inappropriately contracted pelvic floor musculature, treatment with muscle relaxants may be appropriate. These drugs purportedly relax the urethral sphincter and levator ani muscles to improve coordinated voiding.

## ■ Continence Theories

### Anatomic Stress Incontinence

Theories on continence vary in their supportive evidence but can simplistically be distilled into those that involve anatomic stress incontinence or those that describe decreased urethral integrity (sphincteric deficiency). These theories are not mutually exclusive and in many women, both may be contributory.

First, urethral and bladder neck support is integral to continence. This anatomic support derives from: (1) ligaments along the urethra's lateral aspects, termed the pubourethral ligaments; (2) the vagina and its lateral fascial condensation; (3) the arcus tendineus fascia pelvis; and (4) levator ani muscles. A full anatomic description of these ligaments and muscles is found in Chapter 38 (p. 802).

In an ideally supported urogenital tract, increases in intraabdominal pressure are equally transmitted to the bladder, bladder base, and urethra. In women who are continent, increases in downward-directed pressure from cough, laugh, sneeze, and Valsalva maneuver are countered by supportive tissue tone provided by the levator ani muscles and vaginal connective tissue (Fig. 23-10). With loss of support, the ability of the urethra and bladder neck to close against a firm supportive “back-board” is diminished. This results in reduced urethral closing pressures, an inability to resist increases in bladder pressure, and in turn, incontinence. This mechanistic theory is the basis for surgical reestablishment of this support. Traditional procedures such as Burch and Marshall-Marchetti-Krantz (MMK)

**FIGURE 23-10** Drawing describes the pressure transmission theory. **A.** In women with normal support, increases in intraabdominal pressure are equally distributed to contralateral sides of the bladder and urethra. **B.** In those with poor urethral support, increases in intraabdominal pressure alter the urethrovesical angle and continence is lost.

colposuspensions attempt to return this anatomic support to the urethrovesical junction and proximal urethra.

### Sphincteric Deficiency

Another way to conceptualize SUI is to consider the urethra as providing continence through the combination of: urethral mucosal coaptation, the underlying urethral vascular plexus, the combined viscous and elastic properties of the urethral epithelium, and contraction of appropriate surrounding musculature. Taken together, these components contribute to *urethral integrity*. Defects in any or a combination of these components may lead to urine leakage and have traditionally been termed *intrinsic sphincteric defect (ISD)*. For example, prior surgery in the retropubic space may cause denervation and scarring of the urethra and its supporting tissue. These effects subsequently prevent urethral closure and lead to incontinence. Specific causes are varied and include prior pelvic reconstructive surgeries, prior pelvic radiation therapy, diabetic neuropathy, neuronal degenerative diseases, and hypoestrogenism. Namely, in women with atrophic lower genital tracts, vascular changes within the plexus surrounding the urethra lead to poor coaptation and greater incontinence risks.

As noted earlier, nerve dysfunction following birth trauma may lead to defective urethral sphincter function. In addition, childbirth also often injures urethral fascial support. This clinical example highlights the intimate relationship between urethral support and integrity.

Treatments to restore urethral integrity include transurethral injection of bulking agents, surgical sling procedures, and pelvic floor muscle strengthening, which are all described in later sections. In brief, bulking agents are placed at the urethrovesical junction to elevate the epithelium and promote coaptation. Alternatively, sling procedures restore periurethral support anatomy or create partial urethral obstruction to enhance urethral integrity. Last, because the urethra exits through urogenital hiatus, levator ani muscle conditioning with Kegel exercises can bolster urethral integrity. These muscles can be contracted around the urethra when continence is challenged during sudden increases in intraabdominal pressures.

A consideration for surgical management of patients with ISD, particularly those younger than 50 years, is that a retropubic colposuspension procedure merely elevates and stabilizes the urethra and does not promote coaptation. This may be less likely to achieve satisfactory continence than a procedure directed at both anatomic stress incontinence and deficient urethral sphincter function and support (Sand, 1987). That said, a small trial randomizing incontinent women with ISD to Burch or sling procedures did not show differences in postoperative voiding function or in SUI cure rates (Culligan, 2003).

## DIAGNOSIS

### ■ history

#### Symptom Clustering

Assessment of incontinence begins with a patient describing her urinary symptoms. These complaints may be collected through direct conversation but can be augmented with patient

**TABLE 23-2.** The Three Incontinence Questions (3IQ)

1. During the last 3 months, have you leaked urine (even a small amount)?
  - a. Yes (continue questions)
  - b. No (questionnaire completed)
2. During the last 3 months, did you leak urine: (mark all that apply)
  - a. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
  - b. When you had the urge or feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
  - c. Without physical activity and without a sense of urgency?
3. During the last 3 months, did you leak urine most often: (mark only one)
  - a. When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
  - b. When you had the urge or feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
  - c. Without physical activity and without a sense of urgency?
  - d. About equally as often with physical activity as with a sense of urgency?

The response to question 3 with (a) or (b) indicates stress-predominant or urgency-predominant incontinence, respectively, whereas (d) indicates mixed and (c) suggests another cause of incontinence.

questionnaires. Two common forms are the Pelvic Floor Distress Inventory and the Pelvic Floor Impact Questionnaire. Both are available in long and short forms and evaluate urinary, bowel, and prolapse symptoms (Barber, 2001). Such lengthy research questionnaires may be impractical for general clinical practice. Instead, shorter validated questionnaires may easily be incorporated into the clinic setting. As shown in Table 23-2, the 3IQ has only three questions that screen for incontinence and then helps clarify the incontinence type (Brown, 2006).

During inquiry, the number of voids and pads used per day, type of pad, frequency of pad changing, and the degree of pad saturation are important. Although these specifics alone may not establish the exact type of incontinence, they do provide information regarding symptom severity and its effects on patient activities. If a woman’s symptoms do not diminish her quality of life, then simple observation is reasonable. Conversely, those with bothersome symptoms warrant further evaluation.

Specific to incontinence, information that describes the circumstances in which urine leaks and specific maneuvers that incite or provoke leakage are sought. With SUI, triggers may include increases in intraabdominal pressure such as coughing, sneezing, Valsalva maneuver, or deep penetration during intercourse. Alternatively, women with urgency urinary incontinence may describe urine loss after urge sensations that typically

Bladder Diary			
Please record the time and amount of your oral intake, urine output, urine leakage, and pad changes FOR 3 DAYS			
Time	Oral Intake	Voided Urine	Urine Leakage or Pad Change

**FIGURE 23-11** Example of a urinary diary.

cannot be suppressed. *Overflow incontinence* was a term used in the past to refer to women who were unable to empty their bladder well but who also had involuntary, continuous urinary leakage or dribbling and often episodes of incontinence associated with urgency. Currently, however, this is considered by many to reflect another presentation of urgency urinary incontinence.

During questioning, symptoms typically cluster into those most frequently seen with SUI or with urgency urinary incontinence (see Table 23-2). Alternatively, a significant overlap of complaints may reflect coexistent SUI and urgency urinary incontinence, that is, mixed urinary incontinence. For these reasons, pattern identification is helpful as it may direct diagnostic testing and guide initial empiric therapy.

## Voiding Diary

Typically, patients may not have an entirely accurate recollection of their own voiding habits. Accordingly, to obtain a thorough record, a woman ideally completes a urinary diary (Fig. 23-11). With this, the volumes and type of each oral fluid intake, volumes of urine with each void, episodes of urinary leakage, and triggers of incontinence episodes are recorded for 3 to 7 days. During each 24-hour period, women also record times of sleep and awakening to document voluntary nocturnal voiding patterns or enuresis. Three days usually suffices to determine the general trend of incontinence.

The information gained from a voiding/urinary diary is a valuable diagnostic and sometimes therapeutic tool. The first morning void is usually the largest of the day and is a good estimate of bladder capacity. Patients often can identify patterns in intake and voiding and modify behavior. For example, a patient may recognize increased urinary frequency or urgency urinary incontinence episodes after caffeine intake. Moreover, this diary information can serve as a baseline against which treatment effectiveness can be assessed.

## Urinary Symptoms

Specific patient symptoms may help differentiate incontinence types. For example, most women void eight or fewer times per day. Without a history that reflects increased fluid intake, increased voiding may indicate overactive bladder, UTI, calculi, or urethral pathology and often prompts additional evaluation. In addition, urinary frequency is commonly associated

with interstitial cystitis (IC). In women with IC, the numbers of voids may commonly exceed 20 per day. Nocturia may be noted in women with urgency urinary incontinence or in those with systemic fluid management disorders such as congestive heart failure. In the latter case, treatment of the underlying condition frequently leads to symptom improvement or cure of nighttime frequency.

Urinary retention may provide clues. Often incomplete emptying can result in incontinence associated with either stress or urgency. Urethral obstruction, often manifested as an inability to void or an impeded urinary stream, is uncommon in women. Its description prompts careful evaluation for pelvic organ prolapse and underscores the importance of asking about prior pelvic/vaginal surgery or trauma that could scar or obstruct the urethra.

Of other urinary symptoms, the volume of urine lost with each episode may aid diagnosis. Large volumes are typically lost following a spontaneous detrusor contraction associated with urgency urinary incontinence and may often involve loss of the entire bladder volume. In contrast, women with SUI usually describe smaller volumes lost. Moreover, these women often are able to contract the levator ani muscles to temporarily stop their urine stream. Another symptom, postvoid dribbling, is classically associated with urethral diverticulum, which may often be mistaken for urinary incontinence (Chap. 26, p. 582). Hematuria, although a common sign of UTI, may also indicate underlying malignancy and can cause irritative voiding symptoms.

Symptom onset may also prove informative. For example, problems beginning at menopause may suggest hypoestrogenism as an etiology. These patients may benefit from topical vaginal estrogen. In contrast, symptoms after hysterectomy or childbirth may reflect changes in tissue support or innervation.

### Past Medical History

Obstetric trauma may be associated with damage to pelvic floor support, which may lead to SUI. Accordingly, information is sought regarding a prolonged labor, operative vaginal delivery, macrosomia, or postpartum catheterization for urinary retention. As alluded to earlier, urinary incontinence can be linked with several medical conditions or their treatments, which could be modified to improve incontinence. To help remember these potential contributors, a useful mnemonic is “DIAPPERS”: dementia/delirium, infection, atrophic vaginitis, psychological, pharmacologic, endocrine, restricted mobility, and stool impaction (Swift, 2008).

First, continence requires the cognitive ability to recognize and react appropriately to the sensation of a full bladder, motivation to maintain dryness, sufficient mobility and manual dexterity, and ready access to a toilet. Patients with dementia or significant psychological impairments often do not have the necessary cognitive ability for continence. Women with severe physical handicaps or restricted mobility may simply not have time to reach the toilet, especially in the setting of urinary urgency/overactive bladder. Thus, this so-called functional incontinence occurs in situations in which a woman cannot reach a toilet in time because of physical, psychological, or mentation limitations. Often, this group would be continent if

these issues were absent. Simple interventions such as a bedside commode may be helpful in such cases.

Urinary tract infections cause bladder mucosal inflammation. This inflammation is thought to increase sensory afferent activity, which contributes to an overactive bladder. Similarly, estrogen deficiency can lead to atrophic epithelium of the vagina and urethra. These are associated with increased local irritation and greater risks of UTI and overactive bladder.

A detailed medication inventory is collected. Pertinent drugs include estrogen,  $\alpha$ -adrenergic agonists, and diuretics, to name a few (Table 23-3).

Of endocrinopathies, diabetes mellitus can promote osmotic diuresis and polyuria if glucose control is poor. Polydipsia from diabetes insipidus or excessive caffeine or alcohol intake can also lead to polyuria or urinary frequency. Similarly, other disorders of impaired arginine vasopressin secretion or action may cause polyuria and nocturia (Ouslander, 2004). Conditions such as congestive heart failure, hypothyroidism, venous insufficiency, and the effects of certain medications all contribute to peripheral edema, leading to urinary frequency and nocturia when a patient is supine.

Last, stool impaction resulting from poor bowel habits and constipation can contribute to overactive bladder symptoms. This is perhaps from local irritation or direct compression against the bladder wall.

## Physical Examination

### General Inspection and Neurologic Evaluation

Initially, the perineum is inspected for evidence of atrophy, which may be noted throughout the lower genital tract. In addition, a suburethral cystic mass or dilation with transurethral expression of fluid during compression suggests a urethral diverticulum (Fig. 26-6, p. 585).

Examination of an incontinent woman also includes a detailed neurologic evaluation of the perineum. Because neurologic responses may be altered in an anxious patient who is in a vulnerable setting, signs elicited during evaluation may not signify true pathology and are interpreted with caution. Neurologic testing begins with an attempt to elicit a *bulbo-cavernosus reflex*. During this test, one labium majus is stroked with a cotton swab. Normally, both labia generally contract at the same time. The afferent limb of this reflex is the clitoral branch of the pudendal nerve, whereas its efferent limb is conducted through the inferior hemorrhoidal branch of the pudendal nerve. This reflex is integrated at the S2-S4 spinal cord level (Wester, 2003). Thus, reflex absence may reflect central or peripheral neurologic deficits. Second, a normal circumferential anal sphincter contraction, colloquially called an “anal wink,” should follow cotton swab brushing of the perianal skin. External urethral sphincter activity requires at least some degree of intact S2-S4 innervation, and this *anocutaneous reflex* is mediated by the same spinal neurologic level. Thus, an absent wink may indicate deficits in this neurologic distribution.

### Pelvic Support Assessment

Poor urethral support commonly accompanies pelvic organ prolapse. For example, women with significant prolapse are often

**TABLE 23-3.** Medications That May Contribute to Incontinence

Medication	Examples	Mechanism	Effect
<b>Alcohol</b>	Beer, wine, liquor	Diuretic effect, sedation, immobility	Polyuria, frequency
<b><math>\alpha</math>-Adrenergic agonists</b>	Decongestants, diet pills	IUS contraction	Urinary retention
<b><math>\alpha</math>-Adrenergic blockers</b>	Prazosin, terazosin, doxazosin	IUS relaxation	Urinary leakage
<b>Anticholinergic agents</b>		Inhibit bladder contraction, sedation, fecal impaction	Urinary retention and/or functional incontinence
Antihistamines	Diphenhydramine, scopolamine, dimenhydrinate		
Antipsychotics	Thioridazine, chlorpromazine, haloperidol		
Antiparkinsonians	Trihexyphenidyl, benztropine mesylate		
Miscellaneous	Dicyclomine, disopyramide		
Skeletal muscle relaxants	Orphenadrine, cyclobenzaprine		
Tricyclic antidepressants	Amitriptyline, imipramine, nortriptyline, doxepin		
<b>ACE inhibitors</b>	Enalapril, captopril, lisinopril, losartan	Chronic cough	Urinary leakage
<b>Calcium-channel blockers</b>	Nifedipine, nicardipine, isradipine, felodipine	Relaxes bladder, fluid retention	Urinary retention, nocturnal diuresis
<b>COX-2 inhibitors</b>	Celecoxib	Fluid retention	Nocturnal diuresis
<b>Diuretics</b>	Caffeine, HCTZ, furosemide, bumetanide, acetazolamide, spironolactone	Increases urinary frequency, urgency	Polyuria
<b>Narcotic analgesics</b>	Opiates	Relaxes bladder, fecal impaction, sedation	Urinary retention, and/or functional incontinence
<b>Thiazolidinediones</b>	Rosiglitazone, pioglitazone, troglitazone	Fluid retention	Nocturnal diuresis

ACE = angiotensin-converting enzyme; COX-2 = cyclooxygenase-2; HCTZ = hydrochlorothiazide; IUS = internal urethral sphincter; NSAID = nonsteroidal antiinflammatory drug.

unable to completely empty their bladder due to urethral kinking and obstruction. These women frequently must digitally elevate or reduce their prolapse to allow emptying. Thus, an external evaluation for prolapse, as described in Chapter 24 (p. 548), is indicated for all women with urinary incontinence. Following this evaluation for vaginal compartment defects, pelvic muscle strength is also assessed. Women with mild to moderate urinary incontinence often respond well to pelvic floor therapy, and under these circumstances, a trial of this therapy is warranted and often curative (p. 528).

Lack of distal anterior vaginal wall support and resultant urethral hypermobility during increased intraabdominal pressure may help influence choice of surgical intervention in the patient reporting SUI. These patients commonly demonstrate relaxation and descent of the distal anterior vagina with resultant urethral hypermobility during increases in intraabdominal

pressures. In patients with descent to the level of the hymen or beyond with Valsalva, urethral hypermobility is universal (Noblett, 2005). In those with SUI and lesser anterior vaginal wall prolapse, a Q-tip test may provide a more objective assessment of urethral hypermobility. However, it has become a less essential part of pelvic floor assessment due to its poor predictive value for antiincontinence surgery success.

When performed, the soft end of a cotton swab is placed into the urethra to the urethrovesical junction. Failure to insert the swab to this depth can lead to assessment errors. An application of intraurethral analgesia may prove helpful, and 1-percent lidocaine jelly is placed on the cotton swab prior to insertion. Following placement, a Valsalva maneuver is prompted, and the swab-excursion angle at rest and with Valsalva maneuver is measured. An angle change or a resting angle > 30 degrees to the horizon suggests urethral hypermobility.

## Bimanual and Rectovaginal Examination

In general, these portions of the pelvic examination provide fewer diagnostic clues to underlying incontinence causes. However, bimanual examination may reveal a pelvic mass or a uterus enlarged by leiomyomas or adenomyosis. These can create incontinence through increased external pressure transmitted to the bladder. In addition, stool impaction is easily identified with rectal examination.

## ■ Diagnostic Testing

### Urinalysis and Culture

In all women with urinary incontinence, infection or urinary tract pathology must be excluded. Urinalysis and urine culture are sent at an initial visit, and infection is treated as described in Table 3-17 (p. 74). Persistent irritative voiding symptoms, despite appropriate antibiotic treatment, warrant additional evaluation for other conditions such as interstitial cystitis.

### Postvoid Residual Volume

This volume is routinely measured during incontinence evaluation. After a woman voids, the postvoid residual (PVR) volume may be measured by transurethral catheterization or with a handheld sonographic bladder scanner. The latter is a portable 3-dimensional ultrasound device that scans the bladder and provides numeric results (Fig. 23-12). In general, they are quick, easy to use, and more comfortable for the patient. However, if using a handheld scanner, care must be taken in women with a leiomyomatous uterus or other pelvic mass as these may lead to a false report of a large PVR. In these instances, or if a scanner is not available, transurethral catheterization may be used to confirm residual bladder volume.

A large PVR volume may often reflect one of several problems including recurrent infection, urethral obstruction from a

pelvic mass, or neurologic deficits. In contrast, a normally small PVR volume is often found in those with SUI. After continence surgery, PVR measurement is a helpful indicator of a patient's ability to completely empty her bladder. Postoperative PVR determination and voiding trials are described in Chapter 42 (p. 917).

### Urodynamic Studies

Surgical correction of incontinence is invasive and not without risk. However, the "bladder is an unreliable witness," and historical information may not always accurately indicate the true underlying type of incontinence (Blaivas, 1996). Thus, if initial conservative management is unsuccessful or surgical treatment is anticipated, then objective assessment is pursued. In addition, if symptoms and physical findings are incongruous, then objective *urodynamic studies (UDS)*, using simple or multichannel cystometrics, may also be indicated. For example, in a woman with mixed urinary incontinence, who has symptoms of both stress and urgency urinary incontinence, UDS may reveal that only the urgency component is responsible for her incontinence. These cases are treated with behavioral, physical, and/or pharmacologic therapy initially. Thus, if identified by UDS, these individuals can avoid unnecessary surgery. Additionally, surgical therapy may be modified if UDS reveals parameters consistent with ISD.

Despite these indications, UDS remains controversial. Leakage noted during testing is not always clinically relevant. In addition, testing may be uninformative if the original of ending maneuver or situation that led to incontinence cannot be reproduced during testing. Moreover, objective confirmation of the diagnosis is not always necessary, since empiric nonsurgical therapy in women with urgency-predominant symptoms is reasonable. Also, for women with stress-predominant urinary incontinence undergoing surgical treatment, outcomes were no different 1 year later in those screened by UDS compared with those evaluated by a simple office evaluation. The office testing included demonstrable leakage during examination, urine analysis without infection, and PVR < 150 mL (Nager, 2012).

**Simple Cystometrics.** Objective measurement of bladder function, that is, UDS, combines a battery of tests termed *cystometrics*, which may be *simple* or *multichannel*. Simple cystometrics allows determination of SUI and detrusor overactivity and measurement of first sensation, desire to void, and bladder capacity. This procedure is easily performed with room-temperature sterile normal saline, a 60-mL catheter-tipped syringe, and a urinary catheter, either Foley or Robnell. The urethra is sterilely prepared, the catheter is inserted, and the bladder is drained. A 60-mL syringe with its plunger removed is attached to the catheter and is filled upright with sterile water. Water is added in increments until a woman feels a sensation of bladder filling, urge to void, and bladder maximum capacity. A normal bladder capacity for most women ranges from 300 to 700 mL. Changes in the fluid meniscus within the syringe are monitored. In the absence of a cough or Valsalva maneuver that would raise intraabdominal pressure, an abrupt meniscus elevation indicates bladder contraction and suggests detrusor overactivity. Once bladder capacity is reached, the catheter

**FIGURE 23-12** Handheld bladder scanner aids estimation of bladder volume.

is removed, and the woman is asked to perform a Valsalva maneuver or cough while standing. Leakage directly linked to these increases in intraabdominal pressure indicates SUI.

Simple cystometrics require inexpensive equipment and can typically be completed by most gynecologists. One limitation, however, is its inability to assess for ISD, which may preclude certain surgical options. Multichannel cystometrics can evaluate for ISD and thus may offer advantages. An interesting potential application of simple cystometrics is in the evaluation of the *continent* patient planning surgery for prolapse. With 300 mL of saline instilled in the bladder and vaginal prolapse reduced with large cotton swabs, some patients will demonstrate leakage with cough or Valsalva—perhaps when standing if not seen supine. In these women with “potential” or “occult” SUI, some may consider a prophylactic continence procedure. Currently available decision-aid tools attempt to quantify the risk of this unmasked incontinence to help patients balance concomitant continence surgery benefits and risks (Jelovsek, 2014; Wei, 2012).

**Multichannel Cystometrics.** This UDS type provides more information on other physiologic bladder parameters than simple cystometrics. Multichannel cystometrics more commonly is performed by urogynecologists or urologists due to the expense and limited availability of needed equipment. Testing can be performed with a woman standing or seated upright in a specialized testing chair. During evaluation, two catheters are used. One is placed into the bladder and the other into either the vagina or rectum. The vagina is preferred unless advanced prolapse is evident, as stool in the rectal vault may obstruct catheter sensors and lead to inaccurate readings. Additionally, vaginal placement for most women is more comfortable. From each of these two catheters, distinct pressure readings are obtained or calculated. These include: (1) intraabdominal pressure, (2) vesicular pressure, (3) calculated detrusor pressure, (4) bladder volume, and (5) saline-infusion flow rate. As shown in [Figures 23-13](#) and [23-14](#), the various incontinence forms can be differentiated.

**Uroflowmetry.** Initially, women are asked to empty their bladder into a commode connected to a flowmeter (uroflowmetry). After a maximal flow rate is recorded, the patient is catheterized to measure postvoid residual volume and to ensure an empty bladder prior to further testing. This test provides information on a woman’s ability to empty her bladder and can identify women with urinary retention and other types of voiding dysfunction. Presuming that a patient begins with a comfortably full bladder of 200 mL or greater, most patients can empty their bladder over 15 to 20 seconds with flow rates  $> 20$  mL/sec. Maximum flow rates  $< 15$  mL/sec, with a voided volume  $> 200$  mL, are generally considered abnormally slow. In this setting—especially if accompanied by urinary retention—voiding dysfunction is identified. This may result from obstruction from a kinked urethra in the setting of anterior vaginal wall prolapse or postoperatively after creation of antiincontinence support that is too tight. As another example, voiding dysfunction may reflect neurologic dysfunction and poor detrusor contractility, as in those with longstanding poorly controlled diabetes.

**Cystometrography.** Following uroflowmetry, cystometrography is performed to determine whether a woman has urodynamic stress incontinence (USI) or detrusor overactivity (DO). Additionally, this test provides information on bladder threshold volumes at which a woman senses bladder capacity. Delayed sensation or sensation of bladder fullness only with large capacities may indicate neuropathy. Conversely, extreme bladder sensitivity may suggest sensory disorders such as interstitial cystitis.

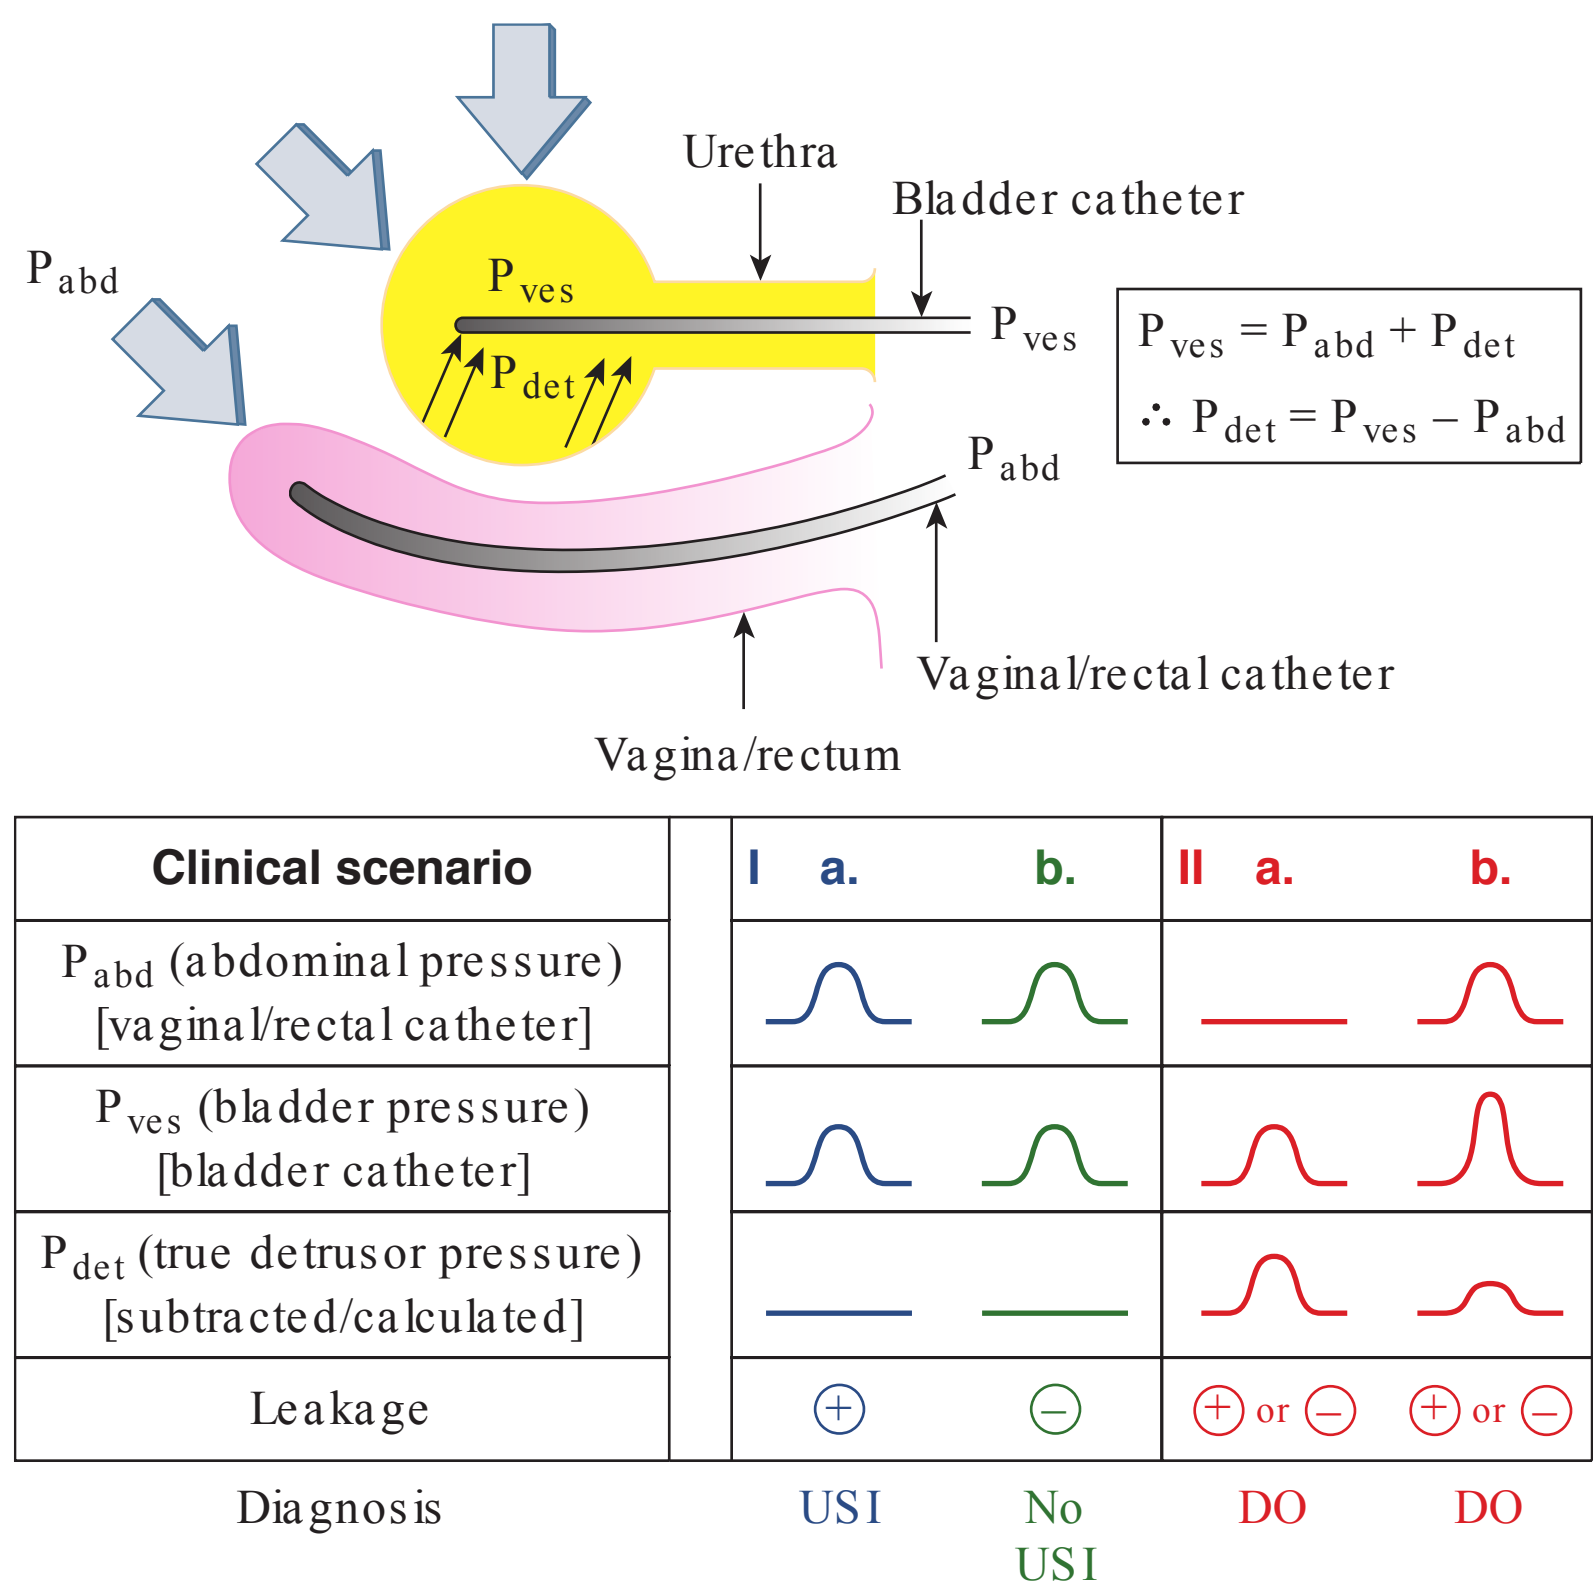

For the cystometrogram, a catheter is inserted transurethrally into the bladder and a second catheter is inserted into the vagina or rectum (see [Fig. 23-14](#)). While the patient is seated, the bladder is filled with room-temperature sterile normal saline, and the patient is asked to cough at regular intervals. Additionally, during filling, the volumes at which a first desire to void and maximal bladder capacity is reached are noted. From pressure readings, DO and/or USI may be identified.

After cystometrography, once approximately 200 mL of saline has been instilled, an abdominal *leak point pressure* is measured. The patient is asked to perform a Valsalva maneuver, and the pressure generated by the effort is measured and evidence of urine leakage is sought. If leakage is seen when a pressure of  $< 60$  cm H<sub>2</sub>O is generated, then criteria have been met for a diagnosis of ISD. At our institution, abdominal leak point pressures are measured at a bladder volume of 200 mL, using the true zero of intravesical pressure as the baseline. However, the volume at which this test is performed varies among institutions, with some choosing to use bladder capacity and others choosing to use 150 mL as the testing volume.

**Pressure Flowmetry.** This evaluation usually follows cystometrography and is similar to the uroflowmetry conducted at the beginning of urodynamic testing. A woman is asked to void into a large beaker that rests on a calibrated weighted sensor. Maximum flow rate and postvoid residual volume are once again recorded. Similar to uroflowmetry, the output from the urodynamics instrumentation provides a graphical representation of the void. However, during voiding, a woman now has a microtip transducer catheter in her bladder, which provides an additional display of detrusor pressure during the void, including pressures at the point of maximum flow rate. This is particularly useful in women who may have incomplete bladder emptying, as the pressure flowmetry may suggest either an obstructive scenario (elevated maximal detrusor pressure with slow flow rate) or poor detrusor contractility (low detrusor pressure and slow flow rate).

**Urethral Pressure Profile.** The final part of cystometric testing is the urethral pressure profile. At our institution, we usually perform this test in the seated patient with a volume of 200 mL instilled in the bladder. However, again, this volume is often institution dependent. A catheter transducer is positioned within the bladder, and the microtip dual-sensor catheter is pulled through the urethra with the aid of an automated puller arm at a speed of 1 mm/sec. Maximum urethral closure pressure (MUCP) is determined by averaging the pressure from three pull-throughs of the thin 7F catheter. As such, the MUCP values provide important information on the intrinsic properties of the urethra and aid in diagnosis of ISD. A diagnosis of ISD is made

**FIGURE 23-13** Interpretation of multichannel urodynamic evaluation: cystometrogram. A catheter is placed in the bladder to determine the pressure generated within it ( $P_{ves}$ ). The pressure in the bladder is produced from a combination of the pressure from the abdominal cavity and the pressure generated by the detrusor muscle of the bladder. Bladder pressure ( $P_{ves}$ ) = Pressure in abdominal cavity ( $P_{abd}$ ) + Detrusor pressure ( $P_{det}$ ). A second catheter is placed in the vagina (or rectum if advanced-stage prolapse is present) to determine the pressure in the abdominal cavity ( $P_{abd}$ ). As room temperature water is instilled into the bladder, the patient is asked to cough every 50 mL and the external urethral meatus is observed for leakage of urine around the catheter. The volume at first desire to void and the bladder capacity is recorded. Additionally, the detrusor pressure ( $P_{det}$ ) channel is observed for positive deflections to determine if there is detrusor activity during testing. The detrusor pressure ( $P_{det}$ ) cannot be measured directly by any of the catheters. However, from the first equation, we can calculate the detrusor pressure ( $P_{det}$ ) by subtracting the abdominal pressure ( $P_{abd}$ ) from the bladder pressure ( $P_{ves}$ ):

Detrusor pressure ( $P_{det}$ ) = Bladder pressure ( $P_{ves}$ ) – Pressure in abdominal cavity ( $P_{abd}$ )

**I. Urodynamic Stress Incontinence (USI)**

Urodynamic stress incontinence is diagnosed when urethral leakage is seen with increased abdominal pressure, in the absence of detrusor pressure.

- a. + USI (Column 1):** Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure ( $P_{ves}$ ) is noted. The calculated detrusor pressure is zero. Leakage is observed and diagnosis of USI is assigned.
- b. No USI (Column 2):** Abdominal pressure is generated with Valsalva maneuver or cough. This pressure is transmitted to the bladder and a bladder pressure ( $P_{ves}$ ) is noted. The calculated detrusor pressure is zero. Leakage is not observed. The patient is not diagnosed as having USI.

**II. Detrusor Overactivity (DO)**

Detrusor overactivity is diagnosed when the patient has involuntary detrusor contractions during testing with or without leakage.

- a. + DO (Column 3):** Although no abdominal pressure is observed, a vesicular pressure is noted. A calculated detrusor pressure is recorded and noted to be present. A diagnosis of DO is made regardless of whether leakage is seen or not.
- b. + DO (Column 4):** In this example, an abdominal pressure as well as a vesicular pressure is observed. Using only the  $P_{abd}$  and the  $P_{ves}$  channels, it is difficult to tell whether or not the detrusor muscle contributed to the pressure generated in the bladder. On subtraction, a calculated detrusor pressure is recorded. Thus, a diagnosis of DO is made, again regardless of whether leakage is seen or not.

In addition to these channels, occasionally a channel to detect electromyographic activity is used.

Flow rate = rate of fluid infusion (usually 100 mL/min);  $P_{abd}$  = pressure in abdominal cavity;  $P_{det}$  = detrusor pressure (calculated);  $P_{ves}$  = bladder pressure; Vol = volume of fluid instilled in the bladder.

if the MUCP is < 20 cm H<sub>2</sub>O or, as described in the last section, if the leak point pressure is < 60 cm H<sub>2</sub>O (McGuire, 1981). These terms and concepts provide the rationale for procedures aimed at correcting stress incontinence. Importantly, however, the values used to define ISD are not well standardized and have not been consistently found to influence surgical outcomes (Monga, 1997; Weber, 2001).

**TREATMENT**

**■ Conservative/Nonsurgical Pelvic Floor Strengthening**

Conservative management is a reasonable initial approach to most patients with urinary incontinence. The rationale behind

**FIGURE 23-14** Multichannel cystometrics. **A.** A patient with normal function. Note that provocation by coughing or Valsalva maneuver does not provoke an abnormal rise in detrusor pressure. **B.** A patient with combined detrusor overactivity and urodynamic stress incontinence. First, spontaneous detrusor activity leads to increased bladder pressure reading in the absence of cough or Valsalva maneuver. **C.** Second, a cough alone leads to urine leakage, independent of detrusor muscle activity. **D.** At maximum capacity and on command, a detrusor contraction is generated and voiding is initiated.

conservative management is to strengthen the pelvic floor and provide a supportive “backboard” against which the urethra may close. For both SUI and urgency urinary incontinence, these fundamentals prove valuable. With SUI, pelvic floor strengthening attempts to compensate for anatomic defects. For urgency urinary incontinence, it intensifies pelvic floor muscle contractions to provide temporary continence during waves of bladder detrusor contraction. For strengthening, options include active pelvic floor exercises and passive electrical pelvic floor muscle stimulation.

Active pelvic floor muscle training (PFMT) may lessen, if not cure, urinary incontinence in women who have mild to moderate symptoms. Also known as *Kegel exercises*, PFMT entails voluntary contraction of the levator ani muscles. As with any muscle building, isometric or isotonic forms of exercise may be selected. Exercise sets are performed numerous times during the day, with some reporting up to 50 or 60 times each day. However, specific details in performance of these exercises are subject to provider preference and clinical setting.

If isotonic contractions are used for PFMT, a woman is asked to squeeze and hold contracted levator ani muscles.

Women, however, often have difficulty isolating these muscles. Frequently, patients will erroneously contract their abdominal wall muscles rather than the levators. To help localize the correct group, an individual may be instructed to identify the muscles that are tightened when snug pants are pulled up and over her hips. Moreover, in an office setting, a provider can determine if the levator ani group is contracted by placing two fingers in the vagina while Kegel exercises are performed.

At our institution, we aim to help patients achieve a sustained pelvic floor contraction of 10 seconds. We begin with the contraction duration a patient can sustain (e.g., 3 seconds) and ask them to hold for this long and then relax for one to two times this duration (e.g., 6 seconds). The squeeze and release is repeated 10 to 15 times. Three sets are performed throughout the day for a total of approximately 45 contractions. Over a series of weeks with frequent follow-up visits, the contraction duration is steadily increased. Patients thus improve the tone of their pelvic floor muscles and are usually able to more forcefully squeeze their muscles in anticipation of sudden increases of intraabdominal pressure for SUI.

Alternatively, if isometric contractions are used for PFMT, a woman is asked to rapidly contract and relax the levator ani muscles. These “quick flicks” may prove advantageous if waves of urinary urgency strike. Of note, there is no value to stopping urination midstream, and women are counseled that this practice often worsens voiding dysfunction.

To augment exercise efficacy, weighted vaginal cones or obturators may be placed into the vagina during Kegel exercises. These provide resistance against which pelvic floor muscles can work.

PFMT for women with urinary incontinence compared with no treatment, placebo or sham treatment, or other inactive control treatment has been reviewed (Dumoulin, 2014a). Although interventions vary considerably, women who performed PFMT are more likely to report cure or improved incontinence and improved continence-specific quality of life than women who did not use PFMT. The exercising women also objectively demonstrated less leakage during office-based pad testing. Prognostic indicators that may predict a poor response to PFMT for SUI treatment include severe baseline incontinence, prolapse beyond the hymenal ring, prior failed physiotherapy, a history of prolonged second-stage labor, BMI  $> 30 \text{ kg/m}^2$ , high psychological distress, and poor overall physical health (Hendriks, 2010).

As an alternative to active pelvic floor contraction, a vaginal probe may be used to deliver low-frequency electrical stimulation to the levator ani muscles. Although the mechanism is unclear, this passive electrical stimulation may be used to improve either SUI or urgency urinary incontinence (Indrekvam, 2001; Wang, 2004). With urgency urinary incontinence, traditionally a low frequency is applied, whereas for SUI, higher frequencies are used. Electrical stimulation may be implemented alone or more commonly in combination with active PFMT.

Many behavioral techniques, often considered together as *biofeedback therapy*, measure physiologic signals such as muscle tension and then display them to a patient in real time. In general, visual, auditory, and/or verbal feedback cues are directed to the patient during these therapy sessions. Specifically, during biofeedback for active PFMT, a sterile vaginal probe that measures pressure changes within the vagina during levator ani muscle contraction is typically used. Visual readings reflect an estimate of muscle contraction strength. Treatment sessions are individualized, dictated by the underlying dysfunction, and modified based on response to therapy. In many cases, reinforcing sessions at various subsequent intervals may also prove advantageous.

### Dietary

Various food groups that may have high acidity or caffeine content can lead to greater urinary frequency and urgency. Dallosso and colleagues (2003) found consumption of carbonated drinks to be associated with development of urgency urinary incontinence symptoms. Accordingly, elimination of these dietary irritants may benefit these women. In addition, certain dietary supplements such as calcium glycerophosphate (Prelief) have been shown to decrease urgency and frequency symptoms (Bologna, 2001). This is a phosphate-based product and is thought to buffer urine acidity.

### Scheduled Voiding

Women with urgency urinary incontinence may feel voiding urges as frequently as every 10 to 15 minutes. Initial goals extend voidings to half-hour intervals. Tools used to achieve this include Kegel exercises during waves of urgency or mental distraction techniques during these times. Scheduled voiding, although used primarily for urgency urinary incontinence, may also be helpful for those with SUI. For these patients, regularly scheduled urination leads to an empty bladder during a greater percentage of the day. Because some women will leak urine only if bladder volumes surpass a specific threshold, frequent emptying can significantly decrease incontinence episodes.

### Estrogen Replacement

Estrogen has been shown to increase urethral blood flow and increase  $\alpha$ -adrenergic receptor sensitivity, thereby increasing urethral coaptation and urethral closure pressure. Hypothetically, estrogen may also increase collagen deposition and increase vascularity of the periurethral capillary plexus. These are purported to improve urethral coaptation. Thus, for incontinent women who are atrophic, administration of exogenous estrogen is reasonable.

Estrogen is commonly administered topically, and many different regimens are appropriate. At our institution, we use conjugated equine estrogen cream (Premarin cream) administered daily for 2 weeks, then twice weekly thereafter. Although no data are available to address the duration of treatment, women may be treated chronically with topical estrogen cream. Alternatively, oral estrogen may be prescribed if other menopausal symptoms for which estrogen would be beneficial coexist (Chap. 22, p. 494). However, despite these suggested benefits, a consensus regarding estrogen's beneficial effects on the lower urinary tract has not been reached. Specifically, some studies have shown worsening or development of urinary incontinence with systemic estrogen administration (Grady, 2001; Grodstein, 2004; Hendrix, 2005; Jackson, 2006).

### ■ Treatment of Stress Urinary Incontinence Medications

Pharmaceutical treatment plays a minor role in the treatment of women with SUI. However, for women with mixed urinary incontinence, a trial of imipramine is reasonable to aid urethral contraction and closure. As discussed earlier, this tricyclic antidepressant has  $\alpha$ -adrenergic effects, and the urethra contains a high content of these receptors.

### Pessary and Urethral Inserts

Certain pessaries have been designed to treat incontinence as well as pelvic organ prolapse. These “incontinence pessaries” are designed to reduce downward excursion or funneling of the urethrovesical junction (Fig. 24-16, p. 551). This provides bladder neck support and thereby helps to reduce incontinence episodes. The success of pessary use in the treatment of urinary incontinence is variable, dependent on the amount of prolapse and other factors. Not all women are appropriate candidates for devices, nor will all desire long-term management of incontinence or prolapse with these.

**TABLE 23-4.** Summary of Incontinence Procedures

Procedure	Description	Indication	Comments
Midurethral slings:	Midurethra supported by mesh placed:		Effective short-term treatment, rapid post-operative recovery; TVT with long-term efficacy data; further study required to determine effectiveness of TOT in patients with ISD
TVT	by retropubic approach	SUI; ISD	
TOT	by transobturator approach	SUI	
Retropubic urethropexy	Pubocervical fascia attached to: Cooper ligament (Burch) or symphysis pubis (MMK)	SUI	Effective long-term treatment; requires surgeon experience; less reproducible benefits than midurethral sling procedure
Pubovaginal slings	Bladder neck supported by fascial strip attached to anterior abdominal wall	ISD; failed SUI procedure	Effective long-term treatment; may be useful when synthetic material is not desirable; requires graft isolation
Urethral injection	Bulking agent into urethral submucosa	ISD	Also for SUI in poor surgical candidates; may require several repeated injections
Needle suspension	Proximal urethra suspended by anterior abdominal wall	SUI	Low long-term success rates; no longer recommended for SUI
Paravaginal defect repair	Lateral vaginal wall attached to ATFP	Vaginal prolapse	No longer recommended for SUI

ATFP = arcus tendineus fascia pelvis; ISD = intrinsic sphincteric deficiency; MMK = Marshall-Marchetti-Krantz procedure; SUI = stress urinary incontinence; TOT = transobturator tape; TVT = tension-free vaginal tape.

A large prospective trial comparing incontinence pessaries and behavioral therapy for women with SUI demonstrated that 40 and 49 percent of patients were either much or very much improved at 3 months, respectively. The women randomized to behavioral therapy reported greater treatment satisfaction, and a greater percentage reported no bothersome incontinence symptoms (Richter, 2010b).

As an alternative to pessaries, urethral occlusive devices include *urethral inserts* (FemSoft and Reliance Urinary Control Insert) and *urethral patches* (CapSure and Re/Stor). Urethral inserts conform to the urethra and create a seal at the bladder neck to prevent accidental leakage. During routine bathroom visits, the insert is removed, discarded, and replaced with a fresh insert. Although data are limited on the effectiveness of inserts, adverse effects of mucosal irritation or superficial bacterial infection are generally minor. In an observational study of 150 women, Sirls and associates (2002) found significantly reduced rates of incontinence episodes with the FemSoft device. With urethral patches, a water-tight seal is created over the urethra after the patch adheres to surrounding periurethral skin using adhesive gel. Similarly, although success rates vary between 44 and 97 percent, these devices are associated with minimal adverse effects (Bellin, 1998; Versi, 1998).

## Surgery

For those who are unsatisfied with or do not desire conservative management, surgery may be an appropriate next step for SUI. As noted earlier, urethral support is integral to continence. Thus, surgical procedures that recreate this support often diminish or cure incontinence. In general, these surgical procedures are believed to prevent bladder neck and proximal urethra descent during increases in intraabdominal pressure

and are grouped as shown in Table 23-4. General postoperative risks for continence surgeries include lower urinary tract injury, failure to correct or recurrence of SUI, and creation of de novo voiding dysfunction such as urgency or retention.

**Midurethral Slings.** The therapeutic mechanism of these slings is based on the integral theory hypothesized by Petros and Ulmsten (1993). In brief, control of urethral closure involves the interplay of three structures: the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. Loss of these supports lead to urinary incontinence and pelvic floor dysfunction. Midurethral slings are believed to recreate this structural support.

There are different variations of these procedures, but all use a vaginal approach to place synthetic mesh beneath the midurethra. Recovery from midurethral sling placement is rapid, and many gynecologists provide this surgery on an outpatient basis. As such, these are often a popular surgical treatment for SUI. Simplistically, they are classified according to the route of placement and are subdivided into those using a retropubic or a transobturator approach.

For the retropubic approach, several commercial kits are available, and one commonly used is the tension-free vaginal tape (TVT). With this, the sling (tape) is placed through a vaginal incision to create a hammock beneath the urethra. On each side of the urethra, the sling's arms are brought out to the lower anterior abdominal wall and affixed. For this procedure, sharp trocars traverse the retropubic space as illustrated in Section 45-3 of the atlas (p. 1063). Thus, bladder puncture and retropubic space vessel laceration are specific risks. Many studies attest to this procedure's efficacy (Holmgren, 2005; Song, 2009). One prospective observational study confirmed the

long-term safety and efficacy of the TVT device. At 17 years, 87 percent were subjectively cured or significantly improved (Nilsson, 2013).

For the transobturator tape (TOT) approach, various kits are also available, and sling material is directed bilaterally through the obturator foramen and underneath the midurethra. The entry point overlies the proximal tendon of the adductor longus muscle of the inner thigh as shown in Section 45-4 (p. 1066). This approach was introduced with the intent to reduce the vascular and lower urinary tract injury risks that can be associated with traversing the retropubic space.

The TOT is indicated for primary SUI secondary to urethral hypermobility (p. 525). For this, subjective success rates range from 73 to 92 percent up to 5 years after surgery (Abdel-Fattah, 2012; Laurikainen, 2014; Wai, 2013). However, abundant longer-term data regarding the efficacy of transobturator approaches are lacking. Moreover, in patients with SUI secondary to ISD, the value of TOT is unclear as results are conflicting and data are limited (Miller, 2006; O'Connor, 2006; Richter, 2010a).

In comparing these two, one multicenter randomized study of 597 found no significant differences in objective and subjective success rates at 12 months between the retropubic (80.8 and 62.2 percent) and the transobturator (77.7 and 55.8 percent) routes, respectively (Richter, 2010a). The retropubic route had a significantly higher rate of postoperative voiding dysfunction requiring reoperation, whereas the transobturator route resulted in more neurologic symptoms. Overall quality of life and satisfaction scores with the two procedures were similar. Others have found similar findings with respect to procedure-related complications. Namely, the retropubic route has a higher rate of bladder injury but required a decreased use of anticholinergic medication postoperatively (Barber, 2006; Brubaker, 2011).

Modification of the TVT and TOT procedure is seen with the minimally invasive slings, sometimes called “microslings” or “minislings.” With this technique, an 8-cm-long strip of polypropylene synthetic mesh is placed across and beneath the midurethra through a small vaginal incision. Mesh is not threaded through the retropubic space as with TVT, nor does it perforate the obturator membrane as with TOT. That said, lower urinary tract injury is not completely averted with this method. Initial results for the minislings suggested high objective and subjective cure rates (Neuman, 2008). However, in one study, the minisling group had a higher proportion of patients with more severe incontinence 1 year after surgery than those in the retropubic sling group (Barber, 2012).

In March 2013, the FDA issued an update regarding considerations about surgical mesh for SUI. In that statement, the established safety and efficacy of mesh sling procedures for the treatment of SUI were upheld for full-length multiincision operations. They further noted that the safety and effectiveness of minislings had not yet been adequately demonstrated.

**Retropubic Urethropexy.** This group includes the Burch and Marshall-Marchetti-Krantz (MMK) colposuspension procedures. Traditionally performed via laparotomy, these suspend and anchor the pubocervical fascia to the musculoskeletal framework of the pelvis (Section 45-2, p. 1061). With the advent of

less invasive procedures for SUI, such as the midurethral sling, these techniques are less commonly performed. The Burch technique uses the strength of the iliopectineal ligament (Cooper ligament) to lift the anterior vaginal wall and the periurethral and perivesicular fibromuscular tissue. In contrast, during MMK surgery, the periosteum of the symphysis pubis is used to suspend these tissues. Thus, an added risk for MMK is osteitis pubis.

Retropubic urethropexy effectively treats SUI. One-year overall continence rates range between 85 and 90 percent, and the 5-year continence rate approximates 70 percent (Lapitan, 2009). As another indication, data suggest that Burch retropubic urethropexy performed concurrently with abdominal sacrocolpopexy (ASC) may significantly reduce rates of later, postoperative de novo SUI (Chap. 24, p. 557) (Brubaker, 2008a). In support of this practice, a 7-year follow-up study showed that patients undergoing ASC and prophylactic Burch urethropexy still demonstrated lower de novo SUI rates than women receiving ASC alone (Nygaard, 2013).

**Pubovaginal Slings.** With this surgery, a strip of either rectus fascia or fascia lata is placed under the bladder neck and through the retropubic space. The ends are secured at the level of the rectus abdominis fascia (Section 45-5, p. 1068). This surgery has traditionally been used for SUI stemming from ISD. In addition, this procedure may also be indicated for patients with prior failed continence operations.

**Urethral Bulking Agent Injection.** Using cystoscopic guidance, agents can be injected into the urethral submucosa to “bulk up” the mucosa and improve coaptation. Surgical steps and agent types are illustrated in Section 45-6 (p. 1070). This option has traditionally been indicated for women who have stress incontinence associated with ISD. However, the Food and Drug Administration (FDA) has broadened criteria for their use to include patients with less severe leak point pressures. Thus, those with leak point pressures < 100 cm H<sub>2</sub>O may also be candidates (McGuire, 2006). Additionally, this office procedure is a useful alternative for women with SUI who have multiple medical problems and are thus poor surgical candidates.

**Transvaginal Needle Procedures and Paravaginal Defect Repair.** In the 1960s through 1980s, needle suspension procedures such as the Raz, Pereyra, and Stamey techniques were popular operations for SUI but have now largely been replaced by other methods. In brief, these surgeries use specially designed ligature carriers to place sutures through the anterior vaginal wall and/or periurethral tissues and suspend them to various levels of the anterior abdominal wall. These rely on the strength and integrity of the periurethral tissue and abdominal wall strength to correct urethral hypermobility and prevent bladder neck and proximal urethra descent. Although initial cure rates are satisfactory, the durability of these procedures decreases with time. Success rates range from 50 to 60 percent, well below rates found with other current continence procedures (Moser, 2006). Failure stemmed largely from “pull-through” of sutures at the level of the anterior vaginal wall.

In addition, abdominal paravaginal defect repair (PVDR) is a surgical procedure that corrects lateral support defects of the

**TABLE 23-5.** Pharmacologic Treatment of Overactive Bladder

Drug Name	Brand Name	Drug Type	Dosage <sup>a</sup>	Available Doses
Oxybutynin (short-acting)	Ditropan	Antimuscarinic	2.5–5 mg three times daily	5-mg tablet, 5 mg/mL syrup
Oxybutynin (long-acting)	Ditropan XL	See above	5–30 mg daily	5-, 10-, 15-mg tablet
Oxybutynin (transdermal)	Oxytrol	See above	3.9 mg/d; change patch twice weekly	36-mg patch, 8 per carton
Oxybutynin (transdermal) 10% gel	Gelnique	See above	Apply 1 g daily	1-g packet, 30 per carton
3% gel			Apply 3 pumps daily	30 doses per bottle
Tolterodine (short-acting)	Detrol	See above	1–2 mg twice daily	1-, 2-mg tablet
Tolterodine (long-acting)	Detrol LA	See above	2–4 mg daily	2-, 4-mg capsule
Fesoterodine fumarate	Toviaz	See above	4–8 mg daily	4-, 8-mg tablets
Trospium chloride	Sanctura	Antimuscarinic quaternary amine	20 mg twice daily	20-mg tablet
Trospium chloride	Sanctura XR	See above	60 mg daily	60-mg tablet
Darifenacin	Enablex	M <sub>3</sub> -selective antimuscarinic	7.5–15 mg daily	7.5-, 15-mg tablet
Solifenacin	Vesicare	M <sub>3</sub> -selective antimuscarinic	5–10 mg daily	5-, 10-mg tablets
Imipramine hydrochloride	Tofranil	Tricyclic antidepressant, anticholinergic, $\alpha$ -adrenergic, antihistamine	10–25 mg one to four times daily. Begin with 10–25 mg nightly.	10-, 25-, 50-mg tablets
Mirabegron	Myrbetriq	$\beta_3$ adrenergic agonist	25–50 mg daily	25-, 50-mg tablets

<sup>a</sup>Oral dosing except for transdermal forms.

anterior vaginal wall. The technique involves suture attachment of the lateral vaginal wall to the arcus tendineus fascia pelvis. Currently, PVDR is primarily a prolapse-correcting operation. Although previously used to correct SUI, long-term data show this to no longer be a superior method for primary treatment of SUI (Colombo, 1996; Mallipeddi, 2001).

### ■ Treatment of Urgency Urinary Incontinence

#### Anticholinergic Medications

These medications appear to work at the level of the detrusor muscle by competitively inhibiting acetylcholine at muscarinic receptors (M<sub>2</sub> and M<sub>3</sub>) (Miller, 2005). These agents thereby blunt detrusor contractions to reduce the number of incontinence episodes and volume lost with each. These medications are significantly better than placebo at improving symptoms of urgency urinary incontinence and overactive bladder. However, in a Cochrane database review, Nabi and colleagues (2006) reported that the reduction in baseline urgency incontinence episodes per day reflects only a modest benefit.

**Oxybutynin, Tolterodine, and Fesoterodine.** These frequently used drugs competitively bind to cholinergic receptors (Table 23-5). As noted, muscarinic receptors are not limited

to the bladder. Thus, drug side effects may be significant. Of these, dry mouth, constipation, and blurry vision are common, and dry mouth is a primary reason for drug discontinuation (Table 23-6). Importantly, anticholinergics are contraindicated in those with narrow-angle glaucoma.

Because of these side effects, the therapeutic goal of bladder M<sub>3</sub> blockade with these antimuscarinic agents is often

**TABLE 23-6.** Potential Anticholinergic Side Effects

Side Effect	Potential Clinical Consequence
Increased pupil size	Photophobia
Decreased visual accommodation	Blurred vision
Decreased salivation	Gingival and buccal ulceration
Decreased bronchial secretions	Small-airway mucus plugging
Decreased sweating	Hyperthermia
Increased heart rate	Angina, myocardial infarction
Decreased detrusor function	Bladder distention and urinary retention
Decreased gastrointestinal mobility	Constipation

limited. Accordingly, drug selection is tailored, and efficacy is balanced against tolerability. For example, Diokno and associates (2003) found oxybutynin to be more effective than tolterodine. However, tolterodine was associated with lower side effect rates. Tolterodine and fesoterodine have also been compared in a randomized study of 1135 patients. Fesoterodine was found to perform better than tolterodine, although once again, side effects were lowest in the tolterodine group (Chapple, 2008). A population-based study reported that only 56 percent of women felt their overactive bladder medication was effective, and half stopped taking the medication (Diokno, 2006).

Most side effects attributed to oxybutynin stem from its secondary metabolite that follows liver metabolism. Therefore, to minimize oral oxybutynin side effects, a transdermal patch was designed to decrease the “first-pass” effect of this drug. This leads to decreased liver metabolism and fewer systemic cholinergic side effects. Dmochowski and coworkers (2003) found fewer anticholinergic side effects with transdermal oxybutynin compared with long-acting oral tolterodine.

Transdermal oxybutynin (Oxytrol) is supplied as a  $7.6 \times 5.7$  cm patch that is applied to the abdomen, hip, or buttock; worn continuously; and changed twice weekly. Each patch contains 36 mg of oxybutynin and delivers approximately 3.9 mg daily. Application-site pruritus is the most frequent side effect, and varying the application site may minimize skin reactions (Sand, 2007). A transdermal oxybutynin gel (Gelnique), available in 3- and 10-percent strengths, is applied daily to skin of the abdomen, upper arms/shoulders, or thigh, and application sites are rotated.

**Imipramine.** This agent is less effective than tolterodine and oxybutynin but displays  $\alpha$ -adrenergic and anticholinergic characteristics. Therefore, it is occasionally prescribed for those with mixed urinary incontinence. Importantly, doses of imipramine used to treat incontinence are significantly lower than those used to treat depression or chronic pain. In our experience, this minimizes the theoretical risk of drug-related side effects.

**Selective Muscarinic-receptor Antagonists.** These drugs were introduced with the aim of reducing anticholinergic side effects. These agents are all  $M_3$ -receptor selective antagonists and include solifenacin (Vesicare), trospium chloride (Santura), and darifenacin (Enblex). Advantages of increased urgency warning time and decreased muscarinic side effects have been shown in randomized controlled studies (Cardozo, 2004; Chapple, 2005; Haab, 2006; Zinner, 2004). However, although the side-effect profiles of these drugs are potentially more attractive, they have not been proved superior in efficacy to nonselective muscarinic agents (Hartmann, 2009).

### Mirabegron

More recently, a  $\beta_3$ -adrenergic receptor agonist, mirabegron (Myrbetriq), has been introduced into the U.S. pharmaceutical market for the treatment of urgency urinary incontinence, urgency, and frequency. Activation of these receptors results in relaxation of the detrusor smooth muscle and increased bladder capacity. Most commonly reported adverse reactions include

hypertension, nasopharyngitis, UTIs, dry mouth, and headache (Herschorn, 2013).

### Sacral Neuromodulation

Urine storage and bladder emptying require a complex coordinated interaction of spinal cord and higher brain centers, peripheral nerves, urethral and pelvic floor muscles, and the detrusor muscle. If any of these levels are altered, normal micturition is lost. To overcome these problems, electrical nerve stimulation, also called neuromodulation, has been used. InterStim is the only implantable neuromodulation system approved by the FDA for treatment of refractory urgency urinary incontinence and for treatment of anal incontinence. It may be also considered for those with pelvic pain, interstitial cystitis, and defecatory dysfunction, although it is not FDA-approved for these indications. Sacral neuromodulation is not considered primary therapy and is typically offered mainly to women who have exhausted pharmacologic and conservative options.

This outpatient surgically implanted device contains a pulse generator and electrical leads that are placed into the sacral foramina to modulate bladder and pelvic floor innervation. Its mode of action is incompletely understood but may be related to somatic afferent inhibition that interrupts abnormal reflex arcs in the sacral spinal cord involved in the filling and evacuation phases of micturition.

Implantation is typically a two-stage process. Initially, leads are placed and attached to an externally worn generator (Section 45-12, p. 1085). After placement, frequency and amplitude of electrical impulses can be adjusted and tailored to maximize effectiveness. If a 50-percent or greater improvement in symptoms is noted, then internal implantation of a permanent pulse generator is planned. This procedure is minimally invasive and is typically completed in a day-surgery setting. Surgical complications are rare but may include pain or infection at the generator insertion site.

Although its use is often reserved for those who have been unsuccessfully treated with behavioral or pharmacologic therapy, this modality is effective for urinary symptom treatment. Studies have found improvement rates ranging from 60 to 75 percent, and cure rates approximating 45 percent (Janknegt, 2001; Schmidt, 1999; Siegel, 2000). Sustained improvement from baseline incontinence parameters has been shown at long-term follow-up. One 3-year study reported a 57-percent reduction in incontinence episodes per day, and similar findings were found in a separate 5-year study (Kerrebroeck, 2007; Siegel, 2000). A systematic review of 17 case series at follow-up periods of 3 to 5 years similarly reported 39 percent of patients cured and 67 percent with greater than 50-percent improvement in incontinence symptoms (Brazzelli, 2006).

### Percutaneous Tibial Nerve Stimulation

Sometimes referred to as posterior tibial nerve stimulation, percutaneous tibial nerve stimulation (PTNS) is becoming a more common therapy for refractory urgency urinary incontinence. It involves percutaneous needle electrode placement into an area cephalic to the medial malleolus of the lower extremity. Electrical pulses are sent via a generator to the tibial nerve. This nerve originates from spinal roots L4-S3, and its stimulation

leads to retrograde neuromodulation. Multicenter studies have demonstrated its efficacy compared with sham or with primary treatment with anticholinergic medication (Peters, 2009, 2010; MacDiarmid, 2010).

### Botulinum Toxin A

Injection of botulinum toxin A (onabotulinumtoxinA) into the bladder wall is approved for the treatment of idiopathic detrusor overactivity. Three placebo-controlled studies showed the effectiveness of this treatment (Anger, 2010). All three used cystoscopic injection of 200 units of botulinum toxin A versus placebo, and each demonstrated significantly improved continence rates. Improvement occurred as early as 4 weeks after injection (Brubaker, 2008b; Flynn, 2009; Khan, 2010; Sahai, 2007). Urinary retention—defined as a postvoid residual volume measuring > 200 mL—is a common side effect and developed in 27 to 43 percent of patients in these randomized trials. Most patients are asymptomatic, but patients receiving botulinum toxin A for overactive bladder or urgency urinary incontinence are counseled that temporary self-catheterization may be required after injection.

More recently, one double-blind, randomized trial compared oral anticholinergic therapy against injections of 100 units of botulinum toxin A in women with idiopathic urgency urinary incontinence. Investigators found comparable reductions in incontinence episodes. The botulinum toxin A group was less likely to complain of dry mouth and more likely to have complete resolution of urgency urinary incontinence (Visco, 2012). In the injection group, the rate of catheter use for urinary retention was only 5 percent. At our institution, we use 100 units for women with idiopathic overactive bladder.

A patient can expect the effects of the toxin to wane over time. In a small study describing the need for repeat injections, 20 patients from a cohort of 34 received a second injection, and nine patients received up to four injections. These repeat injections appear to be equally effective as the primary injection. Median time between injections is approximately 377 days (Sahai, 2010).

REFERENCES . . . . . 558

Pelvic organ prolapse is a common condition that can lead to genital tract dysfunction and diminished quality of life. *Signs* include descent of one or more of the following: the anterior vaginal wall, posterior vaginal wall, uterus and cervix, vaginal apex, or the perineum (Haylen, 2010). *Symptoms* include vaginal bulging, pelvic pressure, and splinting or digitation. Splinting is manual bolstering of the prolapse to improve symptoms, whereas digitation aids stool evacuation. For pelvic organ prolapse to be considered a disease state in a given individual, symptoms should be attributable to pelvic organ descent such that surgical or nonsurgical reduction relieves the symptoms, restores function, and improves quality of life.

EPIDEMIOLOGY

Pelvic organ prolapse (POP) affects millions of women worldwide. In the United States, it is the third most common indication for hysterectomy. Moreover, a woman has an estimated cumulative lifetime risk of 12 percent to undergo surgery for POP (Wu, 2014). Estimates of disease prevalence are hampered by lack of consistent definitions. If the validated Pelvic Organ Prolapse Quantification examination alone is used to describe pelvic organ support, 30 to 65 percent of women presenting for routine gynecologic care have stage 2 prolapse (Bland, 1999; Swift, 2000, 2005; Trowbridge, 2008). In contrast, studies that define prolapse solely based on patient symptoms show a prevalence ranging from 3 to 6 percent in the United States (Bradley, 2005; Nygaard, 2008; Rortveit, 2007).

RISK FACTORS

■ Obstetric-related Risks

Table 24-1 summarizes predisposing factors for POP. It develops gradually over a span of years, and its etiology is multifactorial. The relative importance, however, of each factor is not known.

Of these, vaginal childbirth is the most frequently cited risk factor. Some evidence suggests that pregnancy itself predisposes to POP. But numerous studies have clearly shown that vaginal delivery increases a woman’s propensity for developing POP. In the Pelvic Organ Support Study (POSST), increasing parity was associated with prolapse risk (Swift, 2005). Specifically, the risk of POP increased 1.2 times with each vaginal delivery. In the Reproductive Risks for Incontinence Study at Kaiser (RRISK) study, Rortveit and colleagues (2007) found that the prolapse risk increased significantly in woman with one vaginal delivery (odds ratio [OR] 2.8), two (OR 4.1), or three or more (OR 5.3) deliveries compared with nulliparas. In a longitudinal study of 1011 women, vaginal delivery was associated with a significantly greater risk of prolapse to the hymen or beyond compared with cesarean delivery without labor (OR 5.6) (Handa, 2011).

Although vaginal delivery is implicated in a woman’s lifetime risk for POP, specific obstetric risk factors remain controversial. These include macrosomia, prolonged second-stage labor, episiotomy, anal sphincter laceration, epidural analgesia, forceps use, and oxytocin stimulation of labor. Each is a proposed risk factor. As we await further studies, we can anticipate that although each may have an important effect, it is the cumulative sum of all events occurring as the fetus traverses the birth canal that predisposes to POP.

Currently, two obstetric interventions—elective forceps delivery to shorten second-stage labor and elective episiotomy—are not advocated. Both lack evidence of benefit and carry risks for maternal and fetal harm. First, forceps delivery is directly implicated in pelvic floor injury through its association with anal sphincter laceration. Additionally, recent evidence shows that operative vaginal birth significantly increases the odds for all pelvic floor disorders, especially prolapse (OR 7.5) (Handa, 2011). For these reasons, elective forceps delivery is not recommended to prevent pelvic floor disorders and may be a contributing factor. Likewise, at least six randomized controlled trials (RCTs) comparing elective and selective episiotomy have shown no proven benefit. These studies have shown an association with anal sphincter laceration, postpartum anal incontinence, and postpartum pain (Carroli, 2009).

Elective cesarean delivery to prevent pelvic floor disorders such as POP and urinary incontinence is controversial.

**TABLE 24-1.** Risk Factors Associated with Pelvic Organ Prolapse

Pregnancy
Vaginal childbirth
Menopause
Aging
Hypoestrogenism
Chronically increased intraabdominal pressure
Chronic obstructive pulmonary disease
Constipation
Obesity
Pelvic floor trauma
Genetic factors
Race
Connective tissue disorders
Spina bifida

Theoretically, if all women underwent cesarean delivery, fewer women would have pelvic floor disorders. Keeping in mind that most women do *not* have these disorders, cesarean delivery on maternal request (CDMR) would subject many women to a potentially dangerous intervention who would otherwise not develop the problem. Specifically, given the 12-percent lifetime risk of undergoing surgery for prolapse, for every one woman who would avoid pelvic floor surgery later in life by undergoing primary elective cesarean delivery, approximately nine women would gain no benefit yet would nevertheless assume the potential risks of cesarean delivery. Definitive recommendations will require further studies to define the potential risks and benefits of CDMR for primary prevention of pelvic floor dysfunction (American College of Obstetricians and Gynecologists, 2013b; Patel, 2006). Currently, decisions regarding CDMR to prevent pelvic floor disorders must be individualized. That said, the American College of Obstetricians and Gynecologists (2013a) recommends against CDMR for women desiring several children given the risk of abnormal placentation with accruing cesarean deliveries.

■ **Age**

Data from several studies show that POP prevalence increases steadily with age (Nygaard, 2008; Olsen, 1997; Swift, 2005). In the POSST study, in women aged 20 to 59 years, the incidence of POP roughly doubled with each decade. As with other risks for POP, aging is a complex process. The increased incidence may result from physiologic aging and degenerative processes and from hypoestrogenism. Research clearly demonstrates an important role for reproductive hormones in the maintenance of connective tissues and the extracellular matrix necessary for pelvic organ support. Estrogen and progesterone receptors have been identified in the nuclei of connective tissue and smooth muscle cells of both the levator ani stroma and uterosacral ligaments (Smith, 1990, 1993). Separating the effects of estrogen deprivation from the effects of the aging process is problematic.

■ **Connective Tissue Disease**

Women with connective tissue disorders may be more likely to develop POP. Histologic studies have shown that in women with POP, the ratio of collagen I to collagen III and IV is decreased (Moalli, 2004). The relative decline in well-organized dense collagen is believed to contribute to weakening of vaginal wall tensile strength and an increased susceptibility to vaginal wall prolapse. In a small case series study, one third of women with Marfan syndrome and three fourths of women with Ehlers-Danlos syndrome reported a history of POP (Carley, 2000).

■ **Race**

Racial differences in POP prevalence have been demonstrated in several studies (Schaffer, 2005). Black and Asian women show the lowest risk, whereas Hispanic and white women appear to have the highest risk (Hendrix, 2002; Kim, 2005; Whitcomb, 2009). Although differences in collagen content have been demonstrated between races, racial differences in the bony pelvis may also play a role. For instance, black women more commonly have a narrow pubic arch and an android or anthropoid pelvis. These shapes are protective against POP compared with the gynecoid pelvis typical of most white women.

In addition, emerging evidence suggests that POP may have a genetic component. Recent genome-wide linkage studies have identified specific predisposition genes that may contribute to POP (Allen-Brady, 2015).

■ **Increased Abdominal Pressure**

Chronically elevated intraabdominal pressure is believed to play a role in POP pathogenesis. Elevated pressures are present with obesity, chronic constipation, chronic coughing, and repetitive heavy lifting. Higher body mass index (BMI) correlates with POP risk. In the Women’s Health Initiative (WHI) trial, being overweight (BMI 25 to 30 kg/m<sup>2</sup>) increased the POP rate by 31 to 39 percent, and obesity (BMI > 30 kg/m<sup>2</sup>) raised the POP rate 40 to 75 percent (Hendrix, 2002). With regard to lifting, a Danish study demonstrated that nursing assistants who were involved with repetitive heavy lifting were at increased risk to undergo surgical intervention for prolapse (OR 1.6) (Jorgensen, 1994). In addition, cigarette smoking and chronic obstructive pulmonary disease (COPD) have also been implicated in POP development (Gilpin, 1989; Olsen, 1997). In a matched case-control study, COPD was associated with an increased risk of future pelvic floor repair after hysterectomy (Blandon, 2009). The repetitive increases in intraabdominal pressure resulting from chronic coughing may predispose to POP. Instead, some believe that the inhaled chemical compounds in tobacco may cause tissue changes that lead to POP rather than the chronic cough itself (Wieslander, 2005).

**DESCRIPTION AND CLASSIFICATION**

■ **Visual Descriptors**

Pelvic organ prolapse is descent of the anterior vaginal wall, posterior vaginal wall, uterus (cervix), the vaginal apex after

hysterectomy, rectum, or the perineum, alone or in combination. The terms *cystocele*, *cystourethrocele*, *uterine prolapse*, *uterine procidentia*, *rectocele*, and *enterocele* have traditionally been used to describe the structures behind the vaginal wall thought to be prolapsed (Fig. 24-1). However, these terms are imprecise and misleading, as they focus on what is presumed to be prolapsed rather than what is objectively noted to be prolapsed.

Although these terms are deeply entrenched in the literature, it is more clinically useful to describe prolapse in terms of what one actually sees: anterior vaginal wall prolapse, apical prolapse, cervical prolapse, posterior vaginal wall prolapse, rectal prolapse, or perineal descent.

### ■ Pelvic Organ Prolapse Quantification (POP-Q)

In 1996, the International Continence Society defined a system of Pelvic Organ Prolapse Quantification (POP-Q) (Bump, 1996). Demonstrating high intra- and interexaminer reliability, the POP-Q system allows clinicians and researchers to report findings in a standardized, easily reproducible fashion. This system contains a series of site-specific measurements of a woman's pelvic organ support. Prolapse in each segment is measured relative to the hymen, which is an anatomic landmark that can be identified consistently. Six points are located with reference to the plane of the hymen: two on the anterior vaginal wall (points Aa and Ba), two at the apical vagina (points C and D), and two on the posterior vaginal wall (points Ap and Bp) (Fig. 24-2). The genital hiatus (Gh), perineal body (Pb), and total vaginal length (TVL) are also measured. All POP-Q points, except TVL, are measured during patient Valsalva and should reflect maximum protrusion.

#### Anterior Vaginal Wall Points

*Point Aa* defines a point that lies in the midline of the anterior vaginal wall and is 3 cm proximal to the external urethral meatus. This corresponds to the proximal location of the urethrovesical crease. In relation to the hymen, this point's position ranges from  $-3$  (normal support) to  $+3$  cm (maximum prolapse of point Aa).

*Point Ba* represents the most distal position of any part of the upper anterior vaginal wall, that is, the segment of vagina that normally would extend cephalad from point Aa. It is  $-3$  cm in the absence of prolapse. In a woman with total vaginal eversion posthysterectomy, Ba would have a positive value equal to the position of the cuff from the hymen.

#### Apical Vaginal Points

The two apical points, C and D, which are located in the proximal vagina, represent the most cephalad locations of a normally positioned lower reproductive tract. *Point C* defines a point that is at either the most distal edge of the cervix or the leading edge of the vaginal cuff after total hysterectomy.

*Point D* defines a point that represents the location of the posterior fornix in a woman who still has a cervix. It is omitted in the absence of a cervix. This point represents the level of uterosacral ligament attachment to the proximal posterior cervix and thus differentiates uterosacral-cardinal ligament

**FIGURE 24-1** Sagittal view of pelvic anatomy. **A.** Normal pelvic anatomy. **B.** Anterior vaginal wall prolapse or cystocele. **C.** Distal posterior wall prolapse or rectocele. **D.** Apical posterior wall prolapse or enterocele.

**FIGURE 24-2** Anatomic landmarks used during pelvic organ prolapse quantification (POP-Q).

support failure from cervical elongation. The *total vaginal length* (TVL) is the greatest depth of the vagina in centimeters when point C or D is reduced to its fullest position.

### Posterior Vaginal Wall Points

*Point Ap* defines a point in the midline of the posterior vaginal wall that lies 3 cm proximal to the hymen. Relative to the hymen, this point's range of position is by definition  $-3$  (normal support) to  $+3$  cm (maximum prolapse of point Ap).

*Point Bp* represents the most distal position of any part of the upper posterior vaginal wall. By definition, this point is at  $-3$  cm in the absence of prolapse. In a woman with total vaginal eversion posthysterectomy, Bp would have a positive value equal to the position of the cuff from the hymen.

### Genital Hiatus and Perineal Body

In addition to the hymen, remaining measurements include those of the genital hiatus (Gh) and the perineal body (Pb)

anterior wall	anterior wall	cervix or cuff
Aa	Ba	C
genital hiatus	perineal body	total vaginal length
gh	pb	tvL
posterior wall	posterior wall	posterior fornix
Ap	Bp	D

**FIGURE 24-3** Grid system used for charting in pelvic organ prolapse quantification (POP-Q).

(see Fig. 24-2). The genital hiatus is measured from the middle of the external urethral meatus to the midline of the posterior hymenal ring. The perineal body is measured from the posterior margin of the genital hiatus to the midanal opening.

### Assessment with POP-Q

With the hymenal plane defined as zero, the anatomic position of these points from the hymen is measured in centimeters. Points above or proximal to the hymen are described with a negative number. Positions below or distal to the hymen are noted using a positive number. The point measurements can be organized using a three-by-three grid as shown in [Figure 24-3](#). [Figures 24-4](#) and [24-5](#) illustrate the use of POP-Q in evaluating different examples of POP.

The degree of prolapse can also be quantified using a five-stage ordinal system as summarized in [Table 24-2](#) (Bump, 1996). Stages are assigned according to the most severe portion of the prolapse.

**FIGURE 24-4** POP-Q depiction of varying degrees of uterine prolapse (A–C).

■ **Baden-Walker halfway System**

This descriptive tool is also used to classify prolapse during physical examination and is widely used. Although not as informative as the POP-Q, it is adequate for clinical use if each compartment (anterior, apical, and posterior) is evaluated (Table 24-3) (Baden, 1972).

**PATHOPHYSIOLOGY**

Pelvic organ support is maintained by complex interactions among the pelvic floor muscles, pelvic floor connective tissue, and vaginal wall. These work in concert to provide support and also maintain normal physiologic function of the vagina, urethra, bladder, and rectum. Several factors are implicated in failure of this support, but none fully explain its pathogenesis. These include genetic predisposition, loss of pelvic floor striated muscle support, vaginal wall weakness, and loss of connective attachments between the vaginal wall and the pelvic floor muscles and pelvic viscera. As noted earlier, vaginal birth and aging are two

**TABLE 24-3.** Baden-Walker Halfway System for the Evaluation of Pelvic Organ Prolapse on Physical Examination<sup>a</sup>

Grade	
Grade 0	Normal position for each respective site
Grade 1	Descent halfway to the hymen
Grade 2	Descent to the hymen
Grade 3	Descent halfway past the hymen
Grade 4	Maximum possible descent for each site

major risk factors for POP (Mant, 1997). The loss of support that evolves decades after vaginal delivery may stem from an initial insult compounded by aging and other contributors.

■ **Levator Ani Muscle**

The levator ani muscle is a pair of striated muscles composed of three regions. The *iliococcygeus muscle* forms a flat horizontal shelf spanning from one pelvic sidewall to the other (Figs. 38-7 and 38-8, p. 802). The *pubococcygeus muscle* arises from the pubic bone on either side; is attached to the walls of the vagina, urethra, anus, and perineal body; and inserts on the coccyx. The pubococcygeus muscle thereby helps suspend the vaginal wall to the pelvis. The *puborectalis muscle* forms a sling that originates from the pubic bone. It wraps around and behind the rectum. Connective tissue covers the superior and inferior fascia of the levator ani muscle. In the healthy state, baseline resting contractile activity of the levator ani muscle elevates the pelvic floor and compresses the vagina, urethra, and rectum toward the pubic bone (Fig. 38-10, p. 803). It narrows the genital hiatus and prevents prolapse of the pelvic organs.

**TABLE 24-2.** The Pelvic Organ Prolapse Quantification (POP-Q) Staging System of Pelvic Organ Support

<b>Stage 0:</b>	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at - 3 cm and either point C or D is between - TVL (total vaginal length) cm and - (TVL - 2) cm (i.e., the quantitation value for point C or D is ≤ - [TVL - 2] cm). Figure 24-2 represents stage 0
<b>Stage I:</b>	The criteria for stage 0 are not met, but the most distal portion of the prolapse is > 1 cm above the level of the hymen (i.e., its quantitation value is < - 1 cm)
<b>Stage II:</b>	The most distal portion of the prolapse is ≤ 1 cm proximal to or distal to the plane of the hymen (i.e., its quantitation value is ≥ - 1 cm but ≤ + 1 cm)
<b>Stage III:</b>	The most distal portion of the prolapse is > 1 cm below the plane of the hymen but protrudes no further than 2 cm less than the total vaginal length in centimeters (i.e., its quantitation value is > + 1 cm but < + [TVL - 2] cm). Figure 24-5B represents stage III Bp prolapse
<b>Stage IV:</b>	Essentially, complete eversion of the total length of the lower genital tract is demonstrated. The distal portion of the prolapse protrudes to at least (TVL - 2) cm (i.e., its quantitation value is ≥ + [TVL - 2] cm). In most instances, the leading edge of stage IV prolapse will be the cervix or vaginal cuff scar. Figure 24-4C represents stage IVC prolapse

Data from Bump RC, Mattiasson A, Bø K, et al: The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction, Am J Obstet Gynecol 1996 Jul;175(1):10-17.

When the levator ani muscle has normal tone and the vagina has adequate depth, the upper vagina lies nearly horizontal in the standing female. Thus, during periods of increased intraabdominal pressure, the upper vagina is compressed against the levator plate. It is theorized that when the levator ani muscle loses tone, the vagina drops from a horizontal to a semivertical position (Fig. 38-11, p. 804). This widens or opens the genital hiatus and predisposes pelvic viscera to prolapse. Without adequate levator ani muscle support, the visceral fascial attachments of the pelvic contents are placed on tension and are thought to stretch and eventually fail.

Theoretically, the levator ani muscle may sustain either direct muscle or denervation injury during childbirth, and these injuries are involved in POP pathogenesis. During second-stage labor, nerve injury from stretch or compression or both is believed to partially denervate the levator ani muscle. Denervated muscle loses tone, the genital hiatus opens, and pelvic viscera prolapse (DeLancey, 1993; Peschers, 1997; Shafik, 2000).

The experimental evidence for this theory of denervation-induced injury leading to POP has been difficult to obtain and is contradictory. Some studies demonstrate histomorphologic abnormalities in the levator ani muscle from women with prolapse and stress incontinence, whereas other studies fail to find histologic evidence of levator ani muscle denervation (Gilpin, 1989; Hanzal, 1993; Heit, 1996; Koelbl, 1989). In addition, levator ani muscle biopsies obtained from parous and nulliparous cadavers failed to find evidence of atrophy or other important muscle changes (Boreham, 2009). This suggests that pregnancy and parturition have little or no effect on levator ani muscle histomorphology. Additionally, experimental denervation of the levator ani muscle in the squirrel monkey led to significant muscular atrophy but did not affect pelvic organ support. Taken together, experimental evidence does not support a role for denervation-induced injury in POP pathophysiology.

Importantly, however, loss of skeletal muscle volume and function occurs in virtually all striated muscles during aging. Results obtained from young and older women with POP indicate that the levator ani muscle undergoes substantial morphologic and biochemical changes during aging. Thus, loss of levator tone with age may contribute to pelvic organ support failure in older women, possibly those with preexisting defects in connective tissue support. As striated muscles lose tone, ligamentous and connective tissue support of the pelvic organs must sustain more forces conferred by abdominal pressure. As connective tissues bear these loads for long periods, they stretch and may eventually fail, resulting in prolapse.

## ■ Connective Tissue

A continuous interdependent system of connective tissues and ligaments surrounds the pelvic organs and attaches them to the levator ani muscle and bony pelvis. The connective tissue of the pelvis is comprised of collagen, elastin, smooth muscle, and microfibers, which are anchored in an extracellular matrix of polysaccharides. The connective tissue that invests the pelvic viscera provides substantial pelvic organ support.

Of these, the *arcus tendineus fascia pelvis* is a condensation of parietal fascia covering the medial aspects of the obturator internus and levator ani muscle (Fig. 38-7, p. 801). It provides

the lateral and apical anchor sites for the anterior and posterior vagina. The arcus tendineus fascia pelvis is therefore poised to withstand descent of the anterior vaginal wall, vaginal apex, and proximal urethra. Experts now believe that a major inciting factor for prolapse is loss of connective tissue support at the vaginal apex leading to stretching or tearing of the arcus tendineus fascia pelvis. The result is apical and anterior vaginal wall prolapse.

The *uterosacral ligaments* contribute to apical support by suspending and stabilizing the uterus, cervix, and upper vagina. The ligament contains approximately 20 percent smooth muscle. Several studies have shown a decrease in the fractional area and distribution of smooth muscle in the uterosacral ligaments of women with prolapse (Reisenauer, 2008; Takacs, 2009). These studies suggest that abnormalities in uterosacral ligament support of the pelvic organs contribute to prolapse development.

Abnormalities of connective tissue and connective tissue repair may predispose women to prolapse (Norton, 1995; Smith, 1989). As noted, women with connective tissue disorders such as Ehlers-Danlos or Marfan syndrome are more likely to develop POP and urinary incontinence (Carley, 2000; Norton, 1995).

The pelvic floor fascia and connective tissues may also lose strength consequent to aging and loss of neuroendocrine signaling in pelvic tissues (Smith, 1989). Estrogen deficiency can affect the biomedical composition, quality, and quantity of collagen. Estrogen influences collagen content by increasing synthesis or decreasing degradation. Exogenous estrogen supplementation has been found to increase the skin collagen content in postmenopausal women who are estrogen deficient (Brincat, 1983). Moreover, estrogen supplementation prior to prolapse surgery and/or postoperatively is considered essential by many pelvic reconstruction surgeons. In a systematic review, Rahn and coworkers (2015) found that vaginal estrogen application before POP surgery improved the vaginal maturation index and increased vaginal epithelial thickness. This suggests a possible role in healing and future support. Although this practice may seem logical and empirically sound, evidence does not yet show improved surgical outcomes with this use of adjuvant estrogen.

## ■ Vaginal Wall

Abnormalities in the vaginal wall and its attachments to the pelvic floor muscles may be involved in POP pathogenesis. The vaginal wall is composed of mucosa (epithelium and lamina propria), a fibroelastic muscularis layer, and an adventitial layer that is made up of loose areolar tissue, abundant elastic fibers, and neurovascular bundles (Fig. 24-6). The muscularis and adventitial layers together form the *fibromuscular layer*, which was previously referred to as “endopelvic fascia.” The fibromuscular layer coalesces laterally and attaches to the arcus tendineus fascia pelvis and superior fascia of the levator ani muscle. In the lower third of the vagina, the vaginal wall is attached directly to the perineal membrane and the perineal body. This suspensory system, together with the uterosacral ligaments, prevents the vagina and uterus from descent when the genital hiatus is open.

Abnormalities in the anatomy, physiology, and cellular biology of vaginal wall smooth muscle may contribute to POP. Specifically, in fibromuscular tissue taken at the vaginal apex from both the anterior and posterior vaginal walls, vaginal prolapse is associated with loss of smooth muscle, myofibroblast

**FIGURE 24-6** Photomicrograph shows a cross section of the vaginal wall. Mucosal and muscularis layers are shown here. The adventitia, which is typically seen deep to muscularis, is not shown in this section. The fibromuscular layer is comprised of muscularis and adventitial layers. (Used with permission from Dr. Ann Word.)

activation, abnormal smooth muscle phenotype, and increased protease activity (Boreham, 2001, 2002a,b; Moalli, 2005; Phillips, 2006). Additionally, abnormal synthesis or degradation of vaginal wall collagen and elastin fibers appears to contribute to prolapse.

### ■ The Defect Theory of Pelvic Organ Prolapse

This theory states that tears in different sites of the “endopelvic fascia” surrounding the vaginal wall allow herniation of the pelvic organs. Specifically, attenuation of the vaginal wall without loss of fascial attachments is called a *distention* cystocele or rectocele (Fig. 24-7). With distention-type prolapse, the vaginal wall appears smooth and without rugae, due to abdominal contents pressed against the vagina from within. In contrast, anterior and posterior wall defects due to loss of the connective tissue

**FIGURE 24-7** Photograph shows midline or distention cystocele. Note the characteristic loss of vaginal wall rugae. This contrasts with the findings in Figure 24-8.

attachment of the lateral vaginal wall to the pelvic sidewall are described as *displacement* (paravaginal) cystocele or rectocele (Fig. 24-8). With displacement-type prolapse, vaginal rugae are visible. Both defect types could result from the stretching or tearing of support tissues during second-stage labor.

Many experts now believe the primary defect leading to prolapse is loss of support at the vaginal apex. This allows the apical portions of the anterior and posterior vaginal walls to descend. As such, resuspension of the vaginal apex will restore support to both the anterior and posterior walls.

### ■ Levels of Vaginal Support

The vagina is a fibromuscular, flattened, cylindrical tube with three levels of support, as described by DeLancey (1992). Level I support suspends the upper or proximal vagina. Level II support attaches the midvagina along its length to the arcus tendineus fascia pelvis. Level III support results from fusion of the distal vagina to adjacent structures. Defects in each level of support result in identifiable vaginal wall prolapse: apical, anterior, and posterior.

Level I support consists of the cardinal and uterosacral ligaments attachment to the cervix and upper vagina (Fig. 38-15, p. 808). The cardinal ligaments fan out laterally and attach to the parietal fascia of the obturator internus and piriformis muscles, the anterior border of the greater sciatic foramen, and the ischial spines. The uterosacral ligaments are posterior fibers that attach to the presacral region at the level of S2 through S4. Together, this dense visceral connective tissue complex maintains vaginal length and horizontal axis. It allows the vagina to be supported by the levator plate and positions the cervix just superior to the level of the ischial spines. Defects in this support complex may lead to apical prolapse. This is frequently associated with small bowel herniation into the vaginal wall, that is, enterocele.

Level II support consists of the paravaginal attachments that are contiguous with the cardinal/uterosacral complex at the ischial spine. These are the connective tissue attachments of the

**FIGURE 24-8** Photograph shows a lateral cystocele, also termed paravaginal or displacement cystocele. Rugae are present, which indicates that loss of support is lateral rather than central.

lateral vagina anteriorly to the arcus tendineus fascia pelvis and posteriorly to the arcus tendineus rectovaginalis. Detachment of this connective tissue from the arcus tendineus fascia pelvis leads to lateral or paravaginal anterior vaginal wall prolapse.

Level III support is composed of the perineal body, superficial and deep perineal muscles, and fibromuscular connective tissue. Collectively, these support the distal one third of the vagina and introitus. The perineal body is essential for distal vaginal support and proper function of the anal canal. Damage to level III support contributes to anterior and posterior vaginal wall prolapse, gaping introitus, and perineal descent.

PATIENT EVALUATION

Symptoms

Pelvic organ prolapse involves multiple anatomic and functional systems and is commonly associated with genitourinary, gastrointestinal, and musculoskeletal symptoms (Table 24-4). Prolapse rarely creates severe morbidity or mortality, however, it can greatly diminish quality of life. In contrast, many women with mild to advanced prolapse lack bothersome symptoms. Thus, initial evaluation must include a careful assessment of prolapse-related symptoms and their effect on activities of daily living.

TABLE 24-4. Symptoms Associated with Pelvic Organ Prolapse

Symptoms	Other Possible Causes
<b>Bulge symptoms</b> Sensation of vaginal bulging or protrusion Seeing or feeling a vaginal or perineal bulge Pelvic or vaginal pressure Heaviness in pelvis or vagina	Rectal prolapse Vulvar or vaginal cyst/mass Pelvic mass Hernia (inguinal or femoral)
<b>Urinary symptoms</b> Urinary incontinence Urinary frequency Urinary urgency Weak or prolonged urinary stream Hesitancy Feeling of incomplete emptying Manual reduction of prolapse to start or complete voiding Position change to start or complete voiding	Urethral sphincter incompetence Detrusor overactivity Hypoactive detrusor function Bladder outlet obstruction (i.e., postsurgical) Excessive fluid intake Interstitial cystitis Urinary tract infection
<b>Bowel symptoms</b> Incontinence of flatus or liquid/solid stool Feeling of incomplete emptying Hard straining to defecate Urgency to defecate Digital evacuation to complete defecation Splinting vagina or perineum to start or complete defecation Feeling of blockage or obstruction during defecation	Anal sphincter disruption or neuropathy Diarrheal disorder Rectal prolapse Irritable bowel syndrome Rectal inertia Pelvic floor dyssynergia Hemorrhoids Anorectal neoplasm
<b>Sexual symptoms</b> Dyspareunia Decreased lubrication Decreased sensation Decreased arousal or orgasm	Vaginal atrophy Levator ani syndrome Vulvodynia Other female sexual disorder
<b>Pain</b> Pain in vagina, bladder, or rectum Pelvic pain Low back pain	Interstitial cystitis Levator ani syndrome Vulvodynia Lumbar disc disease Musculoskeletal pain Other causes of chronic pelvic pain

Symptoms are carefully reviewed to determine if they are caused by the prolapse or by other etiologies. “Bulge” symptoms, which are pelvic pressure, the feeling of sitting on a ball, or heaviness in the vagina, are most likely to correlate with prolapse. Other symptoms, such as back pain, constipation, and abdominal discomfort, may coexist with prolapse but not result from it. A thorough history and physical examination will often help delineate the relationship between POP and symptoms.

During symptom inventory, several tools may be useful in assessing severity. Two commonly used questionnaires are the Pelvic Floor Distress Inventory (PFDI) and the Pelvic Floor Impact Questionnaire (PFIQ) (Barber, 2005b). The PFDI assesses urinary, colorectal, and prolapse symptoms, whereas the PFIQ seeks a diminished quality of life due to prolapse (Tables 24-5 and 24-6).

*Bulge symptoms* most strongly correlate with POP. These are typified by feeling or seeing a vaginal or perineal protrusion, and the sensation of pelvic pressure. Women may comment on feeling a ball in the vagina, sitting on a weight, or noting a bulge rubbing against their clothes. These symptoms worsen with prolapse progression (Ellerkmann, 2001). Specifically, women with prolapse beyond the hymen are more likely to report a vaginal bulge and have more symptoms than those with prolapse that stops above the hymen (Bradley, 2005; Tan, 2005; Weber, 2001a). If bulge symptoms are the primary complaint, successful replacement of the prolapse with nonsurgical or surgical therapy will usually provide adequate symptom relief.

*Urinary symptoms* often accompany POP and may include stress urinary incontinence (SUI), urgency urinary incontinence, frequency, urgency, urinary retention, recurrent urinary tract infection, or voiding dysfunction. Although these symptoms may be caused or exacerbated by POP, it should not be assumed that surgical or nonsurgical correction of prolapse will be curative. For example, irritative bladder symptoms

(frequency, urgency, and urgency urinary incontinence) may not improve with prolapse replacement. Moreover, they may be unrelated to the prolapse and require alternative therapy. In contrast, urinary retention has been found to improve with prolapse treatment if the symptom is due to an obstructed urethra (FitzGerald, 2000).

For these reasons, urodynamic testing is a valuable adjunct in women with urinary symptoms who are undergoing treatment of prolapse (Chap. 23, p. 526). Testing attempts to determine the relationship between urinary symptoms and POP and will help guide therapy. Additionally, consideration may also be given to temporarily placing a pessary prior to surgery to determine if urinary symptoms improve. This may predict whether surgical reduction of prolapse will be beneficial.

*Constipation* is often present in women with POP, although it is generally not caused by POP. Thus, surgical repair or treatment with a pessary will not usually cure constipation and may actually worsen it. In one study of defect-directed posterior repair, constipation resolved postoperatively in only 43 percent of patients (Kenton, 1999). Therefore, if a patient’s primary symptom is constipation, treatment of prolapse may not be indicated. Constipation should be viewed as a problem distinct from prolapse and evaluated separately.

*Digital decompression* of the posterior vaginal wall, the perineal body, or the distal rectum to evacuate the rectum is the most common defecatory symptom associated with posterior vaginal wall prolapse (Burrows, 2004; Ellerkmann, 2001). Surgical approaches to this problem provide variable success, and symptom resolution rates range from 36 to 70 percent (Cundiff, 2004; Kenton, 1999).

*Anal incontinence* of flatus, liquid, or solid stool may also associate with POP. On occasion, prolapse may lead to stool trapping in the distal rectum with subsequent leakage of liquid stool around retained feces. If symptoms are present, a full anorectal

evaluation is performed (Chap. 25, p. 564). Most types of anal incontinence would not be expected to improve with surgical repair of prolapse. However, if evaluation reveals an anal sphincter defect as the cause of anal incontinence, anal sphincteroplasty may be performed concurrently with prolapse repair.

*Female sexual dysfunction* is present in women with dyspareunia, low libido, problems with arousal, and inability to achieve orgasm. The etiology is frequently multifactorial and includes psychosocial factors, urogenital atrophy, aging, and male sexual dysfunction. Sexual dysfunction is often also seen in women with POP. However, findings from studies evaluating sexual function in women with prolapse are inconsistent. In one study, a validated sexual function questionnaire was used to compare frequency of intercourse, libido, dyspareunia, orgasmic function, and vaginal dryness in women with and without prolapse (Weber, 1995). No differences were seen between the two groups. In another cross-sectional study of 301 women, pelvic floor symptoms were associated with dyspareunia, reduced arousal, and infrequent orgasm (Handa, 2008). In addition, sexual dysfunction was worse in women with symptomatic prolapse versus those with asymptomatic prolapse. In another study of sexual function in

women with prolapse, decreased activity was associated with decreased vaginal length, and one quarter of women avoided sexual activity due to pelvic floor symptoms (Edenfield, 2015). Accordingly, women with an obstructing bulge as a cause of sexual dysfunction may benefit from therapy to reduce the prolapse. Unfortunately, some prolapse procedures such as posterior repair with levator plication and vaginal placement of mesh may contribute to postoperative dyspareunia. Therefore, care is taken in planning appropriate surgical procedures for women with concomitant sexual dysfunction (Ulrich, 2015).

*Pelvic and back pain* is another complaint in women with POP, but little evidence supports a direct association. A cross-sectional study of 152 consecutive patients with POP did not find an association between pelvic or low back pain and prolapse after controlling for age and prior surgery (Heit, 2002). Swift and colleagues (2003) found that back and pelvic pain were common among 477 women presenting for routine annual gynecologic examination and had no relationship to POP. Some suggest that low back pain in a patient with prolapse may be caused by altered body mechanics. However, if pain is a primary symptom, other sources should be sought (Chap. 11,

**FIGURE 24-9** Degrees of pelvic organ prolapse. **A.** Stage 2. This stage is defined by the most distal edge of the prolapse lying within 1 cm of the hymenal ring. **B.** Stage 3. This stage is defined by the most distal portion of the prolapse being > 1 cm below the plane of the hymen, but protruding no farther than 2 cm less than the total vaginal length in centimeters. **C.** Stage 4. This stage is defined as complete or near complete eversion.

p. 267). In the absence of an identifiable etiology, temporary pessary placement is considered to determine whether prolapse reduction will improve pain symptoms. Referral to a physical therapist may also shed light on a connection among prolapse, altered body mechanics, and pain.

Importantly, although POP is associated with varied complaints, symptoms and their severity do not always correlate well with advancing stages of prolapse. In addition, many common symptoms do not differentiate between compartments (Jelovsek, 2005; Kahn, 2005; Weber, 1998). Thus, when planning surgical or nonsurgical therapy, realistic expectations should be set with regard to symptom relief. A patient is informed that symptoms directly related to prolapse such as vaginal bulge and pelvic pressure are likely to improve with a successful anatomic repair. However, other associated symptoms such as constipation, back pain, and urinary urgency and frequency may or may not improve.

## ■ Physical Examination

### Perineal Examination

Physical examination begins with a full body systems evaluation to identify pathology outside the pelvis. Systemic conditions such as cardiovascular, pulmonary, renal, or endocrinologic disease may affect treatment choices and should be identified early.

The initial pelvic examination is performed with a woman in lithotomy position. The vulva and perineum are examined for signs of vulvar or vaginal atrophy or other abnormalities. A neurologic examination of sacral reflexes is performed using a cotton swab. First, the *bulbocavernosus reflex* is elicited by tapping or stroking lateral to the clitoris and observing contraction of the bulbocavernosus muscle bilaterally. Second, evaluation of anal sphincter innervation is completed by stroking lateral to the anus and observing a reflexive contraction of the anus, known as the *anal wink reflex*. Intact reflexes suggest normal

sacral pathways. However, they can be absent in women who are neurologically intact.

POP examination begins by asking a woman to attempt Valsalva maneuver prior to placing a speculum in the vagina (Fig. 24-9). Patients who are unable to adequately complete a Valsalva maneuver are asked to cough. The “hands-off” approach more accurately displays true anatomy. Namely, with speculum examination, structures are artificially lifted, supported, or displaced. Importantly, this assessment helps answer three questions: (1) Does the protrusion come beyond the hymen? (2) What is the presenting part of the prolapse (anterior, posterior, or apical)? (3) Does the genital hiatus significantly widen with increased intraabdominal pressure?

During examination, a clinician verifies that the full extent of the prolapse is being seen. Specifically, a woman is asked to describe the extent of prolapse beyond the hymen during real-life activities. The degree may be conveyed in terms of inches. Alternatively, a mirror may be placed at the perineum and visual confirmation can be obtained from the patient.

Prolapse is a dynamic condition that responds to the effects of gravity and intraabdominal pressure. It frequently worsens over the course of a day or during physical activity. Thus, prolapse might not be evident during examination early in the morning. If the full extent of prolapse cannot be demonstrated, a woman should be examined in a standing position and during Valsalva maneuver.

### Vaginal Examination

If the POP-Q examination is performed, the genital hiatus (Gh) and perineal body (Pb) are measured during Valsalva maneuver (Fig. 24-10). The total vaginal length (TVL) is then measured by placing a marked ring forceps, or a ruler, at the vaginal apex and noting the distance to the hymen. A bivalve speculum is then inserted to the vaginal apex. It displaces the anterior and posterior vaginal walls, and points C and D are then measured

**FIGURE 24-10** **A.** Measurement of the genital hiatus (Gh). For POP-Q evaluation, a sponge stick is used that is marked at 1-, 2-, 3-, 4-, 5-, 7.5-, and 10-cm increments. Measurement is obtained with a woman performing maximum Valsalva maneuver. **B.** Measurement of the perineal body. **C.** Measurement of points Aa and Ba. Aa is a discrete point lying 3 cm proximal to the urethral meatus and is measured in relation to the hymen. During measurement, a split speculum displaces the posterior vaginal wall, but downward traction is avoided, as this causes artificial descent of the anterior vaginal wall.

with Valsalva. The speculum is slowly withdrawn to assess descent of the apex.

A split speculum is then used to displace the posterior vaginal wall and allow for viewing of the anterior wall and measurement of points Aa and Ba. Attempts are made to characterize the anterior vaginal wall defect. Sagging lateral vaginal sulci with vaginal rugae still present suggest a *paravaginal defect*, that is, a lateral loss of support (Fig. 24-11). A central bulge and loss of vaginal rugae is called a *midline* or *central defect* (see Fig. 24-7). If loss of support appears to arise from detachment of the anterior vaginal wall's apical segment, it is termed a *transverse* or *anterior apical defect* (Fig. 24-12). Transverse defects are assessed by replacing the anterior apical segment and observing whether the prolapse descends during Valsalva maneuver. The urethra is also evaluated during anterior vaginal wall assessment, and Q-tip testing can be performed to determine urethral hypermobility (Chap. 23, p. 524).

The split speculum is then rotated 180 degrees to displace the anterior wall and allow examination of the posterior wall.

Points Ap and Bp are measured (Fig. 24-13). If the posterior vaginal wall descends, attempts are made to determine if rectocele or enterocele is present. Enterocele can only definitively be diagnosed by observing small bowel peristalsis behind the vaginal wall (Fig. 24-14). In general, bulges at the apical segment of the posterior vaginal wall should implicate enteroceles, whereas bulges in the distal posterior wall are presumed to be rectoceles. Further distinction may be found during standing rectovaginal examination. With this, a clinician's index finger is placed in the rectum and thumb on the posterior vaginal wall. Small bowel may be palpated between the rectum and vagina, confirming enterocele.

Differentiation of midline, lateral, apical, and distal defects of the anterior and posterior vaginal walls has not been shown to have good inter- or intraexaminer reliability. However, individual evaluation may help assess prolapse severity and clarify anatomy if surgical correction is planned (Barber, 1999; Whiteside, 2004).

**FIGURE 24-11** **A.** Normal lateral support as shown by normal positioning of the vaginal sulci. **B.** Complete loss of lateral support, shown as absent lateral sulci.

**FIGURE 24-12** A transverse vaginal wall defect. Note detachment of the anterior vaginal wall from the apex and the presence of rugae, which suggests that this is not a midline or central defect.

As mentioned, apical prolapse is believed to be the cause of most anterior and posterior wall descent. Therefore, careful attention is paid to the relationship of the apex to these structures. The apex should be replaced to its normal position. If this maneuver restores anterior and posterior support, it can be determined that the primary defect is at the apex.

Bimanual examination is performed to identify other pelvic pathology. In addition, we strongly recommend assessment of pelvic floor musculature (Fig. 11-5, p. 257). This examination is essential if pelvic floor rehabilitation is being considered as treatment. During part of the evaluation, an index finger is placed 1 to 3 cm inside the hymen, at 4 and then 8 o'clock (Fig. 24-15). Muscle resting tone and strength is assessed using the 0 through 5 Oxford grading scale, in which 5 represents normal tone and strength (Laycock, 2002). Muscle symmetry

**FIGURE 24-13** Split speculum displacing the anterior vaginal wall. This allows for measurement of points Ap and Bp. Ap is always defined as a discrete point lying 3 cm proximal to the hymen.

**FIGURE 24-14** Enterocele. During evaluation, small bowel peristalsis may be noted behind the vaginal wall. Enterocele is most commonly noted at the vaginal apex, although anterior and posterior vaginal wall enteroceles may occur.

is also evaluated. Asymmetric muscles, with palpable defects or scarring, may be associated with a prior obstetric forceps delivery, episiotomy, or laceration.

### APPROACH TO TREATMENT

For women who are asymptomatic or mildly symptomatic, expectant management is appropriate. It is difficult to predict if prolapse will worsen or if symptoms will develop. In this situation, benefits of treatment are balanced against risks. Therefore, in the absence of other factors, invasive therapy is typically not selected for asymptomatic women. Pelvic floor muscle rehabilitation may be offered to a patient seeking to prevent prolapse progression. However, no data support the effectiveness of this practice (Hagen, 2011).

**FIGURE 24-15** Pelvic floor muscle assessment. The index finger is placed 2 to 3 cm inside the hymen at 4 and 8 o'clock. Both resting and contraction tone and strength are evaluated.

For women with significant prolapse or for those with bothersome symptoms, nonsurgical or surgical therapy may be selected. Treatment choice depends on the type and severity of symptoms, age and medical comorbidities, desire for future sexual function and/or fertility, and risk factors for recurrence. Treatment goals strive to provide symptom relief, but therapy benefits should always outweigh risks.

Often a combination of nonsurgical and surgical approaches may be selected. Symptoms are ranked by severity, and options for each are discussed. An evidence-based appraisal of each option's success rate is included. In the simplest case, a patient with prolapse of the vaginal apex beyond the hymen, whose only symptom is bulge or pelvic pressure, could be offered pessary or surgical treatment. In a more complicated case, a woman with prolapse beyond the hymenal ring may note a bulge, constipation, urgency urinary incontinence, and pelvic pain. Symptoms would be ranked by severity and importance of resolution. To address all complaints, therapy might involve pessary or surgery for bulge symptoms, and non-surgical treatment of constipation, incontinence, and pelvic pain.

## NONSURGICAL TREATMENT

### ■ Pessary

#### Pessary Indications

Throughout history, various vaginal devices and materials have been used to physically support vaginal prolapse. Today's pessaries are usually made of silicone or inert plastic, and they are safe and simple to manage. Despite a long history of use, literature describing their indications, selection, and management is often anecdotal or contradictory.

The most common indication for vaginal pessary is POP. Traditionally, pessaries have been reserved for women either unfit or unwilling to undergo surgery. A survey of the American Urogynecologic Society (AUGS) membership confirmed this sentiment among gynecologists with more than 20 years in practice (Cundiff, 2000). However, the same survey showed that younger gynecologists, particularly those who described themselves as urogynecologists, used pessaries as a first-line therapy before recommending surgery.

Of other indications, pessaries may also help some women with prolapse and associated urinary incontinence. One RCT compared two pessary types for relief of prolapse symptoms and urinary complaints. This study demonstrated that pessaries provide a modest improvement in urinary obstructive, irritative, and stress symptoms (Chap. 23, p. 530) (Schaffer, 2006).

Pessaries may also be used diagnostically. As previously discussed, symptoms may not correlate with the type or severity of prolapse. Short-term pessary use may help clarify this relationship. Even if a patient declines long-term pessary use, she may agree to a short trial to determine if her chief complaint is improved or resolved. A pessary may also be placed diagnostically to identify which women are at risk for urinary incontinence after prolapse-correcting surgery (Chaikin, 2000; Liang, 2004).

**FIGURE 24-16** Types of Miley pessaries. **A.** Cube pessary. **B.** Gehrung pessary. **C.** Hodge with knob pessary. **D.** Regula pessary. **E.** Gellhorn pessary. **F.** Shaatz pessary. **G.** Incontinence dish pessary. **H.** Ring pessary. **I.** Donut pessary. (Reproduced with permission from CooperSurgical, Inc.)

#### Pessary Selection

Pessaries are divided into two broad categories: support and space-filling (Fig. 24-16). Support pessaries, such as the ring pessary, use a spring mechanism that rests in the posterior fornix and against the posterior aspect of the symphysis pubis. Vaginal support results from elevation of the superior vagina by the spring, which is supported by the symphysis pubis. Ring pessaries may be constructed as a simple circular ring or as a ring with support that looks like a large contraceptive diaphragm (Fig. 24-17). These are effective in women with first- and second-degree

**FIGURE 24-17** Miley ring pessary with support. (Reproduced with permission from CooperSurgical, Inc.)

prolapse. Also, the diaphragm portion of a support ring is especially useful in women with accompanying anterior vaginal wall prolapse. When properly fitted, the device should lie behind the pubic symphysis anteriorly and behind the cervix posteriorly.

In contrast, space-filling pessaries maintain their position by creating suction between the pessary and vaginal walls (cube), by creating a diameter larger than the genital hiatus (donut), or by both mechanisms (Gellhorn). The Gellhorn is often used for moderate to severe prolapse and for complete procidentia. It contains a concave disc that fits against the cervix or vaginal cuff and has a stem that is positioned just cephalad to the introitus. The concave disc supports the vaginal apex by creating suction, and the stem is useful for device removal. Of all pessaries, the two most commonly used and studied devices are the ring and the Gellhorn pessaries.

### Patient Evaluation and Pessary Placement

A patient must be an active participant in the treatment decision to use a pessary. Its success will depend upon her ability to care for the pessary—either alone or with the assistance of a caregiver—and her willingness and availability to come for subsequent evaluations. Vaginal atrophy should be treated

before or concomitantly with pessary initiation. In women who are suitable candidates for estrogen therapy, vaginal estrogen cream is recommended (Table 22-5, p. 505). In one regimen, 1 g of conjugated equine estrogen cream (Premarin cream) is inserted nightly for 2 weeks, then two times per week thereafter.

Device selection integrates patient factors such as hormonal status, sexual activity, prior hysterectomy, and stage and site of POP. After a pessary is chosen, a woman is fitted with the largest size that can be comfortably worn. If a pessary is ideally fitted, a patient is not aware of its presence. As a woman ages and gains or loses weight, alternate sizes may be required.

Generally, a patient is fitted with a pessary while in the lithotomy position after she has emptied both her bladder and rectum. A digital examination is performed to assess vaginal length and width, and an initial estimation of pessary size is made. [Figure 24-18](#) shows Gellhorn pessary placement. For ring pessary placement, the device is held in the clinician's dominant hand in a folded position. Lubricant is placed on either the vaginal introitus or the pessary's leading edge. While holding the labia apart, the pessary is inserted by pushing in a cephalad direction and against the posterior vaginal wall. Next,

**FIGURE 24-18** Technique for placement and removal of a Gellhorn pessary. Figures **A**, **B**, and **C** show placement. **D**. To remove a Gellhorn pessary, an index finger is placed behind the disk and suction is broken prior to removal.

an index finger is directed into the posterior vaginal fornix to ensure that the cervix is resting above the pessary. The clinician's finger should barely slide between the lateral edges of the ring pessary and the vaginal sidewall. The pessary should fit snugly but not tightly against the symphysis pubis and the posterior and lateral vaginal walls. Too much pressure may increase the risk for pain.

Following pessary placement, a woman is prompted to perform a Valsalva maneuver, which might dislodge an improperly fitted pessary. She should be able to stand, walk, cough, and urinate without difficulty or discomfort. Instruction on removal and placement then follows. For removal of a ring pessary, an index finger is inserted into the vagina to hook the ring's leading edge. Traction is applied along the vaginal axis to bring the ring toward the introitus. Here, it may be grasped by the thumb and index finger and removed.

Ideally, a pessary is removed nightly to weekly, washed in soap and water, and replaced the next morning. Women also receive instructions describing the management of commonly encountered problems (Table 24-7). After initial placement, a return visit may follow in 1 to 2 weeks. For patients comfortable with their pessary management, return visits may be semiannual. If the patient and the provider are motivated, most women can be taught to self-manage a pessary. For those unable or unwilling to remove and replace a device themselves,

a pessary may be removed and the patient's vagina inspected at the provider's office every 2 or 3 months. Delaying visits longer than this may lead to problematic discharge and odor.

Pessary Complications

Serious complications such as erosion into adjacent organs are rare with proper use and usually result only after years of neglect. At each return visit, the pessary is removed, and the vagina is inspected for erosions, abrasions, ulcerations, or granulation tissue (Fig. 24-19). Vaginal bleeding is usually an early sign and should not be ignored. *Pessary ulcers* or abrasions are treated by changing the pessary type or size to alleviate pressure points or by removing the pessary completely until healed. Treatment of vaginal atrophy with local estrogen is commonly required. Alternatively, water-based lubricants applied to the pessary may help prevent these complications. *Prolapse ulcers* have the same appearance as pessary ulcers, however, the former result from the prolapsed bulge rubbing against patient clothing. These are treated by replacing the prolapse either with a pessary or by surgery.

Pelvic pain with pessary use is not normal. This usually indicates that the size is too large, and a smaller pessary would be more suitable. All pessaries tend to trap vaginal secretions and obstruct normal drainage to some degree. The resultant odor may be managed by encouraging more frequent nighttime device removal, washing, and reinsertion the next day.

TABLE 24-7. Guidelines for Pessary Care

Pessary type \_\_\_\_\_  
Size \_\_\_\_\_

1. After your initial pessary fitting is successful, you will be asked to return for a follow-up appointment in about 2 weeks. The purpose of this visit is to check the pessary and examine the vagina to ensure that it is healthy. Follow-up appointments will follow this schedule:

1st year: every 3–6 months  
2nd year and beyond: every 6 months

You may learn to care for the pessary yourself. For those patients who can remove and insert the pessary themselves, we recommend weekly overnight removal and cleansing of the pessary with soap and warm water. These patients should see the doctor at least once per year.
2. The following is a list of problems you may encounter with the pessary and our recommendations for their management.

Problem	Management
A. The pessary falls out.	Keep the pessary and notify your doctor's office. An appointment will be made. It may be possible that a change in the size or the type of pessary is needed.
B. You experience pelvic pain.	Notify your doctor's office. If the pessary has slipped and you can remove it, do so. Otherwise, have your doctor remove the pessary. A change in pessary size or type may be needed.
C. Vaginal discharge and odor.	You can douche with warm water and you may want to try using Trimo-San vaginal gel 1–3 times a week.
D. Vaginal bleeding.	Vaginal bleeding may be a sign that the pessary is irritating the lining of the vagina. Call your doctor's office and arrange an appointment.
E. Leaking from the bladder.	Sometimes, the support provided by the pessary will cause leaking from the bladder. Notify your doctor and discuss this problem.

Trimo-San gel (oxyquinolone sulfate) helps restore and maintain the normal vaginal acidity that helps reduce odor-causing bacteria.  
Reproduced with permission from Farrell SA: Practical advice for ring pessary fitting and management, J SOGC 19:625, 1997.

**FIGURE 24-19** Granulation tissue resulting from pessary trauma.

Alternatively, a woman may use a pH-based deodorant gel such as oxyquinoline sulfate gel (Trimo-San) once or twice weekly or may douche with warm water. Trimo-San gel helps restore and maintain normal vaginal acidity that aids in reducing odor-causing bacteria.

### ■ Pelvic Floor Muscle Exercises

These exercises have been suggested as a therapy that might limit progression and alleviate prolapse symptoms. Also known as Kegel exercises, these muscle-strengthening techniques are described in Chapter 23 (p. 528). Two hypotheses describe the benefits of pelvic floor muscle exercises for prolapse prevention and treatment (Bø, 2004). First, from these exercises, women learn to consciously contract muscles before and during increases in abdominal pressure. This prevents organ descent. Alternatively, regular muscle strength training builds permanent muscle volume and structural support.

Unfortunately, high-quality scientific evidence supporting pelvic exercise for prevention and treatment of prolapse is lacking (Hagen, 2011). However, pelvic floor exercise has minimal risk and low cost. For this reason, it may be offered to asymptomatic or mildly symptomatic women who are interested in preventing prolapse progression or who decline other treatments.

## SURGICAL TREATMENT

In preparing for prolapse surgery, the patient should have an understanding of the expected results, and the surgeon should have an understanding of the patient's expectations. Treatment success varies widely based on the definition of success. Thus, the surgeon and the patient must agree on the desired results. Generally, patients seek relief of symptoms, whereas surgeons may view surgical success as restoration of anatomy. In the CARE trial, absence of vaginal bulge symptoms had the strongest relationship to a patient's assessment of overall improvement and surgical success, whereas anatomic success alone did not (Barber, 2009). It is therefore recommended that surgical success be defined as absence of bulge symptoms in addition to anatomic criteria.

### ■ Obliterative Procedures

The two categories of prolapse surgery are obliterative and reconstructive. Obliterative approaches include Lefort colpocleisis and complete colpocleisis (Chap. 45, p. 1120). These can be performed for women with posthysterectomy prolapse or those retaining a uterus. These procedures involve removing vaginal epithelium, suturing anterior and posterior vaginal walls together, obliterating the vaginal vault, and effectively closing the vagina. Obliterative procedures are only appropriate for elderly or medically compromised patients who have no desire for future coital activity.

Obliterative procedures are technically easier, require less operative time, and offer superior success rates compared with reconstructive procedures. Success rates for colpocleisis range from 91 to 100 percent, although the quality of evidence-based studies supporting these rates is poor (FitzGerald, 2006). After colpocleisis, fewer than 10 percent of patients express regret, often due to loss of coital activity (FitzGerald, 2006; Wheeler, 2005). Thus, the consenting process must include an honest and thoughtful discussion with the patient and her partner regarding future sexual intercourse. Latent SUI can be unmasked with colpocleisis due to resulting downward traction on the urethra. However, the morbidity of a concurrent antiincontinence procedure may outweigh the potential incontinence risk and is considered before adding surgeries in women who may already be medically compromised.

In patients who still have a uterus, vaginal hysterectomy may be performed prior to colpocleisis. However, concurrent hysterectomy increases blood loss and operative time. Again, in compromised patients, this can counteract some of the major benefits of colpocleisis. If retention of the uterus at time of colpocleisis is planned, neoplasia is excluded preoperatively. For this, Pap testing for cervical neoplasia should be current. For endometrial neoplasia, endometrial sampling and/or sonographic interrogation of endometrial stripe thickness is performed.

### ■ Reconstructive Procedures

These surgeries attempt to restore normal pelvic anatomy and are more commonly performed for POP than obliterative procedures. Vaginal, abdominal, laparoscopic, and robotic routes may be used, and in the United States, a vaginal approach is preferred by most for prolapse repairs (Boyles, 2003; Brown, 2002).

Approach selection is individualized and factors the patient's unique characteristics and surgeon's expertise. An abdominal approach may be advantageous for women with prolapse recurrence following a vaginal approach, those with a shortened vagina, or those believed to be at higher risk for recurrence, such as young women with severe prolapse (Benson, 1996; Maher, 2004). In contrast, a vaginal approach typically offers shorter operative time and a quicker return to daily activities. Laparoscopic and robotic approaches may offer smaller incisions, decreased hospital stay, and quicker short-term recovery compared with abdominal approaches.

Of these, laparoscopic and robotic approaches to prolapse repair are becoming more common. Procedures include sacrocolpopexy, paravaginal repair, and vaginal vault suspension to

the uterosacral ligaments. One randomized trial in the United Kingdom compared open and laparoscopic sacrocolpopexy and found similar anatomic and subjective outcomes after 1 year (Freeman, 2013). Perceived advantages to the laparoscopic approach such as earlier return to usual activities were not seen. Several small RCTs have compared laparoscopic and robotic sacrocolpopexy (Anger, 2014; Paraiso, 2011). In general, these studies have found similar short-term outcomes but increased cost with the robotic approach.

The prolapse surgeon should be versatile. Procedure route selection is individualized, and compelling evidence does not support one approach as superior to another. Adoption of new surgical techniques should be driven by patient motives, as determined by evidence-based medicine (American College of Obstetricians and Gynecologists, 2015).

### Surgical Plan

Reconstructive prolapse repair will often involve a combination of procedures in several vaginal compartments. However, the decision regarding which compartments to repair is not always straightforward. In the past, a defect-directed approach to prolapse repair was preferred. With this strategy, all current, latent, or potential defects are evaluated and repaired. However, current expert opinion suggests that asymptomatic areas of prolapse do not always warrant repair, and correction can lead to de novo symptoms in some cases. For instance, repair of an asymptomatic posterior wall prolapse may lead to dyspareunia. Thus, surgery in general is planned to relieve *current* prolapse symptoms.

### Anterior Compartment

Many procedures for anterior vaginal wall prolapse repair have been described. Historically, anterior colporrhaphy has been the most common operation, yet long-term anatomic success rates are poor. In a randomized trial of three anterior colporrhaphy techniques, Weber and associates (2001b) found a low rate of anatomic success. Specifically, satisfactory anatomic results were obtained in only 30 percent of their traditional midline plication group, 46 percent of the ultralateral repair group, and 42 percent of the group undergoing traditional plication plus lateral reinforcement with synthetic mesh. These differences were not statistically significant. Despite anatomic results that may appear suboptimal, symptom relief from anterior colporrhaphy may be acceptable. One reanalysis of data from this trial instead used clinically relevant definitions of surgical success that included no prolapse beyond the hymen, lack of prolapse symptoms, and no retreatment requested. With these, 88 percent of subjects met the definition of success (Chmielewski, 2011). Thus, if a central or midline defect is suspected, anterior colporrhaphy may be performed (Chap. 45, p. 1088).

Mesh or biomaterial may also be used in conjunction with anterior colporrhaphy or by itself. Mesh is used to reinforce the vaginal wall and is sutured in place laterally. However, the use of mesh and mesh kits for anterior vaginal wall prolapse remains controversial (American College of Obstetricians and Gynecologists, 2013b). Although recent studies show improved anatomic success when mesh is used for anterior wall repair, there are significant risks. These include mesh erosion, pain, and dyspareunia and are discussed on page 556 (Sung, 2008).

In many cases, anterior vaginal wall prolapse results from fibromuscular defects at the anterior apical segment or transverse detachment of the anterior apical segment from the vaginal apex. In these situations, an apical suspension procedure such as an abdominal sacrocolpopexy or uterosacral ligament vaginal vault suspension will resuspend the anterior vaginal wall to the apex and reduce anterior wall prolapse. With these procedures, continuity is also reestablished between the anterior and posterior vaginal fibromuscular layers to prevent enterocele formation.

Alternatively, if a lateral defect is suspected, paravaginal repair can be performed through a vaginal, abdominal, or laparoscopic route (Chap. 45, p. 1090). Paravaginal repair is performed by reattaching the fibromuscular layer of the vaginal wall to the arcus tendineus fascia pelvis.

### Vaginal Apex

Support of the vaginal apex is thought by many to be an essential cornerstone of a successful prolapse repair (Brubaker, 2005a). The vaginal apex can be resuspended with several procedures that include abdominal sacrocolpopexy, sacrospinous ligament fixation, or uterosacral ligament vaginal vault suspension. These are all illustrated in Chapter 45 (p. 1098).

Of these, abdominal sacrocolpopexy suspends the vaginal vault to the sacrum using synthetic mesh. Advantages include the procedure's durability over time and conservation of normal vaginal anatomy. For example, compared with other vault suspension procedures, sacrocolpopexy offers greater vaginal apex mobility and avoids vaginal shortening. In addition, sacrocolpopexy provides enduring correction of apical prolapse, and long-term success rates approximate 90 percent. This procedure may be used primarily or as a second surgery for women with recurrences after failure of other prolapse repairs. Sacrocolpopexy may be performed as selected an abdominal, laparoscopic, or robotic procedure. When hysterectomy is performed in conjunction with sacrocolpopexy, consideration is given to performing a supracervical rather than a total abdominal hysterectomy. With the cervix left in situ, the risk of postoperative mesh erosion at the vaginal apex is believed to be diminished (McDermott, 2009). In this case, the mesh is not exposed to vaginal bacteria, which occurs when the vagina is opened with total hysterectomy (Griffis, 2006). In addition, the strong connective tissue of the cervix allows for an additional anchoring point for the permanent mesh.

Another option, sacrospinous ligament fixation (SSLF), is one of the most popular procedures for apical suspension. The vaginal apex is suspended to the sacrospinous ligament unilaterally or bilaterally using a vaginal extraperitoneal approach. After SSLF, recurrent apical prolapse is uncommon. However, anterior vaginal wall prolapse develops postoperatively in 6 to 28 percent of patients and is thought to develop from redirection of abdominal forces anteriorly (Benson, 1996; Morley, 1988; Paraiso, 1996). Complications associated with SSLF include buttock pain from nerve involvement with supporting ligatures in 3 percent of patients and vascular injury in 1 percent (Sze, 1997a,b). Although infrequent, significant and life-threatening hemorrhage can follow injury to blood vessels located near the sacrospinous ligament.

Uterosacral ligament vaginal vault suspension is another apical surgery. With this procedure, the vaginal apex is attached to remnants of the uterosacral ligament at the level of the ischial spines or higher. Performed vaginally or abdominally, the uterosacral ligament vaginal vault suspension is believed to replace the vaginal apex to a more anatomic position than SSLF, which deflects the vagina posteriorly (Barber, 2000; Maher, 2004; Shull, 2000). This procedure has been adopted by many surgeons in the United States in attempts to reduce the rates of anterior vaginal prolapse recurrence following SSLF (Shull, 2000). Although uterosacral ligament vaginal vault suspension has gained popularity, studies supporting its use are limited to retrospective case series (Amundsen, 2003; Karram, 2001; Silva, 2006). In these studies and others, anterior vaginal prolapse recurrence rates range from 1 to 7 percent, and overall recurrence rates from 4 to 18 percent. One landmark RCT compared SSLF and uterosacral ligament vaginal vault suspension and did not find significant differences in anatomic or functional outcomes between the two procedures at 2 years (Barber, 2014).

### Hysterectomy at the Time of Prolapse Repair

In the United States, hysterectomy is often performed concurrently with prolapse surgery. Conversely, in many European countries, it is rarely performed during pelvic floor reconstruction. Although this has not been compared in RCTs, arguments exist for both. If apical or uterine prolapse is present, hysterectomy will more readily allow the vaginal apex to be resuspended with the previously described apical suspension procedures. If hysterectomy is not performed in the context of apical prolapse, these procedures must be modified or specific uterine suspension procedures performed (not described in this text). Alternatively, if apical or cervical prolapse is not present, hysterectomy need not be incorporated into prolapse repair.

### Posterior Compartment

Posterior vaginal wall prolapse may be due to enterocele or rectocele. Enterocele is defined as herniation of the small bowel through the vaginal fibromuscular layer, usually at the vaginal apex. Discontinuity of the anterior and posterior vaginal wall fibromuscular layers allows for this herniation. Accordingly, enterocele repairs have as their goal reattachment of these fibromuscular layers. If posterior wall prolapse is due to enterocele, repair of this defect should reduce the posterior wall prolapse.

If due to rectocele, posterior vaginal wall prolapse is repaired with one of several techniques, which are illustrated in Chapter 45 (p. 1093). Of these, traditional posterior colporrhaphy aims to rebuild the fibromuscular layer between the rectum and vagina by performing a midline fibromuscular plication. The anatomic cure rate is 76 to 96 percent, and most studies report a greater than 75-percent improvement rate of bulge symptoms (Cundiff, 2004). To narrow the genital hiatus and prevent recurrence, some surgeons plicate the levator ani muscle concurrently with posterior repair. However, this practice may contribute to dyspareunia rates of 12 to 27 percent (Kahn, 1997; Mellegren, 1995; Weber, 2000). Thus, it is best avoided in women who are sexually active.

Site-specific posterior repair is an approach based on the assumption that specific tears in the fibromuscular layer can be

repaired in a discrete fashion. Defects may be midline, lateral, distal, or superior. This approach is conceptually analogous to a fascial hernia, in which the fascial tear is identified and repaired. Thus, its theoretical advantage lies in its restoration of normal anatomy rather than plication of tissue in the midline. Although site-specific repair has gained wide acceptance, anatomic cure rates range from 56 to 100 percent, similar to that with traditional posterior colporrhaphy (Muir, 2007). Moreover, anatomic and functional long-term outcomes are unknown.

Mesh reinforcement with allograft, xenograft, or synthetic mesh has been used in conjunction with posterior colporrhaphy and site-specific repair to help reduce prolapse recurrence. However, the efficacy and safety of graft augmentation in the posterior vaginal wall has not been established. Paraiso and coworkers (2006) randomly assigned 105 women to posterior colporrhaphy, site-specific repair, or site-specific repair plus a graft using porcine small intestine submucosa. After 1 year, those with graft augmentation had a significantly higher anatomic failure rate (46 percent) than those who received site-specific repair alone (22 percent) or posterior colporrhaphy (14 percent). More research is needed to determine the safety, efficacy, and optimal material for posterior wall graft augmentation. Until then, the use of mesh in the posterior vaginal wall should generally be avoided.

Last, sacrocolpoperineopexy is a modification of sacrocolpopexy. It may be selected for correction of posterior vaginal wall descent when an abdominal approach is employed for other prolapse procedures or if treatment of perineal descent is necessary (Cundiff, 1997; Lyons, 1997; Sullivan, 2001). With this procedure, the posterior sacrocolpopexy mesh is extended down the posterior vaginal wall to the perineal body. In several case series, anatomic cure rates were greater than 75 percent.

### Perineum

The perineal body provides distal support to the posterior vaginal wall and anterior rectal wall and anchors these structures to the pelvic floor. A disrupted perineal body will allow descent of the distal vagina and rectum and will contribute to a widened levator hiatus.

To recreate normal anatomy, perineorrhaphy is often done in conjunction with posterior colporrhaphy (Chap. 45, p. 1096). During surgery, the perineum is rebuilt through midline plication of the perineal muscles and connective tissue. Importantly, overly aggressive plication can narrow the introitus, create a posterior vaginal wall ridge, and lead to entry dyspareunia. However, in a woman who is not sexually active, high perineorrhaphy with intentional introital narrowing is believed to decrease the risk of posterior wall prolapse recurrence.

## ■ Mesh in Reconstructive Pelvic Surgery

### Mesh Indications

Approximately 30 percent of women undergoing surgery for prolapse will require a repeat operation for recurrence (Olsen, 1997). As such, continuous efforts strive to improve surgical procedures and outcomes.

Synthetic mesh for sacrocolpopexy and midurethral slings has been widely studied and is safe and effective. Mesh erosion

**TABLE 24-8.** Types of Surgical Mesh

<b>Type I:</b>	Macroporous. Pore size > 75 μm (size required for infiltration by macrophages, fibroblasts, blood vessels in angiogenesis, and collagen fibers) GyneMesh, Atrium, Marlex, Prolene
<b>Type II:</b>	Microporous. Pore size < 10 μm in at least 1 dimension Gore-Tex
<b>Type III:</b>	Macroporous patch w/ multifilaments or a microporous component Teflon, Mersilene, Surgipro, Mycro Mesh
<b>Type IV:</b>	Submicronic. Pore size < 1 μm. Often used in association with type I mesh for intraperitoneal adhesion prevention Silastic, Cellgard, Preclude

Data from Amid PK: Classification of biomaterials and their related complications in abdominal wall hernia surgery. Hernia 1:15, 1997.

develops in a small percentage of cases but can be managed with local estrogen therapy and limited vaginal wall mesh excision. Rarely is excision of the entire mesh warranted. In an attempt to limit erosion rates, surgeons have used biologic material grafts, including cadaveric fascia. However, high rates of prolapse recurrence are associated with this material (FitzGerald, 1999, 2004; Gregory, 2005). Therefore, synthetic mesh is recommended for sacrocolpopexy and midurethral slings.

The use of biologic grafts or synthetic mesh for other transvaginal reconstructive pelvic surgery has expanded rapidly and in the absence of supporting long-term safety and efficacy data. Some surgeons routinely use graft or mesh augmentation, others never use it, and some use it only for limited indications. Selective use may include: (1) the need to bridge space, (2) weak or absent connective tissue, (3) connective tissue disease, (4) high risk for recurrence (obesity, chronically increased intraabdominal pressure, and young age), and (5) shortened vagina.

Despite the common use of mesh or grafts, one systematic review on their use in transvaginal prolapse repair found a lack of high-quality scientific data to support this practice (Sung, 2008). Since this review, several RCTs have found that mesh use compared with no mesh for anterior colporrhaphy yields higher short-term rates of successful prolapse treatment. However, more surgical complications and postoperative adverse events are associated with mesh use in these studies (Altman, 2011). In 2011, the Food and Drug administration (FDA) reported the potentially serious complications associated with surgical mesh for transvaginal repair of POP. Noted complications include mesh erosion, scarring, pain, and dyspareunia. Additionally, synthetic mesh may become ingrown and difficult to remove. Complications may therefore be irreversible. Thus, the FDA urges clinicians to weigh the risks versus theoretical benefit of this practice. The American College of Obstetricians and Gynecologists (2011) and AUGS (2012) echo these concerns and recommend that vaginal synthetic mesh for the treatment of POP should be reserved for high-risk women in whom the benefits outweigh the risks.

Mesh Material

Surgeons using mesh or grafts should be familiar with the different types and their characteristics. Biologic grafts may be autologous, allograft, or xenograft. *Autologous* grafts are harvested from another part of the patient’s body such as rectus abdominis

fascia or thigh fascia lata. Morbidity is low but may include increased operative time, pain, hematoma, or weakened fascia at the harvest site. *Allografts* come from a human source other than the patient and include cadaveric fascia or cadaveric dermis. *Xenografts* are biologic tissue obtained from a source or species foreign to the patient such as porcine dermis, porcine small intestinal submucosa, or bovine pericardium. Biologic materials have varying biomechanical properties and, as noted earlier, are associated with high rates of prolapse recurrence. Thus, recommendations on the appropriate clinical situations for biologic material are limited.

Synthetic mesh is classified as types I through IV, based on pore size (Table 24-8) (Amid, 1997). Pore size is the most important property of synthetic mesh. Bacteria generally measure less than 1 μm, whereas granulocytes and macrophages are typically larger than 10 μm. Thus, a mesh with pore size < 10 μm may allow bacterial but not macrophage infiltration and thereby predispose to infection. Accordingly, type I mesh has the lowest rate of infection compared with types II and III. Pore size is also the basis of tissue ingrowth, angiogenesis, flexibility, and strength. Pore sizes of 50 to 200 μm allow for superior tissue ingrowth and collagen infiltration. This again favors type I. Meshes are either monofilament or multifilament. Multifilament mesh has small intrafiber pores that can harbor bacteria, therefore, monofilament mesh is recommended. From these findings, consensus suggests that if synthetic mesh is used, type I monofilament is the best choice for reconstructive pelvic surgery.

Mesh or graft augmentation will undoubtedly persist due to the current poor cure rates with traditional transvaginal repairs. However, evidence to guide the surgeon and provide a patient with accurate safety and efficacy information is scant. Moreover, industry-driven, premature adoption of untested materials and procedures has historically led to unacceptable complications. For these reasons, randomized, prospective trials comparing traditional repairs with graft or mesh augmentation are needed.

■ Concomitant Prolapse and Incontinence Surgery

Prior to prolapse repairs, women should be evaluated for SUI (Chap. 23, p. 526). Those with bothersome SUI symptoms are considered for concurrent antiincontinence surgery. However, in

women without SUI symptoms, latent stress incontinence may be unmasked or SUI may develop de novo following prolapse repair. Therefore, preoperative urodynamic testing with the prolapse replaced is recommended. If SUI is demonstrated, these patients also are considered for a concurrent antiincontinence operation. This has been a difficult decision for patients and surgeons because a procedure with known risks is being performed for a problem that does not currently exist and may never develop.

The CARE (Colpopexy and Urinary Reduction Efforts) trial has helped clarify this problem (Brubaker, 2006). In this trial, women undergoing abdominal sacrocolpopexy for prolapse who did not exhibit symptoms of SUI were randomized to undergo concurrent Burch colposuspension or not. Preoperative urodynamic testing was performed, but surgeons were blinded to the results. Three months after surgery, 24 percent of women in the Burch group and 44 percent of women in the control group met one or more criteria for SUI. The incontinence was bothersome in 6 percent of the Burch group and 24 percent of the control group.

These data can be interpreted in several ways. It can be argued that all women undergoing sacrocolpopexy for stage 2 or greater anterior vaginal wall prolapse should undergo Burch colposuspension, as 44 percent will develop SUI symptoms. However, the opposing argument is that only 24 percent will develop bothersome incontinence symptoms, thus three quarters of women would be subjected to an unnecessary operation.

In a similar trial, the Outcomes Following Vaginal Prolapse Repair and Mid Urethral Sling (OPUS) trial, women undergoing vaginal surgery for POP who did not have SUI symptoms were randomly assigned to receive a midurethral sling or sham incision. Twelve months after surgery, 27 percent of women in the sling group and 43 percent of women in the sham group had incontinence (Wei, 2012).

Importantly, these studies provide high-quality evidence for a surgeon to share during patient counseling. The decision to perform a concurrent antiincontinence operation in women without SUI should be individualized and based on risks, benefits, and patient goals and expectations.

### ANAL INCONTINENCE

Although definitions are inconsistent, anal incontinence (AI) is most commonly defined as an involuntary loss of flatus, liquid, or solid stool that causes a social or hygienic problem (Abrams, 2005; Haylen, 2010). The definition of AI includes incontinence of flatus, whereas that of fecal incontinence (FI) does not.

Despite acceptance of these by healthcare professionals, one survey observed that only 30 percent of nearly 1100 community-dwelling women with FI had heard the term “fecal incontinence,” and 71 percent preferred the term “accidental bowel leakage” (Brown, 2012). Thus, at a recent consensus workshop, this latter more patient-centered term was suggested for use with patients (Bharucha, 2015).

AI can lead to poor self-image and isolation, and the social and quality-of-life effects of AI are significant (Johanson, 1996). Additionally, AI increases the likelihood that an older patient will be admitted to a nursing home rather than cared for at home (Grover, 2010).

#### ■ Epidemiology

Anal incontinence is common, and rates among men and women are similar (Madoff, 2004b; Nelson, 2004). In one National Health and Nutrition Examination Survey (NHANES), FI was also not significantly associated with race or ethnicity, education level, income, or marital status (Whitehead, 2009). Although all age groups may be affected, the AI prevalence increases with age and may reach 46 percent in older, institutionalized women (Nelson, 1998). Using data from NHANES that incorporated years 2005 through 2010, investigators noted that the

prevalence of FI in women approximated 9 percent (Nygaard, 2008; Wu, 2014). Similarly, the estimated prevalence of FI in noninstitutionalized U.S. adults was 8.3 percent (18 million). Of these individuals, liquid stool incontinence was noted in 6.2 percent, mucus in 3.1 percent, and solid stool in 1.6 percent (Whitehead, 2009). The prevalence of FI increased from 2.6 percent in those aged 20 to 30 years and rose to 15.3 percent in subjects aged 70 years or older.

#### ■ Physiology

Normal defecation and anal continence are complex processes that require: (1) a competent anal sphincter complex, (2) normal anorectal sensation, (3) adequate rectal capacity and compliance, and (4) conscious control. Logically, mechanisms responsible for FI include anal sphincter and pelvic floor weakness, reduced or increased rectal sensation, reduced rectal capacity and compliance, and diarrhea (Bharucha, 2015). In many patients these factors may be additive, and thus no single physiologic measure is consistently associated with FI.

#### Muscular Contributions

Essential contributors to fecal continence include the internal and external anal sphincters and the puborectalis muscle (Figs. 38-9 and 38-21, p. 803). Of these, the internal anal sphincter (IAS) is the thickened distal 3- to 4-cm longitudinal extension of the colon’s circular smooth-muscle layer. It is innervated by the autonomic nervous system and provides 70 to 85 percent of the anal canal’s resting pressure (Frenckner, 1975). As a result, the IAS contributes substantially to the maintenance of fecal continence at rest.

The external anal sphincter (EAS) consists of striated muscle and is primarily innervated by somatic motor fibers that course in the inferior rectal branch of the pudendal nerve (Fig. 25-1A). The EAS provides the anal canal’s squeeze pressure and is mainly responsible for maintaining fecal continence when continence is threatened. At times, squeeze pressure may be voluntary or may be induced by increased intraabdominal pressure. In addition, although resting sphincter tone is generally attributed to the IAS, the EAS maintains a constant state of resting contraction and may be responsible for approximately 25 percent of anal resting pressure. During defecation, however, the EAS relaxes to allow stool passage.

The puborectalis muscle is part of the levator ani muscle group and is innervated from its pelvic surface by direct efferents from the third, fourth, and fifth sacral nerve roots (Fig. 25-1B) (Barber, 2002). Although the suggestion is controversial, it may also be innervated from its perineal surface by the inferior rectal

**FIGURE 25-1** Innervation of the anal sphincter complex. **A.** The external anal sphincter is innervated by the pudendal nerve. **B.** Innervation of the female pelvic floor muscles from direct branches of S3-S5.

branch of the pudendal nerve. Its constant tone contributes to the anorectal angle, which aids in preventing rectal contents from entering the anus (Fig. 38-10, p. 803). Similar to the EAS, this muscle can be contracted voluntarily or in response to sudden increases in abdominal pressure.

The role of the puborectalis in maintaining stool continence remains unclear. However, it is best appreciated in women who remain continent of solid stool despite absence of the anterior arch of the external and internal sphincters, as can be seen in those with chronic fourth-degree lacerations (Fig. 25-2). With normal

puborectalis relaxation, evacuation is generally aided by the better longitudinal alignment of the rectoanal lumen. Conversely, paradoxical contraction of the puborectalis muscle during defecation may lead to impaired evacuation. Moreover, atrophy of this muscle has been associated with FI (Bharucha, 2004).

### Anorectal Sensation

Innervation to the rectum and anal canal is derived from the inferior hypogastric nerve plexus that contain sympathetic and parasympathetic components and by intrinsic nerves present in

**FIGURE 25-2** Chronic fourth-degree laceration with complete absence of the perineal body and the anterior portion of external anal sphincter (cloacal-like deformity). Skin dimples at 3 and 9 o'clock (arrows) indicate sites of retracted ends of the external anal sphincter.

the rectoanal wall (Fig. 38-13, p. 806). In addition, the inferior rectal branch of the pudendal nerve conveys sensory input from the lower anal canal and the skin around the anus. Sensory receptors within the anal canal and pelvic floor muscles can detect the presence of stool in the rectum and the degree of distention. Through these neural pathways, information regarding rectal distention and rectal contents can be transmitted and processed and the action of the sphincteric musculature coordinated.

The rectoanal inhibitory reflex (RAIR) refers to the transient relaxation of the IAS and contraction of EAS induced by rectal distention when stool first arrives in the rectum. This reflex is mediated by the intrinsic nerves in the anorectal wall and allows the sensory-rich upper anal canal to come in contact with or “sample” the rectal contents (Whitehead, 1987). Specifically, sampling refers to the process whereby the IAS relaxes, often independently of rectal distention, allowing the anal epithelium to ascertain whether rectal contents are gas, liquid, or solid stools (Miller, 1988).

Following integration of this neural information, defecation can ensue in the appropriate social setting. Alternatively, if required, defecation can generally be postponed, as the rectum can accommodate its contents and the EAS or puborectalis muscle or both can be voluntarily contracted. However, if rectal sensation is impaired, contents may enter the anal canal and may leak before the EAS can contract (Buser, 1986).

Evaluation of the RAIR may clarify the underlying etiology of AI. This reflex is absent in those with congenital aganglionosis (Hirschsprung disease) but preserved in patients with cauda equina lesions or after spinal cord transection (Bharucha, 2006).

### Rectal Accommodation and Compliance

Following anal sampling, the rectum can relax to admit the increased rectal volume in a process known as accommodation. The rectum is a highly compliant reservoir that permits stool storage. As rectal volume increases, an urge to defecate is perceived. If this urge is voluntarily suppressed, the rectum relaxes to continue stool accommodation. A loss of compliance may decrease the ability of the rectal wall to stretch or accommodate, and as a result, rectal pressure may remain high. This may

place increased demands on the other components of the continence mechanism such as the anal sphincter complex.

Rectal compliance can be calculated by measuring the sensitivity to and maximal volume tolerated from a fluid-filled balloon during anorectal manometry (p. 567). Rectal compliance may be decreased in those with ulcerative and radiation proctitis. In contrast, increased compliance may be noted in certain patients with constipation, potentially signaling a megarectum.

## Incontinence Risks

### Obstetric

Abnormal defecation develops if any of the just-described components of anal continence are altered. Logically, causes of AI and defecatory disorders are diverse and are likely multifactorial (Table 25-1).

In younger, reproductive-aged women, the most common association with AI is vaginal delivery and damage to the anal sphincter muscles (Snooks, 1985; Sultan, 1993; Zetterstrom, 1999). This damage may be mechanical or neuropathic and can result in fecal and flatal incontinence at an early age. Interestingly, the incidence of FI following vaginal delivery has declined from 13 percent of primiparous women two decades ago to 8 percent in more recent series (Bharucha, 2015). This may reflect changes in obstetric practices that include decreased use of instrumented vaginal delivery and more restricted episiotomy use.

**TABLE 25-1.** Risk Factors for Fecal Incontinence

### Obstetric

Increasing parity      Anal sphincter damage

### Medical conditions

Obesity	Diabetes mellitus
Aging	COPD
Smoking	Chronic hypertension
Postmenopausal	Stroke
Medications	Scleroderma
Decreased activity	Pelvic radiation

### Urogynecologic

Urinary incontinence      Pelvic organ prolapse

### Gastrointestinal

Constipation	Anal abscess
Diarrhea	Anal fistula
Fecal urgency	Anal surgery
Food intolerance	Cholecystectomy
IBS	Rectal prolapse

### Neuropsychiatric

Spinal cord lesion	Myopathies
Parkinson disease	Psychosis
Spinal surgery	Nerve stretch injury
Multiple sclerosis	Cognitive dysfunction
Brain tumor	

COPD = chronic obstructive pulmonary disease;  
IBS = irritable bowel syndrome.

Rates of sphincter tear during vaginal births in the United States range from 6 to 18 percent (Fenner, 2003; Handa, 2001). In one study of primiparas delivered at term, at both 6 weeks and 6 months postpartum, women who sustained anal sphincter tears during vaginal delivery had twice the risk of FI and reported more severe FI compared with women who delivered vaginally without evidence of sphincter disruption (Borello-France, 2006). In contrast, a retrospective study of 151 women with diverse obstetric histories who delivered 30 years previously reported that women with a prior sphincter disruption were more likely to have “bothersome” flatal incontinence but were not at increased risk for FI compared with women who had an isolated episiotomy or those who underwent cesarean delivery (Nygaard, 1997). Thus, other mechanisms associated with pregnancy and with aging may contribute to AI regardless of delivery mode or anal sphincter disruption. Importantly, cesarean delivery minimizes the risk of anatomic anal sphincter injury, but it does not universally protect against later AI. The National Institutes of Health (NIH) (2006) consensus conference on cesarean delivery on maternal request concluded that evidence was insufficient to support a practice of elective cesarean delivery for the prevention of pelvic floor disorders, including FI.

Other Factors

Few epidemiological studies have evaluated the risk factors for FI in the community. That said, underlying bowel disturbances, particularly diarrhea; the symptom of rectal urgency; and burden of chronic illness, are the strongest independent risk factors for FI (Bharucha, 2015). Inflammatory bowel conditions, especially with chronic diarrhea, are another common risk. Liquid stool is more difficult to control than solid, and thus FI may develop even if all components of the continence mechanism are grossly intact. Alternatively, chronic constipation with straining to defecate may damage the muscular and/or neural components of the sphincter mechanism. Similarly, other neuromuscular injury to the puborectalis and/or anal sphincter muscles, such as that associated with pelvic organ prolapse, may lead to AI.

Radiation therapy involving the rectum can result in poor compliance and loss of accommodation. Also, nervous system dysfunction in those with spinal cord injury, back surgery, multiple sclerosis, diabetes, or cerebrovascular accident may lead to poor accommodation, loss of sensation, impaired reflexes, and myopathy. Finally, loss of rectal sensation and decreased squeeze sphincter pressures can be seen with normal aging. One study suggests that even asymptomatic older nulliparous

women have anal sphincter neurogenic injury, which partly explained weak anal squeeze pressures (Bharucha, 2012).

Diagnosis

There is no current consensus on how best to screen for FI. Proposed barriers include poor patient understanding of the term FI, embarrassment, a belief that FI is a normal part of aging, confusion as to whom they might discuss the problem with, priority of other medical conditions, and unfamiliarity or pessimism regarding treatment options (Bharucha, 2015). In one study, less than one third of patients with FI had disclosed this to a provider (Johanson, 1996). In another that evaluated women presenting for benign gynecologic care, only 17 percent with FI were asked about the symptom by their health care provider (Boreham, 2005).

In contrast to urinary incontinence, no FI classification approach is widely accepted. However, the type (urge, passive, or mixed), etiology, and severity of FI provide some basis to categorize FI. A complete history and physical examination evaluates these prior to treatment planning and often identifies correctable problems.

History

To the patient, relevant questions are posed regarding incontinence duration and frequency, stool consistency, timing of incontinent episodes, use of sanitary protection, and incontinence-related social impairment. Additionally, risk factors noted in Table 25-1 are sought. Importantly, urge-related AI is differentiated from incontinence without awareness, as these may be associated with different underlying pathologies. For example, urgency without incontinence may reflect inability of the rectal reservoir to store stool rather than a sphincteric disorder.

To gather historical data, validated questionnaires, stooling diaries, and the Bristol Stool Scale are objective options. Of these, a patient diary of stool habits is commonly used in research, but its utility is often limited by poor patient adherence. Alternatively, questionnaires reduce patient recall bias and help standardize AI scores. Several incontinence-scoring systems provide objective measure of a patient’s degree of incontinence. Four commonly used symptom severity scores are the Pescatori Incontinence Score; Wexner (Cleveland Clinic) Score; St. Marks (Vaizey) Score; and the Fecal Incontinence Severity Index (FISI) (Tables 25-2 and 25-3) (Jorge, 1993; Pescatori, 1992; Rockwood, 1999; Vaizey, 1999). All of these incorporate the type and frequency of leakage. Of these, the Vaizey Score and the FISI include symptom weighting. The inclusion of patient-assigned severity scores increases the utility of the FISI compared with other scales. The ability of the

Vaizey Score to incorporate a component of fecal urgency makes this scale desirable in certain clinical trials.

In addition to symptom severity, the patient’s quality-of-life decline from AI is also characterized. T e validated fecal incontinence quality-of-life (FI-QOL) questionnaire is a 29-item tool designed to estimate associated worsening lifestyle, coping behavior, depression/self-perception, and embarrassment (Table 25-4) (Rockwood, 2000). Other quality-of-life scales available

**TABLE 25-4.** Fecal Incontinence Quality of Life Scale Composition

<b>Scale 1: Lifestyle</b>	
I am afraid to go out	I avoid traveling
I avoid visiting friends	I avoid traveling by plane or train
I avoid many things I want to do	I avoid staying overnight away from home
I plan my schedule around my bowel pattern	I avoid going out to eat
It is difficult for me to get out and do things	I limit how much I eat before I go out
<b>Scale 2: Coping/Behavior</b>	
I feel I have no control over my bowels	I have sex less often than I would like to
I worry about bowel accidents	I worry about not reaching the toilet in time
The possibility of bowel accidents is always on my mind	
Whenever I go someplace new, I specifically locate where the bathrooms are	
I try to prevent bowel accidents by staying very near a bathroom	
I can’t hold my bowel movement long enough to get to the bathroom	
Whenever I am away from home, I try to stay near a restroom as much as possible	
<b>Scale 3: Depression/Self-perception</b>	
In general, how would you say your health is?	I feel different from other people
I am afraid to have sex	I enjoy life less
I feel depressed	I feel like I am not a healthy person
During the past month, have you felt so sad, discouraged, hopeless, or had so many problems that you wondered if anything was worthwhile?	
<b>Scale 4: Embarrassment</b>	
I leak stool without even knowing it	
I worry about others smelling stool on me	
I feel ashamed	

Reproduced with permission from Rockwood TH, Church JM, Fleshman JW, et al: Fecal incontinence quality of life scale: quality of life instrument for patients with fecal incontinence, Dis Colon Rectum 1999 Dec;42(12):1525–1532.

**FIGURE 25-3** Bristol Stool Scale. Stools are categorized by their shape and texture. (Reproduced with permission from Lewis SJ, Heaton KW: Stool form scale as a useful guide to intestinal transit time. *Scand J Gastroenterol* 1997 Sep;32(9):920–924.)

include the Modified Manchester Health Questionnaire and the Gastrointestinal Quality of Life Index (Kwon, 2005; Sailer, 1998). These validated tools may be used diagnostically and also following treatment to determine response.

Last, the validated Bristol Stool Scale is often selected to determine a patient's usual stool consistency (Lewis, 1997). This scale contains seven descriptions of stool characteristics and pictures of each stool type (Fig. 25-3) (Degen, 1996). Such stool consistency categorization correlates with objective measures of whole-gut transit time (Heaton, 1994).

### Physical Examination

This begins with careful inspection of the anus and perineum to identify stool soiling, scars, perineal body length, hemorrhoids, anal warts, rectal prolapse, dovetail sign, or other anatomic

**FIGURE 25-4** Photograph showing the “dovetail” sign, which is created by disruption of the anterior portion of external anal sphincter (EAS). Radial skin spikes are typically formed by attachment of skin to the EAS but are commonly absent from 10 to 2 o'clock (asterisks) in those with this disruption.

abnormalities (Fig. 25-4). The perianal skin is gently stroked with a cotton-tipped swab to obtain the cutaneous anal reflex. Colloquially termed anal wink, circumferential contraction of the anal skin and underlying EAS is normally seen. This finding provides gross assessment of pudendal nerve integrity.

With digital rectal examination, one can assess anal resting tone, sample for gross or occult blood, and palpate masses or fecal impaction. In addition, squeeze pressure can subjectively be judged during voluntary patient contraction of the EAS around a gloved finger inserted into the anorectum. Last, during patient Valsalva maneuver, one observes for excessive perineal body descent, vaginal wall prolapse, rectal prolapse, or muscle incoordination (Fig. 25-5). With the latter, a paradoxical

**FIGURE 25-5** During patient Valsalva, a full-thickness rectal prolapse protrudes through the anal opening.

contraction—that is, abnormal sphincter contraction around the finger—may be elicited during patient Valsalva when an examining finger is inserted into the anorectum. Digital rectal examination is reasonably accurate relative to manometry for assessing anal resting tone and squeeze function and for identifying dyssynergia (Orkin, 2010; Tantiphlachiva, 2010).

Diagnostic Testing

**Anorectal Manometry.** Physical and historical findings typically guide the remainder of testing, which may include imaging and functional studies. Of these, anorectal manometry is performed mainly in academic institutions with an anophysiology laboratory prior to surgical intervention. It is a functional test that allows objective assessment of: (1) rectal compliance

and rectal sensation, (2) reflexes, and (3) anal sphincter function (Table 25-5). During this test, a small flexible tube containing an inflatable balloon tip and pressure transducer is inserted into the rectum (Fig. 25-6). First, rectal compliance and sensation may be determined by sequentially inflating a rectal balloon to various volumes. Decreased rectal compliance may be noted by an inability to inflate a balloon to typical volumes without patient discomfort. This may indicate a rectal reservoir that is unable to appropriately store stool. In contrast, decreased perception of balloon insufflation may indicate neuropathy.

Second, sphincter reflexes are also assessed during pressure measurements. During balloon insufflation, relaxation of the IAS should accompany rectal distention via the rectoanal inhibitory reflex (p. 563).

**FIGURE 25-6** Manometry tube and balloon, empty (A) and after filling (B).

Third, IAS resting pressure and EAS squeeze pressure are then measured at incremental points as the balloon is slowly withdrawn from the rectum. In general, decreased pressure readings may indicate structural disruption, myopathy, or neuropathy. As an additional test, the rectal balloon expulsion test may be performed as a patient simulates defecation and expels the balloon. The balloon expulsion test is mainly used in patients with constipation and attempts to differentiate between obstructed constipation and functional constipation (Minguez, 2004).

The main limitation with manometry is that normal values may be seen in incontinent patients and vice versa. Despite this disadvantage, anal manometry plays an important role in AI evaluation.

**Endoanal Ultrasonography.** Also known as transanal sonography, this technique is now the primary diagnostic imaging technique to evaluate the integrity, thickness, and length of the IAS and EAS (Fig. 25-7). It is performed for many patients during FI testing, especially if sphincter integrity is in question. The technique uses a rotating endoprobe with a  $\geq 10$ -MHz transducer, which provides a 360-degree evaluation of the anal canal. Sonography gel is placed on the probe tip, which is sheathed with a condom prior to insertion into the anus. This tool allows diagnosis of anterior anal sphincter defects in women with a known history of clinically diagnosed anal sphincter disruption and also in those with unrecognized or misdiagnosed defects at the time of delivery. Prior to the common use of endoanal sonography (EAUS), women with these “occult”—that is, solely sonographically diagnosed—anal sphincter defects were labeled as having “idiopathic” FI and were not considered good candidates for surgical correction.

In addition to the anal sphincters, this modality can image the puborectalis muscle and perineal body. Oberwalder and

colleagues (2004) showed that in a group of incontinent women, perineal body thickness  $< 10$  mm was associated with anal sphincter defects in 97 percent of cases, whereas perineal body thicknesses of 10 to 12 mm were associated with sphincter defect in only one third of patients with FI. Perineal body thickness  $> 12$  mm was infrequently associated with these defects.

Newer techniques may also be informative. For example, dynamic endoanal or transperineal ultrasound can permit functional assessment of the anorectum, similar to defecography, described next (Vitton, 2011).

**Evacuation Proctography.** During this radiographic test, also known as defecography, the rectum is opacified with a thick barium paste, and the small bowel fills with a barium suspension given orally. Radiographic or fluoroscopic imaging is then obtained while a patient is resting, contracting her sphincter, coughing, and straining to expel the barium.

This test of dynamic rectal emptying and anorectal anatomy is not widely used to assess evacuation disorders unless obstructive causes for AI are suspected. Accordingly, it may be obtained if intussusception, internal rectal prolapse, enterocele, or failed relaxation of the puborectalis muscle during defecation is a concern.

**Magnetic Resonance Imaging.** Magnetic resonance (MR) imaging of the anal sphincter complex can be done either with an endoanal coil placed in the anorectum or with external phased-array coils. The latter external coil technique is preferred because physical anatomy is less distorted and the lack of an intraluminal coil increases patient comfort (Van Koughnett, 2013a). MR imaging is more expensive than EAUS, and its value for anal sphincter evaluation is controversial on several points. First, EAUS is more sensitive in detecting IAS

**FIGURE 25-7** Cross-sectional anal endosonography images at level of mid anal canal. **A.** A woman with normal anal sphincters. **B.** Anterior defects of the external and internal anal sphincter muscles. EAS = external anal sphincter; IAS = internal anal sphincter. Dashed lines and (arrows) in B illustrate the ends of the torn EAS.

abnormalities, whereas MR imaging is more sensitive in visualizing EAS morphology, including atrophy (Beets-Tan, 2001; Rociu, 1999). This may have value preoperatively, as patients with EAS atrophy may have poorer results following anal sphincteroplasty compared with those without atrophy (Briel, 1999). Second, MR imaging results vary considerably among interpreters and depend on their experience level. Thus, either EAUS or MR imaging can only be recommended in FI evaluation if sufficient experience is available (Terra, 2006).

Another MR imaging modality, termed dynamic MR imaging, allows dynamic examination of rectal emptying and evaluation of pelvic floor muscles during rest, squeeze, and defecation (Gearhart, 2004; Kaufman, 2001). Thus, it simultaneously permits a survey of pelvic anatomy, organ prolapse, and defecatory function. This may be particularly appealing to patients requiring multiple anorectal tests (Khatri, 2014; Van Koughnett, 2013a). However, it is technically difficult, more expensive, and again requires an experienced radiologist. Moreover, other than avoiding the ionizing radiation of evacuation proctography, this technique offers no advantage for studying rectal function. In addition, the variability of pelvic MR imaging measurements among readers is high (Lockhart, 2008). Despite these limitations, this test has been increasingly adopted in many academic settings, including our institution.

**Electromyography.** This test uses a needle or surface electrode to record electrical activity of muscles at rest and during contraction. During needle electromyography (EMG), needle electrodes are inserted through the skin into a muscle, and electrical activity detected by these electrodes is displayed graphically. In evaluation of AI, EMG may be used to assess the neuromuscular integrity of the EAS and puborectalis muscle. Specifically, by measuring action potentials from muscle motor units, EMG can help clarify which portions of these muscles are contracting and relaxing appropriately. Additionally, following injury, muscle may be partially or completely denervated, and compensatory reinnervation may then follow. Patterns characteristic of such denervation and reinnervation may be identified with EMG.

Unlike needle electrodes, surface patch electrodes are placed on the darker-skinned area of the anus, cause little discomfort to the patient, and carry no risk of infection. However, this technique is prone to artifacts. In comparing the two, needle EMG is painful but provides useful information regarding sphincter innervation. Surface EMG may be best used during repetitive biofeedback sessions. In general, its use is limited to research centers.

**Pudendal Nerve Terminal Motor Latency Test.** This stimulation test of the pudendal nerve measures the time delay between electrical nerve stimulation and EAS motor response. This delay, also termed latency, if prolonged, may indicate pudendal nerve pathology, which may be a cause of AI.

During pudendal nerve terminal motor latency (PNTML) testing, a stimulating electrode positioned on an examiner's gloved fingertip is connected to a pulsed-stimulus generator. The pudendal nerves are transanally stimulated through the lateral walls of the rectum at the level of the ischial spines by this electrode. The action potential response of the EAS is received by recording electrodes at the base of the examining finger and registered on an oscilloscope.

Although PNTML prolongation has long been considered a marker of idiopathic FI, this test provides little information regarding FI etiology. PNTML results have been contradictory and this test is not endorsed by many experts, including the American Gastroenterological Association (Diamant, 1999). Moreover, the relationship of pudendal nerve function, typically assessed by PNTML, to sphincteroplasty outcome remains unclear (Madoff, 2004a). One study found no association between pudendal nerve status and long-term postoperative anal continence (Malouf, 2000). Accordingly, it has been replaced by more specific and sensitive tests for sphincter muscle innervation such as EMG (Barnett, 1999). Currently, needle electromyography is the only available technique for documenting neurogenic injury but is performed only in select academic centers and mostly in the context of research clinical trials.

Unfortunately, EMG and PNTML do not provide an assessment of all the peripheral nerves that innervate the anorectum. In addition, both tests are associated with patient discomfort. These significant limitations have prevented widespread acceptance or use of needle EMG and PNTML testing. Currently, anorectal neurologic injury is assessed by performing anal EMG or PNTML but only in specialized centers. Newer and less invasive approaches for documenting neurogenic injury have been described and are under investigation (Meyer, 2014; Rao, 2014).

**Colonoscopy and Barium Enema.** Based on the history and physical examination, these tests may be indicated to exclude inflammatory bowel conditions or malignancy.

## ■ Treatment

### Nonsurgical Treatment

Treatment of FI is highly individualized and dependent on etiology, severity, available treatment options, and patient health. Because FI etiology is often multifactorial, treatments that target only one mechanism (such as sphincter weakness) are unlikely to benefit all patients with FI. Moreover, because current surgical outcomes are less than optimal, most patients, even those with anatomic defects, are initially treated conservatively. Of conservative options, management may include patient education, normalization of stool consistency, behavioral techniques, and daily pelvic floor muscle strengthening exercises (Whitehead, 2015).

**Medical Management.** For patients with minor incontinence, the use of bulking agents can thicken stool consistency and create feces that are firmer and easier to control (Table 25-6). Common side effects such as abdominal distention and bloating can be improved by starting with smaller doses or switching to a different agent. In support of this practice, a small randomized trial showed that fiber supplementation decreased diarrhea-associated FI (Bliss, 2001). However, evidence that fiber supplements benefit patients with constipation-associated FI is lacking.

Also to bulk stool, agents that slow fecal intestinal transit time can reduce overall stool volume by increasing the time available for the colon to reabsorb fluid from stool. One such agent, loperamide hydrochloride (Imodium), also increases anal resting tone and thus may even benefit patients with FI

TABLE 25-6. Medical Management of Fecal Incontinence

Treatment	Brand Name	Oral Dosage
<b>Bulking agents</b>		
Psyllium	Metamucil	1 tbsp. mixed into 8 oz. of water 1–3 times daily
Psyllium	Konsyl	1 tsp. mixed into 8 oz. of water 1–3 times daily
Methylcellulose	Citrucel	1 tbsp. mixed into 8 oz. of water 1–3 times daily
<b>Loperamide hydrochloride</b>	Imodium	2–4 mg, 1–4 times daily to a maximum daily dose of 16 mg
<b>Diphenoxylate hydrochloride</b>	Lomotil	5 mg, 1–4 times daily to a maximum daily dose of 20 mg
<b>Amitriptyline</b>	Generic	10–25 mg at bedtime; increase by 10–25 mg weekly up to 75–150 mg at bedtime or a therapeutic drug level

and no diarrhea (Read, 1982). Side effects are uncommon and include dry mouth. One ongoing trial is comparing loperamide and oral placebo for FI treatment (National Institute of Child Health and Human Development, 2014).

Diphenoxylate hydrochloride (Lomotil) is used in the same capacity as loperamide, and dosing is similar. Although diphenoxylate is a Schedule V substance, potential for physical dependence is minimal. Of other possible medications, amitriptyline is a tricyclic antidepressant that can be used to treat idiopathic FI. Although the mechanism of action is poorly understood, some of its beneficial effects may be related to its anticholinergic properties. Other agents such as cholestyramine and clonidine, an  $\alpha$ -adrenergic agonist, have been studied, but current data are limited (Whitehead, 2015). The laxative lactulose aids some nursing home residents with FI associated with fecal impaction (Omar, 2013).

To guide drug selection, one systematic review analyzed pharmacologic agent use for FI treatment in adults (Omar, 2013). These reviewers noted that antidiarrheal drugs improve diarrhea-associated FI more than placebo, and loperamide is more effective than diphenoxylate. However, overall, they commented on the poor quality of evidence.

**Bowel Management.** Daily, timed, tap-water enemas or glycerin or bisacodyl suppositories (Dulcolax) may be used to empty the rectum after eating. These provide acceptable and helpful options for some patients with constipation symptoms associated with AI. These may include women with normal stool consistency but difficulty evacuating due to anatomic reasons such as rectocele with stool trapping or those with denervation and impaired rectal sensation. All these may lead to accumulation of a large mass of solid stool in the rectum and leaking of loose stool around it. Bulking agents can be used concurrently with these evacuation methods to diminish stooling between desired defecations.

**Biofeedback and Pelvic Floor Therapy.** Biofeedback is usually selected to increase neuromuscular conditioning. Specifically, for FI, therapy goals aim to improve anal sphincter strength, sensory awareness of stool presence, and coordination between the rectum and the anal sphincter (Rao, 1998). Treatment protocols are individualized and dictated by the underlying dysfunction. Accordingly, the number and frequency of sessions required for improvement varies, but

commonly three to six 1-hour, weekly or biweekly appointments are needed. In many cases, reinforcing sessions at various subsequent intervals are also recommended.

Biofeedback has been noted to be an effective treatment for FI, and up to 80 percent of treated patients show symptom improvement (Engel, 1974; Jensen, 1997; Norton, 2001). Despite this, one Cochrane review found insufficient evidence of biofeedback’s benefits for FI (Norton, 2012). However, a randomized controlled trial by Heymen and coworkers (2009) offers support. These investigators initially provided education materials and instruction regarding fiber supplements and/or antidiarrheal medication. Patients who were adequately treated by these strategies (21 percent) were excluded from further study. The remaining 107 patients, who remained incontinent and dissatisfied, then progressed to treatment, either biofeedback or pelvic floor exercises. Biofeedback training more effectively reduced FI severity and number of days with FI. Moreover, 3 months after training, 76 percent of biofeedback patients reported adequate relief of FI symptoms compared with only 41 percent of patients treated with pelvic floor exercises. Twelve months later, biofeedback improvement persisted.

The results of this and other trials suggest that biofeedback may not be necessary for patients with milder FI symptoms. However, for those with more severe FI symptoms, instrument-assisted biofeedback is effective (Whitehead, 2015).

**Pelvic Floor Muscle Strengthening.** Also known as Kegel exercises, active pelvic floor muscle training (PFMT) exercises voluntarily contract the levator ani muscles. Performance of these exercises is fully described in Chapter 23 (p. 528). As noted, these alone are less effective than biofeedback for patients with more severe FI symptoms (Heymen, 2009). However, exercises are safe and inexpensive and may benefit patients with mild symptoms, especially if performed in conjunction with other interventions, such as patient education, diet modification, and medical management.

In contrast to active PFMT, anal musculature can be passively stimulated electrically by electrodes. However, when used as sole therapy, electrical stimulation of the anus appears to be ineffective (Whitehead, 2015).

Surgical Treatment

Currently available FI surgical procedures are often associated with less than optimal results and with postoperative morbidity.

Accordingly, surgery is reserved for those patients with major structural abnormalities of the anal sphincter(s), those with severe symptoms, and those who fail to respond to conservative management.

**Anal Sphincteroplasty.** This is the most commonly performed FI corrective operation. Repair of the EAS and/or IAS is indicated for women with acquired AI and an anterior sphincter defect following an obstetric or iatrogenic injury. Two methods may be used for sphincter repair and include an end-to-end technique and an overlapping method, both described in Section 45-25 (p. 1125). The end-to-end technique is most frequently used by obstetricians to reapproximate torn ends of an anal sphincter at delivery. However, in patients remote from delivery with a sphincter defect and FI, the overlapping technique is preferred by most colorectal surgeons and urogynecologists.

With the overlapping method performed remote from delivery, short-term continence improvements of 67 percent were previously reported (Madoff, 2004a). However, recent reports show significant deterioration of continence during long-term postoperative surveillance (Bravo Gutierrez, 2004; Glasgow, 2012). In a single, retrospective study, no patients remained completely continent to liquid and solid stool at 10 years (Zutshi, 2009). Hypotheses regarding this deterioration include aging, scarring, and progressive pudendal neuropathy related either to initial injury or to repair. Patients who fail to improve after anal sphincteroplasty and who are found to have a persistent sphincter defect may be candidates for a second sphincteroplasty. However, those with an intact sphincter following repair and persistent symptoms are only considered candidates for conservative management or one of the salvage or minimally invasive surgical procedures described later.

Currently, no conclusive evidence supports that the overlapping method, if used at delivery, leads to results superior to those obtained with the traditional end-to-end method of anal sphincter repair (Farrell, 2012; Fitzpatrick, 2000; Garcia, 2005). Moreover, overlapping repair requires increased technical skills and carries the potential for increased blood loss, operating time, and pudendal neuropathy. For these reasons, the end-to-end technique is likely to remain the standard method for sphincter reapproximation at delivery until further data from randomized trials are available. Importantly, primary prevention of these lacerations should continue to be emphasized.

**Diversion (Colostomy or Ileostomy).** Diversion is reserved for patients with incapacitating FI who have failed other treatments (Sections 46-17 and 46-19, p. 1192). For these selected patients, such procedures can significantly improve their quality of life.

**Other Major Surgeries.** Of these, gracilis muscle transposition is advocated for patients who have failed sphincter repair or those with a sphincter defect too large to allow muscle reapproximation (Baeten, 1991). Dynamic graciloplasty separates the gracilis tendon from its point of insertion at the knee, wraps the muscle around the anus, and attaches the tendon to the contralateral ischial tuberosity. To squeeze the anus closed, the gracilis muscle is then stimulated with an electrical pulse generator that

is implanted in the abdominal wall. This procedure is not currently performed in the United States, as the pulse generator is not approved by the Food and Drug Administration (FDA) (Cera, 2005).

Implanting an artificial anal sphincter is another option to mimic sphincter function, but again, it is infrequently performed in the United States. With this, a fluid-inflated cuff is implanted around the anus, a reservoir balloon is placed within the abdominal wall, and a control pump is inserted into one labium majus. When fully inflated, the cuff occludes the anal canal. When defecation is desired, the control pump in the labia is squeezed to move fluid from the anal cuff into the reservoir balloon. The cuff, when fluid-empty, relaxes pressure around the anus and permits defecation. The fluid within the reservoir then returns to the anal cuff to restore circumferential pressure and continence (Christiansen, 1987).

A third procedure, postanal pelvic floor repair, has largely been abandoned. The procedure is designed to reestablish the anorectal angle and to lengthen and tighten the anal canal. Through an intersphincteric approach, sutures are placed between the ends of the iliococcygeus, pubococcygeus, puborectalis, and external anal sphincter muscles. Although originally reported to improve incontinence in up to 80 percent of patients, similar results have not been replicated (Browning, 1983; Deen, 1993; Parks, 1975).

### Minimally Invasive Procedures

**Sacral Nerve Stimulation.** In 2011, the FDA approved sacral nerve stimulation (SNS) for FI treatment. Also known as sacral neuromodulation, this surgery is typically offered to women who have failed to adequately improve with multiple other conservative therapies, and a full description of the InterStim System procedure appears in Section 45-12 (p. 1085). To summarize, an electrode is placed near the S3 nerve root and connected to a temporary pulse generator. Electrical charges to this nerve root may modulate abnormal afferent impulses, although the exact mechanism of SNS action for FI remains unknown (Gourcerol, 2011). Patients who show  $\geq 50$  percent improvement during the temporary test phase are eligible for a permanent pulse generator.

In one prospective trial, 90 percent of 133 patients proceeded from temporary to permanent stimulation (Wexner, 2010). For this study, therapeutic success was defined as a 50-percent or greater reduction of incontinent episodes per week compared with baseline. At 12 months, 83 percent of subjects achieved therapeutic success, and 41 percent achieved 100 percent fecal continence. At 24 months, therapeutic success was found in 85 percent. At 5 years, 89 percent were deemed a therapeutic success, and 36 percent reported complete continence (Hull, 2013). Limited data are available from patients with an underlying EAS defect, but these suggest that SNS is also effective for this group (Chan, 2008; Matzel, 2011).

**Percutaneous Tibial Nerve Stimulation.** The posterior tibial nerve contains fibers from the sacral nerves. Stimulation of its peripheral fibers transmits impulses to the sacral nerves and reflexively neuromodulates the rectum and anal sphincters (Shafik, 2003). Percutaneous tibial nerve stimulation (PTNS)

is carried out with a needle inserted through the ankle skin in a position posterior and superior to the medial malleolus. The needle is then coupled with an electronic pulse generator. Outpatient stimulation sessions usually last 30 minutes and are provided one to three times weekly. Suitable candidates have criteria similar to those for SNS.

One review of 13 studies showed that 62 to 82 percent of patients reported at least a 50-percent reduction in the frequency of FI episodes (Tomas, 2013). Compared with the InterStim System, PTNS requires repetitive treatments to maintain effectiveness. However, PTNS is a minimally invasive outpatient technique with almost no associated morbidity (Tomas, 2013). A randomized controlled trial comparing SNS and PTNS in the treatment for FI is currently in progress (Marti, 2015).

**Bulking Agent Injection.** Injecting inert substances around the anal canal in patients with FI aims to increase resting anal canal pressure (Shafik, 1993). Although many patients with FI may be candidates for injectables, the ideal candidate is one who has seepage or mild to moderate FI, who has failed medical management, but who is not yet ready to undergo surgery (Van Koughnett, 2013b).

The results of a large multicenter randomized controlled trial support the efficacy of dextranomer injections compared with sham injections (Graf, 2011). At 3 months, 52 percent of the dextranomer-injected patients had at least a 50-percent decline in FI frequency, whereas only 31 percent of sham-treated patients achieved this reduction. A surveillance study showed that benefits persisted for 36 months (Mellgren, 2014).

**Secca Procedure.** This outpatient procedure is currently used in the United States to treat FI in patients with no evidence of sphincter defects or pudendal neuropathy. It delivers temperature-controlled radiofrequency energy to the IAS by means of a specifically designed anoscope. Resulting tissue heating is believed to cause collagen contraction followed by focal wound healing, remodeling, and tightening. Studies to date have involved only small cohorts. Efron and colleagues (2003) showed a median 70-percent resolution of symptoms in 50 patients. However, one retrospective series showed long-term benefit in only 22 percent, and most patients underwent additional treatments (Abbas, 2012).

**Other Therapies.** Several other treatment options are currently under investigation. First, a mesh sling can be inserted surgically through small incisions lateral to the anus. By a transobturator approach, the mesh is then tunneled beneath the puborectalis muscle to add support. A trial evaluating this technique has been completed, but long-term results are not yet available.

Second, a vaginally placed bowel-control device offers a non-surgical option. The vaginal insert contains a silicone-coated stainless steel base and posteriorly directed balloon. Using a pump, the vaginal insert is inflated to collaterally occlude the rectum. Thus, its primary limitation mirrors that for vaginal pessaries, namely, that not all women are successfully fitted. In one study, this device significantly improved objective and subjective measures of FI (Richter, 2015). Approximately 86

percent of patients considered bowel symptoms “very much better” or “much better.” Moreover, no serious adverse events were reported. However, longer-term outcome data are needed.

Anal plugs present another therapy option, but most current devices are uncomfortable and poorly tolerated. However, newer models made of softer material are under investigation (Meyer, 2014).

Last, magnetic beads strung on an elastic band can be inserted surgically around the anal canal to increase the resting pressure. Small studies have shown continence results comparable to the artificial anal sphincter and to SNS but with fewer complications (Whitehead, 2015). However, this device is not yet approved in the United States.

## FUNCTIONAL ANORECTAL DISORDERS

In the current classification of functional gastrointestinal disorders, three functional anorectal disorders are recognized: (1) functional FI, (2) functional anorectal pain, and (3) functional defecation disorders (Table 11-6, p. 266) (Drossman, 2006). Criteria for these and other functional GI disorders have been defined by the Rome III Foundation expert consensus organization and are primarily diagnosed based on patients’ reported symptoms. As with other functional disorders, organic disease is excluded prior to assignment of these diagnoses.

### ■ Functional Fecal Incontinence

Functional FI is defined by Rome III criteria as recurrent uncontrolled passage of fecal material for more than 3 months in an individual with anatomically normal defecatory muscles that function abnormally. As a result, fecal retention or diarrhea is common, and psychologic disorders may be associated. The etiology is varied, and causes may include disturbed intestinal motility, poor rectal compliance, impaired rectal sensation, and weakened pelvic floor muscles (Whitehead, 2001). Once diagnosed, functional FI is primarily treated with medical management or biofeedback, as described earlier.

### ■ Functional Anorectal Pain

Categories within this group are differentiated from one another by the duration of pain and by the presence or lack of associated puborectalis muscle tenderness. Levator ani syndrome, also known as levator ani spasm, usually presents as a pressure or ache in the upper rectum (Chap. 11, p. 269). Rome III criteria require that symptoms be present for more than 3 months; that episodes last at least 20 minutes; and that symptoms be associated with puborectalis muscle tenderness when palpated. In contrast, proctalgia fugax presents as sudden, severe anal or lower rectal pain that lasts for a few seconds to a few minutes. Pain may disrupt normal activities, but episodes rarely occur more than five times a year.

Treatments for levator ani syndrome are varied and may include, among others, trigger-point release maneuvers, biofeedback, local heat, and pharmacologic agents such as non-steroidal antiinflammatory drugs, other analgesics, muscle

relaxants, and tranquilizers. In contrast, proctalgia fugax is typically managed with reassurance.

## ■ Functional Defecation Disorders

This group of disorders includes dyssynergic defecation and inadequate defecatory propulsion disorders. Dyssynergic defecation is also called pelvic floor dyssynergia, anismus, outlet obstruction constipation, or spastic pelvic floor syndrome. It is characterized by failed relaxation of the puborectalis muscle and EAS, which is needed for normal defecation. This condition is common and is thought to account for 25 to 50 percent of chronic constipation cases (Bharucha, 2014; Wald, 1990). Symptoms include chronic straining and impaired or incomplete evacuation. Diagnosis requires confirmation by EMG, manometry, or radiologic testing that shows persistent contraction of these muscles during attempted defecation. Other causes of constipation should also be excluded.

The treatment of constipation is challenging and often ineffective. Schiller and associates (1984) showed that only 53 percent of patients were satisfied with traditional medical therapies. Biofeedback interventions for dyssynergic defecation teach patients to relax their pelvic floor and anal sphincter muscles while simultaneously increasing intraabdominal and intrarectal pressures (Valsalva maneuver). The efficacy of biofeedback compared with laxatives in treating dyssynergic defecation was demonstrated in a controlled trial by Chiarioni and coworkers (2006). Moreover, biofeedback benefits were sustained at 1-year follow-up. In a prospective randomized trial by Rao and associates (2007), biofeedback efficacy was compared with sham feedback therapy and with standard therapy (diet, exercise, laxatives) in 77 subjects with chronic constipation and dyssynergic defecation. Subjects in the biofeedback group had a greater number of complete spontaneous bowel movements and greater satisfaction with bowel function and were more likely to discontinue the use of digital maneuvers than subjects receiving standard or sham therapy. In addition, colonic transit time significantly improved in biofeedback and standard therapy subjects but not in subjects who received sham feedback, suggesting that colonic transit slowing is due to dyssynergia. These findings emphasize the importance of performing neuromuscular conditioning and modifying the underlying physiologic behavior to correct dyssynergia and improve bowel function. Based on current data, biofeedback therapy is the preferred treatment for patients with dyssynergic defecation and chronic constipation, especially for those who have failed diet, exercise, and/or laxative therapy.

Sacral nerve stimulation, described on page 571, is a promising therapeutic option for patients with intractable constipation. Although not yet approved in the United States for this indication, a prospective study showed that SNS effectively treated idiopathic slow- and normal-transit constipation refractory to conservative measures (Kamm, 2010). In this study, primary end points were increased defecation frequency, decreased straining, and decreased sensation of incomplete evacuation. Of 62 patients who underwent a temporary-generator trial, 73 percent proceeded to permanent generator implantation. Treatment success was achieved in 87 percent of these patients.

## RECTOVAGINAL FISTULA

### ■ Definition and Classification

Rectovaginal fistulas (RVFs) are congenital or acquired epithelial lined tracts between the vagina and rectum. They are classified according to their location, size, and etiology. All of these features assist selection of the appropriate management and prediction of surgical repair outcome. Of factors, the underlying cause of a fistula is the most important predictor of outcome success, as it takes into account tissue and overall patient health (Table 25-7).

Most RVFs are related to obstetric events and occur in the distal third of the vagina just above the hymen (Fig. 25-8) (Greenwald, 1978; Lowry, 1988; Tsang, 1998). Defect diameters range from less than 1 mm to several centimeters, and most communicate with the rectum at or above the pectinate (dentate) line (Fig. 38-21, p. 815). In contrast, fistulas with an opening below the dentate line are also appropriately called anovaginal fistulas. Surgical management of these “low” RVFs depends on the condition of the EAS but is usually achieved by a perineal (transvaginal or transanal) approach. Midlevel RVFs are found in the middle third of the vagina, whereas

**TABLE 25-7.** Rectovaginal Fistula Risk Factors

#### **Obstetric complications**

Third- or fourth-degree laceration repair dehiscence  
Unrecognized vaginal laceration during operative vaginal or precipitous delivery

#### **Inflammatory bowel disease**

Most commonly Crohn disease  
Ulcerative colitis less common, as it is not a transmural disease

#### **Infection**

Most commonly cryptoglandular abscess located in the anterior aspect of the anal canal  
Lymphogranuloma venereum  
Tuberculosis  
Bartholin abscess  
Human immunodeficiency virus infection  
Diverticular disease

#### **Previous surgery in the anorectal area**

Hemorrhoidectomy  
Low anterior resection  
Excision of rectal tumors  
Hysterectomy  
Posterior vaginal wall repairs

#### **Pelvic radiation therapy**

#### **Neoplasm**

Invasive cervical or vaginal cancer  
Anal or rectal cancer

#### **Trauma**

Intraoperative  
Coital

**FIGURE 25-8** Rectovaginal fistula in the distal wall of the posterior vagina in a woman who sustained a fourth-degree perineal laceration.

high rectovaginal fistulas have their vaginal communication close to the cervix or the vaginal cuff. In cases with high RVFs, fistulas may open into the sigmoid colon. These fistulas may not be readily seen during examination. They often require contrast or endoscopic studies for diagnosis and an abdominal approach for repair.

### ■ Diagnosis

Patients with RVF usually complain of flatus or stool leakage per vagina. They may also present with recurrent bladder or vaginal infection, rectal or vaginal bleeding, and pain. Symptoms often suggest the underlying etiology. For example, patients with obstetric injury and large defects of the anterior portion of the anal sphincters may have gross fecal incontinence. In contrast, those with an infectious or inflammatory process may complain of diarrhea, abdominal cramping, and fevers in addition to passage of stool per vagina.

During physical examination, most low RVFs can be visualized during inspection of the perineum and distal portion of the posterior vaginal wall. Rectovaginal examination allows assessment of the thickness of the perineal body and anovaginal wall and may allow palpation and visualization of the actual defect. Some RVFs that are not readily seen on initial examination can be identified by noting air bubbles at the fistula's vaginal opening after filling the vagina with water. Alternatively, methylene blue can be instilled in the rectum after a tampon is placed in the vagina. The fistula and a gross assessment of its location can be identified by inspecting the level of blue staining on the tampon following its removal.

If the fistula site is not determined by the preceding maneuvers, a contrast study is indicated. These include barium enema or computed tomography (CT) scanning.

Unless RVFs are obviously due to a prior obstetric event, a biopsy of the fistulous tract is indicated to investigate possible malignancy or inflammatory conditions. In addition, proctoscopy or colonoscopy is often warranted if inflammatory bowel disease, malignancy, or gastrointestinal infection is suspected.

**FIGURE 25-9** Large rectovaginal fistula in a woman who underwent midline episiotomy. Note that the fistula is above an intact external anal sphincter.

### ■ Treatment

Treatment of RVF depends on the underlying etiology and the defect's size and location. Some women with small RVFs following obstetric trauma may be followed conservatively in anticipation of spontaneous healing of the fistulous tract (Goldaber, 1993; Rahman, 2003). If surgical repair is required, it is delayed until surrounding tissues are free of edema, induration, and infection (Wiskind, 1992).

Larger obstetric-related defects and other low fistulas are most often corrected surgically (Fig. 25-9). Surgical techniques include: (1) a transvaginal or transanal approach through episiotomy (conversion of the defect into a complete perineal tear, that is, a fourth-degree laceration), (2) a fistulotomy with transvaginal purse-string method of repair without episiotomy, or (3) a fistulotomy with a tension-free layered closure without episiotomy. A further description of this last operation is found in Section 45-26 of the atlas (p. 1128). Additionally, endorectal flap advancement is used by colorectal surgeons primarily for the treatment of complex perianal fistulas such as those with tract diameters > 2.5 cm or those related to trauma or infection (MacRae, 1995). With flap advancement, the fistulous tract is excised, a broad-based flap of rectal wall is employed to obliterate the fistula's origin, and sphincter muscle division is avoided. Of these methods, better outcomes have been shown following RVF repair using anal sphincteroplasties compared with endorectal advancement flap (Tsang, 1998). In patients with low RVFs, preoperative endoanal ultrasonography of the EAS is important. For example, an episiotomy is avoided if the sphincter is intact (Hull, 2007).

Midlevel vaginal fistulas are also often due to obstetric trauma and are repaired transvaginally or transanally by a tension-free layered closure or an endorectal advancement flap. High fistulas are most commonly repaired by a transabdominal approach using bowel resection of the involved segment followed by primary bowel reanastomosis.

Success rates vary depending on the underlying cause and method of repair. Successful repairs following obstetric injury

vary from 78 to 100 percent (Khanduja, 1999; Tsang, 1998). Success rates of 40 to 50 percent are reported with the rectal advancement flaps and of 74 percent with episiotomy (Mizrahi, 2002; Sonoda, 2002). Fistulas due to other etiologies such as radiation, cancer, or active inflammatory bowel disease are more difficult to treat successfully. In general, success rates are highest with the first surgical attempt at repair (Lowry, 1988).

### GENITOURINARY FISTULA

A genitourinary fistula is defined as an abnormal communication between the urinary (ureters, bladder, urethra) and the genital (uterus, cervix, vagina) systems. The true incidence of genitourinary fistula is unknown and varies according to whether the etiology is obstetric or gynecologic. In Asia and Africa, up to 100,000 new cases of obstetric genitourinary fistula are added each year to the estimated pool of 2 million women with unrepaired fistulas (World Health Organization, 2014). For industrialized countries, most fistulas occur iatrogenically from pelvic surgery, and the generally accepted incidence derives from data on surgeries to correct these fistulas. For example, numbers from the National Hospital Discharge Survey of inpatient women show that approximately 4.8 per 100,000 women underwent lower reproductive tract fistula repair (Brown, 2012). This likely is underestimated as many cases are unreported, unrecognized, or treated conservatively. Of genitourinary fistulas, the vesicovaginal fistula is most common and develops significantly more frequently than ureterovaginal fistulas (Goodwin, 1980; Shaw, 2014).

### PATHOPHYSIOLOGY

The principles and phases of wound healing aid the understanding of genitourinary fistula pathogenesis. After injury, tissue damage and necrosis stimulate inflammation, and the process of cell regeneration begins (Kumar, 2015). Initially at the injury site, new blood vessels form, that is, *angiogenesis*. Three to 5 days after injury, fibroblasts proliferate and subsequently synthesize and deposit extracellular matrix, in particular collagen. This *fibrosis phase* determines the final strength of the healed wound. Collagen deposition peaks approximately 7 days after injury and continues for several weeks. Subsequent scar maturation and organization, termed *remodeling*, augments wound strength. These phases are interdependent and any disruption of this sequence eventually may create a fistula. Most defects tend to present 1 to 3 weeks after tissue injury. This is a time during which tissues are most vulnerable to alterations in the healing environment, such as hypoxia, ischemia, malnutrition, radiation, and chemotherapy. Edges of the wound eventually epithelialize, and a chronic fistulous tract is thus formed.

### CLASSIFICATION

Although many classification systems exist for genitourinary fistula, no single system is considered the accepted standard nor is any one scheme superior in predicting surgical success. Fistulas can develop at any point between the genital and urinary systems, and one classification method reflects the anatomic communication (Table 26-1).

Vesicovaginal fistulas can also be characterized by their size and location in the vagina. They are termed *high vaginal*, when found proximally in the vagina; *low vaginal*, when noted distally; or *midvaginal*, when identified centrally. For instance, posthysterectomy vesicovaginal fistulas are often proximal, or “high” in the vagina, and located at the level of the vaginal cuff.

Others classify vesicovaginal fistula based on the complexity and extent of involvement (Table 26-2) (Elkins, 1999). In this scheme, complicated vesicovaginal fistulas are those that involve pelvic malignancy, prior radiation therapy, a shortened vaginal length, or bladder trigone; those that are distant from the vaginal cuff; or those that measure > 3 cm in diameter.

In one obstetric classification system, high-risk vesicovaginal fistulas are described by their size (> 4 to 5 cm in diameter); involvement of urethra, ureter(s), or rectum; juxtacervical location with an inability to visualize the superior edge; and reformation following a failed repair (Elkins, 1999).

**TABLE 26-1.** Classification of Genitourinary Fistula Based on Anatomic Communication

	Urinary Tract		
	Ureter	Bladder	Urethra
Vagina	Ureterovaginal Vesicoureterovaginal	Vesicovaginal	Urethrovaginal
Cervix	Ureterocervical	Vesicocervical	Urethrocervical
Uterus	Ureterouterine	Vesicouterine	Not reported

A surgical classification to objectively evaluate obstetric urinary fistula repair has also been introduced (Waaldijk, 1995). In this system, type I fistulas are those that do not involve the urethral closure mechanism, type II fistulas do, and type III fistulas involve the ureter and include other exceptional fistulas. Type II fistulas are divided into: (A) without or (B) with subtotal or total urethra involvement. Type IIB fistulas are further subdivided as: (a) without or (b) with a circumferential configuration around the urethra.

To aid objective comparison of surgical outcomes, a more comprehensive and standardized classification system has been developed (Table 26-3). It integrates fistula distance from the external urethral meatus, fistula size, degree of surrounding tissue fibrosis, and extent of vaginal length reduction (Goh, 2004). This system has good inter- and intraobserver reproducibility and has demonstrated efficacy in predicting which patients are at risk of postfistula urinary incontinence and failure of closure (Goh, 2008, 2009). Despite the availability of these numerous classification systems, most clinicians will, from a practical standpoint, often use the anatomic communication and the relative position in the vagina (high, mid, low) in their initial description of the fistula.

ETIOLOGY

Congenital genitourinary fistulas are rare, but if found, are commonly associated with other renal or urogenital abnormalities. Thus, most vesicovaginal fistulas are acquired and typically result from either obstetric trauma or pelvic surgery.

**TABLE 26-2.** Classification of Vesicovaginal Fistulas

<b>Simple</b> Size ≤ 3 cm Located near the cuff (supratrigonal) No prior radiation or malignancy Normal vaginal length
<b>Complicated</b> Prior radiation therapy Pelvic malignancy present Vaginal length shortened Size > 3 cm Located distant from cuff or has trigonal involvement

■ Obstetric Trauma

In developing countries, more than 70 percent of genitourinary fistulas arise from obstetric trauma, specifically from prolonged or obstructed labor or complicated cesarean delivery (Arrowsmith, 1996; Kumar, 2009; Raassen, 2014). Their development in this setting often reflects social practices or obstetric management common to a particular community or geographic region. For example, both childbearing at a young age, before the pelvis has completely developed or fully grown, and female circumcision, more correctly termed *female genital mutilation*, may significantly narrow the vaginal introitus and obstruct labor. Prolonged obstructed labor or anatomic malpresentation of the presenting fetal part can cause pressure and ischemic necrosis of the anterior vaginal wall and bladder, subsequently resulting in fistula formation. Alternatively, the vagina may be damaged by instruments used to deliver stillborn

**TABLE 26-3.** Classification of Genitourinary Fistulas

This new classification divides genitourinary fistulas into four main types, depending on the distance of the fistula's distal edge from the external urinary meatus. These four types are further subclassified by the size of the fistula, extent of associated scarring, vaginal length, or special considerations.
Type 1: Distal edge of fistula > 3.5 cm from external urinary meatus
Type 2: Distal edge of fistula 2.5–3.5 cm from external urinary meatus
Type 3: Distal edge of fistula 1.5 to < 2.5 cm from external urinary meatus
Type 4: Distal edge of fistula < 1.5 cm from external urinary meatus
(a) Size < 1.5 cm, in the largest diameter
(b) Size 1.5–3 cm, in the largest diameter
(c) Size > 3 cm, in the largest diameter
i. None or only mild fibrosis (around fistula and/or vagina) and/or vaginal length > 6 cm, normal capacity
ii. Moderate or severe fibrosis (around fistula and/or vagina) and/or reduced vaginal length and/or capacity
iii. Special consideration, e.g., postradiation, ureteric involvement, circumferential fistula, or previous repair

infants or perform abortion. Malnutrition and limited health care in many of these countries can further diminish wound healing.

In contrast, in most developed countries, fistulas uncommonly follow obstetric procedures or deliveries. Rarely, cesarean deliveries, usually those accompanied by obstetric complications, have led to complex urinary fistula (Billmeyer, 2001). Similarly, rare cases following cervical cerclage have been reported (Massengill, 2012).

## ■ Pelvic Surgery

In developed countries, iatrogenic injury during pelvic surgery is responsible for 90 percent of vesicovaginal fistulas, and the accepted incidence of fistula formation after pelvic surgery is 0.1 to 2 percent (Harris, 1995; Hilton, 2012a,b; Tancer, 1992). The remaining fistulas result from procedures performed by urologists and by colorectal, vascular, and general surgeons. In industrialized countries, hysterectomy is the most common surgical precursor to vesicovaginal fistula, accounting for approximately 75 percent of fistula cases (Symmonds, 1984). When all hysterectomy types are considered, vesicovaginal fistula is estimated to complicate 0.8 per 1000 procedures (Harkki-Siren, 1998). In their review of more than 62,000 hysterectomy cases, laparoscopic hysterectomies were associated with the greatest incidence (2 per 1000), followed by abdominal (1 per 1000), vaginal (0.2 per 1000), and supracervical (0 per 1000) hysterectomies. With hysterectomy for benign disease, Duong and colleagues (2009) noted that bladder wall laceration extending into the bladder neck or a ureteral orifice (trigone) significantly increased the risk of subsequent vesicovaginal fistula.

Because most genitourinary fistulas follow pelvic surgery, prevention and intraoperative recognition of lower urinary tract injury is imperative. As discussed extensively in Chapter 40 (p. 869), intraoperative cystoscopy has been shown to improve the detection rate of lower urinary tract injuries. This in turn may ultimately translate into a lower incidence of genitourinary fistula. Thus, intraoperative cystoscopy can be a useful adjunct, particularly in cases in which the ureters or bladder are suspected to have been at increased injury risk.

## ■ Other Causes

Other etiologies for urinary tract fistulas include radiation therapy, malignancy, trauma, foreign bodies, infections, pelvic inflammation, and inflammatory bowel disease. Of these, *radiation therapy* induces an endarteritis that can lead to tissue necrosis and subsequent potential fistula formation. This modality is a frequent cause, and some series have reported that up to 6 percent of genitourinary fistulas can result from radiation (Lee, 1988). Although most damage following this therapy develops within weeks and months, associated fistulas have been reported to present up to 20 years after the original insult (Graham, 1967; Zoubek, 1989).

*Malignancy* is commonly linked with tissue necrosis and may lead to urinary fistula formation. Emmert and Kohler (1996) found a 1.8-percent incidence of rectovaginal and vesicovaginal fistula in their analysis of nearly 2100 women with cervical cancer. Thus, tissue biopsy is routinely considered

during diagnostic evaluation of women with a fistula and history of malignancy.

*Trauma* sustained during sexual activity or sexual assault can result in genitourinary fistula formation and has been estimated to precede 4 percent of these defects (Kallol, 2002; Lee, 1988). Foreign bodies such as a neglected pessary or vesical calculi are also documented causes (Arias, 2008; Dalela, 2003). Given that transurethral catheter placement has been linked to urethrovaginal fistula, this commonly used device should be placed, maintained, and removed with care (Dakhil, 2014). Foreign material introduced during surgery such as collagen injected transurethrally and complications resulting from synthetic mesh placement for urinary incontinence or pelvic organ prolapse are other inciting agents (Blaivas, 2014; Firoozi, 2012; Pruthi, 2000). Also, during sling surgeries, excess sling tension may increase tissue stress and necrosis. Thus, initial material selection and patient evaluation for poor wound healing risk factors are important prevention steps (Giles, 2005). Ideally, the material selected minimizes the normal foreign-body reaction, is nontoxic and nonantigenic, and is porous enough to admit immune and phagocytic cells and promote native tissue ingrowth (Birch, 2002). Mesh selection is further discussed in Chapter 24 (p. 556).

*Other rare causes* of fistula formation include infections such as lymphogranuloma venereum, urinary tuberculosis, pelvic inflammation, and syphilis; inflammatory bowel disease; and autoimmune disease (Ba-Tike, 1992; Monteiro, 1995). Additionally, conditions that interfere with healing such as poorly controlled diabetes mellitus, smoking, local infection, peripheral vascular disease, and chronic corticosteroid use are potential risks.

## SYMPTOMS

Vesicovaginal fistula classically presents with unexplained continuous urinary leakage from the vagina after a recent operation. Depending on the size and location of the fistula, the urine amount will vary. Occasionally small-volume, intermittent leakage is mistaken for postoperative stress incontinence. For this reason, patients with new-onset urinary leakage, particularly in the setting of recent pelvic surgery, are examined thoroughly to exclude fistula formation. Other less specific symptoms of genitourinary fistula include fever, pain, ileus, and bladder irritability.

Vesicovaginal fistula may present days to weeks after the initial inciting surgery, and those following hysterectomy typically present at 1 to 3 weeks. Some fistulas, however, have longer latency, and symptoms may develop several years later.

## DIAGNOSIS

A thorough history and physical examination identifies most cases of vesicovaginal fistula. Accordingly, information is documented regarding obstetric deliveries, prior surgeries, previous fistula management, and malignancy treatment, especially pelvic surgery and radiation therapy.

Physical examination is equally informative, and vaginal inspection often will identify the defect. A meticulous assessment for other fistulous tracts is performed, and their location and size noted. Visual assistance with an endoscopic lens and translucent

**FIGURE 26-1** A. Cystoscopic view of vesicovaginal fistula (arrow). B. Probe placed through fistulous tract to aid cystoscopic visualization.

vaginal speculum can sometimes help identify a vaginal-apex fistula, which can be more difficult to detect.

It is essential to differentiate between “extraurethral” urinary leakage, as with a fistula, and “transurethral” leakage, that is, through the urethra, as with stress urinary incontinence. Occasionally, the vaginal fluid source is unclear, and a small amount of urine can easily be mistaken for vaginal discharge. Measurement of the vaginal fluid’s creatinine content can sometimes be used to confirm its origin. Although creatinine levels in urine vary, with mean levels reaching 113.5 mg/dL, a value  $> 17$  mg/dL is consistent with urine (Barr, 2005). In contrast, fluid with a concentration  $< 5$  mg/dL is highly unlikely to be human urine.

Although a genitourinary fistula ideally is visualized directly, inspection at times is unrevealing. In these circumstances, retrograde bladder instillation of visually distinct solutions such as sterile milk or dilute methylene blue or indigo carmine can often indicate a fistula and aid in its localization.

If the presence of a urinary fistula is uncertain or its vaginal location is not identified, a *three-swab test*, commonly known as the “*tampon test*,” is recommended (Moir, 1973). This test is commonly performed with a tampon. However, we recommend using two to four pieces of gauze sequentially packed into the vaginal canal. A diluted solution of methylene blue or indigo carmine is instilled into the bladder using a transurethral catheter. Notably, use of the former may increase given current indigo carmine shortages. After 15 to 30 minutes of routine activity, the gauze is removed serially from the vagina, and each is inspected for dye. The specific gauze colored with dye suggests the fistula location—a proximal or high location in the vagina for the innermost gauze and a low or distal fistula for the outermost. If the distally placed sponge is stained with dye, however, confirmation that it was not contaminated by urine leaking out through the urethra, as in the case of stress urinary incontinence, is essential.

Cystourethroscopy is another valuable diagnostic tool (Fig. 26-1). It permits fistula localization, determination of its proximity to the ureteral orifices, inspection for multiple fistula sites, and assessment of surrounding bladder mucosa viability. In addition, the use of cystourethroscopy and vaginoscopy

concurrently to identify vesicovaginal fistula has been described (Andreoni, 2003).

Concomitant ureteral involvement is estimated to complicate 10 to 15 percent of vesicovaginal fistula cases and is sought during diagnostic evaluation (Goodwin, 1980). At our institution, intravenous contrast-enhanced computed tomography (CT) scanning in the excretory phase has become the preferred diagnostic test after initial cystourethroscopic survey is completed (Fig. 26-2). Selection of modalities other than CT for fistulous tract identification may be considered based on cost or availability. First, intravenous pyelography (IVP) can adequately confirm integrity of the upper collecting system and exclude ureteral involvement in a fistula. Second, retrograde pyelography may be used. Often carried out in conjunction with cystoscopy, it is performed by placing a small catheter into the distal ureter. Contrast material is injected through the catheter into one or both ureters. Fluoroscopic or conventional radiographs are then obtained. Retrograde pyelography

**FIGURE 26-2** Ureterovaginal fistula. Both arrows show anomalous tracking of contrast. The lower arrow denotes a fistulous tract to the upper vagina. B= bladder; S= sacrum; SP= symphysis pubis; Ur= ureter; V= vagina. (Used with permission from Dr. April Bailey.)

generally has been reported to have the same diagnostic value as IVP.

In some instances resources are scarce, cost may be a limitation, and access to specialized diagnostic imaging is a challenge. With some advance planning, phenazopyridine hydrochloride (Pyridium) can be used in conjunction with the three-swab test to determine ureteral involvement, as a very rudimentary alternative to the aforementioned more sophisticated imaging. The tablet is administered orally, is excreted renally, acts as a topical bladder analgesic, and stains urine orange as a side effect. Women with suspected ureteral involvement are instructed to take a 200-mg dose a few hours before their clinic appointment. The steps of the three-swab test are then performed, as described earlier. In this case, if the most proximal (innermost) gauze is colored with orange dye, ureteral involvement is suspected. If both orange and blue dyes are seen, then involvement of both the bladder and ureter(s) is suspected.

Voiding cystourethrography (VCUG) can help confirm the presence, location, and number of fistulous tracts. In this, the bladder is filled via catheter with contrast dye, and fluoroscopic images of the lower urinary tract are obtained during patient micturition. However, CT has largely replaced this modality. Transabdominal sonography with applied color Doppler to identify flow through the fistula has been suggested as another diagnostic option (Volkmer, 2000). However, without color Doppler, sonography failed to identify 29 percent of vesicovaginal fistula cases in one study (Adetiloye, 2000).

## TREATMENT

### ■ Conservative Treatment

Occasionally, genitourinary fistulas may spontaneously close during continuous bladder drainage using an indwelling urinary catheter. Approximately 12 percent of women treated by sustained catheterization alone had fistulas that healed spontaneously (Oakley, 2014; Waaldijk, 1994). Romics and colleagues (2002) found that in 10 percent of cases, urinary fistulas close spontaneously after 2 to 8 weeks of transurethral catheterization, especially if the fistula is small (2- to 3-mm diameter). Another series reported fistulas up to 2 cm in diameter spontaneously healed in 50 to 60 percent of patients treated with an indwelling catheter (Waaldijk, 1989).

Despite these series, data that correlate fistula size and success of conservative management are limited. Many reports of successful spontaneous closure with catheter drainage have been limited to fistulas that were 1 cm in size or smaller (Lentz, 2005; Ou, 2004). Many studies are vague regarding how fistula size is measured, and each series has potential for considerable bias in its selection criteria. However, in general, the larger a fistula, the less likely it is to heal without surgery.

Evidence regarding the duration of catheter drainage also varies. Regardless, many agree that if a fistula has not closed within 4 weeks, it is unlikely to do so. This may be secondary to epithelialization of the fistulous tract (Davits, 1991; Tancer, 1992). Moreover, continued urinary drainage may lead to further bladder inflammation and irritation (Zimmern, 1991). Importantly,

if attempting conservative treatment of a vesicovaginal fistula with catheter insertion and chronic drainage, urinary drainage ideally begins shortly after the inciting event.

*Fibrin sealant* (Tisseal, Evicel), also colloquially called fibrin glue, is formed from concentrated fibrinogen combined with thrombin to simulate the final clotting cascade stages. In gynecologic surgery, it is mainly used to control low-pressure bleeding. Although fibrin sealant has been described for the treatment of vesicovaginal fistula, it is often selected as a surgical adjunct rather than primary surgical treatment (Evans, 2003). Data regarding fibrin sealant effectiveness are sparse, and well-designed trials are lacking. Thus, fibrin sealant monotherapy may not be the initial recommended treatment in most vesicovaginal fistula cases due to potential lack of durability and thus a risk for recurrence. However, it may provide a viable alternative in patients with multiple comorbidities that contraindicate a prolonged fistula repair surgery.

In sum, a trial of conservative therapy is usually warranted and reasonable, especially if instituted shortly after the inciting event and if the fistula is small. However, gains from a conservative approach are balanced against a patient's desire for an expedited repair to resolve the leak. Thus, the timing of intervention ideally achieves a compromise between reasonable conservative efforts and addressing the patient's immediate distress and quality of life. As noted, most urinary fistulas ultimately require surgical intervention.

### ■ Surgical Treatment

Incorporating the fundamentals of genitourinary fistula repair is essential to successful resolution. These include accurate fistula delineation; adequate assessment of surrounding tissue vascularity; timely repair; multilayer, tension-free, and watertight defect closure; and postoperative bladder drainage.

Primary surgical repair of genitourinary fistula is associated with high cure rates (75 to 100 percent) (Rovner, 2012b). Factors that support this rate include adequate vascularity of the surrounding tissue, brief fistulous tract duration, no prior radiation therapy, meticulous surgical technique, and surgeon experience. The first attempt at surgical repair is usually associated with the best chance of successful healing. Surgical repair success rates specifically for obstetric fistulas are also high. Of these, 81 percent are corrected with the first attempt, and 65 percent with the second (Elkins, 1994; Hilton, 1998).

#### Timing of Repair

One principle of fistula repair dictates that a repair be performed in noninfected and noninflamed tissues. Early surgical intervention of uncomplicated fistulas within the first 24 to 48 hours following the inciting surgery is possible as it avoids the brisk postoperative inflammatory response. Such early closure does not affect success rates, yet it appears to reduce social and psychologic patient distress (Blaivas, 1995; Persky, 1979).

In instances of extensive and severe inflammation, we recommend delaying operative repair for 6 weeks until the inflammation subsides. During this time, a trial of catheter drainage, while the surrounding tissue has an opportunity to heal, is reasonable.

## Route of Surgical Repair

Many different surgical repair options are available for vesicovaginal fistula. However, data that support an optimal route are limited, and the lack of consensus may reflect variances in surgeon experience and preference. Among important surgical considerations, ability to gain access to the fistula is essential and commonly dictates the surgical approach. Fortunately, success rates are high whether the route of repair is transvaginal or transabdominal.

**Vaginal.** The transvaginal approach to genitourinary fistula repair is straightforward and direct. Compared with abdominal approaches, it is associated with shorter operative times, decreased blood loss, less morbidity, and shorter hospital stays (Wang, 1990). The transvaginal route also allows easy access for the use of ancillary equipment, such as ureteral stents. This is particularly useful if the fistula is located near ureteral orifices.

One transvaginal approach used most commonly by gynecologists, the *Latzko technique*, is illustrated in Section 45-10 (p. 1078). In this technique, likened to a partial colpocleisis, the most proximal portions of the anterior and posterior vaginal walls are surgically apposed to close the defect, without completely removing the fistulous tract. This partially obliterates the upper vagina, similar to that achieved by colpocleisis. Because of the potential for vaginal shortening, this technique may not be appropriate if vaginal depth has already been compromised or if there is preexisting sexual dysfunction. If use of the Latzko technique is anticipated, patient counseling specifically addresses these issues and potential sequelae. That said, recent studies evaluating sexual function show similar or higher functioning scores following vaginal repair routes compared with abdominal routes (Lee, 2014; Mohr, 2014).

The *classical technique*, in contrast to the Latzko method, involves total excision of the fistulous tract and mobilization of the surrounding anterior vaginal wall epithelium. After tract resection, the bladder mucosa is first closed, and a watertight repair is confirmed. This is followed by closure of one or two layers of fibromuscular tissue. Vaginal epithelium is then reapproximated.

Of the two approaches, some favor incomplete fistulous tract excision (Latzko repair) to avoid weakening the surrounding tissue, enlarging the defect, and thereby potentially compromising the repair. By preserving the presumptively stronger scar tissue surrounding the fistula, it theoretically permits a more secure reapproximation of surrounding tissue.

**Abdominal (Transperitoneal).** With this route, the fistula is accessed and excised through an intentional cystotomy on the preperitoneal side of the bladder as shown in Section 45-10 (p. 1081). This approach is used for situations in which the fistula: (1) is located proximally in a narrow vagina, (2) lies close to the ureteral orifices, (3) is complicated by a concomitant ureteric fistula, (4) persists after prior repair attempts, (5) is large or complex in configuration, or (6) requires an abdominal interposition graft, described in the next section.

Evidence-based support for laparoscopic genitourinary fistula repair has been limited to case reports and expert

opinion (Miklos, 2015; Nezhat, 1994). The technique requires advanced laparoscopic surgical skills. Accordingly, success with this approach appears to be highly dependent on surgeon experience.

**Interpositional Flaps.** Surrounding tissue vascularity is essential for successful genitourinary fistula healing after repair. When intervening tissues for fistula closure are thin and poorly vascularized, various tissue flaps may be placed vaginally or abdominally between the bladder and the vagina in an attempt to enhance the repair and to lend support and blood supply (Eisen, 1974; Martius, 1928). Sections 45-10 and 45-11 (p. 1081) illustrate the omental J-flap, which is an abdominal option, whereas the Martius bulbocavernosus fat pad flap is used during vaginal procedures. Although interposition flaps are useful in situations where tissue viability is in question, their utility in uncomplicated cases of vesicovaginal fistula is unclear.

## Other Genitourinary Fistulas

Although vesicovaginal fistulas are the most common type of genitourinary fistula, other fistulas can develop and may be described based on their communication between anatomic structures. Urethrovaginal fistulas can result from surgery involving the anterior vaginal wall, in particular anterior colporrhaphy and urethral diverticulectomy (Blaivas, 1989; Ganabathi, 1994a). In developing countries, as with vesicovaginal fistula, obstetric trauma remains the most common cause of urethrovaginal fistulas. Frequently, patients present with continuous urinary drainage into the vagina or with stress urinary incontinence. The principles of repair are similar, namely, layered closure, tension-free repair, and postoperative bladder drainage. Other types of genitourinary fistula can also develop (see Table 26-1).

## URETHRAL DIVERTICULUM

Paraurethral glands are found along the anterior vaginal wall and communicate directly with the urethra. A urethral diverticulum commonly forms from a cystic enlargement of one of these glands. This isolated outpouching is commonly asymptomatic and is frequently diagnosed incidentally during routine examination. However, many present with symptoms and often require surgical excision.

Urethral diverticulum is reported to develop in 1 to 6 percent of the general female population. With greater awareness and radiologic advances, rates of diagnosis are increasing (Rovner, 2012a). However, the true incidence may be underestimated because diverticula are frequently asymptomatic and thus underreported. In women with lower urinary tract symptoms, the incidence dramatically increases and may reach 40 percent (Stewart, 1981).

Urethral diverticulum is diagnosed most often in the third to sixth decades of life and more commonly in females than in males (Aldridge, 1978). A 6:1 predominance of urethral diverticula in African-Americans compared with whites has been reported, although others have found no racial predisposition (Davis, 1970; Leach, 1987).

**FIGURE 26-3** Complex configuration of paraurethral glands. The three smaller bottom images are cross-sectional views of the urethra and surrounding paraurethral glands. (Adapted with permission from Huffman JW: The detailed anatomy of the paraurethral ducts in the adult human female. *Am J Obstet Gynecol* 1948 Jan;55(1):86–101.)

## ETIOLOGY

The etiology of urethral diverticula is unclear. Although most are thought to be acquired, rare congenital diverticula have been reported. Congenital causes include persistence of embryologic remnants, defective closure of the ventral portion of the urethra, and congenital cystic dilatation of paraurethral glands (Ratner, 1949). Embryology of the female genital tract, described in Chapter 18 (p. 404), contributes to our understanding of congenital urethral diverticulum. During female development, the müllerian ducts form the upper vagina, whereas the urogenital sinus gives rise to the distal vagina, vestibule, and female urethra (Fig. 18-4, p. 408). In the vagina, müllerian mucinous columnar epithelium is replaced by squamous epithelium of the urogenital sinus. When the process of epithelial replacement is arrested, small foci of müllerian epithelium may persist and form cysts or diverticula.

More commonly, diverticula are acquired and can result from infection, birth trauma, or traumatic instrumentation. The most widely held theory regarding urethral diverticular development dates back to Routh (1890) and involves the paraurethral glands and their ducts. The paraurethral glands surround and cluster most densely along the urethra's inferolateral border (Fig. 26-3). Of these glands, the bilateral Skene glands are the most distal and typically the largest. Paraurethral glands connect to the urethral canal via a network of branching ducts. The arborizing pattern in portions of this network helps to explain the complexity of some urethral diverticula (Vakili, 2003).

Routh theorized that infection and inflammation obstruct individual ducts and lead to cystic dilatation. If these do not spontaneously resolve or if infection is not treated promptly, an abscess can form. Subsequent abscess expansion and continued inflammation may rupture the gland into the urethral lumen to create a fistulous communication between the two (Fig. 26-4). As infection clears,

the dilated diverticular sac and new communicating ostium into the urethra persist. Of infectious agents, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are organisms that were once commonly associated with urethritis and severe inflammation of the paraurethral glands. However, positive identification of these organisms is not mandatory for diagnosis, and more often than not, urethral cultures from women who have diverticula yield a polymicrobial result, which typically does not require treatment.

In addition to infection, injured urethral tissue can swell and obstruct paraurethral ducts. Logically, urethral trauma sustained during childbirth or during urethral instrumentation are suggested etiologies (McNally, 1935). Moreover, as described

**FIGURE 26-4** Mechanism of urethral diverticulum development. (Reproduced with permission from Walters MD, Karram MM (eds): *Urogynecology and Reconstructive Pelvic Surgery*. St. Louis: Mosby; 1999.)

earlier, different social customs and obstetric practices in the developing world can potentially contribute to urethral trauma (p. 578). In addition, female genital mutilation or repeated urethral dilatations can traumatize the urethra.

## CLASSIFICATION

Early classification systems organized urethral diverticula according to their radiographic complexity and described them as: (1) simple saccular, (2) multiple, or (3) compound or complex with branching sinuses (Lang, 1959). To help standardize surgical treatment, Ginsburg and Genadry (1983) created a preoperative classification system based on urethral location. This system organized diverticula based on their urethral location and described lesions as type 1 (proximal third), type 2 (middle third), and type 3 (distal third).

In an attempt to fully incorporate all characteristics necessary to adequately assign treatment, Leach and coworkers (1993) constructed the L/N/S/C3 classification system. In this system, the diverticulum characteristics are described according to its location (L), number (N), size (S), and configuration, communication, and continence status of the patient (C3). Of these, location is described in relation to the urethra and defined as distal, mid-, or proximal urethral and as with or without extension beneath the bladder neck. In Leach's series of 61 patients, investigators found that most diverticula were in the midurethra. Logically, this distribution reflects the predominance of paraurethral glands along the middle third of the urethra. Ascertainment of the number of diverticula is important to prevent incomplete excision of multiple lesions and thus symptom persistence. Diverticulum size similarly can influence treatment. For example, some recommend concomitant interpositional tissue flaps for large diverticula. Moreover, urinary incontinence may develop *de novo* or persist if the diverticulum is extremely large and involves sphincter continence mechanisms.

Of the three "C"s, diverticula configuration may be described as solitary or multiloculated and as simple, saddle-shaped, or circumferential (Fig. 26-5). Preoperative delineation

**FIGURE 26-5** Magnetic resonance image of a circumferential urethral diverticulum (arrow) that extends around the urethra.

assists in complete surgical excision and aids preparation for an interpositional flap in those cases requiring extensive urethral resection (Rovner, 2003).

Obviously, successful repair of the urethral wall defect depends in great part on identifying the diverticular opening into the urethral canal. Thus, the communication site is sought preoperatively and classified as proximal, mid-, or distal urethral. In the previously cited study, midurethral communication sites were the most common (60 percent), followed by proximal (25 percent) and distal (15 percent) sites.

Finally, in this classification system, the continence status and urethral hypermobility of the patient are documented. Almost half of the patients in Leach's series had stress urinary incontinence, and these authors suggest that urethral hypermobility is an indication for concomitant incontinence surgery. Although several studies have documented the safety of performing concurrent bladder-neck suspension, some still consider this approach controversial due to concerns of urethral erosion (Bass, 1991; Ganabathi, 1994b; Leng, 1998; Swierzewski, 1993). Although consensus is lacking on this issue, repairing the diverticulum first and then considering antiincontinence surgery if urinary incontinence persists is reasonable. This staged fashion is a particularly realistic option because of the current array of effective minimally invasive surgical procedures, such as midurethral slings. For postoperative comparison, we typically perform baseline preoperative urodynamic testing, although this step may not be adopted by all. Importantly, these data and postoperative expectations are discussed with the patient during preoperative counseling.

## SYMPTOMS

Urethral diverticula are frequently asymptomatic and discovered incidentally during gynecologic or urologic examination. However, symptoms may vary and reflect diverticulum characteristics, especially size, location, and extension. Although postvoid dribbling, dysuria, and egress of discharge through the urethra with finger compression of a suburethral mass are pathognomonic, not all women present so classically (Fig. 26-6). For most patients, symptoms are nonspecific and include pain, dyspareunia, and several urinary symptoms. Romanzi and colleagues (2000) found pain in 48 percent of affected women. Pain most likely stems from cystic dilatation and also possibly from concurrent inflammation. Those with dyspareunia may note either entry or deep dyspareunia, depending on whether diverticula are distal or proximal, respectively.

A large diverticulum can sometimes be mistaken for early-stage pelvic organ prolapse, especially when the presenting complaint is vaginal fullness, bulge, or pressure. In these cases, the palpable diverticular vaginal mass may mimic a cystocele or rectocele. In most, careful systematic palpation of the vaginal wall will distinguish prolapse from a discrete vaginal wall cyst or diverticulum.

Various lower urinary tract symptoms are frequently associated with urethral diverticulum. Specifically, urinary incontinence is noted by 35 to 60 percent of affected women (Gabanathi, 1994b; Romanzi, 2000). In addition, during micturition, urine may enter the diverticular sac, only to later spill from the sac and present as postvoid dribble or as urinary

**FIGURE 26-6** Transurethral expression of discharge with compression of a urethral diverticulum seen in the anterior vaginal wall.

incontinence. In contrast to urine loss, urinary retention has also been reported (Nitti, 1999). Retention frequently accompanies periurethral or diverticular sac cancers, discussed later in this section. Urinary tract infection often complicates urethral diverticulum. In their review of 60 women with diverticula, Pathi and associates (2013) found that recurrent urinary tract infection was highly specific for urethral diverticula.

Less frequently, stones may form from urine stagnation and salt precipitation within the diverticular sac. As such, stones may be singular or multiple and are usually composed of calcium oxalate or calcium phosphate. The reported frequency approximates 10 percent (Perlmutter, 1993).

Malignant transformation within a urethral diverticulum is rare and accounts for only 5 percent of urethral cancers. Most of these tumors are adenocarcinomas, although transitional cell and squamous cell carcinomas have also been identified (Clayton, 1992). Tumors typically present in the sixth or seventh decade of life, and hematuria, irritative voiding complaints, and urinary retention are common. Thus, palpation of an indurated or fixed periurethral mass, coupled with urinary obstructive symptoms, typically prompts further diagnostic evaluation and tissue biopsy (von Pechmann, 2003). Given the rarity of cancers within these diverticula, codified treatment strategies are lacking. Currently, these malignancies are treated by anterior exenteration or by diverticulectomy, alone or with adjuvant radiation therapy (Shalev, 2002).

## DIAGNOSIS

For many women, urethral diverticula may be diagnosed using simply a detailed history, physical examination, and high

index of suspicion. Patient evaluation focuses on the common characteristics and symptoms noted earlier. However, despite available clinical tools, the diagnosis for many women is delayed as they may initially be treated for stress or urgency incontinence, chronic cystitis, trigonitis, urethral syndrome, vulvovestibulitis, pelvic organ prolapse, and idiopathic chronic pelvic pain. Moreover, the diverticulum itself may mimic a Gartner duct cyst, müllerian remnant vaginal cyst, vaginal epidermoid inclusion cyst, ectopic ureterocele, or endometrioma.

## Physical Examination

The most frequent physical finding, an anterior vaginal mass beneath the urethra, is detected in 50 to 90 percent of symptomatic patients (Ganabathi, 1994b; Gerrard, 2003; Romanzi, 2000). Although urethral expression of purulent material during compression of the mass with a finger is common, failure to demonstrate transurethral expression of discharge does not exclude the diagnosis. Stenosis of the diverticular duct may obstruct sac emptying in these cases. Thus, meticulous examination and palpation is performed along the entire length of the urethra. Once diverticula are identified, their number, size, consistency, and configuration are determined.

However, physical examination alone is typically insufficient to completely characterize a mass. Of available ancillary tests, each has its advantages and disadvantages, and investigators may differ as to which is chosen primarily. Accordingly, familiarity with each modality's strengths aids selection of the most appropriate test for a given clinical setting.

## Cystourethroscopy

Of the diagnostic procedures used to detect urethral diverticula, cystourethroscopy is the only tool that allows direct inspection of the urethra and bladder. During endoscopy, fingers pressed upward against the proximal anterior vaginal wall help occlude the bladder neck and allow the distending medium to create positive pressure and open diverticular ostia (Fig. 26-7). A zero-degree cystoscope lens allows complete radial assessment of the urethra to aid identification of diverticular ostia and at times, purulent discharge extruding from them.

**FIGURE 26-7** Diverticular opening visualized during cystourethroscopic examination (arrow). U = urethra.

A primary advantage to cystourethroscopy includes its accuracy for diverticulum detection (Summitt, 1992). Moreover, in those with nonspecific lower urinary tract symptoms, other causes such as urethritis, cystitis, stones, or stenosis can be excluded. Despite these advantages and its common use by urogynecologists, gynecologic generalists employ cystourethroscopy less frequently due to obstacles such as inexperience evaluating bladder and urethral mucosal anatomy, cystoscopic expertise, instrumentation costs, and credentialing challenges. Even for clinicians who are experienced with this tool, it may still fail to display all diverticula. For example, a poor seal between the cystoscope and distal urethral mucosa may lead to inadequate sac distention and failure to identify distally located diverticula. Also, diverticula whose ostia are stenotic, and thus do not communicate with the urethral lumen, can be missed. Although this endoscopy is minimally invasive, patient pain and risk of postprocedural infection are additional legitimate concerns. Last, important information regarding diverticular size and configuration may not be obtained with this tool.

### ■ Magnetic Resonance Imaging

This imaging modality has slowly become the diagnostic standard to characterize periurethral masses because of its superior resolution at soft tissue interfaces. Specifically, for detecting urethral diverticula, magnetic resonance (MR) imaging has comparable or superior sensitivity compared with other radiologic techniques (Lorenzo, 2003; Neitlich, 1998). To improve image resolution with MR imaging, an imaging coil may be placed into the rectum or vagina. The coil, which is housed inside a probe, improves the image quality of structures surrounding the rectum or vagina. Alternatively, an external plate or coil for image resolution enhancement can be used to minimize patient discomfort. Many institutions have opted for this method largely due to patient comfort, without significant loss of diagnostic accuracy. Despite MR imaging's advantages, procedure costs are balanced against the need for additional anatomic information. For a solitary diverticulum with clearly demarcated boundaries and no evidence of extension, costly and extensive imaging may not be necessary.

### ■ Other Imaging Tools

Although we use the two previously mentioned techniques most commonly, other techniques may be performed at other institutions. Of these, *voiding cystourethrogram (VCUG)* is used by some as an initial tool in urethral diverticulum evaluation. Radiographic contrast instilled into the bladder fills a diverticular sac during voiding, and postvoid radiographs then highlight sac volume. This painless, simple test has an overall reported accuracy that approximates 85 percent. However, some prefer positive-pressure urethrography as a primary diagnostic tool, since VCUG requires a diverticular communication to be patent during testing (Blander, 2001). Additionally, VCUG involves ionizing radiation exposure for the patient, although this is minimal.

*Positive pressure urethrography (PPUG)* also uses radiographic contrast and x-ray. With PPUG, a double-balloon, triple-lumen catheter (Trattner catheter) is inserted through the urethra, and its tip enters the bladder (Fig. 26-8). Inflating the proximal

**FIGURE 26-8** Trattner double-balloon catheter used to diagnose urethral diverticula. (Reproduced with permission from Greenberg M, Stone D, Cochran ST, et al: Female urethral diverticula: doubleballoon catheter study, 1981 Feb;136(2):259–264.)

balloon allows it to be pulled snug against and occlude the urethra at the urethrovesical junction. A distal balloon obstructs the distal urethra. A single catheter port between the two balloons allows instillation of radiopaque contrast, subsequent urethral distention, and expansion of the diverticulum under positive pressure. For accurately identifying diverticula, PPUG has a sensitivity surpassing that of VCUG (Golomb, 2003). Disadvantageously, PPUG can be time-consuming, technically difficult, and associated with patient discomfort and postprocedural infection risk. Additionally, similar to VCUG, diverticula may be missed if thick pus or debris prevents adequate filling with contrast medium or if the diverticular ostium is stenotic. Accordingly, although PPUG has been a primary tool for many for diagnosing urethral diverticula, fewer radiologists are proficient with the technique, and it has gradually been replaced by other modalities.

Sonography is a relatively new tool for urethral diverticulum assessment and appears to have some efficacy (Gerrard, 2003). Suggested technical advantages include visualization of diverticula that do not fill during radiographic contrast studies and characterization of diverticular wall thickness, size, and internal architecture (Yang, 2005). Transabdominal, -vaginal, -rectal, -perineal and -urethral sonographic techniques have all been described (Keefe, 1991; Vargas-Serrano, 1997). Although the endourethral technique has been reported to have excellent specificity, it is expensive and may be more invasive than the other sonographic routes (Chancellor, 1995). Advantages of sonography include patient comfort, avoidance of ionizing radiation and contrast exposure, relative low cost, and reduced invasiveness. However, in addition to its learning curve, sonography's role in urethral diverticulum diagnosis has not been clearly established. Currently, it remains an academic or adjunctive technique.

Because there is still no consensus on which modality is best used primarily, it is reasonable to begin with cystourethroscopic evaluation followed by VCUG. At our institution, if the initial evaluation is unrevealing but the diagnostic suspicion remains

high or if the lesion appears more complex, then MR imaging combined with an endorectal coil or external plate may improve the resolution of images and add to the information gained.

## TREATMENT

### ■ Acute Treatment

Women with a urethral diverticulum may present acutely with pain, urinary symptoms, or focal tenderness during examination. Conservative management is recommended in the acute phase and includes sitz baths, administration of a broad-spectrum oral antibiotic such as a cephalosporin or fluoroquinolone, and oral analgesics.

### ■ Chronic Diverticula

For a chronic diverticulum, a conservative approach may be elected by women who have few or no symptoms and decline surgery due to its associated risks of urethrovaginal fistula and sphincter defect incontinence. However, in women electing observation, long-term data are lacking regarding rates of subsequent symptom development, diverticulum enlargement, and eventual need for surgical excision.

Many practitioners may deliberate as to whether an enlarged inflamed cystic connection with the urethra is termed a “Skene gland cyst” or a “urethral diverticulum.” Pragmatically, for those with persistent bothersome symptoms the treatment is the same with surgical intervention often indicated. Procedures include diverticulectomy, transvaginal partial ablation, and marsupialization, which are all described in Section 45-9 (p. 1075) of the atlas.

Of these, *diverticulectomy* is the most frequently chosen to treat diverticula at any site along the urethra. Excision of the entire diverticulum provides long-term correction of the urethral defect, normal urine stream, and high rates of postoperative continence. However, disadvantages include risks for postsurgical urethral stenosis, urethrovaginal fistula, potential injury to the urinary sphincter continence mechanism with subsequent incontinence, and the possibility of recurrence. For patients who also have stress urinary incontinence, some practitioners recommend concomitant placement of either a midurethral or pubovaginal sling. As noted earlier, although this practice is supported by some studies, our preference is to approach it as a staged procedure. We perform the defect repair first and later reassess the need for an antiincontinence procedure.

Another surgery, *partial diverticular sac ablation*, may be preferred for proximal diverticula to avoid bladder entry or bladder neck injury risks. Tancer and associates (1983) described this procedure, during which excess diverticular wall is excised, the diverticular neck is not removed, but remaining diverticular wall tissue is reapproximated to close the defect.

Last and less frequently, diverticulum marsupialization, also known as the Spence procedure, has been used for distal diverticula (Spence, 1970). The procedure is a meatotomy that when healed forms a new wider urethral meatus. Although simple to perform, this procedure alters the shape and function of the urethral meatus, with patients often noting spraying of their urine stream.

Other procedures described in case reports include urethroscopic transurethral electrosurgical fulguration of the diverticular sac and transurethral incision to widen the diverticular ostia (Miskowiak, 1989; Saito, 2000; Vergunst, 1996). Data are lacking, however, regarding long-term efficacy and complication rates with these techniques.

### BIOLOGY OF CANCER GROWTH

In principle, chemotherapeutic drugs are able to treat cancer and spare normal cells by exploiting inherent differences in their individual growth patterns. Each tumor type has its own characteristics, which explain why the same chemotherapy regimen is not equally effective for the whole spectrum of gynecologic cancers. Selecting appropriate drugs and limiting toxicity demands an understanding of cellular kinetics and biochemistry.

#### ■ The Cell Cycle

All dividing cells follow the same basic sequence for replication. The *cell generation time* is the time required to complete the five phases of the cell cycle (Fig. 27-1). The  $G_1$  phase ( $G$  = gap) involves various cellular activities, such as protein synthesis, RNA synthesis, and DNA repair. When prolonged, the cell is considered to be in the  $G_0$  phase, that is, the resting phase.  $G_1$  cells may either terminally differentiate into the  $G_0$  phase or reenter the cell cycle after a period of quiescence. During the S phase, new DNA is synthesized. The  $G_2$  (premitotic) phase is characterized by cells having twice the DNA content as they prepare for division. Finally, actual mitosis and chromosomal division takes place during the M phase.

Tumors do not typically have faster generation times. They instead have many more cells in the active phases of replication and have dysfunctional apoptosis (programmed cell death), hence proliferation. In contrast, normal tissues have a much larger number of cells in the  $G_0$  phase. As a result, cancer cells proceeding through the cell cycle may be more sensitive to

chemotherapeutic agents, whereas normal cells in  $G_0$  are protected. The growth pattern disparity underlies the effectiveness of chemotherapeutic agents.

#### ■ Cancer Cell Growth

Tumors are characterized by a *gompertzian growth* pattern (Fig. 27-2). Fundamentally, a tumor mass requires progressively longer times to double in size as it enlarges. When a cancer is microscopic and nonpalpable, growth is exponential. However, as a tumor enlarges, the number of its cells undergoing replication decreases due to limitations in blood supply and increasing interstitial pressure.

When tumors are in the exponential phase of gompertzian growth, they should be more sensitive to chemotherapy because a larger percentage of cells are in the active phase of the cell cycle. For this reason, metastases should be more sensitive to chemotherapy than the primary tumor. To capitalize on this potential benefit, advanced ovarian cancer is usually first treated with surgery to remove the primary tumor, debulk large masses, and leave only microscopic residual disease for the adjuvant chemotherapy to act on. In addition, when a tumor mass shrinks in response to treatment, the presumption is that a greater number of cells will enter the active phase of the cell cycle to accelerate growth. The larger percentage of replicating cells should also increase the sensitivity of a tumor to chemotherapy.

#### ■ Doubling Time

The time needed for a tumor to double in size is commonly referred to as its *doubling time*. Whereas the cell cycle generally refers to the activity of individual tumor cells, doubling time refers to the growth of an entire heterogeneous tumor mass. In humans, the doubling times of specific tumors vary greatly. The speed with which tumors grow and double in size is largely regulated by the number of cells that are actively dividing—known as the *growth fraction*. Typically, only a small percentage of the tumor will have cells that are rapidly proliferating. The remaining cells are in the  $G_0$  resting phase. In general, tumors that are cured by chemotherapy are those with a high growth fraction, such as gestational trophoblastic neoplasia. When tumor volume is reduced by surgery or chemotherapy, the remaining tumor cells are theoretically propelled from the  $G_0$  phase into the more vulnerable phases of the cell cycle, rendering them susceptible to chemotherapy.

#### ■ Cell Kinetics

Chemotherapeutic agents typically work by first-order kinetics to kill a constant *fraction* of cells rather than a constant

**FIGURE 27-1** Diagram of the cell cycle. Agents are organized according to the cell cycle stage in which they are most effective for tumor control.

number. For example, one dose of a cytotoxic drug may result in a few logs ( $10^2$  to  $10^4$ ) of cell kill. This is, however, not curative since tumor burden may be  $10^{12}$  cells or more. Thus, the magnitude of cell kill necessary to eradicate a tumor typically requires intermittent courses of chemotherapy. In general,

**FIGURE 27-2** The gompertzian growth curve. During early stages of tumor expansion, growth is exponential, but with enlargement, tumor growth slows. Consequently, most tumors have completed their exponential growth phase at the time of clinical detection.

a cancer's curability is inversely proportional to the number of viable tumor cells at the beginning of chemotherapy.

Some drugs achieve cell kill at several phases of the cell cycle. These *cell cycle-nonspecific* agents act in all phases of replication from  $G_0$  to the M phase. *Cell cycle-specific* agents act only on cells that are in a specific phase. By combining drugs that act in different phases of the cell cycle, the overall cell kill should be enhanced.

## CLINICAL USE OF CHEMOTHERAPY

### Clinical Setting

Chemotherapy may be used in at least five different ways. The term *induction chemotherapy* is defined as primary treatment for patients with an advanced malignancy when no feasible alternative treatment exists. *Adjuvant chemotherapy* is given to destroy remaining microscopic cells that may be present after the primary tumor is removed by surgery. *Neoadjuvant chemotherapy* refers to drug treatment directed at an advanced cancer to decrease preoperatively the extent or morbidity of a subsequent surgical resection. *Consolidation* (or *maintenance*) *chemotherapy* is given after cancer has disappeared following the initial therapy to prolong the duration of clinical remission or to prevent ultimate relapse. Therapy applied to recurrent disease or to a tumor that is refractory to initial treatment is

termed *salvage* (or *palliative*) *chemotherapy*. In these incurable patients, the intent is to achieve tumor shrinkage or stability but maintain quality of life.

In general, chemotherapy is used with either curative or palliative intent. When implementing chemotherapy with curative intent, the number of courses is typically predefined. Emphasis is placed on maintaining curative dosages and adhering closely to the treatment schedule. This may lead to significant toxicity and require growth-factor support. However, for the possibility of achieving cure, these side effects are typically deemed acceptable.

Chemotherapy is often not used with curative intent, and the treating clinician must balance several factors to provide effective, compassionate palliation. Thus, in this setting, greater importance is attached to avoiding excessive toxicity. In many ways, the use of chemotherapy for palliation exemplifies the “art” of medicine. Instead of a defined number of treatment courses, a clinician must frequently revisit the treatment effectiveness and alter the dosage and timing of chemotherapy administration accordingly.

### ■ Drug Regimens

With few exceptions, single drugs administered at clinically tolerable doses do not cure cancer. However, using two or more drugs simultaneously may greatly exacerbate toxicity. Thus, in principle, the goal of combination chemotherapy is to provide maximum cell kill with minimal or tolerable adverse patient side effects. Drugs are selected based on their proven efficacy as single agents, different mechanisms of action, and toxicities that overlap minimally or not at all.

Combination chemotherapy is more effective in attacking heterogeneous populations of cells. Moreover, the use of multiple drugs with differing mechanisms of action tends to minimize the emergence of drug resistance. Typically, drugs used in combination should have clinical data indicating that their effects will be synergistic or at least additive. Drugs in combination are used at their optimal doses and schedules. Dose reductions initiated solely to allow the addition of other agents are counterproductive because most drugs must be used near their maximum tolerated dose to ensure efficacy.

Frequently, chemotherapy is combined with radiation therapy or sequenced with surgery. With chemoradiation, the goal is to achieve local control by chemically rendering the tumor more sensitive to radiation. For example, care of locally advanced cervical cancer was transformed by adding weekly cisplatin to standard radiotherapy. In addition, concurrent chemotherapy is intended to treat micrometastases outside the radiation field.

However, treatment-related toxicity is also increased. Patients previously treated with radiation therapy may have bone marrow, skin, or other body systems that are more susceptible to chemotherapy toxicity. As a result, dose reductions or delays are commonplace. Furthermore, chemotherapy is generally less effective in tumors that lie within a previously irradiated field due to increased fibrosis and capillary destruction.

Combining chemotherapy with surgery has many different applications. A woman with endometrial cancer may have nodal metastases detected during surgery, and receive pelvic radiation preceded or followed by combination chemotherapy.

Alternatively, a woman with recurrent ovarian cancer may be treated by combination chemotherapy with or without preceding secondary cytoreductive surgery. The purpose of sequencing treatment in this way is to reduce tumor bulk and thereby augment chemotherapy effectiveness. In general, adjunctive therapy is begun within a few weeks after surgery.

### ■ Directing Care of the patient

To effectively counsel a gynecologic cancer patient and then guide her chemotherapeutic treatment course requires a comprehensive understanding of the diagnosis, alternatives, and goals of care. Coexisting conditions or tumor-related complications (e.g., deep-vein thrombosis) may need to be addressed. As the intended therapy is finalized, extensive information regarding anticipated side effects is provided to allay concerns and reduce anxiety. A consent form must be reviewed and signed by the patient, in addition to clarification of all potential logistical challenges (e.g., intravenous access).

Prior to drug infusion, a complete medical history and comprehensive physical examination are mandatory. Blood work, including a complete blood count, comprehensive metabolic panel, and tumor markers (e.g., CA125) as indicated, are drawn and reviewed before orders to begin infusion are signed. Drug administration must take place in a setting where staff are immediately available to intervene should the need arise. Afterward, the patient is provided contact numbers in case of questions, problems, or other concerns that can often develop prior to the next visit.

Typically, regular office visits shortly before or on the day of treatment allow assessment of toxicity and general health. Patient examination and review of blood work results, in the context of the tumor response and overall treatment goal, will help determine whether drugs are changed or their dosages revised. Over time, the treatment strategy is continually reassessed as circumstances change.

## pHARMACOLOGIC pRINCIPLES

### ■ Dosing and Dose Intensity

Overall, treatment effectiveness depends on drug concentration and duration of exposure to critical tumor sites. Chemotherapeutic agents typically have a narrow therapeutic range or “window.” Thus, doses must be calculated accurately to achieve an optimal effect above a critical threshold while avoiding undue toxicity.

Most commonly, chemotherapy doses are calculated based on the patient’s body surface area (BSA) and are expressed in milligrams per meter squared ( $\text{mg}/\text{m}^2$ ). BSA is a better indicator of metabolic mass than body weight because it is less affected by abnormal adipose mass. This calculation ensures that each patient receives proportionally similar drug amounts. Although height is a fixed variable, patient weights are obtained prior to every therapy course, as they may fluctuate significantly. Rarely, tissue edema or ascites must be factored, since doses should be based on weight without this coexisting fluid. The BSA is most often calculated by using a nomogram (standard reference graph table). Consistent derivation of the BSA at each

visit is important, and various calculators are routinely available via software or online (<http://www.globalrph.com/bsa2.htm>). “Normal” adult BSA for women approximates 1.7 m<sup>2</sup>.

Alternatively, the dosing of some drugs is more specific. For example, bevacizumab is a monoclonal antibody metabolized and eliminated via the reticuloendothelial system. It is dosed only by patient weight (mg/kg). For renally excreted drugs, such as carboplatin, dosing may be based on an estimate of the glomerular filtration rate (Calvert formula).

The amount of drug administered over time is known as the *dose intensity* (or *density*). Its primary importance is in highly responsive tumors, in which cure can be achieved with chemotherapy. However, in other less sensitive tumors, it may not be possible to increase the dose to a level sufficient to produce demonstrable benefit without producing dose-limiting toxicity. On the other hand, reducing dose intensity to decrease toxicity can produce inferior therapeutic results.

### ■ Administration Route and Excretion

Chemotherapy may be administered systemically or regionally. Oral, intravenous (IV), subcutaneous (SC), or intramuscular (IM) routes comprise systemic treatment options. Regional chemotherapy is aimed at delivering drugs directly into the cavity in which the tumor is located. Clearance for many agents from a body cavity is slower than from systemic circulation. As a result, cancer cells are exposed longer to higher concentrations of active agents. This technique has been most extensively studied in ovarian cancer, in which tumors are usually confined to the intraperitoneal (IP) space. Clinical studies have uniformly demonstrated a pharmacologic advantage favoring administration into the IP compartment. However, penetration into peritoneal tumor nodules by passive diffusion is often limited by the presence of intraabdominal adhesions, poor fluid circulation, fibrotic tumor encapsulation, and coexisting ascites. Because of these limitations in drug penetration, IP chemotherapy is typically administered to women with minimal residual disease.

During IV administration, several drugs known as vesicants require special care (Table 27-1). Extravasation of these into the subcutaneous tissue can result in severe pain and necrosis. These drugs require slow infusion either through a rapidly flowing peripheral IV catheter or preferably via a central venous catheter. If extravasation is suspected, the infusion is

immediately stopped, the affected arm elevated, and ice packs applied. In severe cases, a plastic surgeon should be consulted.

Agent activity and toxicity is influenced dramatically by drug inactivation, elimination, or excretion. For the most part, this takes place primarily via the liver or kidneys. As a result, drug activity may be diminished and toxicity exacerbated when normal hepatic or renal function is impaired. In addition, drug toxicity is often more pronounced in the elderly or malnourished. For example, a low serum creatinine level in cachectic women may not accurately reflect underlying renal function. If a carboplatin dose is calculated using this falsely low value, the amount may be excessive and result in considerable morbidity. Instead, a preset creatinine level may need to be selected (0.8 or 1.0 mg/dL) to aid safer dosing in some patients.

### ■ Drug Interactions and Allergic Reaction

Most women who receive chemotherapy are prescribed medication for other noncancerous conditions, such as hypertension. Moreover, women also often receive analgesics, antiemetics, and antibiotics during chemotherapy. Most drug interactions are of little consequence, but some may lead to substantially altered drug toxicity. Drugs that are metabolized in the liver are particularly at risk for such interactions. For example, using methotrexate in a woman taking warfarin (Coumadin) will usually enhance the anticoagulant effect and thus will require a warfarin dose reduction.

An anaphylactic, allergic, or hypersensitivity reaction during or after administration of chemotherapy may develop, despite patient history review and administration of prophylactic medications. Accordingly, a treatment facility must have trained nursing staff and resources to manage these sudden, but common, issues. Prior to drug administration, a woman is instructed to report symptoms that may herald an anaphylactic reaction such as flushing, pruritus, dyspnea, tachycardia, hoarseness, or lightheadedness. Emergency equipment, such as supplemental oxygen, ventilatory face mask and bag, or intubation equipment, must be immediately available. For a localized hypersensitivity response, administration of intravenous diphenhydramine (Benadryl) and/or corticosteroids may be sufficient. However, for a generalized hypersensitivity or anaphylactic response, chemotherapy should be stopped immediately, the emergency team notified, and emergency drugs administered, such as epinephrine (0.1–0.5 mg of a 1:10,000 solution) (Table 27-2).

**TABLE 27-1.** Chemotherapeutic Agents and Their Association with Extravasation Injury

Vesicants	Exfoliants	Irritants	Inflammants	Neutral
Dactinomycin	Cisplatin	Carboplatin	Methotrexate	Bleomycin
Doxorubicin	Docetaxel	Etoposide		Cyclophosphamide
Paclitaxel	Liposomal doxorubicin			Gemcitabine
	Topotecan			Ifosfamide

Vesicant, agent capable of causing skin ulceration and tissue necrosis on extravasation; exfoliant, agent capable of causing skin exfoliation on extravasation; irritant, agent capable of causing skin irritation on extravasation; inflammant, agent capable of causing skin inflammation on extravasation.

TABLE 27-2. Management of Hypersensitivity Reactions

- 1. Stop the chemotherapy infusion
- 2. Assess the patient’s airway, breathing, and circulation
- 3. Administer intravenous normal saline if hypotensive
- 4. Administer oxygen if dyspneic or hypoxic
- 5. Administer intravenous antihistamine (e.g., 50 mg intravenous diphenhydramine or 25–50 mg intravenous promethazine)
- 6. Administer 5 mg of nebulized salbutamol if the patient has bronchospasm
- 7. Administer intravenous corticosteroids (e.g., 100 mg of hydrocortisone); this may have no effect on the initial reaction, but may prevent rebound or prolonged allergic manifestations
- 8. If the patient does not promptly improve or has symptoms of persistent or severe hypotension or persistent bronchospasm or laryngeal edema, administer adrenaline or epinephrine (0.1–0.25 mg intravenous); further acute resuscitation measures may be required
- 9. Reassure the patient that the problem is a recognized and treatable one

■ Drug Resistance

In principle, larger tumor masses have a greater proportion of cells that have already developed resistance. Resistance may be intrinsic or acquired, and it may develop to one drug or to multiple agents. Intrinsic drug resistance is seen if tumors are first exposed to an agent and fail to respond. In contrast, with acquired drug resistance, tumors no longer respond to drugs to which they were initially sensitive. Sometimes, this develops with a specific drug. More often, however, acquired resistance is “pleiotropic,” meaning that a cancer is resistant to multiple chemotherapy agents. This is often mediated by the P-glycoprotein or multidrug resistance pump. Advanced ovarian cancer is a good example. Most patients will initially achieve remission with platinum-based chemotherapy, but 80 percent will ultimately relapse and die from tumors that have become resistant to all cytotoxic therapy.

■ Evaluating Response to Chemotherapy

The effective use of chemotherapy is a dynamic process whereby a treating clinician is constantly weighing toxicity to the patient against tumor response. Numerous factors influence toxicity and include the patient’s baseline nutrition, overall health, extent of disease, and prior therapy. In counseling women to continue treatment or switch to a different regimen, a clinician must have objective criteria for response (Table 27-3). The most important indicator is the *complete response rate*. For

ovarian cancer, this would include normal CA125 levels (usually < 35 U/mL), physical examination findings, and imaging test results. Ultimately, women who have any possibility of cure are those who first achieve a complete response. However, if chemotherapy results in a partial response, many women still view this as advantageous compared with supportive care, even if a survival benefit is unproven.

CHEMOTHERAPEUTIC DRUGS

■ Antimetabolites

The antimetabolites are analogues of naturally occurring components of the metabolic pathways that lead to the synthesis of purines, pyrimidines, and nucleic acids. In most cases, they are S phase-specific agents that are most effective in rapidly growing tumors associated with short doubling times and large growth fractions (Table 27-4).

Methotrexate

This antimetabolite is U.S. Food and Drug Administration (FDA)-approved to be used solely for treatment of women with gestational trophoblastic neoplasia (GTN). It is also commonly used for the medical management of ectopic pregnancy. Methotrexate (MTX) tightly binds to dihydrofolate reductase, blocking the reduction of dihydrofolate to tetrahydrofolate (the active form of folic acid) (Fig. 27-3). As a result, thymidylate

TABLE 27-3. Clinical End Points in Evaluating Response to Chemotherapy

End Point	Definition
Complete response (CR)	Disappearance of all measurable “target” lesions
Partial response (PR)	A decrease of ≥ 30% in the sum of diameters of all target lesions
Progressive disease (PD)	An increase of ≥ 20% in the sum of diameters of target lesions or the identification of one or more new lesions
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR, nor sufficient increase to qualify for PD

Data from Eisenhauer EA, Therasse P, Bogaerts J, et al: New response evaluation criteria in solid tumours: revised RECIST guideline (version 1.1). Eur J Cancer 2009 Jan;45(2):228–47.

**TABLE 27-4.** Chemotherapy Antimetabolites Used for Gynecologic Cancer

Generic Name	Brand Name	Indications	Routes	Common Dosages	Common Toxicity
Methotrexate	Trexall, Rheumatrex	GTN	PO, IM, IV, intrathecal	IM: 1 mg/kg on days 1, 3, 5, 7 of 8-day cycle or 30–50 mg/m <sup>2</sup> /wk IV: 100 mg/m <sup>2</sup> during 30 min, then 200 mg/m <sup>2</sup> during 12 hr	BMD, mucositis, renal toxicity, CNS dysfunction
Gemcitabine	Gemzar	Recurrent ovarian CA, uterine sarcoma	IV	600–1250 mg/m <sup>2</sup> /wk over 30 min × 2–3 wk	BMD, N/V/D, malaise and fever
5-Fluorouracil	Adrucil	Cervical CA, vulvar CA	IV	800–1000 mg/m <sup>2</sup> /d during 96 hr	Mucositis, PPE
	Efudex	VAIN	Vaginal cream	3 mL QOD × 1 wk, then weekly up to 10 wk	Vulvovaginal irritation

BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PPE = palmar-plantar erythrodysesthesia; PO = orally; QOD = every other day; VAIN = vaginal intraepithelial neoplasia.

synthetase and various steps in de novo purine synthesis are halted. This leads to arrest of DNA, RNA, and protein synthesis.

Methotrexate may be administered orally, IM, IV, or intrathecally. Most commonly, single-agent treatment of GTN involves MTX given IM as an 8-day regimen of 1 mg/kg on treatment days 1, 3, 5, and 7, or at dosages of 30 to 50 mg/m<sup>2</sup>

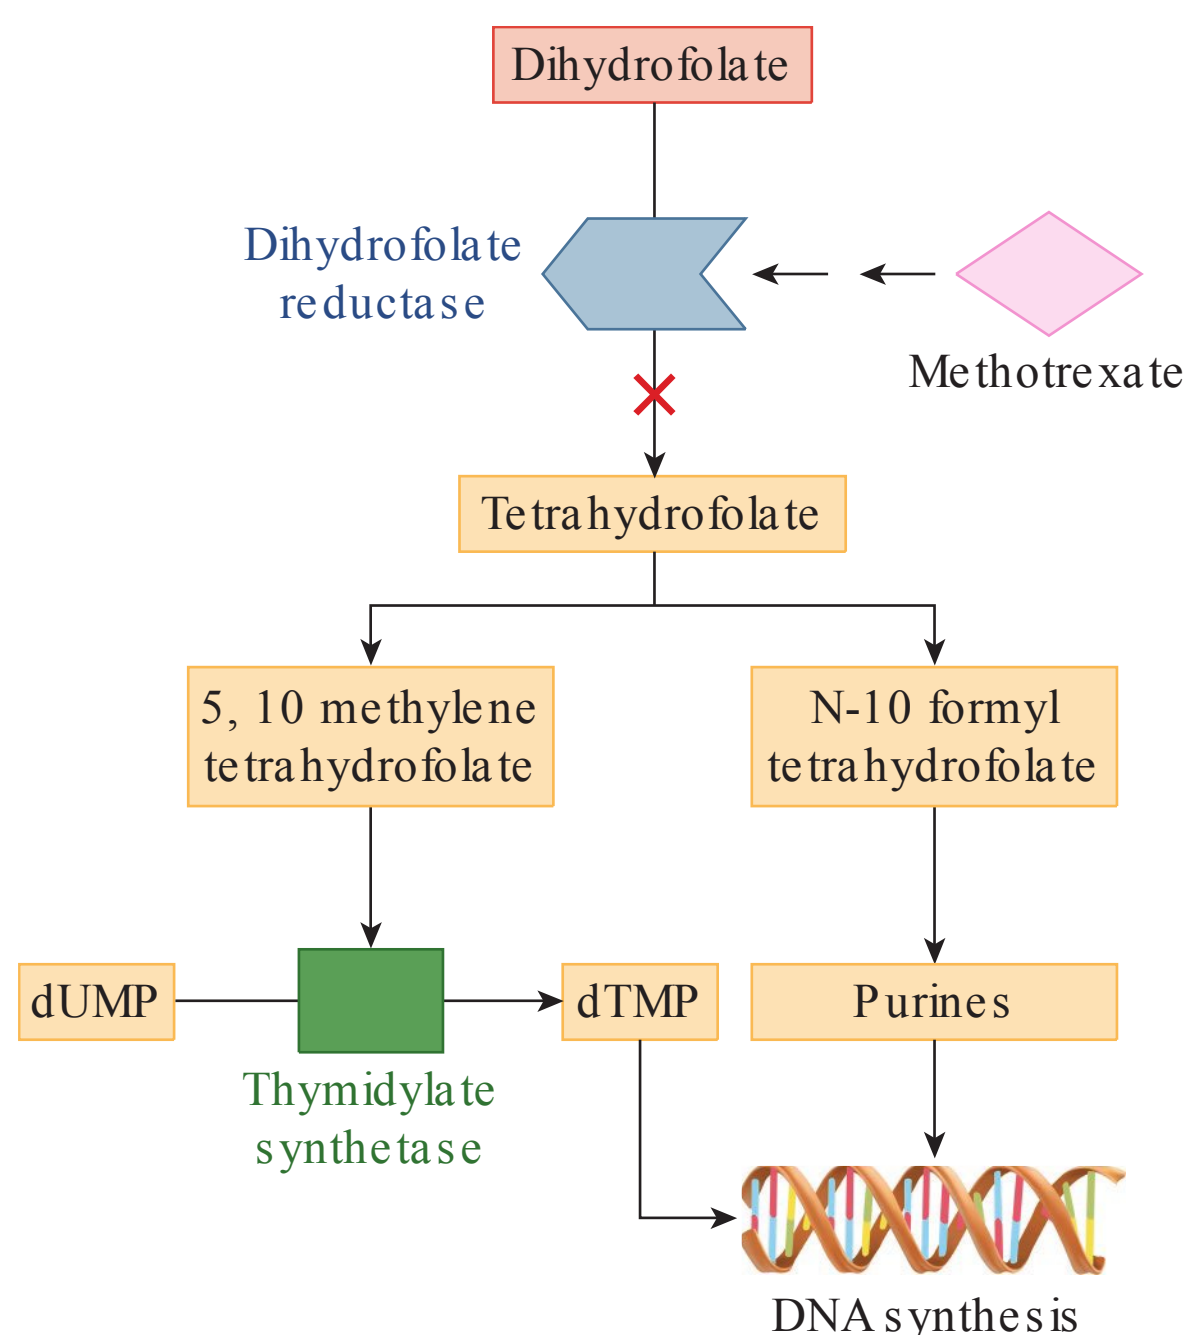

once each week. Combination therapy for high-risk disease includes 100 mg/m<sup>2</sup> MTX given IV over 30 minutes, followed by a 200 mg/m<sup>2</sup> IV dose over 12 hours. With MTX, patients are counseled to avoid folate-containing supplements unless specifically directed.

MTX causes few side effects at typical doses. However, at high doses, although used infrequently, this agent can lead to fatal bone marrow toxicity. This toxicity can be prevented by “rescue” doses of leucovorin. Leucovorin is folinic acid, has activity that is equivalent to folic acid, and thus is readily converted to tetrahydrofolate. Leucovorin, however, does not require dihydrofolate reductase for its conversion. Therefore, its function is unaffected by inhibition of this enzyme by MTX. Leucovorin administration, therefore, allows for some purine and pyrimidine synthesis. Leucovorin rescue is incorporated into the 8-day alternating MTX schedule, and a 0.1 mg/kg leucovorin dose is provided orally on treatment days 2, 4, 6, and 8.

In addition to myelosuppression, renal toxicity and acute cerebral dysfunction are typically only seen at high MTX doses. Methotrexate is predominantly excreted through the kidneys, and thus women with renal insufficiency have doses reduced. Serum MTX levels are carefully monitored in these patients, as they may require prolonged leucovorin rescue.

### Gemcitabine

This antimetabolite is FDA approved to be used with other agents for treatment of recurrent ovarian cancer but is also commonly used for uterine sarcoma. Gemcitabine (Gemzar) is a synthetic nucleoside analogue that undergoes multiple phosphorylations to form the active metabolite. The resulting triphosphate is subsequently incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one additional deoxynucleotide is added to the end of the DNA chain before replication is terminated, and thereby, DNA synthesis is halted.

**FIGURE 27-3** Methotrexate’s primary target is the enzyme dihydrofolate reductase (DHFR). Inhibition of DHFR leads to partial depletion of 5,10 methylene tetrahydrofolic acid and N-10 formyl tetrahydrofolic acid, which are cofactors required for the respective synthesis of thymidylate and purines. As a result, methotrexate leads to arrested DNA, RNA, and protein synthesis. dTMP = deoxythymidine monophosphate; dUMP = deoxyuridine monophosphate.

The usual administration of gemcitabine is by 30-minute infusion. Longer durations, such as those greater than 60 min, are associated with increased toxicity due to intracellular accumulation of the triphosphate. Depending on whether it is used as a single agent or in combination, gemcitabine is typically given at doses between 600 and 1250 mg/m<sup>2</sup> once weekly for 2 to 3 weeks, followed by a week off therapy.

Myelosuppression, especially neutropenia, is the main dose-limiting side effect. Gastrointestinal (GI) toxicity, such as nausea, vomiting, diarrhea, or mucositis, is also common. Approximately 20 percent of patients will develop a fulike syndrome, including fever, malaise, headache, and chills. Pulmonary toxicity is infrequent, but reported.

5-Fluorouracil

5-Fluorouracil (5-FU) is not FDA approved for gynecologic cancer but is occasionally paired with cisplatin during chemoradiation for cervical cancer. A topical form (Efudex) can be used for vaginal intraepithelial neoplasia (VAIN) treatment as discussed in Chapter 29 (p. 646). This “false” pyrimidine antimetabolite acts principally as a thymidine synthetase inhibitor to block DNA replication.

Systemic 5-FU (Adrucil) is usually given as a 96-hour continuous IV infusion of 800 to 1000 mg/m<sup>2</sup>/d. Mucositis and/or diarrhea may be severe and dose-limiting. Hand-foot syndrome (palmar-plantar erythrodysesthesia), described on page 600, is less common but can also be dose-limiting. Myelosuppression, mainly neutropenia and thrombocytopenia, are less frequent. Nausea and vomiting are usually mild.

■ Alkylating Agents  
Cyclophosphamide

The class of alkylating agents is characterized by positively charged alkyl groups that bind to negatively charged DNA to form adducts (Table 27-5). Binding leads to DNA breaks or cross-links and a halt to DNA synthesis. In general, these drugs are cell cycle-nonspecific agents.

Of alkylating agents, cyclophosphamide (Cytosan) is FDA approved by itself or in combination for epithelial ovarian cancer treatment. Cyclophosphamide is the “C” of the EMA-CO (etoposide, methotrexate, actinomycin D, cyclophosphamide, Oncovin [vincristine]), which is a regimen prescribed for high-risk GTN. It is also used, albeit infrequently, as salvage

therapy for recurrent epithelial ovarian cancer (Bower, 1997; Cantu, 2002). Cyclophosphamide is a derivative of nitrogen mustard and is activated through a multistep process by microsomal enzymes in the liver. It promotes DNA cross-linking and DNA synthesis inhibition.

This agent may be administered IV or orally. It is typically given IV at doses of 500 to 750 mg/m<sup>2</sup> over 30 minutes every 3 weeks. Orally, a metronomic (repetitive low-dose) regimen of 50 mg daily is often used to minimize toxicity and target the tumor endothelium or stroma in combination with a biologic agent, such as bevacizumab (Chura, 2007).

Myelosuppression, mainly neutropenia, is the usual dose-limiting side effect. Cyclophosphamide is exclusively excreted by the kidneys. One of its metabolites, acrolein, can alkylate and inflame the bladder mucosa. As a result, hemorrhagic cystitis is a classic complication that may follow from 24 hours to several weeks after administration. To prevent this effect, adequate hydration is imperative to aid acrolein excretion. In addition, GI toxicity, such as nausea, vomiting, or anorexia, is common. Alopecia is typically severe. Moreover, later secondary malignancy rates are increased, particularly acute myelogenous leukemia and bladder cancer.

Of chemotherapeutic drugs, alkylating agents are believed to be particularly damaging to ovarian function. Preventatively, adjuvant GnRH agonists may lower rates of chemotherapy-induced ovarian failure, although the efficacy of this approach remains controversial (Chen, 2011; Elgindy, 2013). Through its hypoestrogenic effects, a GnRH agonist may decrease ovarian blood flow, and thereby decrease chemotherapeutic exposure of the ovaries (Blumenfeld, 2003). Alternatively, pituitary-gonadal axis inhibition may protect the germinal epithelium by inhibiting oogenesis. Last, as GnRH receptors have been identified in the ovary, GnRH agonist may act directly in the ovary to decrease granulosa cell metabolism (Peng, 1994). Importantly, advances in oocyte and ovarian tissue cryopreservation make it likely that the removal of oocytes prior to treatment will become the preferred approach when feasible.

Ifosfamide

This alkylating agent is not FDA approved for gynecologic cancers but is sometimes administered for salvage treatment of recurrent epithelial ovarian cancer, cervical cancer, and uterine sarcoma. Ifosfamide (Ifex) is a structural analogue of cyclophosphamide, differing only slightly. However, its metabolic

TABLE 27-5. Chemotherapy Alkylating Agents Used for Gynecologic Cancer					
Generic Name	Brand Name	Indication	Routes	Dosages	Toxicity
Cyclophosphamide	Cytosan	GTN, recurrent ovarian CA	PO, IV	IV: 500–750 mg/m <sup>2</sup> over 30 min, every 3 wk PO: 50 mg/d	BMD, cystitis, N/V, alopecia
Ifosfamide	Ifex	Recurrent ovarian CA, cervical CA, uterine sarcoma	IV	1.2–1.6 g/m <sup>2</sup> /d, days 1–3 of 3-wk cycle	BMD, cystitis, N/V, alopecia, CNS and renal toxicity
BMD = bone marrow depression; CA = cancer; CNS = central nervous system; GTN = gestational trophoblastic neoplasia; IV = intravenous; N/V = nausea and vomiting; PO = orally.					

**FIGURE 27-4** Ifosfamide is a prodrug, which is ultimately metabolized into active and inactive metabolites. Iso-phosphoramidate mustard is the main active alkylating metabolite. The inactive metabolite, acrolein, is concentrated in the bladder and is bladder toxic. The drug mesna and acrolein join in the bladder to create an inactive compound, which is then excreted by the bladder. This conversion of acrolein to an inactive compound minimizes ifosfamide's bladder toxicity.

activation occurs more slowly and leads to a greater production of chloroacetaldehyde, a possible neurotoxin.

Ifosfamide is administered IV, usually as a short infusion. Common doses of 1.2 to 1.6 g/m<sup>2</sup> are given on days 1 through 3 of a 3-week cycle. As with cyclophosphamide, adequate hydration is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. In addition, concurrent mesna (Mesnex) is used to prevent severe hematuria. A mesna metabolite chemically binds with acrolein, an ifosfamide metabolite, and detoxifies acrolein in the bladder (Fig. 27-4). Other side

effects are similar to those of cyclophosphamide. However, neurotoxicity, manifested as lethargy, confusion, seizure, ataxia, hallucinations, and occasionally coma, is more likely. These symptoms are caused by the chloroacetaldehyde metabolite and are reversible with removal of the drug and supportive care. The incidence of neurotoxicity is higher in the rare patient receiving high-dose therapy and also in those with impaired renal function, where a preventive dose reduction is typically necessary.

## ■ Antitumor Antibiotics

### Dactinomycin

The antitumor antibiotics are generally derived from microorganisms. Most antitumor antibiotics exert their cytotoxic effects by DNA intercalation during multiple phases of the cell cycle. They are considered cell-cycle specific.

In this group, dactinomycin is FDA approved to treat GTN as a single agent or as part of combination chemotherapy (Table 27-6). Dactinomycin (Cosmegen), also known as actinomycin D, is the “A” of the EMA-CO chemotherapy combination. Dactinomycin is a product of a *Streptomyces* species and becomes anchored into purine-pyrimidine DNA base pairs, resulting in DNA synthesis inhibition. It also produces toxic oxygen free radicals that cause DNA breaks. Dactinomycin is mainly excreted through the biliary system.

The usual “pulse” dosage of dactinomycin is 1.25 mg IV push every other week, but is sometimes administered as a 0.5 mg dose on days 1 through 5 every 2 to 3 weeks. Myelosuppression is the main dose-limiting side effect and may be severe. Moreover, GI toxicity, including nausea, vomiting, mucositis, and diarrhea, is often significant. Alopecia is common. As with others in the antibiotic group, dactinomycin is a potent vesicant (see Table 27-1).

### Bleomycin

This antitumor antibiotic is FDA approved for malignant pleural effusion treatment or for palliative therapy of recurrent

**TABLE 27-6.** Chemotherapeutic Antibiotics Used for Gynecologic Cancer

Generic Name	Brand Name	Indication	Route	Dosage	Toxicity
Actinomycin D (dactinomycin)	Cosmegen	GTN	IV	1.25 mg IV push every other wk or 0.5 mg on days 1–5, every 2–3 wk	BMD, N/V/D, alopecia, vesicant
Bleomycin	Blenoxane	Germ cell or SCST ovarian CA, GTN	IV, IM, SC, intrapleural	IV: 20 U/m <sup>2</sup> (maximum dose of 30 U), every 3 wk	Pulmonary toxicity, fever, skin reaction
Doxorubicin	Adriamycin	Uterine sarcoma, recurrent epithelial ovarian CA	IV	45–60 mg/m <sup>2</sup> every 3 wk	BMD, cardiac toxicity, alopecia, vesicant
Liposomal doxorubicin	Doxil	Recurrent epithelial ovarian CA	IV	40–50 mg/m <sup>2</sup> over 30 min, every 4 wk	PPE, stomatitis, infusion reaction

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; IM = intramuscular; IV = intravenous; N/V/D = nausea, vomiting, and diarrhea; PPE = palmar-plantar erythrodysesthesia; SC = subcutaneous; SCST = sex cord-stromal tumor.

squamous cervical or vulvar cancer. An off-label use includes bleomycin as the “B” in BEP (bleomycin, etoposide, cisplatin) regimens, which are used as adjuvant treatment of malignant ovarian germ cell or sex cord-stromal tumors (Park, 2011; Weinberg, 2011). Additionally, it is used in GTN salvage treatment (Alazzam, 2012). Bleomycin (Blenoxane), when complexed with iron, creates activated oxygen free radicals, which cause DNA-strand breaks and cell death. It is maximally effective during the G<sub>2</sub> phase.

The usual dosage of bleomycin is 20 units/m<sup>2</sup> IV (maximum dose of 30 units), given every 3 weeks. Bleomycin can also be administered IM, SC, or intrapleurally. The dose is quantified by international units of “cytotoxic activity.”

Pulmonary toxicity is the main dose-limiting side effect, developing in 10 percent of patients and causing death in 1 percent. Accordingly, for women prescribed bleomycin, chest radiographs and pulmonary function tests (PFTs) are performed at baseline and obtained regularly before every one or two treatment cycles. The most important PFT measurement is the diffusing capacity of the lung for carbon monoxide (DLCO). The DLCO measures the ability to transfer oxygen from the lungs to the blood stream. If the DLCO declines by 15 to 30 percent, it indicates development of restrictive lung disease. In patients receiving bleomycin, therapy may then be stopped before the onset of symptomatic pulmonary fibrosis. Fibrosis often presents clinically as pneumonitis with cough, dyspnea, dry inspiratory crackles, and infiltrates on chest radiograph. This complication is more common in patients older than 70 and with cumulative doses of greater than 400 units. Bleomycin is not myelosuppressive. However, skin reactions are common and include hyperpigmentation or erythema.

### Doxorubicin

This antitumor antibiotic is FDA approved to treat epithelial ovarian cancer. Doxorubicin (Adriamycin) is also used on occasion for uterine sarcoma (Hyman, 2014; Mancari, 2014). This agent intercalates into DNA to inhibit DNA synthesis, inhibits topoisomerase II, and forms cytotoxic oxygen free radicals. The drug is metabolized extensively in the liver and eliminated through biliary excretion.

The usual dose of doxorubicin is 45 to 60 mg/m<sup>2</sup> IV, repeated every 3 weeks. Myelosuppression, particularly neutropenia, is the main dose-limiting side effect. However, cardiotoxicity is a classic complication. Patients are monitored with a multiple-gated acquisition (MUGA) radionuclide scan at baseline and periodically during therapy. The risk of cardiotoxicity is higher in women older than 70 and those with cumulative doses exceeding 550 mg/m<sup>2</sup>. Ultimately, women may develop an irreversible dilated cardiomyopathy associated with congestive heart failure. Gastrointestinal toxicities are generally mild, but alopecia is universal.

### Doxorubicin Hydrochloride Liposome

This antitumor antibiotic is FDA approved for the salvage treatment of recurrent epithelial ovarian cancer (Gordon, 2004). The liposomal encapsulation of doxorubicin (Doxil) dramatically alters the pharmacokinetic and toxicity profiles of the drug. Researchers developed liposomal doxorubicin to reduce cardiotoxicity and to selectively target tumor tissues.

**FIGURE 27-5** Diagram of taxane’s and vinca alkaloid’s mechanism of action. Parts B and C show magnified microtubule structure. **A.** During cellular mitosis, microtubules are essential for chromosome alignment and separation. **B.** Vincristine, one of the vinca alkaloids, attaches consistently to one end of the microtubule to inhibit microtubule assembly. **C.** Paclitaxel, one of the taxanes, binds to the inner ring of the microtubule and prohibits microtubule disassembly. In both B and C, microtubule function is impaired.

Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes and is dosed at 40 to 50 mg/m<sup>2</sup> every 4 weeks. In contrast to doxorubicin, administration of the encapsulated liposome is associated with minimal nausea, vomiting, alopecia, and cardiotoxicity. Infusion-related reactions develop in less than 10 percent of patients and are most common during the first treatment course. However, an increased rate of stomatitis and palmar-plantar erythrodysesthesia (PPE) is noted.

PPE is characterized by a cutaneous reaction of varying intensity. Patients may initially complain of tingling sensations on their soles and palms that generally progresses to swelling and tenderness to touch. Erythematous plaques typically develop that can become extremely painful and often lead to desquamation and skin cracking. Symptoms result from the prolonged blood levels of this time-released cytotoxic agent and may last several weeks.

## ■ plant-derived Agents

### Taxanes

The cytotoxic activity of all the plant-derived agents stems from the disturbance of normal assembly, disassembly, and stabilization of intracellular microtubules to halt cell division during mitosis (Fig. 27-5). The group includes the taxanes, vinca alkaloids, and topoisomerase inhibitors.

**TABLE 27-7.** Chemotherapeutic Plant Alkaloids Used for Gynecologic Cancer

Generic Name	Brand Name	Indications	Routes	Dosages	Toxicity
Paclitaxel	Taxol	Recurrent epithelial ovarian CA, endometrial CA, cervical CA, GTN	IV, IP	IV: 135–175 mg/m <sup>2</sup> every 3 wk, or 80 mg/m <sup>2</sup> /wk for 3 weeks IP: 60 mg/m <sup>2</sup> on day 8 following a day-1 IV dose	HSR, peripheral neurotoxicity, BMD, alopecia, bradycardia and arrhythmia
Docetaxel	Taxotere	Recurrent epithelial ovarian CA, uterine sarcoma	IV	75–100 mg/m <sup>2</sup> every 3 weeks, or 35 mg/m <sup>2</sup> /week for 3 weeks	BMD, peripheral edema, HSR, alopecia
Vincristine	Oncovin	GTN	IV	0.8–1.0 mg/m <sup>2</sup> every other week	Neurotoxicity, abdominal pain, alopecia
Etoposide	VP-16	Germ cell or SCST ovarian CA; recurrent epithelial ovarian CA	IV, PO	IV: 100 mg/m <sup>2</sup> days 1 & 2, every 2 wk, or 75–100 mg/m <sup>2</sup> , days 1–5, every 3 wk PO: 50 mg/m <sup>2</sup> /day for 3 wk	BMD, alopecia, secondary cancers
Topotecan	Hycamtin	Recurrent epithelial ovarian CA, cervical CA	IV	1.5 mg/m <sup>2</sup> /d, days 1–5, every 3 wk, or 4 mg/m <sup>2</sup> /wk for 3 wk, or 0.75 mg/m <sup>2</sup> /d, days 1–3, every 3 wk	BMD, N/V, alopecia, fever, malaise

BMD = bone marrow depression; CA = cancer; GTN = gestational trophoblastic neoplasia; HSR = hypersensitivity reaction; HTN = hypertension; IV = intravenous; N/V = nausea and vomiting; PO = orally; SCST = sex cord-stromal tumor.

Of the taxanes, paclitaxel and docetaxel are both cell cycle-specific agents that have maximal activity during the M phase (Table 27-7). Derived from yew tree species, they act to “poison” the mitotic spindle by preventing depolymerization of the microtubules and inhibiting cellular replication.

**paclitaxel.** The best-selling cancer drug ever manufactured, paclitaxel (Taxol) is FDA approved for the treatment of primary or recurrent epithelial ovarian cancer. It is also extensively used for endometrial cancers, cervical cancers, and GTN.

Paclitaxel is typically administered IV as a 3-hour infusion, but may also be given as an intraperitoneal (IP) dose. The usual IV dosage is 135 to 175 mg/m<sup>2</sup> every 3 weeks. Weekly paclitaxel is also effective in a regimen of 80 mg/m<sup>2</sup> IV for 3 consecutive weeks on a 21-day schedule (“dose-dense” regimen) for primary disease or on a 28-day schedule for recurrent disease (Katsumata, 2009; Markman, 2006). For initial therapy of optimally debulked ovarian cancer following a day-1 IV dose, paclitaxel is usually given IP on day 8 at a dose of 60 mg/m<sup>2</sup> (Armstrong, 2006).

Myelosuppression is the usual dose-limiting side effect. Additionally, a hypersensitivity reaction occurs in approximately one third of patients due to its formulation in Cremophor-EL, an emulsifying agent. Typically, the reaction develops within minutes of starting an initial infusion. Fortunately, the incidence can be decreased 10-fold by premedication with corticosteroids, usually dexamethasone, 20 mg orally 12 and 6 hours before paclitaxel infusion. Neurotoxicity is the principal

nonhematologic dose-limiting side effect. Common symptoms include numbness, tingling, and/or burning pain in a stocking-glove distribution. Peripheral neuropathy progresses with increased paclitaxel exposure and may become debilitating. Alopecia affects almost all patients and results in total body hair loss.

**Docetaxel.** This taxane is not FDA approved for gynecologic cancers but is often used to treat recurrent epithelial ovarian cancer and uterine sarcoma (Gockley, 2014; Herzog, 2014b). In addition, patients with worsening peripheral neuropathy with paclitaxel are often switched to docetaxel. Clinical efficacy is similar, but docetaxel is associated with less neurotoxicity.

The usual dosage of docetaxel (Taxotere) is 75 to 100 mg/m<sup>2</sup> IV, repeated every 3 weeks. For recurrent ovarian cancer, weekly docetaxel is also effective at a dosage of 35 mg/m<sup>2</sup> IV for 3 consecutive weeks on a 28-day schedule (Tinker, 2007).

Unlike paclitaxel, myelosuppression is the main dose-limiting side effect. Fluid retention syndrome develops in approximately half of patients and manifests as weight gain, peripheral edema, pleural effusion, and ascites. Corticosteroid prophylaxis prevents most of this toxicity, as well as dermatologic side effects and hypersensitivity reactions.

### Vinca Alkaloids

Vincristine, vinblastine, and vinorelbine are cell cycle-specific drugs derived from the periwinkle plant with maximal activity in the M phase. These compounds inhibit normal microtubular

polymerization by binding to the tubulin subunit at a site distinct from the taxane-binding site (see Fig. 27-5). These drugs are infrequently used in gynecologic oncology. That said, vincristine is the “O” of EMA-CO combination chemotherapy for GTN treatment. The usual dosage of vincristine (Oncovin) is 0.8 to 1.0 mg/m<sup>2</sup> given IV every other week. The total individual dose is capped at 2 mg to prevent or delay neurotoxicity. This is the most common dose-limiting toxicity and may include peripheral neuropathy, autonomic nervous system dysfunction, cranial nerve palsies, ataxia, or seizures. Moreover, concurrent administration with other neurotoxic agents such as cisplatin and paclitaxel may increase severity. GI toxicity is also common, including constipation, abdominal pain, and paralytic ileus. However, myelosuppression is typically mild.

### Topoisomerase Inhibitors

Topoisomerase (TOPO) enzymes unwind and rewind DNA to aid DNA replication. Topoisomerase inhibitors interfere with this function and halt DNA synthesis. This group is further divided into categories based on the specific topoisomerase enzyme they inhibit. The camptothecins inhibit TOPO I and include topotecan. The podophyllotoxins inhibit TOPO II and include etoposide.

**Topotecan.** This TOPO I inhibitor is a semisynthetic analogue of the alkaloid extract camptothecin. It binds to and stabilizes a transient TOPO I-DNA complex, resulting in double-strand breakage and lethal DNA damage. Topotecan (Hycamtin) is FDA approved as salvage therapy of recurrent epithelial ovarian cancer and recurrent cervical cancer (Long, 2005).

Topotecan is usually administered IV in two different schedules. Standard dosage for recurrent ovarian cancer is 1.5 mg/m<sup>2</sup> for days 1 through 5, given every 3 weeks (Gordon, 2004). However, this schedule is associated with a greater than 80-percent incidence of severe neutropenia. A less toxic regimen is 4 mg/m<sup>2</sup> weekly for 3 weeks during a 28-day schedule (Spannuth, 2007). The usual dosage when combined with cisplatin for recurrent cervical cancer is 0.75 mg/m<sup>2</sup> on days 1 through 3, given every 3 weeks (Long, 2005).

Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect. GI toxicity is also frequent and includes nausea, vomiting, diarrhea, and abdominal pain. Systemic symptoms such as headache, fever, malaise, arthralgias, and myalgias are typical. Alopecia is often as complete as that seen with paclitaxel therapy.

**Etoposide.** This cell-cycle specific agent has maximal activity in the late S and G<sub>2</sub> phase. Etoposide “poisons” the TOPO II enzyme by stabilizing an otherwise transient form of the TOPO II-DNA complex. As a result, DNA cannot unwind, and double-strand DNA breaks form. This agent is not FDA approved for gynecologic cancers. However, it is often used IV as part of combination chemotherapy. Etoposide (VP-16) represents the “E” of the EMA-CO regimen, which is used for GTN. In addition, it is a component of the BEP regimen, used for ovarian germ cell or sex cord-stromal tumors. Oral etoposide may be efficacious as a single agent for salvage treatment of recurrent epithelial ovarian cancer.

The dosage of etoposide varies. In the EMA-CO regimen, 100 mg/m<sup>2</sup> is administered IV on days 1 and 2, every 2 weeks. In the BEP regimen, it is usually prescribed in dosages of 75 to 100 mg/m<sup>2</sup> IV on days 1 through 5, given every 3 weeks. The oral dosage is 50 mg/m<sup>2</sup>/d for 3 weeks, followed by a week off during a 28-day schedule.

Up to 95 percent of etoposide is protein-bound, mainly to albumin. Thus, decreased albumin levels result in a higher fraction of free drug and potentially a higher incidence of toxicity. Myelosuppression, most commonly neutropenia, is the main dose-limiting side effect. GI symptoms of nausea, vomiting, and anorexia are usually minor, except with oral administration. Most patients will develop alopecia. With etoposide, particularly if the total dose exceeds 2000 mg/m<sup>2</sup>, there is a small but significant risk (approximately 1 in 1000) of later secondary malignancies. Of these, acute myelogenous leukemia is the most common.

### Miscellaneous

#### Carboplatin

Several antineoplastic compounds do not clearly fit into any of the preceding categories but have similarities with alkylating agents. Among these cell-cycle nonspecific drugs are carboplatin and cisplatin.

Carboplatin (Paraplatin) produces DNA adducts that inhibit DNA synthesis. This agent is one of the most widely used, particularly in adjuvant or salvage treatment of epithelial ovarian cancer, and is FDA approved for this indication. It is also frequently used off-label for endometrial cancer.

The usual IV dose of carboplatin is calculated to a target “area under the curve” (AUC) of 6, based on the glomerular filtration rate (GFR). The Calvert equation is the most often used (carboplatin total dose [mg] = AUC × [GFR + 25]) for dose calculation. In clinical practice, the estimated creatinine clearance (CrCl) is usually substituted for the GFR and may be calculated by the Cockcroft-Gault equation (CrCl = [140 – age] × weight [kg]/0.72 × serum creatinine level [mg/100 mL]). The infusion takes 30 to 60 minutes, and dosing is repeated every 3 to 4 weeks.

Myelosuppression, most commonly thrombocytopenia, is the main dose-limiting side effect. GI toxicity and peripheral neuropathy are notably less severe than with cisplatin. Hypersensitivity reactions will eventually develop in up to 25 percent of women receiving more than six cycles.

#### Cisplatin

Similar to carboplatin, this agent produces DNA adducts that inhibit DNA synthesis. Cisplatin is one of the oldest and most widely used agents and is FDA approved for ovarian, cervical, and germ cell cancer. It may be given concomitantly with radiation as a radiosensitizing agent for primary treatment of cervical cancer or either as a single agent or in combination for recurrent cervical cancer. Alternatively, cisplatin is part of combination chemotherapy as the “P” of BEP, given for ovarian germ cell or sex cord-stromal tumors. However, for use in epithelial ovarian cancer, cisplatin has largely been replaced by carboplatin, except for IP therapy, due to possibly superior tissue penetration and potentially better outcomes.

**TABLE 27-8.** Dose and Schedule of Antiemetics to Prevent Emesis Induced by Antineoplastic Therapy of High Emetic Risk

Antiemetics	Brand Name	Single Dose Administered before Chemotherapy	Single Dose Administered Daily
<b>5-HT<sub>3</sub> serotonin-receptor antagonists</b>			
Granisetron	Kytril	Oral: 2 mg IV: 1 mg or 0.01 mg/kg	
Ondansetron	Zofran	Oral: 24 mg IV: 8 mg or 0.15 mg/kg	
Palonosetron	Aloxi	IV: 0.25 mg	
<b>Dexamethasone</b>	Decadron	Oral: 12 mg	Oral: 8 mg, days 2–4
<b>Aprepitant</b>	Emend	Oral: 125 mg	Oral: 80 mg, days 2 and 3

5-HT<sub>3</sub>= 5-Hydroxytryptamine-3; IV= intravenous.

Data from Kris MG, Hesketh PJ, Somerfield MR, et al: American Society of Clinical Oncology guideline for antiemetics in oncology: update 2006. *J Clin Oncol* 2006 Jun 20;24(18):2932–2947.

The dosage of cisplatin varies depending on the indication. In cervical cancer, dosages of 40 mg/m<sup>2</sup> IV weekly or 75 mg/m<sup>2</sup> are given every 3 weeks during radiation therapy, or 50 mg/m<sup>2</sup> IV is provided every 3 weeks for patients with recurrent disease (Long, 2005). As part of the BEP protocol, cisplatin is administered 20 mg/m<sup>2</sup> IV on days 1 through 5 every 3 weeks. Alternatively, for ovarian cancer IP chemotherapy, cisplatin is given on day 1 or 2 of a 21-day cycle at a dose of 75 to 100 mg/m<sup>2</sup> (Armstrong, 2006; Dizon, 2011).

Cisplatin has several significant toxicities. Of these, nephrotoxicity is the main dose-limiting side effect. Accordingly, patients must be aggressively hydrated before, during, and after drug administration. Mannitol (10 g) or furosemide (20 to 40 mg) may be necessary to maintain a urine output of at least 100 to 150 mL/hour. With cisplatin, electrolyte abnormalities, such as hypomagnesemia and hypokalemia, are common. In addition, severe, prolonged nausea and vomiting can be dramatic without adequate premedication (Table 27-8). Patients often describe a metallic taste and loss of appetite following treatment. Neurotoxicity, usually in the form of peripheral neuropathy, can also be dose limiting and irreversible. Ototoxicity typically manifests as high-frequency hearing loss and tinnitus. Similar to carboplatin, hypersensitivity reactions may develop with prolonged use. Overall, cisplatin is significantly more toxic than carboplatin, except for its reduced hematologic toxicity.

## ■ Hormonal Agents

### Tamoxifen

Due to their minimal toxicity and reasonable activity, hormonal agents are often used for palliative treatment of endometrial and ovarian cancers despite lacking formal FDA approval for these indications. Of these, tamoxifen is a selective estrogen-receptor modulator. It is a nonsteroidal prodrug and is metabolized into a high-affinity estrogen-receptor antagonist in breast tissue. It does not activate the estrogen receptor and thereby blocks breast cancer cell growth. The complex is then transported into the tumor cell nucleus, where it binds to DNA and halts cellular growth and proliferation in the G<sub>0</sub> or G<sub>1</sub> phase. Antiangiogenic

effects have also been suggested. In addition to breast cancer, tamoxifen (Nolvadex) is occasionally used to treat endometrial and ovarian cancer (Fiorica, 2004; Hurteau, 2010).

Tamoxifen is orally administered, usually prescribed in doses of 20 to 40 mg for continuous daily use. Toxicity associated with tamoxifen is minimal, mainly consisting of menopausal symptoms such as hot flashes, nausea, and vaginal dryness or discharge. Moreover, some degree of fluid retention and peripheral edema develops in one third of patients. Reduced cognition and libido may also be noted during therapy.

In the endometrium, tamoxifen acts as a partial estrogen-receptor agonist. Sustained use increases the risk for endometrial polyp formation, and endometrial cancer risks triple. Moreover, thromboembolic event rates are raised, especially during and immediately after major surgery or periods of immobility. In contrast, tamoxifen prevents osteoporosis due to its partial agonist properties in bone and has beneficial effects on the serum lipid profile.

### Megestrol Acetate

This agent is a synthetic derivative of progesterone that has activity on tumors through its antiestrogenic effects. As such, megestrol acetate (Megace) is most often used to treat endometrial hyperplasia, nonoperable endometrial cancer, and recurrent endometrial cancer, especially in those patients with grade 1 disease (Chap. 33, p. 706).

The usual oral dosage is 80 mg twice daily. Megestrol acetate has minimal toxicity, but patients often gain weight from a combination of fluid retention and increased appetite. Thromboembolic events are rare. Patients with diabetes mellitus are carefully monitored because of the possibility of exacerbating hyperglycemia due to its concurrent glucocorticoid activity.

## BIOLOGICAL AND TARGETED THERAPY

Differing molecular pathways within normal and malignant cells have led to targeted agents that exploit these differences. Targeted therapies offer the potential for improved long-term disease control with less toxicity. Many of these novel agents are currently

being evaluated in clinical trials. Thus, an overview of noncytotoxic drug development is critical for understanding future medical treatment of gynecologic cancer.

### ■ Antiangiogenesis Agents

Angiogenesis is a normal physiologic process that forms new blood vessels and remodels vasculature for oxygen and nutrient transport to tissues. This process is usually transient and tightly regulated by various pro- and antiangiogenic factors. However, the homeostatic balance is dysregulated in malignancy. In cancers, sustained angiogenesis leads to tumor growth and metastasis and provides access to systemic lymphatic and circulatory systems. Thus, targeted inhibition of angiogenesis is an appealing therapeutic approach.

The binding of vascular endothelial growth factor (VEGF) to the VEGF receptor is a vital first step in stimulating normal angiogenesis. Many malignancies, such as ovarian cancer, are characterized by increased levels of VEGF or other proangiogenic factors. Several novel agents interfere with this process to halt tumor growth.

#### Bevacizumab

This agent is a monoclonal antibody that binds to VEGF to prevent VEGF interaction with its receptor (Fig. 27-6A). Currently, bevacizumab (Avastin) is FDA-approved for persistent, recurrent, or metastatic cervical cancer, as well as relapsed platinum-resistant epithelial ovarian cancer (Pujade-Lauraine, 2014; Tewari, 2014). Its usual dosage is 15 mg/kg given IV every 3 weeks with or without cytotoxic chemotherapy. In most cases, toxicity with bevacizumab is minimal. However, GI perforation may occur in up to 10 percent of patients (Cannistra, 2007). This complication is more likely in women with preexisting inflammatory bowel disease or in those with bowel resection at their primary surgery for advanced ovarian cancer (Burger, 2014). Elevated blood pressure is common and may lead to hypertensive crisis. Other possible toxicities include incomplete wound healing, weakness, pain, nosebleed, and proteinuria.

#### VEGF Trap

VEGF-A is the main isoform of VEGF. It can be bound by bevacizumab, as just described, or by a recombinant “fusion protein” named VEGF Trap (afibercept). VEGF Trap is constructed by fusing two specific portions of the VEGF receptor and the “Fc” constant region of the IgG molecule. The receptor portions provide high-affinity binding of VEGF (Fig. 27-6B). Clinical experience in gynecologic cancers is preliminary. Early reports suggest a risk of GI perforation similar to that for bevacizumab (Coleman, 2012; Gotlieb, 2012; Mackay, 2012; Tew, 2014).

#### Sunitinib

Receptor tyrosine kinases (RTKs) are proteins that span the plasma membrane of cells and act as receptors (Fig. 27-7C). If

**FIGURE 27-6** Mechanisms of action for three antiangiogenesis agents. **A.** Bevacizumab is a monoclonal antibody that binds vascular endothelial growth factor (VEGF). Binding prevents VEGF from combining with its endothelial-bound receptor, which is a receptor tyrosine kinase. **B.** VEGF Trap similarly binds VEGF and prevents receptor binding. **C.** Sunitinib binds with the intracellular ATP-binding sites of receptor tyrosine kinase to inhibit receptor action even though VEGF may be bound. In all three cases, angiogenesis is inhibited, and tumor growth is halted.

two side-by-side receptors bind a ligand, then an active dimer is formed. Ligands for RTKs include cytokines, hormones, and growth factors. The activated dimer then phosphorylates tyrosine residues. Phosphorylation first of the tyrosine kinase itself, and then of other proteins, activates them. By this means, RTKs regulate normal cellular processes but also play a critical role in cancer development and progression.

Sunitinib (Sutent) is an oral agent that inhibits several RTKs, including those that bind proangiogenic growth factors, such as VEGF and platelet-derived growth factor. For gynecologic cancers, the clinical efficacy of a 50 mg daily dose is currently under investigation (Baumann, 2012; Hensley, 2009).

#### Cediranib

Another RTK inhibitor of VEGF, cediranib (Recentin), has demonstrated significant clinical activity in relapsed ovarian cancer. With an oral daily dose of 30 mg, a 17-percent response

**FIGURE 27-7** For DNA breaks, BRCA repairs both strands and the cell survives. With BRCA mutations and absent BRCA function, only PARP is available for DNA repair to permit cell survival. If a PARP inhibitor is administered, then DNA breaks are not repaired, and the tumor cell dies.

rate was reported when used as a single agent (Matulonis, 2009). Even more promising results have been recently observed when combined with olaparib, a poly(ADP) ribose polymerase inhibitor (Liu, 2014).

### ■ Mammalian Target of Rapamycin Inhibitors

The *mammalian target of rapamycin (mTOR)* is a protein kinase that regulates membrane trafficking, transcription, translation, and cell cytoskeleton maintenance. mTOR has downstream effects that include increased VEGF production. Thus, efforts to inhibit mTOR signaling also can lead to angiogenesis inhibition. Rapamycin inhibits mTOR, and analogues of this drug, such as temsirolimus (CCI-779) and everolimus (RAD001), are currently being studied for gynecologic cancer treatment (Alvarez, 2013; Fleming, 2014; Slomovitz, 2010).

### ■ poly(ADP) Ribose polymerase Inhibitors

Another promising group of targeted therapies, poly(ADP) ribose polymerase (PARP) inhibitors, exploit the differences in DNA damage repair between normal and malignant cells. During the cell cycle, DNA is routinely damaged thousands of times. The BRCA protein repairs double-strand breaks, and PARP repairs single-strand breaks. In the functioning cell, if BRCA does not repair the break, PARP will (Fig. 27-7).

Five to 10 percent of ovarian cancer patients have a germline *BRCA1* or *BRCA2* gene mutation, which predisposes them to loss of homologous DNA repair. Normal cells do not replicate their DNA as often as cancer cells, and without mutated *BRCA1* or *BRCA2*, still have functional homologous repair. This allows them to survive PARP inhibition. Thus, only tumor cells with BRCA defects are almost entirely dependent on PARP repair. If PARP repair is prevented, damaged cancer cell DNA cannot be repaired and cells die. In contrast, normal cells are unaffected. Several PARP inhibitors are currently in development to take advantage of this unique tumor cell vulnerability.

#### Olaparib (AZD2281)

This PARP inhibitor is now FDA-approved for *BRCA1* and *BRCA2* mutation carriers with relapsed ovarian cancer that has demonstrated resistance to platinum drugs (Kaufman, 2015). It also has clinical activity in patients without mutations (Ledermann, 2014). As a single agent, the usual oral dose is 400 mg twice daily. The most frequent side effects are fatigue, nausea, and vomiting (Kaufman, 2015). Further encouraging studies are evaluating standard cytotoxic drugs compared against olaparib plus other targeted agents as maintenance therapy (Liu, 2014).

## SIDE EFFECTS

Chemotherapy regimens, especially those including cytotoxic drugs, are universally toxic and display a narrow margin of safety. The Cancer Therapy Evaluation Program (CTEP) of the National Cancer Institute (NCI) has developed a detailed and comprehensive set of guidelines for the description and grading of toxicity.

Termed the Common Terminology Criteria for Adverse Events (CTCAE), the most recent revision is version 4.0 and is available at: <http://evs.nci.nih.gov/ftp1/CTCAE/About.html>.

In general, treatment modifications depend on the degree (grade) and duration of toxicity experienced during the preceding therapy course. Doses are reduced if a woman experiences a severe reaction but then may be subsequently increased if tolerance improves. However, treatment is not resumed until toxicity has resolved to baseline or “Grade 1” levels and may be delayed on a week-to-week basis to permit recovery. Dose modification and supportive care are implemented to prevent delays of greater than 2 weeks, which would otherwise compromise therapeutic efficacy. Serious myelosuppression can be partially corrected with the use of hematopoietic growth factors (p. 606). Many of the common toxicities can be prevented with proper use of premedications or alleviated with supportive measures.

### ■ Bone Marrow Toxicity

Myelosuppression, especially neutropenia, is the most common dose-limiting side effect of cytotoxic drugs. The absolute neutrophil count (ANC) is the critical measure when determining patient infection risk and may reflect mild ( $1000\text{--}1500/\text{mm}^3$ ), moderate ( $500\text{--}1000/\text{mm}^3$ ), or severe ( $< 500/\text{mm}^3$ ) neutropenia. Frequently, patients receiving therapy will have a nadir (lowest measurement) into the neutropenic range that will recover before the next scheduled course of treatment. However, if they are admitted to the hospital for fever or other condition, neutropenic precautions should be observed. Although guidelines vary, precautions include assiduous provider hand washing; provider outer gowns, gloves, and masks; and patient isolation from potential infection carriers.

Moderate degrees of anemia often develop in cancer patients receiving chemotherapy and may contribute to chronic fatigue. Frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. Synthetic erythropoietin is infrequently indicated (p. 606).

Thrombocytopenia is less common but may predispose the patient to serious bleeding if the platelet count drops below  $10,000/\text{mm}^3$ . No predetermined platelet value should prompt routine transfusion, but ongoing bleeding in affected patients is a warranted indication.

### ■ Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. Typically, the emetogenic potential of a particular drug or regimen will dictate the antiemetic regimen used (Tables 27-9 and 27-10). Mild nausea and vomiting can often be managed effectively by prochlorperazine (Compazine) with or without dexamethasone (Table 42-7, p. 914). If drugs with more severe emetogenic effects such as cisplatin are administered, then ondansetron, granisetron, or palonosetron, which are 5-hydroxytryptamine antagonists, can be given IV before chemotherapy. Ondansetron (Zofran) and granisetron (Kytril) can also be provided orally to manage delayed and/or chronic nausea after chemotherapy. However, these drugs can induce significant constipation as a side effect.

**TABLE 27-9.** Emetic Risk of Intravenously Administered Antineoplastic Agents Used in Gynecologic Oncology

Emetic Risk	Incidence of Emesis (without antiemetics)	Agent
High	> 90%	Cisplatin Cyclophosphamide $\geq 1500 \text{ mg/m}^2$ Dactinomycin
Moderate	30–90%	Carboplatin Ifosfamide Cyclophosphamide $< 1500 \text{ mg/m}^2$ Doxorubicin
Low	10–30%	Paclitaxel Docetaxel Topotecan Etoposide Methotrexate Gemcitabine
Minimal	< 10%	Bevacizumab Bleomycin Vinblastine Vincristine Vinorelbine

Data from Hesketh, 2008; Kris, 2006; Roila, 2006.

Chemotherapy-related diarrhea, oral mucositis, esophagitis, and gastroenteritis are treated with supportive care.

■ **Dermatologic Toxicity**

Most drugs can cause a toxicity spectrum to the skin or subcutaneous tissues that includes hyperpigmentation, photosensitivity, nail abnormalities, rashes, urticaria, erythema, and alopecia. Many of these are drug specific and self-limited, but occasionally, they may be dose limiting. As discussed earlier, palmar-

plantar erythrodysesthesia is a known toxicity of liposomal doxorubicin (p. 600). In addition, changes in skin pigmentation are seen with bleomycin, whereas nail discoloration and onycholysis have been associated with docetaxel therapy. Mild urticarial reactions are prevented or alleviated by premedication with diphenhydramine hydrochloride, 50 mg IV or orally.

One of the most emotionally distressing side effects of many chemotherapeutic agents is scalp alopecia. Fortunately, this is usually reversible. With some drugs such as paclitaxel, women will also experience loss of eyelashes, eyebrows, and other body hair. In general, techniques to minimize alopecia are unsuccessful. Instead, women are counseled regarding cosmetic options such as false eyelashes and wigs.

■ **Neurotoxicity**

Peripheral neuropathy develops commonly with cisplatin, paclitaxel, and the vinca alkaloids. Cisplatin-induced neurotoxicity usually resolves slowly, due to axonal demyelination and loss. T is toxicity is related to cumulative dose and intensity. To counter this toxicity, amifostine (Ethyol) may be administered, but substitution of carboplatin will avoid much of the toxicity. Gabapentin (Neurontin) is the usual treatment for neuropathic pain, starting at a dosage of 300 mg daily. Other options to treat symptomatic peripheral neuropathy that have shown some efficacy include oral glutamine (up to 15 g twice daily) or oral vitamin B<sub>6</sub> (up to 50 mg three times daily).

With chemotherapeutic agents in general, drug dosing may need to be adjusted if peripheral neuropathy becomes problematic—for example, if a patient can no longer hold a cup of coffee. More dramatic instances of acute cerebellar syndromes, cranial nerve palsies or paralysis, and occasionally acute and chronic encephalopathies are managed with supportive care and usually with discontinuation of the offending agent.

**GROWTH FACTORS**

■ **Synthetic Erythropoietins**

In some clinical situations, incorporation of hematopoietic drug factors to prompt red blood cell (RBC) or granulocyte

**TABLE 27-10.** Drug Regimens for the Prevention of Chemotherapy-Induced Emesis by Emetic Risk Category

Emetic Risk Category (Incidence of Emesis without Antiemetics)	Antiemetic Regimens and Schedules
High (> 90%)	5-HT <sub>3</sub> serotonin receptor antagonist: day 1 Dexamethasone: days 1–3 Granisetron: days 1–3
Moderate (30% to 90%)	5-HT <sub>3</sub> serotonin receptor antagonist: day 1 Dexamethasone: days 1–3
Low (10% to 30%)	5-HT <sub>3</sub> serotonin receptor antagonist: day 1 Dexamethasone: days 1–3
Minimal (< 10%)	Prescribe as needed

5-HT<sub>3</sub> = 5-Hydroxytryptamine-3; see table 27-8.

Data from Kris MG, Hesketh PJ, Somerfield MR, et al: American Society of Clinical Oncology guideline for antiemetics in oncology: update 2006. J Clin Oncol 2006 Jun 20;24(18):2932–2947.

production may have merit. Of these, epoetin alfa and darbepoetin alfa are synthetic erythropoietins that have the same biologic effects as endogenous erythropoietin to stimulate RBC production. These agents are recommended for patients with chemotherapy-associated anemia who have a hemoglobin concentration that is approaching, or has fallen below, 10 g/dL. However, when used at higher hemoglobin levels, they may actually be associated with tumor progression and shorten survival (Rizzo, 2008). Moreover, several large studies have shown that despite reducing the need for RBC transfusions, erythropoiesis stimulating agents (ESAs) increase the risk for thromboembolic events and death in cancer patients treated with epoetin alfa (Aapro, 2012; Tonia, 2012). As a result, the FDA has issued a “black-box” warning to state that a higher mortality rate and/or shortened time to tumor progression were found when ESAs were dosed with the intent to achieve hemoglobin values  $\geq 12$  g/dL compared with placebo or observational controls. Once routinely used, these agents are now infrequently administered to gynecologic cancer patients due to safety concerns.

When used, epoetin alfa (Procrit, Eprex, and Epogen) is usually prescribed as 40,000 units SC, given weekly (Case, 2006). Beyond local pain at the injection site, this agent has minimal side effects. Possible toxicity may include diarrhea, nausea, or hypertension (Bohlius, 2006; Khuri, 2007). For darbepoetin alfa (Aranesp), the usual SC dose is 200  $\mu$ g every other week or 500  $\mu$ g given every 3 weeks. Darbepoetin alfa has minimal side effects beyond local pain at the injection site.

### ■ Granulocyte Colony-Stimulating Factors

Filgrastim and pegfilgrastim are human granulocyte colony-stimulating factors (G-CSF) produced by recombinant DNA technology. As such, these cytokines bind to hematopoietic cells and activate proliferation, differentiation, and activation of granulocyte progenitor cells. These growth factors are mainly used to prevent episodes of febrile neutropenia ( $ANC < 1500$ ), particularly in patients with a greater than 20-percent risk for such an event. Fortunately, none of the common regimens used in the treatment of gynecologic cancer have a risk that exceeds 20-percent, and thus growth factors are typically not required for initial prophylaxis. Instead, growth factors are usually indicated to permit a patient to maintain her treatment schedule.

*Filgrastim* (Neupogen) is given SC, and the usual SC dose is 5  $\mu$ g/kg/d. However, patients typically are given either 300  $\mu$ g or 480  $\mu$ g, which is the content of manufactured vials. It should be administered at least 24 hours after chemotherapy completion. Therapy is terminated when the white blood count (WBC) exceeds 10,000/mm<sup>3</sup> or when the absolute neutrophil count exceeds 1000/mm<sup>3</sup> for 3 consecutive days. Toxicity with filgrastim is limited, and transient bone pain is usually mild to moderate.

*Pegfilgrastim* (Neulasta) acts similarly to filgrastim to stimulate production of granulocyte progenitor cells within the bone marrow. The “peg” in pegfilgrastim refers to a polyethylene glycol unit that prolongs the time it remains in the body. Pegfilgrastim is given as a single 6-mg SC injection once per chemotherapy cycle. This is usually far more convenient than daily filgrastim doses. It should not be administered during

the 14 days before and within 24 hours after administration of cytotoxic chemotherapy. Transient bone pain is usually mild to moderate, but often more pronounced than with filgrastim.

## CHEMOSENSITIVITY AND RESISTANCE ASSAYS

Routinely, the selection of specific chemotherapeutic agents is based on clinical literature describing outcomes for a specific gynecologic cancer. In contrast to this empiric approach, chemotherapy sensitivity and resistance assays are theoretically appealing due to the possibility of tailoring treatment. Using this strategy, viable tumor tissue is collected from the patient during surgery or other intervention (e.g., paracentesis). The sample is shipped to a specialized laboratory. Here, in vitro analysis determines whether tumor growth is inhibited by a drug or panel of drugs.

The potential of selecting effective cancer treatments while sparing unnecessary ones is intriguing, and patients may even request testing. However, no current assay has demonstrated sufficient efficacy to support its use. Thus, these assays are not recommended for individual patients outside of a clinical trial (Burstein, 2011).

## CANCER DRUG DEVELOPMENT

The only proven way to improve cancer treatment success rates is to test new agents, higher doses, novel combinations of drugs, or unique ways of administering treatment. Since gynecologic cancers are relatively uncommon, most landmark Phase III studies are conducted within large collaborative groups such as the NRG Oncology Group. Promising drugs are first identified by demonstrating success in cancer cell lines or in animals inoculated with tumor. After preclinical steps are completed, novel agents proceed through four phases of clinical testing.

Phase I trials use a dose-escalating design to determine the dose-limiting toxicity, maximum tolerated dose (MTD), and pharmacokinetic parameters of the drug. Groups of three to six patients with varied tumor types are enrolled and receive escalating dose levels. The MTD is determined as the dose below which two patients experience dose-limiting toxicity. In a Phase I trial, detecting a tumor response is not critical, since enrolled patients have typically completed extensive prior therapy. However, observed responses would encourage further disease-specific Phase II trials.

After the recommended dose and treatment schedule have been defined in a Phase I trial, the regimen can proceed to Phase II. The primary goal of this trial type is to define the actual response rate in patients with a specific cancer type. Usually a measure of disease (MOD) is required to allow accurate determination of a complete response, partial response, stable disease, or progression. Typically, patients enrolled in Phase II trials have received only one prior chemotherapy regimen. This allows for a reasonable chance of response compared with subjects in Phase I studies. Secondary end points of Phase II trials include determination of the “progression-free interval,” cumulative incidence of dose-limiting toxicity over multiple cycles, and overall survival rates.

Phase III randomized trials are designed to directly compare the drug with existing standard regimens in a particular stage and type of cancer. Phase III trials generally require a minimum of 150 patients per “arm” to provide adequate statistical precision. Finally, Phase IV clinical trials evaluate drugs that are already FDA approved. The goal of Phase IV trials is to study long-term drug safety and efficacy.

The emergence of biologic and targeted therapies has necessitated a reanalysis of this traditional paradigm of cancer drug development. For example, antiangiogenic agents and PARP inhibitors do not have dose-dependent toxicities to establish a MTD. Additionally, instead of measuring tumor shrinkage as an indicator of response for these cytostatic agents, new endpoints are being developed and validated (e.g., 6-month progression-free survival). Novel clinical trial designs will be a vital part of future drug development (Herzog, 2014a).

In general, patients are strongly encouraged to participate in appropriate Phase I, II, and III clinical trials. Doing so expands their options for treatment. In addition, the results of such studies are the primary method to improve the outcomes of women diagnosed with gynecologic cancer in the future. However, fewer than 5 percent of cancer patients currently enroll in a clinical trial.

To effectively incorporate radiation treatment into cancer care, clinicians must understand the fundamental concepts and vocabulary used in radiation oncology. Clinically, radiation therapy, often combined with chemotherapy, can be used as primary treatment for many gynecologic malignancies (Table 28-1). Additionally, radiation therapy may be recommended postoperatively if the probability of tumor recurrence is high. Radiation therapy is also used frequently in the relief of symptoms caused by metastasis of any gynecologic cancer.

RADIATION PHYSICS

Radiation therapy is the focused delivery of energy in tissue to accomplish controlled biologic damage. Radiation used in this therapy can occur as electromagnetic waves or particles.

■ Electromagnetic Radiation

Photons (x-rays) and gamma rays are the two types of electromagnetic radiation used for radiation therapy. Photons, used in external beam therapy, are produced when a stream of electrons collides with a high atomic number target (tungsten) located in the head of a linear accelerator (Fig. 28-1). In contrast, gamma rays originate from unstable atom nuclei and are emitted during decay of radioactive materials, also termed radionuclides, which are widely used in brachytherapy.

■ Particle Radiation

Whereas electromagnetic waves are defined by their wavelengths, particles are defined by their masses. For clinical use, particles include electrons, neutrons, protons, helium ions, heavy charged ions, and pi mesons. Except for electrons, which are available in all modern radiation oncology centers, and protons, other particles have limited clinical use. Proton facility numbers are expanding, with 14 facilities operating in the United States and 10 additional centers under construction.

Particles are produced by linear accelerators or other high-energy generators and are usually delivered by external beam. Of clinically used particles, electrons are negatively charged and deposit most of their energy near the surface. In contrast, heavy charged particles, such as protons, deposit most of their energy in the absorbing tissues as their velocity decreases, that is, near the end of the particle path (the Bragg peak effect). Because of this, a major advantage of proton therapy is the lack of an exiting dose through normal tissues. Proton therapy use for gynecologic malignancies is primarily investigational. But as an example, proton therapy can treat affected deep pelvic and paraaortic lymph nodes, while sparing unnecessary dosing and injury to anterolateral organs, such as the bowel and kidneys (Fig. 28-2).

■ Radiation Sources

Radionuclides

Also called radioisotopes, radionuclides undergo nuclear decay and can emit: (1) positively charged alpha particles, (2) negatively charged beta particles (electrons), and (3) gamma rays. Radionuclides commercially available are shown in Table 28-2. Cesium and iridium are commonly used in gynecologic brachytherapy.

Linear Accelerator

One of the main types of radiation-producing units is the linear accelerator, also called a linac. A linac can produce both photon and electron beams (see Fig. 28-1). In the photon-therapy mode, indicated for deep-seated tumors, the accelerated electron beam is guided to hit a metal target to produce photons. The unit used to describe the energy of a photon beam is MV (million volts). In the electron-therapy mode, indicated for superficial lesions, the electron beam strikes a lead scattering foil instead of the metal target. The unit for electron beam energy is expressed in MeV (million electron volts). Figure 28-3 displays a linac with three moveable components: gantry, treatment head, and couch. These components can all rotate 360 degrees, which allows multiple fields and angles to achieve optimal dose delivery to a tumor.

**TABLE 28-1.** Role of Radiation Therapy in the Management of Gynecologic Cancers

Intent	Site
Curative	Cervix, vulva, vagina, uterus
Adjunctive to surgery	Cervix, vulva, vagina, uterus
Palliative	Metastasis causing symptoms: bleeding, pain, obstruction

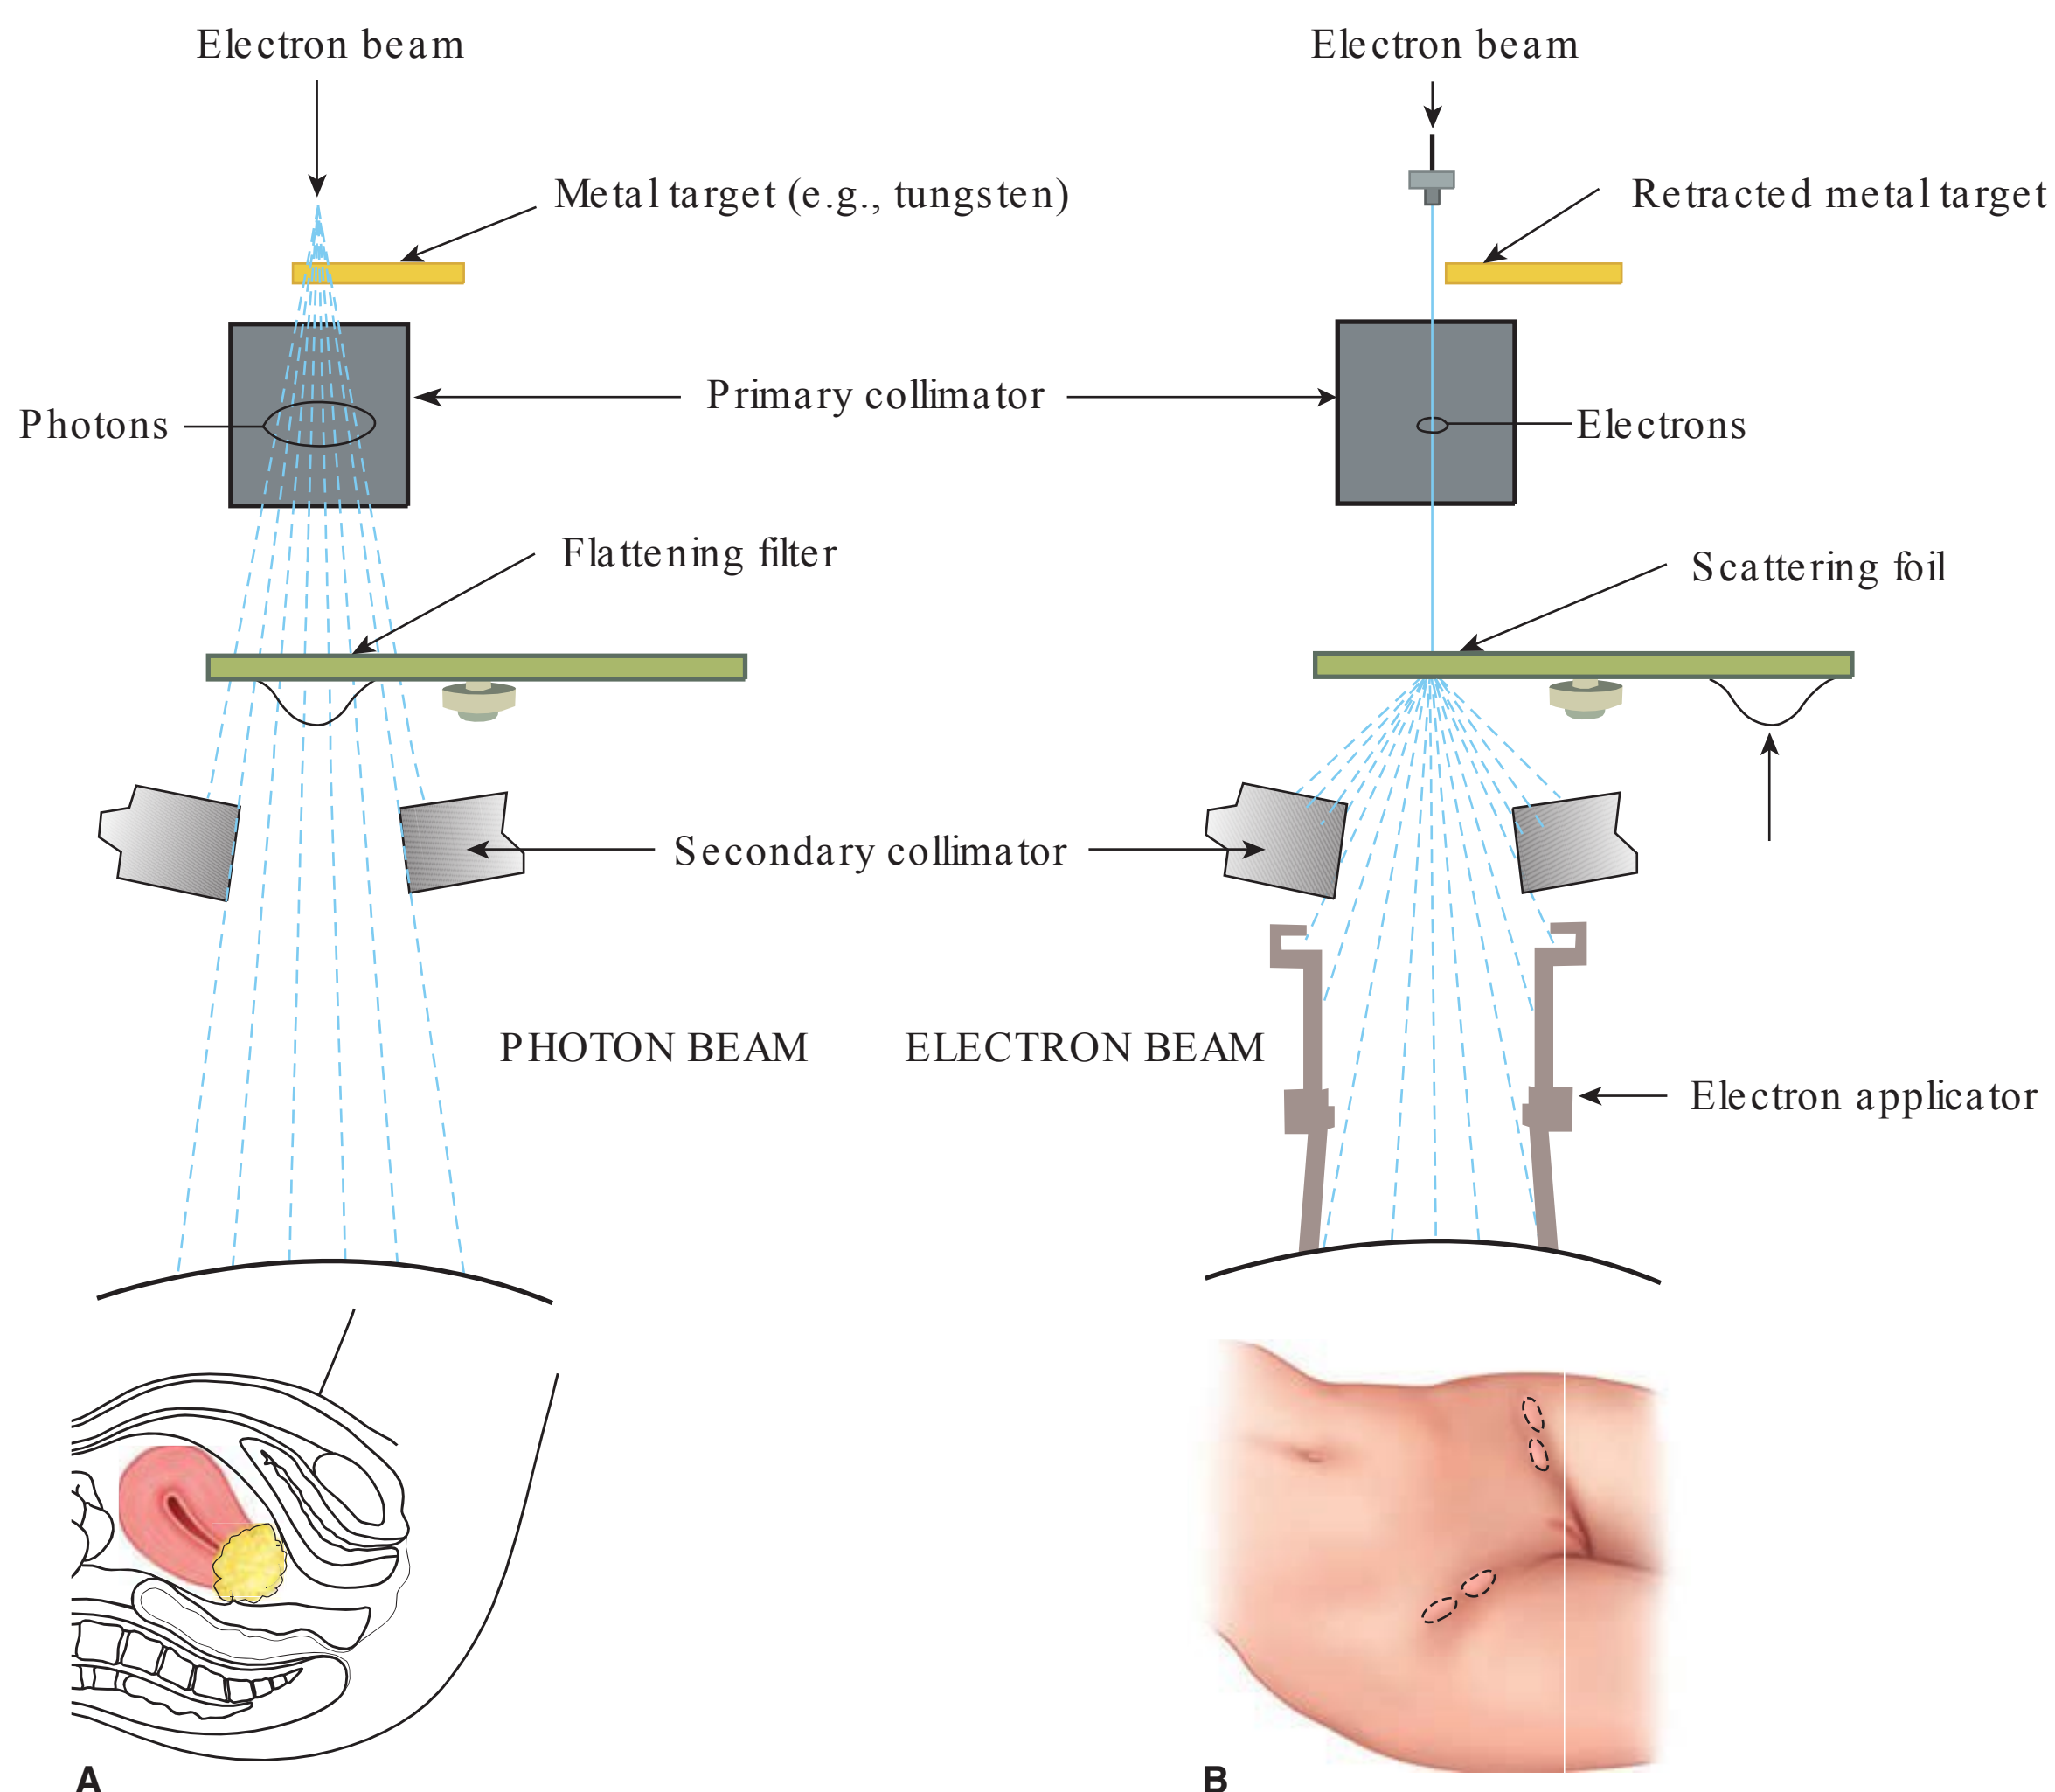

### ■ Electromagnetic Radiation Energy Deposition

When electromagnetic radiation is used in daily clinical practice, it contacts target tissues, and energy is transferred to those tissues. This transfer creates ions by dislodging electrons from atoms within these tissues. These electrons then collide with surrounding molecules to initiate radiation damage.

There are three mechanisms involved in energy transfer: (1) photoelectric effect, (2) Compton effect, and (3) pair production

**FIGURE 28-2** Proton dose distribution in a patient with cervical cancer receiving treatment to the paraaortic lymph nodes. The proton beam originates posteriorly and is directed anteriorly. The red arrow shows the target volume (dark magenta outline). The area anterior to this is bowel (orange outline), which is significantly spared from radiation.

**FIGURE 28-1** Block diagram of a linear accelerator used to create external beam radiation. Either photon beams or electron beams may be produced. **A.** Photon beam therapy is suited for deep tumors such as the cervical cancer shown here. Beam energy is measured in million volts (MV). **B.** Electron beam therapy is indicated for superficial lesions such as inguinal lymph nodes. Beam energy is measured in million electron volts (MeV).

**TABLE 28-2.** Physical Properties and Clinical Use of Selected Radionuclides

Element	Radiation Energy (MeV)	Half-Life	Clinical Use
Cesium-137	0.6	30 years	Brachytherapy
Iridium-192	0.4	74 days	Brachytherapy
Cobalt-60	1.2	5 years	Brachytherapy
Iodine-125	0.028	60 days	Brachytherapy
Phosphorus-32	1.7	14 days	Intraperitoneal instillation
Gold-196	0.4	2.7 days	Intraperitoneal instillation
Strontium-89	1.4	51 days	Diffuse bone metastasis

MeV= million electron volts.

(Fig. 28-4). Depending on the energy level of the incident radiation, one of these mechanisms will predominate. The *photoelectric effect* is dominant if the incident energy is low (less than 100 kV). The *Compton effect* dominates in mid- to high energy ranges (1 MV to 20 MV) and is the most important in clinical radiation therapy. Last, *pair production* occurs when a photon beam with very high energy (beyond 20 MV) strikes the electromagnetic field of the nucleus.

■ **Depth-dose Curve**

Controlled biologic damage is accomplished by greater selective radiation dose distribution within malignant tissue than within the surrounding, “innocent bystander” normal tissues. This is achieved by using radiation beams with differing physical properties to define the spatial distribution of an absorbed dose when these beams strike tissue. Ideally, an absorbed radiation dose is as conformal as possible. Perfect conformality is achieved when the targeted malignant tissue absorbs 100 percent of the prescribed dose and the adjacent normal tissues absorb 0 percent.

**FIGURE 28-3** Linear accelerator currently in use at the University of Texas Southwestern Medical Center. The patient lies on the treatment couch (C). The gantry (G), couch, and head (H) can all rotate and allow radiation beams to reach target tissues through different angles. S= stand.

In practice, this cannot be obtained. However, both acute radiation side effects and the potential for late, delayed radiation complications can be minimized as the spatial radiation dose distribution approaches this ideal.

A *depth-dose curve* specifically illustrates the dose distribution of a given radiation beam as it penetrates tissues. Radiation oncologists rely on these curves when choosing a radiation beam with an appropriate energy to reach a given tumor. With electron beam therapy, the maximum dose lies close to the surface, and therefore, electron beam therapy is indicated for targets that are close to the skin surface, such as metastatic cancer to the inguinal lymph nodes. With high-energy photons, the maximum dose is deposited well below the surface. Beyond this point, the dose gradually tapers as energy is absorbed by the deep surrounding tissues. This explains the so called *skin-sparing effect* of high-energy photons. A patient with a pelvic malignancy is usually treated with at least 6-MV photon beams.

**Dosimetry**

This is the discipline of calculating the radiation dose absorbed by the patient. Dosimetric calculations are based on the depth-dose measurements of the radiation beams used to treat an actual patient. The dose distribution is usually displayed as a colorful map overlaid on the radiologic images of the patient (p. 616). These calculations *predict* the absorbed dose in a given situation.

■ **Radiation Unit**

Quantification of the absorbed radiation dose is essential as it correlates with the biologic effect of radiation. The current Standard International unit for absorbed dose is gray (Gy). One Gy equals 100 rad or 1 joule/kg. Clinically, the radiation doses for curative and palliative treatment are 70 to 85 Gy and 30 to 40 Gy, respectively.

**RADIATION BIOLOGY**

■ **DNA Molecule as Target of Radiation Therapy’s Biologic Effect**

The DNA molecule is the target for the biologic effect of radiation on mammalian cells. DNA injuries involve its strands, bases, and cross-links, but the hallmark damage is breaking of single- and

**FIGURE 28-4** When electromagnetic radiation impacts target tissues, energy is transferred to those tissues. The three mechanisms involved in this energy transfer are the photoelectric effect, Compton effect, and pair production. Both photoelectric effect (A) and Compton effect (B) result in creation of fast electrons, which then initiate the biologic process of radiation damage. **A.** With photoelectric effect, radiation interacts with an inner orbital electron. **B.** With Compton effect, interaction occurs with an outer orbital electron. **C.** During pair production, impact of radiation on the atom's nuclear forces produces a positron-electron pair. When a positron later combines with a free electron in these tissues, two photons are created, which can then lead to radiation damage.

most importantly double-stranded DNA. Double-strand breaks lead to DNA fragmentation when two or more breaks are formed and when cells attempt to repair these strand breaks. The DNA pieces may rejoin incorrectly, leading to gene translocation, mutation, or amplification and, ultimately, cell death.

### ■ Direct versus Indirect Actions of Ionizing Radiation

Radiation can interact *directly* or *indirectly* with the atoms in the DNA molecule. Direct actions create ions that then initiate the biologic damage process. The *direct* effect is predominant with high linear energy transfer (LET) particles such as protons, fast neutrons, and heavy ions (Fig. 28-5). However, most DNA damage is caused indirectly, which is the predominant effect with low-LET particles such as photons. Indirect DNA damage occurs through an important chemical intermediate, the hydroxyl radical ( $\text{OH}\cdot$ ), which is highly reactive because of its unpaired electron.

### ■ Cell Death

The two main cell death pathways after radiation are *apoptosis* and *mitotic catastrophe*. Mitotic catastrophe is thought to be the most common mechanism of cell death after radiation exposure. With this, cells with damaged DNA enter mitosis prematurely, before DNA can be repaired, and die attempting to complete the next two to three mitotic cycles. Apoptosis, or programmed cell death, occurs after an intracellular stress, such as radiation-induced irreparable double-strand breaks. A series of events develop rapidly within hours, leading to cell membrane blebbing, apoptotic body formation in the cytoplasm, chromatin condensation, nuclear fragmentation, and DNA laddering (Okada, 2004).

### ■ Four R's of Radiation Biology: Repair, Reassortment, Repopulation, Reoxygenation

In classic radiation biology, there are four mechanisms by which cells respond to radiation. Cellular *repair* can be described by sublethal damage repair (SLDR) and potentially lethal damage repair (PLDR). SLDR occurs when a radiation dose is split into two or more fractions and a few hours separate the fractions. Cells have time to repair their damage, and their survival rate increases. The last process seen in SLDR is *repopulation*, which is the tissue's response to replenish the cell pool (Trott, 1999).

Following the initial repair of sublethal damage, *reassortment* begins. Within a tumor, proliferating cells are in different

**FIGURE 28-5** Direct and indirect actions of radiation. **A.** Fast electrons may directly strike DNA to create damage. **B.** Alternatively, a fast electron may interact with water to create a hydroxyl radical, which subsequently interacts with DNA to cause injury.

phases of the cell cycle (Fig. 27-1, p. 593). Cells in mitosis (M) and G<sub>2</sub> are most sensitive to radiation. Conversely, cells in G<sub>1</sub> and S (DNA synthesis) phases are less sensitive (Pawlik, 2004). When exposed to radiation, those cells that are in the G<sub>2</sub>/M phase are killed. During reassortment, surviving cell populations restart their progression through the mitotic cycle.

The fourth “R” of radiation biology theory is *reoxygenation*. A tumor cell population is composed of oxygenated and hypoxic components. Cells located within 100 microns of blood capillaries are oxygenated, and beyond 100 microns, cells are hypoxic. After radiation, the oxygenated cells are killed by chemical intermediates described earlier. Following cell death, the tumor shrinks and allows hypoxic cells to be positioned within the oxygen diffusion range of blood capillaries and become oxygenated.

### ■ Linear-quadratic Theory and the Alpha/Beta Ratio

For low-LET radiation, the linear-quadratic curve has been adopted to explain the relationship between the fraction of cells surviving a given dose of radiation (Fig. 28-6). The initial linear (alpha) portion of the curve shows that the probability of cell death is proportional to the radiation dose. In the higher-dose region, the curved quadratic (beta) portion indicates that the probability of cell death is proportional to the *square* of the dose.

The alpha/beta ratio reflects the response of normal tissues to radiation. *Early-responding tissues* have a high alpha/beta ratio and will manifest reactions to radiation within a few days to weeks after treatment. Examples are tissues with high proliferation rates such as bone marrow, reproductive organs, and gastrointestinal tract mucosa. Preventatively, by administering multiple small radiation dose fractions, there is more sublethal damage repair, and early acute reactions can be decreased.

In contrast, *late-responding tissues* show clinical reactions only weeks to months after completion of a radiation therapy course. Examples are the lung, kidney, spinal cord, and brain. These tissues have a low alpha/beta ratio and are slow to respond. More time is needed to repair sublethal damage, and thus high-dose per fraction radiation therapy can easily lead to severe late complications.

### RADIATION ONCOLOGY PRACTICE

The expertise of the radiation oncologist who is designing and monitoring a course of radiation treatment is paramount. Radiation oncology is as inherently “operator dependent” as surgical oncology. The radiation oncologist carves out, en-bloc, a volume of cancerous tissue, its local extensions, and its

**FIGURE 28-6** Linear quadratic mammalian cell survival curve. The cell survival is plotted on a logarithmic scale. The dose (in Gy) is on a linear scale. The typical cell survival curves with low-LET (linear energy transfer) (blue curve) and with high-LET radiation (red line) are shown. With low-LET x-ray doses, the alpha (linear) portion of the curve is flat and shows that cell survival is proportional to the dose. However, as the dose increases, the beta (quadratic) portion bends, which implies that cell survival is proportional to the dose squared. In contrast, with high-LET radiation, such as neutrons, the survival curve is straight.

regional lymphatics similar to radical surgical resection, while accommodating the patient's comorbidities, general health status, and surrounding normal tissue quality.

As cancer management is frequently multimodal, superior treatment outcomes are highly dependent on clear communication between radiation oncologists and their colleagues in surgical and medical oncology. Optimal integration of diagnostic imaging and histologic evaluation is also vital to planning and implementing potentially curative radiation therapy. As such, early involvement of the radiation oncologist in patient evaluation and counseling enhances the probability of effective and coordinated cancer care.

## ■ Radiation Fractionation Schemes

Parameters that affect the efficacy and safety of a radiation course include the total radiation dose applied, the size of each radiation “fraction” (treatment), the time between treatments (“fractionation schedule”), and the elapsed time to deliver the total prescribed dose.

### Standard Fractionation

Successful eradication of a localized cancer requires that the cancer cells be killed more rapidly and efficiently than surviving cancer cells can proliferate and repopulate. Because of the inevitable exposure of some normal tissues to substantial radiation, there are limits to the total radiation dose that can be prudently administered to a given target volume. In general, delivery of this dose over the shortest feasible elapsed time will maximize efficacy. Accomplishing this objective is limited by the known deleterious consequences of a high dose per fraction on normal tissues. As noted, this can result in delayed radiation injury expressed months or years after therapy completion. For this reason, radiation delivered with curative intent is generally administered in daily treatments (Monday through Friday) of 1.8 Gy to 2.0 Gy. Cumulative doses range from 45 Gy to treat microscopic disease to 70 Gy or more to treat gross disease. This concern for delayed injury is lessened when short courses of radiation are administered with palliative intent, often in dose fractions of 2.5 Gy to 4.0 Gy.

### Altered Fractionation

Regimens involving treatments given more than once a day are reserved for selected cases. In such instances, increased local tumor control and decreased long-term complications may be achieved by manipulating both fraction size and overall treatment time. This manipulation leads to a variety of altered fractionations. Two major strategies have been employed, namely, hyperfractionation and accelerated treatment.

With *hyperfractionation*, the reduction of late damage to normal tissues is sought, and accordingly, a smaller dose per fraction is given. Two or more fractions are administered each day, typically 6 hours apart to provide an interval for normal tissue repair.

*Accelerated* fractionation entails shortening the treatment duration with or without a decrease in total dose to overcome tumor cell repopulation. The usual weekend break is either shortened or eliminated. With accelerated treatment, however, severe acute reactions are frequent.

Altered fractionation has been studied in gynecologic cancers. Radiation Therapy Oncology Group (RTOG) trials 88-05 and 92-10 were Phase II trials that investigated the use of twice-daily radiation and chemoradiation, respectively, in advanced cervical cancer. RTOG 88-05 showed similar local control, survival rates, and toxicity compared with historical controls. However, when chemotherapy and larger-field twice-daily radiation were added, there were unacceptable rates of late Grade 4 toxicity (Grigsby, 2001, 2002).

## ■ Radiation Therapy

### External Beam Radiation Therapy

External beam radiation therapy is indicated when an area to be irradiated is large. For example, the fields needed to treat a locally advanced cervical cancer may cover the whole pelvis and occasionally, the paraaortic lymph nodes.

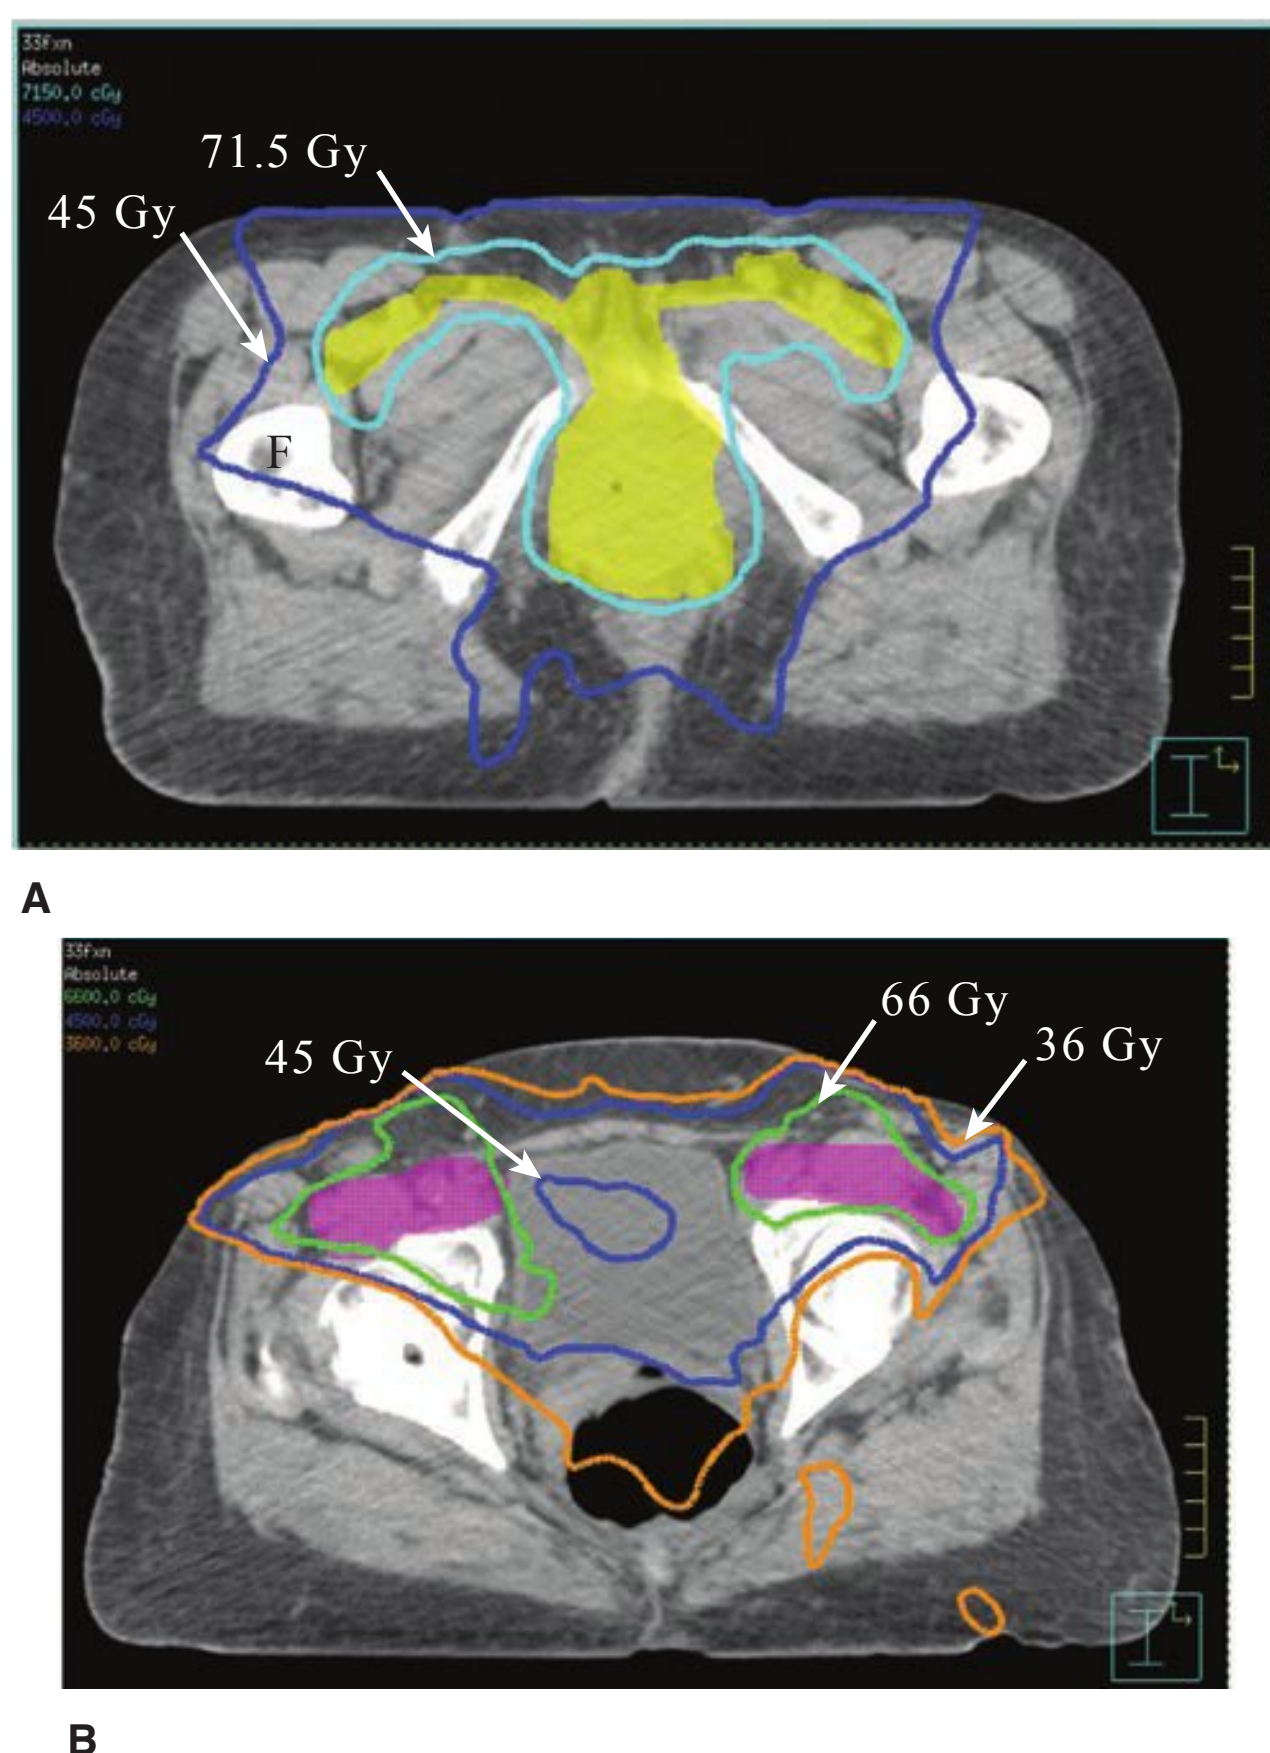

*Conformal radiation therapy* (CRT) describes a radiation treatment technique that maximizes tumor damage while minimizing injury to the surrounding normal tissues. To this goal, the radiation oncologist must know the precise extent of the cancer to be irradiated and its relationship to surrounding normal tissues. This process begins with a review of the patient's cancer imaging including computed tomography (CT), magnetic resonance (MR) imaging, and positron emission tomography (PET). Imaging, along with careful review of the patient's pathology and operative report, assists in defining the 3-dimensional (3-D) target (tumor or regions of potential microscopic tumor spread) and normal tissue volumes.

Next, a simulation is performed in a simulation suite to delineate the anticipated therapy fields prior to an actual treatment session. During this process, patient positioning, immobilization techniques, and treatment fields are defined. If feasible, radiation blocks are also planned to shield normal tissues. The patient is placed in the treatment position, and a CT scan of the area of interest is performed. Later, on each of the computer-based CT scan slices, the radiation oncologist carefully delineates the anatomic areas that will receive a tumoricidal dose. During this, four volumes are defined: (1) a gross tumor volume (GTV), which encompasses any gross disease; (2) a clinical target volume (CTV), which incorporates any areas at risk for microscopic tumor spread; (3) a planning target volume (PTV), which accounts for uncertainties in treatment planning or delivery such as patient motion or daily set-up error; and (4) a volume that defines the normal organs at risk (OAR), which will be exposed, albeit to a lesser radiation dose.

Once simulation is completed, a radiation dosimetrist employs a treatment planning software to develop an optimal plan, called dose optimization. This is often a reiterative process in which the physician and the dosimetrist will arrive at an acceptable option, which means an optimal arrangement of the radiation beams.

One tool that is particularly helpful in the radiation planning and optimization process is the dose volume histogram (DVH). This is a graphic summary of the entire dose distribution to the cancer and normal structures. Thus, the DVH provides information regarding whether the cancer will be adequately treated with a tumoricidal dose and whether surrounding

**FIGURE 28-7** IMRT dose distribution in a patient with stage T4 N2 M0 cancer of the vulva. This technique allows for the delivery of tumoricidal doses to the vulva and inguinal nodes while minimizing that to normal tissues. **A.** The yellow area displays the actual vulvar cancer and inguinal lymph nodes. Doses to the vulva and femoral heads (F) are shown (arrows). The doses to the vulva and femoral heads are 71.5 Gy and 45 Gy, respectively. **B.** Pink shading displays the inguinal nodes. Doses to the inguinal nodes, bladder, and rectum are shown (arrows). The doses to the inguinal nodes, bladder, and rectum were 66 Gy, 45 Gy, and 36 Gy, respectively.

normal structures are minimally affected. In addition to the DVH, dose distributions are displayed as computer-generated radiation dose map images that are overlaid on the CT images (Fig. 28-7). This provides a visual dose-anatomy relationship. These dose distributions are produced for the radiation oncologist to review, adjust, and finally approve. The final chosen plan is reviewed by a radiation physicist who ensures that the physical and technical details can be implemented.

To further improve the conformality of the dose distribution, especially around concave targets, a more advanced 3D-CRT planning system, called *intensity-modulated radiation therapy (IMRT)*, can be used. As a result of this improved conformality, IMRT has the potential to decrease bowel and bladder toxicity during pelvic radiation therapy (Heron, 2003). IMRT modulates the intensity of radiation beams to be used with the help of dedicated computer software. For quality assurance, weekly or sometimes even daily imaging of the treated regions is performed to verify that treatment configurations are correct.

**Stereotactic Body Radiation Therapy.** Over the past decade, a novel external beam radiation therapy technique, *stereotactic body radiation therapy (SBRT)*, has become commonly used in sites such as the lung, liver, and spine. It uses a hypofractionated regimen of five or fewer fractions (10 to 20 Gy per fraction). Using *image-guided radiation therapy (IGRT)*, precise, safe SBRT has become possible through “real-time” approaches to overcome technical factors such as patient or organ motion and tumor size and shape changes during a treatment course.

### Brachytherapy

Brachytherapy means treatment at a short distance. During this therapy, sealed or unsealed radioisotopes are inserted into the cancer or its immediate vicinity. Radiation doses fall sharply with increasing distances from the radioactive source. Thus, brachytherapy is indicated only for small tumor volumes (less than 3 to 4 cm). For this reason, brachytherapy is typically practiced after external beam radiation therapy has decreased a large tumor volume.

Brachytherapy may be intracavitary or interstitial. During *intracavitary brachytherapy*, applicators that hold sealed radioactive sources such as iridium-192 ( $^{192}\text{Ir}$ ) are inserted into a body cavity such as the uterus. Alternatively, *interstitial brachytherapy* requires the placement of catheters or needles directly into the cancer and surrounding tissues.

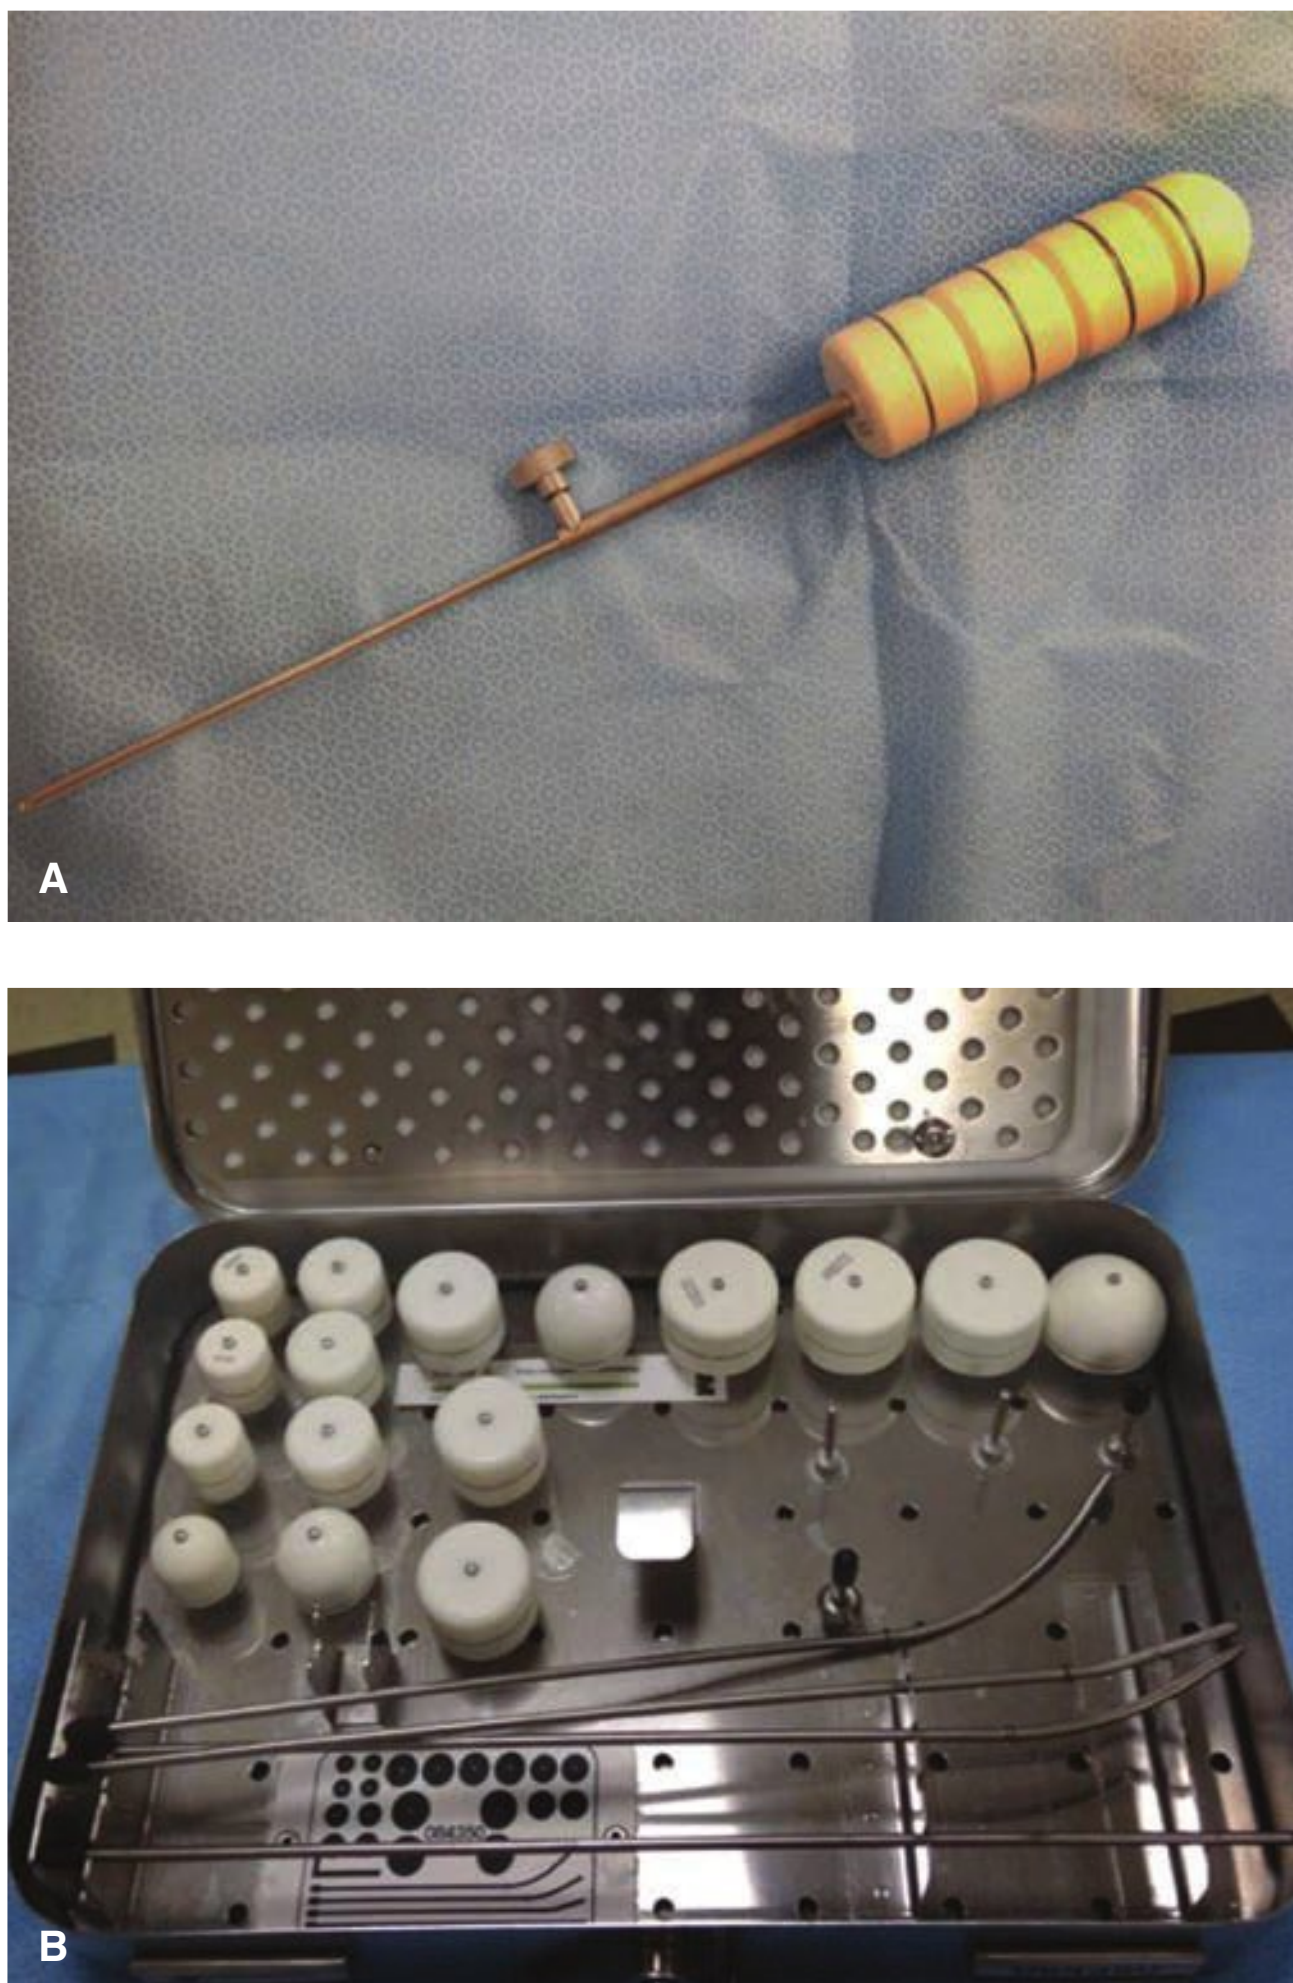

Brachytherapy may be temporary or permanent. In *temporary brachytherapy*, the radioisotopes are removed from the patient after a period of time, ranging from minutes to days. All intracavitary and some interstitial implants are temporary. In *permanent brachytherapy*, the radioisotopes are left permanently to decay within the tissues.

**Equipment.** For routine gynecologic intracavitary implantation, standard equipment includes an applicator, called a *tandem*, which fits into the uterine cavity, and a pair of vaginal applicators, which are known as *ovoids* (Fig. 28-8). The tandem and ovoid device (T&O) is inserted under general anesthesia or conscious sedation. Following placement, radioactive sources can then be loaded into both the tandem and ovoids. In gynecologic oncology, brachytherapy with T&O is indicated for cervical cancer. For uterine cancer, vaginal brachytherapy with a cylinder is used to treat the vaginal apex or length of the

**FIGURE 28-8** Typical tandem and ovoids used for cervical cancer brachytherapy. The long slender portion of the device (tandem) is inserted into the endometrial cavity, and white cylinders (ovoids) are positioned in the proximal vagina. Radioactive sources can be loaded into both the tandem and ovoid reservoirs.

**FIGURE 28-9** Typical cylinder (**A**) used for vaginal brachytherapy after surgery for uterine cancer. The cylinder is placed in the vagina and high-dose-rate brachytherapy is delivered. This treatment decreases the risk of vaginal cuff recurrences. **B**. The cylinder comes in different sizes to allow the most appropriate fit for the patient's anatomy. The largest possible diameter is preferred.

vagina, which is the most common site of disease recurrence after hysterectomy (Fig. 28-9).

For temporary interstitial implantation, flexible plastic catheters or metal needles are surgically placed into the target tissues and held in place by a perineal template. These are then after-loaded with  $^{192}\text{Ir}$  seeds. Templates are suitable for patients with advanced cancers, suboptimal anatomy for T&O application, and selected recurrent cancers.

In addition to T&O, vaginal cylinder, and interstitial needles, physicians may choose to use a tandem and ring, split-ring, or tandem and cylinder. Appropriate brachytherapy applicator selection requires expertise, as applicator choice depends on patient anatomy and a specific device's dose distribution.

**Manual versus Remote Afterloading.** Once the brachytherapy instruments are in place, the radioactive sources are inserted. Historically, the sources were placed manually, however, this method increased hospital staff radiation exposure. Subsequently, a *remote afterloading* approach was developed and is commonly practiced today. This remote control system

delivers a single miniaturized iridium source from a protective safe through connecting cables to the holding devices previously inserted into the patient. Following treatment, the radioactive source is automatically retracted back into the safe.

#### Low Dose-rate versus High Dose-rate Brachytherapy.

Traditionally, low dose-rate (LDR) brachytherapy is delivered over the course of many days and requires patient hospitalization. Over the past few decades, however, high dose-rate (HDR) brachytherapy has become more popular. With this technique, treatment is shortened to minutes. Low dose is defined as dose rates from 0.4 Gy to 2 Gy/hr, and high dose rate as rates higher than 12 Gy/hr. For example, with an intracavitary implant for cervical cancer and an LDR technique, a dose of 30 to 40 Gy is delivered continuously over several days. In contrast, with HDR, an equivalent dose can be delivered in 3 to 5 weekly fractions. The dose per fraction is 5 to 7 Gy and can be given in 10 to 20 minutes. Unlike LDR, HDR avoids lengthy inpatient hospitalization and minimizes patient immobility and thromboembolic events. Furthermore, long-term analysis shows similar local tumor control and late complication rates in patients treated for cervical cancer with both HDR and LDR (Arai, 1991; Hareyama, 2002; Wong, 2003).

#### ■ Tumor Control Probability

With most epithelial cancers, the probability that radiation therapy will control a cancerous mass depends on the tumor's size and intrinsic radiosensitivity and on the radiation dose and delivery schedule. For example, within a given stage, large tumors are more difficult to control with radiation than smaller ones (Bentzen, 1996; Dubben, 1998).

#### Intrinsic Radiosensitivity

It is recognized that a tumor's radiosensitivity in general is determined by its pathologic type (Table 28-3). However, even cancers with a similar histology may have variable responses to radiation. This may be explained by heterogeneity within a given tumor and by the cancer cell's ability to repair radiation damage (Schwartz, 1988, 1996; Weichselbaum, 1992).

#### Treatment Time

When protracted time intervals are required to complete a fractionated radiation therapy course, tumor control probability decreases, especially in rapidly proliferating epithelial cancers. Thus, treatment breaks or delays for any reason are minimized. In a retrospective review of 209 patients with stage I to III cervical cancer treated with radiation therapy, the 5-year pelvic control and overall survival rates were better for those who

**TABLE 28-3.** Radiosensitivity of Some Selected Cancers

Sensitivity	Cancer Type
Highly sensitive	Lymphoma, dysgerminoma, small cell cancer, embryonal cancer
Moderately sensitive	Squamous carcinoma, adenocarcinoma
Poorly sensitive	Osteosarcoma, glioma, melanoma

completed the treatment in less than 55 days (87 percent and 65 percent, respectively) than for those who did so in more than 55 days (72 percent and 54 percent, respectively) (Peterit, 1995).

### Tumor Hypoxia

Tumor hypoxia is a major factor leading to poor local tumor control and poor survival rates in patients with cervical cancer (Brizel, 1999; Nordsmark, 1996). The close relationship between tumor hypoxia, anemia, and angiogenesis was demonstrated in a study involving 87 patients with stage II, III, and IV cervical cancer treated with radiation only. Of these, patients with hemoglobin levels  $< 11$  g/dL and a median tumor oxygen tension  $pO_2 < 15$  mm Hg had decreased 3-year survival rates (Dunst, 2003).

To overcome tumor hypoxia, many strategies have been devised and vary in efficacy. Of these, hyperbaric oxygen used in conjunction with radiation therapy in cervical cancer was not effective in clinical studies (Dische, 1999). An alternate method to increase oxygen delivery to tissues manipulates blood vessel hemodynamics with either inhaled carbogen (95-percent oxygen and 5-percent carbon dioxide) or nicotinamide (a vasoactive agent). This approach of *accelerated radiotherapy with carbogen and nicotinamide (ARCON)* improves tumor control in patients with anemia but is not commonly used (Janssens, 2014).

Another approach to minimize tumor hypoxia effects employs *bio-reductive agents*. This family of hypoxic cell sensitizers selectively kills hypoxic cells. Earlier findings with one of these, tirapazamine (TPZ), was encouraging. However, results of a Gynecologic Oncology Group (GOG) phase III trial that evaluated TPZ, cisplatin, and radiation therapy compared with cisplatin and radiation show no improvement in survival or tumor control rates for patients with cervical cancers (DiSilvestro, 2014).

Last, to ensure adequate oxygen carrying capacity, a hemoglobin level of at least 12 g/dL is desirable in patients receiving radiation therapy. To this goal, transfusion ameliorates tumor hypoxia and increases radiation response. In a study of 204 women with cervical cancer who were treated with radiation, those who were transfused to maintain a hemoglobin level  $> 11$  g/dL had a similar 5-year disease-free survival rate (71 percent) compared with a group of women who never required transfusion. The disease-free survival rate was only 26 percent for those with persistent anemia (Kapp, 2002). The use of erythropoietin to maintain hemoglobin above 12 g/dL was also tested in a randomized trial of patients with cervical cancer receiving chemotherapy and radiation. This trial closed early due to concerns of increased thromboembolic events with the use of erythropoietin (Thomas, 2008).

### ■ Combination of Ionizing Radiation and Chemotherapy

Radiation is often combined with chemotherapy, surgery, or both to increase local disease control and decrease distant metastasis. Radiation therapy and chemotherapy can be administered in a concurrent or alternating fashion to maximize tumoricidal effects and minimize overlapping toxicities and complications (Steel, 1979). This practice is supported by results from many controlled studies involving cervical and other cancers.

In the management of gynecologic cancers, platinum compounds are most commonly used with radiation therapy. Both radiation and cisplatin cause single- and double-strand DNA breaks and base damage. Although most lesions are repaired, if a cisplatin-induced DNA adduct lies close to a radiation-induced single-strand break, then the damage is irreparable and leads to cell death (Amorino, 1999; Begg, 1990). Since the late 1990s, the standard treatment for newly diagnosed locally advanced cervical cancer has been radiation therapy and cisplatin (Keys, 1999; Morris, 1999; Rose, 1999).

Nucleoside analogues such as fludarabine and gemcitabine are also used to enhance the effects of radiation-induced cell killing. These agents inhibit DNA synthesis by blocking cells at the  $G_1/S$  checkpoint. The remaining cell population is synchronized at the  $G_2/M$  junction, the most radiation-sensitive phase of the cell cycle. Clinically, in a Phase III study of cervical cancer patients, the progression-free survival and overall survival rates improved in patients randomized to receive gemcitabine plus cisplatin and radiation followed by adjuvant gemcitabine compared with concurrent cisplatin and radiation alone (Duenãs-González, 2009). However, inclusion of gemcitabine is still considered investigational for cervical cancer treatment.

Taxanes, such as paclitaxel and docetaxel, enhance the effects of radiation by causing microtubule dysfunction and blocking cells at the  $G_2/M$  junction (Mason, 1999). Taxanes have been administered with platinum agents and radiation therapy in small nonrandomized trials involving patients with locally advanced cervical cancer (Lee, 2007).

### ■ Combination of Radiation Therapy and Surgery

Radiation therapy can be given before, after, or at the time of surgery. With this combination, surgical resection and its associated morbidity can often be minimized. For example, the combination of radiation and surgery in locally advanced vulvovaginal cancer can allow surgeons to avoid extensive surgery such as pelvic exenteration (Boronow, 1982).

Preoperative adjuvant radiation may offer several advantages for tumor control. First, primary cancers tend to locally infiltrate surrounding normal tissues with microscopic extension. Accordingly, radiation can be delivered prior to surgery to decrease the potential for locoregional and distant tumor dissemination and the likelihood of positive surgical margins. To sterilize areas of subclinical infiltration, doses of 40 to 50 Gy administered over 4 to 5 weeks are required. Although preoperative radiation therapy is not expected to render the main tumor mass cancer-free at the time of surgery, it is common to find no evidence of cancer in the surgical specimen. Second, in patients who present with unresectable cancers, preoperative radiation therapy can transform them into suitable candidates for a surgical attempt (Montana, 2000). Surgery is usually delayed 4 to 6 weeks after radiation completion. By then, the acute radiation reactions have subsided, and pathologic interpretation of the resected specimen is easier.

Two studies by the GOG (GOG 71 and 123) have investigated preoperative radiation and chemoradiation, respectively, in patients with bulky stage IB cervical cancer (Keys, 1999,

2003). In both trials, the pathologic complete response rate, defined as no residual disease in a resected specimen, approximated 50 percent.

Postoperatively, a high probability for local recurrence may often be predicted by factors such as positive margins, lymph node metastases, lymphovascular invasion, and high-grade disease. In these cases, postoperative radiation therapy may be beneficial and is ideally delivered 3 to 6 weeks following surgery. The delay allows initial wound healing (Sedlis, 1999). The radiation fields should encompass the operative bed due to the possibility of tumor contamination at the time of surgery and adjacent areas that are at risk for tumor dissemination.

Postoperative radiation is employed in the treatment of many gynecologic malignancies. For cervical cancer, postoperative radiation is recommended in those with lymphovascular invasion, deep stromal invasion, or large tumor size (Sedlis, 1999). Postoperative chemoradiation is offered if positive parametria, positive margins, or positive lymph nodes are found. The addition of cisplatin and 5-fluorouracil to radiation in cervical cancer patients with these high-risk features has been shown to improve survival and tumor control (Peters, 2000).

For uterine cancer, postoperative radiation is frequently used for patients with stage IB or greater disease. Several large randomized controlled trials have demonstrated significant improvements in local control in patients with intermediate-risk endometrial adenocarcinoma who receive adjuvant pelvic radiation (ASTEC/EN.5 Study Group, 2009; Creutzberg, 2011; Keys, 2004). Intermediate risk includes older age, lymphovascular invasion, deep myometrial invasion, or intermediate- or high-grade disease. Patients with fewer risk factors can often be treated with vaginal brachytherapy alone. Vaginal brachytherapy treats the vaginal apex, where approximately 75 percent of recurrences are located. A randomized trial showed similar vaginal and pelvic tumor control rates with fewer side effects when vaginal brachytherapy alone was compared with pelvic external beam radiation therapy (Nout, 2010).

Intraoperative radiation therapy (IORT) is infrequently elected. It may be delivered either by interstitial brachytherapy or by an electron beam produced by a dedicated linear accelerator installed in the operating room. A single dose of 10 to 20 Gy is typically directed to the area at risk for recurrence or suspected of harboring residual cancer (Gemignani, 2001).

## ■ Normal Tissue Response to Radiation Therapy

In general, radiation therapy is less well tolerated if: (1) the irradiated tissue volume is large, (2) the radiation dose is high, (3) the dose per fraction is large, and (4) the patient's age is advanced. Furthermore, the radiation damage to normal tissues can be exacerbated by factors such as prior surgery, concurrent chemotherapy, infection, diabetes mellitus, hypertension, and inflammatory bowel disease.

In general, if tissues with a rapid proliferation rate such as epithelium of the small intestine or oral cavity are irradiated, acute clinical symptoms develop within a few days to weeks. This contrasts with muscular, renal, and neural tissues, which have low proliferation rates and may not display signs of radiation

damage for months to years after treatment. To avoid serious complications, radiation oncologists must use published tolerance doses for normal tissues as a guide and rely on their own clinical experience. For example, to avoid severe rectal and bladder complications in patients with cervical cancer, doses of no more than 65 Gy and 70 Gy are recommended to the rectum and bladder, respectively (Milano, 2007).

## Epithelium and Parenchyma

Atrophy is the most consistent sequela of radiation therapy. It affects all lining epithelia—including skin and the epithelia of the gastrointestinal, respiratory and genitourinary tracts and of the endocrine glands. Additionally, necrosis and ulceration may develop. Within the submucosa and deep soft tissues, fibrosis frequently follows radiation therapy, leading to tissue contraction and stenosis (Fajardo, 2005).

Of vascular structures, the capillary is the most radiosensitive, and ischemia results from endothelial damage, capillary wall rupture, loss of capillary segments, and reduction of microvascular networks. In large arteries, atheroma-like calcifications develop (Friedlander, 2003; Zidar, 1997).

## Skin

Four general types of skin reactions may follow radiation therapy. In order of increasing severity, they include erythema, dry desquamation, moist desquamation, and skin necrosis. For many women during a 6 to 7 week radiation therapy course, the first three of these reactions are common. Within 2 weeks following radiation exposure, the skin develops mild erythema. By the fourth week, the redness becomes more pronounced and dry desquamation may begin. After 5 to 6 weeks, moist desquamation may follow. This involves epidermal sloughing, followed by serum and blood oozing through denuded skin. This reaction is mostly pronounced in skin folds, such as the inguinal, axillary, and inframammary creases.

Preventatively, throughout and after a radiation course, the skin is kept clean and aerated. For dry desquamation, ointments or aloe vera-containing creams promote dermal hydration with an emollient effect. During the moist desquamation phase, skin treatment may include moisturizers (e.g., Biafine), sitz baths, and silver sulfadiazine-containing, nonadhering dressings for weeping areas. Importantly, individuals are instructed to avoid applying heating pads, soaps, or alcohol-based lotions to irradiated skin.

Regeneration of the epithelium starts soon after radiation treatment and is usually complete in 4 to 6 weeks. Months later, areas of skin hyper- and hypopigmentation can be seen. The skin may remain atrophied, thin, and dry, and telangiectasias may be visible.

## Vagina

Radiation therapy directed to the pelvis frequently leads to acute vaginal mucositis. Although mucosal ulceration is rare, discharge is present in most cases. For these women, a dilute hydrogen peroxide and water solution used at the vulva provides symptomatic relief.

In contrast to acute changes, delayed reactions to radiation may include atrophic vaginitis, formation of vaginal synechiae

or telangiectasia, and most commonly, vaginal stricture. Less frequently, rectovaginal or vesicovaginal fistulas may develop after radiation therapy, especially with advanced-stage cancers. Of these delayed reactions, Grade 3 vaginal stricture is defined by the Common Terminology Criteria for Adverse Events (CTCAE) as “vaginal narrowing and/or shortening interfering with the use of tampons, sexual activity or physical examination” (National Cancer Institute, 2009). Preventatively, vaginal stricture or syn-echiae may be avoided if intercourse is resumed following treatment or if women are instructed regarding dilator use. Dilators are inserted vaginally by the patient daily for 10 seconds, and this schedule continues from radiation therapy completion until the first follow-up visit at 6 weeks. At this point, weekly insertion or intercourse is recommended. Increased severe late vaginal toxicity is associated with poor dilator compliance, concurrent chemotherapy, and age > 50 (Gondi, 2012). Importantly, stricture prevention also aids the ability to complete thorough vaginal examinations for cancer surveillance.

For women who remain sexually active following radiation therapy, water-based *lubricants* (e.g., Astroglide or K-Y Jelly) may be of benefit during intercourse but have no sustained effects. For chronic vaginal dryness, *vaginal moisturizers* may prove superior. Moisturizers (e.g., Replens and K-Y Silk-E) can be used daily or several times weekly to maintain moist vaginal tissues. Alternatively, topical estrogen cream (e.g., Premarin cream) may improve atrophic symptoms in those who are estrogen candidates (Table 22-5, p. 505).

Despite these products, persistent adverse vaginal changes affect sexual dysfunction. In a study of 118 women treated for cervical cancer, 63 percent of those who engaged in sexual activities before radiation therapy continued to do so following treatment, although less frequently (Jensen, 2003). In a comparison of women treated with radiation versus radical hysterectomy and lymph node dissection for cervical cancer, women treated with radiation reported significantly lower sexual dysfunction scores than patients undergoing surgery (Frumovitz, 2005).

### Ovary and Pregnancy Outcomes

The effects of radiation on ovarian function depend on radiation dose and patient age. For example, a dose of 4 Gy may sterilize 30 percent of young women, but 100 percent of those older than 40. In addition, fractionated radiation therapy appears to be more damaging. Ash (1980) noted that after 10 Gy given in 1 fraction, 27 percent of the women recovered ovarian function compared with only 10 percent of those receiving 12 Gy over 6 days. In patients with gynecologic cancers who receive pelvic radiation therapy, symptoms of ovarian failure mirror those of natural menopause, and symptom treatment is similar in those who are candidates (Chap. 22, p. 494).

To minimize radiation exposure to the ovaries of premenopausal women, the gonads may be surgically repositioned, termed *transposition*, out of the radiation fields. A review of pre-pubescent and adolescent girls undergoing transposition prior to pelvic radiation demonstrated long-term ovarian preservation rates ranging from 33 to 92 percent. However, only 11 of 347 women (3 percent) achieved pregnancy (Irtan, 2013). Moreover, among female childhood-cancer survivors who received abdominal irradiation, higher spontaneous abortion rates and lower

first-born birthweights were observed compared with cancer survivors who were not irradiated (Hawkins, 1989).

### Bladder

Most patients receiving pelvic radiation note some acute cystitis symptoms within 2 to 3 weeks of beginning treatment. Although urinary frequency, spasm, and pain develop commonly, hematuria is rare. Typically, phenazopyridine hydrochloride (Pyridium) or fluid ad lib promptly relieves symptoms. Antibiotics are prescribed when indicated. Major chronic complications following radiation therapy are infrequent and include bladder contracture and hematuria. For severe hematuria, bladder saline irrigation, transurethral cystoscopic fulguration, and temporary urinary diversion are proven techniques. Fistulas involving the bladder typically require urinary diversion.

### Small Bowel

The small bowel is particularly vulnerable to acute early damage from radiation therapy. After a single dose of 5 to 10 Gy, crypt cells are destroyed, and villi become denuded. An acute malabsorption syndrome ensues to cause nausea, diarrhea, vomiting, and cramping. Adequate fluid intake and a low-lactose, low-fat, and low-fiber diet is recommended. Additionally, anti-nausea and antidiarrheal medications may be warranted (Tables 25-6, p. 570, and 42-7, p. 914). Bowel antispasmodics with sedatives (e.g., Donnatal) are also particularly helpful.

Patients are warned about the late, chronic nature of radiation-induced enteritis. Intermittent diarrhea, crampy abdominal pain, nausea, and vomiting, which in combination may mimic a low-grade bowel obstruction, can develop. Patients are at increased risk if there is comorbidity such as obesity, inflammatory conditions of the pelvis or bowel, prior abdominal surgeries, or small-vessel diseases resulting from diabetes or hypertension.

Preventatively, several types of devices have been surgically inserted to displace the small bowel from the pelvis. These have included saline-filled tissue expanders, omental slings, and absorbable mesh (Hoffman, 1998; Martin, 2005; Soper, 1988). Furthermore, defining the areas at risk with surgical clips and careful radiation therapy planning, including the use of IMRT, may minimize bowel toxicity (Portelance, 2001). Consideration of dose constraints can further minimize injury. Studies show that irradiating a volume larger than 15 cm<sup>3</sup> or a point dose greater than 55 Gy is associated with a significant risk of small bowel damage (Stanic, 2013; Verma, 2014). Radiation treatment with patients prone can also limit the small bowel dose (Adli, 2003). In contrast, trials incorporating radiation protectors, such as amifostine, have been unsuccessful (Small, 2011).

### Rectosigmoid

Commonly, within a few weeks after radiation therapy initiation, patients may develop diarrhea, tenesmus, and mucoid discharge, which can be bloody. In these cases, antidiarrheal medications, low-residue diet, steroid-retention or sucalfate enemas, and hydration are management mainstays. Alternatively, rectal bleeding may be seen months to years after radiation therapy. Hemorrhage can at times be severe and require blood transfusion. Moreover, invasive procedures may be needed to control

bleeding neovasculature. These include the topical application of 4-percent formalin, cryotherapy, and vessel coagulation with laser (Kantsevov, 2003; Konishi, 2005; Smith, 2001; Ventrucchi, 2001). During the evaluation of late-onset rectal bleeding, barium enema is often indicated. The study usually reveals narrowing of the rectosigmoid lumen and wall thickening. In cases of severe obstruction, resection of the involved colonic segment is necessary. In addition, rectovaginal fistulas may result from radiation therapy (Chap. 25, p. 573). Small fistulas may heal over many months following a diverting colostomy.

Brachytherapy, in addition to external beam radiation, can further escalate rectal toxicity. The D2cc metric (minimum dose to the most irradiated contiguous volume of 2 cc) is commonly used to evaluate the rectal dose in brachytherapy and has been associated with increased Grade 2 to 4 rectal toxicities when more than 62 Gy are delivered (Lee, 2012). This metric was developed as part of the GEC-ESTRO (Groupe Européen de Curiethérapie—European Society of Therapeutic Radiation Oncology) guidelines, which provide dose-reporting parameters for the bladder, rectum, and sigmoid colon using 3-D image-based treatment planning (Potter, 2006).

### Kidney

Manifestations of acute radiation nephropathy typically appear 6 to 12 months after radiation exposure. Affected patients develop hypertension, edema, anemia, microscopic hematuria, proteinuria, and decreased creatinine clearance (Luxton, 1964). Although deteriorating renal function is occasionally reversible, it usually worsens and leads to chronic nephropathy. Patients receiving concurrent radiation and chemotherapy require special consideration, because of the nephrotoxicity associated with many chemotherapeutics.

### Bone

Radiation-induced insufficiency fractures are not infrequent following pelvic radiation. They develop in weakened bone and typically manifest as pain. The sacroiliac joint is most commonly involved (Cooper, 1985). Rates are higher in patients receiving definitive radiation therapy, and in a large series of 557 patients with cervical cancer, 20 percent developed insufficiency fractures over 5 years (Oh, 2008). In a more recent series of 222 patients receiving postoperative pelvic radiation therapy, only 5 percent developed pelvic insufficiency fractures at a median time of 11.5 months after radiation therapy completion (Shih, 2013). The fracture rate was higher in patients with osteoporosis (16 percent), in those on hormone replacement therapy (15 percent), and in patients with a lower body mass index. Treatment for a pelvic insufficiency fracture is conservative and consists of pain management and rest, with most patients becoming symptom free by 20 months.

### Hematologic Toxicity

Radiation therapy can significantly deplete bone marrow hematopoietic stem cells that include erythrocyte, leukocyte, and platelet precursors. These effects are exacerbated by combined chemoradiation or by irradiation of large fields that contain a significant portion of bone marrow. Accordingly, there are thresholds at which radiation is held to prevent further bone

**TABLE 28-4.** Susceptibility of Selected Tissues to Radiation-Induced Cancer

Susceptibility	Tissues
High	Bone marrow, female breast, thyroid
Moderate	Bladder, colon, stomach, liver, ovary
Low	Bone, connective tissue, muscle, cervix, uterus, rectum

marrow suppression. For example, if platelet levels measure  $< 35,000 \times 10^9/L$  and leukocyte counts are  $< 1.0 \times 10^9/L$ , then radiation may be held until these values rise. For anemia, transfusion is recommended (p. 618). To spare bone marrow injury, IMRT may be beneficial (Klopp, 2013).

### Radiation-induced Carcinogenesis

A secondary cancer may develop as a result of prior radiation therapy. The accepted criteria for the diagnosis of radiation-induced cancer require that the cancer be located within the previously irradiated region and that its pathology differ from that of the original malignancy. Additionally, there should be a latent period of at least a few years. In the updated analysis of the Post-Operative Radiation Therapy in Endometrial Carcinoma (PORTEC-1) trial, which compared postoperative adjuvant pelvic radiation against observation, the secondary cancer rates at 15 years were 22 percent in the radiation group compared with 16 percent in the observation group. However, this difference did not reach statistical significance (Creutzberg, 2011).

Development of a secondary radiation-induced cancer depends on factors such as patient age at exposure, radiation dose, and susceptibility of specific tissue types to radiation-induced carcinogenesis (Table 28-4). In general, those receiving higher radiation doses and those exposed at an earlier age have increased risks for second malignancies. The latency of secondary tumor development also varies depending on the type of second malignancy. For example, the latent period between radiation exposure and the clinical appearance of leukemia is less than 10 years, whereas solid tumors may not develop for decades. The most common example is development of uterine sarcoma years after pelvic radiation for treatment of cervical cancer (Mark, 1996). Preventatively, irradiation of smaller fields with advanced technologies such as IMRT compared with larger field 2-D external beam radiation may reduce the incidence of radiation-induced malignancies (Herrera, 2014).

Office gynecology frequently involves the diagnosis and management of preinvasive lower genital tract disease, most often involving the uterine cervix. Since widespread introduction of the Papanicolaou (Pap) test in the 1950s, cervical cancer screening has reduced the incidence of and mortality rate from invasive cervical cancer by more than 70 percent (Howlader, 2014). This is true despite a continued rise in the incidence of preinvasive lesions (Kurdgelashvili, 2013). Approximately 7 percent of U.S. women who undergo Pap testing will have an abnormal result (Wright, 2012). An abnormal screening test prompts further patient evaluation, usually with colposcopy and biopsy. Histologic results are more definitive and inform appropriate management.

LOWER GENITAL TRACT NEOPLASIA

In the lower genital tract (LGT), the term *intraepithelial neoplasia* refers to squamous epithelial lesions that are potential precursors of invasive cancer. These lesions demonstrate a range of histologic abnormality from mild to severe based on cytoplasmic, nuclear, and histologic changes. The severity of a squamous intraepithelial lesion is graded by the proportion of epithelium with abnormal cells from the basement membrane upward toward the surface. In the case of cervical intraepithelial neoplasia (CIN), abnormal cells confined to the lower third

of the squamous epithelium are referred to as *mild dysplasia* or *CIN 1*, extending into the middle third as *moderate dysplasia* or *CIN 2*, into the upper third as *severe dysplasia* or *CIN 3*, and full-thickness involvement as *carcinoma in situ (CIS)* (Fig. 29-1). Squamous neoplasia of the vagina, vulva, perianal, and anal squamous epithelia (VaIN, VIN, PAIN, and AIN, respectively) are graded similarly with the caveat that VIN 1 is no longer recognized (p. 647). The natural history of these extracervical lesions is less understood than for CIN. In contrast, the cervical columnar epithelium does not demonstrate an analogous neoplastic disease spectrum because it is only one cell-layer thick. Histologic abnormalities are therefore limited to either *adenocarcinoma in situ (AIS)* or *adenocarcinoma*.

The concept of cervical neoplasia as a spectrum has come under question with increasing insight into human papillomavirus (HPV) infection. Mild squamous dysplasia is now recognized as evidence of HPV infection, most of which is transient and unlikely to progress. Moderate to severe dysplastic squamous lesions are considered to be true cancer precursors. Current cytology reporting reflects this two-tier concept (Solomon, 2002). In 1989, the Bethesda System nomenclature replaced CIN with *squamous intraepithelial lesion (SIL)*. Because cytologic and histologic changes of HPV infection and CIN 1 cannot be distinguished reliably and because of their like natural histories, they are categorized together as *low-grade squamous intraepithelial lesions (LSIL)*. Similarly, CIN 2, CIN 3, and CIS are difficult to distinguish, are truer cancer precursors, and are all designated as *high-grade squamous intraepithelial lesions (HSIL)*. The diagnostic distinction between LSIL and HSIL is more reliable, biologically plausible, and clinically meaningful than diagnoses using the CIN system. This two-tiered nomenclature is now recommended, and guidelines for the management of these lesions are grouped accordingly (Darragh, 2012).

ANATOMIC CONSIDERATIONS

■ External Genitalia

Precancerous lesions of the female LGT are often multifocal, can involve any of its structures, and may appear similar to benign processes. For example, *micropapillomatosis labialis* is a benign anatomic variant characterized by minute epithelial projections on the inner labia minora (Fig. 29-2). This condition can be easily mistaken for HPV-related lesions, but true HPV lesions tend to be multifocal and asymmetric, and to have multiple papillations arising from a single base (Ferris, 2004). Micropapillomatosis often shows spontaneous regression, and treatment is not indicated (Bergeron, 1990).

A

B

C

**FIGURE 29-1** **A.** Normal ectocervical epithelium is a nonkeratinizing, stratified squamous epithelium. Mitoses are normally confined to the lower layers, namely, the basal and parabasal epithelial layers. **B.** Low-grade squamous intraepithelial lesion (LSIL). This biopsy's location at the transformation zone is indicated by the presence of both columnar epithelium (asterisk) and squamous epithelium. Low-grade SIL has a disordered proliferation of squamous cells and increased mitotic activity confined to the basal one third of the epithelium. Koilocytotic atypia, which is indicative of proliferative HPV infection, involves the more superficial epithelium. Koilocytosis is typified by nuclear enlargement, coarse chromatin, nuclear "wrinkling," and perinuclear halos. **C.** This high-grade SIL shows disordered, highly atypical squamous cells and increased mitotic activity involving the full thickness of the epithelium. Note the mitotic figure located close to epithelial surface (yellow arrow). (Used with permission from Dr. Kelley Carrick.)

## ■ Vagina

The vagina is lined by nonkeratinized squamous epithelium, and glands are absent. However, areas of columnar epithelium are occasionally found within the vaginal squamous mucosa, a condition termed *adenosis*. It is often attributable to in utero exposure to exogenous estrogen, particularly diethylstilbestrol (DES) (Trimble, 2001). These areas are red patches within the squamous epithelium and can be mistaken for ulcers or other lesions. With DES-related adenosis, careful palpation of the vagina is warranted in addition to visual inspection, as clear cell adenocarcinoma may be palpable before becoming visible.

## ■ Cervix

### Squamocolumnar Junction

During embryogenesis, upward migration of stratified squamous epithelium from the urogenital sinus and vaginal plate is thought to replace müllerian epithelium (Ulfelder, 1976). This process usually terminates near the external cervical os, forming the original (congenital) squamocolumnar junction (SCJ). When visible on the ectocervix, the SCJ is a pink, smooth squamous epithelium juxtaposed against the red, velvety columnar epithelium

surrounding the external cervical os. Rarely, this migration is incomplete resulting in an SCJ in the upper vaginal fornices. This is a normal variant and also seen with in utero DES exposure.

The columnar epithelium is commonly referred to as "glandular." This is because it produces mucus, and its deep infoldings appear histologically similar to glandular tissue (Fig. 29-3). However, true glands, consisting of acini and ducts, are not present on the cervix (Ulfelder, 1976).

The location of the SCJ varies with age and hormonal status (Fig. 29-4). During the reproductive years, it everts outward onto the ectocervix, especially during adolescence, pregnancy, and with combination hormonal contraceptive use. It regresses into the endocervical canal during the natural process of squamous metaplasia and in low-estrogen states such as menopause, prolonged lactation, and long-term progestin-only contraceptive use.

### Squamous Metaplasia

At puberty, the rise in estrogen levels leads to increased glyco-genation of the LGT nonkeratinized squamous epithelium. In providing a carbohydrate source, glycogen allows vaginal flora to be dominated by lactobacilli, which produce lactic acid. The resultant acidic vaginal pH is the suspected stimulus for *squamous*

**FIGURE 29-2** Benign lower genital tract lesions. **A.** Condylomata tend to be multifocal, asymmetric, and have multiple papillations arising from a single base. **B.** Micropapillomatosis labialis is a normal variant of vulvar anatomy encountered along the inner aspects of the labia minora and lower vagina. In contrast to condylomata, projections are uniform in size and shape and arise singly from their base attachments.

**FIGURE 29-3** Endocervical anatomy. **A.** Sagittal view of the cervix. In this drawing, a portion of the endocervical canal is boxed. (Modified with permission from Eastman NJ, Hellman LM: Williams Obstetrics 12th ed., New York: Appleton-Century-Crofts, Inc; 1961.) **B.** The endocervix is lined by a simple columnar, mucin-secreting epithelium. Crypts and small exophytic projections appear pseudopapillary when viewed in cross section. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 29-4** The location of the squamocolumnar junction (SCJ) is variable. **A.** The SCJ is located on the ectocervix and is fully visualized. **B.** The SCJ is located within the endocervical canal and is not visible.

**FIGURE 29-5** Schematic describing relevant cervical landmarks. The original squamocolumnar junction (SCJ) marks the terminal site of the upward migration of squamous epithelium during embryonic development. The SCJ location moves with age and hormonal status. With higher estrogen states, the SCJ everts outward. With low-estrogen states and with squamous metaplasia, the SCJ moves closer to the cervical os. The transformation zone consists of the band of squamous metaplasia lying between the original SCJ and new (current) SCJ. As the metaplastic epithelium matures, it moves outward relative to the newer, less mature areas of metaplasia and can become indistinguishable from the original squamous epithelium.

*metaplasia*, which is the normal replacement of columnar by squamous epithelium on the cervix. Relatively undifferentiated reserve cells underlying the cervical epithelia are the apparent precursors of the new metaplastic cells, which differentiate further into squamous epithelium. This normal process creates a progressively widening band of metaplastic and maturing squamous epithelium, termed the *transformation zone* (TZ), between the congenital (original) columnar epithelium and the squamous epithelium (Fig. 29-5).

### Transformation Zone and Cervical Neoplasia

Nearly all cervical neoplasia, both squamous and columnar, develops within the TZ, usually adjacent to the new or current SCJ. Cervical reserve and immature metaplastic cells appear particularly vulnerable to the oncogenic effects of HPV and cocarcinogens (Stanley, 2010a). Squamous metaplasia is most active during adolescence and pregnancy. This may explain why early ages of first sexual activity and of first pregnancy are cervical cancer risk factors.

## hUMAN PAPILLOMAVIRUS

### Basic Virology

The causative role of HPV in nearly all cervical neoplasia and a significant proportion of vulvar, vaginal, and anal neoplasia is firmly established. HPV primarily infects human squamous or metaplastic epithelial cells. It is a double-stranded DNA virus with a protein capsid unique to each viral type. More than 150

**FIGURE 29-6** The human papillomavirus life cycle is completed in synchrony with squamous epithelium differentiation. Early genes, including the E6 and E7 oncogenes, are expressed most strongly within the basal and parabasal layers. The late genes encoding capsid proteins are expressed later in the superficial layers. Intact virus is shed during normal desquamation of superficial squames. Late genes are not strongly expressed in high-grade neoplastic lesions.

genetically distinct HPV types have been identified, and of these, approximately 40 types infect the LGT (Doorbar, 2012).

The circular HPV genome consists of only nine identified open reading frames (Stanley, 2010a). In addition to one regulatory region, the six “early” (E) genes govern functions early in the viral life cycle, including DNA maintenance, replication, and transcription. Early genes are expressed in the lower squamous epithelial layers (Fig. 29-6). The two “late” genes encode the major (L1) and minor (L2) capsid proteins. These proteins are expressed in the superficial epithelial layers late in the viral life cycle and during the assemblage of new, infectious viral particles. Sequential HPV gene expression is synchronous with and dependent on squamous epithelial differentiation. Thus, completion of the viral life cycle takes place only within an intact, fully differentiating squamous epithelium (Doorbar, 2012). This makes it nearly impossible to culture HPV in vitro. HPV is a nonlytic virus, and therefore infectiousness depends on normal desquamation of infected epithelial cells. A new infection is initiated when the L1 and L2 capsid proteins bind to the epithelial basement membrane and/or basal cells, permitting entry of HPV viral particles into cells of a new host (Sapp, 2009).

Genital HPV is the most common sexually transmitted disease (STD) in the United States, and most sexually active adults are infected at some time (Dunne, 2014). Most incident HPV infections develop in women younger than 25 years. The point prevalence in U.S. females aged 14 to 59 years is 27 percent. It is highest in those aged 20 to 24 years (45 percent) and becomes less prevalent with increasing age (Dunne, 2007). Clinically, HPV types are classified as high-risk (HR) or low-risk (LR) based on their strength of association with cervical cancer. LR HPV types 6 and 11 cause nearly all genital warts, laryngeal papillomas, and a minority of subclinical HPV infections. LR HPV infections are rarely, if ever, oncogenic.

In contrast, persistent HR HPV infection is now viewed as required for the development of cervical cancer. HR HPV types, including 16, 18, 31, 33, 35, 45, and 58, along with a few less common types, account for approximately 95 percent of cervical cancer cases worldwide (Muñoz, 2003). HPV 16 is the most oncogenic, accounting for the largest percentage of

CIN 3 lesions (45 percent) and cervical cancers (55 percent) worldwide. It is also the dominant type in other HPV-related anogenital and oropharyngeal cancers (Schifman, 2010; Smith, 2007). Although the prevalence of HPV 18 is much lower than that of HPV 16 in the general population, it is found in 13 percent of cervical squamous cell carcinomas, and in an even higher proportion of cervical adenocarcinomas and adenosquamous carcinomas (approximately 40 percent) (Bruni, 2010; Smith, 2007). Together, HPVs 16 and 18 account for approximately 70 percent of cervical cancers worldwide, 68 percent of squamous cell carcinomas, and 85 percent of adenocarcinomas (Bosch, 2008). HPV type 45 is the third most common found in cervical cancers (de Sanjose, 2010). HPV 16 accounts for more than 1 in 5 cervical HPV infections and is the most common HPV found among low-grade lesions and in women without neoplasia (Bruni, 2010; Herrero, 2000). Thus, HR HPV infection does not cause neoplasia in most infected women, and additional host, viral, and environmental factors determine progression to LGT neoplasia.

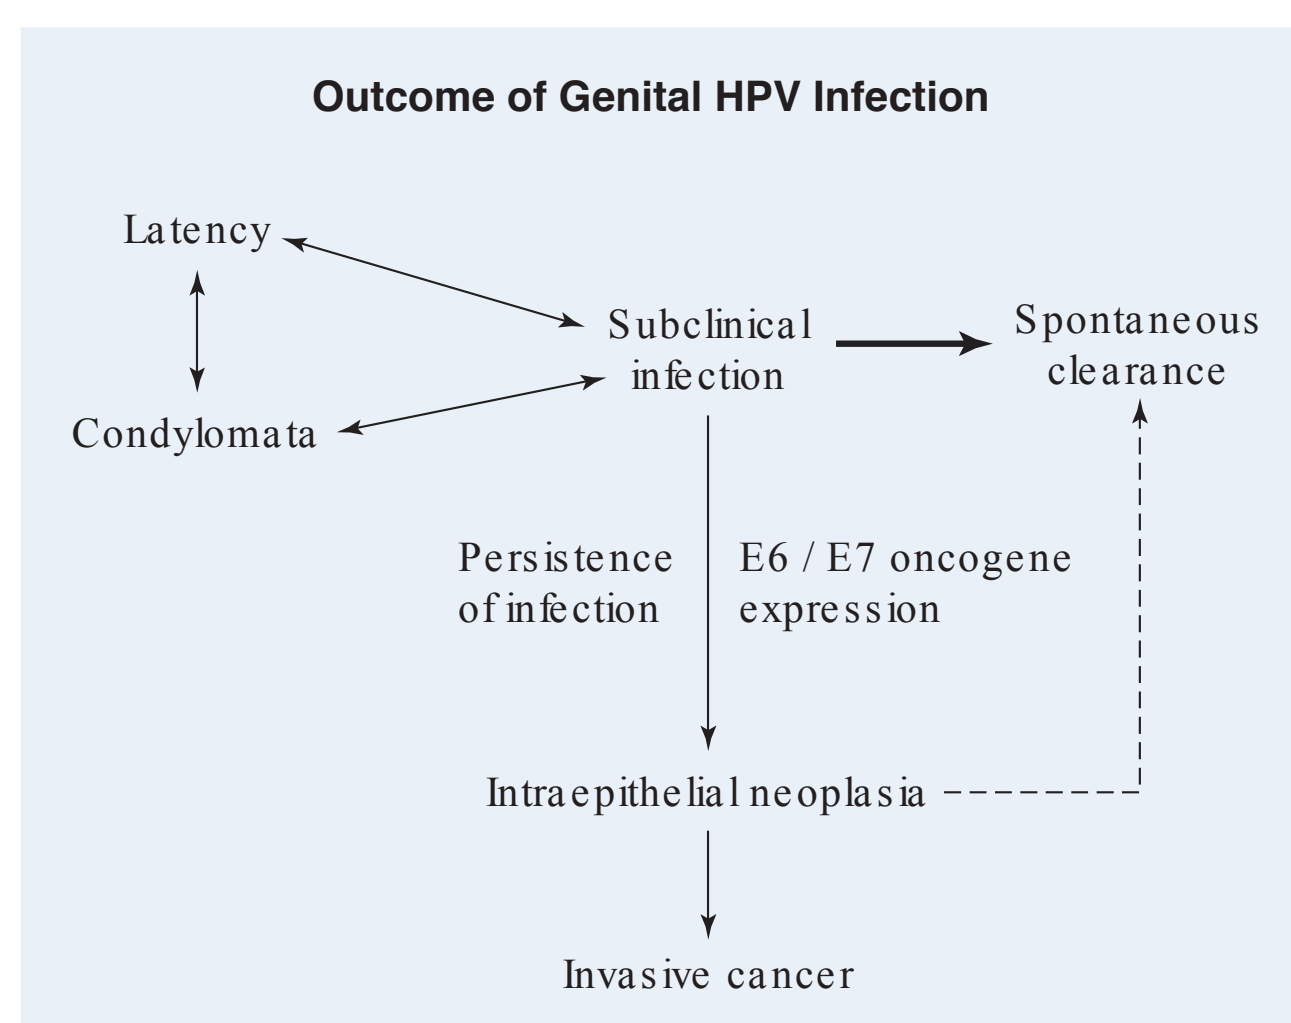

## ■ Transmission

The most important risk factors for the acquisition of genital HPV infection are the number of lifetime and recent sexual partners and early age at first sexual intercourse (Burk, 1996; Fairley, 1994; Franco, 1995). Genital HPV is transmitted by direct, usually sexual, contact with the genital skin, mucous membranes, or body fluids of an individual with either warts or subclinical HPV infection. The infectivity of inapparent (subclinical) HPV is assumed to be high. HPV is thought to access to the basal cell layer and basement membrane through microabrasions of the genital epithelium during sexual contact. Once infected, these basal cells may become a viral reservoir (Stanley, 2010b).

Cervical HR HPV infection generally requires penetrative intercourse. Oral-genital and hand-genital HPV transmissions are possible but are much less common than with genital-genital transmission (Winer, 2003). Women who have sex with women have rates of HR HPV positivity, abnormal cervical cytology, and high-grade cervical neoplasia similar to those of heterosexual women, but undergo cervical cancer screening less often. Women with or without past sexual experiences with men have a similar risk, implying that digital, oral, and perhaps object contact places them at risk of HR HPV infection (Marrazzo, 2000). Thus, all women who are sexually active should undergo cervical cancer screening according to current recommendations regardless of sexual orientation.

Genital HPV detection, including HR HPV, has been reported in apparently sexually naïve girls and young women (Doerfler, 2009; Winer, 2003). Nonetheless, genital warts that develop in children after infancy are always reason to consider the possibility of sexual abuse. HPV infection by nonsexual contact, autoinoculation, or fomite transfer appears possible. This is supported by reports of nongenital HPV types in a significant minority of pediatric and adolescent genital wart cases (Cohen, 1990; Obalek, 1990; Siegfried, 1997).

Congenital HPV infection from vertical transmission (mother to fetus or newborn) beyond transient skin colonization is rare. Conjunctival, laryngeal, vulvar, or perianal warts

**FIGURE 29-7** The natural history of genital human papillomavirus (HPV) infection varies between individuals and over time. Most infections are subclinical. Spontaneous resolution is the most common outcome. Neoplasia is the least common manifestation of HPV infection, developing as the result of persistent infection with integration of HPV DNA.

present at birth or that develop within 1 to 3 years of birth are most likely due to perinatal exposure to maternal HPV (Cohen, 1990). Infection is not linked to maternal genital warts or route of delivery (Silverberg, 2003; Syrjänen, 2010). Accordingly, cesarean delivery generally is not recommended for maternal HPV infection. Exceptions include cases of large genital warts that would obstruct delivery or might avulse and bleed with cervical dilation or vaginal delivery.

## ■ Infection Outcomes

Genital HPV infection causes variable outcomes (Fig. 29-7). These can be broadly grouped as latent or expressed infections. Infection expression may be productive, that is, creating infectious viral particles, or it may be neoplastic, causing preinvasive disease or malignancy. Most productive infections are subclinical, but a smaller percentage yields clinically apparent genital warts. Last, HPV infection can be transient or can become persistent. High-grade neoplasia (CIN 3 or worse) is the least common outcome of genital HPV infection, requiring HPV persistence.

*Latent infection* refers to that in which cells are infected, but HPV remains quiescent. There are no detectable tissue effects, as the virus is not actively replicating. The virus is present below detectable levels. Thus, it is uncertain whether apparent clearance of the HPV constitutes true eradication of HPV from infected tissues or whether it reflects latency.

*Productive infections* are characterized by viral life-cycle completion and plentiful production of infectious viral particles (Stanley, 2010a). Viral gene expression and assemblage are completed in synchrony with terminal squamous differentiation, concluding with desquamation of infected squames. These infections have little or no malignant potential because the HPV genome remains episomal and its oncogenes are expressed at very low levels (Durst, 1985; Stoler, 1996).

In both female and male genital tracts, productive HPV infections cause either visible genital warts (condyloma acuminata) or much more commonly, subclinical infections. Subclinical infections may be indirectly identified as low-grade cytologic, colposcopic, or histologic abnormalities. However, all these observational diagnoses are subjective and poorly reproducible. HPV testing more accurately reflects HPV infection but is limited to specific HPV types and viral loads.

With *neoplastic infection* (CIN 3 and cervical cancer), the circular HPV genome is disrupted and integrates at random locations into a host chromosome (Fig. 30-1, p. 659). Unrestrained transcription of the *E6* and *E7* oncogenes follows (Durst, 1985; Stoler, 1996). The *E6* and *E7* oncoproteins produced interfere with and accelerate degradation of p53 and pRb, which are key tumor suppressor proteins produced by the host (Fig. 30-2, p. 659). This leaves the infected cell vulnerable to malignant transformation by loss of cell-cycle control, cellular proliferation, and accumulation of DNA mutations over time (Doorbar, 2012).

In resultant preinvasive lesions, normal epithelial differentiation is disrupted and incomplete. The degree of disruption is used to grade histology as low-grade (encompassing HPV changes and CIN 1) or high-grade (CIN 2, CIN 3, and CIS). The average age at diagnosis of low-grade cervical disease is younger than that of high-grade lesions and invasive cancers. Thus, disease was thought to progress from milder- to higher-grade lesions over time. An alternative theory now proposes that low-grade lesions are generally acute, transient, and not oncogenic. High-grade lesions and cancers are monoclonal and arise *de novo* rather than from preexistent low-grade disease (Baseman, 2005; Kiviat, 1996).

The pathogenesis of HPV-related neoplasia at other anogenital sites is thought to be similar to that of the cervix. Genital HPV infection is usually multifocal and involves the cervix most often. Neoplasia at one site increases the risk of neoplasia elsewhere in the LGT (Spitzer, 1989).

## ■ Natural history of Infection

Infection with HPV, predominantly HR types, is very common soon after initiation of sexual activity (Brown, 2005; Winer, 2003). This infection often accompanies sexual debut and is not evidence of promiscuity (Collins, 2002).

Most HPV infection and related lesions, whether clinical or subclinical, spontaneously resolve, especially in adolescents and young women (Ho, 1998; Moscicki, 1998). Questions have been raised as to whether apparent clearance reflects true resolution or limited testing sensitivity (Winer, 2011). Several studies show that LR HPV infections resolve faster than those involving HR HPV (Moscicki, 2004; Schlecht, 2003; Woodman, 2001). Younger women frequently change HPV types, reflecting transience of infection and sequential reinfection by new partners rather than persistence (Ho, 1998; Rosenfeld, 1992). Simultaneous or sequential infection with multiple HPV types is common (Schifman, 2010).

Persistent HR HPV infection is necessary for the development of cervical neoplasia. A minority of HPV infections become persistent, but most young women (65 percent) with

HPV 16/18 infections lasting more than 6 months will develop SIL (Trottier, 2009). The risk of progression to high-grade neoplasia increases with age, as HPV infection in older women is more likely to reflect persistence (Hildesheim, 1999). Cell-mediated immunity likely plays the largest role in HPV infection persistence and in progression or regression of benign and neoplastic lesions.

## ■ Infection Diagnosis

HPV infection is suspected based on clinical lesions or results of cytology, histology, and colposcopy, all of which are subjective and often inaccurate. Moreover, serology is unreliable and cannot distinguish past from current infection (Dillner, 1999). As noted, culture of HPV is not feasible. Thus, diagnosis is confirmed only by the direct detection of HPV nucleic acids by methods that include in situ hybridization, nucleic acid amplification testing (NAAT), polymerase chain reaction (PCR), or others (Molijn, 2005). Currently, four HR HPV tests are approved by the Food and Drug Administration (FDA) for clinical use, and all use NAAT to detect any of 13 or 14 HR HPV types. Two of these tests report specifically the presence of HPV 16 or HPV 18 to aid risk stratification and customized management. Due to clinical test limitations, a negative test result does not exclude HPV infection. Therefore, these tests are not indicated or useful for routine STD screening. LR HPV testing has no indication and can lead to inappropriate expense, further evaluation, and unnecessary treatment.

The clinical role of HR HPV testing for cervical cancer screening and for surveillance of SIL continues to evolve. It is not offered as a screen for HPV infection outside of current guidelines. Namely, appropriate clinical uses for HR HPV testing include: cotesting with cervical cytology screening in women aged 30 years or older, triage or surveillance of certain abnormal cytology results and untreated CIN, and posttreatment surveillance (Davey, 2014). One HR HPV test (cobas HPV Test) was recently FDA approved as a stand-alone screening test for cervical cancer for women 25 years of age and older (p. 634).

If typical genital warts are found in a young woman or if high-grade cervical neoplasia or invasive cancer is identified by cytology or histology, then HPV infection is assumed, and HPV testing is unnecessary. Because of high HPV prevalence in young women (less than age 25), HR HPV testing for cervical cancer screening is not recommended. HPV testing is not FDA approved for use in women after complete hysterectomy, and there are no guidelines for managing HPV test results in these women.

## ■ Infection Treatment

The indications to treat HPV-related LGT disease are symptomatic warts, high-grade neoplasia, or invasive cancer. No effective treatment resolves subclinical or latent HPV infection. Needless physical LGT damage may result from unrealistic attempts to eradicate HPV infections, which are usually self-limited. Encouragement of positive health behaviors and optimal management of immune compromise seems sensible. Treatment of cervical LSIL (HPV changes or CIN 1) is not

necessary and is considered only after observation for at least 2 years.

Various treatment modalities are available for genital warts and are chosen according to lesion size, location, and number (Rosales, 2014). Mechanical removal or destruction, topical immunomodulators, and chemical or thermal coagulation can be used (Table 3-15, p. 71). Examination of a male partner does not benefit a female partner either by influencing reinfection or by altering the clinical course or treatment outcome for genital warts or LGT neoplasia (Centers for Disease Control and Prevention, 2010).

## ■ Infection Prevention

### Behavior

Sexual abstinence, delaying coitarche, and limiting the number of sexual partners are logical strategies to avoid genital HPV infection and its adverse effects. However, evidence is lacking from trials of counseling and sexual practice modification. Condoms do not cover all potentially HPV-infected anogenital skin. Therefore, condoms may not be completely protective but are likely to reduce acquisition and transmission of HPV. Winer and associates (2003) conducted the first prospective study of male condom use and showed reductions in HPV infection rates in young women even if condoms were used inconsistently.

### Vaccines

There is the greatest promise for prevention and possibly reversal of its sequelae in those already infected. Local and humoral immunity likely protect against incident infection, and prophylactic vaccines elicit type-specific humoral antibody production that prevents new HPV infection by blocking its entry into host cells (Stanley, 2010b). They do not prevent transient HPV positivity or resolve preexistent infection. HPV vaccines have the potential to prevent malignancies at least six body sites that include cervix, vulva, vagina, penis, anal canal, and oropharynx.

Currently, three HPV vaccines are FDA approved for prevention of incident HPV infection and cervical neoplasia. They use recombinant technologies for the synthetic production of the L1 capsid proteins of each HPV type included in the vaccine. The resultant virus-like particles are highly immunogenic but are not infectious as they lack viral DNA (Stanley, 2010b).

Cervarix (HPV2) is a bivalent vaccine against HPVs 16 and 18. Gardasil (HPV4) is a quadrivalent vaccine against HPV types 6, 11, 16, and 18. HPV4 is being replaced by Gardasil 9 (HPV9), a nonavalent vaccine. HPV9 protects against all HPV types in HPV4 plus types 31, 33, 45, 52, and 58. Coverage of these additional HR HPV types will bring the theoretical percentage of cervical cancers prevented from 65 percent to approximately 80 percent. All three vaccines contain adjuvants that boost the immune response to vaccine antigens. They are administered in three intramuscular doses during a 6-month period. Specifically, the second dose is given 1 to 2 months after the first dose, and the third dose is given 6 months after the first dose. Prolongation of the dosing schedule does not appear to diminish immunogenicity. Optimal vaccination strategies administer these prior to sexual activity initiation, when the potential benefit is great-

est. However, a history of prior sexual activity, HPV-related disease, or HPV-test positivity should not deter vaccine administration. Testing for HPV is not recommended prior to vaccination (American College of Obstetricians and Gynecologists, 2014a). The Advisory Committee on Immunization Practices (ACIP) currently recommends that HPV vaccine be administered routinely to girls aged 11 to 12 years (as early as age 9 years). Vaccination is also recommended for 13- to 26-year-old women not previously vaccinated (Markowitz, 2014; Petrosky, 2015). Vaccination can be given during lactation but is avoided during pregnancy (American College of Obstetricians and Gynecologists, 2014a). Immune compromised women are candidates to receive the vaccine and show high seroconversion rates despite the theoretical risk of a blunted immune response.

All three vaccines show nearly 100-percent efficacy in preventing incident infection and high-grade cervical neoplasia from HPV types included in the vaccines (Future II Study Group, 2007; Paavonen, 2009; Joura, 2015). HPV4 and HPV9 additionally protect against HPV types 6 and 11, which cause nearly all genital warts, laryngeal papillomatosis, and many low-grade cytologic abnormalities. HPV4 and HPV9 are approved for genital wart prevention in both males and females. They are also FDA approved for the prevention of vaginal, vulvar, and anal neoplasia. HPV2 does not prevent genital warts. It is not approved for extracervical LGT disease prevention, although theoretically it should.

HPV vaccines are highly immunogenic with maintenance of protection for at least 5 to 8 years after vaccination (Ferris, 2014; Harper, 2006). No evidence supports the need for later booster dosing. They have excellent safety profiles, are well-tolerated, and can be administered along with other recommended vaccinations.

Because HPV vaccines prevent most, but not all, HPV-related cervical cancers, cervical cancer screening should continue per current guidelines. Countries with high vaccination rates have seen dramatic reductions in anogenital warts, and reductions in Pap abnormalities and cervical neoplasia are expected (Ali, 2013). Despite suboptimal vaccination rates in the United States, HPV4 vaccine-type infections among U.S. adolescents have decreased by 56 percent since vaccine introduction in 2006 (Stokley, 2014).

## CERVICAL INTRAEPITHELIAL NEOPLASIA

### ■ Risk Factors

Henk and associates (2010) estimated that 412,000 cases of CIN are diagnosed in the United States annually. Risk factors are similar to those of invasive cervical cancer, and CIN is most strongly related to persistent genital HR HPV infection and increasing age (Table 29-1) (Ho, 1995; Kjaer, 2002; Remmink, 1995).

The median age of cervical cancer diagnosis in the United States (late fifth decade) is approximately a decade later than for CIN. In an older woman, HPV infection is more likely to persist than resolve. Older age is linked with waning immune competence and also allows accumulation of genetic mutations over time that can lead to malignant cellular transformation.

TABLE 29-1. Risk Factors for Cervical Neoplasia

Demographic risk factors

Ethnicity (Latin American countries, U.S. minorities)  
Low socioeconomic status  
Increasing age

Behavioral risk factors

Early coitarche  
Multiple sexual partners  
Male partner with multiple prior sexual partners  
Tobacco smoking  
Dietary deficiencies

Medical risk factors

Cervical high-risk human papillomavirus infection  
Exogenous hormones (combination hormonal contraceptives)  
Parity  
Immunosuppression  
Inadequate screening

Additionally, adverse socioeconomic factors and decreased need for prenatal care and contraception cause older women to be screened less often.

Behavioral risk factors for CIN mirror those for HPV acquisition and include early onset of sexual activity, multiple sexual partners, and male partner promiscuity (Buckley, 1981; de Vet, 1994; Kjaer, 1991). After adjustments for HPV positivity and lower socioeconomic status, tobacco use also increases the preinvasive disease risk (Castle, 2004; Plummer, 2003).

Dietary deficiencies of certain vitamins such as A, C, E, beta carotene, and folic acid may alter cellular immunity to HPV infection. This may promote viral infection persistence and cervical neoplasia (Paavonen, 1990). However, in the United States, lack of association between dietary deficiencies and cervical disease may reflect the relatively sufficient nutritional status of even lower-income women (Amburgey, 1993).

Combination oral contraceptives (COCs) have been linked with an increased risk of cervical cancer in current users (International Collaboration of Epidemiological studies of Cervical Cancer, 2007). Possible mechanisms include increased persistence of HPV infection and oncogene expression (de Villiers, 2003). Conversely, multiple studies have failed to find an increased CIN risk in users of hormonal contraceptives or postmenopausal hormone therapy (Castle, 2005; Harris, 2009; Yasmeen, 2006). DES exposure in

utero appears to double the risk of developing high-grade cervical disease in addition to an increased risk of cervical and vaginal clear cell adenocarcinoma (Hoover, 2011).

Increasing parity has been correlated with cervical cancer risk, but it is unclear if this is related to earlier sexual activity, a progestin-exposure effect, or other factors. Immune suppression during pregnancy, hormonal influences on cervical epithelium, and physical trauma related to vaginal deliveries have all been suggested (Brinton, 1989; Muñoz, 2002).

Immunosuppressed women in general show increased risks for CIN and for greater lesion severity, multifocal lesion pattern, and lesions at multiple LGT sites. They also experience higher rates of treatment failure, persistence, and recurrence of LGT disease compared with those who are immunocompetent. Specifically, human immunodeficiency virus (HIV)-positive women have higher rates of abnormal Pap results and CIN compared with HIV-negative women (p. 651). Transplant recipients have an increased risk of developing a malignancy after transplantation, including neoplasms of the LGT and anal canal (Gomez-Lobo, 2009). Women on immunosuppressive medications for other disorders have higher rates of LGT neoplasia.

Inadequate screening is another risk factor. Of women diagnosed with cervical cancer in the United States, approximately 60 percent either have never been screened (50 percent) or have not had a Pap test during the previous 5 years (10 percent) (American College of Obstetricians and Gynecologists, 2012b). Lack of screening is a major contributor to higher rates of cervical cancer in socioeconomically disadvantaged women, particularly those of minority ethnicity, rural residence, or older age, and those who are recent immigrants (Benard, 2007).

Natural history

Preinvasive lesions can spontaneously regress, remain stable, or progress. The risk of progression to invasive cancer increases with the severity of CIN. Estimates of CIN progression, persistence, and regression are provided in a review by Ostor (1993) and shown in Table 29-2. Low-grade lesions are thought to be manifestations of acute HPV infection, and most spontaneously regress within a few years. High-grade lesions are less likely to do so. Castle and coworkers (2009b) calculated that approximately 40 percent of CIN 2 regresses spontaneously within 2 years. This is even more frequent (greater than 60 percent) in young, healthy women (Moscicki, 2010). CIN 2 is thought to be a mixture of low- and high-grade lesions that are difficult to distinguish histologically, rather than an intermediate step

TABLE 29-2. Natural History of Cervical Intraepithelial Neoplasia (CIN) Lesions

	Regression (%)	Persistence (%)	Progression to CIS (%)	Progression to Invasion (%)
CIN 1	57	32	11	1
CIN 2	43	35	22	5
CIN 3	32	< 56	—	> 12

CIS = carcinoma in situ.

Reproduced with permission from Ostor AG: Natural history of cervical intraepithelial neoplasia: a critical review. Int J Gynecol Pathol 1993 Apr;12(2):186–192.

in the progression from CIN 1 to CIN 3. The risk of progression to invasive cancer of biopsied but otherwise untreated CIN 3 lesions approximates 30 percent over 30 years (McCredie, 2008).

## CERVICAL NEOPLASIA DIAGNOSIS

Cervical cancer screening ideally finds preinvasive lesions that can be eradicated or finds early-stage cervical cancer that can be treated successfully. Cervical cancer screening was previously limited to cervical cytology. But, during the past decade, HR HPV testing has also become an important screening tool.

In general, LGT preinvasive lesions are visible only with aided inspection. One exception is VIN, which is generally visible, palpable, or both. Only cervical lesions at either end of the neoplastic disease spectrum are grossly visible, namely, condylomata and invasive cancers. Accordingly, all symptoms suspicious for cervical neoplasia and grossly visible cervical lesions require prompt biopsy.

### ■ Cervical Cytology

Cervical cytologic screening is one of modern medicine's great success stories. It detects most cervical neoplasia during the typically prolonged premalignant or early occult invasive phases, when treatment outcomes are optimal. Conventional glass slides (traditionally called the *Pap smear*) and liquid-based Pap tests are considered equally acceptable for screening by all current guidelines (American College of Obstetricians and Gynecologists, 2012b; Saslow, 2012; U.S. Preventive Services Task Force, 2012).

Introduced in the 1940s, cervical cytology has never been evaluated in a randomized, controlled, or masked trial (Koss, 1989). However, countries with organized screening programs have consistently realized dramatic declines in both cervical cancer incidence and mortality rates. The Pap test's specificity is consistently high, approximating 98 percent. However, estimates of its sensitivity for detection of CIN 2 or worse are lower, are more variable, and range from 45 to 65 percent (Whitlock, 2011). This imperfect sensitivity is balanced by recommendations for repetitive screening throughout a woman's life. Although the incidence of cervical squamous carcinoma continues to decline, both the relative and absolute incidences of adenocarcinoma have increased, particularly in women younger than 50 (Herzog, 2007). Adenocarcinoma and adenosquamous carcinoma now account for at least 20 percent of cervical cancers. This increase may be due in part to the Pap test's lower sensitivity for detection of adenocarcinoma than for squamous cancers and their precursor lesions.

False-negative Pap test results may follow sampling error, in which abnormal cells are not present in the Pap test, or by screening error, in which the cells are present but missed or misclassified by the screener (Wilkinson, 1990). Mandated quality assurance measures and computerized slide-screening technologies address screening errors. Suboptimal management of abnormal results by providers and failure of patient follow up also contribute to avoidable cases of cervical cancer. Clinicians can maximize the benefit of screening by obtaining an optimal

cytologic specimen and by adhering to current evidence-based guidelines for the management of abnormal test results.

### Performing a Pap Test

Ideally, Pap tests are scheduled to avoid menstruation. Patients should abstain from vaginal intercourse, douching, vaginal tampon use, and intravaginal medicinal or contraceptive creams for a minimum of 24 to 48 hours before a test. Treatment of cervicitis or vaginitis prior to Pap testing is optimal. However, Pap testing is not deferred due to unexplained discharge or unscheduled bleeding, as these may be signs of cervical or other genital tract cancers.

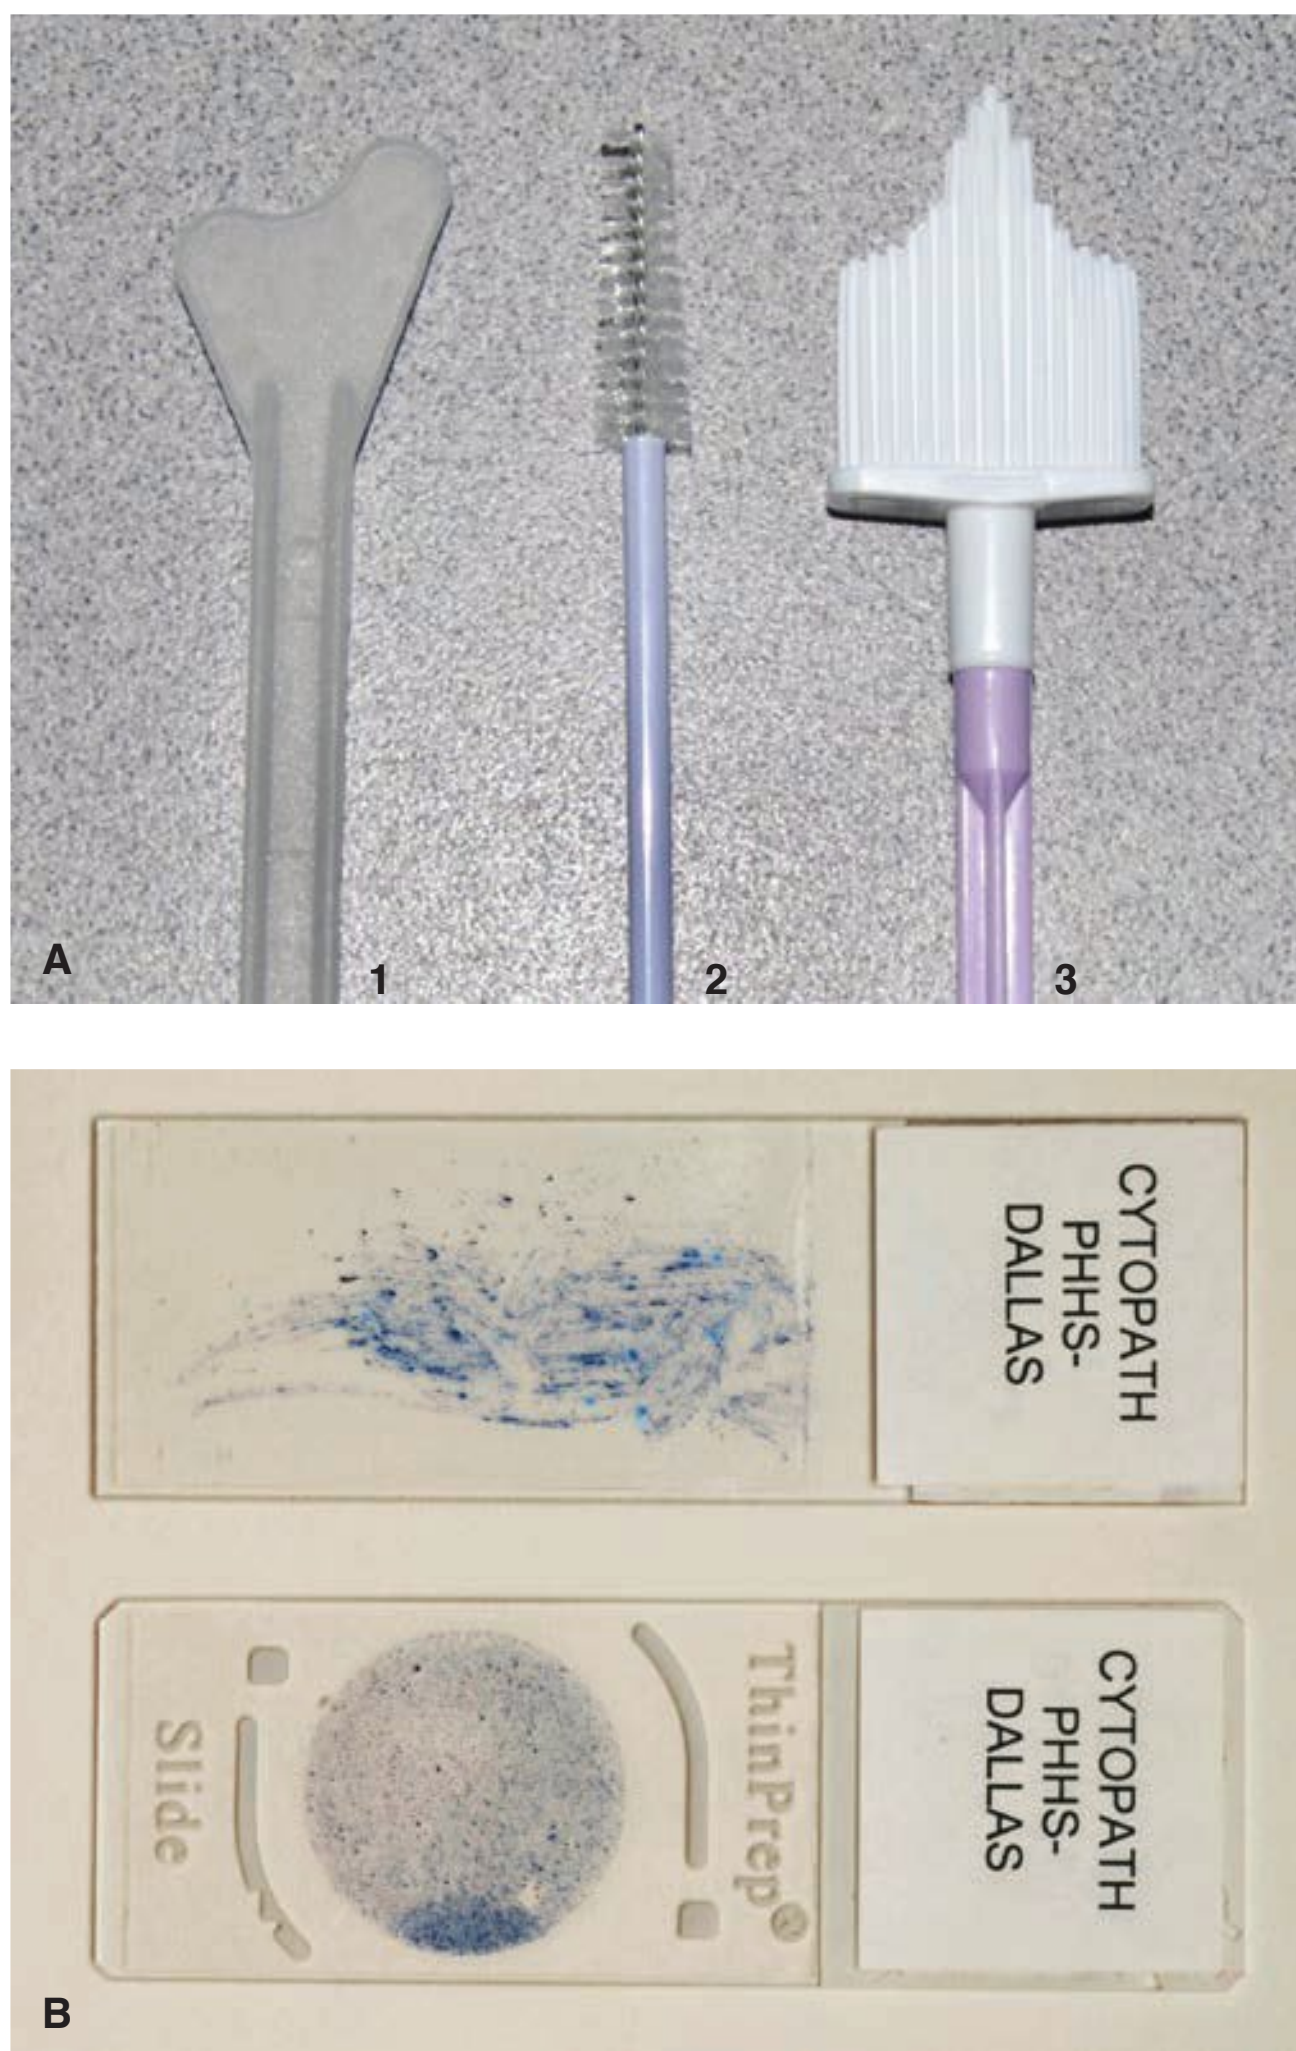

As shown in Figure 21-9 (p. 488), the appearance of cervical squamous cells varies throughout the menstrual cycle and with hormonal status. Thus, clinical information aids accurate Pap interpretation and often includes: date of last menstrual period, current pregnancy, exogenous hormone use, menopausal status, complaints of abnormal bleeding, and prior abnormal Pap test results, CIN, or other LGT neoplasia. Additionally, intrauterine devices (IUDs) can cause reactive cellular changes, and their presence is noted. Full visualization of the cervix is essential for detection of gross lesions and SCJ identification. Speculum placement should be as comfortable as possible. A thin coating of water-based lubricant can be used on the outside of the speculum blades without compromising Pap test quality or interpretation (Griffith, 2005; Harmanli, 2010). Touching the cervix prior to performing a Pap test is avoided, as dysplastic epithelium may be inadvertently removed with minimal trauma. Discharge covering the cervix may be carefully absorbed by a large swab, with care not to contact the cervix. Vigorous blotting or rubbing may cause scant cellularity or a false-negative Pap test result. When indicated, additional sampling to detect other cervical or vaginal infection may follow Pap test collection.

Sampling of the transformation zone at the SCJ is paramount to the sensitivity of the Pap test. Techniques are adapted and sampling devices chosen according to SCJ location, which varies widely with age, obstetric trauma, and hormonal status. Women known or suspected of in utero DES exposure may also benefit from a separate Pap test of the upper vagina, as these women carry an additional risk for vaginal cancer.

Three types of plastic devices are commonly used to sample the cervix: the spatula, broom, and endocervical brush (also known as a cytobrush) (Fig. 29-8). A spatula predominantly samples the ectocervix. An endocervical brush samples the endocervical canal and is used in combination with a spatula. A broom samples both endo- and ectocervical epithelia simultaneously but can be supplemented by an endocervical brush. Wooden collection devices and cotton swabs are no longer recommended due to their inferior collection and release of cells.

A spatula is oriented to best fit the cervical contour, straddle the squamocolumnar junction, and sample the distal endocervical canal. A clinician firmly scrapes the cervical surface, completing at least one full rotation. After the spatula sample is obtained, the endocervical brush, with its conical shape and plastic bristles, is inserted into the endocervical canal only until the outermost bristles remain visible just within the external os. This prevents inadvertent sampling of lower uterine segment cells, which can be mistaken for atypical cervical cells. To avoid

**FIGURE 29-8** **A.** Cervical cytology collection devices: (1) Plastic spatula. (2) Endocervical brush. (3) Plastic broom. **B.** Pap preparations. Conventional cervical cytology is prepared by smearing collected cells directly onto a glass slide with the collection device followed by immediate fixation (upper slide). Liquid-based cytology involves transfer of collected cells from the collection device into a liquid transport medium with subsequent processing and transfer onto a glass slide. Cells are distributed over a smaller area, and debris, mucus, blood, and cell overlap are largely eliminated, allowing computer-assisted screening (lower slide). (Used with permission from Dr. Raheela Ashfaq.)

obscuring blood, the brush is rotated only one-quarter to one-half turn and is used after the ectocervix has been sampled. If the cervical canal is very wide, the brush is moved so as to contact all surfaces of the endocervical canal.

Broom devices have longer central bristles that are inserted into the endocervical canal. These longer bristles are flanked by shorter bristles that splay out over the ectocervix during rotation. Five rotations in the same direction are recommended. Reversing direction may cause loss of cellular material. Broom devices are favored for liquid-based Pap testing.

### Cytology Collection

Conventional slide collection requires special care to avoid air drying artifact, a leading cause of poor slide quality. The spatula

sample is held while the endocervical brush sampling immediately follows. The spatula sample is then quickly spread as evenly as possible over one half to two thirds of a glass slide (see Fig. 29-8). The endocervical brush is firmly rolled over the remaining area of the slide, after which fixation is quickly carried out by spraying from a distance of 10 to 12 inches or immersing the slide in fixative.

Currently, two liquid-based cytology (LBC) Pap tests are FDA approved. Sampling and cell transfer to a liquid medium is performed according to manufacturer specifications. SurePath allows for the use of all three device types but uses modified tips that are broken off and sent to the laboratory in the liquid medium. ThinPrep requires immediate and vigorous agitation of the chosen collection device(s) in the liquid medium, after which the device is discarded.

### ■ hPV Testing

A role for HR HPV testing in cervical cancer screening is attractive due to its improved sensitivity for CIN 3 or cervical cancer and the objectivity of its results. However, strategies for incorporation of HPV testing must compensate for a decreased specificity, particularly in young women.

### Cytology with HPV Cotesting

In 2003, the FDA first approved an HPV test for use with cytology for cervical cancer screening in women 30 years and older. The combination of HR HPV testing with cytology is referred to as *cotesting*. This strategy is not currently endorsed for women younger than 30 due to the high prevalence of HR HPV infection in this age group and the resultant lack of test specificity. HPV testing is usually performed from the residual LBC specimen after the cytology slide is prepared. Alternatively, a cervical sampling for HPV can be sent in a specific collection device separate from the cytology specimen. Testing is performed only for HR HPV types. As noted earlier, there is no clinical role for LR HPV testing (Castle, 2014; Tomsen, 2014).

The combination of HPV testing with cytology increases the sensitivity of a single screening test for high-grade neoplasia to nearly 100 percent and leads to earlier detection and management of HSIL (Ronco, 2010). The lack of sensitivity for cervical adenocarcinoma seen with traditional cytology testing also supports HPV testing use for primary screening (Castellsagué, 2006).

Due to a high negative predictive value for high-grade neoplasia, slow progression of new HPV infection to neoplasia, and increased cost, cotesting is repeated at 5-year intervals if both cytology and HPV test are negative. Clinical guidelines have been developed for management of abnormal cotest results (Saslow, 2012). If cytology is abnormal, current cytology management guidelines are followed (p. 636). Cytology-negative and HPV-positive test results will occur in less than 10 percent of screened patients (Castle, 2009a; Datta, 2008). In such cases, cotesting is repeated 12 months later. This is because the risk of high-grade neoplasia is less than that of a Pap test with an atypical squamous cell of undetermined significance (ASC-US) result, and most HPV infections will resolve during this time (Saslow, 2012). Colposcopy is recommended for persistently

positive HPV DNA test results. An abnormal repeat cytology result is managed according to current guidelines regardless of concurrent HPV status.

An alternative strategy is now available for management of a negative cytology but a positive HR HPV test result. A reflex test specifically for HPVs 16 and 18, called *genotyping*, can be performed. If positive, immediate colposcopy is recommended (American College of Obstetricians and Gynecologists, 2012b; Saslow, 2012). This approach targets those at highest risk for significant disease, and evidence provides a sound basis for this strategy (Khan, 2005; Wright, 2015).

### Primary HPV Testing

A growing body of evidence supports HR HPV testing alone without initial cytology as an option for primary cervical cancer screening (Castle, 2011; Cuzick, 2006; Dillner, 2013). In late 2014, the cobas HPV test was the first HPV test approved by the FDA for primary cervical cancer screening in women 25 years and older. This test gives simultaneous results for the presence or absence of HPVs 16 and 18 and for a group of 12 other oncogenic HPV types. This represents a profound paradigm shift in cervical cancer screening, in which Pap testing assumes a secondary role for the triage of HPV positive results.

HPV testing alone is approximately twice as sensitive (> 90 percent) as a single Pap test and leads to earlier detection of high-grade neoplasias. The very high negative-predictive value of a single negative HPV test was shown by Sankaranarayanan (2009). During this 8-year study, a single round of HPV testing outperformed cytology, with no cervical cancer deaths within 8 years of a negative HR HPV test result. Recent evaluations show that cotesting does not perform any better than HPV testing alone (Dillner, 2013; Whitlock, 2011). However, specificity declines with HPV testing, particularly in younger women (Mayrand, 2007; Ronco, 2006, 2010). This could lead to excessive numbers of colposcopies, biopsies, and treatments. Triage of women with positive non-HPV16/18 HPV test results to reflex cytology is a viable counterbalance to the decreased specificity. Overall, this strategy is expected to result in more colposcopic referrals but yield higher and earlier HSIL detection rates.

Suggested interim guidelines for primary HPV test screening are recently published and will no doubt be debated and revised in coming years (Huh, 2015). These propose that screening with a HR HPV test can be used as an alternative to cytology alone or cotesting in women 25 years and older and at intervals no less than 3 years. Immediate colposcopy is recommended if HPV 16/18 is identified. If other HR HPV types are found, then triage to reflex cytology is proposed. Colposcopy is recommended for any cytologic abnormality. Importantly, as of mid-2015, major cervical cancer screening guidelines do not include this screening option.

## ■ Cervical Cancer Screening Guidelines

### Perspective on Guidelines

Notably, *all* approved cervical cancer screening strategies, including the use of periodic cytology alone, dramatically reduce a woman's lifetime risk of developing or dying from cervical cancer. Since most women with positive HR HPV

test results will not develop significant disease, the choice of screening strategy should be a shared decision by the provider and individual patient. Reviewed by the National Cancer Institute (2015a), the balance of benefits and harms of each screening strategy warrants careful consideration by both health care providers and health care policy agencies. With that perspective, guidelines are subsequently presented.

Evidence-based cervical cancer screening guidelines continue to evolve. In 2012, all major professional societies updated these. The American Cancer Society, the American Society for Colposcopy and Cervical Pathology, and the American Society for Clinical Pathology (ACS/ASCCP/ACP) jointly issued guidelines (Saslow, 2012). The U.S. Preventive Services Task Force (USPSTF) (Moyer, 2012) and the American College of Obstetricians and Gynecologists (2012b) each published guidelines as well. These three sets of guidelines agree with few exceptions and pertain only to average-risk women, that is, immunocompetent women with no history of HSIL or cervical cancer. All agree on the acceptability of both conventional and liquid-based Paps, the age of initiation and cessation of screening, screening intervals, and continued screening after HPV vaccination. Adherence to current guidelines should not preclude or delay other indicated gynecologic care. In particular, provision of contraception is never contingent on compliance with cervical cancer screening recommendations or the evaluation of cytologic abnormalities.

### Screening Initiation

Cervical cancer screening ideally begins at age 21 in average-risk women. This is true regardless of sexual history, sexual orientation, or other risks. In young women, most Pap abnormalities represent transient HPV infection, and the spontaneous regression of even high-grade lesions is common (Moscicki, 2005). Most high-grade lesions are CIN 2 rather than CIN 3 in young women (Moscicki, 2008). Cervical cancer is exceedingly rare in adolescents and not as preventable by screening as for older women (Saslow, 2012). Additionally, treatment of high-grade CIN in adolescents is often followed by persistence of Pap abnormalities, and theoretically may have adverse reproductive consequences (Case, 2006; Moore, 2007).

Whether to begin screening earlier in the presence of significant immune compromise, as with HIV infection, use of immunosuppressive medications, and organ transplantation, is uncertain and not addressed by current guidelines. The Centers for Disease Control and Prevention (CDC) (2015) recommends initiation of screening soon after HIV diagnosis, even if before age 21, and repeat Pap testing in 6 months. As for other such conditions, clinician judgment is exercised, taking into consideration age and severity of immune compromise. In general, initial screening at age 21 seems reasonable (American College of Obstetricians and Gynecologists, 2012a).

### Screening Interval and Strategy

Between ages 21 and 29, all guidelines recommend screening with cytology alone at 3-year intervals. Women aged 30 to 65 can continue screening with cytology alone at 3-year intervals or can begin cotesting at 5-year intervals. The risk of cancer is approximately the same using either strategy. USPSTF sees

both strategies as equally effective, and cotesting is available to women wishing to extend their screening interval. However, both the ACS/ASCCP/ACP (Saslow, 2012) and American College of Obstetricians and Gynecologists (2012b) have deemed cotesting the preferred screening strategy in women 30 years and older. Women with HIV infection and other immune suppression should receive annual cytology screening (Centers for Disease Control and Prevention, 2015; American College of Obstetricians and Gynecologists, 2012a).

Screening Discontinuation

Screening may be stopped in women older than 65 if they have an average risk for cervical cancer and have undergone adequate screening, regardless of sexual history. Adequate screening is three consecutive, negative Pap results or two consecutive, negative cotest results in the prior 10 years, with the most recent within the past 5 years. Women with prior treatment for CIN 2, CIN 3, AIS, or cervical cancer should continue routine screening for at least 20 years, as they remain at increased long-term risk of cervical cancer (Saslow, 2012; Strander, 2007). It is uncertain when HIV-positive women can discontinue screening or whether this should continue annually and indefinitely for as long as there is reasonable life expectancy.

Posthysterectomy

Vaginal cancers are rare and account for less than 2 percent of cancers in women. All guidelines recommend against Pap screening in women who have undergone total hysterectomy for benign disease if there is no past history of high-grade CIN or cervical cancer. The absence of a cervix should be confirmed by examination or pathology report as many women are inaccurate in their reporting of hysterectomy type. Women who have undergone supracervical hysterectomy should continue routine screening. Recommendations for vaginal cytology after hysterectomy in women with histories of high-grade cervical neoplasia or cancer are less clear, as vaginal cancer is still rare, and screening is of uncertain benefit (Saslow, 2012). The American College of Obstetricians and Gynecologists (2012b) recommends cytology of the vaginal cuff every 3 years for 20 years after the initial posttreatment surveillance, which is generally a schedule of three Pap tests in the first 2 years posthysterectomy. HPV testing is not FDA-approved in the absence of a cervix but remains common. Evidence-based recommendations for managing vaginal HPV test results are nonexistent (Chappell, 2010). Such testing should be avoided.

■ The Bethesda System

Cervical cytology reporting is standardized by the Bethesda System nomenclature (National Cancer Institute Workshop, 1989; Nayar, 2015; Solomon, 2002). Clinically, the key elements reported are specimen adequacy and epithelial cell abnormalities (Tables 29-3 and 29-4). An overview of evidence-based guidelines for the initial management of cervical cytology abnormalities for nonpregnant women follows in the next paragraphs (American College of Obstetricians and Gynecologists, 2013; Massad, 2013). Full guidelines should be reviewed and applied on an individualized basis. Guidelines cannot address all clinical situations or prevent all cervical cancers.

TABLE 29-3. The 2014 Bethesda System Cytology Report Components

<b>Specimen type</b>
Conventional (Pap smear)
Liquid-based (Pap test)
Other
<b>Specimen adequacy</b>
Satisfactory for evaluation
Unsatisfactory for evaluation (reason specified)
<b>General categorization (optional)</b>
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormality (see Table 29-4)
Other (see Interpretation/Results)
<b>Interpretation/Results</b>
Negative for intraepithelial lesion or malignancy
Epithelial cell abnormalities (see Table 29-4)
Nonneoplastic findings (optional)
Cellular variations (atrophy, keratosis, metaplasia)
Reactive cellular changes (inflammation, repair, radiation)
Glandular cells status posthysterectomy
Organisms
Trichomonas vaginalis
Fungal organisms consistent with Candida spp
Shift in flora suggestive of bacterial vaginosis
Cellular changes consistent with herpes simplex virus
Cellular changes consistent with cytomegalovirus
Bacteria consistent with Actinomyces spp
Other nonneoplastic findings (optional)
Other
Endometrial cells in a woman ≥ 45 years of age
Other malignant neoplasms (specified)
<b>Adjunctive testing</b>
<b>Computer-assisted interpretation</b>
<b>Educational notes and comments (optional)</b>

Specimen Adequacy

This is reported as *satisfactory* or *unsatisfactory* for evaluation and is based primarily on criteria for slide cellularity and the presence of obscuring blood or inflammation. The presence or absence of TZ components, that is, endocervical and/or squamous metaplastic cells, is also reported. A TZ component is not required for test adequacy. Although its presence is associated with increased detection of cytologic abnormalities, its absence is not associated with failure to diagnose CIN. Pap tests lacking TZ components are repeated in 3 years. For women 30 years and older, HPV testing is preferred and further testing is guided by results.

Unsatisfactory Pap tests are unreliable for the detection of cervical neoplasia and also for HR HPV by some HPV tests. Unsatisfactory Pap tests are repeated in 2 to 4 months. If atrophy or a specific infection is present, treatment before repeat cytology may be helpful. If the result is unsatisfactory again,

**TABLE 29-4.** The 2014 Bethesda System: Epithelial Cell Abnormalities

<b>Squamous cell</b>
Atypical squamous cells (ASC):
of undetermined significance (ASC-US)
cannot exclude HSIL (ASC-H)
Low-grade squamous intraepithelial lesion (LSIL)
High-grade squamous intraepithelial lesion (HSIL)
Squamous cell carcinoma
<b>Glandular cell</b>
Atypical glandular cells (AGC):
Endocervical, endometrial, or not otherwise specified
Atypical glandular cells, favor neoplastic:
Endocervical or not otherwise specified
Endocervical adenocarcinoma in situ (AIS)
Adenocarcinoma

colposcopy is recommended as this persistent result confers increased CIN risk. Rarely, obscuring blood or inflammation on cervical cytology may indicate invasive cancer. Therefore, unexplained vaginal discharge, abnormal bleeding, or abnormal physical findings should prompt immediate evaluation rather than waiting for repeat Pap testing.

**Epithelial Cell Abnormality Management**

A cytology report is a medical consultation that interprets a screening test and does not provide a diagnosis. A final diagnosis is determined clinically, often with results from histologic evaluation. Pap tests are interpreted as either being negative for intraepithelial lesion or malignancy (NILM) or demonstrating one or more epithelial cell abnormalities.

**Atypical Squamous Cells of Undetermined Significance.**

The most common cytologic abnormality is ASC-US. This term indicates cells that suggest SIL but do not fulfill all the criteria. An ASC-US result often precedes the diagnosis of CIN 2 or 3, but this risk approximates only 5 to 10 percent. Cancer is found in only 1 to 2 per thousand (Solomon, 2002).

Management of ASC-US without HPV cotesting is repeat cytology in 1 year, and this is preferred for women aged 21 to 24. If the repeat Pap test result is abnormal, colposcopy is recommended. Reflex HPV testing is preferred in women 25 years and older and acceptable in those age 21 to 24 years. *Reflex testing* refers to HPV testing in response to a specific result and is not performed if cytology is negative. With an ASC-US Pap result, reflex HPV testing is a good discriminator of those with high-grade CIN and those without. ASC-US, HPV-positive test results have a risk profile similar to LSIL results and thus are evaluated with colposcopy. ASC-US, HPV-negative results are followed up with a cotest in 3 years or with cytology alone in women under age 25.

**Low-grade Squamous Intraepithelial Lesion.** LSIL encompasses the cytologic features of HPV infection and

CIN 1 but carries a 15 to 30 percent risk of CIN 2 or 3, similar to ASC-US, HPV-positive. Therefore, colposcopy is generally indicated for LSIL cytology.

Specifically, for LSIL with no HPV testing or with HPV-positive results, colposcopy is indicated in women aged 25 years and older. If a negative HPV test result is obtained due to cotesting, a repeat cotest in 1 year is preferred, but colposcopy is acceptable. Reflex HPV testing with an LSIL result is not useful in reproductive-aged women, as 75 to 85 percent will test positive for HR HPV. In women aged 21 to 24 years with an LSIL result, cytology follow-up is preferred to immediate colposcopy due to high rates of resolution. For postmenopausal women with LSIL and no HPV cotest, options include repeat cytology at 6 and 12 months, HPV testing, or colposcopy.

**Atypical Squamous Cells, Cannot Exclude hSIL.** Five to 10 percent of ASC is designated as atypical squamous cells, cannot exclude HSIL (ASC-H). This finding should not be confused with ASC-US. ASC-H describes cellular changes that do not fulfill criteria for HSIL cytology, but a high-grade lesion cannot be excluded. Histologic HSIL is found in upward of 25 percent of these cases, which is a higher rate than seen with ASC-US or LSIL. Thus, colposcopy is indicated regardless of age or concurrent HPV test result. Reflex HPV testing is not helpful due to a high rate of HPV-positivity. If colposcopy is inadequate, a diagnostic excision procedure is recommended.

**high-grade Squamous Intraepithelial Lesion.** HSIL cytology encompasses features of CIN 2 and CIN 3 (Fig. 29-9). It carries an elevated risk of underlying histologic HSIL (at least 70 percent) or invasive cancer (1 to 2 percent) (Kinney, 1998). Colposcopic evaluation is warranted for all HSIL cytology regardless of age or HPV status. Alternative management of HSIL cytology in women 25 years and older includes immediate loop electrosurgical excision procedure (LEEP), which is referred to as a *see-and-LEEP* approach. This strategy is reasonable because colposcopy may miss a high-grade lesion, and most HSIL cytologies eventually result in excision for diagnosis or treatment. Inadequate colposcopy should prompt excision unless initial biopsies show invasive cancer.

**Glandular Cell Abnormalities.** This group includes atypical glandular cells (AGC); AGC, favor neoplasia; and AIS. This category carries an increased risk of neoplasia (Zhao, 2009). Paradoxically, squamous neoplasia is more frequently diagnosed than glandular neoplasia upon evaluation of AGC cytology (Schnatz, 2006). There is also an elevated risk of endometrial and other reproductive tract cancers and cancers at other sites such as breast and colon. Approximately half of the neoplasia diagnosed subsequent to an AGC Pap is endometrial.

Accordingly, initial evaluation of a glandular abnormality includes colposcopy and endocervical sampling. It also includes endometrial sampling in patients 35 years and older or in younger women with risk factors for endometrial disease, which include abnormal bleeding or history suggesting chronic anovulation. If atypical endometrial cells are specified in the report, then initial endometrial and endocervical sampling is acceptable with subsequent colposcopy if these are negative.

**FIGURE 29-9** **A.** Normal Pap test. A fragment of benign endocervical epithelium with the characteristic “honeycomb” appearance conferred by the presence of cytoplasmic mucin is seen (arrow). Benign parabasal, intermediate, and superficial squamous cells are present in the background. **B.** Pap test reflecting high-grade squamous intraepithelial lesion. The dysplastic squamous cells have nuclear membrane irregularities and coarse chromatin. The increased nuclear to cytoplasmic size ratio would classify this as a moderate squamous dysplasia (CIN 2). (Used with permission from Ann Marie West, MBA, CI[ASCP].)

Reflex HPV testing is not recommended for the triage of glandular cytologic abnormalities. Indeed, a negative reflex HPV test result may dissuade appropriate evaluation of AGC cytology. However, HPV testing at the initial evaluation of AGC may help distinguish cervical from endometrial disease (Castle, 2010; de Oliveira, 2006).

If initial evaluation of glandular cytologic abnormalities is negative, management and surveillance are generally aggressive due to the significant risk of occult disease. Current guidelines should be followed (American College of Obstetricians and Gynecologists, 2013; Massad, 2013). Diagnostic excision is indicated following AGC, favor neoplasia and AIS Paps if initial evaluation does not result in a cancer diagnosis.

**Carcinoma.** Cytologies suspicious for squamous cell carcinoma or adenocarcinoma carry the highest risk of invasive cancer and are evaluated promptly. If initial evaluation fails to reveal invasive cancer, a diagnostic excision procedure is indicated.

**Pregnancy.** Pregnant patients 21 years and older are screened and their abnormal cytologies managed according to guidelines for the general population. However, deferred evaluation of ASC-US and LSIL cytologies until at least 6 weeks postpartum is acceptable (Massad, 2013). When indicated, the goal of colposcopy is to exclude invasive cancer. Colposcopy and ectocervical biopsy are safe and accurate during pregnancy (Economos, 1993). Endocervical and endometrial sampling are not performed during pregnancy to avoid amnionic membrane rupture and infection. Preinvasive neoplasia is not treated but rather is reevaluated postpartum. This is because lesion progression is typically slow and lesion grade may change during delivery and puerperal remodeling (Yost, 1999). Although cervical conization is infrequently performed during pregnancy, indications for this are discussed in Chapter 30 (p. 675).

### Nonneoplastic Findings

Certain nonneoplastic findings may be reported, and these include findings consistent with, but not conclusively diagnos-

tic of, certain organisms. These findings include *Trichomonas vaginalis*, *Candida* species, *Actinomyces* species, herpes simplex virus, or shift in flora consistent with bacterial vaginosis. Sensitivity is generally limited, and accuracy of diagnosis varies (Fitzhugh, 2008). For this reason, confirmatory tests or clinical correlation should dictate any actions related to these findings. Other nonneoplastic findings are reactive changes associated with inflammation or repair, radiation changes, atrophy, and posthysterectomy benign glandular cells. None of these require a clinical response.

Benign endometrial cells seen in the cervical cytology of a postmenopausal woman confer an increased risk of endometrial hyperplasia and cancer. Because menstrual history and menopausal status are often unknown to the cytologist, benign endometrial cells are reported on cervical cytology for all women 45 years and older (Nayar, 2015). Premenopausal women do not require endometrial evaluation in the absence of abnormal bleeding.

## ■ Colposcopy

### Preparation

This outpatient procedure examines the lower anogenital tract with a binocular microscope affixed to a stand and requires skills that encompass colposcopic terminology, lesion identification and grading, and biopsy techniques. Its primary goal is to identify invasive or preinvasive neoplastic lesions for directed biopsy and subsequent management. It remains the gold standard evaluation of patients with abnormal cervical cytology. However, its sensitivity, interobserver agreement, and reproducibility are less than previously thought. Sensitivity estimates range between 50 and 80 percent (American College of Obstetricians and Gynecologists, 2013; Ferris, 2005; Jeronimo, 2007). This highlights the need for further evaluation or surveillance when initial colposcopy fails to reveal high-grade neoplasia.

**FIGURE 29-10** Evaluation of surface vessels. **A.** Benign surface vessels viewed through a colposcope using usual white light source. **B.** Use of a blue-green (red-free) light filter provides higher contrast and definition of vascular patterns.

There are many styles of colposcopes, but they all operate similarly. The colposcope contains a stereoscopic lens or digital imaging system that has magnification settings ranging from 3- to 20-fold. Its stand allows positioning, and a high-intensity light provides illumination. A green (red-free) light filter adds contrast to aid vascular pattern evaluations (Fig. 29-10).

Prior to colposcopic examination, a woman’s medical history and record are reviewed and indications for colposcopy confirmed (Table 29-5). Urine pregnancy testing is performed if clinically indicated. Colposcopic examination is optimally timed to avoid menses. However, it is not delayed in the patient with a visible lesion, abnormal bleeding, or poor appointment compliance. In cases of severe cervicitis or other pelvic infection, treatment may be indicated before performing biopsies or endocervical curettage. Notably, abnormal cervical discharge in the absence of an identified pathogen may be a cancer indicator. A Pap test performed at the time of colposcopy is of questionable value, may obscure colposcopic findings, and should be performed on an individualized basis.

Solutions may aid colposcopic examination and are applied by gently dabbing a saturated swab or sponge or by spray-bottle misting so as not to traumatize the cervical epithelium. High-

**TABLE 29-5.** Clinical Considerations Directing Colposcopy

<b>Clinical objectives</b>
Provide a magnified view of LGT
Identify cervical squamocolumnar junction
Detect lesions suspicious for neoplasia
Direct lesion biopsy
Monitor patients with current or past LGT neoplasia
<b>Clinical indications</b>
Grossly visible LGT lesion
Abnormal cervical cancer screening
In utero diethylstilbestrol exposure
<b>Contraindications:</b> none
<b>Relative contraindications</b>
Upper or lower reproductive tract infection
Uncontrolled severe hypertension
Uncooperative or overly anxious patient

LGT= lower genital tract.

grade cervical lesions are particularly fragile. To begin, normal saline can help remove cervical mucus and allows initial assessment of vascular patterns and surface contours. Abnormal vessels, especially when viewed with green-filtered light, may be more prominent before acetic acid application.

Acetic acid in a 3- to 5-percent solution is a mucolytic agent thought to exert its effect by reversibly clumping nuclear chromatin. This causes neoplastic lesions to assume a thicker density and hues of white depending on the degree of abnormal nuclear density. Applying acetic acid to abnormal epithelium results in the *acetowhite change* characteristic of neoplastic lesions and of some benign conditions. Several minutes may be needed for this effect to become fully developed.

Dilute Lugol iodine solution stains mature squamous epithelial cells a dark purple-brown color in estrogenized women as a result of high cellular glycogen content. Due to incomplete cellular differentiation, dysplastic cells have lower glycogen content, fail to fully stain, and appear various shades of yellow (Fig. 29-11). This solution is particularly useful when abnormal tissue cannot be found using acetic acid alone. It is also used to define the limits of the active TZ, as immature squamous metaplasia does not stain as strongly as mature (fully differentiated) squamous epithelium. Lugol solution should not be used in patients allergic to iodine, radiographic contrast, or shellfish.

**Examination**

Two major components of colposcopic examination are general assessment and specific colposcopic findings. Careful description of these aids diagnosis and management of abnormalities. For this, standard colposcopic terminology used in the United States differs somewhat from that proposed by the International Federation for Cervical Pathology and Colposcopy (IFCPC) (Bornstein, 2012).

General colposcopic assessment has three components: cervical visualization, SCJ visibility, and TZ classification. First,

**FIGURE 29-11** Solutions used for colposcopy. **A.** Cervix after application of acetic acid. Several areas of acetowhite change adjacent to the squamocolumnar junction are apparent. **B.** Same cervix after application of Lugol iodine solution. Nonstaining of the lesions at the 10 to 11 o'clock positions is seen (black arrow), while there is partial iodine uptake of acetowhite areas along the posterior SCJ (white arrow).

every examination is characterized by whether the cervix is fully seen or whether the evaluation is limited by inflammation, bleeding, scarring, or other obscuring causes. The IFCPC labels full cervix visualization as “adequate” and otherwise as “inadequate.” However, current guidelines for management of abnormal cervical cytology and precancers issued by the ASCCP and standard U.S. practice reserve these descriptors for visibility of the SCJ and any lesions present (Massad, 2013).

Second, SCJ visibility is important, as nearly all cervical neoplasia is located within the TZ and at or adjacent to the SCJ. Within a neoplastic lesion, the most severe disease tends to be at the proximal (cephalad or upper) limit of the lesion. Therefore, the ability to see the entire SCJ and the upper limits of all lesions is essential to exclude invasive cancer and to determine disease severity. The IFCPC terminology characterizes the SCJ separately as completely, partially, or not visible. Current ASCCP guidelines define full visualization of both the SCJ and upper limits of all lesions present as “adequate.” Otherwise, the examination is “inadequate” (Fig. 29-12). Finally, the IFCPC classifies the TZ location as types 1, 2, or 3. A type 1 TZ is entirely ectocervical and visible; a type 2 has an endocervical component that is fully visible; and a type 3 TZ has an endocervical component that cannot be completely visualized. Types 2 and 3 may have ectocervical TZ components of varying extent. If treatment is indicated, the size and location of the SCJ, TZ, and visible lesions are important determinants of the modality chosen.

### Lesion Grading

Colposcopically, normal squamous epithelium of the cervix appears as a featureless, smooth, pale-pink surface. Blood vessels lie below this layer and therefore are not visible or are seen only as a fine capillary network. The mucin-secreting columnar epithelium appears red due to its thinness and the close proximity of blood vessels to the surface. It has a polypoid appearance due

to infoldings that form peaks and clefts (see Fig. 29-3). Against this normal colposcopic landscape, colposcopists discern abnormal tissue and choose for biopsy the sites most likely to harbor the most severe neoplasia. Several colposcopic grading systems quantify lesion qualities to improve diagnostic accuracy (Coppleson, 1993; Reid, 1985). Best known, the Reid Colposcopic Index is based on four lesion features, which are margin, color, vascular pattern, and Lugol solution staining. Each category is scored from 0 to 2, and the summation provides a numeric index that correlates with histology (Table 29-6).

The IFCPC has proposed a standardized nomenclature for lesion grading and recommends that it replace prior

**FIGURE 29-12** In colposcopic cases in which the squamocolumnar junction is initially inadequately seen, an endocervical speculum can aid in viewing the endocervical canal.

TABLE 29-6. Reid Colposcopic Index

Colposcopic Sign	Zero Points	1 Point	2 Points
Margin	Condylomatous Micropapillary Feathery Satellite lesions	Smooth Straight	Rolled Peeling Internal border
Color: acetowhitening	Shiny Snowy Translucent Transient	Duller white	Dull white Gray
Vessels	Fine patterns Uniform caliber and patterns	Absent	Coarse patterns Dilated with variable caliber and intercapillary distances
Iodine staining	Positive	Partial	Negative

Modified with permission from Reid R, Scalzi P: Genital warts and cervical cancer. VII. An improved colposcopic index for differentiating benign papillomaviral infections from high-grade cervical intraepithelial neoplasia. *Am J Obstet Gynecol* 1985 Nov 15;153(6):611–618.

terminologies (Bornstein, 2012). Lesions with low-grade characteristics are labeled grade 1 (minor) lesions, whereas higher-grade characteristics are grade 2 (major) findings.

Of Reid index features, lesion margins and color are best assessed following application of acetic acid. The color or degree of whiteness obtained, rapidity and duration of acetowhitening, and sharpness of lesion borders are observed. Grade 2 (major or high-grade) lesions demonstrate a more persistent, duller shade of white, whereas grade 1 (minor or low-grade) lesions are translucent or bright white and fade quickly. Generally, grade 1 lesions have feathery or irregular “geographic” margins, whereas grade 2 lesions have straighter, sharper outlines (Figs. 29-13 and 29-14). Other lesion features suggestive of a high-grade lesions are: internal borders (inner border sign), an opaque protuberance within a lesion (ridge sign), and cuffed crypt openings.

Abnormal vascular patterns include punctation, mosaicism, and atypical vessels. Punctate and mosaic patterns are graded on the basis of vessel caliber, intercapillary distance, and the

uniformity of each of these. Fine punctation and mosaicism, which are created by narrow vessels and short, uniform intercapillary distances, typify low-grade (grade 1) lesions. A coarse pattern results from wider and more variable vessel diameters and spacing and indicates high-grade (grade 2) abnormalities. Atypical vessels are irregular in caliber, shape, course, and arrangement and raise suspicion for invasive cancer (Fig. 29-15).

■ Biopsy  
Ectocervical Biopsy

Under direct colposcopic visualization, suspicious lesions are biopsied using cervical biopsy forceps (Fig. 29-16). Generally, cervical biopsy does not require an anesthetic. The tickened Monsel solution (ferric subsulfate) or a silver nitrate applicator are applied with pressure to the biopsy site, providing hemostasis if needed. Heavier bleeding is rare and can be controlled with direct pressure or brief vaginal packing.

FIGURE 29-13 Low-grade squamous intraepithelial lesion (LSIL). After 5-percent acetic acid application, LSIL is often multifocal and bright white with irregular borders.

FIGURE 29-14 High-grade squamous intraepithelial lesion (HSIL). After 5-percent acetic acid application, HSIL demonstrates off-white dull color and coarse vascular pattern.

**FIGURE 29-15** Colposcopy shows a large high-grade lesion with cuffed crypt openings (arrow) and atypical vessels (arrowheads) that are worrisome for invasive cancer.

Traditionally, biopsies have been limited to the most severe-appearing lesions. However, two studies have shown that colposcopically directed biopsy detects only 60 to 70 percent of high-grade disease. Disease detection rates increase with the addition of random biopsies of normal-appearing epithelium and with the total number of biopsies taken (Gage, 2006; Pretorius, 2004; Zuchna, 2010)). The American College of Obstetricians and Gynecologists (2013) recommends biopsy of all acetowhite lesions regardless of colposcopic impression, and repeat colposcopic evaluation is suggested for persistent low-grade cytologic abnormalities or HPV-positive results to counter the imperfect detection of HSIL by colposcopy.

### Endocervical Sampling

For nonpregnant patients, endocervical sampling by curettage or brushing evaluates the endocervical canal epithelium that lies beyond the colposcope's view. Endocervical sampling is currently recommended during colposcopy in the following situations

**FIGURE 29-16** Tools used for cervical evaluation and biopsy. From top to bottom: endocervical curette, endocervical speculum, and cervical biopsy forceps.

(American College of Obstetricians and Gynecologists, 2013; Massad, 2013):

- Colposcopy is inadequate, or colposcopy is adequate but no lesion is identified. Endocervical sampling is acceptable in other cases at provider discretion.
- Initial evaluation of ASC-H, HSIL, AGC, or AIS cytology test results.
- Surveillance 4 to 6 months after excisional therapy if specimen margins are positive for HSIL.
- Surveillance after conization for AIS has been performed in women wishing fertility preservation. Negative endocervical curettage results add reassurance to this management (Schorge, 2003).

Endocervical sampling can be performed by either curettage or brushing. Endocervical curettage is performed by introducing an endocervical curette 1 to 2 cm into the cervical canal (see Fig. 29-16). The length and circumference of the canal is firmly curetted, carefully avoiding sampling of the ectocervix or the lower uterine segment. Endocervical scrapings admixed with cervical mucus are then removed using a ring forceps or cytobrush and included with the curettage specimen. Alternatively, vigorous brushing with a cytobrush may be used to obtain an endocervical tissue specimen. Endocervical brushing is more sensitive than curettage, but grading of any dysplasia present is more difficult. Endocervical sampling is often the most uncomfortable part of a colposcopic evaluation, and cramping is common.

## CERVICAL INTRAEPITHELIAL NEOPLASIA MANAGEMENT

Evidence-based guidelines for the management of women with biopsy-confirmed CIN were developed by the ASCCP and updated in 2012 (Massad, 2013). These continue to use the CIN nomenclature since outcome data stratified by the newer SIL terminology are not yet available. Management of CIN involves either observation or treatment. Goals are to diagnose occult invasive cancer, detect progression of minor abnormalities, and treat high-grade dysplasia to decrease cancer risk. Detection and prevention of invasive cervical cancer, a relatively rare outcome, must be balanced against the potential harms of excessive testing and overtreatment that include procedure-related morbidities, possible adverse reproductive outcomes, and psychologic stress.

Special populations considered include women age 21 to 25 years and pregnant women. Immunosuppressed women are no longer considered a special population and can now be managed in accordance with general guidelines. However, the CDC (2010) and American College of Obstetricians and Gynecologists (2013) still question HPV testing for ASC-US triage and surveillance of HIV-positive women.

In general, women with higher grades of Pap abnormality and CIN, inadequate colposcopic examinations, abnormal endocervical samplings, and age older than 24 years are considered at higher risk of invasive cancer and are managed more aggressively. An overview of current CIN management guidelines for nonpregnant patients is presented here, but providers should consult comprehensive recommendations (American College of Obstetricians

and Gynecologists, 2013; Massad, 2013). Guidelines are complex and are applied on an individualized basis, as they cannot address all clinical scenarios or individual patient situations. No guidelines can prevent all cases of cervical cancer.

### ■ CIN 1

CIN 1 exhibits a high rate of spontaneous regression. The diagnosis is poorly reproducible and thus unreliable. For this reason, CIN 1 is no longer treated aggressively. When diagnosed after a “lesser” cytologic abnormality such as ASC-US, LSIL, or a negative Pap with either an HPV 16/18 genotype-positive or a persistent HR HPV-positive result, it can be observed indefinitely. Treatment is acceptable only if CIN 1 persists for more than 2 years regardless of colposcopic examination adequacy or presence of CIN 1 in an endocervical sampling. Treatment of CIN 1 in women under age 25 years is not recommended, even if persistent.

Observation consists of a cotest 12 months after CIN 1 diagnosis. If this is negative, resumption of routine screening is recommended 3 years later. In women age 21 to 25 years, observation with cytology alone at 12 months and 24 months is recommended instead of cotesting due to high rates of HPV positivity in this population. If CIN 1 is detected only in the endocervical sampling, sampling is repeated in 1 year in addition to other recommended surveillance. Abnormal surveillance results are followed by repeat colposcopy. Persistent CIN 1 may be treated by ablation or excision provided the colposcopic examination is adequate and endocervical sampling lacks HSIL (CIN 2/3) or ungraded CIN. If these criteria are not met, excision is recommended and ablation is unacceptable.

CIN 1 diagnosed after an ASC-H or HSIL Pap test result carries a higher risk of occult high-grade CIN. In women age 25 years or older with an adequate colposcopic examination, either a diagnostic excision or observation with cotesting at 12 and 24 months is acceptable. If colposcopy is inadequate, a diagnostic excision is indicated. Women age 21 to 24 years with CIN 1 diagnosed after a high-grade Pap abnormality can be monitored by colposcopic evaluation and cytology at 6-month intervals provided the colposcopic examination is adequate and endocervical samplings negative. Otherwise, excision is recommended. Persistent unexplained HSIL cytology results after 24 months of observation warrant an excision procedure.

### ■ CIN 2 and CIN 3

Generally, treatment is recommended for CIN 2 or 3 due to its significant malignant potential and the efficacy of treatment in preventing progression. Either ablation or excision is acceptable and is chosen according to individual patient, cervical TZ, and lesion characteristics.

When CIN 2/3 or ungraded CIN is found in an endocervical sampling or with an inadequate colposcopic examination, a diagnostic excision is needed to exclude occult invasive cancer. An unequivocal histologic diagnosis of CIN 3 is treated, not observed, regardless of age or reproductive history. Recurrence or persistence is treated with repeat excision, not ablation. Hysterectomy as primary therapy is unacceptable. It may be

indicated if repeat excision is needed but not anatomically feasible or if high-grade CIN recurs or persists.

For young women, particularly of low parity, with CIN 2 or CIN 2/3 (HSIL, not otherwise specified) either observation or treatment are acceptable if colposcopy is adequate. In this context, “young women” refers to those individuals for whom the possible risk to future pregnancies from treatment outweighs the risk of progression to malignancy, although either of these is difficult to quantify. No upper age limit is recommended. Observation consists of repeat cytology and colposcopy at 6-month intervals. Observation of CIN 2 is preferred to treatment in younger women. If colposcopy is inadequate, CIN 3 is specified, or CIN 2 or CIN 2/3 persists at 24 months, then treatment is recommended.

### ■ Adenocarcinoma in Situ

Adenocarcinoma in situ (AIS) of the cervix, although uncommon, is increasing in incidence and typically diagnosed at a younger age (Herzog, 2007). Exclusion of invasive cancer and removal of all affected tissue are primary clinical goals. Management differs somewhat from that of CIN2/3 because AIS and adenocarcinoma are not easily identified colposcopically. Lesions can be multifocal, located deep within endocervical clefts, and extend farther into the endocervical canal (Massad, 2013). Diagnostic excision is required to exclude invasive cancer with maximum certainty. For nonpregnant women, excision is complemented by endocervical curettage. Choice of excision modality should favor an intact specimen with the most interpretable margins. Cold-knife conization is thus favored by many, but guidelines do not explicitly favor it over LEEP. If used, loop excision should be large enough to obviate the need for a second, deeper pass and should minimize cautery artifact. If there is no invasive cancer in the excision specimen, simple hysterectomy is recommended in women who have completed childbearing.

Women with AIS who strongly desire fertility preservation can be managed conservatively after an excision procedure. Individuals are counseled regarding the significant ongoing risk even with negative excision margins and endocervical sampling. The risk of residual AIS is reported to be as high as 80 percent in patients with positive margins (Krivak, 2001). Accordingly, repeat excision is advisable if hysterectomy is not planned. Close, long-term surveillance is recommended until hysterectomy is performed (Massad, 2013).

### ■ Postcolposcopy Surveillance without Treatment

When colposcopy fails to reveal high-grade CIN or there is spontaneous regression of high-grade CIN in young women, further surveillance is indicated given the significant false-negative rate of colposcopy and an increased risk of developing CIN in the future. This involves repeat cytology, HPV testing, or colposcopy alone or in combination depending on the original abnormal cytology result and age of the patient. Early surveillance generally is either cytology or cotest once or twice at 1-year intervals. Return to routine screening or an additional cotest generally occurs 3 years later. Exceptions are AGC, favor

neoplasia and AIS Pap test results. These are always followed by excision unless invasive cancer is diagnosed during initial colposcopic examination and biopsy.

CERVICAL INTRAEPITHELIAL NEOPLASIA TREATMENT

Current treatment of CIN is limited to ablation or excision procedures encompassing the entire TZ. Unlike ablation, excision provides a histologic specimen for evaluation of excised margins and further assurance that invasive cancer is not present. Any treatment should reach a depth of 5 to 7 mm from the surface to treat CIN adequately. Excess depth is avoided to minimize potential adverse consequences. Treatment using topical agents or therapeutic vaccines remains investigational. Selection of treatment modality is individualized. Salient factors include patient age, parity, size and severity of lesions, cervix contour, prior CIN treatment, and coexisting medical conditions. Treatment selection also depends on an operator’s experience and available equipment. No clear evidence shows any treatment technique to be superior, and surgical treatments have an approximate 90-percent success rate (Martin-Hirsch, 2013). A review of clinical considerations is provided by Khan and Smith-McKune (2014).

Ablation

In general, ablation of the TZ is effective for noninvasive ectocervical disease. Before ablation, evidence of glandular neoplasia or invasive cancer is excluded with the greatest certainty possible. Namely, cytology, histology, and colposcopic impression should be concordant; colposcopic examination must be adequate; and endocervical sampling should be negative for high-grade or ungraded CIN. Ablation should not be used after prior therapy, for an unexplained glandular cytologic abnormality, or for AIS. The most commonly used ablative treatment modalities are cryosurgery and carbon dioxide (CO<sub>2</sub>) laser, and both techniques are illustrated in the atlas (Chap. 43, p. 989). Before the introduction of LEEP, when cold knife conization was the only excision option, these ablative techniques were used more commonly. The relative decreased morbidity and ease of performing loop excision compared with cold knife conization and the trends toward observation of CIN 1 and of some CIN 2 and CIN 2/3 lesions in young women has led to decreased use of ablative procedures.

Cryosurgery is an ablative method that delivers a refrigerant gas, usually nitrous oxide, to a metal probe that freezes tissue on contact. Cryonecrosis is achieved by crystallizing intracellular water. This treatment is most appropriate for lesions and TZ lying entirely on the ectocervix, for a smooth cervical surface without deep crevices, and for CIN limited to two quadrants of the cervix (Table 29-7). Cryosurgery is generally not favored for the treatment of CIN 3 due to higher rates of disease persistence following treatment and lack of a histologic specimen to exclude occult invasive cancer (Martin-Hirsch, 2013). Moreover, cryosurgery and other ablative techniques are not favored for HIV-positive women with CIN due to higher failure rates (Spitzer, 1999). Less evidence suggests subsequent adverse

TABLE 29-7. Cryosurgery: Clinical Characteristics

<b>Advantages</b>
Favorable safety profile
Outpatient procedure
No anesthetic requirements
Ease of procedure
Low-cost equipment with minimal maintenance
Bleeding complications rare
No proven adverse reproductive effects
Acceptable primary cure rate
<b>Disadvantages</b>
No tissue specimen for histopathology evaluation
Cannot treat lesions with unfavorable sizes or shapes
Uterine cramping
Potential for vasovagal reaction
Profuse vaginal discharge postprocedure
Cephalad migration of squamocolumnar junction

Data from Martin-Hirsch PL, Paraskevaidis E, Bryant A: Surgery for cervical intraepithelial neoplasia. Cochrane Database Syst Rev 2013 Dec 4;12:CD001318.

effects on pregnancy outcome with cryotherapy than with loop excision. Thus, cryotherapy may be underused (Khan, 2014).

CO<sub>2</sub> laser is another ablative option and is delivered using colposcopic guidance with a micromanipulator. Cervical tissue is vaporized to a depth of 5 to 7 mm. Laser ablation is appropriate for CIN lesions associated with an adequate colposcopic examination. It is well suited for large, irregularly shaped CIN lesions of all grades and for condylomatous and preinvasive lesions at other LGT sites. If the cervical lesion extends onto the vagina, laser ablation may help customize removal of the entire lesion with favorable depth control. Laser ablation can also be augmented by laser or loop excision of central tissue for cases in which an ectocervical lesion extends into the endocervical canal or in which colposcopy is inadequate (American College of Obstetricians and Gynecologists, 2013).

Excision

Clinical scenarios with the highest risk of occult invasive cancer but without definitive histologic confirmation are evaluated further with an excision procedure. These include high-grade cytologic abnormalities with discordant (negative or low-grade) biopsy results or with inadequate colposcopy; AGC, favor neoplasia or AIS cytology; AIS histology; and endocervical sampling indicating ungraded or high-grade CIN or glandular neoplasia. With glandular cytologic abnormalities or AIS, an excisional modality that provides an intact specimen with the most interpretable margins should be chosen (Massad, 2013). Excision is indicated for recurrence of high-grade CIN after treatment due to the increased risk for occult invasive cancer (Paraskevaidis, 1991). Diagnostic excision refers to situations in which invasive cancer has not been excluded by the criteria needed before an ablation is performed. A therapeutic excision refers to one performed when these criteria have been met.

Excisional treatment modalities include LEEP, cold-knife conization (CKC), and laser conization, which are all illustrated in the atlas (p. 992). Excisional procedures are associated with operative and long-term risks that include subsequent cervical stenosis and adverse pregnancy outcomes. For decades, CKC has been associated with cervical incompetence and preterm birth. The relationship between preterm birth and LEEP remains uncertain. Although some studies show LEEP to be an independent risk factor for preterm birth and premature rupture of membranes, others do not (Jakobsson, 2009; Kyrgiou, 2006; Sadler, 2004; Samson, 2005; Werner, 2010). An important confounder is the increased risk of preterm birth in women with cervical neoplasia compared with the general population even if they have not undergone an excisional procedure (Bruinsma, 2007; Conner, 2014; Shanbhag, 2009). This indicates that CIN and preterm birth have overlapping risk factors, making the contribution of treatment to this risk difficult to ascertain and controversial.

Of options, LEEP uses a thin wire on an insulated handle through which an electrical current is passed. This creates an instrument that can simultaneously cut and coagulate tissue, ideally during direct colposcopic visualization. Because LEEP can be performed using local anesthesia, it has become the primary outpatient treatment modality for high-grade cervical lesions, including those that extend into the endocervical canal (Table 29-8). LEEP provides a tissue specimen with margins that can be histologically assessed. Additionally, the size and shape of tissue excision can be customized by varying loop sizes and the order in which loops are used. This helps conserve cervical stroma volume.

Cold-knife conization is surgery that uses sharp excision to remove the cervical TZ and CIN lesion. It is performed in an operating room under general or regional anesthesia (Table 29-9). CKC is often preferred to LEEP for patients at highest risk for invasive cancer. These indications include cervical cytology suspicious for invasive cancer, patients older than 35 with CIN 3 or CIS, large high-grade lesions, and glandular neoplasia.

CO<sub>2</sub> laser conization allows precise tailoring of the cone shape to minimize stromal excision and yields less blood loss. Disadvantages are its expense, some thermal compromise of specimen margins, and special training requirements. This procedure can be performed under local, regional, or general anesthesia.

**TABLE 29-8.** Loop Electrosurgical Excision Procedure: Clinical Characteristics

<b>Advantages</b>
Favorable safety profile
Ease of procedure
Outpatient procedure using local anesthesia
Low-cost equipment
Tissue specimen for histopathology evaluation
<b>Disadvantages</b>
Thermal damage may obscure specimen margin status
Special training required
Risk of postprocedure bleeding
Theoretical risk of vapor plume inhalation

**TABLE 29-9.** Cold-Knife Conization Clinical Characteristics

<b>Advantages</b>
Anesthetized patient
Tissue specimen without margin compromise
Enhanced patient support if hemorrhage is encountered
Variety of instruments to individualize conization
<b>Disadvantages</b>
Potential for hemorrhage
Lengthier procedure
Postoperative discomfort
General or regional anesthesia required
Operating room setting
High cost
Larger volume of cervical stroma removed
Increased risk of adverse reproductive outcomes

■ **Surveillance after Treatment**

Additional surveillance is required to assess treatment success (American College of Obstetricians and Gynecologists, 2013; Massad, 2013). Patients who have undergone a cervical excision with margins negative for HSIL or who have undergone an ablative procedure may be followed with cotesting 1 year later or serial cotesting at 12 and 24 months depending on whether the original abnormal cytology or biopsies showed low- or high-grade changes. Additional cytology or cotesting again at 3 years is recommended before returning to routine screening. After treatment of HSIL, routine screening should continue for at least 20 years due to a persistently increased risk of cervical neoplasia, even if screening extends beyond age 65.

If excision margins or endocervical curettage performed immediately after an excision are positive for CIN 2 or CIN 3, then surveillance with repeat cytology and endocervical sampling 4 to 6 months later is preferred. Repeat excision is acceptable. Repeat diagnostic excision is indicated for special circumstances such as AIS or microinvasive carcinoma at the excision margins.

■ **hysterectomy**

Hysterectomy is unacceptable as primary therapy for CIN (American College of Obstetricians and Gynecologists, 2013; Massad, 2013). However, it may be considered when treating recurrent high-grade cervical disease if childbearing has been completed or when a repeat cervical excision is strongly indicated but not technically feasible. Although hysterectomy provides the lowest CIN recurrence rate, invasive cancer must always be excluded beforehand. The choice of either a vaginal or abdominal approach is directed by other clinical factors. Hysterectomy is the preferred treatment of AIS when future fertility is not desired.

Even with negative cervical margins, hysterectomy performed for CIN 2 or worse is not completely protective. Patients, particularly those who are immunosuppressed, are at risk for recurrent disease and require postoperative interval cytologic screening of the vaginal cuff as described on page 635.

## VAGINAL PREINVASIVE LESIONS

### ■ Pathophysiology

Vaginal cancer is a rare malignancy comprising only 1 to 2 percent of gynecologic cancers. Nearly 50 percent of cases are diagnosed in women aged 70 years and older (Kosary, 2007). Approximately 90 percent of vaginal cancers are squamous cell carcinomas. These appear to develop slowly from precancerous epithelial changes, called vaginal intraepithelial neoplasia (VaIN), in a fashion similar to cervical cancer from CIN.

VaIN demonstrates histopathology similar to CIN and VIN. It is rarely found as a primary lesion and most often develops as an extension of CIN, mainly in the upper third of the vagina (Diakomanolis, 2002; Hofman, 1992a). Unlike the cervix, the vagina lacks a TZ susceptible to HPV-induced neoplasia. However, HPV may gain entry from vaginal mucosal abrasions and reparative metaplastic squamous cell activity (Woodruff, 1981). In one review, investigators found HPV DNA in up to 98 percent of VaIN lesions and in three quarters of vaginal cancers. HPV 16 is the most common type (Alemany, 2014). Thus, HPV vaccination against HPV types 16 and 18 has the potential to also prevent vaginal cancers (Smith, 2009).

The natural history of VaIN is less understood than that of CIN, although their similar risk factors suggest a similar etiology. Cervical and vulvar neoplasia increase the risk for VaIN and vaginal squamous cancer. Women treated for CIN 3 are at increased risk of developing both cervical and vaginal cancers, and this risk accelerates in those older than 60 (Strander, 2014). Moreover, a retrospective study suggests that hysterectomy is not definitive therapy for high-grade neoplasia, as researchers have found a subsequent high-grade VaIN recurrence rate greater than 7 percent (Schockaert, 2008).

### ■ Diagnosis

Generally, VaIN is asymptomatic. If present, symptoms may include spotting, discharge, and odor. Abnormal cytology is often the first indication of VaIN. Subsequent examination of the vagina with a colposcope, termed *vaginoscopy*, frequently identifies a lesion for biopsy. Prior to visual evaluation, careful palpation of the vagina is advisable, particularly if the patient has undergone hysterectomy for high-grade cervical neoplasia. In such cases, invasive cancer may present as a nodular lesion buried within the vaginal cuff before it becomes visible.

During vaginoscopy, inspecting the entire vagina using a colposcope can be challenging because of a large surface area, rugation, and surfaces parallel to the colposcope's visual axis. Particular attention is paid to the upper third of the vagina due to the common etiology of VaIN as an extension of CIN. After hysterectomy for high-grade CIN, abnormal vaginal cytology should prompt careful inspection of the vaginal cuff. By applying 3- to 5-percent acetic acid to the vaginal mucosa, acetowhite changes consistent with HPV infection or neoplasia are identified (Fig. 29-17). Vascular patterns are less common in VaIN lesions than with CIN, but coarse punctation and even atypical vessels may be seen in high-grade and invasive lesions. High-grade VaIN tends to demonstrate flat, dense acetowhitening with sharply demarcated borders. Half-strength Lugol

**FIGURE 29-17** Vaginoscopy showing multifocal acetowhite human papillomavirus (HPV) lesions after application of 5-percent acetic acid.

solution applied to the vagina further delineates abnormal areas. Similar to cervical dysplasia, strongly nonstaining areas most likely contain abnormal epithelium. Iodine staining aids biopsy site selection, and areas with the least staining and straightest lesion margins are preferred. Biopsy may be obtained by means of a cervical biopsy forceps, and an Emmett hook can be used to elevate and stabilize vaginal tissue if needed. Local anesthesia is usually not necessary for biopsies of the upper third of the vagina but may be needed for more distal biopsies. The vaginal tissue is grasped and lifted to limit the biopsy depth. Menopausal women may have significant thinning of the vaginal mucosa, and biopsy is done with greater care or with a smaller biopsy forceps to avoid perforation of the vaginal wall. Hemostasis is achieved using silver nitrate applicators or Monsel paste. Vaginal lesion size, location, and specific biopsy sites are carefully documented for future management and surveillance.

### ■ Management

Like high-grade CIN, high-grade VaIN is believed to be a precancerous lesion and generally warrants eradication (Punnonen, 1989; Rome, 2000). Because vaginal neoplasia is uncommon, most management strategies are derived from small, retrospective, and statistically underpowered studies. Management of VaIN depends on the grade of neoplasia and may include observation, excision, ablation, topical antineoplastics, or rarely, radiation therapy. Each treatment method has advantages and disadvantages, and none has proven superior efficacy. Management strategies are determined by lesion size, number, and location; histologic diagnosis; and comprehensive patient counseling.

#### Low-Grade VaIN

In a long-term study of 132 patients with VaIN, Rome and associates (2000) found that an observational approach after biopsy resulted in VaIN 1 regression in seven of eight patients (88 percent). No VaIN 1 lesion progressed to high-grade VaIN or invasive cancer. Vaginal LSIL often represents atrophy or a transient HPV infection. Spontaneous regression is common, and observation is preferable in most cases. Aggressive treatment

is avoided. Although no evidence-based guidelines are available, surveillance similar to that for low-grade CIN with repeat cytology with or without vaginography every 6 to 12 months seems reasonable until abnormalities resolve or progress to HSIL.

### High-grade VaIN

Observation of VaIN 2 may be considered in selected patients, but the safety of this approach is not established. Treatment choice for patients with high-grade VaIN is influenced by several factors including the location and number of lesions, the patient's sexual activity status, vaginal length, prior radiation therapy, previous treatment modalities in patients with recurrent VaIN, and clinician experience. Potential adverse effects of treatment on subsequent quality of life such as pain, difficulties with sexual intercourse, and scarring are always considered when choosing a therapeutic modality.

*Wide local excision* of a high-grade unifocal lesion or partial vaginectomy for multifocal lesions may be used. Hoffman (1992a) found that nine of 32 patients (28 percent) with prior hysterectomy and VaIN 3 had occult invasive cancer in the vaginal cuff. Therefore, surgical excision is considered for high-grade lesions involving the vaginal cuff, particularly if any thickening or nodularity of vaginal apex suggests occult invasive disease. Excisional procedures have the advantage of providing a surgical specimen for which resected-margin status can be determined and the presence of invasive vaginal cancer excluded. Partial vaginectomy is surgically challenging but has the highest cure rate and fewest recurrences for high-grade disease (Dodge, 2001). Wide local excision carries less morbidity than vaginectomy, but both procedures may be complicated by bladder or rectal injury and hemorrhage. In addition, subsequent vaginal scarring and stenosis may compromise vaginal intercourse or cause dyspareunia. Sharp dissection is favored for local excision and for partial vaginectomy. Laser causes significant thermal damage to the tissue specimen and generally is not recommended for excision of vaginal mucosa. Loop excision has poor depth control and carries a substantial risk of thermal damage to underlying pelvic structures, including the bladder and bowel. LEEP should not be used for vaginal surgery.

*CO<sub>2</sub> laser ablation* is an option for lesions not concerning for invasive disease. It is well suited for eradication of multifocal lesions and causes less scarring and blood loss than tissue excision. Rarely, excessive bleeding and thermal damage to the bladder and bowel can occur. In one study, investigators monitored 21 patients after high-grade VaIN CO<sub>2</sub> laser ablation and found that 14 percent had persistent disease requiring retreatment. One patient progressed to invasive carcinoma, which underscores the importance of long-term surveillance (Perrotta, 2013). A broader explanation of laser ablation techniques is found in Section 43-26 (p. 991).

*Topical therapy*, as with ablative procedures, is suitable if there is no suspicion of invasive disease by cytology, vaginography, or histology. Persistent VaIN 2 and selected VaIN 3 lesions may be medically treated using 5-percent fluorouracil (5-FU) cream "of -label," as it is not FDA approved for this specific indication (Krebs, 1989). Its efficacy is unproven in large, randomized trials, and studies with small numbers of patients have demonstrated mixed results. Treatment regimens vary widely. One

dosing schedule calls for a 3-mL dose of cream placed in the vaginal vault by plastic vaginal applicator every other day for 3 days during the first week of treatment and once weekly thereafter for up to 10 weeks. 5-FU cream is often associated with a robust inflammatory reaction that can include vaginal burning and vulvar irritation. To minimize leakage onto the vulva, it is best applied intravaginally at bedtime, when a recumbent position will be maintained for hours. Additionally, an occlusive, water-resistant ointment can be used to protect the vulva. Protective gloves are worn when handling 5-FU cream, and measures are taken to avoid 5-FU contact by sexual partners. Patients selected for this treatment require thorough counseling, effective contraception as needed, consent for off-label medication use, and close monitoring for excessive inflammation and ulceration, which can lead to vaginal or vulvar scarring and loss of function.

*Radiation therapy* has a very limited role for treatment of high-grade VaIN. It carries a significant risk of serious morbidity and is reserved for select cases. In a review of 136 cases of vaginal carcinoma in situ, radiation therapy was used in 27 patients, and a 100-percent cure rate was noted. However, 63 percent developed significant complications including vaginal stenosis, adhesions, ulceration, necrosis, and fistula formation (Benedet, 1984). Furthermore, radiation treatment compromises subsequent cytologic, colposcopic, and histologic interpretation. Disease recurrence often necessitates radical surgery.

### ■ Prognosis

In a study of 132 patients treated for high-grade VaIN, excision and CO<sub>2</sub> laser ablation had similar cure rates of 69 percent. Topical 5-FU cream was curative in 46 percent of cases (Rome, 2000). Patients with any grade of vaginal neoplasia require long-term monitoring, as the persistence and recurrence rate for high-grade disease is significant. Currently, no evidence-based guidelines are available for posttreatment surveillance of VaIN. Monitoring includes collection of vaginal cytology and performance of vaginography approximately 2 to 4 months after treatment is completed. Continued surveillance with periodic cytology with or without vaginography at 6- to 12-month intervals for several years thereafter seems prudent. Long-term cytologic screening is needed thereafter.

## VULVAR PREINVASIVE LESIONS

### ■ Pathophysiology

Vulvar cancer is rare. In 2015, vulvar cancer made up less than 5 percent of all gynecologic cancers and less than 0.6 percent of all cancers in the U.S. women (American Cancer Society, 2015). Ninety percent of vulvar cancer is squamous and in some cases may develop slowly from VIN (Fig. 29-18) (Judson, 2006). However, compared with CIN, VIN less often progresses to high-grade disease and cancer. The incidence of vulvar carcinoma in situ has increased significantly over the past several decades. This trend is particularly pronounced in younger women and is thought to be linked to the increased incidence of STDs, including HPV (Howe, 2001). Jones and coworkers (2005) reported that the mean age of women with VIN has decreased from 50 to 39 years since 1980.

**FIGURE 29-18** **A.** Normal vulvar histology. The squamous epithelium contains cells that show increasing cytoplasm as cells mature from the base to surface. In nondysplastic squamous epithelium, nuclei appear orderly and are devoid of atypical features such as nuclear membrane irregularities, chromatin coarseness, and pleomorphism. Mitoses are usually confined to the basal cell layers. **B.** High-grade squamous intraepithelial lesion (HSIL), usual type. In this example of HSIL/VIN 3 (usual type), the dysplastic squamous epithelium shows virtually no maturation from base to surface, as evidenced by a high nucleus-to-cytoplasm ratio in cells in all epithelial layers. The nuclei are crowded and disorderly. Although not appreciable at this medium power (10 $\times$ ), the epithelium showed increased mitoses and mitoses high in the epithelium. This particular example has a papillomatous surface, a common finding in vulvar HSIL lesions. (Used with permission from Dr. Kelley Carrick.)

Although HPV DNA has been found in up to 80 percent of VIN lesions, HPV is less commonly associated with vulvar cancers, and rates range between 15 and 80 percent (Del Pino, 2013). The progression of vulvar carcinoma in situ to invasive cancer has been strongly suggested, although not confirmed conclusively. Therefore, VIN 3 lesions are generally treated (van Seters, 2005).

## ■ Classification

Terminology for squamous VIN was introduced by the International Society for the Study of Vulvar Disease (ISSVD) in 1986. Under this classification, VIN grades 1, 2, and 3 were defined by abnormal cellular changes found to varying thicknesses within the squamous epithelium, similar to CIN (Wilkinson, 1986). In 2004, classification of VIN was simplified by the ISSVD (Sideri, 2005). The older designation of VIN 1 has been eliminated, whereas VIN 2 and 3 categories have been combined. This redefinition reflects whether lesions are likely to be premalignant and thus whether lesions require therapy. The VIN 1 category was eliminated because evidence is lacking that such lesions are cancer precursors. These lesions likely represent benign reactive changes or HPV effect usually caused by low-risk HPV types 6 and 11 (Smith, 2009; Srodon, 2006). Since the histologic distinction between VIN 2 and VIN 3 is not reliably reproducible, they are now combined under the term *VIN* (Table 29-10). Most recently, use of LSIL and HSIL terminology similar to other anogenital sites has been recommended for vulvar lesions (Darragh, 2012).

VIN is now categorized as *usual type* (*uVIN*), *differentiated type* (*dVIN*), or *unclassified type*. Of these, *uVIN* encompasses most former VIN 2, VIN 3, and vulvar CIS lesions. *uVIN* lesions can be subcategorized histologically as warty

(condylomatous), basaloid, or mixed and are associated with oncogenic HPV infection. HPV 16 is the most prevalent HPV type found in VIN 2/3 and vulvar cancer (Smith, 2009). In general, HPV-related high-grade VIN lesions histologically resemble high-grade CIN and tend to be multicentric (Feng, 2005; Haefner, 1995).

The entire lower genital tract is vulnerable to HPV infection. Therefore, risk factors for *uVIN* are similar to those for *VaIN* and CIN. Accordingly, *uVIN* risk is strongly associated with multiple sexual partners, STDs, and tobacco smoking, particularly in younger women (Hofman, 1992b; Jones, 2005). It is

**TABLE 29-10.** Vulvar Intraepithelial Neoplasia (VIN): Terminology and Characteristics

VIN Type	Clinical Presentation and Risk Factors
VN, usual type	Formerly VIN 2, VIN 3, vulvar CIS
Warty	Younger women
Basaloid	Multicentric disease
Mixed	Oncogenic HPV infection
	Smoking, other STDs, immunosuppression
VN, differentiated type	2–10% of former VIN 3 lesions
	Older, postmenopausal women
	Oncogenic HPV infection uncommon
VN, unclassified type	Rare pagetoid lesions

CIS = carcinoma in situ; HPV = human papillomavirus; STD = sexually transmitted disease.

also seen as part of multifocal LGT neoplasia in immune compromised women.

In contrast, dVIN is less common and accounts for only 2 to 10 percent of all VIN cases (Hart, 2001). Such lesions tend to be unifocal and are typically found in older, nonsmoking, postmenopausal women in their sixth and seventh decade. Infection with oncogenic HPV is uncommon and probably does not play a role in the genesis of these lesions. Instead, they tend to be associated with chronic inflammatory skin conditions or p53 inactivation mutations (Del Pino, 2013). However, dVIN is more likely to progress to squamous cell carcinoma than uVIN. One study noted that progression of dVIN to vulvar squamous cell carcinoma was five times higher than for uVIN (van de Nieuwenhof, 2009). The pathologic diagnosis of dVIN is difficult and interobserver agreement is low. If clinical findings warrant, review by an experienced gynecologic pathologist may be helpful (van den Einden, 2013).

Rare pagetoid types of VIN 2 and 3 cannot be classified in any of the foregoing categories. These are termed *VIN, undifferentiated type* (Sideri, 2005).

## ■ Diagnosis

### Clinical Findings

VIN may be asymptomatic and discovered with routine gynecologic examinations or during evaluation of abnormal cervical or vaginal cytology. When present, signs and symptoms (itching, burning, pain) may affect a patient's sexual functioning and quality of life. Whereas high-grade lesions of the cervix and vagina are generally invisible without acetic acid application and use of a colposcope, clinically significant VIN lesions are usually visible without the aid of special techniques. Lesions vary widely in appearance but are usually sharply demarcated (Del Pino, 2013). They may be white, hyperkeratotic plaques; hyperpigmented lesions; or areas of erythema. Lesions may be raised or flat. uVIN is associated with HPV-related lesions or neoplasia elsewhere in the anogenital tract. Often, lesions appear bulky, resemble condylomata, and are multifocal with extensive involvement of the perineum and adjacent skin (Fig. 29-19).

dVIN is generally unifocal and may be associated with lichen sclerosis or lichen simplex chronicus of the adjacent skin. A lesion may appear as an ulcer, warty papule, or hyperkeratotic plaque.

To avoid diagnostic delay, most focal vulvar lesions are biopsied, particularly lesions that are irregularly or darkly pigmented, asymmetric, large, elevated, roughened, nodular, or ulcerated. Ulceration, surrounding induration, or inguinal adenopathy raises suspicion for invasive cancer. Other scenarios suspicious for VIN include enlarging lesions, warty lesions in postmenopausal or immune compromised women, and warts that are atypical in appearance or persist despite topical therapies (American College of Obstetricians and Gynecologists, 2014b).

### Vulvoscopy

Histologic confirmation is necessary before high-grade VIN is managed. Selection of the best location to biopsy is aided by magnification of the vulva, perineum, and perianal skin, usually with a colposcope. This examination is termed *vulvoscopy*. Alternatively, any good light source and a handheld magnifying lens can be used.

Vulvar epithelial changes are enhanced by applying a 3- to 5-percent acetic-acid-soaked gauze pad to the vulva for 5 minutes prior to examination. This is usually well tolerated but may cause pain or burning in the presence of vulvar irritation, ulceration, or fissures. Acetic acid accentuates the surface topography of lesions and may reveal acetowhite lesions not seen grossly. Pigmented VIN lesions tend to turn a dusky gray due to hyperkeratosis. Vascular patterns are generally not seen, but high-grade VIN rarely may demonstrate coarse punctation. Normal vulvar tissue, particularly the inner, posterior labia minora, may turn diffusely acetowhite and should not be treated based on this appearance.

As an alternative, 1-percent toluidine blue, a nuclear stain, may help define the best site for biopsy or for surgery margins (Joura, 1998). Its use is technically more challenging, and results are fraught with both false positives and false negatives. Therefore, its use has been largely abandoned.

**FIGURE 29-19** **A.** Bulky lesion of vulvar intraepithelial neoplasia (VIN), differentiated type. **B.** Extensive perineal and perianal extension of VIN, usual type.

The most abnormal-appearing areas are biopsied, although necrotic areas often yield nondiagnostic findings and are avoided if possible. Biopsies measuring up to 6 mm in diameter can be obtained using a Keyes punch after provision of a local anesthetic injection (Fig. 4-2, p. 88). Topical anesthetics can be applied several minutes prior to injection of local anesthesia to decrease discomfort. If lesions are close to the clitoral hood, general anesthesia is often warranted due to increased pain with injection of local anesthesia and increased vascularity. Biopsy sites measuring 4 mm or greater occasionally require suturing for hemostasis or cosmetic closure, especially on mucosal surfaces that stretch.

## ■ Management

### VIN 1

As noted, the progression of VIN 1 to VIN 3 has not been established, and the VIN 1 category has been eliminated entirely. Thus, lesions reported as VIN 1 are not treated, but instead reassessed annually in patients at risk for high-grade VIN. Reassessment may include gross inspection or vulvoscopy and biopsy as clinically indicated if high-grade neoplasia is suspected.

### VIN 2 and 3

With rare exception, high-grade VIN is treated (American College of Obstetricians and Gynecologists, 2014b). Standard treatment of high-grade lesions of the vulva consists of local destruction or excision. Medical management is currently limited (Pepas, 2011). VIN involving the hair-bearing areas of the vulva (external to Hart line) may extend deeper into pilosebaceous units, whereas mucosal lesions tend to be more superficial (Wright, 1992). VIN involves the pilosebaceous units in up to two thirds of cases, but rarely exceeds 2.5 mm in depth from the epidermal surface (Shatz, 1989). This is important for disease management, particularly if ablative procedures are considered. Regardless of the modality selected, treatment side effects are common and can include vulvar discomfort, poor wound healing, infection, and scarring that may result in chronic pain or dyspareunia. Thus, treatment objectives include: (1) improving patient symptoms, (2) preserving the appearance and function of the vulva, and (3) excluding and preventing invasive disease.

*Wide local excision (WLE)* with a surgical margin of at least 5 mm of normal tissue is preferred for large VIN lesions in which the possibility of invasive carcinoma cannot be excluded. Because disease recurrence is related to surgical margin status, frozen section histology of the specimen margins is advantageous (Friedrich, 1980; Jones, 2005). Hopkins (2001) reported disease recurrence rates of 20 percent for cases with negative surgical margins but 40 percent for those with positive margins. WLE can be disfiguring and may require plastic surgical techniques or skin grafting to minimize anatomic distortion, pain, and loss of function. Moreover, due to disease location, some patients are best treated by combined excisional and ablative procedures.

*Laser ablation* of VIN provides good cosmetic results, and the depth of tissue destruction can be adjusted for hair-bearing areas. However, CO<sub>2</sub> lesion ablation does not allow evaluation of a surgical specimen. Therefore, invasive carcinoma must be

excluded beforehand by adequate biopsy. Laser is generally less disfiguring than WLE but can result in prolonged, painful healing. Preoperative counseling regarding anticipated postoperative results mirrors that for WLE. VIN recurrence has been reported more commonly following laser vaporization than after WLE (Herod, 1996). However, Hofman (1992b) reported that 15 of 18 patients (83 percent) with VIN 3 remained free of recurrent disease after CO<sub>2</sub> laser ablation.

*Cavitation ultrasonic surgical aspiration (CUSA)* may be used to treat VIN confined solely to non-hair-bearing vulvar skin. Ultrasound is used to cause cavitation and disruption of affected tissue, which is then aspirated and collected (Section 43-28, p. 996). CUSA offers the advantages of laser, less scarring and pain than WLE, while additionally providing a pathologic specimen (von Gruenigen, 2007). However, the tissue specimen is fragmented and lacks the diagnostic accuracy of surgically excised tissue. Miller (2002) evaluated CUSA in 37 patients with VIN 2/3. They found an overall recurrence rate of 35 percent within a mean of 33 months.

*Topical therapy* can be considered if there is no concern for invasive cancer, the patient is able to self-administer the topical medication correctly, and the importance of compliance to follow-up is understood. No topical agent is FDA-approved specifically for the treatment of VIN. Cidofovir cream must be compounded. 5-FU is potentially caustic and teratogenic and is not a first-line choice for VIN treatment (National Cancer Institute, 2015b). The clinical efficacy of these two agents has not been demonstrated in clinical trials, and they are generally no longer used (American College of Obstetricians and Gynecologists, 2014b). Topical imiquimod (of-label) has garnered the most interest. It has lower toxicity, and numerous studies including two randomized controlled trials have reported favorable regression rates of high-grade VIN (Mahto, 2010; van Seters, 2008). A phase II study on the use of imiquimod in treating VIN 2/3 found a response rate of 77 percent and 20 percent recurrence rate compared with a recurrence rate of 53 percent in a surgically treated cohort (Le, 2007). The use of topical imiquimod for the treatment of lower genital tract neoplasia was recently reviewed by de Witte and colleagues (2015).

## ■ Prognosis and Prevention

Case reports exist describing the invasive potential of untreated, high-grade VIN (Jones, 2005). Jones and associates (1994) reviewed the outcome of 113 patients with VIN 3. They found that 87 percent of untreated patients progressed to vulvar cancer, whereas only 3.8 percent of treated patients progressed to invasive carcinoma. It is currently not possible to predict high-grade VIN lesion behavior. Regardless of the treatment modality chosen, recurrence is common (up to 50 percent), particularly in patients with multifocal disease or immune compromise. Indefinite surveillance for multifocal LGT disease is recommended. Moreover, some consider high-grade VIN to be an indication for colposcopic evaluation of the cervix and vagina regardless of normal cervical cytology. Posttreatment surveillance consists of careful vulvar reevaluation at 6 and 12 months and annual vulvar inspection thereafter (American College of Obstetricians and Gynecologists, 2014b).

For prevention, prophylactic HPV vaccination against types 16 and 18 has the potential to prevent approximately one third of vulvar cancers (Smith, 2009). Smoking cessation and optimization of compromised immune status are also important strategies.

## ANAL INTRAEPITHELIAL NEOPLASIA

### ■ Pathophysiology

In 2015, 4630 new anal cancers and 610 anal cancer deaths are predicted for U.S. women, and this cancer's incidence and mortality rates have risen since 1975 (American Cancer Society, 2015). Anal cancer is strongly associated with anal intraepithelial neoplasia (AIN) (Palefsky, 1994). Studies also continue to suggest an association between high-risk cervical HPV infection, abnormal anal cytology, and anal cancer (Lamme, 2014; Sehnal, 2014; Valari, 2011). Santoso and associates (2010) reported a 12-percent prevalence of biopsy-proven AIN in a group of women with HPV-related disease. As with cervical cancers, HPV types 16 and 18 are the principal etiologic agents (Zbar, 2002).

Little is known of the natural history of anal HPV infection and its progressive potential in women, but it is suspected to behave similarly to cervicovaginal lesions. Cervical and anal lesions generally are manifested at or near their respective squamocolumnar epithelial junctions, which is called the *transition zone* in the anal canal (Goldstone, 2001). Anal disease is classified by the same cytologic and histologic nomenclature used to describe cervical disease. Thus, AIN 1, 2, and 3 correspond to mild, moderate, and severe dysplasia, respectively (Fig. 29-20). The newer nomenclature for squamous neoplasia throughout the anogenital tract replaces AIN 1 with anal LSIL, and AIN 2/3 with anal HSIL (Darragh, 2012).

Risk factors for AIN include anal HPV infection, receptive anal intercourse, tobacco smoking, and history of other STDs, including HIV. Anal cancer and its likely precursor, AIN 3, are increasing at higher rates in the HIV-positive compared with the HIV-negative population (Heard, 2015; Tandon, 2010).

**FIGURE 29-20** High-grade anal intraepithelial neoplasia (AIN) histology. (Used with permission from Dr. Raheela Ashfaq.)

### ■ Diagnosis

Currently, neither the American College of Obstetricians and Gynecologists nor the USPSTF provides screening recommendations for AIN in women. Potential approaches include periodic testing with anal cytology, HPV testing, or anoscopy, or a combination of these. Some suggest that annual cervical and anal cytology should be offered to all HIV-positive women, but only if the infrastructure necessary to evaluate and manage abnormal cytology results and precancerous lesions is available (Palefsky, 2005; Panther, 2005). For the generalist, patients may be referred to tertiary care centers or colorectal surgeons.

Anal cytology as a screening test has uncertain efficacy for AIN and anal cancer (Nahas, 2009; Santoso, 2010). If used, anal cytology may be more sensitive using liquid-based preparations than conventional glass slides (Friedlander, 2004; Sherman, 1995). Sampling is obtained by inserting a Dacron swab or endocervical brush moistened with water or a small amount of water-based lubricant approximately 5 cm into the anal canal, presumed above the anal transformation zone. The device is then withdrawn with a twirling motion while applying lateral pressure to the anal canal walls. The swab is then either swirled in the cytology solution to release exfoliated cells or smeared on a glass slide and fixed with isopropyl alcohol as with cervical cytology. Nothing per rectum is recommended 24 hours prior to an anal cytology test. Anal cytology may be reported using terminology analogous to the Bethesda 2001 nomenclature for cervical cytology.

*High-resolution anoscopy* uses illumination and magnification provided by a colposcope. Anoscopy is more challenging to perform than colposcopy for both patient and the provider, and special training is recommended. Acetic acid is applied to evaluate the anal canal in a manner similar to colposcopy (Fig. 29-21) (Jay, 1997). Anal neoplasia demonstrates colposcopic features similar to those of CIN, and analogous lesion grading and terminology are used. Biopsies are directed at the most abnormal areas. Some consider high-resolution anoscopy to be the gold standard for diagnosing AIN, but its role for primary screening or for the evaluation of abnormal anal cytology is not yet defined. It is presently available in a limited number of health centers.

### ■ Management

The benefits of screening for, identification of, and eradication of anal cancer precursor lesions are currently under investigation, and clinical guidelines are not yet unavailable. Some suggest that eradication of high-grade anal lesions may decrease the incidence of invasive anal cancer (Santoso, 2010). However, in contrast to cervical neoplasia, the protective effect of treating precursor lesions of the anal canal remains unproven (Williams, 1994; Scholefield, 2005). Thus, decisions regarding screening for and managing AIN should be shared by provider and patient on an individual basis. Abnormal anal cytology is best evaluated with high-resolution anoscopy. High-grade AIN lesions are referred to appropriate specialists for possible excision or ablative procedures.

Treatment is restricted to locally ablative or excisional procedures that eliminate individual high-grade intraepithelial lesions. Unlike the cervix, the entire anal squamocolumnar junction cannot be destroyed or removed due to potential morbidity.

**FIGURE 29-21** **A.** Translucent acetowhite lesion of low-grade anal intraepithelial neoplasia (AIN). **B.** Dense acetowhite lesion of high-grade AIN. (Used with permission from Naomi Jay, RN NP PhD.)

Biopsy-proven high-grade AIN lesions can be ablated using CO<sub>2</sub> laser or electrosurgical coagulation performed under general anesthesia, or infrared coagulation as an office procedure (Chang, 2002; Goldstone, 2005). Cryoablation and topically applied 85-percent trichloroacetic acid are other alternatives. Finally, as prevention, the FDA (2010) has approved both the quadrivalent (Gardasil) and nonavalent HPV (Gardasil 9) vaccines for the prevention of anal cancer and precancerous lesions associated with HPV types 6, 11, 16, and 18 in both males and females.

#### h IV-INFECTED PATIENTS

HIV-infected women have a high burden of HPV-associated anogenital disease. In this population, up to 60 percent of Pap tests are abnormal, and up to 40 percent have colposcopic evidence of dysplasia. Compared with rates in HIV-uninfected women, HIV-infected women show higher rates of both CIN and VIN (Ellerbrock, 2000; Spitzer, 1999; Wright, 1994). Moreover, abnormal cervical cytology and/or cervical HPV results increase risks for anal HPV infection and anal neoplasia (Tandon, 2010; Heard, 2015). The risks of all HPV-associated

cancers of the vulva, vagina, and anus appear to increase during the period from 5 years before to 5 years after HIV seroconversion (Chaturvedi, 2009).

HIV infection influences LGT disease prognosis. For example, during the early years of the acquired immunodeficiency disease (AIDS) epidemic, Maiman and colleagues (1990) observed 100-percent mortality rates in HIV-positive women with cervical cancer compared with only 37 percent of HIV-negative women in a study cohort. Because of the increased risk of cervical cancer and poorer prognosis, cervical cancer was designated as an AIDS-defining condition. Fortunately, HIV-infected women who receive regular screening and recommended follow-up for CIN experience the same incidence of invasive cervical cancer as do HIV-negative women (Massad, 2009).

Because of a significantly higher risk of developing SIL, cervical cytologic screening is obtained every 6 months for the first year after an HIV infection diagnosis (Centers for Disease Control and Prevention, 2015). Thereafter, indefinite annual screening is recommended (American College of Obstetricians and Gynecologists, 2012a; Kaplan, 2009). In addition, women with HIV may benefit from anal Pap screening (Palefsky, 2001). However, evidence-based screening recommendations for AIN and anal cancer are not yet available. Women with HIV infection are routinely questioned about anorectal symptoms such as pain or bleeding and provided periodic digital rectal examinations.

The 2012 Consensus Guidelines recommend that Pap test abnormalities, including ASC-US, in HIV-positive women be managed as in the general population (Massad, 2013). However, the Centers for Disease Control and Prevention has questioned the utility of HPV testing for the triage of ASC-US in this group and thus recommends that all HIV-positive women with ASC-US results be referred for colposcopy (Kaplan, 2009). Because HIV-positive women with CIN are often found to have extensive, multifocal dysplastic epithelial disease, any colposcopic examination includes inspection of the entire LGT (Hillemanns, 1996; Tandon, 2010).

HIV-positive women are at higher risk of disease persistence, recurrence, and progression after CIN or VIN treatment, and poorer outcomes appear to correlate with degree of immune suppression. Cryotherapy for CIN has a particularly high failure rate among treatment methods (Korn, 1996; Spitzer, 1999). Additionally, ablative modalities have an increased risk of obscuring occult invasive cancer in high-grade lesions. Cervical excisional procedures including loop excision and cold-knife conization provide histologic confirmation and margins for evaluation. Although excisional therapy is effective for eradicating CIN in immune competent patients, the same treatment may be effective only in preventing progression to cancer in HIV-infected women (Heard, 2005).

The therapeutic impact of highly active antiretroviral therapy (HAART) on HPV infection is poorly understood, and results are conflicting (Heard, 2004). To date, HAART has not been shown consistently to improve the natural history of HPV-related diseases. In fact, anal cancer rates in HIV-infected individuals have continued to increase over the past decade (De Vuyst, 2008; Tandon, 2010). Indeed, if HAART does not alter the incidence or progression of HPV-related disease, individuals on

HAART may gain sufficient longevity to develop HPV-related epithelial cancers (de Sanjose, 2002).

Cervical cancer is the most common gynecologic cancer in women worldwide. Most of these cancers stem from infection with the human papillomavirus (HPV), although other host factors affect neoplastic progression following initial infection. Compared with other gynecologic malignancies, cervical cancer develops in a younger population. Thus, screening for this neoplasia typically begins in young adulthood.

Most early cancers are asymptomatic. Thus, diagnosis usually follows histologic evaluation of biopsies taken during colposcopic examination or from a grossly abnormal cervix. Once cancer is staged clinically, and this in turn directs treatment. In general, early-stage disease is effectively eradicated surgically. For advanced disease, chemoradiation is primarily selected. As expected, disease prognosis differs with tumor stage, and stage is the most important indicator of long-term survival.

Prevention lies mainly in identifying and treating women with high-grade dysplasia, and in HPV vaccination. Accordingly, as detailed in Chapter 29, regular screening is recommended and

HPV vaccination is encouraged to lower rates of cervical cancer in the future.

INCIDENCE

Worldwide, cervical cancer is common, and it ranks fourth among all malignancies for women (World Health Organization, 2012). In general, higher incidences are found in developing countries, and these countries contribute 85 percent of reported cases annually. Mortality rates are similarly higher in these populations (Torre, 2015). This incidence and survival disparity highlights successes achieved by long-term cervical cancer screening programs.

In the United States, cervical cancer is the third most common gynecologic cancer and the 11th most common solid malignant neoplasm among women. Women have a 1 in 132 lifetime risk of developing this cancer. In 2015, the American Cancer Society estimated 12,900 new cases and 4100 deaths from this malignancy (Siegel, 2015). Of U.S. women, black women and those in lower socioeconomic groups have the highest age-adjusted cervical cancer death rates, and Hispanic women have the highest incidence rates (Table 30-1). This trend is thought to stem mainly from financial and cultural characteristics affecting access to screening and treatment. The age at which cervical cancer develops is in general earlier than that of other gynecologic malignancies, and the median age at diagnosis is 49 years (Howlader, 2014).

RISKS

In addition to demographic differences, other risks may alter HPV acquisition or action. Notably, the greatest risk is the lack of regular cervical cancer screening (Abed, 2006; Leyden, 2005). Most communities adopting such screening have documented decreased incidences of this cancer (Jemal, 2006).

HPV is the primary etiologic infectious agent associated with cervical cancer (Ley, 1991; Schiffman, 1993). Although other sexually transmitted factors, including herpes simplex virus 2, may play a concurrent causative role, 99.7 percent of cervical cancers are associated with an oncogenic HPV subtype (Walboomers, 1999). In one study, 57 percent of invasive cervical cancer cases were attributable to HPV serotype 16. Serotype 18 was associated with 16 percent of invasive disease cases (Li, 2010). Each of these serotypes can lead to either squamous cell carcinoma or adenocarcinoma of the cervix. However, HPV 16 is more commonly associated with squamous cell carcinoma of the cervix, whereas HPV 18 is a risk factor for cervical adenocarcinoma (Bulk, 2006).

**TABLE 30-1.** Cervical Cancer Age-Adjusted Incidence and Death Rates (per 100,000 women per year)

	All Races	White	Black	Asian American & Pacific Islander	American Indian & Alaskan Native	Hispanic
Incidence	7.8	7.8	9.4	6.4	7.6	10.2
Death	2.3	2.1	4.1	1.8	3.4	2.8

Based on cases diagnosed during 2007 through 2011 from 18 geographic areas in the Surveillance, Epidemiology and End Results (SEER) Program.

Data from Howlader N, Noone AM, Krapcho M, et al: SEER Cancer Statistics Review, 1975-2011, National Cancer Institute. 2014.

Of other risks, lower educational attainment, older age, obesity, smoking, and neighborhood poverty are independently related to lower rates of cervical cancer screening. Specifically, those living in impoverished neighborhoods have limited access to testing and may benefit from screening outreach programs (Datta, 2006).

*Cigarette smoking*, both active and passive, increases cervical cancer risk. Among HPV-infected women, current and former smokers have a two- to threefold increased incidence of high-grade squamous intraepithelial lesion (HSIL) or invasive cancer. Passive smoking is also associated with increased risk, but to a lesser extent (Trimble, 2005). The mechanism underlying the association between smoking and this cancer is unclear, but smoking may alter HPV infection in those who smoke. For example, “ever smoking” has been associated with reduced clearance of high-risk HPV (Koshiol, 2006; Plummer, 2003). Tobacco smoke may also alter viral oncoprotein expression in cells in which the HPV is not integrated into the host genome (Wei, 2014).

*Parity* has a significant association with cervical cancer. Specifically, women with seven prior full-term pregnancies have an approximately fourfold risk, and those with one or two have a twofold risk compared with nulliparas (Muñoz, 2002).

Long-term *combination oral contraceptive (COC)* use is another risk. In women who are positive for cervical HPV DNA and who use COCs, cervical carcinoma rates increase by up to fourfold compared with women who are HPV-positive and never users (Moreno, 2002). Additionally, current COC users and women who are within 9 years of use have a significantly higher risk of developing both squamous cell and adenocarcinoma of the cervix (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006). Encouragingly, the relative risk to COC users appears to decline after cessation. Data from 24 epidemiologic studies showed that by 10 or more years following COC cessation, cervical cancer risk returns to that of never users (International Collaboration of Epidemiological Studies of Cervical Cancer, 2007).

*Sexual activity* logically has an association as HPV is sexually transmitted. Having more than six lifetime sexual partners elevates the relative risk of cervical cancer. Similarly, an early age of first intercourse before age 20 confers an increased risk of developing this malignancy. Intercourse after age 21 only shows a trend toward an elevated risk. Moreover, abstinence from sexual activity and barrier protection during sexual intercourse decrease cervical cancer incidence (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006).

*Immunosuppressed women* have an increased risk of developing cervical cancer. Cervical cancer is an acquired immune deficiency syndrome (AIDS)-defining illness. The standardized incidence ratio (SIR) of developing this cancer in HIV-infected women is 5.82. For transplant recipients the SIR is 2.013 for this malignancy (Grulich, 2007). Women with autoimmune diseases who use immunosuppressants do not appear to have an increased cervical cancer risk, except for azathioprine users (Dugue, 2015).

## PATHOPHYSIOLOGY

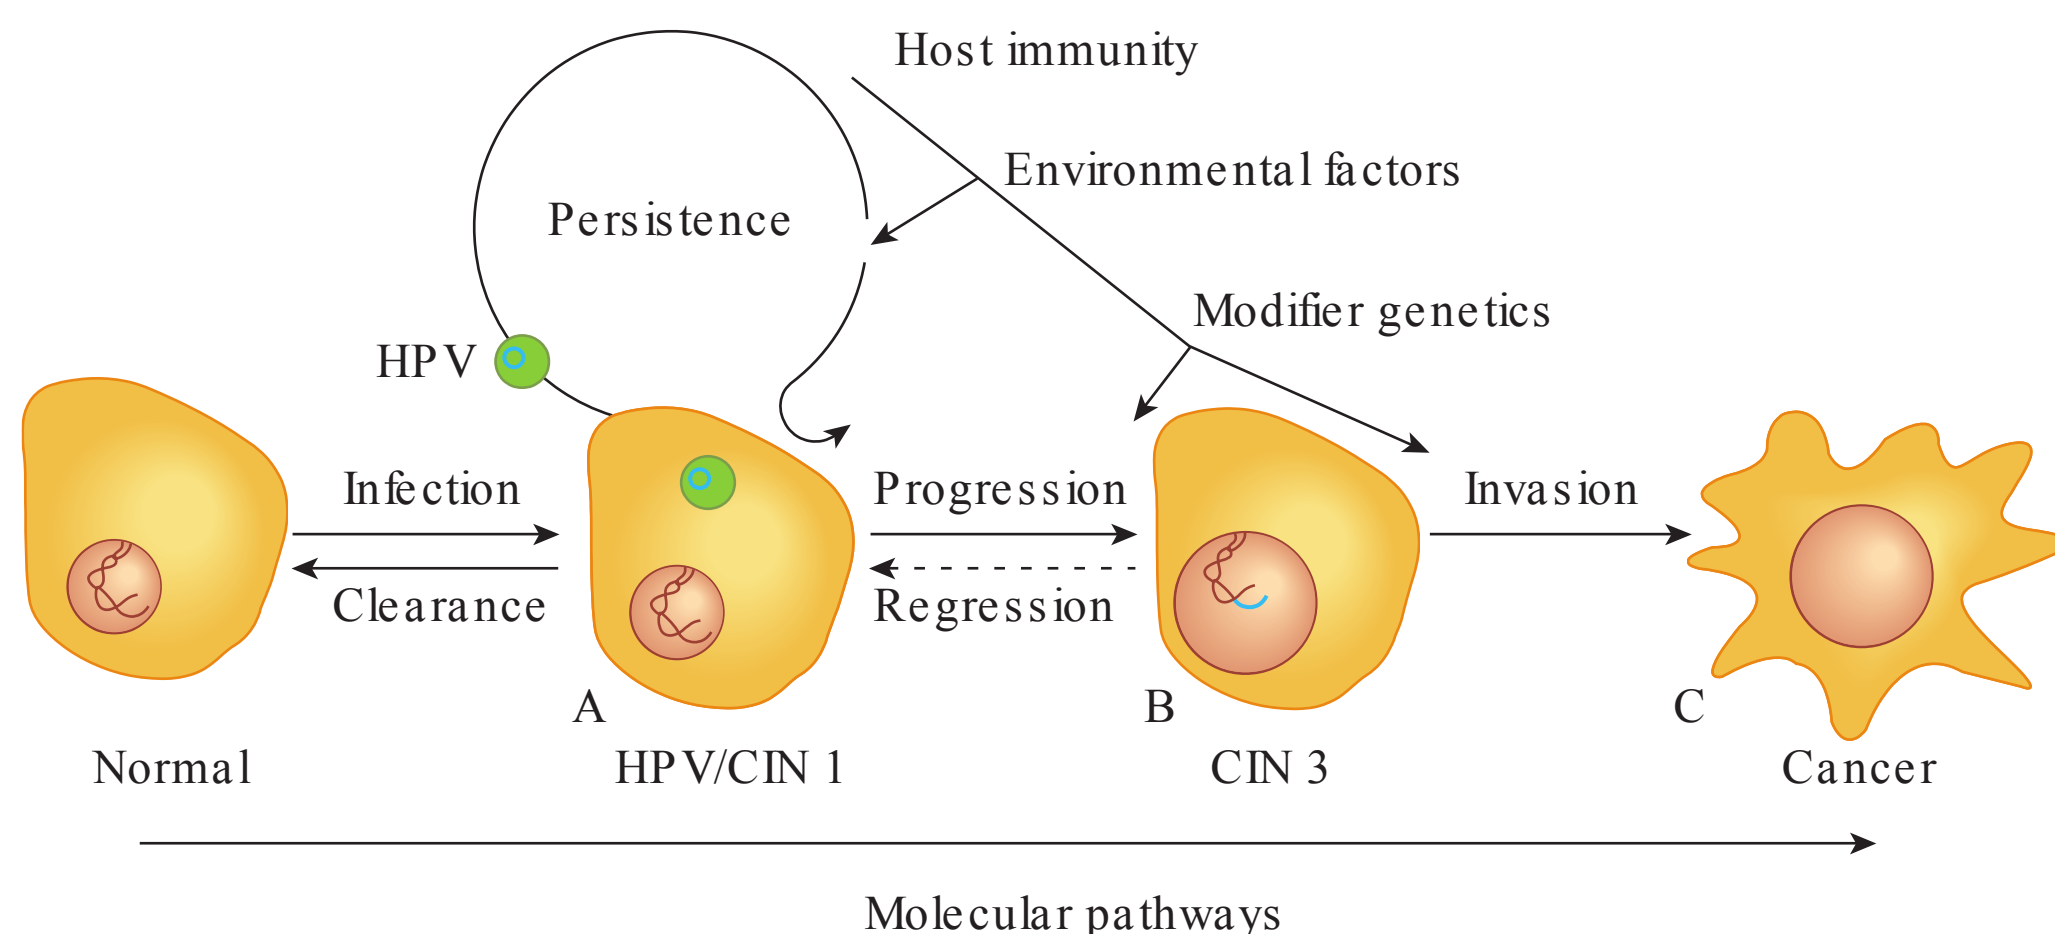

### ■ Tumorigenesis

Most women readily clear HPV, but those with persistent infection may develop preinvasive dysplastic cervical lesions. From such lesions, squamous cell carcinoma of the cervix typically arises at the squamocolumnar junction (Bosch, 2002). In general, progression from dysplasia to invasive cancer requires several years, although times can vary widely. The molecular alterations involved with cervical carcinogenesis are complex and not fully understood. Carcinogenesis currently is suspected to result from the interactive effects among environmental insults, host immunity, and somatic-cell genomic variations (Helt, 2002; Jones, 1997, 2006; Wentzensen, 2004).

Increasing evidence suggests that HPV oncoproteins may be a critical component of continued cancer cell proliferation (Mantovani, 1999; Munger, 2001). Unlike low-risk serotypes, oncogenic HPV serotypes can integrate into human DNA (Fig. 30-1). As a result, with infection, oncogenic HPV's early replication proteins E1 and E2 enable the virus to replicate within cervical cells. These proteins are expressed at high levels early in HPV infection. They can lead to cytologic changes detected as low-grade squamous intraepithelial (LSIL) cytologic findings on Pap smears.

Amplification of viral replication and subsequent transformation of normal cells into tumor cells may follow (Mantovani, 1999). Specifically, the viral gene products E6 and E7 oncoproteins are implicated in this transformation (Fig. 30-2). E7 protein binds to the retinoblastoma (Rb) tumor suppressor protein, whereas E6 binds to the p53 tumor suppressor protein. In both instances, binding leads to degradation of these suppressor proteins. The E6 effect of p53 degradation is well studied and linked with the proliferation and immortalization of cervical cells (Jones, 1997, 2006; Mantovani, 1999; Munger, 2001).

**FIGURE 30-1** Critical end points lie on the spectrum of cervical dysplasia. **A.** This initial point is the cell at risk due to active HPV infection. The HPV genome (blue ring) exists as a plasmid, separate from the host DNA. **B.** The clinically relevant preinvasive lesion, cervical intraepithelial neoplasia 3 (CIN 3) or carcinoma in situ (CIS), is an intermediate stage in cervical cancer development. The HPV genome has become integrated into the host DNA, resulting in increased proliferative ability. **C.** Interactive effects between environmental insults, host immunity, and somatic cell genomic variations lead to invasive cervical cancer.

## ■ Tumor Spread

Following tumorigenesis, the pattern of local growth may be exophytic if a cancer arises from the ectocervix, or may be endophytic if it arises from the endocervical canal (Fig. 30-3). Lesions lower in the canal and on the ectocervix are more likely to be clinically visible during physical examination. Alternatively, growth may be infiltrative, and in these cases, ulcerated lesions are common if necrosis accompanies this growth. As primary

lesions enlarge and lymphatic involvement progresses, local invasion increases and will eventually become extensive.

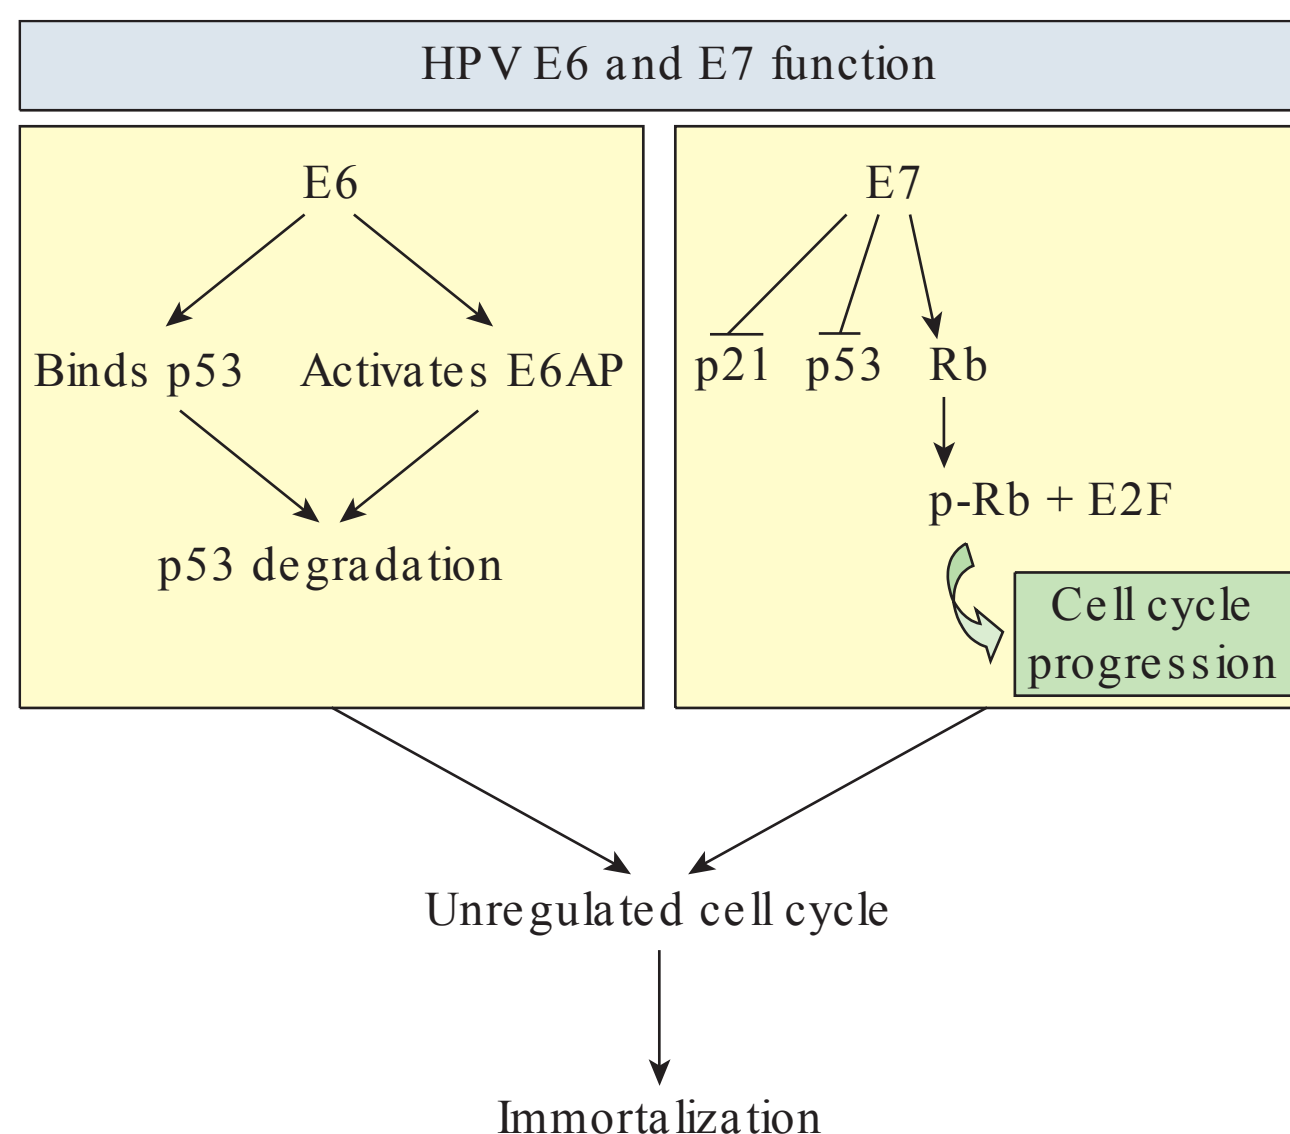

## Lymphatic Spread

**Lymph Node Groups.** The pattern of tumor spread typically follows cervical lymphatic drainage. Thus, familiarity with this drainage aids understanding the surgical steps of radical hysterectomy performed for this cancer (Section 46-1, p. 1134). The cervix has a rich network of lymphatics, which follow the course of the uterine artery (Fig. 30-4). These channels drain principally into the paracervical and parametrial lymph nodes. These lymph nodes are clinically important and thus are removed as part of parametrial resection during radical hysterectomy. From the parametrial and paracervical nodes, lymph subsequently flows into the obturator lymph nodes and into the internal, external, common iliac lymph nodes, and ultimately the paraaortic lymph nodes. Accordingly, pelvic and common iliac lymph nodes are also traditionally removed concurrently with radical hysterectomy. In contrast, lymphatic channels from the posterior cervix course through the rectal pillars and the uterosacral ligaments to the rectal lymph nodes. These nodes are also encountered and are removed during the extended resection of the uterosacral ligaments that is characteristic of radical hysterectomy.

**Lymphovascular Space Involvement.** As tumor invades deeper into the stroma, it enters blood capillaries and lymphatic channels (Fig. 30-5). Termed *lymphovascular space involvement* (LVSI), this type of invasive growth is not included in the clinical staging of cervical cancer. However, its presence is regarded as a poor prognostic indicator, especially in early-stage cervical cancers. Thus, the presence of LVSI often requires tailoring the planned surgical procedure and adjuvant radiation treatment.

## Local and Distant Tumor Extension

With extension through the parametria to the pelvic sidewall, ureteral blockage frequently develops, resulting in hydronephrosis

**FIGURE 30-2** Effects of E6 and E7 oncoproteins. On the left, viral oncoprotein E6 directly binds p53 and also activates E6AP to degrade p53 tumor suppressor protein. On the right, E7 oncoprotein phosphorylates retinoblastoma tumor suppressor protein, resulting in release of E2F transcription factors, which are involved in cell cycle progression. E7 also downregulates p21 tumor suppressor protein production and subverts p53 function. The cumulative effect of E6 and E7 oncoproteins eventually results in cell cycle alteration, promoting uncontrolled cell proliferation.

**FIGURE 30-3** Cervical adenocarcinoma. **A.** Invasive cancer originating from the endocervix. (Photograph contributed by Dr. David Miller.) **B.** Exophytic growth of cervical adenocarcinoma into the endocervical canal (arrowheads). In this radical hysterectomy specimen, proximal vagina (V) is excised with the cervix, and an arrow marks the ectocervix.

(Fig. 30-6). Additionally, the bladder may be invaded by direct tumor extension through the vesicouterine ligaments (bladder pillars). The rectum is invaded less often because it is anatomically separated from cervix by the posterior cul-de-sac. Distant metastasis results from hematogenous dissemination, and the lungs, ovaries, liver, and bone are the most frequently affected.

**FIGURE 30-4** Lymphatic drainage of the cervix. The parametrial lymph nodes are removed as part of the radical hysterectomy. Lymph node dissection for cervical cancer includes removal of pelvic lymph nodes (from the external iliac artery and vein, internal iliac artery, and the common iliac artery) with or without a paraaortic lymph node dissection to the level of the inferior mesenteric artery. (Reproduced with permission from Henriksen E: The lymphatic spread of carcinoma of the cervix and of the body of the uterus; a study of 420 necropsies, *Am J Obstet Gynecol* 1949 Nov;58(5):924–942.)

## HISTOLOGIC TYPES

### ■ Squamous Cell Carcinoma

The two most common histologic subtypes of cervical cancer are squamous cell and adenocarcinoma (Table 30-2). Of these, squamous cell tumors predominate, comprise about 70 percent of all cervical cancers, and arise from the ectocervix. Over the past 30 years, the incidence of squamous cell cancers has declined, whereas that of cervical adenocarcinoma has risen. These changes may be attributed to an improved method of screening for early squamous lesions of the cervix and an increase in HPV prevalence (Vizcaino, 2000). Squamous cell carcinomas can be subdivided into keratinizing and nonkeratinizing carcinomas (Fig. 30-7).

**FIGURE 30-5** Photomicrograph of lymphovascular space involvement. A large lymphatic channel is plugged with squamous cell carcinoma (arrow). (Used with permission from Dr. Raheela Ashfaq.)

**TABLE 30-2.** Histologic Subtypes of Cervical Cancer**Squamous**

Adenosquamous  
Glassy cell

**Neuroendocrine cervical tumor**

Large cell neuroendocrine  
Small cell neuroendocrine

**Others**

Sarcoma  
Lymphoma  
Melanoma

Squamous cell carcinomas represent 75% of all cervical cancer, and adenocarcinomas account for 20–25% of cervical cancers. The other cell types are rare.

**FIGURE 30-6** Computed tomography (CT) scan reveals hydronephrosis (arrow) caused by tumor compression of the left ureter.■ **Adenocarcinomas**

Adenocarcinomas are a group of cervical cancers composed of the subtypes listed in Table 30-2. In contrast to squamous cell cervical carcinoma, adenocarcinomas make up 25 percent of cervical cancers and arise from the endocervical mucus-producing columnar cells. Because of this origin within the endocervix, adenocarcinomas are often occult and may be advanced before becoming clinically evident. They often give the cervix a palpable barrel shape during pelvic examination.

Adenocarcinomas exhibit various histologic patterns composed of diverse cell types. Of these, *mucinous adenocarcinomas* are the most common and are subdivided as shown in Table 30-2. The mucinous endocervical type retains resemblance to normal endocervical tissue (Fig. 30-8). The intestinal type resembles intestinal cells and may include goblet cells. *Minimal deviation adenocarcinoma*, also known as adenoma malignum,

**FIGURE 30-7** Squamous cell cervical cancer. Irregular nests of malignant cells (arrows) show eosinophilic keratin pearls at their center, which is a classic diagnostic feature. These nests invade the stroma accompanied by a brisk lymphocytic response (asterisks). (Used with permission from Dr. Raheela Ashfaq.)**FIGURE 30-8** This invasive cervical adenocarcinoma is characterized by columnar cells with moderate nuclear atypia and mitotic activity. Tumor cells form glands that resemble native endocervical glands but invade the stroma haphazardly. A chronic inflammatory infiltrate is present on the right (asterisk).

is characterized by cytologically bland glands that are abnormal in size and shape. These tumors contain an increased number of glands positioned at a deeper level than normal endocervical glands. Women with Peutz-Jeghers syndrome are at increased risk of developing adenoma malignum. *Villoglandular adenocarcinomas* are made up of surface papillae.

*Endometrioid adenocarcinomas* are the second most frequently identified and display glands resembling those of the endometrium. *Serous carcinoma* is identical to serous carcinomas of the ovaries or uterus and is rare. *Clear cell adenocarcinoma* accounts for less than 5 percent of cervical adenocarcinomas and is named for its clear cytoplasm (Jaworski, 2009). Rarely, adenocarcinomas arise in mesonephric remnants in the cervix and are termed *mesonephric adenocarcinomas*.

### Prognosis Comparison

Evidence describing the prognosis of squamous cell carcinoma compared with that of adenocarcinoma is contradictory. For stage IB and IIA cervical cancer, one study showed a statistically significant lower overall survival rate in those with adenocarcinoma compared with women with squamous cell carcinoma (Landoni, 1997). However, the Gynecologic Oncology Group (GOG) found in a subsequent study that overall survival rates in women with stage IB squamous and adenocarcinomas of the cervix are similar (Look, 1996).

For advanced-stage (stage IIB to IVA) cancers, evidence suggests that cervical adenocarcinomas may portend a poorer overall survival rate compared with similarly staged squamous cell carcinomas (Eifel, 1990; Lea, 2002). The 2006 International Federation of Obstetricians and Gynecologists (FIGO) annual report, which reported on more than 11,000 squamous carcinomas and 1613 adenocarcinomas, demonstrated that women with adenocarcinomas have worse overall survival rates at every stage compared with those with squamous cell carcinoma (Quinn, 2006). In sum, evidence suggests that adenocarcinoma of the cervix is a high-risk cell type.

### ■ Other Tumor Types

*Mixed cervical carcinomas* are rare. Of these, *adenosquamous carcinomas* do not differ grossly from adenocarcinomas of the cervix. The squamous component is poorly differentiated and shows little keratinization. *Glassy cell carcinoma* describes a form of poorly differentiated adenosquamous carcinoma in which cells display cytoplasm with a ground-glass appearance.

*Neuroendocrine tumors of the cervix* include large cell and small cell tumors. These rare malignancies are highly aggressive, and even early-stage cancers have a relatively low disease-free survival rate despite treatment with radical hysterectomy and adjuvant chemotherapy (Albores-Saavedra, 1997; Viswanathan, 2004). Often, neuroendocrine markers, including chromogranin, synaptophysin, and CD56, are used to confirm the diagnosis. Uncommonly, endocrine and paraendocrine tumors are associated with these neuroendocrine tumors.

Of other rare types, the cervix may be the site of sarcomas, malignant lymphomas, and melanomas. Cervical leiomyosarcomas and cervical stromal sarcomas have a poor prognosis, similar to that for uterine sarcomas. Melanomas often present as ulcerated blue or black nodules and also have a poor prognosis.

## DIAGNOSIS

### ■ Symptoms

Some women diagnosed with this cancer are asymptomatic. In others, early-stage cervical cancer may create a watery, blood-tinged vaginal discharge. Intermittent vaginal bleeding that follows coitus or douching can also be noted. As a malignancy enlarges, bleeding typically intensifies, and occasionally, a woman presents with uncontrolled hemorrhage from a tumor bed. In such cases, bleeding can often be controlled with a combination of Monsel paste (ferric subsulfate) and vaginal packing. Topical acetone can also be used to obtain hemostasis, especially in cases refractory to Monsel paste (Patsner, 1993). Burning from acetone makes it a less desirable choice than Monsel paste. With vaginal packing, the patient ideally remains at bed rest, and a Foley catheter is concurrently inserted to drain the bladder. The pack may interfere with normal voiding, and the catheter also allows for accurate monitoring of urine output during volume repletion. If bleeding continues, emergent radiation can be delivered. Alternatively, internal iliac artery embolization or ligation can be performed in cases of refractory hemorrhage. However, caution is used for these latter two options, as tumor oxygenation is decreased if these blood supplies are occluded. Radiation therapy is a primary component of advanced-stage cancer, and as noted in Chapter 28 (p. 613), radiation's effects are diminished in low-oxygen environments and can translate into worsening disease-specific survival rates (Kapp, 2005). In those with significant bleeding, hemodynamic support of the patient follows that described in Chapter 40 (p. 864).

### ■ Physical Examination

Most women with this cancer have normal general physical examination findings. In those with suspected cervical cancer, a thorough external genital and vaginal examination is performed. Because HPV is a shared risk factor for cervical, vaginal, vulvar, and anal cancers, concomitant lesions are sought. With speculum examination, the cervix may appear grossly normal if cancer is microinvasive. Visible disease displays varied appearances. Lesions may be an exophytic or endophytic growth; a polypoid mass, papillary tissue, or barrel-shaped cervix; a cervical ulceration or granular mass; or necrotic tissue. A watery, purulent, or bloody discharge can also be seen. For this reason, cervical cancer may mirror the appearance of a cervical leiomyoma, cervical polyp, vaginitis, cervical eversion, cervicitis, threatened abortion, placenta previa, cervical pregnancy, condyloma acuminata, herpetic ulcer, chancre, or a prolapsing uterine leiomyoma, polyp, or sarcoma.

During bimanual examination, a clinician may palpate an enlarged uterus resulting from tumor invasion and growth. Alternatively, hematometra or pyometra may expand the endometrial cavity following obstruction of fluid egress by a primary cervical cancer. In this case, the uterus may feel enlarged and boggy. Advanced cervical cancer cases can extend into the vagina, and disease extent can be appreciated during anterior vaginal wall palpation or during rectovaginal examination. With posterior spread, palpation of the rectovaginal septum between the index and middle finger of an examiner's hand

reveals a thick, hard, irregular septum. The proximal posterior vaginal wall is most commonly invaded. In addition, during digital rectal examination, parametrial, uterosacral, and pelvic sidewall involvement can be appreciated. Either one or both parametria may be invaded, and involved tissues feel thick, irregular, firm, and less mobile. A fixed mass indicates that tumor has probably extended to the pelvic sidewalls. However, a central lesion can become as large as 8 to 10 cm in diameter before reaching the sidewall.

With advancing disease, enlarged supraclavicular or inguinal lymphadenopathy suggest lymphatic tumor spread. Lower extremity edema and low back pain, often radiating down the posterior leg, may reflect compression of the sciatic nerve root, lymphatics, veins, or ureter by an expanding tumor. With ureteral obstruction, hydronephrosis and uremia can follow and may occasionally be the initial presenting finding. In these cases, ureteral stenting or percutaneous nephrostomy tube insertion are usually required. Kidney function is ideally preserved for chemotherapy. Additionally, with tumor invasion into the bladder or rectum, hematuria and/or vesicovaginal or rectovaginal fistula may be found.

### ■ Papanicolaou Test and Cervical Biopsy

Histologic evaluation of cervical biopsy is the primary tool to diagnose cervical cancer. Although Papanicolaou (Pap) tests are performed extensively to screen for this cancer, this test does not always detect cervical cancer. Specifically, Pap testing has only a 53- to 80-percent sensitivity for detecting high-grade lesions on any given single test (Agorastos, 2015; Benoit, 1984; Soost, 1991). Thus, the preventive power of Pap testing lies in regular serial screening (Fig. 30-9). Moreover, in women who have stage I cervical cancer, only 30 to 50 percent of single cytologic smears obtained are read as positive for cancer (Benoit, 1984). Hence, Pap testing alone for evaluation of a suspicious lesion is discouraged. Instead, these lesions are directly biopsied with Tischler biopsy forceps or a Kevorkian curette (Fig. 29-16, p. 641). When possible, biopsies are taken from the tumor periphery, as central

portions often contain only necrotic tissue, which will fail to yield a diagnosis. Moreover, biopsies ideally include underlying stroma, so that invasion, if present, can be assessed.

If abnormal Pap test findings are noted, colposcopy is often performed, and adequate cervical and endocervical biopsies are obtained. In some cases, cold knife conization is needed for this. Indications for colposcopy and conization are outlined in Chapter 29, and cervical punch biopsies or conization specimens are the most accurate for allowing assessment of cervical cancer invasion. Both sample types typically contain underlying stroma and enable differentiation between invasive and in situ carcinomas. For this determination, conization specimens provide a larger tissue sample and are most helpful.

## STAGING

Cervical cancers are staged clinically. Allowable components of staging include cold-knife conization, pelvic examination under anesthesia, cystoscopy, proctoscopy, chest radiograph, and intravenous pyelogram (or this portion of the computed tomography [CT] scan can be used). Table 30-3 lists these and also contains radiologic and laboratory tools that are not included in formal staging but may contribute additional information. Bullous edema is not sufficient for the diagnosis of bladder involvement, and this involvement must be biopsy proven. Lymph node metastasis does not change the clinical stage. The staging system widely used for cervical cancer is that developed by the FIGO in collaboration with the World Health Organization (WHO) and the International Union Against Cancer (UICC). This staging was updated in 2009 and is detailed in Table 30-4 and Figure 30-10. In this chapter, *early-stage disease* refers to FIGO stages I through IIA. The term *advanced-stage disease* describes stages IIB and higher.

Within each oncology chapter of this text, staging of each cancer type (cervix, vulva, vagina, uterus, ovary) will be presented. FIGO classification is used for gynecologic cancers.

**FIGURE 30-9** **A.** Pap smear, squamous cell carcinoma. Some show spindled tumor cells and/or cytoplasmic keratinization, as evidenced by dense orangeophilic cytoplasm. **B.** Pap smear, endocervical adenocarcinoma. This shows malignant cytologic features including nuclear pleomorphism, nuclear membrane abnormalities, and nucleolar prominence. Cytoplasm tends to be more delicate than in squamous carcinoma and may contain mucin. (Photographs contributed by Ann Marie West, MBA, CT[ASCP].)

TABLE 30-3. Testing Used During Cervical Cancer Evaluation	
Testing	To Identify:
<b>Laboratory</b>	
CBC	Anemia
Urinalysis	Hematuria
Chemistry profile	Electrolyte abnormality
Liver function	Liver metastasis
Creatinine/BUN	Renal impairment or obstruction
<b>Radiologic</b>	
Chest radiograph	Lung metastasis
Intravenous pyelogram	Hydronephrosis
CT scan (abdominopelvic)	Nodal or distant organ metastasis; hydronephrosis
MR imaging	Local parametrial invasion; nodal metastasis
PET scan	Nodal or distant organ metastasis
<b>Procedural</b>	
Cystoscopy	Bladder tumor invasion
Proctoscopy	Rectal tumor invasion
EUA	Extent of pelvic tumor spread; clinical staging
BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; EUA = examination under anesthesia; MR = magnetic resonance; PET = positron emission tomography.	

TABLE 30-4. Clinical Stages of Cervical Cancer (FIGO, Revised 2009)	
Stage	Characteristics
<b>0</b>	<b>Carcinoma in situ, cervical intraepithelial lesion (CIN) 3</b>
<b>I</b>	<b>Carcinoma is strictly confined to cervix (extension to corpus should be disregarded)</b>
IA	Microscopic lesion, invasion is limited to measured stromal invasion with a maximum depth of 5 mm and no wider than 7 mm
IA1	Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm
IA2	Measured invasion of stroma greater than 3 mm and no greater than 5 mm in depth and no wider than 7 mm
IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA
IB1	Clinical lesions no greater than 4 cm in size
IB2	Clinical lesions greater than 4 cm in size
<b>II</b>	<b>Carcinoma extends beyond cervix but has not extended to pelvic wall; it involves vagina, but not as far as the lower third</b>
IIA	No obvious parametrial invasion
IIA1	Clinical lesions no greater than 4 cm in size
IIA2	Clinical lesions greater than 4 cm in size
IIB	Obvious parametrial involvement
<b>III</b>	<b>Carcinoma has extended to the pelvic wall; on rectal examination there is no cancer-free space between tumor and pelvic wall; tumor involves lower third of vagina; all cases with hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to another cause</b>
IIIA	No extension to pelvic wall, but involvement of lower third of vagina
IIIB	Extension to pelvic wall, or hydronephrosis or nonfunctioning kidney due to tumor
<b>IV</b>	<b>Carcinoma has extended beyond true pelvis or has clinically involved mucosa of bladder or rectum</b>
IVA	Spread of growth to adjacent pelvic organs
IVB	Spread to distant organs
FIGO = International Federation of Obstetricians and Gynecologists. Modified with permission from Pecorelli S: Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. Int J Gynaecol Obstet 2009 May;105(2):103–104.	

**FIGURE 30-10** The International Federation of Gynecologists and Obstetricians (FIGO) stages of cervical cancer. D = depth; W = width.

In contrast, the American Joint Committee on Cancer (AJCC) developed the *TNM Staging System*, which is based on the extent of the tumor (T), the extent of spread to the lymph nodes (N), and the presence of metastasis (M). Breast cancer is staged with this latter system, as shown in Table 12-5 (p. 290).

## RADIOLOGIC IMAGING

As discussed, cervical cancer is staged clinically, and accurate evaluation is critical to appropriate treatment planning. For

example, early-stage tumors may be treated surgically, whereas more advanced tumors require radiation and/or chemotherapy. Although imaging does not affect assignment of stage (except lung metastases seen on chest radiograph and hydronephrosis seen on CT scan), imaging results can tailor treatment for an individual. In addition, lymph node metastases, although not included in the FIGO system, worsen patient prognosis and may be identified with imaging. Thus, radiologic tools such as CT scanning, magnetic resonance (MR) imaging, or positron emission tomography (PET) scanning are commonly used as

adjuncts in initial cervical cancer evaluation. However, no uniform approach to the use of these has been developed.

### ■ Magnetic Resonance Imaging

For defining anatomy, this high-resolution imaging tool offers superior contrast resolution at soft-tissue interfaces. T us, MR imaging effectively measures tumor size, delineates cervical tumor boundaries, and identifies surrounding bladder, rectal, or parametrial invasion. Unfortunately, MR imaging is less accurate for diagnosing microscopic or deep cervical stromal invasion or identifying minimal parametrial extension (Mitchell, 2006). T ese particular distinctions are important as both stromal and parametrial invasion may affect suitability for a given planned treatment. In addition, false-negative findings occur with small volumes of disease and with tissue foci in which cancer cannot be differentiated from scar or necrosis. In these cases, PET scanning identifies metabolic rather than anatomic changes and can be a complementary tool.

For primary cervical cancer, MR imaging is superior to CT for determining carcinoma size, local tumor extension, and lymph node involvement (Bipat, 2003; Mitchell, 2006; Subak, 1995). MR imaging is often preferred for patients being considered for fertility-sparing radical trachelectomy (Abu-Rustum, 2008; Olawaiye, 2009). Overall, however, both MR imaging and CT perform similarly in cervical cancer (Hricak, 2005).

### ■ Computed Tomography

T is is the most widely used imaging tool for the assessment of nodal involvement and distant metastatic disease. It offers high-resolution depiction of anatomy, especially when used with contrast. CT scanning is not a component of FIGO staging. However, it is obtained in many women with cervical cancer to evaluate tumor size and bulky extension beyond the cervix. CT can also aid detection of enlarged lymph nodes, ureteral obstruction, or distant metastasis (Follen, 2003).

However, CT has limitations similar to MR imaging. CT is not accurate for assessing subtle parametrial invasion or deep cervical stromal invasion because of its poor soft-tissue contrast resolution. CT is also limited by its inability to detect small-volume metastatic involvement in normal-size lymph nodes. Moreover, internal node architecture is often poorly defined. T is makes distinction between reactive node hyperplasia and true metastatic disease difficult.

### ■ Positron Emission Tomography

T is nuclear medicine imaging technique creates an image of functional processes within the body. With FDG-PET, a radiolabeled analogue of glucose, fluorodeoxyglucose (FDG), is injected intravenously and is taken up by metabolically active cells such as tumor cells. PET provides a poor depiction of detailed anatomy, thus scans are frequently read side-by-side with CT scans. T e combination allows correlation of metabolic and anatomic data. As a result, current PET scanners are now commonly integrated with CT scanners, and the two scans can be performed during the same session (Fig. 2-33, p. 46).

FDG-PET is superior to CT or MR imaging for lymph node metastasis identification (Belhocine, 2002; Havrilesky, 2005;

Selman, 2008). However, PET is insensitive for lymphatic metastasis < 5 mm. Moreover, its role in early-stage smaller, resectable tumors is limited (Sironi, 2006; Wright, 2005). PET scans can be useful in planning radiation treatment fields and also in identifying those patients who have distant metastatic disease and are candidates for palliative chemotherapy rather than curative-intent chemoradiotherapy.

## LYMPH NODE DISSECTION

As noted, cervical cancer is staged clinically and not surgically. However, surgical evaluation of retroperitoneal pelvic and para-aortic lymph nodes offers accurate metastasis detection that is superior to radiologic imaging (Goff, 1999). As a result, lymph node dissection may modify a patient's primary treatment strategy based on the level of nodal disease. For example, radiation fields may be altered to ensure that patients with negative paraaortic lymph nodes are not overtreated with extended-field radiation and that patients with positive paraaortic lymph nodes are not undertreated. Potential candidates include patients with positive or suspected positive pelvic nodes undergoing chemoradiation treatment. Supporting studies show that if positive pelvic/paraaortic nodes are identified, patients may receive a significant survival benefit from extended chemotherapy and/or extended field radiation therapy (Hacker, 1995; Holcomb, 1999; Leblanc, 2007).

In addition, tumor-laden nodes may be debulked. Several studies report similar disease-free survival rates for patients whose macroscopic nodal disease is resected compared with women with microscopic nodal disease (Cosin, 1998; Downey, 1989; Hacker, 1995). T at said, there is virtually no long-term survival for patients with unresectable bulky paraaortic lymph nodes.

During lymphadenectomy, most experts recommend lymph node dissection in the common iliac and paraaortic region and resection of macroscopic lymph nodes (Querleu, 2000). Traditional laparotomy and minimally invasive surgery (MIS) approaches have been compared. Although diagnostically equivalent, laparoscopic approaches offer postoperative MIS advantages. In addition, laparoscopic lymph node dissection has been associated with significantly less radiation morbidity than that with radiation following laparotomic approaches (Vasilev, 1995).

Despite these suggested benefits, some experts argue that the benefits of surgical staging, if any, are minimal. T ese studies estimate only a 4- to 6-percent survival benefit after aggressive surgical debulking of retroperitoneal lymph nodes (Kupets, 2002; Petereit, 1998).

## PROGNOSIS

T e significance of tumor burden on survival is well demonstrated, whether measured by FIGO stage, centimeter size, or surgical staging (Stehman, 1991). Of these definers, FIGO stage is the most significant prognostic factor (Table 30-5). However, within each stage distribution, lymph node involvement also becomes an important modifier in determining prognosis. For example, in early-stage cervical cancer (stages I through IIA), nodal metastases are an independent predictor of survival (Delgado, 1990; Tinga, 1990). One GOG study demonstrated

**TABLE 30-5.** Cervical Cancer Survival Rates According to Stage

Stage	5-Year Survival
IA	100%
IB	88%
IIA	68%
IIB	44%
III	18–39%
IVA	18–34%

Data from Grigsby, 1991; Komaki, 1995; Webb, 1980.

a 3-year survival rate of 86 percent for women with early-stage cervical cancer and negative pelvic lymph nodes, compared with a 3-year survival rate of 74 percent in patients who had one or more positive lymph nodes (Delgado, 1990).

In addition, the number of nodal metastases is predictive. Studies demonstrate significantly higher 5-year survival rates in those with one positive lymph node compared with rates in women with multiple involved nodes (Tinga, 1990). In advanced-stage (stage IIB through IV) cervical cancer, lymph node metastases also worsen prognosis. In general, microscopic nodal involvement has a better prognosis than macroscopic nodal disease (Cosin, 1998; Hacker, 1995).

## EARLY-STAGE PRIMARY DISEASE TREATMENT

### ■ Stage IA

The term *microinvasive cervical cancer* identifies this subgroup of small tumors. By definition, these tumors are not visible to the naked eye. Specifically, as seen in Table 30-4, criteria for stage IA tumors limit invasion depth to no greater than 5 mm and lateral spread to no wider than 7 mm. Microinvasive cervical cancer carries a minor risk of lymph node involvement and excellent prognosis following treatment. A retrospective study compared tumors with horizontal spread  $\leq 7$  mm and those with  $> 7$  mm spread. Higher rates of pelvic lymph node metastasis and recurrence rates were noted as tumor spread further than 7 mm (Takeshima, 1999).

Stage IA tumors are further divided into IA1 and IA2. These cancers are subdivided to reflect increasing depth and width of invasion and increasing risks for lymph node involvement.

#### Stage IA1

These microinvasive tumors invade no deeper than 3 mm, spread no wider than 7 mm, and are associated with the lowest risk for lymph node metastasis. Squamous cervical cancers with stromal invasion less than 1 mm have a 1-percent risk of nodal metastasis, and those with 1 to 3 mm of stromal invasion carry a 1.5-percent risk. Of 4098 women studied with this tumor stage, less than 1 percent died of disease following surgery (Ostor, 1995). Because of the low risk of spread into the parametrial or uterosacral nodes, these lesions may be

effectively treated with cervical conization alone (Table 30-6) (Keighley, 1968; Kolstad, 1989; Morris, 1993; Ostor, 1994). However, a total extrafascial hysterectomy (type I hysterectomy) is preferred for women who have completed childbearing. Hysterectomy types are described in Table 30-7.

In stage IA1 microinvasive cancers, the presence of LVSI increases the risk of lymph node metastasis and cancer recurrence to approximately 5 percent. Accordingly, at our institution, these cases are traditionally managed with modified radical hysterectomy (type II hysterectomy) and pelvic lymphadenectomy. Radical trachelectomy with pelvic lymph node dissection can be considered in women desiring fertility preservation (Olawaiye, 2009). This is described on page 670.

Adenocarcinomas are typically diagnosed at a more advanced stage than squamous cell cervical cancers. Thus, microinvasive adenocarcinomas present a unique management dilemma, due to sparse data regarding this tumor stage. However, based on evaluation of Surveillance Epidemiology and End Result (SEER) data provided by the National Cancer Institute, the incidence of lymph node involvement is similar to that with squamous cancers (Smith, 2002; Spoozak, 2012). Of microinvasive cervical adenocarcinomas, 59 cases managed with uterine preservation and conization have been reported in the literature (Baalbergen, 2011; Bisseling, 2007; Ceballos, 2006; McHale, 2001; Reynolds, 2010; Schorge, 2000; Yahata, 2010). Of these cases, following conization, no recurrences were identified during surveillance in women without LVSI. According to SEER data, the 5-year overall survival for women with stage IA1 adenocarcinoma treated with conization is 98 percent (Spoozak, 2012).

#### Stage IA2

These microinvasive cervical lesions have 3 to 5 mm of stromal invasion, have a 7-percent risk of lymph node metastasis, and carry a  $> 4$ -percent risk of disease recurrence. In this group of women, the safety of conservative therapy is yet to be proven. Thus, for this degree of invasion, radical hysterectomy and pelvic lymphadenectomy is recommended.

For fertility preservation, stage IA2 squamous cervical lesions may be treated with radical trachelectomy and lymphadenectomy. A nonabsorbable cerclage may be placed concurrently with such radical trachelectomy to improve cervical competence during pregnancy. These procedures have high cure rates, and successful pregnancies have been reported. If women are carefully selected for age  $< 45$  years, smaller tumor size ( $< 2$  cm), and negative nodal involvement, then reported recurrence rates are similar to those of radical hysterectomy (Burnett, 2003; Covens, 1999a,b; Gien, 2010; Olawaiye, 2009). Some experts will offer radical trachelectomy to patients with tumors up to 4 cm (stage IB1). However, prior to surgery, approximately one third of patients with this tumor stage will instead be found to need radical hysterectomy or adjuvant chemoradiation due to intermediate- or high-risk features (Abu-Rustum, 2008; Gien, 2010). Preoperative MR imaging to evaluate the parametria and/or CT scan to evaluate extracervical disease is recommended in these cases. If tumor has extended proximally past the internal cervical os, then trachelectomy is contraindicated. Although this technique is promising, it carries a learning curve, and further studies to validate its efficacy are needed.

**TABLE 30-6.** General Treatment for Primary Invasive Cervical Carcinoma<sup>a</sup>

Cancer Stage	Treatment
IA1 <sup>b</sup>	Simple hysterectomy preferred if childbearing completed or Cervical conization
IA1 <sup>b</sup> (with LVSI)	Modified radical hysterectomy and pelvic lymphadenectomy or Radical trachelectomy and pelvic lymphadenectomy for selected patients desiring fertility
IA2 <sup>b,c</sup>	Radical hysterectomy and pelvic lymphadenectomy or Radical trachelectomy and pelvic lymphadenectomy for selected patients desiring fertility
IB1 <sup>c</sup> Some IB2 IIA1	Radical hysterectomy and pelvic lymphadenectomy or radical trachelectomy and pelvic lymphadenectomy for selected patients desiring fertility or Chemoradiation
Bulky IB2 IIA2	Chemoradiation
IIIB to IVA	Chemoradiation or Rarely, pelvic exenteration <sup>d</sup>
IVB	Palliative chemotherapy and/or Palliative radiotherapy OR Supportive care (hospice)

<sup>a</sup>For individual patients, recommendations for treatment can vary, depending on the clinical circumstances.  
<sup>b</sup>Intracavitary brachytherapy may be selected for nonsurgical candidates.  
<sup>c</sup>Some institutions perform modified (type II) radical hysterectomy and pelvic lymphadenectomy for stage IA2 lesions and smaller stage IB tumors.  
<sup>d</sup>A patient with stage IVA lesion with a fistula may be a candidate for a pelvic exenteration.

In addition to stage IA1 tumors, some centers are evaluating the safety of conization or extrafascial hysterectomy for a broader group of women with early-stage cervical cancer, since parametrial involvement in microinvasive cervical cancer is rare (Hou, 2011). One study, which included 51 women with stage IA1 to stage IB1 cervical cancer, demonstrated no recurrences at a median surveillance of 21 months for women treated with conization or extrafascial hysterectomy and no nodal dissection (Bouchard-Fortier, 2014). Two women received adjuvant chemoradiation based on specimen histologic analysis results. In addition, SEER data that included 3987 women with microinvasive cervical cancer showed similar survival rates for women with adenocarcinoma treated with conization compared with hysterectomy. However, women with squamous cell carcinoma undergoing hysterectomy had improved survival rates compared with women undergoing conization (Spoozak, 2012).

Alternatively, patients with microinvasive carcinoma (stages IA1 and IA2) can be treated with intracavitary brachytherapy alone with excellent results (Grigsby, 1991; Hamberger, 1978). Potential candidates for vaginal brachytherapy include women who are elderly or who are not surgical candidates due to comorbid medical disease.

Hysterectomy

Women with FIGO stage IA2 through IIA cervical cancer, that is, those without obvious parametrial involvement, may be selected for radical hysterectomy with pelvic lymph node dissection and with or without paraaortic lymph node dissection. Surgery is appropriate for those who are physically able to tolerate an aggressive surgical procedure, those who wish to avoid the long-term effects of radiation therapy, and/or those who have contraindications to pelvic radiotherapy. Typical candidates include young patients who desire ovarian preservation and retention of a functional, nonirradiated vagina.

Historically, there are five types of hysterectomy, as described by Piver and colleagues (1974). However, hysterectomy techniques used clinically today vary depending on the degree of surrounding tissue that is resected and are categorized as type I, II, or III (see Table 30-7).

Type I hysterectomy, also known as an *extrafascial hysterectomy* or *simple hysterectomy*, removes the uterus and cervix, but does not require excision of the parametrium or paracolpium. It is appropriately selected for benign gynecologic pathology, preinvasive cervical disease, and stage IA1 cervical cancer.

**TABLE 30-7.** Tissues Resected During Simple and Extended Hysterectomy

Procedure <sup>b</sup>	Type <sup>c</sup>	Involved Tissues <sup>a</sup>			
		Parametria & Paracolpos	Uterine Vessels	Uterosacral Ligament	Vagina
Simple hysterectomy	I	Preserve	Ligate at uterine isthmus	Transect at uterine insertion	Preserve
Modified radical hysterectomy	II	Removed medial to ureter	Ligate at level of ureter	Transect midway between uterus & rectum	Remove 1–2 cm
Radical abdominal hysterectomy	III	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels	Transect near rectum <sup>d</sup>	Remove $\geq 2$ cm
Type	IV <sup>e</sup>	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels; ligate superior vesical artery	Transect near rectum	Remove 3/4ths
Type	V <sup>e,f</sup>	Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels; ligate superior vesical artery	Transect near rectum	Remove 3/4ths
Radical vaginal hysterectomy		Removed medial to ureter	Ligate at level of ureter	Partially removed	Remove $\geq 2$ cm
Radical vaginal trachelectomy		Partially removed	Ligate descending cervicovaginal branch	Transect midway between uterus & rectum	Remove 1–2 cm
Radical abdominal trachelectomy		Removed medial to uterine vessel origin	Ligate at origin from internal iliac vessels	Transect near rectum	Remove $\geq 2$ cm

<sup>a</sup>Pelvic lymph node dissection accompanies all except simple hysterectomy.

<sup>b</sup>Hysterectomy includes corpus and cervix removal. For all procedures, unaffected ovaries may remain in premenopausal women, but entire adnexa are usually removed in postmenopausal patients.

<sup>c</sup>Rutledge classification of extended hysterectomy (Piver, 1974).

<sup>d</sup>Although Piver, 1974, described resection of the entire uterosacral ligament, this is not done in practice today due to the high incidence of postoperative urinary retention. Instead, the uterosacral ligaments are divided near the rectum.

<sup>e</sup>Although described by Piver, 1974, these procedures are currently not used clinically.

<sup>f</sup>With Type V, the bladder and proximal ureter are removed.

Type II hysterectomy, also known as *modified radical hysterectomy*, removes the cervix, proximal vagina, and parametrial and paracervical tissue. This hysterectomy is well suited for tumors in patients with stage IA1 cervical cancer who have positive margins following conization and have insufficient cervix to repeat conization. This hysterectomy is also appropriate for patients with stage IA1 cervical cancer with LVSI. Some institutions perform type II hysterectomies in women with stage IA2 tumors and smaller stage IB tumors with good outcomes (Landoni, 2001).

Type III hysterectomy, also known as *radical hysterectomy*, requires greater resection of the parametria. Its goal is to remove microscopic disease that has extended into the parametrium, paracolpium, and around the uterosacral ligaments. To summarize surgical steps, the uterine arteries are ligated at their origin from the internal iliac arteries near the pelvic sidewall, and all tissue medial to this origin, that is, the parametrium, is resected (Fig. 30-11) (Section 46-1, p. 1134). The ureters are completely dissected from their beds and moved laterally for protection during wide excision of the parametrium and

**FIGURE 30-11** Gross surgical specimen following radical hysterectomy. The specimen includes the uterus, parametria (arrows), adnexa, and 2 cm of proximal vagina.

paracolpium. The bladder and rectum are mobilized caudally and off the vagina to permit resection of  $\geq 2$  cm of proximal vagina. The uterosacral ligaments are clamped at their midpoint. This procedure is performed for stage IA2, stage IB1, stage IIA1, and for some stage IB2 lesions, and for patients with relative contraindications to radiation. These contraindications include diabetes, pelvic inflammatory disease, hypertension, collagen disease, inflammatory bowel disease, or adnexal masses.

The approach for type I, II, and III hysterectomies can be abdominal, laparoscopic, robot-assisted, or vaginal, depending on patient characteristics and surgeon experience. Advantages of MIS include less blood loss and shorter hospital stay. Intra- and postoperative complications are similar regardless of approach (Ramirez, 2008). Long-term follow-up of patients undergoing laparoscopic radical hysterectomy demonstrates excellent overall survival rates (Lee, 2010).

### Radical Trachelectomy

This surgical option can preserve fertility in selected young women with cervical cancer, and the cancer stages appropriate for radical trachelectomy mirror those for radical hysterectomy. Compared with radical hysterectomy, radical trachelectomy is less often performed.

Radical trachelectomy was originally completed vaginally, as described by Dargent (2000), but an abdominal approach is now used more commonly (Abu-Rustum, 2006). The abdominal approach allows for a larger resection of the parametria and is suitable for patients with larger tumors ( $> 2$  cm). With radical trachelectomy, steps of radical hysterectomy proceed and thus the uterine vessels are ligated, the parametria is resected, ureterolysis is completed, the bladder and rectum are mobilized, and the upper vagina is resected. To remove the cervix, the uterus is incised at or just below the level of the internal os, with the goal to leave 5 mm of endocervix still attached to the uterus. At this remaining endocervical margin, a thin tissue sample is sharply excised, termed a *shave margin*, and sent for frozen section. If cancer is absent in this specimen, then reconstruction may proceed. For this, a cerclage using permanent suture is placed, and the knot is tied posteriorly. The uterus is then stitched to the vagina using absorbable sutures. From each side, the corpus ultimately retains blood supply through the uterine branch of the ovarian artery.

Following radical trachelectomy, women continue to menstruate, and conception can occur naturally. However, cervical stenosis may develop, and thus intrauterine insemination or in vitro fertilization is often needed. Pregnancies are frequently complicated by second-trimester loss and higher rates of preterm birth (Plante, 2005; Shepherd, 2008). In a review of 485 women for whom a radical abdominal trachelectomy was planned, 47 cases (10 percent) were converted to radical hysterectomy. Another 25 women required adjuvant therapy based on final pathologic specimen findings. Thus, 413 women (85 percent) retained fertility. In this fertile cohort, there were 75 pregnancies, 18 miscarriages, 47 deliveries (19 term, 12 preterm, 16 not stated), and 10 women were pregnant at the time of publication (Pareja, 2013). Cesarean delivery with a classical incision is recommended.

**FIGURE 30-12** Computed tomography (CT) scan of stage IB2 cervical cancer (arrow).

### ■ Stage IB to IIA

Stage IB lesions are defined as those extending past the limits of microinvasion yet still confined to the cervix. This stage is subcategorized either as IB1 if tumors measure  $\leq 4$  cm or as IB2 if they measure  $> 4$  cm (Fig. 30-12).

Stage II cancers extend outside the cervix. They may invade the upper vagina and the parametria but do not reach the pelvic sidewalls. Stage IIA tumors have no parametrial involvement but do extend vaginally as far as the proximal two thirds of the vagina. Stage IIA is further subdivided into stage IIA1 for tumor size  $\leq 4$  cm and IIA2 for tumor size  $> 4$  cm. Stage IIB cancer may invade the vagina to a similar extent and also invade the parametria.

### Treatment

Stage IB to IIA cancers do not extend into the parametria and thus can be managed with either surgery or chemoradiation. In a prospective study of primary therapy, 393 women were randomly assigned to undergo radical hysterectomy and pelvic lymphadenectomy or receive primary radiation therapy. Five-year overall survival and disease-free survival rates were statistically equivalent (83 percent and 74 percent, respectively). Patients who underwent radical surgery followed by radiation had the worst morbidity (Landoni, 1997).

Because chemoradiation and surgery are both viable options, the optimum treatment for each woman ideally assesses clinical factors such as menopausal status, age, concurrent medical illness, tumor histology, and cervical diameter. For stage IB1 and IIA1 cervical cancers, it is left to the physician's discretion and patient preference as to which treatment modality is preferred. Our general approach to patients with bulky stage IB2 or stage II cervical cancers, that is, those measuring  $> 4$  cm, is to manage them primarily with chemoradiation, in a similar fashion to advanced-stage cervical cancers.

In general, radical hysterectomy for stage IB through IIA tumors is usually selected for premenopausal women who wish to preserve ovarian function and for women who have concerns about altered sexual functioning following radiotherapy. Age and weight are not contraindications to surgery. However,

in general, older women may have longer hospital stays, and heavier women can have longer operative time, greater blood loss, and higher rates of wound complications. Surgery is contraindicated in patients with severe cardiac or pulmonary disease.

In those electing surgery, oophorectomy may be deferred in younger women. One GOG study evaluated tumor spread to the ovary in those with IB tumors electing radical hysterectomy without adnexectomy. Ovarian metastases were identified in only 0.5 percent of 770 women with stage IB squamous cell cancers and in 2 percent of those with adenocarcinomas (Sutton, 1992). For those electing ovarian preservation, ovarian transposition, accomplished by oophoropexy of the ovary into the upper abdomen, can be performed during radical hysterectomy. T is repositioning helps preserve ovarian function, in case postoperative pelvic radiation is indicated. In addition, to reduce complications from radiotherapy that might be needed following radical hysterectomy, a surgeon may perform an omental J-flap. Namely, after surgery, the small bowel may become fixed in the pelvis by adhesions, which renders it vulnerable to radiation damage. T e omental J-flap can fill the pelvis to reduce this adhesion risk and is described in Section 46-14 (p. 1186).

Systematic lymphadenectomy can lead to complications such as lymphocyst and lymphedema. T erefore, in women with cervical cancer, sentinel lymph node mapping to assess lymphatic spread while avoiding extensive nodal resection is attractive. As a review, the sentinel node is the first node(s) receiving lymphatic drainage from a given tumor. To find this node, either blue dye or a technetium radioactive tracer or both are separately injected preoperatively into the cervix. At surgery, the sentinel node is stained blue and emits radioactivity discernible by Geiger counter. From a metaanalysis including 67 studies, the pooled sentinel node detection rate was 89 percent and sensitivity was 90 percent. Both were highest in women injected with both radiotracer and blue dye. Smaller tumor size (< 2 cm) and early-stage diseases were associated with the highest sensitivity and detection rate. At this time, sentinel node for cervical cancer remains experimental (Kadkhodayan, 2015).

### Weighing Surgical and Radiotherapy Complications

Complications for early-stage cervical cancer radical surgery include ureteral stricture, ureterovaginal fistula, vesicovaginal fistula, bladder dysfunction, constipation, wound breakdown, lymphocyst, and lymphedema. T e risk of venous thromboembolism warrants chemoprophylaxis and/or sequential compression devices as outlined in Table 39-8 (p. 836). If radiotherapy is added as an adjuvant to surgery, the risk of many of these is increased.

On the other hand, radiation therapy also carries long-term complications described in Chapter 28 (p. 619). Of these, altered sexual function secondary to a shortened vagina, dyspareunia, psychological factors, and vaginal stenosis are common. Late urinary and bowel complications such as fistula formation, enteritis, proctitis, and bowel obstruction may also develop following radiotherapy.

### Positive Pelvic Lymph Nodes

Approximately 15 percent of patients with stage I through IIA cervical cancers will have positive pelvic nodes. Risk factors for lymph node involvement include those listed in Table 30-8. Of those with involved nodes, 50 percent will have grossly positive pelvic nodes intraoperatively. In most cases involving grossly

positive nodes, radical hysterectomy is abandoned. After recovering from surgery, whole-pelvic radiation and brachytherapy with concomitant chemotherapy is administered. T e 50 percent of patients with involved nodes not grossly identified intraoperatively are considered to be at high risk of recurrence following their radical hysterectomy. As described subsequently, these women require postoperative adjuvant chemoradiation therapy.

### Recurrence Risk

For women who have completed radical surgery for early-stage cervical cancer, the GOG has defined risk factors to help identify women for tumor recurrence. *Intermediate risk* describes

those who on average would have a 30-percent risk of cancer recurrence within 3 years. Factors included in this model are depth of tumor invasion, clinical tumor diameter, and LVSI.

To determine appropriate treatment, patients with these intermediate-risk factors have been studied. In one trial, women were randomly assigned to receive pelvic radiation therapy following radical hysterectomy or to undergo radical hysterectomy and observation. A nearly 50-percent reduced risk of recurrence was found in those who received postoperative adjuvant radiation therapy (Sedlis, 1999). However, this adjuvant radiation does not prolong overall survival. Notably, these patients did not receive chemoradiation. In our practice, these intermediate-risk patients are counseled regarding their recurrence risk and offered the option of adjuvant chemoradiation therapy. A GOG clinical trial (GOG #263) that is assessing chemoradiation in this patient population is ongoing.

A *high-risk* category of early-stage cervical cancer patients who underwent radical surgery has also been described. High-risk is defined as a 50- to 70-percent risk of recurrence within 5 years. These women have positive lymph nodes, positive surgical margins, or microscopically positive parametria (Peters, 2000). This group is routinely offered adjuvant radiation therapy. Moreover, the GOG demonstrated that the addition of concurrent chemotherapy significantly prolongs disease-free and overall survival rates in this group of women with high-risk early-stage cancer (Peters, 2000).

### Adjuvant Hysterectomy Following Primary Radiation

Treating bulky stage I (IB2) cervical cancers with adjuvant hysterectomy after radiation therapy has been evaluated. Adjuvant hysterectomy reduces locoregional relapse but does not contribute to an overall improvement in survival rates. However, initial lesion size may affect efficacy. In one study, those with tumors measuring < 7 cm who underwent postradiation hysterectomy survived longer than did women with equivalent tumors in the radiation-only regimen group. In contrast, those with lesions  $\geq 7$  cm who underwent postradiation hysterectomy fared worse than their counterparts receiving only radiotherapy (Keys, 2003).

### Early-stage Cervical Adenocarcinoma

These cancers may be more radioresistant than squamous cell cervical carcinomas. Although some prefer radical hysterectomy to radiotherapy, studies suggest equivalent survival rates with either (Eifel, 1991, 1995; Hopkins, 1988; Nakano, 1995). However, larger lesions may not regress if managed by radiation alone (Leveque, 1998; Silver, 1998). The centers of bulky tumors may be less radiosensitive due to relative cellular hypoxia. This effect underscores the advantages of radical hysterectomy for women with stage I cervical adenocarcinoma.

## ADVANCED-STAGE PRIMARY DISEASE TREATMENT

### ■ Stages IIB through IVA

Advanced-stage cervical cancers extend past the confines of the cervix and often involve adjacent organs and retroperitoneal lymph

nodes. If untreated, these tumors progress rapidly. Treatment for these tumors is individualized, yet most advanced-stage tumors have a poor prognosis and 5-year survival rates are < 50 percent.

### Radiation Therapy

This modality forms the cornerstone of advanced-stage cervical cancer management. Both external beam pelvic radiation and brachytherapy are typically delivered (Chap. 28, p. 615). Of these, external beam radiation usually precedes intracavitary radiation, which is one form of brachytherapy. External beam radiation is commonly administered in 25 fractions during 5 weeks (40 to 50 Gy). During evaluation, if paraaortic nodal metastases are found, then extended-field radiation can be added to treat these affected lymph nodes.

During brachytherapy, bowel and bladder are packed away from the intracavitary source using vaginal packing during tandem insertion to limit radiation to these organs. Treatment is often prescribed to point A, that is, a point 2 cm lateral and 2 cm superior to the external cervical os, and to point B, which is a point 3 cm lateral to point A. Side effects during and following radiation therapy are common, and these are discussed in Chapter 28 (p. 619).

### Chemoradiation

Current evidence indicates that chemotherapy given concurrently with radiation therapy significantly improves overall and disease-free survival rates of women with cervical cancer. Chemoradiation is also associated with superior survival rates compared with pelvic and extended-field paraaortic region irradiation alone (Morris, 1999). After five trials demonstrated improved survival rates, it is now recommended that cisplatin-based chemotherapy should be considered in women undergoing radiation for cervical cancer (Keys, 1999; Morris, 1999; Peters, 2000; Rose, 1999; Whitney, 1999).

Of chemotherapy agents, cisplatin-containing regimens have been associated with the best survival rates (Rose, 1999; Whitney, 1999). The characteristics of this agent are described in Chapter 27 (p. 602), and Figure 30-13 describes its

**FIGURE 30-13** Cisplatin can bind covalently to DNA bases. Radiation therapy may create single-strand breaks. If occurring alone, each damaging event is likely to be repaired. However, if both occur in close proximity, irreparable damage can lead to cell death.

tumoricidal action. Nonplatinum regimens also have activity but have not been directly compared with cisplatin-containing regimens (Vale, 2008). At our institution, cisplatin is given weekly for 5 weeks. It is administered concurrently with external beam radiation and with brachytherapy. Unfortunately, the recurrence risk remains as high as 40 percent after chemoradiation given for curative intent (Chemoradiotherapy for Cervical Cancer Meta-Analysis Collaboration, 2009). Therefore, a large international randomized Phase III trial is currently evaluating whether the addition of adjuvant chemotherapy after completion of chemoradiation improves overall survival rates for women with stage IB1 with positive nodes and for those with stage IB2 through IVA disease.

### Pelvic Exenteration for Primary Disease

This ultraradical surgery encompasses removal of the bladder, rectum, uterus, fallopian tubes and ovaries (if present), vagina, and surrounding tissues (Section 46-4, p. 1149). Primary exenteration may be considered for women with stage IVA cancer, that is, with direct tumor invasion into bladder and/or bowel but without distant spread. Exenteration is rarely performed for this indication, yet for suitable candidates, the survival rate can reach 30 percent (Million, 1972; Upadhyay, 1988).

### ■ Stage IVB

Patients with stage IVB disease have a poor prognosis and are treated with a goal of palliation. Pelvic radiation is administered to control vaginal bleeding and pain. Systemic chemotherapy is offered to palliate symptoms and prolong overall survival. The chemotherapy regimens used in this group of women are similar to those used in the setting of recurrent cancer.

## SURVEILLANCE

### ■ Following Radiotherapy

Women who receive radiotherapy are closely monitored to assess their response. Tumors may be expected to regress for up to 3 months after therapy. Pelvic examination and/or radiologic scanning should document progressive shrinkage of the cervical mass. The rectovaginal examination is used to detect nodularity in the ligaments and parametria. If disease progresses locally after this interval, prognosis is poor. Pelvic exenteration may sometimes be indicated for this clinical setting.

In general, patients are seen at 3-month intervals for 2 years, then every 6 months until 5 years have passed from treatment, and then annually. At each visit, in addition to pelvic examination, a thorough manual nodal survey includes neck, supraclavicular, axillary, and inguinal lymph nodes. A cervical or vaginal cuff Pap test is also collected annually for 20 years after treatment completion. Findings of high-grade squamous intraepithelial lesions with screening should prompt colposcopic evaluation and biopsy of suspicious lesions. If recurrent cancer is diagnosed from these biopsies, then CT imaging is performed.

Once radiotherapy is completed, patients are encouraged to use a vaginal dilator or have vaginal intercourse three times per week. This helps keep the vagina patent, aids pelvic examination

and Pap testing in the future, and ensures that the patient can remain sexually active if desired. Otherwise, radiation may result in vaginal fibrosis, leading to a shortened, nonfunctional vagina. The use of a water-based lubricant is also recommended.

### ■ Following Surgery

After a radical hysterectomy, 80 percent of recurrences are detected within the subsequent 2 years. During patient surveillance, an abnormal pelvic mass or abnormal pelvic examination finding typically prompts CT scanning of the abdomen and pelvis. Findings include cervical or vaginal lesion, rectovaginal nodularity, pain radiating down the posterior thigh, or new-onset lower extremity edema. Pelvic recurrences after radical hysterectomy, if diagnosed early, can be treated with radiation therapy. The same schedule of visits and Pap testing as just outlined for surveillance following radiotherapy is then recommended.

### ■ Hormone Therapy

Cervical cancer is not estrogen-dependent and thus hormone therapy is not contraindicated to treat menopausal symptoms, taking into account the risks and benefits discussed in Chapter 22 (p. 494). Moreover, hormone therapy is strongly considered for any premenopausal patient undergoing radiation treatment for cervical cancer until the average age of menopause. This is because radiation doses given for cervical cancer lead to menopause. Ovaries previously transposed out of the pelvic radiation field may be exceptions. Either systemic or vaginal forms are suitable. Estrogen alone is used if the uterus has been surgically removed, whereas combination hormonal therapy is given if the uterus remains.

## SECONDARY DISEASE

This is defined as either persistent or recurrent cancer. *Persistent disease* is cervical cancer that has not completely regressed within 3 months of finishing radiotherapy. *Recurrent disease* is defined as a new lesion after primary therapy completion and initial regression.

Treatment of persistent or recurrent disease depends on its location and extent. The intent in these cases is usually palliative. However, in certain instances, a woman may qualify for pelvic radiation if she previously had not received this treatment. Alternatively, a woman may be a candidate for curative-intent surgery. Metastatic cervical cancer is not curable. In this setting, the goal of chemotherapy is to maximize existing patient quality of life and prolong survival.

### ■ Pelvic Exenteration for Secondary Disease

When curative-intent surgery is contemplated, local disease should be biopsy proven. Clinically, a patient may be considered for pelvic exenteration if the triad of lower extremity edema, back pain, and hydronephrosis are absent. If present, these suggest disease extension to the pelvic sidewalls, which would contraindicate surgery. In addition, regional and distant metastasis should be excluded by both physical examination and radiologic imaging, which typically is a PET/CT scan.

**TABLE 30-9.** Combination Chemotherapy Regimens and Response Rates of Cervical Cancer

Study	Chemotherapy Agents	Response Rates (%)	Progression-free Survival (months)	Overall Survival (months)
Moore, 2004	Cisplatin vs.	19	2.8	8.8
	Cisplatin and paclitaxel	36	4.8	9.7

Monk, 2009	Cisplatin and paclitaxel vs.	29	5.8	12.9
	Cisplatin and vinorelbine vs.	26	4	10–10.3
	Cisplatin and gemcitabine vs.	22	4.7	
	Cisplatin and topotecan	23	4.6	
Tewari, 2014	Cisplatin and paclitaxel ±	45	7.6	14.3
	bevacizumab vs.	50		17.5
	Topotecan and paclitaxel ±	27	5.7	12.7
	bevacizumab	47		16.2

Pelvic exenteration begins with exploratory laparotomy, biopsies of suspicious lesions, and paraaortic lymph node evaluation. Exenteration is completed only if no disease is found in frozen section specimens sampled at the beginning of the surgery. A complete surgical description of this procedure is found in Section 46-4 (p. 1149).

Alternatively, in highly selected patients, radical hysterectomy may be considered as an alternative to pelvic exenteration (Coleman, 1994). In these circumstances, women should have small cervical recurrences measuring less than 2 cm and have disease-free pelvic lymph nodes both prior to and during surgery.

With either operation, intraoperative and postoperative complications can be significant. Reported 5-year survival rates approximate 50 percent. Most recurrences occur in the first 2 years postoperatively (Berek, 2005; Goldberg, 2006).

■ **Radiotherapy or Chemotherapy for Secondary Disease**

Patients with central or limited peripheral recurrences who are radiotherapy naïve are candidates for curative-intent chemoradiation treatment. In these groups, survival rates of 30 to 70 percent have been reported (Ijaz, 1998; Ito, 1997; Lanciano, 1996; Potter, 1990).

Antineoplastic drugs are used to palliate both disease and symptoms of advanced, persistent, or recurrent cervical cancer (Table 30-9). Cisplatin is considered the single most active cytotoxic agent in this setting (Tigpen, 1995). Overall, response duration to cisplatin is 4 to 6 months, and survival in such women only approximates 7 months (Vermorken, 1993). A four-arm prospective randomized study demonstrated that the combinations of cisplatin with topotecan, vinorelbine, or gemcitabine are not superior to the combination of cisplatin and paclitaxel (Monk, 2009). Most recently, a randomized study evaluated adding bevacizumab to combination chemotherapy. Bevacizumab (Avastin) is a monoclonal antibody targeting vascular endothelial growth factor (VEGF). This addition

increased the median overall survival length by 3.7 months (see Table 30-9) (Tewari, 2014).

**PALLIATIVE CARE**

Palliative chemotherapy is administered only if this treatment does not significantly lower patient quality of life and is balanced against the benefits of supportive care. Women with persistent nausea and vomiting from tumor-associated ileus may benefit from a gastrostomy tube. Bowel obstruction can be managed surgically, provided a patient is an appropriate surgical candidate. Percutaneous nephrostomy tubes may be placed for urinary fistulas or urinary tract obstruction.

Pain management forms the basis of palliation, and an extensive list of pain medications is found in Table 42-2 (p. 910). Cervical cancer patients can experience significant pain, and this is assessed at each visit. Many will require narcotics. If a patient has been using opioids and is hospitalized for inadequate pain control, then patient-controlled analgesia is considered. The total dose that controls the pain in a 24-hour period is determined. This dose can then be converted an equivalent dose of long-acting opioids. To allow for incomplete cross-tolerance between narcotics, the dose should be decreased by 25 to 50 percent. A supplemental short-acting opioid can be available for breakthrough pain and is typically prescribed at a dose that is 10 to 20 percent of the long-acting total daily dose and given at appropriate intervals. Narcotics can constipate, and patients using these are given a bowel regimen. This can be individualized, and suitable agents are listed in Table 25-6 (p. 570). In particular, a combination of stool softeners (docusate sodium) plus laxative (senna) plus polyethylene glycol is often effective.

We recommend discussion of medical directives if a patient has adequate mental capability. Often, such discussion is conducted over time, giving a woman an opportunity to understand the severity and progression of her disease. Home hospice is an invaluable part of terminal care for most of these women,

who require intensive pain management and considerable assistance with daily living activities.

## MANAGEMENT DURING PREGNANCY

Survival rates between pregnant and nonpregnant women with cervical cancer do not differ when matched by age, stage, and year of diagnosis. Overall survival rates are slightly better for cervical cancer in pregnancy, because an increased proportion of patients have stage I disease.

### ■ Diagnosis

A Pap test is recommended for all pregnant patients older than 21 at the initial prenatal visit. Additionally, clinically suspicious lesions are directly biopsied. If Pap test results reveal HSIL, adenocarcinoma in situ (AIS), or suspected malignancy, then colposcopy is performed and biopsies are obtained. However, endocervical curettage is excluded to prevent amnionic sac rupture.

If Pap testing indicates malignant cells and colposcopy-directed biopsy fails to confirm malignancy, then diagnostic conization may be necessary. Many experts recommend delaying conization until the second trimester due to concern about pregnancy loss, however, median blood loss during excisional procedures increases with gestational age, especially in the third trimester. In pregnant patients, a loop electrosurgical excision procedure (LEEP) does not appear to offer an advantage compared with cold-knife conization. Moreover, one study found a surgical complication rate of 25 percent with LEEP in pregnancy, and 47 percent of the women had persistent or recurrent disease (Robinson, 1997).

### ■ Stages I and II Cancer in Pregnancy

Women with microinvasive squamous cell cervical carcinoma found during conization that measures  $\leq 3$  mm and contains no LVSI (stage IA1) may deliver vaginally and be reevaluated 6 weeks postpartum. Moreover, for those with stage IA or IB disease, studies find no increased maternal risk if treatment is intentionally delayed to optimize fetal maturity regardless of the trimester in which the cancer was diagnosed. Given the outcomes, a planned treatment delay is generally acceptable for women who are 20 or more weeks' gestational age at diagnosis with stage I disease and who desire to continue their pregnancy. However, a patient may be able to delay from earlier gestational ages if she wishes. For women who wish to continue pregnancy, pelvic lymph node dissection can be performed in pregnancy in the first and second trimester via MIS (Vercellino, 2014). Women with positive nodes may elect to be treated with definitive treatment, rather than delay treatment, or may opt for neoadjuvant chemotherapy during pregnancy or for early delivery. For women who have a previable gestation and who desire definitive treatment of early-stage disease, a radical hysterectomy with the fetus in situ and lymphadenectomy can be performed. For patients with stage IA2 through IIA1, a cesarean section via a classical uterine incision may be performed at term, followed immediately by radical hysterectomy and lymph node dissection. Notably, a classical cesarean incision minimizes the

risk of cutting through tumor in the lower uterine segment, which can cause serious blood loss and result in tumor spread.

### ■ Advanced Cervical Cancer in Pregnancy

Women with advanced cervical cancer diagnosed prior to fetal viability are offered primary chemoradiation. Spontaneous abortion of the fetus tends to follow whole-pelvis radiation therapy. For women who decline pregnancy termination, systemic chemotherapy can be administered. Cisplatin with vincristine or with paclitaxel can be administered in pregnancy. Congenital anomalies, growth restriction, and preterm delivery do not appear to be increased in fetuses of women who receive chemotherapy after the first trimester (Cardonick, 2010). If cancer is diagnosed after fetal viability is reached and a delay until fetal pulmonary maturity is elected, then a classical cesarean delivery is performed. Chemoradiation is administered after uterine involution. For patients with advanced disease and treatment delay, pregnancy may impair prognosis. A woman who elects to delay treatment, to provide quantifiable benefit to her fetus, will have to accept an undefined risk of disease progression.

## CHAPTER 31

# Vulvar Cancer

RELEVANT ANATOMY	679
EPIDEMIOLOGY	679
RISK FACTORS	680
DIAGNOSIS	681
PROGNOSIS	682
TREATMENT	684
SURVEILLANCE	688
RECURRENT DISEASE	688
MELANOMA	688
OTHER VULVAR MALIGNANCIES	690
REFERENCES	692

Vulvar cancers comprise only about 4 percent of all gynecologic malignancies. Most vulvar cancers are diagnosed at an early stage (I and II). Advanced disease is found mainly in older women, perhaps due to clinical and behavioral barriers that lead to diagnostic delays. Thus, biopsy of any abnormal vulvar lesion is imperative to help diagnose this cancer early.

In the United States, vulvar cancers carry a comparatively good prognosis with a 5-year relative survival rate of 78 percent (Stroup, 2008). For resectable disease, traditional therapy includes radical excision of the vulva plus inguinal lymphadenectomy or plus sentinel lymph node biopsy. For advanced stages, chemoradiation may be used either primarily or as an adjunct to surgery to aid tumor control. All of these treatments can result in extensive short- and long-term morbidity and dramatic anatomic and functional deformity. Accordingly, vulvar cancer management recently has trended toward more conservative surgery that preserves oncologic outcome, lessens morbidity, and improves psychosexual well-being.

### RELEVANT ANATOMY

The *vulva* includes the mons pubis, labia majora and minora, clitoris, vestibule, vestibular bulbs, Bartholin glands, lesser vestibular glands, paraurethral glands, and the urethral and vaginal openings. Lateral margins of the vulva are the labiocrural folds (Fig. 38-25, p. 818). Vulvar cancer may involve any of these external structures and typically arises within the covering

squamous epithelium. Unlike the cervix, the vulva lacks an identifiable transformation zone. That said, squamous neoplasia arises predominantly on the vestibule at the border between the vulvar keratinized stratified squamous epithelium, which lies laterally, and the nonkeratinized squamous mucosa, which lies medially. This demarcation line is termed Hart line.

Deep to the vulva are the superficial and deep urogenital triangle compartments. The superficial space lies between Colles fascia (superficial perineal fascia) and the perineal membrane (deep perineal fascia) (Fig. 38-26 p. 819). Within this space lie the ischiocavernosus, bulbospongiosus, and transverse perineal muscles and the highly vascular vestibular bulb and clitoral crus. During radical vulvectomy, dissection is carried to the depth of the perineal membrane. As a result, contents of this superficial urogenital triangle compartment that lie beneath the mass are removed during tumor excision.

The lymphatics of the vulva and distal third of the vagina typically drain into the superficial inguinal node group (Fig. 38-29, p. 823). From here, lymph travels through the deep femoral lymphatics and the node of Cloquet to the pelvic nodal groups. Importantly, lymph can also drain directly from the clitoris and upper labia to the deep femoral nodes (Way, 1948). Vulvar lymphatics cross at the mons pubis and the posterior fourchette but do not cross the labiocrural folds (Morley, 1976). Thus, lesions found within 2 cm of the midline may spread to lymph nodes on either side. In contrast, lateral lesions rarely send metastases to contralateral nodes. This anatomy point influences the decision for ipsilateral or bilateral node dissection, as discussed later.

The superficial inguinal nodes cluster within the femoral triangle formed by: the inguinal ligament, sartorius muscle, and adductor longus muscle. The deep femoral nodes lie within the borders of the fossa ovalis and just medial to the femoral vein. An *inguinofemoral lymphadenectomy* typically refers to removal of both superficial inguinal and deep femoral lymph nodes (Levenback, 1996).

### EPIDEMIOLOGY

In the United States, women have a 1 in 333 chance of developing this cancer at some point. In 2014, approximately 4850 new vulvar cancers and 1030 cancer deaths were predicted (National Cancer Institute, 2014). The age-adjusted incidence of invasive vulvar tumors in the United States has trended upward during the past three decades due to an aging population and greater longevity of human immunodeficiency virus (HIV)-infected women. This increase persists among all age groups and all geographic areas (Bodelon, 2009). Specifically, the age-adjusted incidence of vulvar carcinoma in situ (CIS)

**FIGURE 31-1** Vulvar squamous cell carcinoma. **A.** Low-power view. The surface epithelium shows high-grade squamous dysplasia. Nests of invasive squamous cell carcinoma (arrow) are present. A brisk chronic inflammatory infiltrate is present as is often the case with invasive squamous cell carcinoma. Portions of the surface epithelium extend deep and are cut tangentially (asterisks), giving the false impression of invasive tumor at these sites. **B.** Tumor shows classic diagnostic features of invasive squamous cell carcinoma that include a squamoid appearance, intercellular bridges, and brightly eosinophilic keratin pearls (arrows). Nests of invasive tumor are surrounded by chronic inflammation. (Used with permission from Dr. Kelley Carrick.)

has increased by 3.5 percent per year, whereas that of invasive cancers has risen by 1 percent yearly (Jemal, 2010).

Of vulvar tumors, approximately 90 percent are squamous cell carcinoma (Fig. 31-1). Malignant melanoma is the second most common, but rare histologic subtypes may also be encountered (Table 31-1).

**RISK FACTORS**

*Age* is a prominent factor and positively correlates with this cancer. Less than 20 percent of affected women are younger than

50 years, and more than half of cases develop in women older than 70. Survival rates also differ by age. Kumar and associates (2009) described a hazard ratio of nearly 4 for death in women older than 50 years compared with younger women. Last, vulvar cancer pathology can be divided into two distinct age-dependent profiles. Those that develop in younger women (< 55 years) tend to have the same risk profile as other anogenital cancers. These cancers are usually described histologically as basaloid or warty and are linked with human papillomavirus (HPV) in 50 percent of cases. In contrast, older affected women typically are nonsmokers and lack a history of prior sexually transmitted infections. Their cancers are largely keratinizing, and HPV DNA is found in only 15 percent (Canavan, 2002; Madeleine, 1997). Such HPV-independent vulvar cancers have been associated with lichen sclerosus and with genetic alterations such as mutations in *p53*. This tumor suppressor gene normally modulates cell death, and its mutation can be carcinogenic.

*Infection* with high-risk HPV serotypes is another vulvar cancer risk. Serotype 16 predominates, although HPV serotypes 18, 31, 33, and 45 are also reported. Although HPV is implicated in many vulvar cancers, stronger correlations are noted between HPV infection and preinvasive vulvar lesions (Hildesheim, 1997). Specifically, HPV DNA is detected in 50 to 70 percent of invasive lesions but is seen in > 90 percent of vulvar intraepithelial neoplasia (VIN) lesions (Gargano, 2012). HPV becomes a stronger contributor when combined with other cofactors such as smoking or herpes simplex virus (HSV) infection (Madeleine, 1997). Women who have smoked and have a history of HPV genital warts have a 35-fold increased risk for developing vulvar cancer compared with women without these predispositions (Brinton, 1990; Kirschner, 1995). For these reasons, prophylactic vaccination against high-risk HPV may ultimately reduce vulvar cancer incidence. A full discussion of HPV and VIN is found in Chapter 29 (p. 646)

<b>Yolk sac tumors</b>

*Herpes simplex virus infection* is also linked with vulvar cancer in several studies (Hildesheim, 1997; Madeleine, 1997). As noted, the association is more prominent when coupled with other cofactors such as smoking. Thus, the causal link between HSV alone and vulvar cancer is not considered conclusive.

*Chronic immunosuppression* can predispose to vulvar cancer. For example, transplant patients have a high incidence. In this group, vulvar cancer develops at a much younger age than in the general population, and more than 50 percent have a prior history of condyloma acuminata (Penn, 2002). With HIV, vulvar cancer rates are also increased (Elit, 2005; Frisch, 2000). And, of the increased high-grade VIN and invasive vulvar carcinoma incidence noted in younger women, HIV-infected patients make up the majority (Casolati, 2003). A possible explanation for this is the association of HIV and high-risk HPV subtypes. However, vulvar cancer is not yet considered an acquired immunodeficiency syndrome (AIDS)-defining malignancy. Because of these links with vulvar cancer, we recommend that all immunocompromised women undergo thorough vulvar inspection and, when indicated, vulvoscopy and biopsy.

*Lichen sclerosus* is a chronic vulvar inflammatory disease and is related to vulvar cancer development. Keratinocytes affected by lichen sclerosus show a proliferative phenotype and can exhibit markers of neoplastic progression. As such, lichen sclerosus may be a precursor lesion in some invasive squamous vulvar cancers (Rolfe, 2001). Vulvar cancers coexistent with lichen sclerosus tend to develop in older women, predominate in near the clitoris, and lack association with VIN 3.

Last, progression from *VIN 3* to invasive cancer is suspected. Several reports demonstrate that in a small percentage of women older than 30 years, untreated lesions can progress to invasive cancer within a mean of 4 years (Jones, 2005; van Seters, 2005). Although this progression cannot be conclusively validated, we recommend that patients with moderate and severe vulvar dysplasias receive early definitive treatment (Chap. 29, p. 649).

## DIAGNOSIS

### ■ Symptoms

Women with VIN and vulvar cancer commonly present with pruritus and a visible lesion (Fig. 31-2). However, pain, bleeding, ulceration, or inguinal mass may be other complaints (Fig. 31-3). Manifestations can persist for weeks or months before diagnosis, as many patients may be embarrassed or may not recognize the significance of their symptoms.

### ■ Lesion Evaluation

Lesions may be raised, ulcerated, pigmented, or warty, but in younger women with multifocal disease, a well-defined mass is not always present. Importantly, other clinical entities may present similarly and include preinvasive neoplasia (VIN), infection, chronic inflammatory disease, and granulomatous disease. Thus, the goal of evaluation is to obtain an accurate and definitive pathologic diagnosis.

For this, colposcopic examination of the vulva, termed *vulvoscopy*, can direct biopsy site selection. To begin, the vulva is soaked with 3-percent acetic acid for 5 minutes to allow

**FIGURE 31-2** Early-stage squamous cell cancer of the vulva.

adequate penetration into the keratin layer. This aids identification of acetowhite areas and abnormal vascular patterns, which are characteristics of vulvar neoplasia. The entire vulva and perianal skin are systematically examined. We recommend obtaining multiple biopsies, as illustrated in Figure 4-2 (p. 88), from the most suspicious raised or dyspigmented skin. Specimens removed with a Keyes punch should be approximately 4 mm thick to include the surface epithelial lesion and the underlying stroma. This permits evaluation for invasion and depth of invasion. Concurrent colposcopic examination of the cervix and vagina and careful evaluation of the perianal area are recommended to diagnose any synchronous lesions or associated neoplasm of the lower genital tract.

### ■ Cancer Patient Evaluation

Following histologic diagnosis, a patient with vulvar cancer is assessed for the clinical extent of disease and for comorbid conditions. Thus, detailed physical examination includes measurement

**FIGURE 31-3** Enlarged inguinal lymph node containing metastatic squamous cell vulvar cancer. (Used with permission from Dr. William Griffith.)

**FIGURE 31-4** Photograph of invasive vulvar cancer.

of the primary tumor and evaluation of cancer extension into other genitourinary system compartments, the anal canal, the bony pelvis, and inguinal lymph nodes. At our institution, if a thorough physical examination is not possible because of patient discomfort or disease extent, an examination under anesthesia is performed. This may be coupled with cystourethroscopy, proctosigmoidoscopy, or both if suspicion of tumor invasion into the urethra, bladder, or anal canal is high (Fig. 31-4).

Women with small tumors and clinically negative groin nodes require few additional diagnostic studies other than those

needed for surgical preparation (Chap. 39, p. 825). Although not a formal part of surgical tumor staging, preoperative imaging may complement staging in those with larger tumors or with clinically suspected metastatic disease. In such cases, a chest radiograph and computed tomography (CT), positron emission tomography (PET), or magnetic resonance (MR) imaging of the abdomen and pelvis provide information regarding disease extent or metastases that may modify preoperative planning.

■ **Staging Systems**

The International Federation of Gynecology and Obstetrics (FIGO) advocates surgical staging of patients with vulvar cancer that is based on a tumor, nodal, metastatic (TNM) classification. Thus, staging involves: (1) primary tumor resection to obtain tumor dimensions and (2) dissection of superficial and deep inguinofemoral lymph nodes to evaluate tumor spread (Pecorelli, 2009). This system is used to direct treatment and predict prognosis (Van der Steen, 2010). Table 31-2 and Figure 31-5 describe FIGO staging and American Joint Committee on Cancer (AJCC) staging criteria for all vulvar cancer types except melanoma. This cancer’s staging is discussed separately on page 688. The general nuanced differences between FIGO and AJCC systems are described in Chapter 30 (p. 663).

**PROGNOSIS**

Overall survival rates of women with squamous cell carcinoma of the vulva are relatively good. Five-year survival rates of 75

**TABLE 31-2.** Invasive Vulvar Cancer Staging

TNM <sup>a</sup>	Stage <sup>b</sup>	Characteristics
	<b>I</b>	<b>Tumor confined to the vulva</b>
T1a	IA	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1.0 mm <sup>c</sup> , no nodal metastasis
T1b	IB	Lesions > 2 cm in size or with stromal invasion > 1.0 mm <sup>c</sup> , confined to the vulva or perineum, with negative nodes
T2	<b>II</b>	<b>Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes</b>
	<b>III</b>	<b>Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinofemoral lymph nodes</b>
N1b	IIIA	(i) With 1 lymph node metastasis (≥ 5 mm), or
N1a		(ii) 1–2 lymph node metastasis(es) (< 5 mm)
N2b	IIIB	(i) With 2 or more lymph node metastases (≥ 5 mm), or
N2a		(ii) 3 or more lymph node metastases (< 5 mm)
N2c	IIIC	With positive nodes with extracapsular spread
	<b>IV</b>	<b>Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures</b>
T3	IVA	Tumor invades any of the following: (i) upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) fixed or ulcerated inguinofemoral lymph nodes
M1	IVB	Any distant metastasis including pelvic lymph nodes

to 90 percent are routinely cited for stage I and II disease. As anticipated, 5-year survival rates for higher stages are poorer, and rates of 54 percent for stage III and 16 percent for stage IVB are reported (American Cancer Society, 2015). Apart from FIGO stage, other important prognostic factors include lymph node metastasis, lesion size, depth of invasion, resected-margin status, and lymphatic vascular space involvement (LVSI) (Table 31-3).

Of these, *lymph node metastasis* is the single most important vulvar cancer predictor, since inguinal node metastasis reduces long-term survival rates by 50 percent (Farias-Eisner, 1994; Figge, 1985). Nodal status is determined by surgical resection and histologic evaluation. Among patients with nodal metastasis,

other factors further predict poor prognosis. These include a high number of involved lymph nodes, large nodal metastasis size, extracapsular invasion, and fixed or ulcerated nodes (Homesley, 1991; Origoni, 1992).

*Tumor diameter* also influences survival rates. But this stems mainly from the positive correlation between lesion size and nodal metastasis rates (Homesley, 1993).

*Depth of invasion* is another prognostic element. As shown in Figure 31-6, this depth is measured from the basement membrane to the deepest point of invasion (Kurman, 2014). Tumors with a depth of invasion  $< 1$  mm carry little or no risk of inguinal lymph node metastasis. However, increased nodal metastasis rates positively correlate with greater invasion rates.

**TABLE 31-3.** Prognostic Predictors and Clinical Effects

Depth of Invasion (mm)	Positive Nodes (%)
1	3
2	9
3	19
4	31
5	33
≥ 5	48

Tumor Diameter (cm)	5-Year Survival (%)
0–1	90
1–2	89
2–3	83
3–4	63
> 4	44

*Surgical margins* that are tumor-free decrease local tumor recurrence rates, and traditionally a 1- to 2-cm tumor-free margin is desired. More specifically, two large retrospective series demonstrated that a tumor-free surgical margin  $\geq 8$  mm yielded a high rate of local control. In contrast, if tumor was found within this 8-mm margin, the recurrence rate was 23 to 48 percent (Chan, 2007; Heaps, 1990). Hence, when lesions are close to the clitoris, anus, urethra, or vagina, a 1-cm surgical tumor-free margin may be used to preserve important anatomy yet still provide optimal resection.

*Lymphatic vascular space invasion (LVSI)* describes histologic identification of tumor cells within lymphatic vessels and is a predictor of early disease recurrence (Preti, 2005). LVSI is also associated with a higher frequency of lymph node metastasis and a lower overall 5-year survival rate (Hoskins, 2000).

**FIGURE 31-6** Histologic measurement of invasive vulvar cancer. Depth of invasion is measured from the junction between the epithelium and stroma of the most superficial dermal papilla to the greatest depth of tumor invasion.

**TREATMENT**

**■ Surgery**

For vulvar cancer treatment, surgery is often an integral part. Potential procedures, in increasing order of radicality, include wide local excision (WLE), radical partial vulvectomy, and radical complete vulvectomy.

Of these, *wide local excision* is appropriate only for microinvasive tumors (stage IA) of the vulva. With this excision, also termed *simple partial vulvectomy*, 1-cm surgical margins are obtained around the lesion. Deep surgical margins measuring 1 cm are also preferred. T is deep margin usually corresponds to Colles fascia (Fig. 38-25, p. 818).

With *radical partial vulvectomy* (Section 46-25, p. 1210), tumor-containing portions of the vulva are completely removed, wherever they are located. Skin margins are 1 to 2 cm, and excision extends deep to the perineal membrane (Fig. 31-7). Radical

**FIGURE 31-7** **A.** Vulvar cancer following radiation therapy and in preparation for surgical excision. **B.** Radical partial vulvectomy. **C.** Final surgical closure. (Used with permission from Dr. David Miller.)

partial vulvectomy is typically reserved for unifocal lesions that are clinically confined to the labia majora, labia minora, mons, vestibule, and/or perineum and that have limited involvement of the adjacent urethra, vagina, and/or anus. Moreover, only patients with a solitary tumor that is not too large or too extensive and with an otherwise normal vulva are considered for this vulva-conserving surgery.

**Radical total vulvectomy** (Section 46-26, p. 1213) is a complete dissection of vulvar tissue to the level of the perineal membrane and the periosteum of the pubic rami or symphysis. Adequate margins will generally require an incision in the labiocrural fold that extends down to the fourchette and up over the mons pubis. All intervening subcutaneous tissue is excised. Lesions involving or adjacent to the clitoris may require wider margins cephalad to the mons. Such radical resections are performed for large midline or multifocal vulvar cancers. Flap reconstruction is occasionally needed and described in Section 46-28 (p. 1219). Contraindications to a radical complete vulvectomy include poor surgical risk, poor patient compliance, and metastatic disease beyond regional lymph nodes.

Of the three procedures shown in [Figure 31-8](#), the en bloc incision, colloquially termed the *butterfly* or *longhorn* incision, has largely been abandoned. It has survival rates equivalent to radical complete vulvectomy but carries significantly greater morbidity.

### Inguinofemoral Lymphadenectomy

This procedure is usually an integral part of surgical cancer staging and accompanies radical partial or radical complete vulvectomy. It is recommended for all vulvar squamous carcinomas that invade deeper than 1 mm on initial biopsy or have a tumor diameter > 2 cm regardless of invasion depth (stages IB-IVA). To maximize metastatic disease detection and staging accuracy, surgical evaluation of the groin nodes is recommended. Traditionally, both the superficial inguinal and deep femoral lymph nodes have been removed for evaluation of metastatic disease (Gordinier, 2003). Moreover, lymph nodes may be excised unilaterally or bilaterally. Traditionally, an ipsilateral inguinofemoral lymphadenectomy is performed for a “lateralized” vulvar lesion, namely, one that lies > 2 cm beyond the midline. Bilateral node excision is recommended for all lesions within 2 cm of the midline. Aside from acquiring staging information, inguinofemoral lymphadenectomy may also be used to debulk large, cancerous lymph nodes.

Entire steps for lymphadenectomy are described and illustrated in Section 46-27 (p. 1216). To summarize, the superficial inguinal lymph nodes lie within the fatty tissue caudal to the inguinal ligament and superficial to the thigh’s fascia lata. This node-containing tissue is dissected free to reach the fossa ovalis. Here, deep femoral nodes are excised from their location medial to and alongside the femoral vein. For these deep nodes, a modified approach preserves the cribriform fascia (portion of fascia lata overlying the fossa ovalis) by removing the deep femoral nodes through the cribriform fascia’s perforations. This modification yields cancer recurrence rates comparable to those obtained following classic inguinofemoral node dissection (Bell, 2000; Hacker, 1983). Advantageously, complication rates of wound breakdown, infection, and lymphedema are significantly

**FIGURE 31-8** Types of vulvectomy used in the treatment of vulvar cancer. **A.** En bloc radical vulvectomy with bilateral inguinofemoral lymphadenectomy. **B.** Radical complete vulvectomy with bilateral inguinofemoral lymphadenectomy. **C.** Radical partial vulvectomy with ipsilateral inguinofemoral lymphadenectomy.

decreased ([Table 31-4](#)). However, a classic inguinofemoral node dissection on occasion is required to reach these deep femoral lymph nodes. In such cases, the cribriform fascia is transected, lymph nodes are removed, and the sartorius muscle can then be transposed over the femoral vessels. This transposition may reduce the risk of postoperative erosion into the skeletonized femoral vessels if superficial wound dehiscence occurs. However,

**TABLE 31-4.** Postoperative Complications of Inguinofemoral Lymphadenectomy

Complication	No. of Events	Percent of Groins
Lymphedema	13	14.0
Lymphocele	11	11.8
Groin infection	7	7.5
Groin necrosis	2	2.2
Groin separation	7	7.5

Reproduced with permission from Bell JG, Lea JS, Reid GC: Complete groin lymphadenectomy with preservation of the fascia lata in the treatment of vulvar carcinoma, *Gynecol Oncol* 2000 May;77(2):314–318.

this transposition does not reduce overall postoperative wound morbidity rates (Judson, 2004; Rouzier, 2003).

Surgical evaluation of the groin nodes has been reported to confer a superior prognosis compared with primary groin irradiation. A phase III randomized controlled trial conducted by the Gynecologic Oncology Group (GOG) showed that patients undergoing primary groin dissection experienced significantly fewer groin recurrences and a better prognosis compared with women receiving groin irradiation (Stehman, 1992b). Furthermore, limiting node dissection to only the superficial inguinal nodes also confers a higher groin recurrence rate compared with historical controls undergoing removal of both superficial and deep nodes (Stehman, 1992a). Higher than acceptable groin recurrence rates have also been described for patients who received primary groin irradiation (Manavi, 1997; Perez, 1993). Thus, in general, both deep and superficial inguinal lymph node removal is recommended to allow for thorough evaluation for nodal metastasis. But, because of groin dissection morbidity, this advantage has been challenged for those with early-stage disease and clinically negative nodes. Namely, recent evidence supports the use of sentinel lymph node biopsy in vulvar lesions < 4 cm in diameter and assures a low false-negative rate of undetected nodal metastasis.

### Sentinel Lymph Node Biopsy

As another less morbid option, selective dissection of a solitary node or nodes, termed *sentinel lymph node biopsy (SLNB)*,

dramatically reduces surgical morbidity yet adequately assesses nodal involvement. Physiologically, the first lymph node to receive tumor lymphatic drainage is termed the *sentinel lymph node*. Thus, a sentinel lymph node devoid of disease implies absent lymph node metastases within the entire lymph node basin. SLNB is not performed if groin node metastases are clinically suspected.

Currently, both lymphoscintigraphy and isosulfan blue dye techniques are recommended when performing SLNB for vulvar cancer (Levenback, 2008). To begin, intraoperative lymphatic mapping is accomplished by injecting radionuclide intradermally at the tumor border that lies closest to the ipsilateral groin. For midline tumors, both sides of the tumor are injected. A handheld gamma counter aids attempts to identify the sentinel node subcutaneously, and the skin is marked by pen over the strongest signal. Next, isosulfan blue dye is injected at the same tumor border. Last, the groin skin over the prior pen mark is incised approximately 5 minutes later (Fig. 31-9). The tracer and dye are taken up by the specific node that drains the tumor site first. The handheld gamma counter signal may assist in localizing the sentinel node, and/or it can be visually identified by its blue color. Once identified, it is separated and excised from the other nodes within that regional group.

Several studies have confirmed the accuracy of SLNB to predict vulvar cancer metastasis in the inguinal lymph nodes. One multicenter trial by the GOG reported the sensitivity of this technique was > 90 percent and the false negative rate was 2 percent for tumors measuring < 4 cm. Patients with tumors measuring  $\geq 2$  cm and invading to a depth > 1 mm and with clinically negative nodes were included in the study (Levenback, 2012). SLNB for patients with a vulvar lesion that does not involve midline structures but that also does not meet the definition of a lateralized lesion is appealing as it potentially avoids unnecessary groin exploration on one side (Coleman, 2013).

A second study, the GROningen International Study on Sentinel nodes in Vulvar cancer (GROINSS-V), evaluated SLNB for patients with squamous cell cancer of the vulva measuring < 4 cm. It too confirmed the predictive value of SLNB. Moreover, this study concluded that the risk of metastasis to additional inguinal lymph nodes increases with sentinel-node metastasis

**FIGURE 31-9** Sentinel lymph node evaluation. **A.** Blue dye and radiotracer are injected at the tumor periphery. **B.** Blue dye is taken up by the specific node that drains the tumor site. **C.** This sentinel node can be visually identified, separated from the other nodes within the regional group, and removed for evaluation.

size (Oonk, 2010; Van der Zee, 2008). Last, one ongoing prospective study (GROINSS-V-II) is observing early-stage vulvar cancer patients with a sentinel node metastasis measuring  $\leq 2$  mm to see if complete inguinofemoral lymphadenectomy can be safely replaced by adjuvant radiotherapy following vulvectomy.

### ■ Microinvasive Tumors (Stage IA)

Within the FIGO system, stage I vulvar cancers are divided into two categories. Stage IA lesions measure  $\leq 2$  cm in diameter, are confined to the vulva or perineum, and display stromal invasion  $\leq 1$  mm. These lesions, termed *microinvasive cancers*, reflect a subpopulation in which the risk of inguinal metastasis is negligible (Binder, 1990; Donaldson, 1981; Hacker, 1984). Women with microinvasive stage IA tumors tend to be younger and have multifocal disease associated with HPV. For probable cure, these patients can undergo wide local excision with a 1-cm margin. Lymphadenectomy is not indicated because associated lymph node metastasis is rare.

### ■ Stage IB–II

Patients with early-stage vulvar cancer typically present with T1B and T2 lesions (stage IB and II) of the vulva and clinically negative groin nodes. For stage IB lesions, radical resection of the primary tumor and inguinofemoral lymphadenectomy is recommended. If adequate margins and dissection to the perineal membranes can be achieved, then radical partial vulvectomy offers similar recurrence rates but less morbidity than radical complete vulvectomy (Tantipalakorn, 2009). Because 20 to 30 percent of women with T1 and T2 disease will have diseased nodes, SLNB and/or inguinofemoral lymphadenectomy is performed. As described on page 685, lesion laterality and clinical impression regarding groin involvement guides the decision to perform ipsilateral or bilateral groin dissection.

Stage II cancers are most often managed with a larger radical partial excision. For example, a 4-cm lesion involving the clitoral hood may be managed by an anterior hemivulvectomy and bilateral inguinofemoral lymphadenectomy. Again, reported experience with conservative surgery suggests identical local recurrence rates if 1- to 2-cm surgical margins are achieved (Burke, 1995; Farias-Eisner, 1994; Tantipalakorn, 2009). Occasionally, a radical complete vulvectomy may be required, depending on tumor size and location.

### ■ Stage III

By definition, stage III vulvar cancers include node-positive tumors. Affected patients have T1 or T2 vulvar lesions with regional nodal spread that is not fixed or ulcerated. Most patients with clinically negative nodes have typically undergone a radical partial or complete vulvectomy and inguinofemoral lymphadenectomy. However, in cases where groin nodes are grossly positive and resectable, “nodal debulking” is performed but further nodal dissection is forfeited. This allows adjuvant radiotherapy to treat any residual microscopic disease yet minimize additional groin dissection morbidity. In practice, most women with stage III vulvar cancer are treated with adjuvant radiation therapy directed to both groins and the pelvis.

Efficacy for this was shown in a randomized GOG trial of 114 patients with invasive squamous cell carcinoma of the vulva and diseased groin nodes. Adjuvant radiation to both groins and the pelvic midplane proved superior to extended pelvic node resection. However, 12 percent of women completing radiotherapy still relapsed in the groin and pelvis, and 8.5 percent at distant sites (Homesley, 1986; Kunos, 2009).

Nodal metastasis does not increase the risk of recurrence on the vulva. Hence, adjuvant radiation to the vulva is the treating physician’s decision and guided by margin status, tumor size, and LVSI.

The addition of platinum-based chemotherapy concurrent with radiation therapy stems from treatment of cervical cancer. Also, extrapolation of apparent efficacy in phase II trials of more locally advanced vulvar cancer suggests a role for this for postoperative patients with lymph node metastases (Moore, 1998, 2012). To improve control in both inguinal and pelvic lymph nodes and survival rates, a randomized phase III trial (GOG protocol #185) is currently comparing adjuvant radiation therapy and the combination of radiation plus weekly cisplatin chemotherapy in vulvar cancer patients with positive nodes.

### ■ Stage IVA

These locally advanced vulvar cancers involve the proximal urethra, proximal vagina, bladder or rectal mucosa, or pelvic bone and may or may not have affected inguinal lymph nodes. With stage IVA vulvar cancers, women occasionally can be treated with radical primary surgery. Much more often, tumor size and location necessitate some form of exenterative surgical procedure to remove the entire lesion with adequate margins. Such unresectable, locally advanced vulvar cancers can be effectively treated with neoadjuvant chemoradiation to drastically minimize the surgical resection required. Two Phase II studies conducted by the GOG have demonstrated the feasibility of this approach using cisplatin regimens (Moore, 1998, 2012). An on-going Phase II trial is currently evaluating the efficacy of cisplatin, gemcitabine, and intensity-modulated radiation therapy (IMRT) for primary treatment of locally advanced squamous cell carcinoma of the vulva. As described in Chapter 28 (p. 616), IMRT offers greater sculpting of radiation delivery to minimize toxicity.

Our current practice is to offer preoperative cisplatin-based chemoradiation to women with inoperable primary tumors or with extensive lesions that would require pelvic exenteration. In cases without fixed groin nodes, pretreatment inguinofemoral lymphadenectomy is performed to determine the need for groin irradiation. If groin nodes are fixed or ulcerated, then primary chemoradiation is administered.

If residual disease remains on the vulva following chemoradiation, then local resection is indicated. If there has been complete clinical response, the primary tumor site undergoes excisional biopsy to confirm pathologic response. Unresected groins that are clinically or radiographically positive 8 weeks after surgery are biopsied by fine-needle aspiration (FNA). If the FNA is positive, a targeted excision of the groin is performed.

In contrast, for stage IVB vulvar cancer, treatment is individualized. A multimodality approach is used to achieve palliation.

## SURVEILLANCE

After completing primary treatment, all patients receive thorough physical examination, including inguinal lymph node palpation and pelvic examination every 3 months for the first 2 to 3 years. Surveillance examinations are then scheduled every 6 months to complete a total of 5 years. Thereafter, disease-free women may be seen annually. Vulvoscopy and biopsies are performed if concerning areas are noted during history or physical examination. Radiologic imaging and biopsies to diagnose possible tumor recurrence are performed as indicated.

## RECURRENT DISEASE

### ■ Vulvar Recurrences

In a woman with suspected recurrence, careful evaluation is completed to define the disease extent. Local vulvar recurrences are most common, and surgical reexcision is usually the best option. Radical partial vulvectomy is appropriate for smaller lesions. For large central recurrences involving the urethra, vagina, or rectum, a total pelvic exenteration with reconstructive surgery may be required (Section 46-4, p. 1149). With exenteration, to maintain sexual function, vaginal reconstruction can be completed at the time of surgery or after a short postoperative interval (Section 46-9, p. 1165). Radiated tissue often has a poor blood supply. Thus, vulvar recurrences in a previously radiated field typically require myocutaneous flaps for reconstruction after surgical resection. Last, for patients who are not surgical candidates and are radiation naïve to the vulva, external beam radiation combined with interstitial brachytherapy can be an option.

### ■ Distant Recurrences

Inguinal lymph node recurrences are virtually always associated with ultimately fatal disease, and few women are alive at the end of the first year following this diagnosis. Women with pelvic or distant metastases can be offered palliative chemotherapy. Combination platinum-based chemotherapy has modest activity in recurrent vulvar cancers (Cunningham, 1997; Moore, 1998). Platinum-based regimens (e.g., cisplatin/paclitaxel) as recommended for advanced cervical cancer might be considered for vulvar cancer if palliative chemotherapy is indicated.

## MANAGEMENT DURING PREGNANCY

Squamous cell cancer of the vulva diagnosed and surgically treated during pregnancy is rare, and an incidence of 1 per 20,000 deliveries has been reported (DiSaia, 1997). Nevertheless, any suspicious lesion is evaluated, even during pregnancy.

Radical complete or partial vulvectomy and inguinofemoral lymphadenectomy can be performed when indicated after the first trimester. During the third trimester, markedly increased genital vasculature can increase surgical morbidity. In general, if a diagnosis is made during the late third trimester, lesions may be removed by wide local excision, and definitive surgery completed postpartum. In cases diagnosed at delivery, definitive surgery is performed typically 2 to 3 weeks postpartum.

The mode of delivery following cancer surgery is heavily influenced by the state of the postsurgical vulva. In instances of vaginal stenosis, significant fibrosis, or tumor involvement, a cesarean delivery is recommended, otherwise vaginal delivery is appropriate.

## VERRUCOUS CARCINOMA

This rare variant of squamous cell carcinoma constitutes less than 1 percent of all vulvar cancers. Its etiology is unknown, but HPV genome has been found in some of these tumors. Verrucous carcinomas are locally invasive and rarely metastasize. Most women have a cauliflower-shaped vulvar mass that usually elicits pruritus or pain. Surgery is preferred, and most tumors are excised by wide local excision that ensures a 1-cm surrounding margin. Inadequate margins risk local recurrence. Verrucous carcinomas are resistant to radiotherapy and may undergo anaplastic transformation to become more aggressive and invasive. Enlarged groin lymph nodes are evaluated preoperatively by FNA because they usually are inflammatory.

## MELANOMA

### ■ Clinical Presentation and Staging

Melanoma is the second most common vulvar cancer and accounts for 10 percent of all vulvar malignancies. Vulvar melanoma disproportionately affects the elderly and develops more commonly among whites than other races. Vulvar melanoma has an overall poor prognosis, and 5-year survival rates range from 8 to 55 percent (Evans, 1994; Piura, 1992).

Malignant vulvar melanomas most commonly arise from the labia minora, labia majora, or clitoris (Fig. 31-10) (Moore, 1998; Woolcott, 1988). Some benign pigmented lesions can also be found here and include lentigo simplex, vulvar melanosis, acanthosis nigricans, seborrheic keratosis, and nevi (Chap. 4, p. 95). Last, pigmented vulvar neoplasia may be VIN, squamous cell carcinoma, or Paget disease. Thus, tissue sampling is mandatory, and immunohistochemical studies or electron

**FIGURE 31-10** Vulvar melanoma. (Used with permission from Dr. William Griffith.)

**FIGURE 31-11** Photomicrographs of vulvar melanoma. **A.** Medium-power view. Atypical, hyperchromatic melanoma cells are identified within the basal portion of the surface epithelium. Melanoma cells containing intracytoplasmic melanin pigment invade subepithelial stroma in a broad swath. **B.** High-power view. The malignant melanoma cells in this case have occasionally prominent nucleoli, abundant intracytoplasmic melanin pigment, and frequent mitoses including abnormal mitoses (arrows). (Used with permission from Dr. Kelley Carrick.)

microscopy can help clarify the diagnosis (Fig. 31-11). Three histologic subtypes of vulvar melanoma have been described: superficial spreading melanoma (SS), nodular melanoma (NM), and acral lentiginous melanoma (AL).

Vulvar melanomas have been staged by several microstaging systems that include the Chung, the Clark, and the Breslow systems and by the macroscopic systems published by FIGO and AJCC (Table 31-5). Of these, the AJCC stage and Breslow thickness are major predictors of overall survival and are used most often. Breslow thickness measures in millimeters the thickest portion of the lesion from the intact epithelium's most superficial surface to the deepest point of invasion (Moxley, 2011; Verschraegen, 2001).

## ■ Treatment

### Surgery

Vulvar melanoma has limited response to both chemotherapy and radiotherapy. Thus, excision is the single best definitive therapy. Conservative surgery, such as wide local excision or a radical partial vulvectomy, is preferred as radical surgery appears to offer no greater survival advantage (Irvin, 2001; Verschraegen, 2001).

Nodal metastasis is a major predictor of prognosis. The incidence of occult inguinal lymph node metastases is < 5 percent for thin melanomas measuring < 1 mm thickness, but > 70 percent for lesions > 4 mm (Hoskins, 2000). Women with clinically positive groin lymph nodes should undergo inguinofemoral lymphadenectomy if possible, as surgical removal of regional disease is the most effective method of control. In patients with clinically negative groins, the decision to perform inguinofemoral lymphadenectomy or SLNB is influenced by lesion thickness. Primary lesions that warrant inguinofemoral node evaluation are those that have a Breslow thickness > 1 mm. Other high-risk candidate lesions are lesions < 1 mm thick but showing ulceration, a mitotic rate > 1 per mm<sup>2</sup>, or

LVSI, and those lesions with ambiguous thickness due to a biopsy's positive deep margin (Lens, 2002b). At our institution, we encourage women with clinically negative groins to first undergo SLNB. If diseased nodes are detected, then an inguinofemoral lymphadenectomy can be considered.

### Adjuvant Therapy

Women may be considered for adjuvant therapy if their primary vulvar melanoma poses a great risk for disease recurrence. Factors include lesions that are 2 to 4 mm thick and ulcerated, deep primary tumors, positive nodes, or other high-risk features.

Of options, in certain patients with regional cutaneous melanoma involving other body surfaces, adjuvant alpha interferon (IFN- $\alpha$ ) increases both progression-free and overall survival rates (Lens, 2002a). At our institution, however, we strongly advocate enrollment in a trial for such patients, recognizing that interferon regimens have considerable toxicity and offer limited benefit.

Adjuvant radiation therapy also shows some promise to reduce locoregional recurrence rates (Ballo, 2005). The National Comprehensive Cancer Network (NCCN) guidelines for treatment of positive resection margins or macroscopically positive fully resected nodal basins include radiotherapy to the affected areas.

### Metastatic Disease

Metastatic melanoma is challenging to treat, and 5-year survival rates are < 20 percent (Sugiyama, 2007). Resection of distant metastases can be considered for selected patients in whom a survival benefit might be expected compared with medical treatment.

For systemic therapy, several options are available. Preferred regimens include ipilimumab, vemurafenib, or high-dose interleukin-2 (HD IL-2). Of these, HD IL-2 (Proleukin) was approved by the Food and Drug Administration (FDA) in 1998 for metastatic melanoma and benefits a small patient

TABLE 31-5. Melanoma Staging

Staging	Class	Thickness (mm)	Tumor Ulceration Status/Mitoses
IA	T1a, N0, M0	≤ 1	a: Without ulceration and mitosis < 1/ mm <sup>2</sup>

subset. Based on these findings, other novel immunotherapeutic approaches have subsequently been investigated.

One novel approach involves T-cell mechanisms that self-regulate T-cell activation through expression of *cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4)*. Ipilimumab is a fully human monoclonal antibody that blocks CTLA-4, thereby increasing T-cell activity and promoting antitumor actions. Ipilimumab (Yervoy) received FDA approval for treatment of metastatic melanoma in March 2011. Although the response rate and overall survival rates with ipilimumab are modest, therapy toxicities, which include immune-related enterocolitis, hepatitis, and dermatitis, are manageable.

In addition, recognition of other key molecular mutations that drive melanoma tumorigenesis has led to promising agents that selectively inhibit the actions of these mutations. Namely, *BRAF* and *c-KIT* mutations may be found in these tumors, and women with melanoma often have their tumors tested for these mutations. Vemurafenib (Zelboraf), a BRAF inhibitor, was approved by the FDA for treatment of metastatic or unresectable melanoma that exhibits the *BRAF* mutation (Robert, 2011). Imatanib (Gleevec) may be used for tumors with the *c-KIT* mutation.

Last, *biochemotherapy* refers to regimens that combine cytotoxic agents with IFN-α and/or HD IL-2. Biochemotherapy may provide a palliative benefit in patients who are symptom-

atic and/or have rapidly progressive disease. However, the lack of survival benefit with biochemotherapy suggests that alternative therapies should be considered.

BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) of the vulva accounts for < 2 percent of all vulvar cancers and is most commonly found in elderly women (DiSaia, 1997). Lesions typically arise on the labia majora, are characterized by poor pigmentation and pruritus, and often mimic eczema, psoriasis, or intertrigo. As a result, correct diagnosis is often delayed due to treatment for other presumed inflammatory or infectious dermatoses.

Although ultraviolet radiation is thought to be the primary risk factor for BCC on sun-exposed areas, its development on sun-protected areas raises the possibility of other, yet undefined, etiologies. Some suggest that local trauma and advancing age may contribute at these sites (LeSueur, 2003; Wermuth, 1970).

Basal cell carcinoma is removed by radical partial vulvectomy using a minimum surgical margin of 1 cm. Lymphatic or distant spread is rare, but inguinofemoral lymphadenectomy or SLNB is considered for clinically suspicious nodes. However, disease may locally recur, particularly in tumors removed with suboptimal margins. Most basal cell carcinomas of the vulva are indolent

**FIGURE 31-12** Vulvar epithelioid sarcoma.

and locally invasive, but rarely metastatic. If surgery is contraindicated, then primary radiation therapy can be considered. Local immunomodulators such as imiquimod can be selected for patients who are inappropriate surgical candidates. Because surgery is the recommended treatment, any other treatment modalities will warrant close observation to detect cancer progression.

### VULVAR SARCOMA

Sarcoma of the vulva is rare, and leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, and malignant rhabdoid tumor are the more frequently encountered histologic types. Of these, leiomyosarcoma appears to be most common. Tumors typically develop as isolated masses on labia majora, clitoris, or Bartholin gland (Fig. 31-12). Unlike squamous cell carcinoma, the age of affected women is significantly broader and varies between histologic types.

The outcome of vulvar sarcomas is influenced by size, degree of mitotic activity, and level of infiltration. That is, disease associated with lesions > 5 cm in diameter, with infiltrating margins, with extensive necrosis, and with more than five mitoses per 10 high-power fields is most likely to recur after surgical resection (Magné, 2011).

Hematogenous metastasis is the most frequent route of tumor dissemination. Radical partial or complete vulvectomy or pelvic exenteration is recommended if total surgical resection is possible. Removal of inguofemoral lymph nodes is performed if nodes are large and/or symptomatic. Adjuvant radiation, chemotherapy or both can be considered depending on risk factors for recurrence. Neoadjuvant chemotherapy and/or radiotherapy are considerations for unresectable vulvar sarcomas.

### BARTHOLIN GLAND CARCINOMA

Primary malignant tumors arising from the Bartholin gland can be adenocarcinomas, squamous cell carcinomas, or transitional cell carcinomas. The incidence of Bartholin gland carcinomas peaks in women in their mid-60s. Soft, distensible tissue normally surrounds these glands, and tumors may reach considerable

size before patients develop symptoms. Dyspareunia is a common first complaint. Bartholin gland enlargement in a woman older than 40 years and recurrent cysts or abscesses warrant a biopsy or excision. Similarly, all solid masses require FNA or biopsy to establish a definitive diagnosis.

Bartholin gland carcinomas tend to spread into the ischio-rectal fossa and have a propensity for lymphatic spread into the inguinal and pelvic lymph nodes. Therapy for most early cancer stages includes a radical partial vulvectomy with inguofemoral lymphadenectomy. Decisions to perform ipsilateral or bilateral groin dissection follow the same criteria as for squamous cell tumors. Postoperative chemoradiation has been shown to reduce the likelihood of local recurrence for all stages. If the initial lesion impinges on the rectum or anal sphincter, preoperative chemoradiation can be used to avoid extensive surgery.

### VULVAR PAGET DISEASE

Extramammary Paget disease is a heterogeneous group of intraepithelial neoplasias and when present on the vulva, appears as an eczematoid, red, weeping area (Fig. 31-13). These are often localized to the labia majora, perineal body, or clitoris. This disease typically develops in older white women and accounts for approximately 2 percent of all vulvar tumors. Vulvar Paget disease is accompanied by invasive Paget disease or adenocarcinoma of the vulva in 10 to 20 percent of cases (Hoskins, 2000). Moreover, 20 percent of patients with extramammary Paget disease will have a carcinoma at another non-vulvar location (Pang, 2010; Wilkinson, 2002).

A histologic classification proposed by Wilkinson and Brown (2002) includes: (1) primary vulvar cutaneous Paget disease, (2) Paget disease as an extension of transitional cell carcinoma of the bladder or urethra, and (3) Paget disease as an extension of an associated adjacent primary cancer such as vulvar, anal, or rectal cancers. The histologic differentiation of these Paget disease types is important because the specific diagnosis significantly influences treatment selection.

Of these, primary cutaneous vulvar Paget disease displays slow growth. Diseased areas ideally are resected by wide local excision with a 1- to 2-cm margin. In contrast to VIN 3 treatment, margins are frequently positive, and disease recurrence is common regardless of the surgical margin status (Black, 2007). If invasive disease is suspected, radical partial vulvectomy is warranted by extending the deep margins to the perineal membrane. The latter is frequently accompanied with an ipsilateral or bilateral inguofemoral lymphadenectomy.

Recurrent Paget disease is common, and long-term surveillance is prudent since repeat surgical excision is often necessary. Moreover, screening and surveillance for tumors at nongynecologic sites is considered and includes evaluation of the breasts and the gastrointestinal and genitourinary tracts. A detailed discussion of Paget disease of the breast is presented in Chapter 12 (p. 285).

### CANCER METASTATIC TO THE VULVA

Metastatic tumors make up approximately 8 percent of all vulvar cancers. Tumors may extend from primary cancers of

**FIGURE 31-13** **A.** Vulvar Paget disease involving the labia bilaterally, perineum, perianus, and solid right perianal mass. (Used with permission from Dr. Claudia Werner.) **B.** Photomicrograph of primary cutaneous vulvar Paget disease. This is characterized microscopically by the presence of relatively large atypical cells with prominent nucleoli and abundant delicate cytoplasm (arrow). These cells are disposed singly or in clusters at various levels within the epidermis. The neoplastic cells are most often confined to the epidermis and would in these instances be classified as an adenocarcinoma in situ. (Used with permission from Dr. Kelley Carrick.)

the bladder, urethra, vagina, or rectum. Less proximate cancers include those from the breast, kidney, lung, stomach, and gestational choriocarcinoma (Wilkinson, 2011).

Cancer found in the vagina is most likely metastatic disease. Primary vaginal carcinoma is rare and makes up only 3 percent of all gynecologic malignancies (Siegel, 2015). The low incidence reflects the infrequency with which primary carcinoma arises in the vagina and the strict criteria for its diagnosis. According to International Federation of Gynecology and Obstetrics (FIGO) staging criteria, a vaginal lesion that involves adjacent organs such as the cervix or vulva, by convention, is deemed primary cervical or vulvar, respectively (Pecorelli, 1999). The most common histologic type of primary vaginal cancer is squamous cell carcinoma, followed by adenocarcinoma (Platz, 1995).

RELEVANT ANATOMY

During embryogenesis, the müllerian ducts fuse caudally to form the uterovaginal canal (Chap. 18, p. 404). The canal’s distal portion forms the proximal vagina, whereas the distal vagina arises from the urogenital sinus. The uterovaginal canal is lined by columnar epithelium, which is subsequently replaced by squamous cells migrating cephalad from the urogenital sinus. These squamous cells stratify, and the vaginal epithelium matures and thickens. Underlying this epithelium, muscularis and adventitial layers surround the vaginal tube.

With vaginal cancer, local extension and lymphatic invasion are common patterns of spread. The lymphatic channels that drain the vagina form extensive, complex, and variable anastomoses. As a result, any node in the pelvis, groin, or anorectal area may drain any part of the vagina. Of these, the external, internal, and common iliac lymph nodes are the primary sites of vaginal lymphatic drainage. Thus, pelvic lymphadenectomy, which samples these nodal groups, is commonly performed during primary surgical excision of proximally located vaginal cancers. Alternatively, lymphatic vessels of the posterior vagina may empty into the inferior gluteal, presacral, or perirectal

nodes, and those of the vagina’s distal third may drain to the superficial and deep inguinal lymph nodes (Frank, 2005).

Hematogenous spread of vaginal cancer is less frequent, and venous drainage consists of the uterine, pudendal, and rectal veins, which drain into the internal iliac vein. Arterial blood supply to the vagina comes primarily from internal iliac artery branches, which include the uterine, vaginal, middle rectal, and internal pudendal arteries (Fig. 38-12, p. 805).

INCIDENCE

According to estimates for 2015, 4070 new cases of vaginal cancer will be diagnosed in the United States, and there will be 910 deaths (Siegel, 2015). The overall incidence is 0.45 cases per 100,000 women but is notably lower in whites (0.42 cases) compared with black and Hispanic women (0.73 and 0.56 cases, respectively). Vaginal cancer rates increase with age and peak among women ≥ 80 years. The median age at diagnosis is 58 (Watson, 2009). Of histologic forms, squamous cell carcinoma accounts for 70 to 80 percent of all primary vaginal cancer cases (Beller, 2003; Platz, 1995).

SQUAMOUS CELL CARCINOMA

Risks

Squamous cell cancer of the vagina arises within its stratified nonkeratinized epithelium (Fig. 32-1). As with other cancers of the lower reproductive tract, human papillomavirus (HPV) has been closely linked with squamous cell vaginal cancer (Chap. 30, p. 658). A systematic review found an HPV prevalence of 65 percent in samples from invasive vaginal cancer, and a 93-percent prevalence in high-grade vaginal dysplasia lesions. HPV 16 was the most common type and was present in 55 percent of vaginal cancer samplings (Smith, 2009). A retrospective cross-sectional study involving 31 countries found similar results (Alemany, 2014).

Because of this association with HPV infection, vaginal in situ and invasive squamous cell carcinomas share risk factors similar to those for cervical cancer. Some of these include multiple lifetime sexual partners, early age at first intercourse, and current cigarette smoking. Women with a vulvar or cervical cancer history are also at increased risk. This last association may stem from the field effect of HPV affecting multiple lower genital tract epithelia or may result from direct tumor spread.

Vaginal intraepithelial neoplasia (VaIN) is a precursor to invasive vaginal cancer, and approximately 2 to 3 percent of patients with VaIN will progress to invasive cancer (Dodge,

**FIGURE 32-1** Sections showing invasive squamous cell carcinoma of the vagina. **A.** Invasive, well-differentiated squamous cell carcinoma of the vagina (bracket) invading the subepithelial stroma ( $\times 4$ ). **B.** Invasive, well-differentiated squamous cell carcinoma of the vagina ( $\times 10$ ). Invasive tumor is composed of irregular nests of malignant squamous cells with keratin pearls (arrow) and intercellular bridges. (Used with permission from Dr. Kelley Carrick.)

2001; Ratnavelu, 2013). The quadrivalent HPV vaccine is effective in preventing VaIN 2 and 3 associated with HPV 16 or 18 (Joura, 2007). It is possible that use of this vaccine will decrease invasive vaginal cancer rates in the future.

## ■ Diagnosis

Vaginal bleeding is the most common complaint associated with vaginal cancer, although pelvic pain and vaginal discharge also may be noted. Less frequently, lesions involving the anterior vaginal wall may lead to dysuria, hematuria, or urgency. Alternatively, constipation may result from posterior wall masses. Most vaginal cancers develop in the upper third of the vagina. Moreover, of those with cancers, women who have had a prior hysterectomy are significantly more likely to have lesions in the upper vagina (70 percent) than those without prior hysterectomy (36 percent) (Chyle, 1996).

During pelvic evaluation in all women, the vagina is inspected as the speculum is inserted or removed. If a gross lesion is found, vaginal cancer usually can be diagnosed by punch biopsy in the office. Biopsy may be obtained with Tischler biopsy forceps (Fig. 29-16, p. 641). An Emmett hook, one type of skin hook, may be useful to elevate and stabilize vaginal tissue during biopsy. Monsel paste is applied as needed for hemostasis. If a gross lesion is not detectable, vaginotomy can guide directed biopsy. Bimanual examination assists in determining the tumor size, and rectovaginal examination is especially important for posterior wall lesions.

Once cancer is diagnosed, no specific laboratory testing other than that used generally for preoperative preparation such as complete blood count and serum chemistry panel is required.

## ■ Staging and Classification

Vaginal cancer staging is similar to that for cervical cancer and is completed clinically by physical examination and with the

assistance of cystourethroscopy and/or proctosigmoidoscopy depending on tumor location. Chest radiography aids the search for metastatic disease (Table 32-1 and Table 32-2). If needed, general anesthesia can permit a more detailed pelvic examination for accurate staging. Proctosigmoidoscopy to a depth of at least 15 cm can detect local bowel invasion, whereas cystourethroscopy assists identification of bladder or urethral involvement.

Computed tomography (CT) scanning, magnetic resonance (MR) imaging, and fluorodeoxyglucose-positron emission tomography (FDG-PET) may also be useful in treatment planning but are not classically used to determine disease stage. CT scanning can delineate the size and extent of many tumors (Fig. 32-2). However, if the extent of cancer expansion is unclear, MR imaging is the most useful radiologic tool available to visualize the vagina due to its superior soft tissue resolution. FDG-PET can also be selected to evaluate lymph node involvement and distant metastases. In one study, FDG-PET was more sensitive than CT for detection of abnormal lymph nodes (Lamoreaux, 2005).

■ **prognosis**

The prognosis of vaginal squamous cell carcinoma has improved since the 1950s, when the 5-year survival rate was only 18 percent. Advances in radiation technology and earlier diagnosis are largely responsible for the improved 5-year survival rate, which now ranges from 45 to 68 percent for all stages (Ghia, 2011; Hellman, 2006).

The prognosis of vaginal squamous cell carcinoma depends primarily on FIGO stage (Fig. 32-3 and Table 32-2) (Frank, 2005; Peters, 1985). Other factors associated with poor prognosis include larger tumor size, adenocarcinoma cell type, and older age (Hellman, 2006; Tjalma, 2001; Tran, 2007). The 5-year disease-specific survival rate is 85 to 92 percent for women with stage I disease, 68 to 78 percent for those with stage II, and 13 to 58 percent for those with stage III or IV (Fig. 32-4) (Frank, 2005; Tran, 2007).

■ **Treatment**

**Stage I**

Because of vaginal cancer’s rarity, data are limited to guide evidence-based treatment. Therefore, therapy is individualized and based on factors such as tumor type, stage, location, and size.

For stage I disease, both surgery and radiotherapy are options. However, surgery is preferred for most if negative surgical margins can be achieved. Surgery includes radical vaginectomy, radical hysterectomy (for women with an intact uterus), and pelvic lymphadenectomy for most tumors located in the upper third of the vaginal vault. A review of the National Cancer Data Base showed that women with stage I disease treated

**FIGURE 32-2** Computed tomography (CT) scan reveals size and extent of vaginal mass (arrow).

with surgery alone had a significantly improved 5-year survival rate compared with those treated with radiation (90 percent versus 63 percent) (Creasman, 1998). However, other reports have found no significant difference in disease-free survival rates in women with stage I disease treated with surgery compared

**FIGURE 32-3** FIGO (International Federation of Gynecology and Obstetrics) staging of vaginal cancer.

**FIGURE 32-4** Disease-specific survival stratified by International Federation of Gynecology and Obstetrics (FIGO) stage. (Reproduced with permission from Tran PT, Su Z, Lee P, et al: Prognostic factors for outcomes and complications for primary squamous cell carcinoma of the vagina treated with radiation. *Gynecol Oncol* 2007 Jun;105(3):641–649.)

with radiation alone (Stock, 1995). Radiotherapy may be delivered by external beam, with or without brachytherapy. Further, brachytherapy alone has been used successfully to treat selected small stage I lesions (Nori, 1983; Perez, 1999; Reddy, 1991).

### Stage II

Depending on circumstances and the treating clinician, primary surgery or radiation may be selected for stage II cancers. Stock and colleagues (1995) found a significant survival advantage at 5 years in those with stage II disease treated with surgery compared with those treated with radiation (62 percent versus 53 percent). Review of the National Cancer Data Base showed that the 5-year survival rate for women with stage II disease treated with surgery alone was 70 percent; with radiotherapy alone, 57 percent; and with a combination of surgery and radiotherapy, 58 percent (Creasman, 1998). However, other researchers have found no survival advantage from surgery compared with radiotherapy in stage II disease (Davis, 1991; Rubin, 1985).

Radiation is generally recommended if negative margins cannot be achieved surgically due to tumor location or size or to patient comorbidities that preclude surgery. If primary radiation is administered for stage II disease, a combination of external beam radiation and brachytherapy is the most common regimen. External beam radiation generally is given first, and depending on tumor response, brachytherapy is tailored to remaining disease. As discussed subsequently, adjuvant chemotherapy is often administered during radiation therapy.

### Stage III and IVA

For advanced disease, external beam radiation alone or in combination with brachytherapy is usually administered (Frank, 2005). Concurrent chemotherapy with cisplatin as a radiation sensitizer is generally also recommended.

### Stage IVB

Metastatic vaginal cancer is not curable, and treatment may include systemic chemotherapy or supportive hospice care. The most common sites of distant spread include liver, lung, and bone.

The choice of chemotherapeutic agents is commonly extrapolated from cervical cancer data. For example, bevacizumab (Avastin) was approved by the Food and Drug Administration (FDA) in 2014 as a treatment for metastatic cervical cancer, in combination with paclitaxel and either cisplatin or topotecan. The addition of bevacizumab to these chemotherapy combinations improved overall survival length by approximately 4 months in women with metastatic cervical cancer (Tewari, 2014).

### Chemoradiation

The numbers of women with vaginal cancer have been too small to make a prospective, randomized trial feasible. However, concurrent chemotherapy with cisplatin can be considered to benefit those with locally advanced vaginal cancer because of its proven efficacy in cervical cancer treatment. The characteristics of this agent are described in Chapter 27 (p. 602) and Figure 30-13 (p. 672). In a small series of vaginal cancer cases, adjuvant chemotherapy provided a 10- to 33-percent decline in the total radiation dose delivered (Dalrymple, 2004). Although not intending to show an improved survival rate with chemoradiation, the authors found that local control of tumor growth and survival rates were comparable with those who had received higher radiation doses alone. Smaller total radiation doses may lead to lower rates of vaginal stenosis and fistula formation.

In a Surveillance Epidemiology and End Result (SEER) database analysis of 326 patients with vaginal cancer treated with external beam radiation and/or brachytherapy between 1991 and 2005, a notable increase in sensitizing chemotherapy use was observed after the 1999 National Cancer Institute announcement confirmed the efficacy of chemoradiation in cervical cancer. Despite this increased use, the authors did not observe any survival advantage among those vaginal cancer patients who received chemoradiation compared with radiation alone (Ghia, 2011).

A recent phase II trial, which included 22 cervical cancer patients and three with stage II–IV vaginal cancer, demonstrated a 96-percent response rate for women given weekly cisplatin, radiation, and triapine, a ribonucleotide reductase inhibitor (Kunos, 2013). Larger studies are planned in cervical cancer patients.

### Chemotherapy

In general, chemotherapy alone is ineffective to treat vaginal cancer, although data are limited. The Gynecologic Oncology Group (GOG) performed a Phase II trial evaluating 50 mg/m<sup>2</sup> doses of cisplatin given every 3 weeks for advanced or recurrent vaginal cancer in 26 patients. Only one woman with squamous cell carcinoma achieved a complete response. Five of 16 patients with squamous cell carcinoma had stable disease, and 10 had cancer progression. Based on this trial, single-agent cisplatin is considered to have insignificant activity at that dose and schedule (Tigpen, 1986). To date, this has been the only prospective GOG trial evaluating chemotherapy alone for vaginal cancer.

### Radiation Therapy

Radiation to the primary tumor usually involves pelvic external beam with or without brachytherapy, and often concurrent platinum-based sensitizing chemotherapy depending on the stage and other factors described above. Additionally, groin radiation is effective in patients with palpable nodal metastases.

Moreover, elective irradiation may be delivered to clinically negative inguinal lymph nodes if the distal third of the vagina is involved. In a retrospective review, Perez and colleagues (1999) found that of 100 women who did not receive groin radiation, if disease was confined to the upper two thirds of the vagina, then none developed groin metastases. However, 10 percent of patients with lower-third primary tumors and 5 percent with tumors involving the entire length of the vagina developed inguinal node metastases.

### ■ Surveillance

Treatment failures usually develop within 2 years of primary therapy completion. Thus, patients are typically examined every 3 months for the first 2 years and then every 6 months until 5 years of surveillance is completed (Pingley, 2000; Rubin, 1985). After 5 years following treatment, women can be seen annually. A Pap smear and pelvic examination with careful attention to the inguinal and scalene nodes are performed. Surveillance with CT or MR imaging is at the clinician's discretion.

### ■ Recurrent Disease

Disease recurrence should be confirmed by biopsy if further treatment is planned. Therapeutic options in women with central pelvic recurrence who have had prior pelvic radiation are limited. Pelvic exenteration can be considered if a patient is psychologically and medically fit to undergo radical surgery associated with high morbidity (Chap. 46, p. 1149). It is attempted only in those whose disease is limited to the central pelvis. Therefore, clinicians are alert to the triad of sciatic pain, leg edema, and hydronephrosis, which suggests pelvic sidewall disease. These women are not surgical candidates but can be managed with chemoradiation or with chemotherapy alone for women previously irradiated.

Survival after relapse is poor. In a review of 301 patients, 5-year survival was 20 percent for local recurrence and 4 percent for metastatic disease recurrence (Chyle, 1996).

## ADENOCARCINOMA

Primary adenocarcinoma of the vagina is rare, making up only 13 percent of all vaginal cancers (Platz, 1995). Histologic types include clear cell, endometrioid, mucinous, and serous carcinoma, and these may arise in endometriosis foci, in areas of vaginal adenosis, in periurethral glands, or in wolffian duct remnants. *Adenosis* in the vagina is defined by subepithelial glandular structures lined by mucinous columnar cells that resemble endocervical cells (Sandberg, 1965). These represent residual glands of müllerian origin. Clinically, adenosis appears as red granular spots or patches and does not stain following Lugol solution application. Vaginal adenosis is a condition common in females exposed in utero to diethylstilbestrol (DES) (Chap. 18, p. 423).

More commonly, vaginal adenocarcinoma is metastatic disease, typically from a lesion higher in the genital tract. Disease is frequently metastatic from the endometrium, although it also may originate from the cervix or ovary (Saitoh, 2005). In addition, adenocarcinoma metastases from the breast, pancreas, kidney, and colon also have been identified in the vagina.

Treatment is similar to that for squamous cell carcinoma. Thus, surgery, radiation, or a combination of both can be used. Primary vaginal adenocarcinoma in general is more aggressive than squamous cell carcinoma. In one series of 30 patients, it was associated with local and metastatic relapse rates that were more than double those for squamous cell carcinoma (Chyle, 1996).

### ■ Clear Cell Adenocarcinoma

Of primary vaginal adenocarcinomas, the clear cell type is most closely associated with DES exposure. In the United States starting around 1940, DES was used off-label to prevent miscarriage. In 1971, clear cell adenocarcinoma of the vagina was linked to in utero DES exposure, and subsequently, pregnancy became a contraindication to DES use. Despite this, an estimated 1 to 4 million women used this synthetic estrogen and approximately 0.01 percent of females exposed in utero developed vaginal clear cell adenocarcinoma (Melnick, 1987). Most DES-exposed patients with vaginal cancer were born between 1951 and 1953, when the drug was prescribed most frequently. The median age at diagnosis of vaginal clear cell carcinoma in the United States is 19 years.

However, in the Netherlands, a bimodal distribution of vaginal clear cell carcinoma has been observed—the first peak occurring with a mean age of 26 years and the second at 71 years. The younger group had all been exposed in utero to DES, whereas the older group, born before 1947, had not been exposed (Hanselaar, 1997). It remains to be seen if the incidence of vaginal clear cell carcinoma will rise as the DES-exposed population ages.

Treatment is similar to that for squamous cell carcinoma of the vagina. The 5-year survival rate for 219 women with stage I vaginal clear cell adenocarcinoma was 92 percent and was equivalent regardless of therapy mode (Senekjian, 1987). The reported 5-year survival for 76 patients with stage II disease was 83 percent (Senekjian, 1988). A smaller study from MD Anderson shows worse pelvic control (31 versus 81 percent) and worse 5-year overall survival rate (34 versus 58 percent) for women with primary adenocarcinoma of the vagina not associated with DES exposure compared with squamous cell carcinoma of the vagina. Five-year survival rates for non-DES-associated vaginal cancer were 80 percent for stage I disease, 34 percent for stage II, 26 percent for stage III, and no survivors with stage IV disease (Frank, 2007).

## MESENCHYMAL TUMORS

### ■ Embryonal Rhabdomyosarcoma

This is the most common malignancy of the vagina in infants and children, and most embryonal rhabdomyosarcomas are the sarcoma botryoides subtype. This rare tumor develops almost exclusively in girls younger than 5 years, although vaginal and cervical sarcoma botryoides have been reported in females aged 15 to 20 years (Copeland, 1985). In infants and children, sarcoma botryoides usually is found in the vagina; in reproductive-aged women, within the cervix; and after menopause, within the uterus. Its name, derived from the Greek word *botrys*, which means “bunch of grapes,” describes its appearance (Fig. 32-5).

**FIGURE 32-5** Sarcoma botryoides protruding through the vaginal introitus. (Reproduced with permission from the North American Society for Pediatric and Adolescent Gynecology.)

The gross specimen can exhibit multiple polyp-like structures or can be a solitary growth with a nodular, cystic, or pedunculated appearance (Hilgers, 1970). Although this distinctive appearance may guide diagnosis, the classic histologic finding of this tumor is the rhabdomyoblast. Typical complaints include bleeding or a vaginal mass.

Embryonal rhabdomyosarcomas have a poor prognosis, but sarcoma botryoides is the easiest to treat and has the best chance of cure. It may be that its superficial location allows earlier detection (Copeland, 1985). Childhood sarcoma botryoides treatment has dramatically changed. It has gradually shifted away from radical pelvic exenteration surgery and toward primary chemotherapy plus adjuvant conservative surgery to excise residual tumor (Andrassy, 1995, 1999; Hays, 1981, 1985).

### ■ Leiomyosarcoma

This is the most common type of vaginal sarcoma in adults. However, it makes up no more than 1 percent of vaginal malignancies, and only 140 cases have been described in the literature to date (Ahram, 2006; Khosla, 2014; Suh, 2008). The age of affected individuals is broad, but most are older than 40 years (Zaino, 2011). Because of the small number of these tumors, their epidemiology has not been widely studied, and few risk factors have been identified. However, patients previously treated with pelvic radiotherapy for cervical cancer appear to be at risk.

Affected women most often complain of an asymptomatic vaginal mass, but other symptoms mirror those of their squamous cell counterpart. Any wall of the vagina may be affected, but most tumors develop posteriorly (Ahram, 2006). Microscopically, tumors resemble uterine leiomyosarcoma (Fig. 34-2, p. 725). Tumors spread by local invasion and hematogenous dissemination.

Surgical resection with negative margins is the preferred primary treatment. The benefit of adjuvant radiation is unclear due to a lack of controlled trials. However, some clinicians recommend adjuvant radiation for those with high-grade tumor or local recurrence (Curtin, 1995).

## MELANOMA

Primary malignant melanoma in the vagina is rare, accounting for less than 3 percent of all vaginal cancers. In women, only 1.6 percent of melanomas are genital. The most common site is the vulva (70 percent), followed by the vagina (21 percent) and the cervix (9 percent) (Miner, 2004). Using data from the SEER database, the incidence of vaginal melanoma is between 0.26 and 0.46 per 1 million women per year (Hu, 2010; Weinstock, 1994). Both U.S. and Swedish studies have shown the mean age at diagnosis to be 66 years (Ragnarsson-Olding, 1993; Reid, 1989).

The most frequent presenting symptoms include vaginal bleeding, discharge, and vaginal mass (Fig. 32-6) (Gupta, 2002; Reid, 1989). Most are located in the distal vagina (Frumovitz, 2010; Xia, 2014). Vaginal melanoma is often detected late, and this may be largely responsible for poor treatment outcomes.

With a reported 5-year survival rate ranging from 10 to 20 percent, the prognosis is among the worst of vaginal malignancies (Ragnarsson-Olding, 1993; Weinstock, 1994; Xia, 2014). Although survival rates are significantly better for those with vaginal lesions measuring < 3 cm, FIGO staging of vaginal melanomas does not accurately predict survival (Reid, 1989). Thus, staging criteria specific to melanoma are used. Cutaneous melanomas at other body sites are staged by microstaging systems, including the Chung, the Clark, and the Breslow systems, which use criteria such as depth of invasion, tumor size, and tumor thickness (Chap. 31, p. 688). However, Clark levels are not applicable to vaginal melanoma because the typical microscopic skin landmarks used are not present. Therefore, staging is based on tumor thickness, as described by Breslow or Chung.

Treatment is extrapolated from cutaneous melanomas, due to the rarity of vaginal melanoma. Surgery is preferred, when feasible. Although some advocate radical surgery, including exenteration, growing evidence shows that wide local excision has similar survival rates and less morbidity (Buchanan, 1998; Xia, 2014). However, the recommended clinical surgical margin for a melanoma with a Breslow thickness  $\leq 1$  mm is 1 cm; a thickness 1 to 2 mm warrants a 1- to 2-cm margin; and a thickness

**FIGURE 32-6** Vaginal melanoma of the anterior vaginal wall. Below the mass, a tenaculum can be seen on the uninvolvement cervix. (Used with permission from Drs. Siobhan Kehoe and Dustin Manders.)

> 2 mm requires a 2-cm margin (National Comprehensive Cancer Network, 2014). One study demonstrated a survival benefit to the wide local excision approach (Frumovitz, 2010). However, because of their size or location, many vaginal melanomas are not amenable to this less radical approach.

Melanomas generally are thought to be radioresistant. However, radiation therapy in one series was found to provide local tumor control in women who had surgically unresectable disease (Miner, 2004).

Treatment of advanced and metastatic cutaneous melanoma has progressed, and multiple targeted biologic agents are now available. Mutations in the *BRAF* and *KIT* oncogenes have been found in cutaneous and mucosal melanomas, and women with vaginal melanoma have their tumor tested for these mutations (Leitao, 2014). Options for those with *BRAF*<sup>V600E</sup> mutations include vemurafenib, dabrafenib, and trametinib (Chapman, 2011; Flaherty, 2012a,b; Hauschild, 2012; Sosman, 2012). Imatinib may be used for tumors with the *c-KIT* mutation (Carvajal, 2011). Ipilimumab is a monoclonal antibody that promotes T-cell activation, which in turn produces antitumor effects. Its use in patients with metastatic melanoma improves overall survival rates (Hodi, 2010). Recently, the monoclonal antibodies pembrolizumab and nivolumab, which target programmed death 1 protein (PD-1), have been compared with and also combined with ipilimumab for advanced melanoma. The anti-PD-1 immunotherapy drugs are now preferred for the treatment of advanced melanoma, as they offer increased progression-free survival rates, objective-response rates, but fewer serious adverse events than ipilimumab monotherapy (Postow, 2015; Robert, 2015).

In the United States, endometrial cancer is the most common gynecologic malignancy. Risk factors include obesity and advancing age. As these factors are now more prevalent, the incidence of endometrial cancer continues to increase. Fortunately, patients usually seek medical attention early due to vaginal bleeding, and endometrial biopsy leads quickly to diagnosis. The primary treatment is hysterectomy with bilateral salpingo-oophorectomy (BSO) and staging lymphadenectomy for most women. Three quarters will have stage I disease that is curable by surgery alone. Patients with more advanced disease typically require postoperative combination chemotherapy, radiotherapy, or both.

EPIDEMIOLOGY AND RISK FACTORS

In the United States, women have a 3-percent lifetime risk of developing endometrial cancer. Although an estimated 54,870 new cases were diagnosed, only 10,170 deaths are expected in 2015. As noted, most patients are diagnosed early and subsequently cured. As a result, endometrial cancer is the fourth leading cause of cancer, but the seventh leading cause of cancer deaths among women (Siegel, 2015).

Endometrial adenocarcinomas are categorized as type I or type II based on histology. Type I, that is, endometrioid type, makes up 80 to 90 percent of all cases (Felix, 2010). The other 10 to 20 percent are type II cancers, namely, the non-endometrioid histologic types that include serous and clear cell adenocarcinomas. Risk factors for developing endometrial cancer are numerous (Table 33-1). Risks specifically for type I cancers are associated with an excess-estrogen environment.

Of these, *obesity* is the most common cause of endogenous overproduction of estrogen. Excessive adipose tissue increases peripheral aromatization of androstenedione to estrone. In premenopausal women, elevated estrone levels trigger abnormal feedback in the hypothalamic-pituitary-ovarian axis. The clinical result is oligo- or anovulation. In the absence of ovulation, the endometrium is exposed to virtually continuous estrogen stimulation without subsequent progestational effect and without menstrual withdrawal bleeding.

*Unopposed estrogen therapy* is the next most important potential inciting factor. Fortunately, the malignant potential of continuously administered estrogen was recognized more than three decades ago (Smith, 1975). Currently, it is rare to encounter a woman with a uterus who has taken unopposed estrogen for years. Instead, combined estrogen plus progestin hormonal replacement therapy (combination HRT) is routinely prescribed for postmenopausal women with a uterus to reduce estrogen-related endometrial cancer risk (Strom, 2006). Moreover, in one study, the endometrial cancer risk was lower in women taking continuous combination HRT for greater than 6 months compared with those women who had never taken HRT (Phipps, 2011).

*Menstrual and reproductive influences* are commonly associated with endometrial cancer. For example, early age at menarche or late age of menopause are both associated with increased risk (Wernli, 2006). Classically, women with polycystic ovarian syndrome (PCOS) are anovulatory and thus also have an increased risk of developing this cancer (Fearnley, 2010; Pillay, 2006).

*Environment* is implicated in endometrial cancer in several ways. Women in Western and developed societies have a much higher incidence (Parkin, 2005). Obvious confounding variables within these populations, such as obesity and low parity, account for much of this effect. However, a possible role for nutrition—especially a diet with a high animal-fat content—is another explanation (Goodman, 1997). Immigrant populations tend to assume the risks of native populations within one or two generations, highlighting the importance of environmental influences (Liao, 2003).

*Older age* is linked with endometrial cancer development. The average age at diagnosis is the early 60s, and overall,

**TABLE 33-1.** Factors Affecting Endometrial Cancer Risk

Obesity
Polycystic ovarian syndrome
Long-term, high-dose unopposed menopausal estrogens
Early age of menarche
Late age of natural menopause
Infertility
Nulliparity
Menstrual irregularities
North America or northern Europe residence
Higher education or income level
White race
Older age
Tamoxifen, high cumulative doses
DM, CHIN, or gallbladder disease
Long-term COC use
Cigarette smoking

CHIN = chronic hypertension; COCs = combination oral contraceptives; DM = diabetes mellitus.

approximately 80 percent of these cancers are diagnosed in postmenopausal women older than 55 years (Madison, 2004; Schottenfeld, 1995). Approximately 8 percent of endometrial cancers develop in patients younger than 45 years (Howlader, 2014). Of note, Nevadunsky and associates (2014) found that the age at diagnosis of endometrioid cancer decreased linearly with increasing body mass index (BMI).

*Family history* is another risk for endometrial cancer. Endometrial cancer is the most common extracolonic manifestation in Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) (Hemminki, 2005). This autosomal-dominant syndrome results primarily from mutations in the mismatch repair genes. The mismatch-repair genes associated with Lynch are *MLH1*, *MSH2*, *MSH6*, and *PMS2* (Bansal, 2009). Gene mutation prevents repair of base mismatches, which are commonly produced during DNA replication. Inactivity of this DNA repair system leads to mutations that can promote carcinogenesis. Mutation carriers have a risk of developing endometrial cancer that ranges from 40 to 60 percent. Among affected women, the endometrial cancer risk actually exceeds that for colorectal cancer and often develops at a young age (Aarnio, 1999; Delin, 2004). Of endometrial cancer cases, 2 to 5 percent are attributable to Lynch syndrome (Hampel, 2006). In general, most familial cases develop in premenopausal women (Gruber, 1996).

Women who carry mutations in *BRCA1* and *BRCA2* genes are at increased risk for breast and ovarian cancer. They may also have a slightly elevated risk for endometrial cancer, but only because associated breast cancers are often treated with tamoxifen (Beiner, 2007; Tai, 1998).

*Tamoxifen* causes a two- to threefold higher risk of developing endometrial cancer by its modest “unopposed” estrogenic effect on the endometrium (Chap. 27, p. 603). The increased risk of endometrial cancer affects postmenopausal women almost exclusively, and cancer rates increase linearly with the

duration and cumulative dose of tamoxifen therapy (Fisher, 1998; van Leeuwen, 1994). Accordingly, women taking tamoxifen are counseled regarding this endometrial risk and should report vaginal spotting, bleeding, or discharge. That said, unless a tamoxifen-treated patient has such symptoms or is identified to be at otherwise high risk for endometrial cancer, routine endometrial surveillance does not increase early detection rates (American College of Obstetricians and Gynecologists, 2014c).

*Coexisting medical conditions* such as diabetes mellitus, hypertension, and gallbladder disease are more commonly associated with endometrial cancer (Morimoto, 2006; Soliman, 2005). In general, these are frequent sequelae of obesity and an environment of chronic excess estrogen.

In contrast, *combination oral contraceptive* (COC) use for at least 1 year confers as much as a 30- to 50-percent reduced risk of endometrial cancer, and risk reduction extends for 10 to 20 years (Dossus, 2010; Stanford, 1993). This is most likely derived from a chemopreventive effect on the endometrium provided by the progestin component (Maxwell, 2006). Logically, progesterone intrauterine devices (IUDs) also confer long-term endometrial cancer protection (Tao, 2006). Moreover, similar protective effects have been found with inert and copper IUD types (Felix, 2015).

*Smokers* have a lower risk of developing endometrial cancer. The biologic mechanism is multifactorial but in part involves lower circulating estrogen levels from weight reduction, earlier age at menopause, and altered hormonal metabolism. Both current and past smoking have a long-lasting influence (Viswanathan, 2005).

## ENDOMETRIAL HYPERPLASIA

Most endometrial cancers arise following progression of histologically distinguishable hyperplastic lesions. In fact, endometrial hyperplasia is the only known direct precursor of invasive disease. Endometrial hyperplasia is defined as endometrial thickening with proliferation of irregularly sized and shaped glands and an increased gland-to-stroma ratio (Fig. 33-1) (Ellenson, 2011b). In the absence of such thickening, lesions are best designated as *disorderly proliferative endometrium* or *focal glandular crowding*.

### Classification

Endometrial hyperplasia represents a continuum of histopathologic findings. The classification system used by the World Health Organization (WHO) and International Society of Gynecological Pathologists designates four different types with varying malignant potential (Table 33-2) (Kurman, 1985, 2014). Hyperplasias are classified as *simple* or *complex*, based on the absence or presence of architectural abnormalities of the endometrial glands. Abnormalities include gland crowding and complexity (see Fig. 33-1). Most importantly, hyperplasias are additionally labeled as *atypical* if they demonstrate nuclear atypia of the endometrial gland cells. Atypical endometrial hyperplasias are clearly associated with the subsequent development of adenocarcinoma. Simple atypical hyperplasia is a relatively uncommon diagnosis. In general, most have a complex architecture.

Normal proliferative endometrium

Simple hyperplasia

Complex hyperplasia

Simple hyperplasia with atypia

Complex hyperplasia with atypia

**FIGURE 33-1** **A.** This high-power view of normal proliferative endometrium shows regularly spaced glands composed of stratified columnar epithelium with bland, slightly elongate nuclei. **B.** In simple hyperplasia, glands are modestly crowded and typically display normal tubular shape or mild gland-shape abnormalities. Nuclei are bland. **C.** In this case of simple hyperplasia with atypia, glands are only mildly crowded. Occasional glands show nuclear atypia characterized by nuclear rounding and visible nucleoli. **D.** In complex hyperplasia, glands are more markedly crowded. Some specimens show architectural abnormalities such as papillary infoldings, although the gland profiles in this case are fairly regular. **E.** In complex hyperplasia with atypia, glands are markedly crowded and some have papillary infoldings. Nuclei show variable atypia. (Used with permission from Dr. Kelley Carrick.)

Although endometrial hyperplasias are formally classified in these four different groups, they tend to be morphologically heterogeneous, both within and between individual patients. This histologic diversity explains why only a small number of conserved features are useful as diagnostic criteria. As a result, reproducible scoring of cytologic atypia is often challenging, particularly with a small amount of tissue from a biopsy sample.

*Endometrial intraepithelial neoplasia* (EIN) is a term introduced to more accurately distinguish the two very different clinical categories of hyperplasia: (1) normal polyclonal endometria diffusely responding to an abnormal hormonal environment and (2) intrinsically proliferative monoclonal lesions that arise focally and confer an elevated risk of adenocarcinoma (Mutter, 2000). This nomenclature emphasizes the malignant potential

**TABLE 33-2.** World Health Organization Classification of Endometrial Hyperplasia

Types	Progressing to Cancer (%)
Simple hyperplasia	1
Complex hyperplasia	3
Simple atypical hyperplasia	8
Complex atypical hyperplasia	29

Data from Kurman RJ, Kaminski PF, Norris HJ: The behavior of endometrial hyperplasia. A long-term study of “untreated” hyperplasia in 170 patients. *Cancer* 1985 Jul 15;56(2):403–412.

of endometrial precancers and is in keeping with similar precedents in the cervix (CIN [cervical intraepithelial neoplasia]), vagina (VaIN), and vulva (VIN) (Chap. 29, p. 624).

Using this system, anovulatory or prolonged estrogen-exposed endometria without atypia are generally designated as *endometrial hyperplasias*. In contrast, EIN is used to describe all endometria delineated as premalignant by a combination of three morphometric features. The qualities reflect glandular volume, architectural complexity, and cytologic abnormality. The EIN classification system is a more accurate and reproducible way to predict progression to cancer (Baak, 2005; Hecht, 2005). This classification is endorsed by the Society of Gynecologic Oncology and American College of Obstetricians and Gynecologists (2015) but has not been universally implemented.

### ■ Clinical Features and Diagnosis

The risks for developing endometrial hyperplasia generally mirror those for invasive carcinoma (Anastasiadis, 2000; Ricci, 2002). Two thirds of women present with postmenopausal bleeding (Horn, 2004). However, premenopausal women with abnormal uterine bleeding (AUB) are also evaluated as described in Chapter 8 (p. 182).

As hyperplasia is a histologic diagnosis, a Pipelle office endometrial biopsy (EMB) or outpatient dilatation and curettage (D & C) are suitable choices for endometrial sampling. The American College of Obstetricians and Gynecologists (2014a) recommends such sample for women older than 45 years with AUB. EMB is also considered for those younger than 45 with chronic excess estrogen exposure (exogenous or endogenous), failed medical management, and persistent AUB.

In those with AUB, transvaginal sonography to measure endometrial thickness is also a feasible method for predicting endometrial hyperplasia (Granberg, 1991; Jacobs, 2011). In postmenopausal women, endometrial stripe thickness measurements  $\leq 4$  mm are associated with bleeding that is attributed to endometrial atrophy (American College of Obstetricians and Gynecologists, 2013). Postmenopausal women with a thicker endometrium warrant biopsy. Sonography may also identify abnormal echostructural changes in the endometrium. Cystic endometrial changes suggest polyps, homogeneously thickened endometrium may indicate hyperplasia, and a heterogeneous structural pattern is suspicious for malignancy (Figs. 33-2 and 33-3). However, these sonographic findings show great overlap and cannot be used alone.

**FIGURE 33-2** Transvaginal sonographic image of a uterus. In this sagittal view, the markedly thickened endometrium, which is measured by the calipers, suggests endometrial hyperplasia. (Used with permission from Dr. Elysia Moschos.)

For premenopausal women, transvaginal sonography is often performed to exclude structural sources of abnormal bleeding. Similarly, researchers have attempted to create endometrial thickness guidelines. However, endometrial thicknesses can vary considerably among premenopausal women during normal menstrual cycling. From studies, suggested evidence-based abnormal thresholds range from  $> 4$  mm to  $> 16$  mm (Breitkopf, 2004; Goldstein, 1997; Shi, 2008). Thus, consensus for an endometrial thickness threshold has not been established for this group. That said, in reproductive-aged women with a thick endometrium combined with other hyperplasia risk factors, EMB may be prudent.

Of other tools, hysteroscopy is more sensitive for focal endometrial lesions. Hyperplastic endometrium is grossly indistinct,

**FIGURE 33-3** Transvaginal sagittal image of the endometrium from a 38-year-old woman with chronic oligomenorrhea. The abnormal endometrium is thickened, echogenic, and heterogeneous in echotexture and contains tiny cystic foci. Biopsy revealed grade 1 endometrioid adenocarcinoma, which was confirmed at surgery. (Used with permission from Dr. Elysia Moschos.)

and thus hysteroscopy has poor sensitivity for this diagnosis (Ben Yehuda, 1998; Garuti, 2006).

Occasionally, an adnexal mass may be palpable during examination and in most cases is a benign ovarian cyst. However, any solid features noted during transvaginal sonography raises the possibility of a coexisting ovarian granulosa cell tumor. These tumors produce excess estrogen that results in up to a 30-percent risk of endometrial hyperplasia or less commonly, endometrial carcinoma (Chap. 36, p. 770) (Ayhan, 1994).

## ■ Treatment

Management of women with endometrial hyperplasia mainly depends on a patient's age, comorbid risks for surgery, desire for fertility, and specific histologic features such as cytologic atypia. Traditional treatment has been surgery. Hormonal therapy is another option and includes oral or injectable progestins or the progestin (levonorgestrel-releasing) IUD.

There is some inconsistency of diagnosis and uncertainty in predicting the stability of individual lesions. Specifically, several studies have documented low reproducibility for WHO classifications of endometrial hyperplasia (Allison, 2008; Sherman, 2008; Zaino, 2006). In addition, there is no way to anticipate which types will involute with progestin therapy. However, as long as an endometrial sample is representative and a provider has no reason to suspect a coexisting invasive carcinoma, the decision to treat endometrial hyperplasia through hormonal or surgical means relies on clinical judgment.

## Nonatypical Endometrial Hyperplasia

**Premenopausal Women.** Nonatypical lesions may spontaneously regress without therapy. However, progestins are generally used to address the underlying etiology, that is, chronic anovulation and excess estrogen (Terakawa, 1997). Premenopausal women with nonatypical endometrial hyperplasia typically require a 3- to 6-month course of low-dose progestin therapy. Cyclic medroxyprogesterone acetate (MPA) (Provera) given orally for 12 to 14 days each month at a dose of 10 to 20 mg daily is commonly used. Continuous daily dosing with MPA 10 mg is suitable and may be more effective than cyclic administration in reversing hyperplastic changes. Another frequently used option is COC pills for those without contraindications. The levonorgestrel-releasing IUD is also effective (Gallos, 2010; Ørbo, 2014; Scarselli, 2011).

In general, follow-up endometrial biopsy is performed to document regression. In those with an IUD, endometrial biopsy can be performed without device removal. After regression, a key point is to continue endometrial protection. Thus, once hyperplastic changes resolve, patients are continued on progestins and observed until menopause. Additional endometrial sampling is required for new bleeding.

**Postmenopausal Women.** Postmenopausal women with nonatypical endometrial hyperplasia may also be treated with low-dose oral cyclic MPA or a continuous 10-mg daily regimen. However, it is particularly important in older women to be confident that the sample obtained is adequate for excluding cytologic atypia. D & C may be indicated in some

circumstances, especially if the tissue from Pipelle sampling is scant or if recurrent bleeding is noted.

In most cases, a form of progestin therapy is used to treat endometrial hyperplasia without atypia. But, affected postmenopausal patients who have a contraindication to progestin therapy or who cannot tolerate the therapy can be expectantly managed. Complex hyperplasia without atypia is usually treated chronically with progestins. With either complex or simple hyperplasia without atypia, office endometrial biopsy is recommended every 3 to 6 months until lesion resolution is achieved.

**Response to Progestins.** In cases of endometrial hyperplasia without atypia, the risk of progression to endometrial cancer is low (1 to 3 percent). The overall clinical and pathologic regression rates to progestin therapy range from 70 to 80 percent for nonatypical endometrial hyperplasia (Rattanachaiyanont, 2005; Reed, 2009). Patients with persistent disease on repeated biopsy may be switched to a higher-dose regimen such as MPA, 40 to 100 mg orally daily. Also, megestrol acetate (Megace), 160 mg daily or 80 mg twice daily, is suitable. It can be increased even up to 160 mg twice daily if no regression is initially achieved. Again, a clinician must confirm that hormonal ablation has occurred by resampling the endometrium after a suitable therapeutic interval, usually 3 to 6 months. Hysterectomy may also be considered for lesions that are refractory to medical management.

If surgery is selected, a minimally invasive surgery (MIS) approach is considered, and options are laparoscopic, robotic, or vaginal hysterectomy. In cases in which hyperplasia has been proven or is suspected, the uterus is removed in toto and without morcellation, which might disseminate the lesion. Because the lesion may extend into the lower uterine segment or upper endocervix, supracervical hysterectomy is not appropriate for women undergoing hysterectomy for treatment of endometrial hyperplasia.

## Atypical Endometrial Hyperplasia

Hysterectomy is the preferred treatment for women with atypical endometrial hyperplasia because the risk of progression to cancer over time approximates 29 percent. There is also a high rate of finding concurrent invasive malignancy coexistent with the atypical hyperplasia (Horn, 2004; Trimble, 2006). In postmenopausal women, a hysterectomy with removal of both tubes and ovaries is recommended.

In premenopausal women who have completed childbearing, hysterectomy is performed for atypical hyperplasia. Risk-reducing salpingectomy is encouraged to potentially lower cancer risk that arises from the fallopian tubes (American College of Obstetricians and Gynecologists, 2015d). For premenopausal women, removal of the ovaries is optional. The deciding factors mirror those for women contemplating BSO for other benign indications and are outlined fully in Section 43-12 (p. 951).

Premenopausal women who strongly wish to preserve fertility can be treated with progestins (Trimble, 2012). High-dose progestin therapy, megestrol acetate 80 mg orally twice daily, is an option for motivated patients who will be compliant with surveillance (Randall, 1997). The IUD that releases 20 µg of intrauterine levonorgestrel daily (Mirena) is also suitable (Ørbo, 2014). Poor surgical candidates may also warrant an

attempt at hormonal ablation with progestins. Resolution of the hyperplasia must be confirmed by serial endometrial biopsies every 3 months until response is documented. Otherwise, hysterectomy is recommended. Following hyperplasia resolution, surveillance and progestins continue long-term due to the potential for eventual progression to carcinoma (Rubatt, 2005). Once fertility is complete, hysterectomy is again recommended.

The Gynecologic Oncology Group (GOG) performed a prospective cohort study of 289 patients who had a diagnosis of atypical endometrial hyperplasia. Participants underwent hysterectomy within 3 months of their biopsy, and 43 percent were found to have a concurrent endometrial carcinoma (Trimble, 2006). Suh-Burgmann and associates (2009) found a similarly high number of 48 percent. Results demonstrate the difficulty in attaining an accurate diagnosis before hysterectomy and the potential risks of conservative hormonal treatment.

Generalists in obstetrics and gynecology who perform hysterectomy for atypical endometrial hyperplasia should recognize the possibility of a coexisting invasive malignancy and the possible need for surgical staging. At a minimum, peritoneal washings are obtained prior to performing a hysterectomy. In addition, the uterus should be opened and examined in the operating room. From this, a frozen section analysis can be performed to search for concurrent cancer and determine grade and depth of invasion if found. Any suspicion for myometrial invasion is an appropriate indication for intraoperative consultation with a gynecologic oncologist.

ENDOMETRIAL CANCER

■ Pathogenesis

Endometrial cancer is a biologically and histologically diverse group of neoplasms characterized by a dualistic model of pathogenesis. As noted, type I endometrioid adenocarcinomas comprise most cases. They are estrogen-dependent, low grade, and derived from atypical endometrial hyperplasia. In contrast, type II cancers are serous or clear cell histology, have no precursor lesion, and portend a more aggressive clinical course (Table 33-3). The morphologic and clinical differences are paralleled by genetic distinctions. Namely, type I and II tumors carry mutations of independent sets of genes (Bansal, 2009; Hecht, 2006). The two pathways of endometrial cancer pathogenesis have significant overlap and thus result in a spectrum of histologic features.

TABLE 33-3. Type I and II Endometrial Carcinoma: Distinguishing Features

Feature	Type I	Type II
Chronic estrogen	Present	Absent
Menopause status	Pre-/peri-	Post-
Hyperplasia	Present	Absent
Race	White	Black
Grade	Low	High
Invasion <sup>a</sup>	Minimal	Deep
Behavior	Stable	Aggressive
Subtypes	Endometrioid	Serous Clear cell

<sup>a</sup>Myometrial invasion.

■ Prevention

Education can be effective prevention, as many endometrial cancer risks are alterable. Women with PCOS may benefit from weight loss and chronic progestin supplementation (Chap. 17, p. 397). Assessing and managing obesity as described in Chapter 1 may also lower risks.

For women at average risk or increased risk, routine screening of hyperplasia or endometrial cancer is not advocated. Instead, at the onset of menopause, women are counseled on the risks and symptoms of endometrial cancer and strongly encouraged to report unexpected bleeding or spotting to their provider. One screening exception is the woman with Lynch syndrome. For these individuals, EMB is recommended every 1 to 2 years beginning at age 30 to 35 years (American College of Obstetricians and Gynecologists, 2014b; Smith, 2015).

Genetic testing criteria have been published to identify the individual with Lynch syndrome (Table 33-4) (Lancaster, 2015). Lynch syndrome cancers include colon, endometrium, small bowel, renal pelvis and ureter, and ovary, among others (Vasen, 1999). Referral for genetic counseling can further clarify which patients may benefit from specific germline testing (Balmana, 2006; Chen, 2006). Endometrial cancer is the most common “sentinel cancer,” thus, obstetrician-gynecologists play a pivotal role in the identification of women with Lynch syndrome (Lu, 2005).

Since women with Lynch syndrome have such a high lifetime risk of developing endometrial cancer (40 to 60 percent),

TABLE 33-4. Lynch Syndrome Genetic Screening Recommendations

Patients with endometrial or colorectal cancer and tumor evidence of: Microsatellite instability or DNA mismatch repair protein loss
First-degree relative with endometrial or colorectal cancer who was diagnosed: Before age 60 years or Is at risk for Lynch syndrome based on personal and medical history
First- or second-degree relative with a known DNA mismatch repair gene mutation

Reproduced with permission from Lancaster JM, Powell CB, Chen LM, et al: Society of Gynecologic Oncology statement on risk assessment for inherited gynecologic cancer predispositions, Gynecol Oncol 2015 Jan;136(1):3–7.

prophylactic hysterectomy is recommended once affected women reach the early to mid 40s. In a cohort of 315 HNPCC-mutation carriers, Schmeler and coworkers (2006) confirmed the benefit of this approach by reporting a 100-percent endometrial cancer risk reduction. In general, BSO is also performed due to the 9- to 12-percent lifetime risk of ovarian cancer. Prior to hysterectomy, colon cancer screening with colonoscopy should be up to date (American College of Obstetrician and Gynecologists, 2014b).

## ■ Diagnosis

### Signs and Symptoms

Early diagnosis of endometrial cancer is almost entirely dependent on the prompt recognition and evaluation of irregular vaginal bleeding. In premenopausal women, a clinician must maintain a high index of suspicion for a history of prolonged, heavy menstruation or intermenstrual spotting, because many other benign disorders give rise to similar symptoms (Table 8-1, p. 181). Postmenopausal bleeding is particularly worrisome, leading to a 5- to 10-percent likelihood of diagnosing endometrial carcinoma (Gredmark, 1995; Iatrakis, 1997). Abnormal vaginal discharge may be another symptom in older women.

Unfortunately, some patients do not seek medical attention despite months or years of heavy, irregular bleeding. In more advanced disease, pelvic pressure and pain may reflect uterine enlargement or extrauterine tumor spread. Patients with serous or clear cell tumors often present with signs and symptoms suggestive of advanced epithelial ovarian cancer that include pelvic pain or pressure, bloating, early satiety, and increasing abdominal girth (Chap. 35, p. 741).

### Papanicolaou Test

Pap testing is not an indicated test to diagnose endometrial cancer, and 50 percent of women with endometrial cancer will have normal findings (Gu, 2001). Liquid-based cytology appears to increase the detection of glandular abnormalities, but not enough to cause a shift in clinical practice (Guidos, 2000; Schorge, 2002). However, some findings from Pap testing should prompt further investigation. Benign endometrial cells are occasionally recorded on a routine Pap test report in women 45 years or older. In premenopausal women, this is often a finding of limited importance, especially if a test is obtained following menses. However, postmenopausal women with such findings have a 3- to 5-percent risk of endometrial cancer (Simsir, 2005). In those using HRT, the prevalence of benign endometrial cells on smears is increased, and the associated risk of malignancy is less (1 to 2 percent) (Mount, 2002). Although endometrial biopsy is considered in asymptomatic postmenopausal women if this finding is reported, most patients ultimately diagnosed with hyperplasia or cancers also have concomitant abnormal bleeding (Ashfaq, 2001).

In contrast, *atypical* glandular cells found during Pap testing carry higher risks for underlying cervical or endometrial neoplasia. Accordingly, evaluation of a glandular abnormality includes colposcopy and endocervical curettage (ECC). It may

also include endometrial sampling in nonpregnant patients older than 35 years or in those younger if there is a history of abnormal bleeding, if risk factors for endometrial disease are noted, or if the cytology specifies that the atypical glandular cells are of endometrial origin.

### Endometrial Sampling

Office Pipelle biopsy is preferred for the initial evaluation of women with bleeding suspicious for malignancy (Feldman, 1993). However, if sampling techniques fail to provide sufficient diagnostic information or if abnormal bleeding persists, D & C may be required to clarify the diagnosis.

The American College of Obstetricians and Gynecologists (2015b) considers hysteroscopy acceptable for AUB evaluation in those without suspected advanced-stage uterine or cervical cancer. However, hysteroscopy is more sensitive for focal endometrial lesions and thus has proved less helpful in diagnosing early endometrial cancer. In those cases in which hysteroscopy is used to evaluate abnormal bleeding and in which cancer is ultimately diagnosed, an increased incidence of positive peritoneal cytology has been noted during subsequent staging surgery (Obermair, 2000; Polyzos, 2010; Zerbe, 2000). Although the risk of peritoneal contamination by cancer cells may be increased by retrograde reflux of hysteroscopic media, patient prognosis overall does not appear to be worsened (Cicinelli, 2010; Revel, 2004).

### Laboratory Testing

The only clinically useful tumor marker in the management of endometrial cancer is a serum CA125 level. Preoperatively, an elevated level indicates the possibility of more advanced disease (Powell, 2005). In practice, it is most useful in patients with advanced disease or serous subtypes to assist in monitoring response to therapy or during posttreatment surveillance. However, even in this setting, its utility in the absence of other clinical findings is limited (Price, 1998).

### Imaging Studies

In general, for women with a well-differentiated type I endometrioid tumor, chest radiography is the only required preoperative imaging study. All other preoperative testing is directed toward general surgical preparation (Chap. 39, p. 825).

Computed tomography (CT) or magnetic resonance (MR) imaging is usually not necessary (American College of Obstetricians and Gynecologists, 2015c). However, CT scanning can be obtained preoperatively in cases with higher-grade lesions to assess for lymph node involvement or metastatic disease. MR imaging can occasionally help distinguish an endometrial cancer with cervical extension from a primary endocervical adenocarcinoma (Nagar, 2006). Moreover, women with serous features or other high-risk histology on preoperative biopsy and those with physical examination findings suggesting advanced disease are most appropriate for abdominopelvic CT scanning (Fig. 33-4). In these cases, advance knowledge of intraabdominal disease may help guide surgery and treatment. MR imaging is also recommended for women who are considering fertility-sparing management

**FIGURE 33-4** Computed tomographic (CT) images in the axial plane of a 61-year-old woman with endometrial cancer. **A.** Massively enlarged and inhomogeneous uterus (arrows) in the upper pelvis. **B.** At the level of the aortic bifurcation, enlarged lymph nodes are seen bilaterally (arrows), consistent with lymph node involvement. (Used with permission from Dr. Diane Twickler.)

with hormonal therapy, since it may not be an option if deep invasion is found.

### ■ Role of the Generalist

Although most endometrial cancers are cured by hysterectomy and BSO, primary management by gynecologic oncologists has advantages. It is an efficient use of health care resources, minimizes potential morbidity, is more likely to lead to staging, and improves the survival of patients with high-risk disease (Chan, 2011; Roland, 2004). Therefore, preoperative consultation is generally advisable for any patient with endometrial cancer who is being prepared for surgery by a generalist in obstetrics and gynecology. Postoperatively, a gynecologic oncologist should be consulted if cervical extension, extrauterine disease, or positive peritoneal washing cytology was found during surgery.

If treated by an oncologist, early-stage patients treated by surgery alone will return in many cases to their primary obstetrician-gynecologist for surveillance. Consultation is again recommended if recurrent disease is later suspected or identified.

When an endometrial cancer is unexpectedly diagnosed after hysterectomy performed by a generalist for other indications, consultation is also recommended. Possible therapeutic options include no further therapy and surveillance only, reoperation to complete surgical staging, or radiotherapy to prevent local recurrence. In general, the survival advantages of staging must be weighed against the complications from another surgical procedure (American College of Obstetricians and Gynecologists, 2015c). Fortunately, the advent of laparoscopic and robotic delayed staging offers the potential for less morbidity (Spirtos, 2005).

### ■ Pathology

The spectrum of aggressiveness within the histopathologic types of endometrial cancer is broad (Table 33-5). Most patients have endometrioid adenocarcinomas that behave indolently. However, some will have an unfavorable histology that portends

a much more aggressive tumor. In addition, the degree of tumor differentiation is an important predictor of disease spread.

### Histologic Grade

The most widely used grading system for endometrial carcinoma is the three-tiered International Federation of Gynecology and Obstetrics (FIGO) system (Table 33-6). Grade 1 lesions typically are indolent with little propensity to spread outside the uterus or recur. Grade 2 tumors have an intermediate prognosis. Grade 3 cancers pose an increased potential for myometrial invasion and nodal metastasis.

Histologic grading is primarily determined by the tumor's architectural growth pattern (Zaino, 1994). However, there are a few exceptions, and the optimal method for determining grade is somewhat controversial. Nuclear atypia that is inappropriately advanced relative to the architectural grade raises a grade 1 or 2 tumor by one level. For example, a grade 2 lesion based on architectural features may be increased to a grade 3 lesion if significant nuclear atypia is present (Zaino, 1995). Nuclear grading based on the FIGO system is also used for all serous and clear cell adenocarcinomas (Pecorelli, 1999).

Histologic Type

**Endometrioid Adenocarcinoma.** T is is the most common histologic type of endometrial cancer and accounts for more than 75 percent of cases. T is type I tumor characteristically contains glands that resemble those of the normal endometrium (Fig. 33-5). T e concomitant presence of hyperplastic endometrium correlates with a low-grade tumor and a lack of myometrial invasion. However, when the glandular component decreases and is replaced by solid nests and sheets of cells, the tumor is classified as a higher grade (Kurman, 2014). In addition, an atrophic endometrium is more frequently associated with high-grade lesions that have a greater potential to metastasize (Kurman, 1994).

Endometrioid adenocarcinomas may also display variant forms. T ese include endometrioid adenocarcinoma with squamous differentiation or with villoglandular or secretory types

**FIGURE 33-5** Endometrioid adenocarcinomas are composed of neoplastic glands resembling those of the normal endometrium. Cells are typically tall columnar with mild to moderate nuclear atypia. They form glands that are abnormally crowded or “back-to-back.” Gland cribriforming, confluence, and villous structures are also common. It is these architectural forms, with the associated disappearance of intervening stroma, that distinguish well-differentiated endometrioid adenocarcinoma from complex hyperplasia. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 33-6** Endometrioid adenocarcinomas may show foci of squamous differentiation, which may be focal or relatively prominent. The squamous elements can have obvious squamous features such as keratinization or intercellular bridges or may be represented by less well-differentiated squamous morules (white arrows ), as in this example. (Used with permission from Dr. Raheela Ashfaq.)

(Fig. 33-6). In general, the biologic behavior of these variant tumors reflects that of classic endometrioid adenocarcinoma.

**Serous Carcinoma.** Accounting for 5 to 10 percent of endometrial cancers, serous carcinoma typifies the highly aggressive type II tumors that arise from the atrophic endometrium of older women (Jordan, 2001). T ere is typically a complex pattern of papillary growth, and cells demonstrate marked nuclear atypia (Fig. 33-7). Commonly referred to as uterine papillary serous carcinoma (UPSC), its histologic appearance resembles epithelial ovarian cancer, and psammoma bodies are seen in 30 percent of cases (Kurman, 2014).

Grossly, the tumor is exophytic with a papillary appearance emerging from a small, atrophic uterus. T ese tumors may occasionally be confined within a polyp and have no evidence for spread (Carcangiu, 1992). However, UPSC has a known propensity for myometrial and lymphatic invasion. Intraperitoneal spread, such as omental caking, which is unusual for typical endometrioid adenocarcinoma, is also common even when myometrial invasion is minimal or absent (Fig. 33-8) (Sherman, 1992). As a result, it may be impossible to distinguish UPSC from epithelial ovarian cancer during surgery. Like ovarian carcinoma, these tumors usually secrete CA125. T us, serial serum measurements can be useful marker to monitor disease postoperatively. UPSC is an aggressive cell type, and women with mixed endometrial cancers containing as little as 25 percent of UPSC have the same survival as those with pure uterine serous carcinoma (Ellenson, 2011a).

**Clear Cell Carcinoma.** Fewer than 5 percent of endometrial cancers are clear cell variants, but this is the other major type II tumor (Abeler, 1991). T e microscopic appearance may be predominantly solid, cystic, tubular, or papillary. Most frequently, it consists of a mixture of two or more of these patterns (Fig. 33-9).

Endometrial clear cell adenocarcinomas are similar to those arising in the ovary, vagina, and cervix. Grossly, there are no characteristic features, but like UPSC, they tend to

**FIGURE 33-7** Uterine papillary serous carcinoma. **A.** Uterine specimen. (Used with permission from Dr. Raheela Ashfaq.) **B.** This tumor is typically characterized by a papillary architecture. Psammoma bodies, which are concentrically laminated calcifications (arrow), may be present. **C.** Cells are typically rounded as opposed to columnar. They have high-grade nuclear features including relatively large, pleomorphic nuclei; prominent nucleoli; and frequent, abnormal mitoses. Multinucleate tumor cells are also common. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 33-8** Computed-tomographic (CT) images of liver metastases, ascites, and omental caking in a 51-year-old woman with endometrial cancer. **A.** Black arrows demarcate multiple low-density areas in the liver that are consistent with metastases, and ascites (curved, white arrows) surrounding the liver. **B.** A more caudal image reveals omental caking (white arrows), surrounded by massive ascites (curved, white arrows).

be high-grade, deeply invasive tumors. Patients are often diagnosed with advanced disease and have a poor prognosis (Hamilton, 2006).

**Mucinous Carcinoma.** One to 2 percent of endometrial cancers have a mucinous appearance that forms more than half of the tumor. However, many endometrioid adenocarcinomas will have this as a focal component (Ross, 1983). Typically, mucinous tumors have a glandular pattern with uniform columnar cells and minimal stratification (Fig. 33-10). Almost all are stage I grade 1 lesions and carry a good prognosis (Melhem, 1987). Since endocervical epithelium merges with the lower uterine segment, the main diagnostic dilemma is

**FIGURE 33-9** Clear cell adenocarcinomas are composed of cells with clear to eosinophilic granular cytoplasm. Cells are arranged in papillae, sheets, tubulocystic structures, or most often, some combination of these. Eosinophilic hyaline globules (arrows) are a common feature. In this example, nuclei are moderately pleomorphic, with nucleolar prominence. (Used with permission from Dr. Kelley Carrick.)

differentiating this tumor from a primary cervical adenocarcinoma. Immunostaining may be helpful, and MR imaging may further clarify the most likely site of origin. In general, to define anatomy, MR imaging is preferable to CT scanning as MR offers superior contrast resolution at soft-tissue interfaces.

**Mixed Carcinoma, Undifferentiated Carcinoma, and Rare Types.** An endometrial cancer may demonstrate combinations of two or more pure types. To be classified as a mixed carcinoma, a component must make up at least 10 percent of the tumor. Except for serous and clear cell histology, the combination of other types usually has no clinical significance. As a result, mixed carcinoma usually refers to an admixture of a type I (endometrioid adenocarcinoma and its variants) and a type II carcinoma (Kurman, 2014).

**FIGURE 33-10** Mucinous adenocarcinoma of the endometrium has tumor cells containing intracytoplasmic mucin (arrows). Tumor cells form sheets and cribriform structures (asterisks), which in this example contain bluish mucin and numerous neutrophils. (Used with permission from Dr. Kelley Carrick.)

*Undifferentiated carcinoma* lacks architectural differentiation and is characterized by medium-sized, monotonous epithelial cells growing in solid sheets without a pattern (Silva, 2007). These represent 1 to 2 percent of endometrial cancers. Overall, the prognosis is worse than in patients with poorly differentiated endometrioid adenocarcinomas (Altrabulsi, 2005).

Of rare histologic types, fewer than 100 cases of *squamous cell carcinoma* of the endometrium have been reported. Diagnosis requires exclusion of an adenocarcinoma component and no connection with the squamous epithelium of the cervix (Varras, 2002). Typically, the prognosis is poor (Goodman, 1996). *Transitional cell carcinoma* of the endometrium is also rare, and metastatic disease from the bladder or ovary must be excluded during diagnosis (Ahluwalia, 2006).

Patterns of Spread

Endometrial cancers have several different potential ways to spread beyond the uterus (Morrow, 1991). Type I endometrioid tumors and their variants most commonly spread, in order of frequency, by: (1) direct extension, (2) lymphatic metastasis, (3) hematogenous dissemination, and (4) intraperitoneal exfoliation. Type II serous and clear cell carcinomas have a particular propensity for extrauterine disease, in a pattern that closely resembles epithelial ovarian cancer. In general, the various patterns of spread are interrelated and often develop simultaneously.

*Invasion of the endometrial stroma and exophytic expansion* within the uterine cavity follows initial growth of an early cancer. Over time, the tumor invades the myometrium and may ultimately perforate the serosa (Table 33-7). Tumors situated in the lower uterine segment tend to involve the cervix early, whereas those in the upper corpus tend to extend to the fallopian tubes or serosa. Advanced regional growth may lead to direct invasion into adjacent pelvic structures, including the bladder, large bowel, vagina, and broad ligament.

*Lymphatic channel invasion* and metastasis to the pelvic and paraaortic nodal chains can follow tumor penetration of the myometrium (Table 33-8). The lymphatic network draining the uterus is complex, and patients can have metastases to any single nodal group or combination of groups (Burke, 1996). This haphazard pattern is in contrast to cervical cancer, in which lymphatic spread usually follows

**TABLE 33-7.** Correlation of Histologic Grade and Depth of Myometrial Invasion in Stage I Patients (n = 5,095)

Myometrial Invasion	Grade		
	1	2	3
None	29%	11%	15%
≤ 50%	51%	59%	46%
> 50%	20%	30%	39%

None	1%	7%	16%	< 1%	2%	5%
≤ 50%	2%	6%	10%	< 1%	2%	4%
> 50%	11%	21%	37%	2%	6%	13%

G = histologic grade.  
Data from Creasman WT, Odicino F, Maisonneuve P, et al: Carcinoma of the corpus uteri. FIGO 26th Annual Report on the Results of Treatment in Gynecological Cancer, Int J Gynaecol Obstet. 2006 Nov;95 Suppl 1:S105–S143.

a stepwise progression from pelvic to paraaortic to scalene nodal groups.

*Hematogenous dissemination* most commonly results in metastases to the lung and less commonly to the liver, brain, bone, and other sites. Deep myometrial invasion is the strongest predictor of this pattern of spread (Mariani, 2001a).

*Retrograde transtubal transport* of exfoliated endometrial cancer cells carries malignant cells to the peritoneal cavity. Serosal perforation of the tumor is another possible pathway. Most types of endometrial cancer cells found in the peritoneal cavity disappear within a short time and have low malignant potential (Hirai, 2001). Alternatively, in the presence of other high-risk features, such as adnexal metastases or serous histology, widespread intraabdominal disease may result.

*Port-site metastasis* is a rare but possible method of cancer spread. Martínez and coworkers (2010) evaluated nearly 300 laparoscopic staging procedures for endometrial cancer. Port-site metastases complicated 0.33 percent of cases. Similarly, cancer dissemination following specimen morcellation has been reported (Graebe, 2015).

■ **Treatment**

**Surgical Management**

Patients with endometrial cancer should undergo hysterectomy, BSO, and surgical staging (including pelvic washings and lymphadenectomy) using the revised FIGO system (Table 33-9 and Fig. 33-11) (Mutch, 2009). For optimal patient management, the histopathologic description of the preoperative biopsy findings is carefully reviewed. Almost three quarters of patients are stage I at diagnosis (Table 33-10). Only a few circumstances contraindicate primary surgery and include a desire to preserve fertility, massive obesity, high operative risk, and clinically unresectable disease. In general, an extrafascial hysterectomy, also known as type I or simple hysterectomy, is sufficient. However, radical hysterectomy (type III hysterectomy) may be preferable for patients with clinically obvious cervical extension of endometrial cancer (Cornelison, 1999; Mariani, 2001b). Differences in these hysterectomy types are outlined in Table 30-7 (p. 669). Vaginal hysterectomy with or without BSO is another option for women who cannot undergo systematic surgical staging

**TABLE 33-9.** International Federation of Gynecology and Obstetrics (FIGO) Surgical Staging System for Endometrial Cancer

Stage <sup>a</sup>	Characteristics
<b>I</b>	<b>Tumor confined to the corpus uteri</b>
IA	No or less than half myometrial invasion
IB	Invasion equal to or more than half of the myometrium
<b>II</b>	<b>Tumor invades cervical stroma, but does not extend beyond the uterus<sup>b</sup></b>
<b>III</b>	<b>Local and/or regional spread of the tumor</b>
IIIA	Tumor invades the serosa of the corpus uteri and/or adnexae <sup>c</sup>
IIIB	Vaginal and/or parametrial involvement <sup>c</sup>
IIIC	Metastases to pelvic and/or paraaortic lymph nodes <sup>c</sup>
IIIC1	Positive pelvic nodes
IIIC2	Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
<b>IV</b>	<b>Tumor invades bladder and/or bowel mucosa, and/or distant metastases</b>
IVA	Tumor invasion of bladder and/or bowel mucosa
IVB	Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes

<sup>a</sup>Either G1, G2, or G3. G = histologic grade.  
<sup>b</sup>Endocervical glandular involvement only should be considered as stage I and no longer as stage II.  
<sup>c</sup>Positive cytology has to be reported separately without changing the stage.

**FIGURE 33-11** International Federation of Gynecology and Obstetrics (FIGO) staging of endometrial cancer.

due to comorbidities (American College of Obstetricians and Gynecologists, 2015c). Previously, laparotomy had been the standard approach. However, laparoscopic and robotic surgical staging are increasingly used for endometrial cancer that appears clinically confined to the uterus. Such MIS staging is safe, feasible, and now recommended (Walker, 2009).

Regardless of approach, upon entering the peritoneal cavity, washings are obtained by pouring 50 to 100 mL of sterile

saline into the pelvis and collecting it for cytologic assessment. Retrieval of ascitic fluid is an acceptable alternative, but ascites is infrequently encountered. Next, a thorough intraabdominal and pelvic exploration is performed, and suspicious lesions are biopsied or excised. These preliminary procedures are followed by hysterectomy and BSO. The uterus is opened away from the operating table, and the depth of myometrial penetration may be determined by intraoperative gross examination or microscopic frozen section analysis (Sanjuan, 2006; Vorgias, 2002).

As noted, the risk of lymph node metastasis correlates with the tumor grade and depth of invasion into the myometrium. Historically, the combination of preoperative biopsy grade and intraoperative assessment of the depth of myometrial invasion were the two factors that surgeons used to determine whether to proceed with pelvic and paraaortic lymph node dissection. The inaccuracy of this approach has been reported (Eltabbakh, 2005; Leitao, 2008; Papadia, 2009). In addition, the depth of myometrial invasion determined in the operative room is often inaccurate (Frumovitz, 2004a,b).

Following hysterectomy and BSO, concurrent lymphadenectomy allows detection of positive nodes to guide appropriate treatment. Some retrospective studies have shown improved survival rates in patients who had undergone an adequate lymph node dissection (Kilgore, 1995; Todo, 2010). However, the advantage appears to be confined to those in high-risk groups. Thus, although still with some controversy, complete surgical staging with pelvic and paraaortic lymphadenectomy is recommended for patients

with high-risk grade 1 endometrioid cancer and any case of grade 2, grade 3 or type II cancers. Lymph nodal staging for cases of low-risk grade 1 endometrioid cancer also is debated (Miller, 2006). Authors in two randomized trials reported no improvement in disease-free or overall survival rates after lymphadenectomy in patients with early-stage disease (Benedetti Panici, 2008; Kitchener, 2009). However, these trials were criticized because lymph node counts were low and lymph node status did not dictate treatment, as many patients received postoperative radiation regardless of their lymph node status. Moreover, concern exists that omitting lymphadenectomy may lead to missed metastatic disease and subsequent insufficient postoperative treatment. In addition, microscopic nodal disease may be unknowingly resected during lymphadenectomy and prevent future relapse.

Distinct from the above discussion, any suspicious pelvic or paraaortic lymph nodes should be removed and histologically evaluated. Excision of grossly involved lymph nodes leads to a survival advantage (Havrilesky, 2005).

Those patients with serous or clear cell features on preoperative biopsy should have extended surgical staging with an infracolic omentectomy and bilateral peritoneal biopsies of the

Data from Creasman WT, Odicino F, Maisonneuve P, et al: Carcinoma of the corpus uteri. FIGO 26th Annual Report on the Results of Treatment in Gynecological Cancer, *Int J Gynaecol Obstet*. 2006 Nov;95 Suppl 1:S105–S143.

pelvis, pericolic gutter, and diaphragm (Bristow, 2001a). As in ovarian cancer, a surgeon is also prepared to resect any metastases (Bristow, 2000).

Sentinel lymph node evaluation, as done in vulvar and breast cancers, is being investigated and may become a useful technique in endometrial cancer (Abu-Rustum, 2009). The practice does vary but usually involves injecting the ectocervix prior to surgery at the 3, 6, 9 and 12 o'clock positions with technetium sulfur colloid. Subsequent lymphoscintigraphy guides one to the sentinel lymph nodes. At the time of surgery, the cervix is also injected with lymphazurin or isosulfan blue at the 3 and 9 o'clock position. The radioactive and blue nodes are then identified (Frati, 2015). Although investigational, sentinel lymph node evaluation is appealing in that it reduces the potential side effects associated with complete lymphadenectomy, including lymphedema and lymphocyst formation, longer operating times, and increased blood loss. The sensitivity of sentinel lymph node mapping appears acceptable in small series, and a prospective study is being considered by the GOG.

As noted, an MIS approach is acceptable for suitable candidates undergoing hysterectomy and staging for endometrial cancer (Childers, 1994; Spirtos, 2005). The GOG LAP2 study was the first multicenter randomized trial of laparoscopy to address this. In the trial, conventional surgery including pelvic/paraortic lymphadenectomy was compared with the same steps completed laparoscopically for clinical stage I and IIA endometrial carcinoma. Investigators found laparoscopic staging to be feasible and safe (Walker, 2009). Laparoscopy was completed without conversion in 74 percent of patients randomized to MIS. Advantageously, compared with those undergoing laparotomy, patients undergoing laparoscopy had similar rates of intraoperative injuries (9 versus 8 percent), fewer moderate to severe complications (14 versus 21 percent), shorter hospital stays (median 3 versus 4 days), and better quality of life at 6 weeks postoperatively. However, laparoscopic staging was linked with longer operative times (Kornblith, 2009; Walker, 2009). Long-term treatment success is not compromised with laparoscopic staging, and overall survival and recurrence rates in early reports are similar to those for a traditional abdominal approach (Ghezzi, 2010; Magrina, 1999; Walker, 2012; Zullo, 2009).

Robot-assisted laparoscopic staging of endometrial cancer has been embraced by many gynecologic oncologists to overcome MIS technical challenges, especially in obese patients. Early evidence shows it to be feasible and safe (Hoekstra, 2009). Compared with a laparoscopic approach for endometrial cancer staging, both major complication rates and mean number of lymph nodes removed are similar. The robotic approach results in less blood loss (Cardenas-Goicoechea, 2010; Seamon, 2009).

As described in Chapter 41 (p. 874), not all women are candidates for MIS. Limiting factors can include extensive adhesive disease, a large bulky uterus, morbid obesity, cardiopulmonary disease, and other patient comorbidities. Importantly, morcellation is avoided in cancer cases to prevent disease spread.

## Surveillance

Most surgically treated patients can simply be followed by pelvic examination every 3 to 6 months for the first 2 years and then every 6 to 12 months thereafter (National Comprehensive

Cancer Network, 2015). Pap testing is not a mandatory part of surveillance, as an asymptomatic vaginal recurrence is identified in less than 1 percent of patients (Bristow, 2006a; Cooper, 2006).

Women who have more advanced cancer that requires postoperative radiation or chemotherapy or both warrant more aggressive monitoring. Serum CA125 measurements may be valuable, particularly for UPSC, if the level was elevated prior to treatment. Intermittent imaging using CT scanning or MR imaging may also be indicated. In general, the pattern of recurrent disease depends on the original sites of metastasis and the treatment received.

## Chemotherapy

Only three cytotoxic drugs with definite activity for endometrial cancer have been identified. Paclitaxel (Taxol), doxorubicin (Adriamycin), and cisplatin (Platinol) form TAP chemotherapy, which is one of the adjuvant treatment options for advanced endometrial cancer following surgery. In one GOG trial of 273 women (protocol #177), administration of seven courses of TAP was superior to doxorubicin plus cisplatin, but toxicity was increased—particularly peripheral neuropathy (Fleming, 2004). A less toxic alternative to TAP chemotherapy is paclitaxel plus carboplatin. Routinely used for ovarian cancer, this regimen is effective in advanced-stage endometrial cancer (Hoskins, 2001; Sovak, 2006, 2007). One GOG trial (protocol #209) compared TAP and the regimen of carboplatin plus paclitaxel. Results demonstrated that carboplatin plus paclitaxel was not inferior to TAP in terms of progression-free and overall survival rates. The toxicity profile favored carboplatin plus paclitaxel, and this regimen is generally used at our institution (Miller, 2012).

In practice, cytotoxic chemotherapy is frequently combined, sequenced, or sandwiched with radiotherapy in patients with advanced endometrial cancer following surgery. To reduce toxicity, directed pelvic or paraaortic radiation is usually employed rather than whole abdominal irradiation (Homesley, 2009; Miller, 2009).

## Targeted Therapy

In some cases, current therapies fail to provide long-term disease control, and thus novel treatments are being investigated for endometrial cancer. Bevacizumab (Avastin), a vascular endothelial growth factor (VEGF) inhibitor, blocks angiogenesis. In a phase II trial for recurrent/persistent endometrial cancer, this targeted agent showed some salutary action, but further study is needed (Aghajanian, 2011). Another pathway, the fibroblast growth factor receptor pathway, is a potential target (Lee, 2014). The mTOR pathway is an additional target, as mutations in this pathway may lead to endometrial cancer. The GOG (protocol #0286B) is currently studying metformin with chemotherapy for the treatment of advanced/recurrent endometrial cancer. Early data show that metformin inhibits cell proliferation in endometrial cancer cell lines and that this effect is partially mediated through mTOR pathway inhibition. In addition, treatment with metformin in combination with paclitaxel resulted in a synergistic antiproliferative effect in these cell lines.

## Radiation

**Primary Radiation Therapy.** This option rather than surgery is selected rarely and mainly for exceptionally poor surgical

candidates. Intracavitary brachytherapy such as Heyman capsules with or without external beam pelvic radiation is the typical method (Chap. 28, p. 616). In general, the survival rate is 10 to 15 percent lower than that with surgical treatment (Chao, 1996; Fishman, 1996). These poor results suggest that a careful preoperative evaluation and appropriate consultation should be completed before any woman is denied the benefits of hysterectomy (American College of Obstetricians and Gynecologists, 2015c).

**Adjuvant Radiation Therapy.** In general, this option is offered after staging surgery to women at risk for endometrial cancer recurrence. Those with low-risk early-stage cancer are typically adequately treated with surgery, may not benefit from adjuvant therapy, and usually simply begin surveillance. The use of radiation in early-stage disease has been evaluated in three major trials, all of which demonstrated that adjuvant radiation improved local disease control and recurrence-free survival rates but did not decrease the rate of distant metastases or improve overall survival rates at 5 years (Aalders, 1980; Creutzberg, 2001, 2004; Keys, 2004).

However, in one of these trials, the recurrence-rate reduction was particularly evident in a high-intermediate risk subgroup of women: (1) with three risk factors (grade 2 or 3 tumors, lymphovascular invasion, and invasion of the outer third of the myometrium); (2) with age > 50 years and two of these risk factors; and (3) with age > 70 years and one risk factor (Keys, 2004). These elements have found their way into both clinical management and the design of more contemporary trials. Therefore, adjuvant radiation is usually offered to patients with high-intermediate risk stage I uterine cancers. However, because of the results of subsequent trials, the type of radiation offered is vaginal brachytherapy. The PORTEC-2 trial showed that vaginal brachytherapy was equivalent to whole pelvic radiation in those patients with high-intermediate risk endometrial cancer (Nout, 2010). Of note, local radiation can reduce the risk of local recurrence but does not improve overall survival rates.

For women with stage II endometrial cancer, the efficacy of postoperative radiotherapy is even harder to decipher. Most data derive from retrospective, single-institution experiences, and evidence supports external beam pelvic radiation, vaginal brachytherapy, both, or no further treatment (Cannon, 2009; Elshaikh, 2015; Rittenberg, 2005). As such, there is no standard approach, and most patients are treated individually based on coexisting risk factors (Feltmate, 1999).

For most women with stage III endometrial cancer, chemotherapy and/or tumor-directed postoperative external beam radiation is indicated (Barrena-Medel, 2009; Homesley, 2009). Most commonly, radiation therapy is specifically directed at pelvic disease but may extend to the paraaortic area if metastases are detected. Currently, results are pending from a randomized trial that compares chemoradiation and chemotherapy (carboplatin and paclitaxel) for advanced endometrial cancer (protocol #258).

Few patients with stage IV disease are candidates for radiotherapy with curative intent. Infrequently, a locally confined stage IVA tumor may be an exception. With stage IV disease, intraperitoneal metastases most often lie outside a tolerated radiation field. Therefore, whole abdominal irradiation is not generally preferable to chemotherapy (Randall, 2006). As a result, the role of radiotherapy is generally palliative in these

women (Goff, 1994). Chemotherapy is a reasonable option for patients with advanced endometrial cancer.

## Hormonal Therapy

**Cancer Treatment.** One of the unique characteristics of endometrial cancer is its hormonal responsiveness. Thus, for women who are not surgical candidates, continuous chronic progestin treatment or a levonorgestrel-releasing IUD can be primary treatment (Dhar, 2005; Montz, 2002). Also, in young premenopausal patients who desire fertility, similar primary progestin therapy can be used to reverse pathology.

As adjuvant therapy, single-agent high-dose progestins also have activity in women with advanced or recurrent disease (Lentz, 1996; Tigpen, 1999). Tamoxifen upregulates progesterone-receptor expression and is postulated to thereby improve progestin therapy efficacy. Clinically, high response rates have been noted with tamoxifen used adjunctively with progestin therapy (Fiorica, 2004; Whitney, 2004). In general, toxicity is low, but this combination is most often used for recurrent disease.

**Estrogen Replacement Therapy.** Due to the presumed role of excess estrogen in endometrial cancer development, estrogen supplementation following endometrial cancer treatment is often met with concern for stimulating malignancy recurrence. However, this effect has not been observed (Suriano, 2001). The GOG attempted to determine the risk of estrogen replacement therapy in endometrial cancer survivors by randomly assigning 1236 women who had undergone surgery for stage I and II endometrial cancer to receive either estrogen or placebo. Although the study did not meet its enrollment goals, the low recurrence rate (2 percent) was promising (Barakat, 2006). Women should be individually counseled regarding risks and benefits before beginning posttreatment estrogen replacement for menopausal symptoms.

## Uterine Papillary Serous Carcinoma Management

This most aggressive type of endometrial carcinoma is uncommon, and thus, randomized trials are difficult to perform. As a result, most data are single-institution, retrospective analyses. Treatment is usually individualized but is often different from typical endometrioid adenocarcinoma.

If a preoperative biopsy demonstrates serous features, comprehensive surgical staging for UPSC is recommended. This includes total hysterectomy, BSO, peritoneal washings, pelvic/paraortic lymph node dissection, infracolic omentectomy, and peritoneal biopsies (Chan, 2003). Even noninvasive disease is often widely metastatic (Gehrig, 2001). Fortunately, patients tend to have a good prognosis if surgical staging confirms that disease is confined to the uterus (stage I/II) (Grice, 1998).

Occasionally, no residual UPSC is evident on the hysterectomy specimen, or the tumor minimally involves the tip of a polyp. These women with surgical stage IA can safely be observed. However, all other patients with stage I disease are considered for adjuvant treatment. For this, one effective strategy is postoperative paclitaxel and carboplatin chemotherapy for three to six cycles combined with concomitant vaginal brachytherapy (Dietrich, 2005; Kelly, 2005). However, some data suggest an intrinsic radioresistance for UPSC tumors (Martin, 2005). In addition, based on the largest reported retrospective

review of surgical stage I patients, Huh and coworkers (2003) questioned the benefit of any radiation therapy.

Women with stage II UPSC are more likely to benefit from pelvic radiotherapy with or without chemotherapy following surgery. Those having stage III disease are especially prone to have recurrent disease at distant sites. Accordingly, paclitaxel and carboplatin is considered in addition to tumor-directed radiotherapy after surgery (Bristow, 2001a; Slomovitz, 2003).

In practice, many patients will have stage IVB disease. Aggressive surgical cytoreduction is perhaps most important, because one of the strongest predictors of overall survival is the amount of residual disease. Postoperatively, at least six cycles of paclitaxel and carboplatin chemotherapy are indicated (Barrena-Medel, 2009; Bristow, 2001b; Moller, 2004). Enrollment in a clinical trial is strongly considered for cases of advanced uterine cancer.

### Fertility-sparing Management

Hormonal therapy without hysterectomy is an option in carefully selected young women with endometrial cancer who desperately wish to preserve their fertility. Currently, patients considering fertility-sparing treatment are recommended to undergo a diagnostic hysteroscopy, sampling by D & C, and imaging to exclude deep myometrial invasion or extrauterine disease (Burke, 2014). Careful selection is also aided by a reproductive endocrinology consultation that clarifies the patient's posttreatment conception chances. Importantly, many of the biologic processes that lead to endometrial cancer also contribute to decreased fertility. In general, this strategy should apply only to those with grade 1 (type I tumor) adenocarcinomas and with no imaging evidence of myometrial invasion. Rarely, women with grade 2 lesions may be considered candidates, although it may be advisable to further assess their disease laparoscopically (Morice, 2005). The aim of hormonal treatment is to reverse the lesion. However, any type of medical management obviously involves inherent risk that a patient must be willing to accept (Yang, 2005).

Progestins are most commonly used for conservative treatment. Oral megestrol acetate, 160 mg given daily or 80 mg twice daily, can promote cancer regression. Alternatively, oral or intramuscular MPA may be delivered at varying doses (Gotlieb, 2003). The levonorgestrel-releasing IUD is another acceptable option. Combining progestin therapy with tamoxifen or with gonadotropin-releasing hormone agonists is less frequently done (Wang, 2002). Regardless of the hormonal agent, recurrence rates are high during long-term observation (Gotlieb, 2003; Niwa, 2005). Despite the feasibility of this option, dosages, therapy duration, and surveillance schedules are not specifically defined.

Women receiving fertility-sparing management are carefully monitored by repeated endometrial biopsy or D & C every 3 months to assess treatment efficacy. Evidence for persistence often prompts a change in agent or a dosage increase. Hysterectomy and operative staging is recommended if a lesion fails to regress with hormonal therapy or if disease progression is suspected.

Delivery of a healthy infant is a reasonable expectation for those patients who respond to treatment and have normal histologic findings in surveillance endometrial samplings. However, assisted reproductive technologies may be required to achieve pregnancy in some cases. Postpartum, patients are again regularly monitored for recurrent endometrial adenocarcinoma (Ferrandina, 2005). In general, women should undergo

hysterectomy at completion of childbearing or whenever the preservation of fertility is no longer desired.

### Prognostic Factors

Many clinical and pathologic factors influence the likelihood of endometrial cancer recurrence and survival (Table 33-11) (Lurain, 1991; Schink, 1991). Of these, FIGO surgical stage is the most important overriding variable because it incorporates many of the most important risk factors (Table 33-12). Metastatic disease to the adnexa, pelvic/para-aortic lymph nodes, and peritoneal surfaces is reflected by the FIGO stage.

### Recurrent Disease

Patients with recurrent endometrial cancer typically require individualized treatment. In general, the site of relapse is the most important predictor of survival. Depending on the circumstances, surgery, radiation, chemotherapy, or a combination of these may be the best strategy. The most curable scenario is an isolated relapse at the vaginal apex in a previously unirradiated patient. These women are usually effectively treated by external beam pelvic radiotherapy. In patients who were previously irradiated, exenteration is often the only curative option (Section 46-4, p. 1149) (Barakat, 1999; Morris, 1996). Nodal recurrences or isolated pelvic disease is more likely to result in further disease progression, regardless of treatment modality. However, either is often an appropriate indication for external

**TABLE 33-12.** Endometrial Cancer 5-year Survival Rates for Each Surgical Stage (n = 5562 patients)

beam radiotherapy in those not previously irradiated. Salvage cytoreductive surgery may also be beneficial in selected patients (Awtrey, 2006; Bristow, 2006b).

Widely disseminated endometrial cancer or a relapse not amenable to radiation or surgery is an indication for systemic chemotherapy (Barrena-Medel, 2009). Patients are ideally enrolled in an experimental trial due to the limited duration of response with current salvage regimens and the urgent need for more effective therapy. Paclitaxel and carboplatin is an active combination for recurrent disease and found not to be inferior to TAP (Miller, 2012). Progestin therapy with or without tamoxifen is a less toxic option that is particularly useful in selected cases (Fiorica, 2004; Whitney, 2004). In general, effective palliation of women with incurable, recurrent endometrial cancer requires an ongoing dialogue to achieve the optimal balance between symptomatic relief and treatment toxicity.

REFERENCES . . . . . 732

Malignant tumors of the uterine corpus are broadly divided into three main types: carcinomas, sarcomas, and carcinosarcomas. Although the latter two categories are rarely encountered, they tend to behave more aggressively and contribute to a disproportionately higher number of uterine cancer deaths. Pure sarcomas differentiate toward smooth muscle (leiomyosarcoma) or toward endometrial stroma (endometrial stromal tumors). Carcinosarcomas are mixed tumors demonstrating both epithelial and stromal components. These have also been known as malignant mixed müllerian tumor (MMMT). In general, uterine sarcomas and carcinosarcomas grow quickly, lymphatic or hematogenous spread occurs early, and the overall prognosis is poor. However, there are several notable exceptions among these tumors.

EPIDEMIOLOGY AND RISK FACTORS

Sarcomas account for approximately 3 to 8 percent of all malignancies of the uterine corpus (Brooks, 2004; D’Angelo, 2010; Major, 1993). Historically, uterine sarcomas included carcinosarcomas, accounting for 40 percent of cases; leiomyosarcomas, 40 percent; endometrial stromal sarcomas, 10 to 15 percent; and undifferentiated sarcomas, 5 to 10 percent. In 2009, the International Federation of Gynecology and Obstetrics (FIGO) reclassified carcinosarcomas as a metaplastic form of endometrial carcinoma. Despite this, carcinosarcomas are still commonly included in most retrospective studies of uterine sarcomas and in the 2014 World Health Organization (WHO) classification (Greer, 2015; Kurman, 2014; McCluggage, 2002).

Because of their infrequency, uterine sarcomas and carcinosarcomas have few identified risk factors. These include chronic excess estrogen exposure, tamoxifen use, African American race, and prior pelvic radiation. In contrast, combination oral contraceptive pill use and smoking appear to lower risks for some of these tumors (Felix, 2013).

PATHOGENESIS

Leiomyosarcomas have a monoclonal origin, and although commonly believed to arise from benign leiomyomas, for the most part they do not. Instead, they appear to develop de novo as solitary lesions (Zhang, 2006). Supporting this theory, leiomyosarcomas have molecular pathways distinct from those of leiomyomas or normal myometrium (Quade, 2004; Skubitz, 2003). They are, however, often found in proximity to leiomyomas.

Endometrial stromal tumors (ESS) have heterogeneous chromosomal aberrations (Halbwedl, 2005). However, the pattern of rearrangements is clearly nonrandom, and chromosomal arms 6p and 7p are frequently involved (Micci, 2006). Translocations involving several chromosomes and the resultant fusion proteins are thought to be involved in ESS pathogenesis (Lee, 2012; Panagopoulos, 2012).

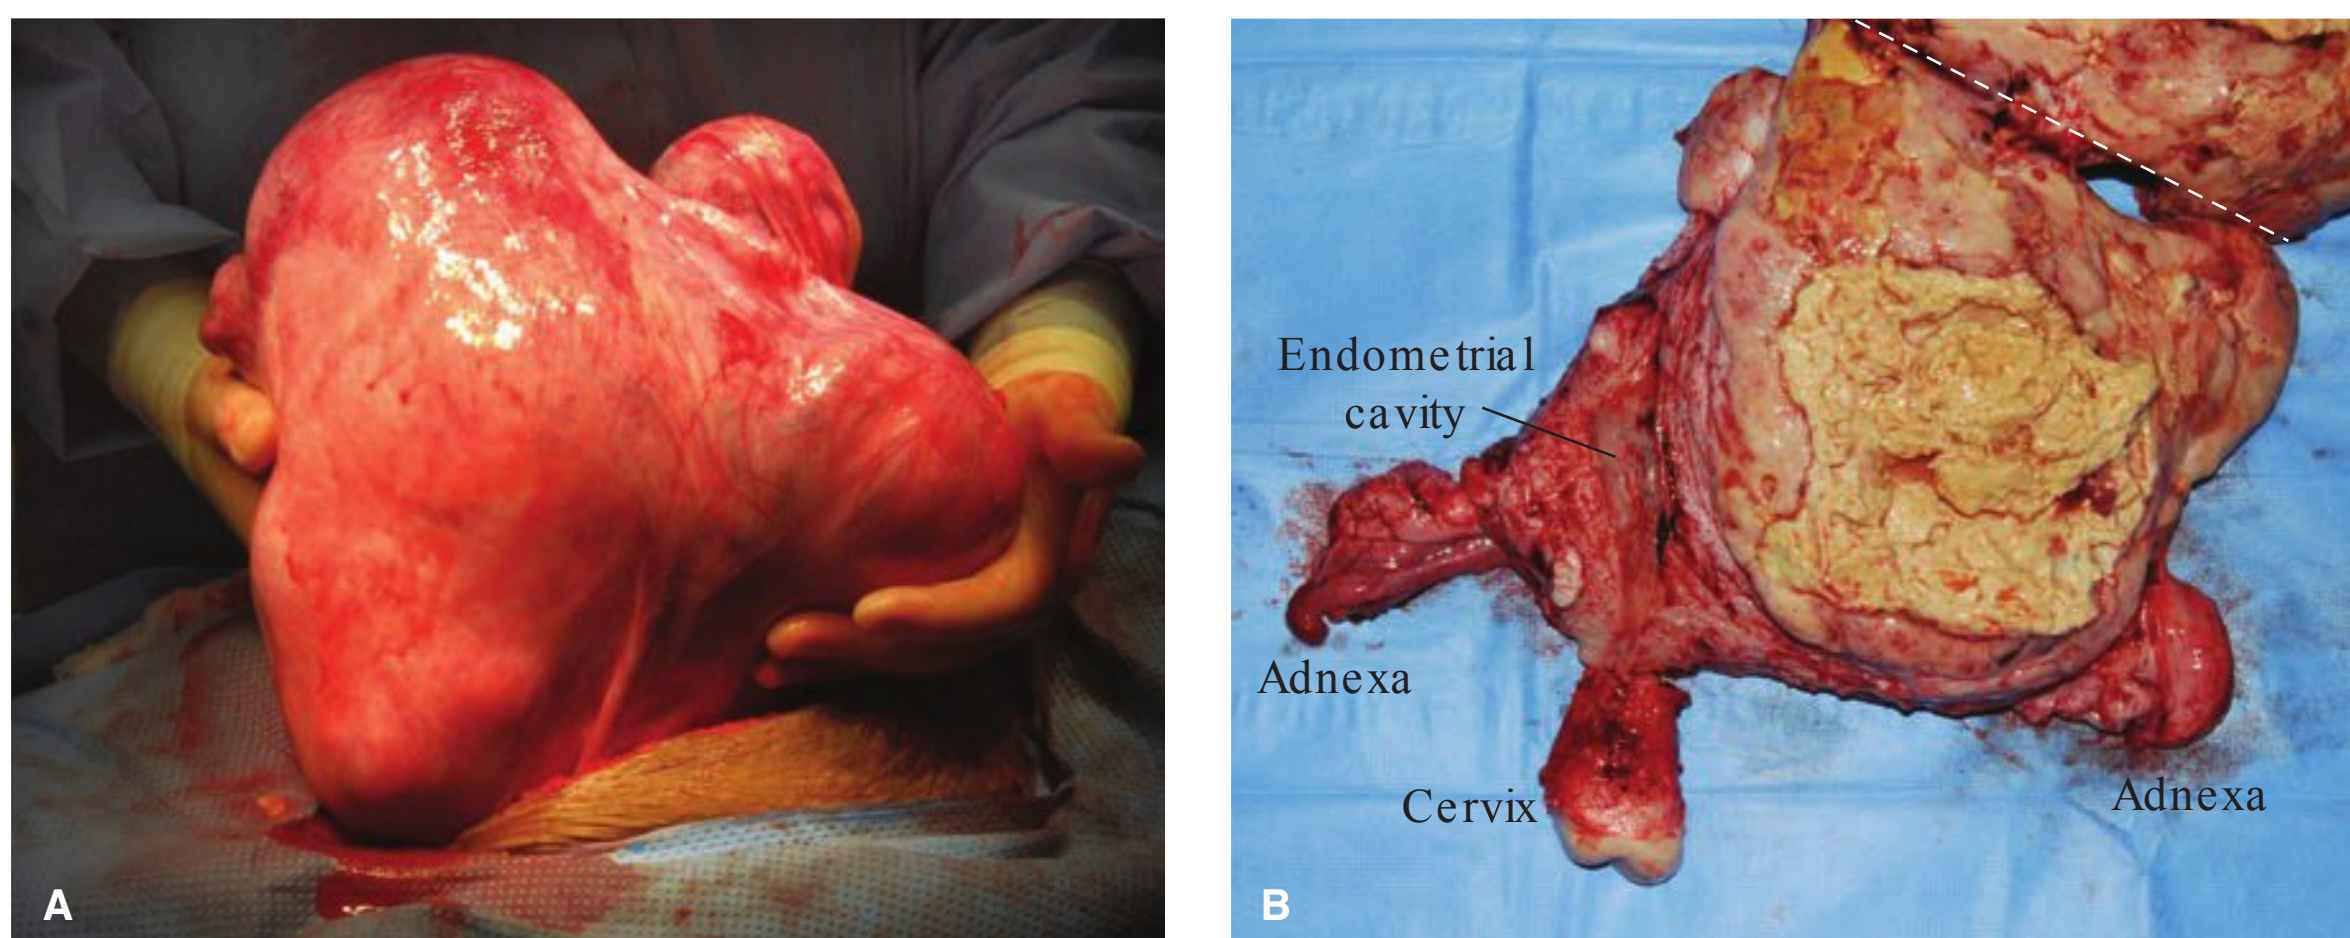

Uterine carcinosarcomas are monoclonal, biphasic neoplasms. Namely, they are composed of separate but admixed malignant epithelial and malignant stromal elements (D’Angelo, 2010; Wada, 1997). Both the carcinoma and sarcoma components are thought to arise from a common epithelial progenitor cell. Acquisition of any number of genetic mutations, including defects in *p53* and DNA mismatch repair genes, may be sufficient to trigger tumorigenesis (Liu, 1994). These early molecular defects will be shared by both components as the tumor undergoes divergent carcinomatous and sarcomatous differentiation. Thereafter, acquired molecular defects will be discordant between the two components (Taylor, 2006). This genetic progression and subsequent diversion parallels the varying phenotypes observed in these tumors (Fujii, 2000).

DIAGNOSIS

■ Signs and Symptoms

As in endometrial cancer, abnormal vaginal bleeding is the most frequent symptom for uterine sarcomas and carcinosarcomas (Gonzalez-Bosquet, 1997). Pelvic or abdominal pain is also common. Up to one third of women will describe significant discomfort that may result from passage of clots, rapid uterine enlargement, or prolapse of a sarcomatous polyp through

**FIGURE 34-1** Leiomysarcoma. **A.** Intraoperative photograph of an enlarged uterus before hysterectomy. **B.** Surgical specimen has been bisected and remains joined at the fundus. The other half of the specimen lies above the white dashed line and out of view. The large tumor lies to the right of the endometrial cavity. It has central necrosis seen as yellow amorphous debris with the tumor borders. (Used with permission from Dr. Martha Rac.)

an effaced cervix (De Fusco, 1989). In addition, a profuse, foul-smelling discharge may be obvious, and gastrointestinal and genitourinary complaints are also frequent. Importantly, degenerating leiomyomas with necrosis can mimic these same signs and symptoms.

With rapid growth, a uterus may extend out of the pelvis into the mid- or upper abdomen (Fig. 34-1). Fortunately, the incidence of malignancy in such cases is low (< 0.5 percent), and in most instances, benign enlarging leiomyomas are found (Leibsohn, 1990; Parker, 1994). Although uterine leiomyosarcomas do tend to grow quickly, no criteria define what constitutes significant growth. Despite these often-dramatic presentations, many women with uterine sarcoma and carcinosarcoma will have few symptoms other than abnormal vaginal bleeding and a seemingly normal uterus on physical examination.

### ■ Endometrial Sampling

The sensitivity of an office endometrial biopsy or dilatation and curettage (D & C) to detect sarcomatous elements is lower than that for endometrial carcinomas. Specifically, with leiomyosarcoma, symptomatic women receive a correct preoperative diagnosis in only 25 to 50 percent of cases. This inability to accurately sample the tumor is probably related to the origin of these neoplasms in the myometrium rather than the endometrium. Similarly, endometrial stromal nodules and endometrial stromal sarcomas may be undetectable by Pipelle biopsy, especially if the neoplasm is intramural (Yang, 2002). With carcinosarcoma, sampling will more often lead to a correct diagnosis, although in many cases only the carcinomatous features are evident. The reverse is also true, and occasionally a uterine carcinosarcoma is suspected based on endometrial biopsy findings, but no sarcomatous features are found within the hysterectomy specimen.

### ■ Laboratory Testing

Elevated preoperative serum cancer antigen 125 (CA125) levels may indicate extrauterine disease and deep myometrial invasion in patients with carcinosarcoma. After surgery, CA125

measurement may be a somewhat useful marker to monitor disease response (Huang, 2007).

### ■ Imaging Studies

Imaging studies are often helpful if sarcoma is diagnosed before hysterectomy. In most cases, a computed tomography (CT) scan of the abdomen and pelvis is routinely performed. This serves at least two purposes. First, sarcomas often violate normal soft tissue planes in the pelvis, and therefore, unresectable tumors may be identified preoperatively. Second, extrauterine metastases may be found. In either case, treatment may be altered based on radiographic findings.

If a diagnosis is still in question, magnetic resonance (MR) imaging helps distinguish uterine sarcoma from a benign “mimic” (Kido, 2003). As a diagnostic tool for sarcoma, sonography is far less helpful. Positron emission tomography (PET) scanning is most effective in the setting of recurrent uterine sarcoma but offers little advantage compared with CT or MR imaging (Sharma, 2012).

### ■ Role of the Generalist

Preoperative consultation with a gynecologic oncologist is recommended for any patient with a biopsy suggesting uterine sarcoma or carcinosarcoma. The potential for intraabdominal metastases and disruption of tissue planes within the pelvis increases the technical difficulty and surgical risks. The approach to staging is subtly dissimilar to that of endometrial carcinomas. For example, due to the low rate of metastasis, only sampling nodes suspicious for leiomyosarcomas may be appropriate instead of performing complete pelvic and paraaortic lymphadenectomy (Leitao, 2003; Major, 1993). Moreover, ovarian preservation may be suitable with certain sarcomas because of their low risk for spread to the adnexa (Kapp, 2008; Li, 2005). In general, a treatment plan is best organized preoperatively, if possible.

Many uterine sarcomas and carcinosarcomas are not diagnosed until surgery or several days later when a pathology report is available. As a result, unstaged cases are common, and a gynecologic

oncologist is consulted at the earliest feasible time. If the diagnosis is made postoperatively, the criteria to recommend surveillance only, reoperation, or radiotherapy vary widely and depend on the sarcoma type and other clinical circumstances. Generally, these options are less straightforward than in typical endometrial carcinomas, largely due to the rarity of these tumors and the comparatively limited data supporting one strategy over another.

With adoption of minimally invasive surgery (MIS), gynecologists are faced with uterine or myoma extraction through small incisions. Tissue fragmentation using power morcellation is one approach, but morcellation and dispersion of uterine or cervical cancers are concerns. In general, encountering unexpected sarcoma during surgery for presumed benign disease is rare, and rates range from 0.09 to 0.6 percent (Lieng, 2015; Lin, 2015). These investigators also found no clear preoperative risk factors. However, if a patient undergoes inadvertent morcellation and dispersion of an occult sarcoma, it may worsen her prognosis (Perri, 2009). In 2014, the Food and Drug Administration warned that power morcellator use should be curtailed in patients who are peri- or postmenopausal or who are candidates for en bloc removal through the vagina or a minilaparotomy. Moreover, if uncontained intraperitoneal morcellation is selected, patients should be aware of the risks that it poses.

**PATHOLOGY**

Uterine mesenchymal tumors are classified broadly into pure and mixed tumors (Table 34-1). Also, the term *homologous* denotes tissues normally found in the uterus and *heterologous* refers to tissue foreign to the uterus. Pure sarcomas are virtually all homologous and differentiate into mesenchymal tissue that is normally present within the uterus, such as smooth muscle (leiomyosarcoma) or stromal tissue within the endometrium (endometrial stromal tumors). Pure heterologous sarcomas, such as chondrosarcoma, are rare.

Mixed sarcomas contain a malignant mesenchymal component admixed with an epithelial element. If the epithelial element is also malignant, the tumor is termed *carcinosarcoma*. If the epithelial element is benign, the term *adenosarcoma* is used. Carcinosarcomas can be either homologous or heterologous, reflecting the pluripotentiality of the uterine primordium.

■ **Leiomyosarcoma**

Leiomyosarcomas account for 1 to 2 percent of all uterine malignancies. In a Surveillance, Epidemiology, and End Results (SEER) database study of 1396 patients, the median age at presentation was 52 years. Most tumors (68 percent) were stage I at the time of diagnosis, and stage II (3 percent), stage III (7 percent), and stage IV cancer (22 percent) formed the remainder (Kapp, 2008).

The histologic criteria for diagnosing leiomyosarcoma are somewhat controversial but include the frequency of mitotic figures, extent of nuclear atypia, and presence of coagulative tumor cell necrosis (Fig. 34-2). In reading Table 34-2, each row illustrates combinations of histologic findings that may be found in leiomyosarcomas. In most cases, the mitotic index exceeds 15 mitotic figures total when 10 high-power fields are examined, moderate to severe cytologic atypia is seen, and tumor cell

necrosis is prominent (Hendrickson, 2003; Zaloudek, 2011). Occasionally, a leiomyosarcoma will be reported as low-, intermediate-, or high-grade, but the overall utility of grading is controversial, and no universally accepted grading system exists.

■ **Smooth Muscle Tumor of Uncertain Malignant Potential (STUMP)**

Tumors that show some worrisome histologic features, such as necrosis or nuclear atypia, but that cannot be diagnosed reliably as benign or malignant based on generally applied criteria fall into this category. The diagnosis should be used sparingly and

**FIGURE 34-2** Leiomyoma (**A, B**) and leiomyosarcoma (**C, D**). **A**, Leiomyomas tend to be well-circumscribed masses. This leiomyoma shows a well-demarcated interface (arrows) with the less cellular myometrium above it. **B**, Although leiomyomas may have variable histologic features, most are composed of bland spindled cells with blunt-ended nuclei and limited mitotic activity. **C**, Leiomyosarcoma is a malignant smooth muscle neoplasm that may differ markedly in its microscopic appearance from case to case. Generally, leiomyosarcoma shows some combination of coagulative tumor necrosis, increased mitotic activity, and/or nuclear atypia. This example has marked nuclear atypia and pleomorphism and an infiltrative growth pattern at its periphery. This differs from the usually smooth, pushing border of typical leiomyomas. **D**, This particular example has moderate to marked nuclear atypia. (Used with permission from Drs. Kelley Carrick and Raheela Ashfaq.)

is reserved for smooth muscle neoplasms whose appearance is ambiguous (Hendrickson, 2003).

### ■ Endometrial Stromal Tumors

Significantly less common than leiomyosarcomas, the group of endometrial stromal tumors comprise fewer than 10 percent

of all uterine sarcomas. In a SEER database study of 831 patients, the median age at diagnosis was 52 years (Chan, 2008). Although constituting a wide morphologic spectrum, endometrial stromal tumors are composed exclusively of cells that resemble the endometrial stroma, and this category includes both benign stromal nodules and malignant stromal tumors (see Table 34-1).

Historically, there has been controversy in subdividing these tumors. The division of endometrial stromal sarcomas into low-grade and high-grade categories has fallen out of favor. In its place, the designation *endometrial stromal sarcoma* is now best restricted to neoplasms that were formerly referred to as low-grade. Alternatively, the term *high-grade undifferentiated sarcoma* is believed to more accurately reflect those tumors without recognizable evidence of a definite endometrial stromal phenotype. These lesions are almost invariably high grade and often resemble the mesenchymal component of a uterine carcinosarcoma (Oliva, 2000). In this revised classification, the distinctions are not determined by mitotic count but by features such as nuclear pleomorphism and necrosis (Evans, 1982; Hendrickson, 2003).

### Endometrial Stromal Nodule

Representing less than a quarter of tumors in the endometrial stromal tumor group, these rare nodules are benign, characterized by a well-delineated margin, and composed of neoplastic cells that resemble proliferative-phase endometrial stromal cells. Grossly, the tumor is a solitary, round or oval, fleshy nodule measuring a few centimeters. Histologically, they are distinguished from endometrial stromal sarcomas by their lack of myometrial infiltration (Dionigi, 2002). Because these nodules are benign, myomectomy is an appropriate option. However, because differentiation between endometrial stromal sarcoma and this benign lesion cannot be determined clinically, it is important to remove the entire nodule. Thus, for large lesions, hysterectomy may be required (Hendrickson, 2003).

### Endometrial Stromal Sarcoma

The precise frequency of these tumors is difficult to estimate because they are excluded from some reports and included in others, and the terminology used has been inconsistent. In general, endometrial stromal sarcomas (formerly called low grade) are thought to be the most frequently encountered stromal tumor variant and are twice as common as high-grade undifferentiated sarcomas.

**TABLE 34-2.** Diagnostic Criteria for Uterine Leiomyosarcoma

Coagulative Tumor Cell Necrosis	Mitotic Index <sup>a</sup>	Degree of Atypia
Present	≥ 10 MF/10 HPF	None
Present	Any	Diffuse, significant
Absent	≥ 10 MF/10 HPF	Diffuse, significant

<sup>a</sup>MF/10 HPF = the total number of mitotic figures (MF) counted when 10 high-powered fields (HPF) are examined. Adapted with permission from Tavassoli FA, Devilee P (eds): World Health Organization Classification of Tumours. World Health Organization, 2003.

**FIGURE 34-3** Endometrial stromal sarcoma. The surgical specimen has been bisected and remains joined at the fundus.

Typically, they extensively invade the myometrium and extend to the serosa in approximately half of cases (Fig. 34-3). Less often, they present as a solitary well-delineated, predominantly intramural mass that is difficult to grossly distinguish from an endometrial stromal nodule. Microscopically, endometrial stromal sarcomas resemble the stromal cells of proliferative-phase endometrium (Fig. 34-4).

Metastases are rarely detected prior to the diagnosis of the primary lesion. However, permeation of the lymphatic and vascular channels is characteristic. In up to one third of cases, extrauterine extension is present, often appearing as “worm-like” plugs of tumor within the vessels of the broad ligament and adnexa. At operation, this may resemble intravenous leiomyomatosis or a broad ligament leiomyoma, both described in Chapter 9 (p. 204). Frozen section analysis can usually make the distinction.

### High-grade Undifferentiated Sarcoma

Compared with endometrial stromal sarcomas, these tumors tend to be larger and more polypoid, often filling the uterine cavity. Instead of an infiltrating pattern, high-grade undifferentiated sarcomas displace the myometrium more destructively, leading to prominent hemorrhage and necrosis.

Microscopically, the cells are larger and more pleomorphic. The presence of marked cellular atypia is characteristic. Typically, there are more than 10 mitoses per 10 high-power fields, but frequently there are more than 20 in the most active areas. These tumors lack specific differentiation and bear no histologic resemblance to endometrial stroma (Hendrickson, 2003; Zaloudek, 2011).

### ■ Carcinosarcoma

Accumulating clinical and pathologic evidence suggests that carcinosarcomas actually represent endometrial carcinomas that have undergone clonal evolution, resulting in the acquisition of sarcomatous features. In principle, these tumors are metaplastic carcinomas. Clinically, their pattern of spread more closely mirrors that of aggressive endometrial carcinomas than that of

**FIGURE 34-4** Endometrial stromal sarcoma (ESS), same patient as in Figure 34-3. **A.** ESS is composed of cells morphologically similar to proliferative phase endometrial stromal cells. In this low-power view that involved the corpus and cervix, irregular tongues of tumor (asterisks) are seen dissecting into the cervical stroma. **B.** The tumor cells are spindled and relatively bland, similar to normal endometrial proliferative phase stroma. Two mitoses are identified in this single medium-power field (white arrows). **C.** Endometrial stroma marks positively with CD10, as does ESS. A battery of immunostains, including CD10, may be used to help distinguish ESS from other spindle cell neoplasms. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 34-5** Carcinosarcoma. Photograph of the surgical specimen after it has been bisected and remains joined at the fundus.

sarcomas. In addition, metastases usually show carcinomatous elements, with or without sarcomatous differentiation.

However, by convention, carcinosarcomas are usually grouped with uterine sarcomas, accounting for 2 to 3 percent of all uterine malignancies. Patients are often older, having an average age of 65 years. Fewer than 5 percent are diagnosed in women younger than 50. At the time of diagnosis, most cancers (40 percent) are stage I. Stage II (10 percent), stage III (25 percent), and stage IV disease (25 percent) make up the remainder (Sartori, 1997; Vaidya, 2006).

Grossly, the tumor is sessile or polypoid, bulky, necrotic, and often hemorrhagic (Fig. 34-5). It often fills the endometrial cavity and deeply invades the myometrium. On occasion, a large tumor protrudes through the external cervical os and fills the vaginal vault.

**FIGURE 34-7** Carcinosarcoma with heterologous elements. In this carcinosarcoma with cartilaginous differentiation, malignant glands are present at the periphery (arrows). Centrally is a focus of malignant cartilage (asterisk), with its characteristic lacunae embedded within a bluish chondroid matrix. (Used with permission from Dr. Kelley Carrick.)

Microscopically, carcinosarcomas have an admixture of epithelial and mesenchymal differentiation. The malignant epithelial element is typically an adenocarcinoma of endometrioid type, but serous, clear cell, mucinous, squamous cell, and undifferentiated carcinoma are also common (Fig. 34-6). Mesenchymal components can be homologous, usually resembling endometrial stromal sarcomas or fibrosarcomas. Alternatively, heterologous mesenchymal differentiation can be found in association with areas of endometrial stromal or undifferentiated sarcomas. Most commonly, rhabdomyosarcoma or chondrosarcoma compose these cases of heterologous mesenchymal differentiation (Fig. 34-7). Although interesting,

**FIGURE 34-6** **A.** Carcinosarcoma is a biphasic malignant neoplasm composed of both carcinomatous and sarcomatous elements. In this example, malignant endometrioid-type glands are present within an atypical spindled stroma. **B.** Immunohistochemical stain for cytokeratin marks the epithelial component but not the stromal component. **C.** Conversely, an immunohistochemical stain for vimentin (a mesenchymal marker) stains the sarcomatous component. (Used with permission from Dr. Raheela Ashfaq.)

**FIGURE 34-8** Gross uterine specimen with adenosarcoma.

there is no clinical importance to designating a uterine carcinosarcoma as homologous or heterologous (McCluggage, 2003).

### ■ Adenosarcoma

This rare, biphasic neoplasm is characterized by a benign epithelial component and a sarcomatous mesenchymal component. Tumors may develop in women of all ages. Grossly, adenosarcomas grow as exophytic polypoid masses that extend into the uterine cavity (Fig. 34-8). Rarely, they may arise in the myometrium, presumably from adenomyosis. Microscopically, isolated glands are dispersed throughout the mesenchymal component and are often dilated or compressed into thin slits (Fig. 34-9). Typically, the mesenchymal component resembles an endometrial stromal sarcoma or fibrosarcoma and contains varying amounts of fibrous tissue and smooth muscle. In general, these are considered low-grade tumors with mild atypia and relatively few mitotic figures. However, 10 percent have a more malignant behavior due to one-sided proliferation of the

sarcomatous, often high-grade, component. These adenosarcomas are designated as having “sarcomatous overgrowth,” and patients have a poor prognosis, similar to that of carcinosarcomas (Krivak, 2001; McCluggage, 2003).

### PATTERNS OF SPREAD

Uterine sarcomas generally fall into two categories of malignant behavior. Leiomyosarcomas, high-grade undifferentiated sarcomas, and carcinosarcomas are consistently characterized by an aggressive growth pattern and rapid disease progression despite treatment. In contrast, endometrial stromal sarcomas and adenosarcomas have an indolent growth pattern with long disease-free intervals. All of these tumors invade, to some degree, by direct extension.

Leiomyosarcomas have a propensity for hematogenous dissemination. Lung metastases are particularly common, and more than half of patients will have distant spread if diagnosed with recurrent disease. To a lesser extent, leiomyosarcomas metastasize via lymphatic channels (Leitao, 2003). In a clinico-pathologic Gynecologic Oncology Group (GOG) study, fewer than 5 percent of clinical stage I and II patients had nodal involvement (Major, 1993).

The opposite is true for carcinosarcomas, in which one third of patients with clinically stage I tumors will have nodal metastases (Park, 2010). Thus, comprehensive pelvic and paraaortic lymphadenectomy is particularly important (Temkin, 2007). Extraabdominal spread is less common, and most recurrences are found in the pelvis or abdomen.

### STAGING

Uterine sarcomas are surgically staged. Formerly, most clinicians used the FIGO surgical staging system for endometrial cancer to stage uterine sarcomas. However, beginning in 2009, only carcinosarcomas share the same staging criteria as endometrial carcinomas (Table 33-9, p. 713). Endometrial

**FIGURE 34-9** Adenosarcoma. **A.** A broad-based villous architecture is seen typically. **B.** Normal endometrial glands are surrounded by a cellular stroma consisting of a low-grade sarcoma. In this case, an endometrial stromal sarcoma is the sarcoma component. (Used with permission from Dr. Raheela Ashfaq.)

**TABLE 34-3.** FIGO Staging for Uterine Sarcomas (Leiomyosarcomas, Endometrial Stromal Sarcomas, Adenosarcomas, and Carcinosarcomas)

Stage	Characteristics
<b>Leiomyosarcomas</b>	
<b>I</b>	<b>Tumor limited to uterus</b>
IA	< 5 cm

<b>Carcinosarcomas</b>	
Carcinosarcomas should be staged as carcinomas of the endometrium (Table 33-9, p. 713).	
<sup>a</sup> Note: Simultaneous tumors of the uterine corpus and ovary/pelvis in association with ovarian/pelvic endometriosis should be classified as independent primary tumors. FIGO = International Federation of Gynecology and Obstetrics.	

stromal sarcomas and adenosarcomas share new criteria, whereas leiomyosarcomas have a different system for stage I (Table 34-3 and Fig. 34-10).

## TREATMENT OF EARLY-STAGE DISEASE (STAGES I AND II)

### ■ Surgery

The highest chance of cure is achieved by complete surgical resection of a sarcoma that is confined to the uterus. In general, laparotomy is performed due to the typical features of sarcomas, which include uterine enlargement, parametrial extension,

and tumor metastasis. Laparoscopic or vaginal approaches have not yet been shown to yield equivalent outcomes.

The staging laparotomy described for endometrial cancer in Chapter 33 (p. 713) can be revised to incorporate the unique spread patterns of uterine sarcomas. For instance, peritoneal washings may be easily obtained upon opening the abdomen but are not part of the staging system and have limited value (Kanbour, 1989). Exploration is particularly important to assess the abdomen for unresectable or widely metastatic disease that might indicate a need to abort the procedure. As in endometrial carcinomas, some evidence shows benefit from aggressive cytoreductive surgery (Dinh, 2004; Leath, 2007; Thomas, 2009).

**FIGURE 34-10** FIGO staging of leiomyosarcoma and that for adenosarcoma and endometrial stromal sarcoma (ESS).

With *uterine leiomyosarcoma*, all patients should undergo a hysterectomy, if feasible. A modified radical or radical procedure may be occasionally required if there is parametrial infiltration. In the absence of other gross disease, fewer than 5 percent will have ovarian or nodal metastases. Ovarian preservation is therefore an option for premenopausal women. In addition, lymph node dissection is reserved for patients with

clinically suspicious nodes (Kapp, 2008; Leitao, 2003; Major, 1993). For STUMP, hysterectomy alone is sufficient.

*Endometrial stromal tumors* and *adenosarcomas* are also best treated by hysterectomy. Again, a more radical procedure may be required to encompass local disease. Preservation of the ovaries is generally accepted for endometrial stromal sarcomas or adenosarcomas in the absence of extrauterine disease (Chan,

2008; Li, 2005; Shah, 2008). However, bilateral salpingo-oophorectomy (BSO) is indicated for high-grade undifferentiated sarcomas (Leibsohn, 1990). Unlike leiomyosarcoma, lymph node dissection is typically more informative. Although nodal metastases are most often identified in patients with obvious extrauterine disease, they do occur in 5 to 10 percent of patients with no evidence for intraabdominal spread (Dos Santos, 2011; Goff, 1993; Signorelli, 2010).

For *uterine carcinosarcoma*, hysterectomy and BSO are mandatory. Lymph node metastases will be found in up to one third of patients with clinical stage I disease, and thus, comprehensive lymphadenectomy should be performed as for poorly differentiated endometrial cancers (Major, 1993; Nemani, 2008; Park, 2010; Temkin, 2007). Typically, disease spread is histologically consistent with the carcinomatous element of this mixed tumor. Because this component may be serous or clear cell, extended surgical staging with infracolic omentectomy and random peritoneal biopsies is also advisable (Greer, 2015).

## ■ Surveillance

In women with early-stage uterine sarcoma, adjuvant treatment is routinely employed but has not been demonstrated to improve survival rates (Greer, 2015; Reed, 2008). Thus, because the recurrence rate for the clinically aggressive types is excessive, enrollment in an experimental clinical trial should be carefully considered, if available. In practice, many patients receive postoperative radiation with or without chemotherapy.

After surgery, menopausal symptoms such as hot flashes may be treated as appropriate for uterine leiomyosarcomas, high-grade undifferentiated sarcomas, and adenocarcinomas. However, although it is considered safe to preserve the ovaries in a premenopausal woman with endometrial stromal sarcoma, the use of estrogen replacement therapy has been associated with disease progression and is avoided (Chu, 2003; Pink, 2006). Similar caution is warranted for patients with uterine carcinosarcoma.

Surgically treated patients with uterine sarcoma should have a physical examination every 3 months for the first 2 years and then at 6- to 12-month intervals thereafter. Most recurrences will be distant, and thus Pap tests are largely irrelevant. In addition, serum CA125 levels are not routinely recommended, unless initially elevated prior to surgery. Depending on the type of sarcoma, a chest radiograph or CT imaging is performed every 6 to 12 months for 2 years, then annually. When clinically indicated, intermittent CT or MR imaging may also be helpful (Greer, 2015).

## ■ Adjuvant Radiation

Approximately half of patients with stage I disease who are observed without adjuvant therapy will relapse (Leath, 2009). Due to the rarity of these tumors and limited data to support a consistent approach, the use of postoperative therapy is usually individualized.

The role of postoperative radiotherapy for nonmetastatic disease is controversial. Prior retrospective studies of adjuvant external beam pelvic radiotherapy suggested reduced pelvic recurrence rates for carcinosarcoma, leiomyosarcoma, and endometrial stromal sarcoma (Callister, 2004; Hornback,

1986; Mahdavi, 2009; Malouf, 2010). However, results from a prospective trial that randomly assigned 224 women over 13 years with all subtypes of surgical stage I or II uterine sarcomas to receive either pelvic radiation or no further treatment have been reported. Although a reduced rate of pelvic relapse for those with carcinosarcomas was noted, no benefit was gained for those with leiomyosarcomas and no significant increase in survival rates for either group. Unfortunately, the number of patients with endometrial stromal sarcoma was too small to permit analysis (Reed, 2008).

Pelvic radiation does not prevent distant recurrences and has yet to be shown to improve survival rates (Nemani, 2008). In many circumstances, vaginal brachytherapy may be an alternative, especially if paired with systemic chemotherapy (Greer, 2015). Whole abdominal radiotherapy (WAR) has been proposed as a more definitive option. In one randomized phase III study of 232 patients with stage I-IV carcinosarcoma, WAR was compared with ifosfamide and cisplatin chemotherapy. Although no survival advantage was demonstrated, the observed differences favored the use of combination chemotherapy in future trials (Wolfson, 2007).

## ■ Adjuvant Chemotherapy

There is no proven survival benefit for using adjuvant chemotherapy in patients with stage I uterine sarcoma (Omura, 1985). However, because most patients will recur distantly, adjuvant systemic treatment is frequently used. For leiomyosarcomas, completely resected stage I and II disease treated with doxorubicin and ifosfamide was not associated with a significantly improved disease-free or overall survival benefit (Mancari, 2014). In high-grade undifferentiated sarcomas and carcinosarcomas, chemotherapy regimens used for more advanced disease may be considered. For stages I and II endometrial stromal sarcoma and adenocarcinoma, observation is recommended (Greer, 2015).

## ■ Fertility-sparing Management

Rarely, young patients may desire to delay definitive hysterectomy after a fertility-sparing “myomectomy” demonstrates sarcomatous features on the final pathology report (Lissoni, 1998; Yan, 2010). Although expectant management following tumor resection can result in successful pregnancies in select patients, it is risky not to perform a hysterectomy, and eventually all such women should undergo hysterectomy (Lissoni, 1998). Most patients, even those with negative margins, should be counseled regarding definitive surgery and ovarian preservation during surgery for clinical stage I uterine leiomyosarcomas or endometrial stromal sarcomas. Egg retrieval, assisted reproductive technologies, and pregnancy surrogacy would still be possible. For more advanced disease, fertility-sparing management is not a reasonable option.

## TREATMENT OF ADVANCED (STAGES III AND IV) OR RECURRENT DISEASE

Patients with advanced or recurrent uterine sarcoma generally have a dismal prognosis. For advanced-stage disease, upfront surgery with maximal effort to completely remove all visible

disease (similar in approach to advanced ovarian cancer) is considered standard. T is is generally followed by adjuvant chemotherapy. Neoadjuvant chemotherapy can be considered for patients whose disease is considered unresectable or who are medically unfit for surgery.

For recurrent disease, secondary cytoreductive surgery may be feasible in some circumstances (Giuntoli, 2007). Palliative radiation may also have a role, depending on the site and distribution of the tumor. In general, uterine sarcomas have a propensity for relapse at distant sites, and chemotherapy is more useful. Since current treatment options have only modest efficacy, patients are encouraged to enroll in experimental clinical trials.

■ **Leiomyosarcoma**

Doxorubicin is considered the most active single agent (Miller, 2000; Omura, 1983). However, treatment with the combination of gemcitabine and docetaxel currently has the highest proven response rate (36 percent) (Hensley, 2008). Addition of bevacizumab to this regimen was not beneficial (Hensley, 2015).

For late recurrences of leiomyosarcoma, surgery must be individualized. Five-year survival rates of 30 to 50 percent have been reported following pulmonary resection for lung metastases. Local and regional recurrences may also be amenable to surgical resection (Giuntoli, 2007).

■ **Endometrial Stromal Tumors**

Surgical resection may be feasible for some patients with recurrent endometrial stromal sarcoma, but hormonal therapy is particularly useful. In general, these tumors are estrogen- and progesterone-receptor (ER/PR) positive (Sutton, 1986). Progestins such as megestrol acetate and medroxyprogesterone acetate are most commonly used either postoperatively for advanced-stage disease or for relapses (Reich, 2006). Using this strategy, complete responses are often possible. Aromatase inhibitors and gonadotropin-releasing hormone (GnRH) agonists have also demonstrated activity (Burke, 2004; Leunen, 2004).

High-grade undifferentiated sarcomas do not exhibit the same level of sensitivity to hormonal agents, primarily because they are usually ER/PR negative. Advanced disease or recurrences of these rare tumors are also typically not amenable to surgical resection, although palliative radiation may have some utility. Systemic chemotherapy is usually the only option, and ifosfamide is the only cytotoxic drug with proven activity (Sutton, 1996).

■ **Carcinosarcoma**

Ifosfamide is the most active single agent for carcinosarcoma. T e combination of ifosfamide and paclitaxel is the current preferred treatment for advanced or recurrent uterine carcinosarcoma (Galaal, 2011). In a recent phase III GOG trial randomizing 179 patients, this regimen demonstrated a superior response rate (45 versus 29 percent) and survival advantage compared with ifosfamide alone (protocol #161) (Homesley, 2007). T e combination of carboplatin and paclitaxel is also active and is being compared with ifosfamide and paclitaxel in an ongoing GOG trial (protocol #261) (King, 2009; Powell, 2010).

**TABLE 34-4.** Overall Survival Rates of Women with Uterine Sarcomas (All Stages)

Type	5-Year Survival
Carcinosarcoma	35%
Leiomyosarcoma	25%
Endometrial stromal tumors	
Endometrial stromal sarcoma	60%
High-grade undifferentiated sarcoma	25%

Data from Acharya S, Hensley ML, Montag AC, et al: Rare uterine cancers, *Lancet Oncol* 2005 Dec;6(12):961–71.

**SURVIVAL AND PROGNOSTIC FACTORS**

In general, women with uterine sarcoma have a poor prognosis (Table 34-4). In a study of 141 women followed for a median of 3 years, 74 percent died of disease progression. FIGO stage is the most important independent variable associated with survival (Livi, 2003). Other poor prognostic factors across all subtypes include older age, African-American race, and lack of primary surgery (Chan, 2008; Kapp, 2008; Nemani, 2008).

Tumor histology is the other main predictor of outcome. Leiomyosarcomas have the worst prognosis and are followed by carcinosarcoma and the group of endometrial stromal tumors (Livi, 2003). Endometrial stromal sarcomas and uterine adenocarcinomas without sarcomatous overgrowth are the two notable exceptions. Patients with these tumors tend to have a good prognosis due to their indolent growth (Pautier, 2000; Verschraegen, 1998).

In the United States, ovarian cancer accounts for more deaths than all other gynecologic malignancies combined. Worldwide each year, more than 225,000 women are diagnosed, and 140,000 women die from this disease (Jemal, 2011). Of these, epithelial ovarian carcinomas make up 90 to 95 percent of all cases, including the more indolent low-malignant-potential (borderline) tumors (Quirk, 2005). The remainder includes germ cell and sex cord-stromal tumors, which are described in Chapter 36 (p. 760). Due to the similarities of primary peritoneal carcinomas and fallopian tube cancers, they are included within this section for simplicity.

Approximately one quarter of patients will have stage I disease and an excellent long-term survival rate. However, there are no effective screening tests for ovarian cancer and few notable early symptoms. As a result, two thirds of patients have advanced disease when they are diagnosed. Aggressive debulking surgery, followed by platinum-based chemotherapy, usually results in clinical remission. However, up to 80 percent of these women will develop a relapse that eventually leads to disease progression and death.

EPIDEMIOLOGY AND RISK FACTORS

One in 78 American women (1.3 percent) will develop ovarian cancer during her lifetime. Because the incidence has slowly declined since the early 1990s, ovarian cancer is now the ninth leading cause of cancer in women. In 2015, 21,290 new cases and 14,180 deaths are expected, and ovarian cancer remains the fifth leading cause of cancer-related death (Siegel, 2015). Overall, the average age at diagnosis is in the early 60s.

Numerous reproductive, environmental, and genetic risk factors have been associated with ovarian cancer (Table 35-1). The most important is a *family history* of breast or ovarian cancer, and approximately 10 percent of patients have an inherited genetic predisposition. For the other 90 percent with no identifiable genetic link for their ovarian cancer, most risks are related to a pattern of uninterrupted ovulatory cycles during the reproductive years (Pelucchi, 2007). Repeated stimulation of the ovarian surface epithelium is hypothesized to lead to malignant transformation (Schildkraut, 1997).

*Nulliparity* is associated with long periods of repetitive ovulation, and patients without children have double the risk of developing ovarian cancer (Purdie, 2003). Among nulliparous women, those with a history of infertility have an even higher risk. Although the reasons are unclear, it is more likely to be an inherent ovarian predisposition rather than an iatrogenic effect of ovulation-inducing drugs. For example, women treated for infertility who successfully achieve a live birth do not have an increased risk of

**TABLE 35-2.** Women Who Should Undergo Genetic Testing

Epithelial ovarian cancer <sup>a</sup> at any age
Breast cancer diagnosed at age 45 or younger
Breast cancer with two distinct and sequential primaries, first one diagnosed at age 50 or younger
Breast cancer that is triple-negative diagnosed at age 60 or younger
Breast cancer at any age, with at least one close relative <sup>b</sup> diagnosed at age 50 or younger
Breast cancer diagnosed at any age, with two or more close relatives with breast cancer; one close relative with epithelial ovarian cancer; or two close relatives with pancreatic cancer or aggressive prostate cancer
Breast cancer, with a close male relative with breast cancer at any age
Breast cancer and Ashkenazi Jewish ancestry
Individuals from a family with a known deleterious BRCA1 or BRCA2 mutation

<sup>a</sup>Throughout table, peritoneal and fallopian tube cancer are considered as part of the spectrum of the Hereditary Breast/Ovarian Cancer syndrome.

<sup>b</sup>Throughout table, close relative is defined as a first-, second-, or third-degree relative (i.e., mother, sister, daughter, aunt, niece, grandmother, granddaughter, first cousin, great grandmother, great aunt).

ovarian cancer (Rossing, 2004). In general, risks decrease with each live birth, eventually plateauing in women delivering five times (Hinkula, 2006). One theory suggests that pregnancy may induce premalignant ovarian cell shedding (Rostgaard, 2003).

*Early menarche* and *late menopause* are also associated risks. In contrast, breastfeeding has a protective effect, perhaps by prolonging amenorrhea (Yen, 2003). Presumably by also preventing ovulation, long-term combination oral contraceptive use reduces the risk of ovarian cancer by 50 percent. The duration of protection lasts up to 25 years after the last use (Riman, 2002). In contrast, hormone replacement therapy after menopause has an elevated associated risk (Lacey, 2006; Mørch, 2009).

*White women* have the highest incidence of ovarian cancer among all racial and ethnic groups (Quirk, 2005). Compared with that of black and Hispanic women, the risk is elevated by 30 to 40 percent (Goodman, 2003). Although exact reasons are unknown, racial discrepancies in parity and rates of gynecologic surgery may account for some of the differences.

*Tubal ligation* and *hysterectomy* are each associated with a substantial reduction in risk (Rice, 2014). Theoretically, any gynecologic procedure that precludes irritants from reaching the ovaries via ascension from the lower genital tract might plausibly exert a similar protective effect. In turn, women who regularly use perineal talc may possibly have an elevated risk (Gertig, 2000; Houghton, 2014; Rosenblatt, 2011).

*Age* is another risk, and the overall incidence of ovarian cancer rises with age up to the mid-70s and then declines slightly among women beyond 80 years (Goodman, 2003). In general, aging allows an extended period to accumulate random genetic alterations within the ovarian surface epithelium.

Women residing in North America, Northern Europe, or any industrialized Western country have a higher ovarian cancer risk. Globally, the incidence varies greatly, but developing countries and Japan have the lowest rates (Jemal, 2011). Regional dietary habits may be partly responsible (Kiani, 2006). For example, consumption of foods low in fat but high in fiber, carotene, and vitamins appears protective (Zhang, 2004).

A family history of ovarian cancer in a first-degree relative, that is, a mother, daughter, or sister, triples a woman's lifetime risk. The

risks further escalate with two or more afflicted first-degree relatives, or with other individuals with premenopausal breast cancer. If a family history is mainly composed of colon cancer, clinicians may consider Lynch syndrome, also known as *hereditary nonpolyposis colorectal cancer* (HNPCC). Patients with this syndrome have a high lifetime risk of colon cancer (85 percent) and ovarian cancer (10 to 12 percent). Because the predominant gynecologic malignancy is endometrial cancer (40 to 60 percent lifetime risk), HNPCC is described in more detail in Chapter 33 (p. 703).

■ Hereditary Breast and Ovarian Cancer Genetic Screening

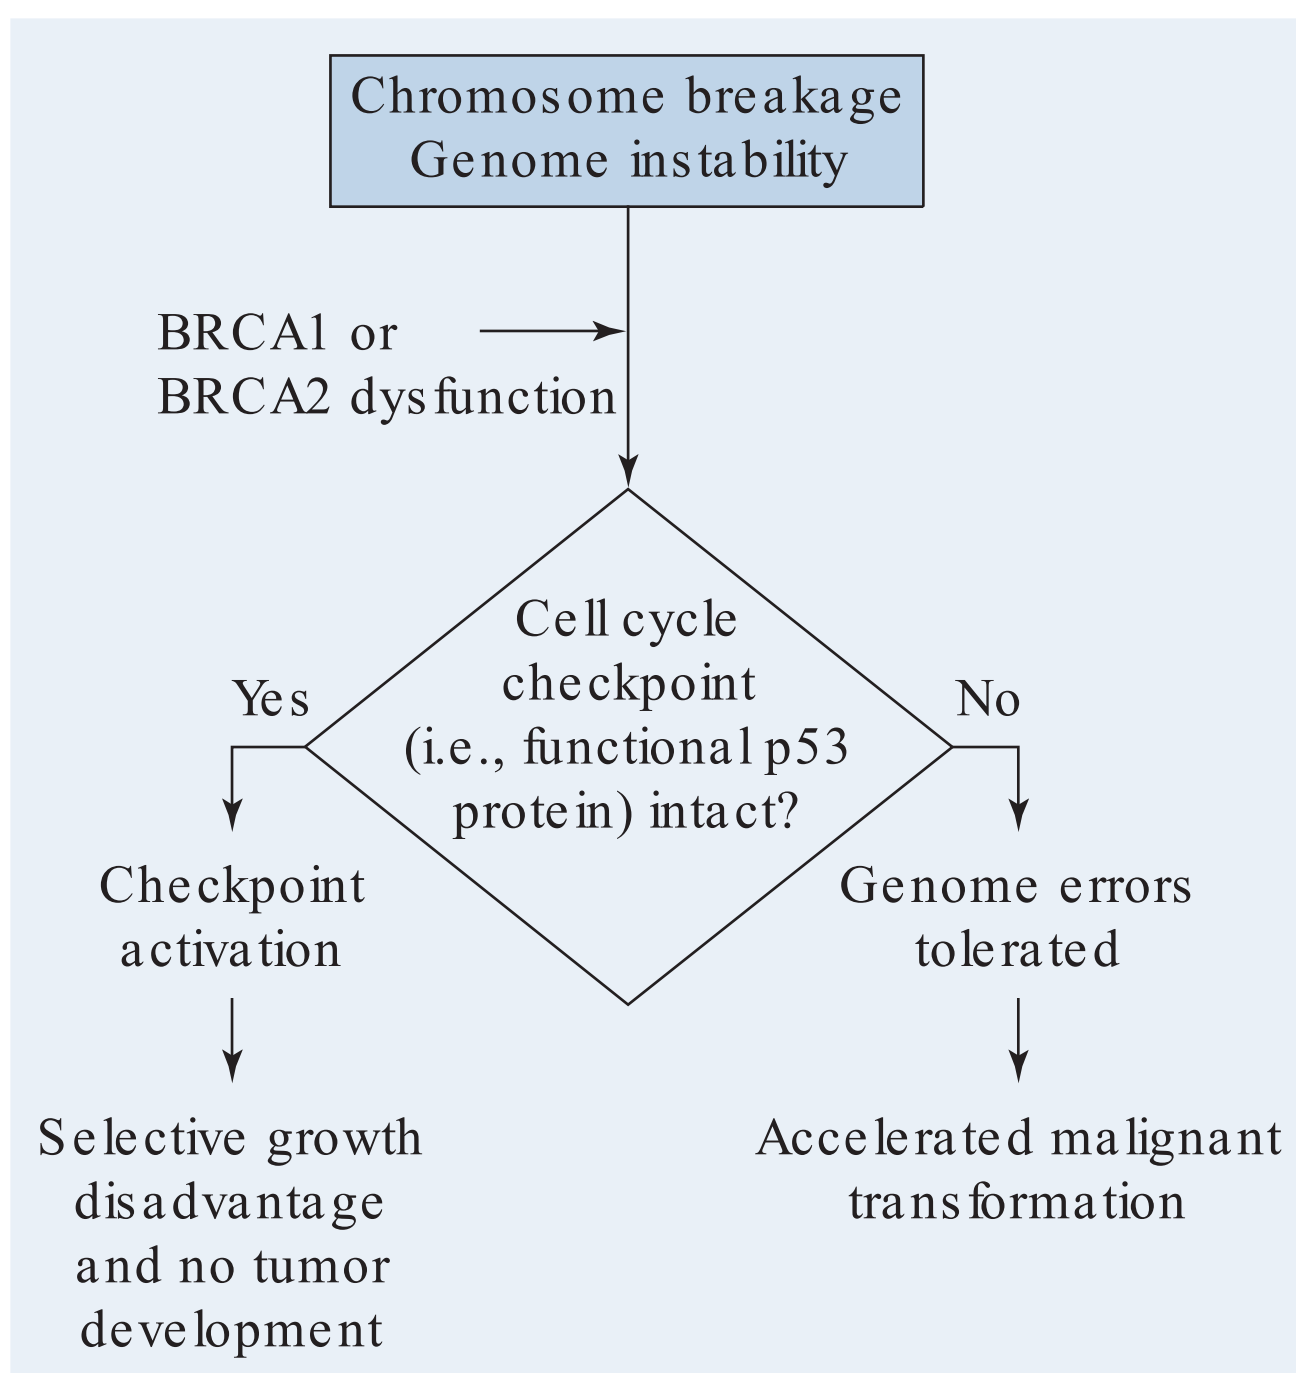

More than 90 percent of inherited ovarian cancers result from germline mutations in the *BRCA1* or *BRCA2* genes. Thus, any patient with a personal history of epithelial ovarian cancer or breast cancer in certain circumstances, or from a family with a known deleterious mutation, should undergo testing (Table 35-2) (Daly, 2014).

Typically, a patient is referred to a certified genetic counselor, and a comprehensive pedigree is constructed first. Then, risk assessment is performed using one of several validated population models. These include the BRCAPRO and Tyrer-Cuzick programs, which are available, respectively, at: <http://www4.utsouthwestern.edu/breasthealth/cagene/default.asp>, and by contacting the International Breast Cancer Intervention Study (IBIS) at [ibis@cancer.org.uk](mailto:ibis@cancer.org.uk). These models and their associated software allow quantification of an individual's risk for carrying a germline deleterious mutation of the *BRCA1* and *BRCA2* genes (Euhus, 2002; James, 2006; Parmigiani, 2007). However, assessment of family history, even by a validated model, cannot effectively target testing to a high-risk ovarian cancer patient population, which strongly supports the recommendation to offer *BRCA1/BRCA2* genetic testing to all patients with high-grade serous ovarian cancer regardless of family history (Daniels, 2014; Norquist, 2013).

BRCA1 and BRCA2 Genes

These are two tumor-suppressor genes, whose protein products are BRCA1 and BRCA2. These two proteins interact with

**FIGURE 35-1** Diagram describing the role of the *BRCA* mutation in tumor development. Cells with damaged DNA are frequently blocked at checkpoints along the cell cycle and thereby prohibited from moving to the mitotic phase. If these checkpoints are non-functional, then these genomic errors may be tolerated and lead to malignant transformation. (Reproduced with permission from Scully R, Livingston DM: In search of the tumour-suppressor functions of *BRCA1* and *BRCA2*, *Nature* 2000 Nov 23;408(6811):429–432.)

recombination/DNA repair proteins to preserve intact chromosomal structure. Mutations of *BRCA1* and *BRCA2* genes lead to *BRCA1* and *BRCA2* protein dysfunction, which results in genetic instability and subjects cells to a higher risk of malignant transformation (Fig. 35-1) (Deng, 2006; Scully, 2000).

The *BRCA1* gene is located on chromosome 17q21. Patients with a proven mutation have a dramatically elevated risk of developing ovarian cancer (39 to 46 percent). *BRCA2* is located on chromosome 13q12 and in general is less likely to lead to ovarian cancer (12 to 20 percent). The estimated lifetime risk of breast cancer with a *BRCA1* or *BRCA2* mutation is 65 to 74 percent (American College of Obstetricians and Gynecologists, 2013; Chen, 2006; Risch, 2006). Both genes are inherited in an autosomal dominant fashion, but with variable penetrance. In essence, a carrier has a 50:50 chance of passing the gene to a son or daughter, but it is uncertain whether an individual with the gene mutation will actually develop breast or ovarian cancer. As a result, manifestations of *BRCA1* or *BRCA2* mutations can appear to skip generations.

### Genetic Testing

Ideally, genetic testing identifies women with deleterious *BRCA1* and *BRCA2* mutations, leads to intervention with prophylactic surgery, and thereby prevents ovarian cancer. Three distinct results are possible with this testing. A “positive” test suggests the presence of a deleterious mutation. The most common are the three “Jewish founder” mutations: 185delAG or 5382insC in *BRCA1* and 6174delT in *BRCA2*. Each of these “frameshift” mutations significantly alters the downstream

amino acid sequence, resulting in alteration of the *BRCA1* or *BRCA2* tumor suppressor protein. As suggested, these three specific mutations are thought to have originated from within the Ashkenazi population thousands of years ago. Although Jewish founder mutations are most common, any frameshift mutation within the *BRCA* genes may result in a deleterious predisposition to developing breast and ovarian cancer.

Second, “variants of uncertain clinical significance” may actually be pathogenic (true mutations) or just polymorphisms (normal variants found in at least 1 percent of alleles in the general population). These unclassified variants are common, representing approximately one third of *BRCA1* test results and half of those for *BRCA2*. Most are missense mutations, which result in a single amino acid change in the protein, without a frameshift. Given the prognostic uncertainty and high rate of reclassification, individualized counseling and directing efforts toward surveillance, chemoprevention, or salpingectomy are recommended (Garcia, 2014).

The third potential and most reassuring genetic test result is “negative.” However, due to the large size of the *BRCA1* and *BRCA2* genes, the false-negative rate is 5 to 10 percent. To capture additional, otherwise undetected mutations, reflex testing of large genomic rearrangements is available for high-risk patients (Palma, 2008).

## PREVENTION

### ■ Ovarian Cancer Screening

In addition to genetic testing, other screening strategies for ovarian cancer have been evaluated. However, despite enormous effort, there is no proof that routine screening with serum markers, sonography, or pelvic examinations decreases mortality rates (American College of Obstetricians and Gynecologists, 2013; Morgan, 2014; Schorge, 2010a). Hundreds of possible markers have been identified, yet no test currently available approaches sufficient levels of accuracy (American College of Obstetricians and Gynecologists, 2011).

### High-risk Women

For the most part, screening strategies are directed at *BRCA1* or *BRCA2* carriers, in addition to women with a strong family history of breast and ovarian cancer. Most commonly, cancer antigen 125 (CA125) level measurements and/or transvaginal sonography have been tested, albeit with marginal success. Thus, in *BRCA1* or *BRCA2* mutation carriers who do not wish to undergo prophylactic surgery, a screening strategy that combines thorough pelvic examination, transvaginal sonographic evaluation, and CA125 blood testing may be offered (American College of Obstetricians and Gynecologists, 2013).

CA125 is a glycoprotein that is not produced by normal ovarian epithelium but that may be produced by both benign and malignant ovarian tumors. CA125 is synthesized within affected ovarian epithelial cells and often secreted into cysts. In benign tumors, excess antigen is released into and may accumulate within cyst fluid. Hypothetically, abnormal tissue architecture associated with malignant tumors allows antigen release into the vascular circulation (Verheijen, 1999).

Alone, CA125 is not a useful marker for detecting ovarian cancer. However, a more sensitive Risk of Ovarian Cancer

Algorithm (ROCA) has been developed and is based on the slope of serial CA125 measurements drawn at regular intervals (Skates, 2003). If a ROCA score exceeds a 1-percent risk of having ovarian cancer, patients then undergo transvaginal sonography to determine whether additional intervention is warranted. This strategy is currently being studied in a prospective, international trial of 2605 high-risk women who initially chose to undergo either risk-reducing salpingo-oophorectomy or screening alone (Greene, 2008).

### General Population

Because no sufficiently accurate early detection tests are currently available, routine screening for women at average risk is not recommended (Moyer, 2012). For example, in the United States' prospective Prostate, Lung, Colorectal and Ovarian (PLCO) Trial of screening versus usual care, 34,261 women without prior oophorectomy were randomly assigned to annual CA125 level measurement and transvaginal sonographic examination. Of those with an abnormal screen, approximately 1 percent had invasive ovarian cancer, demonstrating a relatively low predictive value of both tests (Buys, 2005, 2011; Partridge, 2009).

To evaluate the efficacy, cost, morbidity, compliance, and acceptability of ROCA-based CA125 screening and study-directed sonography, a randomized trial of 202,638 patients was conducted. In The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), asymptomatic, average-risk postmenopausal women aged 50 to 74 years were randomly assigned to no treatment, to annual CA125 screening with transvaginal sonography as a second-line test if indicated by ROCA interpretation, or to annual screening with transvaginal sonography. The ROCA-directed approach demonstrated a 35-percent positive-predictive value, more than 10 times higher than annual sonography (3 percent). Although in this study ROCA-directed sonography was shown to be feasible, the results of ongoing screening to determine whether there is any meaningful effect on mortality rates will be available in 2015 (Menon, 2009, 2014). Despite most major professional and government groups recommending against it, approximately a third of U.S. physicians continue to order CA125 or sonography to screen for ovarian cancer (Baldwin, 2012).

### New Biomarkers and Proteomics

To identify a more accurate screening test for early ovarian cancer detection, various potential biomarkers have been described. Dozens have been evaluated alone and in combination with CA125 (Cramer, 2011; Yurkovetsky, 2010).

One example, based on a preliminary study published in 2002, suggested that proteomics may help detect early-stage ovarian cancer (Petricoin, 2002). By profiling the patterns of thousands of proteins with a high degree of sensitivity and specificity, it was hoped that an accurate test, such as OvaCheck, would reliably distinguish those with early ovarian cancer from unaffected women.

Another entry, the OvaSure blood test, has also generated enthusiasm. Based on the simultaneous evaluation of six analytes (leptin, osteopontin, insulin-like growth factor-II, macrophage inhibitory factor, and CA125), it was reported to yield high sensitivity and specificity for ovarian cancer (Mor, 2005; Visintin, 2008).

Importantly, prospective clinical trials must be designed and completed before any of these new diagnostic tests can be offered outside of a trial. Unfortunately, neither proteomics nor any other screening strategy is currently near implementation into routine clinical practice.

### Physical Examination

In general, pelvic examination only occasionally detects ovarian cancer, generally when the disease is already in advanced stages. In asymptomatic women, there is no evidence that it lowers mortality or morbidity rates as a screening test (Bloomfield, 2014). As a result, bimanual examination was not even included as a screening modality in either the PLCO or UKCTOCS trials.

### Chemoprevention

Oral contraceptive use is associated with a 50-percent decreased risk of developing ovarian cancer. However, there is a short-term increased risk of developing breast cancer and cervical cancer that should be considered when counseling patients (International Collaboration of Epidemiological Studies of Cervical Cancer, 2006, 2007; National Cancer Institute, 2014a).

### Prophylactic Surgery

The only proven way to directly prevent ovarian cancer is surgical removal. In *BRCA1* or *BRCA2* carriers, prophylactic bilateral salpingo-oophorectomy (BSO) may be performed either upon completion of childbearing or by age 40 years (American College of Obstetricians and Gynecologists, 2013, 2014). In these patients, the procedure is approximately 90-percent effective in preventing epithelial ovarian cancer (Kauff, 2002; Rebbeck, 2002). Prophylactic BSO reduces the risk of developing breast cancer by 50 percent (Rebbeck, 2002). Predictably, the protective effect is strongest among premenopausal women (Kramer, 2005). In women with HNPCC, the ovarian cancer risk reduction approaches 100 percent (Schmeler, 2006). Yet, significant adverse consequences accompany premature menopause. Moreover, recent studies suggest that a substantial proportion of "ovarian cancers" in high-risk women actually arise from precursor lesions located in the distal fallopian tube. Thus, prophylactic salpingectomy followed later by postmenopausal oophorectomy may be a safe alternative (Holman, 2014; Kwon, 2013; Perets, 2013). Surgical excision ideally removes the entire tube from fimbria to uterotubal junction, but the interstitial portion within the myometrium remains.

The term *prophylactic* implies that the tubes and ovaries are normal at the time of removal. However, approximately 4 to 5 percent of *BRCA* mutation carriers undergoing prophylactic BSO will have an otherwise undetected, often microscopic, cancer at the time of surgery (Sherman, 2014). In fact, the distal fallopian tube seems to be the dominant site of origin for occult malignancies detected during risk-reducing surgery (Callahan, 2007). To account for this possibility, cytologic washings, peritoneal biopsies, and an omental sample may be routinely collected during surgery. When submitting the final surgical specimen, the pathology requisition should clearly state that the BSO was performed for a prophylactic indication. In these cases, the ovaries and tubes, especially the fimbria, undergo more intensive scrutiny and are serially microsectioned to identify occult

disease. Using a rigorous operative and pathologic protocol such as this can significantly increase the detection rate of occult tubal or ovarian malignancy in *BRCA* mutation carriers (Powell, 2005). Typically, the excision, washings, and biopsies can all be completed by laparoscopic surgery.

Prophylactic BSO in young women will induce premature menopause and its associated effects of vasomotor and urogenital symptoms, decline in sexual interest, and osteoporosis (National Cancer Institute, 2014a). Estrogen replacement therapy is commonly used to alleviate these symptoms but may be less effective than is often assumed (Madalinska, 2006). Overall, mainly due to the favorable impact in reducing cancer worries, prophylactic BSO does not adversely affect quality of life (Madalinska, 2005).

In women with the HNPCC syndrome, hysterectomy is mandatory when performing prophylactic BSO because of coexisting endometrial cancer risks. In *BRCA* mutation carriers, it should not be recommended routinely (Vyarvelska, 2014). Few reports have suggested a meaningful association between *BRCA* mutations and an increased risk of endometrial cancer. Mainly, these develop in patients taking tamoxifen for breast cancer treatment or breast cancer chemoprevention (Beiner, 2007).

In low-risk patients who are not *BRCA* carriers, risk-reducing salpingectomy is now also considered in those undergoing hysterectomy or permanent sterilization, in hopes of preventing pelvic serous cancers (Creinin, 2014; Lessard-Anderson, 2014; McAlpine, 2014; Morelli, 2013). This consideration has been endorsed by both the Society of Gynecologic Oncology (2013) and the American College of Obstetricians and Gynecologists (2015). Pathologic specimen processing in low-risk women includes representative sections of the tube, any suspicious lesions, and entire sectioning of the fimbriae. Neither organization specifies pelvic washing collection in this low-risk population.

## LOW-MALIGNANT-POTENTIAL TUMORS

### ■ Pathology

Ten to 15 percent of epithelial ovarian cancers have histologic and biologic features that are intermediate between clearly benign cysts and frankly invasive carcinomas. In general, these low-malignant-potential (LMP) tumors, also termed *borderline tumors*, are associated with risk factors that are similar to those for epithelial ovarian cancer (Huusom, 2006). Typically, they are not considered part of any of the hereditary breast-ovarian cancer syndromes. Although LMP tumors may develop at any age, on average, patients are in their mid-40s, which is 15 years younger than women with invasive ovarian carcinoma. For various reasons, their diagnosis and optimal management are frequently problematic.

Histologically, LMP tumors are distinguished from benign cysts by having at least two of the following features: nuclear atypia, epithelial stratification, microscopic papillary projections, cellular pleomorphism, or mitotic activity (Fig. 35-2). Unlike invasive carcinomas, LMP tumors lack stromal invasion. However, up to 10 percent of LMP tumors will exhibit areas of *microinvasion*, defined as foci measuring < 3 mm in diameter and forming < 5 percent of the tumor (Buttin, 2002). Due to

**FIGURE 35-2** Mucinous borderline tumor. These tumors are distinguished from benign mucinous cystadenomas by the presence of epithelial proliferation and nuclear atypia. This example of a mucinous borderline tumor has mild to moderate nuclear atypia as evidenced by limited nuclear pleomorphism and visible nucleoli. A mitotic figure is also seen (arrow). Epithelial proliferation is indicated by epithelial tufts (asterisks), which are unsupported by fibrovascular cores. (Used with permission from Dr. Kelley Carrick.)

the subtle nature of many of these findings, it is challenging to diagnose an LMP tumor with certainty based on frozen section specimen analysis.

### ■ Clinical Features

Ovarian LMP tumors present similar to other adnexal masses. Patients may have pelvic pain, distention, or increasing abdominal girth. Alternatively, an asymptomatic mass may be palpated during routine pelvic examination. These tumors are occasionally detected as an incidental finding during routine obstetric sonographic examination or at the time of cesarean delivery.

As with other ovarian tumors, size varies widely. Preoperatively, there is no pathognomonic sonographic appearance, and serum CA125 levels are nonspecific. Depending on the clinical setting, computed tomography (CT) scanning may be indicated to exclude ascites or omental caking, which would suggest a more typical ovarian cancer. Regardless, any woman with a suspicious adnexal mass should have it removed.

### ■ Treatment

Surgery is the cornerstone management for LMP tumors. The operative plan will vary, depending on circumstances, and patients are carefully counseled beforehand. All women should be prepared for complete ovarian cancer surgical staging or debulking, if necessary. In many cases, a laparoscopic approach is appropriate. If laparotomy is planned, then a vertical incision is selected to allow access to the upper abdomen and paraaortic nodes, if needed, for cancer staging.

During surgery, peritoneal washings are immediately collected upon entrance into the abdomen, followed by exploration. The ovarian mass is removed intact and submitted for pathologic consultation and frozen section evaluation. However, it is almost impossible to know with certainty whether a patient

**FIGURE 35-3** Noninvasive implant from patient with ovarian serous borderline tumor. A noninvasive implant does not have destructive invasion of the underlying tissue. In this noninvasive implant, proliferative serous-type epithelium (black arrows) and psammoma bodies (blue arrow) typical of serous proliferations appear to adhere to the peritoneal tissue, but do not invade it. Psammoma bodies are fragmented in this tissue, as calcified material often shatters when sectioned if not decalcified prior to sectioning. (Used with permission from Dr. Raheela Ashfaq.)

has a benign adnexal mass, LMP tumor, or invasive ovarian cancer until final histologic slides have been reviewed (Houck, 2000; Tempfer, 2007). Accordingly, in those with LMP diagnosed intraoperatively, premenopausal women who have not completed childbearing may undergo fertility-sparing surgery with preservation of the uterus and contralateral ovary (Park, 2009; Zanetta, 2001). This is a reasonable approach even if the final diagnosis shows invasive stage I cancer (Schilder, 2002). Alternatively, postmenopausal women should undergo hysterectomy with BSO.

Limited staging biopsies of the peritoneum and omentum are considered, although they rarely contain microscopic foci of metastatic LMP unless the tissues appear abnormal (Kristensen, 2014). Additionally, the appendix is also examined and potentially removed, especially if the tumor has mucinous histology (Timofeev, 2010). In the absence of enlarged nodes or a frozen section suggestive of frankly invasive disease, routine pelvic and paraaortic lymph node dissection may not be necessary (Rao, 2004).

LMP tumors are staged with the same FIGO criteria used for invasive ovarian cancer (p. 748). For the most part, surgical staging has limited value in altering the prognosis of those with LMP tumors unless invasive cancer is ultimately diagnosed (Wingo, 2006). Although 97 percent of gynecologic oncologists advocate comprehensive surgical staging of LMP tumors, in current practice it is performed in only 12 percent of patients (Lin, 1999; Menzin, 2000). This disparity stems from the fact that often the diagnosis is not suspected intraoperatively, no frozen section is requested or it is inaccurate, and a clinician is alerted only when the final pathology report has been completed. In this circumstance, consultation with a gynecologic oncologist is recommended, but comprehensive surgical restaging is not necessarily required if the tumor appears confined to a single ovary (Zapardiel, 2010). However, if a cystectomy has

been performed, the risk of residual disease should prompt a discussion regarding removal of the entire adnexa with washings and limited staging (Poncelet, 2006).

For patients with stage II-IV disease, usually demonstrated by noninvasive implants (Fig. 35-3) or nodal metastases, the utility of adjuvant chemotherapy is speculative (Shih, 2010; Sutton, 1991). The most worrisome finding is invasive peritoneal implants. In general, these patients are treated like those with typical epithelial ovarian carcinoma, including debulking and postoperative chemotherapy (Leary, 2014).

## ■ Prognosis

The prognosis is excellent for patients with ovarian LMP tumors. Five-year survival rates range from 96 to 99 percent for stages I-III, whereas it reaches 77 percent for stage IV disease (Trimble, 2002). Overall, more than 80 percent have stage I disease,

and if treated by hysterectomy and BSO, stage I tumors rarely, if ever, recur (du Bois, 2013). In fact, such women have an overall survival similar to the general population (Hannibal, 2014). Fertility-sparing surgery is associated with up to a 15-percent risk of relapse, usually in the contralateral ovary, but remains highly curable by reoperation and resection (Park, 2009; Rao, 2005).

Approximately 15 percent of LMP tumors have stage II and III disease, almost invariably of serous histology. Stage IV ovarian LMP tumors account for fewer than 5 percent of diagnoses and have the worst prognosis (Trimble, 2002). For these advanced-stage tumors, the most reliable prognostic indicators are the presence of invasive peritoneal implants or residual disease after surgery (Morice, 2014; Seidman, 2000).

Due to the indolent nature of these tumors, symptomatic recurrence often takes place years or even decades after diagnosis (Silva, 2006). Approximately 70 percent of relapses have only LMP histology. Malignant transformation into an invasive ovarian cancer develops in the other 30 percent. Most of these are low-grade carcinomas, but approximately one third will have high-grade features, which adversely affects prognosis (du Bois, 2013; Harter, 2014). As in primary ovarian LMP tumors, complete surgical excision is the most effective therapy for recurrent disease (Crane, 2015). Chemotherapy is reserved for patients with invasive features, but low-grade tumors tend to be particularly resistant to standard agents, such as carboplatin and paclitaxel. Typically, multiple different regimens are used, including hormonal therapy (Gourley, 2014).

## EPITHELIAL OVARIAN CANCER

### ■ Pathogenesis

There are at least three distinct tumorigenic pathways to account for the heterogeneity of epithelial ovarian cancer. First, relatively few cases seem to arise from an accumulation

**FIGURE 35-4** **A.** Normal fallopian tube epithelium is composed of three cell types—ciliated cells, secretory cells, and intercalary cells. **B.** Serous carcinoma in situ of the fallopian tube. The cells of serous carcinoma lining this tube are markedly atypical, with nuclear pleomorphism, chromatin coarseness, loss of nuclear polarity, mitotic activity (arrow), and epithelial proliferation/tufting. (Used with permission from Dr. Kelley Carrick.)

of genetic alterations that leads to malignant transformation of benign cysts to LMP tumors and ultimate progression to invasive ovarian carcinoma (Makarla, 2005). Typically, these invasive tumors are low-grade and clinically indolent, and *K-ras* oncogenic mutations occur early. The *ras* family of oncogenes includes *K-ras*, *H-ras*, and *N-ras*. Their protein products participate in cell cycle regulation and cell proliferation control. As such, *ras* mutations are implicated in carcinogenesis by their inhibition of cellular apoptosis and promotion of cellular proliferation (Mammas, 2005).

Second, at least 10 percent of epithelial ovarian carcinomas, invariably high-grade serous tumors, result from an inherited predisposition. Women born with a *BRCA* gene mutation require only one “hit” to the other normal copy (allele) to “knock out” the *BRCA* tumor-suppressor gene product. As a result, *BRCA*-related cancers develop approximately 15 years before sporadic cases. Current data suggests that serous tubal intraepithelial carcinoma (STIC) is a precursor condition for a significant percentage of serous carcinomas, which were formerly thought to arise spontaneously on the ovarian or peritoneal surface (Fig. 35-4) (Levanon, 2008; Medeiros, 2006; Perets, 2013). Thereafter, *BRCA*-related serous cancers appear to have a unique molecular pathogenesis, requiring *p53* inactivation to progress (Buller, 2001; Landen, 2008; Schorge, 2000). *p53* is a tumor suppressor gene. Its protein product prohibits cells from entering subsequent stages of cell division and thereby halts uncontrolled tumor cell replication. Mutations in *p53* are linked with various cancers. In fact, loss of *BRCA* and *p53* protein function has been detected prior to invasion, further supporting its importance as an early triggering event (Werness, 2000).

Third, most carcinomas appear to originate *de novo* from ovarian surface epithelial cells that are sequestered in cortical inclusion cysts (CICs) within the ovarian stroma. Numerous inciting events and subsequent pathways have been proposed. For example, cyclic repair of the ovarian surface during long periods of repetitive ovulation requires abundant cellular proliferation. In these women, spontaneous *p53* mutations arising

during the DNA synthesis that accompanies this proliferation appear to play a primary carcinogenic role (Schildkraut, 1997). Ultimately, the replicative stress and DNA damage transforms the entrapped surface epithelial cells within CICs into any of the histologic ovarian cancer variants (Levanon, 2008).

## ■ Diagnosis

### Symptoms and Physical Findings

Ovarian cancer is typically portrayed as a “silent” killer that lacks appreciable early signs or symptoms. This is a misconception. Actually, patients are often symptomatic for several months before the diagnosis, even with early-stage disease (Goff, 2000). The difficulty is distinguishing these symptoms from those that normally occur in women.

In general, persistent symptoms that are more severe or frequent than expected and have a recent onset warrant further diagnostic investigation. Commonly, increased abdominal size, bloating, urinary urgency, and pelvic pain are reported. Additionally, fatigue, indigestion, inability to eat normally, constipation, and back pain may be noted (Goff, 2004). Abnormal vaginal bleeding occurs rarely. Occasionally, patients may present with nausea, vomiting, and a partial bowel obstruction if carcinomatosis is particularly widespread. Unfortunately, many women and clinicians are quick to attribute most symptoms to menopause, aging, dietary changes, stress, depression, or functional bowel problems, and diagnosis is often delayed.

A pelvic or pelvic-abdominal mass is palpable in most patients with ovarian cancer during bimanual evaluation. Malignant tumors tend to be solid, nodular, and fixed, but there are no classic findings that distinguish these growths from benign tumors. Paradoxically, a huge mass filling the pelvis and abdomen more often represents a benign or borderline tumor. To aid surgical planning, a rectovaginal examination is also performed. For example, a woman with cancer involving the rectovaginal septum may need to be positioned in dorsal lithotomy to perform a low anterior colon resection as a part of tumor excision.

The presence of a fluid wave, or less commonly, flank bulging, suggests the presence of significant ascites. In a woman with a pelvic mass and ascites, the diagnosis is ovarian cancer until proven otherwise. However, ascites without an identifiable pelvic mass suggests the possibility of cirrhosis or other primary malignancies such as gastric or pancreatic cancers. In advanced disease, examination of the upper abdomen usually reveals a central mass signifying omental caking.

Auscultation of the chest is also important, since patients with malignant pleural effusions may not be overtly symptomatic. The remainder of the examination includes palpation of the peripheral nodes in addition to a general physical assessment.

### Laboratory Testing

A routine complete blood count and metabolic panel often demonstrates a few characteristic features. Of affected women, 20 to 25 percent will present with thrombocytosis (platelet count  $> 400 \times 10^9/L$ ) (Li, 2004). Malignant ovarian cells releasing cytokines are believed to increase platelet production rates. Hyponatremia, typically ranging between 125 and 130 mEq/L, is another common finding. In these patients, tumor secretion of a vasopressin-like substance can cause a clinical picture suggesting a syndrome of inappropriate antidiuretic hormone (SIADH).

The serum CA125 level is integral to epithelial ovarian cancer management. In 90 percent of women presenting with malignant nonmucinous tumors, CA125 levels are elevated. However, there are caveats during adnexal mass evaluation. Half of stage I ovarian cancers will have a normal CA125 measurement (false-negative). Also, an elevated value (false-positive) may be associated with various common benign indications such as pelvic inflammatory disease, endometriosis, leiomyomas, pregnancy, and even menstruation. Thus, in postmenopausal women with a pelvic mass, a CA125 measurement may better predict a higher likelihood of malignancy (Im, 2005).

Another marker, the human epididymal protein 4 (HE4) tumor marker, is approved by the U.S. Food and Drug Administration (FDA), along with CA125, when used in the Risk of Ovarian Malignancy Algorithm (ROMA) to determine the likelihood of finding malignancy at surgery in women with an adnexal mass. The ROMA score is derived from the results of both blood tests, plus menopausal status (Moore, 2009, 2010).

OVA1 is another biomarker blood test panel that may be used for the preoperative triage of women with an identified ovarian mass when surgery is planned (Ueland, 2011; Ware Miller, 2011). Scores  $\geq 5.0$  in premenopausal and scores  $\geq 4.4$  in postmenopausal women suggest a need for gynecologic oncologist consultation. Importantly, this test is not a screening tool and is reserved for those with a known surgical mass to aid preoperative triage (Vermillion Inc, 2012; Zhang, 2010). Validation studies evaluating ROMA and OVA1 are limited, and their role in preoperative triage is yet to be clearly defined. As a result, they are not necessarily recommended for determining the status of an undiagnosed pelvic mass (Morgan, 2014). Last, when a mucinous ovarian tumor is identified, serum tumor markers that may be better indicators of disease are cancer antigen 19-9 (CA19-9) and carcinoembryonic antigen (CEA).

### Imaging

*Transvaginal sonography* is typically the most useful imaging test to differentiate benign tumors and early-stage ovarian cancers (Chap. 2, p. 33). In general, malignant tumors are multiloculated, solid or echogenic, and large ( $> 5$  cm), and they have thick septa with areas of nodularity (Fig. 35-5A). Other features may include papillary projections or neovascularization—demonstrated by adding color Doppler (Figs. 35-5B and 35-5C). Although several presumptive models have been described in an attempt to distinguish benign masses from ovarian cancers preoperatively, none have been universally implemented (Timmerman, 2005; Twickler, 1999).

In patients with advanced disease, sonography is less helpful. The pelvic sonogram may be particularly difficult to interpret if a large mass encompasses the uterus, adnexa, and surrounding structures. Ascites, if present, is easily detected, but in general, abdominal sonography has limited use.

Of *radiographic tests*, patients with suspected ovarian cancer should have a chest radiograph to detect pulmonary effusions or infrequently, pulmonary metastases. Rarely, a barium enema is clinically helpful in excluding diverticular disease or colon cancer or in identifying ovarian cancer involvement of the rectosigmoid.

*Computed tomography* (CT) scanning has a primary role in treatment planning for women with advanced ovarian cancer. Preoperatively, implants in the liver, retroperitoneum, omentum, or other intraabdominal site are detected to thereby guide surgical cytoreduction or demonstrate obviously unresectable disease (Fig. 35-6) (Suidan, 2014). However, CT is not particularly reliable in detecting intraperitoneal disease smaller than 1 to 2 cm in diameter. Moreover, CT scanning accuracy is poor for differentiating a benign ovarian mass from a malignant tumor when disease is limited to the pelvis. In these cases, transvaginal sonography is superior. Other radiologic studies such as magnetic resonance (MR) imaging, bone scans, and positron emission tomography (PET) in general provide limited additional information preoperatively.

### Paracentesis

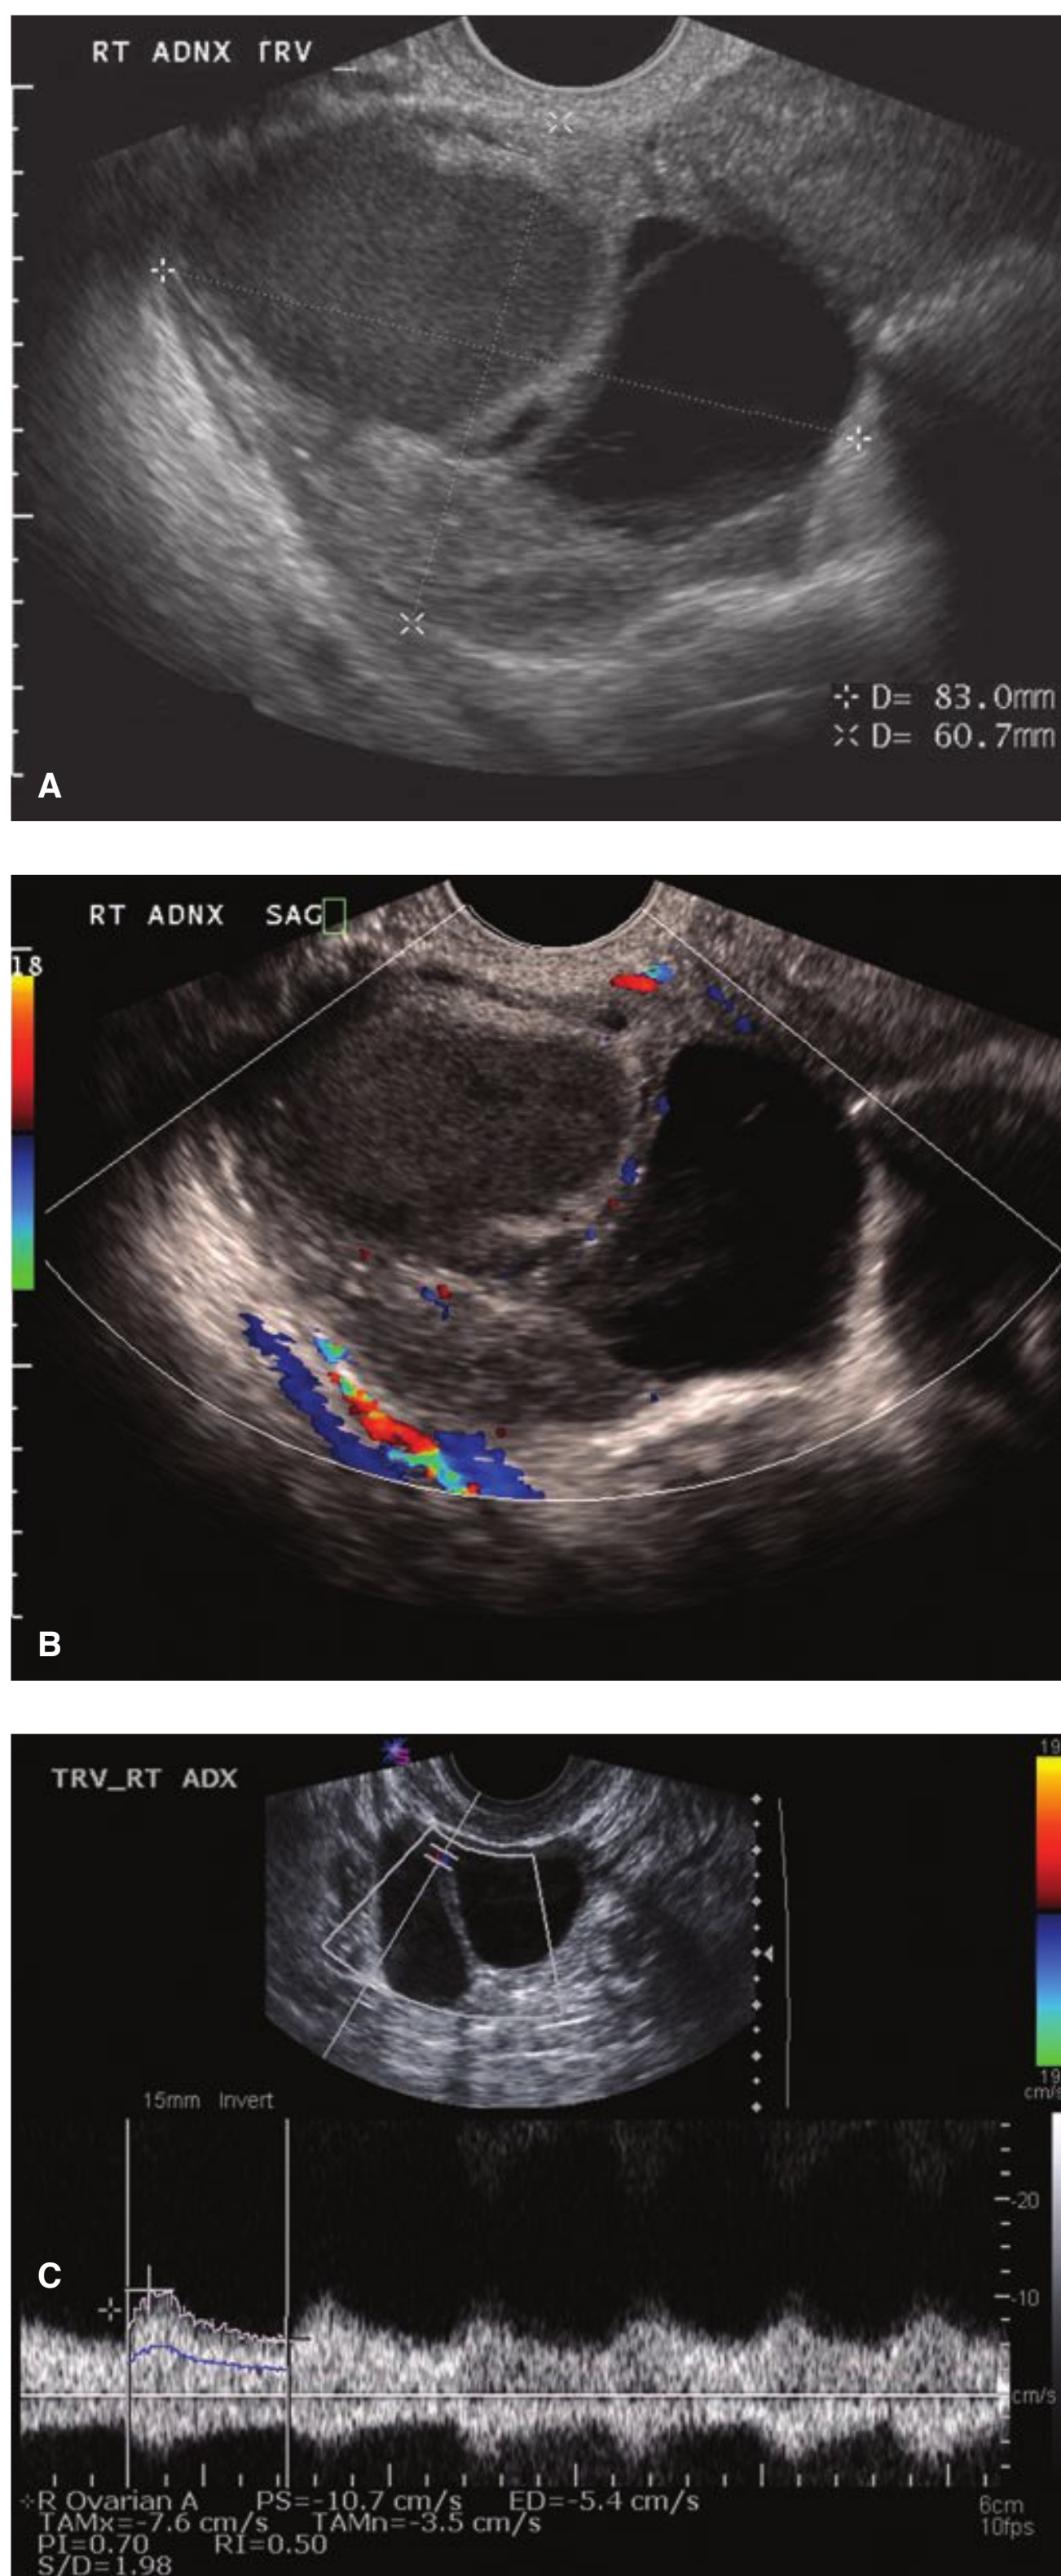

A woman with a pelvic mass and ascites can usually be assumed to have ovarian cancer until surgically proven otherwise. Thus, few patients require diagnostic paracentesis. Moreover, this procedure is typically avoided diagnostically as cytologic results are usually nonspecific and abdominal wall metastases may form at the needle entry site (Kruitwagen, 1996). However, paracentesis may be indicated for those with ascites in the *absence* of a pelvic mass.

Aside from diagnosis, paracentesis may also relieve volume-related symptoms in those with large accumulations. This may be done at the bedside, using connector tubing and vacuum bottles, or completed by an interventional radiologist. Relative dehydration is common afterward and manifest by thirst, oliguria, and short-term creatinine level rise, which all correct with normal oral intake.

### ■ Role of the Generalist

Using the currently available diagnostic modalities, clinicians often face tremendous difficulty in distinguishing benign from

**FIGURE 35-5** Sonograms of an ovarian cyst. **A.** Transvaginal sonogram depicts a complex ovarian mass (calipers). Cystic and solid components and a thick intracystic septum are seen. These findings increase clinical concern for malignancy. **B.** Color Doppler transvaginal sonogram shows neovascularization within this ovarian tumor. **C.** Transvaginal Doppler study of ovarian mass vessels reveals decreased impedance. (Used with permission from Dr. Diane Twickler.)

malignant. However, ascites or evidence of metastases should prompt consultation with an oncologist (American College of Obstetricians and Gynecologists, 2011). Additionally, premenopausal women with elevated CA125 levels (i.e.,  $> 200$  U/mL) or an OVA1 score  $\geq 5.0$  and postmenopausal women with any CA125 level elevation or an OVA1 score  $\geq 4.4$  are at higher risk.

Ideally, for patients with suspicious adnexal masses, surgery is performed in a hospital with a pathologist able to reliably interpret an intraoperative frozen section. At minimum, samples for peritoneal cytology are obtained when the abdomen is entered. The mass is then removed intact through an incision that permits thorough staging and resection of possible metastatic sites (American College of Obstetricians and Gynecologists, 2011).

If malignancy is diagnosed, then surgical staging is completed. However, in a study of more than 10,000 women with ovarian cancer, almost half of those with early-stage disease did not undergo the recommended surgical procedures (Goff, 2006). Surgeons should be prepared to appropriately stage and potentially debulk ovarian cancer or have a gynecologic oncologist immediately available. This type of careful planning has been shown to achieve the best possible surgical result and improve survival rates (Earle, 2006; Engelen, 2006; Mercado, 2010). Moreover, since broader resources are usually available, patients cared for at high-volume hospitals also tend to have better outcomes (Bristow, 2010).

For women with malignancy identified only postoperatively or intraoperatively and without adequate staging, management will vary. Women with suspected early-stage disease may be restaged laparoscopically. Those with advanced disease may undergo a second laparotomy to obtain optimal tumor debulking (Grabowski, 2012). However, if extensive disease is found at the initial surgery, then chemotherapy may be selected first and followed later by laparotomy to obtain optimal interval cytoreduction.

At some point during postoperative surveillance, many women with early-stage disease, depending on the diagnosis, will return to their referring physician. Monitoring for relapse is often coordinated between the gynecologic oncologist and generalist in obstetrics and gynecology, especially if no chemotherapy is required following surgery.

## ■ Pathology

Although epithelial ovarian cancer is often considered a single entity, the different histologic types vary in their behavior (Table 35-3). Sometimes, two or more cell types are mixed. Within each histologic type, tumors are further categorized as benign, borderline (low malignant potential), or malignant.

Mainly in early-stage disease, grade is an important prognostic factor that affects treatment planning (Morgan, 2014). Unfortunately, no grading system for epithelial ovarian carcinoma is universally accepted. Instead, numerous different schemata, most based on architecture and/or nuclear pleomorphism, are currently used. In general, tumors are classified as grade 1 (well-differentiated), grade 2 (moderately differentiated), and grade 3 (poorly differentiated) lesions (Pecorelli, 1999).

**FIGURE 35-6** Computed tomographic scans in a woman with ovarian cancer. **A.** Axial CT scan at the level of the liver and spleen reveals metastatic lesions in the spleen and liver (curved arrows) and a bulky lesion at the splenorenal ligament (arrow). **B.** More caudal axial CT reveals ascites (curved arrows) and marked omental caking (arrows). (Used with permission from Dr. Diane Twickler.)

Grossly, there are no distinguishing features among the types of epithelial ovarian cancer. In general, each has solid and cystic areas of varying sizes (Fig. 35-7).

Serous Tumors

More than 50 percent of all epithelial ovarian cancers have serous histology. Microscopically, in well-differentiated tumors, cells may resemble fallopian tube epithelium, whereas in poorly differentiated tumors, anaplastic cells with severe nuclear atypia predominate (Fig. 35-8). During frozen section analysis, psammoma bodies are essentially pathognomonic of an ovarian-type serous carcinoma. Often, these tumors contain various other cell types as a minor component (< 10 percent) that may cause diagnostic problems but do not influence outcome (Lee, 2003).

**FIGURE 35-7** **A.** Excised cystic ovarian mass. Note the fallopian tube stretched over the top of the ovarian capsule. **B.** Opened tumor reveals the inner cyst wall and scattered papillary tumor growth (arrow). (Photographs contributed by Dr. David Miller.)

**FIGURE 35-8** Serous carcinomas vary in regard to their degree of differentiation, as manifested by their architecture, degree of cytologic atypia and pleomorphism, and mitotic rate. **A.** In this relatively well-differentiated example of serous carcinoma, serous-type cells with moderate nuclear atypia form papillae and project into a cystic space. Numerous psammoma bodies, which are extracellular round laminar eosinophilic collections of calcium, are seen here. **B.** In this less well-differentiated example of serous carcinoma, moderately to markedly atypical cells form sheets, as opposed to the glands and papillae formed by better-differentiated tumors. (Used with permission from Dr. Kelley Carrick.)

### Endometrioid Tumors

*Endometrioid adenocarcinomas* compose 15 to 20 percent of epithelial ovarian cancers and are the second most common histologic type (Fig. 35-9). The lower frequency results largely because poorly differentiated endometrioid and serous tumors cannot be easily distinguished and such cases are usually classified as serous. As a result, well-differentiated endometrioid tumors are proportionally more common, which may also explain their overall relatively good prognosis.

In 15 to 20 percent of cases, uterine endometrial adenocarcinoma coexists. This is usually regarded as a synchronous

tumor, but metastasis from one site to the other is difficult to exclude (Soliman, 2004). A müllerian “field effect” is theorized to account for these independently developing, histologically similar tumors. In addition, many such patients are noted to have pelvic endometriosis.

*Malignant mixed müllerian tumor*, now preferably termed *carcinosarcoma*, by definition contains malignant epithelial and mesenchymal elements. It represents < 1 percent of ovarian cancers, carries a poor prognosis, and is histologically similar to uterine primary tumors (Rauh-Hain, 2011).

### Mucinous Tumors

Mucinous adenocarcinomas compose 5 to 10 percent of true epithelial ovarian cancers. The frequency is usually overestimated because many are undetected primary intestinal cancers from the appendix or colon. Well-differentiated ovarian mucinous tumors closely resemble mucin-secreting adenocarcinomas of intestinal or endocervical origin (Fig. 35-10). Histologically, the distinction may be impossible without clinical correlation (Lee, 2003). Advanced-stage mucinous ovarian carcinomas are rare, tend to be resistant to platinum chemotherapy, and have a prognosis significantly worse than that for serous tumors (Zaino, 2011).

**Pseudomyxoma Peritonei.** This clinical term describes the rare finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity, surrounded by thin fibrous capsules. An ovarian mucinous carcinoma with ascites rarely results in this condition, and evidence suggests that ovarian mucinous tumors associated with pseudomyxoma peritonei are almost all metastatic rather than primary. As a result, appendiceal or other intestinal sites of origin should be excluded (Ronnett, 1997). The primary appendiceal tumor may be small relative to the ovarian tumor(s) and may not be appreciated macroscopically. Thus, removal and thorough histologic examination of the appendix is indicated in all cases of pseudomyxoma peritonei.

**FIGURE 35-9** Ovarian endometrioid adenocarcinomas are morphologically similar to their more common counterparts arising in the endometrium. Better-differentiated tumors like this one have glands resembling proliferative endometrial glands, which grow in a confluent pattern. More poorly differentiated tumors have a variable percentage of solid growth and/or increased nuclear atypia. Like their endometrial counterparts, these tumors may show squamous differentiation. (Used with permission from Dr. Raheela Ashfaq.)

If the peritoneal epithelial cells are benign or borderline-appearing, the condition is referred to as *disseminated peritoneal adenomucinosis*. Affected patients have a benign or protracted, indolent clinical course (Ronnett, 2001). If the peritoneal epithelial cells appear malignant, the clinical course is invariably fatal.

### Clear Cell Adenocarcinoma

Comprising 5 to 10 percent of epithelial ovarian cancers, clear cell adenocarcinomas are most frequently associated with pelvic endometriosis. These tumors appear similar to clear cell carcinomas that develop sporadically in the uterus, vagina, and cervix. Typically, tumors are confined to the ovary and generally are cured by surgery alone. However, the 20 percent presenting with advanced disease tend to be platinum resistant and carry a worse prognosis than serous carcinoma (Al-Barrak, 2011).

Microscopically, both clear and “hobnail” cells are characteristic (Fig. 35-11). In clear cells, the visibly clear cytoplasm results from the dissolution of glycogen as the tissue specimen is histologically prepared. Hobnail cells have bulbous nuclei that protrude far into the cystic lumen beyond the apparent cytoplasmic limits of the cell (Lee, 2003).

### Transitional Cell Tumors

Of these, the rare *malignant Brenner tumor* characteristically has poorly differentiated transitional cell carcinoma coupled with foci of benign or borderline Brenner tumor. Microscopically, the transitional cell component resembles carcinomas arising from the urinary tract, often with squamous differentiation. Brenner tumors classically have a dense, abundant fibrous stroma with embedded nests of transitional epithelium.

*Transitional cell carcinoma* accounts for fewer than 5 percent of ovarian cancers. These tumors lack a demonstrable Brenner component. Patients with transitional cell carcinoma have a

**FIGURE 35-10** This mucinous carcinoma arose within a 15-cm mucinous cystadenoma. Benign mucinous-type epithelium lining cystic spaces of the background cystadenoma is seen (arrows). A carcinomatous component (arrowhead) invades the stroma in a haphazard fashion at the center of the photomicrograph. The malignant cells are arranged in clusters and poorly formed glands, which have intracytoplasmic and intraluminal mucin (asterisks). (Used with permission from Dr. Kelley Carrick.)

**FIGURE 35-11** Clear cell adenocarcinoma is typically composed of cells with clear to eosinophilic cytoplasm that are arranged in cysts, tubules, papillae, and/or sheets. In the ovary, it looks similar to its counterparts in the endometrium and cervix/vagina. In this example, hobnail cells are marked by the arrows. (Used with permission from Dr. Kelley Carrick.)

worse prognosis than those with malignant Brenner tumors, but a better prognosis than those with other histologic types of epithelial ovarian cancer (Guseh, 2014). Microscopically, transitional cell carcinoma resembles a primary bladder carcinoma but has an immunoreactive pattern consistent with ovarian origin (Lee, 2003). Thus, transitional cell carcinoma is now considered a high-grade form of serous carcinoma.

### Other Histologic Types

Of these, primary squamous cell carcinoma of the ovary is rare. This is the newest category to be recognized and typically carries a poor prognosis for most with advanced disease (Park, 2010). More commonly, squamous cell carcinomas arise from mature cystic teratomas (dermoid cysts) and are classified as malignant ovarian germ cell tumors (Pins, 1996). In other cases, ovarian endometrioid variants may have extensive squamous differentiation, or alternatively, metastases from a cervical primary are present.

*Mixed carcinoma* describes an ovarian cancer that contains more than 10 percent of a second cell type. Common combinations include mixed clear cell/endometrioid or serous/endometrioid adenocarcinomas.

*Undifferentiated carcinomas* are rare epithelial ovarian tumors that are too poorly differentiated to be classified into any of the müllerian types previously described. Microscopically, the cells are arranged in solid groups or sheets with numerous mitotic figures and marked cytologic atypia. Typically, foci of müllerian carcinoma, usually serous, are found within the tumor. Overall, undifferentiated carcinomas of the ovary have a poor prognosis compared with the other histologic types (Silva, 1991).

*Small cell carcinomas* are rare, extremely malignant, and consist of two subgroups. Most patients have a *hypercalcemic type*, which typically develops in young women. Nearly all tumors are unilateral, and two thirds are associated with elevated serum calcium levels that resolve postoperatively (Young, 1994). Recent

**TABLE 35-4.** Criteria for Diagnosing Primary Peritoneal Carcinoma When Ovaries Are Present

Both ovaries must be normal in size or enlarged by a benign process
The involvement in the extraovarian sites must be greater than the involvement on the surface of either ovary
The ovarian tumor involvement must be either nonexistent, confined to the ovarian surface epithelium without stromal invasion, or involving the cortical stroma with tumor size less than $5 \times 5$ mm

data suggest these highly lethal tumors arise via a specific mutation in the *SMARCA4* gene (Jelinic, 2014). The *pulmonary type* resembles oat-cell carcinoma of the lung and develops in older women. Half of these women have bilateral ovarian disease (Eichhorn, 1992). In general, patients with small cell carcinoma die within 2 years from rapid disease progression.

### ■ Primary Peritoneal Carcinoma

Up to 15 percent of “typical” epithelial ovarian cancers are actually primary peritoneal carcinomas that develop *de novo* from the lining of the pelvis and abdomen. In some cases, especially among *BRCA1* mutation carriers, independent malignant transformation occurs at multiple peritoneal sites simultaneously (Schorge, 1998). However, more recent data suggest that nearly half of presumed cases actually arise in the tubal fimbria (Carlson, 2008).

Clinically and histologically, these tumors are virtually indistinguishable from epithelial ovarian cancer. However, primary peritoneal carcinoma may develop in a woman years after undergoing BSO. If ovaries are still present, several criteria are required to make the diagnosis (Table 35-4). By far the most common variant is papillary serous, but any of the other histologic types are possible. In general, the staging, treatment, and prognosis of primary peritoneal carcinoma are the same as for epithelial ovarian cancer (Mok, 2003). The differential diagnosis mainly includes malignant mesothelioma.

### ■ Fallopian Tube Carcinoma

Historically, this carcinoma was assumed to be rarer than epithelial ovarian cancer. However, the fallopian tube fimbria have recently been identified as an origin for many high-grade pelvic serous carcinomas that were previously assumed to arise from the ovary or peritoneum (Fig. 35-12) (Levanon, 2008).

Clinically, this fallopian tube carcinoma is similar to epithelial ovarian cancer. For the most part, risk factors, histologic types, surgical staging, pattern of spread, treatment, and prognosis are comparable. To be considered a primary fallopian tube carcinoma, the tumor must be located macroscopically within the tube or its fimbriated end. Additionally, the uterus and ovary must not contain carcinoma, or if they do, it must be clearly different from the fallopian tube lesion (Alvarado-Cabrero, 2003).

### ■ Secondary Tumors

Malignant tumors that metastasize to the ovary are almost invariably bilateral. The term *Krukenberg tumor* refers to a metastatic mucinous/signet ring cell adenocarcinoma of the ovaries that typically originates from primary tumors of the intestinal tract, characteristically the stomach (Fig. 35-13). Ovarian metastases

often represent a late disseminated stage of the disease in which other hematogenous metastases are also found (Prat, 2003).

### ■ Patterns of Spread

In general, epithelial ovarian cancers predominantly metastasize by *exfoliation*. Malignant cells are first released into the peritoneal

**FIGURE 35-12** A. Epithelial cells from the fimbria are released and implant on the denuded surface of the ovary at the site of ovulation. B & C. Subsequently, an inclusion cyst is formed.

**FIGURE 35-13** Krukenberg tumor. This metastatic, poorly differentiated adenocarcinoma is characterized by singly disposed cells with an intracytoplasmic mucin globule that displaces the nucleus to the cell periphery, producing a signet-ring-like cytomorphology. (Used with permission from Dr. Raheela Ashfaq.)

cavity when the tumor penetrates through the ovarian capsule surface. By following the normal circulation of peritoneal fluid, cells may then develop into implants anywhere in the abdomen. A unique characteristic of ovarian cancer is that metastatic tumors do not usually infiltrate visceral organs, but exist as surface implants. As a result, aggressive debulking is possible with reasonable morbidity.

Due to its marked vascularity, the omentum is the most frequent location to support metastatic disease and is often extensively involved with tumor (**Fig. 35-14**). Nodules are also commonly present on the undersurface of the right hemidiaphragm and small bowel serosa, but all intraperitoneal surfaces are at risk.

*Lymphatic dissemination* is the other primary mode of spread. Malignant cells move through channels that follow the ovarian blood supply along the infundibulopelvic ligament

**FIGURE 35-14** Photograph showing omental caking caused by tumor invasion.

and that terminate in paraaortic lymph nodes up to or above the level of the renal vessels. Other lymphatics pass laterally through the broad ligament and parametrium to the external iliac, obturator, and internal iliac nodal chains. Infrequently, metastases can also follow the round ligament to the inguinal nodes (Lee, 2003).

*Direct extension* of a progressively enlarging ovarian cancer may create confluent tumor involvement of the pelvic peritoneum and adjacent structures, including the uterus, rectosigmoid colon, and fallopian tubes. Usually, this is associated with significant induration of the surrounding tissues.

In advanced disease, several liters of ascites may collect. Either increased production of carcinomatous fluid or decreased clearance by obstructed lymphatic channels are purported causes. Similarly, by traversing the diaphragm, a malignant pleural effusion may develop, almost invariably on the right.

*Hematogenous spread* is atypical. In most cases, metastases to the liver or lung parenchyma, brain, or kidneys are observed in patients with recurrent, end-stage disease, and not at initial diagnosis.

## ■ Staging

Ovarian cancer is surgically staged, and stage is assigned according to findings before tumor removal and debulking (**Fig. 35-15**). The International Federation of Gynecology and Obstetrics (FIGO) stages reflect the typical patterns of ovarian cancer spread (**Table 35-5**) (Prat, 2014). Even if a tumor appears clinically confined to the ovary, in many cases it will have detectable metastases. Therefore, accurate surgical staging is crucial to guide treatment. Approximately one third of patients have surgical stage I or II disease (**Table 35-6**).

## ■ Management of Early-stage Ovarian Cancer

### Surgical Staging

If a malignancy appears clinically confined to the ovary, surgical removal and comprehensive staging is performed. Typically, the abdominal incision must be adequate to identify and resect any disease that may have been missed during physical examination or imaging. The operation begins by aspirating free ascitic fluid or collecting peritoneal washings. This is followed by inspection and palpation of all peritoneal surfaces. Next, an extrafascial hysterectomy and BSO are performed. In the absence of gross extra-ovarian disease, the infracolic omentum should be removed or at least biopsied (Section 46-14, p. 1186). Additionally, random peritoneal biopsies or scrapings are obtained, ideally near the diaphragms (Lee, 2014; Timmers, 2010). The most prognostically important step, a pelvic and infrarenal paraaortic lymphadenectomy, is also completed (Sections 46-11, p. 1172) (Chan, 2007; Cress, 2011; Whitney, 2011).

Laparoscopic staging is particularly valuable as a primary treatment in women who have an apparent stage I ovarian cancer. Alternatively, unstaged patients may have their staging completed laparoscopically. In general, for minimally invasive staging, all of the required procedures can be safely performed (Chi, 2005). The main putative benefits are a shorter hospital stay and quicker recovery (Tozzi, 2004). However, nodal

**FIGURE 35-15** International Federation of Gynecology and Obstetrics (FIGO) staging for ovarian cancer.

counts may be inferior, and required exploration of the abdomen during staging is unavoidably limited.

### Fertility-sparing Management

Approximately 10 percent of epithelial ovarian cancers develop in women younger than 40 years. In selected cases, fertility-sparing surgery may be an option if disease appears confined to one ovary. Although many patients will be up-staged as a result of the operative findings, those with surgical stage I disease have an excellent long-term survival following unilateral adnexectomy. In some cases, postoperative chemotherapy may be required, but patients will usually retain their ability to conceive and

ultimately carry a pregnancy to term (Schilder, 2002).

### Postsurgical Management

In women with stage IA or IB, grade 1 or 2 epithelial ovarian carcinoma, observation without further treatment following surgery is appropriate (Young, 1990). However, one third of patients who appear to have disease confined to the ovary will be “up-staged” by surgical staging and require postoperative chemotherapy.

Women with stage IA or IB, grade 3 epithelial ovarian cancer and all stage IC and II tumors are treated with carboplatin (Paraplatin) and paclitaxel (Taxol) chemotherapy (Morgan, 2014; Trimbos, 2003). In a Phase III Gynecologic Oncology Group (GOG) trial (protocol #157), women with early-stage disease were randomly assigned to either three or six cycles of this combination. Overall, three cycles resulted in a relapse rate comparable to that for six cycles but caused less toxicity (Bell, 2006). However, in a subanalysis of patients in this study who had serous tumors, treatment with six cycles decreased the relapse risk (Chan, 2010a).

Despite chemotherapy, more than 20 percent of women with early-stage disease develop recurrences within 5 years. In response, the GOG conducted a randomized Phase III trial of postoperative carboplatin and paclitaxel chemotherapy followed by observation or weekly paclitaxel for 24 weeks (protocol

#175). Unfortunately, no benefit to maintenance paclitaxel was observed for early-stage patients (Mannel, 2011).

### Surveillance

After treatment completion, women with early-stage ovarian cancer may be followed every 2 to 4 months for the first 2 years, then twice yearly for an additional 3 years, and then annually. At each visit, complete physical and pelvic examinations are performed. In addition, a serum CA125 level may be indicated if it was initially elevated (Morgan, 2014). However, a multi-institutional European trial evaluated the utility of CA125 levels for ovarian cancer monitoring after primary therapy completion.

**TABLE 35-5.** FIGO Staging of Carcinoma of the Ovary, Fallopian Tube, and Primary Peritoneal Carcinoma

Stage	Characteristics
<b>I</b>	<b>Tumor confined to ovaries (or to fallopian tubes)<sup>a</sup></b>
IA	Tumor limited to 1 ovary (or 1 tube); capsule intact, no tumor on surface, negative washings
IB	Tumor involves both ovaries (or both tubes), otherwise like IA
IC1	Tumor limited to 1 or both ovaries (or tubes), with surgical spill
IC2	Tumor limited to 1 or both ovaries (or tubes), with capsule rupture before surgery or tumor on ovarian surface
IC3	Tumor limited to 1 or both ovaries (or tubes), with malignant cells in ascites or peritoneal washings
<b>II</b>	<b>Tumor involves 1 or both ovaries (or 1 or both tubes)<sup>a</sup> with pelvic extension (below the pelvic brim) or primary peritoneal cancer</b>
IIA	Extension and/or implants on uterus and/or fallopian tubes (and/or ovaries)
IIIB	Extension to other pelvic intraperitoneal tissues
<b>III</b>	<b>Tumor involves 1 or both ovaries (or 1 or both tubes)<sup>a</sup> with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to retroperitoneal lymph nodes</b>
IIIA1	Positive retroperitoneal lymph nodes only
(i)	Metastasis ≤ 10 mm
(ii)	Metastasis > 10 mm
IIIA2	Microscopic, extrapelvic (above the brim) peritoneal involvement ± positive retroperitoneal nodes
IIIB	Macroscopic, extrapelvic, peritoneal metastasis ≤ 2 cm ± positive retroperitoneal nodes. Includes extension to capsule of liver/spleen
IIIC	Macroscopic, extrapelvic, peritoneal metastasis > 2 cm ± positive retroperitoneal nodes. Includes extension to capsule of liver/spleen
<b>IV</b>	<b>Distant metastasis excluding peritoneal metastasis</b>
IVA	Pleural effusion with positive cytology
IVB	Hepatic and/or splenic parenchymal metastasis, metastasis to extraabdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

<sup>a</sup>Content in parentheses referring to tubes pertains to fallopian tube carcinoma.

Women with relapsed ovarian cancer did not live longer by starting chemotherapy earlier based on a rising CA125 level compared with delaying treatment until symptoms developed. The group monitored with CA125 tests received 5 more months of chemotherapy overall, whereas women who were diagnosed and treated later for clinically evident recurrence had higher quality-of-life measures (Rustin, 2010).

**TABLE 35-6.** Distribution of Epithelial Ovarian Cancer by FIGO Stage (n = 4825 patients)

FIGO Stage	Percent
I	28
II	8
III	50
IV	13

Data from Heintz APM, Odicino F, Maisonneuve P, et al: Carcinoma of the ovary. FIGO 26th Annual Report on the Results of Treatment in Gynecological Cancer, *Int J Obstet Gynecol* 92006 Nov;95 Suppl 1:S161–S92.

Whether suspected by examination, CA125 level elevation, or new symptoms, recurrent disease must be confirmed with the aid of imaging. Of modalities, CT is initially most helpful to identify intraperitoneal disease.

■ **Management of Advanced Ovarian Cancer**

Approximately two thirds of patients will have stage III-IV disease, and sequenced multimodality therapy offers the most successful outcomes (Earle, 2006). Ideally, surgical cytoreduction is initially performed to remove all gross disease and is followed by six courses of platinum-based chemotherapy. However, some women are not appropriate candidates for primary surgery due to their medical condition, and others will have unresectable tumor. Additionally, one randomized trial concluded that initial treatment with chemotherapy followed by interval debulking surgery might achieve equivalent results (Vergote, 2010). To effectively balance all clinical factors, each patient is individually assessed before initiating treatment.

**Primary Cytoreductive Surgery**

**Residual Disease.** Since the initial report by Griffiths (1975) suggested the clinical benefits of debulking, its value has been largely assumed. Numerous retrospective studies have

subsequently supported the apparent survival advantage in women with advanced ovarian cancer. For subsequent decades, a cytoreductive effort was considered “optimal” if less than or equal to *1 cm residual disease* could be achieved. Specifically, 1 cm residual disease describes a surgical result in which none of any remaining areas of tumor individually measures greater than 1 cm. However, the assessment of gross remaining disease is entirely subjective, and often inaccurate due to tissue induration or other factors (Chi, 2007). Perhaps due to the inability to reliably quantify remaining disease, a subanalysis of accumulated data from several prospective GOG trials was completed. It demonstrated for those with stage III ovarian cancer that patients with 0.1 to 1.0 cm residual had only marginally improved overall survival compared with patients with greater than 1 cm. In fact, dramatic survival benefit was only achieved with complete resection (Winter, 2007). Based on these findings and other similar reports, a growing consensus supports that optimal debulking should be defined as no gross residual disease (Chang, 2012; Schorge, 2014).

Several reasons substantiate beliefs that ovarian cancer implant resection prolongs survival. First, surgery removes large volumes of chemoresistant tumor cell clones. Second, excision of necrotic tissue improves drug delivery to remaining well-vascularized cells. Third, small residual tumor implants should be faster growing and therefore more susceptible to chemotherapy. Fourth, smaller cancer cell populations should require fewer chemotherapy cycles, which lowers chances of chemoresistance. Finally, removal of bulky disease potentially enhances the immune system.

Whether any of these supposed advantages to debulking are actually clinically relevant is debatable (Covens, 2000). However, because of the presumed benefits, primary surgical cytoreduction is generally performed whenever an optimal result is clinically feasible. Yet, physical examination and imaging findings alone inherently limit the ability to accurately predict surgical success. As a result, preoperative laparoscopic evaluation is being studied as a method for patient triage (Fagotti, 2005, 2013; Morgan, 2014). However, since the goal is the maximal resection of the primary ovarian cancer and all metastatic disease, laparoscopic or robotic surgery has a limited role in debulking (Magrina, 2011; Nezhat, 2010). Typically, various procedures are required to achieve minimal residual disease, as described subsequently.

**Surgical Approach to Cytoreductive Surgery.** In general, a vertical incision is recommended to provide access to the entire abdomen. Women with advanced disease do not require peritoneal washings or cytologic assessment of fluid, but often several liters of ascites will need to be evacuated to improve visualization. Next, the abdomen is carefully explored to quickly determine if optimal debulking is feasible. It is preferable to perform a limited surgical procedure rather than extensive debulking if it is obvious that bulky tumors will be left behind. If hysterectomy and BSO is not possible, a biopsy of the ovary and sampling of the endometrium by dilatation and curettage is performed to confirm an ovarian primary and exclude the possibility of widely metastatic uterine papillary serous carcinoma. However, if disease is resectable, then surgery should begin with the least complicated procedure.

Often, an infracolic omentectomy can be easily performed and extended (i.e., gastrocolic), as needed, to encompass the disease. A frozen section analysis can then be requested to confirm the presumed diagnosis of epithelial ovarian cancer. The

pelvis is assessed next. Usually, an extrafascial type I abdominal hysterectomy and BSO is sufficient. However, when the tumor is confluent or invading the rectosigmoid, an en bloc resection, low anterior resection, or modified posterior pelvic exenteration may be required. These and other surgeries mentioned in this section are described and illustrated in Chapter 46 (p. 1134).

Patients with abdominal tumor nodules measuring < 2 cm (apparent stage IIIB) should have bilateral pelvic and paraaortic node lymphadenectomy to provide the most accurate surgical staging. In patients with stage IV disease and those with abdominal tumor nodules at least 2 cm (already stage IIIC disease), nodal dissection is not necessarily required for staging purposes (Whitney, 2011). However, if it is not performed, a significant percentage of otherwise completely resected patients may not benefit from removal of unrecognized macroscopic nodal disease (Eisenkop, 2001). Systematic lymphadenectomy in advanced ovarian cancer appears to benefit mainly those patients with complete intraperitoneal debulking (du Bois, 2010; Panici, 2005).

Optimal surgical cytoreduction may also require various other radical procedures, including splenectomy, diaphragm stripping/resection, and small or large bowel resection (Aletti, 2006; McCann, 2011). Surgically aggressive centers experienced in such techniques report higher rates of achieving minimal residual disease that correspond to better outcomes (Aletti, 2009; Chi, 2009a; Wimberger, 2007). For diagnostic purposes and since it is a frequent site of disease, an appendectomy is also commonly included (Timofeev, 2010).

### Neoadjuvant Chemotherapy and Interval Cytoreductive Surgery

Many women do not undergo initial optimal surgical debulking. In some of these cases, imaging studies may suggest unresectable disease. Other patients may be too medically compromised, may not have received initial care by a gynecologic oncologist, or may have large-volume “suboptimal” residual disease despite attempted debulking. In such circumstances, three to four courses of chemotherapy are used to shrink disease before attempting an “interval” cytoreductive surgery.

Such neoadjuvant chemotherapy with an interval procedure is associated with less perioperative morbidity, increased rates of optimal cytoreduction, and similar survival rates, but had never been directly compared with primary debulking until more recently (Hou, 2007; Kang, 2009). Vergote and colleagues (2010) reported results of a randomized phase III trial of 634 patients with stage IIIC or IV epithelial ovarian cancer, many of whom had extensive upper abdominal disease. In that study, neoadjuvant chemotherapy followed by interval debulking was *not* inferior to primary cytoreductive surgery. Since fewer than half of the primary surgery patients had debulking to 1 cm residual disease, the survival rates of both groups were comparable to those in other chemotherapy trials of patients with large-volume residual disease (Ozols, 2003). As many expert centers in the United States routinely incorporate ultraradical procedures to achieve complete resection, it is reasonable to think that a more aggressive cytoreductive attempt might have led to a better outcome for the group randomized to surgery (Chi, 2012). Although this remains unproven, the strongest variable predicting overall survival was debulking to microscopic residual disease, whether performed as primary treatment or after three

cycles of chemotherapy (Vergote, 2010). Thus, the benefits of interval debulking mainly occur in patients who have very advanced, unresectable disease or who did not initially have a maximal surgical effort by a gynecologic oncologist (Rose, 2004; Tangjitgamol, 2009; van der Burg, 1995).

Adjuvant Chemotherapy

**Intravenous Chemotherapy.** Advanced ovarian cancer is considered to be relatively sensitive to cytotoxic agents. Largely due to recent advances in identifying active drugs, survival duration among patients has increased over the past two decades. Despite such improvements, fewer than 20 percent of those requiring chemotherapy will be cured. This is largely due to clinically occult residual chemoresistant tumor cells.

Platinum-based chemotherapy is the foundation for systemic treatment of most epithelial ovarian cancer types, although alternative regimens are currently being studied for advanced mucinous and clear cell carcinomas because of their known resistance. In two large collaborative group trials (GOG protocol #158 and Arbeitsgemeinschaft Gynäkologische Onkologie [AGO] protocol OVAR-3), the combination of carboplatin and paclitaxel was easier to administer, similarly efficacious, and less toxic than a cisplatin/paclitaxel regimen (du Bois, 2003; Ozols, 2003). As a result, the most widely used intravenous (IV) regimen in the United States is six courses of carboplatin and paclitaxel. If additional cycles are required to achieve clinical remission, this suggests relative tumor chemoresistance and usually leads to an earlier relapse. In Europe, single-agent carboplatin is often used. This preference is based on two large Phase III trials of the International Collaborative Ovarian Neoplasm (ICON) Group, which did not detect a survival advantage for combination chemotherapy (The ICON Collaborators, 1998; The ICON Group, 2002).

Although the carboplatin and paclitaxel regimen is undoubtedly effective, other modifications have been studied. For instance, the addition of a third cytotoxic agent was postulated to further improve outcome. Unfortunately, none of the experimental regimens demonstrated superiority compared with the control group (Bookman, 2009). Addition of the biologic agent bevacizumab (Avastin) during primary chemotherapy, followed by use as maintenance therapy, has been shown to provide only a modest improvement in progression-free survival (GOG protocol #218 and ICON-7) (Burger, 2011; Perren, 2011). Finally, administering paclitaxel in a dose-dense weekly schedule may have some advantages but at the cost of additional toxicity (Katsumata, 2009). The GOG conducted a definitive phase III trial comparing dose-dense paclitaxel with carboplatin versus every-3-week paclitaxel and carboplatin. In addition, suboptimally debulked patients in both groups received optional bevacizumab (protocol #262). The results are not yet available.
