**Intraperitoneal Chemotherapy.** In 2006, the National Cancer Institute issued a rare Clinical Announcement encouraging the use of intraperitoneal (IP) chemotherapy. This coincided with the publication of results from a Phase III GOG trial (protocol #172) of optimally debulked stage III ovarian cancer patients who were randomly assigned to receive either IV or combination IV/IP paclitaxel and cisplatin chemotherapy

TABLE 35-7. Intraperitoneal Chemotherapy Regimen for Ovarian Cancer

Day 1	Paclitaxel 135 mg/m <sup>2</sup> IV over 24 hour
Day 2	Cisplatin 75 to 100 mg/m <sup>2</sup> intraperitoneal
Day 8	Paclitaxel 60 mg/m <sup>2</sup> intraperitoneal

©National Comprehensive Cancer Network, Inc., 2014. Ovarian cancer, including fallopian tube cancer and primary peritoneal cancer, version 3.2014.

(Table 35-7). The median duration of overall survival was 66 months in the IV/IP group compared with 50 months in the IV group (Armstrong, 2006). By comparison, survival in both groups far exceeded patients treated in the Vergote trial (29 to 30 months median survival), described on page 751 (Vergote, 2010). Despite this dramatic improvement in survival, many clinicians still remain unconvinced of its efficacy and do not routinely recommend IP chemotherapy (Gore, 2006).

The theoretical advantages of IP chemotherapy are dramatic. In general, epithelial ovarian cancer mainly spreads along peritoneal surfaces. In postoperative patients with minimal residual disease, a much higher dose of chemotherapy can be achieved at the tumor site by administration directly into the abdomen (Alberts, 1996; Markman, 2001).

Obviously, not every woman with advanced ovarian cancer is an appropriate candidate for IP chemotherapy. Stage IV patients and those with large-volume residual disease are theoretically least likely to benefit. In addition, toxicity is generally higher with IP therapy, catheter-related problems are common, and the true long-term survival advantage remains controversial (Walker, 2006). Regardless, IP therapy should certainly be considered for low-volume, optimally debulked disease (Morgan, 2014). However, the choice to receive or not receive IP chemotherapy should ultimately be a decision made by an informed patient (Alberts, 2006).

In light of the National Cancer Institute clinical announcement and ensuing debate, newer IP regimens are currently being tested. One current randomized phase III GOG trial (protocol #252) compared: (1) dose-dense paclitaxel and IV carboplatin, (2) dose-dense paclitaxel and IP carboplatin, and (3) a modified GOG protocol #172 IP cisplatin regimen. All groups received concurrent bevacizumab followed by maintenance bevacizumab. It is anticipated that when these data are published, they will shape future applications of ovarian cancer IP therapy.

Management of Patients in Remission

In most women with advanced ovarian cancer, the combination of surgery and platinum-based chemotherapy will result in clinical remission (normal examination, CA125 levels, and CT scan findings). However, up to 80 percent will eventually relapse and die from disease progression. Lower CA125 levels, that is, single-digit values, are generally associated with longer time until relapse and better survival rates (Juretzka, 2007). Since most patients achieving remission will have residual, clinically occult drug-resistant cells, several options are appropriate to consider and include surveillance, second-look surgery, maintenance chemotherapy, and abdominal radiotherapy. Unfortunately, there is no solid proof that any intervention is beneficial.

First, surveillance after treatment completion may include regular examinations and CA125 levels, as in early-stage disease. In those with new symptoms, physical findings, or rising CA125 titers, imaging may be indicated. In general, clinicians should maintain a heightened suspicion for relapse.

Another option, *second-look surgery*, is the “gold standard” to identify residual disease at treatment completion. For numerous reasons, mainly a lack of proven clinical benefit, this is not routinely performed. Instead, a second-look laparotomy or laparoscopy primarily serves as a useful early end point in assessing the treatment effectiveness within an experimental protocol. Otherwise, no prospective clinical trials have demonstrated a survival advantage. Second-look surgery does have prognostic value, since a procedure that reveals no recurrent disease is associated with an improved survival rate.

A third option is *maintenance chemotherapy*, also termed *consolidation therapy*. There is limited evidence to suggest any advantage for additional treatment in women who achieve clinical remission after six courses of platinum-based chemotherapy. However, due to the known high rate of recurrence, several agents have been tested as maintenance therapy, in randomized studies. Of these, monthly paclitaxel for 12 cycles was observed to extend progression-free survival by 7 months compared with only three courses of treatment. However, cumulative toxicity, most notably neuropathy, was substantial and resulted in frequent dose reductions. Unfortunately, the trial did not demonstrate improved overall survival rates among patients receiving prolonged maintenance therapy (Markman, 2003, 2009). To determine whether lower-dose paclitaxel or CT-2103 (Xyotax) could reduce the death rate compared with no maintenance therapy, the GOG is currently conducting a Phase III trial of women with advanced ovarian cancer who achieved clinical remission after standard platinum-based chemotherapy (protocol #212).

Bevacizumab, an antiangiogenic agent, has also been studied as maintenance therapy in several phase III trials. In GOG protocol #218 and the Gynecologic InterGroup Trial (ICON-7) studies noted earlier (p. 752), when bevacizumab was combined with paclitaxel and carboplatin, then continued alone for a year of maintenance therapy, it demonstrated only a 2- to 4-month prolongation of progression-free survival, but no overall survival benefit. Of added interest, when maintenance bevacizumab was stopped, several patients experienced relapse soon after (Burger, 2011; Perren, 2011). Therefore, current trials allow maintenance bevacizumab to be continued indefinitely or until there is evidence for disease progression.

Pazopanib, an oral multikinase inhibitor of vascular endothelial growth factor receptor (VEGFR), has also shown some promise as maintenance therapy. In a Phase III trial, patients receiving pazopanib had a 5.6-month improvement in progression-free survival compared with placebo, but with significant toxicity and lack of overall survival benefit (du Bois, 2014).

A fourth option, *radiation therapy*, is rarely used in the United States for patients in remission after primary therapy. Whole abdominal radiotherapy has unproven benefit, and fears of excessive toxicity such as radiation enteritis are a concern (Sorbe, 2003). However, the long-term effectiveness of this consolidation strategy is comparable to that achieved in women treated with other modalities.

**TABLE 35-8.** Epithelial Ovarian Cancer 5-Year Survival Rates

Stage	5-Year Survival (%)
Localized (confined to primary site)	92
Regional (spread to regional nodes)	72
Distant (cancer has metastasized)	27
Unknown (unstaged)	22

## ■ Prognostic Factors

The overall 5-year survival rate of all stages of epithelial ovarian cancer approximates 45 percent, far lower than uterine (84 percent) or cervical cancer (73 percent) (National Cancer Institute, 2014b). Survival rates mirror the assigned FIGO stage and largely depend on whether the disease has metastasized or not (Table 35-8). Additional prognostic factors are shown in Table 35-9). Interestingly, BRCA mutation carriers have a better prognosis, chiefly due to increased platinum sensitivity (Alsop, 2012; Lacour, 2011). However, even with favorable prognostic factors and despite recent innovations, most patients will ultimately relapse.

## ■ Management of Recurrent Ovarian Cancer

Gradual elevation of the CA125 level is usually the first sign of relapse. Tamoxifen may be administered when there is only “biochemical” evidence for disease progression, because it has some activity in treating recurrent disease and toxicity is minimal (Hurteau, 2010). Alternatively, patients may be offered participation in a clinical trial, started on conventional cytotoxic chemotherapy, or observed until clinical symptoms arise. Without treatment, the recurrence will usually become clinically obvious within 2 to 6 months. Almost invariably, the tumor will be located somewhere within the abdomen. Women who progress during primary chemotherapy are classified as having “platinum-refractory” disease and have a dismal prognosis. Those who relapse within 6 months of therapy have

**TABLE 35-9.** Most Important Favorable Prognostic Factors for Ovarian Cancer

Younger age
Good performance status
Cell type other than mucinous and clear cell
Well-differentiated tumor
Smaller disease volume prior to surgical debulking
No ascites
Smaller residual tumor after primary cytoreductive surgery

Reproduced with permission from National Cancer Institute: Ovarian epithelial cancer treatment (PDQ), 2014b. Available at: [www.cancer.gov/cancertopics/pdq/treatment/ovarianepithelial/healthprofessional](http://www.cancer.gov/cancertopics/pdq/treatment/ovarianepithelial/healthprofessional). Accessed January 12, 2015.

“platinum-resistant” ovarian cancer and a somewhat prolonged survival. In general, patients in either category are treated with palliative single-agent nonplatinum chemotherapy. For this, participation in an experimental clinical trial is offered whenever possible. Otherwise, response rates typically range from 5 to 15 percent using FDA-approved conventional cytotoxic drugs such as paclitaxel, pegylated liposomal doxorubicin (Doxil), docetaxel (Taxotere), topotecan (Hycamtin), or gemcitabine (Gemzar). Recently, bevacizumab in combination with weekly paclitaxel, doxorubicin, or topotecan was shown to provide a 27-percent response rate, which more than doubled the rate with single-agent chemotherapy alone in patients with platinum-resistant disease (Pujade-Lauraine, 2014). As a result, bevacizumab is now FDA-approved for this indication.

Women who relapse more than 6 to 12 months after primary therapy completion are considered “platinum-sensitive.” These patients, especially those in prolonged remission beyond 18, 24, or 36 months, are usually treated with a platinum-based combination. Carboplatin combined with either paclitaxel or gemcitabine has demonstrated modest superiority compared with carboplatin alone (Parmar, 2003; Pfisterer, 2006). Moreover, in one randomized phase III trial, the novel combination of carboplatin and pegylated liposomal doxorubicin was superior to carboplatin and paclitaxel (Pujade-Lauraine, 2010). Of interest, although patients with primary early-stage ovarian cancer have a more favorable overall prognosis, survival after relapse is comparable to those who recurred after treatment of advanced-stage disease (Chan, 2010b).

### Secondary Cytoreductive Surgery

Although patient selection is somewhat arbitrary, the best candidates for secondary cytoreductive surgery have: (1) platinum-sensitive disease, (2) a prior prolonged disease-free interval, (3) a solitary-site recurrence, and (4) no ascites (Chi, 2006). To achieve a maximal survival benefit, debulking must result in minimal residual disease (Harter, 2006; Schorge, 2010b). However, approximately half of patients will be explored without achieving this goal.

The overall survival benefit of this approach is currently being studied in a Phase III GOG trial (protocol #213). This randomizes surgical candidates with platinum-sensitive relapsed disease to secondary debulking or not, followed by carboplatin and paclitaxel with or without additional bevacizumab. Of patients enrolled in this study, only 15 to 20 percent have thus far been considered surgical candidates.

### Salvage Chemotherapy

In general, most relapsed ovarian cancer patients will end up receiving multiple sequential courses of chemotherapy (Morgan, 2014). Regardless of which regimen is selected initially, reevaluation usually follows two to four cycles of chemotherapy (depending on the agent) to determine the clinical benefit (Morgan, 2014). Typically, a CA125 level decline with or without confirmation of tumor shrinkage by CT provides sufficient reassurance to continue therapy. Nonresponders are changed to a different regimen. Patients with a germline *BRCA1* or *BRCA2* gene mutation who develop resistance to platinum may benefit from targeted therapy with olaparib (Lynparza), now FDA-approved for

this indication (Chap. 27, p. 605) (Kaufman, 2015). However, at some point, usually after multiple agents have been tried, treatment will no longer be efficacious, which should prompt a discussion about further goals of care.

It would seem plausible that targeting therapy for an individual patient's disease might be more effective than empiric drug selection. In vitro chemosensitivity testing is occasionally used for this purpose. In principle, different agents are tested against the patient's tumor, and the chemotherapeutic drug demonstrating the best response should result in a better outcome. Unfortunately, this approach lacks demonstrable efficacy and is not recommended outside of a clinical trial (Burstein, 2011; Morgan, 2014).

### ■ Palliation of End-stage Ovarian Cancer

At some point, patients with recurrent disease will develop worsening symptoms that warrant reevaluation of their overall treatment strategy. Of these, intermittent episodes of partial small and large bowel obstruction are common during treatment.

Bowel obstruction that does not resolve with nasogastric suction can be managed in two very different ways. Patients at first relapse or early in their course may warrant an aggressive approach that includes chemotherapy with or without surgical intervention and incorporates total parenteral nutrition. A colostomy, ileostomy, or intestinal bypass will often relieve symptoms (Chi, 2009b). Unfortunately, a satisfactory surgical result is sometimes impossible due to disease burden, and multiple sites of partial or complete obstruction. In addition, successful palliation is rarely achieved when the transit time is prolonged due to diffuse peritoneal carcinomatosis or when anatomy requires a bypass that results in the short bowel syndrome. Further, recovery may be complicated by an enterocutaneous fistula, reobstruction, or other morbid event (Pothuri, 2004). For patients with a refractory bowel obstruction due to progressive disease despite multiple lines of chemotherapy, the best approach is usually placement of a palliative gastrostomy tube, IV hydration, and hospice care. The final decision regarding how to proceed should be based on a frank discussion. Topics include treatment options, the natural history of progressive ovarian cancer, and the realistic improbability of further disease response by switching to a different therapy.

Another common scenario is a woman with symptomatic, rapidly reaccumulating ascitic fluid. This may be alleviated by repeated paracenteses or by placement of an indwelling peritoneal catheter (Pleurx), which can be self-drained as needed. Similarly, a refractory malignant pleural effusion can usually be managed by thoracentesis, indwelling pleural catheter placement, or pleurodesis. With the last, irritants are instilled into the pleural space to incite adhesions that obliterate the space.

Although these procedures and others may be appropriate in selected patients, the inability to halt disease progression should be acknowledged. In addition, any intervention has the potential to result in an unanticipated, catastrophic complication. Overall, palliative procedures are most compassionately used when incorporated into the overall treatment plan. For example, in a woman with stable disease and normal renal function, tumor-induced ureteral compression and hydronephrosis does not necessarily require stent placement or a nephrostomy tube.

All patients deserve a positive, hopeful, but honest approach to the management of progressive, incurable disease. Often, there are unrealistic expectations regarding the benefit of palliative chemotherapy, but emotionally it may be preferable to the idea of “giving up” (Doyle, 2001). There is no substitute for mutual trust in the doctor–patient relationship when making sound decisions aimed at improving the quality of life of women with end-stage ovarian cancer.

Three major categories account for virtually all malignant ovarian tumors. Organization of these groups is based on the anatomic structures from which the tumors originate (Fig. 36-1). Epithelial ovarian cancers account for 90 to 95 percent of malignant ovarian tumors (Chap. 35, p. 735). Germ cell and sex cord-stromal ovarian tumors account for the remaining 5 to 10 percent and have unique qualities that require a special management approach (Quirk, 2005).

MALIGNANT OVARIAN GERM CELL TUMORS

Germ cell tumors arise from the ovary’s germinal elements and make up one third of all ovarian neoplasms. The mature cystic teratoma, also called *dermoid cyst*, is by far the most common subtype. This accounts for 95 percent of all germ cell tumors, is clinically benign, and discussed in Chapter 9 (p. 219). In contrast, malignant germ cell tumors compose 2 to 3 percent of malignant ovarian cancers in Western countries and include *dyserminoma*, *yolk sac tumor*, *immature teratoma*, and other less common types.

Three features distinguish malignant germ cell tumors from epithelial ovarian cancers. First, individuals typically present at a younger age, usually in their teens or early 20s. Second, most have stage I disease at diagnosis. Third, prognosis is excellent—even for those with advanced disease—due to exquisite tumor chemosensitivity. Fertility-sparing surgery is the primary treatment for women seeking future pregnancy, although most will require postoperative chemotherapy.

Epidemiology

The age-adjusted incidence rate of malignant ovarian germ cell tumors in the United States is much lower (0.4 per 100,000 women) than that of epithelial ovarian carcinomas (15.5) (Quirk, 2005). Smith and associates (2006) analyzed 1262 cases of malignant ovarian germ cell from 1973 to 2002 and observed that incidence rates have declined 10 percent during the past 30 years. Unlike a significant proportion of epithelial ovarian carcinomas, malignant germ cell tumors are not generally considered heritable, although rare familial cases are reported (Galani, 2005; Stettner, 1999).

These tumors are the most common ovarian malignancies diagnosed during childhood and adolescence, although only 1 percent of all ovarian cancers develop in these age groups. At age 20, however, the incidence of epithelial ovarian carcinoma begins to rise and exceeds that of germ cell tumors (Young, 2003).

Diagnosis

Patient Findings

The signs and symptoms associated with these tumors vary, but in general, most originate from tumor growth and the hormones they produce. Subacute abdominal pain is the presenting symptom in 85 percent of patients and reflects rapid growth of a large, unilateral tumor undergoing capsular distention, hemorrhage, or necrosis. In 10 percent of cases, cyst rupture, torsion, or intraperitoneal hemorrhage leads to an acute abdomen (Gershenson, 2007a). In more advanced disease, ascites may develop and cause abdominal distention. Because of the hormonal changes that frequently accompany these tumors, menses can become heavy or irregular. Although most individuals note one or more of these symptoms, one quarter of individuals are asymptomatic, and a pelvic mass is noted unexpectedly during physical or sonographic examination (Curtin, 1994).

Individuals typically seek care within 1 month of the onset of abdominal complaints, although some note subtle waxing and waning of symptoms for more than a year. Vague pelvic symptoms are common during adolescence due to initiation of ovulation and menstrual cramping. As a result, early symptoms may be missed. Moreover, girls may be silent about changes to their normal pattern, fearful of their significance. Most young women with these tumors are nulligravidas with normal periods, but as discussed later, dysgenetic gonads is a known risk factor for development of these tumors (Brown, 2014b). Therefore, adolescents who present with pelvic masses and delayed menarche should be evaluated for gonadal dysgenesis (Chap. 16, p. 373).

**FIGURE 36-1** Origins of the three main types of ovarian tumors. (Adapted with permission from Chen VW, Ruiz B, Killeen JL, et al: Pathology and classification of ovarian tumors, Cancer 2003 May 15;97(10 Suppl):2631–42.)

Distinguishing physical findings are typically lacking in individuals with malignant germ cell tumors. A palpable mass on pelvic examination is the most common. In children and adolescents, however, completing a comprehensive pelvic or transvaginal sonographic examination can be difficult and can lead to diagnostic delay. Accordingly, premenarchal patients may require examination under anesthesia to adequately assess a suspected adnexal tumor. The remainder of the physical examination searches for signs of ascites, pleural effusion, and organomegaly.

### Laboratory Testing

In patients with a suspected malignant germ cell tumor, serum human chorionic gonadotropin (hCG) and alpha-fetoprotein (AFP) tumor markers, complete blood count, and liver function tests are drawn before treatment. Alternatively, the appropriate tumor markers may be ordered in the operating room if the diagnosis was not previously suspected (Table 36-1). Preoperative karyotyping of young women with primary amenorrhea

and a suspected germ cell tumor can clarify whether both ovaries should be removed, as in the case of individuals with gonadal dysgenesis (Hoepfner, 2005).

### Imaging

Early symptoms can be misinterpreted as those of pregnancy, and acute pain may be confused with appendicitis. Finding an adnexal mass is the first diagnostic step. In most cases, sonography can adequately display those qualities that typically characterize benign and malignant ovarian masses (Chap. 9, p. 217). Functional ovarian cysts are vastly more common in young women. Once these hypoechoic smooth-walled cysts are identified by sonography, they may be observed. Mature cystic teratomas (dermoid cysts) usually display characteristic features when imaged with sonography or computed tomography (CT) (Chap. 9, p. 220). In contrast, the appearance of malignant germ cell tumors differs, and a multilobulated complex ovarian mass is typical (Fig. 36-2). Moreover, prominent blood flow in the fibrovascular septa may be seen using color flow Doppler sonography and suggests the likelihood of malignancy (Kim, 1995). Additional preoperative CT or magnetic resonance (MR) imaging may be indicated based on clinical suspicion. Chest radiography is warranted upon diagnosis to search for tumor metastases in the lungs or mediastinum.

### Diagnostic Procedures

Surgical resection is generally required for definitive tissue diagnosis, staging, and treatment. The surgeon should request a frozen section analysis to confirm the diagnosis, but discrepancies between frozen section interpretations and the final paraffin histology are commonplace (Kusamura, 2000). In addition, specific immunostaining is often required to resolve equivocal cases (Cheng, 2004; Ramalingam, 2004; Ulbright, 2005). In contrast, a sonographically or CT-guided percutaneous biopsy has a very limited role in the management of select patients with an ovarian mass suspicious for malignancy.

### ■ Role of the Generalist

Most patients will initially be seen by a generalist gynecologist. Initial symptoms may point to the more common functional

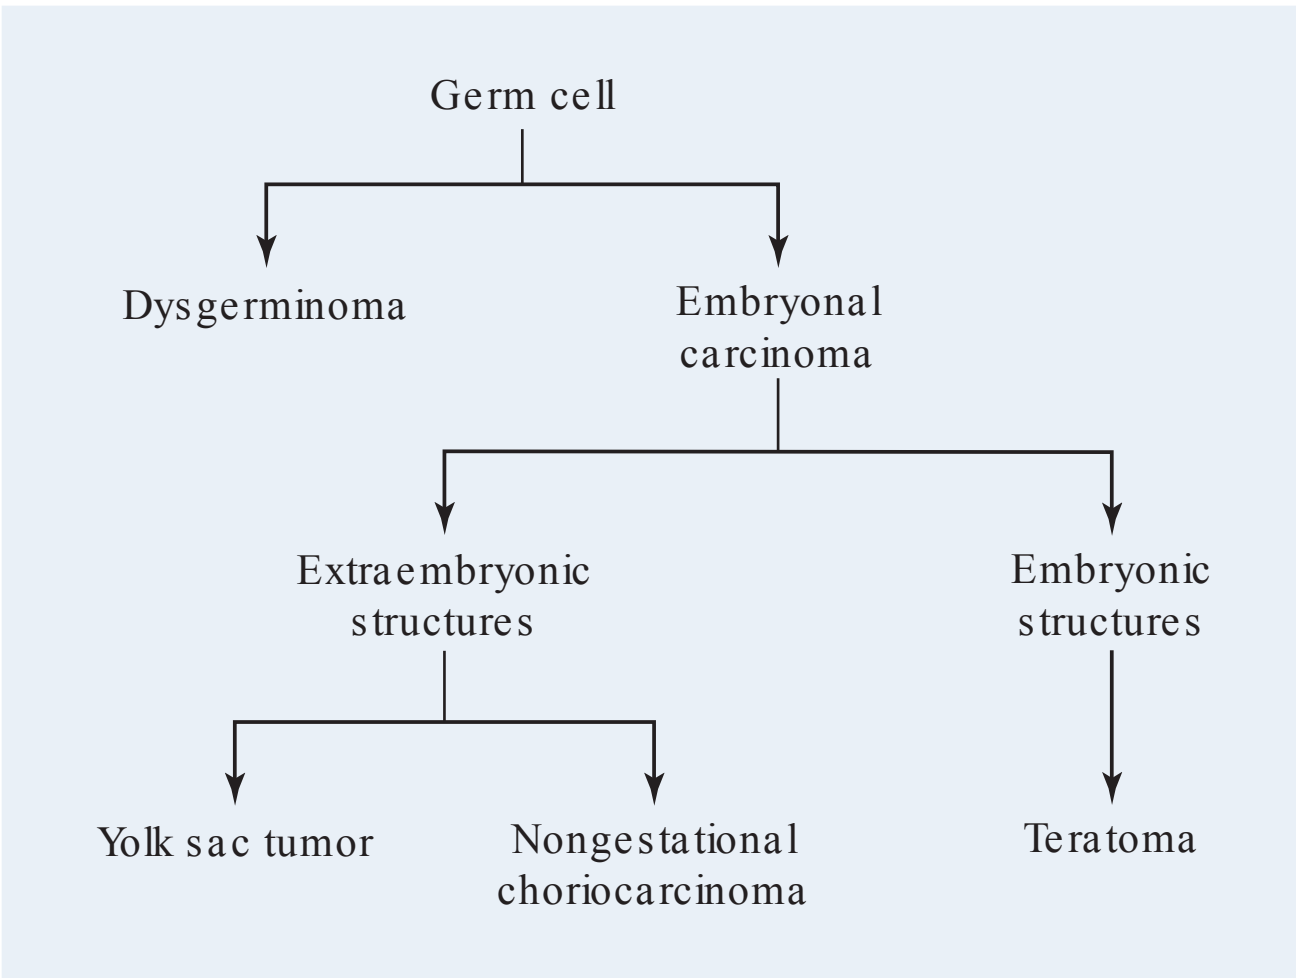

ovarian cyst. Persistent symptoms or an enlarging pelvic mass, however, should prompt sonographic evaluation. If a complex ovarian mass with solid features is noted in this young age group, then measurement of serum hCG and AFP levels and referral to a gynecologic oncologist for primary surgical management should ensue.

If a specialist is unavailable or the diagnosis is not anticipated beforehand, intraoperative decision making is crucial to adequately treat the patient without compromising future fertility. Peritoneal washings are obtained and set aside before proceeding with dissection of any suspicious adnexal mass. These can be discarded later if malignancy is excluded. Initially, the decision to perform cystectomy or oophorectomy depends on the clinical circumstances (Chap. 9, p. 216). In general, the entire adnexa should be removed once a malignant ovarian germ cell tumor is diagnosed. A generalist gynecologist should request intraoperative assistance with staging from a gynecologic oncologist or refer the patient postoperatively if a specialist is not immediately available. At minimum, the abdomen should be explored. Palpation of the omentum and upper abdomen and inspection of the pelvis—especially the contralateral ovary—is easy to perform and document.

■ Pathology
 Classification

The modified World Health Organization (WHO) classification of ovarian germ cell tumors is presented in Table 36-2. These tumors are composed of several histologically different tumor types derived from primordial germ cells of the embryonic gonad. There are two major categories: primitive malignant germ

TABLE 36-2. Modified WHO Classification of Ovarian Germ Cell Tumors
<b>Germ cell tumors</b> Dysgerminoma Yolk sac tumor (endodermal sinus tumor) Embryonal carcinoma Nongestational choriocarcinoma Mature teratoma Solid Cystic(dermoid cyst) Immature teratoma Mixed germ cell tumor
<b>Monodermal teratoma and highly specialized types arising from a mature cystic teratoma</b> Thyroid tumors (struma ovarii: benign or malignant) Carcinoids Neuroectodermal tumors Carcinomas (squamous cell or adeno-) Sebaceous tumors

**FIGURE 36-3** Differentiation pathway of germ cell tumors.

cell tumors (dysgerminomas) and teratomas, almost all of which are accounted for by mature cystic teratomas (dermoid cysts).

Histogenesis

Primitive germ cells migrate from the wall of the yolk sac to the gonadal ridge (Fig. 18-1, p. 405). As a result, most germ cell tumors arise in the gonad. Rarely, these tumors may develop primarily in extragonadal sites such as the central nervous system, mediastinum, or retroperitoneum (Hsu, 2002).

Ovarian germ cell tumors have a variable pattern of differentiation (Fig. 36-3). Dysgerminomas are primitive neoplasms that do not have the potential for further differentiation. Embryonal carcinomas are composed of multipotential cells that are capable of further differentiation. This lesion is the precursor of several other types of extraembryonic (yolk sac tumor, choriocarcinoma) or embryonic (teratoma) germ cell tumors. The process of differentiation is dynamic, and the resulting neoplasms may be composed of different elements that show various stages of development (Teilum, 1965).

Dysgerminoma

Because their incidence has declined by approximately 30 percent over the past few decades, dysgerminomas currently account for only approximately one third of all malignant ovarian germ cell tumors (Chan, 2008; Smith, 2006). Dysgerminomas are the most common ovarian malignancy detected during pregnancy. This is believed to be an age-related coincidence, however, and not due to some particular characteristic of gestation.

Five percent of dysgerminomas are discovered in phenotypic females with karyotypically abnormal gonads, specifically, with the presence of a normal or abnormal Y-chromosome (Morimura, 1998). Commonly, this group includes those with Turner syndrome mosaicism (45,X/46,XY) and with Swyer syndrome (46,XY, pure gonadal dysgenesis) (Chap. 16, p. 373). The dysgenetic gonads of these individuals often contain gonadoblastomas, which are benign germ cell neoplasms. These tumors may regress or alternatively may undergo malignant transformation, most commonly to dysgerminoma. Because approximately 40 percent of gonadoblastomas in these individuals undergo malignant transformation, both ovaries should be removed (Brown, 2014b; Hoepfner, 2005; Pena-Alonso, 2005).

**FIGURE 36-4** Dysgerminoma. **A.** Intraoperative photograph. **B.** Dysgerminoma is characterized microscopically by a relatively monotonous population of cells resembling primordial germ cells, with a central rounded or square-edged nucleus and abundant clear, glycogen-rich cytoplasm. As in this case, the tumor often contains fibrous septa, seen here as eosinophilic strands, which are infiltrated by chronic inflammatory cells including lymphocytes, macrophages, and occasional plasma cells. (Used with permission from Dr. Kelley Carrick.)

Dysgerminomas are the only germ cell malignancy with a significant rate of bilateral ovarian involvement—15 to 20 percent. Half of patients with bilateral lesions will have grossly obvious disease, whereas cancer in the remainder will only be detected microscopically. Five percent of women have elevated serum hCG levels due to intermingled syncytiotrophoblast. Similarly, serum lactate dehydrogenase (LDH) and the isoenzymes LDH-1 and LDH-2 may also be useful in monitoring individuals for disease recurrence (Pressley, 1992; Schwartz, 1988).

Dysgerminomas have a variable gross appearance, but in general are solid, pink to tan to cream-colored lobulated masses (Fig. 36-4). Microscopically, there is a monotonous proliferation of large, rounded, polyhedral clear cells that are rich in cytoplasmic glycogen and contain uniform central nuclei with one or a few prominent nucleoli. The tumor cells closely resemble the primordial germ cells of the embryo and are histologically identical to seminoma of the testis.

The standard treatment of dysgerminoma usually involves fertility-sparing surgery with unilateral salpingo-oophorectomy (USO). In some extenuating circumstances, ovarian cystectomy may be considered (Vicus, 2010). Surgical staging is generally extrapolated from epithelial ovarian cancer, but lymphadenectomy is particularly important (Chap. 35, p. 748). Of

the malignant germ cell tumors, dysgerminoma has the highest rate of nodal metastases, approximately 25 to 30 percent (Kumar, 2008). Although staging deviations do not adversely affect survival, comprehensive staging allows a safe observation strategy for stage IA tumors (Billmire, 2004; Palenzuela, 2008).

Preservation of the contralateral ovary leads to “recurrent” dysgerminoma in 5 to 10 percent of retained gonads during the next 2 years. This finding in many cases is thought to reflect the high rate of clinically occult disease in the remaining ovary rather than true recurrence. Indeed, at least 75 percent of recurrences develop within the first year of diagnosis (Vicus, 2010). Other common recurrence sites are within the peritoneal cavity or retroperitoneal lymph nodes. Despite this significant incidence of recurrent disease, a conservative surgical approach does not adversely affect long-term survival because of this cancer’s sensitivity to chemotherapy (Liu, 2013).

Dysgerminomas have the best prognosis of all malignant ovarian germ cell tumor variants. Two thirds are stage I at diagnosis, and the 5-year disease-specific survival rate approximates 99 percent (Table 36-3). Even those with advanced disease have high survival rates following chemotherapy. For example, those with stage II-IV disease have a greater than 98-percent survival rate with platinum-based agents (Chan, 2008).

**TABLE 36-3.** Stage at Diagnosis and 5-Year Survival of Common Malignant Ovarian Germ Cell Tumors

	Dysgerminoma	Yolk Sac Tumor	Immature Teratoma
<b>Stage</b>			
I	66%	61%	72%
II–IV	34%	39%	28%
<b>Survival</b>			
Stage I	99%	93%	98%
Stage II–IV	> 98%	64–91%	73–88%

Sources for survival figures are referenced within the text.

## Yolk Sac Tumors

These tumors account for 10 to 20 percent of all malignant ovarian germ cell tumors. These lesions were previously called endodermal sinus tumors, but the terminology has been revised. One third of individuals are premenarchal at the time of initial presentation. Involvement of both gonads is rare, and the other ovary is usually involved with metastatic disease only when there are other metastases in the peritoneal cavity.

Grossly, these tumors form solid masses that are more yellow and friable than dysgerminomas. They are often focally necrotic and hemorrhagic, with cystic degeneration and rupture. The microscopic appearance of yolk sac tumors is often diverse. The most common appearance, the reticular pattern, reflects extraembryonic differentiation, with the formation of a network of irregular anastomosing spaces that are lined by primitive epithelial cells. *Schiller-Duval bodies* are pathognomonic when present (Fig. 36-5). These characteristically have a single papilla, which is lined by tumor cells and contains a central vessel. Alpha-fetoprotein is commonly produced. As a result, yolk sac tumors usually contain cells that stain immunohistochemically for AFP, and serum levels can serve as a reliable tumor marker in posttreatment surveillance.

Yolk sac tumors are the deadliest malignant ovarian germ cell tumor type. As a result, all patients are treated with chemotherapy regardless of stage. Fortunately, more than half present with stage I disease, corresponding to a 5-year disease-specific survival rate of approximately 93 percent (Chan, 2008). Disadvantageously, yolk sac tumors have a greater propensity for rapid growth, peritoneal spread, and distant hematogenous dissemination to the lungs. Accordingly, individuals with stage II-IV disease have a 5-year survival rate ranging from 64 to 91 percent. Of tumor recurrences, most will occur within the first year, and treatment is usually ineffective (Cicin, 2009).

**FIGURE 36-5** Schiller-Duval body. This structure consists of a central capillary surrounded by tumor cells, present within a cystic space that may be lined by flat to cuboidal tumor cells. When present, the Schiller-Duval body is pathognomonic for yolk sac tumor, although they are conspicuous in only a minority of cases. In any given case, Schiller-Duval bodies may be few in number, absent, or have atypical morphologic features. (Used with permission from Dr. Kelley Carrick.)

## Other Primitive Germ Cell Tumors

The rarest subtypes of nondysgerminomatous tumors are typically mixed with other more common variants and usually are not found in pure form.

**Embryonal Carcinoma.** Patients diagnosed with embryonal carcinoma are characteristically younger, with a mean age of 14 years, than those having other types of germ cell tumors. Epithelial cells resembling those of the embryonic disc form these primitive tumors. The solid disorganized sheets of large anaplastic cells, glandlike spaces, and papillary structures are distinctive and allow easy identification of these rare tumors (Ulbright, 2005). Although dysgerminomas are the most common germ cell tumor resulting from malignant transformation of gonadoblastomas in individuals with dysgenetic gonads, occasionally embryonal “testicular” tumors may also originate (LaPolla, 1990). Embryonal carcinomas typically produce hCG, and 75 percent also secrete AFP.

**Polyembryoma.** These rare tumors characteristically contain many embryolike bodies. Each has a small central “germ disc” positioned between two cavities, one mimicking an amniotic cavity and the other a yolk sac. Syncytiotrophoblast giant cells are frequent, but elements other than the embryoid bodies should constitute less than 10 percent of the tumor for the “polyembryoma” designation to be used. Conceptually, these tumors may be viewed as a bridge between the primitive (dysgerminoma) and differentiated (teratoma) germ cell tumor types. For this reason, polyembryomas are often considered to be the most immature of all teratomas (Ulbright, 2005). Serum AFP or hCG levels or both may be elevated in these individuals due to the yolk sac and syncytial components, respectively (Takemori, 1998).

**Choriocarcinoma.** Primary ovarian choriocarcinoma arising from a germ cell appears similar to gestational choriocarcinoma with ovarian metastases, which is discussed in Chapter 37 (p. 785). The distinction is important because nongestational tumors have a poorer prognosis (Corakci, 2005). The detection of other germ cell components indicates nongestational choriocarcinoma, whereas a concomitant or proximate pregnancy suggests a gestational form (Ulbright, 2005). Clinical manifestations are common and result from high hCG levels produced by these rare tumors. These elevated levels may induce sexual precocity in prepubertal girls or heavy, irregular bleeding in reproductive-aged women (Oliva, 1993).

## Mixed Germ Cell Tumors

Ovarian germ cell tumors have a mixed pattern of cellular differentiation in 25 to 30 percent of cases, although the incidence of these tumors has also declined by approximately 30 percent over the past few decades (Smith, 2006). Dysgerminoma is the most common component and is typically seen with yolk sac tumor or immature teratoma or both. The frequency of bilateral ovarian involvement depends on the presence or absence of a dysgerminoma component and increases when it is present. However, treatment and prognosis are determined by the nondysgerminomatous component (Low, 2000). For this reason, elevated serum hCG and particularly AFP levels in a woman

with a presumed pure dysgerminoma should prompt a search for other germ cell components by a more extensive histologic evaluation (Aoki, 2003).

### Immature Teratomas

Due to a 60-percent increased incidence during the past few decades, immature teratomas are now the most common variant and account for 40 to 50 percent of all malignant ovarian germ cell tumors (Chan, 2008; Smith, 2006). They are composed of tissues derived from the three germ layers: ectoderm, mesoderm, and endoderm. The presence of immature or embryonal structures, however, distinguishes these tumors from the much more common and benign mature cystic teratoma (dermoid cyst). Bilateral ovarian involvement is rare, but 10 percent have a mature teratoma in the contralateral ovary. Tumor markers are often not elevated unless the immature teratoma is mingled with other germ cell tumor types. Alpha-fetoprotein, cancer antigen 125 (CA125), CA19-9, and carcinoembryonic antigen (CEA) may be helpful in some cases (Li, 2002).

With gross external inspection, these tumors are large, rounded or lobulated, soft or firm masses. They frequently perforate the ovarian capsule and invade locally. The most frequent site of dissemination is the peritoneum and much less commonly the retroperitoneal lymph nodes. With local invasion, surrounding adhesions commonly form and are thought to explain the lower rates of torsion with this tumor compared with that of its benign mature counterpart (Cass, 2001). On cut surface, the interior is typically solid with intermittent cystic areas, but occasionally the reverse is seen, with solid nodules present only in the cyst wall (Fig. 36-6). Solid parts may correspond to the immature elements, cartilage, bone, or a combination of these. Cystic areas are filled with hair and with serous fluid, mucinous fluid, or sebum.

Microscopic examination reveals a disorderly mixture of tissues. Of the immature elements, neuroectodermal tissues almost always predominate and are arranged as primitive tubules and sheets of small, round, malignant cells that may be

associated with glia formation. The diagnosis is usually difficult to confirm during frozen section analysis, and most tumors are confirmed only on final pathologic review (Pavlakakis, 2009). Tumors are graded 1 to 3 primarily by the amount of immature neural tissue they contain. O'Connor and Norris (1994) analyzed 244 immature teratomas and noted significant inconsistencies in grade assignment by different observers. For this reason, they proposed changing the system to two grades: low (previous grades 1 and 2) and high (previous grade 3). This practice, however, has not been universally accepted.

In general, survival is predicted most accurately by stage and by histologic grade of the tumor. For example, almost three quarters of immature teratomas are stage I at diagnosis and have a 5-year survival rate of 98 percent (Chan, 2008). Those with stage IA grade 1 immature teratomas have an excellent prognosis and do not require adjuvant chemotherapy (Bonazzi, 1994; Marina, 1999). Patients with stage II-IV disease have a 5-year survival rate ranging from 73 to 88 percent (Chan, 2008).

Unilateral salpingo-oophorectomy is the standard care for these and other malignant germ cell tumors in reproductive-aged women. Beiner and colleagues (2004), however, treated eight women with early-stage immature teratoma with ovarian cystectomy and adjuvant chemotherapy and noted no recurrences.

Immature teratomas may be associated with mature tissue implants studding the peritoneum that do not increase the stage of the tumor or diminish the prospect of survival. However, these implants of mature teratomatous elements, even though benign, are resistant to chemotherapy and can enlarge during or after chemotherapy. Termed the *growing teratoma syndrome*, these implants require second-look surgery and resection to exclude recurrent malignancy (Zagame, 2006).

### Malignant Transformation of Mature Cystic Teratomas (Dermoid Cysts)

These rare tumors are the only germ cell variants that typically develop in postmenopausal women. Malignant areas are

**FIGURE 36-6** Immature teratoma. **A.** This opened surgical specimen shows characteristic solid and cystic architecture. As in mature teratomas, hair and other skin elements are often found. **B.** Immature teratomas contain a disorderly mixture of mature and immature tissues derived from the three germ cell layers—ectoderm, mesoderm, and endoderm. Of the immature elements, immature neuroepithelium is the most common. Here, immature neuroepithelial cells arranged in rosettes lie within a background of mature neural tissue. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 36-7** This opened surgical specimen reveals squamous cell carcinoma malignant transformation within a mature cystic teratoma.

usually found as small nodules in the cyst wall or a polypoid mass within the lumen after removal of the entire mature cystic teratoma (Pins, 1996). Squamous cell carcinoma is most common and is found in approximately 1 percent of mature cystic teratomas (Fig. 36-7). Platinum-based chemotherapy with or without pelvic radiation is most often used for adjuvant treatment of early-stage disease (Dos Santos, 2007). However, regardless of treatment received, patients with advanced disease do poorly (Gainford, 2010).

Other uncommon types of malignant features may include basal-cell carcinomas, sebaceous tumors, malignant melanomas, adenocarcinomas, sarcomas, and neuroectodermal tumors. Moreover, endocrine-type neoplasms such as struma ovarii (teratoma composed mainly of thyroid tissue) and carcinoid may also be found within mature cystic teratomas.

## ■ Treatment

### Surgery

A vertical abdominal incision is traditionally recommended if ovarian malignancy is suspected. However, increasingly, investigators with advanced endoscopic skills have noted laparoscopy to be a safe and effective alternative for women with smaller ovarian masses and apparent stage I disease (Shim, 2013).

If present, ascites is evacuated and sent for cytologic evaluation. Otherwise, washings of the pelvis and paracolic gutters are collected for analysis prior to manipulation of the intraperitoneal contents. The entire peritoneal cavity is systematically inspected. The ovaries are assessed for size, tumor involvement, capsular rupture, external excrescences, and adherence to surrounding structures.

Fertility-sparing USO is performed in all reproductive-aged women diagnosed with malignant ovarian germ cell tumors, as this conservative approach in general does not adversely affect survival (Chan, 2008; Lee, 2009). Following USO, blind biopsy or wedge resection of a normal-appearing contralateral ovary is not recommended. For those who have completed child-bearing, hysterectomy with bilateral salpingo-oophorectomy

(BSO) is appropriate (Brown, 2014b). In either case, following removal of the affected ovary, surgical staging by laparotomy or laparoscopy proceeds as previously described for epithelial ovarian cancer (Chap. 35, p. 748) (Gershenson, 2007a). Because of tumor dissemination patterns, lymphadenectomy is most important for dysgerminomas, whereas staging peritoneal and omental biopsies are particularly valuable for yolk sac tumors and immature teratomas (Kleppe, 2014).

Cytoreductive surgery is recommended for advanced-stage malignant ovarian germ cell tumors if it can be accomplished with minimal residual disease (Bafna, 2001; Nawa, 2001; Suita, 2002). The same general principles for debulking are applied as described for epithelial ovarian cancer. Because of the exquisite chemosensitivity of most malignant germ cell tumors, however, neoadjuvant chemotherapy is a reasonable option for patients thought to be unresectable (Talukdar, 2014).

Many women will be referred to an oncologist after USO for a tumor that was clinically confined to the excised ovary. For such patients, if initial surgical staging was incomplete, options may include a second surgery to complete primary staging, regular surveillance, or adjuvant chemotherapy. Unfortunately, few data support a preferred approach. Because of its minimally invasive qualities, laparoscopy is a particularly attractive option for delayed surgical staging following primary excision and has been shown to accurately detect those women who require chemotherapy (Leblanc, 2004). Surgical staging following primary excision, however, is less important for scenarios in which chemotherapy will be administered regardless of surgical findings such as clinical stage I yolk sac tumors and high-grade clinical stage I immature teratomas (Stier, 1996). In such patients, reassurance of no abnormalities by CT imaging is often sufficient prior to proceeding with adjuvant chemotherapy (Gershenson, 2007a).

### Surveillance

Patients with malignant ovarian germ cell tumors are followed by careful clinical, radiologic, and serologic surveillance every 3 months for the first 2 years after therapy completion (Dark, 1997). Ninety percent of recurrences develop within this time frame (Messing, 1992). Second-look surgery at the completion of therapy is not necessary in women with completely resected disease or in those individuals with advanced tumor that does not contain teratoma. However, incompletely resected immature teratoma is the one circumstance among all types of ovarian cancer in which patients clearly benefit from second-look surgery and excision of chemorefractory tumor (Culine, 1996; Rezk, 2005; Williams, 1994).

### Chemotherapy

Stage IA dysgerminomas and stage IA grade 1 immature teratomas do not require additional chemotherapy. More advanced disease and all other histologic types of malignant ovarian germ cell tumors have historically been treated with combination chemotherapy after surgery (Suita, 2002; Tewari, 2000). However, there is a strong trend toward exploring the feasibility of surgery followed by close surveillance in pediatric and adolescent girls (Billmire, 2014). Because chemotherapy remains effective when used at the time of relapse, some investigators are attempting to identify additional low-risk, early-stage subgroups that

may be observed postoperatively and thereby avoid treatment-related toxicity (Bonazzi, 1994; Cushing, 1999; Dark, 1997). However, before this strategy can be incorporated into general practice, additional large studies are needed.

The standard regimen is a 5-day course of bleomycin, etoposide, and cisplatin (BEP) given every 3 weeks (Gershenson, 1990; Williams, 1987). Modified 3-day BEP combinations are also safe and effective (Chen, 2014; Dimopoulos, 2004). Carboplatin and etoposide, given in three cycles, has shown promise as an alternative for selected patients (Williams, 2004). For women with incompletely resected disease, at least four courses of BEP are usually recommended (Williams, 1991).

### Radiation

Chemotherapy has replaced radiation as the preferred adjuvant treatment for all types of malignant ovarian germ cell tumors. This transition was prompted primarily by the exquisite sensitivity of these tumors to either modality, but higher likelihood of retained ovarian function using chemotherapy (Solheim, 2015). Patients treated with radiotherapy are also much more likely to develop a second cancer within 10 years (Solheim, 2014). Occasional situations may still exist in which radiotherapy is considered, such as palliation of a germ cell tumor that has demonstrated resistance to chemotherapy.

### Relapse

At least four courses of BEP chemotherapy is the preferred treatment for recurrent ovarian germ cell tumors in women initially managed with surgery alone. Patients who achieved a sustained clinical remission of greater than 6 months after completing BEP or another platinum-based chemotherapy regimen may be treated again with BEP. Because their tumors are generally more responsive, these “platinum-sensitive” patients have a much better prognosis. However, women who do not achieve remission with BEP chemotherapy or relapse within a few months (fewer than 6) are considered “platinum-resistant,” and treatment options are limited. Chemorefractory cases with dysgerminoma or immature teratoma appear to have a better outcome than other subtypes, and surgical salvage aimed at achieving no residual disease may benefit some patients (Li, 2007). Another option for this group is vincristine, dactinomycin, and cyclophosphamide (VAC) (Gershenson, 1985). Other potentially active drugs include paclitaxel, gemcitabine, and oxaliplatin (Hinton, 2002; Kollmannsberger, 2006).

Second-look procedures with surgical debulking have a limited role because of the inherent chemosensitivity of these recurrent tumors. Chemorefractory immature teratomas are notable exceptions (Munkarah, 1994). Growth or persistence of a tumor after chemotherapy does not necessarily imply progression of malignancy, but these masses should still be resected (Geisler, 1994).

### ■ Prognosis

Malignant ovarian germ cell tumors have an excellent overall prognosis (see Table 36-3) (Solheim, 2013, 2014). Moreover, the number of cases with distant and unstaged disease has dramatically declined, suggesting that germ cell tumors are being

diagnosed earlier. In addition, the survival rates have significantly improved for all subtypes, especially with the demonstrated efficacy of cisplatin-based combination therapy (Smith, 2006). Histologic cell type, elevated serum marker levels, surgical stage, and the amount of residual disease at initial surgery are the major variables affecting prognosis (Murugaesu, 2006; Smith, 2006). Typically, pure dysgerminomas recur within 2 years and are highly treatable (Vicus, 2010). However, for nondysgerminomatous tumors, outcome after relapse is poor, and fewer than 10 percent of patients achieve long-term survival (Murugaesu, 2006).

Most women treated with fertility-sparing surgery, with or without chemotherapy, will resume normal menses and are able to conceive and bear children (Gershenson, 2007b; Zanetta, 2001). In addition, none of the reported studies has noted an increased rate of birth defects or spontaneous abortion in those treated with chemotherapy (Brewer, 1999; Low, 2000; Tangir, 2003; Zanetta, 2001).

### ■ Management During Pregnancy

Persistent adnexal masses are detected in 1 to 2 percent of all pregnancies. These neoplasms are usually seen during routine obstetric sonographic examination, but occasionally a dramatically elevated maternal serum alpha-fetoprotein (MSAFP) level is the presenting sign of a malignant germ cell tumor (Horbelt, 1994; Montz, 1989). Mature cystic teratomas (dermoid cysts) make up one third of tumors resected during pregnancy. In contrast, dysgerminomas account for only 1 to 2 percent of such neoplasms but still are the most common ovarian malignancy during pregnancy. Development of other germ cell tumors is rare (Shimizu, 2003).

Initial surgical management including surgical staging is the same as for the nonpregnant woman (Horbelt, 1994; Zhao, 2006). Fortunately, very few patients have advanced disease necessitating radical dissection for cytoreduction. The decision to administer chemotherapy during pregnancy is controversial. Malignant ovarian germ cell tumors have the propensity to grow rapidly, and delaying treatment until after delivery is potentially hazardous. Treatment with BEP appears to be safe during pregnancy, but some reports have speculated that fetal complications are possible (Elit, 1999; Horbelt, 1994). For this reason, some advocate postponing treatment until the puerperium (Shimizu, 2003). Unfortunately, there are no results from large studies to resolve this dilemma. Although BEP administration may be delayed until the puerperium for completely resected dysgerminomas, patients with nondysgerminomatous tumors (mainly yolk sac tumors and immature teratomas) and incompletely resected disease warrant strong consideration of chemotherapy during pregnancy.

## OVARIAN SEX CORD-STROMAL TUMORS

Sex cord-stromal tumors (SCSTs) are a heterogeneous group of rare neoplasms that originate from the ovarian matrix. Cells within this matrix have the potential for hormone production, and nearly 90 percent of hormone-producing ovarian tumors are SCSTs. As a result, individuals with these tumors typically present with signs and symptoms of estrogen or androgen excess.

Surgical resection is the primary treatment, and SCSTs are generally confined to one ovary at the time of diagnosis. Moreover, most have an indolent growth pattern and low malignant potential. For these reasons, few patients ever require platinum-based chemotherapy. Although recurrent disease often responds poorly to treatment, patients may live for many years because of characteristically slow tumor progression.

The overall prognosis of ovarian SCSTs is excellent—primarily due to early-stage disease at diagnosis and curative surgery. The scarcity of these tumors, however, limits the understanding of their natural history, treatment, and prognosis.

■ Epidemiology

SCSTs account for 3 to 5 percent of ovarian malignancies (Ray-Coquard, 2014). These tumors are more than twice as likely to develop in black women for reasons that are unclear (Quirk, 2005). In contrast with epithelial ovarian cancers or malignant germ cell tumors, ovarian SCSTs typically affect women of all ages. This range contains a unique bimodal distribution that reflects inherent tumor heterogeneity. For example, juvenile granulosa cell tumors, Sertoli-Leydig cell tumors, and sclerosing stromal tumors are found predominantly in prepubertal girls and women within the first three decades of life (Schneider, 2005). Adult granulosa cell tumors commonly develop in older women, at an average age in the mid-50s (van Meurs, 2013).

There are no proven risk factors for SCSTs. However, in a hypothesis-generating case-control study, Boyce and coworkers (2009) observed that obesity as a hyperestrogenic state was independently associated, whereas parity, smoking, and oral contraceptive use were protective.

The etiology of SCSTs is largely unknown. However, a single, recurrent *FOXL2* gene mutation (402C>G) is present in virtually all adult-type granulosa cell tumors. Thus, mutant *FOXL2* appears to be a highly specific event in the pathogenesis of these rare tumors (Schrader, 2009; Shah, 2009). The other major finding is that women with a germline *DICER1* mutation are predisposed to developing SCSTs (Heravi-Moussavi, 2012). Otherwise, there is no known inherited predisposition for the development of these tumors, and familial cases are rare (Stevens, 2005). However, ovarian SCSTs do develop in association with several defined hereditary disorders at a frequency that exceeds mere chance. Associated disorders include Ollier disease, which is characterized by multiple benign but disfiguring cartilaginous neoplasms, and Peutz-Jeghers syndrome, characterized by intestinal hamartomatous polyps (Stevens, 2005).

■ Diagnosis

Patient Findings

Isosexual precocious puberty is the presenting sign in more than 80 percent of prepubertal girls ultimately diagnosed with an ovarian SCST (Kalfa, 2005). Adolescents often report secondary amenorrhea. As a result, these young individuals presenting with endocrinologic symptoms tend to be diagnosed at earlier stages. Abdominal pain and distention are other common complaints in this age group (Schneider, 2003a).

In adult women, heavy, irregular bleeding and postmenopausal bleeding are the most frequent symptoms. In addition,

**TABLE 36-4.** Tumor Markers for Ovarian Sex Cord-Stromal Tumors with Malignant Potential

Granulosa cell tumors (adult and juvenile)	Inhibin A and B; estradiol (not as reliable)
Sertoli-Leydig cell tumors	Inhibin A and B; occasionally alpha-fetoprotein
Sex cord tumor with annular tubules	Inhibin A and B
Steroid cell tumors not otherwise specified	Steroid hormones elevated pretreatment

mild hirsutism that rapidly progresses to frank virilization should prompt evaluation to exclude these tumors. The classic presentation is a postmenopausal woman with rapidly evolving stigmata of androgen excess and a complex adnexal mass. Abdominal pain or a mass palpable by the patient herself are other telling signs and symptoms (Chan, 2005).

The size of SCSTs varies widely, but most women have a palpable abdominal or pelvic mass during examination regardless of their age. A fluid wave and other physical findings suggestive of advanced disease, however, are rare.

Laboratory Testing

Elevated circulating levels of testosterone or androstenedione or both are strongly suggestive of an ovarian SCST in a woman with signs and symptoms of virilization. Clinical hyperandrogenism is more likely to be idiopathic or related to polycystic ovarian syndrome, but serum testosterone levels > 150 g/dL or dehydroepiandrosterone sulfate (DHEAS) levels > 8000 g/L strongly suggest the possibility of an androgen-secreting tumor (Carmina, 2006). In most instances, tumor marker studies are not obtained preoperatively, because the diagnosis of ovarian SCST is often not suspected. When the diagnosis is confirmed, the appropriate tumor markers may be drawn during or following surgery (Table 36-4).

Imaging

The gross appearances of SCSTs range from large multicystic masses to small solid masses—effectively precluding a specific radiologic diagnosis. Granulosa cell tumors often sonographically demonstrate semisolid features but are not reliably discernible from epithelial tumors (Fig. 36-8) (Sharony, 2001). In addition, the endometrium may be thickened from increased tumor estrogen production. Although CT or MR imaging has been used to clarify indeterminate sonograms, there is no definitive radiologic study to diagnose these tumors (Jung, 2005).

Diagnostic Procedures

Patients with an ovarian mass suspicious for malignancy based on clinical and sonographic findings require surgical resection for definitive tissue diagnosis, staging, and treatment. Sonographically or CT-guided percutaneous biopsy has no role. Moreover, diagnostic laparoscopy or laparotomy with visual assessment of the adnexal mass alone is inadequate. Thus, excision and pathologic evaluation are necessary. Following removal, ovarian SCSTs can usually be distinguished histologically from germ cell tumors, epithelial ovarian cancers, or other

**FIGURE 36-8** Adult granulosa cell tumor. **A.** Abdominal sonography displays a large adnexal mass with solid and cystic areas. With application of color Doppler, thick vascular septa are seen. **B.** Computed tomographic (CT) scan of the same tumor. **C.** The tumor was opened after excision, and again its mixed architecture is noted. spindle-cell neoplasms by immunostaining for inhibin (Cathro, 2005; Schneider, 2005).

### ■ Role of the Generalist

Preoperatively, patients with a potentially malignant ovarian SCST are ideally referred to a gynecologic oncologist for evaluation. Most ovarian SCSTs, however, are diagnosed by generalist gynecologists following resection of a seemingly benign but complex mass in a woman with a CA125 level that is typically normal, if known beforehand. The initial surgery is often performed in a community-based hospital and without adequate staging. In this setting, prior to referral, histologic results should be reviewed and confirmed by an experienced pathologist. Following referral to a gynecologic oncologist, surgical staging may be indicated.

### ■ Pathology

#### Classification

Ovarian SCSTs arise from sex cord and mesenchymal cells of the embryonic gonad (Chap. 18, p. 407). Granulosa and Sertoli cells develop from the sex cords and thus from the coelomic epithelium. In contrast, theca cells, Leydig cells, and fibroblasts are derived from the mesenchyme. The primitive gonadal stroma possesses sexual bipotentiality. Therefore, developing tumors may be composed of a male-directed cell type (Sertoli or Leydig cell) or a female-directed cell type (granulosa or theca cell). Although distinct categories of SCSTs have been defined, mixed tumors are relatively common (Table 36-5). For example, ovarian granulosa cell tumors may have admixed Sertoli components. Similarly, tumors that are predominantly Sertoli or

Sertoli-Leydig cells may contain minor granulosa cell elements. These mixed tumors are believed to arise from a common lineage with variable differentiation and do not represent two concurrent separate entities (McKenna, 2005; Vang, 2004).

### Histologic Grading

Ovarian granulosa cell tumors are universally considered to have malignant potential, but most other SCST subtypes do not have definitive criteria for clearly defining benign and malignant. Attempts to grade these tumors using nuclear characteristics or mitotic activity counts have produced inconsistent results (Chen, 2003).

### Patterns of Growth and Spread

The natural history of SCSTs in general differs greatly from that of epithelial ovarian carcinomas. For example, most of these tumors have low malignant potential. They are typically unilateral and remain localized, retain hormone-secreting functions, and infrequently relapse. Recurrences tend to be late and usually develop in the abdomen or pelvis (Abu-Rustum, 2006). Bone metastases are rare (Dubuc-Lissioir, 2001).

### Granulosa Cell Tumors

**Adult Granulosa Cell Tumors.** Seventy percent of ovarian SCSTs are granulosa cell tumors (Colombo, 2007). These tumors are formed by cells believed to arise from those surrounding the germinal cells within ovarian follicles. There are two clinically and histologically distinct types: the adult form, which makes up 95 percent of cases, and the juvenile type, accounting for 5 percent.

With adult granulosa cell tumor, most women are diagnosed after age 30, and the average age approximates 55 years. Heavy, irregular menstrual bleeding and postmenopausal bleeding are common and reflect prolonged exposure of the endometrium to estrogen. Related to this estrogen excess, coexisting pathology such as endometrial hyperplasia or adenocarcinoma has been found in 25 to 30 percent of patients with adult granulosa cell tumor (van

Meurs, 2013). Similarly, breast enlargement and tenderness are frequent associated complaints, and secondary amenorrhea has been reported (Kurihara, 2004). Alternatively, symptoms may stem from the mass of the ovary rather than from hormones produced (Ray-Coquard, 2014). An enlarging and potentially hemorrhagic tumor can cause abdominal pain and distention. Acute pelvic pain may suggest adnexal torsion, or tumor rupture with hemoperitoneum can mimic ectopic pregnancy.

During surgery, if an adult granulosa cell tumor is confirmed, tumor markers may be requested. Of these, inhibin B seems to be more accurate than inhibin A, frequently being elevated months before clinical detection of recurrence (Mom, 2007). The diagnostic value of these markers, however, is often hampered by their physiologically broad normal ranges (Schneider, 2005). Estradiol also has limited use in surveillance. This is particularly true for the younger patient wishing to preserve fertility and having the contralateral ovary left in situ.

Grossly, adult granulosa cell tumors are large and multicystic and often exceed 10 to 15 cm in diameter (see Fig. 36-8). The surface is frequently edematous and unusually adhered to other pelvic organs. For this reason, more extensive dissection is typically required than for epithelial ovarian cancers or malignant germ cell tumors. During excision, inadvertent rupture and intraoperative bleeding from the tumor itself is also common.

The interior of the tumor is highly variable. Solid components may predominate with large areas of hemorrhage and necrosis. Alternatively, it can be cystic, with numerous locules filled with serosanguinous or gelatinous fluid (Colombo, 2007). Microscopic examination shows predominately granulosa cells with pale, grooved, “coffee bean” nuclei. The characteristic microscopic feature is the *Call-Exner body*—a rosette arrangement of cells around an eosinophilic fluid space (Fig. 36-9).

Adult granulosa cell tumors are low-grade malignancies that typically demonstrate indolent growth. Ninety-five percent are unilateral, and 70 to 90 percent are stage I at diagnosis (Table 36-6). The 5-year survival for patients with stage I disease is 90 to 95 percent (Colombo, 2007; Zhang, 2007). However, 15 to

**FIGURE 36-9** Adult granulosa cell tumor. **A.** Cells are typically crowded and contain scant, pale cytoplasm. Their elongated nuclei may have a longitudinal fold or groove that gives them a “coffee bean” appearance. **B.** Call-Exner bodies are identified by their rosette appearance. **TABLE 36-6.** Stage and Survival of Common Ovarian Sex Cord-Stromal Tumors

	Adult Granulosa Cell	Sertoli-Leydig Cell
<b>Stage at diagnosis</b>		
I	70–90%	97%
II–IV	10–20%	2–3%
<b>Five-year survival</b>		
Stage I	90–95%	90–95%
Stage II–IV	30–50%	10–20%

Sources for survival figures are referenced within the text.

25 percent of stage I tumors will eventually relapse. The median time to recurrence is 5 to 6 years, but may be several decades (Abu-Rustum, 2006; East, 2005). Advantageously, these indolent tumors usually progress slowly thereafter, and the median length of survival after relapse is another 6 years. Advanced tumor stage and residual disease are poor prognostic factors (Al Badawi, 2002; Sehouli, 2004). Patients with stage II–IV tumors have a 5-year survival rate of 30 to 50 percent (Malmstrom, 1994; Miller, 1997; Piura, 1994). Cellular atypia and mitotic count may help in determining the prognosis but are difficult to reproducibly quantify (Miller, 2001).

**Juvenile Granulosa Cell Tumors.** These rare neoplasms develop primarily in children and young adults, and approximately 90 percent are diagnosed before puberty (Colombo, 2007). The mean age at diagnosis is 13 years, but patient ages range from newborn to 67 years (Young, 1984). Juvenile granulosa cell tumors are sometimes associated with Ollier disease or with Mafucci syndrome, which is characterized by endochondromas and hemangiomas (Young, 1984; Yuan, 2004).

In affected females, estrogen, progesterone, and testosterone levels may be elevated and lead to suppression of gonadotropins. As a result, menstrual irregularities or amenorrhea are common. Prepubertal girls typically display isosexual precocious puberty, which is characterized by breast enlargement and development of pubic hair, vaginal secretions, and other secondary sexual characteristics. These tumors infrequently secrete androgens, but in such cases may induce virilization. Despite these endocrinologic signs, a delayed diagnosis of juvenile granulosa cell tumors in pre- and postpubertal girls is common and associated with a higher risk of peritoneal tumor spread (Kalfa, 2005).

In addition to hormonal changes, individuals may display tumor effects. For example, older patients usually seek medical attention for abdominal pain or swelling. Preoperative rupture with resulting hemoperitoneum may create acute abdominal symptoms in 5 to 10 percent of cases (Colombo, 2007). Ascites is present in 10 percent (Young, 1984).

Juvenile granulosa cell tumors are grossly similar to the adult-type tumor and display variable solid and cystic components. They can attain significant size and have an average diameter of approximately 12 cm. Microscopically, cytologic features that distinguish these tumors from the adult type are their rounded, hyperchromatic nuclei without “coffee-bean”

grooves. Call-Exner bodies are rare, but often there is a theca cell component (Young, 1984).

Prognosis is excellent, and the 5-year survival rate is 95 percent. Similar to adult-type tumors, 95 percent of juvenile granulosa cell tumors are unilateral and stage I at diagnosis (Young, 1984). However, the juvenile type is more aggressive in advanced stages, and the time to relapse and death is much shorter. Recurrences typically develop within 3 years and are highly lethal. Later recurrences are unusual (Frausto, 2004).

### Thecoma-Fibroma Group

**Thecomas.** These are relatively common SCSTs and are rarely malignant. Thecomas are unique because they typically develop in postmenopausal women in their mid-60s and develop infrequently before age 30. These solid tumors are among the most hormonally active of the SCSTs and usually produce excess estrogen. As a result, the primary signs and symptoms are abnormal vaginal bleeding or pelvic mass or both. Many women also present with concurrent endometrial hyperplasia or adenocarcinoma (Aboud, 1997). These tumors are composed of lipid-laden stromal cells that are occasionally luteinized. Half of these luteinized thecomas are either hormonally inactive or androgenic with the potential for inducing masculinization.

Thecomas are solid tumors whose cells resemble the theca cells that normally surround the ovarian follicles (Chen, 2003). Because of this texture, these tumors appear sonographically as solid adnexal masses and may mimic extrauterine leiomyomas.

Bilateral ovarian involvement and extraovarian spread are rare. Fortunately, ovarian thecomas are clinically benign, and surgical resection is curative.

**Fibromas-Fibrosarcomas.** Fibromas are also relatively common, hormonally inactive SCST variants that usually occur in perimenopausal and menopausal women (Chechia, 2008). These solid, generally benign ovarian neoplasms arise from the spindled stromal cells that form collagen. Most fibromas are found incidentally during pelvic or sonographic examination. They are round, oval, or lobulated solid tumors associated with free fluid or less commonly, with frank ascites and possess minimal to moderate vascularization (Paladini, 2009).

Perhaps 1 percent of women present with *Meigs syndrome*, which is a triad of pleural effusion, ascites, and a solid ovarian mass (Siddiqui, 1995). Pleural effusions are usually right-sided, and these, as well as accompanying ascites, are typically transudative and resolve after tumor resection (Majzlin, 1964). Despite this association of ascites with benign fibromas, when ascites and a pelvic mass coexist, evaluation is based on an assumption of malignancy.

The prognosis following excision of fibromas is that for any benign tumor. However, 10 percent will demonstrate increased cellularity and varying degrees of pleomorphism and mitotic activity that indicate a tumor better characterized as having low malignant potential. In 1 percent of cases, malignant transformation to fibrosarcoma is found.

**Sclerosing Stromal Tumors.** These tumors are rare and account for less than 5 percent of SCSTs. The average patient age is approximately 20 years, and 80 percent develop before

age 30. Sclerosing stromal tumors are clinically benign and typically unilateral. Menstrual irregularities and pelvic pain are both frequent symptoms (Marelli, 1998). Ascites is seldom encountered (unlike fibromas), and sclerosing stromal tumors are hormonally inactive (unlike thecomas). Tumor size ranges from microscopic to 20 cm. Histologically, the presence of pseudolobulation of cellular areas separated by edematous connective tissue, increased vascularity, and prominent areas of sclerosis are distinguishing features.

### Sertoli-Stromal Cell Tumors

**Sertoli Cell Tumors.** Ovarian Sertoli cell tumors are rare and account for less than 5 percent of all SCSTs. The mean patient age at diagnosis is 30 years, but ages range from 2 to 76 years. One quarter of patients present with estrogenic or androgenic manifestations, but most tumors are clinically nonfunctional.

Sertoli cell tumors are typically unilateral, solid, and yellow and measure 4 to 12 cm in diameter. Derived from the cell type that gives rise to the seminiferous tubules, these tumor cells often organize into histologically characteristic tubules (Young, 2005). Sertoli cell tumors, however, may also mimic many different tumors, and immunostaining in these cases is invaluable to confirm the diagnosis.

More than 80 percent are stage I at diagnosis, and most are clinically benign. Moderate cytologic atypia, brisk mitotic activity, and tumor cell necrosis are indicators of greater malignant potential and are found in 10 percent of individuals with stage I disease and most of those with stage II-IV tumors. The risk of recurrence is higher when these features are identified (Oliva, 2005).

**Sertoli-Leydig Cell Tumors.** Sertoli-Leydig cell tumors comprise only 5 to 10 percent of ovarian SCSTs (Zhang, 2007). Their incidence mirrors that of Sertoli cell tumors, and the average age is 25 years. Although Sertoli-Leydig cell tumors have been identified in children and postmenopausal females, more than 90 percent develop during the reproductive years.

These tumors frequently produce sex-steroid hormones, most commonly androgens. As a result, frank virilization develops in one third of affected women, and another 10 percent have clinical manifestations of androgen excess (Young, 1985). Menstrual disorders are also common. Accordingly, Sertoli-Leydig cell tumors are suspected preoperatively in a patient with a unilaterally palpable adnexal mass and with androgenic manifestations. For these women, an elevated serum testosterone-to-androstenedione ratio further suggests the diagnosis.

Although these hormonal effects frequently develop, one half of patients will have nonspecific abdominal mass symptoms as their only presenting complaint. Associated ascites is infrequent (Outwater, 2000). Thyroid abnormalities also coexist with Sertoli-Leydig cell tumors at a frequency that exceeds mere chance.

These tumors tend to be large at the time of excision with an average diameter greater than 10 cm, but ranges from 1 to 50 cm have been reported. In most cases, Sertoli-Leydig cell tumors appear yellow and lobulated. Tumors can be solid, partially cystic, or completely cystic, and they may or may not have polypoid or vesicular structures in their interior (Fig. 36-10).

**FIGURE 36-10** Sertoli-Leydig cell tumor (SLCT). **A.** SLCTs show variable gross features depending on the degree of differentiation and presence of heterologous elements. This opened surgical specimen has a predominantly solid cut surface with focal cysts, variegated yellow-brown color, and foci of hemorrhage. **B.** Well-differentiated SLCT composed of hollow tubules admixed with clusters of mature Leydig cells. **C.** This intermediate-differentiated SLCT contains solid tubules, which are thought to resemble those of the fetal testis. (Used with permission from Dr. Katja Gwin.)

Microscopically, these morphologically diverse tumors contain cells resembling epithelial and stromal testicular cells in varying proportions. The five subtypes of differentiation (well, intermediate, poor, retiform, and heterologous) have considerable overlap. Well-differentiated tumors are all clinically benign (Chen, 2003; Young, 2005).

Overall, 15 to 20 percent of Sertoli-Leydig cell tumors are clinically malignant. Prognosis depends predominantly on the stage and degree of tumor differentiation in these malignant variants. For example, Young and Scully (1985) performed a clinicopathologic analysis of 207 cases and identified stage I disease in 97 percent. The 5-year survival rate for patients with stage I disease exceeds 90 percent (Zaloudek, 1984). Malignant features were observed in approximately 10 percent of tumors with intermediate differentiation and in 60 percent of poorly differentiated tumors. Retiform and heterologous elements are seen only in intermediate or poorly differentiated Sertoli-Leydig cell tumors and typically are associated with poorer prognosis. Overall, the 2 to 3 percent of patients with stage II-IV disease have a dismal prognosis (Young, 1985).

### Sex Cord Tumors with Annular Tubules

This tumor accounts for 5 percent of SCSTs and is characterized by ring-shaped tubules and distinctive cellular elements that are histologically intermediate between Sertoli-cell and granulosa cell tumors. There are two clinically distinct types. One third are clinically benign and develop in patients with Peutz-Jeghers syndrome (PJS). These tumors are typically small, multifocal, calcified, bilateral, and diagnosed incidentally. Fifteen percent of PJS-associated cases will also develop adenoma malignum of the cervix, which is a rare, extremely well-differentiated adenocarcinoma. In contrast, two thirds of tumors are not associated with PJS. These masses are usually larger, unilateral, and symptomatic and carry a clinical malignancy rate of 15 to 20 percent (Young, 1982).

### Steroid Cell Tumors

Fewer than 5 percent of SCSTs are steroid cell tumors. The average age at diagnosis is the mid-20s, but patients can present at virtually any age. These tumors are composed entirely or predominantly of cells that resemble steroid hormone-secreting cells and are categorized according to the histologic composition of these cells.

*Stromal luteomas* are clinically benign tumors that by definition lie completely within the ovarian stroma. They are usually seen in postmenopausal women. Estrogenic effects are common, but occasional individuals have androgenic manifestations.

*Leydig cell tumors* are also benign and typically are seen in postmenopausal women. They are distinguished microscopically by rectangular, crystal-like cytoplasmic inclusions, termed crystals of Reinke. Leydig cells secrete testosterone, and these tumors are usually associated with androgenic effects.

*Steroid cell tumors not otherwise specified (NOS)* are the most common subtype within this group and typically present in younger reproductive-aged women. Some of these cases may represent large stromal luteomas that have grown to reach the ovarian surface or Leydig-cell tumors in which Reinke crystals cannot be identified. These tumors are typically associated

with androgen excess, but estrogen or cortisol overproduction (i.e., Cushing syndrome) has also been reported. One third of steroid cell tumors NOS are clinically malignant and have a dismal prognosis (Oliva, 2005).

### Unclassified Sex Cord-Stromal Tumors

Unclassified tumors account for 5 percent of SCSTs and have no clearly predominant pattern of testicular (Sertoli cells) or ovarian (granulosa cells) differentiation. These ill-defined tumors are especially common during pregnancy due to alterations in their usual clinical and pathologic features (Young, 2005). They may be estrogenic, androgenic, or nonfunctional. The prognosis is similar to that of granulosa cell tumors and Sertoli-Leydig cell tumors of similar degrees of differentiation.

### Gynandroblastomas

These are the rarest type of ovarian SCST. Patients present at a mean age of 30 years and typically have menstrual irregularities or evidence of hormonal excess. The tumors are characterized by intermingled granulosa cells and tubules of Sertoli cells. Theca or Leydig cells or both may also be present in varying degrees. Gynandroblastomas have low malignant potential, and only one death has been reported (Martin-Jimenez, 1994).

## ■ Treatment

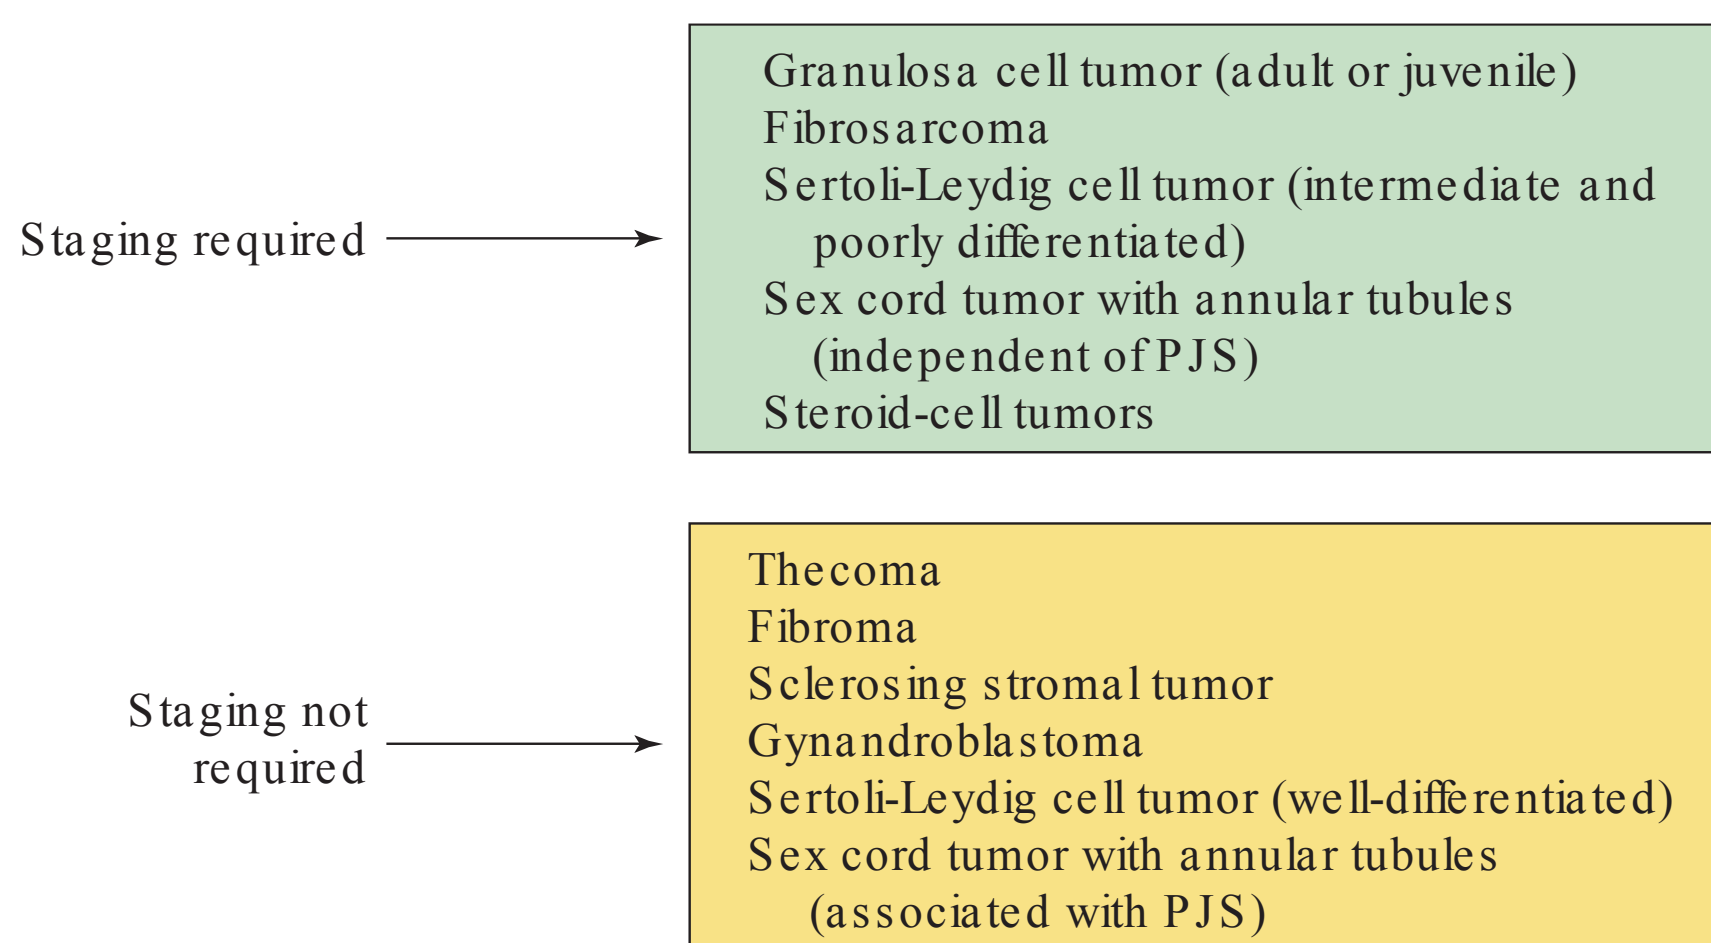

### Surgery

The mainstay of treatment for patients with an ovarian SCST is complete surgical resection. This group shows relative insensitivity to adjuvant chemotherapy or radiation. Thus, operative goals are to establish a definitive tissue diagnosis, determine the extent of disease, and also remove all grossly visible tumors in those infrequent patients with advanced-stage disease. Moreover, during preoperative planning, clinicians should consider the patient's age and desire for future fertility. Hysterectomy with BSO is performed for those who have completed childbearing, whereas fertility-sparing USO with preservation of the uterus and remaining ovary may be appropriate in the absence of obvious disease spread to these organs (Zanagnolo, 2004). Endometrial sampling is performed, especially if fertility-sparing surgery is planned in women with granulosa cell tumors or thecomas. This is because many of these patients will have coexisting endometrial hyperplasia or adenocarcinoma that may affect the decision for hysterectomy.

Minimally invasive laparoscopic surgery has a variety of relevant applications. For some, the diagnosis of SCST may not be discovered until the mass is laparoscopically removed and sent for frozen section analysis. Laparoscopic surgical staging can then proceed. When the diagnosis is not made until the final pathology report is confirmed postoperatively, laparoscopic staging may be proposed to determine whether metastatic disease is present. This can reduce the morbidity of a second operation (Shim, 2013).

Surgical staging is essential to determine the extent of disease and the need for adjuvant therapy in most individuals with potentially malignant SCST subtypes (Fig. 36-11). That said, only approximately 20 percent of cases have complete staging (Abu-Rustum, 2006; Brown, 2009). More recent data suggest

**FIGURE 36-11** Staging of sex cord-stromal tumors. PJS = Peutz-Jeghers syndrome.

that, due to surface and hematogenous routes of spread, the standard ovarian cancer procedure can be modified. Pelvic washings, exploration of the abdomen, peritoneal biopsies, and partial omentectomy remain important. However, the utility of routine pelvic and paraaortic lymphadenectomy has been increasingly challenged. In a study of 262 ovarian SCSTs, none of the 58 patients undergoing nodal dissection had positive nodes (Brown, 2009). Additionally, performing a lymphadenectomy has not been shown to improve survival rates in those with SCSTs (Chan, 2007).

Surgical removal of hormone-producing SCSTs results in an immediate drop in elevated preoperative sex-steroid hormone levels. Physical manifestations of these elevated levels, however, partially or completely resolve more gradually.

### Surveillance

In general, women with stage I ovarian SCSTs have an excellent prognosis following surgery alone and usually can be followed at regular intervals without the need for further treatment (Schneider, 2003a). Surveillance includes a general physical and pelvic examination, serum marker level testing, and imaging as clinically indicated.

### Chemotherapy

The decision to administer postoperative therapy depends on various factors (Fig. 36-12). Although typically treated solely with surgery, malignant stage I ovarian SCSTs may require adjuvant chemotherapy when large tumor size, high mitotic index, capsular excrescences, tumor rupture, incomplete staging, or equivocal pathology results are noted. Women with one or more of these suspicious features are thought to be at higher risk of relapse and are considered for platinum-based chemotherapy (Schneider, 2003b). In addition,

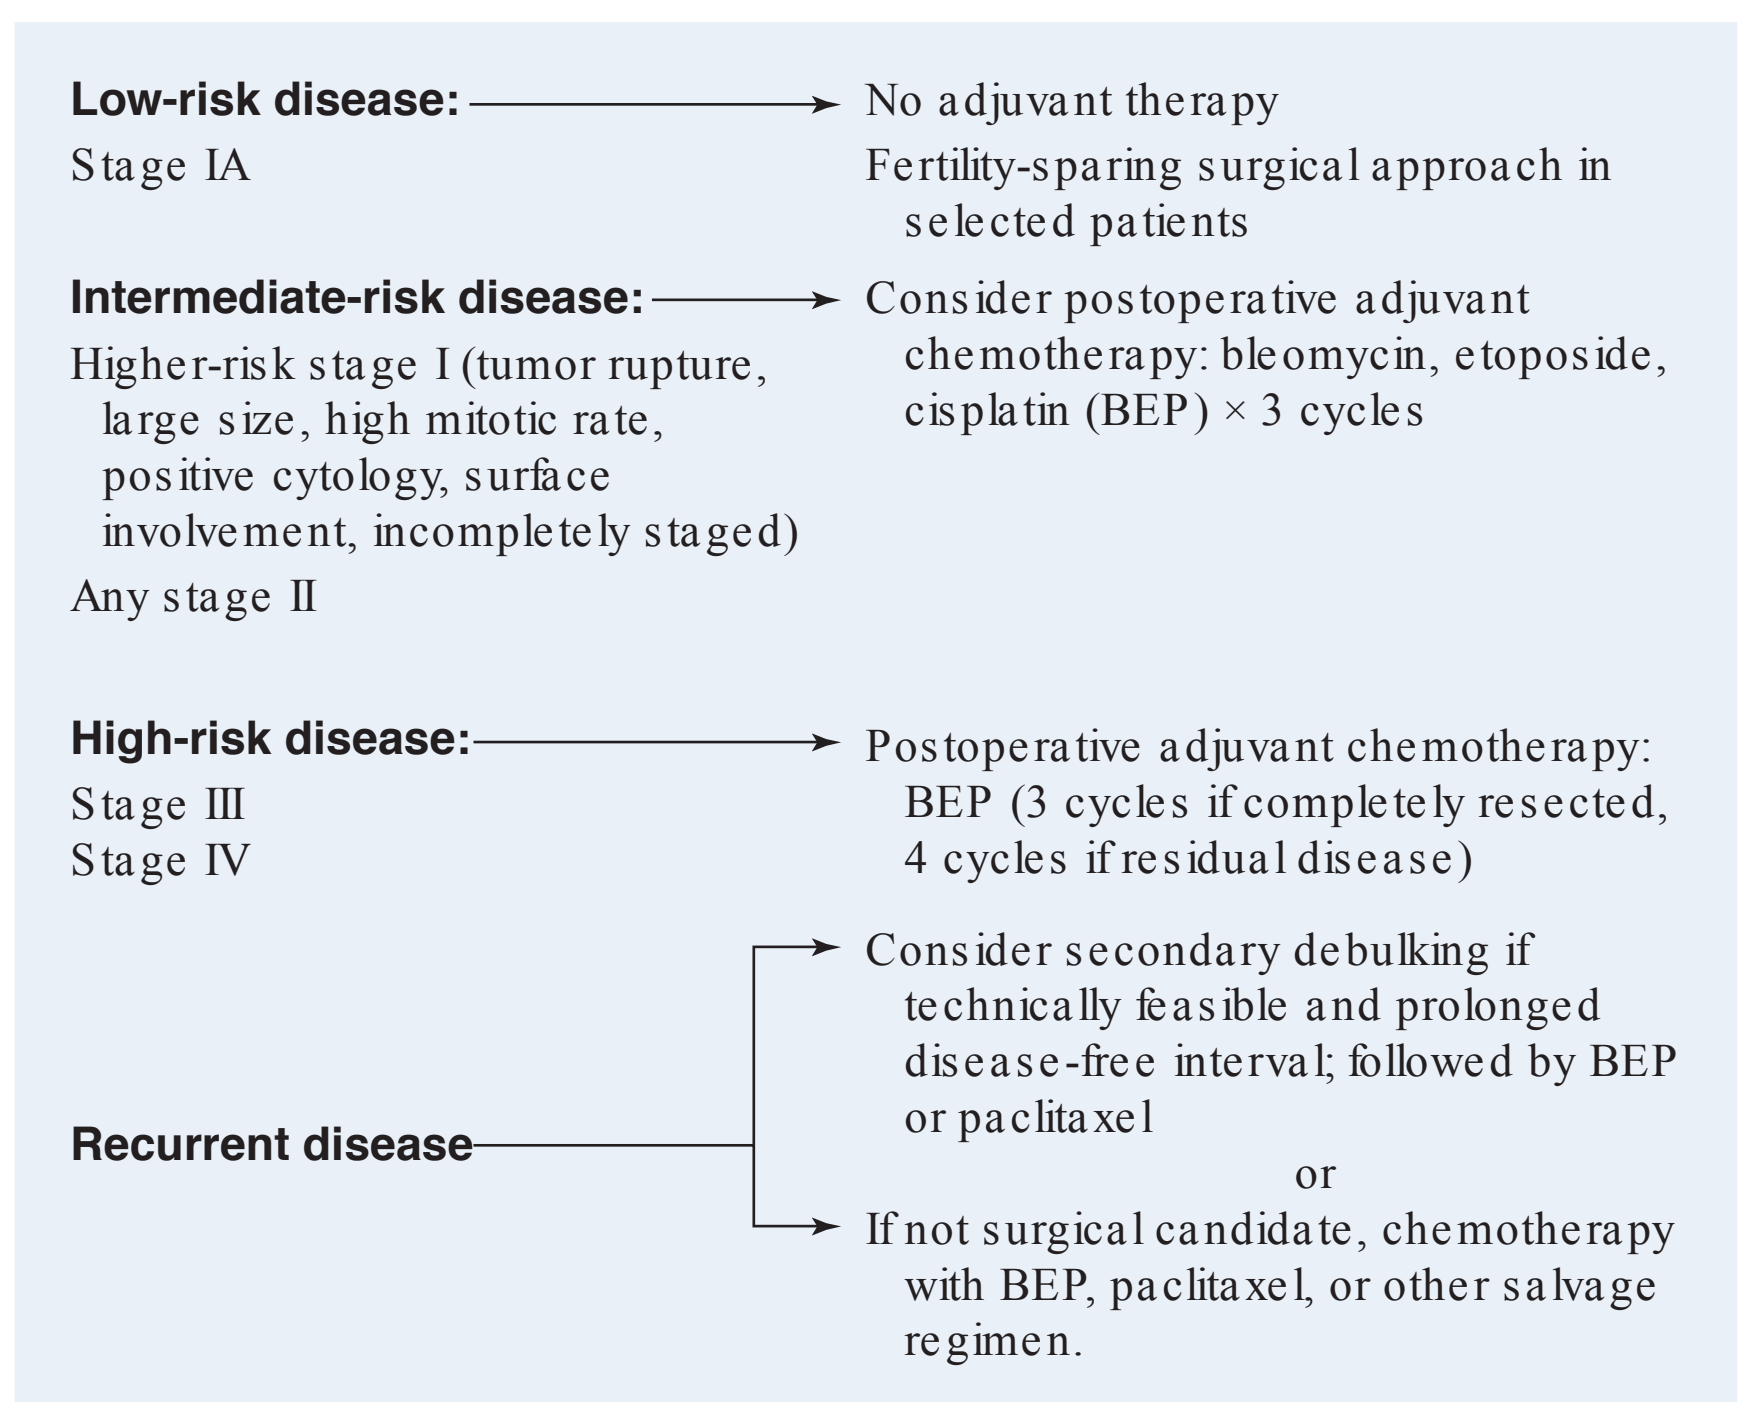

stage II-IV disease warrants postoperative treatment. In general, SCSTs display less sensitivity to chemotherapy than other ovarian malignancies, but most women at high risk for disease progression can be treated successfully with adjuvant platinum-based chemotherapy (van Meurs, 2014).

The 5-day bleomycin, etoposide, and cisplatin (BEP) regimen is the most widely used first-line chemotherapy combination (Gershenson, 1996; Homesley, 1999). For completely resected disease, three courses given every 3 weeks are sufficient. Four cycles are recommended for patients with incompletely resected tumor (Homesley, 1999). In addition to BEP, taxanes have demonstrated activity against ovarian SCSTs, and combination paclitaxel and carboplatin

chemotherapy shows promising results (Brown, 2004, 2005). To determine the most effective regimen, a prospective randomized study is currently underway, comparing paclitaxel and carboplatin to BEP in those with newly diagnosed ovarian SCSTs (GOG protocol #264). Unfortunately, the relative scarcity of women who have ovarian SCST and receive chemotherapy limits the ability to conduct large randomized studies.

### Radiation

Postoperative radiation therapy currently has a limited role in the management of ovarian SCSTs. There is some evidence indicating a prolonged survival in at least some women with newly diagnosed disease who received whole-abdominal radiotherapy (Wolf, 1999). However, chemotherapy is usually the

**FIGURE 36-12** Postoperative treatment of sex cord-stromal tumors.

primary postoperative treatment because it is generally better tolerated, more widely accessible, and easier to administer. Radiation is best reserved for palliation of local symptoms (Dubuc-Lissoir, 2001).

## Relapse

The management of recurrent ovarian SCST depends on the clinical circumstances. Secondary surgical debulking is strongly considered due to the indolent growth pattern, the typically long disease-free interval after initial treatment, and the inherent insensitivity to chemotherapy (Crew, 2005; Powell, 2001). Platinum-based combination chemotherapy is the primary treatment chosen for recurrent disease with or without surgical debulking (Uygun, 2003). Of regimens, BEP is most frequently administered because it has the highest known response rate (Homesley, 1999). Paclitaxel is another promising agent that was evaluated as a single agent in a phase II Gynecologic Oncology Group trial (GOG protocol #187).

There is no standard treatment for women who have progressive disease despite aggressive surgery and platinum-based chemotherapy. Bevacizumab (Avastin) demonstrated a 17-percent response rate in a Phase II trial (GOG protocol #251) (Brown, 2014a). Vincristine, actinomycin D, and cyclophosphamide (VAC) regimen has limited activity (Ayhan, 1996; Zanagnolo, 2004). Hormonal therapy is minimally toxic, but the clinical experience with this approach is extremely limited (Hardy, 2005). Medroxyprogesterone acetate and the gonadotropin-releasing hormone (GnRH) agonist leuprolide acetate (Lupron) have each demonstrated activity in halting the growth of recurrent ovarian SCSTs (Fishman, 1996; Homesley, 1999). GnRH antagonists, however, may not be as effective (Ameryckx, 2005).

In addition to traditional drugs, discovery of the *FOXL2* 402C>G mutation occurring exclusively in all adult granulosa cell tumors may lead to the development of targeted therapies for women with advanced or recurrent disease. Currently, *FOXL2* as a transcription factor does not represent a pharmacologic target. Further insights into its function and downstream effects may identify molecular alterations in these tumors that can be targeted (Kobel, 2009).

## Prognosis

In general, ovarian SCSTs portend a much better prognosis than epithelial ovarian carcinomas chiefly because most women with SCSTs are diagnosed with stage I disease. Stage II-IV tumors are rare, but women with these cancers have a poor prognosis similar to their counterparts with epithelial disease. Unfortunately, improvements in survival rates have not been observed in ovarian SCSTs during the past few decades (Chan, 2006).

Of the clinical factors affecting prognosis, surgical stage and residual disease are the most important (Lee, 2008; Zanagnolo, 2004). Further, in a Surveillance, Epidemiology and End Results (SEER) database study, Zhang and colleagues (2007) performed a multivariate analysis of 376 women with SCSTs. They concluded that age younger than 50 years was also an independent predictor of an improved survival rate.

## Management During Pregnancy

Ovarian SCSTs are rarely detected during pregnancy (Okada, 2004). In a California population-based study of more than 4 million obstetric patients, one granulosa cell tumor was diagnosed among 202 women with an ovarian malignancy (Leiserowitz, 2006). Granulosa cell tumors are most common, but only 10 percent are diagnosed during pregnancy (Hasiakos, 2006). One third of pregnant women with SCSTs are incidentally diagnosed at cesarean delivery, one third has abdominal pain or swelling, and the remainder may present with hemoperitoneum, virilization, or vaginal bleeding (Young, 1984). Surgical management should be the same as for the nonpregnant woman. For most, conservative management with USO and staging is the primary procedure, but hysterectomy and BSO may be indicated in selected circumstances (Young, 1984). Postoperative chemotherapy is typically withheld until after delivery because SCSTs have an indolent growth pattern.

REFERENCES . . . . . 791

*Gestational trophoblastic disease (GTD)* refers to a spectrum of interrelated but histologically distinct tumors originating from the placenta (Table 37-1). These diseases are characterized by a reliable tumor marker, which is the  $\beta$ -subunit of human chorionic gonadotropin ( $\beta$ -hCG), and have varied tendencies for local invasion and spread.

*Gestational trophoblastic neoplasia (GTN)* refers to the subset of GTD that develops malignant sequelae. These tumors require formal staging and typically respond favorably to chemotherapy. Most commonly, GTN develops after a molar pregnancy but may follow any gestation. The prognosis for most GTN cases is

excellent, and patients are routinely cured, even with widespread metastases. The outlook for preservation of fertility and for successful subsequent pregnancy outcomes is equally bright (Vargas, 2014; Wong, 2014). Accordingly, although GTD is uncommon, because the opportunity for cure is great, clinicians should be familiar with its presentation, diagnosis, and management.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of GTD has remained fairly constant at approximately 1 to 2 per 1000 deliveries in North America and Europe (Drake, 2006; Loukovaara, 2005; Lybol, 2011). Although historically higher incidence rates have been reported in parts of Asia, some of this disparity may reflect discrepancies between population-based and hospital-based data collection (Chong, 1999; Kim, 2004; Matsui, 2003). Improved socioeconomic conditions and dietary changes may be partly responsible as well. That said, certain Southeast Asian populations as well as Hispanics and Native Americans living in the United States do have increased incidences (Drake, 2006; Smith, 2003; Tam, 2003).

Maternal age at the upper and lower extremes carries a higher risk of GTD (Altman, 2008; Loukovaara, 2005). This association is much greater for complete moles, whereas the risk of partial molar pregnancy varies relatively little with age. Moreover, compared with the risk in those aged 15 years or younger, the degree of risk is much greater for women 45 years (1 percent) or older (17 percent at age 50) (Savage, 2010; Sebire, 2002a). One explanation relates to ova from older women having higher rates of abnormal fertilization. Similarly, older paternal age has been associated with increased risk (La Vecchia, 1984; Parazzini, 1986).

A history of prior unsuccessful pregnancies also increases the risk of GTD. For example, previous spontaneous abortion at least doubles the risk of molar pregnancy (Parazzini, 1991). More significantly, a personal history of GTD increases the risk of developing a molar gestation in a subsequent pregnancy at least 10-fold. The frequency in a subsequent conception is approximately 1 percent, and most cases mirror the same type of mole as the preceding pregnancy (Garrett, 2008; Sebire, 2003). Furthermore, following two episodes of molar pregnancy, 23 percent of later conceptions result in another molar gestation (Berkowitz, 1998). For this reason, women with a prior history of GTD should undergo first-trimester sonographic examination in subsequent pregnancies. Familial molar pregnancies, however, are rare (Fallahian, 2003).

Of other risk factors, combination oral contraceptive (COC) pill use has been associated with an increased risk of GTD. Specifically, prior COC use approximately doubles the risk, and longer duration of use also correlates positively with risk (Palmer, 1999; Parazzini, 2002). Moreover, women who

**FIGURE 37-1** **A.** Complete hydatidiform mole. These moles classically have swollen enlarged villi, some of which show cistern formation, that is, central cavitation within the large villi (black asterisks). Seen diffusely throughout the placenta, these villous changes create the vesicles noted grossly in complete moles (see Fig. 37-3). Complete moles also typically show trophoblastic proliferation (yellow asterisk), which may be focal or widespread. (Used with permission from Dr. Erika Fong.) **B.** Normal term placenta showing smaller, nonedematous villi and absence of trophoblastic proliferation. (Used with permission from Dr. Kelley Carrick.)

used COCs during the cycle in which they conceived have a higher risk in some but not all studies (Costa, 2006; Palmer, 1999). Many of these associations, however, are weak and could be explained by confounding factors other than causality (Parazzini, 2002).

Some epidemiologic characteristics differ markedly between complete and partial moles. For example, vitamin A deficiency and low dietary intake of carotene are associated only with an increased risk of complete moles (Berkowitz, 1985, 1995; Parazzini, 1988). Partial moles have been linked to higher educational levels, smoking, irregular menstrual cycles, and obstetric histories in which only male infants are among the prior live births (Berkowitz, 1995; Parazzini, 1986).

**HYDATIDIFORM MOLE  
(MOLAR PREGNANCY)**

Hydatidiform moles are abnormal pregnancies characterized histologically by aberrant changes within the placenta. Classically, the chorionic villi in these placenta show varying

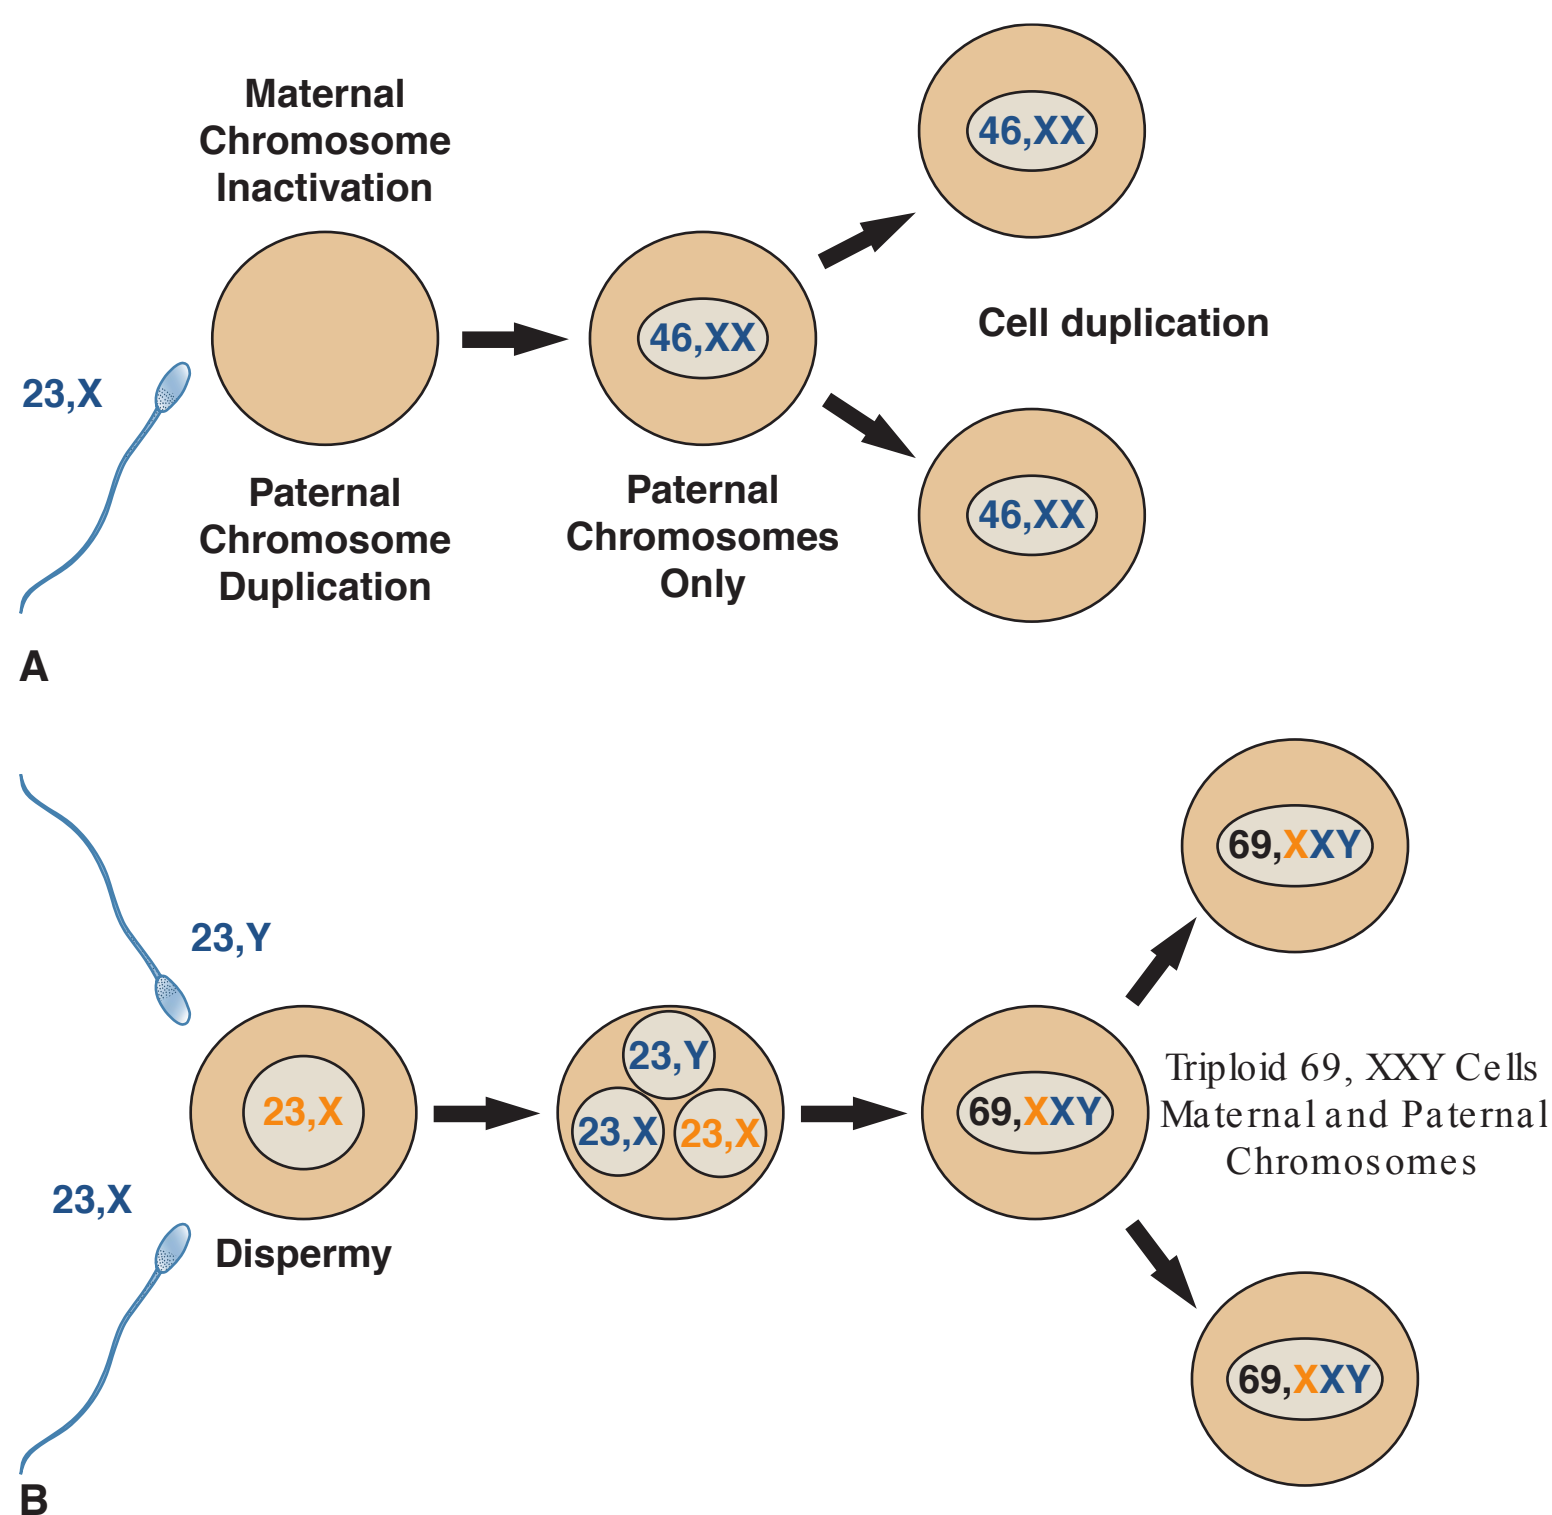

degrees of trophoblast proliferation and edema of the stroma within villi (Fig. 37-1). Hydatidiform moles are categorized as either *complete hydatidiform moles* or *partial hydatidiform moles* (Table 37-2). Chromosomal abnormalities play an integral role in hydatidiform mole development.

**Complete Hydatidiform Mole**

These molar pregnancies differ from partial moles with regard to their karyotype, their histologic appearance, and their clinical presentation. First, complete moles typically have a diploid karyotype, and 85 to 90 percent of cases are 46,XX. The chromosomes, however, in these pregnancies are entirely of paternal origin, and thus, the diploid set is described as *diandric*. Specifically, complete moles are formed by *androgenesis*, in which the ovum is fertilized by a haploid sperm that then duplicates its own chromosomes after meiosis (Fig. 37-2) (Fan, 2002; Kajii, 1977). The ovum fails to contribute chromosomes. Most of these moles are 46,XX, but dispermic fertilization of a single ovum, that is, simultaneous fertilization by two sperm, can produce a 46,XY karyotype (Lawler, 1987). Although

TABLE 37-2. Features of Hydatidiform Moles		
Feature	Complete Mole	Partial Mole
<b>Karyotype</b>	46,XX or 46,XY	69,XXX or 69,XXY
<b>Pathology</b>		
Fetus/embryo	Absent	Present
Villous edema	Diffuse	Focal
Trophoblastic proliferation	Can be marked	Focal and minimal
p57Kip2 immunostaining	Negative	Positive
<b>Clinical presentation</b>		
Typical diagnosis	Molar gestation	Missed abortion
Postmolar malignant sequelae	15%	4–6%

**FIGURE 37-2** **A.** A 46,XX complete mole may be formed if a 23,X-bearing haploid sperm penetrates a 23,X-containing haploid egg whose genes have become “inactive.” Paternal chromosomes then duplicate to create a 46,XX diploid chromosomal complement solely of paternal origin. Alternatively, this same type of inactivated egg can be fertilized independently by two sperm, either 23,X- or 23,Y-bearing, to create a 46,XX or 46,XY chromosomal complement, again of paternal origin only. **B.** Partial moles may be formed if two sperm, either 23,X- or 23,Y-bearing, both fertilize a 23,X-containing haploid egg, whose genes have not been inactivated. The resulting fertilized egg is triploid. Alternatively, a similar haploid egg may be fertilized by an unreduced diploid 46,XY sperm.

nuclear DNA is entirely paternal, mitochondrial DNA remains maternal in origin (Azuma, 1991).

Microscopically, complete moles display enlarged, edematous villi and abnormal trophoblastic proliferation. These changes diffusely involve the entire placenta (see Fig. 37-1). Macroscopically, these changes transform the chorionic villi into clusters of vesicles with variable dimensions. Indeed, the name *hydatidiform mole* literally stems from this “bunch of grapes” appearance. In these pregnancies, no fetal tissue or amnion is produced. As a result, this mass of placental tissue completely fills the endometrial cavity (Fig. 37-3).

Clinically, the presentation of a complete mole has changed considerably. In the 1960s and 1970s, more than half of affected patients had anemia and uterine sizes in excess of that predicted for their gestational age. In addition, hyperemesis gravidarum, preeclampsia, and theca-lutein cysts developed in approximately one quarter of women (Soto-Wright, 1995). As described in Chapter 9 (p. 219), theca-lutein cysts develop with prolonged exposure to luteinizing hormone (LH) or  $\beta$ -hCG (Fig. 37-4). These cysts range in size from 3 to 20 cm, and most regress with falling  $\beta$ -hCG titers after molar evacuation. If such cysts are present, and especially if they are bilateral, the risk of postmolar GTN is increased.

Complete moles, however, infrequently present today with these traditional signs and symptoms (Mangili, 2008). As a result of  $\beta$ -hCG testing and sonography, the mean gestational age at evacuation currently approximates 12 weeks, compared with 16 to 17 weeks in the 1960s and 1970s (Drake, 2006; Soto-Wright, 1995). A large proportion of patients are asymptomatic at diagnosis (Joneborg, 2014). For the remainder, vaginal bleeding remains the most common presenting symptom, and  $\beta$ -hCG levels are often greater than expected. One quarter of women will present with uterine size greater than dates, but the incidence of anemia is less than 10 percent. Moreover, hyperemesis gravidarum, preeclampsia, and symptomatic theca-lutein cysts are now rare (Soto-Wright, 1995). Currently, these sequelae typically develop chiefly in patients without early prenatal care who present with a more advanced gestational age and markedly elevated serum  $\beta$ -hCG levels. Last, plasma thyroxine levels are often increased in women with complete moles, but clinical hyperthyroidism is infrequent. In these circumstances, serum free thyroxine levels are elevated as a consequence of the thyrotropin-like effect of  $\beta$ -hCG (Chap. 15, p. 335).

### ■ Partial Hydatidiform Mole

These moles differ from complete hydatidiform moles clinically, genetically, and histologically. The degree and extent of trophoblastic proliferation and villous edema are decreased compared with those of complete moles. Moreover, most partial moles contain fetal tissue and amnion, in addition to placental tissues.

As a result, patients with partial moles typically present with signs and symptoms of an incomplete or missed abortion. Many women will have vaginal bleeding. However, because trophoblastic proliferation is slight and only focal, uterine enlargement in excess of gestational

**FIGURE 37-3** Photograph of a complete hydatidiform mole. Note the grapelike fluid-filled clusters of chorionic villi. (Used with permission from Dr. Sasha Andrews.)

**FIGURE 37-4** Transvaginal sonogram of multiple theca-lutein cysts within one ovary of a woman with a complete molar pregnancy. Bilateral, multiple simple cysts are characteristic findings.

age is uncommon. Similarly, preeclampsia, theca-lutein cysts, hyperthyroidism, or other dramatic clinical features are rare. Preevacuation  $\beta$ -hCG levels are typically much lower than those for complete moles and often do not exceed 100,000 mIU/mL. For this reason, partial moles are often not identified until after a histologic review of a curettage specimen.

Partial moles have a triploid karyotype (69,XXX, 69,XXY, or less commonly 69,XYY) that is composed of one maternal and two paternal haploid sets of chromosomes (see Fig. 37-2) (Lawler, 1991). The coexisting fetus present with a partial mole is nonviable and typically has multiple malformations with abnormal growth (Jauniaux, 1999).

## ■ Diagnosis

### Clinical Assessment

In reproductive-aged women with vaginal bleeding, diagnoses may include gynecologic causes of bleeding and complications of first-trimester pregnancy. The trophoblast of molar pregnancies produce  $\beta$ -hCG, and elevated hormone levels reflect their proliferation. Accordingly, initial urine or serum  $\beta$ -hCG measurement and transvaginal sonography are invaluable in guiding evaluation. Because of these, first-trimester diagnosis of hydatidiform mole is now common.

Although  $\beta$ -hCG levels are helpful, the diagnosis of molar pregnancy is more frequently found sonographically. Most first-trimester complete moles demonstrate a complex, echogenic, intrauterine mass containing many small cystic spaces, which reflect swollen chorionic villi. Fetal tissues and amniotic sac are absent (Fig. 37-5) (Benson, 2000). In contrast, sonographic features of a partial molar pregnancy include a thickened, hydropic placenta with a concomitant fetus (Zhou, 2005).

However, there are diagnostic limitations. For example,  $\beta$ -hCG levels in early molar pregnancies may not always be elevated in the first trimester (Lazarus, 1999). Moreover, sonography can lead to a false-negative diagnosis if performed at very early gestational ages, before the chorionic villi have attained their characteristic vesicular pattern. Studies show that only 20 to 30 percent of patients may have sonographic evidence to indicate a partial mole

**FIGURE 37-5** Transverse sonographic view of a uterus with a complete hydatidiform mole. The classic “snowstorm” appearance is created by the multiple placental vesicles. The mole completely fills this uterine cavity, and calipers are placed on the outer uterine borders.

(Johns, 2005; Lindholm, 1999; Sebire, 2001). Consequently, diagnosis in early gestations is usually difficult. Often, the diagnosis commonly is not made until after histologic review of the abortal specimen. In unclear cases with a live fetus and a desired pregnancy, fetal karyotyping to identify a triploid fetal chromosomal pattern can clarify the diagnosis and management.

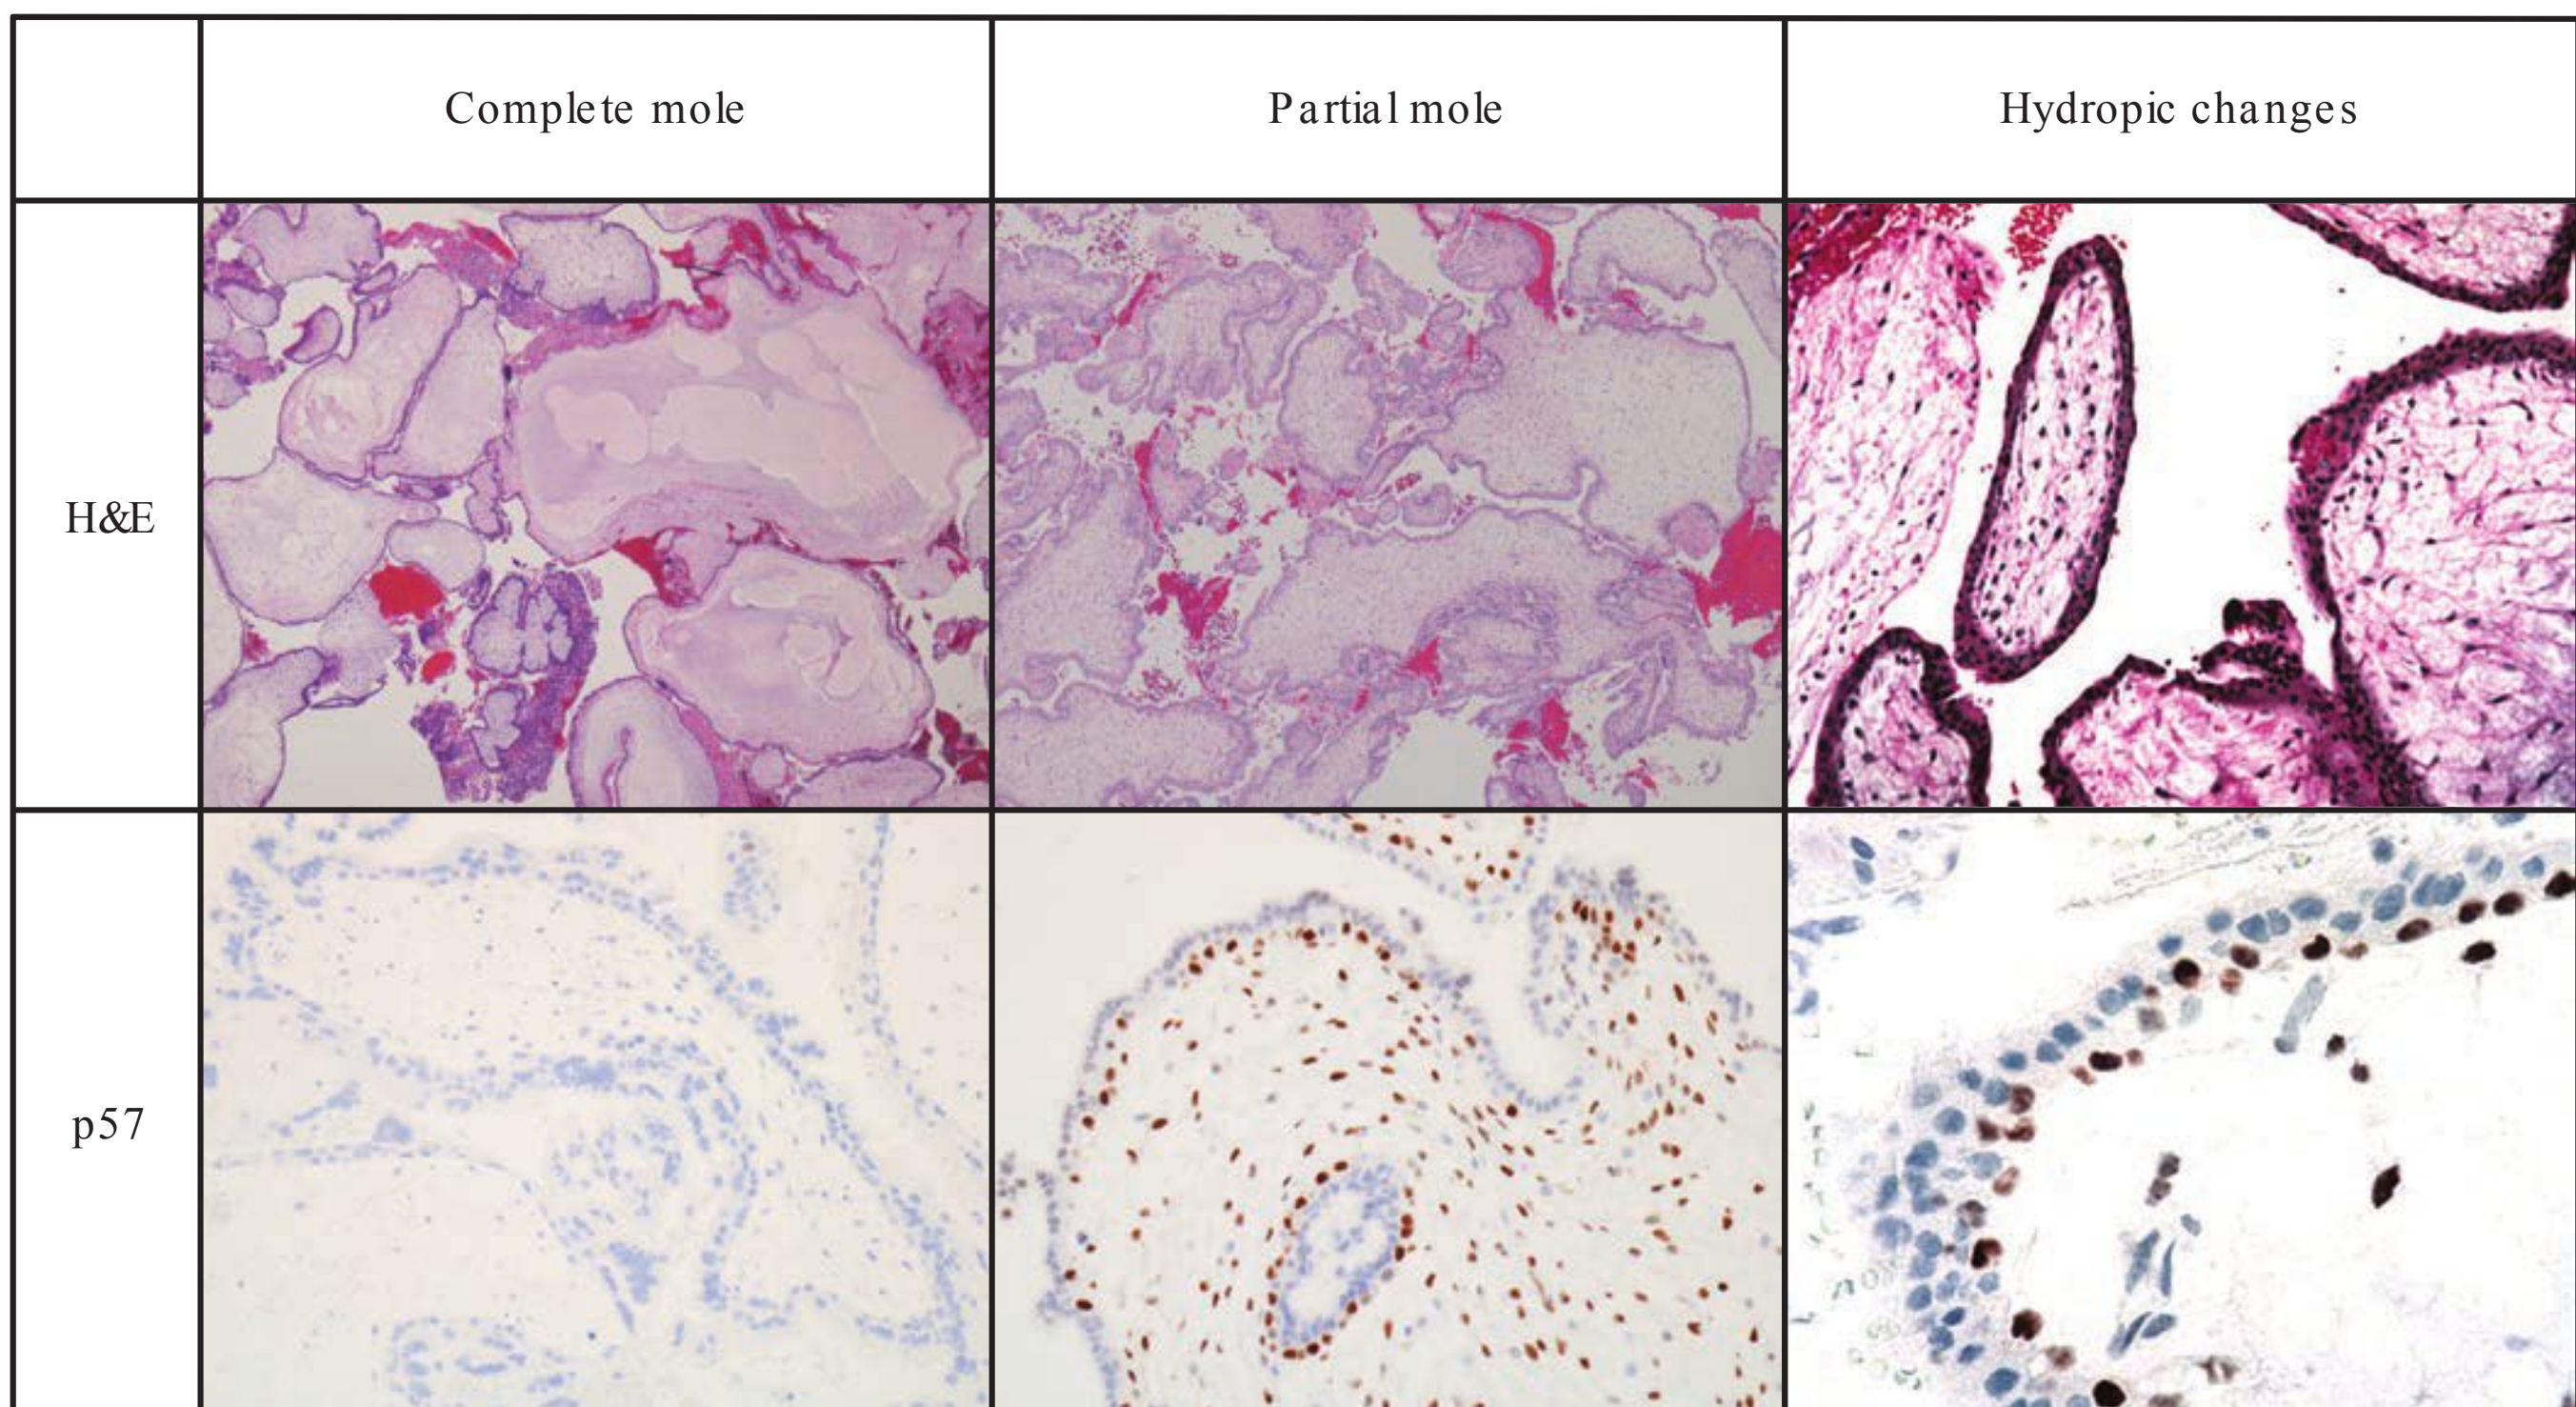

### Histopathology

The histopathologic changes typical of hydatidiform moles are listed in Table 37-2. But, in early pregnancy, it may be difficult to distinguish among these and a hydropic abortus. Hydropic abortuses are pregnancies formed by the traditional union of one haploid egg and one haploid sperm but are pregnancies that have failed. Their placentas display *hydropic degeneration*, in which villi are edematous and swollen, and thus mimic some villous features of hydatidiform moles (Fig. 37-6). Although no single criterion distinguishes these three, complete moles generally have two prominent features: (1) trophoblastic proliferation and (2) hydropic villi. In gestations younger than 10 weeks, however, hydropic villi may not be apparent, and molar stroma may still be vascular (Paradinas, 1997). As a result, identification of early complete moles must rely on more subtle histologic abnormalities, supplemented by immunohistochemical and molecular diagnostic techniques. Partial moles are optimally diagnosed when three or four major diagnostic criteria are demonstrated: (1) two populations of villi, (2) enlarged, irregular, dysmorphic villi (with trophoblast inclusions), (3) enlarged, cavitated villi ( $\geq 3$  to 4 mm), and (4) syncytiotrophoblast hyperplasia/atypia (Chew, 2000). Good diagnostic reproducibility can still be achieved in most circumstances using these histologic distinctions of complete and partial mole.

### Ancillary Techniques

Histopathologic evaluation can be enhanced by immunohistochemical staining for *p57* expression and by molecular genotyping. *p57KIP2* is a nuclear protein whose gene is paternally imprinted and maternally expressed. This means that the gene product is produced only in tissues containing a maternal

**FIGURE 37-6** Composite diagram of differences among normal hydropic abortuses and partial or complete hydatidiform moles. The first row shows typical appearances after hematoxylin and eosin (H&E) staining. The second row shows results after p57 staining. p57 is a nuclear protein whose gene product is produced only in tissues containing a maternal allele. After immunostaining for p57, note the positive (brown) staining in the villi of the partial hydatidiform mole and normal hydropic abortus. This contrasts to the absent staining for p57 in the complete mole (only blue counterstain is seen). (Used with permission from Drs. Kelley Carrick and Raheela Ashfaq.)

allele. Because complete moles contain only paternal genes, the p57KIP2 protein is absent in complete moles, and tissues do not pick up this stain (Merchant, 2005). In contrast, this nuclear protein is strongly expressed in normal placentas, in spontaneous pregnancy losses with hydropic degeneration, and in partial hydatidiform moles (Castrillon, 2001). Accordingly, immunostaining for p57KIP2 is an effective means to isolate complete mole from the diagnostic list. For distinction of a partial mole from a nonmolar hydropic abortus, both of which express p57, molecular genotyping can be used. Molecular genotyping determines the parental source of polymorphic alleles. Thereby, it can distinguish among a diploid diandric genome (complete mole), a triploid diandric-monogynic genome (partial mole), or biparental diploidy (nonmolar abortus) (Ronnett, 2011).

## ■ Treatment

Suction curettage is the preferred method of evacuation regardless of uterine size in patients who wish to remain fertile (American College of Obstetricians and Gynecologists, 2014; Tidy, 2000). Nulliparous women are not given prostanoids to ripen the cervix since these drugs can induce uterine contractions and might increase the risk of trophoblastic embolization to the pulmonary vasculature (Seckl, 2010). Hysterectomy is rarely recommended unless the patient wishes surgical sterilization or is approaching menopause (Elias, 2010). Symptomatic theca-lutein ovarian cysts are an unusual finding and tend to regress after molar evacuation. In extreme cases, these may be aspirated, but oophorectomy is not performed except when torsion leads to extensive ovarian infarction (Mungan, 1996).

Prior to surgery, patients are evaluated for associated medical complications. Fortunately, thyroid storm from untreated hyperthyroidism, respiratory insufficiency from trophoblastic emboli, and other severe coexisting conditions are rare. Because of the tremendous vascularity of these placentas, blood products should be available prior to the evacuation of larger moles, and adequate infusion lines established.

At the beginning of the evacuation, the cervix is dilated to admit a 10- to 12-mm plastic suction curette. As aspiration of molar tissues ensues, intravenous oxytocin is given. At our institution, 20 units of synthetic oxytocin (Pitocin) are mixed with 1 L of crystalloid and infused at rates to achieve uterine contraction. In some cases, intraoperative sonography may be indicated to help reduce the risk of uterine perforation and assist in confirming complete evacuation. Finally, a thorough, gentle curettage is performed.

Following curettage, because of the possibility of partial mole and its attendant fetal tissue, Rh immune globulin is given to nonsensitized Rh D-negative women. Rh immune globulin, however, may be withheld if the diagnosis of complete mole is certain (Fung Kee, 2003).

## ■ Postmolar Surveillance

Gestational trophoblastic neoplasia develops after evacuation in 15 percent of patients with complete moles (Golfier, 2007; Wolfberg, 2004). Despite the trend of diagnosing these abnormal pregnancies at earlier gestational ages, this incidence has not declined (Seckl, 2004). Of those women who develop GTN, three quarters have locally invasive molar disease and the

remaining one quarter develop metastases. In contrast, GTN develops in only 4 to 6 percent of patients with partial moles following evacuation (Feltmate, 2006; Lavie, 2005). Malignant transformation into metastatic choriocarcinoma does occur after partial mole evacuation, but this is rare (0.1 percent) (Cheung, 2004; Seckl, 2000).

No pathologic or clinical features at presentation accurately predict which patients will ultimately develop GTN. Because of the trophoblastic proliferation that characterizes these neoplasms, serial serum  $\beta$ -hCG levels following molar evacuation can be used to effectively monitor patients for GTN development. Therefore, postmolar surveillance with serial quantitative serum  $\beta$ -hCG levels is the standard. Titers are monitored following uterine evacuation at least every 1 to 2 weeks until they become undetectable.

After undetectable  $\beta$ -hCG levels are achieved, subsequent monthly levels are drawn during 6 months of surveillance for all patients with a molar gestation (Sebire, 2007). However, poor compliance with prolonged monitoring has been reported—especially among indigent women and certain ethnic groups in the United States (Allen, 2003; Massad, 2000). A single blood sample demonstrating an undetectable level of  $\beta$ -hCG following molar evacuation is sufficient to exclude the possibility of progression to GTN in most patients. Thus, some women, especially those with a partial mole, may be safely discharged from routine surveillance once an undetectable value is achieved (Lavie, 2005; Wolfberg, 2004). Shortened surveillance could enable women to attempt a subsequent pregnancy sooner. However, GTN may still rarely develop after an hCG level has returned to normal, potentially leading to increased morbidity (Kerkmeijer, 2007; Sebire, 2007).

When pregnancies occur during the monitoring period, the resulting normal  $\beta$ -hCG production can hinder detection of postmolar progression to GTN (Allen, 2003). But other than complicating the monitoring schedule, these pregnancies fortunately are otherwise uneventful (Tuncer, 1999). To prevent difficulties with interpretation, women are encouraged to use effective contraception until achieving a  $\beta$ -hCG titer  $< 5$  mIU/mL or below the individual assay's threshold. COC use decreases the likelihood of pregnancy compared with less effective barrier contraception and does not increase the risk of GTN (Costa, 2006; Gafeld, 2009). Injectable medroxyprogesterone acetate is particularly useful when poor compliance is anticipated (Massad, 2000). In contrast, intrauterine devices are not inserted until the  $\beta$ -hCG level is undetectable because of the risk of uterine perforation if an invasive mole is present.

### ■ Prophylactic Chemotherapy

At the time of molar evacuation, chemotherapy can be administered to help prevent GTN development in high-risk patients who are unlikely to be compliant or for whom  $\beta$ -hCG surveillance is not available. In clinical practice, however, correctly categorizing a woman as high-risk for GTN development is difficult, as no combination of risk factors is universally accepted. Typical patients have complete moles and multiple risk factors, such as age  $> 40$  years, previous history of molar pregnancy, or

an excessively high  $\beta$ -hCG titer prior to evacuation. That said, few women are ultimately assigned to this group. Moreover, due to the risks of increased drug resistance, delayed treatment of GTN, and toxic side effects, this practice cannot currently be recommended (American College of Obstetricians and Gynecologists, 2014; Fu, 2012). Prophylactic chemotherapy is not routinely offered in the United States and Europe.

However, a single dose of dactinomycin has been shown to reduce the incidence of postmolar GTN in certain populations. For example, in one randomized trial, 60 Thai women who had high-risk complete moles were assigned to receive either prophylactic dactinomycin or placebo at the time of evacuation (Limpongsanurak, 2001). Adjuvant chemotherapy reduced the incidence of GTN from 50 percent to 14 percent, but toxicity was significant. As a result, prophylactic chemotherapy is generally used only in those countries with limited resources to reliably monitor patients after evacuation (Uberti, 2009).

### ■ Ectopic Molar Pregnancy

The true incidence of GTD developing outside the uterine cavity approximates 1.5 per 1 million births (Gillespie, 2004). More than 90 percent of suspected cases will reflect an overdiagnosis of florid extravillous trophoblastic proliferation in the fallopian tube (Burton, 2001; Sebire, 2005b). As with any ectopic pregnancy, initial management usually involves surgical removal of the conceptus and histopathologic evaluation.

### ■ Coexistent Fetus

At times, a twin pregnancy can consist of a hydatidiform mole and a coexisting fetus. The estimated incidence is 1 per 20,000 to 100,000 pregnancies (Fig. 37-7). Sebire and associates (2002b) described the outcome of 77 twin pregnancies, each composed of a complete mole and a healthy cotwin. Of this group, 24 women chose to have an elective termination, and 53 continued their pregnancies. Twenty-three gestations spontaneously aborted at less than 24 weeks, two were terminated due to severe preeclampsia, and 28 pregnancies lasted at least 24 weeks—resulting in 20 live births. The authors demonstrated that coexisting complete moles and healthy cotwin pregnancies have a high risk of spontaneous abortion, but approximately 40 percent result in live births. The risk of progression to GTN was 16 percent in first-trimester terminations and not significantly higher (21 percent) in women who continued their pregnancies. Because the risk of malignancy is unchanged with advancement of gestational age, pregnancy continuation may be allowed, provided that severe maternal complications are controlled and fetal growth is normal. Importantly, these cases should be distinguished early from a single partial molar pregnancy with its abnormal associated fetus. Fetal karyotyping to confirm a normal fetal chromosomal pattern is also recommended (Marcorelles, 2005; Matsui, 2000).

## GESTATIONAL TROPHOBLASTIC NEOPLASIA

This term primarily encompasses pathologic entities that are characterized by aggressive invasion of the endometrium and

**FIGURE 37-7** Photograph of placentas from a twin pregnancy with one normal twin and with a complete mole. The complete mole (left) shows the characteristic vesicular structure. The placenta on the right appears grossly normal. A transverse section through the border between these two is shown (inset). (Used with permission from Drs. April Bleich and Brian Levenson.)

myometrium by trophoblast cells. Histologic categories include common tumors such as the invasive mole and gestational choriocarcinoma, as well as the rare placental-site trophoblastic tumor and epithelioid trophoblastic tumor. Although these histologic types have been characterized, in most cases of GTN, no tissue is available for pathologic study. Instead, GTN is diagnosed based on elevated  $\beta$ -hCG levels and managed clinically.

Gestational trophoblastic neoplasia typically develops with or follows some form of pregnancy. Most cases follow a hydatidiform

mole. Rarely, GTN develops after a live birth, miscarriage, or termination. Occasionally, the antecedent gestation cannot be confirmed with certainty. Many of the reported nonmolar cases may actually represent disease originating from an unrecognized early mole (Sebire, 2005a).

## ■ Histologic Classification

### Invasive Mole

The common manifestation of GTN is characterized by whole chorionic villi that accompany excessive trophoblastic overgrowth and invasion (Fig. 37-8). These tissues penetrate deep into the myometrium, sometimes to involve the peritoneum, adjacent parametrium, or vaginal vault. Such moles are locally invasive but generally lack the pronounced tendency to develop widespread metastases typical of choriocarcinoma. Invasive moles originate almost exclusively from a complete or a partial hydatidiform mole (Sebire, 2005a).

### Gestational Choriocarcinoma

It is an extremely malignant tumor that contains sheets of anaplastic trophoblast and prominent hemorrhage, necrosis, and vascular invasion (see Fig. 37-8). However, formed villous structures are characteristically absent. Gestational choriocarcinoma initially invades the endometrium and myometrium but tends to develop early blood-borne systemic metastases (Fig. 37-9).

Most cases develop following evacuation of a molar pregnancy, but these tumors may also follow a nonmolar pregnancy. Specifically, gestational choriocarcinoma develops in approximately 1 in 30,000 nonmolar pregnancies. Two thirds of such cases follow term pregnancies, and one third develop after a spontaneous abortion or pregnancy termination. One

**FIGURE 37-8** **A.** An invasive mole contains whole villi that invade locally. The arrow marks one villus invading deeply into the adjacent myometrium. (Used with permission from Dr. Ona Faye-Peterson.) **B.** Choriocarcinoma is a biphasic tumor characterized by intermediate trophoblast and cytotrophoblast (asterisk), intimately admixed with multinucleate syncytiotrophoblast (S). Choriocarcinoma is a vascular tumor, typically with prominent hemorrhage, as evidenced by the abundant blood in the background. (Used with permission from Dr. Kelley Carrick.)

**FIGURE 37-9** Computed-tomography (CT) scan of choriocarcinoma invading the uterus.

review of 100 patients with nonmolar gestational choriocarcinoma reported that 62 presented after a live birth, 6 after a live birth preceded by a molar pregnancy, and 32 after a nonmolar abortion (Tidy, 1995). Vaginal bleeding was the most common symptom in all groups. For this reason, abnormal bleeding for more than 6 weeks following any pregnancy warrants evaluation with  $\beta$ -hCG testing to exclude a new pregnancy or GTN.

When choriocarcinoma is diagnosed after a live birth, the antecedent pregnancy usually proceeded normally to term. One case series collected between 1964 and 1996 showed that in 89 percent of cases, the preceding pregnancy had produced an uncomplicated live birth (Rodabaugh, 1998). Hydrops, while a notable complication in the remaining fetuses in this earlier series, was not observed in a more recent cohort compiled between 1996 and 2011 (Diver, 2013). Occasionally, unanticipated choriocarcinoma is detected in an otherwise normal-appearing placenta at delivery. More commonly, however, the diagnosis of choriocarcinoma is delayed for months due to subtle signs and symptoms. Most patients present with intermenstrual bleeding, and high  $\beta$ -hCG levels are detected (Lok, 2006). Less frequently, the diagnosis is made in an asymptomatic woman by an incidental positive pregnancy test (Diver, 2013). In part because of the typical delay to diagnosis, choriocarcinomas following term pregnancies are associated with high-risk features and a higher mortality rate than GTN following nonmolar abortions. Death rates range from 10 to 15 percent (Diver, 2013; Lok, 2006; Rodabaugh, 1998; Tidy, 1995).

In contrast to this gestational choriocarcinoma, primary “nongestational” choriocarcinoma is an ovarian germ cell tumor (Chap. 36, p. 764). Although rare, ovarian choriocarcinoma has a histologic appearance identical to that of gestational choriocarcinoma. It is in part distinguished by the lack of a preceding pregnancy (Lee, 2009).

### Placental-site Trophoblastic Tumor

This tumor consists predominantly of intermediate trophoblasts at the placental site. It is a rare GTN variant with unique disease behavior. Placental-site trophoblastic tumor (PSTT) can follow

any type of pregnancy but develops most commonly following a term gestation (Papadopoulos, 2002). Typically, patients have irregular bleeding months or years after the antecedent pregnancy, and the diagnosis is not entertained until endometrial sampling has been performed (Feltmate, 2001). PSTT tends to infiltrate only within the uterus, disseminates late in its course, and produces low  $\beta$ -hCG levels (van Trommel, 2013). Of interest, an elevated proportion of free  $\beta$ -subunit can help to discriminate it from other GTN types if the endometrial biopsy is equivocal (Cole, 2008; Harvey, 2008). When this tumor does spread, the pattern mirrors that of gestational choriocarcinoma. Metastases often spread to the lungs, liver, or vagina (Baergen, 2006).

Hysterectomy is the primary treatment for nonmetastatic PSTT due to its relative insensitivity to chemotherapy. In particularly motivated patients, fertility-sparing procedures have mixed results (Feltmate, 2001; Machtinger, 2005; Papadopoulos, 2002; Taylor, 2013b).

Metastatic PSTT has a much poorer prognosis than its postmolar GTN counterparts. As a result, aggressive combination chemotherapy is indicated. EMA/EP regimens of etoposide, methotrexate, and dactinomycin (actinomycin D) that alternate with etoposide and cisplatin (Platinol) are considered the most effective (Newlands, 2000). Radiation, however, may also have a role. The overall 10-year survival is 70 percent, but patients with metastases, especially stage IV disease, have a much poorer prognosis (Hassadia, 2005; Hyman, 2013; Schmid, 2009).

### Epithelioid Trophoblastic Tumor

This rare trophoblastic tumor is distinct from gestational choriocarcinoma and PSTT. The preceding pregnancy event may be remote, or in some cases, a prior gestation cannot be confirmed (Palmer, 2008). Epithelioid trophoblastic tumor develops from neoplastic transformation of chorionic-type intermediate trophoblast. Microscopically, this tumor resembles PSTT, but the cells are smaller and display less nuclear pleomorphism. Grossly, epithelioid trophoblastic tumor grows in a nodular fashion rather than the infiltrative pattern of PSTT (Shih, 1998). Hysterectomy is again the primary treatment due to presumed chemoresistance and since the diagnosis is usually confirmed in advance by endometrial biopsy. More than one third of patients will present with metastatic disease and demonstrable chemoresistance to multiagent therapy, which portends a poor prognosis (Davis, 2015; Palmer, 2008).

### ■ Diagnosis

Most GTN cases are clinically diagnosed, using  $\beta$ -hCG evidence to identify persistent trophoblastic tissue (Table 37-3). Tissue is infrequently available for pathologic diagnosis, unless a diagnosis of placental-site or nongestational tumor is being considered. As a result, most centers in the United States diagnose GTN on the basis of rising  $\beta$ -hCG values or a persistent plateau of  $\beta$ -hCG values for at least 3 weeks. Unfortunately, uniformity is lacking in the definition of a persistent plateau. Additionally, the diagnostic criteria are less stringent in the United States than in Europe. This is partly because of concern that some patients may be lost to follow-up if stricter criteria are used.

**TABLE 37-3.** FIGO Criteria for Gestational Trophoblastic Neoplasia Diagnosis

- β-hCG level plateau persists in four measurements during a period of 3 weeks or longer (days 1, 7, 14, and 21)
- β-hCG level rise in 3 weekly consecutive measurements or longer, over a period of 2 weeks or more (days 1, 7, and 14)
- β-hCG level remains elevated for 6 months or more
- Histologic diagnosis of choriocarcinoma

β-hCG = beta human chorionic gonadotropin; FIGO = International Federation of Gynecology and Obstetrics.  
Data from FIGO Oncology Committee: FIGO staging for gestational trophoblastic neoplasia 2000. *Int J Gynaecol Obstet* 2002 Jun;77(3):285–287.

When serologic criteria for GTN are met, a new intrauterine pregnancy is excluded using β-hCG levels that are correlated with sonographic findings. This is done especially if there has been a long delay in monitoring of serial β-hCG levels or non-compliance with contraception or both.

■ **Assessment**

Patients with GTN undergo a thorough pretreatment assessment to determine disease extent. The initial evaluation may be limited to pelvic examination, chest radiograph, and pelvic sonography or abdominopelvic computed tomography (CT) scanning. Although approximately 40 percent of patients will have micrometastases not otherwise visible on chest radiography, chest CT is not needed because these small lesions do not affect outcome (Darby, 2009; Garner, 2004). However, pulmonary lesions identified on chest radiograph should prompt CT of the chest and magnetic resonance (MR) imaging of the brain. Fortunately, central nervous system involvement is rare in the absence of neurologic symptoms or signs (Price, 2010). Positron emission tomography (PET) may occasionally be useful to evaluate occult choriocarcinoma or relapse from previously treated GTN when conventional imaging is equivocal or fails to identify metastatic disease (Dhillon, 2006; Numnum, 2005).

■ **Staging**

Gestational trophoblastic neoplasia is anatomically staged based on a system adopted by the International Federation of Gynecology and Obstetrics (FIGO) (Table 37-4 and Fig. 37-10). Patients at low risk for therapeutic failure are distinguished from those at high risk by using the modified prognostic scoring system of the World Health Organization (WHO) (Table 37-5). About 95 percent of patients will have a WHO score of 0 to 6 and will be considered to have low-risk disease (Sita-Lumsden, 2012). The remainder will have a score of 7 or higher and be assigned to the high-risk GTN

group. For the most accurate description of affected patients, the Roman numeral corresponding to FIGO stage is separated by a colon from the sum of the risk factor scores, for example, stage II:4 or stage IV:9. This description best reflects disease behavior (Ngan, 2004). Women with high-risk scores are more likely to have tumors that are resistant to single-agent chemotherapy. They are therefore treated initially with combination chemotherapy. Although patients with stage I disease infrequently have a high-risk score, those with stage IV disease invariably have a high-risk score. Women diagnosed with FIGO stage I, II, or III GTN have a survival rate approaching 100 percent (Lurain, 2010).

**Nonmetastatic Disease**

Invasive moles arising from complete molar gestations make up most nonmetastatic GTN cases. Approximately 12 percent of complete moles develop locally invasive disease after evacuation, compared with only 4 to 6 percent of partial moles. Epithelioid trophoblastic tumor and PSTT are other rare causes of non-metastatic GTN. Locally invasive trophoblastic tumors may perforate the myometrium and lead to intraperitoneal bleeding (Mackenzie, 1993). Alternatively, vaginal hemorrhage can follow tumor erosion into uterine vessels, or necrotic tumor may involve the uterine wall and serve as a nidus for infection. Fortunately, the prognosis is typically excellent for all types of nonmetastatic disease despite these possible manifestations.

**Metastatic Disease**

Choriocarcinomas originating from complete molar gestations account for most cases of metastatic GTN. Three to 4 percent of complete moles develop metastatic choriocarcinoma after evacuation. This event is rare following any other type of molar or nonmolar gestation. Choriocarcinomas have a propensity for distant spread and should be suspected in any woman of reproductive age with metastatic disease from an unknown primary (Tidy, 1995). Moreover, because of this tendency,

**TABLE 37-4.** FIGO Anatomic Staging of GTN

Stage	Characteristics
I	Disease confined to the uterus
II	GTN extends outside of the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
III	GTN extends to the lungs, with or without known genital tract involvement
IV	All other metastatic sites

**FIGURE 37-10** International Federation of Gynecology and Obstetrics (FIGO) staging of gestational trophoblastic neoplasia.

chemotherapy is indicated whenever choriocarcinoma is diagnosed histologically.

Although many patients are largely asymptomatic, metastatic GTN is highly vascular and prone to severe hemorrhage either spontaneously or during biopsy. Heavy menstrual bleeding is a common presenting symptom. The most common sites of spread are the lungs (80 percent), vagina (30 percent), pelvis (20 percent), liver (10 percent), and brain (10 percent) (Fig. 37-11). Patients with pulmonary metastases typically have asymptomatic lesions identified on routine chest radiograph and infrequently present with cough, dyspnea, hemoptysis, pleuritic chest pain, or signs of pulmonary hypertension (Seckl, 1991). In patients with early development of respiratory failure that requires intubation, the overall outcome is poor. Hepatic

or cerebral involvement is encountered almost exclusively in patients who have had an antecedent nonmolar pregnancy and a protracted delay in tumor diagnosis (Newlands, 2002; Savage, 2015b). These women may present with associated hemorrhagic events. Virtually all patients with hepatic or cerebral metastases have concurrent pulmonary or vaginal involvement or both. Great caution is used in attempting excision of any metastatic disease site due to the risk of profuse hemorrhage. Thus, this practice is almost uniformly avoided except in extenuating circumstances of life-threatening brainstem herniation or chemotherapy-resistant disease.

■ Treatment

Surgery

Most patients diagnosed with postmolar GTN have persistent tumor confined to the endometrial cavity and are treated primarily with chemotherapeutic agents. Repeat dilatation and curettage is generally avoided to prevent morbidity and mortality caused by uterine perforation, hemorrhage, infection, uterine adhesions, and anesthetic complications (American College of Obstetricians and Gynecologists, 2014). Accordingly, second evacuations are not typically performed in the United States unless patients have persistent uterine bleeding and substantial amounts of retained molar tissue. Repeat uterine curettage is a more standard part of postmolar GTN management in Europe. This practice reduces both the number of patients needing any further treatment and the number of courses in those who do require chemotherapy (Pezeshki, 2004; van Trommel, 2005). A second evacuation followed by continued surveillance, however, is a less attractive option, even for poorly compliant patients, than single-agent chemotherapy (Allen, 2003; Massad, 2000).

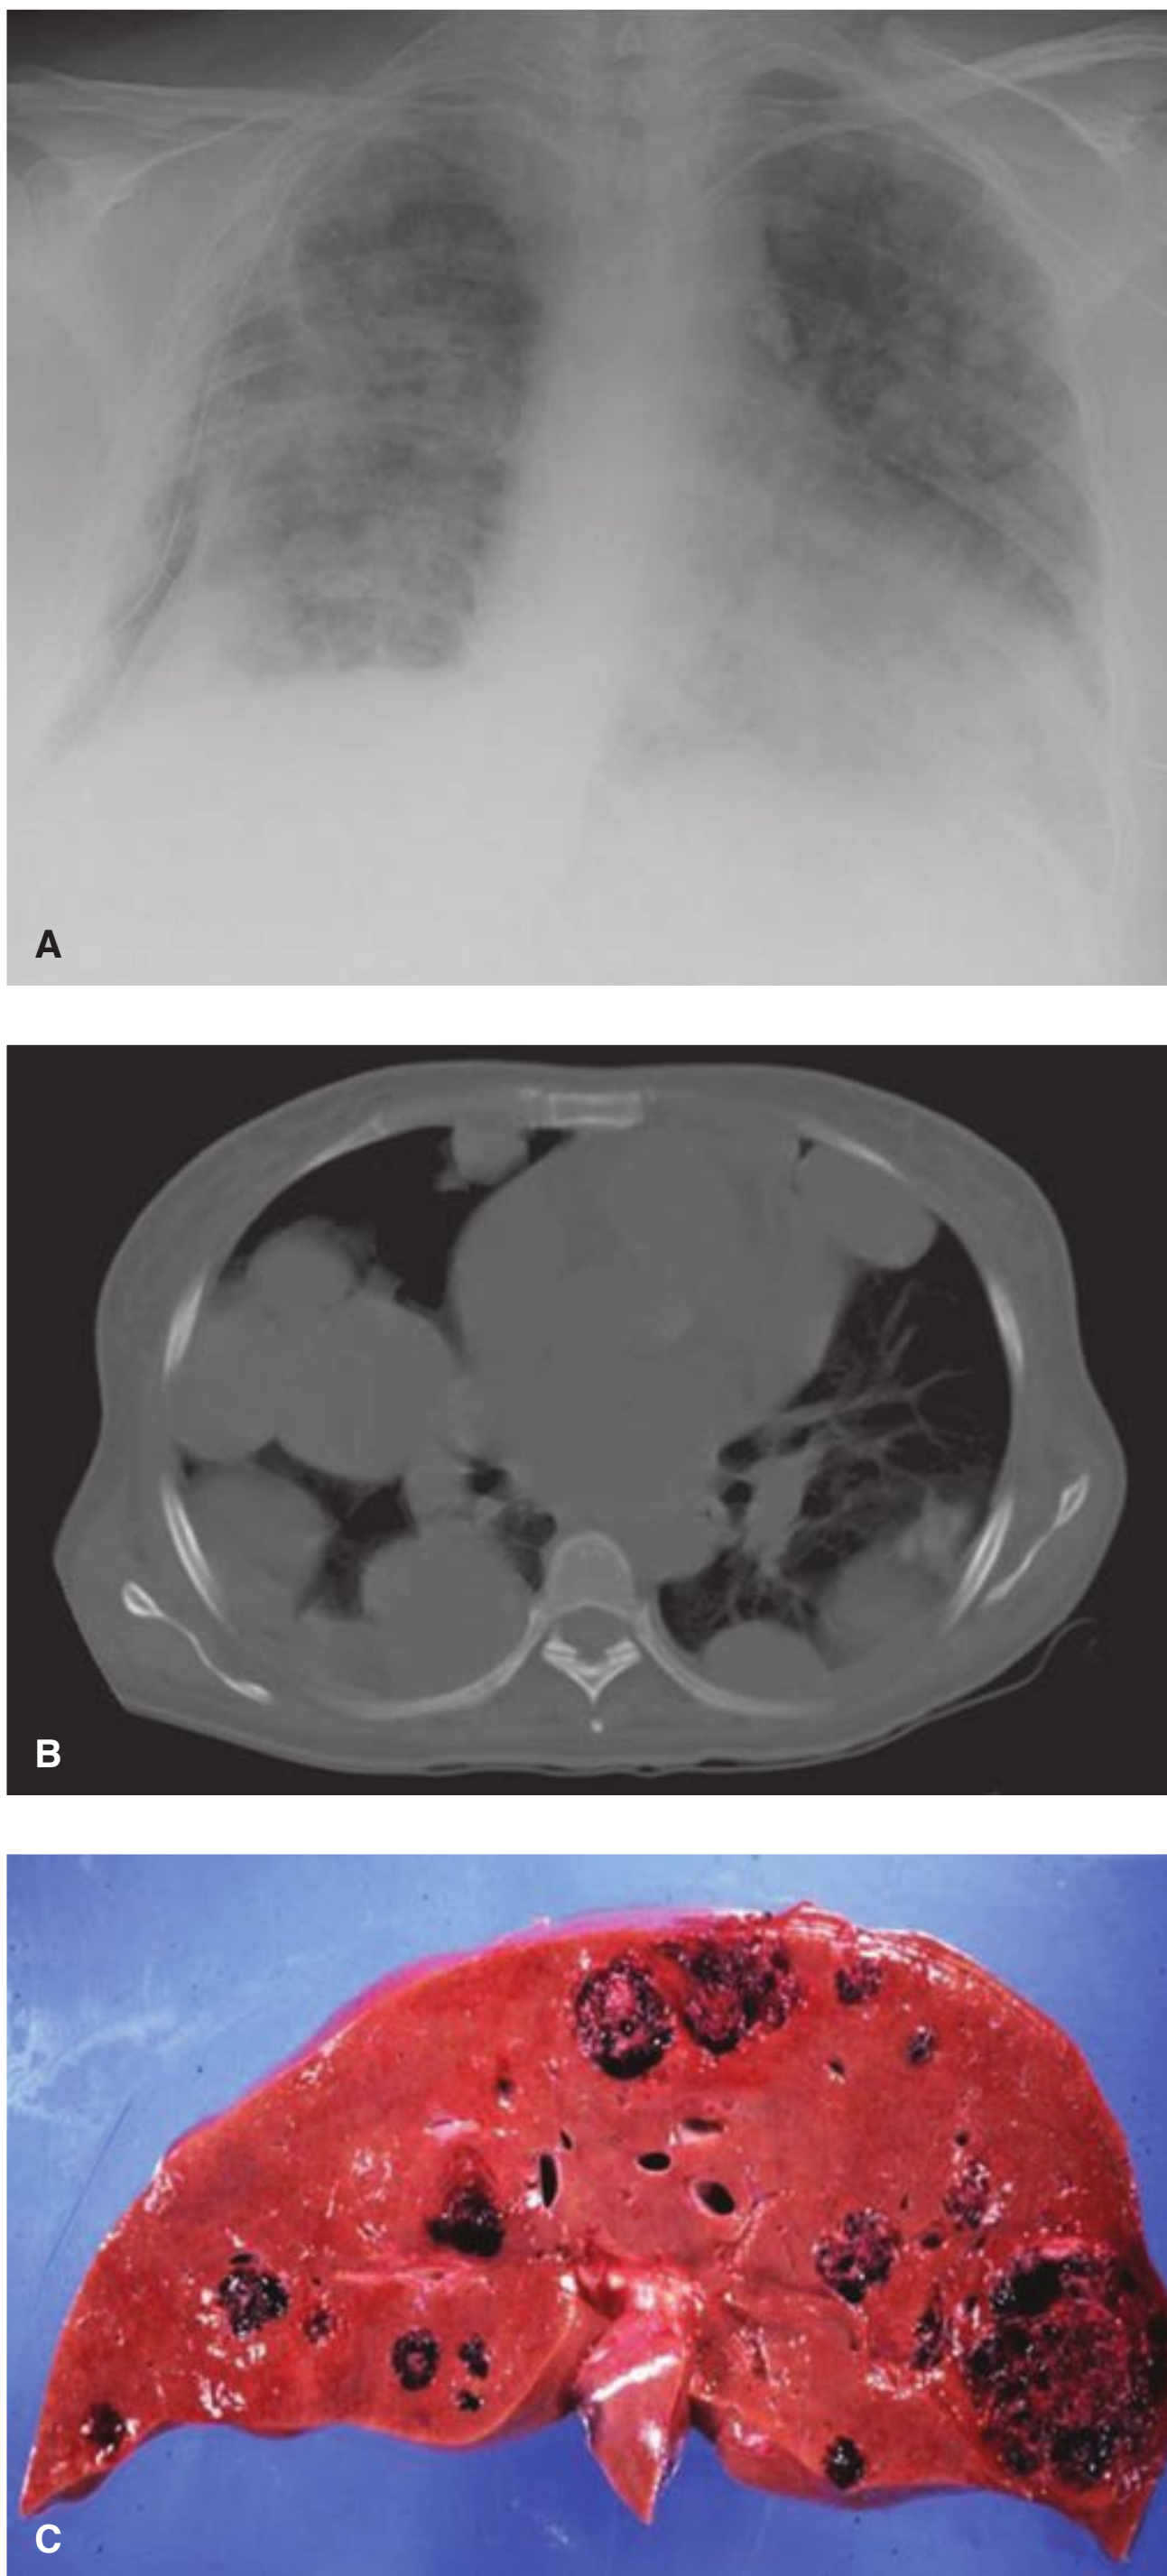

Hysterectomy may play several roles in GTN treatment. First, it may be performed to primarily treat PSTT, epithelioid trophoblastic tumors, or other chemotherapy-resistant disease. Second, severe uncontrollable vaginal or intraabdominal bleeding may necessitate hysterectomy as an emergency procedure (Clark, 2010). Because of these more extreme indications,

**TABLE 37-5.** Modified WHO Prognostic Scoring System as Adapted by FIGO

Scores	0	1	2	4

Connor.) **B.** Computed-tomography (CT) scan of metastatic disease to the lung. **C.** Autopsy specimen shows multiple hemorrhagic hepatic metastases. (Used with permission from Dr. Michael G. Connor.)

most women undergoing hysterectomy have elevated pretreatment risk scores, unusual pathology, and higher mortality rates (Pisal, 2002). Finally, adjuvant hysterectomy decreases the total dose of chemotherapy needed to achieve clinical remission in low-risk GTN. Patients with disease apparently confined to the uterus who do not desire future fertility should

be counseled about this option (Suzuka, 2001). However, the risk of GTN persistence after hysterectomy remains approximately 3 to 5 percent, and these patients should be monitored postoperatively (American College of Obstetricians and Gynecologists, 2014).

Residual lung metastases may persist in 10 to 20 percent of patients achieving clinical remission of GTN after chemotherapy completion. These patients do not appear to have an increased risk of relapse compared with those having normal chest radiographs or CT scans. Thus, thoracotomy is not usually necessary unless remission cannot otherwise be achieved (Powles, 2006). In general, the optimal patient to be counseled for thoracotomy will have stage III GTN, a preoperative  $\beta$ -hCG level  $< 1500$  mIU/mL, and a solitary lung nodule resistant to chemotherapy (Cao, 2009; Fleming, 2008).

### Chemotherapy for Low-Risk GTN

**Methotrexate.** Most patients with hydatidiform mole who develop GTN are at low risk of chemotherapy resistance (score 0-6) (Seckl, 2010). Single-agent methotrexate is the most common treatment, and complete response rates range from 67 to 81 percent for variations of the two most common intramuscular (IM) methotrexate regimens (Table 37-6). Although bundled as low-risk disease, the highest cure rates occur in patients with the lowest WHO scores (0-1), and rates decline proportionally as WHO scores rise (Sita-Lumsden, 2012). Thus, patients with a WHO score of 6 should at least be considered for upfront combination therapy (Taylor, 2013a). Overall, 19 to 33 percent of women develop methotrexate resistance and are switched to other agents, described subsequently.

With methotrexate, the Gynecologic Oncology Group (GOG) conducted a prospective cohort dose-escalation study (protocol #79) of weekly administration that established a maximum dose of  $50 \text{ mg/m}^2$  with minimal toxicity (Homesley, 1988, 1990). This regimen is continued weekly until  $\beta$ -hCG levels are undetectable, and then two or three additional weekly doses are given (Lybol, 2012). Alternatively, Charing Cross Hospital and University of Sheffield investigators currently use an 8-day alternating regimen of  $50 \text{ mg}$  IM methotrexate on treatment days 1, 3, 5, and 7, and oral folinic acid, 7.5 to 15 mg taken orally on days 2, 4, 6, and 8. Treatment is repeated every 2 weeks (Taylor, 2013a).

As discussed more fully in Chapter 27 (p. 596), methotrexate is a folic acid antagonist that inhibits DNA synthesis. Mild stomatitis is the most common side effect, but other serosal symptoms, especially pleurisy, develop in up to one quarter of patients treated with low-dose methotrexate. Pericarditis, peritonitis, and pneumonitis are infrequent (Sharma, 1999). Toxicity develops more frequently with the more intense 8-day regimens compared with weekly administration. This is despite routine folinic acid “rescue,” which is provided to protect normal mucosal and serosal cells (Chap. 27, p. 597) (Gleeson, 1993).

**Dactinomycin.** Dactinomycin is less frequently used for the primary treatment of low-risk disease due to toxicity concerns, but it has superior efficacy as a single agent (Alazzam, 2012a; Yarandi, 2008). In a prospective GOG trial (protocol #174) of low-risk GTN, patients were randomly assigned to biweekly

**TABLE 37-6.** Intramuscular Methotrexate Regimens for Treatment of Low-Risk GTN

Frequency	Dose	Population Studied	CR Rate (%)	Study

CR= clinical remission (calculated for first-line treatment without needing alternative chemotherapy); GTN= gestational trophoblastic neoplasia.

“pulse” 1.25-mg dose dactinomycin or to weekly methotrexate, 30 mg/m<sup>2</sup>. Among 215 eligible patients, a complete response was observed in 69 percent given dactinomycin and in 53 percent given methotrexate. However, advocates of methotrexate have speculated that the unexpectedly low efficacy of methotrexate observed in this study may be due to subtherapeutic dosing. Moreover, those randomized to dactinomycin were twice as likely to develop alopecia and were the only patients to develop grade 4 toxicity, defined in Chapter 27 (p. 605) (Osborne, 2008). As yet, no trials have directly compared pulse dactinomycin and the widely used 8-day methotrexate regimen. Since survival rates are so high, methotrexate is usually tried first because most clinicians consider it to be the least toxic.

Patients who do not respond to an initial single-agent chemotherapeutic regimen fail to have persistently dropping  $\beta$ -hCG levels. These women should have their score recalculated using the modified WHO prognostic scoring system. Most women will still be considered low-risk and may be switched to a single-agent second-line therapy. Methotrexate-resistant GTN often responds to dactinomycin (Chapman-Davis, 2012; Chen, 2004). The GOG demonstrated a 74-percent success rate in a Phase II trial (protocol #176) of pulse dactinomycin as salvage treatment in 38 patients with methotrexate-resistant GTN (Covens, 2006). Etoposide is less commonly used in this setting but is also effective (Mangili, 1996). Patients initially treated with pulse dactinomycin who develop resistant GTN may still be successfully treated with the 5-day course of dactinomycin (Kohorn, 2002). Alternatively, single-agent methotrexate or etoposide is often effective in these cases (Matsui, 2005).

**Chemotherapy for High-Risk GTN**

Approximately 5 percent of GTN patients present with high-risk disease and usually have numerous metastases months or years after the causative pregnancy. Such patients are likely to develop drug resistance to single-agent chemotherapy (Seckl, 2010). Etoposide, methotrexate, and dactinomycin (actinomycin D) alternating with cyclophosphamide and vincristine (Oncovin) (EMA/CO) chemotherapy is a well-tolerated and highly effective regimen for high-risk GTN. It is considered the preferred treatment for most high-risk disease. Bower and associates (1997) reported a 78-percent complete remission rate in 272 consecutive women. Similarly, other investigators have observed a 71- to 78-percent complete response rate with the EMA/CO regimen (Escobar, 2003; Lu, 2008).

Response rates are comparable whether patients are treated primarily or after failure of single-agent methotrexate and/or dactinomycin.

Patients with high-risk disease have an overall survival rate of 86 to 92 percent, although approximately one quarter become refractory to or relapse from EMA/CO (Bower, 1997; Escobar, 2003; Lu, 2008; Lurain, 2010). Secondary treatment usually involves platinum-based chemotherapy combined with possible surgical excision of resistant disease (Alazzam, 2012b). Newlands and colleagues (2000) reported an 88-percent survival rate among 34 patients by replacing the cyclophosphamide and vincristine component with etoposide and cisplatin (EMA/EP). EMA/EP is an effective option in patients resistant to EMA/CO, but paclitaxel (Taxol) plus cisplatin alternating with paclitaxel plus etoposide (TP/TE) has comparable efficacy and appears less toxic (Patel, 2010; Wang, 2008). Bleomycin, etoposide, and cisplatin (BEP) is another potentially effective regimen (Lurain, 2005).

High-risk patients with a large disease burden are at risk for early death with standard EMA/CO due to tumor-lysis related hemorrhage and clinical deterioration. In these selected circumstances, “induction low-dose etoposide-cisplatin” appears to reduce the mortality risk 10-fold (Alifrangis, 2013).

**Brain Metastases**

Patients with cerebral metastases may present with seizures, headaches, or hemiparesis (Newlands, 2002). Occasionally, they are moribund on arrival after not recognizing the significance of their symptoms or following an extended delay in diagnosis. In such extenuating circumstances, emergency craniotomy may be indicated to stabilize the patient and is followed by critical care support throughout the active phase of treatment (Savage, 2015b). In experienced centers, virtually all GTN-related deaths occur in stage IV patients with WHO risk scores of 12 or more (Lurain, 2010).

Fortunately, the cure rate for those with brain metastases is high if neurologic deterioration does not occur within the first weeks after diagnosis. The sequence of aggressive multimodality therapy is controversial but may include chemotherapy, surgery, and radiation. Savage and coworkers (2015b) reported an 85-percent survival rate among 27 patients treated from 1991 to 2013 by EMA/CO or EMA/EP with an enhanced intravenous dose (1 g/m<sup>2</sup>) of methotrexate combined with intrathecal methotrexate until  $\beta$ -hCG levels were undetectable. Whole-brain radiation therapy can also be an efficacious adjunct to combination

chemotherapy and surgery but can induce permanent intellectual impairment (Cagayan, 2006; Schechter, 1998).

## ■ Posttreatment

### Surveillance

Monitoring of patients with low-risk GTN consists of weekly  $\beta$ -hCG measurements until the level is undetectable for 3 consecutive weeks. T is followed by monthly titers until the level is undetectable for 12 months. Patients with high-risk disease are followed for 24 months due to the greater risk of late relapse. Patients are encouraged to use effective contraception, as outlined earlier, during the entire surveillance period.

### Treatment Sequelae

Despite the favorable prognosis, patients and their partners carry pregnancy concerns for a protracted time (Wenzel, 1992). Sexual dysfunction is an underreported complication (Cagayan, 2008). These and other potential sequelae highlight the importance of a multidisciplinary approach to management (Ferreira, 2009).

Although patients may expect a normal reproductive outcome after achieving remission from GTD, some evidence suggests that adverse maternal outcomes and spontaneous abortion occur more frequently among those who conceive within 6 months of chemotherapy completion (Braga, 2009). Women having a pregnancy affected by a histologically confirmed complete or partial mole may be counseled that the risk of a repeat mole in a subsequent pregnancy approximates 1 percent (Garrett, 2008). Most will be of the same type of mole as the preceding pregnancy (Sebire, 2003). Women who become pregnant within 12 months postchemotherapy for GTN can be reassured of a likely favorable outcome, although the safest option is still to delay pregnancy for the full year (Williams, 2014). Pregnancy after combination EMA/CO chemotherapy for GTN also has a high probability of success and favorable outcome (Lok, 2003). All major cytotoxic treatments except methotrexate increase the risk of early menopause (Savage, 2015a).

In some cases, secondary tumors can develop as a result of cancer treatment. Etoposide-based combination chemotherapy has been associated with an increased risk of leukemia, colon cancer, melanoma, and breast cancer up to 25 years after treatment for GTN. An overall 50-percent excess risk was observed (Rustin, 1996). Etoposide is therefore reserved to treat patients who are likely to be resistant to single-agent chemotherapy and, in particular, those with high-risk metastatic disease.

## Quiescent Gestational Trophoblastic Disease

Patients with persistent mild elevations (usually  $\leq 50$  mIU/mL) of true  $\beta$ -hCG may have a dormant premalignant condition if no tumor is identified by physical examination or imaging studies (Khanlian, 2003). In this instance, phantom  $\beta$ -hCG, described next, should also be conclusively excluded as a possibility. The low  $\beta$ -hCG titers may persist for months or years before disappearing. Chemotherapy and surgery usually have no effect. Hormonal contraception may be helpful in lowering titers to an undetectable level, but patients are closely monitored since metastatic GTN may eventually develop (Khanlian, 2003; Kohorn, 2002; Palmieri, 2007).

## ■ Phantom $\beta$ -hCG

Occasionally, persistent mild elevations of serum  $\beta$ -hCG are detected that lead physicians to erroneously treat patients with cytotoxic chemotherapy or hysterectomy or both, when in reality no true  $\beta$ -hCG molecule or trophoblastic disease is present (Cole, 1998; Rotmensch, 2000). This is “phantom”  $\beta$ -hCG reading results from heterophilic antibodies in the serum that interfere with the  $\beta$ -hCG immunoassay and cause a false-positive result.

Several steps can clarify the diagnosis. First, a urine pregnancy test can be performed. With phantom  $\beta$ -hCG, the heterophilic antibodies are not filtered or renally excreted. Thus, these test-altering antibodies will be absent from the urine, and urine testing will show true negative results for  $\beta$ -hCG. Importantly, to conclusively exclude trophoblastic disease by this method, the index serum  $\beta$ -hCG level must be significantly higher than the detection threshold of the urine test. Second, performing serial dilutions of the serum sample leads to a proportional decrease in the  $\beta$ -hCG level if  $\beta$ -hCG is truly present. However, phantom  $\beta$ -hCG measurements will be unchanged by dilution. In addition, if phantom  $\beta$ -hCG is suspected, some specialized laboratories may be able to block the heterophilic antibodies. Last, heterophilic antibodies will cause interference with one assay, but they may bind poorly to another assay’s antibodies. Thus, switching  $\beta$ -hCG assay kits to one by a different manufacturer may accurately demonstrate the absence of true  $\beta$ -hCG (Cole, 1998; Olsen, 2001; Rotmensch, 2000).

### ANTERIOR ABDOMINAL WALL

The anterior abdominal wall provides core support to the human torso, confines abdominal viscera, and contributes muscular action for functions such as respiration and elimination. In gynecology, an understanding of the layered structure of the anterior abdominal wall is needed to effectively enter the peritoneal cavity for surgery without neurovascular complications.

#### ■ Skin and Subcutaneous Layer

Within the skin, the term *Langer lines* describes the orientation of dermal fibers. In the anterior abdominal wall, they are arranged primarily transversely (Fig. 38-1). As a result, vertical skin incisions sustain more lateral tension and thus in general, develop wider scars compared with transverse skin incisions.

The subcutaneous layer lies deep to the skin. In the anterior abdominal wall, this layer is separated into a superficial, predominantly fatty layer known as *Camper fascia* and a deeper, more membranous layer known as *Scarpa fascia* (Fig. 38-2). Camper and Scarpa fasciae are not discrete layers but represent a continuum. If traced caudally, scarpa fascia is continuous with Colles fascia in the perineum.

Clinically, Scarpa fascia is better developed in the lower abdomen and during surgery can be best identified in the lateral portions of a low transverse incision, just superficial to the rectus fascia. In contrast, this fascia is rarely recognized during midline incisions.

#### ■ Rectus Sheath

The *external oblique*, *internal oblique*, and *transversus abdominis* muscles (flank muscles) all contain a lateral muscular portion and medial fibrous aponeurotic portion. All of their aponeuroses conjoin, and these layers create the rectus sheath (see Fig. 38-2). In the midline, the aponeurotic layers fuse to create the *linea alba*. In the lower abdomen, transition from the muscular to the aponeurotic component of the external oblique muscle takes place along a vertical line through the anterior superior iliac spine. Transition from muscle to aponeurosis for the internal oblique and transversus abdominis muscles takes place at a more medial site. Accordingly, during low transverse incisions, muscle fibers of the internal oblique muscle are often noted below the aponeurotic layer of the external oblique muscle.

The anatomy of the rectus sheath above and below the *arcuate line* has significance (see Fig. 38-2). This horizontal line defines the level at which the rectus sheath passes only anterior to the rectus abdominis muscle, and this line typically lies midway between the umbilicus and pubic symphysis. Cephalad to the arcuate line, the rectus sheath lies both anterior and posterior to the rectus abdominis muscle. At this level, the anterior rectus sheath is formed by the aponeurosis of the external oblique muscle and the split aponeurosis of the internal oblique muscle. The posterior rectus sheath is formed by the split aponeurosis of the internal oblique muscle and aponeurosis of the transversus abdominis muscle. Caudad to the arcuate line, all aponeurotic layers pass anterior to the rectus abdominis muscle. Thus, in the lower abdomen, the posterior surface of the rectus abdominis muscle is in direct contact with the transversalis fascia, described next.

Surgically, because the aponeuroses of the internal oblique and transversus abdominis muscles in the lower abdomen fuse, only two layers are identified during low transverse fascial incisions. In contrast, during midline vertical incision, only one fascial layer, namely, the *linea alba*, is encountered.

Similar to skin fibers, the flank muscle and rectus sheath fibers are oriented primarily transversely. Thus, suture lines placed in a vertical fascial incision must withstand more tension than those in a transverse incision. As a result, vertical fascial incisions are more prone to dehiscence and hernia formation. In addition to incisional hernias, ventral wall hernias are most common along the *linea alba*. Another type of anterior abdominal wall hernia, the *Spigelian hernia*, is rare and forms at the lateral rectus abdominis border, typically at the level of the arcuate line (Fig. 11-8, p. 267).

#### ■ Transversalis Fascia

This thin fibrous tissue layer lies between the inner surface of the transversus abdominis muscle and preperitoneal fat. Thus,

**FIGURE 38-1** Langer lines of skin tension.

it serves as part of the general fascial layer that lines the abdominal cavity (see Fig. 38-2) (Memon, 1999). Inferiorly, the transversalis fascia blends with the periosteum of the pubic bones.

Surgically, this fascia is best recognized as the layer bluntly or sharply dissected off the anterior surface of the bladder during entry into the abdominal cavity. This is the layer of tissue that is last penetrated to gain extraperitoneal entry into the retropubic space (p. 813).

## ■ Peritoneum

The peritoneum that lines the inner surface of the abdominal walls is termed *parietal peritoneum*. In the anterior abdominal wall, there are five elevations of parietal peritoneum that are raised by different structures (see Fig. 38-2). All five converge toward the umbilicus and are known as *umbilical ligaments*.

The single *median umbilical ligament* is formed by the *urachus*, an obliterated tube that extends from the apex of the bladder to the umbilicus. In fetal life, the urachus, which is a fibrous remnant of the allantois, extends from the umbilical cord to the urogenital sinus, which gives rise to the bladder. The paired *medial umbilical ligaments* are formed by the obliterated umbilical arteries that connected the internal iliac arteries to the umbilical cord in fetal life. The paired *lateral umbilical ligaments* contain the patent inferior epigastric vessels. The initial course of

**FIGURE 38-2** Transverse sections of the anterior abdominal wall above (A) and below (B) the arcuate line.

**FIGURE 38-3** Anterior abdominal wall anatomy.

these vessels is just medial to the round ligament as the ligament enters the deep inguinal ring (Fig. 38-3).

Surgically, transection of a patent urachus can result in extravasation of urine into the abdominal cavity. In addition, the differential diagnosis of a midline anterior abdominal wall cyst includes urachal cyst, urachal sinus, and urachal diverticulum.

The umbilical ligaments serve as valuable laparoscopic landmarks. First, the inferior epigastric vessels can be injured during accessory trocar placement (Hurd, 1994; Rahn, 2010). Thus, direct visualization of the lateral umbilical folds can prevent injury to these vessels during laparoscopic port placement. Second, the medial umbilical ligaments, if followed proximally, can guide a surgeon to the internal iliac artery and then to the uterine arteries. The medial umbilical ligament also forms the medial border of the paravesical space, which is developed during radical hysterectomy to isolate the parametrium.

## ■ Blood Supply

### Femoral Branches

The superficial epigastric, superficial circumflex iliac, and external pudendal arteries arise from the femoral artery just below the

inguinal ligament in the femoral triangle, which is bordered by this ligament, the sartorius muscle, and the adductor longus muscle (p. 823). These vessels supply the skin and subcutaneous layers of the anterior abdominal wall and mons pubis. The superficial epigastric vessels course diagonally toward the umbilicus, similar to the inferior “deep” epigastric vessels.

Surgically, during low transverse skin incision creation, the superficial epigastric vessels can usually be identified halfway between the skin and the rectus fascia, several centimeters from the midline. During laparoscopic procedures in thin patients, these vessels can be identified by transillumination (Chap. 41, p. 895).

The external pudendal vessels form rich anastomoses with their contralateral equivalents and with other superficial branches. These anastomoses account for the extensive bleeding often encountered with incisions made in the mons pubis area such as for retropubic midurethral sling incisions.

### External Iliac Branches

The inferior “deep” epigastric vessels and deep circumflex iliac vessels are branches of the external iliac vessels (see Fig. 38-3). They supply the muscles and fascia of the anterior abdominal wall.

**FIGURE 38-4** Inguinal and upper thigh anatomy.

The inferior epigastric vessels initially course lateral to, then posterior to the rectus abdominis muscle, which they supply. They then pass anterior to the posterior rectus sheath and course between the sheath and the rectus muscles (see Figs. 38-2 and 38-3). Near the umbilicus, the inferior epigastric vessels anastomose with the superior epigastric artery and veins, which are branches of the internal thoracic vessels.

Hesselbach triangle is the region in the anterior abdominal wall bounded inferiorly by the inguinal ligament, medially by the lateral border of the rectus muscles, and laterally by the inferior epigastric vessels (Fig. 38-4). Direct hernias protrude through the abdominal wall within Hesselbach triangle. In contrast, indirect hernias protrude into the deep inguinal ring lying lateral to this triangle.

Surgically, low transverse abdominal incisions that extend beyond the lateral margins of the rectus muscles can lead to inferior epigastric vessel laceration with severe hemorrhage or anterior abdominal wall hematoma formation. These vessels should be identified and ligated when performing a Maylard incision. As another surgical landmark, the deep circumflex iliac vein serves as the caudal border during pelvic lymph node dissection.

## ■ Innervation

The anterior abdominal wall is innervated by the abdominal extensions of the intercostal nerves (T7-T11), the subcostal nerve (T12), and the iliohypogastric and the ilioinguinal nerves (L1) (see Fig. 38-3). The T10 dermatome approximates the level of the umbilicus. Of these, the iliohypogastric nerve provides sensation to the skin over the suprapubic area. The ilioinguinal nerve supplies the skin of the lower abdominal wall and

upper portion of the labia majora and medial portion of the thigh through its inguinal branch (see Fig. 38-4). At a site 2 to 3 cm medial to the anterior superior iliac spine, these two nerves pierce through the internal oblique muscle and course superficial to it and toward the midline (Whiteside, 2003).

Clinically, the ilioinguinal and iliohypogastric nerves can be entrapped during closure of low transverse incisions, especially if incisions extend beyond the lateral borders of the rectus abdominis muscle. They may also be wounded by lower abdominal insertion of accessory trocars. The risk of iliohypogastric and ilioinguinal nerve injury can be minimized if lateral trocars are placed superior to the anterior superior iliac spines and if low transverse fascial incisions are not extended beyond the lateral borders of the rectus muscle (Rahn, 2010).

## BONY PELVIS

### ■ Pelvic Bones and Joints

The *sacrum*; the *coccyx*; and two hip bones, termed the *innominate bones* form the bony pelvis (Fig. 38-5). The innominate bones consist of the *ilium*, *ischium*, and *pubis*, which fuse at the *acetabulum*, a cup-shaped structure that articulates with the femoral head. The ilium articulates with the sacrum posteriorly at the sacroiliac joint, and the pubic bones articulate with each other anteriorly at the symphysis pubis. The sacroiliac joint is a synovial joint that connects the articular surfaces of the sacrum and ilium. This joint and its ligaments contribute significantly to the stability of the bony pelvis. The symphysis pubis is a cartilaginous joint, which connects the articular surfaces of the pubic bones by way of a fibrocartilaginous disc. The ischial

**FIGURE 38-5** Right os coxae.

spines are clinically important bony prominences that project posteromedially from the medial surface of the ischium approximately at the level of the fifth sacral vertebra (S5).

## ■ Pelvic Openings

The posterior, lateral, and inferior walls of the pelvis have several openings through which many important structures pass. The large *obturator foramen* between the ischium and pubis is filled almost completely by the obturator membrane. In the superior portion of this membrane, a small aperture known as the *obturator canal* allows passage of the obturator neurovascular bundle into the medial (adductor) compartment of the thigh (**Fig. 38-6**).

The posterolateral walls of the pelvis are not covered by bone. Instead, two important accessory ligaments, the *sacrospinous* and *sacrotuberous ligaments*, divide the greater and lesser sciatic notches of the ischium into the *greater sciatic foramen* and *lesser sciatic foramen*. Through the greater sciatic foramen, the

**FIGURE 38-6** Bones, ligaments, and openings of the pelvic walls and associated structures. Note the obturator internus muscle extending below the levator ani muscle and then exiting through the lesser sciatic foramen to insert into the lateral femoral trochanter. Ischial spine is marked by an asterisk. L5 = fifth lumbar vertebra; LST = lumbosacral trunk; PS = pubic symphysis; S1–S3 = first through third sacral nerves; SSL = sacrospinous ligament; STL = sacrotuberous ligament.

**FIGURE 38-7** Muscles and fascia of the pelvic walls and pelvic floor innervation. Ischial spine is marked by an asterisk. L5 = fifth lumbar vertebra; PS = pubic symphysis; R = rectum; S1–S5 = first through fifth sacral nerves; U = urethra; V = vagina.

piriformis muscle, internal pudendal and superior and inferior gluteal vessels, sciatic and pudendal nerve, and other branches of the sacral nerve plexus pass in close proximity to the ischial spines. Surgically, this anatomy is critical to avoid neurovascular injury during sacrospinous fixation procedures and when administering pudendal nerve blockade (Roshanravan, 2007).

The internal pudendal vessels, pudendal nerve, and obturator internus tendon pass through the lesser sciatic foramen. Posteriorly, four pairs of pelvic sacral foramina allow passage of the anterior divisions of the first four sacral nerves and lateral sacral arteries and veins.

## ■ Ligaments

The ligaments of the pelvis vary in composition and function. They range from connective tissue structures that support the bony pelvis and pelvic organs to smooth muscle and loose areolar tissue that add no significant support. The *sacrospinous*, *sacrotuberous*, and *anterior longitudinal ligaments* of the sacrum consist of dense connective tissue that joins bony structures and contributes significantly to bony pelvis stability (see Fig. 38-6).

The round and broad ligaments consist of smooth muscle and loose areolar tissue, respectively. Although they connect the uterus and adnexa to the pelvic walls, they do not contribute to

the support of these organs. In contrast, the cardinal and uterosacral ligaments do aid pelvic organ support and are discussed later (p. 808).

Clinically, the sacrospinous and anterior longitudinal ligament serve as suture fixation sites in suspensory procedures used to correct pelvic organ prolapse. The iliopectineal ligament, also termed Cooper ligament, is a thickening in the pubic bone periosteum, which is often used to anchor sutures in retropubic bladder neck suspension procedures (Fig. 38-7).

## PELVIC WALL MUSCLES AND FASCIA

The posterior, lateral, and inferior walls of the pelvis are partially covered by striated muscles and their investing layers of fasciae (see Fig. 38-7). The *piriformis muscle* arises from the anterior and lateral surface of the sacrum and partially fills the posterolateral pelvic walls. It exits the pelvis through the greater sciatic foramen, attaches to the greater trochanter of the femur, and functions as an external or lateral hip rotator. Clinically, stretch injury to the piriformis muscle may cause persistent hip pain that can be confused with other hip or pelvic pathology.

The obturator internus muscle partially fills the sidewalls of the pelvis. This muscle arises from the pelvic surfaces of the ilium and ischium and from the obturator membrane. It exits

**FIGURE 38-8** Superior view of pelvic floor and pelvic wall muscles.

the pelvis through the lesser sciatic foramen, attaches to the greater trochanter of the femur, and also functions as an external hip rotator.

The fascia that invests striated muscles is termed *parietal fascia*. Pelvic parietal fascia provides muscle attachment to the bony pelvis and serves as anchoring points for *visceral fascia*, also termed *endopelvic fascia*. The *arcus tendineus levator ani* is a condensation of parietal fascia covering the medial surface of the obturator internus muscle (see Fig. 38-7 and Fig. 38-8). This structure serves as the point of origin for parts of the very important levator ani muscle. Also shown is the *arcus tendineus fascia pelvis*, a condensation of parietal fascia covering the medial aspects of the obturator internus and levator ani muscles. It serves as the lateral point of attachment of the anterior vaginal wall.

## PELVIC FLOOR

The muscles that span the pelvic floor are collectively known as the *pelvic diaphragm* (see Figs. 38-7, 38-8, and Fig. 38-9). This diaphragm consists of the levator ani and coccygeus muscles, along with their superior and inferior investing fascial layers. Inferior to the pelvic diaphragm, the perineal membrane and perineal body also contribute to the pelvic floor (p. 820). The *urogenital hiatus* is the U-shaped opening in the pelvic floor muscles through which the urethra, vagina, and rectum pass.

### Levator Ani Muscles

These are the most important muscles in the pelvic floor and provide critical pelvic organ support (see Figs. 38-7 through

38-9). Physiologically, normal levator ani muscles maintain a constant state of contraction, thus providing a stable floor, which supports the weight of the abdominopelvic contents against intraabdominal forces.

The levator ani muscle is a complex unit, which consists of several muscle components with different origins and insertions and therefore different functions. The *pubococcygeus*, *puborectalis*, and *iliococcygeus* muscles are the three components. Of these, the *pubococcygeus* muscle is further divided into the *pubovaginalis*, *puboperinealis*, and *puboanalis* muscles according to their fiber attachments. Due to the significant attachments of the *pubococcygeus* muscle to the walls of the pelvic viscera, the term *pubovisceral muscle* is frequently used (Kerney, 2004; Lawson, 1974).

### Pubococcygeus Muscle

The anterior ends of the *pubococcygeus* (*pubovisceral* muscle) arise on either side from the inner surface of the pubic bone. The *pubovaginalis* refers to the medial fibers that attach to the lateral walls of the vagina (see Fig. 38-9). Although there are no direct attachments of the levator ani muscles to the urethra in females, those fibers of the muscle that attach to the vagina are responsible for elevating the urethra during a pelvic muscle contraction and hence may contribute to urinary continence (DeLancey, 1990). The *puboperinealis* refers to the fibers that attach to the perineal body and draw this structure toward the pubic symphysis. The *puboanalis* refers to the fibers that attach to the anus at the intersphincteric groove between the internal and external anal sphincters. These fibers elevate the anus and, along with the rest of the *pubococcygeus* and *puborectalis* fibers, keep the urogenital hiatus narrowed (see Fig. 38-8).

**FIGURE 38-9** Inferior view of pelvic floor.

### Puborectalis Muscle

The puborectalis represents the medial and inferior fibers of the levator ani muscle that arise on either side from the pubic bone and form a U-shaped sling behind the anorectal junction (Figs. 38-8 through 38-10). The action of the puborectalis draws the anorectal junction toward the pubis, contributing to the anorectal angle. This muscle is considered part of the anal sphincter complex and may contribute to fecal continence (Chap. 25, p. 561).

### Iliococcygeus Muscle

This muscle is the most posterior and thinnest part of the levator ani muscle and has a primarily supportive role. It arises laterally from the arcus tendineus levator ani and the ischial spines (see Figs. 38-7 through 38-10). Muscle fibers from one side join those from the opposite side in the midline between the anus and the coccyx. This meeting line is termed the *iliococcygeal* or *anococcygeal raphe*. In addition to the iliococcygeus muscle, some fibers of the pubococcygeus muscle pass behind the rectum and attach to the coccyx. These muscle fibers course cephalad or deep to the iliococcygeus muscle and may also contribute to the anococcygeal raphe. The *levator plate* is the clinical term used to describe the anococcygeal raphe (see Fig. 38-10). This portion of the levator muscles forms a supportive shelf on which the rectum, upper vagina, and uterus rest.

The levator plate in women with normal support has a mean angle of 44 degrees relative to a horizontal reference line during Valsalva, although earlier studies suggested no elevation (Berglas, 1953; Hsu, 2006). During Valsalva, women with prolapse have a statistically greater levator plate angle compared with controls. This larger angle moderately correlates with larger levator hiatus length and greater displacement of the perineal body in women with prolapse compared with controls.

**FIGURE 38-10** Pelvic organs and pelvic floor muscle and connective tissue interaction at rest (A) and with increasing intraabdominal pressure (B).

**FIGURE 38-11** Pelvic floor muscles and connective tissue interaction in setting of pelvic organ prolapse.

With this in mind, one theory suggests that levator plate support prevents excessive tension or stretching of the connective tissue pelvic ligaments and fasciae (Paramore, 1908). Neuromuscular injury to the levator muscles may lead to eventual sagging or vertical inclination of the levator plate and opening of the urogenital hiatus. Consequently, the vaginal axis becomes more vertical, and the cervix is oriented over the opened hiatus (Fig. 38-11). The mechanical effect of this change is to increase strain on connective tissues that support the pelvic viscera. Increased urogenital hiatus size has been shown to correlate with increased prolapse severity (DeLancey, 1998).

■ **Pelvic Floor Innervation**

The pelvic diaphragm muscles are primarily innervated by direct somatic efferents from the second through the fifth sacral nerve roots (S2-5) (see Fig. 38-7) (Barber, 2002; Roshanravan, 2007). Traditionally, a dual innervation has been described. The pelvic or superior surface of the muscles is supplied by direct efferents from S2-5, collectively known as the nerve to the levator ani muscle. The perineal or inferior surface is supplied by pudendal nerve branches. This latter relationship has been challenged, and investigators suggest that the pudendal nerve does not contribute to levator muscle innervation (Barber, 2002). Pudendal branches do, however, innervate parts of the

striated urethral sphincter and external anal sphincter muscles (p. 822). Such separate innervation may explain why some women develop pelvic organ prolapse and others develop urinary or fecal incontinence (Heit, 1996).

■ **Pelvic Connective Tissue**

Subperitoneal perivascular connective tissue and loose areolar tissue are found throughout the pelvis. This tissue connects the pelvic viscera to the pelvic walls and is termed *visceral* or *endopelvic* “fascia.” Recall that visceral fascia differs from parietal fascia, which invests most striated muscles (Table 38-1). Visceral fascia is intimately associated with the walls of the viscera and cannot be dissected in the same way that parietal fascia can be separated from its skeletal muscle. Condensations of visceral connective tissue that have assumed special supportive roles have been given different names. Some examples include the cardinal and uterosacral ligaments and the vesicovaginal and rectovaginal fascia. These are described further in later sections.

**PELVIC BLOOD SUPPLY**

The pelvic organs are supplied by the visceral branches of the internal iliac (hypogastric) artery and by direct branches from the abdominal aorta (Fig. 38-12). Clinically, the internal iliac artery can be separated into an anterior and posterior division in the area of the greater sciatic foramen (see Fig. 38-6). Each division has three parietal branches that supply nonvisceral structures. The *iliolumbar*, *lateral sacral*, and *superior gluteal arteries* are the three parietal branches of the posterior division. The *internal pudendal*, *obturator*, and *inferior gluteal arteries* are parietal branches that most commonly arise from the anterior division. The remaining branches of the anterior division supply pelvic viscera (bladder, uterus, vagina, and rectum). These include the *uterine*, *vaginal*, and *middle rectal arteries* and the *superior vesical arteries*. The superior vesical arteries commonly arise from the patent part of the umbilical arteries (Table 38-2). Internal iliac branches that supply the inferior and middle portions of the bladder are present in women, but their origin is highly variable. The middle rectal arteries are generally very small-caliber vessels but may be absent. They usually contribute to posterior vaginal wall blood supply. The two most important direct branches of the aorta that contribute to pelvic organ blood supply are the superior rectal and ovarian arteries. The *superior rectal artery*, which is the terminal branch of the inferior mesenteric artery, anastomoses with the middle rectal arteries, thus contributing blood supply to the

TABLE 38-1. Differences between Visceral and Parietal Fascia of the Pelvic Floor Muscles		
Type of Fascia		
Characteristic	Visceral or Endopelvic	Parietal
Histologic	Loose arrangements of collagen, elastin, and adipose tissue	Organized collagen arrangements
Function	Allows expansion and contraction of invested structures	Provides muscle attachment to bones
Supportive role	Condensations lend some support to invested organs; encases neurovascular structures	Invests muscles to provide pelvic floor stability and function
Tensile strength	Elastic	Rigid

rectum and vagina. The *ovarian arteries* arise directly from the aorta just inferior to the renal vessels and anastomose with the ascending branch of the uterine artery. These anastomoses contribute to the blood supply of the uterus and adnexa. Other important anastomoses between the aorta and internal iliac arteries include anastomoses between the middle sacral and lateral sacral arteries and anastomoses between the lumbar and iliolumbar arteries.

## PELVIC INNERVATION

Nerve supply to the visceral structures in the pelvis (bladder, urethra, vagina, uterus, adnexa, and rectum) arises from the autonomic nervous system. The two most important components of this system in the pelvis include the *superior* and *inferior hypogastric plexuses*. The superior hypogastric plexus, also known as the *presacral nerve*, is an extension of the aortic plexus found below the aortic bifurcation (Fig. 38-13). This plexus primarily contains sympathetic fibers and sensory afferent fibers from the uterus.

The superior hypogastric plexus terminates by dividing into the hypogastric nerves. These nerves join parasympathetic efferents from the second through the fourth sacral nerve roots

(pelvic splanchnic nerves) to form the *inferior hypogastric plexus*, also known as the *pelvic plexus*. In addition, the inferior hypogastric plexus generally receives contributions from the sacral sympathetic trunk.

With variability, fibers of the inferior hypogastric plexus accompany the branches of the internal iliac artery to the pelvic viscera. Accordingly, they are divided into three portions: the vesical, uterovaginal (Frankenhäuser ganglion), and middle rectal plexuses. Extensions of the inferior hypogastric plexus reach the perineum along the vagina and urethra to innervate the clitoris and vestibular bulbs.

Clinically, the sensory afferent fibers contained within the superior hypogastric plexus are targeted in presacral neurectomy, a surgical procedure performed to treat central pelvic pain (Chap. 11, p. 260). Although visceral and sexual dysfunction has been reported following complete interruption of the superior hypogastric plexus, contributions from the sacral sympathetic trunk may offset interruption of this sympathetic component to the inferior hypogastric plexus. Injury to the branches of the inferior hypogastric plexus during cancer debulking or other extensive pelvic surgeries can lead to varying degrees of voiding, sexual, and defecatory dysfunction.

**FIGURE 38-13** Pelvic autonomic nerves. Superior and inferior hypogastric plexuses. S1–S4 = first through fourth sacral nerves.

## PELVIC VISCERA

### ■ Uterus

The uterus is a fibromuscular hollow organ situated between the bladder and the rectum. The uterus is divided into two portions: an upper muscular body, the *corpus*, and a lower fibrous *cervix* (Fig. 38-14). The transition between the corpus and the cervix is known as the *uterine isthmus*. This also marks the transition from endocervical canal to endometrial cavity. The portion of the corpus that extends above the entry level of the fallopian tubes into the endometrial cavity is known as the *fundus*.

The shape, weight, and dimensions of the uterus vary according to parity and estrogen stimulation. Before menarche and after menopause, the corpus and cervix are approximately equal in size, but during the reproductive years, the uterine corpus is significantly larger than the cervix. In the adult, nonpregnant woman, the uterus measures approximately 7 cm in length and 5 cm in width at the fundus.

### Endometrium and Serosa

The uterus consists of an inner mucosal layer called the *endometrium*, which surrounds the endometrial cavity, and a thick muscular wall known as the *myometrium*. The endometrium consists of columnar epithelium and specialized stroma. The superficial portion of the endometrium undergoes cyclic changes with the menstrual cycle.

The spiral arterioles located in the endometrium undergo hormonally mediated constriction or spasm that promotes shedding of the superficial portion of the endometrium with

each menstrual cycle. The deeper basalis layer of the endometrium is preserved after this shedding and is responsible for regeneration of a new superficial layer.

Peritoneal serosa overlies the uterus, except at two sites. First, the anterior portion of the cervix is covered by the bladder. Second, the lateral portions of the corpus and cervix attach to the broad and cardinal ligaments.

### Cervix

The uterine cervix begins caudal to the uterine isthmus and is approximately 3 cm in length. The wall of the cervix consists primarily of fibrous tissue and a smaller amount of smooth muscle. The smooth muscle is found on the cervical wall periphery and serves as the attachment point for the cardinal and uterosacral ligaments and for the fibromuscular walls of the vagina.

The attachments of the vaginal walls to the outer cervix divide it into a vaginal part known as the *portio vaginalis* and a supravaginal part known as the *portio supravaginalis* (see Fig. 38-14). The portio vaginalis is covered by nonkeratinizing squamous epithelium.

The endocervical canal is lined by columnar, mucus-secreting epithelium. The lower border of the canal, called the external cervical os, contains a transition from the squamous epithelium of the portio vaginalis to the columnar epithelium of the cervical canal. The exact location of this transition, termed the *squamocolumnar junction*, varies depending on hormonal status (Fig. 29-5, p. 625). At the upper border of the endocervical canal is the internal cervical os, where the narrow cervical canal becomes continuous with the wider endometrial cavity.

**FIGURE 38-15** Pelvic viscera and their connective tissue support. Relationship of the urethra, bladder trigone, and distal ureter to the anterior vaginal wall and to the uterine cervix.

### Uterine Support

The main support of the uterus and cervix is provided by the levator ani muscles and the connective tissue that attaches the outer cervix to the pelvic walls. The connective tissue that attaches lateral to the uterus and cervix on each side is called the *parametrium* and continues caudad along the vagina as the *paracolpium*. The parametrium consists of what is clinically known as the *cardinal ligament* and *uterosacral ligament* (Fig. 38-15).

The cardinal ligaments, also termed *transverse cervical ligaments* or *Mackenrodt ligaments*, consist primarily of perivascular connective tissue (Range, 1964). They attach to the posterolateral pelvic walls near the origin of the internal iliac artery and surround the vessels supplying the uterus and vagina.

The uterosacral ligaments insert broadly into the posterior pelvic walls and sacrum and form the lateral boundaries of the cul-de-sac of Douglas. These ligaments originate from the posterior inferior surface of the cervix, but may also originate, in part, from the proximal posterior vagina (Umek, 2004). They consist primarily of smooth muscle and contain some pelvic autonomic nerves (Campbell, 1950; Ripperda, 2015).

Clinically, during pelvic reconstructive surgeries that use the uterosacral ligaments as attachment sites for the vaginal apex, surrounding structures are especially vulnerable (Wieslander, 2007). Namely, the rectum lies medial to the uterosacral ligaments. The ureter, pelvic sidewall vessels, and sacral nerves run lateral to and close to these ligaments.

### Round Ligaments

These ligaments are smooth muscle extensions of the uterine corpus and represent the homologue of the gubernaculum testis. The round ligaments arise from the lateral aspect of the corpus just below and anterior to the origin of the fallopian tubes. They extend laterally to the pelvic sidewall (see Fig. 38-14). They enter the retroperitoneal space and pass lateral to the inferior epigastric vessels before entering the inguinal canal through the internal inguinal ring. After coursing through the inguinal canal, the round ligaments exit through the external inguinal ring to terminate in the subcutaneous tissue of the labia majora (see Fig. 38-4). The round ligaments do not significantly contribute to uterine support. They receive their blood supply from a small branch of the uterine or ovarian artery known as *Sampson artery*.

Clinically, the location of the round ligament anterior to the fallopian tube can assist a surgeon during tubal sterilization through a minilaparotomy incision. This may be especially true if pelvic adhesions limit tubal mobility and thus hinder identification of fimbria prior to tubal ligation.

Division of the round ligament is typically an initial step in abdominal and laparoscopic hysterectomy. Its transection opens the broad ligament leaves and provides access to the pelvic sidewall retroperitoneum. This access allows direct visualization of the ureter and permits isolation of the uterine artery for safe ligation.

## Broad Ligaments

These ligaments are double layers of peritoneum that extend from the lateral walls of the uterus to the pelvic walls (see Fig. 38-14). Within the upper portion of these two layers, the fallopian tube, the ovarian ligament, and round ligament are found. Each of these has its separate mesentery, called the *mesosalpinx*, *mesovarium*, and *mesometery*, respectively, which carry nerves and vessels to these structures. At the lateral border of the fallopian tube and the ovary, the broad ligament ends where the infundibulopelvic ligament, described later on this page, blends with the pelvic wall. The cardinal and distal uterosacral ligaments lie within the lower portion or “base” of the broad ligament.

## Uterine Blood Supply

The blood supply to the uterine corpus arises from the ascending branch of the uterine artery and from the medial or uterine branch of the ovarian artery (see Figs. 38-14 and 38-15). The uterine artery may originate directly from the internal iliac artery, or it may have a common origin with the internal pudendal or with the vaginal artery (see Fig. 38-12). The uterine artery approaches the uterus in the area of the uterine isthmus. Here, the uterine artery courses over the ureter and provides a small branch to it. Several uterine veins course along the side of the artery and are variably found over or under the ureter. The uterine artery then divides into a larger ascending and a smaller descending branch that course alongside the uterus and cervix, respectively. These vessels connect on the lateral border of the uterus but form an anastomotic arterial arcade that supplies the uterine walls (Fig. 8-3, p. 182). The cervix is supplied by the descending or cervical branch of the uterine artery and by ascending branches of the vaginal artery.

Clinically, because the uterus receives dual blood supply from both ovarian and uterine vessels, some surgeons during myomectomy place tourniquets at both the infundibulopelvic ligament and uterine isthmus. This decreases blood flow from the ovarian and uterine arteries, respectively.

## Uterine Lymphatic Drainage

Lymphatic drainage of the uterus is primarily to the obturator and internal and external iliac nodes (Fig. 38-16). However, some lymphatic channels from the uterine corpus may pass along the round ligaments to the superficial inguinal nodes, and others may extend along the uterosacral ligaments to the lateral sacral nodes.

## Uterine Innervation

The uterus is innervated by fibers of the uterovaginal plexus, also known as Frankenhäuser ganglion. These fibers travel along the uterine arteries and are found in the connective tissue of the cardinal ligaments (see Fig. 38-13).

## ■ Ovaries and Fallopian Tubes

### Ovaries

The ovaries and fallopian tubes constitute the *uterine adnexa*. The size and hormonal activity of the ovaries are dependent on age, stage of the menstrual cycle, and exogenous hormonal suppression. During reproductive years, the ovaries measure 2.5 to

5 cm in length, 1.5 to 3 cm in thickness, and 0.7 to 1.5 cm in width.

The ovaries consist of an *outer cortex* and an *inner medulla*. The ovarian cortex is made up of a specialized stroma punctuated with follicles, corpora lutea, and corpora albicantia. A single layer of mesothelial cells covers this cortex as a surface epithelium. The medullary portion of the ovary primarily consists of fibromuscular tissue and blood vessels. Vessels and nerves enter the medulla at the *hilum*, which is a depression along the mesenteric border of the ovary. The medial aspect of the ovary is connected to the uterus by the *uteroovarian ligament* (see Fig. 38-14). Laterally, each ovary is attached to the pelvic wall by an *infundibulopelvic ligament*, also termed *suspensory ligament* of the ovary, which contains the ovarian vessels and nerves.

The blood supply to the ovaries comes from the *ovarian arteries*, which arise from the anterior surface of the abdominal aorta just below the origin of the renal arteries and from the ovarian branches of the uterine arteries (see Fig. 38-16). The *ovarian veins* follow the same retroperitoneal course as the arteries. The right ovarian vein drains into the inferior vena cava, and the left ovarian vein drains into the left renal vein.

Lymphatic drainage of the ovaries follows the ovarian vessels to the lower abdominal aorta, where they drain into the paraaortic nodes. For their innervation, the ovaries are supplied by extensions of the renal plexus that course along the ovarian vessels in the infundibulopelvic ligament and variably by contributions of the inferior hypogastric plexus.

## Fallopian Tubes

The fallopian tubes are tubular structures that measure 7 to 12 cm in length (see Fig. 38-14). Each tube has four identifiable portions. The *interstitial portion* passes through the body of the uterus at the region known as the *cornua*. The *isthmic portion* begins adjacent to the uterine corpus. It consists of a narrow lumen and a thick muscular wall. The *ampullary portion* is recognized as the lumen of the isthmic portion of the tube widens. In addition, this segment has a more convoluted mucosa. The *fimbriated portion* is the distal continuation of the ampullary segment. The fimbriated end has many frondlike projections that provide a wide surface area for ovum pickup. The *fimbria ovarica* is the extension that contacts the ovary.

The ovarian artery runs along the ovary's hilum and sends several branches through the mesosalpinx to supply the fallopian tubes (see Fig. 38-14). The venous plexus, lymphatic drainage, and nerve supply of the fallopian tubes follow a similar course to that of the ovaries.

## ■ Vagina

The vagina is a hollow viscus whose shape is determined by the structures that surround it and by the attachments of its lateral walls to the pelvic walls. The distal portion of the vagina is constricted by the action of the levator ani muscles (see Fig. 38-10). Above the pelvic floor, the vaginal lumen is more capacious and distensible. In the standing or anatomic position, the apex of the vagina is directed posteriorly toward the ischial spines, and the upper two thirds of the vaginal tube lie almost parallel to the plane of the levator plate. Although variable, the average

**FIGURE 38-16** Pelvic lymph nodes and the course of the ureter and ovarian vessels.

length of the anterior vaginal wall is 7 cm and that of the posterior wall is 9 cm. The recesses within the vaginal lumen in front of and behind the cervix are known as the *anterior fornix* and *posterior fornix*, respectively (Fig. 38-17). The vaginal walls consist of three layers: (1) adjacent to the lumen, a layer of nonkeratinized squamous epithelium with an outer lamina propria; (2) a muscular layer of smooth muscle, collagen, and elastin; and (3) an outer adventitial layer of collagen and elastin (Weber, 1995, 1997). These latter two form the fibromuscular component of the vagina.

The vagina lies between the bladder and rectum and, along with its connections to the pelvic walls, provides support to these structures (see Figs. 38-15 and 38-17). The vagina is separated from the bladder anteriorly and the rectum posteriorly by the vaginal adventitia. The lateral continuation of this adventitial layer contributes the paravaginal tissue that attaches the walls of the vagina to the pelvic walls. This paravaginal tissue constitutes the paracolpium. This tissue consists of loose areo-

lar and fatty tissue containing blood vessels, lymphatics, and nerves. The anterior fibromuscular vaginal wall and its paravaginal attachments to the arcus tendineus fascia pelvis represent the layer that supports the bladder and urethra and is clinically referred to as pubovesicocervical fascia (see Fig. 38-15).

The lateral attachments of the posterior vaginal walls are to the fascia covering the upper surface of the levator ani muscles. The posterior vaginal wall and its connective tissue attachments to the sidewall support the rectum. This layer is clinically known as the rectovaginal fascia or fascia of Denonvilliers. However, similar to microscopic findings of the anterior vaginal wall, histologic studies have failed to show a separate layer between the posterior wall of the vagina and the rectum except in the distal 3 to 4 cm. Here, the dense fibromuscular tissue of the perineal body separates these structures (DeLancey, 1999).

Surgically, dissections in the anterior vaginal wall or in the posterior vaginal wall separate portions of the vaginal muscularis from the epithelium for surgeries such as anterior and posterior

**FIGURE 38-17** Surgical cleavage planes and vaginal wall layers.

colporrhaphy. In contrast, posterior or anterior access to the coccygeus-sacrospinous ligament complex is accomplished by incising the full thickness of the anterior or posterior fibromuscular wall of the vagina, respectively. This deeper dissection allows access to the vesicovaginal or rectovaginal space and lateral dissection from these spaces allows access to the pararectal space. Because there is no true histologic “fascial” layer between the vagina and the bladder and between the vagina and the rectum, some recommend that terms such as “pubocervical/pubovesical fascia” or “rectovaginal fascia” be abandoned. They propose that these be replaced by more accurate descriptive terms such as *vaginal muscularis* or *fibromuscular layer of the anterior and posterior vaginal walls*.

### Vesicocervical and Vesicovaginal “Potential” Spaces

The *vesicocervical space* begins below the vesicouterine peritoneal fold or reflection, which represents the loose attachments of the peritoneum in the anterior cul-de-sac (see Figs. 38-17 and 38-18). The vesicocervical space continues down as the *vesicovaginal space*, which extends to the junction of the proximal and middle thirds of the urethra. Below this point, the urethra and vagina fuse.

Clinically, during an abdominal hysterectomy or cesarean delivery, surgeons easily lift and incise the vesicouterine peritoneal fold to create a bladder flap and then open the vesicocervical space. For vaginal hysterectomy, the distance between the anterior vaginal fornix and the anterior cul-de-sac peritoneum

spans several centimeters. Thus, to successfully enter the peritoneal cavity anteriorly, proper identification and sharp dissection of the loose connective tissue that lies within the vesicovaginal and then vesicocervical spaces is necessary (see Fig. 38-17) (Balgobin, 2011).

### Rectovaginal Space

This is adjacent to the posterior surface of the vagina. It extends from the cul-de-sac of Douglas down to the superior border of the perineal body, which extends 2 to 3 cm cephalad to the hymeneal ring (see Figs. 38-17 and 38-18). Rectal pillars, also known as the deep uterosacral or rectouterine ligaments, are fibers of the cardinal-uterosacral ligament complex that extend down from the cervix and attach to the upper portion of the posterior vaginal wall. These fibers connect the vagina to the lateral walls of the rectum and to the sacrum. These pillars also separate the midline rectovaginal space from the more lateral pararectal spaces.

Clinically, the rectovaginal space contains loose areolar tissue and is easily opened with finger dissection during abdominal surgery (see Fig. 38-18). Perforation of the rectal pillar fibers allows access to the sacrospinous ligaments used in vaginal suspension procedures.

The posterior cul-de-sac peritoneum extends down the posterior vaginal wall 2 to 3 cm inferior to the posterior vaginal fornix (Kuhn, 1982). Thus, during vaginal hysterectomy, in contrast to anterior peritoneal cavity entry, entering the peritoneal cavity posteriorly is readily done by incising the vaginal wall in the area of the posterior fornix (see Fig. 38-17).

**FIGURE 38-18** Connective tissue and surgical spaces of the pelvis.

### Vaginal Support

The main support of the vagina is provided by the levator ani muscles and the connective tissue that attaches the lateral walls of the vagina to the pelvic walls. These attachments are the cardinal and uterosacral ligaments. Although the visceral connective tissue in the pelvis is continuous and interdependent, DeLancey (1992) has described three levels of vaginal connective tissue support that help explain pelvic support dysfunction.

For upper vaginal support, the parametrium continues caudally down the vagina as the paracolpium (see Fig. 38-15). This tissue attaches the upper vagina to the pelvic wall, suspending it over the pelvic floor. These attachments are known as *level I support* or *suspensory axis* and provide connective tissue support to the vaginal apex after hysterectomy. In the standing position, level I support fibers are vertically oriented. Clinical manifestations of level I support defects include uterine prolapse or posthysterectomy vaginal vault prolapse.

For midvaginal support, the lateral walls of the vagina's midportion are attached to the pelvic walls on each side by visceral connective tissue known as endopelvic fascia. These lateral attachments of the vaginal walls blend into the arcus tendineus fascia pelvis and to the medial aspect of the levator ani muscles, and in doing so create the anterior and posterior lateral vaginal sulci (see Fig. 38-15). These grooves run along the vaginal side-walls and give the vagina an "H" shape when viewed in cross section. As noted earlier, the arcus tendineus fascia pelvis covers the medial aspect of the obturator internus and levator ani muscles. It spans from the inner and lower surface of the pubic bones to the ischial spines (see Figs. 38-7 and 38-15).

Attachment of the anterior vaginal wall to the levator ani muscles is responsible for the bladder neck elevation noted with cough or Valsalva maneuver (see Fig. 38-10). Thus, these

midvaginal attachments may have significance for stress urinary continence and are referred to as *level II support* or the *attachment axis*. Clinical manifestations of level II support defects include anterior and posterior vaginal wall prolapse and stress urinary incontinence.

For distal vaginal support, the distal third of the vagina is directly attached to its surrounding structures (see Fig. 38-9). Anteriorly, the vagina is fused with the urethra. Laterally it attaches to the pubovaginalis muscle and perineal membrane, and posteriorly to the perineal body. These vaginal attachments are referred to as *level III support* or the *fusion axis* and are considered the strongest of the vaginal support components. Clinically, failure of this level of support can result in distal rectoceles or perineal descent. Anal incontinence may also result if the perineal body is absent, as may follow obstetric trauma.

### Vaginal Blood Supply, Lymphatics, and Innervation

The main blood supply to the vagina arises from the descending or cervical branch of the uterine artery and from the vaginal artery, a branch of the internal iliac artery (see Fig. 38-12). These vessels form an anastomotic arcade along the lateral sides of the vagina at the level of the vaginal sulci. They also anastomose with the contralateral vessels at points on the anterior and posterior walls of the vagina. Additionally, the middle rectal artery from the internal iliac artery contributes to the posterior vaginal wall supply. The distal walls of the vagina also receive contributions from the internal pudendal artery (p. 822). Lymphatic drainage of the upper two thirds of the vagina is similar to that of the uterus as described on page 809. The distal part of the vagina drains with the vulvar lymphatics to the inguinal nodes. A more detailed description of the vulvar lymphatics is presented on page 822. Last, vaginal innervation

**FIGURE 38-19** Midsagittal view of pelvic structures and associated anatomy. L4 = fourth lumbar vertebra; PS = pubic symphysis; S1, S3 = first and third sacral vertebrae.

comes from inferior extensions of the uterovaginal plexus, a component of the inferior hypogastric plexus (see Fig. 38-13).

## ■ Lower Urinary Tract Structures

### Bladder

The bladder is a hollow organ that stores and evacuates urine (Fig. 38-19). Anteriorly, the bladder rests against the inner surface of the pubic bones and then, as it fills, also against the anterior abdominal wall. Posteriorly, it rests against the vagina and cervix. Anteroinferiorly and laterally, the bladder contacts the loose connective and fatty tissue that fills the retropubic space, and here, the bladder lacks a peritoneal covering. The reflection of the bladder onto the abdominal wall is triangular, and the triangle apex is continuous with the median umbilical ligament.

Clinically, an intentional cystotomy can be made to confirm patency of the ureteral orifices, to assist with surgical dissection, or to place ureteral stents. The incision is ideally placed in the retropubic extraperitoneal portion of the bladder close to the apex. This avoids direct contact between the abdominopelvic viscera and the cystotomy site and minimizes the risk of fistula formation.

The bladder wall consists of coarse bundles of smooth muscle known as the *detrusor muscle*, which extends into the upper

part of the urethra. Although separate layers of the detrusor are described, they are not as well defined as the layers of other viscous structures (Fig. 23-1, p. 517). The innermost layer of the bladder wall is plexiform, which can be seen from the pattern of trabeculations noted during cystoscopy. The mucosa of the bladder consists of transitional epithelium and underlying lamina propria. A submucosal layer intervenes between this mucosa and the detrusor muscle.

The bladder is divided into a *dome* and a *base* approximately at the level of the ureteral orifices. The dome is thin walled and distensible, whereas the base is thicker and undergoes less distention during filling (see Fig. 38-15). The bladder base consists of the *vesical trigone* and the *detrusor loops*. These loops are two U-shaped bands of fibers found at the *vesical neck*, where the urethra enters the bladder wall. Ureteral orifices lie within the trigone and empty here into the bladder. The pelvic ureter courses in the pelvic sidewall retroperitoneum and is discussed on page 816.

The blood supply to the bladder arises from the superior vesical arteries, which are branches of the patent portion of the umbilical artery. Other contributors are the middle and inferior vesical arteries, which, when present, often arise from either the internal pudendal or the vaginal arteries (see Fig. 38-12). The nerve supply to the bladder arises from the vesical plexus, a component of the inferior hypogastric plexus (see Fig. 38-13).

**FIGURE 38-20** Urethra and associated muscles.

### Urethra

The female urethra measures 3 to 4 cm in length. The urethral lumen begins at the internal urinary meatus within the bladder, and then courses through the bladder base for less than a centimeter. This region where the urethral lumen traverses the bladder base is called the *bladder neck*. The distal two thirds of the urethra are fused with the anterior vaginal wall.

The walls of the urethra begin outside the bladder wall. They consist of two layers of smooth muscle, an inner longitudinal and an outer circular, which are in turn surrounded by a circular layer of skeletal muscle referred to as the *sphincter urethrae* or *rhabdosphincter* (Fig. 38-20). Approximately at the junction of the middle and lower third of the urethra, and just above or deep to the perineal membrane, two strap skeletal muscles called the *urethrovaginal sphincter* and *compressor urethrae* are found. These muscles were previously known as the *deep transverse perineal muscles* in females. Together with the sphincter urethrae, they constitute the *striated urogenital sphincter complex*. Together, these three muscles function as a unit and have a complex and controversial innervation. Their fibers act cumulatively to supply constant tonus and to provide emergency reflex activity mainly in the distal half of the urethra to sustain continence.

Distal to the depth of the perineal membrane, the walls of the urethra consist of fibrous tissue, serving as the nozzle that directs the urine stream. The urethra has a prominent submucosal layer that is lined by hormonally sensitive stratified squamous epithelium (Fig. 23-8, p. 520). Within the submucosal layer on the dorsal (vaginal) surface of the urethra is a group of glands known as the paraurethral glands, which open into the urethral lumen (Fig. 26-3, p. 583). Duct openings of the two most prominent glands, termed Skene glands, are seen on the inner surface of the external urethral orifice (p. 818).

The urethra receives its blood supply from branches of the inferior vesical/vaginal and internal pudendal arteries. Although still controversial, the pudendal nerve is believed to innervate the most distal part of the striated urogenital sphincter complex. Somatic efferent branches from S2–S4 that course along the

inferior hypogastric plexus variably innervate the sphincter urethrae. An additional discussion of lower urinary tract innervation is found in Chapter 23 (p. 516).

Clinically, chronic infection of the paraurethral glands can lead to urethral diverticula. Due to the multiple openings of these glands along the length of the urethra, diverticula may develop at various sites along the urethra.

### Rectum

The rectum is continuous with the sigmoid colon approximately at the level of the third sacral vertebra (see Fig. 38-19). It descends on the anterior surface of the sacrum for approximately 12 cm and ends in the anal canal after passing through the levator hiatus. The anterior and lateral portions of the

proximal two thirds of the rectum are covered by peritoneum. The peritoneum is then reflected onto the posterior vaginal wall to form the posterior *cul-de-sac of Douglas*, also termed *rectouterine pouch*. In women, the cul-de-sac is located approximately 5 to 6 cm from the anal orifice and can be palpated manually during rectal or vaginal examination. At its commencement, the rectal wall is similar to that of the sigmoid, but near its termination it becomes dilated to form the rectal ampulla, which begins below the posterior cul-de-sac peritoneum.

The rectum contains several, usually three, transverse folds called the *plicae transversales recti*, also termed valves of Houston (Fig. 38-21). The largest and most constant of these folds is located anteriorly and to the right, approximately 8 cm from the anal orifice. These folds may contribute to fecal continence by supporting fecal matter above the anal canal. Clinically, in the empty state, the transverse rectal folds overlap each other, making it difficult at times to manipulate an examining finger or endoscopy tube past this level.

## RETROPERITONEAL SURGICAL SPACES

### Pelvic Sidewall

Several retroperitoneal spaces are important for the pelvic surgeon. Of these, the retroperitoneal space of the pelvic sidewalls contains the internal iliac vessels and pelvic lymphatics, pelvic ureter, and obturator nerve.

During surgery, entering the retroperitoneum at the pelvic sidewall can be used to identify the ureter (Fig. 38-22). Moreover, it is an essential step for many of the surgeries described in gynecologic oncology.

### Vessels

The major pelvic vessels are shown in Figures 38-12, 38-14, and 38-22. The internal iliac and external iliac vessels and their corresponding lymph node groups lie within the pelvic sidewall retroperitoneal space (see Fig. 38-16).

Clinically, if severe hemorrhage is encountered during pelvic surgery, the internal iliac artery may be ligated to decrease the

**FIGURE 38-21** Ischioanal fossa and anal sphincter complex.

**FIGURE 38-22** Surgical view of left pelvic sidewall retroperitoneal space showing the ureter attached to medial leaf of broad ligament.

pulse pressure to pelvic organs. When this vessel is dissected, the ureter is also identified and avoided. The internal iliac artery is ligated distal to the origin of its posterior division branches. This helps to prevent significant devascularization of the gluteal muscles. These posterior division branches generally arise from the posterolateral wall of the internal iliac artery at a site 3 to 4 cm from its origin off the common iliac artery (Bleich, 2007).

### Pelvic Ureter

As the ureter enters the pelvis, it crosses over the bifurcation of the common iliac artery or the proximal portion of the external iliac artery and passes just medial to the ovarian vessels (see Fig. 38-15). It descends into the pelvis attached to the medial leaf of the pelvic sidewall peritoneum. Along this course, the ureter lies medial to the internal iliac branches and anterolateral to the uterosacral ligaments (see Figs. 38-14, 38-15, and 38-22). The ureter then traverses through the cardinal ligament approximately 1 to 2 cm lateral to the cervix. Near the level of the uterine isthmus, it courses below the uterine artery (“water under the bridge”). It then travels anteromedially toward the bladder base (see Fig. 38-15). In this path, it runs close to the upper third of the anterior vaginal wall (Rahn, 2007). Finally, the ureter enters the bladder and travels obliquely for approximately 1.5 cm before opening at the ureteral orifices.

The pelvic ureter receives blood supply from the vessels it passes: the common iliac, internal iliac, uterine, and superior vesical vessels. The ureter’s course runs medial to these vessels, and thus its blood supply reaches the ureter from lateral sources. This is important during ureteral isolation. In contrast, the abdominal part of the ureter courses lateral to major vessels and accordingly, it receives most of its blood supply from medially located vessels. Vascular anastomoses on the connective tissue sheath enveloping the ureter form a longitudinal network of vessels.

Clinically, because of the pelvic ureter’s proximity to many structures encountered during gynecologic surgery, emphasis is placed on its precise intraoperative identification. Most ureters are injured during gynecologic surgery for benign disease. More than 50 percent of these injuries are not diagnosed intraoperatively (Ibeanu, 2009). The most common sites of injury include: (1) the pelvic brim area during infundibulopelvic ligament clamping; (2) the isthmic region during uterine artery ligation, (3) the pelvic sidewall during uterosacral ligament suturing, and (4) the lateral vaginal apex during vaginal cuff clamping or suturing.

### ■ Presacral Space

This retroperitoneal space lies between the rectosigmoid/posterior abdominal wall peritoneum and the sacrum (Figs. 38-18 and 38-23). It begins below the aortic bifurcation and extends

**FIGURE 38-23** Presacral space. L5 = fifth lumbar vertebra; S1 = first sacral nerve.

inferiorly to the pelvic floor. Laterally, this space is bounded by the internal iliac vessels and branches and by the fascia that covers the piriformis muscle and sacral nerves. Contained within the loose areolar and connective tissue of this space are the superior hypogastric plexus, hypogastric nerves, and portions of the inferior hypogastric plexus (see Figs. 38-14 and 38-23). The sacral lymph node group is also found here (see Fig. 38-16). In addition, the sacral sympathetic trunk, a continuation of the lumbar trunk, lies against the sacrum's ventral surface and medial to the sacral foramina.

The presacral space contains an extensive and intricate venous plexus, termed the *sacral venous plexus*. This plexus is formed primarily by the anastomoses of the middle and lateral sacral veins on the anterior surface of the sacrum. The *middle sacral vein* commonly drains from this plexus into the left common iliac vein, whereas each *lateral sacral vein* opens into its respective internal iliac vein. Ultimately, these vessels drain into the caval system. The sacral venous plexus also receives contributions from the *lumbar veins* of the posterior abdominal wall and from the *basivertebral veins* that pass through the pelvic sacral foramina. The *middle sacral artery*, which courses in proximity to the *middle sacral vein*, arises from the posterior and distal part of the abdominal aorta.

In studies of presacral space vascular anatomy, the left common iliac vein was the closest major vessel identified both cephalad and lateral to the midsacral promontory. The average distance of the left common iliac vein from the midsacral promontory is 2.7 cm (range 0.9–5.2 cm) (Good, 2013b; Wieslander, 2006).

Surgically, the presacral space is most commonly entered to perform abdominal sacrocolpopexy or presacral neurectomy.

Importantly, during these procedures, bleeding from the sacral venous plexus may be difficult to control as the veins may retract into the sacral foramina. For sacrocolpopexy, the sacral promontory's midpoint is an important landmark, and the right ureter, right common iliac artery, and left common iliac vein are found within 3 cm of the midsacral promontory (Good, 2013b; Wieslander, 2007). Moreover, the first sacral nerve can be expected approximately 3 cm from the upper surface of the sacrum and 1.5 cm from the midline (Good, 2013b). In supine women, the most prominent presacral space structure is the L5–S1 disc, which extends approximately 1.5 cm cephalad to the “true” sacral promontory (Good, 2013a). Awareness of a 60-degree average drop between the anterior surfaces of L5 and S1 vertebrae assists intraoperative localization of the promontory.

### ■ Prevesical Space

This space is also called the retropubic space or *space of Retzius*. During laparotomy, if an extraperitoneal approach is selected, this space can be entered by perforating the transversalis fascial layer of the anterior abdominal wall (see Fig. 38-19). If an intraperitoneal approach is chosen, then only the anterior abdominal wall peritoneum is incised to access this space. The prevesical space is bounded by the bony pelvis and muscles of the pelvic wall anteriorly and laterally and by the anterior abdominal wall ventrally (see Figs. 38-18, 38-19, and Fig. 38-24). The bladder and proximal urethra lie posterior within this space. Attachments of the paravaginal connective tissue to the arcus tendineus fascia pelvis constitute the posterolateral limit of the space and separate this space from the vesicovaginal and vesicocervical spaces.

**FIGURE 38-24** Retropubic space. PS = pubic symphysis.

There are several vessels and nerves in this space. The *dorsal vein of the clitoris* passes under the lower border of the pubic symphysis and drains into the *periurethral-perivesical venous plexus*, also termed the *plexus of Santorini* (Pathi, 2009). The *obturator neurovascular bundle* courses along the lateral pelvic walls and enters the obturator canal to reach the medial compartment of the thigh. The autonomic nerve branches that supply the bladder and urethra course on the lateral borders of these structures. Additionally, in most women, accessory obturator vessels that arise from or open into the inferior epigastric or external iliac vessels are found crossing the superior pubic rami and connecting with the obturator vessels near the obturator canal. Clinically, the obliterated umbilical or the superior vesical arteries are used to describe the medial boundary of the paravesical space. The paravesical space represents the lateral boundaries of the prevesical space (see Fig. 38-18).

Surgically, injury to the obturator neurovascular bundle or accessory obturator vessels is most often associated with pelvic lymph node dissection, paravaginal defect repair, and pelvic fractures. The obturator canal is found approximately 5 to 6 cm from the midline of the pubic symphysis, and 1 to 2 cm below the upper margin of the iliopectineal ligament (Drewes, 2005).

Bleeding from the periurethral-perivesical venous plexus is often encountered while placing sutures or passing needles into this space during retropubic bladder neck suspensions and midurethral retropubic procedures, respectively. This venous ooze usually stops when pressure is applied or sutures are tied.

In a cadaver study, proximal paravaginal defect repair sutures placed at the level of the ischial spines were found an

average of 2.3 cm away from the ureter but as close as 5 mm (Rahn, 2007). This further highlights the value of intraoperative cystoscopy during retropubic surgeries.

## VULVA AND PERINEUM

### Vulva

The external female genitalia, collectively known as the *vulva*, lie on the pubic bones and extend posteriorly. Structures included are the mons pubis, labia majora and minora, clitoris, vestibule, vestibular bulbs, greater vestibular glands (Bartholin glands), lesser vestibular glands, Skene and paraurethral glands, and the urethral and vaginal orifices (Fig. 38-25). The embryologic development and homologues of these structures can be found in Table 18-1 (p. 404).

### Mons Pubis and Labia Majora

The *mons pubis*, also called the *mons veneris*, is the rounded fat pad that lies ventral to the pubic symphysis. The labia majora are two prominent folds that extend from the mons pubis toward the perineal body posteriorly. Skin over the mons pubis and labia majora contains hair and has a subcutaneous layer similar to that of the anterior abdominal wall. The subcutaneous layer consists of a superficial fatty layer similar to Camper fascia, and a deeper membranous layer, *Colles fascia* (see Fig. 38-25). Also known as the *superficial perineal fascia*, Colles fascia is similar to and continuous with Scarpa fascia of the anterior abdominal wall.

**FIGURE 38-25** Vulvar structures and subcutaneous layer of anterior perineal triangle. Note the continuity of Colles and Scarpa fasciae. Inset: Vestibule boundaries and openings onto vestibule.

**FIGURE 38-26** Anterior (superficial space of anterior triangle) and posterior perineal triangles. On the image's left are the structures noted after removal of Colles fascia. On the image's right are the structures noted after removal of the superficial perineal muscles.

The round ligament and obliterated *processus vaginalis*, which is also termed the *canal of Nuck*, exit the inguinal canal and attach to the adipose tissue or skin of the labia majora.

Clinically, Colles fascia attaches firmly to the ischiopubic rami laterally and the perineal membrane posteriorly. These attachments prevent the spread of fluid, blood, or infection from the superficial perineal space to the thighs or posterior perineal triangle. Anteriorly, Colles fascia has no attachments to the pubic rami, and it is therefore continuous with the lower anterior abdominal wall (see Fig. 38-25). This continuity may allow the spread of fluid, blood, and infection between these compartments.

Clinically, a mass found in one labium majus may be a leiomyoma arising from the distal round ligament, a persistent *processus vaginalis*, or breast tissue along the distal milk line. An indirect inguinal hernia may also reach the labium majus by passing through the deep inguinal ring and inguinal canal.

### Labia Minora

These two cutaneous folds lie between the labia majora (see Fig. 38-25). Anteriorly, each labium minus bifurcates to form two folds that surround the glans of the clitoris. The prepuce is the anterior fold that overlies the glans, and the frenulum is the fold that passes below the clitoris. Posteriorly, the labia minora end at the fourchette.

In contrast to the skin that overlies the labia majora, the skin of the labia minora does not contain hair. Also, the subcutaneous tissue is devoid of fat and consists primarily of loose connective tissue. This latter attribute allows mobility of the skin during sex and accounts for the ease of dissection with vulvectomy.

Clinically, labia minora are typically symmetric, but their size and shape can vary widely between women. In some, these winglike structures are pendulous and can be drawn into the vagina during coitus. If associated with dyspareunia in this setting, the labia can be surgically reduced. Moreover, chronic

dermatologic diseases such as lichen sclerosus may lead to significant atrophy or disappearance of the labia minora.

### Clitoris

This is the female erectile structure homologous to the penis. It consists of a glans, a body, and two crura. The glans contains many nerve endings and is covered by a thinly keratinized stratified squamous epithelium. The body measures approximately 2 cm and is connected to the pubic ramus by the crura (Fig. 38-26).

### Vaginal Vestibule

This is the area between the two labia minora. It is bounded laterally by the line of Hart and medially by the hymeneal ring. Hart line represents the demarcation between the skin and mucous membrane on the inner surface of the labia minora. The vestibule extends from the clitoris anteriorly to the fourchette posteriorly (see Fig. 38-25 inset). It contains the openings of the urethra; vagina; greater vestibular glands, also known as Bartholin glands; and Skene glands, which are the largest pair of paraurethral glands. It also contains the numerous openings of the lesser vestibular glands. A shallow vestibular depression known as the navicular fossa lies between the vaginal orifice and the fourchette.

Clinically, localized vulvar dysesthesia—also termed vulvar vestibulitis—is characterized by pain with vaginal penetration, localized point tenderness, and erythema of the vestibular mucosa. In other women, when choosing incision sites for Bartholin gland drainage or marsupialization, Hart line is clinically relevant. That is, in attempts to recreate near-normal gland duct anatomy following these procedures, incisions placed external to Hart line are avoided (Kaufman, 1994).

### Vestibular Bulbs

These are homologues to the male penile bulb and corpus spongiosum. They are two elongated, approximately 3-cm long,

richly vascular erectile masses that surround the vaginal orifice (see Fig. 38-26). Their posterior ends are in contact with the Bartholin glands. Their anterior ends are joined to one another and to the clitoris. Their deep surfaces are in contact with the perineal membrane, and their superficial surfaces are partially covered by the bulbospongiosus muscles.

Clinically, the proximity of the Bartholin glands to the vestibular bulbs accounts for the significant bleeding often encountered with Bartholin gland excision (Section 43-20, p. 975). Following vulvar trauma, laceration of these bulbs or the clitoral crus may lead to sizable hematomas.

### Bartholin Glands

These are the homologues of the male bulbourethral or Cowper glands. They are in contact with and often overlapped by the posterior ends of the vestibular bulbs (see Fig. 38-26). Each gland is connected to the vestibule by an approximately 2-cm long duct. The ducts open in the groove between the hymen and the labia minora—the vestibule—at approximately 5 and 7 o'clock positions.

The glands contain columnar cells that secrete clear or whitish mucus with lubricant properties. These glands are stimulated by sexual arousal. Contraction of the bulbospongiosus muscle, which covers the superficial surface of the gland, expresses gland secretions.

Clinically, obstruction of the Bartholin ducts by proteinaceous material or by inflammation from infection can lead to cysts of variable sizes. An infected cyst can lead to an abscess, which typically requires surgical drainage. Symptomatic or recurrent cysts may require marsupialization or gland excision.

## ■ Perineum

The *perineum* is the diamond-shaped area between the thighs (see Fig. 38-25). It is bounded deeply by the inferior fascia of the pelvic diaphragm and superficially by the skin between the thighs. The anterior, posterior, and lateral boundaries of the perineum are the same as those of the bony pelvic outlet: the pubic symphysis anteriorly, ischiopubic rami and ischial tuberosities anterolaterally, coccyx posteriorly, and sacrotuberous ligaments posterolaterally. An arbitrary line joining the ischial tuberosities divides the perineum into the anterior or *urogenital triangle*, and a posterior or *anal triangle*.

### Anterior (Urogenital) Triangle

Structures that comprise the vulva or external female genitalia lie in the anterior triangle of the perineum. The base or posterior border of this triangle is the *interischial line*, which usually overlies the *superficial transverse perineal muscles* (see Fig. 38-26).

The anterior perineal triangle can be further divided into a *superficial* and a *deep pouch* or *space* by the *perineal membrane*. The superficial perineal space lies superficial to the perineal membrane, and the deep space lies above or deep to the membrane.

**Superficial Space.** This space of the anterior triangle is an enclosed compartment that lies between Colles fascia and the perineal membrane. It contains the ischiocavernosus, bulbospongiosus, and superficial transverse perineal muscles; Bartholin

glands; vestibular bulbs; clitoris; and branches of the pudendal vessels and nerve. The urethra and vagina traverse this space.

The *ischiocavernosus muscle* attaches to the medial aspect of the ischial tuberosities posteriorly and the ischiopubic rami laterally. Anteriorly, it attaches to the crus of the clitoris. This muscle may help maintain clitoral erection by compressing the crus of the clitoris, thus retarding venous drainage.

The *bulbospongiosus muscle*, also known as the bulbocavernosus muscle, covers the superficial portion of the vestibular bulbs and Bartholin glands. These muscles attach to the body of the clitoris anteriorly and the perineal body posteriorly. The muscles act to constrict the vaginal lumen, contributing to the release of Bartholin gland secretions. They may also contribute to clitoral erection by compressing the deep dorsal vein of the clitoris. The bulbospongiosus muscle, along with the ischiocavernosus muscle, acts to pull the clitoris downward.

The *superficial transverse perineal muscles* are narrow strips that attach to the ischial tuberosity laterally and the perineal body medially. They may be attenuated or even absent, but when present, they contribute to the perineal body.

**Deep Perineal Space.** This pouch lies deep or superior to the perineal membrane (Fig. 38-27). In contrast to the superficial space, which is a closed compartment, the deep space is continuous superiorly with the pelvic cavity. It contains the compressor urethrae and urethrovaginal sphincter muscles, parts of the urethra and vagina, branches of the internal pudendal artery, and the dorsal nerve and vein of the clitoris.

**Perineal Membrane (Urogenital Diaphragm).** Traditionally, a trilaminar, triangular urogenital diaphragm has been described as the main component of the deep perineal space. According to this concept, the urogenital diaphragm consisted of the deep transverse perineal muscles and sphincter urethrae muscles between the perineal membrane (inferior fascia of the urogenital diaphragm) and a superior layer of fascia (superior fascia of the urogenital diaphragm). However, the term *diaphragm* is used to describe a closed compartment. As described earlier, the deep perineal space is an open compartment. It is bounded inferiorly by the perineal membrane and extends up into the pelvis (Oelrich, 1980, 1983). As a result, when describing perineal anatomy, the terms *urogenital diaphragm* or *inferior fascia of the urogenital diaphragm* are misnomers and have been replaced by the anatomically correct term, *perineal membrane*.

The perineal membrane constitutes the deep boundary of the superficial perineal space (see Fig. 38-27). It attaches laterally to the ischiopubic rami, medially to the distal third of the urethra and vagina, and posteriorly to the perineal body. Anteriorly, it attaches to the arcuate ligament of the pubis. In this area, the perineal membrane is particularly thick and is often referred to as the *pubourethral ligament*.

The perineal membrane consists of two histologically and probably functionally distinct portions that span the opening of the anterior pelvic triangle (Stein, 2008). The dorsal or posterior portion is a dense fibrous tissue sheet that attaches laterally to the ischiopubic rami and medially to the distal third of the vagina and to the perineal body (see Fig. 38-27). The ventral or anterior portion of the perineal membrane is intimately associated with the compressor urethrae and urethrovaginal sphincter

**FIGURE 38-27** Deep space of anterior perineal triangle. On the image's right lie structures noted after removal of the perineal membrane. Also shown are all structures that attach to perineal body: bulbospongiosus, superficial transverse perineal, external anal sphincter, and puboperinealis muscles, perineal membrane, and urethrovaginal sphincter. Inset: Striated urogenital sphincter muscles.

muscles, previously called the deep transverse perineal muscles in the female (see Fig. 38-27 inset). Moreover, the ventral portion of the perineal membrane is continuous with the insertion of the arcus tendineus fascia pelvis to the pubic bones (see Fig. 38-20). The deep or superior surface of the perineal membrane appears to have direct connections to the levator ani muscles, and the superficial or inferior surface of the membrane fuses with the vestibular bulb and clitoral crus.

Clinically, the perineal membrane attaches to the lateral walls of the vagina approximately at level of the hymen. It provides support to the distal vagina and urethra by attaching these structures to the bony pelvis. In addition, its attachments to the levator ani muscles suggest that the perineal membrane may play an active role in support.

### Posterior (Anal) Triangle

This triangle contains the ischioanal fossa, anal canal, anal sphincter complex, and branches of the internal pudendal vessels and pudendal nerve (Figs. 38-21, 38-27, and Fig. 38-28). It is bounded deeply by the fascia overlying the inferior surface of the levator ani muscles, and laterally by the fascia overlying the medial surface of the obturator internus muscles. A splitting of the obturator internus fascia in this area is known as the *pudendal* or *Alcock canal* (see Figs. 38-6 and 38-21). This canal allows passage of the internal pudendal vessels and pudendal nerve before these structures split into terminal branches to supply the structures of the vulva and perineum (see Fig. 38-28).

The *ischioanal* or *ischioanal fossa* fills most of the anal triangle (see Figs. 38-21 and 38-28). It contains adipose tissue

and occasional blood vessels. The anal canal and anal sphincter complex lie in the center of this fossa. The ischioanal fossa is bounded superomedially by the inferior fascia of the levator muscles; anterolaterally by the fascia covering the medial surface of the obturator internus muscles and the ischial tuberosities; and posterolaterally by the lower border of the gluteus maximus muscles and sacrotuberous ligaments. At a superficial level, the ischioanal fossa is bounded anteriorly by the superficial transverse perineal muscles. At a superior or deeper level, there is no fascial boundary between the fossa and the tissues deep to the perineal membrane. Posterior to the anus, the contents of the fossa are continuous across the midline except for the attachments of the external anal sphincter fibers to the coccyx. This continuity of the ischioanal fossa across perineal compartments allows fluid, infection, and malignancy to spread from one side of the anal canal to the other, and also into the anterior perineal compartment deep to the perineal membrane.

The anal sphincter complex consists of two sphincters and the puborectalis muscle. The external anal sphincter consists of striated muscle that surrounds the distal anal canal. It consists of a superficial and a deep portion. The more superficial fibers lie caudal to the internal sphincter and are separated from the anal epithelium only by submucosa. The deep fibers blend with the lowest fibers of the puborectalis muscle. The external sphincter is primarily innervated by the inferior rectal branch of the pudendal nerve. The external anal sphincter is responsible for the squeeze pressure of the anal canal.

The internal anal sphincter is the thickening of the circular smooth muscle layer of the anal wall (see Fig. 38-21). It

**FIGURE 38-28** Pudendal nerve and vessels. Nerve supply to striated urogenital sphincter and external anal sphincter muscles.

is under the control of the autonomic nervous system and is responsible for approximately 80 percent of the resting pressure of the anal canal.

As noted earlier, the puborectalis muscle comprises the medial portion of the levator ani muscle that arises on either side from the inner surface of the pubic bones. It passes behind the rectum and forms a sling behind the anorectal junction, contributing to the anorectal angle and possibly to fecal continence (see Figs. 38-9, 38-10, and 38-27).

### Perineal Body

This fibromuscular tissue mass lies between the distal part of the posterior vaginal wall and the anus. It is formed by the attachment of several structures. Inferiorly or superficially, the structures that attach to and contribute to the perineal body include the bulbospongiosus, superficial transverse perineal, and external anal sphincter muscles (see Fig. 38-26). Structures that attach at a superior or deeper level are the perineal membrane, levator ani muscles and covering fascia, urethrovaginal sphincter muscles, and distal part of the posterior vaginal wall (see Fig. 38-27). The anterior-to-posterior and the superior-to-inferior extents of the perineal body each measure approximately 2 to 4 cm (see Fig. 38-17).

Clinically, during vaginal laceration repairs and with pelvic reconstructive procedures, particular attention is given to perineal body reconstruction. As noted on page 812, the distal support provided by the perineal body helps prevent pelvic organ prolapse and other pelvic floor dysfunction.

### ■ Blood Supply, Lymphatics, and Innervation

#### Blood Vessels

The external pudendal artery is a branch of the femoral artery and supplies the skin and subcutaneous tissue of the mons

pubis (see Fig. 38-3). The internal pudendal artery is a terminal branch of the internal iliac artery (see Fig. 38-6). It exits the pelvis through the greater sciatic foramen, passes behind the ischial spines, and reenters the perineum through the lesser sciatic foramen. It then has a variable course through the pudendal or Alcock canal, and then divides into terminal branches. These are the inferior rectal, perineal, and clitoral arteries (see Fig. 38-28). Branches to the perineum sometimes arise from the pudendal artery before it exits the pelvis. These vessels are called accessory pudendal arteries. Other accessory vessels may also arise directly from the anterior or posterior division of the internal iliac artery.

The veins that drain the structures of the vulva and perineum have courses and names similar to those of the arteries. Venous blood from the vestibular bulbs and other structures, with the exception of the erectile tissue of the clitoris, drains into the internal pudendal veins. The erectile tissue drains into the dorsal vein of the clitoris (see Fig. 38-27). This vein courses backward into the pelvis and terminates in the periurethral-perivesical venous plexus (see Fig. 38-24). The venous plexus that drains the rectum and anal canal empties into the superior, middle, and inferior rectal veins. The superior rectal vein drains into the inferior mesenteric vein, a tributary of the portal vein. The middle rectal vein drains into the internal iliac vein. The inferior rectal vein drains into the internal pudendal and then the internal iliac vein.

### Lymphatic Drainage

Structures of the vulva and perineum drain into the inguinal lymph nodes, which are located below the inguinal ligament in the upper anterior and medial thigh (Fig. 38-29). There are 10 to 20 inguinal nodes, which are divided into a superficial and a deep group. Nodes of the superficial inguinal group are

**FIGURE 38-29** Inguinal lymph nodes and contents of femoral triangle. Superficial inguinal nodes are shown on the image's left, and deep inguinal nodes appear on the image's right.

more numerous, and they are found in the membranous layer of the subcutaneous tissue of the anterior thigh, just superficial to the fascia lata.

The deep inguinal nodes vary from one to three in number and are located deep to the fascia lata in the femoral triangle. This triangle is bordered superiorly by the inguinal ligament, laterally by the medial border of the *sartorius muscle*, and medially by the medial border of the *adductor longus muscle*. The *iliopsoas* and *pectineus muscles* form its floor. From lateral to medial, the structures found in this triangle are the femoral nerve, artery, vein, and deep inguinal lymphatics. The femoral canal is the space that lies on the medial side of the femoral vein and that contains the deep inguinal nodes. The femoral ring is the abdominal opening of the femoral canal. The *fossa ovalis* or *saphenous opening* is an oval opening in the fascia lata and allows communication between superficial and deep inguinal nodes. Of the deep inguinal nodes, the highest one—*Cloquet node*—is located in the lateral part of the femoral ring. Efferent channels from the deep inguinal nodes pass through the femoral canal and femoral ring to the external iliac nodes. Lymphatics from the skin of the labia, clitoris, and remainder of the perineum drain into the superficial inguinal nodes. The glans and corpora cavernosa of the clitoris may drain directly to the deep inguinal nodes.

Surgically, sampling of the superficial, and sometimes also the deep, inguinal nodes is completed as one part of radical vulvectomy. Familiarity with the surrounding anatomy is essential.

### Innervation

The inferior anal, perineal, and dorsal nerve of the clitoris are branches of the pudendal nerve and provide sensory and motor innervation to the perineum (see Fig. 38-28). The pudendal nerve is a branch of the sacral plexus and is formed by the anterior rami of the second through the fourth sacral nerves (see Fig. 38-6).

It has a course and distribution similar to those of the internal pudendal artery. In addition, the perineal branches of the posterior femoral cutaneous nerve (S1-S3) supply the skin of the external genitalia and adjacent proximal medial surface of the thigh.

Clinically, pudendal nerve blocks can be performed transvaginally or transgluteally by injecting local anesthesia just medial and inferior to the ischial spine. Importantly, inadvertent injection of local anesthetic into the internal pudendal vessels may lead to seizure activity and other complications (Chap. 40, p. 842).

Postsurgical pain in the distribution of the dorsal nerve of the clitoris has been reported following midurethral sling procedures. However, anatomic studies show that this nerve courses superficial or caudal to the perineal membrane, and trocar and mesh placement during these procedures remains deep or cephalad to the membrane (Montoya, 2011; Rahn, 2006).

Clitoral erection requires parasympathetic visceral efferents derived from the pelvic plexus nerves, sometimes called *nervi erigentes*. These arise from the second to the fourth sacral spinal cord segments. They reach the perineum along the urethra and vagina, passing through the urogenital hiatus (see Fig. 38-13). Sympathetic fibers reach the perineum with the pudendal nerve.

Each year, more than 30 million surgical procedures are performed. During these, nearly 1 million patients suffer a postoperative complication (Mangano, 2004). As surgeons, gynecologists assume responsibility for assessing a patient's clinical status to identify modifiable risk factors and prevent perioperative morbidity. However, clinicians should also be prepared to diagnose and manage such complications if they arise.

### PREOPERATIVE PATIENT EVALUATION

A properly performed preoperative evaluation serves three important functions. It uncovers comorbidities that require further evaluation and improvement to avert perioperative complications. Second, evaluation allows effective use of operating room resources (Roizen, 2000). Finally, the surgeon is able to anticipate potential problems and devise an appropriate perioperative plan (Johnson, 2008).

In many cases, a thorough history and physical examination averts the need for medical consultation. However, if a poorly controlled or previously undiagnosed disease is discovered, consultation with an internist can be beneficial. Preoperative internal medicine consultation does not provide "medical clearance" but rather offers a risk assessment of a woman's current medical state. For consultation, a summary of the surgical illness is provided, and clear questions are posed to the consultant (Fleisher, 2009; Goldman, 1983). In addition, a complete his-

tory and physical examination and prior medical records that report already completed diagnostic testing should be available to the consulting physician. This can prevent unnecessary surgical delays and cost from redundant testing.

### PULMONARY EVALUATION

#### ■ Risk Factors for Pulmonary Complications

Common postoperative pulmonary morbidities include atelectasis, pneumonia, and exacerbation of chronic lung diseases. Incidences of such complications following surgery are estimated to be between 20 and 70 percent (Bernstein, 2008; Brooks-Brunn, 1997; Qaseem, 2006).

Risks for pulmonary complications fall into one of two major categories: procedure-related and patient-related. Of procedure-related risks, upper abdominal incisions as they approach the diaphragm can worsen pulmonary function through three mechanisms, shown in [Figure 39-1](#). Resulting poor diaphragmatic movement can produce persistent declines in vital capacity and in functional residual capacity. These predispose to atelectasis (Warner, 2000). Surgery duration is another procedure-associated factor. Operations in which patients receive general anesthesia for longer than 3 hours are associated with nearly double the rate of postoperative pulmonary complications. Finally, emergency surgery remains a significant independent risk. Although these factors are largely unmodifiable, an appreciation of their sequelae should prompt increased postoperative vigilance.

Of patient-associated factors, *age* plays a role. Individuals older than 60 years are at increased risk for developing postoperative pulmonary complications. After patients are stratified for comorbidities, those between 60 and 69 years have a two-fold increased risk. In those older than 70 years, risk rises three-fold (Qaseem, 2006). Importantly, for at-risk patients, baseline cognition should be documented and postoperative sensorium monitored, as changes may be an early indicator of pulmonary function compromise.

*Smoking*, specifically a greater than 20-pack-year smoking history, confers a high incidence of postoperative pulmonary complications. Fortunately, this risk can be reduced with smoking abstinence before surgery. Preoperative cessation for at least 6 to 8 weeks offers significant improvement in lung function and reversal of smoking-related immune impairment (Akrawi, 1997; Buist, 1976). Other short-term benefits may be related to reduced nicotine and carboxyhemoglobin levels, improved mucociliary function, decreased upper airway hypersensitivity, and improved wound healing (Møller, 2002; Nakagawa, 2001). Patients with a 6-month or longer history of smoking cessation have complication risks similar to those who have never

**FIGURE 39-1** Surgical factors producing respiratory muscle dysfunction. These factors can reduce lung volumes and produce hypoventilation and atelectasis. (Reproduced with permission from Warner DO: Preventing postoperative pulmonary complications: the role of the anesthesiologist. *Anesthesiology* 2000 May;92(5):1467–1472.)

smoked. Moreover, patients often see surgery as an opportunity for positive change (Shi, 2010). Brief interventions offered in close proximity to surgery may have small benefit on long-term smoking behavior (Tomsen, 2014). Education alone may prompt successful behavior modification. For others, agents to assist with smoking cessation can be found in Table 1-4, (p. 11).

In *chronic obstructive pulmonary disease (COPD)*, inflammatory mediators may account for the intra- and extrapulmonary complications observed in affected patients (Maddali, 2008). Simple COPD optimization may not reduce the incidence of postoperative pulmonary complications. However, postoperative physiotherapy and incentive spirometry with inspiratory muscle training reduce complication rates (Agostini, 2010).

*Obesity* can decrease chest wall compliance and functional residual capacity and predispose patients with a body mass index (BMI)  $\geq 30$  kg/m<sup>2</sup> to intra- and postoperative atelectasis (Agostini, 2010; Zerah, 1993). Eichenberger and colleagues (2002) observed that pulmonary changes in these patients may persist for more than 24 hours and require aggressive postoperative lung expansion. Moreover, in obese patients undergoing laparoscopy, these pulmonary parameters are further compromised by increased intraabdominal pressures from pneumoperitoneum, as described in Chapter 41 (p. 874).

*Asthma*, if well-controlled, is not a risk factor for postoperative pulmonary complications. Warner and coworkers (1996) reported that rates of bronchospasm were less than 2 percent in asthmatic patients.

## ■ Diagnostic Evaluation

### History and Physical Examination

Elements in a pulmonary review of systems that may serve as harbingers of underlying disease include poor exercise tolerance, chronic cough, and otherwise unexplained dyspnea (Smetana, 1999). Examination findings of decreased breath sounds, dullness to percussion, rales, wheezes, rhonchi, and a prolonged expiratory phase can carry a nearly sixfold increase in pulmonary complications (Straus, 2000).

### Pulmonary Function Tests (PFTs) and Chest Radiography

In general, pulmonary function tests (PFTs) offer little information during preoperative pulmonary assessment of patients undergoing nonthoracic procedures. Outside of diagnosing COPD, PFTs are not superior to a thorough history and physical examination (Johnson, 2008; Qaseem, 2006). However, if the etiology of pulmonary symptoms remains unclear after clinical examination, then PFTs may provide information to alter perioperative management.

Chest radiography is not routinely obtained preoperatively. Compared with a clinical history and physical examination, preoperative chest radiographs rarely provide evidence to modify therapy (Archer, 1993). The American College of Radiology (2011) recommends that patients with new or exacerbated cardiopulmonary symptoms or those older than 70 years with chronic cardiopulmonary disease as suitable candidates for imaging. Although not exhaustive, conditions for which radiography may be reasonable include acute or chronic cardiovascular or pulmonary disease, cancer, American Society of Anesthesiologist (ASA) status  $> 3$ , heavy smoking, immunosuppression, recent chest radiation therapy, and recent emigration from areas with endemic pulmonary disease.

### Biochemical Markers

The National Veterans Administration Surgical Quality Improvement Program reported that serum albumin levels less than 3.5 g/dL were significantly associated with increased perioperative pulmonary morbidity and mortality rates (Arozullah, 2000; Lee, 2009). For each 1 mg/dL decline in serum albumin concentration, the odds of mortality are increased by 137 percent and morbidity by 89 percent (Vincent, 2004). Serum albumin's association with morbidity and mortality may be due to confounding comorbidity, and thus it is a marker of malnutrition and disease (Goldwasser, 1997). Although a serum albumin level is not routinely recommended for gynecologic procedures, the information may be predictive in the elderly or in those with multiple comorbidities. Moreover, serum blood urea nitrogen (BUN) levels greater than 21 mg/dL similarly correlate with increased morbidity and mortality rates, but not to the same degree as serum albumin levels.

### Preoperative Pulmonary Guidelines

The ASA Classification was created to help predict perioperative mortality rates. It also serves to assess risks for cardiovascular and pulmonary complications (Wolters, 1996). Table 39-1 summarizes the ASA categories and associated rates of postoperative pulmonary complications (Qaseem, 2006).

**TABLE 39-1.** American Society of Anesthesiologists (ASA) Classification

ASA Class	Class Definition	Rates of PPCs by Class (%)
I	Normally healthy patient	1.2
II	With mild systemic disease	5.4
III	With systemic disease that is not incapacitating	11.4
IV	With an incapacitating systemic disease that is a constant threat to life	10.9
V	Moribund patient who is not expected to survive for 24 hours with or without operation	NA

NA = not applicable; PPCs = postoperative pulmonary complications.

Modified with permission from Qaseem A, Snow V, Fitterman N, et al: Risk assessment for and strategies to reduce perioperative pulmonary complications for patients undergoing noncardiothoracic surgery: a guideline from the American College of Physicians. *Ann Intern Med* 2006 Apr 18;144(8):575–580.

## ■ Postoperative Prevention

### Lung Expansion Modalities

Techniques aimed at reducing anticipated postoperative decreases in lung volume can be simple and include deep breathing exercises, incentive spirometry, and early ambulation. In conscious and cooperative patients, deep breathing effectively improves lung compliance and gas distribution (Chumillas, 1998; Ferris, 1960; Tomas, 1994). With these exercises, a woman is asked to take five sequential deep breaths every hour while awake and hold each for 5 seconds. An incentive spirometer can be added to provide direct visual feedback of her efforts. Last, early ambulation can enhance lung expansion and provide some protection against venous thromboembolism. Meyers and associates (1975) demonstrated an increase in functional residual lung capacity of up to 20 percent by simply maintaining an upright posture. Alternatively, formal respiratory physiotherapy may include chest physical therapy in the form of percussion, clapping, or vibration; intermittent positive-pressure breathing (IPPB); and continuous positive airway pressure (CPAP).

The simple and the more formal prophylactic methods are all effective in preventing postoperative pulmonary morbidity, and no method is superior to another. Tomas and colleagues (1994) performed a metaanalysis to compare incentive spirometry (IS), IPPB, and deep-breathing exercises (DBE). In comparison with no therapy, IS and DBE are superior in preventing postoperative pulmonary complications, and greater than 50-percent reductions were observed. In addition, no significant differences were noted comparing IS to DBE, IS to IPPB, and DBE to IPPB (Tomas, 1994). However, chest physical therapy, IPPB, and CPAP are more expensive and labor intensive (Pasquina, 2006). Accordingly, these methods are typically reserved for patients who are unable to perform simpler effort-dependent therapies.

## Nasogastric Decompression

Postoperatively, nasogastric tubes (NGTs) are often placed for gastric decompression. However, nasogastric intubation bypasses normal upper and lower respiratory tract mucosal defenses and exposes patients to risks for nosocomial sinusitis and pneumonia. Routine use of NGT after surgery is associated with increased cases of pneumonia, atelectasis, and aspiration compared with selective use (Cheatham, 1995). Indications for selective use might include symptomatic abdominal distention or postoperative nausea and vomiting from suspected ileus. Accordingly, the choice to implement NGT drainage is balanced against respiratory risks.

## CARDIAC EVALUATION

### ■ Risk Factors for Cardiac Complications

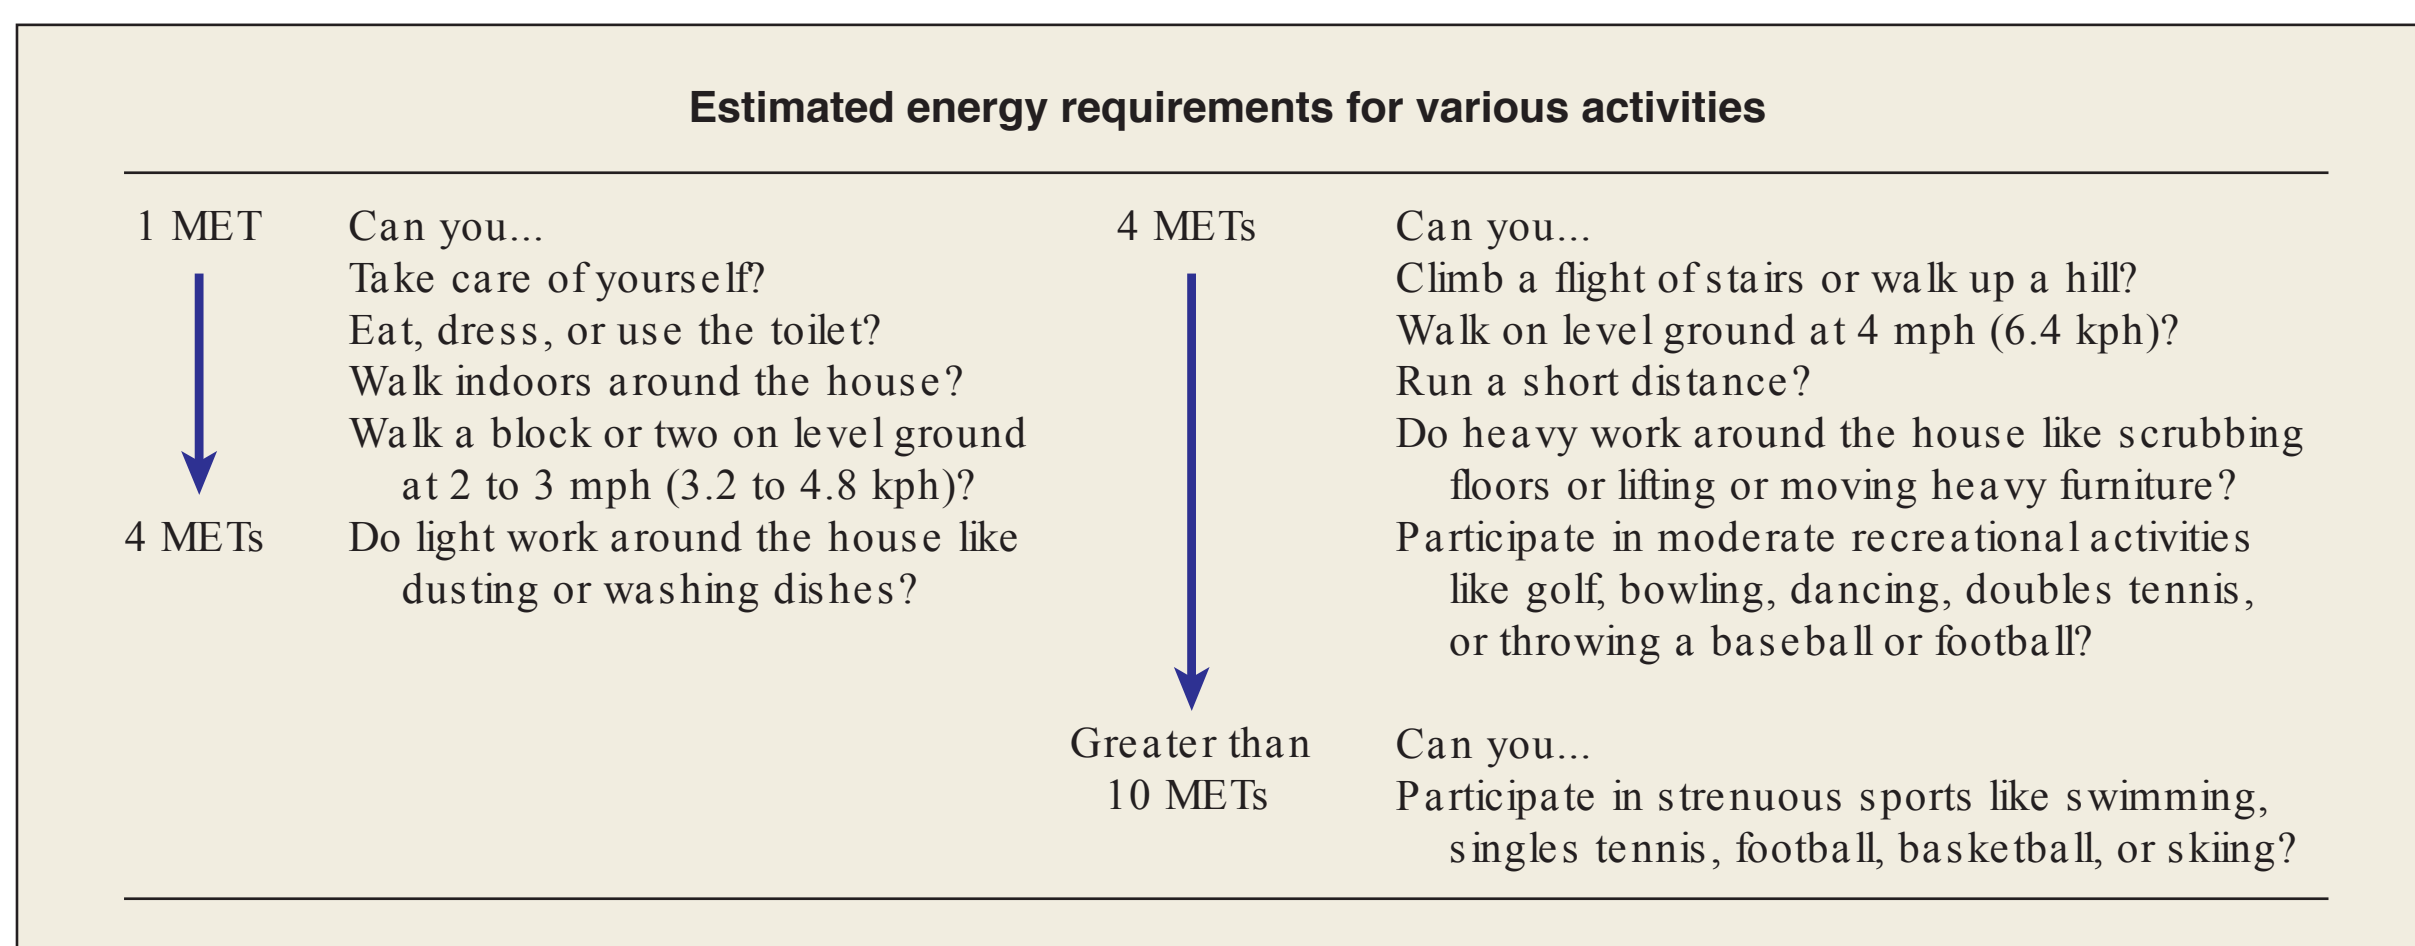

*Coronary artery disease (CAD)* is a leading cause of death in developed countries and contributes significantly to perioperative cardiac complication rates in patients undergoing procedures (Stepp, 2005; Williams, 2009). Accordingly, much of cardiac risk assessment focuses on CAD and is described on page 828.

For *congestive heart failure (CHF)*, a cardiologist may employ strategies to maximize hemodynamic function, such as preoperative coronary revascularization or perioperative medical therapy. With CHF, diuretics are commonly used. However, perioperatively, restraining their use will usually avoid intraoperative hypovolemia and related hypotension. But, if fluid resuscitation is needed, it ideally is gradual and limited to avoid volume overload.

*Arrhythmias* are usually symptoms of underlying cardiopulmonary disease or electrolyte abnormalities. Accordingly, preoperative management focuses on correcting the primary process. However, if pacemakers and implantable cardioverter-defibrillators (ICDs) are required for arrhythmia treatment prior to surgery, they are typically placed for the same indications as in nonoperative circumstances (Gregoratos, 2002). For those with pacemakers in place, electrosurgery can create electromagnetic interference even during noncardiac surgical and endoscopic procedures. Although encountered less frequently with newer devices, such interference can lead to pacing failure or complete system malfunction (Cheng, 2008). Thus, current guidelines recommend that all systems be evaluated by an appropriately trained physician before and after any invasive procedure (Fleisher, 2009). In addition, as discussed in Chapter 40 (p. 859), intraoperative efforts strive to minimize the chance for electromagnetic interference from electrosurgery. Practices include selecting bipolar electrosurgery if possible, using short intermittent bursts of electric current at the lowest possible energy levels, maximizing the distance between the current source and cardiac device, and placing the grounding pad in a position to minimize current flow toward the device.

*Hypertension* is not predictive of perioperative cardiac events and should not postpone surgery (Goldman, 1979; Weksler, 2003). Exceptions for elective procedures might include systolic blood pressures > 180 mm Hg and diastolic blood pressures > 110 mm Hg. If possible, to lower postoperative cardiac complications related to hypertension, blood pressure is lowered several months prior to an anticipated procedure (Fleisher, 2002). Preoperatively, patients on angiotensin-converting enzyme inhibitors and angiotensin-receptor antagonists have

**FIGURE 39-2** Questions used to assess functional capacity. METs are used in the algorithm in Figure 39-3. CAD = coronary artery disease; kph = kilometers per hour; MET = metabolic equivalent; mph = miles per hour. (Reproduced with permission from Fleisher LA, Beckman JA, Brown KA, et al: 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 2009 Nov 24;120(21):e169–e276.)

their morning dose held to reduce the risk of immediate post-induction hypotension (Comfere, 2005). In all patients with hypertension, avoiding hypo- or hypertension intraoperatively with careful postoperative monitoring is recommended. Importantly, intravascular volume expansion, pain, and agitation may exacerbate postoperative hypertension.

*Valvular heart disease* is a less frequently encountered cardiac comorbidity. Of these, aortic stenosis carries the highest independent factor for perioperative complications (Kertai, 2004). For other lesions, the degree of heart failure and associated cardiac arrhythmias are the best indicators of risk. If cardiac sounds are suggestive of valvular disease, echocardiography will assist in defining the abnormality. Importantly, endocarditis prophylaxis for valvular lesions during gastrointestinal (GI) or genitourinary (GU) procedures is no longer recommended by the American Heart Association (Nishimura, 2014). The transient enterococcal bacteremia caused by these procedures has not been irrefutably correlated to infective endocarditis.

## ■ Diagnostic Evaluation

### History and Physical Examination

As with pulmonary disease, history and physical examination can effectively identify or characterize cardiac disease. One questioning strategy is outlined in Figure 39-2. During physical examination, surgeons observe for dependent edema or jugular venous distention, whereas chest palpation searches for the point of maximum impulse and possible thrills. Auscultation of carotid arteries should exclude bruits, and listening at cardiac points investigates cardiac rate, regularity, and extra heart sounds.

### Cardiac Testing

Of preoperative cardiac tests, 12-lead electrocardiogram (ECG) and chest radiograph are commonly considered. According to the American College of Cardiology and the American Heart Association (ACC/AHA), ECG is reasonable for patients with known coronary heart disease, significant arrhythmia, peripheral arterial disease, cerebrovascular disease, or other significant struc-

tural heart disease. ECG is not recommended for those undergoing low-risk surgeries. For asymptomatic patients without known coronary heart disease, ECG may be considered, but again is not useful in those undergoing low-risk procedures (Fleisher, 2014). Indications for preoperative chest radiography are limited and discussed on page 826. Other testing is usually ordered by a consulting cardiologist and often directed by guidelines discussed next.

## Preoperative Cardiac Guidelines

Preoperative guidelines have been developed by several groups to help predict perioperative cardiac complications and direct perioperative care. The two most prominent are: (1) those jointly developed by the ACC/AHA and (2) the Revised Cardiac Risk Index (RCRI) (Fleisher, 2014; Lee, 1999).

Of the two, ACC/AHA guidelines provide a stepwise strategy to assess three major considerations—clinical predictors, surgery-specific risk, and functional capacity—to ascertain the need for cardiac testing (Fig. 39-3). In general, for gynecologic surgery, cardiac complication risks are greatest with major emergency procedures and operations associated with large intravascular fluid shifts. In contrast, lowest risks are found with planned, brief endoscopic procedures.

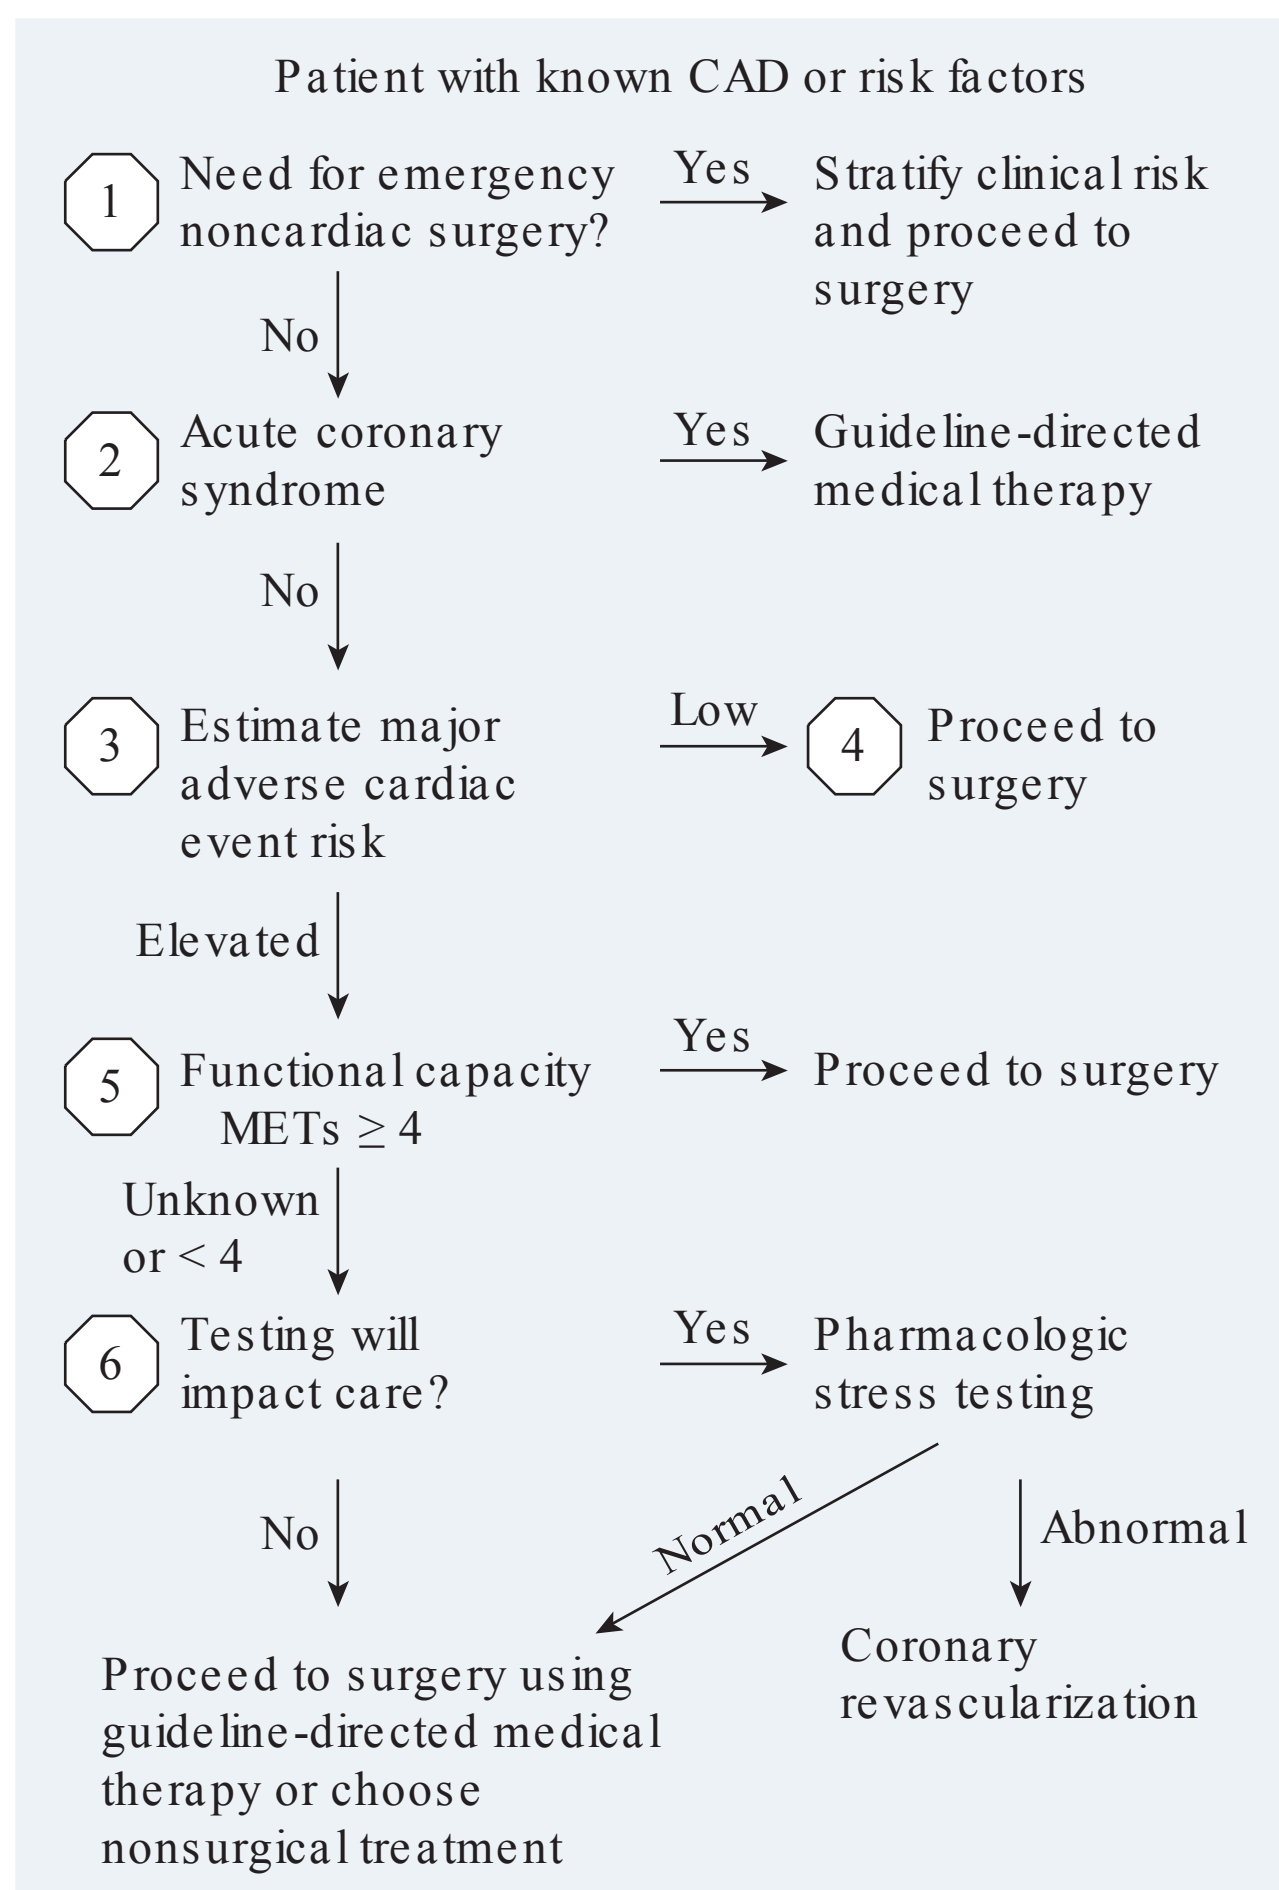

The Revised Cardiac Risk Index is an easy assessment of clinical predictors. It has been tested extensively and offers accurate estimates of cardiac risk (Lee, 1999). The major difference between the RCRI and the ACC/AHA guidelines is the incorporation of exercise capacity in the ACC/AHA tool. Creators of the RCRI suggest that cardiac risk may be overestimated by a patient's noncardiac limitations in exercise function, such as musculoskeletal pain. Thus, these investigators place greater emphasis on cardiac and vascular disease markers.

## ■ Prevention Strategies

### Perioperative Beta-blockers

Preoperative beta-blocker use to reduce in-hospital mortality rates were advocated as a result of the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography

**FIGURE 39-3** Stepwise approach to perioperative cardiac assessment in those with coronary artery disease (CAD). MET = metabolic equivalent. (Adapted with permission from Fleisher LA, Fleischmann KE, Auerbach AD, et al: 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: a Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014 Dec 9;64(22):e77–137.)

(DECREASE) family of studies. Unfortunately, fictitious databases and errant methods led to a discounting of these results (Erasmus Medical Centre, 2012). Subsequently, Bouri and colleagues (2014) conducted a metaanalysis of the available secure data from randomized controlled trials assessing the value of perioperative beta-blockade. They found the use of beta-blockers caused a statistically significant increase in all-cause mortality rates by 27 percent. Despite a reduction in non-fatal myocardial infarctions, rates of stroke and hypotension increased significantly. These new findings challenge the current AHA guidelines recommending beta-blockade in targeted high-risk patients and even suggest that they may benefit the least (Poldermans, 2009).

### Coronary Revascularization

Diagnostic cardiac catheterization is considered in high-risk cardiac patients if noninvasive stress testing suggests advanced disease. In such cases, revascularization through coronary artery bypass grafting (CABG) or percutaneous coronary interventions offer comparable benefits perioperatively (Hassan, 2001).

### Anemia

It has been shown to be an independent risk factor for congestive heart failure (Kannel, 1987). A study by Silverberg and associates (2001) found that correction of even mild anemia (Hgb < 12.5 percent) offered significant improvements in cardiac function. Iron therapy is not a substitution for appropriate cardiac disease treatment, but extrapolated data suggest that maintaining a hemoglobin level above 10 percent is important and reduces perioperative morbidity and mortality rates for those with cardiac disease.

## HEPATIC EVALUATION

The rising incidence of hepatic disease has similarly increased the number of patients with hepatic dysfunction. Perioperative care must address this impairment, as the liver plays a central role in drug metabolism; synthesis of proteins, glucose, and coagulation factors; and excretion of endogenous compounds.

Patients with suspected disease are queried regarding family histories of jaundice or anemia, recent travel history, exposure to alcohol or other hepatotoxins, and medication use (Suman, 2006). Physical findings include jaundice, scleral icterus, spider angiomas, ascites, hepatomegaly, asterixis, and cachexia.

If underlying liver disease is known or suspected, hepatic function is assessed. In addition, prothrombin time (PT), partial thromboplastin time (PTT), serum albumin level, and a serum chemistry panel are valuable adjuncts.

Of liver diseases, acute and chronic hepatitis are commonly encountered. With acute hepatitis, regardless of the cause, high associated perioperative mortality rates have been documented by multiple investigators. For this reason, primary management involves supportive care and delay of elective surgery until the acute process has subsided (Patel, 1999). In those with chronic hepatitis, hepatic dysfunction is variable. Compensated disease carries a low risk of perioperative complications (Sirinek, 1987). However, in patients with cirrhosis, the Child-Pugh score is a useful tool to predict survival after abdominal surgery. Clinical measures include serum total bilirubin and albumin levels, international normalized ratio (INR) values, and severity of associated ascites and encephalopathy. Approximate mortality risks based on Child-Pugh class are class A—10 percent; class B—30 percent; and class C—70 percent (Mansour, 1997).

## RENAL EVALUATION

The kidney is involved with metabolic waste excretion, erythropoietin production, and fluid and electrolyte balance. Accordingly, patients with known renal insufficiency typically have serum electrolytes, renal function, and complete blood count (CBC) evaluated prior to surgery. Chronic anemia due to renal insufficiency will typically require preoperative administration of erythropoietin or perioperative transfusion depending on the procedure planned and degree of anemia. Dialysis patients require intensive pre- and postoperative surveillance for signs of electrolyte abnormalities and fluid overload. Ideally, these patients' volume status and electrolytes (potassium in particular) are optimized by performing dialysis the day prior to surgery. Additionally, further renal insult is averted by avoiding nephrotoxic agents. Pharmacokinetic consultation may be

warranted to adjust other medication dosages as serum levels in these patients may be unpredictable postoperatively.

## HEMATOLOGIC EVALUATION

### ■ Anemia

This is frequently encountered in preoperative gynecologic surgery evaluation. In the absence of a clear etiology, evaluation serves to potentially correct reversible causes. Queries focus on signs of symptomatic anemia such as fatigue, dyspnea with exertion, and palpitations. Inquiry also seeks to identify risk factors for underlying cardiovascular disease as anemia is less well tolerated in these individuals. The physical examination incorporates thorough pelvic and rectal examination, stool guaiac screening, and urinalysis.

With chronic anemia, erythrocyte indices derived from a CBC reflect a microcytic, hypochromic anemia and show decreases in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Moreover, in classic iron-deficiency anemia from chronic blood loss, an elevated platelet count and decreased reticulocyte count can be seen. In those for whom the cause of anemia is unclear, those with profound anemia, or those who fail to improve with oral iron therapy, additional testing is prudent. Iron studies, vitamin B<sub>12</sub>, and folate levels are often indicated. Iron-deficiency anemia produces low serum ferritin and iron levels, elevated total iron-binding capacity, and normal vitamin B<sub>12</sub> and folate levels.

Several pharmacologic options are available for preoperative iron supplementation. For oral intake, ferrous sulfate (Feosol, Slow Fe), ferrous gluconate (Fergon), ferrous fumarate (Ircon, Fero-Sequels), and iron polysaccharide (Ferrex) are available. Importantly, each of the ferrous salts has a different content of *elemental iron*. In general, therapy to correct iron deficiency ideally provides 150 to 200 mg of elemental iron daily. Thus, common and equivalent oral replacement regimens include ferrous sulfate, 325 mg tablet (contains 65 mg elemental iron), or ferrous fumarate, 200 mg tablet (contains 64 mg elemental iron), three times daily. Okuyama and associates (2005) found that provision of 200 mg of elemental iron 2 weeks preoperatively significantly reduced the need for intraoperative transfusion. Constipation is the primary source of preparation intolerance and can be improved with dietary changes, bulk laxatives, and stool softeners (Table 25-6, p. 570).

In addition to oral forms, several Food and Drug Administration (FDA)-approved intravenous (IV) iron preparations are currently available. These include ferric gluconate (Ferrlecit), iron sucrose (Venofer), ferumoxytol (Feraheme), ferric carboxymaltose (Injectafer), and low-molecular-weight iron dextran (INFeD) (DeLoughery, 2014). The newer preparations have a much lower risk of anaphylactic reactions and are considered safe (Shander, 2010). The hemoglobin effects can be seen as quickly as 1 week after the first dose. For most women, iron therapy administered orally is effective to correct anemia. However, these IV forms may be most appropriate for women with poor absorption secondary to gastrointestinal disease, those with chronic renal disease, or those with an intolerance or lack of response to oral iron.

In women with acute bleeding, transfusion may be required perioperatively. The decision to transfuse depends in part on

a patient's cardiac status. A full discussion of resuscitation is found in Chapter 40 (p. 864).

### ■ Autologous Blood Donation

Fear of infection from allogeneic blood transfusions has led to development of autologous transfusion practices. Two of the most popular options include preoperative autologous donation and salvage autologous transfusions. Both are discussed in detail in Chapter 40 (p. 859) (Vanderlinde, 2002).

### ■ Coagulopathies

Coagulopathies are generally grouped into two categories—*inherited* or *acquired*. Of acquired forms, a careful review of systems and complete medication list, including herbal preparations, may highlight potential causes. In either form, disorders involving platelets or clotting factors can be identified with a careful history and physical examination. A personal history of easy bruising, unexpected amounts of bleeding with minor injury, or lifelong menorrhagia alert a clinician to the possibility of coagulopathy. Screening for coagulopathies is outlined in Chapter 8 (p. 192), and the specifics of replacement are described in Chapter 40 (p. 867). In general, for those undergoing procedures, a transfusion threshold of  $\leq 50,000/\mu\text{L}$  is used, and for major surgery,  $\leq 100,000/\mu\text{L}$  (James, 2011).

### ■ Oral Anticoagulation

In patients who take anticoagulants following a venous thromboembolism (VTE), the timing of surgery can often lower the risk of postoperative VTE. After an acute VTE, the recurrence risk without anticoagulation is between 40 and 50 percent. However, the risk of recurrent disease drops significantly after 3 months of warfarin therapy. Moreover, a delay in surgery and continued warfarin therapy for an additional 2 to 3 months (6 months total) drops the recurrence risk to 5 to 10 percent and avoids a need for preoperative heparin (Kearon, 1997; Levine, 1995). Thus, in those with recent VTE, a surgical delay, if feasible, may be advantageous and should be considered. When surgery must proceed, protocols for anticoagulant management are described next.

### Preoperative Management

Women with atrial fibrillation, mechanical heart valve, or recent VTE are at increased risk for VTE. As a result, chronic oral warfarin therapy is typically prescribed. For these patients, a surgeon must compromise between the need for anticoagulation and risk of surgical bleeding complications. The American College of Obstetricians and Gynecologists (2014b) has summarized recommendations to address this balance (Table 39-2). In general, anticoagulation is typically halted prior to surgery and started shortly postoperatively. Unfortunately, the effects of warfarin reverse slowly. Thus, patients are often transitioned or “bridged” to heparin, which can be stopped and restarted more readily. Both low-molecular-weight heparin (LMWH) and unfractionated heparin (UFH) are options (Table 39-3). Of LMWH choices, enoxaparin (Lovenox) is commonly selected. During bridging, warfarin is stopped several days before surgery, and heparin is begun (Douketis, 2012; White,

**TABLE 39-2.** Perioperative Management of Patients on Chronic Antithrombotic Therapy

Condition	Bleeding Risk	High VTE Risk	Moderate VTE Risk	Low VTE Risk
Prior VIE	High Moderate	Protocol A Protocol A	Protocol C Protocol B or C Consider mechanical prophylaxis	Protocol C Protocol C
Atrial fibrillation	High Moderate	Protocol A Protocol A	Protocol C or B Protocol A or B	Protocol C or B Protocol B or C
Mechanical heart valve	High Moderate	Protocol A Protocol A	Protocol A or B Protocol A	Protocol C Protocol C or B
Protocol A: Use bridging therapy with therapeutic-dose low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH). Therapeutic-dose enoxaparin is 1 mg/kg subcutaneously (SC) twice daily or 1.5 mg/kg once daily. Therapeutic-dose intravenous (IV) UFH is 80 units/kg IV push, then 18 units/kg/hr. Protocol B: Use bridging therapy with low-dose LMWH or low-dose UFH. Low-dose enoxaparin is 30 mg twice SC daily or 40 mg once SC daily. Low-dose UFH is 5000–7500 units SC twice daily. Protocol C: Stop long-term anticoagulation therapy. Do not use bridging therapy. Restart long-term anticoagulation after surgery. Use mechanical prophylaxis with an intermittent compression device during surgery and until long-term anticoagulation is therapeutic.				

<sup>a</sup>Protocol steps for warfarin bridging are found in Table 39-3.  
VIE = venous thromboembolism.  
Data from Committee opinion no 610: chronic antithrombotic therapy and gynecologic surgery, Obstet Gynecol 2014 Oct;124(4):856–862.

1995). In those with a therapeutic INR (between 2.0 and 3.0), approximately 5 to 6 days are required for this ratio to reach 1.5. Once this is achieved, surgery can safely proceed. During bridging therapy, the last dose of LMWH is administered 24 hours prior to surgery. With UFH, therapy is halted 4 to 6 hours prior to surgery (Douketis, 2012).  
Unfortunately, emergency surgery may not allow time for such bridging. In these cases, warfarin is halted, and vitamin K is provided. This vitamin promotes factor synthesis, and in urgent

cases, a 5- to 10-mg IV dose is suitable (Holbrook, 2012). To minimize the anaphylactic risk, vitamin K is mixed in a minimum 50 mL of IV fluid and administered over at least 20 minutes. Vitamin K requires 4 to 6 hours to achieve clinical effects. Thus, fresh frozen plasma (FFP) may be added at a dose of 15 mL/kg, and each FFP unit has a volume of 200 to 250 mL. Prothrombin complex concentrate (PCC) is a human-derived product containing factors II, IX, and X. PCC does not require thawing and may be used in place of FFP (Ageno, 2012).

**TABLE 39-3.** Anticoagulant Management

<b>Bridging protocol for warfarin</b>	
5 days before surgery	Stop warfarin; start LMWH or UFH
	Stop LMWH 24 hours before surgery or stop UFH at least 4–6 hours before surgery
1 day before surgery	Check INR. If INR > 1.5, give 1–2 mg of oral vitamin K
	Recheck INR
Surgery day	Start LMWH or UFH 12–24 hours after surgery, if bleeding risk is low
1 day after surgery	Start warfarin
5 days after surgery	Stop LMWH or UFH once INR is > 2. Continue warfarin
<b>Protocol for direct oral anticoagulant</b>	
1–2 days before surgery	Stop agent: dabigatran 2 days prior; apixaban and rivaroxaban 1 day prior
1 day after surgery	Start agent
<b>Protocol for antiplatelet agents</b>	
7 days before surgery	Stop aspirin or clopidogrel
1 day after surgery	Start agent 12–24 hours after surgery

INR = international normalized ratio; LMWH = low-molecular-weight heparin; UFH = unfractionated heparin.  
Data from Committee opinion no 610: chronic antithrombotic therapy and gynecologic surgery, Obstet Gynecol 2014 Oct;124(4):856–862; Douketis J, Bell AD, Eikelboom J, et al: Approach to the new oral anticoagulants in family practice: Part 2: addressing frequently asked questions, Can Fam Physician 2014 Nov;60(11):997–1001.

Although warfarin antagonizes all vitamin K-dependent clotting factors, newer *direct oral anticoagulants (DOACs)* inhibit specific factors. The three currently licensed medications are dabigatran (Pradaxa), which targets factor IIa (thrombin), and rivaroxaban (Xarelto) and apixaban (Eliquis), which target factor Xa. Because of their recent introduction, few studies provide recommendations for their perioperative management (Kozek-Langenecker, 2014). The pharmacologic half-life is 14 hours for dabigatran and 9 hours for rivaroxaban and apixaban (Schaden, 2010). Thus, in women with normal preoperative creatinine clearance, stopping rivaroxaban and apixaban 24 hours prior to surgery and halting dabigatran 48 hours prior to surgery is reasonable. The withdrawal time is doubled if the creatinine clearance is  $< 50$  mL/min or the risk of perioperative bleeding is high (Ortel, 2012).

For the DOACs, global coagulation tests such as INR, PT, and activated partial thromboplastin time (aPTT) less reliably reflect coagulant activity. For the factor Xa inhibitors rivaroxaban and apixaban, anti-factor Xa assays can be used to measure their activity. For dabigatran, an aPTT  $> 90$  seconds and an INR  $> 2$  suggest possible overdosing (Lindahl, 2011). Also for dabigatran, thrombin time testing is more sensitive and normal values exclude significant anticoagulant effect. However, the turnaround time with this specific test can be long.

For emergent surgery, the DOACs have no antidote, and management of life-threatening bleeding remains empirical. Fortunately, anticoagulant effects rapidly dissipate because of the drugs' short half-lives. Indirect evidence suggests that recombinant factor VIIa (NovoSeven) or a prothrombin complex concentrate may be helpful (Ageno, 2012).

Last, antiplatelet agents such as aspirin and clopidogrel (Plavix) may increase surgical bleeding. These are generally stopped 7 days prior to surgery (American College of Obstetricians and Gynecologists, 2014b).

### Postoperative Management

After surgery, heparin, either UFH or LMWH, is restarted 12 to 24 hours after major surgery (see Table 39-3). Oral warfarin therapy is started concurrently as several days are required to regain therapeutic levels (Harrison, 1997; White, 1994). Once the INR ranges between 2 and 3, then heparin is discontinued. DOACs are typically restarted 24 hours following surgery. Antiplatelet agents may be resumed 12 to 24 hours following surgery. In all cases, agents are begun only after surgical hemostasis is confirmed.

## ENDOCRINE EVALUATION

### ■ Hyperthyroidism and Hypothyroidism

The pathophysiologic stress of surgery can exacerbate endocrine conditions such as thyroid dysfunction, diabetes mellitus, and adrenal insufficiency. Of these, both hyper- and hypothyroidism have anesthetic and metabolic derangements unique to each disease state. Nevertheless, management goals for each aim to achieve a euthyroid state before surgery.

Hyperthyroidism carries the risk of developing thyroid storm perioperatively. Moreover, airway compromise is a risk in those

with goiter. Thus, during physical examination, tracheal deviation is sought. In addition to thyroid function tests, an ECG and serum electrolyte levels can help predict signs of preexisting metabolic stress. Patients are encouraged to maintain their usual medications at prescribed dosages until the day of surgery.

Newly diagnosed hypothyroidism generally does not require preoperative therapy other than thyroid hormone replacement. Exceptions include cases of severe disease with signs of cardiac depression, electrolyte irregularities, and hypoglycemia.

### ■ Diabetes Mellitus

Long-term complications of diabetes mellitus may include vascular, neurologic, cardiac, and renal dysfunction. Thus, a vigilant preoperative risk assessment for these in affected women is essential. In addition, increased postoperative morbidity rates have been linked with poor preoperative glycemic control. Specifically, glucose levels  $> 200$  mg/dL and hemoglobin A<sub>1c</sub> levels  $> 7$  are both associated with significantly increased rates of postoperative wound infection (Dronge, 2006; Trick, 2000).

At minimum, diabetic patients undergoing major surgical procedures benefit from three diagnostic tests—serum electrolyte levels, urinalysis, and ECG. These screen for metabolic disturbances, undiagnosed nephropathy, and unrecognized cardiac ischemia, respectively.

In general, stress induced by surgery and anesthesia elevates catecholamine levels, relative insulin deficiency, and hyperglycemia (Devereaux, 2005). Although glycemic responses vary with surgery, overt hyperglycemia is avoided to minimize postoperative complications related to dehydration, electrolyte abnormalities, diminished wound healing, and even ketoacidosis in type 1 diabetics (Jacober, 1999). However, fluctuations in oral intake and metabolic needs make optimal glycemic control labor intensive. Moreover, clear evidence for glucose targets are lacking. As a result, most providers aim for glucose readings below 200 mg/dL (Table 39-4) (Finney, 2003; Garber, 2004; Hoogwerf, 2006). Table 39-5 and Figure 39-4 summarize perioperative recommendations set forth by Jacober and coworkers (1999) based on disease severity.

### ■ Adrenal Insufficiency

Inadequacy of the hypothalamic-pituitary-adrenal (HPA) axis due to secondary suppression from chronic steroid use can lead to perioperative hypotension. Despite this physiologic understanding, controversy surrounds perioperative corticosteroid supplementation.

Corticosteroid users who undergo minor surgical procedures or who use lower doses are generally assumed not to be at risk for adrenal suppression, and additional corticosteroid therapy is not recommended. The value of perioperative supplementation remains an area of chronic debate (Bromberg, 1991; Marik, 2008). Systematic reviews of the literature regarding perioperative supplemental doses of corticosteroids find no evidence to support additional suprathreshold “stress doses.” Instead, patients should continue their usual daily dose (Kelly, 2013; Marik, 2008). Close hemodynamic monitoring is performed to look for volume-refractory hypotension, at which time stress-dose corticosteroids are initiated for presumed secondary

TABLE 39-4. Sliding-Scale Insulin Order Example<sup>a</sup>

Blood Glucose, mmol/L (mg/dL) <sup>b</sup>	Increment Formula	Calculation	Short-Acting Insulin, units
0–11.0 (0–200)	0	0	0
11.1–14.0 (201–250)	1 × (TDI/30)	1 × (120/30)	4
14.1–17.0 (251–300)	2 × (TDI/30)	2 × (120/30)	4
17.1–20.0 (301–350)	3 × (TDI/30)	3 × (120/30)	12
20.1–23.0 (251–400)	4 × (TDI/30)	1 × (120/30)	16
23.1–26.0 (401–450)	5 × (TDI/30)	5 × (120/30)	20
> 26.0 (> 450)	Call physician	Call physician	Call physician

<sup>a</sup>Example uses a preoperative total daily insulin dose (TDI) of 120 units.  
<sup>b</sup>For convenience, conversions of millimoles per liter to milligrams per deciliter are approximate.

adrenal insufficiency. Of note, Marik and Varon (2008) observed that patients receiving corticosteroids due to *primary* hypothalamic-pituitary-adrenal axis disease require stress doses in the perioperative period. One regimen is hydrocortisone, 100 mg administered IV every 8 hours and titrated to reduced doses as the patient improves.

DIAGNOSTIC TESTING GUIDELINES

In the absence of a clinical indication, a rote panel of preoperative tests does not enhance the safety or quality of care. Roizen and colleagues (2000) noted that nearly half of abnormalities found on routine preoperative testing were ignored by clinicians. Moreover, multiple studies have documented the inefficiency of hematologic tests for obtaining clinically significant diagnoses (Kaplan, 1985; Korvin, 1975). Most importantly, diagnostic testing has not been shown to outperform a clinical history and physical examination (Rucker, 1983). Thus, in the absence of changes in clinical status, diagnostic tests found to be normal 4 to 6 months prior to surgery may be used as “preoperative tests.” In patients managed this way, MacPherson and coworkers (1990) found that fewer than 2 percent had significant changes during the course of 4 months.

Codified guidelines for preoperative testing have not been crafted in the United States. However, in the United Kingdom, the National Institute for Health and Clinical Excellence

(NICE) has indications for such testing. Complete documents are available at: <http://www.nice.org.uk/guidance/cg3>.

INFORMED CONSENT

Obtaining informed consent is a process and not merely a medical record document (Lavelle-Jones, 1993; Nandi, 2006). The conversation between a clinician and patient enhances a woman’s awareness of her diagnosis and contains a discussion of medical and surgical care alternatives, procedure goals and limitations, and surgical risks. Multimedia decision support tools, such as photographs, pamphlets, and educational videos, can augment the discussion (Coulter, 2007; Stacey, 2014). When informed consent cannot be obtained from the patient, an independent surrogate should be identified to represent the patient’s best interest and wishes (American College of Obstetricians and Gynecologists, 2012). Ultimately, written documentation of the entire process serves as a historical record of a patient’s understanding and agreement within the medical records.

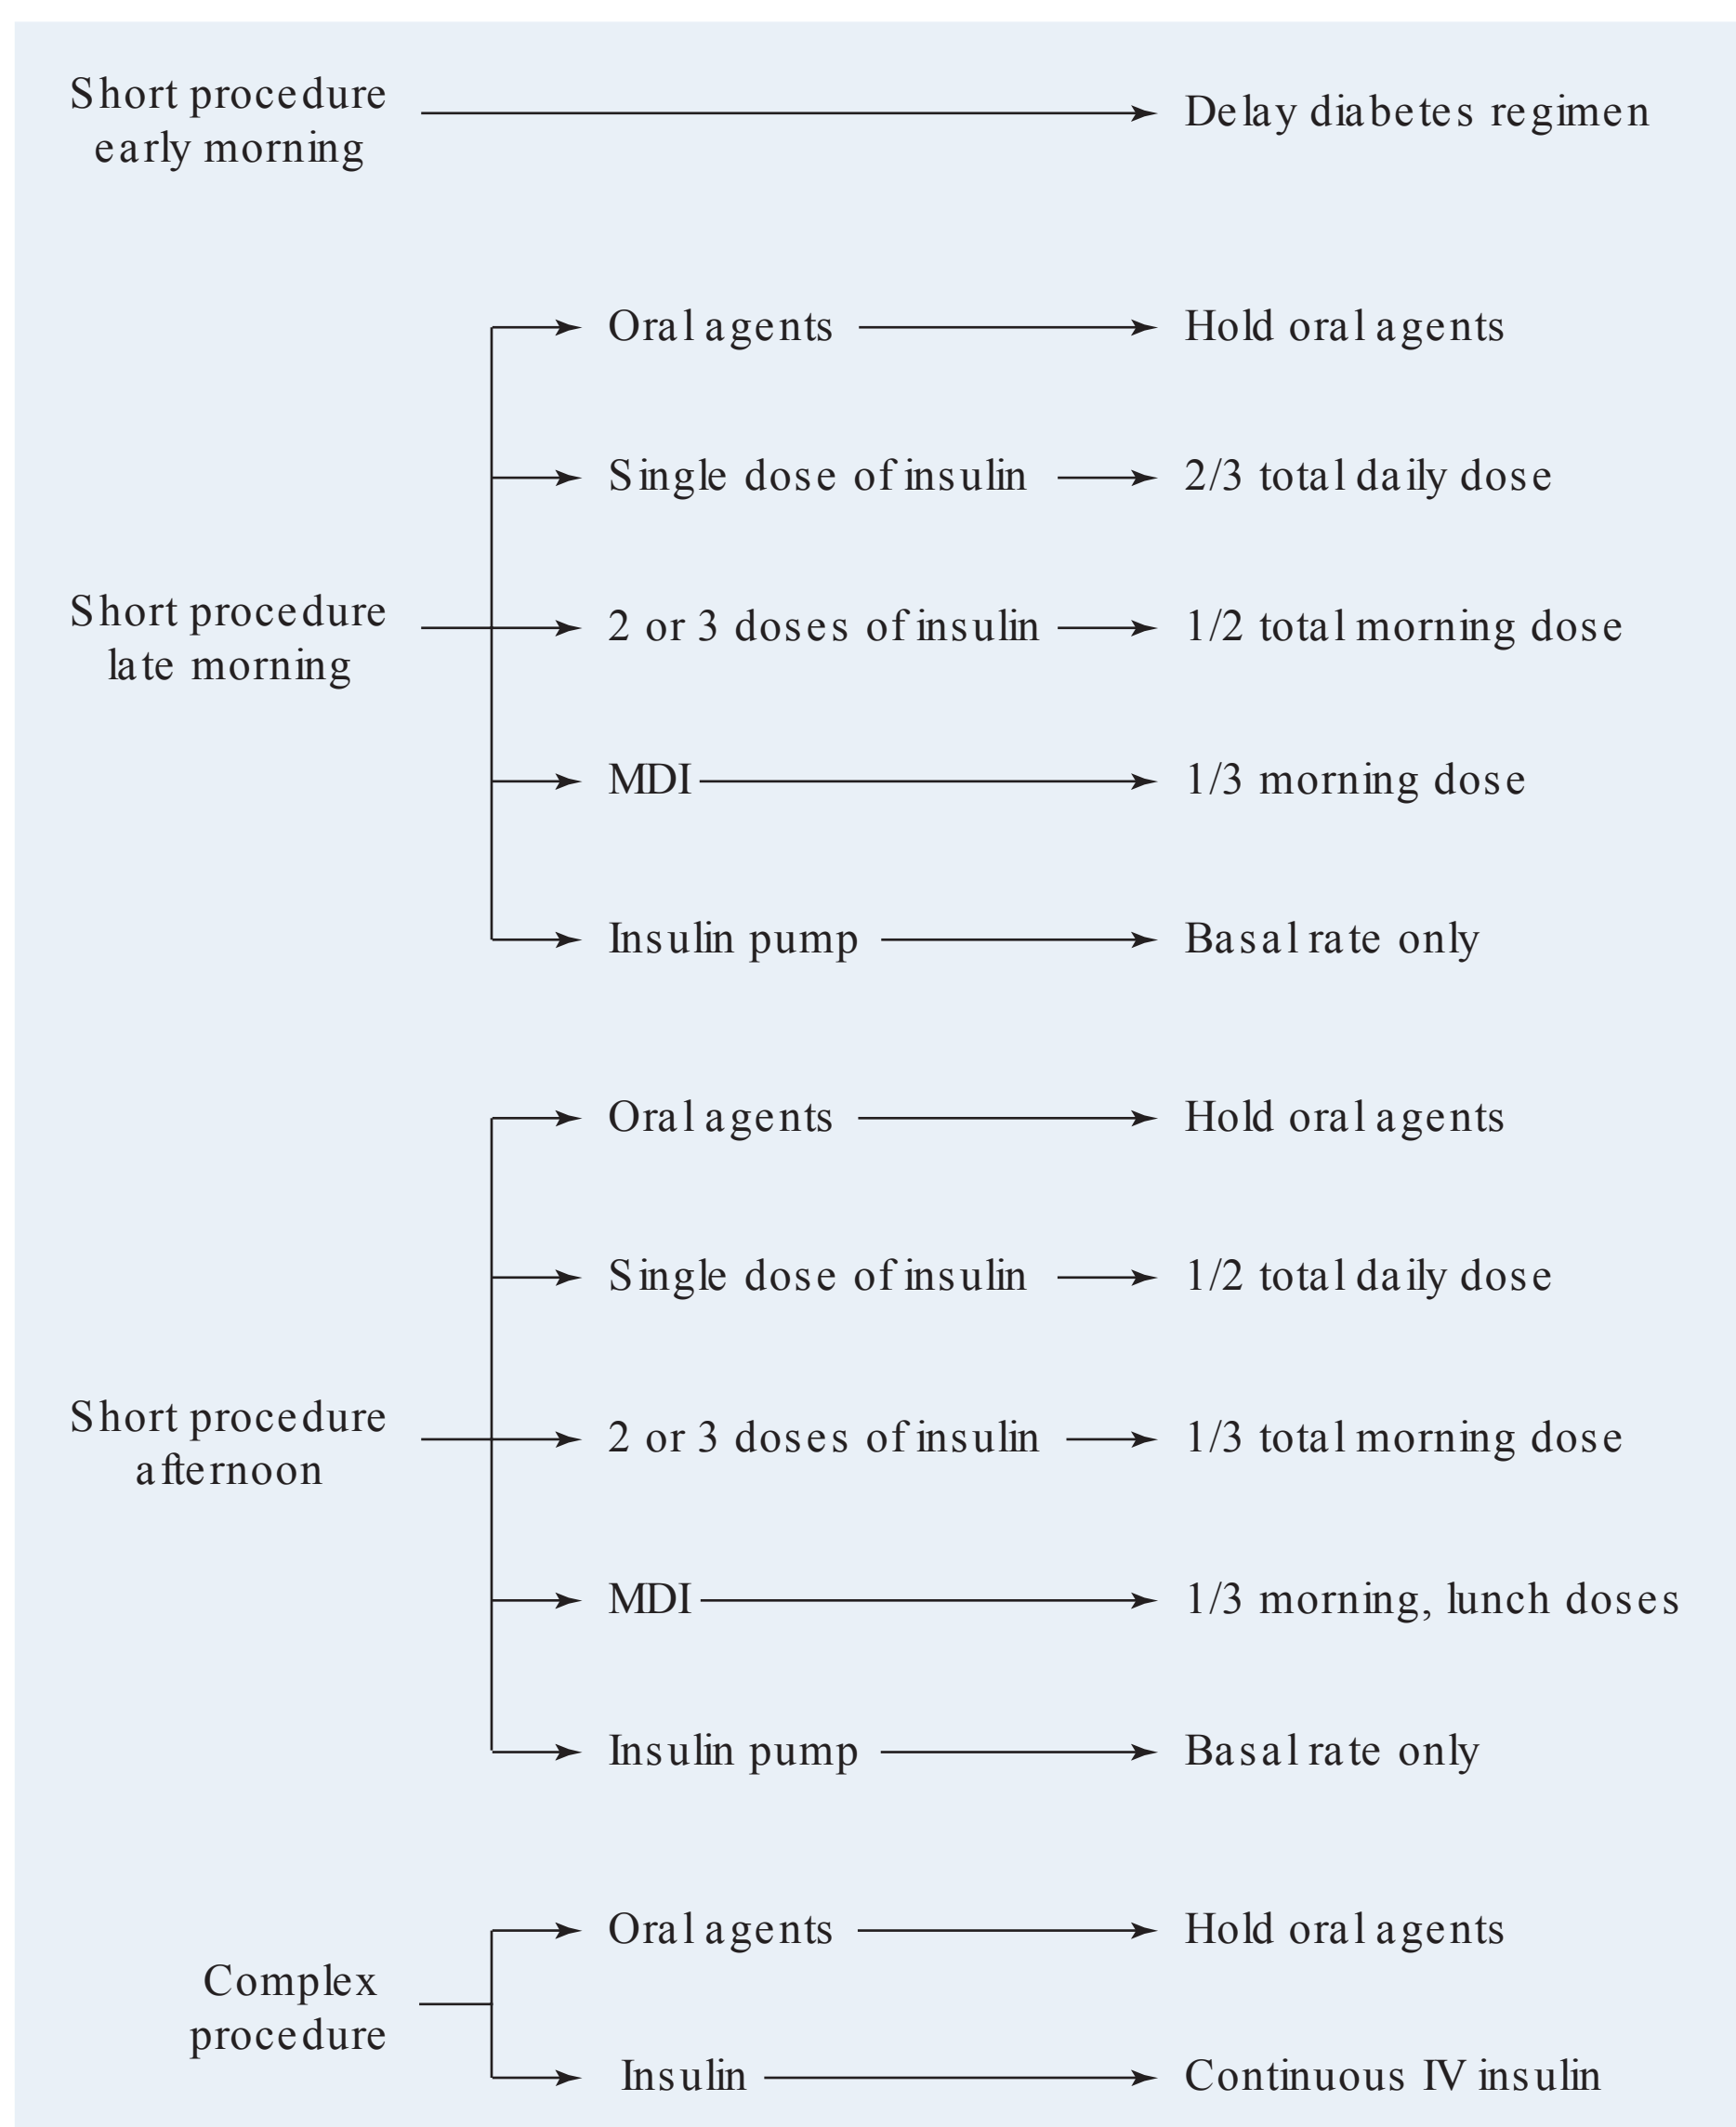

Despite a clinician’s recommendations, an informed patient may decline a particular intervention. A woman’s decision-making autonomy must be respected, and a clinician documents informed refusal in the medical record. Appropriate documentation includes: (1) a patient’s refusal to consent to the recommended intervention, (2) notation that the value of the intervention has been explained to the patient, (3) a

TABLE 39-5. Perioperative Management of Diabetes Mellitus by Disease Type

Disease	Preoperative Management	Postoperative Management
Type 2 DM treated with diet alone	No additional care with PRN subcutaneous regular insulin for AM hyperglycemia	PRN subcutaneous regular insulin
Type 2 DM treated with oral hypoglycemic agents	Discontinue all agents on the day of surgery	Supplemental subcutaneous insulin until return of normal diet, at which time preoperative therapy can be reinstituted
Type 1 or 2 DM treated with insulin	See Figure 39-3	Sliding-scale insulin (see Table 39-4)

DM = diabetes mellitus; PRN = as needed.

patient's reasons for refusal, and (4) a statement describing the health consequences as described to the patient.

### INFECTION PROPHYLAXIS

Appropriate antibiotic prophylaxis can significantly reduce hospital-acquired infections following gynecologic surgery. Selection recommendations are summarized in [Table 39-6](#). Decisions regarding the choice, timing, and duration of antibiotic prophylaxis are guided by the intended procedure and the anticipated organisms to be encountered (Chap. 3, p. 76). Typically, a single dose of antibiotics is given at anesthesia induction. Additional doses are considered in cases with blood loss > 1500 mL or with duration longer than 3 hours. For obese individuals, a higher antibiotic dose is suggested (American College of Obstetricians and Gynecologists, 2014a). Recommendations do not support subacute bacterial endocarditis prophylaxis prior to GI or GU surgeries, as noted on page 828.

### GASTROINTESTINAL BOWEL PREPARATION

Mechanical bowel preparation was previously advocated if the risk for colon injury was high. It is supposedly prevented bowel anastomosis leaks from passage of hard feces and reduced fecal and bacterial loads to lower wound infection rates (Barker, 1971; Nichols, 1971).

Multiple studies, however, question routine mechanical bowel preparation (Duncan, 2009; Platell, 1997). Güenaga and coworkers (2011) performed a review of trials to determine the effectiveness of such preparation on morbidity and mortality rates in colorectal surgery. They found no evidence to support the perceived benefit from mechanical bowel preparation. Similar results have been found with laparoscopic surgery and pelvic floor procedures (Ballard, 2014; Muzii, 2006). Moreover, bowel preparation does not decrease microbial contamination of the peritoneal cavity and subcutis after elective open colon surgery (Fa-Si-Oen, 2005).

**TABLE 39-6.** Antimicrobial Prophylactic Regimens by Procedure<sup>a</sup>

Procedure	Antibiotic	Dose (single dose)
Hysterectomy	1. Cefazolin <sup>b</sup>	1 g or 2 g <sup>c</sup> IV
Urogynecology procedures	2. Clindamycin <sup>d</sup>	600 mg IV
	PLUS	
	Gentamicin	1.5 mg/kg IV
	or	
	Quinolone <sup>e</sup>	400 mg IV
	or	
	Aztreonam	1 g IV
	3. Metronidazole <sup>d</sup>	500 mg IV
	PLUS	
	Gentamicin	1.5 mg/kg IV
	or	
	Quinolone <sup>e</sup>	400 mg IV
Laparoscopy <sup>f</sup> : diagnostic or operative	None	
Laparotomy	None	
Hysteroscopy: diagnostic or operative	None	
Hysterosalpingogram or chromotubation	Doxycycline <sup>g</sup>	100 mg orally, twice daily
IUD insertion	None	
Endometrial biopsy	None	
Induced abortion dilatation and evacuation	Doxycycline	100 mg orally 1 hour before and 200 mg orally after surgery or
	Metronidazole	500 mg orally twice daily for 5 d
Urodynamics	None	

<sup>a</sup>A convenient time to administer antibiotic prophylaxis is just before anesthesia induction.

<sup>b</sup>Acceptable alternatives include cefotetan, cefoxitin, cefuroxime, or ampicillin-sulbactam.

<sup>c</sup>A 2-g dose is recommended in women with a body mass index > 35 or weight > 100 kg or 220 lb.

<sup>d</sup>Antimicrobial agents of choice in women with a history of immediate hypersensitivity to penicillin.

<sup>e</sup>Ciprofloxacin, levofloxacin, or moxifloxacin.

<sup>f</sup>For total laparoscopic hysterectomy, prophylaxis is given.

<sup>g</sup>If patient has a history of pelvic inflammatory disease or procedure demonstrates dilated fallopian tubes. No prophylaxis is indicated for a study without dilated tubes.

IV= intravenously; IUD= intrauterine device.

Reproduced with permission from ACOG Committee on Practice Bulletins—Gynecology: ACOG practice bulletin No. 104: antibiotic prophylaxis for gynecologic procedures, Obstet Gynecol. 2009 May;113(5):1180–1189.

Although its routine use should be limited, mechanical bowel preparation may be elected for certain advanced laparoscopic surgeries or for female pelvic reconstructive procedures involving the posterior vaginal wall and anal sphincter. In these cases, evacuation of rectal stool provides additional operating space and undistorted anatomy. Moreover, following sphincteroplasty, preoperative evacuation typically delays stooling and allows initial healing. Various regimens exist: (1) low-residue or clear liquid diets the day(s) prior to surgery, (2) oral cathartics such as 240 mL of senna extract (Senokot, X-Prep) or 240 mL of magnesium citrate, (3) sodium phosphate enemas (Fleet), (4) oral phosphates (Visicol, Fleet Phospho-soda), or (5) oral polyethylene glycol (PEG) solutions (GoLYTELY, NuLYTELY, HalfLyte).

## THROMBOEMBOLISM PREVENTION

Prophylaxis against VTE ranks in the top 10 patient safety practices recommended by the Agency for Healthcare Research and Quality (AHRQ) and the National Quality Forum (Kaafarani, 2011). In the United States alone, the annual incidence of deep-vein thrombosis (DVT) and pulmonary thromboembolism are estimated to approach 600,000, with more than 100,000 deaths each year (Beckman, 2010). Ten to 30 percent of those diagnosed with VTE die within 1 month of diagnosis. National recommendations for prophylaxis against VTE follow a risk-based approach. The Caprini score is a tool validated using a large sample of general, vascular, and urologic surgery patients (Table 39-7) (Gould, 2012). Despite not being validated in gynecologic surgery, the patient populations are similar enough

TABLE 39-7. Caprini Risk Assessment Model

1 Point	2 Points	3 Points	5 Points
Age 41–60 yr	Age 61–74 yr	Age ≥ 75 yr	Stroke < 1 month
Minor surgery	Arthroscopic surgery	Prior VTE	Elective arthroplasty
BMI > 25 kg/m <sup>2</sup>	Major laparotomy (> 45 min)	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopy (> 45 min)	Factor V Leiden	Acute spinal cord injury
Varicose veins	Malignancy	Prothrombin 20210A	< 1 month
Pregnancy or postpartum	Bed rest > 72 hr	Lupus anticoagulant	
Recurrent spontaneous abortion	Immobilizing plaster cast	Anticardiolipin antibodies	
COC or HRT use	Central venous access	Elevated serum homocysteine	
Sepsis < 1 month		Heparin-induced	
Serious lung disease < 1 month		thrombocytopenia	
Abnormal pulmonary function		Other thrombophilia	
Acute myocardial infarction			
CHF < 1 month			
Inflammatory bowel disease			
Bed rest			

BMI = body mass index; CHF = congestive heart failure; COC = combination oral contraceptive; HRT = hormone replacement therapy; VTE = venous thromboembolism.

Chest 2012 Feb;141(2 Suppl):e227S–2277S.

that extrapolation is reasonable. Caprini scores of 0–1 points categorize a patient as “very low risk,” 2 points reflect “low risk,” 3–4 points confer “moderate risk,” and ≥ 5 points places patients at “high risk.” These points are transferable to Table 39-8.

Thrombophilias

Of VTE risk factors, thrombophilias are inherited or acquired deficiencies of inhibitory proteins of the coagula-

tion cascade. These can lead to hypercoagulability and recurrent VTE.

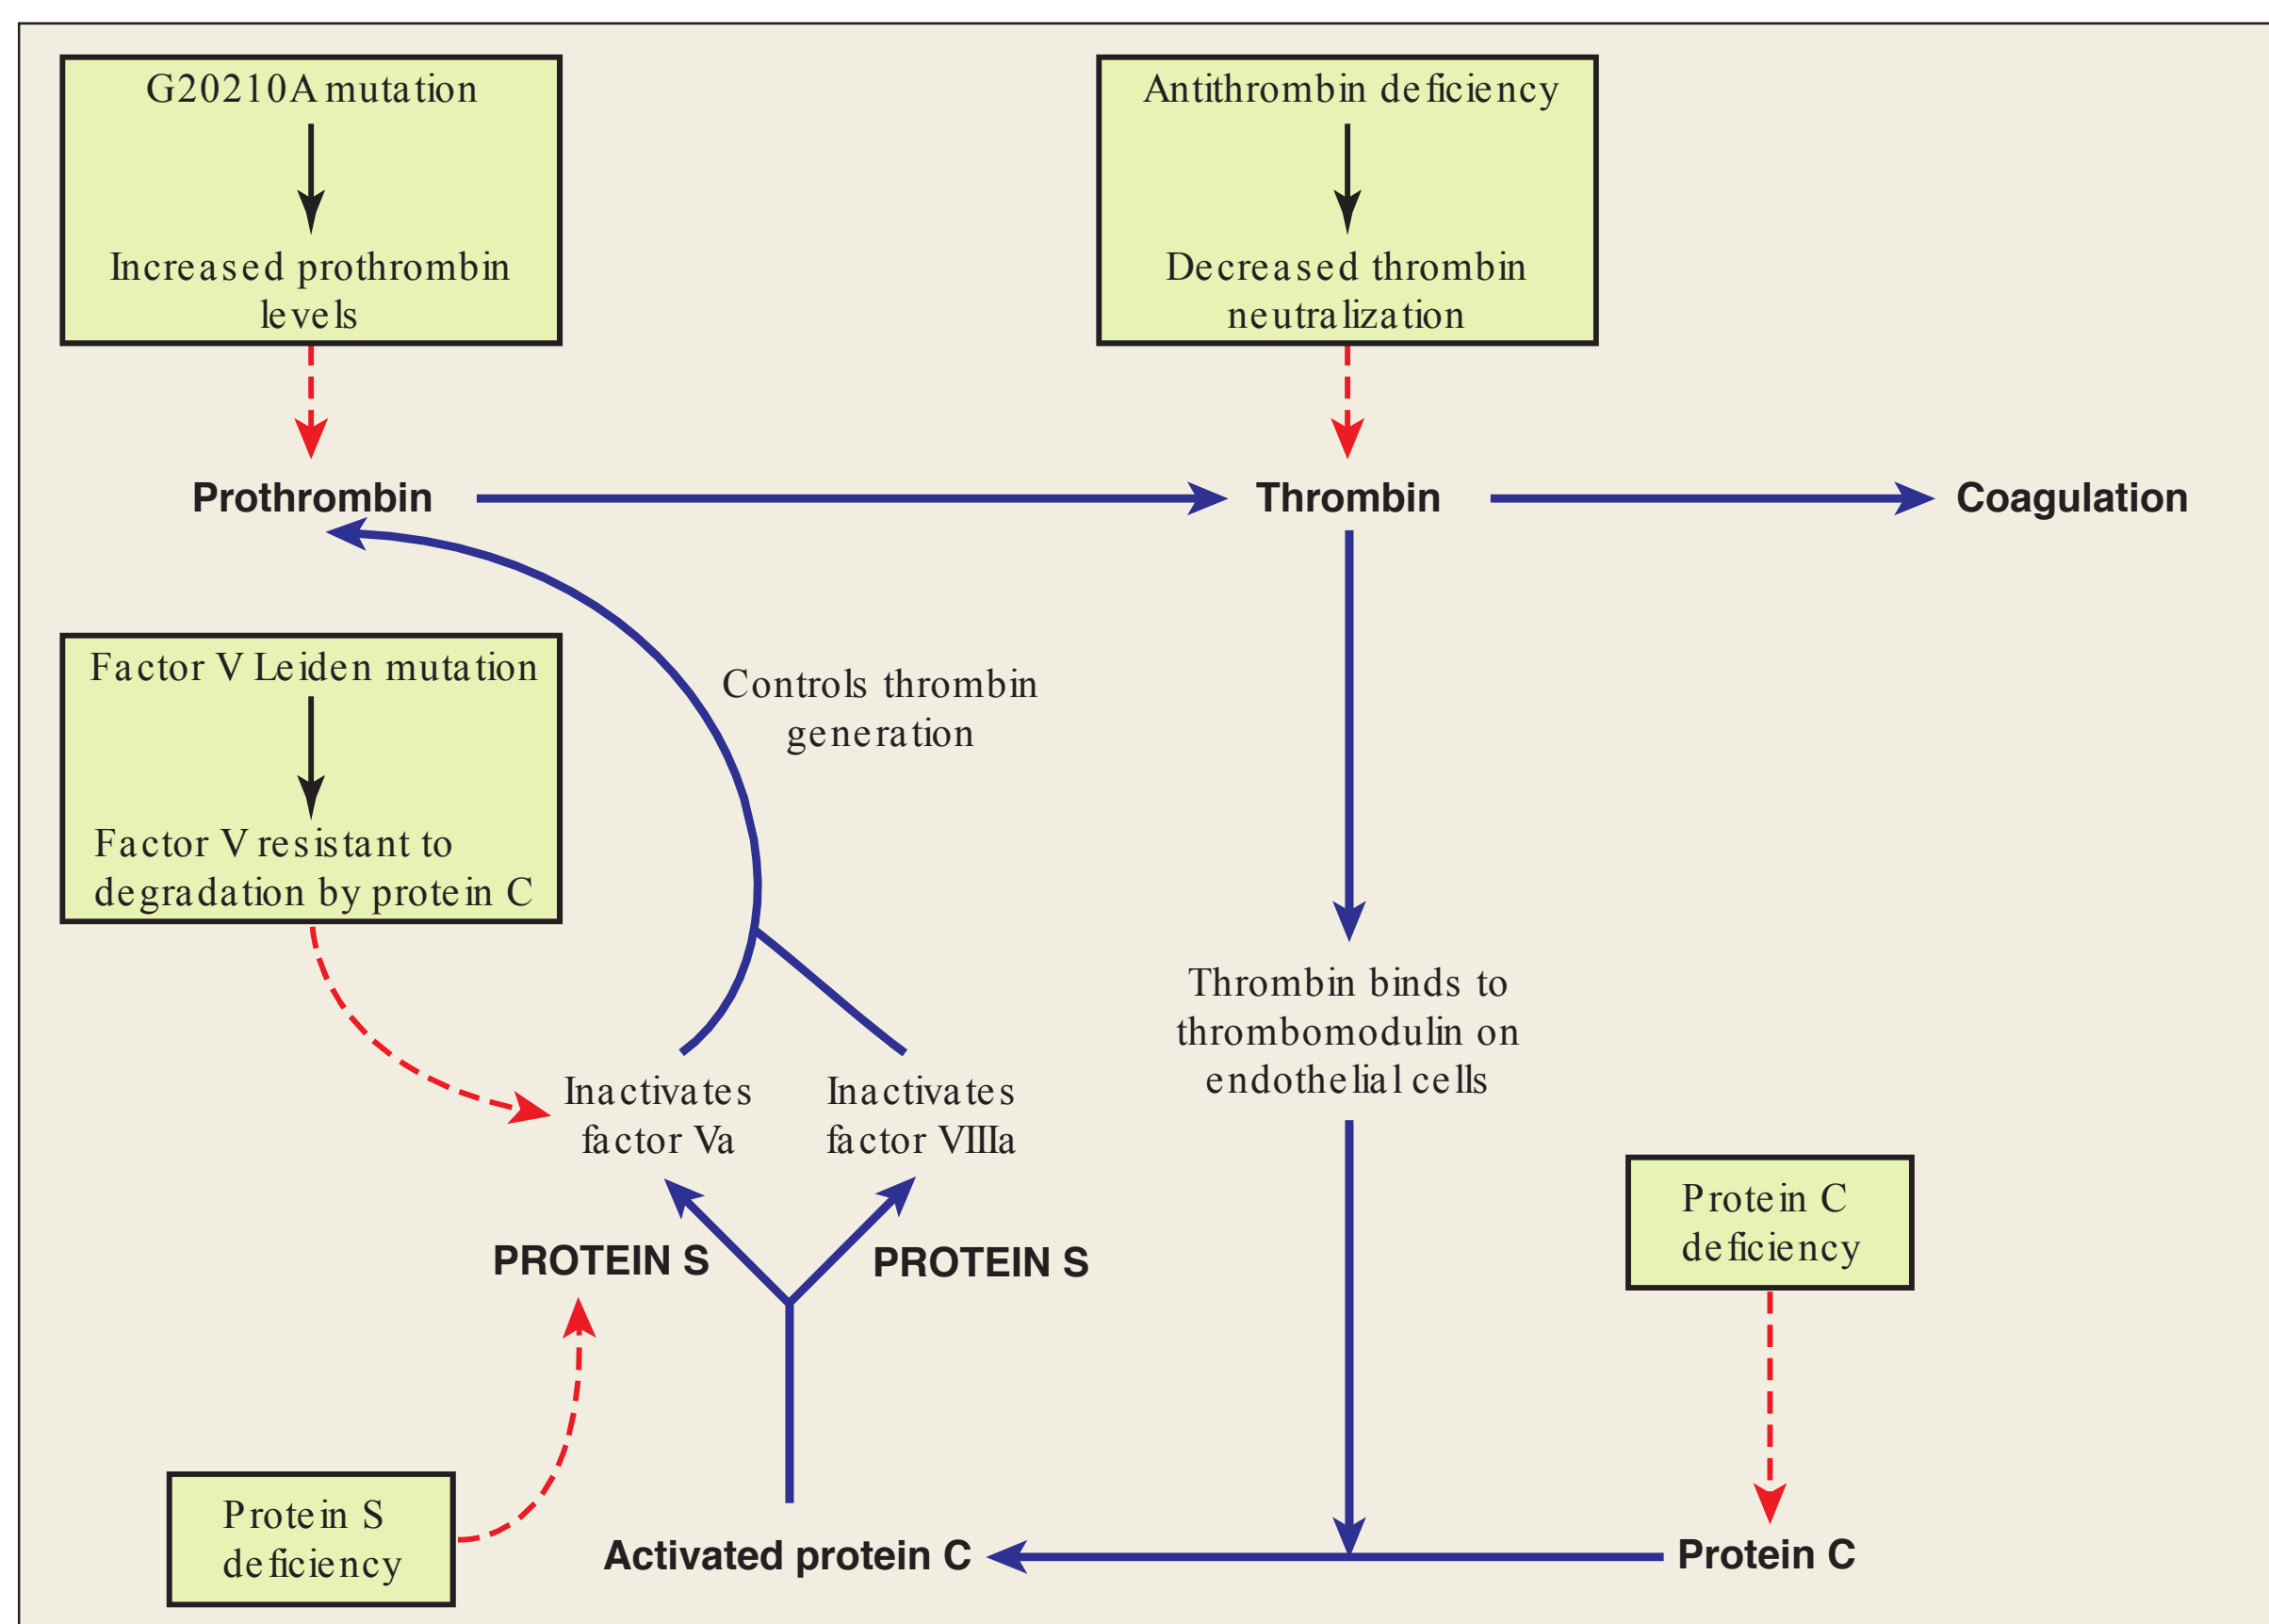

Of these heritable coagulopathies, antithrombin deficiency, although rare, is the most thrombogenic. Thrombin is produced by the enzymatic cleavage of prothrombin (Fig. 39-5). Thrombin converts fibrinogen to an active form that assembles into fibrin for clot formation. Antithrombin, previously known as antithrombin III, binds to and inactivates thrombin and the

TABLE 39-8. Thromboprophylaxis based on VTE and Bleeding Risks

Risk of VTE (Caprini score) <sup>a</sup>	Risk & Consequences of Major Bleeding Complications	
	Average Bleeding Risk	High Bleeding Risk or Severe Consequences
Very low (0–1)	No specific prophylaxis	
Low (2)	Mechanical prophylaxis (IPC preferred)	
Moderate (3–4)	LDUH, LMWH, or MP (IPC preferred)	Mechanical prophylaxis (IPC preferred)
High (≥ 5)	LDUH or LMWH PLUS MP (CS or IPC)	
High-risk, cancer surgery	Same as high risk PLUS extended LMWH prophylaxis	MP (IPC preferred), until bleeding risk subsides and pharmacologic prophylaxis can be added
High-risk, heparin NA or CI	Fondaparinux or low-dose ASA or MP (IPC preferred) or both	

<sup>a</sup>Calculation of Caprini score is found in Table 39-7  
ASA = aspirin; CI = contraindicated; CS = compression stockings; LDUH = low-dose unfractionated heparin; LMWH = low-molecular-weight heparin; IPC = intermittent pneumatic compression; MP = mechanical prophylaxis; NA = not available; VTE = venous thromboembolism.

**FIGURE 39-5** Points of the coagulation cascade affected by some of the thrombophilias.

activated coagulation factors IXa, Xa, XIa, and XIIa. If thrombin is not inactivated, then coagulation is favored.

*Protein C* and *protein S* deficiencies are other thrombophilias. When thrombin is bound to thrombomodulin on intact endothelium, its procoagulant activities are neutralized. In this bound state, thrombin also activates protein C, a natural anticoagulant. Protein C and its cofactor, protein S, limit coagulation, in part, by inactivating factors Va and VIIIa.

*Activated protein C resistance (Factor V Leiden mutation)* is the most prevalent thrombophilia and is caused by a single mutation in the factor V gene. The mutation makes FVa resist to degradation by activated protein C. The unimpeded abnormal factor V protein retains its procoagulant activity and predisposes to thrombosis.

*Prothrombin G20210A mutation* is a thrombophilia stemming from a prothrombin gene missense mutation that leads to excessive prothrombin accumulation. This may then be converted to thrombin to create a hypercoagulable state.

Guidelines to direct thrombophilia testing are lacking in the United States, and those of other international groups are incongruous (De Stefano, 2013). The UK-based NICE guidelines (2012) recommend screening patients who have an unprovoked VTE but not those with a provoked VTE. They also recommend against screening asymptomatic first-degree relatives of a known thrombophilia patient who experienced a VTE.

## ■ Hormone Discontinuation

Of risks, hormone use is one factor that can be modified prior to elective surgery. Combined oral contraceptive pills (COCs) induce hypercoagulable changes that are reversed if COCs are

stopped at least 6 weeks prior to surgery (Robinson, 1991; Vessey, 1986). To balance the risk of unintended pregnancy in women halting COCs, a suitable alternative is recommended with clear instructions on use. In the decision to halt COCs prior to surgery, the risk of VTE in an individual must be weighed against the risk of unintended pregnancy. In those undergoing major surgery and COC continuation, heparin prophylaxis is considered (American College of Obstetricians and Gynecologists, 2013).

Postmenopausal hormone replacement therapy (HRT) may slightly increase the incidence of postsurgical VTE but not to the same degree as the surgical procedure itself (Ueng, 2010). Thus, women are appropriately counseled on this additional postoperative risk, but the value and duration of HRT cessation to negate this increased risk is unclear.

## ■ Prophylaxis Options

Various options for VTE prevention exist. Early ambulation, although encouraged after surgery, is not regarded as a primary strategy for VTE prophylaxis (Michota, 2006). Graded compression stockings (T.E.D. hose) prevent pooling of blood in the calves. If these are used alone and fitted properly, DVT rates are reduced 50 percent. If used in conjunction with other methods of prophylaxis, additional benefit is achieved (Amaragiri, 2000). Intermittent pneumatic compression (IPC) primarily works by improving venous flow. It appears to be effective in moderate- and high-risk patients, if initiated prior to the induction of anesthesia and continued until patients are fully ambulating (Clarke-Pearson, 1993; Gould, 2012). Pharmacologic methods of VTE prophylaxis include low-dose

UFH, LMWH, and DOACs. Table 39-8 summarizes appropriate treatment strategies based on risk status.

Gynecologic surgery is used to treat a broad spectrum of underlying pathology. As a result, the list of surgical procedures is extensive, but in general, techniques maximize tissue healing and patient recovery. Successful outcomes depend on appropriate patient and procedure selection, sound intraoperative technique, and preparation for possible complications.

### ANESTHESIA SELECTION

Many anesthetic options are available for patients undergoing gynecologic procedures and include general anesthesia, regional analgesia, or local paracervical blockade with or without conscious sedation. These anesthetic techniques are provided by clinicians who are skilled with their placement and capable of managing their side effects. Thus, paracervical blockade and intravenous sedation may be provided by gynecologists. General and regional anesthesia typically are delivered and managed by anesthesiology staff.

Anesthesia selection for gynecologic surgery is complex and influenced by the procedure planned, extent of disease, patient comorbidities, and personal preferences of the patient, anesthesiologist, and surgeon. Last, the providing hospital or clinic

may further define options based on their practicing norms and availability of personnel or equipment. For example, an outpatient gynecology clinic may be equipped to provide paracervical blockade or intravenous conscious sedation, but may lack sophisticated equipment or expertise required for regional or general anesthesia.

In all cases, both the anesthesia provider and the surgeon communicate regarding patient and surgery progress and are prepared for potential problems. Difficult patient intubation may complicate general anesthesia, and regional anesthetic procedures may lead to higher than anticipated levels of blockade and respiratory muscle dysfunction. Cases using paracervical blockade may be complicated by inadequate levels of anesthesia, or conversely by anesthetic toxicity. Conscious sedation may also fail to provide adequate analgesia, or alternatively may lead to respiratory depression. Thus, no procedure is free of risk, and contingency plans for each should be in place.

### ■ Paracervical Block

Paracervical block is used most commonly during first-trimester pregnancy evacuation but also may be selected for cervical ablative or excisional procedures, transvaginal sonographically guided oocyte retrieval, and in-office hysteroscopy. Some studies have also described preemptive analgesia with paracervical block for vaginal hysterectomy (Long, 2009; O'Neal, 2003). Paracervical blockade is often combined with nonsteroidal antiinflammatory drugs (NSAIDs) or intravenous conscious sedation or both. Conscious sedation may be achieved with several agents, but intravenous midazolam (Versed) and fentanyl (Sublimaze) is a frequent combination (Lichtenberg, 2001).

### Technique

The cervix, vagina, and uterus are richly supplied by nerves of the uterovaginal plexus (Fig. 38-13, p. 806). Also known as *Frankenhäuser plexus*, this plexus lies within the connective tissue lateral to the uterosacral ligaments. For this reason, paracervical injections are most effective if placed immediately lateral to the insertion of the uterosacral ligaments into the uterus (Rogers, 1998). Thus, divided doses are given at the 4 and 8 o'clock positions at the cervical base (Fig. 40-1).

In most cases, total doses of 10 mL of 0.25-percent bupivacaine, 1-percent mepivacaine, or 1- or 2-percent lidocaine may be administered (Cicinelli, 1998; Hong, 2006; Lau, 1999). However, specific calculation of a maximum safe dose for each patient before injection is recommended (Dorian, 2015). The toxic dose of lidocaine approximates 4.5 mg/kg (Table 40-1). For a 50-kg woman, this would equal 225 mg. Thus, if a

**FIGURE 40-1** Paracervical blockade. **A.** Abdominal view of a paracervical block. Local anesthetic is infiltrated near sensory innervation of the cervix, which lies near the uterosacral ligament. **B.** Vaginal view of the injection of local anesthetics into the cervical base at 4 and 8 o'clock. (Reproduced with permission from Penfield JA: Gynecologic Surgery under Local Anesthesia. Baltimore: Urban and Schwarzenberg; 1986.)

1-percent lidocaine solution is used, the calculated allowed amount would be:  $225 \text{ mg} \div 10 \text{ mg/mL} = 22.5 \text{ mL}$ . Of note, for any drug solution, 1-percent = 10 mg/mL.

Anesthesia is presumed to result from pharmacologic nerve conduction blockade by the local anesthetic agent (Chanrachakul, 2001). The injection itself may have an immediate anesthetic effect by swelling surrounding tissue and exerting mechanical pressure on nerves to disrupt neural transmission (Phair, 2002; Wiebe, 1995). Addition of epinephrine to these solutions leads to local vasoconstriction, which enhances analgesia quality, prolongs duration of action, and decreases toxicity.

Thus, higher maximum doses may be used. Return of neural function is spontaneous as the drug is metabolized.

In general, increased doses of local anesthetics may lead to clinically significant conduction blockade within the central nervous system (CNS) and heart. Signs range from drowsiness, tinnitus, perioral tingling, and visual disturbances to confusion, seizure, coma, and ventricular arrhythmia. Monitoring patients for the subtle symptoms of CNS toxicity is important because the therapeutic-to-toxic ratios are often narrow with these agents.

When toxicity develops, cardiac effects are potentiated by acidosis, hypercapnia, and hypoxia. Thus, treatment typically

TABLE 40-1. Characteristics of Local Anesthetics				
Drug (Brand name)	Available Concentrations (%)	Maximum Dose (mg/kg)	Maximum Dose with Epinephrine (mg/kg)	Duration (hr)
<b>Moderate-duration</b>				
Lidocaine (Xylocaine)	0.5, 1, 2	4.5	7	0.5–1
Mepivacaine (Carbocaine)	1, 1.5, 2	4	7	0.75–1.5
Prilocaine (Citanest)	0.5, 1	7	8.5	0.5–1.5
<b>Long-duration</b>				
Bupivacaine (Marcaine)	0.25, 0.5, 0.75	2.5	3	2–4
Etidocaine (Duranest)	0.5, 1	4	5.5	2–3

includes intravenous access, adequate oxygenation, and seizure control. A benzodiazepine such as diazepam (Valium) given intravenously is effective anticonvulsant therapy (Naguib, 1998). For treatment, diazepam, 2 mg/min, is administered until seizures stop or a total dose of 20 mg is delivered.

### ■ Intrauterine Instillation

Injection of local anesthetic solutions through a catheter into the uterine cavity has been reported to safely lower pain scores in women undergoing in-office hysteroscopy or endometrial biopsy (Cicinelli, 1997; Trolice, 2000). The presumed mechanism is anesthetic blockade of nerve endings within the endometrial mucosa. Studies have used 5-mL doses of 2-percent lidocaine or of 2-percent mepivacaine. For first-trimester abortion procedures, Edelman and coworkers (2004, 2006) evaluated instillation of 5 mL of 4-percent lidocaine combined with paracervical blockade. However, for this indication, a significant number of women reported symptoms attributed to lidocaine toxicity.

### ■ Postoperative Pain

Anesthesiologists are employing multimodal strategies intraoperatively to reduce postoperative pain. Gabapentin and ketorolac are now in common use (Alayed, 2014; De Oliveira, 2012). The transversus abdominis plane (TAP) block has been studied in abdominal and laparoscopic hysterectomy with promising results (Carney, 2008; De Oliveira, 2014). The surgeon may also improve postoperative analgesia by implanting suprafascial wound soaker catheters to administer local anesthesia (Iyer, 2010; Kushner, 2005). Additionally, local infiltrative analgesia, using a long-acting medication such as liposomal bupivacaine, may be injected into the incision by the surgeon (Barrington, 2013).

## SURGICAL SAFETY

Communication between all members of the team is vital to the success of an operation and avoidance of patient harm. The Joint Commission established the *Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery* (Joint Commission, 2009). This protocol encompasses three components: (1) preprocedural verification of all relevant documents, (2) marking the operative site, and (3) completion of a “time out” prior to procedure initiation. The “time out” requires attention of the entire team to assess that patient, site, and procedure are correctly identified. Important interactions also include introduction of the patient care team members, verification of prophylactic antibiotics, anticipated procedure length, and communication of anticipated complications such as potential for large blood loss. Additionally, requests for special instrumentation are addressed preoperatively to prevent potential patient compromise that may accompany lacking an instrument at the time it is needed. Breakdowns in communication are common across pre-, intra-, and postoperative phases of care and are linked to adverse events and patient harm (Greenberg, 2007; Nagpal, 2010). Specifically, the transfer of a patient to a new care team or new location has been identified

as a time particularly vulnerable to communication breakdowns (Greenberg, 2007).

## SURGICAL ASSISTANT

A gynecology resident may sometimes feel that the role of assistant is unimportant. However, an experienced surgeon knows the critical difference that good assistance can provide. Assistants should anticipate surgeon needs and aid smooth progress of the operation. Therefore, an assistant must be familiar with the planned procedure’s steps, relevant anatomy, and clinical patient details.

Maintaining exposure by proper retraction and keeping the operative field clear of obstruction are primary functions. Laparotomy sponge or suction use is timed to avoid interfering with the surgeon, and a sponge is used to blot rather than wipe. Immediate pressure is placed on bleeding surfaces until the situation can be assessed systematically. Clamps are released slowly to avoid tissue slippage. Attention must be fixed on the procedure. Thus, if music or conversation is distracting, they are avoided.

## NERVE INJURY PREVENTION

Anesthetized patients who undergo prolonged gynecologic procedures are at risk for peripheral neuropathy of their upper or lower extremities. These neuropathies are uncommon, and cited incidences approximate 2 percent of gynecologic cases (Cardosi, 2002). Neurologic deficits typically are mild, transient, and resolve spontaneously. Infrequently, prolonged or permanent disability may result.

During gynecologic surgery, lower extremity injuries can involve nerves of the lumbosacral plexus. Mechanisms of injury include surgical nerve transection, rupture following increased stretch, or nerve ischemia. Ischemia may result from compression of perineural vessels during prolonged or pronounced nerve stretch or compression. Although any patient may develop postoperative neuropathy, higher rates are noted in patients who smoke, who have anatomic abnormalities, or who are thin, diabetic, or alcoholic. Use of self-retaining retractors and prolonged surgical duration are additional factors (Warner, 2000).

Symptoms reflect functional loss of the affected nerve. Motor loss typically manifests as muscle weakness, whereas sensory loss may be noted as anesthesia, paresthesia, or pain in the nerve’s sensory distribution (Fig. 40-2 and Table 40-2). Therefore, a detailed neurologic examination allows clinical identification of most peripheral neuropathies. Electrodiagnostic testing is indicated if motor function is diminished (Knockaert, 1996). Generally, electromyography is most useful after a 2- to 3-week delay to permit denervational changes to fully develop within affected muscles (Winfree, 2005).

Treatment will vary depending on whether motor or sensory function is affected. If motor function is impaired, neurologic consultation is typically warranted. Physical therapy begins immediately to minimize contracture and muscle atrophy. Alternatively, for those with only mild sensory losses, observation for return of function is reasonable. For those with pain, treatments may include oral analgesics, gabapentin, biofeedback, and serial trigger point injection with local anesthetics.

**FIGURE 40-2** Peripheral nerves and their corresponding areas of sensory innervation.

**Laparotomy**  
**Femoral Nerve**

The femoral nerve perforates the psoas muscle early in its course and passes medially beneath the inguinal ligament before exiting the pelvis. It then enters the femoral triangle to lie lateral to the femoral artery and vein. This nerve can be compressed

**FIGURE 40-3** If poorly positioned, the lateral blade of a self-retaining retractor can press against the femoral nerve lying atop the psoas muscle.

anywhere along its course but is particularly susceptible within the body of the psoas muscle and at the inguinal ligament. Improper placement of a self-retaining retractor is the most common cause of surgical femoral nerve injury, and rates following abdominal hysterectomy may reach 10 percent (Fig. 40-3) (Goldman, 1985; Kvist-Poulsen, 1982). In affected women, the patellar reflex is usually absent in addition to impaired sensory and motor function.

In prevention, lateral retractor blades are selected and positioned such that only the rectus abdominis muscle and not the psoas muscle is retracted (Chen, 1995). The retractor blades are evaluated when placed, to confirm that they are not resting on the psoas muscle. For thin patients, folded laparotomy towels may be placed between the retractor

**TABLE 40-2.** The Lumbosacral Plexus Nerve Plexus (L1-S4)

Nerve	Origin	Motor Function	Sensory Function
Ilioinguinal	L1	None	Inferior abdominal wall, mons pubis, labia majora
Iliohypogastric	L1	None	Inferior abdominal wall, upper lateral gluteal region
Genitofemoral	L1–2	None	Labia majora, anterior superior thigh
Femoral	L2–3	None	Anterolateral thigh
Cutaneous femoral	L2–4	Hip flexion, adduction; knee extension	Anterior and inferomedial thigh, medial calf
Obturator	L2–4	Thigh adduction, lateral rotation	Superomedial thigh
Pudendal	S2–4	Muscles of perineum; external anal and urethral sphincters	Perineum
<b>Sciatic</b>	L4-S3		
Common peroneal	L4-S2	Knee flexion; foot dorsiflexion, eversion; toe extension	Lateral calf, foot dorsum
Tibial	L4-S3	Thigh extension; knee flexion; foot plantar flexion, inversion	Foot plantar surface, toes

rim and skin to elevate blades away from the psoas muscle. Importantly, a small percentage of cases occur when a retractor has not been used.

### Genitofemoral and Lateral Femoral Cutaneous Nerve

The genitofemoral nerve pierces the medial border of the psoas muscle and traverses below the peritoneum on this muscle's surface. Similar to the femoral nerve, the genitofemoral nerve may suffer injury during psoas muscle compression (Murovic, 2005). In addition, this nerve may be injured during removal of a large pelvic mass adhered to the sidewall or during pelvic lymph node dissection (Irvin, 2004).

The lateral femoral cutaneous nerve appears at the lateral border of the psoas major muscle just above the crest of the ilium. It courses obliquely across the anterior surface of the iliacus muscle and dips beneath the inguinal ligament laterally as the nerve exits the pelvis. This nerve may also be compressed or be injured during dissections (Aszmann, 1997). Painful neuropathy specifically involving the lateral femoral cutaneous nerve carries the specific name *meralgia paresthetica*.

### ■ Transverse Incisions

Nerve injury during transverse abdominal entry is common and typically involves the ilioinguinal and iliohypogastric nerves or less frequently, genitofemoral nerve branches. The ilioinguinal and iliohypogastric nerves emerge through the internal oblique muscle approximately 2 to 3 cm inferomedial to the anterosuperior iliac spine (Whiteside, 2003). The iliohypogastric nerve extends a lateral branch to innervate the lateral gluteal skin. An anterior branch reaches horizontally toward the midline and runs deep to the external oblique muscle. Near the midline, this nerve perforates the external oblique muscle and becomes cutaneous to innervate the superficial tissues and skin in the region above the symphysis pubis. The ilioinguinal nerve extends medially to enter the inguinal canal and innervates the lower abdomen, labia majora, and upper thigh.

These are sensory nerves, and fortunately, most skin anesthesia or paresthesias that follow their injury resolves with time. Accordingly, injuries frequently are underreported by both patients and clinicians. Less often, pain can begin immediately or many years later and is usually sharp and episodic and radiates to the upper thigh, labia, or upper gluteal region. Later, sensations may become chronic and burning, as described in Chapter 11 (p. 249). To avoid compromising these nerves, a surgeon ideally avoids extending the fascial incision beyond the lateral border of the rectus abdominis muscles (Rahn, 2010).

### ■ Pelvic Sidewall Dissection

The obturator nerve pierces the medial border of the psoas muscle and extends anteriorly along the lesser wall of the pelvis. The

obturator nerve exits through the obturator foramen. Lymph node dissection, tumor excision, or endometriosis resection performed at the pelvic sidewall may injure the obturator or genitofemoral nerves. Moreover, the obturator nerve also can be injured during dissection within the space of Retzius during some urogynecologic procedures.

### ■ Dorsal Lithotomy

This surgical position is used for vaginal, laparoscopic, and hysteroscopic surgeries. It is modified and described as standard or low lithotomy positions (Fig. 40-4). Dorsal lithotomy may be associated with injury to several nerves derived from the lumbosacral plexus, including the femoral, sciatic, and peroneal nerves. For example, compression and ischemic injury of the femoral nerve beneath the rigid inguinal ligament can follow prolonged sharp flexion, abduction, and external hip rotation in dorsal lithotomy (Fig. 40-5) (Ducic, 2005; Hsieh, 1998). Ideal positioning as shown can minimize these injuries.

The sciatic nerve, derived from the lower sacral plexus, exits the pelvis through the greater sciatic foramen. It extends down the posterior thigh and branches into the tibial nerve and common peroneal nerve above the popliteal fossa. The sciatic and common peroneal nerves are anatomically fixed at the sciatic notch and head of the fibula, respectively. For this reason, sciatic nerve injury may reflect impaired function of the entire sciatic nerve or only the common peroneal division. Sciatic nerve stretch injury can develop if a patient's hips are placed in sharp flexion or pronounced external rotation or both. Moreover, even an appropriately positioned patient may be injured if a surgical assistant during vaginal surgery leans against the thigh and creates extreme hip flexion.

The common peroneal nerve, now termed the *common fibular nerve*, originates above the popliteal fossa and crosses the lateral head of the fibula before it descends down the lateral calf. At the lateral fibular head, this nerve is at risk for compression against leg stirrups. Therefore, the addition of cushioned padding or patient positioning that avoids pressure at this point is warranted (Philosophe, 2003).

**FIGURE 40-4** Lithotomy positions used in gynecologic surgery.

**FIGURE 40-5** Lithotomy positioning. **A.** Hyperflexion of the hip can lead to compression of the femoral nerve against the inguinal ligament. (Redrawn from Anderton, 1988.) **B.** Ideal dorsal lithotomy positioning with limited hip flexion, abduction, and external rotation. (Adapted with permission from Irvin W, Andersen W, Taylor P, et al: Minimizing the risk of neurologic injury in gynecologic surgery. *Obstet Gynecol* 2004 Feb;103(2):374–382.)

### ■ Brachial Plexus

This plexus derives from the ventral rami of C5–T1, traverses the neck and axilla, and supplies the arm and shoulder. Positioning injuries can follow hyperextension of the upper extremity, for example, when the arm is positioned at an angle to the body that exceeds 90 degrees. Additionally, even in situations in which the arm has been positioned appropriately, inadvertently leaning against the arm or placing the patient in steep Trendelenburg position may push the extremity into hyperextension. With

injury, either motor or sensory function can be lost (Warner, 1998). Peripheral ulnar neuropathies can also develop by external compression if the arm is placed at the patient's side. Padding the elbow may help avoid this (Warner, 1998).

## SURGICAL INCISIONS

In women for whom laparotomy is selected, an ideal abdominal incision allows rapid entry, affords adequate exposure, permits early ambulation, promotes strong wound healing, does not compromise pulmonary function, and maximizes cosmetic results. These criteria form the foundation in choosing the best incision for each patient. In gynecology, opening the abdomen typically is achieved using a midline vertical incision or one of three low transverse incisions, the Pfannenstiel, Cherney, or Maylard incisions.

### ■ Midline Vertical Incision

This incision is used frequently if access to the upper abdomen and generous operating space are required. It can be extended up and above the umbilicus and thus is preferred when the preoperative diagnosis is uncertain. Moreover, simple midline anatomy allows quick entry into the abdomen and low rates of neurovascular injury to the anterior abdominal wall (Greenall, 1980; Lacy, 1994). Moreover, because of decreased midline vascularity, Nygaard and Squatrito (1996) recommend this incision in patients who have coagulopathy, decline transfusion, or are administered systemic anticoagulation.

Its greatest disadvantage stems from increased tension on the incision when abdominal muscles contract. For this reason, compared with transverse incisions, midline vertical incisions are associated with higher rates of fascial dehiscence and hernia formation and poorer cosmetic results (Grantcharov, 2001; Kisielinski, 2004). Additionally, patients who have repeat vertical incisions for gynecologic indications tend to develop more adhesive disease than with low transverse incisions (Brill, 1995).

### ■ Transverse Incisions

These incisions are used commonly in benign gynecologic surgery, provide several advantages, and are illustrated in the atlas (p. 929). They follow Langer lines of skin tension and thus offer superior cosmetic results. They also carry low rates of incisional hernia (Luijendijk, 1997). Moreover, their placement in the lower abdomen is associated with decreased postoperative pain and improved pulmonary function compared with midline vertical incisions. Of low transverse incisions, Pfannenstiel incision is typically the simplest to perform, and for this reason, it is selected most often.

Despite these advantages, transverse incisions have limitations. These incisions limit access to the upper abdomen and offer smaller operating space compared with midline incisions. This is especially true of the Pfannenstiel incision and results from narrowing of the surgical field by intact rectus abdominis muscle bellies, which straddle the incision.

Consequently, Cherney and Maylard incisions were developed to overcome this restriction, and to some degree, they do improve exposure. The Cherney incision releases the rectus abdominis muscle at its inferior tendinous insertion. This

approach affords greater exposure of pelvic organs and access to the space of Retzius. The Cherney incision may also be used if a Pfannenstiel incision has already been initiated, but then additional exposure is required.

The Maylard incision transects the rectus abdominis muscle and provides substantial operative space. However, it is technically more difficult because isolation and ligation of the inferior epigastric arteries are required. The incision is used infrequently because of concerns regarding operative pain, decreased abdominal wall strength, longer operating times, and increased febrile morbidity. Randomized studies, however, have not supported these concerns (Ayers, 1987; Giacalone, 2002). This incision is avoided in patients whose superior epigastric vessels have been interrupted and in those with significant peripheral vascular disease who may rely on the inferior epigastric arteries for lower-extremity collateral blood supply.

## ■ Incision Creation

Entry into the abdomen begins with scalpel incision of the skin, and scars are excised to improve wound healing and cosmetic results. Although an electrosurgical blade may be used to incise the skin, faster healing and improved appearance in general follow scalpel incision (Hambley, 1988; Singer, 2002b).

For the remaining layers, scalpel or electrosurgical blade may be selected, with no differences in short- or long-term wound healing with either (Franchi, 2001). However, in evaluating surgical bleeding and postoperative pain, Jenkins (2003), in his review, noted an advantage with electrosurgical blade use. Regardless of type of incision or instrument used, adherence to proper technique is emphasized: obtaining meticulous hemostasis, minimizing devitalized tissue, and avoiding dead space creation.

## WOUND CLOSURE

Following laparotomy, closure of a laparotomy incision must address the peritoneum, fascia, subcutaneous layer, and skin. Wound closure may be broadly categorized as either primary or secondary. With primary closure, materials are used to approximate tissue layers. In closure by secondary intention, wound layers remain open and heal by a combination of contraction, granulation, and epithelialization. Secondary closure is used infrequently in gynecologic surgery and typically is indicated if tissues planned for closure contain significant infection. The option of delayed primary closure is also available in these situations once infection has cleared.

Optimal closure of a laparotomy incision is the subject of much debate. Most data stem from general surgery and gynecologic oncology studies on midline abdominal incision closure and from research on cesarean delivery techniques. Ideally, closure avoids wound infection, adhesion formation, dehiscence, and hernia or sinus tract formation; minimizes patient discomfort; yet preserves cosmesis to the extent possible.

## ■ Peritoneum and Fascia

The peritoneum provides no abdominal wall strength, and closure of this layer has been suggested to prevent adhesions between the anterior abdominal wall and adjacent organs.

However, evidence is conflicting, and several studies have shown that nonclosure of the peritoneum compared with closure decreases operating time without increasing adhesion formation, wound complications, or infection (Franchi, 1997; Gupta, 1998; Tulandi, 1988). However, few well-done randomized controlled trials have assessed long-term adhesion formation. Accordingly, closure of the visceral or parietal peritoneum is often provider dependent. Without closure, this layer typically regenerates within days following surgery (Lipscomb, 1996).

Thus in many cases, the first tissue closed is fascia. Many studies have supported the use of a continuous running-stitch closure of abdominal incisions compared with interrupted closure of the fascia (Colombo, 1997; Orr, 1990; Shepherd, 1983). Continuous closure usually is faster and associated with comparable rates of dehiscence, wound infection, and hernia formation. Suture material selection tends to favor delayed-absorbable suture compared with nonabsorbable. Delayed-absorbable sutures appear to afford adequate wound support yet lead to less pain and lower rates of sinus tract formation (Carlson, 1995; Leaper, 1977; Wissing, 1987). However, nonabsorbable suture is considered if a hernia is identified or if the incision has cut through previously placed mesh. A 0-gauge or no. 1 suture is suitable for closure of most fascial incisions. Sutures are placed approximately 1 cm apart and 1.2 to 1.5 cm from the fascial edge. Little additional security is attained beyond 1.5 cm (Campbell, 1989). Stitches ideally appose fascial edges and allow tissues to swell postoperatively without cutting through fascia or causing avascular necrosis.

## ■ Subcutaneous Adipose Layer and Skin

Collections of blood and fluid serve as potential accelerants to bacterial growth. For this reason, to decrease rates of hematoma or seroma, investigators have evaluated subcutaneous layer suture closure or drains. In those with layers less than 2 cm thick, most studies have found no advantage to either practice. However, wound infection and fat thickness are the greatest risk factors for subcutaneous layer dehiscence (Soper, 1971; Vermillion, 2000). For patients with subcutaneous layers 2 cm or more thick, closing the subcutaneous layer is effective prevention (Gallup, 1996; Guvenal, 2002; Naumann, 1995). The ideal suture and technique for closure of this layer are unknown, but efforts ideally close dead space yet minimize suture burden and inflammatory reaction. A 2-0 gauge plain gut suture is one suitable choice.

Skin may be closed effectively with staples, subcuticular suturing, wound tape, or tissue adhesive. Thus, in most instances, surgeon preference influences closure method. Technically, the incision line is approximated without skin tension, and subcutaneous adipose or deep dermal suturing may assist with carrying tension loads.

Of options, the running subcuticular suture is placed by taking horizontal bites through the dermis on alternating sides of the wound using absorbable suture (Fig. 40-6). Delayed-absorbable material such as polyglactin (Vicryl) or poliglecaprone (Monocryl) in a fine gauge, such as 3-0 or 4-0, is suitable. Advantages include decreased cost, effective skin approximation, and no required suture removal. However, this method

**FIGURE 40-6** During subcuticular suturing, stitches are placed with a needle horizontal to the dermis. Suturing is advanced by sequentially piercing just below the dermis on alternating sides. The spot where the first stitch exits the subcutis marks the site along the wound length that the needle should enter on the opposite side.

typically requires the greatest amount of time and technical expertise.

Automatic stapling devices are favored because of their fast application and secure wound closure. However, they do not allow as meticulous a closure as sutures, and wounds requiring accurate approximation of tissue are not ideal candidates for staple closure (Singer, 1997). Staples may be uncomfortable, may be associated with discomfort during removal, and require the patient to return for staple removal.

Before stapling, the wound edges are everted, preferably by a second operator. If the edges of a wound invert or if one edge rolls under the opposite side, a poorly formed, deep, noticeable scar will result. Additionally, pressing too hard against the skin surface with the stapler is avoided to prevent placing the staple too deep and causing ischemia within the staple loop. When placed properly, the crossbar of the staple is elevated a few millimeters above the skin surface (Lammers, 2004). Staples are removed in a timely fashion to avoid leaving “track mark” scarring.

Of topical skin adhesives, octyl-2-cyanoacrylate (Dermabond) is applied as a liquid and polymerizes to a firm, pliable film that binds to the epithelium and bridges wound edges (Fig. 40-7). It can be used for closure of skin incisions that carry minimal tension such as laparoscopy trocar or transverse laparotomy incisions, or as an adjunct protective layer in larger incisions. Tissue adhesives achieve results similar to those for traditional sutures (Blondeel, 2004; Singer, 2002a).

Following approximation of deeper incision layers, the adhesive is applied in three thin layers above apposed skin edges. The adhesive extends at least ½ cm on each side of the apposed wound edges. Placement of the liquid between skin edges is avoided because the adhesive may retard healing (Quinn, 1997). Although 30 seconds between layers for drying is required, application is fast. Moreover, adhesives create their own dressing and appear to afford some antibacterial protection (Bhende, 2002). The adhesive sloughs in 7 to 10 days. Showering and gentle washing of the site are allowed, but swimming is discouraged. Petroleum-based products on the wound can decrease adhesive tensile strength and are avoided.

**FIGURE 40-7** Application of topical skin adhesive to incision. Adhesive should be placed over apposed skin edges. Application should extend out approximately 0.5 cm laterally from the incision. (Used with permission from Dr. Christine Wan.)

The primary indication for tape closure is a superficial straight laceration under little tension. Thus, closure of laparoscopy trocar sites or laparotomy incisions in which deep layer closure has brought skin edges into close proximity are suitable cases. Moreover, skin edges ideally are thoroughly dry for proper adhesion. Thus, tape may not be appropriate for a wet or oozing wound, for concave surfaces such as the umbilicus, for areas of significant tissue tension, or for areas of marked tissue laxity.

Tape closure is fast, inexpensive, and associated with high patient satisfaction scores. Tapes typically are removed by the patient 7 to 10 days following surgery. They may also be used after staple removal to provide additional strength, as wounds have regained only approximately 3 percent of their final strength at 1 week. Adhesive tape strips are applied in a parallel, nonoverlapping fashion after coating the entire application area with adjuvant adhesive such as tincture of benzoin (Katz, 1999). Importantly, skin blistering may develop if tape is stretched excessively taut across the wound (Lammers, 2004; Rodeheaver, 1983).

## INSTRUMENTS

### ■ Scalpel and Blades

Surgical instruments have been designed to extend the capability of a surgeon's hands and thus are crafted to retract, cut, grasp, and clear the operative field. Tissue types encountered in gynecologic surgery vary, and accordingly, so too do the size, fineness, and strength of the tools used.

Of these tools, typical surgical blades used in gynecologic surgery are pictured in Figure 40-8 and include number 10, 11, 15, and 20 blades. Function follows form, and larger blades are used for coarser tissues or larger incisions, whereas a no. 15 blade is selected for finer incisions. The acute angle and pointed tip of a no. 11 blade can easily incise tough-walled abscesses for drainage, such as those of the Bartholin gland duct.

With a correct scalpel grasp, a surgeon can direct blade movement. Fingers may be positioned either to straddle the scalpel, termed the “power grip,” “violin grip,” or “bow grip,”

**FIGURE 40-8** Photograph of surgical blades commonly used in gynecology. **A.** No. 10. **B.** No. 20. **C.** No. 15. **D.** No. 11.

which maximizes the use of the knife belly. Alternatively, the scalpel is held like a pencil, termed the “pencil grip” or “precision grip” (Fig. 40-9). With the no. 10 and no. 20 blades, the scalpel is held at a 20- to 30-degree angle to the skin and drawn firmly along the skin toward the surgeon using the arm with minimal wrist and finger movement. This motion aids cutting with the full length of the scalpel belly and avoids burying the tip. The initial incision penetrates the dermis, and the scalpel remains perpendicular to the surface to prevent skin edge beveling. Firm and symmetrical lateral skin traction keeps the incision straight and helps avoid multiple tracks and irregular skin edges.

The no. 15 and 11 blades, in contrast, are typically held using the pencil grip to make fine, precise incisions. With the no. 15 blade, the scalpel is held approximately 45 degrees to the skin surface. Fine knife dissection is best controlled using the fingers, and the heel of the hand can be stabilized on adjacent tissue. The no. 11 blade scalpel is ideal for stab incisions and is held upright at nearly 90 degrees to the surface. Creating tension at the skin surface is important as it reduces the amount of force required for penetration. Omission of this can result in

**FIGURE 40-9** Scalpel grips. **A.** Scalpel is held as one would a pencil, and movement is directed by the thumb and index finger. **B.** Scalpel is held between the thumb and third finger. The end of the blade is forced up against the thenar muscles of the hand.

**FIGURE 40-10** Scissors. **A.** Jorgenson. **B.** Metzenbaum. **C.** Curved Mayo. **D.** Straight Mayo. (Used with permission from U.S. Surgitech, Inc.)

uncontrolled penetration of underlying structures. To lengthen the incision, a gentle in-and-out sawing motion is used.

### ■ Scissors

These are used commonly to divide tissues, and modification in blade shape and size allows their use across various tissue textures (Fig. 40-10). For correct positioning, the thumb and fourth finger are placed within the instrument's rings, and the index finger is set against the crosspiece of the scissors for greater control. This “tripod” grip allows maximum shear, torque, and closing forces to be applied and provides superior stability and control. In general, surgeons cut away from themselves and from dominant to nondominant sides.

The fine blades of Metzenbaum or iris scissors are used routinely to dissect or define natural tissue planes such as dividing thin adhesions or incising peritoneum or vaginal epithelium. During dissection, traction on opposing poles of the tissue to be dissected typically simplifies the process, and a small nick is often necessary to enter the correct tissue plane. The blades are closed and inserted between planes, following the natural curves of tissues being dissected (Fig. 40-11). The blades are opened and then withdrawn. After turning both wrist and blades 90 degrees, the surgeon reinserts the lower blade, and tissues are divided. When dissecting around a curve, the scissors follow the natural curve of the structure. Dissection proceeds in the same plane to avoid burrowing into the structure or deviating away and toward unintended adjacent tissues.

For thicker tissues, sturdier scissors such as curved Mayo scissors are used. Similarly, Jorgenson scissors have thick blades and tips that are curved at a 90-degree angle. These are used commonly to separate the vagina and uterus during the final steps of hysterectomy. Suture-cutting scissors have blunt, flat blades and are reserved for this function to avoid dulling tissue scissors.

### ■ Needle Holders

These may be straight or curved, and commonly, one with straight, blunt jaws is chosen during routine tissue approximation

**FIGURE 40-11** Plane dissection. **A.** During development of tissue planes, the tips of closed Metzenbaum scissors are placed at the border between two tissues, and forward pressure is applied to advance the tips. **B.** Scissors are spread to expand the tissue plane. **C.** The scissors are retracted and rotated 90 degrees. The lower blade is reinserted into the newly created tissue plane, and tissues are divided.

and pedicle ligation. Needles ideally pierce tissues perpendicularly. Thus, in most cases, the needle holder grasps a needle at a right angle and at a site approximately two-thirds from the needle tip.

Alternatively, some needle holders, such as the Heaney needle holder, are curved and aid needle placement in confined or angled areas. If a curved holder is used, the needle is grasped similarly, and the inner curve of the holder typically faces the needle swage (Fig. 40-12).

Traditionally, the needle holder is held with the thumb and fourth finger in the rings. The greatest advantage of this grip is the precision afforded. The spring tension of the handles is relieved from the lock in a controlled fashion, thereby releasing and regripping the needle more precisely. Alternatively, with the “palmar grip,” the needle holder is held between the ball of the thumb and the remaining fingers, and no fingers enter the instrument rings. This grip allows a simple rotating motion for driving curved needles through an arc. Its greatest advantage is the time saved during continuous suturing, as the needle can be released, regripped, and redirected efficiently without replacing fingers into the instrument rings. Disadvantageously, this grip has the potential to lack precision during needle release. When

**FIGURE 40-12** Correct grasp of a needle using a curved needle holder. The curve of the tip faces the needle swage. (Used with permission from U.S. Surgitech, Inc.)

unlocking the needle driver, release of the spring lock should be smooth and gradual. This avoids an abrupt release, which may suddenly pop the handles apart with potential for awkwardness, loss of needle control, and tissue injury.

## ■ Tissue Forceps

Forceps function to hold tissue during cutting, retract tissue for exposure, stabilize tissue during suturing, extract needles, grasp vessels for electrosurgical coagulation, pass ligatures around hemostats, and pack sponges. Forceps are held so that one blade functions as an extension of the thumb and the other as an extension of the opposing fingers. Alternate grips may appear awkward and limit the full range of wrist motion, leading to suboptimal instrument use.

Heavy-toothed forceps, such as the Potts-Smith single-toothed forceps, Bonney forceps, and Ferriss-Smith forceps, are used when a firm grasp is more important than gentle tissue handling (Fig. 40-13A). These tools are often used to hold fascia for abdominal wound closure.

Light-toothed forceps, such as the single-toothed Adson, concentrate force on a tiny area and give more holding power with less tissue destruction. These are used for more delicate work on moderately dense tissue such as skin. Nontoothed forceps, also known as smooth forceps, exert their grip through serrations on the opposing tips (Fig. 40-13B). They are typically used for delicate tissue handling and provide some holding power with minimal injury. DeBakey forceps are another type of smooth forceps originally designed as vascular forceps but can be occasionally used for other delicate tissues. In contrast, the broader, shallow-grooved tips of Russian forceps and Singley forceps may be preferred if a broader or thicker area of tissue is manipulated.

## ■ Retractors

### Abdominal Surgery Retractors

Clear visualization is essential during surgery, and retractors conform to body and organ angles to allow tissues to be pulled back from an operative field. In gynecology, retractors may be grouped broadly as self-retaining or handheld and as vaginal or abdominal.

During abdominal surgery, retractors that by themselves hold abdominal wall muscles apart, termed *self-retaining*, are used commonly. Styles such as the Kirschner and O'Connor-O'Sullivan

**FIGURE 40-13** Forcep types. **A.** Tip of toothed forceps allows a firm tissue grasp. **B.** Smooth tissue forceps. **A,** Russian. **B,** Dressing. **C,** DeBakey. **D,** Short smooth. (Used with permission from U.S. Surgitech, Inc.)

contain four broad, gently curved blades and retract in four directions. Blades pull the bladder caudally and the anterior abdominal wall muscles laterally and cephalad. The Balfour retractor retracts in three directions but can be made to retract in four with the addition of an upper arm attachment. Alternatively, ring-shaped retractors such as the Bookwalter and Denis Browne styles offer greater variability in the number and positioning of retractor blades. However, these styles usually require more time to assemble and place. With all of these retractors, deep or shallow blades can be attached to the outer metal frame according to the abdominal cavity depth. As discussed earlier, blades should be shallow enough to avoid femoral nerve compression.

In addition to these metal bladed styles, several disposable retractors consist of two equal-sized plastic rings connected by a cylindrical plastic sheath. One ring collapses into a canoe shape that can be threaded through the incision and into the abdomen. Once inside the abdomen, it springs again to its circular form. The second ring remains outside. Between these rings, the plastic sheath spans the thickness of the abdominal wall and creates 360-degree retraction. As shown in Figure 44-8.7, Alexis or Mobius brands can be ideal for minilaparotomy, but sizes are also available for laparotomy.

Handheld retractors may be used in addition to or in place of self-retaining styles. These instruments allow retraction in

only one direction but can be placed and repositioned quickly. The Richardson retractor has a sturdy, shallow right-angled blade that can hook around an incision for abdominal wall retraction (Fig. 40-14). Alternatively, Deaver retractors have a gentle arching shape and conform easily to the curve of the anterior abdominal wall. Compared with Richardson retractors, they offer increased blade depth and are often used to retract bowel, bladder, or anterior abdominal wall muscles. A Harrington retractor, also called a *sweetheart retractor*, has a broader tip that also effectively holds back bowel.

In certain instances, such as during suturing of the vaginal cuff, a thin, deep retractor blade, termed a *malleable retractor*, may be required to retract or protect surrounding organs. Also called a *ribbon retractor*, this tool is a long, relatively flexible metal strip that can be bent to conform to various body contours for effective retraction. Narrow and wider sizes are available. These also may be used to cover and protect underlying bowel from needle-stick injury during abdominal wall closure.

For smaller incisions, the preceding retractors are too large, and those with smaller blades such as the Army-Navy retractor or S-retractor are selected. S-retractors offer thinner, deeper blades, whereas the sturdier blades of the Army-Navy style allow stronger retraction (Fig. 40-15). A Weitlaner self-retaining retractor may also be used for minilaparotomy incisions.

**FIGURE 40-16** Vaginal self-retaining retractors. **A.** Gelpi retractor (left). Rigby retractor (right). **B.** Auvar weighted vaginal speculum. (Used with permission from U.S. Surgitech, Inc.)

### Vaginal Surgery Retractors

The vaginal walls can be separated using several self-retaining models. The Gelpi retractor has two narrow teeth that are placed distally against opposing lateral vaginal walls and is most appropriate for perineal procedures (Fig. 40-16A). The Rigby retractor, with its longer blades, effectively separates lateral vaginal walls, whereas a Graves speculum, shown in Figure 1-6 (p. 5), holds apart anterior and posterior walls. An Auvar weighted speculum contains a long, single blade and ballasted end, which uses gravity to pull the posterior vaginal wall downward (Fig. 40-16B).

The degree of retraction offered by vaginal self-retaining retractors, however, at times may be limited. Therefore, handheld retractors are often required to augment or replace these instruments. Handheld retractors used in vaginal surgery include the Heaney right-angle retractor, the narrow Deaver retractor, and the Breisky-Navratil retractor (Figs. 40-17). Additionally, during vaginal procedures, the cervix often must be manipulated. Lahey thyroid clamps offer a secure grip dur-

ing vaginal hysterectomy, but their several sharp teeth can cause significant trauma. These are therefore less than ideal in patients in whom the cervix will remain. In these patients, in whom curettage or laparoscopy is performed, a single-toothed tenaculum can afford a firm grip but with less cervical damage (Fig. 40-18).

### Tissue Clamps

Retraction is a fundamental requirement during most gynecologic surgery. As a result, various shapes, sizes, and strengths of clamps have been created to manipulate the different tissues encountered. For example, the smooth, cupped jaws of a Babcock clamp are ideal for gentle elevation of fallopian tubes, whereas the serrated teeth of the Allis and Allis-Adair clamps can provide a fine, firm grip on covering epithelia or serosa during dissection (Fig. 40-19).

Clamps are also used to occlude vascular and tissue pedicles during organ excision. Hemostats and Mixer right-angle clamps have small, slender jaws with fine inner transverse ridges to atraumatically grasp delicate tissue, especially vessels (Fig. 40-20).

Heavier clamps are required to grasp and manipulate stiffer tissues such as fascia and include Pean (also termed Kelly) and Kocher (also termed Ochsner) clamps. These clamps have finely spaced transverse grooves along their inner jaws to minimize tissue slippage. They may be straight or curved to fit tissue contours and like Kocher clamps, may contain a set of interlocking teeth at the tip for additional grip security. Another choice, the ring forceps, has large open circular jaws with fine transverse grooves. These effectively grasp broad, flat surfaces. Additionally, a folded gauze sponge can be placed between its jaws and used to absorb blood from the operative field or gently retract tissues.

Ligaments that support the uterus and vagina are fibrous and vascular. Thus, a sturdy clamp that resists tissue slippage

**FIGURE 40-17** Vaginal handheld retractors. **A.** Breisky-Navratil retractor. **B.** Right-angle retractor. (Used with permission from U.S. Surgitech, Inc.)

**FIGURE 40-18** Clamps shown both open (left) and closed (right). **A.** Ring forceps. **B.** Lahey-thyroid clamp. **C.** Single-toothed tenaculum. (Used with permission from U.S. Surgitech, Inc.)

**FIGURE 40-19** Tissue clamps. **A.** Allis. **B.** Babcock. **C.** Allis-Adair. (Used with permission from U.S. Surgitech, Inc.)

from its jaws is required during hysterectomy. Several clamps, including Heaney, Ballantine, Rogers, Zeppelin, and Masterson clamps, among others, are effective (Fig. 40-21). The thick, durable jaws of these clamps carry deep, finely spaced grooves or serrations arranged either transversely or longitudinally for secure tissue grasping. Additionally, some contain a set of interlocking teeth at the tip or heel or both. Although this modification improves grip, it also may increase tissue trauma. More acutely angled clamps are typically selected when available operating space is cramped.

Securing tissue pedicles may be accomplished using a variety of suturing techniques (Fig. 40-22). A single tie alone may be placed around the pedicle. In addition, a second distal trans-

**FIGURE 40-20** Vascular clamps. **A.** Tonsil. **B.** Hemostat. **C.** Mixer right-angle clamp. (Used with permission from U.S. Surgitech, Inc.)

fixing suture can be placed to minimize dislodgement of the suture by vessel pulse pressures or pedicle manipulation.

### ■ Suction Tips

During gynecologic surgery, bleeding, peritoneal fluids, pus, ovarian cyst contents, and irrigants may obscure the operating field. Accordingly, choice of suction tip typically is dictated by the type and amount of fluid encountered. Adson and Frazier

**FIGURE 40-22** Different pedicle ligation techniques. All are transfixing ligatures except for **(A)**. (Used with permission from U.S. Surgitech, Inc.)

**FIGURE 40-23** Suction tips. **A.** Yankauer. **B.** Frazier. **C.** Poole. (Used with permission from U.S. Surgitech, Inc.)

suction tips are fine bore and are useful in shallow or confined areas and when little bleeding is noted (Fig. 40-23).

Alternatively, a Yankauer suction tip offers a midrange-sized tip and is used commonly in general gynecology cases. However, if a larger volume of fluid or blood is expected, then a Poole suction tip may be desired. Its multiple pores allow continued suction even if some are obstructed with clot or tissue. In addition to removing large volumes of fluid quickly, this suction tip's sieved sheath may be removed. The thinner-bore inner suction cannula can then be used for finer suctioning. Larger-bore Karman suction cannulas are used for products of conception evacuation and are discussed in Section 43-16 (p. 966).

## NEEDLES, SUTURES, AND KNOTS

These are foundational tools of tissue approximation, vessel ligation, and wound closure. They are crafted in various strengths, shapes, and sizes to meet surgical needs. Appropriate selection can profoundly affect wound healing and patient recovery. Thus, surgeons should be familiar with their characteristics and most appropriate applications.

### ■ Needles

The ideal surgical needle pierces tissue with ease, with minimal tissue damage, and without bending or breaking. Tissues differ in their density and location, and thus needles are designed with variable sizes, shapes, and tips. The anatomy of a needle is simple: each contains a tip, body, and site of suture attachment (Fig. 40-24). For most gynecologic cases, the suture and needle used are attached as a continuous unit, which is described as *swaged*. This contrasts with needles that have eyes for suture threading. Swaged needles may be firmly secured to the suture and require cutting at the end of suturing. Alternatively, *controlled-release*, or “pop-off,” swaged needles detach from the suture with a brisk tug. Controlled-release needles are often used when securing vascular pedicles or placing interrupted sutures. Continuous running suturing typically requires a swaged needle without the controlled-release feature.

In certain urogynecologic procedures, such as abdominal sacrocolpopexy, a *double-armed suture* is often chosen. This

**FIGURE 40-24** Various needle configurations and characteristics of a curved surgical needle.

suture contains identical swaged needles at each of its ends. This design enables surgeons to suture distant tissues with different ends of the suture before approximating them.

Descriptors of needle size and shape are noted in Figure 40-24. Of these, needle radius, circle configuration, and gauge more frequently influence surgical selection. For example, a needle should be large enough to pass completely through the tissue and exit far enough to allow the needle holder to be repositioned on the end of the needle at a safe distance from the tip. Repeated grasping of the needle tip leads to a dulled tip. A dulled tip subsequently leads to difficult tissue penetration and greater tissue trauma.

For thicker tissues, a larger radius and gauge are warranted. For confined surgical spaces, a needle with smaller radius and greater circle configuration typically is required. Thus, for most gynecologic procedures, a three-eighths or one-half circle configuration is used. For some urogynecologic operations, a five-eighths circle configuration is preferred.

The tip should allow passage of the needle through tissue with the smallest amount of tissue damage. Those with tapered points are used for suturing thin tissues, such as peritoneum (Fig. 40-25). Alternatively, cutting needles are preferred for denser tissue such as fascia and ligaments. Cutting points have sharp edges laterally and a third sharp edge extending either toward or away from the needle's inner curve. A conventional cutting needle features the third cutting edge on the inside curve and provides shallower tissue bites. In contrast, reverse cutting needles have the third cutting edge directed away from the inner curve of the needle and are used for particularly tough tissues.

### ■ Sutures

Sutures maximize wound healing and tissue support and are categorized by their biologic or synthetic derivation, their

**FIGURE 40-25** Configurations of various needle tips and bodies.

filamentous structure, and their ability to be degraded and reabsorbed (Table 40-3). Other qualities are described in the subsequent paragraphs.

Sutures such as catgut, silk, linen, and cotton are derived from biologic sources. As a group, biologic sutures produce the greatest tissue reaction and have the lowest tensile strength profile. Accordingly, most suture materials currently used in gynecologic surgery are synthetic.

Of synthetic materials, the number of strands that make up a given suture defines it as either *monofilament* or *multifilament*. Monofilament suture is constructed as a single strand, whereas multifilament suture contains multiple strands that are braided or twisted. Monofilament sutures have lower friction coefficients and therefore pull more easily through tissues, and as a result, they create less tissue injury. As a group, they tend to incite less tissue reaction. Moreover, braid crevices are absent, and bacteria therefore are less likely to adhere (Bucknall, 1983; Sharp, 1982). However, monofilament sutures are in general less pliant for knot tying and, if nicked by instruments, are more prone to break.

**TABLE 40-4.** Suture Designation

U.S.P. Designation	Synthetic absorbable diameter (mm)
5	0.7
4	0.6
3	0.6
2	0.5
1	0.4
0	0.35
2-0	0.3
3-0	0.2
4-0	0.15
5-0	0.1

The diameter of a suture reflects its size and is measured in tenths of a millimeter (Table 40-4). A midpoint diameter size is designated as 0, and as suture diameter increases above this, arabic numbers are assigned. For example, no. 1 catgut is thicker than 0-gauge catgut. As suture diameter decreases from this midpoint, 0s are added. By convention, an arabic number followed by a 0 also may be used to reflect the total number of 0s. For example, 3-0 suture also may be represented as 000. Moreover, 3-0 suture is greater in diameter than 4-0 (0000) suture.

Ideally, the appropriate suture caliber is fine enough to limit tissue damage during placement and minimize subsequent tissue reaction yet provide ample tensile strength to support and approximate involved tissues. Defined as the amount of weight necessary to break a suture divided by its cross-sectional area, *tensile strength* is an important characteristic for suture selection. The tensile strength of material chosen should approximate the strength of the tissues being sutured.

Tensile strength is lost at different rates among suture types. Materials that have lost most of their tensile strength by 60 days following surgery are considered to be *absorbable* (Bennett, 1988).

**TABLE 40-3.** Specific Suture Material Characteristics

Type	Configuration	Tensile Strength	Handling	Knot Security	Reactivity
<b>Nonabsorbable</b>					
Silk	Braided	Good	Good	Good	High
Nylon	Monofilament	High	Fair	Fair	Low
Prolene	Monofilament	Good	Poor	Poor	Low
Mersilene	Braided synthetic	High	Good	Good	Moderate
Ethibond	Braided, coated	High	Fair	Fair	Moderate
<b>Absorbable</b>					
Gut (plain)	Twisted	Poor	Fair	Poor	Low
Chromic (gut)	Twisted	Poor	Fair	Poor	High
Dexon	Braided	Good	Good	Good	Low
Vicryl	Braided	Good	Good	Fair	Low
PDS II	Monofilament	Good	Fair	Poor	Low
Monocryl	Monofilament	Fair	Good	Good	Low

Absorbable suture is destroyed enzymatically or hydrolyzed, whereas nonabsorbable suture persists and ultimately is encapsulated. Ideally, absorbable suture material remains throughout wound healing but no longer. Logically, individual tissue healing characteristics typically dictate whether short- or long-term sutures are required. Accordingly, nonabsorbable material plays a greater role in pelvic floor reconstruction procedures, whereas absorbable suture is used routinely in general gynecologic surgery.

All sutures, when placed within tissue, will incite inflammation. This response mirrors the total amount of suture placed and the suture's chemical composition (Edlich, 1973). In general, lower inflammatory responses are elicited by monofilament structure compared with multifilament, and synthetically derived compared with natural fiber (Sharp, 1982).

The ease of fluid to wick from the wet end of a suture to its dry end defines its *capillarity*. A suture's *fluid absorption ability* describes the amount of fluid it absorbs when immersed. Both properties are presumed to have an impact on the access of contaminating bacteria. Increased capillarity and fluid absorption ability greatly increase the amount of bacteria similarly absorbed (Blomstedt, 1977). In general, multifilament sutures, even those with coatings, display greater capillarity compared with synthetic monofilament sutures (Geiger, 2005).

The ability of a material to return to its prior length following stretch defines its *elasticity*. For tissues in which swelling or movement is expected postoperatively, a suture with increased elasticity is preferred because it will stretch rather than cut into approximated tissues. *Memory* defines the ability of material to return to original form following deformation. Sutures with greater memory tend to untie more easily during knot tying.

## ■ Knots

The surgical knot is the weakest link in a tied suture loop, and the force necessary to break a knotted suture is less than that to break an individual suture strand. Knot failure can lead to serious complications such as bleeding, hernias, and wound dehiscence (Batra, 1993; Trimbos, 1984). Thus, an understanding of knots is essential.

A surgical knot consists of: a loop, which maintains tissue apposition, and a knot, composed of several throws snugged against each other. A single throw is formed when one strand is wrapped around the other one time, and when wrapped twice, a double throw is created (Zimmer, 1991). This double weave forms the basis of a surgeon's knot. In characterizing knots, each throw is given a numerical description, in which single throws are designated as number 1, and double throws as number 2. If successive throws are identical, a multiplication sign is placed between the numbers. If throws mirror one another, then an equal sign is used. Thus, a square knot is described as  $1 = 1$ ; granny knot,  $1 \times 1$ ; and square surgeon's knot,  $2 = 1$  (Fig. 40-26). Alternative nomenclature schemes exist, but understanding the basic principles of knot construction is more clinically relevant than these descriptive definitions (Dinsmore, 1995).

### Flat and Sliding Knots

Surgical knots can have flat or sliding configurations. Flat configurations include square, granny, and surgeon's knots.

FIGURE 40-26 Surgical knots.

To construct a flat square knot, forehanded and backhanded throws are alternated, and the suture strands are pulled with equal tension in opposite directions but in the same plane. In addition, the suture strands or the hands may have to cross with each throw to ensure that the knot lies flat.

In contrast, sliding knots, also termed slip knots, are characterized as identical, nonidentical, and parallel. They are created when unequal tension is applied to the strands, such as during one-hand knot tying. Sliding knots are useful in situations when flat square knotting is difficult or cumbersome, such as in the deep pelvis or vagina (Ivy, 2004b). In general, sliding knots have been shown to have a higher failure rate than that of flat knots (Hurt, 2005; Schubert, 2002).

*Identical sliding knots* are created by holding one strand constantly under tension and repeating identical tying maneuvers with the other hand. Unfortunately, these identical sliding knots carry a high failure rate and are not recommended for general use (Schubert, 2002; Trimbos, 1984, 1986). *Nonidentical sliding knots* are formed when a suture strand is held under constant tension, and one hand alternates forehanded and backhanded tying around this strand (Trimbos, 1986). This knot is the most frequent and practical knot used for vaginal surgery. Although these knots can unravel, additional throws can greatly improve their security (Ivy, 2004a; Trimbos, 1984; van Rijssel, 1990). A loop-to-strand variation of the nonidentical sliding knot is performed by holding the final loop of a continuous suture line taut, while alternate throws are made around the loop with the remaining single strand. Scant data support the security of this knot type in gynecologic surgery. When completed with monofilament suture, these knots carry high failure rates (Hurt, 2005).

Finally, with a *parallel sliding knot*, the suture strand under tension is alternated with each throw, causing alternate throws to slide down the other strand each time. Existing studies show this knot to be strong and reliable (Ivy, 2004b; Trimbos, 1986).

## Surgical Knot Effectiveness

The effectiveness of surgical knots depends mainly on two parameters: initial loop security and knot security. *Loop security* describes the ability to maintain a tight suture loop around the tissue as the initial knot throws are placed (Lo, 2004). Suture loops that are initially loose will fail to secure tissues no matter how tightly the knot is tied and will result in ineffective knots, colloquially termed “air knots” (Burkhart, 1998). Three ways to optimize loop security include: maintenance of tension on both strands during tying, use of an initial surgeon’s throw, and slip knots (Anderson, 1980). If slip knots are placed initially, they can be converted to square knots or reinforced with a square knot once the pedicle or vessel is secured. Importantly, upward tension on both strands deep within a body cavity should be limited. Excessive force can avulse the pedicle or cause the suture loop to pull completely off.

For *knot security*, the tension with which a given throw is tied is the most important. A knot laid down tightly under great tension is less likely to slip than a knot with the same configuration but with more throws tied loosely (Gunderson, 1987).

The number and type of knots required to secure various suture materials vary. Qualities such as elasticity and memory often direct these recommendations. In general, multifilament sutures are easier to handle and display less memory, whereas synthetic monofilament suture or multifilament sutures with coatings have increased memory and may hold a knot poorly. For most sutures, four to six throws appears to be adequate, but the exact number depends on the type of suture and whether a flat or sliding knot is formed. Up to a point, additional throws provide more security to a knot, but this benefit must be balanced against the corresponding elevated infection risk from increased knot volume (van Rijssel, 1990).

## ELECTROSURGERY

Semantically, *electrosurgery* differs from *electrocautery*, although the terms are often incorrectly interchanged. With electrocautery, electric current passes through a metal object, such as a wire loop, with internal resistance. Passage of current heats the loop, which then may be used surgically. The flow of current is limited to the metal being heated, and no current enters the patient. In contrast, electrosurgery directs the flow of current to the tissues themselves and produces localized tissue heating and destruction. As a result, electric current must pass through tissues to produce the desired effect (Amaral, 2005). The electrosurgical circuit contains four main parts: the generator, the active electrode, the patient, and the return electrode. Electrosurgery may be broadly categorized as monopolar or bipolar depending on the proximity of these two electrodes.

### ■ Monopolar Electrosurgery

Electric current is the flow of electrons through a circuit (Fig. 40-27). *Voltage* is the force that drives those charges around the circuit. *Impedance* is the combination of resistance, inductance, and capacitance that alternating current meets along the way (Morris, 2006). In monopolar electrosurgery, the return electrode in clinical use is the grounding pad. Current

**FIGURE 40-27** Circuits in electrosurgery. **A.** Monopolar electrosurgical circuit. **B.** Bipolar electrosurgical circuit.

therefore flows: (1) from the generator, which is the source of voltage, (2) through the electrosurgical tip to the patient, the source of impedance, and then (3) onto the grounding pad, where it is dispersed. Current leaves the pad to return to the generator, and the circuit is completed (Deatrack, 2015). In electrosurgery, tissue impedance converts electric current into thermal energy that causes tissue temperatures to rise. It is these thermal increases that create electrosurgery’s tissue effects.

### Surgical Effects

Differing tissue effects are created by altering the manner in which current is produced and delivered. First, altering the current wave pattern can affect tissue temperatures. For example, the high-frequency continuous sinusoidal waveform produced with cutting current creates higher tissue temperatures than that with coagulation current (Fig. 40-28). Second, the extent

**FIGURE 40-28** Tissue effects vary with cutting, blended, and coagulation currents. There is more lateral thermal damage with a pure coagulation current compared with a pure cutting or blended current. The duration of applied energy varies between current types.

to which current is spread over an area, also termed *current density*, alters the rate of heat generation (Fig. 40-29). Thus, if current is concentrated onto a small area, such as a needle-tip electrode, greater tissue temperatures are generated than if delivered over a wider area, such as an electrosurgical blade. In addition to current density, voltage can alter tissue effects. As voltage increases, the degree of thermal tissue damage similarly increases. And finally, the qualities and impedance of the tissues themselves affect energy transfer and heat dissipation. For example, water has low electrical impedance and liberates little heat, whereas skin with its greater impedance generates significantly higher tissue temperatures (Amaral, 2005).

With electrosurgical cutting, a continuous sine wave of current is produced. The flow of high-frequency current typically is concentrated through an electrosurgical needle or blade and meets tissue impedance. Sparks are created between the tissue and electrode, intense heat is produced, cellular water vaporizes, and cells in the immediate area burst. Tissues are cut cleanly, and there is minimal coagulum production. As a result, few vessels are sealed, and minimal hemostasis accompanies electrosurgical cutting.

In contrast, coagulation current does not produce a constant waveform. Less heat is produced than with cutting current. However, tissue temperature still rises sufficiently to denature protein and disrupt normal cellular architecture. Cells are not vaporized instantly, and cellular debris remains associated with

wound edges. The coagulum seals smaller blood vessels and controls local bleeding (Singh, 2006).

Variations in the percentage of time that current is flowing can create electrosurgical effects that contain both cutting and coagulating features. Such *blended currents* are used commonly in gynecologic surgery. In most cases, selection of specific percentages of cutting and coagulation current is affected by surgeon preference and type of tissues encountered. The inner vascular tissue may be best suited for a blend with less active current time, whereas denser avascular tissues may require a greater percentage of active current.

### Patient Grounding

As discussed earlier, current is concentrated at the electrode tip and enters the patient at a small site. Current follows the path of least resistance and exits the body through a grounding pad that is designed to have a large surface area, high conductivity, and low resistance. Dissipation across this large surface area allows current to leave the body without generating significant tissue temperatures at the exit site.

However, patient burns may result if current is concentrated through a return electrode. Clinically, this may occur if a grounding pad is partially dislodged. In this setting, the surface area is decreased, and the exiting current concentration and the tissue temperatures at the exit site rise. In addition, patient jewelry, metal candy cane stirrups, or other surfaces with high conductivity and low resistance may serve as a return electrode. In such cases, patients may be burned by concentrated current exiting through these small contact sites. Ideally, grounding

**FIGURE 40-29** Current concentration and its effects. Thermal energy and risk for tissue injury diminish as current density decreases and electrode area increases.

pads are firmly adhered to a relatively flat body surface that is near the operative field. Thus, in most gynecology procedures, grounding pads are placed along the lateral upper thigh.

Patients with pacemakers, implantable cardioverter-defibrillators (ICDs), or other electrical implants require special precautions. Stray electrosurgical current may be interpreted as an intracardiac signal by an implanted device and lead to pacing changes. In addition, myocardial electrical burns may result from conduction of current through the pacing electrode rather than through the grounding pad (Pinski, 2002). Accordingly, for patients with these devices, preventive recommendations include pre- and postoperative cardiology consultation; use of minimal monopolar electrosurgical current settings or substitution with bipolar electrosurgery or harmonic scalpel; continuous cardiac monitoring; contingency plans for arrhythmias; and close proximity of active and return electrodes (Crossley, 2011).

### ■ Bipolar Electrosurgery

This form of electrosurgery differs from monopolar electrosurgery in that the tip of a bipolar device contains both an active electrode and a return electrode. For this reason, a distant grounding return pad is not required. Coagulation current is concentrated on tissues grasped between the electrodes, and tissue must remain between them. If tissue slips from between the tips, then active and return electrodes contact and create a short circuit. Coagulation will not occur (Michelassi, 1997). Bipolar electrosurgery uses only coagulation current and lacks cutting capability. However, it is useful for vessels coagulation and also is used during laparoscopic sterilization to coagulate fallopian tubes (Section 44-2, p. 1007).

### ■ Argon Beam Coagulation

With argon beam coagulation (ABC), radiofrequency energy is transferred to tissues through a jet of inert argon gas to create noncontact monopolar electrothermal coagulation. Additionally, the gas jet clears blood and tissue debris during coagulation. Advantages of ABC include the ability to coagulate broad surface areas and larger vessels (Beckley, 2004). In gynecologic surgery, ABC is used most often during ovarian staging cases in which extensive debulking may be required.

## ULTRASONIC ENERGY

Sound waves are mechanical waves that transport energy through a medium. Those above audible range are described as *ultrasound* or *ultrasonic*. In medicine, ultrasound waves that are applied at low levels such as those used in diagnostic sonography are harmless. However, if higher power levels are used, then mechanical energy transferred to the affected tissues is strong enough to produce cutting, coagulation, or tissue cavitation.

Of tools, the ultrasonic scalpel, also known as a *Harmonic scalpel*, has a tip that vibrates at high frequency. This allows the surgical device to be used effectively for both cutting and coagulating during laparotomy or laparoscopy (Gyr, 2001; Wang, 2000). The vibrating tip transfers mechanical energy to tissues. Mechanical energy breaks hydrogen bonds and generates

heat within tissues to denature protein and form a sticky coagulum that produces hemostasis. A balance between cutting and coagulation is controlled by three factors: power levels, tissue tension, and blade sharpness. Higher power level, greater tissue tension, and a sharp blade will lead to cutting. Lower power, decreased tissue tension, and a blunt blade will create slower cutting and greater hemostasis (Sinha, 2003).

Used most commonly in laparoscopic surgery, the ultrasonic scalpel serves as an alternative to suture ligation, electrosurgical coagulation, laser, and stapling or clipping devices. However, only a few studies have compared the clinical effectiveness of this method with other methods of hemostasis (Kauko, 1998).

Cavitation ultrasonic surgical aspiration (CUSA) is another ultrasound-based tool. The ultrasonic surgical aspirator handpiece contains three main components: a high-frequency vibrator, which transfers the ultrasonic energy to tissues; irrigation tubing, which directs cooling saline to the tip; and a suction system, which draws tissue up to the tip for contact with the vibrator and which also clears away tissue fragments and irrigant. Ultrasound energy can be used to raise tissue temperatures dramatically and thereby disrupt tissue architecture by a process termed *cavitation*. For cavitation, the CUSA tip produces mechanical waves that create heat and vapor pockets around cells in tissues with high water content such as adipose, muscle, and carcinoma. Collapse of these pockets leads to disruption of cell architecture (Jallo, 2001). Affected tissues are removed subsequently by suction aspiration. However, tissues containing less water and higher contents of collagen and elastic fibers, such as blood vessels, nerves, ureters, and serosa, are more resistant to damage (van Dam, 1996).

In gynecology, CUSA has a limited surgical role. It may be used effectively in the treatment of vulvar intraepithelial neoplasia and bulky condyloma acuminata (Section 43-28, p. 996). It can also speed cytoreductive ovarian cancer surgery (Aletti, 2006; Deppe, 1988; Robinson, 2000; van Dam, 1996).

## MANAGEMENT OF HEMORRHAGE

### ■ Autologous Donation and Cell Salvage

Although the risk of hemorrhage accompanies most gynecologic procedures, certain factors are associated with higher rates of bleeding and are assessed prior to surgery. Specifically, obesity, the presence of a large pelvic mass, adhesions such as those from endometriosis or pelvic inflammatory disease, cancer or prior radiation, and coagulation dysfunction have been linked with an increased risk of hemorrhage. For those identified to be at risk, intraoperative red cell salvage or preoperative autologous blood donation can be considered.

Red blood cell (RBC) salvage machines (Autolog; Cell Saver) collect, filter, and centrifuge blood lost during surgery. RBCs are heavier and are separated from plasma and smaller blood components during centrifugation and are then reinfused into the patient. Anticoagulants such as heparin or citrate are added to prevent clotting (Karger, 2005). Salvage efficiencies approximate 60 percent with good technique. However, vacuum levels, suction tip size, and thoroughness of salvaging efforts can affect this value. For example, turbulence destroys RBCs. Thus, suction

**FIGURE 40-30** Steps in vessel isolation, ligation and transection. **A.** During vessel isolation, a clamp tip can be opened and closed parallel to the side of the vessel to dissect away loose surrounding tissue. **B.** The tip of the clamp is insinuated beneath the vessel, and the jaws are opened and elevated. A suture ligature can then be grasped and pulled beneath the vessel. **C.** Two sutures are placed around the vessel, and it is transected between these ligation points.

tips with greater diameters and lower suction force can minimize hemolysis (Waters, 2005). Additionally, laparotomy sponges can be rinsed in sterile saline to maximize RBC removal. The RBC-containing saline then is suctioned into the salvage device for processing. The filtering systems in these devices have limitations. Accordingly, RBC salvage is not appropriate for contaminated cases or those in which malignancy, hemostatic agents, or amniotic fluid may be present (Waters, 2004).

Another approach for cases with expected hemorrhage involves preoperative autologous donation. Thus, to avoid potential transfusion reaction or blood-borne infection, a patient may elect to donate her own blood for personal use approximately once a week for 3 to 5 weeks preceding surgery. Patient hemoglobin levels should be greater than 11.0 g/dL before each donation. Moreover, units are not collected within 72 hours before surgery. This allows intravascular volume to be replenished by the patient and units to be processed by the blood bank (Goodnough, 2005). Disadvantageously, this process has been associated with preoperative anemia secondary to donation, more liberal transfusion, transfusion reaction following clerical error, volume overload, and bacterial contamination of blood products during processing (Henry, 2002; Kanter, 1996, 1999).

Improved blood banking safety has accompanied a decline in preoperative autologous donation (Brecher, 2002). Moreover, for most gynecologic cases, the risk of transfusion is low. For these reasons, autologous donation typically is reserved for selected instances in which the risk of transfusion is significant, such as radical hysterectomy or surgery for patients with coagulopathies. Additionally, patients with rare blood phenotypes in whom acquisition of compatible blood may be difficult may benefit from autologous donation.

### ■ Proper Surgical Method

In many instances, proper surgical technique can minimize vascular injury and hemorrhage. Thus, prior to ligation, vessels ideally have excess connective tissue removed sharply in a process called *skeletonizing*. Additionally, tissue clamps selected for grasping a vascular pedicle are large enough to contain the

entire pedicle in the distal portion of the clamp. Large pedicles that force excess tissue toward the clamp's heel carry greater risk of tissue slipping from the heel and bleeding. Once secure, sutures placed on vascular pedicles are not to be used for traction because the risk of avulsing the suture or vessel increases.

Tying an intact vessel at two places along its length before tissue cutting is considered in certain situations. This technique may be appropriate if a vessel is on tension or if space for a clamp is limited, such as when the ureter or bowel is in close proximity. A window is created below the vessel and ties are passed beneath the vessel before doubly ligating and dividing it (Fig. 40-30).

### ■ Steps of Hemorrhage Management

A methodical approach to intraoperative hemorrhage is critical to minimize patient morbidity. If an isolated vessel is clearly identified, then grasping it with a hemostat, vascular clamp, or fine forceps may allow ligation, electrosurgical coagulation, or vascular clip application.

In contrast, venous bleeding in the pelvis is typically from a venous plexus and rarely stems from a single vessel. A pelvic venous plexus contains thin-walled veins. Accordingly, indiscriminate clamping, suturing, clipping, and electrosurgical coagulation can cause further laceration and bleeding. However, if other vulnerable structures have been retracted and protected, a few shallow stitches that incorporate the bleeding area can be placed using fine absorbable suture.

If these initial efforts are unsuccessful and significant hemorrhage continues, the bleeding site is compressed with fingertips, sponge stick, or laparotomy sponges. Anesthesia staff is informed of events to allow for additional monitoring. Nursing staff is also informed as additional resources may be required, such as specialized instruments, suture, clips, and blood products. Fluid resuscitation is individualized depending on the degree of hemorrhage and other patient factors described later.

Adequate exposure typically aids control of bleeding. The operative field is assessed and increased as needed by extending a vertical incision cephalad, converting a Pfannenstiel incision to a Cherney incision, adding retractors, or converting a vaginal

or laparoscopic approach to laparotomy. A second suctioning system may be required, and appropriate suture or clips are made available before removing pressure. Additional dissection of avascular planes around the bleeding site may improve isolation and ligation of a lacerated vessel. Furthermore, nearby vulnerable structures such as the bladder, ureter, or other vessels are identified and protected. After these steps, the surgeon may remove the tamponading pressure to assess the location, amount, and character of bleeding and to formulate the most appropriate technique for controlling it.

Vessel Ligation

As noted, bleeding vessels may be tied, clipped, or coagulated. Advantages to suture ligation include low cost and effectiveness over a broad range of vessel diameters. However, knot tying in general is time-consuming, is difficult in narrow spaces, and can be associated with ligature slippage or breakage. Small vessels may be ligated by a free-tie suture placed around the heel and tip of a vascular clamp and then secured with knots (see Fig. 40-23A). Alternatively, surgeons often prefer to secure larger vascular pedicles with two separate sutures. The first ligature is a free tie placed around the toe and heel of a vascular clamp and tied. The second ligature is distal to the first and typically incorporates a bite through the tissue pedicle (see Fig. 40-23B, C). Such *transfixion* of the ligature to the pedicle decreases the risk that it will slip off the pedicle’s end. Importantly, this second

ligature is placed distal to the first to avert hematoma formation if a vessel is pierced during transfixion.

Alternatively, titanium clips seal vessels by direct compression. They are used more commonly during gynecologic oncology cases and offer the advantage of speed. However, clips are expensive, require surgical dissection of the vessel prior to application, and may dislodge from a vessel. Their use in routine gynecology is limited by these factors and surgeon preference.

Electrical and ultrasound energy also may be used to seal vessels. Ultrasonic coagulating shears (Autosonix; Harmonic scalpel; Sonosurg) and electrosurgical bipolar vessel sealing clamps (Enseal; LigaSure) transfer energy that denatures vascular collagen and elastin. Some of these seal vessels up to 7 mm in diameter (Heniford, 2001). Thermal spread for these devices is comparable and averages 2.5 mm (Harold, 2003). These tools are particularly useful for laparoscopic surgeries, in which knot tying is time-consuming.

Local Topical Hemostats

These topical products may be placed on bleeding sites where ligature or vessel coagulation is not possible or has been ineffective. They are most effective in controlling low-pressure bleeding, such as from veins, capillaries, and small arteries. Commercially available materials are categorized as mechanical hemostats, active hemostats, flowable hemostats, and fibrin sealants (Table 40-5). Some liquid hemostats deliver topical thrombin or thrombin

TABLE 40-5. Topical Hemostatic Agents

Type of Agent	Brand Name	Material
<b>Mechanical Hemostats</b>		
Oxidized, regenerated methylcellulose	Surgicel	Flat loose woven fabric
	Surgicel Fibrillar	Flat peelable layers and tufts
	Surgicel Nu-knit	Flat loose woven fabric
	Surgicel SNoW	Flat nonwoven fabric
Porcine gelatin	Surgifoam	Powder or flat sponge
	Gelfoam	Powder or flat sponge
	Surgiflo <sup>a</sup>	Powder
Bovine collagen	Avitene	Powder, sheet, or flat sponge
	Instat	Powder
<b>Active Hemostats</b>		
Bovine thrombin	Thrombin-JMI	Liquid spray
Bovine thrombin + gelatin	Thrombi-Gel	Flat sponge
Bovine thrombin + methylcellulose	Thrombi-Pad	Flat sheet
Human thrombin	Evithrom <sup>a</sup>	Liquid
Recombinant thrombin	Recothrom	Liquid
<b>Flowable Hemostats</b>		
Bovine gelatin + human thrombin	FloSeal Matrix	Liquid
Porcine gelatin + Human thrombin	Surgiflo + Evithrom	Liquid
<b>Fibrin Sealants</b>		
Human thrombin, fibrinogen, plasminogen	Tisseel	Spray or drip application
Human thrombin, fibrinogen	Evicel	Spray or drip application

<sup>a</sup>Surgiflo and Evithrom can be combined to form flowable hemostat.

plus fibrinogen and thereby induce clot formation. Others provide combined effects that, in sum, create direct pressure against wound surfaces, entrap platelets, promote platelet aggregation, and serve as a scaffold on which clot can organize.

Although effective, these agents do have disadvantages. They should not be introduced intravascularly or used with RBC salvage machines. Packing agents tightly into bony foramina is avoided because these agents can swell and cause neurologic dysfunction or pressure necrosis. Moreover, they are not placed within skin edges because they may retard edge reapproximation. They may serve as an infection nidus and thus may not be appropriate in grossly infected tissue (Baxter Healthcare, 2014; Pfizer, 2014). Few data support the use of one agent over another. Selection typically is dictated by surgeon preference and availability in the operating room.

### Tranexamic Acid

Intravenous administration of tranexamic acid, an effective antifibrinolytic, has been widely investigated in trauma surgery (Hunt, 2015). It is a synthetic lysine derivative, which blocks the conversion of plasminogen to plasmin, as illustrated in Figure 8-12 (p. 196). Massive hemorrhage may be complicated by coagulopathy and uncontrollable microvascular hemorrhage. Tranexamic acid, 1 g given intravenously, may be of benefit in this setting in concert with pelvic pressure and blood component administration.

### Pelvic Artery Embolization or Pelvic Packing

As described in Chapter 9 (p. 209), embolization similar to that used to treat symptomatic leiomyomas can be used to occlude either the internal iliac artery or the uterine artery. This technique has been described in the management of hemorrhage in both gynecologic and obstetric cases.

In other cases, for patients with persistent heavy bleeding despite attempts at control, pelvic packing with gauze and termination of the operation may be warranted. Rolls of gauze are packed against the bleeding site to provide constant local pressure. Typically, 24 to 48 hours later, if the patient is stable and bleeding appears to have stopped clinically, packing is removed. Some surgeons recommend leaving one end of the gauze outside the wound. After administration of general anesthesia, packing is pulled slowly through a small opening left in the incision. Alternatively, entire gauze rolls may be packed into the abdomen and removed during a second laparotomy (Newton, 1988).

### Internal Iliac Artery Ligation

The internal iliac artery, also called the *hypogastric artery*, contains anterior and posterior divisions. Its anterior division supplies blood to central pelvic viscera (Fig. 38-12, p. 805). Occlusion of the internal iliac artery decreases mean blood flow by 48 percent in branches distal to ligation, which in many cases slows hemorrhage sufficiently to allow identification of specific bleeding sites (Burchell, 1968). Fortunately, the female pelvis has extensive collateral circulation, and the internal iliac artery shares arterial anastomoses with branches of the aorta, external iliac artery, and femoral artery. For this reason, ligation of the internal iliac's anterior division can be performed without compromise to pelvic organ viability. Several studies

have described normal postligation fertility in these women (Demirci, 2005; Nizard, 2003).

To perform ligation, the round ligament is divided, and the pelvic sidewall peritoneum lateral to the infundibulopelvic ligament is incised cephalad. Identification of the internal iliac artery is essential because ligation of the common or external iliac arteries will have vascular consequences to the lower extremity. Once the internal iliac artery is located, a Mixter right-angle clamp is placed under the vessel at a point 2 to 3 cm distal to the bifurcation of the common iliac artery. Two free ties of no. 1 or 0 absorbable suture are passed beneath the artery and then secured (Fig. 40-31). The artery is ligated but not transected. If the internal iliac is ligated at this site, its posterior division theoretically should be spared (Bleich, 2007). Care is required in passing instruments beneath the artery because the thin-walled internal iliac vein is easily lacerated.

## ■ Specific Sites of Bleeding

### Infundibulopelvic Ligament

During or after ligation of this vascular pedicle, a lacerated ovarian vessel may retract into the retroperitoneum to create a hematoma. In most cases, isolation of the bleeding vessel is required to halt hematoma expansion. For this, the pelvic sidewall peritoneum lateral to the ureter and the hematoma is opened, and the incision is extended cephalad to the upper pole of the hematoma. The incision in the peritoneum may be carried up the white line of Toldt. This line, found on the right and the left, is the peritoneum's posterior reflection over the mesenteric attachment site of the ascending or descending colon to the posterior abdominal wall. The upper pole of the hematoma is identified by a return to normal vessel caliber above the hematoma. The ovarian vessels are identified, and a closed Mixter right-angle clamp is placed beneath them. A tie on a pass then is threaded beneath and used to ligate these vessels. If large, the hematoma then is evacuated to minimize infection risk (Tomacruz, 2001). In rare cases in which vascular or ureteral anatomy is unclear, an ovarian artery may require ligation as proximal as its aortic origin below the renal arteries (Masterson, 1995).

### Space of Retzius and Presacral Venous Plexus

The space of Retzius, also called the retropubic space, is often entered during urogynecologic procedures and contains important vascular structures such as the venous plexus of Santorini, the obturator vessels, and the aberrant obturator vessel (Fig. 38-24, p. 817). Approximately 2 percent of tension-free vaginal tape procedures are complicated by bleeding in this space (Kolle, 2005; Kuuva, 2002). In most instances, bleeding is controlled with pressure or suturing.

In contrast, the presacral venous plexus can be lacerated by dissection or suturing during sacrocolpopexy (Fig. 38-23, p. 816). Cut vessels may retract into the vertebral bone, and problematic bleeding can follow. Management is described in full in Section 45-17 (p. 1099).

### Major Pelvic Vessels

High-volume pelvic vessels include the internal, external, and common iliac vessels, the inferior vena cava, and aorta. These

**FIGURE 40-31** Internal iliac artery ligation. After opening the retroperitoneal space, the ureter is identified and retracted medially. **Inset.** The internal iliac artery is identified and gently elevated with a Babcock clamp. A Mixer right-angle clamp is placed beneath the artery to receive a free tie for ligation. (Reproduced with permission from Cunningham FG, Vandorsten JP, Gilstrap LC: *Operative Obstetrics*, 2nd ed. New York: McGraw-Hill; 2002.)

may be lacerated during tumor removal, endometriosis excision, or laparoscopic trocar placement.

Initially following large vessel injury, pressure is applied for several minutes. Although gynecologic surgeons may attempt to repair these injuries, excessive delay in obtaining vascular surgery assistance often leads to greater blood loss (Oderich, 2004). Therefore, in many instances, pressure is applied, a vascular surgeon is consulted for repair, blood products are made available, and exposure is maximized. If a large vessel is punctured by a trocar or needle during laparoscopic entry, the instrument should remain in place to act as a plug while preparations for repair are made.

As discussed earlier, internal iliac artery ligation does not lead to ischemia of central pelvic organs due to collateral blood supply. However, injury to the external or common iliac arteries requires repair to maintain blood supply to the lower extremity. Consultation with a vascular surgeon may be indicated depending on the degree of laceration and surgeon skill. Maneuvers

that may extend the injury are avoided until appropriate assistance is available.

If repair is undertaken, familiarity with this vascular anatomy is essential. On the left, the common and external iliac arteries remain lateral to their respective veins. On the right, however, the common iliac artery runs medial to the vein.

These arteries can be repaired by placing vascular clamps 2 to 3 cm proximal and distal to the tear, then closing the defect with a continuous suture line using monofilament synthetic 5-0 suture (Gostout, 2002; Tomacruz, 2001). The proximal clamp is removed first to allow air and debris to exit the suture line, and then the distal clamp is removed.

### Parametrial and Paravaginal Vessels

During obstetric and gynecologic surgery, vessels supplying the uterus and vagina, especially venous plexuses, can be lacerated. At times, bleeding may not be easily identified and controlled by direct pressure, suturing, or clips. In these extreme

situations, ligation of the internal iliac artery, which is a main source of blood supply to the pelvis, may decrease pooling of blood and afford a better opportunity to find a bleeding source. Alternatively, if resources are available, pelvic artery embolization is effective in controlling pelvic hemorrhage. Despite these techniques, in rare persistent situations, pelvic packing and termination of surgery may be indicated.

FLUID RESUSCITATION AND BLOOD TRANSFUSION

The intraoperative and immediate postoperative periods are viewed as resuscitative phases, with a goal of attaining relative euvolemia. With acute hemorrhage, priorities include control of additional losses and replacement of sufficient intravascular volume for tissue perfusion and oxygenation. In hypoperfused areas, progressive failure of oxidative metabolism with lactate production leads to worsening systemic metabolic acidosis and eventual organ damage. To avoid these effects, resuscitation begins with an assessment of the patient’s clinical status, calculation of total blood volume, and estimation of blood loss.

Clinical Assessment

Total blood volume for an adult approximates 70 mL/kg, and thus a 50-kg woman’s calculated blood volume is 3500 mL. Of this volume, 15 percent can be lost by most patients with no changes in arterial pressure or heart rate. A 15-percent blood loss can be roughly calculated by multiplication of a patient’s weight in kilograms by 10. Thus, for a 50-kg woman, a 15-percent loss approximates 500 mL.

With losses of 15 to 30 percent (500 to 1000 mL for a 50-kg woman), tachycardia and narrowing of the pulse pressure are seen (Table 40-6). Peripheral vasoconstriction leads to pale, cool extremities and poor capillary refill. In unanesthetized patients,

there may be mild confusion or lethargy. In most women with normal preoperative hemoglobin levels, this amount of blood loss requires fluid volume replacement, but RBC transfusion typically is not required. Greater losses, however, lead to worsening perfusion, hypotension, and tachycardia. In these cases, blood transfusion in combination with fluid resuscitation typically is indicated (Murphy, 2001).

During surgery, blood collects in suction canisters and laparotomy sponges. Although calculations from these sources provide surgeons with an approximation, blood loss estimates typically are low, and inaccuracy increases as the length and extent of a procedure increases (Bose, 2006; Santoso, 2001). Additionally, a hematocrit may be measured to assess hemorrhage. However, hematocrit values typically lag true losses, and values may reflect only the degree of hemorrhage. For example, following a blood loss of 1000 mL, hematocrit levels typically fall only 3 volume percent in the first hour but usually show an 8 volume percent drop at 72 hours (Schwartz, 2006). Hemorrhage leads to global tissue hypoxia, anaerobic metabolism, and lactate production. Thus, elevated serum lactate levels can be a helpful marker. Blood gas analysis can also provide a rapid estimate of the serum base deficit. Hemorrhage severity can be predicted using the following stratification of these base deficits: 2 to –5 (mild hemorrhage), –6 to –14 (moderate hemorrhage), and –15 or less (severe hemorrhage). If patients continue to have dropping base deficits despite aggressive resuscitation, ongoing hemorrhage is a concern (Davis, 1988).

Fluid Resuscitation

If hypovolemia is identified, fluid resuscitation begins with crystalloid solutions. If hypotension and tachycardia are present, rapid replacement is warranted, and 1 or 2 liters, as indicated, may be infused over several minutes. Normal saline and lactated Ringer solutions are the two crystalloids used

TABLE 40-6. Clinical Findings Associated with Increasing Severity of Hemorrhage

Hemorrhage Class	Class I	Class II	Class III	Class IV
Blood loss				
Percentage	< 15	15–30	30–40	> 40
Volume (mL)	750	800–1500	1500–2000	> 2000
Blood pressure				
Systolic	Unchanged	Normal	Reduced	Very low
Diastolic	Unchanged	Raised	Reduced	Very low, unrecordable
Pulse (beats/min)	Slight tachycardia	100–120	(thready)	> 120 (thready)
Capillary refill	Normal	Slow (> 2 sec)	Slow (> 2 sec)	Undetectable
Respiratory rate	Normal	Normal	Tachypnea (> 20/min)	Tachypnea (> 20/min)
Urinary flow rate (mL/hr)	> 30	20–30	10–20	0–10
Extremities	Normal color	Pale	Pale	Pale and cold
Complexion	Normal	Pale	Pale	Ashen
Mental state	Alert	Anxious or aggressive	Anxious, aggressive, or drowsy	Drowsy, confused, or unconscious

commonly, and their composition is described in Chapter 42 (p. 908). For moderate hemorrhage, both perform equally well as fluid replacements (Healey, 1998).

Although crystalloids have an immediate effect to expand intravascular volume, a portion will extravasate into extracellular tissues. Thus, in the setting of hemorrhage, crystalloid volume is administered in a 3:1 ratio to blood lost (Moore, 2004). Clinically, urine output of 0.5 mL/kg/per hour or 30 mL or more per hour, heart rate less than 100 beats per minute, and systolic blood pressure greater than 90 mm Hg may be used as general indicators of volume improvement. If rapid crystalloid infusion fails to correct hypotension or tachycardia, then RBC transfusion usually is prudent.

In addition to or as an alternative to crystalloid solutions, colloids may be used for volume expansion. These fluids have higher molecular weights than crystalloids. As a result, a greater portion remains intravascular and is not lost to extracellular extravasation. Despite this perceived advantage, studies comparing survival rates when crystalloids or colloids are administered find no superiority with colloids but greater expense (Perel, 2013).

Intraoperative fluid management strategies broadly fall into categories of liberal (sometimes thought of as fixed volume), restrictive, or goal directed. Of these, evidence from colorectal and trauma surgery is now more supportive of restrictive management. Less bowel edema, quicker return of bowel function, and fewer pulmonary complications are all purported benefits (Chappell, 2008; Joshi, 2005). Restrictive strategies generally use colloid to replace blood loss in a 1:1 ratio, unless red cell transfusion is indicated. Crystalloids are then used to replace urine and insensible losses 1:1. In contrast, liberal strategies rely on large volumes of crystalloid. Last, goal directed therapy refers to using a monitoring device (such as an arterial line) and administering fluids to achieve a goal (such as maximizing stroke volume). Patients with severe comorbid conditions undergoing major procedures may benefit from this strategy (Chappell, 2008).

## ■ Red Blood Cell Replacement

### Clinical Assessment

The decision to administer RBCs is complex and must balance the risks of transfusion with needs for adequate tissue oxygenation. Assessment includes hemoglobin level, vital signs, patient age, risks for further blood loss, and underlying medical conditions, especially cardiac disease. These needs will vary depending on the clinical setting. Accordingly, no specific hemoglobin threshold dictates when RBCs are administered. Consensus guidelines suggest that in those without significant cardiac disease, transfusion to a hemoglobin level above 10 g/dL is rarely indicated (Carless, 2010). If hemoglobin levels acutely drop to 6 g/dL, transfusion almost always is required (Madjdpour, 2006). Hemoglobin levels between 6 and 10 g/dL are more problematic, and patient factors and risk for continued hemorrhage dictate therapy (American Society of Anesthesiologists, 2015). In one randomized study of 838 critically ill patients, one group of euvolemic patients received transfusion when their hemoglobin levels fell below 7 g/dL. These individuals

fared better than those transfused at an earlier threshold (hemoglobin below 10 g/dL), excepting those with significant cardiac disease (Hébert, 1999).

### Transfusion

When the possible need for transfusion is present, an order for a *type and screen* informs blood bank personnel that blood products may be required and initiates two tests to characterize a patient's RBCs. The first evaluation, termed *typing*, mixes commercially available standardized controls with a patient's blood sample to determine her ABO type and Rh phenotype. The second test, or *screen*, combines a patient's plasma sample with control RBCs that express clinically significant RBC antigens. If a patient has formed antibodies to any of these specific RBC surface antigens, then agglutination or hemolysis of the sample is seen. However, if blood is needed immediately and a full screen is not possible, then ABO type-specific blood or O-negative blood may be used. Typing and screening require approximately 45 minutes for completion and are valid for 3 days in patients who do receive transfusion. In those who are not transfused, the validity is considerably longer and typically is determined by individual blood banks. Alternatively, an order to *type and crossmatch* blood products alerts blood bank personnel to designate specific units of blood solely for one individual's use. These specific units are tested against the patient's for specific antigen reactions.

Previously, whole-blood transfusion was used commonly to provide RBCs, coagulation factors, and plasma proteins. This is largely has been replaced by component therapy. Packed RBCs are the primary product used for most clinical situations and are prepared by removing most of the supernatant plasma during centrifugation. One unit of packed RBCs contains the same red cell mass as 1 unit of whole blood at approximately half the volume and twice the hematocrit (70 to 80 percent). One unit of packed RBCs raises the hematocrit approximately 3 volume percent in an adult or increases the hemoglobin level of a 70-kg individual by 1 g/dL (Table 40-7) (Gorgas, 2004). With severe hemorrhage that is anticipated to require  $\geq 10$  RBC units, massive transfusion protocols that combine units of packed RBCs, platelets, and plasma in 1:1:1 ratios are effective (McDaniel, 2014).

### Complications

Despite numerous tests for compatibility, adverse reactions to blood products can develop. An acute or delayed hemolytic transfusion reaction, febrile nonhemolytic transfusion reaction, allergic reaction, infection, or associated lung injury are among these.

First, *acute hemolytic transfusion reaction* involves acute immune-mediated hemolysis usually from destruction of transfused RBCs by patient antibodies. This most commonly results from ABO incompatibility. Symptoms begin within minutes or hours of transfusion and may include chills, fever, urticaria, tachycardia, dyspnea, nausea and vomiting, hypotension, and chest and back pain. In addition, these reactions can lead to acute tubular necrosis or disseminated intravascular coagulopathy, and treatment is directed to these serious complications.

If acute hemolysis is suspected, transfusion is halted immediately. A sample of the patient's blood is sent with the remaining donor unit for evaluation in the blood bank. In patients

TABLE 40-7. Characteristics of Blood Components

Component	Volume, mL	Content	Clinical Response
PRBCs	180–200	RBCs	Increases Hb 1 g/dL and Hct 3%
Platelets			Increases platelet count:
Random-donor unit	50–70	$5.5 \times 10^{10}$ platelets	$5\text{--}10 \times 10^9/\text{L}$
Single-donor collection	200–400	$3.0 \times 10^{11}$ platelets	$> 10 \times 10^9/\text{L}$ within 1 hr and $> 7.5 \times 10^9/\text{L}$ within 24 hr posttransfusion
FFP	200–250	Coagulation factors, including fibrinogen, proteins C and S, antithrombin	Increases coagulation factors $\square$ 2%
Cryoprecipitate	10–15	Fibrinogen, factor VIII, vWF	Increases fibrinogen level 0.1 g/L

FFP = fresh-frozen plasma; Hct = hematocrit; Hb = hemoglobin; PRBCs = packed red blood cells; RBCs = red blood cells; vWF = von Willebrand factor.

with significant hemolysis, laboratory values will be altered. Specifically, serum haptoglobin levels will be lowered; serum lactate dehydrogenase and bilirubin levels will be increased; and serum and urine hemoglobin levels will be elevated. Serum creatinine and electrolyte levels and coagulation studies additionally are ordered. To prevent renal toxicity, diuresis is prompted with intravenous crystalloids and administration of furosemide or mannitol. Alkalinization of urine may prevent precipitation of hemoglobin within the renal tubules, and therefore, intravenous bicarbonate also may be given.

In contrast to acute hemolytic transfusion reaction, *delayed hemolytic transfusion* reactions may develop days or weeks later. Patients often lack acute symptoms, but lowered hemoglobin levels, fever, jaundice, and hemoglobinemia may be noted. Clinical intervention typically is not required in these cases.

*Febrile nonhemolytic transfusion reaction* is characterized by chills and a greater than 1°C rise in temperature and is the most common transfusion reaction. Blood transfusion typically is stopped to exclude a hemolytic reaction, and treatment is supportive. For patients with a previous history of febrile reaction, premedication with an antipyretic such as acetaminophen prior to transfusion is reasonable.

Last, an *allergic reaction* can follow an antibody-mediated response to donor plasma proteins. Urticaria alone may develop during transfusion and typically is not associated with serious sequelae. The transfusion does not need to be stopped, and treatment with an antihistamine, such as diphenhydramine (Benadryl) 50 mg orally or intramuscularly, usually suffices. Rarely, an anaphylactic reaction may complicate transfusion, and treatment follows that for classic anaphylaxis (Table 27-2, p. 596).

*Infectious complications* associated with packed RBC transfusion are uncommon. The risk for transmission of HIV and hepatitis B and C virus has diminished over the past decade, and bacterial contamination now stands as a greater infection risk. In addition, emerging infection concerns include transmission of West Nile virus, transfusion-transmitted virus (TTV), hepatitis G, Epstein-Barr virus, and Creutzfeldt-Jakob disease (Luban, 2005).

*Transfusion-related acute lung injury (TRALI)* is an infrequent but serious complication of blood component therapy

that is similar clinically to acute respiratory distress syndrome (ARDS). Symptoms develop within 6 hours of transfusion and may include extreme respiratory distress, frothy sputum, hypotension, fever, and tachycardia. Noncardiogenic pulmonary edema with diffuse bilateral pulmonary infiltrates on chest radiography is characteristic (Toy, 2005). Treatment of TRALI is supportive and focuses on oxygenation and blood pressure support (Silliman, 2005; Swanson, 2006).

■ Platelet Replacement

For patients with moderate hemorrhage, RBC transfusion typically is sufficient, but for patients with severe hemorrhage, platelet transfusion also may be indicated. Platelets may be acquired from a single individual during plateletpheresis and are termed *single-donor platelets*. Alternatively, platelets may be derived from random units of whole blood and are referred to as *random-donor platelets*.

Fewer platelets are harvested from a unit of whole blood compared with the amount removed during donor plateletpheresis. Specifically, a single-donor platelet dose contains at least  $3 \times 10^{11}$  platelets in 250 to 300 mL of plasma, and this approximates the dose from six random-donor platelet concentrates. Each random-donor platelet concentrate contain  $5.5 \times 10^{10}$  platelets suspended in approximately 50 mL of plasma. Each concentrate transfused should raise the platelet count by 5 to  $10 \times 10^9/\text{L}$ , and the usual therapeutic dose is one platelet concentrate per 10 kg of body weight. Five to six concentrates provide a typical adult dose. Donor plasma must be compatible with recipient erythrocytes because a few RBCs are invariably transfused along with the platelets. Only platelets from D-negative donors should be given to D-negative recipients.

Surgical patients with bleeding usually require platelet transfusion if the platelet count is less than  $50 \times 10^9/\text{L}$  and rarely require therapy if it is greater than  $100 \times 10^9/\text{L}$  (American Society of Anesthesiologists, 2015). With counts between 50 and  $100 \times 10^9/\text{L}$ , the decision to provide platelet transfusion is based on a patient’s risk for additional significant bleeding.

## ■ Factor Replacement

Fresh-frozen plasma (FFP) is one option for factor replacement and is prepared from whole blood or by plasmapheresis. It is stored frozen, and approximately 30 minutes are required for it to thaw. One unit contains all coagulation factors, including 2 to 5 mg/mL of fibrinogen in 250 mL of volume. Recommended FFP dosing is 15 mL/kg. Fresh-frozen plasma is used commonly as first-line hemostatic therapy in massive hemorrhage because it replaces multiple coagulation factors. It is considered in a bleeding woman with a fibrinogen level below 1.0 g/L or with abnormal prothrombin and partial thromboplastin times.

Another option, cryoprecipitate, is prepared from fresh-frozen plasma and contains fibrinogen, factor VIII, von Willebrand factor, factor XIII, and fibronectin. Cryoprecipitate was developed and used originally for treatment of hemophilia A and von Willebrand disease. However, specific factor concentrates are now available for these disorders, and thus, the clinical indications for cryoprecipitate are limited. Fresh-frozen plasma provides all coagulation factors and is favored in severe hemorrhage over cryoprecipitate. However, cryoprecipitate is an excellent source of fibrinogen and may be indicated if fibrinogen levels persist below 1.0 g/L despite administration of fresh-frozen plasma, such as in disseminated intravascular coagulopathy (DIC). The dose of cryoprecipitate is usually 2 mL/kg of body weight, and each unit contains approximately 15 mL volume. One unit typically increases the fibrinogen level by 10 mg/dL (Erber, 2006).

## ADJACENT ORGAN SURGICAL INJURY

### ■ Lower Urinary Tract

Sound anatomic knowledge, adequate operating exposure, meticulous technique, and surgical experience are essential to avoid surrounding organ injury during pelvic surgery. The lower gastrointestinal and urinary tracts are closely related to the female reproductive organs, and disease processes, anatomic distortion, and adverse operating conditions can increase their injury risk.

Iatrogenic damage to the lower urinary tract is common, and up to 75 percent of ureter or bladder injuries sustained during gynecologic surgery occur during hysterectomy (Walters, 2007). Most injuries have no antecedent risk factors, but high-risk elements are ideally sought preoperatively. These include compromised visibility from large pelvic masses, hemorrhage, pregnancy, obesity, inadequate incision, suboptimal retraction, and poor lighting. Additionally, scarring or anatomic distortion from cervical and broad ligament leiomyomas, malignancy, endometriosis, pelvic organ prolapse, and prior pelvic infection, surgery, or radiation are risks (Brandes, 2004; Francis, 2002).

Patients who sustain surgical injury to the bladder or ureter suffer significantly greater morbidity. In one case-control study, women with injury to the lower urinary tract during abdominal hysterectomy had significantly greater operative time, estimated blood loss, blood transfusion rates, febrile morbidity, and postoperative stay length than their respective controls (Carley, 2002).

### ■ Bladder Injury

Cystotomy is common and complicates approximately 0.3 to 11 per 1000 benign gynecologic surgeries, especially urogyneco-

logic procedures and hysterectomy (Gilmour, 2006; Mathevet, 2001). In sum, depending on the procedure, the bladder may be at greater risk during: (1) initial abdominal entry when incising the anterior parietal peritoneum, (2) dissection within the space of Retzius, (3) vaginal epithelium dissection during anterior colporrhaphy, or (4) hysterectomy when dissecting in the vesicocervical space, entering the anterior vagina, or suturing the vaginal cuff. With hysterectomy, bladder injury traditionally has been associated more often with the vaginal hysterectomy, but some data suggest that laparoscopic procedures pose the greatest risk (Francis, 2002; Frankman, 2010; Harris, 1997). Preventatively, clear identification of the bladder, gentle retraction, meticulous surgical technique, sharp dissection, and maintenance of a drained bladder intraoperatively are standard principles.

Cystotomy is suspected if a Foley bulb, bloody urine, or urine leaking into the operative field is seen. During laparoscopy, the Foley bag may also distend with gas from the pneumoperitoneum. For diagnosis, retrograde instillation of sterile milk through a catheter confirms injury and delineates its full extent. This is superior to methylene blue and indigo carmine dyes, as infant formula does not stain surrounding tissues and is readily available. In addition, small defects can be difficult to identify and repair if the tissues surrounding the defect become dye stained. Prior to repair, cystoscopy is indicated for any bladder base injury to assess ureteral patency. In addition, the full extent of injury can be defined, and the bladder can be evaluated for additional injuries or intravesical sutures. If bladder distension cannot be maintained during cystoscopy or if the patient is not in dorsal lithotomy, the ureteral orifices can also be evaluated grossly through the cystotomy site. If the cystotomy is small, suprapubic teloscopy, which is described in Chapter 45, is also an option, or the cystotomy can be extended to allow evaluation.

Repair during the primary surgery is preferred and lowers risks of later vesicovaginal fistula formation. Principles of repair include injury delineation; wide mobilization of surrounding tissues; tension-free, multilayered, watertight closure; and adequate postoperative bladder drainage (Utrie, 1998). Suture identified in the bladder is cut, as persistence can lead to cystitis, stone formation, or both. Needle-stick and subcentimeter lacerations can be managed conservatively. Larger defects may be closed in two or three layers with a running stitch using 3-0 absorbable or delayed-absorbable suture (Fig. 40-32). The first layer inverts the mucosa into the bladder, and subsequent layers reapproximate the bladder muscularis and serosa. In the area of the trigone, the ureters are typically stented first, and the repair may be performed with interrupted sutures to avoid ureteral kinking (Popert, 2004). Postoperatively, continuous bladder drainage is continued for 7 to 10 days (Utrie, 1998). Evidence is conflicting regarding the use of prophylactic antibiotics for the expected duration of catheterization, and thus remains at the provider's discretion.

### ■ Urethral Injury

The female urethra is rarely injured during gynecologic surgery, but cystoscopy, urethral diverticulum repairs, antiincontinence operations, and possibly anterior colporrhaphy are at-risk procedures. Repair is completed with 3-0 or 4-0 absorbable suture in an interrupted fashion and in multiple layers, if possible. Similar to cystotomy, a Foley catheter is typically placed

**FIGURE 40-32** Cystotomy repair. The primary layer inverts the bladder mucosa with running or interrupted sutures of 3-0 delayed-absorbable or absorbable suture. Second and possibly a third layer approximate the bladder muscularis to reinforce the incision closure. (Reproduced with permission from Cunningham FG, Vandorsten JP, Gilstrap LC: *Operative Obstetrics*, 2nd ed. New York: McGraw-Hill; 2002.)

postoperatively for 7 to 10 days, with antibiotic prophylaxis provided at the surgeon's discretion (Francis, 2002).

### ■ Ureteral Injury

This is uncommon in benign gynecologic surgery, and the incidence approximates 0.2 to 7.3 per 1000 surgeries. For hysterectomy, the highest rate of ureteral injury is linked with laparoscopic hysterectomy, and the lowest with vaginal hysterectomy (Gilmour, 2006). Other associated procedures include operations for pelvic organ prolapse, incontinence, malignancy, or endometriosis (Patel, 2009; Utrie, 1998).

The ureter is 25 to 30 cm long, and its anatomy is described in Chapter 38 (p. 816). Gynecologic ureteral injury typically occurs in the distal third and includes transection, ligation, kinking, and crushing (Brandes, 2004; Utrie, 1998). Trauma to the outer sheath can also disrupt ureteral blood supply. Of these, the ureter more often is transected or kinked, and each accounts for approximately 40 percent of injuries. During hysterectomy, the most common trauma site is at the level of the uterine artery and accounts for 80 percent of injuries (Ibeanu, 2009). The ureter is also vulnerable near the pelvic brim during adnexectomy and at the distal uterosacral ligaments. Mechanisms of injury include clamping or suturing with the ureter poorly visualized. Thermal insult or devascularization may lead to stricture or leak.

Injury prevention measures include preoperative risk evaluation and if indicated, intravenous pyelography (IVP) or computed tomography (CT). Ureteral stenting assists with intraoperative recognition but does not necessarily prevent injury. As with bladder injury, the best prevention is sound intraoperative technique and direct visualization of the peristaltic ureter. Also, the ureter may be felt to “snap” if palpated and stretched along its course on the broad ligament's medial leaf. However, vessels, adipose tissue, and peritoneal folds can mimic this.

### Diagnosis

Iatrogenic injury ideally is diagnosed early, as immediate repair is associated with improved outcomes and less patient morbidity (Neuman, 1991; Sakellariou, 2002). Damage may be seen directly or identified during intraoperative cystoscopy. Intravenous administration of indigo carmine or methylene blue can aid cystoscopic evaluation, with observation of blue-stained urine from the ureteral orifices. This is described fully in Section 45-1 of the atlas (p. 1057). However, use of the latter may increase given current indigo carmine shortages. With these dyes, blue effluent is usually seen in 5 to 10 minutes. Failure to see dye after 30 to 40 minutes mandates further evaluation with either IVP or ureteral catheterization. Unfortunately, normal-appearing findings at cystoscopy do not guarantee ureteral integrity, as nonobstructive, partially obstructive, or late ureteral injuries may be unrecognized.

Diagnosing injury shortly after surgery is challenging, as patient symptoms may be attributable to other causes. Thus, thorough patient evaluation and a high clinical suspicion are crucial. Renal damage may begin 24 hours after obstruction and can be irreversible in 1 to 6 weeks (Walter, 2002). Symptoms usually develop about 48 hours after surgery, and fever, abdominal pain, flank pain, and watery discharge may be among these. Findings can include leukocytosis, elevated blood urea nitrogen level, and ileus. Prolonged skin or vaginal drainage suggests a urinary leak, and high creatinine levels in these fluids are diagnostic of urine. Serum creatinine measurement may or may not be helpful. In one retrospective study of 187 patients, a 24-hour postoperative change  $< 0.3$  mg/dL from preoperative levels had a specificity of 98 percent and negative predictive value of 100 percent in confirming bilateral ureteral patency. Because an increase  $> 0.2$  mg/dL has been associated with obstruction, the authors recommended repeating a creatinine measurement and renal imaging for persistent elevation above this level (Walter, 2002). With elevated serum creatinine levels, calculation of the fractional excretion of sodium (FENa) or assessment of urine sodium levels may also help clarify the renal injury source as prerenal, intrarenal, or postrenal, as described in Chapter 42 (p. 916).

Sonography, CT, or magnetic resonance (MR) imaging will help identify hydronephrosis, urinoma, or abscess. Lack of contrast in the distal ureter on delayed CT images confirms total obstruction (Armenakas, 1999). IVP can also help localize injury. However, IV contrast can be nephrotoxic, and thus CT with contrast may be a less than ideal choice for those with already elevated creatinine levels. Retrograde pyelography with fluoroscopic guidance and attempted retrograde ureteral stent placement can be considered in cases where suspicion remains high, and IVP is contraindicated or has equivocal findings. All of these imaging modalities can be used to diagnose injury in both the early and late postoperative periods.

### Treatment

The best repair method depends on the location, extent, time from surgery, and mechanism of injury. Expert assistance from a urogynecologist, gynecologic oncologist, or urologist may be prudent. The ureter can be repaired by stenting, reimplantation, or end-to-end reanastomosis. For low-grade sheath injuries from clamping or suturing, removal of the insult and stent placement

may be sufficient. For incomplete obstruction or injury identified postoperatively, stenting alone can resolve injuries in up to 80 percent of cases. For more extensive injury, either reimplantation or reanastomosis is performed (Utrie, 1998).

Reimplantation, namely, *ureteroneocystotomy*, is preferred for injuries within 6 cm of the bladder. Uncommonly with this, if the ureter is short, a psoas hitch, that is, mobilizing the bladder and attaching it to the psoas muscle tendon, may be necessary to bridge the gap and relieve tension on the repair. An alternative to the psoas hitch is a Boari flap. In this procedure, the bladder ipsilateral to the injury is mobilized, and a pedicle of anterior bladder wall is fashioned into a tube to bridge to the ureter.

For injuries greater than 7 cm from the bladder, ureteral reanastomosis, that is, *ureteroureterostomy*, is preferred. Rarely, transureteroureterostomy is needed for a more proximal injury or one in which the bladder cannot be mobilized. With this procedure, the injured ureter is tunneled across and connected to the healthy ureter.

Little evidence guides the decision for reoperation in the early postoperative period. Intraoperatively, tissues are in their best condition, and the likelihood for successful repair is great. However, most iatrogenic injuries are recognized after a delay and tend to be complex (Brandes, 2004). In general, reexploration within the first few days appears to be well tolerated, leads to good outcomes, and is not technically difficult (Preston, 2000; Stanhope, 1991). Firm recommendations regarding reoperation beyond this early postoperative period are lacking, but reexploration 2 to 3 weeks after initial surgery is difficult due to inflammation, fibrosis, adhesions, hematoma, and distorted anatomy (Brandes, 2004).

For delayed diagnoses, retrograde stenting is unsuccessful in 50 to 95 percent of cases and recommended only for certain low-grade injuries (Brandes, 2004). Occasionally, an antegrade stent can be placed percutaneously, which will avoid the need for laparotomy, provided there is no ureteral leak or stricture. More extensive damage, such as complete transection, cannot be easily stented and is more appropriately repaired by definitive surgery. When diagnosis is significantly delayed, urinary diversion with a percutaneous nephrostomy (PCN) and later repair is preferred. For some low-grade lesions, such as ligation with absorbable suture, proximal urinary diversion by PCN may allow spontaneous healing without further surgery. In addition, PCN diversion may be used as a temporizing measure for patients temporarily unfit for surgery (Preston, 2000).

## ■ Universal Cystoscopy

Lower urinary tract injury is poorly detected by direct visualization, and rates range from 7 to 12 percent for ureteral trauma and approximate 35 percent for bladder damage (Vakili, 2005). To increase early diagnosis, universal intraoperative cystoscopy has been advocated, and detection rates are near 96 percent (Ibeanu, 2009; Vakili, 2005; Visco, 2001). Proponents argue that the procedure is cost-effective, carries minimal risk, and prevents both postoperative morbidity and liability. Opponents cite overall low rates of injury, imperfect detection rates, increased costs, credentialing problems, and a need for training

(Patel, 2009). Using a decision analysis model, one study estimated that routine cystoscopy was cost-effective when ureteral injury rates were above 1.5 percent for abdominal hysterectomy and 2 percent for vaginal and laparoscopically assisted hysterectomy (Visco, 2001).

Cystoscopy is currently indicated for urogynecologic procedures, but there are no strict recommendations for other routine gynecologic procedures, including hysterectomy (American College of Obstetricians and Gynecologists, 2013; Patel, 2009). At present, the decision remains at the surgeon's discretion. Some have elected selective cystoscopy, or cystoscopy restricted to patients with risk factors or when intraoperative events make injury more likely.

## ■ Bowel Injury

Injury to the bowel infrequently complicates gynecologic surgery, and rates are < 1 percent (Harris, 1997; Makinen, 2001). A traumatic breach during dissection is the most common, particularly if the bowel wall is abnormally fixed by adhesions (Mathevet, 2001; Maxwell, 2004). Additional risks include reduced organ mobility from Crohn disease or diverticulitis, laparoscopic trocar or Veress needle insertion, diathermy use, and anterior abdominal wall entry during laparotomy.

For the gynecologic surgeon, prevention and injury recognition help avoid serious postoperative sequelae. Strict adherence to surgical principles with sharp dissection for adhesions, gentle tissue handling, adequate exposure, light retraction, and sparing use of diathermy near hollow organs is key. Entering through prior abdominal incisions, dissection proceeds methodically in layers. Alternatively, a separate incision or extension of the existing one to an area that has not been previously opened can be considered. After any extensive pelvic dissection, the bowel is systematically inspected along its entire length to detect serosal defects and unrecognized perforation. At suspected sites, the bowel is scrutinized for mucosal eversion and content leakage. Evaluation is gentle to avoid additional damage.

Management of enterotomy depends on the site and size of injury, surgeon skill, degree of blood supply compromise, and time of recognition. With the small intestines, serosal defects may be either left alone or reinforced with small-gauge absorbable suture (Maxwell, 2004). Short small-intestine enterotomies may be repaired in layers using fine absorbable suture. During repair, rubber-shod clamps are placed across the intestinal lumen on either side of the wound to prevent content spill. To avoid narrowing of the bowel lumen, the suture line should lie transverse to the normal axis of the intestine (Stanton, 1987). Postoperative antibiotics are typically not required.

Large-bowel injuries increase the risk of fecal peritonitis, sepsis, and poor wound healing. Serosal defects and small lacerations may be managed similarly to those of the small intestine. For more extensive injuries or fecal soiling that may require resection, diversion, or complicated repair, consultation with a gynecologic oncologist or colorectal surgeon is often indicated. Broad-spectrum antibiotic prophylaxis is provided for the next 24 hours in these cases. In general, for both small and large intestinal injuries, early feeding is acceptable and not associated with repair site complications (Fanning, 2001).

Rectal injury occurs most commonly during vaginal surgery, especially during posterior colpotomy or posterior colporrhaphy. These injuries are typically midline, extraperitoneal, and less than 2 cm. Postmenopausal status, prior posterior colporrhaphy, or pathology that obliterates the cul-de-sac or limits organ mobility increases injury risk (Hoffman, 1999; Mathevet, 2001). Prevention centers on careful examination under anesthesia to detect cul-de-sac fullness or uterine immobility, sharp dissection with the aid of a guiding rectal finger, and vasoconstricting agent use to reduce obscuring operative field bleeding.

Rectal injury may be extraperitoneal or intraperitoneal, and rectal examination will typically detect the injury and delineate its borders. Minor intraperitoneal injuries with minimal or no contamination can be repaired primarily in layers as described previously. Larger injuries with gross soiling may require expert consultation. Broad-spectrum antibiotic prophylaxis is provided for the next 24 hours in these cases.

Low extraperitoneal rectal injury during vaginal surgery in a healthy patient can be repaired primarily and rarely requires a diverting colostomy or abdominal repair. Repair is accomplished transvaginally using two to three layers of fine absorbable suture. The peritoneum may be used as an additional layer for injuries near the peritoneal reflection. During repair, a digit in the rectum exposes the defect, tissues surrounding the defect are mobilized, the site is copiously irrigated, and appropriate antibiotic prophylaxis is provided for 24 hours (Hoffman, 1999). In general, small (< 2 cm) rectal injuries recognized and repaired at the time of vaginal surgery tend to heal well without complications or fistula formation (Mathevet, 2001). Diet can be advanced as tolerated, but a stool softener is recommended once the patient is taking solid foods (Hoffman, 1999).

HYSTEROSCOPIC COMPLICATIONS . . . . . 905

REFERENCES . . . . . 905

Minimally invasive surgery (MIS) is characteristically performed through a small incision or no incision, and visualization is provided by endoscopes. Both laparoscopy and hysteroscopy are considered in this category. With laparoscopy, small abdominal incisions provide access to introduce an endoscope and surgical instruments into the abdomen. To increase operative space, a pneumoperitoneum is created. As such, laparoscopy provides a minimally invasive option for women undergoing intraabdominal gynecologic surgery. And, with its technology improvements, almost all major intraabdominal gynecologic procedures can now be performed with MIS.

Hysteroscopy uses an endoscope and uterine cavity distending medium to provide an internal view of the endometrial cavity. This tool permits both the diagnosis and operative treatment of intrauterine pathology.

FACTORS IN CHOOSING LAPAROSCOPY

In theory, laparoscopic surgery differs from laparotomy only by its mode of access to the operative field. However, inherent qualities can make some surgical steps more difficult. These include indirect palpation of tissue, counterintuitive motion, a finite number of ports for abdominal access, restricted movement, and replacement of normal 3-dimensional (3-D) vision by 2-dimensional (2-D) video images. In appropriately selected

patients, the trade-off is a faster recovery, improved cosmesis, less postoperative pain, diminished adhesion formation, and at least equivalent surgical results (Ellström, 1998; Falcone, 1999; Lundorff, 1991; Mais, 1996; Nieboer, 2009). The decision to perform laparoscopy is based on several parameters. Primary among these are patient factors, availability of appropriate instrumentation, and surgeon skill.

■ Patient Factors

Laparoscopy using a pneumoperitoneum is contraindicated in very few clinical conditions, but these include acute glaucoma, retinal detachment, increased intracranial pressure, and some types of ventriculoperitoneal shunts. Thus, laparoscopy is appropriate for many, although modifications are warranted for certain clinical situations. Several are discussed subsequently.

Prior Surgeries

With laparoscopy, adhesive disease increases the risk of visceral and vascular injury during abdominal entry. Adhesions are also associated with higher conversion rates to laparotomy because long and tedious adhesiolysis may be completed by some surgeons more quickly with open surgical dissection techniques. Thus, during preoperative physical examination, a surgeon notes the location of previous surgical scars and ascertains the risk of possible intraabdominal adhesive disease (Table 41-1). Similarly, a history of endometriosis, pelvic inflammatory disease, or radiation treatment may predispose to adhesions. In addition, abdominal wall hernias or hernia repairs and any reparative mesh are identified and avoided during trocar insertion. If abnormal findings are found during this preoperative evaluation, plans for an alternative entry site are considered (p. 894).

Laparoscopic Physiology

Compared with traditional open laparotomy, laparoscopy produces several distinct cardiovascular and pulmonary physiologic changes. These result mainly from: (1) absorption across the peritoneum and into circulation of carbon dioxide (CO<sub>2</sub>) used for insufflation, (2) increased intraabdominal pressure created by the pneumoperitoneum, and (3) head-down Trendelenburg positioning. These changes are typically tolerated by those in generally good health but may be less so in those with cardiovascular or pulmonary compromise. Thus for patient safety, surgeons should be familiar with these physiologic alterations.

During laparoscopy, a pneumoperitoneum is created, in most cases with CO<sub>2</sub>. Absorption of this gas across the peritoneum can lead to systemic CO<sub>2</sub> accumulation and hypercarbia. In turn, hypercarbia produces sympathetic stimulation that raises systemic and pulmonary vascular resistance and increases blood pressure. If

**TABLE 41-1.** Frequency of Umbilical Adhesions Found at Laparoscopy in Women with and without Prior Abdominal Surgery

	Sample Size/ Prior Surgery	No Prior Surgery	Prior Laparoscopy	Prior Low Transverse Incision	Prior Vertical Midline Incision (VML)
Agarwala (2005)	918/ surgery	—	16%	22%	62%
Brill (1995)	360/ laparotomy	—	—	27%	55% with VML below umbilicus 67% with VML above umbilicus
Audebert (2000)	814/laparoscopy	0.68%	1.6%	19.8%	51.7%
Sepilian (2007)	151/ laparoscopy	—	21%	—	—

hypercarbia is not cleared by compensatory ventilation, acidemia develops. From this, direct myocardial contractility depression and decreased cardiac output can follow (Ho, 1995; Reynolds, 2003; Sharma, 1996). Hypercarbia can also lead to tachycardia and arrhythmia. Less commonly, bradycardia can stem from vagal stimulation. This may follow pelvic organ manipulation, cervical stretching during uterine manipulator placement, or peritoneal stretching during pneumoperitoneum creation.

Insufflation of any gas elevates intraabdominal pressure. This increased pressure decreases flow in the inferior vena cava, causes blood pooling in the legs, and raises venous resistance. In sum, venous return to the heart is decreased, and thereby cardiac output is lowered. Increased intraabdominal pressure can also directly lower splanchnic blood flow.

Intraoperative pulmonary function may be challenged during laparoscopy. First, the diaphragm is displaced upward by intraabdominal pressure from the pneumoperitoneum. This can be accentuated by organs also being pushed cephalad against the diaphragm during Trendelenburg positioning. Moreover, insufflation pressures stiffen the diaphragm and chest wall. Together, these alterations lead to higher required airway pressures to achieve adequate mechanical ventilation. Also, as the diaphragm moves up, lung volume and functional residual capacity are diminished, which in turn reduces the reserve volume for oxygenation. Moreover, this lung volume decline favors a tendency for the lung to collapse, leading to atelectasis. This can create ventilation and perfusion mismatching and an increased alveolar-arterial oxygen gradient. In sum, all of these factors favor poorer oxygenation.

Urinary output commonly is diminished during laparoscopy. This may result from the lowered cardiac output, decreased splanchnic blood flow, direct renal parenchymal compression, or the release of renin, aldosterone, or antidiuretic hormone. Together, these lessen renal blood flow, reduce glomerular filtration rate, and diminish urine output. Importantly, renal function returns to normal following pneumoperitoneum decompression (Demyttenaere, 2007).

### Health Conditions

Several coexistent medical disorders are particularly relevant when considering laparoscopy. These include cardiac and pulmonary disease, intestinal obstruction, hemoperitoneum and hemodynamic instability, and pregnancy. As just described, in those with severe cardiac or pulmonary disease, elevated

intraabdominal pressures and steep Trendelenburg positioning may not be tolerated, as they decrease venous return and pulmonary reserve. Unfortunately, with laparoscopy, these techniques are often required for adequate visualization and instrument manipulation. In addition, CO<sub>2</sub> is used to distend the abdomen during laparoscopy. As noted, it is absorbed across the peritoneum into circulation, and hypercarbia may follow. Accordingly, in those with pulmonary or cardiovascular limitations, lowering intraabdominal pressures and flattening the degree of Trendelenburg are advantageous.

For a clinically stable patient with hemoperitoneum, laparoscopy is not contraindicated. Thus, ruptured ectopic pregnancies or a ruptured bleeding ovarian cyst may be treated via MIS. Although an unstable patient was previously considered a contraindication to laparoscopic surgery, many skilled surgeons feel they can safely and quickly enter the abdomen laparoscopically. That said, the lowered venous return and cardiac output must be factored into the decision to select laparoscopy for such patients.

Concurrent intestinal obstruction and its associated bowel distention may increase risks for bowel injury during abdominal entry. In these situations, open entry to gain initial abdominal access may be beneficial (p. 893). However, ischemic bowel may be poorly served by pneumoperitoneum-related diminished splanchnic blood flow.

### Obesity

In the past, obesity had been considered a relative contraindication for gynecologic laparoscopy. First, adequate ventilation may be difficult. In general, obese patients display reduced lung compliance that is proportional to their body mass index (BMI). Moreover, abdominal wall adiposity lowers abdominal wall compliance, which in turn elevates the pneumoperitoneum pressure required for surgery. Also, fattier omentum and mesenteric fat add to the bulk forced against the diaphragm in Trendelenburg position. Other limitations include a thick subcutaneous layer that encumbers laparoscopic instrument motion. It can also hinder abdominal entry, and trocar tunneling during insertion is common. Just patient girth relative to surgeon arm length may limit instrument manipulation.

As possible fixes, placement of an extra ancillary port for adequate manipulation of omentum and bowel out of the operative field can be helpful. Coordination with the anesthesia team to find a comfortable degree of Trendelenburg for both successful operative manipulations and adequate ventilation is

essential. Longer “bariatric” instruments can overcome many length limitations.

As a result, with a skilled surgeon, obese patients may actually benefit from MIS. In studies, healthy obese patients experience less pain, quicker recovery, and fewer postoperative complications such as wound infections and postoperative ileus after laparoscopy compared with laparotomy (Eltabbakh, 1999, 2000; Scribner, 2002). That said, certain operative parameters may be adversely affected in obese patients undergoing laparoscopy compared with normal-weight patients. Higher conversion rates to laparotomy, longer operating times, and longer hospitalizations have been noted (Chopin, 2009; Heinberg, 2004; Thomas, 2006). However, this has not been found by all investigators, and overall outcomes may be superior to an open abdominal approach (Camanni, 2010; O’Hanlan, 2003; Shah, 2015).

### Pregnancy

Nonurgent conditions identified during pregnancy may often be delayed and addressed postpartum. However, laparoscopy may be performed during any trimester. Thus, familiarity with the superimposed physiologic changes of pregnancy can improve maternal and fetal safety (O’Rourke, 2006; Reynolds, 2003).

Perioperatively, a wedge can be placed beneath the mother’s back on the right to create a left-lateral tilt and displace the uterus. For second- or third-trimester pregnancies, this can minimize the decreased venous return that results from pneumoperitoneum and from an enlarged uterus compressing pelvic veins and inferior vena cava. Also, rates of venous thromboembolism (VTE) are increased during pregnancy due to gestational hypercoagulability. Placing sequential compression stockings can help lower this risk.

Intraoperatively, steps involve avoiding placement of intra-cervical uterine manipulators, limiting insufflation pressures to 10 to 15 mm Hg, maintaining maternal end-tidal CO<sub>2</sub> levels between 32 and 34 mm Hg, moving trocar placement appropriately cephalad to avoid puncture of the gravid uterus, and limiting uterine manipulation (Pearl, 2011). Of note, the routine use of perioperative prophylactic tocolytics is not recommended in these cases. However, pre- and postoperative fetal heart rate assessment and contraction monitoring for more advanced gestations are typically implemented.

### Underlying Pathology

For adnexal masses, myomectomy, and supracervical hysterectomy, operative planning must address appropriate specimen removal. As discussed later, options include endoscopic bags, morcellation, colpotomy, or minilaparotomy incisions (p. 896). To guide selection, specimen size and the risks for occult malignancy and abdominal tumor seeding are assessed. Importantly, for masses that are known or strongly suspected to be malignant, laparoscopy is avoided if patient outcome could be compromised by specimen rupture, seeding, or morcellation or by incomplete resection or staging.

### ■ Facility Factors

In addition to patient factors, a surgeon must also consider environmental factors. The availability of appropriate anesthesia

care, surgical nursing, support staff, and proper instrumentation influences procedure selection. Advanced operative laparoscopy is a coordinated team effort that requires multiple simultaneous activities, overseen and directed by the surgeon.

## PATIENT PREPARATION

### ■ Prophylaxis

Randomized clinical trials have demonstrated that prophylactic antibiotics significantly reduce postoperative infectious morbidity rates following abdominal or vaginal hysterectomy. During laparoscopic hysterectomy, the vagina is similarly opened. Thus, preoperative antibiotics are recommended, and selection can be aided by American College of Obstetricians and Gynecologists guidelines (2014) found in Table 39-6 (p. 835). Antibiotics are generally given at the induction of anesthesia. For other types of laparoscopic procedures, data do not support antibiotic prophylaxis for clean surgical cases, that is, those that do not enter the vagina, bowel, or urinary tract (Chap. 3, p. 75).

For thromboprophylaxis, the same principles used for other abdominal surgeries are applied to laparoscopic cases (American College of Obstetricians and Gynecologists, 2013). Specific to laparoscopy, pneumoperitoneum pressure may decrease venous return from the lower extremities (Caprini, 1994; Ido, 1995). Thus, for those in whom VTE prophylaxis is planned, preventative measures are administered early and prior to anesthesia induction. A complete list of VTE prophylaxis and guidelines for its use can be found in Table 39-8 (p. 836).

### ■ Preoperative Bowel Preparation

The benefits of routine mechanical bowel preparation are debatable, and thus plans for bowel preparation are individualized (Chap. 39, p. 834). If the risk of bowel injury and stool spillage is increased because of pelvic adhesions or advanced endometriosis, then bowel preparation may limit fecal contamination at the surgical site. Moreover, if proctosigmoidoscopy is planned, an appropriate bowel preparation allows adequate visualization.

### ■ Anesthesia Selection

Laparoscopy can be completed using general or regional anesthesia. In most cases, general anesthesia with endotracheal intubation is selected to provide: (1) adequate patient comfort, (2) controlled ventilation to correct hypercarbia, (3) muscle relaxation, (4) airway protection from regurgitation due to increased intraabdominal pressures, and (5) orogastric tube placement. Some studies suggest that injection of local anesthesia at port sites may diminish postoperative pain (Einarsson, 2004).

### ■ Consent

Laparoscopy itself is usually associated with little associated morbidity. Of major complications, the most common is organ injury caused by puncture or by electrosurgical tools and is described later. If these occur or if surgery is hindered by bleeding or adhesions, conversion to laparotomy may be necessary.

Overall, this risk of conversion is low, and logically, rates decline as surgeon experience accrues.

Minor complications of laparoscopy occur more frequently. These may include wound infection or hematoma, subcutaneous emphysema from CO<sub>2</sub> infiltration, vulvar edema, and postoperative peritoneal irritation from retained intraabdominal CO<sub>2</sub>. Irritation stems from conversion of CO<sub>2</sub> to carbonic acid, which can be a direct irritant.

### Puncture Injuries

Because sharp tools are used during laparoscopic entry, vessels and abdominal organs may be punctured. Risk factors have been identified and include intraabdominal adhesions, insufficient gastric emptying, full bladder, insufficient pneumoperitoneum, poor muscle relaxation, thin patient habitus, and unsuitable angle or force of tool insertion. As discussed later, several authors advocate an open entry method as a means to help lower puncture injury rates (Catarci, 2001; Hasson, 2000; Long, 2008).

### Organ Injury

The organ most frequently injured during laparoscopy is bowel, and rates of 0.6 and 1.6 per 1000 cases are reported (Chapron, 1999; Harkki-Siren, 1997). Women with previous laparotomy have a higher incidence of abdominal adhesions and are at greatest risk for this complication.

Unfortunately, bowel injury sustained during laparoscopy is often missed intraoperatively. For example, in an observational study by Chandler and coworkers (2001), nearly 50 percent of both small- and large-bowel injuries were unrecognized for 24 hours or longer. Typically, these patients present with fever, abdominal pain, nausea, and vomiting within 48 hours of surgery (Li, 1997).

In laparoscopic cases, decompression of the stomach with an orogastric tube prior to obtaining laparoscopic access can lower the stomach puncture risk. Moreover, in those with suspected abdominal adhesive disease, several preventative steps can help avoid bowel injury. These include: (1) introduction of a micro-laparoscope to scout for adhesions, (2) preoperative sonography using the visceral slide test to exclude bowel adhered to the anterior abdominal wall, and (3) an alternative site for primary trocar entry, for example in the left hypochondrium (Palmer point), rather than at the umbilicus.

Bladder puncture is uncommon with laparoscopy. Bladder decompression prior to and during surgery and careful placement of secondary trocars under direct visualization will prevent many injuries. However, with increased rates of laparoscopic hysterectomy, rates of bladder and ureteral damage have concurrently risen. These occur at the same surgical steps associated with urinary tract injury during abdominal hysterectomy.

### Vascular or Nerve Injury

Major vascular injury associated with laparoscopy is rare and typically results during primary trocar insertion. Puncture rates are cited as 0.09 to 5 per 1000 cases, and characteristically, the terminal aorta, inferior vena cava, and iliac vessels, particularly the right common iliac artery, may be injured (Bergqvist, 1987; Catarci, 2001; Nordestgaard, 1995). Rarely, air embolism from gas insufflation following vessel puncture may occur.

Although infrequent, a significant number of deaths result from large vessel injury (Baadsgaard, 1989; Munro, 2002). Prevention may include use of the open entry technique or awareness of the angle and force of trocar entry. Despite these steps, if a large vessel is punctured, the wounding instrument is not removed because it may act as a vascular plug. Moreover, this tool is held stable to avoid extending the laceration. In most cases, laparotomy, direct manual pressure on the vessel, steps for hemodynamic resuscitation, and notification of a vascular surgeon should follow expeditiously.

In contrast, if the inferior epigastric artery is injured, several simple techniques can control hemorrhage. First, bipolar electrosurgical coagulation of the bleeding site may suffice in many cases. If this fails to control bleeding, a 14F Foley catheter can be threaded through the cannula of the wounding trocar or through the defect created by this trocar. The Foley balloon then is inflated and pulled upward to create direct pressure against the posterior surface of the anterior abdominal wall. At the skin surface, a Kelly clamp is placed perpendicular across the Foley catheter and parallel to the skin to hold the balloon firmly in place. The balloon and catheter can be removed approximately 12 hours later. Alternatively, sutures can be placed that traverse the skin, abdominal wall, and peritoneum; arch under the bleeding vessel; and exit the abdomen to directly ligate the vessel (Fig. 41-1). Similarly, the Carter-Thomason tool can be used to ligate both ends of this vessel.

**FIGURE 41-1** Ligation of lacerated inferior epigastric artery.

**A.** Suture with an attached straight Keith needle is driven through the anterior abdominal wall lateral and caudal to the bleeding artery. This is performed using direct laparoscopic visualization to avoid organ injury. A laparoscopic needle driver regrasps the needle.

**B.** The needle is then driven upward and through the anterior abdominal wall on the other side of the vessel. The suture loop is tied. This process is repeated cephalad to the bleeding vessel. This places sutures proximal and distal to the site of vessel laceration.

Nerve injury can follow in patients placed for extended periods in the dorsal lithotomy position with arms abducted. From this, injury to the common peroneal, femoral, lateral femoral cutaneous, obturator, sciatic, and ulnar nerves and to the brachial plexus is possible (Barnett, 2007). Specific injuries and prevention are described in Chapter 40 (p. 843). Attention paid to patient position and surgery duration prevent many of these complications.

### Thermal Injury

Accidental burns may follow direct instrument contact or stray electric current. Fortunately, the risk of this complication is low. Prevention steps include keeping instrument tips within the visual field when electric current is applied, strict instrument maintenance to identify insulation defects, employment of bipolar coagulation or harmonic energy for hemostasis when feasible, and use of lower-voltage (cutting) current whenever possible to reduce the applied voltage (Wu, 2000).

### Incisional Hernia

Incisional hernias are a potential long-term consequence of laparoscopy. The incidence approximates 1 percent but may rise in the future with increased use of larger trocars for operative laparoscopy and single-port umbilical techniques. Approximately one fourth of hernias are umbilical, and the remainder develop at secondary trocar sites (Lajer, 1997).

A major risk for incisional hernia is use of large trocars measuring  $\geq 10$  mm in diameter or port sites from which larger specimens are extracted. Preventatively, smaller trocar use when possible and fascial closure of larger trocars wound sites is advocated. The use of trocars with conical rather than pyramidal tips can also lower this incidence (Leibl, 1999). Finally, peritoneal tissue is ideally not drawn into the superficial layers of the wound when removing the cannulas (Boughey, 2003; Montz, 1994).

### Trocar-site Metastasis

Rates of trocar-site cancer metastasis are low, and this complicates the clinical course of approximately 1 percent of patients in whom gynecologic malignancy is identified. Similarly, port-site seeding of other tissues such as endometriosis has been reported. Metastases are more frequent with ovarian cancer than other malignancies, and higher rates are seen with more advanced disease (Abu-Rustum, 2004; Childers, 1994; Zivanovic, 2008). Although most trocar-site metastases are associated with advanced stages of disease, metastasis has followed surgery for tumors of low malignant potential. As a result, the steps of laparoscopy itself have been evaluated as a risk for tumor spread to the trocar sites (Ramirez, 2004). Currently, no evidence-based consensus addresses prevention of this complication. Thus, the careful tissue extraction techniques described on page 896 are encouraged.

## OPERATING ROOM ORGANIZATION

### Operating equipment

In laparoscopy, tool movement is limited compared with laparotomy, secondary to instrument angle restrictions and fixed ports (Berguer, 2001). Thus, room organization is essential, and equipment is positioned *before* the procedure begins. Also preoperatively, all instruments are checked and tested to confirm proper functioning.

Although equipment positioning may vary based on surgeon preference, the following is suggested to optimize efficiency and safety. The operating room table is centered in the room, and surgical lights lie directly above the operative field. Prior to surgery, this bed is checked to ensure it moves up and down and into steep Trendelenburg position. Obese patients may require a larger bariatric operating table.

Video monitors may be fixed to the ceiling with articulating arms or may be placed on portable stands. One monitor may suffice for simple procedures, however, two monitors provide easy viewing by the surgeon and assistant. When operating in the pelvis, the monitor is placed directly in front of the surgeon, and the surgeon, forearm-instrument axis, and video monitor are aligned in a straight line. Thus, placement of the video monitor for most gynecologic surgeries is near the patient's upper thigh (Fig. 41-2). For best surgeon ergonomics, monitor height is 10 to 20 degrees below eye level to prevent neck strain (van Det, 2009). Also, surgeons stand an appropriate distance and height relative to the operating table such that their arms

**FIGURE 41-2** Operating room arrangement for laparoscopy.

are slightly abducted, their shoulders are inwardly rotated, and their elbows are extended from 90 to 120 degrees. This positioning can minimize surgeon fatigue. The scrub technician and Mayo stand generally are positioned on the side of the primary surgeon near the patient's leg. Here, instruments can be easily passed to both surgeons. The Mayo stand is organized with frequently used handheld instruments.

A dedicated cabinet or "tower" houses the laparoscopic light source, gas insufflator, and image capture equipment. The tower is positioned on the side opposite the primary surgeon such that he or she has an unobstructed view of equipment display panels. All insufflation tubing, camera, and light cords ideally exit the operating field from the same direction and connect to the equipment tower. Similarly, electrosurgical equipment and pedals are organized so that all these cords are aligned in one direction to reach a separate cart that houses these electrosurgical units. Pedals are oriented appropriately for the primary surgeon to comfortably reach without adjusting his body or moving his eyes from the monitor.

### ■ Patient Positioning

This is another essential component of safe laparoscopy. Following anesthesia induction, a patient is placed in low dorsal lithotomy position with the legs in booted support stirrups (see Fig. 41-2). To aid proper leg positioning, the stirrup brackets, which holster the stirrups, are attached to the table at the level of the patient hips. To prevent femoral nerve injury, the hips are positioned without sharp flexion or marked abduction or external hip rotation. The knees are not flexed more than 90 degrees and are appropriately positioned and padded to avoid common peroneal nerve compression. To avert slipping when in steep Trendelenburg position and to minimize lower back pressure, a patient can be placed directly on an antiskid material such as egg-crate or gel pad. With these, patient skin directly contacts the padding (Klauschie, 2010; Lamvu, 2004). If uterine manipulation is needed, the buttocks are placed slightly past the edge of the table.

Patient arms are tucked to the side in military position. This allows improved patient access and prevents upper extremity hyperextension, which can result in brachial plexus injury. The arms may be tucked using an extended draw sheet, which is placed under the gel pad. This relationship limits arm slippage, which can generate pressure against the brachial plexus. Even in obese patients, the use of antiskid material and arm tucking is useful in preventing slippage for long periods in steep Trendelenburg position (Klauschie, 2010). The arms are padded to avert compression of the ulnar and median nerves. Fingertips are facing the thighs, well-padded, and positioned away from the moving foot of the bed to prevent unintentional amputation. During arm positioning, finger oxygen monitors and intravenous access should not be dislodged.

Shoulder braces are padded brackets that are placed on the cephalic side of the operating room bed and arch around to the

patient's acromion. Their goal is to brace the shoulder and prevent the head from slipping off the bed when in Trendelenburg position. If shoulder braces are required, we recommend tucking the arms in addition to using well-padded braces. However, due to the risk of nerve injury, the use of shoulder braces in general should be limited. Specifically, brachial plexus injury complicates 0.16 percent of gynecologic laparoscopic procedures. When shoulder braces are used, compression over the acromion may apply pressure that stretches the plexus. Moreover, lateral compression by braces may compress the humerus against the plexus. Both predispose to brachial plexus injury (Romanowski, 1993).

## LAPAROSCOPIC INSTRUMENTS

### ■ Instrument Anatomy

Successful laparoscopic surgery relies on the use of appropriate surgical instruments. Most surgeons have designated preferences for certain types of graspers, dissectors, and cutting instruments. Many of these have been adapted and modified for laparoscopic surgery and undergo frequent updates. Moreover, new designs further aid retraction and dissection, thereby increasing the number of procedures that can be performed laparoscopically.

The components of a laparoscopic instrument include the hand grip, shaft, jaw, and tip (Fig. 41-3). In general, an instrument tip's diameter is concordant with its shaft diameter, and standard sizes fit through 5-mm or 10-mm diameter cannulas. Additionally, 3-mm, 8-mm, and 15-mm instrument diameters are available for many tips. The tip defines instrument function. Jaws may be double action or single action. With a single-action jaw, one tip is fixed, lies in the same axis as the shaft, and offers greater stability during the action performed. Double-action jaws have tips that move synchronously, and this jaw offers a wider angle in which to perform its function. Some jaws are now modified by a compression feature that allows full-length scissor blades to secure the tissue in the tip crux and then cut tissue with greater stability and precision.

Important instrument qualities are comfort and ease of use, which stem primarily from the hand grip shape, the instrument length, and its locking capability. Most laparoscopic instruments have a standard 33-cm length. Due to the popularity of bariatric MIS, extended instruments are now available for procedures in obese patients. Specifically, long Veress needles

**FIGURE 41-3** Parts of a typical laparoscopic instrument.

and trocars and longer instrument shaft lengths offer improved manipulation through a thickened pannus. Although permitting better access, these longer instruments are often more difficult to manipulate due to altered operating angles caused by the extended length.

In the hand grip, a locking feature allows a surgeon to hold tissue without maintaining constant pressure against the grip. This decreases hand fatigue. The ability to rotate an instrument tip 360 degrees is now preferred. This versatility allows access to additional anatomic spaces and decreases the need for uncomfortable surgeon hand or arm rotation.

### ■ Disposable versus Reusable

Many laparoscopic instruments are available in both reusable and disposable forms, each having its own advantages. The main advantage to reusable instruments is lowered expense. Analyses demonstrate that disposable instruments add significant cost compared with reusable ones (Campbell, 2003; Morrison, 2004). The main advantage to disposable instruments is the consistent tool sharpness and avoidance of lost instrument parts. For example, dull scissors may lead to longer operating times and ineffectual surgical technique. Corson and associates (1989) showed that reusable trocars, although sharpened at regular intervals, still required twice the force for entry compared with disposable trocars. As a compromise, modified trocar systems combine the strength of these two features. Namely, the cannula is reusable, whereas a disposable inner trocar offers a consistently sharper tip.

### ■ Manipulators

#### Atraumatic Manipulators

During laparoscopic surgery, abdominopelvic organs may be elevated, retracted, or placed on tension (Fig. 41-4). Most current instrument designs have incorporated safety considerations to

minimize organ trauma yet allow effective manipulation. Of these, the blunt probe has an end that is modified to decrease the perforation risk to retracted tissues. It is used for exploration and retraction and is a preferred tool during diagnostic laparoscopy. Most blunt probes are stainless steel and are conductive of electric current. However, disposable probes constructed of nonconductive materials are available.

Graspers are divided into two main categories, atraumatic and those with toothed or serrated tips. Atraumatic graspers are used for exploration, gentle traction, and delicate tissue handling. The 5-mm diameter is a popular size, although 3-mm and 10-mm sizes are available. Most of these graspers have a double-action jaw, and the hand grip is typically nonlocking. Their gradually tapering curved tip permits the surgeon to define and separate tissue planes and is generally preferred for blunt dissection.

The Maryland clamp is an example of a curved blunt tip used for dissection and grasping. It compares to the pean, hemostat, or munion, which are used in open surgery. Additionally, it can double as a needle driver if needed. Although technically considered atraumatic, this clamp may crush delicate tissues such as the fallopian tube or bowel.

The alligator clamp is a blunt grasper with a long, wide tip that handles delicate tissues with minimal crush-injury risk. It is useful for manipulating bowel, larger vessels, or reproductive organs or for exploration of vascular compartments that may be easily punctured or lacerated. However, its ability to retract tissues under tension is limited due to its atraumatic characteristics.

The Babcock clamp is another atraumatic tip that handles delicate tissues with minimal crushing. Its surgical role is similar to that in open techniques. However, as with the alligator clamp, its ability to retract or grasp during applied tension is poor due to slippage.

Ideally, all of these clamps are included in a general laparoscopic surgical tray for most laparoscopic procedures. Figure 41-4 shows additional tips with similar characteristics. As seen, some tips have window openings and are described as fenestrated. These are useful for tissue elevation or retraction or for passing sutures during vessel ligation.

#### Traumatic Graspers

Graspers with tips that are serrated or toothed are used in procedures that involve resection and tissue approximation (Fig. 41-5). Generally, such tissues are placed on tension, and a strong hold is required. In addition, a locking hand grip is typically preferred to keep grasped tissues secured. Most of these instruments have double-action jaws to allow a wide tissue purchase. In situations in which greater grip and tension strength is required, however, a tip with a single-action jaw and locking hand grip may be preferred.

Toothed graspers have teeth at their tip's end. These are superior for tissue manipulation but function poorly as graspers for sutures or needles. One example is the

**FIGURE 41-4** Laparoscopic atraumatic graspers. (Reproduced with permission from Stryker Endoscopy.)

**Traumatic graspers****A. Serrated****B. Cobra****C. Biopsy forceps****Scissors****A. Hook****B. Curved****C. Straight**

**FIGURE 41-5** Laparoscopic traumatic graspers (left) and scissors (right). (Reproduced with permission from Stryker Endoscopy.)

laparoscopic tenaculum. Single-tooth and double-tooth tenaculums are both available and effectively hold and retract dense, heavy tissue. The single-tooth tenaculum usually has a double-action jaw, whereas the double-tooth tenaculum is available with either a single- or double-action jaw. Both usually offer a locking hand grip. A tenaculum is traumatic and thus is generally used only on tissue to be resected or repaired. One common use is to grasp and remove tissue during morcellation.

The cobra grasper is a toothed instrument with a double-action jaw. It has short teeth on each side and is excellent for tissue retraction due to its strong grip strength. It is considered a traumatic grasper and is not used on delicate tissues.

Some of the toothed instruments are designed with less traumatic teeth and are selected when less tissue crushing is desired. For example, ovarian biopsy forceps provide adequate grasp with minimal tissue crushing. An appropriate setting might be ovarian cyst resection and subsequent ovarian repair. An Allis grasper has blunter teeth for grasping and holding tissue during resection. However, it provides less gripping strength than the cobra.

Serrated graspers are considered traumatic but are less damaging than toothed graspers. They offer a secure grip with minimal tissue damage and generally are used in repairs or tissue approximation. Because of their variety, a surgeon should be familiar with their grips and tissue effects to select the one that best fits the planned procedure. Serrated graspers may be fenestrated or nonfenestrated, may offer a locking hand grip, and may have single-action or double-action jaws.

A corkscrew tip probe is frequently used for marked retraction of more solid masses such as leiomyomas. It offers superior grip and strength but is limited by the trauma created as it is screwed into the tissue to be held. Additionally, surgeons are

mindful of the tip location when advancing it, as the downward force required to spiral the corkscrew tip may inadvertently perforate adjacent tissues. Despite this risk, this tool can be invaluable when manipulating solid, bulky leiomyomas or uteri.

Newer, small, 2-mm and 3-mm accessory manipulators have a trocar built around the instrument shaft. These can be placed percutaneously to augment surgical manipulation yet leave only a tiny residual abdominal wall scar. Of the two available designs, one is fully disposable and the other is reusable.

**Uterine Manipulators**

These devices were originally designed to offer manipulation of the uterus to create tension, expand operating space, or improve access to specific parts of the pelvis. The Hulka and the Sargis uterine manipulators are reusable stainless steel instruments that contain the following: a stiff blunt tip for insertion into the endocervical canal, a toothed tip that affixes to the cervical lip for stabilization, and a handle for vaginal placement (Fig. 41-6).

For these manipulators, the cervix should be patent to allow entry into the lower uterine cavity.

Uterine manipulators have become increasingly versatile and offer additional functions. The Cohen cannula manipulator has

**FIGURE 41-6** **A.** Hulka uterine manipulator. **B.** A balloon-type uterine manipulator. The deflated balloon tip is inserted into the endometrial cavity. The balloon is inflated to hold the stiff manipulator in place.

**FIGURE 41-7** Cohen cannula. This device is used in conjunction with a separate tenaculum. The tenaculum is placed horizontally on the anterior cervical lip. **A.** The narrow cephalad tip of the cannula fits into the endocervical canal. The conical head abuts the external cervical os and limits insertion into the endometrial cavity. **B.** The caudad portion contains a crossbar into which the ratcheted handle of the cervical tenaculum fits.

a hard-rubber conical tip with a patent cannula for dye injection into the uterus, such as with chromotubation (Fig. 41-7). For placement, a single-tooth tenaculum is placed on the anterior cervical lip. The manipulator's conical tip wedges firmly against the cervix and thereby minimizes retrograde dye egress back through the os. The distal end of the Cohen manipulator then articulates with the crossbar that extends between the tenaculum's finger rings. Although commonly used, its range of motion is hindered by its straight shaft. Thus, the ability to dramatically flex a uterus anteriorly or posteriorly may be limited. The Rubin cannula manipulator is similar, with the same disadvantages. Greater flexion may be offered by the Hayden and Valtchev uterine manipulators. These have tip options, either conical or longer blunt intrauterine probes, which attach to a wristed joint at the distal end of the instrument shaft. This joint permits improved anteflexion and retroflexion. All of the manipulators just described affix to the cervical lip for stability. Thus, the risk of cervical trauma, although usually minimal, is disadvantageous.

Disposable uterine manipulators such as the Harris-Kronner Uterine Manipulator Injector (HUMI) or the Zinnati Uterine Manipulator Injector (ZUMI) also have a cannula for introducing dye to assess uterine and tubal patency (see Fig. 41-6). Rather than affixing to the cervix, an intracavitary balloon at the manipulator's uterine end is expanded

similar to a Foley balloon once the manipulator is placed. This prevents the device from dislodging. Due to the length and firmness of the material used, these devices are advantageous for oversized uteri.

At times, a vaginal sponge stick is a practical manipulator for elevation and identification of pelvic structures. This may be selected by an advanced surgeon who wishes to eliminate the manipulator or chosen in cases in which the uterine fundus is absent. Last, newer manipulator designs have emerged to complement laparoscopic hysterectomy and are illustrated in Chapter 44 (p. 1034).

## ■ Scissors

These are integral to most laparoscopic procedures and are available in reusable and disposable models. Scissor tips vary depending on the type of dissection or resection needed (see Fig. 41-5). Scissors preferred for dissection commonly have a curved, somewhat blunted, tip that tapers similar to Metzenbaum scissors. This shape allows a surgeon to use standard techniques for tissue separation and resection with minimal trauma to the surrounding tissues (Chap. 40, p. 849). These curved blades may be smooth or slightly serrated. A serrated edge tends to hold tissue and minimize slippage prior to cutting. A smooth blade is preferred for sharp dissection, such as with adhesiolysis.

Straight scissors also come with smooth or serrated blades. They are used more for cutting and are less desired for dissection. Many straight scissors are designed with a single-action jaw, and some surgeons feel this offers better control.

Hooked scissors have a rounded, blunt tip and hooked blades. When initially approximated, the blades close around the tissue without cutting and then cut from the tip toward the hinge. This offers a controlled transection and is useful for partial transection of tissues. Moreover, its design allows a surgeon to confirm optimum placement before cutting. This type of scissors is commonly used for suture cutting.

## ■ Suction and Irrigation Devices

Successful laparoscopy requires a clear visual field. Thus, an effective and efficient suction and irrigation system is integral to procedures that require fluid or smoke removal (Fig. 41-8). Older systems were extremely slow and thereby prolonged operative time or failed to adequately clear a field with brisk bleeding. Newer motorized systems provide faster irrigation and evacuation, and motors usually have two speeds, which can be manually adjusted. The suction tips are available in 3-, 5-, and 10-mm diameters, thereby tailoring instrument capability

**FIGURE 41-8** Suction-irrigator. Inset: Irrigator tip.

to the clinical setting. The latest generation systems also permit additional instruments to be placed through the hollow suction tip for concurrent monopolar electrosurgery. Newer models also have attachments to fluid management systems to monitor infused and extracted volumes.

When using a suction irrigation system, all of the suction holes are ideally submerged in the fluid to be removed. This avoids inadvertent insufflation gas removal, which then collapses the operative field. Additionally, the probe may cause suction damage to viscera, especially delicate structures such as tubal fimbria and bowel epiploica. To avoid damage, suction is used when there is a safe distance from vulnerable structures and with the assistance of another instrument to move these structures away from the suction tip.

## ■ Tissue extraction

### Morcellators

These tools cut excised tissues into smaller pieces, which can then be extracted. Available morcellators use either thin cutting blades or pulsatile kinetic energy. Bladed morcellators consist of a hollow large-bore shaft that contains razorlike blades to shave tissues into thin strips. One of these, the Storz Rotocut, is reusable but houses disposable stainless steel blades that are efficient in cutting through dense masses. Although bulkier and heavier than others, it is among the fastest and most effective. The Lina Morcellator has a built-in battery pack, is slower but more ergonomic, and is disposable. The MOREsolution morcellator offers a 2-cm-diameter blade, which is currently the largest and may be helpful for large masses. Another device, the Gynecare Morcellex, is currently unavailable due to a voluntary suspension of worldwide sales. Each mechanical morcellator has its advantages, and familiarity with these allows selection of the most suitable instrument for a given tissue.

Another morcellator, the PKS PlasmaSORD Bipolar Morcellator, is bladeless. Instead, it uses plasma kinetic energy, which is a form of pulsatile bipolar energy. It works well for hysterectomy and myomectomy specimen morcellation. However, it produces a large smoke plume, which reduces visibility and thereby increases operative time. Accordingly, cases with larger specimens may have extended operative times with this instrument compared with bladed instruments. However, no randomized studies support the superiority of one morcellator over another.

### Endoscopic Retrieval Pouches

Endoscopic bags for tissue retrieval vary in size and vinyl strength. Some are free-standing sacs designed for manual introduction into the abdominal cavity through cannulas and are preferred for larger and denser masses. Once loaded, the sac is simply lifted through an appropriately sized abdominal wall incision.

Other types are manufactured as pouches attached to support arms at the end of a laparoscopic shaft to create a self-contained unit. As shown in Figure 41-9, the support arms open the sac. Once the mass is bagged, the arms and pouch are retracted and removed through the cannula. The cannula is then removed, bringing the bag to the incision where it is extracted.

**FIGURE 41-9** Endoscopic sac during progressing stages of deployment.

With either sac type, if a specimen does not compress or cannot be drained, the incision may require enlargement.

### Self-retaining Retractors

Designed to complement MIS, nonmetal self-retaining retractors consist of two equal-sized plastic rings connected by a cylindrical plastic sheath. One ring collapses into a canoe shape that can be threaded through the incision and into the abdomen. Once inside the abdomen, it springs again into its circular form. The second ring remains exteriorized. Between these rings, the plastic sheath spans the thickness of the abdominal wall. To hold the retractor in place, a surgeon everts the exterior ring multiple times until the plastic sheath is tight against the skin and subcutaneous layers. This form creates 360-degree retraction. These disposable retractors maximize incision size because of their circular shape and by eliminating thick metal retractor blades within the wound opening. Brands include the Alexis and Mobius retractors, and available sizes range from extra small to extra large. In some studies, these retractors provide wound protection and lower wound infection rates (Horiuchi, 2007; Reid, 2010).

For MIS cases, these devices offer several functions. First, they retract minilaparotomy incisions to aid large specimen removal. Moreover, certain procedures, such as laparoscopic myomectomy, can also be completed through these incisions (Section 44-8, p. 1025). Second, concern about tissue dissemination has prompted development of retrieval bags that are coupled with these self-retaining retractors. For this, the retrieval bag is initially placed into the abdomen. The bag containing the excised specimen is then brought to the surface and is fanned open outside and around the minilaparotomy incision. The self-retaining circular retractor is then placed into the bag's interior and simultaneously opened within the incision. This creates a closed environment in which the specimen can be sharply morcellated

manually with scissor or knife. Long-term data on safety and efficacy of this enclosed approach are not yet available.

### ■ **Energy Systems in Minimally Invasive Surgery**

Understanding principles and correct use of electrosurgical instruments is essential to safe laparoscopy. The same principles of electrosurgery in open surgery apply to laparoscopy (Chap. 40, p. 857). However, special considerations are necessary in a closed, minimally invasive environment. For example, the entire length of an instrument may extend past a surgeon's visual field, thus risking unintended electrosurgical burns. Fortunately, advances in instrumentation mitigate many of the physical constraints inherent to MIS.

#### **Monopolar Electrosurgery**

Monopolar instruments may be useful for tissue cutting, dissection, vaporization, and desiccation. Delivery of this energy is usually through scissors or needle point tip. Of these, monopolar scissors coagulate tissues within its jaws prior to incision. This is typically used for thin tissues and small vessels. In addition, closed blade tips can act simultaneously to cut tissue and achieve hemostasis. Monopolar energy delivered through a needle point tip is used for functions ranging from ovarian drilling to development of peritoneal planes during hydrodissection.

Unintended thermal injuries form the main risk with this energy type. With monopolar instruments, insulation failures, direct coupling, or capacitive coupling may each result in unintended, potentially serious electrosurgical burns. First, insulation failures are breaches in an instrument's insulation. This break provides an alternate pathway for current flow. When a monopolar instrument is activated, electric current may travel from the electrode through the insulation breach and discharge to any tissue in contact with this breach. This current flow may cause thermal damage to surrounding visceral and vascular structures without the surgeon ever being aware. Accordingly, before electrosurgical tools are used, systematic inspection should look for insulation cracks throughout their length, for aberrant or loose cord connections, and for assurance that a grounding pad is correctly placed on the patient.

Another monopolar effect is direct coupling, which occurs when an activated electrode contacts another metal object—either intentionally or unintentionally. This technique is frequently used during open surgery to achieve hemostasis of small vessels, such as when the electrosurgical blade tip is touched to a hemostat around a small vessel. However, in laparoscopy, unintentional direct coupling may occur when a metal instrument or object (such as a metal cannula) contacts an active monopolar instrument and thus provides an alternate and undesired current flow to surrounding viscera.

Another hazard with monopolar instruments is the risk of capacitive coupling. A capacitor is defined as two conductors separated by a nonconducting medium. During laparoscopy, an “inadvertent capacitor” can be created when a conductive active electrode (e.g., monopolar scissors) is surrounded by a nonconducting medium (insulation around the scissors) and is placed through another conductive medium (a metal cannula).

This capacitor creates an electrostatic field between the two conductors. When current is activated through one of the conductors, this in turn will induce a current in the second conductor. Capacitive coupling occurs when this system discharges current into other surrounding conductive material. In the case of an all-metal cannula, current can be dissipated throughout the abdominal wall. With hybrid cannula systems, in which a metal cannula is anchored by a plastic sleeve or collar, the capacitor that is created has no place to discharge. Stray current can then exit to adjacent tissue that is in contact with the metal portion of the cannula, thereby damaging nearby vascular or visceral structures. This risk can be reduced by avoiding hybrid cannulas and by selecting bipolar instruments. Moreover, the addition of an integrated shield on the electrode shaft of some monopolar instruments, which monitors for stray current, can prevent this complication.

#### **Bipolar Electrosurgery**

Bipolar energy is mainly used in laparoscopy for tissue desiccation and hemostasis. Many types of bipolar forceps are available for various uses (Fig. 41-10). The 3-mm paddle forceps are used for tubal coagulation during sterilization procedures. Flat-tip forceps desiccate larger vessels and tissue pedicles. Fine-tip, “microbipolar” forceps aid hemostasis near or on vulnerable structures such as the ureter, bowel, and fallopian tubes. Burns are less of a concern with bipolar energy because the currents used are typically lower. Currents, for the most part, also stay confined between the two closely approximated electrodes.

For hemostasis, energy is delivered to denature collagen and elastin in vessel walls and thus seal the vessel. During this process, the bipolar device uniformly compresses the tissue and provides internal monitoring to adjust energy delivery. When evaluating these devices, important considerations include thermal spread, ability to provide desired tissue effects, consistency of results, time required to achieve results, plume produced, and maximum vessel diameter that can be securely sealed (Lamberton, 2008; Newcomb, 2009).

Currently used advanced bipolar devices such as the LigaSure, Plasmakinetic (PK) Gyrus, and Enseal are multifunctional tools that can be used for both tissue desiccation and dissection. Each of these devices employs a low voltage to deliver energy to tissue and carry impedance feedback to the electrosurgical unit to locally regulate thermal tissue effects. These adaptations allow for reduced collateral injury from thermal spread, an improved tissue seal, less plume production, and diminished tissue sticking. Whereas the LigaSure delivers a continuous bipolar radiofrequency waveform, the PK delivers energy in a pulsed waveform. The Enseal system has a temperature-controlled feedback mechanism at its tip, which “locally” modulates energy delivery.

#### **Ultrasonic Energy**

The Harmonic scalpel, also known as an ultrasonic scalpel, uses ultrasonic energy, which is converted to mechanical energy at the active blade. Seen as the lower blade in Figure 41-10F, the active blade vibrates to deliver high-frequency ultrasonically generated frictional force, whereas the inactive upper arm holds tissues in apposition against the active blade. Alternatively, the active blade may be used alone. Either cutting or coagulating effects

**FIGURE 41-10** A-C. Laparoscopic monopolar tools. D and E. Bipolar tools. (Reproduced with permission from Stryker Endoscopy.) F. Laparoscopic Harmonic scalpel. (Reproduced with permission from Ethicon.)

can be achieved, and a balance between these two is created by controlling several factors: power levels, tissue tension, blade sharpness, and application time. Higher power level, greater tissue tension, and a sharp blade will lead to cutting. Lower power, decreased tissue tension, and a blunt blade will create slower cutting and greater hemostasis. Limitations of the Harmonic scalpel include limited ability to coagulate vessels larger than 5 mm and the requirement for the surgeon to balance the factors listed above (Bubenik, 2005; Lamberton, 2008).

### Laser Energy

Lasers were widely used in laparoscopy in the 1980 through 1990s and include the CO<sub>2</sub>, argon, KTP (potassium titanyl phosphate), the Nd-YAG (neodymium:yttrium-aluminum-garnet) lasers. These are generally used through an operative channel on the laparoscope or via a separate port. These lasers can cut, coagulate, and vaporize tissues and are employed for lysis of adhesions, tubal surgery, and endometriosis fulguration or resection. In the hands of skilled surgeons, lasers offer precision and control with minimal effect on surrounding tissue. Thus, a laser is able to work near or over sensitive structures such as bowel, bladder, ureters, and vessels. Disadvantages are its learning curve, expense, lack of portability, and smoke production.

### Laparoscopic Leiomyoma Ablation

Myolysis describes leiomyoma puncture by energy-based probes that incite tissue necrosis and subsequent shrinkage. Of these,

bipolar energy and cryoablation have been used with varying degrees of success and thus have not gained widespread popularity with gynecologic surgeons.

The Acesa procedure instead uses monopolar energy combined with ultrasound guidance through laparoscopic instrumentation (Fig. 41-11). For this, a special ultrasound probe is placed during laparoscopy through a 10-mm lower abdominal port and directly contacts the uterus to localize myomas. This allows better myoma visualization by permitting views from several angles. A thick radio-frequency needle is inserted through a separate abdominal wall puncture site and then punctures each tumor serially under sonographic guidance. Once the needle is inserted into a myoma, a deployable electrode array housed within the needle is expanded within the tumor to deliver the destructive energy. Real-time laparoscopic and sonographic surveillance confirm that the electrodes remain within the mass. The outpatient Acesa procedure is typically performed in the operating suite with general anesthesia. Postoperative oral narcotics or nonsteroidal antiinflammatory drugs (NSAIDs) provide sufficient postoperative analgesia for most women (Galen, 2013).

With this approach, early evidence shows improved patient symptoms and a reintervention rate of 11 percent at 3 years (Berman, 2014). Other long-term data regarding outcomes are lacking, but current ongoing studies will add information.

## ■ Laparoscopic Optics

### Laparoscope Construction

Successful MIS requires excellent visual acuity provided by high-intensity light sources and laparoscopes with focused lenses. The modern-day rod lens system contains a series of lenses that are the diameter of the laparoscope cylinder. At the periphery of each lens are small scalloped grooves that permit light-carrying fibers to reach the endoscope end. This provides a well-lit image and minimal distortion. Uniquely, the space between lenses is filled with small, tightly packed glass rods. These rods fit exactly, which make them self-aligning to require no other structural support. Appropriate curvature and coatings to the rod ends and optimal glass type permit superb image quality—even with cylinder tubes measuring only 1 mm in diameter.

In addition to its main cylinder, a laparoscope contains an eyepiece, to which a camera can be affixed. The camera usually is an attachable springed plastic cap that can be clipped onto the eyepiece. The main cylinder also has an adapter on its exterior to attach the light-source cable. Laparoscope diameters range from 0.8 to 15 mm. In general, greater diameters offer superior optics but require a larger incision. This trade-off typically dictates laparoscope selection for a given procedure.

Differing from traditional straight-shaft endoscopes, operative laparoscopes have an eyepiece that branches off at a 45- or 90-degree angle from the straight operative shaft. This permits tools to be placed through the operative shaft, which are then seen by the endoscope. Instruments used are generally longer than instruments typically placed in accessory ports. Most instruments are 45 cm, which is considered bariatric length. Lasers are also frequently placed through the operative shaft and can allow for precise energy application.

### Angles of View

Similar to hysteroscopes and cystoscopes, laparoscopes vary in their angle of view. The most common are 0-, 30-, and 45-degree laparoscopes, and each offers a different view of the peritoneal cavity. A 0-degree endoscope offers a forward view and is preferred by most gynecologists. This laparoscope is used in most diagnostic procedures or simple surgeries involving biopsies, simple adhesiolysis, and excision of small masses or organs such as an ovary, fallopian tube, or appendix.

In contrast, angled-view endoscopes provide a lateral and larger field of view. These are useful during cases with more complicated pathology such as dense adhesions that obstruct the traditional forward view. For example, during difficult dissection in which multiple instruments are in action, an angled-view laparoscope offers a panoramic view at a distance. This provides a surgical field in which all instruments in use can be seen.

Angled-view endoscopes also allow a lateral view of pathology. For example, if an angled-view laparoscope is placed at one pelvic sidewall and is directed to the opposite sidewall, a surgeon is provided a large lateral visual operating space. Moreover, angled views are valuable along the sides of organs. With a large myomatous uterus, it may be challenging to identify the uterine artery and cardinal ligaments. An angled-view laparoscope permits a surgeon to “slide” along the lateral border of the uterus to

reach these. Similar benefits are gained when operating in small spaces such as in the deep pelvis or space of Retzius.

Clearly, the 0-degree laparoscope is easier to master. However, the advantages for advanced procedures warrant the time needed to operate using an oblique view. Importantly, during orienting with an angled-view laparoscope, when the field of view is directed downward, the light cord attached to the endoscope is positioned up. Conversely, if the view is upward, the light cord will be positioned down. To maintain orientation when changing viewing polarity, the camera buttons remain facing upward, while the light cord rotates in relation to it.

### Flexible Laparoscopes

The tips of these special laparoscopes are able to bend to a greater degree. As such, they can travel into smaller spaces or around corners. Whereas traditional fiberoptic laparoscopes contain fiber bundles that run the length of the endoscope, these flexible endoscopes house a camera chip at their end to transmit images as electrical signals. This results in less image distortion. This concept has also provided the option of dual camera technology, which uses two camera chips at the tip. As benefits, optics and opportunities for more advanced procedures are improved. Some newer models afford a 3-D view and are used for single-port laparoscopic approaches, in which there is traditionally less maneuverability (p. 894).

### Lighting

Light is transmitted through the laparoscope from a light source via the light cable. Originally, endoscopic light was provided by incandescent lightbulbs, which produced little light and transmitted increased heat. Currently, a cold light source is used and provides a more intense beam. The term “cold light” describes the dissipation of heat along the length of the cable. Cold light sources use halogen, xenon, or halide modalities for the lamps. Despite heat dissipation, the light source still creates a hot tip at the distal laparoscope end. Thus, prolonged exposure of the tip to surgical drapes, patient skin, or internal organs is avoided. Thermal injuries have resulted from such exposure.

Light cables connect the light source to the endoscope. Of these, two types are available: fiberoptic and fluid filled. The fiberoptic cable contains multiple coaxial quartz fibers that transmit light with relatively little heat conduction. However, these cables suffer from fiber breakage and need to be serviced often. In contrast, fluid-filled cables transmit more light and conduct more heat than the fiber cables. They are stiffer and have decreased maneuverability. This coupled with difficulty in sterilization may make this type less preferred.

Once attached to a camera and light source, most laparoscopes must be adjusted to a “true white” to ensure that the colors in the viewing field are accurate. This is called *white balancing* and is performed at the procedure’s beginning.

## ROBOTIC SURGERY

One modern approach to MIS uses robotic assistance, and most abdominal gynecologic procedures can be completed with this technique. Similar to laparoscopy, robotic surgery uses abdominal ports to introduce instruments and a pneumoperitoneum

to expand the operative field. One positive difference is the miniaturized and wristed articulating instrument tips that allow successful completion of complex procedures in tight operating spaces. The instrument tips mimic those used in open surgery and in laparoscopy and include graspers, needle drivers, and cutting instruments. Advanced video technology within an 8-mm laparoscope provides a high-definition and magnified view.

Of disadvantages, tactile feedback is lost with robotic surgery and forces a surgeon to use visual cues. This is a learned skill that carries a significant learning curve. However, surgeons experienced in advanced laparoscopic techniques adapt more quickly. Other disadvantages include extended initial set-up time needed during each case, physician training costs, and robot and instrument expenses.

## ■ Robot

Currently, the only commercially available robot is the da Vinci system. As shown in Figure 41-12, one or two surgeon consoles are used to control robot arm movement. A separate cart stands at the surgical bedside and serves as the base for the four robotic arms. Of these arms, one controls the laparoscope, whereas the other arms hold robotic instruments. Procedures are performed using two or three of the instrument arms according to the procedure's needs and surgeon's preference. The second surgeon console is generally used for training. If port sites in addition to the basic four are needed, an assistant surgeon can also work at the patient bedside through one or two traditional laparoscopic accessory ports. These are generally placed in the right or left upper quadrants. Typically, 5- to 15-mm trocars are used for

**FIGURE 41-12** Da Vinci Surgical System. **A.** Operator console. **B.** A surgeon's finger movements are translated into robotic instrument movement. **C.** Wristed instruments provide a wide range of motion. **D.** Robot at operative bedside. (Reproduced with permission from Intuitive Surgical, Inc.)

**FIGURE 41-13** Typical port placements for robotic surgery. The  $R_1$  port will house the laparoscope. Its site may be moved cephalad depending on the size of pelvic pathology as illustrated by  $R_{1A}$ - $R_{1C}$ . The other robot port sites are marked as  $R_2$ ,  $R_3$ , and  $R_4$ . The assistant surgeon port site is marked as  $A_1$ . Here the superficial epigastric artery is shown arising from the femoral artery, whereas the inferior epigastric artery is a branch of the external iliac artery. The iliohypogastric and ilioinguinal nerves are also seen.

the accessory port(s), depending on the instruments required for a given procedure.

During port placement, initial abdominal entry and subsequent accessory trocars are inserted similar to laparoscopy (p. 889). Port placement for robotic surgery is unique in that ports must be placed with a minimum intervening distance of 8 cm. This keeps the robot arms from colliding with each other and with any accessory ports. As shown in Figure 41-13, the level of the laparoscope's port depends on the procedure, the complexity of the pathology, and previous patient surgeries. Importantly, a black ring around the cannula marks the depth to which a trocar is inserted. Insertion to this depth is essential to provide the robot arms the correct fulcrum to function optimally and lessens port-site tissue trauma.

Of newer modifications, reduced-port robotic surgery uses microtip percutaneous instruments to minimize the number of 8-mm ports. Its advantage is yet to be proven with randomized trials. As another modification, the Food and Drug Administration (FDA) has approved instrumentation for single-site robotic

surgery for certain gynecologic procedures. A fuller discussion of single-site laparoscopy is found on page 894.

### ■ Patient Selection

When selecting a robotic approach, both patient and procedure characteristics are considered. First, procedures that are currently performed efficiently by conventional laparoscopy should not be replaced by robotic surgery (American College of Obstetricians and Gynecologists, 2015). Rather, this modality is an alternative to laparotomy and thus may offer the patient a more rapid recovery and decreased postoperative morbidity. Second, patients chosen for this technique should be able to withstand conventional laparoscopic physiologic changes discussed earlier (p. 874). As with laparoscopy, a high patient BMI may limit the robotic approach but is not a contraindication and must have the joint effort of the anesthesiologist.

## LAPAROSCOPIC ANATOMY

### ■ Anterior Abdominal Wall

The laparoscopic view of pelvic anatomy may differ slightly from laparotomy due to the effects of pneumoperitoneum, Trendelenburg positioning, and the translation of a 3-D reality into a 2-D image on the monitor.

When planning abdominal entry, key structures of the anterior abdominal wall are considered to avert neurovascular complications. Key landmarks include the umbilicus, anterior superior iliac spine, and pubic symphysis. Especially in the obese patient in whom a large pannus may alter anatomic relationships, bony landmarks are used to plan safe port placement.

The umbilicus is generally located at the level of the L3-L4 vertebrae, although it may lie above or below depending on habitus. In most patients, the aorta bifurcates at the union of L4-L5 vertebrae (Nezhat, 1998). However, in obese patients, the umbilicus tends to be caudal to this aortic bifurcation. In all patients, the left common iliac vein crosses the midline approximately 3 to 6 cm caudal to the aortic bifurcation, and the umbilicus is always cephalad to this point. The umbilicus is more caudal in heavier women. In normal-weight supine patients, these structures are considered during initial trocar entry at the umbilicus as they lie approximately 6 cm deep to the base of the umbilicus and may be closer in thinner patients (Hurd, 1992).

Accessory ports are placed under direct visualization of important anatomic structures including the bladder, bowel, and the inferior (deep) and superficial epigastric vessels. The inferior epigastric artery travels along the lateral third of the posterior surface of the rectus abdominis muscle and should be visualized intraperitoneally, running lateral to the medial umbilical ligaments (see Fig. 41-13). The superficial epigastric artery, a branch of the femoral artery, travels in the subcutaneous tissue in a path

similar to that of the inferior epigastric vessels. The superficial epigastric artery may be identified by transillumination of the anterior abdominal wall with the laparoscope. Although it cannot be visualized, nerve supply of the anterior abdominal wall is also considered to avoid trauma during trocar placement. Both the ilioinguinal and iliohypogastric nerves can be lacerated during ancillary port placement. Steps to limit injury to these nerves and vessels are described on page 895.

## ■ Retroperitoneal Structures

Along the anterior abdominal wall, five prominent ligaments lie beneath the peritoneum and can be seen laparoscopically. These superficial intraperitoneal landmarks run cephalad to caudad and may be used to identify key anatomic structures in the retroperitoneum (Fig. 41-14). In the midline, the *median umbilical ligament* traverses from the bladder dome to the umbilicus and is the obliterated urachus.

Lateral to this lie the *medial umbilical folds*, which cover the obliterated umbilical arteries. Identification of the medial umbilical ligament is essential in the setting of a frozen pelvis and can provide access to the internal iliac artery. For this, the medial umbilical ligament is followed underneath the round ligament, through the broad ligament, to the superior vesicle artery, and finally to the internal iliac artery.

Running laterally to the medial umbilical folds and to the round ligaments are the *lateral umbilical folds*. These folds are formed by peritoneum overlying the inferior epigastric vessels before they enter the rectus sheath. Direct intraperitoneal visualization of the lateral umbilical folds will prevent injury to these vessels during port placement.

In the pelvic retroperitoneum, laparoscopy usually allows easy direct identification of the ureter and vessels of the pelvic sidewall. Moreover, the course of the pelvic ureter traveling from the pelvic brim, along the pelvic sidewall, and lateral to the cervix should routinely be appreciated with every laparoscopy to ensure normal peristalsis and caliber. To avoid injury to the ureter, its course is frequently confirmed during adnexal surgery, hysterectomy, and cases with adhesive disease.

**FIGURE 41-14** Umbilical ligaments relative to trocar placement.

## ABDOMINAL ACCESS

The choice of entry site and method is influenced by factors that include body habitus, prior surgery, risk of encountering adhesive disease, intended procedure, surgeon skill, and the site, size, and type of pathology. Nearly half of all laparoscopic complications occur during abdominal entry, and nearly one quarter of these are undetected until the postoperative period (Bhojru, 2001; Chandler, 2001). Thus, entry carefully factors the above variables. Each of the methods discussed below may be beneficial in different situations, but all have potential risks. It has not been established which entry method is safest.

## ■ Umbilical entry

The umbilicus is the most frequent entry site, although the left upper quadrant and subxiphoid area are others. The umbilicus is preferred for primary trocar placement because the subcutaneous and preperitoneal tissue layers are thinnest at the fused umbilical plate. Thus, the transumbilical approach is the shortest distance to the abdominal cavity, even in obese patients. From a cosmetic standpoint, the umbilical fossa also conceals the port-site scar.

Laparoscopic entry can be performed with an open or closed technique. With closed entry, either a Veress needle or laparoscopic trocar is used to pierce the fascia and peritoneum to gain abdominal entry. Closed entry techniques offer quick access to the abdominal cavity with a low risk of injury (Bonjer, 1997; Catarci, 2001). With open entry, the fascia is grasped with Allis clamps or peans and surgically incised. The peritoneum is then grasped and opened. Some authors advocate an open entry method as a way to lower puncture injury rates. However, metaanalyses fail to show that any of the following techniques are superior to the others (Ahmad, 2008; Vilos, 2007).

## Closed Entry

During laparoscopic entry, surgeons appropriately assess patient habitus and their physical relationship to the supine patient. To diminish the downward thrust when placing the Veress needle and trocars, a surgeon adjusts the table height and uses a short stepstool if necessary. The aorta and its bifurcation lie beneath the umbilicus. To maximize the distance between the puncturing instrument and these vessels and avert vascular injury, premature Trendelenburg positioning is avoided, and the patient should lie flat. Moreover, to minimize visceral puncture during abdominal entry, the surgeon should empty the patient's bladder and confirm with the anesthesiologist that an orogastric tube has emptied the stomach. Palpation over these areas can confirm adequate decompression. The sacral promontory and aorta are also palpated, and a Veress needle or trocar with a length sufficient to reach the peritoneal cavity is selected. Finally, once all equipment is checked and correctly connected,

the surgeon confirms with the anesthesiologist that the patient is fully paralyzed to prevent involuntary patient movement during abdominal entry.

**Veress Needle entry.** The goal of this closed technique is to first create a pneumoperitoneum with a 14-gauge Veress needle. Once a pneumoperitoneum is created, the fascia and peritoneum are then secondarily punctured with a trocar. The pneumoperitoneum serves to tense the peritoneum and increases the distance of the viscera and retroperitoneal structures from the trocar entering the abdominal wall. These ideally help lower the risk of puncture injury during trocar insertion.

With all the closed methods, a skin incision appropriate to the trocar size is created, usually at the umbilicus. The incision can be either horizontal or vertical, is placed centrally within the umbilicus, and can be made with a no. 11 or 15 blade. Skin hooks or Allis clamps can aid in everting the umbilicus.

To begin, a Veress needle tip pierces through the fascia and peritoneum and enters the intraabdominal cavity to allow its insufflation with CO<sub>2</sub>. During both Veress and trocar placement, many surgeons recommend abdominal wall elevation, either manually or with instruments such as towel clips (Fig. 41-15). A study using computed tomography images revealed that up to 8 cm can be added between the incision and retroperitoneum by elevation with towel clips (Shamiyeh,

**FIGURE 41-15** Primary trocar insertion. **A.** With anterior abdominal wall elevation. **B.** Without anterior abdominal wall elevation.

**FIGURE 41-16** The Veress needle consists of a sharp outer needle (**A**), which houses a blunt-tipped, spring-loaded inner stylet (**B**).

2009). Abdominal wall elevation also provides a controlled countertension to the downward thrust of the Veress needle and subsequent trocar during insertion.

The Veress needle has a spring-loaded obturator (Fig. 41-16). As the device contacts the fascia, the obturator is pushed back, and the needle pierces the fascia and peritoneum. As soon as the tip enters the abdominal cavity, the obturator springs forward to prevent the needle from injuring abdominal viscera.

Prior to insertion, the Veress needle is checked for patency by flushing saline through the needle. The spring mechanism is also confirmed to function appropriately. The patient and operating table are flat, and the anterior abdominal wall is elevated. The Veress needle is inserted at a 45- to 90-degree angle depending on patient habitus and abdominal wall thickness. In patients with a normal BMI, angling the needle at a 45-degree angle permits abdominal entry yet minimizes the risk of great vessel injury (Fig. 41-17). With the Veress needle angled toward the hollow of the pelvis in the midline, there is a sensation of two “pops” as the tip of the needle penetrates the fascia and then the peritoneum. As shown in the figure, in overweight and obese individuals, smaller insertion angles are needed to successfully enter the abdomen.

Entry failures with this method usually stem from Veress needle tip placement into the preperitoneal space (Fig. 41-18). Flow of gas through the needle creates an extraperitoneal insufflation. This gaseous dissection of the peritoneum away from the anterior abdominal wall hinders the trocar in piercing the peritoneum. Instead, the trocar further stretches and pushes the peritoneum internally. Fortunately, this problem can often be overcome by a second attempt with the Veress needle above the umbilicus or by switching to an open entry technique (Fig. 41-19).

Preperitoneal insertion of the Veress needle is common and can lead to abandonment of the laparoscopic procedure. Thus, confirmation of correct needle placement in the peritoneal cavity is essential. For confirmation, a 10-mL syringe containing 5 mL of saline is attached to the hub of the inserted Veress needle. With aspiration, air bubbles should be seen in the syringe. If blood or bowel contents are aspirated, concern for vascular or

**FIGURE 41-17** The appropriate angle needed for the Veress needle to enter the abdomen without injury to the aorta varies with the degree of body fat.

visceral injury should be high. In these cases, the needle is left in place to help localize the puncture site and act as a vascular plug as discussed on page 877.

After aspiration, saline is easily injected with no resistance. The surgeon should be unable to reaspirate this saline, which has dispersed into the abdominal cavity. Similarly, a hanging drop test can be used. With this, a few drops of saline are placed on the external open end of the Veress needle. If the needle tip is correctly inserted, the fluid drops disappear into the negative pressure of the abdominal cavity. If incorrect entry is suspected, the needle is withdrawn and checked for patency. Moving the Veress needle from side to side is avoided at this stage. Such movement can create rents in the omentum or injure bowel.

Once correct placement is confirmed by these methods, the CO<sub>2</sub> insufflation tubing can be attached to the needle. A low-volume flow of CO<sub>2</sub> is selected, and initial intraabdominal pressure recordings should be < 8 mm Hg while the abdominal wall is manually lifted. If the pressure is elevated, the needle is immediately removed. The initial pressure is the most sensitive measurement of correct intraperitoneal Veress needle placement (Vilos, 2007). With the needle correctly inserted, pressure and gas flow may be increased. Simultaneously, the electronic insufflator parameters are closely monitored to ensure a steady increase in the pressure and continued flow. If the intraperitoneal pressure rises rapidly prior to insufflation of 1.5 to 2 L of gas, one again is concerned for preperitoneal insufflation.

During insufflation, the abdomen is observed for a uniform distention and dullness to percussion over the liver. Since the total volume required to appropriately insufflate an abdomen will vary depending on patient habitus, intraperitoneal pressure, rather than total volume of gas, is used to determine adequate peritoneal insufflation. During normal insufflation, pressures should not exceed 20 mm Hg. Such elevated pressure can lead to hemodynamic and pulmonary compromise. When an intraperitoneal pressure of 20 mm Hg is achieved, the Veress needle may be withdrawn, and the pneumoperitoneum should assist safe primary trocar insertion. This transiently elevated intraabdominal pressure provides a volumetric countertension for primary trocar insertion. However, once the primary trocar is inserted, the insufflation pressure is dropped to < 15 mm Hg, or to the lowest pressure that allows the planned procedure to be adequately visualized and safely performed.

Although data from multiple studies are conflicting, it has been proposed that the use of humidified CO<sub>2</sub> for insufflation throughout a case may have advantages. These include decreased postoperative pain, improved visualization from less lens fogging, and in animal studies, less de novo adhesion formation (Farley, 2004; Ott, 1998; Peng, 2009; Sammour, 2008).

**Primary Trocar Placement.** Once adequate insufflation is achieved, the primary trocar may then be placed. Trocars are

**FIGURE 41-18** Veress needle tenting the peritoneal layer.

**FIGURE 41-19** Veress needle replaced above the umbilicus.

**FIGURE 41-20** Trocars consist of outer cannula and inner obturator. The trocar is used to gain access to the abdomen. The obturator then is removed, and the cannula serves as a conduit through which to introduce instruments. Obturators may have a pyramidal (top), conical (middle), or blunt tip (bottom). (Reproduced with permission from Karl Storz America, Inc.)

used gain access to the abdominal cavity. First-generation trocars consist of a hollow, long, slender cannula that sheaths an inner obturator. Trocars typically range from 5 to 12 mm in diameter, and their tips may be conical, pyramidal, or blunt (Fig. 41-20).

Conical trocars are smooth except for their more pointed tip and have no cutting edges. They split the fascia rather than cut it and thus are preferred by some to lower risks of postoperative hernia formation and vessel injury (Hurd, 1995; Leibl, 1999). However, they require more penetration force to insert. In contrast, pyramidal trocars have sharp edges and tip and as a result, cut the fascia as they are inserted into the abdomen.

In the 1980s, trocars with retractable shields were introduced. Similar to the concept used with the Veress needle, a hollow plastic retractable shield covers the trocar tip both before and after the trocar pierces the abdominal wall. In this manner, the cutting edge is exposed only during its passage through the fascia. Despite theoretical advantages to these shielded trocars in preventing organ injury, studies have failed to show superiority of this design (Fuller, 2003).

Initial trocar entry is a blind procedure and is completed with the patient still supine and flat. The Veress needle is removed, and the trocar's tip is placed in the umbilical incision. The trocar handle is cupped in the palm of the dominant hand, and the same hand's index finger is extended along the trocar shaft to splint the trocar from too deep of insertion. The angle of trocar insertion should mirror that of the Veress needle. The anterior abdominal wall is elevated. With control and minimal downward force, the trocar punctures the fascia and underlying peritoneum and enters the abdominal cavity. After insertion, the trocar obturator is removed, and the cannula may be advanced slightly to ensure adequate placement into the peritoneal cavity. At this point, the laparoscope is inserted through the umbilical cannula to visually confirm safe and atraumatic entry.

**VersaStep System.** Similar to the Veress needle method, a VersaStep System may be used. This consists of a stretchable nylon sheath over a disposable Veress needle (Fig. 41-21). The first step of insertion is identical to Veress needle insertion and peritoneal insufflation. Once insufflation is complete, the Veress needle is removed, leaving the nylon sheath in situ. A trocar with a blunt inner obturator is inserted into the nylon sheath. Downward, gradual continuous pressure by the trocar causes the nylon sheath to stretch and accommodate as the trocar is advanced. The obturator is then removed, leaving only the nylon sheath and cannula as the operative port. The benefit of this system is that only a blunt trocar is used, thus potentially

**FIGURE 41-21** VersaStep system. **A.** The Veress needle housed within a nylon sheath is placed as a traditional Veress needle would be. Once inserted intraabdominally, the Veress needle is removed and the sheath remains within the abdominal incision. **B.** Next, the white obturator is placed within the black cannula. **C.** Together, this trocar is threaded intraabdominally through the nylon sheath. **D.** Last, the obturator is removed. The black cannula is completely sheathed by the nylon sleeve and has gained access to the abdomen.

diminishing traumatic injuries from a cutting blade. Also, the conical dilator may create a smaller fascial defect.

**Optical Access Trocar entry.** To reduce bowel injury risk at the time of primary trocar insertion, optical trocars were developed. These devices, in essence, combine the laparoscope and trocar into one tool. Importantly, the laparoscope should be focused once it is housed within the trocar and prior to insertion. During use, the optical trocar transmits images of the abdominal wall layers to the television monitor. These layers then are pierced under direct visualization by trocar tip advancement. If choosing an umbilical entry, the layers visualized, in sequence, should be the subcutaneous fat, the linea alba (fascia), preperitoneal fat, and peritoneum.

Optical entry methods can be used with and without the prior establishment of pneumoperitoneum. Despite the theoretical advantage of this type of trocar, major organ injury still has been reported. Moreover, no large studies have established its clinical superiority over other entry techniques (Sharp, 2002).

**Direct Trocar entry.** Because of entry failures associated with preperitoneal insufflation, a direct trocar entry method may be preferred (Copeland, 1983; Dingfelder, 1978). For this, the abdominal wall is elevated and directly pierced with a trocar without prior insufflation. Comparative studies between Veress needle and direct trocar techniques show lower rates of entry failure with the direct method (Byron, 1993; Clayman, 2005; Gunenc, 2005). Moreover, investigators note comparable or lower associated minor complication rates with the direct entry method.

### Open Umbilical Entry

To lower puncture injury rates with closed entry methods, an open entry technique was described by Hasson (1971, 1974). For this, a 1- to 2-cm transverse skin incision at the lower edge of the umbilicus is made while applying tension with fine-toothed forceps to its lateral borders. Skin edges are retracted laterally, and the subcutaneous layer is divided to expose the linea alba. This fascia is lifted and everted upward with two Allis clamps (Fig. 41-22). A 0.5- to 1-cm incision with scalpel

**FIGURE 41-22** Fascial incision for open entry.

**FIGURE 41-23** Peritoneal entry during open entry.

or scissors then transects the fascia. The Allis clamps are repositioned, one on each free fascial edge.

A hemostat or finger is used to bluntly open the peritoneum, and the end of an S-retractor is placed into the abdomen. The abdominal portion of the retractor is used to elevate the abdominal wall and shield the underlying organs as a stitch of 0-gauge delayed-absorbable suture is placed parallel on one side of the fascial opening (Fig. 41-23). This suture is not tied. This suturing step is repeated on the opposite fascial edge.

The distal, blunt end of the Hasson trocar then is inserted into the incision. The fascial tag sutures are pulled firmly upward and threaded into the suture holders found on either side of the cannula's proximal end (Fig. 41-24). The blunt obturator is removed, and the laparoscope is threaded through the cannula.

**FIGURE 41-24** Primary trocar placement with open entry.

In a retrospective review of more than 5000 open entry procedures, Hasson and associates (2000) noted that minor and medium-risk complications developed at a rate of 0.5 percent. Moreover, in studies comparing open and closed techniques, open methods showed lower rates of entry failure and organ injury (Bonjer, 1997; Merlin, 2003). Open entry is recommended by many surgeons for patients with prior abdominal surgery, for those following a closed technique entry failure, for those with a large cystic mass, and for pediatric or pregnant patients (Madeb, 2004). This technique, however, is not foolproof, and organ injury, mainly bowel, has been described (Magrina, 2002). Typically, this method of entry takes longer than closed entry, and the pneumoperitoneum can be difficult to maintain in some cases due to air escape around the cannula.

## ■ Alternative entry Sites

### Anterior Abdominal Wall

At times, the umbilicus may be unsuitable for initial abdominal entry, and surgeons should develop comfort with entry at an alternative site. Of concerns, adhesive disease may tether bowel beneath the umbilicus and is suspected in women with prior intraabdominal surgery, infection, endometriosis, or malignancy (see Table 42-1). Similarly, surgical mesh placed during umbilical herniorrhaphy is also linked with adhesive disease, and entry at this site may also disrupt the hernia repair. Nonumbilical entry can also avoid inadvertent trauma to or rupture of a large intraabdominal mass or gravid uterus.

Nonumbilical anterior abdominal wall entry has been described at various locations. The left upper quadrant is most common, but the subxiphoid area is another. Both have the advantage of providing working ports at these sites once safe entry is achieved.

Of these, left upper quadrant entry is simple, has a low risk of complications, and usually is free of adhesions (Agarwala, 2005; Howard, 1997; Palmer, 1974). Although left upper quadrant access may be obtained at either Palmer point or the ninth intercostal space, the easy accessibility of Palmer point makes this a favored site. Palmer point is located 3 cm below the left costal margin in the midclavicular line. Organs in close proximity to this point are the stomach, left lobe of the liver, spleen, and retroperitoneal structures, which may be as close as 1.5 cm (Giannios, 2009; Tulikangas, 2000).

For entry at Palmer point, one ensures that the stomach is emptied using suction with an orogastric or nasogastric tube. Palpating the area will ensure adequate emptying and exclude incidental splenomegaly. A skin incision adequate for trocar insertion is made at Palmer point. With anterior abdominal wall elevation, the Veress needle is inserted in the skin incision at an angle slightly less than 90 degrees and is directed caudad to avoid liver injury. Initial intraabdominal pressure of < 10 mm Hg indicates correct intraperitoneal placement. Once adequate insufflation is obtained, the Veress needle may be removed and a trocar inserted. Alternatively, direct trocar entry may be performed at Palmer point as well. We favor an optical access trocar to permit each layer of the anterior abdominal wall to be seen as it is penetrated (Vellinga, 2009).

For this, the anterior abdominal wall is elevated, and the trocar with laparoscope is placed into the skin incision. The trocar is directed at a 90-degree angle. During insertion, one should observe the following in sequence: subcutaneous fat, outer fascial layer, muscle layer, inner fascial layer, peritoneum, and finally, abdominal organs. Remember that above the level of the arcuate line, posterior rectus sheath fascia is present and is the inner fascial layer.

## Natural Orifice Transluminal Endoscopic Surgery

This method uses existing natural orifices such as the vagina, stomach, bladder, and rectum to access the peritoneum. In addition, a transuterine approach has been described. Although infrequently used in current practice, interest is renewed in laparoscopic access through the posterior fornix. Proposed advantages of this method are improved access to organs, better cosmesis from elimination of an external scar, shorter hospitalizations, and possibly less postoperative pain and fewer postoperative complications.

## ■ Single-port Access Laparoscopy

Single-incision surgery is a laparoscopic approach in which a sole 2- to 3-cm incision accommodates a single larger port that concurrently houses multiple instruments. It is also known as single-incision laparoscopic surgery (SILS), laparoendoscopic single-site surgery (LESS), and single-port access (SPA). The proposed advantages of this method are improved cosmesis from a single port, which is usually buried in the umbilicus, and possibly faster return to normal activity. This is balanced against the longer incision that potentially has greater risks for postoperative pain, wound infection or dehiscence, and later incisional hernia. Moreover, single-incision surgery is technically more challenging than conventional laparoscopy due to instrument crowding at a single port, limited visualization, and loss of instrument triangulation (Uppal, 2011). *Triangulation* describes instruments converging on a focal point from lateral angles of origin. These angles create opposing forces, which are essential for effective tissue retraction, dissection, and resection. However, SPA has grown in popularity with advances in articulating instruments and flexible-tip endoscopes, which help deal with some of these challenges.

For laparoscopic SPA, several ports are popular. The SILS port (Covidien) is limited to umbilical placement and may not be suitable for large pathology that encroaches on the umbilicus. The Gelpoint (Applied Medical) may be inserted almost anywhere on the abdominal wall due to the variable depth of its self-retaining sheath attached between the two rigid loops (Fig. 41-25). Moreover, the gel dome lacks preset silos for the trocars, and thus allows any size trocar to be inserted in individualized groupings.

For robotic SPA, the Single Site port (da Vinci) is placed in the umbilicus and contains cannulas for the curved trocars used in this approach. This system is limited by the required port placement but offers an alternative for suitable candidates. Instrument choices and movement are more limited. For example, the traditional wristed models are not offered, but the longer curved trocars may offer sufficient triangulation.

**FIGURE 41-25** GelPOINT Advanced Access System. (Reproduced with permission from Applied Medical Resources Corporation.)

### ■ Gasless Laparoscopy

This variation of traditional laparoscopy addresses the physiologic disadvantages of pneumoperitoneum just described. With this method, an abdominal wall lift device elevates the abdominal wall to create the laparoscopic working space, and thus no gas is required. Additional advantages include the sustained visualization after colpotomy or with continuous suctioning. Despite advantages, drawbacks are a “tent-shaped” operating space, additional required incisions, and time needed for the lift device assembly. These currently limit its routine use, but gasless laparoscopy may still have value in high-risk patients with cardiorespiratory diseases (Cravello, 1999; Goldberg, 1997; Negrin Perez, 1999).

### ■ Accessory Port Placement

Once primary abdominal access is achieved, additional operative ports are needed to insert instruments. The number, location, and size of these cannulas will vary depending on the tools required and the laparoscopic procedure. For additional port placement, the patient is placed in Trendelenburg position to displace bowel from the pelvis and provide an unobstructed view. Ancillary trocars are always placed under direct laparoscopic visualization to minimize the puncture risk to anterior abdominal wall vessels or abdominal viscera. The camera is generally driven by the first assistant or in some cases by the second assistant to free two surgeons' hands for the actual operative tasks.

Appropriate ancillary port site selection is a key step in operative planning. Correct placement permits triangulation. Poorly placed ports may create instrument angles that lead to ineffective movement, surgeon fatigue, and iatrogenic complications.

Of sites, the suprapubic midline site is most frequently used. Prior to trocar insertion, the bladder is emptied, and the trocar is placed after identification of both the bladder and the urachus. For operative laparoscopy, placement of two lower quadrant ports lateral to the inferior epigastric vessels is also common. Their sites are individualized according to patient anatomy and pathology. Generally, larger pelvic masses require more cephalad placement.

During accessory port placement, transillumination of the anterior abdominal wall is useful to avoid puncture of the superficial epigastric vessels. In this process, the laparoscope, within the abdominal cavity, is placed directly against the peritoneal surface of the anterior wall. This light is seen externally as a red circular glow, and the superficial epigastric arteries are seen as dark vessels traversing it.

Unfortunately, the inferior epigastric arteries lie deep to the rectus abdominis muscle and are poorly seen with transillumination. These arteries, however, can be seen by direct laparoscopic visualization in most cases (Fig. 41-26) (Hurd, 2003). Also, anatomic landmarks can be used to limit vessel puncture risks. For example, Epstein and coworkers (2004) noted that the main stem of the inferior epigastric artery can be avoided if trocars are inserted within the lateral third of the distance between the midline and anterior superior iliac spine (ASIS). Rahn and colleagues (2010) noted that the inferior epigastric vessels were 3.7 cm from the midline at the level of the ASIS and were always lateral to the rectus abdominis muscle at a level 2 cm superior to the pubic symphysis.

Ideally, port placement will also minimize the risk of ilioinguinal and iliohypogastric nerve injury. Most injuries to these

**FIGURE 41-26** Common abdominal access sites include a primary entry site inferior to umbilicus and smaller accessory trocar sites in the lower abdomen.

nerves and to the inferior epigastric vessels can be averted by placing the accessory ports superior to the ASIS and  $> 6$  cm from the abdomen's midline (Rahn, 2010). Once all ports are positioned, the planned procedure is begun.

### ■ Tissue extraction

Near the end of many MIS procedures, safe tissue extraction is an essential step. However, port-site seeding and inadvertent dissemination of both benign and malignant tissue during specimen fragmentation and extraction are risks. Several studies have described peritoneal leiomyomatosis, parasitic myomas, and de novo endometriosis following power morcellation of uteri and myomas (Kho, 2009; Milad, 2013; Sepilian, 2003). Moreover, morcellation of occult cancer may worsen patient prognosis. This may be particularly likely with uterine sarcoma, which has been a topic of debate (Park, 2011; Pritts, 2015).

Alternatives to power morcellation are varied. First, through minilaparotomy incisions ranging from 1 to 4 cm, myomas and uteri may be brought to the anterior abdominal wall (Fig. 44-8, p. 1025). Here, they can be hand morcellated with a scalpel or scissors and extracted (Alessandri, 2006; Panici, 2005).

Second, posterior colpotomy is safe and effective to open the cul-de-sac for bulky tissue removal (Ghezzi, 2012). As shown in Figure 41-27, a posterior colpotomy is created similar to that for vaginal hysterectomy. Namely, the cervix is lifted upward, and the vagina of the posterior fornix is stretched outward and downward to create tension. Curved Mayo scissors then incise the intervening vaginal wall and peritoneum to enter the abdomen via the posterior cul-de-sac. Once entry is confirmed, vaginal retractors can be placed for exposure. Alternatively, posterior colpotomy can be completed during laparoscopy. As

**FIGURE 41-27** Posterior colpotomy incision from a vaginal approach.

**FIGURE 41-28** Posterior colpotomy incision from an abdominal approach.

Figure 41-28 illustrates, the uterosacral ligaments and ureters are first identified. A wide, blunt vaginal probe is inserted to elevate, accentuate, and stretch the posterior vaginal fornix for incision. Using an energy-based device, the vaginal wall is incised below the level of the cervix and between the uterosacral ligaments to create the posterior colpotomy incision. Whether through this opening or a minilaparotomy, the addition of a tissue retrieval bag during tissue extraction can create a closed environment for morcellation (Fig. 41-29). This reduces the

**FIGURE 41-29** Through the posterior colpotomy, enclosed morcellation can be completed. In this instance, a large myoma is being sharply divided.

risk of inadvertent tissue dissemination during fragmentation, although long-term safety data are needed.

A third method, enclosed power morcellation, is still being studied. For this, a large endoscopic bag that can house the insufflation gas, conform to the abdominal cavity, and flatten against the intraperitoneal organs is introduced through a laparoscopic port. In the abdomen, it is unfolded to allow the specimen and gas to be contained. Depending on the pathology, the bag may be exteriorized through one abdominal port or incision, or may function during morcellation simply as a liner that catches any disseminated tissue (Einarsson, 2014). Following morcellation, the gas is released, and bag and tissue fragments are removed. Limitations of currently available retrieval bags involve the pouch size, the working aperture diameter, tensile strength, and permeability (Cohen, 2014).

## ■ Abdominal entry Closure

The intraabdominal pressure produced by the pneumoperitoneum has an excellent hemostatic effect. Thus, at the end of cases, sites of potential bleeding are evaluated under a reduced pressure. A portion of the pneumoperitoneum is allowed to escape, and the intraabdominal pressure gauge is reset to 7 or 8 mm Hg. Vessels that need sealing will be seen and treated prior to procedure completion.

With surgery completed, CO<sub>2</sub> insufflation is halted, and the gas tubing is disconnected from the primary cannula. The gas ports on all cannulas are opened to deflate the abdominal cavity. To prevent diaphragmatic irritation from retained CO<sub>2</sub>, manual pressure is placed on the abdomen to help expel remaining gas. Next, cannulas are removed under laparoscopic visualization. This allows evaluation for bleeding from punctured vessels that may have been tamponaded by the cannula or the pneumoperitoneum. These sites and other potential bleeding sites are reinspected as the pneumoperitoneum diminishes. Additionally, visualization prevents herniation of bowel or omentum up through the cannula track and into the anterior abdominal wall. Once all secondary cannulas are out, the laparoscope and then the primary cannula are removed.

Many surgeons recommend reapproximation of fascial defects at port sites to prevent anterior abdominal wall hernia formation. Although closure of the fascial defect does not obviate the risk of hernia formation, in general, most surgeons close ancillary ports sites  $\geq 10$  mm. The fascia can be closed by direct visualization with the assistance of S-retractors. The fascia is grasped with Allis clamps and then reapproximated with interrupted stitches of 0-gauge delayed-absorbable suture. Also, several laparoscopic closure devices (Carter-Thomason, EndoClose, and neoClose devices) are available. With these, fascial defects are reapproximated during direct laparoscopic visualization.

Skin incisions are closed with a subcuticular stitch of 4-0 gauge delayed-absorbable suture. Alternatively, the skin may be closed with cyanoacrylate tissue adhesive (Dermabond) or with skin tape (Steri-Strip Elastic) plus benzoin tincture (Chap. 40, p. 847).

## Open Entry Incision Closure

During removal of the Hasson trocar, sutures originally placed in the fascia are unthreaded from the cannula. Each of these

FIGURE 41-30 Ski needle.

sutures then is brought to the midline of the incision, and square knots are tied to close the fascial defect. The skin is reapproximated in a similar manner to that just described with closed abdominal entry.

## SURGICAL BASICS

### ■ Tissue Approximation

#### Suturing Tools

Following tissue excision, reapproximation with suture is often needed. Subsequent knot tying may be performed using either inside the body, *intracorporeal*, or outside the body, *extracorporeal*, techniques. For these skills, a learning curve demands a time investment, not only in the operating room, but also with box trainers or simulators. Some newer devices can make these essential steps of surgery less challenging. Typically, selection is based on the procedure planned, surgeon preference, and reapproximation goals.

*Needles* for MIS suturing must pass through the placed ports. For this, the suture is grasped approximately 1 cm from the needle swage and passed through an appropriately sized cannula. Thus, the needle type chosen will depend on the size of available cannulas. One option, the ski needle, can pass through a narrow cannula (Fig. 41-30). Straight Keith needles can also be easily passed through cannulas of any size. However, their wide, flat arcs prohibit their use in tight anatomic spaces, which require a needle with a fuller arc. Conventional needle shapes and sizes often require higher-diameter ports.

*Needle driver styles* are also varied and are curved or straight and have either a smooth or finely serrated inner surface (Fig. 41-31). Driver tips are tapered to limit tissue trauma. They also have a single-action jaw to provide a stable needle grasp.

A. Straight

B. Curved

FIGURE 41-31 Laparoscopic needle driver. (Reproduced with permission from Stryker Endoscopy.)

To assist with needle grasping, some driver tips are designed to guide the needle into a correct driving position. Termed *self-righting*, these drivers may be less desirable for suturing in difficult-to-reach anatomic spaces. Here, the needle may need to be grasped by the driver at an oblique angle to achieve correct suture placement. Other needle driver features include a coaxial (rotating) handle and a locking grip. These hold the needle in place yet decrease hand strain. With suturing, the needle driver is held in the dominant hand, while the nondominant hand holds a tissue grasper. Alternatively, some surgeons prefer to use a second needle driver in the nondominant hand. This assists in grasping the tissue, retrieving the needle or sutures from the dominant hand, and providing counter-traction when needed.

*Disposable suturing devices* render needle drivers unnecessary for tissue approximation. The Endo Stitch is a 10-mm-diameter instrument with a double-action jaw. A short, straight needle juts at a right angle from the inner surface of one tip. As the instrument tips are closed, the needle passes through the desired tissue. Then, with the tips still closed and with the flip of a handle toggle, the detachable needle is released from the first tip and reanchors at a right angle into the opposite tip. Instruments containing delayed-absorbable, barbed, or nonabsorbable suture are available. Also, the LSI suturing device is a 5-mm instrument with a hooked tip that passes a straight needle through the tissue. Both suturing tools have benefits and limitations, and familiarity with both is advantageous.

*Sutures* are broadly categorized as: (1) absorbable, delayed-absorbable, and permanent, (2) as monofilament or braided, (3) as natural or synthetic, and (4) as barbed or unbarbed. Suture selection depends primarily on the characteristics of tissues to be approximated and on the functional goals of reapproximation. Importantly, compared with traditional surgery, laparoscopic knot tying creates increased friction and suture fraying, and time between knot throws is longer. Thus, greater tensile strength and increased memory become more valued suture traits. For example, synthetic delayed-absorbable suture offers high tensile strength, less tissue reactivity, greater knot reliability, and easy handling for either intracorporeal or extracorporeal knot tying. Of filament types, although monofilament suture passes more smoothly through tissues, braided suture ties more easily and breaks less frequently. Last, the most common absorbable suture is catgut. However, compared with delayed-absorbable suture, this material provides less tensile strength and less knot security. Accordingly, catgut is less popular for MIS. If used, intracorporeal knot tying is generally preferred due to the significant fraying that occurs with this suture during extracorporeal tying.

For laparoscopy, narrow sutures in the 2-0 and 3-0 gauge range are preferred. This diameter provides suitable tensile strength to prevent suture breakage. Yet, it is thin enough to limit scarring from foreign-body reaction and to harbor fewer bacteria compared with thicker suture. However, for some procedures, such as vaginal cuff closure, the greater tensile strength provided by a 0-gauge suture is required.

Barbed sutures offer the unique ability to maintain tensile pressure on a continuous suture line. With this synthetic suture,

**FIGURE 41-32** Barbed suture. (Reproduced with permission from Angiotech Pharmaceuticals, Inc.)

multiple barbs are evenly spaced around the suture's outer surface (Fig. 41-32). These barbs flatten as they pass through the tissues to be approximated but flare out once through to the other side. These flared barbs prevent suture from slipping back through the approximated tissues. As a result, the tissues remain joined with evenly distributed tissue tension (Greenberg, 2008). By its design, this suture obviates the need for knot tying. Available barbed-suture products include Quill, Stratafix, and V-Loc sutures.

Barbed suture may be uni- or bidirectional, and these differ in the direction that suturing can proceed. *Unidirectional suture* has a small preformed loop at the tail end, which serves as the knot for that end of the suture line. Suturing moves from the looped end in the other direction. *Bidirectional suture* has needles at each end. Suturing begins at the incision midpoint and can then progress in both directions along the incision. With either suture type, the tissue is approximated by cinching the final suture line or placing a suture loop in the opposite direction. No final knot is needed to secure the suture line, which is held in place by the barbs. Alternatively, an anchoring hemostatic clip may be placed to secure the suture line end. In general, barbed suture may be advantageous for myometrial reapproximation during laparoscopic myomectomy or for vaginal cuff closure during total laparoscopic hysterectomy. At completion of the running suture line, the suture is cut short to avoid puncture of adjacent tissue by a barb.

### Knots

The length of suture will depend on the proposed suturing and knot tying. In general, 6 to 8 cm is needed for intracorporeal knot tying, and 24 to 36 cm for extracorporeal tying. Longer lengths are required for running stitches and for complicated knots compared with simple interrupted stitches.

Once tissues are approximated, the suture is tied by the intracorporeal or extracorporeal technique and then trimmed. Of the two, intracorporeal tying has a steeper learning curve because the surgeon must use laparoscopic instruments rather than fingers to loop the suture (Fig. 41-33). Extracorporeal knot tying is simpler for most surgeons because the suture is looped with fingers as in traditional tying. Each formed knot throw is

**FIGURE 41-33** Intracorporeal knot tying.

then guided through a laparoscopic cannula and cinched with a knot pusher to create the knot (Fig. 41-34). Of suture types, stronger braided suture is preferred if the knot pusher is used because suture fraying is a side effect of this technique. Another disadvantage of extracorporeal knot tying compared with intracorporeal methods is that it often causes more tissue tension and can tear delicate tissues.

As an alternative to manual knot tying, disposable clips can be placed at the end of a suture line for security. Specifically, a hemoclip is a titanium V-shaped clip with arms that can be squeezed together during application. These clips were originally designed to compress vessels for hemostasis and are available in various sizes. At the end of a running suture line, hemoclips can also be placed across the suture tail to prevent stitch unraveling. If used for this purpose, two clips are advisable. More recent developments include the Lapra-Ty. This has a locking clip made of delayed-absorbable polydioxanone, which is also used in the suture brand PDS. Its ability to be absorbed and its lock are advantages, whereas its need for a 11- to 12-mm port may be disadvantageous in some settings. Also, these ties are only approved to anchor suture diameters greater

than 4-0 gauge. Another option is the 5-mm Ti-KNOT instrument. With this disposable device, a special titanium clip is placed around a single or a double strand of suture. With any of these alternatives to laparoscopic knot tying, the cost may be justified by the time saved in the operating room.

### Stapling

In gynecologic surgery, vascular tissue is typically ligated first and then transected. Ligation may be achieved with electro-surgical tools described earlier, with stapling devices, or with suture loops. Linear staplers are mainly used for achieving anastomoses as in bowel surgery and are not frequently employed for gynecologic procedures. When selected in gynecologic laparoscopic surgery, they are chiefly used to ligate vascular pedicles, such as the infundibulopelvic ligament. Once fired, the stapler lays down three staggered double rows of staples while dividing tissue in between.

The staplers are available in 35- or 45-cm lengths and contain an end called the “anvil,” which houses the staple cartridges. *Vascular cartridges* apply staples that are 1 mm high when closed. *Tissue cartridges* apply those that are 1.5 mm when closed and are suitable for thicker pedicles. Stapling provides hemostasis and gentle handling of tissue, which should lead to less necrosis and better healing.

Newer models have added articulating and rotating capabilities at the jaw. These attributes permit stapling at an angle. Most staples are titanium. However, newer angled staplers for the vaginal cuff use delayed-absorbable material such as Polyglactin 910 for their staples. A main limitation to stapler use is generally the price of the device and cartridges, which can be costly compared with suture. However, if operating time is reduced, these costs can be negligible.

**FIGURE 41-34** Extracorporeal knot tying.

**FIGURE 41-35** Laparoscopic suture loop.

### Suture Loops

Preformed suture loops, such as the Endoloop, may also be used to ligate tissue pedicles (Fig. 41-35). This instrument has a length of suture housed within a stiff, 5-mm-diameter rod and has a pretied loop at the end. The loop is guided around the intended tissue pedicle by the stiff rod and then is cinched like a noose. The rod tip, similar to an index finger during manual knot tying, adds pressure to secure the knot in place. Loops of absorbable, delayed-absorbable, and permanent suture are available. Other types of knots that are pretied loops include the Roeder knot, Meltzer knot, and Tayside knot. These currently are not as popular as the square knot.

### ■ Laparoscopic Dissection Techniques

Pelvic adhesions are often lysed to reestablish normal anatomy and complete planned surgery. Some situations require the use of sharp dissection, especially if adhesions are not amenable to blunt tissue separation. For cutting fine adhesions, the tissue band may be placed on gentle stretch using an atraumatic grasper or blunt probe. Curved scissors with a dissecting tip or an energy modality (monopolar, bipolar, or harmonic) are frequently used.

If denser adhesions are found, they are divided in layers to prevent injury to adjacent adhered organs. Traction and countertraction aid in tissue plane identification. As the surgeon begins to separate tissues with tension, the plane of attachment may be identified, and the scissor tips create a small incision (Fig. 40-11, p. 850). The tip is then eased between the tissue layers to create an opening by spreading the blades outward. The initial snip carries the risk of injury to the underlying viscera or vessel and is made as shallow as possible. The use of energy sources in these situations is generally discouraged, as thermal injury may have a wider effect that may not be readily apparent. Conversely, a sharp cut is easier to identify and repair intraoperatively. The scissors used may be curved or straight depending on the contour of the pelvic organs. Once a plane is developed, wider and deeper strokes are used to complete tissue dissection.

Hydrodissection is another technique often used in MIS. With this, normal saline or other irrigation fluid is injected under pressure to separate tissue planes. For example, peritoneal endometriosis can be lifted and excised with greater ease and less trauma to retroperitoneal structures. Other uses include resection of cysts from an ovary, removal of ectopic products from a fallopian tube, or separation of tissue planes that might be obscured or in close proximity to vascular spaces or bowel.

**FIGURE 41-36** Hydrodissection to remove endometriotic implants on peritoneum that overlies the ureter, seen here in cross section. **A.** Needle insertion and fluid instillation. **B.** Peritoneal implant excision is completed without injury to the ureter.

As shown in Figure 41-36, an atraumatic grasper lifts the tissue at the junction point, and a needle tip is inserted with the bevel away from the structure to be protected. Irrigation fluid is injected and creates a balloon effect. Depending on the location, 5 to 30 mL of fluid is instilled. A suction-irrigation system also is helpful for this technique. With this instrument, once the peritoneum is incised, the suction tip is insinuated into the opening. Fluid is forced to gently separate the tissue planes (Fig. 44-4.2, p. 1014). Often, hydrodissection allows a surgeon to identify natural planes that might otherwise be obscured.

### ■ Hemostasis

As tissue planes are developed, bleeding is variably encountered. Requirements for vessel sealing differ according to vessel diameters. For small vessels, spot coagulation is suitable, and a monopolar tool is satisfactory and mimics the electrosurgical blade (Bovie) use in open procedures. For larger vessels, the bipolar or Harmonic technologies are preferred. Of these, the Harmonic grasper coagulates or denatures the vessel tissue and can seal vessels up to 5 mm in diameter. Advanced bipolar technologies achieve vessel sealing by desiccation and can effectively seal vessels ranging from 5 to 7 mm in diameter. When choosing a modality, the thermal spread of a device is considered. Last, microbipolar probes and needle-tip monopolar probes are useful for delicate tissues such as the fallopian tubes. The thermal spread is minimal, and the tip sizes are optimal for the small but friable vessels.

Liquid topical hemostatic agents have also gained popularity and have been adapted for laparoscopic use (Table 40-5, p. 861). When using a laparoscopic adaptor, a portion of the matrix may remain in the applicator cannula. Thus, to avoid retained and thus wasted sealant, a surgeon flushes the cannula following initial matrix application. For this, a plunger is included in many sealant kits, or a syringe filled with air may be used to force matrix through the cannula and onto the desired tissue. Alternatively, an oxidized regenerated cellulose fabric sheet (Surgicel) can be used.

## HYSTeROSCOPIC PReOPeRATIVE CONSIDeRATIONS

### ■ Patient evaluation

Hysteroscopy allows an endoscopic view of the endometrial cavity and tubal ostia for both the diagnosis and operative treatment of intrauterine pathology. The role of hysteroscopy in modern gynecology has expanded rapidly with development of more effective hysteroscopic instruments and smaller endoscopes, bringing many procedures into the office. Indications for hysteroscopy vary and include evaluation and in some cases, treatment of infertility, recurrent miscarriage, abnormal uterine bleeding, amenorrhea, and retained foreign bodies. With hysteroscopic techniques, abnormal bleeding can be treated with endometrial ablation, polypectomy, or submucous myomectomy. Infertility may be improved with resection of intrauterine adhesions or a septum. Additionally, obstructed tubal ostia may be unblocked or dilated. Alternatively, for those seeking sterilization, hysteroscopic tubal occlusion can serve as an effective and safe method of contraception.

Because the indications for hysteroscopy are varied, patient evaluations for specific disorders are discussed in their respective chapters. More generally, continuing pregnancy is an absolute contraindication to hysteroscopy and should be excluded with serum or urine  $\beta$ -human chorionic gonadotropin testing prior to surgery. In addition, cervicitis or pelvic infection is treated prior to hysteroscopy, and screening for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in those with risk factors is prudent (Table 1-1, p. 6). For those with abnormal bleeding and significant risks for endometrial cancer, preoperative endometrial Pipelle sampling is reasonable as seeding of the peritoneal cavity with cancer cells has been noted following hysteroscopy (Chap. 8, p. 187).

If diagnostic hysteroscopy is planned to locate and remove a foreign body, preoperative imaging is recommended, usually with transvaginal sonography. For example, in some cases, an intrauterine device (IUD) or retained fetal bone may have perforated the uterine wall, lie predominantly outside the uterus, and thus be best removed by laparoscopy.

### ■ Consent

The risk of complications for women undergoing hysteroscopy is low and cited at less than 1 to 3 percent (Hulka, 1993; Jansen, 2000; Propst, 2000). Complications are similar to those associated with dilatation and curettage and include uterine perforation, inability to sufficiently dilate the cervix, hemorrhage, cervical laceration, and postoperative endometritis. In addition, because either gas or liquid medium is required to distend the endometrial cavity during hysteroscopy, gas venous embolism and excessive intravascular fluid absorption are risks discussed later. In general, complication rates increase with the length and complexity of the procedure planned.

In the event of uterine perforation during hysteroscopy, diagnostic laparoscopy may be indicated for evaluation of the surrounding pelvic organs. Thus, patients are additionally consented and aware of the possible need for laparoscopy.

### ■ Patient Preparation

Infectious and venous thromboembolic (VTE) complications following hysteroscopic surgery are rare. Accordingly, preoperative antibiotics or VTE prophylaxis is typically not required (American College of Obstetricians and Gynecologists, 2013, 2014).

### Endometrial Thickness

In premenopausal women, hysteroscopy is ideally performed in the early proliferative phase of the menstrual cycle, when the endometrium is relatively thin. This allows small masses to be identified and easily removed. Alternatively, agents that induce endometrial atrophy such as progestins, combination oral contraceptives, or gonadotropin-releasing hormone (GnRH) agonists have been administered individually prior to an anticipated surgery. Although these effectively thin the endometrium, many of these agents have disadvantages including expense, adverse side effects, and surgical delay while atrophy ensues.

### Cervical Dilatation

For operative hysteroscopy, dilatation of the cervix is typically required to insert an 8- to 10-mm hysteroscope or resectoscope. To ease dilatation and lower the risk of uterine perforation, cervical preparation is considered. Misoprostol (Cytotec), a synthetic prostaglandin  $E_1$  analogue, may be administered orally the night before and if desired, again the morning of surgery to aid cervical softening. Commonly used dosing options include 200 or 400  $\mu$ g vaginally or 400  $\mu$ g orally once 12 to 24 hours prior to surgery. Common side effects include cramping, uterine bleeding, or nausea. Thus, the need for softening is balanced against these side effects, especially bleeding that might limit endoscopic visualization.

If cervical stenosis is encountered intraoperatively, smaller caliber tools, such as a lacrimal duct probe, may be guided into the external cervical os to define the canal path. In these situations, transabdominal sonography may be helpful when done simultaneously with dilatation to help ensure proper placement (Christianson, 2008). Also, injection of intracervical dilute vasopressin can diminish the force required for cervical dilation (Phillips, 1997). Because the onset of action is rapid, this is especially helpful if stenosis was not anticipated preoperatively. As a potent vasoconstrictor, however, vasopressin is ideally avoided in those with serious hypertension and cardiovascular disease.

## HYSTeROSCOPIC INSTRUMENTS

### ■ Rigid Hysteroscope

Hysteroscopy requires a hysteroscope, light source, uterine distention medium, and, in many cases, a video camera system. Most hysteroscopes consist of a 3- to 4-mm-diameter endoscope surrounded by an outer sheath. Smaller diameter hysteroscopes have been developed, although their use is limited by their decreased field of view and lower light intensity. Hysteroscopes are broadly classified as diagnostic or operative. Diagnostic hysteroscopes offer a small diameter, which provides an adequate endometrial cavity view yet requires minimal if any cervical dilatation. Operative hysteroscopes have sheaths that increase

**FIGURE 41-37** Differences between a 0-degree hysteroscope (left) and 30-degree hysteroscope (right). **A.** Intracavitary views **B.** A 30-degree endoscope has an angled tip. **C.** Views of the endocervical canal (black dot) during hysteroscope insertion.

the overall diameter and necessitate cervical dilation in most cases. Thus, cases requiring operative hysteroscopes are best managed under general or regional anesthesia in the operating room for patient comfort and safety.

Individual endoscopes offer specific angles of view. Although 0- through 70-degree angles (0, 12, 25, 30, and 70 degrees) are available, a 0- or 12-degree hysteroscope allows the easiest orientation within the uterine cavity for most procedures (Fig. 41-37). The 12-, 25-, 30-, and 70-degree angles provide additional lateral views, which are often required for complex operative procedures. There are also devices that have 90- to 110-degree angles of view, although these are infrequently used.

In general, the light source system used in hysteroscopy is the same type as for laparoscopy. However, the intensity is typically less than for most laparoscopic procedures. During assembly of the hysteroscope at the beginning of the procedure, the light source attaches directly to the endoscope.

An outer sheath surrounds the endoscope and directs fluid, and in some cases instruments, to the endometrial cavity. In directing fluid flow, sheaths are constructed to allow either

**FIGURE 41-38** Distention medium flow through resectoscope.

unidirectional or bidirectional flow of distending media. Sheaths that allow continuous flow, that is, bidirectional inflow and outflow circulation of the distention medium, are most valuable in cases in which bleeding or large fluid volume deficits are expected (Fig. 41-38). This circulation helps clear blood from the operative field and assists with fluid volume deficit calculation. The type of tubing attached to the hysteroscope sheath is dictated by the fluid management system.

In operative hysteroscopes, the outer sheath also allows the use of semirigid, rigid, and flexible instruments. The basic set that will suffice for most cases includes biopsy forceps, grasping forceps, and scissors. Of these, biopsy forceps are somewhat sharp and cuplike. Grasping forceps permit removal of tissue or foreign bodies and may be toothed. Last, scissors can lyse adhesions, resect masses, or excise an intrauterine septum. Generally 5F in diameter and 34 to 40 cm long, these instruments are much smaller than the instruments used with the resectoscope. None of these requires special distention media or energy. Flexible electrodes used to vaporize tissue may also be passed through this sheath.

### ■ Bettochi Hysteroscope

This small, 4-mm-diameter rigid operative hysteroscope has a 5F (1.67 mm) operating channel that provides diagnostic and operative capability. Additionally, the hysteroscope diameter is oblong rather than circular, which conforms to the cervical canal's configuration (Bradley, 2009). Biopsy forceps, monopolar and bipolar electrosurgical scissors, bipolar needle-like tip, or delivery devices for transcervical sterilization can easily pass through this hysteroscope's working channel. The flow sheath has a small diameter yet permits sufficient flow to avoid compromised optical quality. These hysteroscopes are available in 0-degree and angled views.

### ■ Flexible Hysteroscope

These hysteroscopes have tips that can deflect over a range of 120 to 160 degrees. Although their optical view is less clear than that

with rigid hysteroscopes, they offer easy maneuverability within irregularly shaped endometrial cavities. This can be helpful when tubal access is required or during lysis of adhesions. Additionally, flexible hysteroscopes cause less intraoperative pain than rigid ones and may benefit office procedures (Unfried, 2001).

## ■ Resectoscope

If resection of intrauterine tissues is planned, a resectoscope may be used. This tool consists of inner and outer sheaths. The inner sheath houses a 3- to 4-mm-diameter endoscope and a channel for fluid medium inflow. The 8- to 10-mm outer sheath contains an electrosurgical resection loop and allows fluid egress from the uterus through a series of small holes near the sheath's distal end. By means of a spring mechanism, the resection loop can be extended and then retracted to shave off contacted tissues. Through its central cannula, larger instruments that are energy-based for tissue resection can also be passed. These include the roller bar, roller ball, vaporizing electrodes (monopolar, bipolar, laser), hot scalpel, and motorized morcellator.

## ■ Hysteroscopic Morcellator

For resection of polyps, submucosal leiomyomas, septa, or synechiae, a hysteroscopic morcellator may be chosen. Hysteroscopic

morcellators offer different tips depending on tissue type. For polyp resection, a rakelike tip is used. For resection of firmer tissue, a cutting tip is selected. Both tips contain a mechanized blade that fragments tissue. These tips are attached to a hollow cannula that evacuates the tissue fragments by suction to a collection receptacle. The morcellator fits through the working channel of a 9-mm or greater operative hysteroscopic cannula.

## DISTENTION MEDIA

Because the anterior and posterior uterine walls lie in apposition, a distention medium is required to expand the endometrial cavity for viewing. Fluid media include saline, and low-viscous fluids, such as sorbitol, mannitol, and glycine solutions (Table 41-2). Historically, carbon dioxide was used for diagnostic hysteroscopy but is infrequently employed today. Each group has distinct advantages and properties. To expand the cavity, intrauterine pressures of these media must reach 45 to 80 mm Hg. Rarely is more than 100 mm Hg required. Moreover, because for most women, mean arterial pressure approximates 100 mm Hg, higher pressures can result in increased intravasation of media into the patient's circulation to create fluid volume overload.

**TABLE 41-2.** Hysteroscopic Media

Medium	Properties	Indications	Risks	Safety Measures
<b>Gas</b>				
Carbon dioxide	Colorless gas	Diagnostic	Gas embolism	Avoid Trendelenburg Keep flow < 100 mL/min Intrauterine pressure < 100 mm Hg
<b>electrolyte fluid</b>				
0.9% saline	Isotonic 380 mOsm/kg H <sub>2</sub> O	Diagnostic Operative w/ bipolar tools	Volume overload	Plan to complete procedure at 750 mL deficit Stop procedure at 2.5 L deficit End earlier in patients with comorbidities or elderly
Lactated Ringer	Isotonic 273 mOsm/kg H <sub>2</sub> O	Same as above	Volume overload	Same as above
<b>electrolyte-poor fluid</b>				
Sorbitol 3%	Hypoosmolar 178 mOsm/kg H <sub>2</sub> O	Operative w/ monopolar tools	Volume overload Hyponatremia Hypoosmolality Hyperglycemia	Plan to complete procedure at 750 mL deficit Stop procedure at 1–1.5L deficit End earlier in patients with comorbidities or elderly
Mannitol 5%	Isoosmolar 280 mOsm/kg H <sub>2</sub> O	Operative w/ monopolar tools	Volume overload Hyponatremia	Same as above
Glycine 1.5%	Hypoosmolar 200 mOsm /kg H <sub>2</sub> O	Operative w/ monopolar tools	Volume overload Hyponatremia Hypoosmolality Hyperammonemia	Same as above

Data from Cooper, 2000; American Association of Gynecologic Laparoscopists, 2013; American College of Obstetricians and Gynecologists, 2011.

## ■ Carbon Dioxide

T is gaseous distention medium, when used under pressure, tends to flatten the endometrium and provides excellent visibility. A continuous flow is necessary to replace any gas lost through the tubes, and typically flow rates of 40 to 50 mL/min are adequate. Rates higher than 100 mL/min are associated with increased risks for gas embolism and therefore discouraged. Specialized hysteroscopic machines, which limit maximum flow rates, should be used. Importantly, because *laparoscopic* insufflating machines can permit flow rates > 1000 mL/min, these should not be used for hysteroscopy.

Disadvantages to CO<sub>2</sub> include its tendency, when mixed with blood or mucus, to form visually obstructive gas bubbles. Accordingly, prior to hysteroscope insertion, blood and mucus are carefully removed from the cervical os with a dry swab (Sutton, 2006). Similarly, use of CO<sub>2</sub> with thermal energy sources is avoided as smoke production prohibits adequate viewing. Because of these limitations, CO<sub>2</sub> is best used in cases in which minimal bleeding is anticipated, such as diagnostic hysteroscopy. The most serious complication associated with CO<sub>2</sub> use is venous gas embolism and is discussed on page 905.

## ■ Fluid Media

Bleeding is common with operative hysteroscopy procedures. Thus rather than CO<sub>2</sub>, fluid media are typically selected because of their optical clarity and ability to mix with blood. The main risk of fluid distention media, however, involves increased fluid absorption and circulatory fluid volume overload. Volume overload may develop with any of the fluid media and results from various mechanisms. As examples, absorption across the endometrium, intravasation through surgically opened venous channels, and spill from the fallopian tubes with absorption by the peritoneum have all been suggested. Therefore, clinical settings in which procedures are long, increased distention pressures are used, or large tissue areas are resected all carry a greater risk.

Fluid distention media can be divided according to their viscosity and electrolyte status. In general, low-viscosity fluids are used in modern hysteroscopy. An appropriate medium is selected based on its compatibility with electrosurgical instrumentation.

### Low-viscosity Electrolyte Fluids

Normal saline and lactated Ringer solutions are isotonic, electrolyte fluids. They are readily available in the operating room and are frequently used for diagnostic hysteroscopy. However, these fluids cannot be used with monopolar electrosurgery. Specifically, these solutions conduct current; thus, dissipate the energy; and thereby render the instrument useless.

These electrolyte-containing, isotonic fluids have lower associated risks of hyponatremia compared with hypoosmolar fluids, described in the next section. Still, rapid absorption can lead to pulmonary edema. In general, when using isotonic medium in a healthy patient, a surgeon should consider terminating the procedure when the fluid deficit nears 2500 mL (American Association of Gynecologic Laparoscopists, 2013; American College of Obstetricians and Gynecologists, 2011).

### Low-viscosity, Electrolyte-poor Fluids

Of other available media, 1.5-percent glycine, 3-percent sorbitol, and 5-percent mannitol are all low-viscosity, electrolyte-poor fluids. Because they are nonconducting, these media are used for electrosurgery involving monopolar instruments. Unfortunately, these fluids can create volume overload with concurrent development of hyponatremia and hypoosmolality and the potential for cerebral edema and death (American College of Obstetricians and Gynecologists, 2011). Mechanistically, sorbitol is a six-carbon sugar and is metabolized following absorption. T is effectively leaves free water in the intravascular space. Normal serum sodium levels are 135 to 145 mEq/L, and levels significantly below this may lead to seizure followed by respiratory arrest. In addition, hypokalemia and hypocalcemia can often develop concurrently. Five-percent mannitol, also a six-carbon sugar, is isoosmolar and so has diuretic properties but does not lead to serum osmolality changes (American Association of Gynecologic Laparoscopists, 2013).

In cases in which large fluid volume deficits are calculated, measurement of serum electrolyte levels is warranted. If a serum sodium level lower than 125 mEq/L is reached, post-operative care should be continued in a critical care setting. Treatment includes stimulation of diuresis with furosemide (Lasix), 20 to 40 mg given intravenously. Correction of hyponatremia is achieved with 3-percent sodium chloride, administered at a rate of 0.5 to 2 mL/kg/hr. In those with acute neurologic symptoms, 3-percent saline can instead be given in a 100-mL infusion over 30 minutes and repeated an additional two times if needed (Nagler, 2014; Verbalis, 2013). The goal of therapy is to reach a serum sodium level of 135 mEq/L within 24 hours. Overcorrection is avoided to prevent additional cerebral effects (Nagler, 2014; Verbalis, 2013). Consultation with an internal medicine specialist may be helpful.

To assist with intraoperative fluid volume calculation, most operative hysteroscopes contain continuous flow systems that allow fluid deficits to be calculated. Calculation of deficits is performed every 15 minutes during procedures. If a procedure has the potential for larger deficits, a Foley catheter is also warranted for urine output monitoring. Moreover, an ongoing communication with participating anesthesia staff regarding large fluid deficits is prudent. If deficits of a hypotonic solution reach 1000 mL, a surgeon should consider procedure termination, measure electrolytes, and give diuretics as indicated (American Association of Gynecologic Laparoscopists, 2013). At the end of every hysteroscopic procedure, a final deficit is determined, and this value is recorded in the operative note.

### Hysteroscopic Electrosurgery

Many widely used hysteroscopic tissue resection or desiccation techniques rely on monopolar current. Because current is dissipated and is thus ineffective in electrolyte solutions, these techniques have typically required nonelectrolyte solutions such as sorbitol, mannitol, and glycine. However, as just discussed, these media can be associated with hyponatremia if fluid volume overload develops.

Alternatively, bipolar electrosurgery systems (Versapoint Bipolar Electrosurgery System and Karl Storz bipolar resectoscope)

allow use of traditional hysteroscopic tools in a saline solution. The Versapoint system has attachments that include a loop resecting electrode and multiedged vaporizing electrode. There are also ball, spring, and twizzle tips that can be employed for vaporization, desiccation, and cutting. The Karl Storz resectoscope (22F) has a cutting loop, ball tip, and pointed coagulation electrode attachments.

## HYSTeroscopic Complications

### ■ Uterine Perforation

In addition to fluid overload, uterine perforation or bleeding may complicate hysteroscopy. The uterus may be perforated during uterine sounding, cervical dilatation, or hysteroscopic procedures. Fundal perforations created by sounds, dilators, or hysteroscopes can be managed conservatively, as the myometrium will typically contract around these defects. In contrast, lateral perforation may perforate the broad ligament or injure larger pelvic vessels; posterior perforation may injure the rectum; and those caused by electrosurgical tools may cause organ laceration or burn. Diagnostic laparoscopy is indicated in these cases. Similarly, anterior perforations should prompt cystoscopy to evaluate associated bladder injury.

### ■ Gas embolization

If vessels are opened during cervical dilation or during endometrial or myometrial disruption, gas under pressure can be forced into the vasculature. Any undissolved portion can reach the lungs. CO<sub>2</sub> is many times more soluble in plasma than is room air, and it typically dissolves sufficiently during transit from the pelvis (Corson, 1988). As a result, pulmonary embolism is rare in diagnostic hysteroscopic cases using CO<sub>2</sub> (Brandner, 1999). In contrast, room air is poorly soluble in blood, and embolization can lead to rapid cardiovascular collapse. Signs and symptoms include chest pain, dyspnea, and hypotension. Anesthesia staff may note decreased end-tidal CO<sub>2</sub> levels, oxygen desaturation, dysrhythmias, or a “mill wheel” murmur (Groenman, 2008). To manage this emergency, the patient is placed in the left lateral decubitus position with the head tilted downward. This aids movement of the air from the right outflow tract to the apex of the right ventricle, where the embolus may be aspirated (American College of Obstetricians and Gynecologists, 2011).

Surgeons can minimize the risk of gas embolism by avoiding Trendelenburg positioning of the patient during hysteroscopy, ensuring that air bubbles are purged from all tubing prior to introduction of the hysteroscope into the uterus, maintaining intrauterine pressures < 100 mm Hg, minimizing the effort needed to dilate the cervix, avoiding deep myometrial resections, and limiting multiple removals and reinsertions of the hysteroscope in and out of the uterine cavity.

### ■ Hemorrhage

Heavy bleeding may develop during or following resection procedures. Although hysteroscopic electrosurgical electrodes may be used to contact and coagulate smaller vessels, these may be less effective for larger ones. If heavy bleeding is encountered

and is refractory to electrosurgical coagulation, termination of the procedure may be indicated. A Foley catheter balloon can be placed into the endometrial cavity and inflated incrementally with 5 to 10 mL of saline until moderate resistance to catheter tension is noted. An attached collection bag can be used to document blood loss and bleeding cessation. After several hours, the catheter may be removed.

FLUID AND ELECTROLYTE ABNORMALITIES. . . . . 918

POSTOPERATIVE FEVER . . . . . 919

POSTOPERATIVE WOUND. . . . . 919

REFERENCES . . . . . 922

Many problems following surgery can be avoided by the preoperative risk assessment and prevention strategies described in Chapter 39. However, despite ideal preparation, complications may still develop, and vigilance for these adverse events can help ensure successful convalescence for most patients.

POSTOPERATIVE ORDERS

These written instructions address support of each organ system, while normal function is gradually reestablished. Although orders are customized for each woman, goals are common among all surgical patients—resuscitation, pain control, and resumption of daily activities. Table 42-1 offers a template for both inpatient and outpatient postoperative orders.

■ Fluid and Electrolytes

Nearly half of the average female body’s weight is water. Two thirds of this water is contained in the intracellular compartment, and the remainder is stored extracellularly. This extracellular compartment is divided into a vascular space filled with plasma and an interstitium, which is the collection of small spaces between cells. Of extracellular fluid volume, 25 percent makes up intravascular plasma, and 75 percent fills the interstitium. This 1 to 3 ratio is relevant during fluid resuscitation. Extracellular compartment osmolarity is controlled primarily by sodium and chloride, whereas potassium, magnesium, and phosphate are the major intracellular electrolytes. Osmotic balance is

maintained by the free movement of water between the intra- and extracellular spaces.

To support these fluid volumes, the daily liquid requirement for an average adult approximates 30 mL/kg/day. Urine output and insensible losses offset these requirements (Marino, 2007). Thus, postoperatively, crystalloid fluids are primarily used for maintenance and in some cases for resuscitation. Sodium chloride is the main component of these fluids. Because sodium is most abundant in the extracellular space, the fluid is uniformly distributed between the interstitial areas. With crystalloid resuscitation, the primary effect is interstitial volume expansion rather than plasma volume growth. Two of the most commonly used crystalloid fluids for resuscitation and maintenance requirements are isotonic saline and lactated Ringer solution.

Compared with plasma, isotonic saline, also colloquially called normal saline, has a higher chloride concentration (154 mEq/L versus 103 mEq/L) and lower pH (5.7 versus 7.4). Thus, if isotonic saline is infused at large volumes, it can result in a hyperchloremic metabolic acidosis (Prough, 1999). The saline-induced acidosis usually has no adverse clinical consequences, but differentiating it from lactic acidosis (a marker of tissue necrosis) can be challenging in certain settings. Gastric secretions lost during vomiting or nasogastric tube suctioning are commonly replaced by a 5-percent dextrose in 0.45-percent normal saline solution with 20 mEq/L KCl added.

Also known as Hartmann solution, lactated Ringer solution contains potassium and calcium concentrations similar to plasma, but the sodium concentration (130 mEq) is comparatively reduced to that of isotonic saline to maintain cationic neutrality. The addition of 28 mEq/L of lactate necessitates a reduction in chloride concentrations to a level similar to plasma. In sum, the hyperchloremic metabolic acidosis risk observed with large-volume isotonic saline infusion is avoided. Disadvantageously, lactated Ringer solution leads to increased calcium binding of certain drugs that limits their efficacy (Griffith, 1986). Moreover, calcium can bind the citrated anticoagulant found in blood products and promote clot formation in donor blood. Advantageously, lactated Ringer solution does not significantly change serum lactate levels because only 25 percent of the infused volume remains intravascular. Therefore lactated Ringer solution is commonly employed in cases of isotonic dehydration, such as bowel sequestration in times of obstruction.

■ Pain Management

Postoperative pain management remains undervalued, and many patients continue to experience intense pain after surgery.

**TABLE 42-1.** Typical Postoperative Orders (Inpatient and Outpatient)

Postoperative Orders (Inpatient)	Postoperative Orders (Outpatient)
Admit to: recovery room/assigned hospital floor/ attending physician's name	Admit to: recovery room; transfer to DSU when cleared by anesthesia
Diagnosis: s/p what surgical procedure	Diagnosis: s/p what surgical procedure
Condition: stable	Condition: stable
Vital signs: q 1h $\times$ 4, q2h $\times$ 2, then q4h	VS per routine
Activity: bed rest	Allergies: NKDA
Allergies: NKDA	Bed rest until A&A, then activity ad lib
Notify MD for: T > 101°F; BP > 160/110, < 90/60; P > 130; RR > 30, < 10; UOP < 120 mL/4 hr; acute changes	NPO until A&A, then clear liquids
Diet: NPO except ice chips	IV fluids: LR at 125 mL/hr until tolerating PO, then D/C IV
IV fluids: LR at 125/hr	Notify MD for: T > 101°F; BP > 160/110, < 90/60; P > 130; RR > 30, < 10; acute changes
Special:	D/C patient home when A&A, cleared by anesthesia, taking PO, ambulating, and able to void
Strict I/Os	F/U at _____ clinic in _____ weeks
Turn, cough, deep breath q 1h while awake	Write any necessary prescriptions
IS to BS, q 1h while awake	
Foley to gravity	
SCD hose to pump	
Medications:	
1. PCA orders: mix 30 mg MSO <sub>4</sub> in 30 mL NS; load 4–6 mg, then IV q6min on demand; lockout 20 mg in 4 hours	
2. Phenergan 25 mg IV q6h prn N/V	
3. $\pm$ Toradol 30 mg IM q6h $\times$ 24 h (only if Cr is okay)	
Labs: H & H in AM (or that afternoon if necessary)	
A&A = awake and alert; BS = bedside; Cr = creatinine; D/C = discontinue, discharge; DSU = day surgery unit; F/U = follow-up; H&H = hemoglobin and hematocrit; I/Os = input and output; IM = intramuscular; IS = incentive spirometry; IV = intravenous; LR = lactated Ringer; MSO <sub>4</sub> = morphine sulfate; NKDA = no known drug allergies; NPO = nil per os; NS = normal saline; N/V = nausea and vomiting; P = pulse; PCA = patient-controlled analgesia; PO = per os; RR = respiratory rate; SCD = sequential compression device; s/p = status post; UOP = urine output; VS = vital signs.	

A survey by Apfelbaum and colleagues (2003) revealed that more than 85 percent of respondents following surgery have moderate to severe pain. Poor pain control leads to decreased satisfaction with care, prolonged recovery time, increased use of health care resources, and increased costs (Joshi, 2005; McIntosh, 2009). Options for patient analgesia may be broadly classed as opiate-based or nonopiod.

### Nonopiod Treatment Options

The two major classes of nonopiod therapies are acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs). Multimodal pain control postoperatively using intravenous (IV) NSAIDs and/or acetaminophen can reduce or enhance analgesia, lower narcotic needs, decrease the incidence of postoperative nausea and vomiting by as much as 30 percent, and reduce hospital length of stay (Akarsu, 2004; Chan, 1996; Khalili, 2013; Mixer, 1998; Santoso, 2014). In general, these drugs are well tolerated and carry a low risk of serious side effects. However, acetaminophen can be toxic to the liver in high doses. Thus, patients should avoid total doses exceed-

ing 4000 mg/day and use of alcohol while taking acetaminophen-containing products (Food and Drug Administration, 2011). A list of oral NSAIDs and their dosages are found in Table 10-1 (p. 239).

### Opioid Treatment Options

Despite the common side effects that all opiates share—respiratory depression and nausea and vomiting—opiate therapy is the primary choice for managing moderate to severe pain. The three most common opiates prescribed after gynecologic surgeries are morphine, fentanyl, and hydromorphone. Meperidine, although commonly administered in many obstetric units, is avoided in part because of neurologic side effects associated with its active metabolite, normeperidine. Normeperidine is a cerebral irritant that can cause effects ranging from irritability and agitation to seizure.

*Morphine* is prescribed most frequently following gynecologic surgery and is a potent  $\mu$ -opiate-receptor agonist. Action at this receptor accounts for the analgesia, euphoria, respiratory depression, and decreased gastrointestinal (GI) motility seen

with morphine. Onset of action is rapid, and peak effects are seen within 20 minutes of IV administration. Its action typically lasts for 3 to 4 hours. Its active metabolite, morphine-6-glucuronide, is renally excreted and thus is well tolerated in low doses in those with liver disease.

Pruritus is common after administration, although its genesis is poorly understood. Some investigators theorize that central opiate receptors are stimulated, whereas others speculate a histamine release as evidenced by urticaria, wheals, and flushing. In these cases, changing to another pain medication is logical. For pruritus treatment, most evidence-based data derive from studies of regional analgesia. Success has been found with ondansetron, 4 mg IV (George, 2009). Antihistamines, such as diphenhydramine (Benadryl) 25 mg IV, are another option. Naloxone, an opioid antagonist, can be used but may reverse the analgesia provided by morphine.

*Fentanyl*, a potent synthetic opiate, is more lipophilic than morphine and displays a shorter duration of action and half-

life. Peak analgesia is reached within minutes of IV administration and lasts for 30 to 60 minutes. Many conscious sedation protocols used during of ce gynecologic procedures combine fentanyl with a sedative such as midazolam (Versed).

*Hydromorphone* (Dilaudid), another semisynthetic analogue of morphine, is less lipophilic than fentanyl. It is available for delivery by multiple routes, including oral, intramuscular (IM), IV, rectal, and subcutaneous (SC). Hydromorphone achieves its peak analgesia 15 minutes after IV administration, and its effects last 3 to 4 hours. Although commonly used during epidural analgesia, hydromorphone is a suitable patient-controlled analgesia (PCA) alternative in patients with a morphine allergy. [Table 42-2](#) provides a summary of various pain medications and dosage equivalents.

■ **Hormone Replacement Therapy**

Some women will have significant menopausal symptoms after surgical removal of both ovaries. Symptoms can range from severe

**TABLE 42-2.** Opioid Equivalency Chart/Dosing Data for Opioids

Drugs	Approximate Opioid Equianalgesic Dose			Usual Starting Dose			
				Adults > 50 kg Body Wt		Children and Adults < 50 kg	
	Parenteral (mg)	Oral (mg)	Duration (h)	Parenteral	Oral	Parenteral	Oral
Morphine IR (Roxanol)	10	30	3–4	10 mg	30 mg	0.1 mg/kg	0.3 mg/kg

hot flashes to headaches or sudden mood swings. In these women, estrogen replacement therapy is considered for those without contraindications (Chap. 22, p. 494). For women completing surgery for endometriosis, a progestin may be added for those with residual disease, as discussed in Chapter 10 (p. 243).

## PULMONARY COMPLICATIONS

Broad definitions hinder our ability to accurately assess the incidence of postoperative pulmonary complications, but reported estimates range from 9 to 69 percent (Calligaro, 1993; Hall, 1991). Postoperative pulmonary complications include atelectasis, pulmonary embolism (PE), and less commonly, pneumonia and acute respiratory distress syndrome (ARDS). All can potentially lead to acute respiratory failure.

### ■ Acute Respiratory Failure

In the general postsurgical population, acute respiratory failure (ARF) has an incidence ranging from 0.2 to 3.0 percent and an associated mortality rate that can exceed 25 percent (Arozullah, 2000; Johnson, 2007). ARF is classically divided into four subtypes defined by inadequate exchange of oxygen or carbon dioxide or both. Type 1 lesions exchange oxygen poorly, and examples include atelectasis, pneumonia, PE, and ARDS, all discussed subsequently.

Type 2 is typified by hypercapnia. It is seen in anesthesia overdose and muscle fatigue, in which ventilation suffers and carbon dioxide ( $\text{CO}_2$ ) is retained. Also, increased metabolic processes such as fever, severe sepsis, overfeeding, and hyperthyroidism can generate excess  $\text{CO}_2$ . As a result, ventilatory work increases as the body attempts to maintain appropriate arterial  $\text{pCO}_2$  levels. This can ultimately lead to respiratory failure.

Type 3 is similar to type 1 but merits a distinct category because of its common occurrence following anesthesia and surgery. Physiologically, general anesthesia reduces muscle tone to decrease lung volumes and airway diameters. The resulting atelectasis and airway closure can drive abnormal gas exchange and ventilation-perfusion mismatching, which creates a decrease in  $\text{PaO}_2$ . This hypoxemia is further aggravated by hypoventilation from central decreases in respiratory drive, residual effects of anesthetics, lung edema, or bronchospasm (Canet, 1989). To help circumvent type 3 ARF, important considerations include early treatment of hypoxemia, multimodal approaches to pain management, and chest physiotherapy.

Type 4 stems from shock and its associated cardiopulmonary hypoperfusion. For treatment, circulatory resuscitation, discussed in Chapter 40 (p. 864), accompanies oxygen therapy.

### ■ Atelectasis

This reversible closure or collapse of alveoli is seen in 90 percent of surgical patients (Lundquist, 1995). Development is associated with decreased lung compliance, gas exchange abnormalities, and increased pulmonary vascular resistance. Thus, characteristic signs are diminished breath sounds, dullness to percussion over affected lung fields, and decreased oxygenation. Pulse oximetry readings  $> 92$  percent represent adequate oxygenation, however, a  $\text{PaO}_2$  measurement by arterial blood gas will most accurately assess a patient with hypoxic respiratory

failure. In addition to bedside findings, chest radiography typically shows linear densities in the lower lung fields. Classically, atelectasis is associated with low-grade fevers. However, Mavros and colleagues (2011) reviewed eight studies with a total of 998 patients and found no association between atelectasis and postoperative fever.

Prevention using lung expansion therapies is described in Chapter 39 (p. 827), and these can be used for treatment as well. Atelectasis is usually temporary (up to 2 days) and self-limited, and it rarely slows patient recovery or hospital discharge (Platell, 1997). Its importance mainly lies in its clinical similarity to PE and pneumonia. Thus, in women with risks for these more life-threatening complications, atelectasis may ultimately be a diagnosis of exclusion.

### ■ Hospital-acquired Pneumonia

This is the second most common nosocomial infection in the United States and carries high associated morbidity and mortality rates (Tablan, 2004). Its incidence in surgical patients varies and ranges from 1 to 19 percent depending on surgical procedure and hospital surveyed (Kozlow, 2003). With these infections, bacterial pathogens most typically include aerobic gram-negative bacilli, such as *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Acinetobacter* species.

Clinically, pneumonia is diagnosed if chest radiography reveals a new or progressive radiographic infiltrate and if two of three clinical features (leukocytosis, fever  $> 38^\circ\text{C}$ , or purulent secretions) are present. Broad-spectrum antibiotic regimens are recommended for hospital-acquired pneumonia treatment (Table 42-3). If aspiration is highly suspected, specific treatment

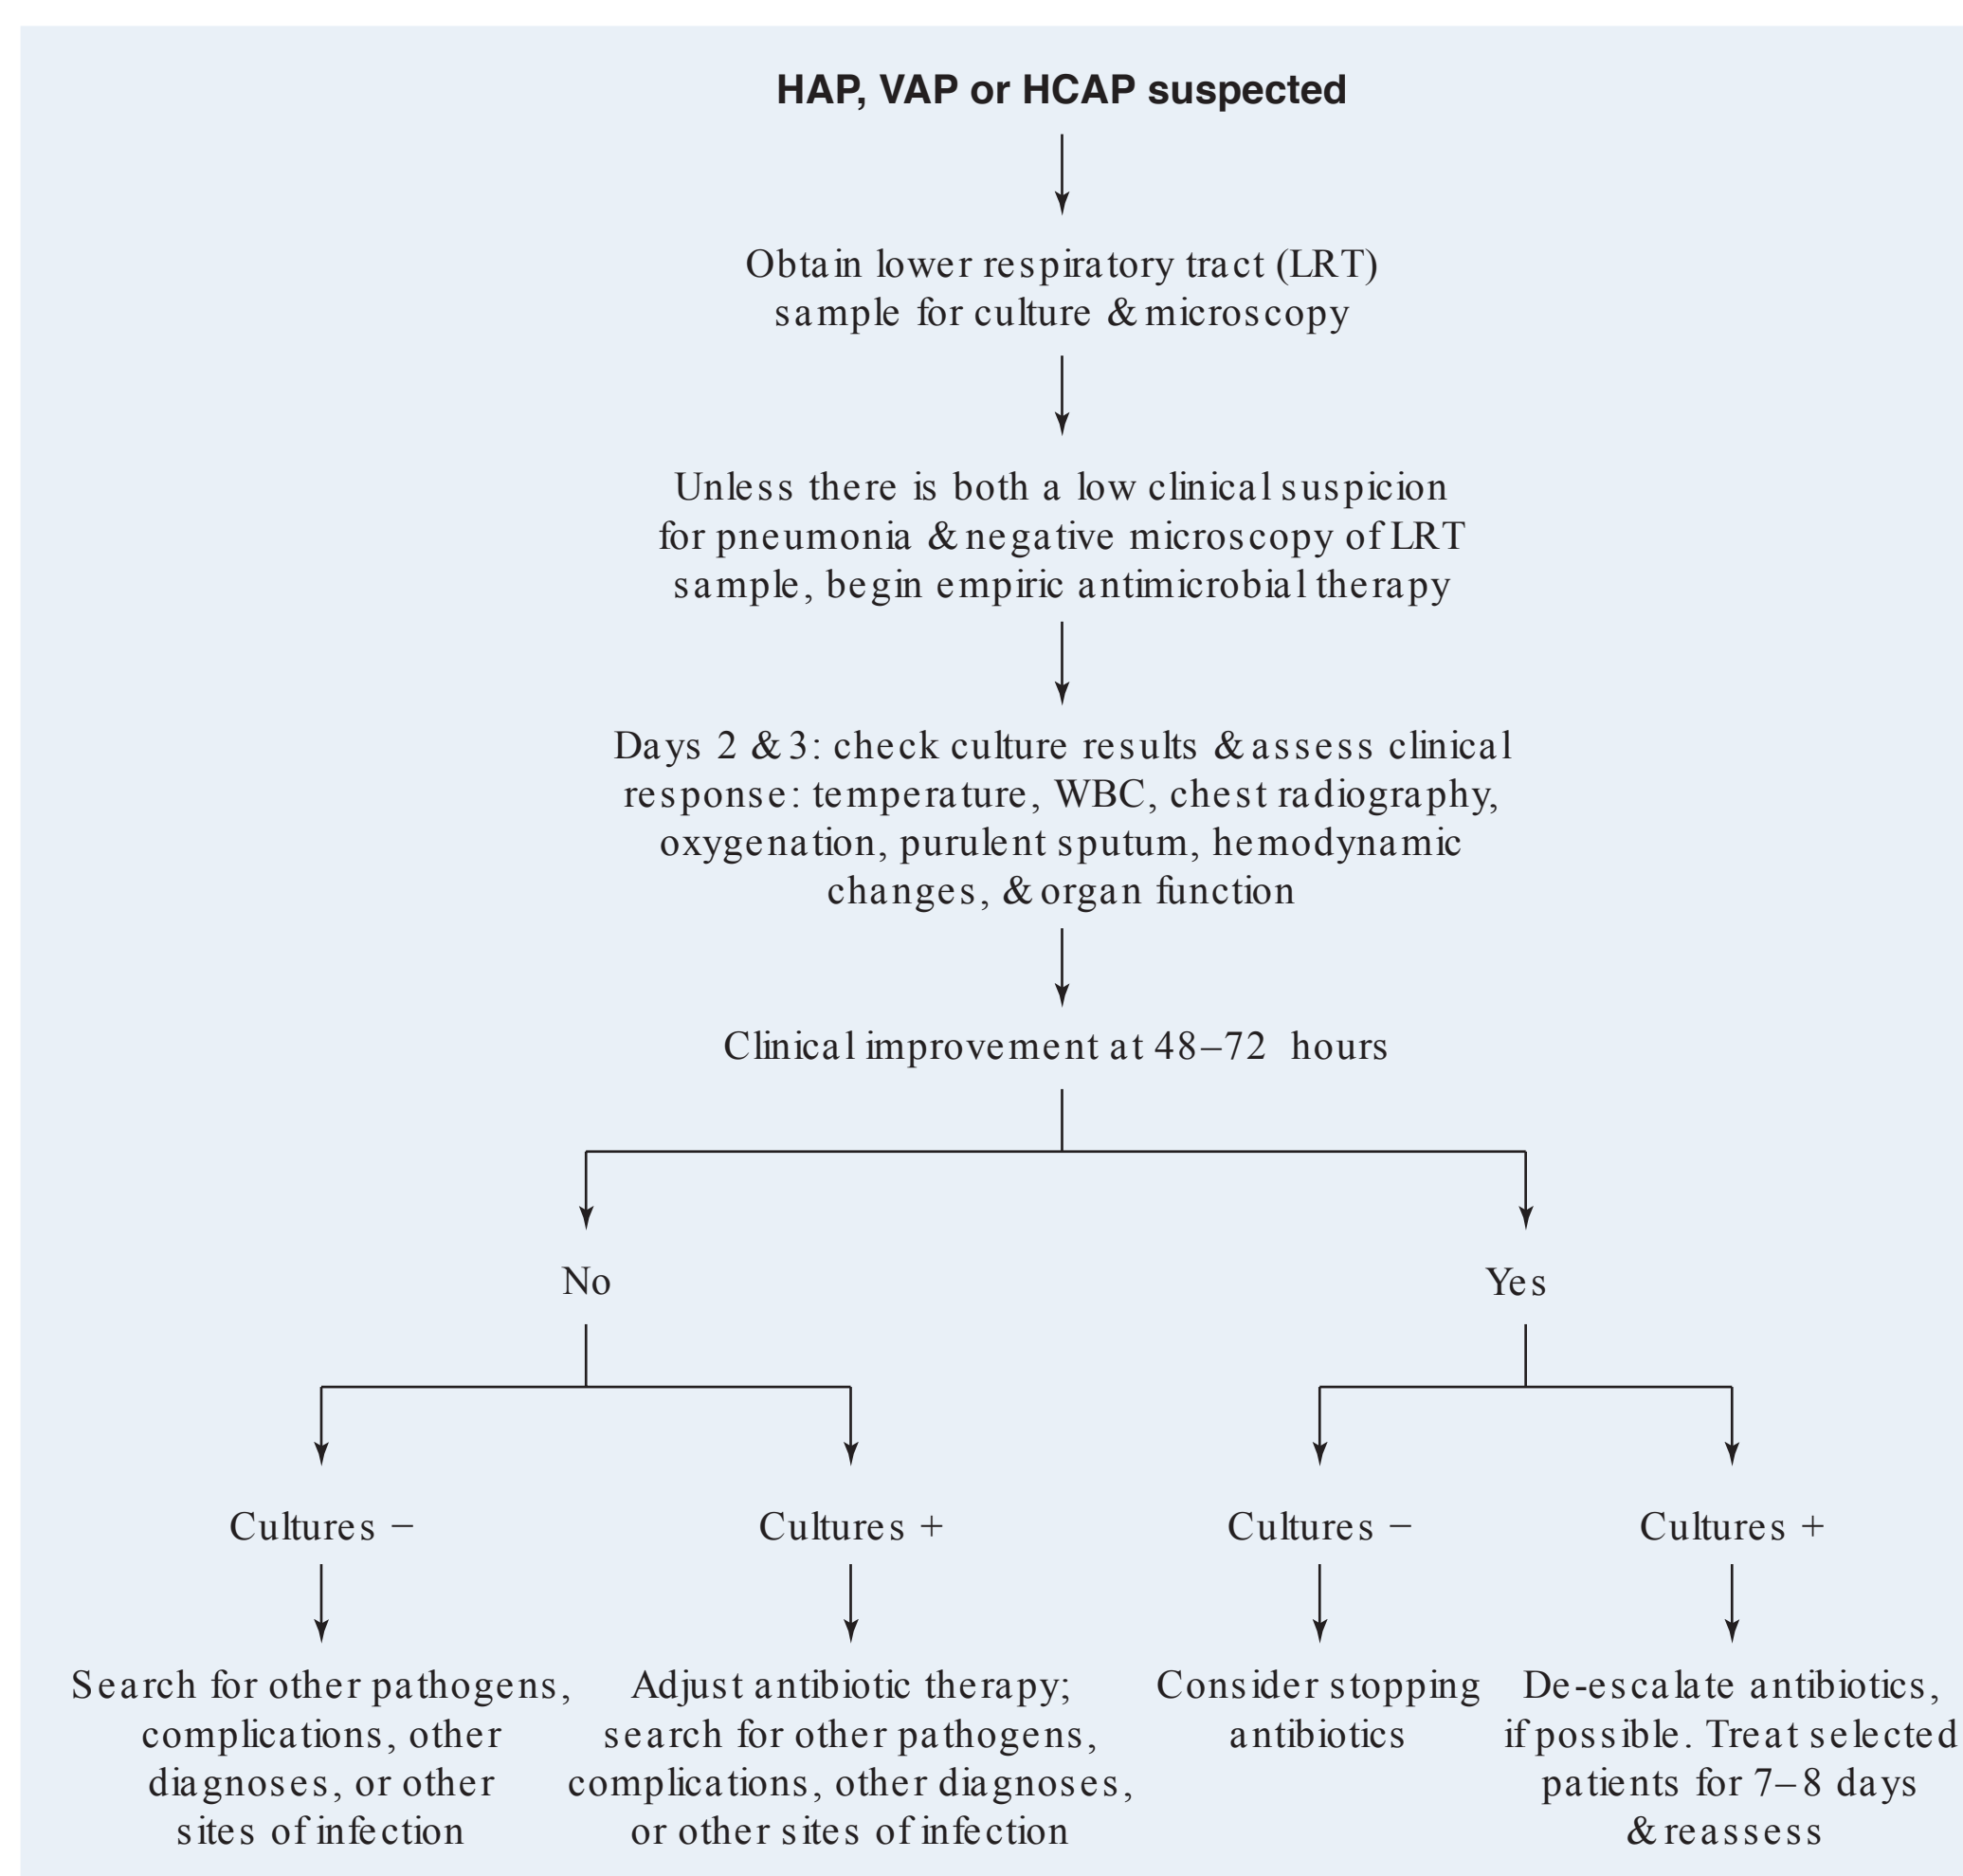

**TABLE 42-3.** Empiric Antibiotic Therapy for Hospital-acquired Pneumonia<sup>a</sup>

Regimen Options	Dosage
Cefepime or ceftazidime	2 g every 8 hr

for anaerobes with metronidazole or clindamycin is considered. An algorithm supported by the American Thoracic Society is shown in [Figure 42-1](#). Preventive steps include substituting oral endotracheal and orogastric tubes in place of nasal tubes; elevating the head of the bed 30 to 45 degrees, particularly during feeding; and removing subglottic secretions in those unable to clear these (American Thoracic Society, 2005; Ferrer, 2010).

## ■ Pulmonary Embolism

If venous thromboembolism (VTE) is suspected, evaluation begins with clinical examination and risk estimation. Wells and colleagues (1995) described one of the most widely used pretest probability assessments for DVT ([Table 42-4](#)). When indicated, duplex sonography is highly sensitive for detecting proximal leg DVTs, with a false-negative rate of 0 to 6 percent (Gottlieb, 1999).

For PE, because symptoms may reflect other cardiopulmonary pathology, clinicians often initially elect chest radiography and electrocardiogram (ECG). The radiograph is typically abnormal but nonspecific, and findings can include atelectasis, elevated hemidiaphragm, cardiomegaly, and small pleu-

ral effusions (Worsley, 1993). ECG may display tachycardia or may reflect right heart strain by showing a large S wave in lead I, a Q wave in lead III, and inverted T wave in lead III (Stein, 1991). If suspicion for PE remains, then computed tomographic angiography (CTA) or less frequently, ventilation/perfusion (V/Q) scanning is ordered. These serve as alternatives to the invasive gold standards—pulmonary angiography or contrast venography.

Acute management of VTE involves anticoagulation with intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin ([Tables 42-5](#) and [42-6](#)). After achieving adequate anticoagulation, oral vitamin K antagonists such as warfarin are initiated. To avoid paradoxical hypercoagulability, heparin is continued for at least 5 days after the initiation of warfarin (Houman Fekrazad, 2009). Once the international normalized ratio (INR) reaches a therapeutic range of 2 to 3, then heparin is stopped. Long term, anticoagulation therapy duration is dictated by clinical and patient circumstances. For those with a provoked first DVT or PE, anticoagulants are recommended for 3 months. Provocateurs include surgery, exogenous estrogen, or local trauma. Extended therapy is preferred for both those with unprovoked VTE or with second VTE,

**TABLE 42-4.** Pretest Probability for Deep-Vein Thrombosis

Major Points	Minor Points
Cancer	Recent trauma to
Immobilization	symptomatic leg
Recent major surgery	Unilateral edema
Thigh or calf tenderness	Erythema
Calf swelling	Dilated superficial veins
Family history of DVT	Hospitalized in last 6 months

**Clinical Probability**

**High**

- > 3 major points and no alternative diagnosis
- > 2 major points and > 2 minor points + no alternative diagnosis

**Low**

- 1 major point + > 2 minor points + has an alternative diagnosis
- 1 major point + > 1 minor point + no alternative diagnosis
- 0 major points + > 3 minor points + has an alternative diagnosis
- 0 major points + > 2 minor points + no alternative diagnosis

unless the risk of bleeding is high, in which case, treatment is halted at 3 months. For those with concurrent cancer, therapy is extended regardless of bleeding risk (Kearon, 2012).

■ **Acute Respiratory Distress Syndrome**

Acute lung injury that causes a form of severe permeability pulmonary edema and ARF is termed acute respiratory distress

**TABLE 42-6.** Characteristics of Some Low-Molecular-Weight Heparins

Name (Brand Name)	Dose
Enoxaparin (Lovenox)	1 mg/kg every 12 hr 1.5 mg/kg daily
Tinzaparin (Innohep)	175 IU/kg daily
Dalteparin (Fragmin)	100 IU/kg every 12 hr 200 IU/kg daily

IU = international units.

syndrome. T is is a pathophysiologic continuum from mild pulmonary insuf ciency to dependence on high inspired oxygen concentrations and mechanical ventilation. T e theory that multiple insults lead to postoperative ARDS offers insight into modifiable intra- and postoperative alveolar damage prevention (Litell, 2011; Warner, 2000). Intraoperative strategies minimize lung trauma by keeping airway pressure and tidal volumes within set limits and by avoiding repeated alveolar opening and closing (Hemmes, 2013). Other measures strive to prevent infection, limit IV fluid volumes, and avoid blood product transfusion (Güldner, 2013).

**CARDIAC COMPLICATIONS**

■ **Myocardial Infarction**

Postoperative myocardial infarction (MI) is rare, and its generally reported incidence ranges from nearly 1 percent to as high as 37 percent among patients with surgery within 3 months following an MI (Mangano, 1990; Tinker, 1978). Declines in oxygen supply and increased demand classically underlie this coronary ischemia. Events that decrease oxygen supply include hypotension, lowered coronary perfusion, or poor carrying capacity caused by anemia. Increased afterload, tachycardia, and increased cardiac contractility can raise myocardial oxygen demands.

**TABLE 42-5.** Parkland Hospital Protocol for Continuous Heparin Infusion for Patients with Venous Thromboembolism

<b>Initial Heparin Dose:</b> __ units IV push (recommended 80 units/kg rounded to nearest 100, maximum 7500 units), then __ units/hr by infusion (recommended 18 units/kg/hr rounded to nearest 50).		
<b>Infusion Rate Adjustments</b> —based on partial thromboplastin time (PTT):		
PTT (sec) <sup>a</sup>	Intervention <sup>b</sup>	Baseline Infusion Rate Change <sup>c</sup>
< 45	80 units/kg bolus	↑ by 4 units/kg/hr
45–54	40 units/kg bolus	↑ by 2 units/kg/hr
55–84	None	None
85–100	None	↓ by 2 units/kg/hr

<sup>a</sup>PTT goal 55–84.  
<sup>b</sup>Rounded to nearest 100.  
<sup>c</sup>Rounded to nearest 50.

Most patients with postoperative MI do not have classic symptoms of chest pain or pressure. These are in part masked by postoperative analgesics (Muir, 1991). Dyspnea is the most common complaint and may be accompanied by acute cardiac failure or hemodynamic instability. ECG changes of postoperative MI tend to be less well defined, and most demonstrate a non-Q wave variant (Badner, 1998). CK isoenzyme (CK-MB) abnormalities are seen within 6 hours, and cardiac troponin I and T are highly specific later for diagnosis of MI (Zimmerman, 1999).

Postoperative MI treatment differs from that of nonsurgical patients, and its main tenets focus on shifting the oxygen delivery and utilization balance. Special attention is given to arrhythmia correction and hemodynamic status improvement. Ideally, these patients are cared for in a unit that provides intense monitoring, cardiopulmonary support, and cardiology consultation.

■ Hypertension

This is frequently encountered both preoperatively and postoperatively. As standard definitions are lacking, the reported incidence ranges from 3 to 90 percent, depending on the thresholds set and the type of surgery. Patients with poorly controlled hypertension preoperatively tend to have more blood pressure lability compared with normotensive patients or those with well-controlled hypertension. In general, a diastolic blood pressure greater than 110 mm Hg preoperatively best predicts those who will have postoperative hypertension issues.

Several possible triggers may raise blood pressures in the first 24 hours after surgery. First, abrupt withdrawal of  $\beta$ -blocker or of centrally acting sympatholytic agents such as clonidine can cause rebound hypertension. Pain and bladder distention may also contribute. Later in postoperative recovery, sympathetic hyperactivity may stem from inadequate pain management or from alcohol withdrawal. Last, return of excess interstitial fluid back into the vascular space may create fluid overload and hypertension.

Two approaches have been described for blood pressure treatment: fixed thresholds and relative changes from baseline. Charlson and colleagues (1990) demonstrated increased rates of postoperative cardiac and renal complications when the mean blood pressure rose 20 percent or more compared with preoperative levels. Given the paucity of good evidence, it is reasonable to initiate treatment if mean blood pressure readings rise by this percentage. With acute blood pressure management, the mean blood pressure should not be lowered by more than 20 percent or to a level less than 160/100 mm Hg.

GASTROINTESTINAL COMPLICATIONS

■ Postoperative Nausea and Vomiting

This is one of the most common complaints following surgery, and its incidence ranges from 30 to 70 percent in high-risk patients (Møller, 2002). Those at risk for postoperative nausea and vomiting (PONV) include females, nonsmokers, those with prior motion sickness or prior PONV, and those with extended surgeries (Apfelbaum, 2003).

A multimodal approach to prevention is recommended (Apfel, 2004). Currently, combinations of 4 to 8 mg of dexamethasone prior to anesthesia induction are followed, toward the end of surgery, by less than 1 mg of droperidol (Inapsine) and 4 mg of ondansetron (Zofran). This pretreatment significantly reduces symptoms by 25 percent. However, if symptoms develop within 6 hours of surgery, antiemetics from a different pharmacologic class than previously administered are considered (Habib, 2004). Persistent nausea may benefit from combining agents from different classes (Table 42-7).

■ Bowel Function and Diet Resumption

Normal GI function requires synchronized motility, mucosal transport of nutrients, and evacuation reflexes (Nunley, 2004).

TABLE 42-7. Commonly Used Medications for Nausea and Vomiting

Medication (Brand Name)	Usual Dosage	Route(s)
<b>Antihistamines</b>	<b>Every 6 hr</b>	
Diphenhydramine (Benadryl)	25–50 mg	IM, IV, PO
Hydroxyzine (Atarax, Vistaril)	25–100 mg	IM, PO
Meclizine (Antivert)	25–50 mg	PO
<b>Benzamides</b>	<b>Every 6 hr</b>	
Metoclopramide (Reglan)	5–15 mg	IM, IV, PO
Trimethobenzamide (Tigan)	250 mg	IM, PO, PR
<b>Phenothiazines</b>	<b>Every 6 hr</b>	
Prochlorperazine (Compazine)	5–10 (25 PR) mg	IM, IV, PO, PR
Promethazine (Phenergan)	12.5–25 mg	IM, IV, PO, PR
<b>Serotonin Antagonists</b>		
Ondansetron (Zofran)	8 mg every 8 hr	IV, PO
Granisetron (Kytril)	2 mg daily	IV, PO
Dolasetron (Anzemet)	100 mg daily	IV, PO

IM = intramuscular; IV = intravenous; PO = orally; PR = per rectum.

However, following intraabdominal surgery, dysfunction of enteric neural activity typically disrupts normal propulsion. Activity first returns in the stomach and is noted typically within 24 hours. The small intestine also exhibits contractile activity within 24 hours after surgery, but normal function may be delayed for 3 to 4 days (Condon, 1986; Dauchel, 1976). Rhythmic colonic motility resumes last, at approximately 4 days following intraabdominal surgery (Huge, 2000). Passage of flatus characteristically marks this return of function, and stool passage usually follows in 1 to 2 days.

Postoperative feeding is most effective when started early. It improves wound healing, promotes gut motility, decreases intestinal stasis, raises splanchnic blood flow, and stimulates reflexes that elicit GI hormone secretion to shorten postoperative ileus (Anderson, 2003; Braga, 2002; Correia, 2004; Lewis, 2001). The decision to initiate “early feeding” with liquids or with solid food has been studied prospectively (Jeffery, 1996). In patients who were given solid food as the first postoperative meal, the number of calories and amount of protein consumed on the first postoperative day were higher. In addition, the number of patients requiring diet changes to NPO (nil per os) was not statistically different (7.5 percent in regular diet and 8.1 percent in the clear diet groups). The improved tolerance and better palatability of solids makes this a reasonable option.

## ■ Ileus

Postoperative ileus (POI) is a transient impairment of GI activity that leads to abdominal distention, hypoactive bowel sounds, nausea and vomiting related to GI gas and fluid accumulation, and delayed passage of flatus or stool (Livingston, 1990).

The genesis of POI is multifactorial. First, bowel manipulation during surgery leads to production of contributory factors. These include: (1) neurogenic factors related to sympathetic overactivity, (2) hormonal factors related to the release of hypothalamic corticotropin-releasing hormone (CRH), which plays a key role in the stress response, and (3) inflammatory factors (Tache, 2001). Second, perioperative opioid use also increases POI rates. Thus, in selecting opiates, clinicians balance the beneficial analgesia produced by central opioid receptor binding against the GI dysfunction that results from peripheral receptor binding effects (Holzer, 2004).

No single treatment defines POI management. Electrolyte repletion and IV fluids to reestablish euvoemia are traditional. In contrast, routine nasogastric tube (NGT) decompression to promote bowel rest has been challenged by multiple prospective randomized trials. A metaanalysis including nearly 5240 patients found routine NGT decompression unsuccessful and inferior to its selective use in symptomatic patients. Specifically, patients without NGTs had significantly earlier return of normal bowel function and decreased risks of wound infection and ventral hernia (Nelson, 2007). Additionally, tube-related discomfort, nausea, and hospital stays were reduced. For these reasons, postoperative NGTs are recommended only for symptomatic relief of abdominal bloating and recurrent vomiting (Nunley, 2004).

Gum chewing after laparotomy as a preventive modality for POI has been the focus of several small but randomized studies.

In these, sugarless gum is usually chewed 15 to 30 minutes at least three times daily. In evaluations, this practice is associated with earlier improvement in bowel motility markers (Ertas, 2013; Jernigan, 2014). However, compared with placebo, gum chewing achieves these goals on average only several hours earlier (Li, 2013).

## ■ Bowel Obstruction

Obstruction of the small intestines may be partial or complete and can result from adhesions following intraabdominal surgery, infection, or malignancy. Of these, surgical adhesions are the most common cause (Krebs, 1987; Monk, 1994). Small bowel obstruction (SBO) develops following 1 to 2 percent of total abdominal hysterectomies, and nearly 75 percent of obstructions are complete (Al-Sunaidi, 2006). Obstruction may be remote from surgery, and the mean interval between primary intraabdominal procedure and SBO approximates 5 years (Al-Took, 1999).

Initial SBO management is similar to that for POI, but distinguishing between the two is important to prevent serious SBO sequelae. During SBO, the bowel lumen dilates proximal to the obstruction, and decompression may develop distally. Bacterial overgrowth in the proximal small bowel can promote bacterial fermentation and worsening dilation. The bowel wall also becomes edematous and dysfunctional (Wright, 1971). Progressive increases in bowel pressure compromise perfusion to the intestinal segment and can ultimately lead to ischemia or rupture (Megibow, 1991).

Clinical signs that may help distinguish SBO from POI include tachycardia, oliguria, and fever. Physical examination may reveal abdominal distention, high-pitched bowel sounds, and an empty rectal vault during digital examination. Last, leukocytosis with a neutrophil dominance should alert to possible coexistent bowel ischemia.

Computed tomography (CT) scanning is the primary imaging tool to identify SBO. Water-soluble contrast can safely help identify the cause and severity of an obstruction. Gastrografin, the most commonly used water-soluble dye, is a mixture of sodium amidotrizoate and meglumine amidotrizoate and may aid resolution of small bowel edema due to its high osmotic pressure. Gastrografin is also theorized to enhance smooth muscle contractility (Assalia, 1994). Although the use of oral Gastrografin does appear to reduce hospital length of stay, it has no therapeutic benefit in adhesion-related SBO (Abbas, 2007).

Treatment of SBO varies with the degree of obstruction. For partial obstruction, feedings are held, IV fluids and antiemetics are initiated, and an NGT is placed for significant nausea and vomiting. Continued surveillance monitors for signs of bowel ischemia. Symptoms in most cases of partial SBO improve within 48 hours. In contrast, for most of those with complete bowel obstruction, surgery to relieve the obstruction is indicated.

Colonic obstruction is rare following gynecologic surgery but carries a high mortality rate (Krstic, 2014). The colon can be obstructed by intrinsic lesions such as colon cancer or diverticulitis-related strictures or can be compressed by a

pelvic mass or foreign body, such as a retained surgical sponge. An enlarged cecum found on an abdominal radiograph requires further evaluation by either a barium enema or colonoscopy. Immediate intervention is necessary when the cecal diameter exceeds 10 to 12 cm to minimize perforation risks.

■ **Diarrhea**

Transient episodes of postoperative diarrhea are not uncommon after major gynecologic surgery as the GI tract returns to its baseline motility and function. Protracted episodes and excessive amounts of diarrhea almost always stem from infection and warrant further evaluation. Stool samples are examined for ova and parasites, cultured for bacteria, and assayed for *Clostridium difficile* toxin. Of potential etiologies, broad-spectrum antibiotics can impair normal GI flora growth and thereby promote *C difficile* toxin-associated pseudomembranous colitis. If toxin is identified, oral metronidazole or vancomycin is initiated and continued for 10 to 14 days after diarrhea resolution (Cohen, 2010). Regardless of the pathogen, aggressive fluid and electrolyte replacement is critical to prevent further aberrations that can delay recovery.

■ **Nutrition**

The primary goals of postoperative nutrition are to improve immune function, promote wound healing, and minimize metabolic disturbances. Despite the additional stress in the immediate postoperative period, underfeeding is accepted for a brief period (Seidner, 2006). Table 42-8 offers a summary of basic immediate postoperative metabolic needs. However, extended protein calorie restriction in a surgical patient can lead to impaired wound healing, diminished cardiac and pulmonary function, bacterial overgrowth within the GI tract, and other complications that increase hospital stays and patient morbidity (Elwyn, 1975; Kinney, 1986; Seidner, 2006). If substantial oral caloric intake is delayed for 7 to 10 days, nutritional support is warranted.

In the absence of contraindications, enteral nutrition is preferred to a parenteral route, especially when infectious complications are compared (Kudsk, 1992; Moore, 1992). Other advantages of enteral nutrition include fewer metabolic disturbances and lower cost (Nehra, 2002).

**URINARY COMPLICATIONS**

■ **Oliguria**

**Prerenal Oliguria**

Postoperative oliguria is defined as urine production less than 0.5 mL/kg/hr. Oliguria can be caused by a prerenal, intrarenal, or postrenal insult, and a systematic approach typically allows differentiation among these.

Prerenal oliguria is a physiologic response to hypovolemia, and coexistent tachycardia and orthostatic hypotension usually reflect this volume depletion. Causes of postoperative hypovolemia are varied and include acute hemorrhage, vomiting, severe diarrhea, and inadequate intraoperative volume replacement. In response to hypovolemia, the renin-angiotensin system is activated, and antidiuretic hormone (ADH) is released to prompt reabsorption of sodium and water by the renal tubules. Prerenal oliguria is the result of this sequence.

Treatment focuses on volume replacement. Thus, an accurate assessment of the patient's fluid deficit is critical. Tallying estimated surgical blood loss and data from the intraoperative fluid logs kept by the anesthesiologist will help begin the calculations. Insensible loss during laparotomy approximates 150 mL/hr.

**Intrarenal Oliguria**

Ischemic injury can lead to necrosis of the renal tubules and decreased filtration. This damage may be more common in a prerenal setting, in which the renal tubules are more vulnerable to insult from nephrotoxic agents such as NSAIDs, aminoglycosides, and contrast media. In many cases, intrarenal and prerenal oliguria can be differentiated by calculating the fractional excretion of sodium (FENa). Using sodium (Na<sup>+</sup>) and creatinine (Cr) levels from both serum and urine, this is defined as:

$$(\text{Urine Na}^+ / \text{plasma Na}^+) \div (\text{Urine Cr} / \text{plasma Cr}).$$

A ratio < 1 suggests a prerenal source, whereas a ratio > 3 indicates an intrarenal insult. Another difference is urine sodium levels. In prerenal oliguria, the level is typically < 20 mEq/L, whereas in intrarenal states, it usually is > 80 mEq/L.

**Postrenal Oliguria**

The most common cause of postrenal oliguria is urinary catheter obstruction. In those without a catheter, urinary retention is most

**TABLE 42-8.** Postoperative Nutritional Requirements

Nutritional Requirements	Recommendations
BEE in women	65.5 + 1.9 (height in cm) + 9.6 (weight in kg) - 4.7 (age in years)
Total calories	100% to 120% BEE
Glucose	50–70% total caloric intake. Maintain blood glucose level < 200 mg/dL
Protein	1.5 g/kg/d of current weight (BMI < 25) 2.0 g/kg/d of ideal weight (BMI > 25)

BEE = Basal energy expenditure; BMI = body mass index.  
Data from Nehra V: Fluid electrolyte and nutritional problems in the postoperative period. Clin Obstet Gynecol 2002 Jun;45(2):537–544.

likely. More seriously, ligation or laceration to the ureter or bladder may be sources. Importantly, partial or unilateral obstruction may exist despite adequate urine output. With this, associated findings may include hematuria, flank or abdominal pain, or ileus.

For diagnosis, renal sonography is highly sensitive and specific for confirming hydronephrosis. Additional diagnostic tools to identify ureteral obstruction include CT with IV contrast or retrograde pyelography. Importantly, IV contrast can be nephrotoxic, and thus CT with contrast may be a less than ideal choice for those with already elevated creatinine levels. As discussed in Chapter 40 (p. 868), the obstruction may be relieved with ureteral stenting alone or may require surgical repair.

## ■ Urinary Retention

Inability to void with a full bladder is common after gynecologic surgery, and incidences range from 7 to 80 percent depending on the definition used and surgical procedure (Stanton, 1979; Tammela, 1986). Overdistention can lead to prolonged difficulty with micturition and even permanent detrusor damage (Mayo, 1973). In addition to patient discomfort, recatheterization to treat retention increases the risk of urinary tract infection and may extend hospitalization.

Keita and colleagues (2005) prospectively evaluated risk factors potentially predictive of early postoperative urinary retention. Three major factors were independently associated with an increased risk—age greater than 50 years, intraoperative IV fluid administration greater than 750 mL, and bladder urine volume greater than 270 mL measured upon entry to the recovery room. Among gynecologic procedures, the risk is higher after laparotomy compared with laparoscopy (Bodker, 2003).

Despite identifiable risks, all women are advised on the need for immediate evaluation of absent or difficult voiding. Clinical markers that include pain, tachycardia, urge to void without success, and bladder enlargement by palpation or percussion are diagnostically equivalent to evaluation using bedside bladder sonography (Bodker, 2003).

Once retention is identified, catheterization and bladder drainage should follow. Lau and Lam (2004) sought to determine the best catheterization strategy for managing postoperative urinary retention. Compared with overnight bladder decompression with an indwelling catheter, episodic in-and-out catheterization is equally effective. Moreover, infectious morbidity rates do not significantly differ between the two.

## Voiding Trials

Normal urination requires appropriate bladder contractility in the absence of significant urethral resistance (Abrams, 1999). Objective criteria that define normal function postoperatively vary and may be assessed using either active or passive voiding trials.

With an *active voiding trial*, the bladder is filled with a set volume, and following patient voiding, residual bladder urine volumes are calculated. To begin, the bladder is completely emptied by catheterization. It may be helpful for a woman to stand upright to clear the most dependent portions of her bladder. Next, sterile water infused under gravity is instilled into the bladder through the same catheter until approximately 300 mL is used or until a subjective maximum capacity is reached. A

patient is then given up to 30 minutes to void spontaneously into a urine collection device. The difference between volume infused and volume retrieved is recorded as the *postvoid residual*.

The only published study evaluating the effectiveness of this strategy was reported by Kleeman and associates (2002). They evaluated women following surgery for incontinence and prolapse. In their study, a postvoid residual of less than 50 percent carried a recatheterization rate of 8 percent. If patients could spontaneously void greater than 70 percent of the instilled volume, there were no failures.

A *passive voiding trial* serves as an alternative, and residuals may be assessed following passive, physiologic filling of the bladder. To begin, the Foley catheter is removed, and a woman is encouraged to drink increased amounts of liquid. She is encouraged to void spontaneously at her first urge to urinate or after 4 hours, whichever is first. Urine volumes in a collection device are measured. An in-and-out catheterization or bladder sonogram is then performed to measure the postvoid residual (Fig. 23-12, p. 526).

An easy rule to remember for evaluating either active or passive voiding trials is the “75/75 rule,” which is spontaneously voiding greater than 75 mL *and* voiding greater than 75 percent of the total volume. This constitutes a successful voiding trial and obviates the need for Foley catheter reinsertion. Alternatively, on the Urogynecology Service at Parkland Memorial Hospital, a postvoid residual of less than 100 mL constitutes a success.

## PSYCHIATRIC COMPLICATIONS

Brief periods of confusion are not uncommon after general anesthesia. Delirium is estimated to complicate approximately 10 to 60 percent of all surgical cases (Ganai, 2007). Elderly patients have an elevated risk, which is associated with longer hospital stays, greater hospital costs, and even risk of death (Bilotta, 2013).

The clinical diagnosis of delirium is based on five criteria as outlined by the Diagnostic and Statistical Manual of Psychiatric Disorders (DSM-5): cognition changes, disturbance in attention and awareness, an acutely fluctuating time course, changes unrelated to a neurocognitive disorder, and a direct physiologic cause that underlies the delirium (American Psychiatric Association, 2013). There is no standard definition of postoperative delirium, but most studies note it between 24 and 72 hours after surgery. The Confusion Assessment Method (CAM) is a simple four-question tool, which has a sensitivity of 94 percent and specificity of 89 percent (Table 42-9) (Inouye, 2014).

Risk factors for postoperative delirium can be categorized as modifiable or nonmodifiable. Risks that can be altered include infection, pain, sodium and potassium electrolyte abnormalities, anemia, hypoxia, polypharmacy, sleep-wake cycle disruption, and certain medication classes (American Geriatric Society, 2015; Sanders, 2011). Notable groups are opiates, antihistamines, anticholinergics, benzodiazepines, and dihydropyridines, which include calcium-channel blocking agents. Nonmodifiable factors are increased age, preexisting cognitive deficits, poor preoperative functional status, and comorbid disease.

Treatment for postoperative delirium engages several strategies. First, oxygenation, electrolyte, and fluid imbalances are

**TABLE 42-9.** Confusion Assessment Method Short Form Questionnaire

**Feature 1: Acute Onset and Fluctuating Course**

- Acute change in mental state from baseline?
- Did this behavior fluctuate during interview?

**Feature 2: Inattention**

- Did the patient have difficulty focusing attention?

**Feature 3: Disorganized Thinking**

- Was the patient’s thinking disorganized or incoherent?

**Feature 4: Altered Level of Consciousness**

- Hyperalert, lethargic, stuporous, or unarousable?

Delirium is diagnosed if the following are present:  
Feature 1 and feature 2 PLUS either feature 3 or 4.  
Data from Inouye SK, van Dyck CH, Alessi CA, et al:  
Clarifying confusion: the confusion assessment method.  
A new method for detection of delirium. *Ann Intern Med* 1990 Dec 15;113(12):941–948.

corrected. Second, pain and potential infection are carefully assessed. In addition, all nonessential medications are halted to minimize confounding factors. Other strategies incorporate increased activity through physical therapy, establishment of distinct sleep-wake cycles, and even light therapy (de Jonghe, 2011; Ono, 2011).

**FLUID AND ELECTROLYTE ABNORMALITIES**

■ **Hypovolemic Shock**

Circulatory dysfunction decreases tissue oxygenation and results in multiorgan failure if not recognized and treated promptly. In gynecology, the most frequent cause of shock is hemorrhage-related hypovolemia, although cardiogenic, septic, and neurogenic shock are considered during patient evaluation. Hypovolemic shock may develop before, after, or during surgery, and a full discussion of the topic is found in Chapter 40 (p. 864).

■ **Hyponatremia**

This common imbalance is defined as a serum sodium level < 135 mEq/L and may produce symptoms as levels drop below 125 mEq/L. Of causes, hypotonic fluid administration is often implicated. Aggressive IV crystalloid resuscitation with comparatively hypotonic fluids is one example. Another is venous absorption of large volumes of certain distending media during long operative hysteroscopy cases (Chap. 41, p. 904). Second, pain or drugs can induce water retention through a syndrome of inappropriate ADH (SIADH) (Steele, 1997). Alternatively, excessive renal excretion of sodium is seen with diuretic overuse and adrenal insufficiency. Last, extrarenal sodium losses may follow profuse diarrhea, vomiting, or nasogastric suctioning.

Severe hyponatremia can lead to metabolic encephalopathy with associated cerebral edema, seizures, increased intracranial pressure, and even respiratory arrest. Symptoms are not related to the specific serum sodium level as much as to the rate of change in these levels.

Treatment strategies incorporate the patient’s extracellular volume status and the presence or absence of neurologic

symptoms. The speed of correction ideally does not exceed 0.5 mEq/L/hr or a serum sodium goal of 130 mEq/L. Over aggressive correction can result in a specific demyelination disorder known as central pontine myelinolysis. In those without symptoms, careful replacement with isotonic fluids and treatment of underlying conditions will correct most cases. Frequent serum sodium levels are drawn to direct care. With associated hypervolemia, furosemide (Lasix) may be added. In those with acute neurologic symptoms, 3-percent saline can be given in a 100 mL infusion over 30 minutes and repeated an additional two times if needed (Nagler, 2014; Verbalis, 2013).

■ **Hypernatremia**

Hypernatremia is defined as a serum sodium concentration exceeding 145 mEq/L. Common causes are loss of hypotonic body fluids such as diarrhea, gastric secretions, and sweat. The resulting plasma hypertonicity draws water out of cells to maintain intravascular fluid compartment volume. Brain cell shrinkage can cause vascular bleeds and permanent neurologic damage. To restore brain cell volume, the brain metabolically generates compensatory compounds, termed idiogenic osmoles, which pull water back into its cells. Therefore, aggressive treatment with hypotonic fluids can overcorrect to create cerebral edema, seizure, coma, and even death (Adrogué, 2000). Volume replacement to correct hemodynamic instability is initiated with isotonic fluids or colloid fluids. Then, hypernatremia is corrected using hypotonic solutions.

Diabetes insipidus is a condition of renal water wasting, and an excessive amount of urine devoid of solutes is produced. Central diabetes insipidus is caused by a failure to release ADH whereas nephrogenic diabetes insipidus is caused by a deficit in the renal responsiveness to ADH. As treatment, the free water deficit is replaced over 2 to 3 days. In cases of central diabetes insipidus, the addition of ADH (vasopressin) prevents ongoing free water loss (Blevins, 1992).

■ **Hypokalemia**

This imbalance is defined as serum potassium below 3.5 mEq/L. Hypokalemia is usually caused by diarrhea or by abnormal renal loss secondary to metabolic alkalosis. Mild hypokalemia is often asymptomatic, but nonspecific symptoms seen with progression include generalized weakness and constipation. When the serum levels fall below 2.5 mEq/L, muscle necrosis can begin, and an ascending paralysis can develop with levels below 2.0 mEq/L. Hypokalemia in isolation does not produce cardiac arrhythmia, but it can promote dysfunction in combination with magnesium depletion, myocardial ischemia, and digitalis use (Schaefer, 2005).

The cornerstone of hypokalemia management is potassium replacement. Compared with IV replacement, oral potassium is safer, as it enters the circulation more slowly and reduces the risk of iatrogenic hyperkalemia. The maximum rate of IV potassium replacement is 20 mEq/hr, and the patient’s cardiac rhythm is concurrently monitored (Kruse, 1990). Magnesium depletion can cause hypokalemia refractory to replacement efforts, and magnesium may need to be concomitantly replenished (Whang, 1985).

## ■ Hyperkalemia

This imbalance is defined as a serum potassium concentration exceeding 5.0 to 5.5 mEq/L. Pseudohyperkalemia can result from traumatic hemolysis, release from muscles distal to a tourniquet, or cellular release from a clotted specimen tube. Unsuspected findings in an asymptomatic patient should prompt a repeat measurement. Transcellular shifts in potassium are seen with digitalis and  $\beta$ -receptor antagonists. More importantly, medication-induced renal excretion impairment is one of the leading causes of hyperkalemia. The most commonly implicated medication classes are angiotensin-converting enzyme (ACE) inhibitors, potassium-sparing diuretics, and NSAIDs (Palmer, 2004; Perazella, 2000).

Hyperkalemia can slow electrical conduction in the heart. The earliest ECG findings of hypokalemia are narrowing and tenting of the T waves. As hyperkalemia progresses, the PR interval lengthens, P waves disappear, and QRS intervals ultimately widen.

Three principles govern hyperkalemia management: (1) protecting the myocardium, (2) shifting potassium intracellularly, and (3) enhancing potassium excretion. Intravenous calcium gluconate administered as 10 mL of a 10-percent solution over 2 to 3 minutes antagonizes the effect of potassium on myocardial repolarization and the conduction system. If there are no improvements in the ECG, calcium administration can be repeated 5 to 10 minutes later. Also, a combination of IV insulin (10 units) and 50 mL of 50-percent dextrose can temporarily shift potassium to the intracellular compartment. In addition, a  $\beta_2$  agonist, such as inhaled albuterol, can help by activating the  $\text{Na}^+/\text{K}^+$ -ATPase channel to also drive a potassium shift. Finally, potassium excretion can be cleared across the GI mucosa using sodium polystyrene sulfonate (Kayexelate), cleared renally using loop diuretics, or cleared with dialysis for those with impaired renal function.

## POSTOPERATIVE FEVER

### ■ Pathophysiology

Fever is a response to inflammatory mediators, termed pyrogens, which originate either endogenously or exogenously. Circulating pyrogens lead to production of prostaglandins (primarily  $\text{PGE}_2$ ), which elevate the thermoregulatory set point. The inflammatory cascade also produces several cytokines after various events, namely, surgery, cancer, trauma, and infection (Wortel, 1993). Thus, fever is common after surgery and is self-limited in most cases (Garibaldi, 1985). However, for those with persistent symptoms, a systematic approach to patient evaluation helps differentiate inflammatory from infectious etiologies.

Fevers that develop more than 2 days after surgery are more likely to be infectious. More broadly, causes may be categorized by the mnemonic, the “Five Ws,” which represent wind, water, walking, wound, and “wonder” drug. First, pneumonia is considered, and women at greatest risk are those who have been mechanically ventilated for a prolonged period, have an NGT in place, or have preexisting chronic obstructive pulmonary disease (COPD). Second, catheterization places women at risk for urinary tract infection. Logically, catheterization duration correlates positively with this infection risk. Third, VTE may pres-

ent with low-grade fever and other disease-specific symptoms. For example, women with DVT often complain of unilateral lower-extremity edema and erythema. Those with PE may note dyspnea, cough with blood-tinged sputum, chest pain, tachycardia, and symptoms of hypotension. Fourth, fever related to surgical site infections usually develops 5 to 7 days after surgery. These infections may involve the pelvis or abdominal wall layers. Last, medications commonly used postoperatively—such as heparin,  $\beta$ -lactam antibiotics, and sulfonamide antibiotics—may cause a rash, eosinophilia, or drug fever.

### ■ Clinical Evaluation

In multiple studies, fever evaluations that rotely include complete blood count (CBC), urinalysis, blood cultures, and chest radiographs are reported to be ineffective (Badillo, 2002; de la Torre, 2003; Schey, 2005). Thus, initial assessment of a woman with postoperative fever is individualized and begins with a focused history and physical examination. The simple diagnostic algorithm presented in Figure 42-2 can be used as one high-yield, cost-effective strategy. Treatment of wound infections is described in Chapter 3, whereas management of pulmonary complications and VTE were discussed earlier (p. 912).

## POSTOPERATIVE WOUND

### ■ Acute Wound Healing

Wound healing has three phases—inflammatory reaction, proliferation, and remodeling (Li, 2007). Hemostasis by coagulation initiates the first step in the *inflammatory phase*. The infiltration of leukocytes and release of cytokines helps initiate the *proliferative phase* of wound repair. During this, two activities happen simultaneously—the growth of granulation tissue to fill the wound and the formation of epithelium to cover the wound. The final stage, *remodeling*, restores the structural integrity and functional aptitude of the new tissue.

### ■ Wound Dehiscence

#### Classification and Incidence

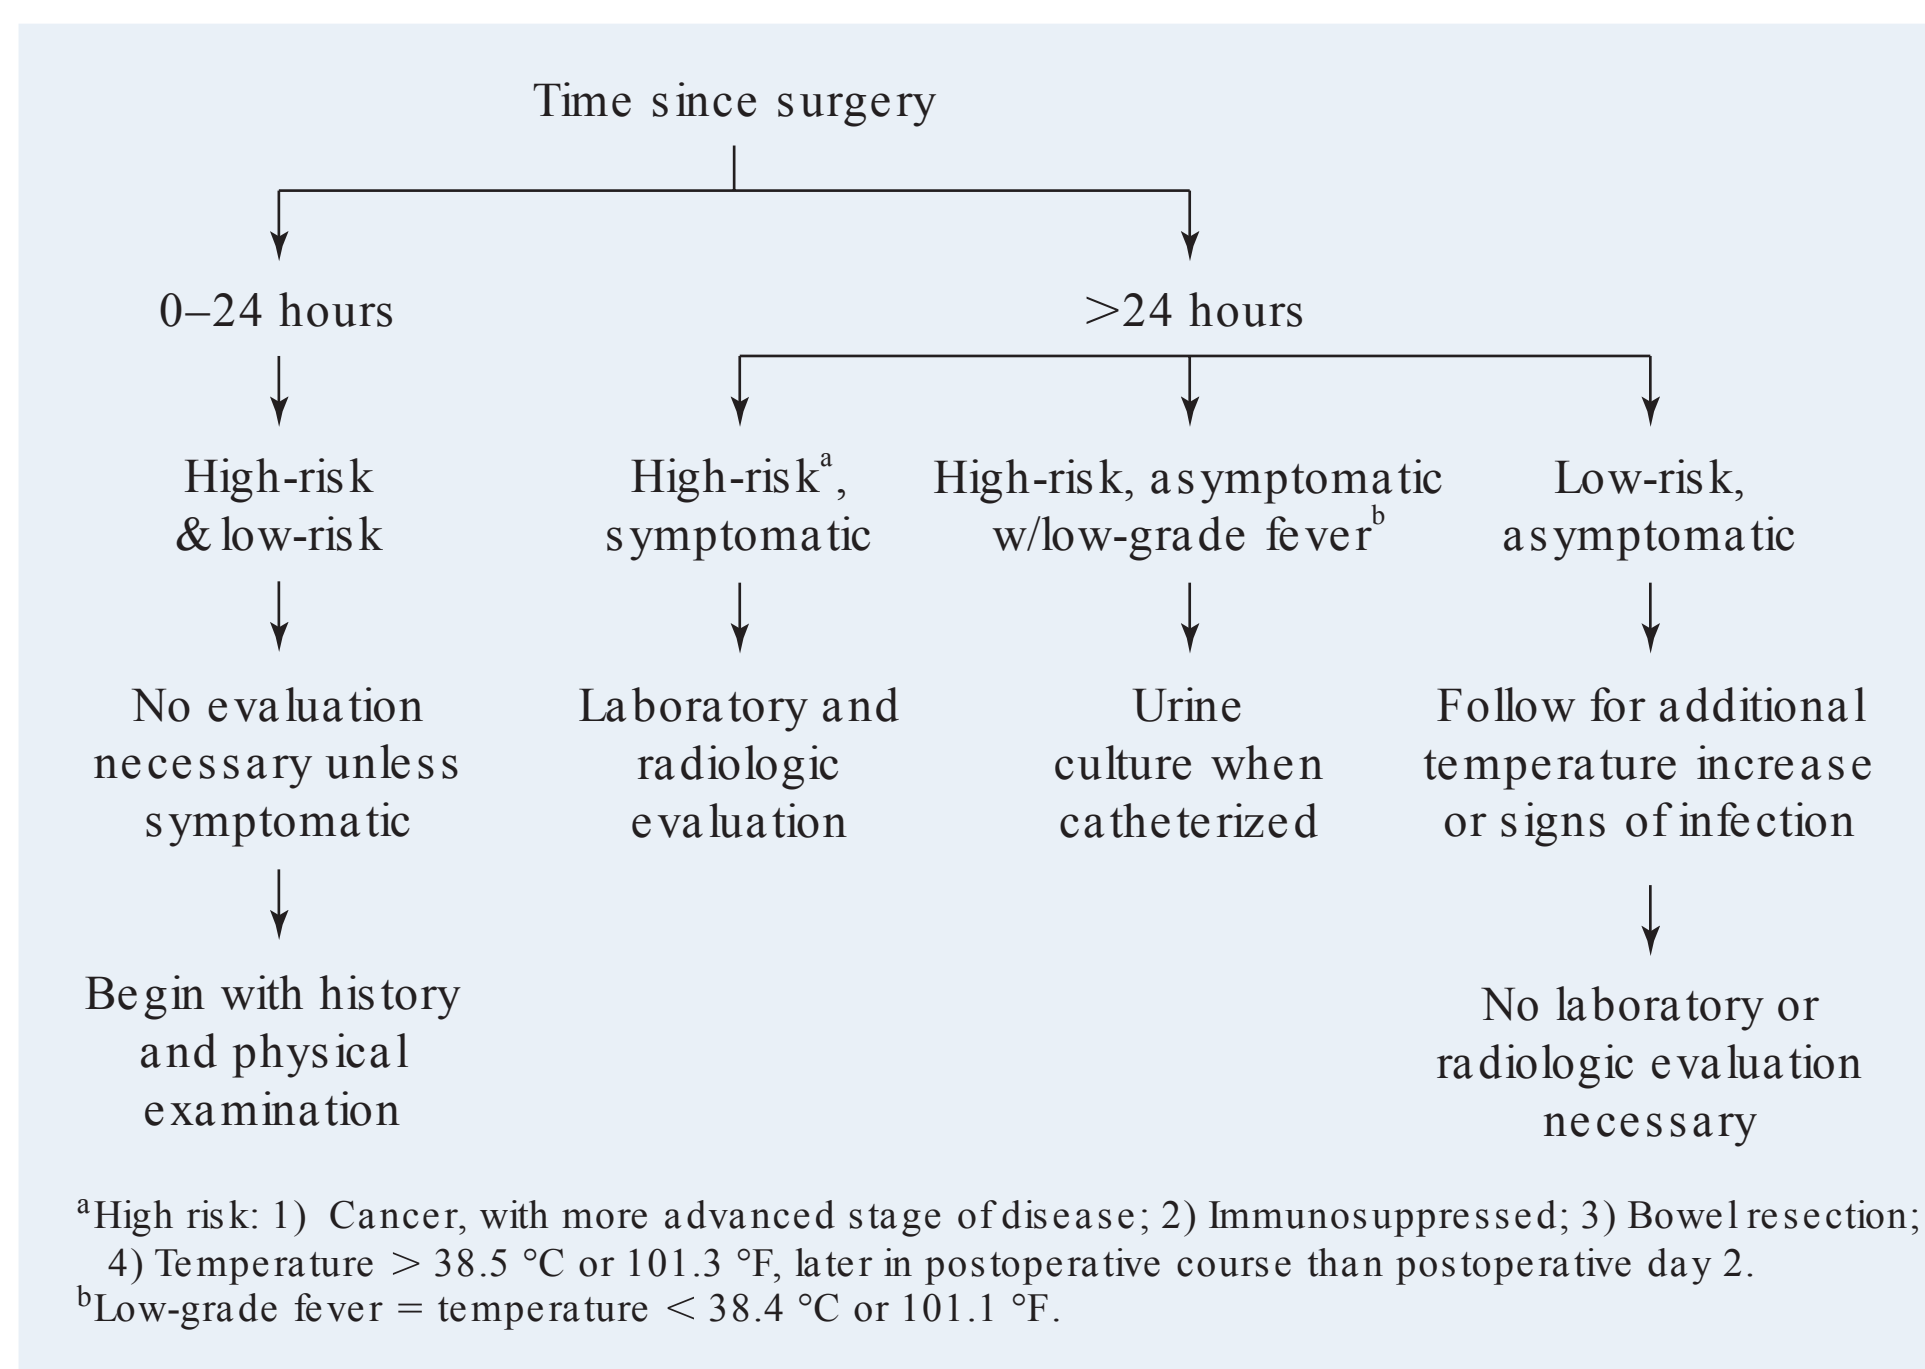

The depth to which a wound may open varies and may involve only the subcutaneous and skin layers. Such superficial separation can result solely from a hematoma or seroma, but more commonly is a consequence of wound infection. The reported incidence of superficial separations ranges from 3 to 15 percent (Owen, 1994; Taylor, 1998).

More seriously, separation can include the abdominal wall fascia. Fascial dehiscence occurs less frequently and is fatal in nearly 25 percent of cases (Carlson, 1997). Infection or sutures held under too much tension are notorious causes and lead to fascial necrosis. Sutures remain poorly anchored in necrotic fascia (Bartlett, 1985). These layers then separate with only minimal increases in intraabdominal pressure.

#### Prevention

Rates of wound dehiscence are affected by general patient health, surgical technique, and risks associated with wound infections. Of these, patient health factors may or may not be modifiable.

**FIGURE 42-2** Algorithm for evaluation of postoperative fever. (Reproduced with permission from de la Torre SH, Mandel L, Goff BA: Evaluation of postoperative fever: usefulness and cost-effectiveness of routine workup. *Am J Obstet Gynecol* 2003 Jun;188(6):1642–1647.)

Characteristics that confer an increased wound disruption risk include age greater than 65 years, pulmonary disease, malnutrition, obesity, malignancy, immunocompromised states, diabetes mellitus, and hypertension (Hodges, 2014; Riou, 1992).

Using proper surgical technique, a surgeon has multiple opportunities to lower wound disruption rates. Described in greater detail in Chapter 40 (p. 847), ideal technique advocates hemostasis, gentle tissue handling, removal of devitalized tissue, closure of dead space, use of monofilament suture in tissue at risk for infection, judicious use of closed-suction drains, and sustained normothermia (Mangram, 1999).

Last, infection is a common underlying cause of wound disruption. Risk factors for infection are numerous and are listed in Table 3-18 (p. 75). Of these, many conditions can be improved preoperatively (Table 42-10).

## Diagnosis

Superficial wound separations usually present 3 to 5 days after surgery, with wound erythema and new drainage. A delay in evacuating inflammatory exudates from within subcutaneous-layer dead space can lead to fascial weakening and an increased risk of fascial dehiscence.

Fascial dehiscence generally presents within the first 10 days postoperatively. Superficial disruption of the subcutaneous layer and extensive leakage of peritoneal fluid or purulent drainage are indicative. Given the high mortality risk associated with fascial dehiscence and bowel evisceration, examination under anesthesia to estimate the extent of separation is often warranted.

## Superficial Wound Dehiscence Treatment

**Wet-to-dry Dressing Changes.** With initial wound management, all hematomas, seromas, or pus are evacuated, and necrotic tissue is debrided. If needed, underlying infection is

treated with antibiotics. As discussed in Chapter 3 (p. 80), most abdominal wound infections that follow clean cases originate from *Staphylococcus aureus*. In contrast, those after clean-contaminated cases have a greater chance of being polymicrobial. Thus, antibiotic regimens that cover gram-positive and gram-negative organisms are suitable (Table 3-20, p. 79). In these infections, anaerobes play a lesser role. Importantly, the number of infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) has increased dramatically, and coverage for this pathogen is considered.

After evacuation, wounds are typically gently filled with fluffed-out gauze to provide continued wound drainage and access for additional debridement. This dressing is usually removed daily and replaced with new moist gauze. Solutions used in this dressing remove surface bacteria without disrupting normal healing components. Thus, povidone iodine, iodophor gauze, dilute hydrogen peroxide, and Daiken solution, which are cytotoxic to white blood cells, should play a limited role in wound care (Bennett, 2001; O'Toole, 1996). In very necrotic wounds, allowing gauze to dry and pulling tissue adherent to the gauze with each change is acceptable. More frequent dressing changes are avoided as they lead to aggressive debridement of vital tissues and slow wound healing. Table 42-11 lists products used in modern wound care.

**Negative-pressure Wound Therapy.** This is primarily used for acute wounds to minimize scarring or for chronic wounds that have been resistant to other forms of wound care. The five mechanisms by which this technology aids wound healing are wound retraction, continuous wound cleaning, stimulation of granulation tissue formation, reduction of interstitial edema, and removal of exudates. The external forces create microdefects in individual cells that stimulate the cellular repair process and lead to cell proliferation within the wound. The negative pressure generated by such devices provides three wound care actions: (1) evacuates wound drainage to reduce bacterial

**TABLE 42-10.** Selected Interventions for Surgical Site Infection Prevention

**Preoperative**

Reduce hemoglobin A<sub>1c</sub> levels to < 7% before operation  
Stop smoking 30 d before operation (Table 1-4, p. 11)  
Administer specialized nutritional supplements or enteral nutrition for severe malnutrition for 7–14 d preoperatively  
Adequately treat preoperative infections, such as UTI or cervicitis

**Perioperative**

Remove interfering hair immediately before surgery by clipping or depilatories; no perioperative shaving  
Use an antiseptic surgical scrub or alcohol-based hand antiseptic for preoperative cleansing of the operative team members’ hands and forearms  
Prepare the skin around the operative site with an antiseptic agent based on chlorhexidine, alcohol, or iodine/iodophors  
Administer prophylactic antibiotics for most clean-contaminated, contaminated, and dirty procedures (Table 39-6, p. 835).  
Administer prophylactic antibiotics within 1 hr before incision (2 hr for vancomycin and fluoroquinolones)  
Use higher dosages of prophylactic antibiotics for morbidly obese patients  
Use vancomycin as a prophylactic agent only when there is a significant MRSA infection risk  
Provide adequate ventilation, minimize operating room traffic, and clean instruments and surfaces with approved disinfectants  
Avoid flash sterilization

**Intraoperative**

Carefully handle tissue, eradicate dead space, and adhere to standard principles of asepsis  
Avoid use of surgical drains unless absolutely necessary  
Leave contaminated or dirty-infected wounds open  
Redose prophylactic antibiotics with short half-lives intraoperatively if operation is prolonged (for cefazolin if operation is > 3 hr) or if there is extensive blood loss (> 1500 mL)  
Maintain intraoperative normothermia

**Postoperative**

Maintain serum glucose levels < 200 mg/dL on postoperative days 1 and 2  
Monitor wound infection

MRSA = methicillin-resistant *Staphylococcus aureus*; SSI = surgical site infection; UTI = urinary tract infection.

**TABLE 42-11.** Wound Care Products

Product	Description
Antifungal cream	Topical cream used as treatment for superficial fungal infections of the periwound skin; contains 2% miconazole nitrate.
Calcium alginate	Calcium alginate is a solid that exchanges calcium ions for sodium ions when it contacts any substance containing sodium such as wound fluid. The resulting sodium alginate is a gel that is nonadhesive, nonocclusive, and conformable to the wound bed. Indicated for moderately or highly draining wounds.
Enzymatic debrider	Topical solution that breaks down necrotic tissue by directly digesting the components of slough or by dissolving the collagen that holds necrotic tissue to the underlying wound bed.
Film	Thin, transparent polyurethane sheets coated on one side with acrylic, hypoallergenic adhesive. The adhesive will not stick to moist surfaces, and the film is impermeable to fluids and bacteria, but semipermeable to oxygen and water vapor. Indicated in superficial wounds with little or no exudate.
Foam	Polyurethane sheets containing open cells capable of holding fluids and pulling them away from the wound bed. Foams provide absorbency while keeping the wound moist. Indicated in moderately or highly draining wounds.
Gauze	Woven or nonwoven cotton or synthetic blends.
Hydrogel	Formulated in sheets or gels. Glycerin-, saline-, or water-based to hydrate the wound. Indicated in dry or minimally draining wounds.
Silver nitrate	Used to treat overgrown granulation tissue. Apply stick to hypergranulation tissue.

Reproduced with permission from Sarsam SE, Elliott JP, Lam GK: Management of wound complications from cesarean delivery. *Obstet Gynecol Surv* 2005 Jul;60(7):462–473.

**FIGURE 42-3** Wound vacuum in place. Porous synthetic sponge fills the wound. Negative pressure is created by one end of tubing placed within the sponge and the other attached to a suction-generating device. The sponge and wound are covered by an occlusive adhesive dressing, which helps to maintain the suction seal.

colonization, (2) promotes release of cytokines that are helpful in wound healing, and (3) increases blood flow and oxygenation to tissues to uniformly reduce wound size and improve angiogenesis (Fabian, 2000; Morykwas, 1997; Sullivan, 2009).

The two most commonly used dressings are foam and moistened nonadherent cotton gauze. After the initial application, the dressing is typically changed within 48 hours and then two to three times a week thereafter. After the dressing is covered with an adhesive film dressing, a suction-generating evacuation tube runs through the dressing to help draw excessive exudates away from the wound and into a canister attached at the other end (Fig. 42-3). The vacuum pump offers either continuous or intermittent negative pressure.

**Delayed Primary Closure.** Approximately 4 days after wound disruption and resolution of subcutaneous infection, a superficial vertical mattress closure with delayed-absorbable suture may be used to reapproximate tissue edges (Wechter, 2005). Depending on wound depth and patient tolerances, this can be completed in the operating room or at the bedside using a local anesthetic complemented by systemic analgesia. Overall, this strategy reduces healing time by 5 to 8 weeks and significantly decreases the number of postoperative visits.

### Fascial Dehiscence Treatment

Early recognition of abdominal wall separation is critical in reducing the serious morbidity and mortality rates. Fascial dehiscence is regarded as a surgical emergency, and a gynecologist must first determine if it is associated with evisceration of abdominal content. If abdominal contents are extruded, sterile towels soaked in saline and an outer abdominal binder can be used to cover and gently replace abdominal contents. Broad-spectrum antibiotics are generally recommended to minimize ensuing peritonitis.

The final goal of treatment is fascial closure. For critically ill patients with significant edema, temporarily maintaining

anterior abdominal wall integrity with retention sutures until a patient is stable enough to tolerate a definitive operative closure is reasonable. After sufficient debridement of necrotic or infected tissue under general anesthesia, fascial closure may be performed. An interrupted mass closure using a no. 2 permanent suture is typically recommended. However, if primary fascial closure is under significant tension, a synthetic mesh bridge may be required. Typically considered a dirty wound, the subcutaneous layer is often left open. Wet-to-dry dressing changes are performed until the decision is made to proceed with delayed primary closure or allow secondary intention to complete the process (Cliby, 2002).

43-1

Midline Vertical Incision

Abdominal entry is the first step for many gynecologic surgeries. Either vertical or transverse incisions may be used, and each offers particular advantages. Vertical incisions may be midline or paramedian, but of the two, the midline is chosen more often. This incision offers quick entry, minimal blood loss,

superior access to the upper abdomen, generous operating room, and the flexibility for easy wound extension if greater space or access is needed. No important neurovascular structures traverse this incision. Thus, it may be favored for patients using anticoagulation agents. Despite advantages, midline incisions are more frequently associated with greater postoperative pain, poorer cosmetic results, and increased risks of wound dehiscence or incisional hernia compared with low transverse incisions. Last, for those with prior laparotomy, the incision type is typically repeated for subsequent surgeries.

PREOPERATIVE

- **Consent**  
For abdominal entry, patients are informed of wound infection or dehiscence risks. Additionally, the chance of bowel or bladder injury is present with any abdominal entry, especially when extensive adhesions are encountered.
- **Prophylaxis**  
Laparotomy per se does not require antibiotic prophylaxis or bowel preparation. These are

dictated by the planned procedure. Prevention for venous thromboembolism is warranted, and options are described in Chapter 39 (p. 835).

## INTRAOPERATIVE

### Surgical Steps

#### □ Anesthesia and Patient Positioning.

After administration of adequate regional or general anesthesia, the patient is positioned supine. If needed, hair in the path of the planned incision is clipped; a Foley catheter is placed; and abdominal preparation is completed.

□ **Skin and Subcutaneous Layer.** The skin is incised vertically in the midline beginning 2 to 3 cm above the symphysis pubis and extending cephalad to within 2 cm of the umbilicus. If less space is required, this incision may be shortened. For greater space or access, the incision may arch around the umbilicus and then continue cephalad in the upper abdominal midline. The extension passes to the left of the umbilicus to avert transection of the ligamentum teres. The remnant of the umbilical vein courses in the free border of the falciform ligament. The umbilicus itself contains attenuated fascia. Thus, the periumbilical incision should arch laterally enough to provide quality fascia on either side of the incision to allow an ultimately secure closure.

The subcutaneous layers of Camper and Scarpa are then incised either sharply with long even strokes or with electrosurgical blade to reach the linea alba fascia. Ideally, the number of blade strokes is minimized to avoid hatch marking the tissue, which increases tissue damage and wound infection risks.

□ **Fascia.** Tendinous fibers from the anterior abdominal wall aponeuroses merge in the midline of the abdomen to form the linea alba. This fascia layer is sharply entered near the midpoint of the incision (Fig. 43-1.1). This incision is extended first cephalad and then caudally to mirror the length of the skin incision. To minimize injury to viscera during this extension, the linea alba is elevated by index fingers of the surgeon and assistant or by the open tips of a pean clamp (Fig. 43-1.2).

Once the fascia is incised, the right and left rectus abdominis muscle bellies are bluntly separated laterally. Inferiorly, sharp incision may be required to complete this. To avert injury to organs below, the rectus muscles are elevated during this division. Each half of the pyramidalis muscle lies atop its respective rectus belly, and this muscle is similarly divided sharply at the midline.

FIGURE 43-1.1 Fascial incision.

□ **Peritoneum.** For entry, the peritoneum is identified between the rectus abdominis muscle bellies. It is grasped with two hemostats in the upper portion of the incision to avoid cystotomy. The interposed peritoneum should be palpated or visually examined to exclude intervening viscera. Only then is it sharply cut (Fig. 43-1.3). Next, an index finger sweeps directly beneath it to identify adhered bowel or omentum. If free, the peritoneum is elevated by fingers of the surgeon and assistant to protect viscera beneath. As the incision is extended cephalad above the arcuate line, the transverse fibers of the posterior rectus sheath are seen and are cut along with the peritoneum. As the incision is extended caudally, the transversalis fascia is found superficial to the peritoneum. To prevent bladder dome injury, this thin fascia layer is elevated by insinuating fingers beneath it and is cut, with the incision extending caudally. Next, the peritoneum beneath the transversalis fascia is similarly incised (Fig. 43-1.4). The bladder dome is identified by increasing tissue vascularity and thickness. Of note, the urachus, which is the remnant of the allantois, may be seen as a white cord extending from the bladder dome toward the umbilicus in the midline.

During abdominal entry, prior surgery may blur clear tissue planes. For example, the true midline may be deviated laterally, and after fascial incision, only rectus fibers may be seen. To find the midline after incising the fascia, fibers of the pyramidalis muscles can

FIGURE 43-1.2 Fascial incision extended cephalad.

be followed as they angle toward the midline. Also, visually recreating a line between the symphysis and umbilicus can aid orientation. To reach the midline, the fascia closest to the presumed midline is grasped both

FIGURE 43-1.3 Peritoneal incision.

**FIGURE 43-1.4** Peritoneal incision extended caudad.

cephalad and caudad along its length with Kocher clamps to create upward tension (Fig. 43-1.5). Simultaneously, downward manual pressure atop the ipsilateral rectus belly accentuates fibers between the fascia and underlying rectus belly. These fibers are then cut to permit lateral dissection of the fascia away from the rectus belly. This is continued laterally until the midline is identified. If the midline is not identified after some dissection on one side, the same steps can be repeated on opposite side.

Also with prior surgery, planes between the fascia, peritoneum, and viscera may be poorly defined. In these cases, a gradual layered entry is required to avoid organ injury. One technique uses Metzenbaum scissors. Scissor tips are insinuated between tissue layers such that

**FIGURE 43-1.5** Lateral subfascial dissection.

the tips are seen each time prior to cutting. This minimizes the risk that the thicker bowel or bladder wall will be cut. If adhesions are found, they are divided. Dissection is maintained close to the fascial or peritoneal edge to minimize visceral injury.

**Operative Field.** After abdominal entry, a self-retaining retractor is commonly placed to retract the bowel, omentum, and abdominal wall muscles. Moist laparotomy sponges are placed around the bulk of bowel and gently directed cephalad. Adhesiolysis may be required to adequately free intestines for this repositioning. Upper blades of the retractor assist in holding these loops up and away from the pelvis and operating field. The shortest blades possible are preferred for lateral

retraction. This reduces the risk of femoral or genitofemoral nerve compression by a blade resting atop the psoas major muscle. Once pelvic organs are adequately exposed, the planned abdominal surgery can proceed.

**Wound Closure.** Closure of the visceral or parietal peritoneum is not required and is individualized (Chap. 40, p. 847). Starting from each end of the incision, the fascia is closed to its midpoint using a continuous running suture with a 0-gauge delayed-absorbable suture. These sutures are then tied together. If the subcutaneous layer measures less than 2 cm, then no closure is typically necessary. For deeper wounds, interrupted stitches of 2-0 to 4-0 gauge absorbable or delayed-absorbable suture are used to close this layer. The skin is closed with a subcuticular stitch using 4-0 gauge delayed-absorbable suture, staples, or other suitable method (Chap. 40, p. 847).

## POSTOPERATIVE

For most gynecologic surgeries, recovery from the abdominal incision constitutes the greatest portion of postsurgical healing. Midline incisions lead to significant pain during ambulation, coughing, and deep breathing. As a result, women undergoing laparotomy are at greater risk of postoperative thrombotic and pulmonary complications. Prevention of these is warranted and described in Chapter 42 (p. 911). In addition, return of normal bowel function is commonly slowed, and signs of ileus should be monitored. Hospitalization typically varies from 1 to 3 days, and return of normal bowel function usually dictates this course. Postoperative activity in general can be individualized, although vigorous abdominal exercise is delayed for 6 weeks to allow for fascial healing. Driving can be resumed when pain does not limit the ability to brake quickly and when narcotic medications are not in use. Return to work is variable, although 6 weeks is commonly cited.

## 43-2

## Pfannenstiel Incision

The Pfannenstiel, Cherney, and Maylard incisions are transverse abdominal incisions used for gynecologic procedures. Of these, the Pfannenstiel incision is the most commonly used incision for laparotomy in the United States. Because the transverse incision follows Langer lines of skin tension, excellent cosmetic results can be achieved. Additionally, decreased rates of postoperative pain, fascial wound dehiscence, and incisional hernia are noted. Use of the Pfannenstiel incision, however, is often discouraged for cases in which greater operating space or upper abdominal access is anticipated. Last, because of the layers created by incision of the internal and external oblique aponeuroses, purulent fluid can collect between these. Therefore, cases involving abscess or peritonitis favor use of a midline incision, which divides the fused linea alba.

## PREOPERATIVE

## ■ Consent

General risks associated with transverse laparotomy incisions are similar to those for vertical incisions. Transverse incisions, however, carry risk of injury to the iliohypogastric and ilioinguinal nerves. These injuries frequently involve only transient sensory loss but rarely may lead to debilitating, chronic neuropathic pain.

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** After administration of adequate regional or general anesthesia, the patient is positioned supine. If needed, hair in the path of the planned incision is clipped; a Foley catheter is placed; and abdominal preparation is completed.

□ **Skin and Subcutaneous Layer.** Two to 3 cm above the symphysis pubis, an 8- to 10-cm transverse incision is made with its lateral margins arching slightly cephalad. If less space is required, this length can be shortened. The incision is deepened sharply with scalpel or electrosurgical blade until the anterior rectus sheath is reached. The superficial epigastric vessels typically lie several centimeters from the midline and halfway between the skin and fascia. Coagulation of these vessels will limit incisional blood loss.

FIGURE 43-2.1 Fascial incision.

□ **Fascia.** The anterior rectus sheath is sharply incised transversely in the midline (Fig. 43-2.1). At the level of the incision, the anterior rectus sheath is composed of two visible layers, the aponeuroses from the external oblique muscle and a fused layer containing aponeuroses of the internal oblique and transversus abdominis muscles. Lateral extension of the anterior rectus sheath incision requires cutting each layer individually (Fig. 43-2.2). This permits identification and ideally, avoidance of the iliohypogastric and ilioinguinal nerves as they run between these two fascial layers.

Of note, at the level of the incision, the inferior epigastric vessels typically lie outside the lateral border of the rectus abdominis muscle and beneath the fused aponeuroses of the internal oblique and transversus abdominis muscles. Thus, lengthening the incision farther laterally may cut these vessels. If significant lateral extension is required, these

vessels are identified, clamped, and ligated. This prevents bleeding and vessel retraction with later hemorrhage. In addition, risk of iliohypogastric and ilioinguinal nerve injury also increases as the incision is carried lateral to the rectus abdominis muscle borders (Rahn, 2010).

The superior edge of the fascial incision is grasped with a Kocher clamp on either side of the midline. Traction is directed cephalad and slightly outward. In the area superior to the initial incision, the anterior rectus sheath is then bluntly or sharply separated from the underlying rectus abdominis muscle (Fig. 43-2.3). With blunt dissection, upward facing fingers first push cephalad and then roll to direct pressure laterally. The fascia separates easily from the bellies of the rectus muscle, but it may be densely adhered along the midline and require sharp dissection (Fig. 43-2.4). Several small perforating nerves and vessels traverse the space between

FIGURE 43-2.2 Incision extended laterally.

**FIGURE 43-2.3** Blunt separation of anterior rectus sheath from underlying rectus abdominis muscle.

**FIGURE 43-2.4** Sharp separation in the midline.

**FIGURE 43-2.5** Fascial closure.

the anterior rectus sheath and rectus muscle. These vessels are coagulated to avoid laceration and bleeding. Upon completion of this dissection, a semicircular area with a radius of 6 to 8 cm has been created. A similar separation is performed in the area inferior to the initial fascial incision.

The rectus abdominis muscle bellies are then separated laterally from the midline either bluntly or sharply. The pyramidalis muscle, located superficial to the rectus muscle, usually requires sharp division at the midline.

**Peritoneum.** Peritoneal entry is fully described and illustrated in Section 43-1, Steps 3 and 4 (p. 927). To summarize, upon separation of the rectus muscle bellies, the thin, filmy peritoneum is identified, grasped with two hemostats, and sharply incised. The peritoneal incision is then extended superiorly and inferiorly. Once the abdominal cavity has been entered and clear visualization established, the surgeon can proceed with the planned operation.

**Wound Closure.** Closure of the visceral or parietal peritoneum is not required and is individualized. Starting from each end of the incision, the fascia is closed to its midpoint using a continuous running suture line with a 0-gauge delayed-absorbable suture (Fig. 43-2.5). These strands are then tied together. The subcutaneous layer and skin are closed similar to the midline vertical incision (Section 43-1, p. 928).

## POSTOPERATIVE

The postoperative course for low transverse incisions follows that described for midline incisions (p. 928).

## 43-3

## Cherney Incision

The Cherney incision is a transverse abdominal incision that is similar to the Pfannenstiel incision in its early steps. After the anterior rectus sheath is opened, however, the tendons of the rectus abdominis and pyramidalis muscles are transected 1 to 2 cm above their insertion into the symphysis pubis. These muscles are then lifted cephalad to provide access to the peritoneum. At this level, the inferior epigastric vessels run well lateral to the rectus bellies and typically are spared. However, if additional lateral extension is required, these vessels are ligated and transected.

This incision offers generous operating space and access to the space of Retzius. Thus, it may be a primary choice when these requirements are anticipated. Additionally, Pfannenstiel incisions may be converted to Cherney incisions when an unexpected need for additional space arises.

## PREOPERATIVE

Preparation and consenting prior to Cherney incision are similar to that for Pfannenstiel incision (p. 929).

## INTRAOPERATIVE

## Surgical Steps

□ **Initial Steps.** The initial steps mirror that of the Pfannenstiel incision (Steps 1-3, p. 929). Thus, the skin is incised transversely beginning 2 to 3 cm above the symphysis, the fascia is divided transversely, and the rectus sheath is dissected off the rectus abdominis muscle bellies. After these steps, however, the techniques diverge.

□ **Fascia.** The fascial opening reveals the rectus abdominis and pyramidalis muscles. Cephalad to the symphysis pubis, fingers are insinuated beneath the rectus muscle tendons. This blunt dissection begins laterally and extends toward the midline. During insinuation, fingers exert pressure dorsally and against the bladder to protect it during tendon division. After this, fingers lift up the muscle tendons, which are then transected 1 to 2 cm above the symphysis pubis (Fig. 43-3.1). The muscles are flipped up and cephalad.

The peritoneum is grasped with two hemostats at a level above the bladder dome and is sharply incised. This incision is extended laterally. Once the abdominal cavity

FIGURE 43-3.1 Tendon transection.

has been accessed, the planned surgery can proceed. Importantly, the risk of injury, particularly to the femoral and genitofemoral nerves, is increased when self-retaining retractors are used with this generally wider incision. This is also true for the Maylard incision. Thus, lateral retractor blades should fit just under the edges of the incision and not rest atop the psoas muscle.

□ **Wound Closure.** During wound closure, the cut ends of the rectus muscle tendons are affixed with interrupted sutures of 0-gauge delayed-absorbable sutures to the undersurface of the inferior fascial edge (Fig. 43-3.2). To avoid osteitis pubis or

osteomyelitis, the tendons should not be affixed directly to the symphysis pubis.

Starting from each end of the incision, the fascia is closed to its midpoint using a continuous running suture with a 0-gauge delayed-absorbable suture. These strands are then tied together. The subcutaneous layer and skin are closed as with the midline vertical incision (p. 928).

## POSTOPERATIVE

The postoperative course for low transverse incisions follows that described for midline incisions (p. 928).

FIGURE 43-3.2 Wound closure.

## 43-4

## Maylard Incision

The Maylard incision differs mainly from the Pfannenstiel incision in that the rectus sheath is not dissected away from the rectus abdominis muscle and that the bellies of the rectus abdominis muscle are transected. Transection affords extensive access to the pelvis. However, it is technically more difficult due to its required isolation and ligation of the inferior epigastric vessels. Moreover, the Maylard incision has been used infrequently because of concerns regarding greater postoperative pain, decreased abdominal wall strength, longer operating times, and increased febrile morbidity. Randomized studies, however, have not supported these concerns (Ghanbari, 2009; Mathai, 2013). The Maylard incision should be avoided in those patients in whom the superior epigastric vessels have been interrupted, as this leaves the rectus abdominis muscles with inadequate blood supply. Also, patients with significant peripheral vascular disease may rely on the inferior epigastric vessels for collateral blood supply to their lower extremities (Salom, 2007).

## PREOPERATIVE

Preparation and consenting prior to Maylard incision are similar to that for Pfannenstiel incision (p. 929).

## INTRAOPERATIVE

## Surgical Steps

□ **Initial Steps.** The initial steps mirror that of the Pfannenstiel incision (Steps 1 and 2, p. 929). Thus, the skin is incised transversely beginning 2 to 3 cm above the symphysis, and the fascia is divided transversely. After these steps, the techniques diverge, and in contrast to the Pfannenstiel incision, the anterior rectus sheath is not dissected away from the underlying rectus muscle.

The inferior epigastric vessels lie posterolateral to the rectus abdominis muscle bellies. Bilaterally, these vessels are identified, ligated, and transected. This step avoids their laceration and hemorrhage when the rectus abdominis muscle is transected.

□ **Rectus Abdominis Muscle.** With fingers, the rectus abdominis muscle is bluntly dissected away from the underlying transversalis fascia and peritoneum. These latter are the encountered layers because the posterior

rectus sheath ends at the arcuate line and is absent caudal to this line. The surgeon's fingers are slid behind the rectus muscle bellies, and this muscle is then transected using an electrocautery blade (Fig. 43-4.1).

□ **Peritoneum.** With two hemostats, the peritoneum is grasped, and it is sharply incised above the level of the bladder dome. This incision is then extended laterally (Fig. 43-4.2). After access is obtained to the abdominal cavity, planned surgery can proceed. As with Cherney incisions, careful self-retaining retractor placement is necessary to lessen the risk of femoral or genitofemoral nerve injury.

□ **Wound Closure.** At incision closure, the fascia is closed with a running stitch

using 0-gauge delayed-absorbable suture. Closing the fascia adequately reapproximates the transected muscle fibers, and therefore the divided muscle bellies are not directly sutured together. Starting from each end of the incision, the fascia is closed to its midpoint using a continuous running suture line with a 0-gauge delayed-absorbable suture. These strands are then tied together. The subcutaneous layer and skin are closed as with the midline vertical incision (p. 928).

## POSTOPERATIVE

The postoperative course for low transverse incisions follows that described for midline incisions (p. 928).

FIGURE 43-4.1 Rectus abdominis muscle transection.

FIGURE 43-4.2 Suture placement through rectus abdominis muscle and fascia, and also peritoneal incision.

## 43-5

## Ovarian Cystectomy

Ovarian cyst excision is typically prompted by patient symptoms or by ovarian qualities that suggest a lower concern for ovarian malignancy (Chap. 9, p. 215). Removal of the cyst alone can offer those with ovarian pathology an opportunity to preserve hormonal function and reproductive capacity. Accordingly, ovarian cystectomy goals include gentle tissue handling to limit postoperative adhesions and reconstruction of normal ovarian anatomy to aid the later transfer of ova to the fallopian tube.

In some women, a cystectomy may be performed laparoscopically rather than with laparotomy. Several studies support the safe and effective use of laparoscopy for this purpose (Chap. 9, p. 216). That said, there are settings in which its role is limited. In general, if a cyst is large, adhesive disease limits access and mobility, or the risk of malignancy is greater, then laparotomy is preferred.

## PREOPERATIVE

## ■ Consent

In addition to general surgical risks of laparotomy, the major risk of cystectomy is extensive bleeding from or injury to the ovary that, in turn, necessitates removal of the entire ovary. Also, a variable degree of ovarian reserve may be lost with ovarian cystectomy. If ovarian cancer is suspected prior to surgery, patients should be educated regarding the possibility of surgical staging, including the need for hysterectomy and removal of both ovaries (Chap. 35, p. 748).

Many patients undergoing cystectomy for ovarian pathology have associated pain. Although in most cases cystectomy will be curative, in other instances, pain may persist despite cyst excision. This is especially true in those with coexistent endometriosis. Thus, patients are counseled that cystectomy may not relieve chronic pain in all cases.

## ■ Patient Preparation

Bowel preparation and antibiotics are typically not required preoperatively. If hysterectomy is required during ovarian staging, antibiotics may be given intraoperatively. Laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

FIGURE 43-5.1 Ovarian incision.

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Because of the potential for cancer staging in the upper abdomen if malignancy is found, general anesthesia is typically indicated for this inpatient procedure. The patient is supine. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is inserted; and abdominal preparation is completed. Because hysterectomy may be needed if malignancy is found, the vagina is also surgically prepared.

□ **Abdominal Entry.** Most ovarian cysts can be removed through a Pfannenstiel incision. Extremely large cysts or those with a greater concern for malignancy usually require a vertical incision. This latter incision provides generous operating space and adequate upper abdomen access for cancer staging.

As described in Chapter 35 (p. 748), cell washings from the pelvis and upper abdomen are collected prior to ovarian manipulation and are saved if a cancer is found. The upper abdomen and pelvis are explored, and excrescences or suspicious areas are sampled and sent for intraoperative frozen-section analysis.

A self-retaining retractor is placed within the incision, and the bowel and omentum are packed from the operating field. The ovary is brought into view, and moist laparotomy sponges are placed in the cul-de-sac and beneath the ovary. This helps to minimize contamination of the pelvis if the cyst ruptures during excision.

□ **Ovarian Incision.** The ovary is held between the surgeon's thumb and opposing fingers. The ovarian capsule that overlies the

dome of the cyst is then cut with either scalpel or electrosurgical needle tip. This incision is ideally placed on the antimesenteric surface of the ovary to minimize dissection into vessels at the ovarian hilum. The incision is ideally deepened to reach the cyst wall without entering and rupturing the cyst (Fig. 43-5.1). Allis clamps are then placed on the incised edges of the ovarian capsule to aid traction and countertraction during dissection.

□ **Cyst Dissection.** Blunt dissection with fingertip or knife handle or sharp dissection with Metzenbaum scissor tips is used to develop the cleavage plane between the cyst wall and the remaining ovarian stroma (Fig. 43-5.2). If adhesions obliterate the cleavage plane, sharp dissection is preferred. As an assistant gently pulls the Allis clamps in a direction away from the cyst wall, the surgeon places fingers proximate to the advancing cleavage plane and pulls the cyst in the direction opposite the Allis clamps. Such traction and countertraction across the cleavage plane aid dissection. Because the surface of the cyst wall is often smooth and slippery, the surgeon may place an unfolded thin gauze sponge between fingers and the cyst wall to afford a better grip.

As dissection approaches completion, the highly vascular ovarian hilum is reached. If possible, a hemostat or pean clamp is placed across the small remaining tissue bridge between the cyst and normal ovary. The clamp is positioned closer to the ovary to allow space for scissors to cut the tissue pedicle and free the cyst without rupture. The pedicle is suture ligated with a fine absorbable suture. The ovarian bed is then examined, and bleeding points are coagulated or ligated.

□ **Cyst Excision.** Once the cyst is removed, it may be sent to the pathology department for intraoperative frozen-section

**FIGURE 43-5.2** Cyst dissection.

analysis. In benign cases, excess capsule can be sharply trimmed from ovaries in which large cysts have stretched and thinned the ovarian surface. This excision is performed to help restore normal ovarian anatomy. But because ovarian follicles are contained within even extremely thinned capsules, this tissue is preserved whenever possible.

□ **Ovarian Closure.** The ovarian bed is then closed in layers using 3-0 or 4-0 gauge delayed-absorbable suture. These sutures reapproximate the ovarian tissue that previously surrounded the cyst on both sides

(Fig. 43-5.3). With a thinned ovarian cortex, the needle tip should not be driven through the capsule. Exposed suture on the ovarian surface may increase adhesion formation. The ovarian incision is closed with a running subcortical stitch (similar to subcuticular stitch) using 5-0 gauge delayed-absorbable suture.

□ **Incision Closure.** Laparotomy sponges are removed from the cul-de-sac, and the pelvis is copiously irrigated with an isotonic solution such as lactated Ringer solution. Irrigation assumes an even greater importance with ovarian cyst rupture. For example, spill

**FIGURE 43-5.3** Ovarian closure.

from a mature cystic teratoma (dermoid), if neglected, may induce a chemical peritonitis. Depending on the surgeon's preference and the patient's anatomy, an adhesion barrier may be placed around the ovary (Chap. 11, p. 261). The remaining packs and retractor are removed, and the abdominal incision is closed.

## POSTOPERATIVE

After surgery, patient care in general follows that described for laparotomy (p. 928).

## 43-6

## Salpingo-oophorectomy

Removal of the ovary and fallopian tube is more commonly performed by laparoscopy. However, laparotomy is typically indicated if the potential for malignancy is great, if the ovary is larger than 8 to 10 cm, or if extensive adhesions are anticipated. With either approach, the essential steps of salpingo-oophorectomy (SO) are: preventive identification of the ipsilateral ureter, infundibulopelvic (IP) ligament ligation, combined ligation of the proximal fallopian tube and uteroovarian ligament, and transection of the intervening mesovarium and mesosalpinx. Indications are varied and include suspicion for ovarian malignancy, ovarian cancer prevention for at-risk women, large symptomatic ovarian cysts in postreproductive females, and for reproductive-aged women, large, symptomatic ovarian cysts that are not suitable for cystectomy.

### PREOPERATIVE

#### ■ Patient Evaluation

This surgery is typically performed to remove ovarian pathology that has been evaluated sonographically. If anatomy is unclear, magnetic resonance (MR) imaging may add information. As listed in Chapters 35 and 36 (pp. 742 and 761), tumor markers are selectively drawn prior to surgery if malignancy is suspected.

#### ■ Consent

In general, serious complications with SO are infrequent but include organ injury, especially to the ureter; hemorrhage; wound infection or dehiscence; and anesthesia complications. Ovarian pathology is the most common indication for SO. Thus, the possibility of cancer staging and a description of its steps are explained. Moreover, malignant cyst rupture and spillage are risks, and patients are informed that this will advance the cancer stage (Chap. 35, p. 748). Many women undergoing SO for ovarian pathology have associated pain. Although removal of the ovary in most cases will be curative, in other instances, pain may persist despite SO. Last, if performed bilaterally, SO dramatically curtails estrogen production. Thus, a preoperative discussion of consequences, as outlined on page 951, is recommended.

#### ■ Patient Preparation

Bowel preparation and antibiotics are typically not required preoperatively. If hysterectomy is required during ovarian staging, antibiotics may be given intraoperatively. Laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Salpingo-oophorectomy performed via laparotomy typically requires general anesthesia to allow staging of the upper abdomen if malignancy is found. The patient is supine. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is inserted; and abdominal preparation is completed. Because of a possible need for hysterectomy if malignancy is found, the vagina is also surgically prepared.

□ **Abdominal Entry.** Either a transverse or vertical incision may be used for SO. Clinical factors such as ovarian size and risk of malignancy influence this selection, as discussed on page 926.

Following abdominal entry, cell washings from the pelvis and upper abdomen are collected prior to ovarian manipulation. These are sent for pathologic evaluation if cancer is found. The upper abdomen and pelvis are explored. Peritoneal or omental implants are sampled and sent for intraoperative frozen-section analysis.

□ **Exposure.** A self-retaining retractor such as an O'Connor O'Sullivan or Balfour retractor is placed, and the bowel is packed from the operating field. The affected adnexa is grasped and elevated from the pelvis. If extensive adhesions are found, normal anatomic relationships are restored.

□ **Ureter Location.** Because of its close proximity to the IP ligament, the ureter is identified prior to clamp placement. In many instances, the ureter is seen beneath the posterior pelvic sidewall peritoneum. Here, it can often be identified as it enters the pelvis and crosses over the common iliac artery bifurcation just medial to the ovarian vessels. In other cases, retroperitoneal isolation of the ureter is required. For this, the peritoneum within the area bounded by the round and IP ligaments and the external iliac vessels is tented with tissue forceps and incised. The first peritoneal incision is extended cephalad toward the pelvic brim (Fig. 43-6.1). The incision also later assists in isolating the IP ligament for ligation. Once this peritoneal window is open, blunt dissection is directed deep, cephalad, and slightly medially through gauzy areolar connective tissue (see Step 6 of abdominal hysterectomy, p. 952). The ureter is typically found attached to the medial leaf of the incised peritoneum.

□ **Infundibulopelvic Ligament.** The adnexa is lifted from the pelvis and inspected. To isolate the IP ligament, a second peritoneal opening is sharply created with Metzenbaum scissors or electrosurgical blade. It is made in the posterior leaf of the broad ligament below the IP ligament but above the ureter.

**FIGURE 43-6.1** Retroperitoneal entry.

**FIGURE 43-6.2** Infundibulopelvic ligament ligation.

This incision is extended medially beneath the fallopian tube and uteroovarian ligament and toward the uterus. While remaining parallel to the IP ligament, it is also extended lateral and cephalad towards the pelvic brim. Ideally, the ureter is in view during this entire incision.

As a result of both peritoneal incisions, the IP ligament is isolated. This vascular ligament is then clamped with a Heaney or other sturdy clamp, and the clamp curve faces upward (Fig. 43-6.2). Of note, if SO is performed for cancer risk reduction, the clamp is brought across the IP close to the sidewall. A single Kelly (pean) clamp is placed across the IP at a distance medial to the Heaney clamp. During completion of adnexectomy, this medial clamp prevents “back-bleeding” and is removed with the specimen.

As shown, the ligament is transected between the Heaney and Kelly clamps. To ligate the IP pedicle, a free tie of 0-gauge delayed-absorbable suture is placed around the Heaney clamp. As the knot is secured,

this clamp is opened and closed quickly, that is, “flashed.” Next, a transfixing suture is placed around the Heaney clamp (Fig. 40-22, p. 853). This suture is placed below the clamp yet distal to the first free tie to avoid hematoma formation by needle puncture of ovarian vessels. As this knot is cinched in place, the Heaney clamp is removed.

**□ Fallopian Tube and Uteroovarian Ligament.** With the adnexa elevated, a Heaney or similar clamp is placed across both the proximal uteroovarian ligament and fallopian tube. It also incorporates some of the mesosalpinx and mesovarium. The clamp’s curve faces the ovary. Next, another clamp enters laterally and is directed medially to close around the remaining mesosalpinx and mesovarium beneath the ovary (Fig. 43-6.3). Again, the clamp curve faces the ovary. Ideally, the tips of both clamps touch beneath the adnexa. Above both of these clamps are stacked second clamps, which lie a distance above their partners and closer to the ovary.

**FIGURE 43-6.3** Ligation of uteroovarian ligament, fallopian tube ligation, and proximal adjacent mesovarium and mesosalpinx.

Tissue between the stacked clamps is cut with curved Mayo scissors to free the adnexa.

The freed adnexa is removed from the operative site and sent to pathology for evaluation. If malignancy is suspected, an intraoperative frozen section is requested. Tissue within each of the remaining two clamps is individually suture ligated with 0-gauge delayed-absorbable suture.

**□ Wound Closure.** The retractor and packing sponges are removed from the abdomen. The abdominal incision is then closed as described for vertical or Pfannenstiel incisions (pp. 928 and 930).

## POSTOPERATIVE

Patient recovery is similar to that described for laparotomy (p. 928). In reproductive-aged women, if only one ovary is removed, hormonal and reproductive function is preserved. However, if both are excised, then surgical menopause follows, and hormone replacement is considered (Chap. 22, p. 494).

## 43-7

## Interval Partial Salpingectomy

Interval partial salpingectomy is similar to puerperal midsegment salpingectomy and differs mainly in procedure timing and in abdominal entry. In contrast to postpartum or postabortal sterilization, the term *interval* designates performance unrelated in time to pregnancy. Accordingly, for most women undergoing interval sterilization, the uterus is small and lies within the confines of the pelvis. Thus, fallopian tubes are reached either laparoscopically or through a low transverse incision.

In general with interval partial salpingectomy, a midtubal segment of fallopian tube is excised, and the severed ends seal by fibrosis and reperitonealization. Commonly used methods of interval sterilization include the Parkland and Pomeroy techniques.

Of tubal sterilization methods, interval partial salpingectomy is infrequently selected for U.S. women who elect sterilization (Peterson, 1996). More commonly, laparoscopic techniques are employed, mainly because of laparoscopy's postsurgical advantages (Chap. 41, p. 874). Accordingly, interval partial salpingectomy is typically selected for cases in which laparoscopy may not be indicated. Examples include cases complicated by extensive adhesions, those in which other concurrent pelvic pathology dictates laparotomy, or those in which laparoscopic equipment or surgical skills are lacking. Moreover, new recommendations advocate for risk reducing total salpingectomy when feasible as described on page 939. Thus, the opportunities for laparotomic interval salpingectomy may be few.

### PREOPERATIVE

#### ■ Patient Evaluation

As with any sterilization procedure, pregnancy should be excluded prior to the procedure by means of either urine or serum  $\beta$ -human chorionic gonadotropin (hCG) testing. Similarly, to limit the possibility of an early, undetected luteal-phase conceptus, sterilization is ideally performed during the follicular phase of the menstrual cycle, and an effective contraceptive method is used until surgery.

#### ■ Consent

Partial salpingectomy is an effective method of sterilization. Pregnancy rates of less than

2 percent are typical. Failures may result from tubal recanalization or technical errors, such as ligation of the wrong structure.

Tubal sterilization is a safe surgical procedure, and complication rates are below 2 percent (Pati, 2000). Of these, anesthesia complications, organ injury, and wound infection are the most frequent. In addition, although pregnancy is uncommon following sterilization, when pregnancy does occur, the risk of ectopic pregnancy is high and approximates 30 percent (Peterson, 1996; Ryder, 1999). However, because tubal sterilization is highly effective contraception, the overall risk of pregnancy is low, and therefore also is the risk of ectopic pregnancy.

Aside from physical risks, some women experience regret following sterilization. Rates are highest in those 30 years or younger (Curtis, 2006; Hillis, 1999). Accordingly, prior to surgery women are counseled regarding the risk of regret, the permanence of the procedure, and alternative effective long-term contraceptive methods (American College of Obstetricians and Gynecologists, 2011).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Interval partial salpingectomy is usually an outpatient procedure, performed under general or regional anesthesia. Following administration of anesthesia, the patient is placed supine, the abdomen surgically prepared, and the bladder drained.

□ **Minilaparotomy.** For most patients, a 4- to 6-cm transverse Pfannenstiel incision is sufficient. Small Richardson or army-navy retractors provide adequate intraabdominal visualization in most cases. A vaginally placed sponge stick or uterine manipulator can elevate the uterus to help bring fallopian tubes into view.

□ **Tubal Identification.** A common reason for sterilization failure is ligation of the wrong structure, usually the round ligament. Identification and isolation of the fallopian tube prior to ligation and submission of tubal segments for pathologic confirmation is therefore required. In some cases, especially those with associated tubal adhesions, this step may be challenging. Lateral extension of the incision may be needed for improved exposure.

Initially, the uterine fundus is identified. At the cornu, insertion of the fallopian tube lies posterior to that of the round ligament, and this orientation can initially guide the surgeon to the correct structure. A primary Babcock clamp is used to elevate the fallopian tube proximally, while a second clamp grasps the tube more distally. The primary clamp is then moved again and is placed distal to the second. The second is then removed and again placed distal to the first. In this manner, the surgeon “marches” down the length of the tube to reach the ampulla and identify fimbria.

□ **Parkland Method.** At the midpoint of the fallopian tube, an avascular space in the mesosalpinx is identified, and a hemostat is placed directly beneath the tube. The selected site should allow excision of a 2-cm tubal segment that does not incorporate the fimbria. Ligation of the fimbrial portion leads to a greater risk of tubal recanalization and higher failure rates.

The hemostat is bluntly advanced through the mesosalpinx as counterpressure is applied with the index finger. Once advanced through the defect, the hemostat tips are gently opened to expand the aperture (Fig. 43-7.1). The end of a 0-gauge chromic free tie is placed in the tip of the hemostat and pulled through the opening. This is repeated, bringing another tie through the rent. The midsegment is lifted, and the distal suture tied. The second tie is then secured around the proximal fallopian tube.

FIGURE 43-7.1 Parkland method: mesosalpinx opening created.

**FIGURE 43-7.2** Parkland method: tubal excision.

**FIGURE 43-7.3** Pomeroy method.

□ **Tubal Excision.** The Metzenbaum scissor tips are inserted through the mesosalpingeal defect, and the proximal portion of the fallopian tube is cut. A 0.5-cm pedicle is left to ensure that the tube will not slip through its ligature (Fig. 43-7.2). The tube is sharply dissected from the mesosalpinx toward the distal ligature, thereby freeing the tubal segment from the mesosalpinx. The distal part of the segment is excised to leave a 0.5-cm pedicle, and an adequate 2-cm tubal segment is obtained. The pedicles and mesosalpinx are inspected for hemostasis. The procedure is then repeated on the other side. Tubal segments are sent

for histologic confirmation of complete transection.

□ **Pomeroy Method.** This technique involves grasping and elevating a 2-cm mid-segment of tube, ligating the tubal loop with a 2-0 plain catgut suture, and then excising the distal portion of the loop (Fig. 43-7.3). Prompt absorption of the suture following surgery causes the ligated ends to fall away, creating a resulting 2- to 3-cm gap that separates the ends.

□ **Wound Closure.** The wound is closed as that for other transverse abdominal incisions (p. 930).

## POSTOPERATIVE

The recovery following minilaparotomy is typically rapid and without complication, and women may resume regular diet and activities as tolerated. Sterilization is immediate following surgery, and intercourse may resume at the patient's discretion. Aside from regret, the risk of long-term physical or psychologic sequelae is low. Peterson and coworkers (2000) found that women who had undergone tubal sterilization were no more likely than those without this surgery to have menstrual abnormalities. Moreover, interval tubal ligation is unlikely to negatively affect sexual interest or pleasure (Costello, 2002).

## 43-8

## Salpingectomy and Salpingostomy

*Salpingostomy* describes a lengthwise linear incision of the fallopian tube and is usually used to remove intraluminal ectopic pregnancy contents. In contrast, *salpingectomy* removes the fallopian tube with sparing of the ovary. Indications are varied, and this procedure may be selected for ectopic pregnancy removal, for sterilization, or for hydrosalpinx removal to improve in vitro fertilization success rates. Also, for ovarian cancer prevention, the Society of Gynecologic Oncology (2013) now recommends consideration of salpingectomy in lieu of tubal ligation or at the time of other pelvic surgery. The fallopian tube may be the origin of pelvic serous carcinomas (Chap. 35, p. 738).

Laparoscopic surgery offers patients the advantages of shorter hospitalizations, quicker recoveries, and less postoperative pain. Accordingly, laparoscopic treatment of ectopic pregnancy is generally preferred. As a result, laparotomic approaches for salpingectomy and salpingostomy are now reserved typically for patients with ruptured ectopic pregnancies who are hemodynamically unstable or in those with contraindications to laparoscopy. For hemoperitoneum, laparotomy offers fast entry into the abdomen for control of bleeding.

### PREOPERATIVE

#### Consent

Most complications associated with salpingectomy and salpingostomy occur in conjunction with ectopic pregnancies, and the risk of bleeding is prominent. Injury to the ipsilateral ovary, however, is an attendant risk regardless of the indication. In certain cases, if severe, this damage can demand concurrent oophorectomy. Additionally, involvement of the ovary with tubal pathology may necessitate ovarian removal.

If salpingectomy is performed for sterilization, then consenting should mirror that for interval tubal sterilization found in Section 43-7.

#### Persistent Trophoblastic Tissue

Following any surgical treatment of ectopic pregnancy, trophoblastic tissue can persist. Remnant implants typically involve the fallopian tube, but extratubal trophoblastic implants have been found on the omentum and on pelvic and abdominal peritoneum. Peritoneal implants typically measure 0.3 to

2.0 cm and appear as red-black nodules. As expected, the risk of persistent trophoblast tissue is lower with salpingectomy compared with salpingostomy (Farquhar, 2005).

#### Preservation of Fertility

Most, but not all, studies show comparable subsequent fertility rates whether salpingectomy or salpingostomy is performed to treat ectopic pregnancy if the other tube is normal. This discussion is detailed in Chapter 7 (p. 172). Thus, with a healthy contralateral tube, neither salpingostomy nor salpingectomy offers a distinct fertility advantage. However, salpingostomy is considered a preferred option for tubal ectopic pregnancy if there is contralateral tubal disease and a desire for fertility. Unfortunately, in some cases of rupture, the extent of tubal damage or bleeding may limit tubal salvage, and salpingectomy may be required.

#### Patient Preparation

If performed for ectopic pregnancy, both salpingectomy and salpingostomy may be associated with substantial bleeding. Baseline complete blood count (CBC) and  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG) level are obtained. Patients undergo type and screen to establish blood type. Those with significant bleeding also require a type and cross-match for packed red blood cells and other blood products as indicated. If performed for interval sterilization, then preparation follows that found in Section 43-7.

Salpingectomy and salpingostomy are associated with low infection rates. Accordingly, preoperative antibiotics are usually not required. Laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### Surgical Steps

##### Anesthesia and Patient Positioning.

In most cases of ectopic pregnancy managed by laparotomy, surgery is an inpatient procedure and requires general anesthesia. For other indications, regional analgesia may be an option. The patient is supine. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is placed; and abdominal preparation is completed.

**Abdominal Entry.** Most salpingectomy or salpingostomy procedures can be managed through a Pfannenstiel incision (p. 929). However, with a hemodynamically unstable patient and large hemoperitoneum, vertical incision may offer quicker entry.

**Salpingectomy.** Once access to the pelvic organs has been achieved, the adnexa is elevated. Distal and proximal Babcock clamps are placed around the fallopian tube and direct the tube away from the uterus and ovary. This extends the mesosalpinx (Fig. 43-8.1).

Beginning at the distal, fimbriated end of the tube, one Kelly clamp or hemostat is placed across a 2-cm-long segment of the mesosalpinx, close to the fallopian tube. The clamp's curve faces the tube. Another clamp is similarly placed, but lies closer to the ovary. These clamps occlude vessels that traverse the mesosalpinx. Scissors then cut the interposed mesosalpinx.

The severed tissue pedicle that is closer to the ovary is tied with 2-0 or 3-0 gauge delayed-absorbable suture, and the clamp is removed. The clamp closer to the tube remains and leaves with the final specimen. Such clamping, cutting, and ligating are repeated serially,

FIGURE 43-8.1 Salpingectomy.

with each clamp incorporating approximately 2 cm of mesosalpinx. Progression is directed from the ampullary end of the fallopian tube toward the uterus.

The last clamp is placed across the proximal mesosalpinx and fallopian tube. Scissors then cut the mesosalpinx and tube and free these from the uterus. The pedicle is similarly ligated.

□ **Salpingostomy.** Surgical steps for salpingostomy mirror those used in laparoscopic salpingostomy and can be reviewed in Section 44-5 (p. 1013). To summarize, the affected fallopian tube is elevated with Babcock clamps. At the ectopic pregnancy site, the tube is sharply incised lengthwise on its antimesenteric border. The incision, usually 1 to 2 cm long, varies based on pregnancy

size. The products of conception are grasped and gently extracted or are delivered by hydrodissection. Bleeding sites are made hemostatic with electrosurgical coagulation, and the tubal incision is left to heal by secondary intention.

□ **Wound Closure.** The pelvis is irrigated and rid of blood and tissue debris. The abdominal incision is closed as previously described for vertical or Pfannenstiel incision (pp. 928 and 930).

## POSTOPERATIVE

In cases performed for ectopic pregnancy, salpingectomy or salpingostomy represents pregnancy termination. Accordingly, the Rh status of the patient should be evaluated.

Administration of 50 or 300 µg (1500 IU) of anti-D immune globulin intramuscularly within 72 hours after pregnancy termination in Rh negative women can dramatically lower the risk of alloimmunization in future pregnancies.

Because of the increased risk of persistent trophoblastic tissue in patients undergoing salpingostomy, serial weekly serum β-hCG levels should be measured until undetectable levels are reached. During this time, contraception should be used to avoid confusion between persistent trophoblastic tissue and a new pregnancy.

For elective sterilization, postoperative instructions follow those for interval tubal sterilization in Section 43-7. For all indications, resumption of activity and diet follow that for laparotomy (p. 928).

## 43-9

## Cornuostomy and Cornual Wedge Resection

Interstitial pregnancy develops in a distensible portion of the tube surrounded by myometrium (Fig. 43-9.1). It is often located at the cornu, where uterine and ovarian arteries anastomose, can lead to brisk and significant hemorrhage. Fortunately, high-resolution sonography,  $\beta$ -hCG testing, and use of established diagnostic criteria have led to earlier diagnosis of interstitial pregnancy. It averts rupture in many circumstances.

In selected cases, this unusual type of ectopic pregnancy may be managed medically, but it is more frequently managed by various surgical techniques. *Cornuostomy* is analogous to linear salpingostomy for tubal ectopic pregnancy, whereas *cornual wedge resection* removes the interstitial pregnancy with its surrounding myometrium and fallopian tube (Moawad, 2010). Cornual wedge resection, often performed via laparotomy, has remained a cornerstone of therapy. However, many cases of interstitial pregnancy are now managed laparoscopically (Hwang, 2011). Factors to consider in selecting surgical route and specific procedure include gestational age, presence of rupture, hemodynamic stability, patient's desire for future fertility, and surgeon's preference and skill.

This discussion describes a laparotomic approach. However, the principles and surgical steps presented here are applicable to laparoscopic management with only minor modifications.

### PREOPERATIVE

#### ■ Patient Evaluation

In some cases, particularly those in which the cornu has ruptured and the woman is hemodynamically unstable, fluid resuscitation and blood transfusion are initiated preoperatively. Further, because there is risk for excessive intraoperative bleeding, a patient is typed and crossmatched for packed red blood cells and other blood products as indicated. A patient is counseled regarding the possible need for blood products, which includes anti-D immune globulin for those with Rh-negative blood. Baseline CBC and  $\beta$ -hCG levels are obtained.

Additional risks include removal of the ipsilateral ovary and the possibility of hysterectomy for uncontrollable bleeding. In the event that the patient has completed her childbearing, tubal ligation or bilateral salpingectomy or rarely even hysterectomy may be acceptable at the time of surgery.

#### ■ Patient Preparation

Other than optimizing hemodynamic stability of the patient and ensuring blood availability, no special preparation is required. Prophylactic antibiotics or bowel preparation are generally not required. Laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Cornual wedge resection and cornuostomy are usually performed under general anesthesia, particularly if cornual rupture is suspected. The

patient is supine. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is inserted; and abdominal preparation is completed.

□ **Abdominal Entry.** Either a transverse or vertical incision may be used depending on the clinical situation as discussed in Section 43-1 (p. 926).

□ **Exposure.** In the absence of cornual rupture and active bleeding, the bowel is packed away to provide adequate exposure of the pelvis. A self-retaining retractor may then be placed. If significant hemoperitoneum is encountered upon abdominal entry, the operator can attempt to remove obscuring blood with suction and laparotomy sponges. Failing this, the surgeon may consider manually elevating the uterus out of the pelvis where it may be inspected for rupture and hemorrhage. The uterus can be compressed between the operator's thumb and fingers to tamponade bleeding. Two heavy clamps can then be placed across the base of the cornu. In rare cases, temporary compression of the aorta may be helpful if bleeding is torrential and poorly controlled.

□ **Inspection of the Pelvis.** The location of the ectopic pregnancy is identified. Additional information including presence or absence of rupture, pregnancy size, amount of bleeding, and appearance of the contralateral (unaffected) adnexa is needed before deciding on the exact procedure to perform.

□ **Vasopressin Injection.** For either cornuostomy or cornual wedge resection, dilute vasopressin (20 units in 30-100 mL of normal saline) may be injected into the myometrium surrounding the interstitial pregnancy to aid hemostasis. Needle aspiration prior to injection is imperative to avoid intravascular injection of this potent vasoconstrictor. The anesthesiologist is concurrently informed of vasopressin injection because a sudden increase in patient blood pressure may follow injection. Blanching at the injection site is expected.

□ **Cornuostomy: Incision.** A linear incision is made through the uterine serosa and myometrium overlying the interstitial pregnancy (Fig. 43-9.2). As the incision is carried downward, some products of conception may extrude through the incision (Fig. 43-9.3). Products of conception may be removed by means of blunt, sharp, suction, or hydrodissection (Fig. 43-9.4). Despite vasopressin, bleeding from the myometrium is common and is best managed with electrosurgical coagulation or figure-of-eight stitches with 2-0 gauge absorbable or delayed-absorbable suture.

FIGURE 43-9.1 Interstitial pregnancy.

**FIGURE 43-9.2** Incision line for cornuostomy.

**FIGURE 43-9.3** Cornuostomy with extrusion of products of conception.

□ **Cornuostomy: Incision Closure.** The myometrial incision is usually closed with absorbable or delayed-absorbable suture in an interrupted or continuous running fashion (Fig. 43-9.5). A gauge of sufficient strength to prevent breakage during muscle approximation is selected, typically 2-0 or 0-gauge. For this, chromic suture may be preferred due to its slight elasticity that provides tensile strength and minimal tissue cutting. Closure may be completed with one layer of sutures or may require two to three layers to aid hemostasis, avert hematoma formation, and reapproximate myometrium. Additionally, some prefer a subserosal closure, similar to a subcuticular running stitch, as a final layer. This

theoretically minimizes the amount of exposed suture and thereby limits adhesion formation.

□ **Cornual Wedge Resection: Salpingectomy.** With this approach, the pregnancy, surrounding myometrium, and ipsilateral fallopian tube are excised en bloc. The fallopian tube is removed to avoid future ectopic pregnancy in this tube. Such pregnancies form when the ipsilateral ovary's eggs are fertilized by sperm that travel out the contralateral tube and are transported by peritoneal fluid to the isolated and ligated tube.

Initially, salpingectomy is completed as described in Section 43-8.1 (p. 939). To summarize, the mesosalpinx is serially clamped

and ligated across its length (Fig. 43-9.6). This separates the tube from its mesosalpinx and ipsilateral ovary (Fig. 43-9.7).

□ **Cornual Wedge Resection: Myometrial Incision.** Following vasopressin injection, the cornual serosa surrounding the pregnancy is incised with an electro-surgical blade (Fig. 43-9.8). The incision is angled inward as it is deepened. This creates a wedge into the myometrium (Fig. 43-9.9). Hemostasis can be achieved with electro-surgical blade coagulation or with sutures.

□ **Cornual Wedge Resection: Incision Closure.** The myometrial incision is usually

**FIGURE 43-9.4** Suction removal of products of conception.

**FIGURE 43-9.5** Myometrial incision closure.

**FIGURE 43-9.6** Mesosalpinx serially clamped and ligated.

**FIGURE 43-9.7** Salpingectomy completed.

**FIGURE 43-9.8** Myometrial incision.

**FIGURE 43-9.9** En bloc excision of interstitial pregnancy.

**FIGURE 43-9.10** Incision closure.

closed in two to three layers with absorbable or delayed-absorbable suture in an interrupted or continuous running fashion. As with cornuostomy, some recommend a final subserosal layer closure. However, depending on the degree of wound tension created by the contracted myometrium, this suture may pull through the serosa, and a simple interrupted or running suture line may be required to approximate the serosa (Fig. 43-9.10).

As noted earlier, there can be cases with rupture and brisk bleeding, in which two clamps are quickly placed across the base of the cornu to halt hemorrhage. In these cases, salpingectomy is similarly completed.

Then, the cornual myometrium above these clamps is sharply removed. The myometrium within each clamp is then suture ligated with a transfixing stitch.

## POSTOPERATIVE

After surgery, patient care in general follows that described for laparotomy (p. 928). As with salpingostomy for treatment of tubal pregnancy, there is increased risk of persistent trophoblastic tissue following cornuostomy. Therefore, serial  $\beta$ -hCG levels are followed postoperatively until a negative test result is obtained. For Rh-negative women,

50 or 300  $\mu$ g (1500 IU) of anti-D immune globulin is given intramuscularly within 72 hours after pregnancy termination to lower the risk of alloimmunization in future pregnancies. Patients should also be counseled that there is also an increased risk of future ectopic pregnancy in the remaining tube following an interstitial pregnancy. Last, as is the case with other types of uterine surgery such as classical cesarean delivery or myomectomy, the uterine rupture rate in subsequent pregnancies and particularly during labor is increased. For this reason, delivery by cesarean at term before labor onset is generally recommended.

## 43-10

## Abdominal Myomectomy

Myomectomy involves surgical removal of leiomyomas from their surrounding myometrium. Indications can include abnormal uterine bleeding, pelvic pain, infertility, and recurrent miscarriage. Hysterectomy is chosen to treat many of these indications. However, myomectomy is often selected by those desiring organ preservation for childbearing or those wishing to avoid hysterectomy.

Myomectomy often requires laparotomy. However, laparoscopic excision may be performed by those with skills in laparoscopic suturing and is described in Section 44-8 (p. 1022) (Seracchioli, 2000; Sizzi, 2007).

### PREOPERATIVE

#### ■ Patient Evaluation

Because of their influence on pre- and intraoperative planning, leiomyoma size, number, and location are evaluated prior to surgery with sonography, MR imaging, or hysteroscopy (Chap. 9, p. 206). For example, submucous tumors are more easily removed hysteroscopically (Section 44-14, p. 1040), whereas intramural and serosal types typically require laparotomy or laparoscopy. Leiomyomas may be small and buried within the myometrium. Thus, accurate information as to leiomyoma number and location aids complete excision. Last, multiple large tumors or those that are located in the broad ligament, encroach on the tubal ostia, or involve the cervix may increase the risk of conversion to hysterectomy. Patients are so counseled.

#### ■ Consent

Myomectomy has several risks including significant bleeding and need for transfusion. Moreover, uncontrolled hemorrhage or extensive myometrial injury during tumor removal may force hysterectomy. Fortunately, rates of conversion to hysterectomy during myomectomy are low and range from 0 to 2 percent (Iverson, 1996; LaMorte, 1993; Sawin, 2000). Postoperatively, the risk of pelvic adhesion formation is significant. Also, leiomyomas can recur.

#### ■ Patient Preparation

**Hematologic Status.** Abnormal uterine bleeding is a common indication for myomectomy. As a result, many women

who elect to undergo this surgery are anemic. In addition, significant intraoperative blood loss during myomectomy is possible. Accordingly, attempts to resolve anemia and bleeding prior to surgery are pursued. Toward this goal, oral iron therapy, gonadotropin-releasing hormone (GnRH) agonists, and progesterone antagonists may have benefits (Chap. 9, p. 208).

**GnRH Agonists.** In addition to preoperative control of abnormal uterine bleeding, these agents have been shown to significantly decrease uterine volume after several months of use (Benagiano, 1996; Friedman, 1991). Decreased uterine size following treatment may allow a less invasive surgical procedure. For example, myomectomy may be completed through a smaller laparotomy incision or by laparoscopy or hysteroscopy (Lethaby, 2002; Mencaglia, 1993). These agents have also been found to diminish leiomyoma vascularity and uterine blood flow (Matta, 1988; Reinsch, 1994). For this surgery, there is conflicting evidence regarding a final benefit of adhesion prevention (Coddington, 2009; Imai, 2003).

The use of preoperative GnRH agonists, however, may also have disadvantages. Within leiomyomas, GnRH agonists can incite hyaline or hydropic degeneration, which may obliterate the pseudocapsule connective tissue interface between the tumor and the myometrium. Such obliterated cleavage planes may lead to tedious and lengthy tumor enucleation (Deligdisch, 1997). Moreover, studies have shown higher rates of leiomyoma recurrence in women treated with GnRH agonists prior to myomectomy (Fedele, 1990; Vercellini, 2003). Leiomyomas treated with these agents may shrink in volume and be missed during surgical removal.

For these reasons, GnRH agonists are not used routinely in all patients undergoing myomectomy. They can be recommended for preoperative use in women with greatly enlarged uteri or preoperative anemia or in cases in which a decrease in uterine volume would allow a less invasive approach to leiomyoma removal.

Similar to GnRH agonists, the oral progesterone agonists preoperatively shrink myoma volume and diminish menorrhagia (Donnez, 2012a,b). Currently available outside the United States, ulipristal acetate (Esmya) in dosages of 5 mg or 10 mg daily may be used during the 3 months prior to surgery.

**Other Preoperative Methods.** The risk of blood transfusion varies among studies and ranges from less than 5 percent to nearly 40 percent (Darwish, 2005; LaMorte, 1993; Sawin, 2000; Smith, 1990). Accordingly, in women with large uteri, especially those with multiple leiomyomas, cell-saver blood scav-

enger and reuse techniques may be selected (Son, 2014; Yamada, 1997). Indications, benefits, and limitations are discussed fully in Chapter 40 (p. 859).

Also with large leiomyomas, tourniquets or vasopressin may fail to adequately limit bleeding. For these, preoperative uterine artery embolization (UAE) on the morning of surgery may be an effective tool to limit blood loss. And unlike GnRH agonist use, UAE allows tissue planes to be preserved (Chua, 2005; Ngeh, 2004; Ravina, 1995).

Several disadvantages of UAE include risks for subsequent pregnancy complications, collateral ovarian infarction, and formation of uterine synechiae, among others discussed in Chapter 9 (p. 209). Thus, preoperative UAE may best be limited to patients with large uteri in whom excessive blood loss is expected and in those not seeking future pregnancy.

**Prophylaxis.** Few studies address the benefits of preoperative antibiotic use. Iverson and coworkers (1996), in their analysis of 101 myomectomy cases, found that although 54 percent of cases received prophylaxis, infectious morbidity was not lowered compared with cases in which antibiotics were not used. However, in cases performed for infertility, because of the potential for tubal adhesions associated with pelvic infection, antibiotic prophylaxis has been advocated (Milton, 2013). For those in whom prophylaxis is planned, selection can follow that for hysterectomy (Table 39-6, p. 835). For all cases, because the risk of conversion to hysterectomy is present, vaginal preparation immediately prior to surgical draping is warranted.

With myomectomy, the risk of bowel injury is low. Thus, bowel preparation is typically not required unless extensive adhesions are anticipated. Last, laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Myomectomy performed through a laparotomy incision is typically an inpatient procedure performed under general or regional anesthesia. The patient is supine. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is inserted; and abdominal preparation is completed.

□ **Abdominal Entry.** The choice of Pfannenstiel incision is typically appropriate for uteri 14-weeks size or smaller (Section 43-2, p. 929). Larger uteri usually require a midline vertical abdominal incision.

□ **Leiomyoma Identification.** Following abdominal entry, the surgeon inspects the serosal surface to identify leiomyomas to be removed. Additionally, squeezing palpation of the myometrium before and during the surgery will help identify firm buried intramural or submucous leiomyomas.

□ **Use of Uterine Tourniquet.** Tourniquets have been used for years to temporarily occlude blood flow through the uterine arteries. Because the uterus receives collateral flow through the ovarian arteries, some tourniquet techniques include occlusion of both uterine and ovarian vessels. First, bilateral windows are created in the leaves of the broad ligament at the level of the internal cervical os. A Penrose drain or Foley catheter is threaded through the opening to encircle the uterine isthmus. Once in place, the Penrose drain is tied or the ends of the Foley catheter are clamped to compress the uterine vessels. Alternatively, the uterine arteries can be ligated bilaterally (Helal, 2010; Sapmaz, 2003). In combination with uterine artery compression, occlusion of the uteroovarian ligaments or infundibulopelvic ligaments to compress the ovarian arteries has been described (Al-Shabibi, 2009; Taylor, 2005). Large, isthmic, or broad-ligament leiomyomas, however, may limit the use of tourniquets in some.

□ **Use of Vasopressin.** 8-Arginine vasopressin (Pitressin) is a sterile, aqueous solution of synthetic vasopressin. It is effective in limiting uterine blood loss during myomectomy because of its ability to cause vascular spasm and uterine muscle contraction. Compared with placebo, vasopressin injection significantly decreases blood loss during myomectomy (Frederick, 1994). Compared with tourniquet techniques, vasopressin injection has also been associated with either comparable or less intraoperative blood loss, with equally low patient morbidity, and lower myometrial hematoma formation rates (Darwish, 2005; Fletcher, 1996; Ginsburg, 1993).

Each vial of Pitressin is standardized to contain 20 pressor units/mL, and doses used for myomectomy are 20 U diluted in 30 to 100 mL of saline (Frishman, 2009). Vasopressin is typically injected along the planned serosal incision(s). The plasma half-life of this agent is 10 to 20 minutes. For this reason, injection of vasopressin is ideally discontinued 20 minutes prior to uterine repair to allow evaluation of bleeding from myometrial incisions (Hutchins, 1996).

The main risks associated with local vasopressin injection result from inadvertent intravascular infiltration and include transient increases in blood pressure, bradycardia, atrioventricular block, and pulmonary edema (Deschamps, 2005; Tulandi, 1996).

For these reasons, patients with a history of cardiovascular disease, cardiomyopathy, congestive heart failure, uncontrolled hypertension, migraine, asthma, and severe chronic obstructive pulmonary disease may not be candidates for vasopressin use. In addition to vasopressin, other less-researched agents for blood loss prevention have been reviewed by Kongnyuy and Wiysonge (2014).

□ **Serosal Incision.** Because of postoperative adhesion formation risks, surgeons ideally minimize the number of serosal incisions and attempt to place incisions on the anterior uterine wall. Tulandi and colleagues (1993) found that posterior wall incisions result in a 94-percent adhesion formation rate compared with a 55-percent rate for anterior incisions.

For most patients, a midline vertical uterine incision allows removal of the greatest number of leiomyomas through the fewest incisions. The length should accommodate the approximate diameter of the largest tumor. The incision depth should afford access to all leiomyomas (Fig. 43-10.1). To reach lateral tumors, a surgeon may create lateral myometrial incisions within the initial central incision. However, at times, separate incision may be required to excise tumors. In these instances, a horizontal incision decreases the number of arcuate vessels transected.

□ **Tumor Enucleation.** The first leiomyoma is grasped with a Lahey or single-tooth tenaculum (Fig. 43-10.2). Applying traction

on the leiomyoma outward and away from the myometrial incision aids in the development of a tissue plane between myometrium and leiomyoma. Sharp and blunt dissection of the pseudocapsule surrounding the leiomyoma frees the tumor from the adjacent myometrium.

□ **Bleeding.** Hemorrhage during myomectomy primarily develops during tumor enucleation and is positively correlated with preoperative uterine size, total weight of leiomyomas removed, and operating time (Ginsburg, 1993). Approximately two to four main arteries feed each leiomyoma and enter the tumor at unpredictable sites. Accordingly, surgeons should watch for these vessels, ligate them prior to transection when possible, and be ready to immediately grasp them with hemostats for ligation or fulguration if lacerated during tumor excision (Fig. 43-10.3).

□ **Myometrial Incision.** Smaller, internal incisions into the myometrium may be required to excise all leiomyomas. If the endometrial cavity is entered, it should be closed with a running suture of 4-0 or 5-0 gauge delayed-absorbable suture (Fig. 43-10.4).

□ **Myometrial Closure.** After removal of all tumors, redundant serosa may be excised. Smaller internal myometrial incisions are closed first with delayed-absorbable suture (see Fig. 43-10.4). The myometrium is then closed in several layers to improve hemostasis

**FIGURE 43-10.1** Uterine incision.

**FIGURE 43-10.2** Tumor enucleation.

**FIGURE 43-10.3** Vessel ligation.

and prevent hematoma formation. A gauge of sufficient strength to prevent breakage during muscle approximation is selected, typically 2-0 to 0-gauge.

**⑪ Serosal Closure.** Closure of the serosal incision using a running baseball stitch

or a subserosal running closure, similar to a running subcuticular closure, may help to limit adhesion formation. For this, 4-0 or 5-0 monofilament, delayed-absorbable suture may be selected. Moreover, absorbable adhesion barriers may help reduce the incidence of adhesion formation following

myomectomy (Ahmad, 2015; Canis, 2014; Tinelli, 2011).

## POSTOPERATIVE

After surgery, care in general follows that described for laparotomy (p. 928). Febrile morbidity of greater than 38.0°C is a common event following myomectomy (Iverson, 1996; Rybak, 2008). Purported causes include atelectasis, myometrial incisional hematomas, and factors released with myometrial destruction. Although fever is common following myomectomy, pelvic infection is not. For example, LaMorte and colleagues (1993) noted only a 2-percent rate of pelvic infection in their analysis of 128 myomectomy cases.

Following myomectomy, there are no clear guidelines as to the timing of pregnancy attempts. Darwish and associates (2005) performed sonographic examinations on 169 patients after myomectomy. Following myometrial indicators, they concluded that wound healing is usually completed within 3 months. There are no clinical trials that address the issue of uterine rupture and therefore route of delivery of pregnancies occurring after myomectomy (American College of Obstetricians and Gynecologists, 2012). Management of these cases requires sound clinical judgment and individualization of care.

**FIGURE 43-10.4** Uterine incision closure.

## 43-11

## Vaginal Myomectomy for Prolapsed Leiomyoma

Prolapse of a pedunculated submucosal leiomyoma is an unusual occurrence but certainly not rare. Vaginal myomectomy is usually a relatively simple procedure and is frequently curative for the patient. Myoma and stalk size and patient discomfort are the most important variables for management. With a thin stalk, simply twisting the leiomyoma slowly off its stalk may be sufficient for removal. With larger stalk diameter or greater patient pain, removal in the operating room is typically preferred. Finally, for those with a large obstructive myoma on a thick, short stalk, hysterectomy may be necessary (Caglar, 2005; Golan, 2005).

### PREOPERATIVE

#### ■ Patient Evaluation

In many cases, diagnosis of a prolapsed pedunculated submucosal leiomyoma will be obvious, as will the size of the prolapsed leiomyoma. However, as many of these patients present with abnormal uterine bleeding, evaluation for other less obvious causes of abnormal bleeding is appropriate. In other cases, only partial prolapse of a leiomyoma through the cervix may preclude assessment of total leiomyoma and stalk size, or the mass may be of unclear etiology. Accordingly, imaging studies, particularly transvaginal or transabdominal sonography or both, may yield additional information beyond pelvic examination. Specifically, uterine size, shape, and degree of involvement with additional leiomyomas or other pathology can be obtained. Moreover, biopsy of any mass of uncertain etiology is considered, and Tischler biopsy forceps may be selected (Fig. 29-16, p. 641). If required, Monsel solution can be applied to control bleeding from the biopsy site similar to that following colposcopic biopsy.

#### ■ Consent

Risks with vaginal myomectomy are low. Uncontrollable bleeding and procedural failure are potential complications. Rarely, severing a stalk on great tension may concomitantly resect the attached uterine wall and injure intraabdominal organs. The possibility of hysterectomy and its consequences are also discussed with the patient beforehand. Leiomyoma prolapse recurrence is

uncommon but may occur if additional submucosal leiomyomas are present or develop within the uterus.

#### ■ Patient Preparation

In an otherwise healthy woman, little preparation is needed for vaginal myomectomy. However, uterine bleeding with leiomyoma prolapse is common, and hypovolemia and acute blood loss anemia are corrected as needed with crystalloid and blood products (Chap. 40, p. 864). If fever is present and infection of the prolapsed leiomyoma or lower genital tract is suspected, treatment with broad-spectrum antibiotics are initiated prior to vaginal myomectomy. Suitable options are found in Table 39-6 (p. 835). The need for thromboembolism prophylaxis will vary by patient age and anticipated length of surgery as outlined in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

The patient is placed in standard dorsal lithotomy position. Vaginal myomectomy may be performed under general or regional anesthesia, intracervical or paracervical blockade, conscious sedation, or intramuscular analgesia. For those women who are taken to the operating room at our institution, we usually prefer general anesthesia for several reasons. First, hysteroscopy is often done following vaginal myomectomy to further evaluate the uterine cavity and status of the stalk. Secondly, many leiomyomas are bulky and require at least a moderate amount of manipulation and vaginal retraction for removal.

An examination is done once the patient is relaxed to assess the size of the prolapsed leiomyoma; location, length, and thickness of the stalk; and general pelvic anatomy. The vagina is then surgically prepared, and the bladder is drained.

##### □ Leiomyoma Stalk Ligation.

To retract the posterior vaginal wall, an Auvard weighted vaginal speculum is positioned. Heaney retractors are used as needed for sidewall and anterior vaginal wall retraction. The prolapsed leiomyoma is grasped with a tenaculum. Traction is applied on the leiomyoma to allow access to the stalk (Fig. 43-11.1). Excessive traction on the leiomyoma is avoided. It is can invert the uterine wall that is attached to the stalk and thereby risk resection of this wall rather than the proximal stalk. In addition, undue traction may avulse the tumor prior to stalk ligation.

**FIGURE 43-11.1** Suture loop surrounding leiomyoma stalk placed on tension.

The stalk is doubly ligated with delayed-absorbable suture. Preformed knotted loops with a knot pusher (as used in laparoscopy cases) work well in this setting (Fig. 41-35, p. 900). With this, the tenaculum is removed to place a loop and then reclamped. In

**FIGURE 43-11.2** Suture loop cinched and tumor stalk transected.

**FIGURE 43-11.3** Leiomyoma excision completed.

contrast, manual knot tying may be technically difficult given the size of the obstructing leiomyoma, the stalk length (or lack thereof), and the cramped vaginal operating space. In such cases, tips of a Heaney right-angle clamp can be maneuvered past the myoma and then across the stalk.

□ **Leiomyoma Removal.** The stalk is then sharply incised at an appropriate point distal to the ligature to prevent the ligature from slipping off (Fig. 43-11.2). With complete stalk transection, the prolapsed leiomyoma is freed for removal, and the ligated stalk retracts into the uterine cavity (Fig. 43-11.3). If a Heaney clamp has been placed, then the stalk is severed, the mass is removed, and a ligature is placed around the proximal

stalk. As the suture is tied, the clamp is removed.

As alternatives, the stalk may be incised electrosurgically without ligature placement, or the leiomyoma can be twisted from its stalk if the stalk is not excessively thick. After leiomyoma removal, hysteroscopy may optionally be performed to assess hemostasis and the uterine cavity.

### POSTOPERATIVE

No special care beyond routine postoperative surveillance is necessary following vaginal myomectomy for a pedunculated prolapsed leiomyoma. Regular diet and activities are resumed quickly and can be individualized.

## 43-12

## Abdominal Hysterectomy

Hysterectomy is one of the most frequently performed gynecologic procedures, and more than 500,000 women undergo this procedure for benign disease annually in the United States (Jacoby, 2009). Of benign reasons, symptomatic leiomyomas and pelvic organ prolapse are the most frequent, although adenomyosis, endometriosis, chronic pain, and premalignant uterine or cervical disease are also relatively common.

### PREOPERATIVE

#### ■ Patient Evaluation

To reach the preoperative diagnosis, testing varies on clinical signs and symptoms and is discussed within the respective chapters covering specific etiologies. Prior to hysterectomy, all patients require cervical cancer screening. With abnormal findings, further evaluation is completed to exclude invasive cancer, which is treated instead with radical hysterectomy or chemoradiation. Similarly, women at risk for endometrial cancer and whose indication includes abnormal bleeding are also usually screened before surgery (Chap. 8, p. 184). Last, concurrent cervical infection or bacterial vaginosis is sought for preoperative eradication to lower postoperative infection risks.

#### ■ Decision-making for Approach Selection

Hysterectomy may be completed using an abdominal, vaginal, laparoscopic, or robotic approach, and selection is influenced by many factors. For example, shape and size of the uterus and pelvis, surgical indications, presence or absence of adnexal pathology, extensive pelvic adhesive disease, surgical risks, hospitalization and recovery length, hospital resources, and surgeon expertise are all weighed once hysterectomy is planned. Each approach carries distinct advantages and disadvantages, discussed subsequently.

#### Vaginal Hysterectomy

Surgeons usually choose this approach if the uterus is relatively small, extensive adhesions are not anticipated, no significant adnexal pathology is expected, and some degree of pelvic organ descent is present. When this procedure is compared with abdominal hysterectomy, patients usually benefit from faster recovery and from reduced hospital

stays, costs, and postoperative pain (Johnson, 2005; Nieboer, 2009).

#### Abdominal Hysterectomy

Despite the advantages of vaginal hysterectomy, most uteri in the United States are removed through an abdominal incision (Jacoby, 2009). Either a transverse or vertical incision may be selected depending on the clinical setting (p. 926).

Abdominal hysterectomy allows the greatest ability to manipulate pelvic organs. Thus, it may be preferred if large pelvic masses or extensive adhesions are anticipated. Additionally, an abdominal approach affords access to the ovaries if oophorectomy is desired, to the space of Retzius or presacral space if concurrent urogynecologic procedures are planned, or to the upper abdomen for cancer staging. However, for surgeons with advanced skills in minimally invasive surgery (MIS), most of these limitations are overcome, and their indications for abdominal hysterectomy may be few. That said, abdominal hysterectomy typically requires less operating time than laparoscopic or robotic hysterectomy and requires no advanced MIS expertise or instrumentation. Moreover, the Food and Drug Administration (FDA) (2014) has recently discouraged the use of laparoscopic power morcellators due to the potential dispersion of occult cancer cells. While data are being collected regarding this risk, many surgeons and patients may forego MIS hysterectomy for larger uteri, and thus rates of abdominal hysterectomy may increase.

Disadvantages of abdominal hysterectomy include longer patient recovery and hospital stays, increased incisional pain, and greater risk of postoperative fever and wound infection (Marana, 1999; Nieboer, 2009). Additionally, compared with a vaginal approach, abdominal hysterectomy is associated with greater risk for ureteral injury, but lower rates of bladder injury (Frankman, 2010; Gilmour, 2006).

#### Laparoscopic Hysterectomy

Selected more and more frequently, this hysterectomy group uses laparoscopic techniques to complete some or all steps of hysterectomy, and specific definitions are provided in Chapter 44 (p. 1026) (Turner, 2013). Although criteria vary depending on surgeon skill, this approach is often selected if the uterus is not excessively large, extensive adhesions are not expected, and some limitation deters vaginal hysterectomy alone. Patient recovery, hospital stays, and postoperative pain scores are comparable with those of vaginal hysterectomy, but a laparoscopic approach allows greater visualization and access to the abdomen and pelvis. This may be advantageous if oophorectomy is planned or if adhesive disease or bleeding is encountered. However, laparoscopy typically requires longer operating times, expensive equipment, and MIS expertise. In addition, in most studies, laparoscopic hysterectomy has been associated with greater rates of ureteral injury than either abdominal or vaginal hysterectomy (Frankman, 2010; Gilmour, 2006; Mamik, 2014).

#### Approach Selection

If all factors are equal, vaginal hysterectomy should be considered. However, with large pelvic masses or large uteri, with risk of gynecologic cancer, with extensive adhesions, or with poor uterine descent, either abdominal or laparoscopic hysterectomy may be required. Of note, surgical expertise is factored into the decision and strongly dictates the approach selected.

#### Total versus Supracervical Hysterectomy

Prior to hysterectomy, the decision to concurrently remove the cervix is discussed with the patient. Hysterectomy may include removal of the uterus and cervix, termed *total hysterectomy*, or may involve only the uterine corpus, called *supracervical hysterectomy (SCH)* (Fig. 43-12.1). The term *subtotal hysterectomy* is ambiguous and is not a preferred term.

FIGURE 43-12.1 Hysterectomy classification.

Most hysterectomies performed are total, but SCH may be selected preoperatively. For example, SCH is purported to reduce the risk of mesh erosion at the cuff if concurrent hysterectomy and sacrocolpopexy are planned (Osmundsen, 2012; Tan-Kim, 2011). At one point, SCH was also suggested to improve urinary, bowel, or sexual function compared with total abdominal hysterectomy. But, several studies have shown no short- or long-term differences in these functions between total abdominal or supracervical hysterectomy (Learman, 2003; Lethaby, 2012; T akar, 2002). Frequently, SCH may be an intraoperative decision during cases in which excision of the cervix risks increased bleeding, surrounding organ damage, or increased operating time.

As a disadvantage, 10 to 20 percent of women following SCH will still note cyclic vaginal bleeding, presumably from retained isthmic endometrium in the cervical stump. Procedures that ablate or core out the endocervical canal can help prevent this complication (Schmidt, 2011). Also, pelvic organ prolapse may develop (Hilger, 2005). For either complication, cervical stump excision, termed trachelectomy, may be required. Last, critics noted the persistent risk for cancer in the conserved stump. However, the risk for cervical cancer in these women is comparable to that in women without hysterectomy. Moreover, the prognosis for cervical stump cancer mirrors that in women with a complete uterus (Hannoun-Levi, 1997; Hellstrom, 2001).

In sum, SCH alone offers no distinct long-term advantages compared with total abdominal hysterectomy (American College of Obstetricians and Gynecologists, 2013b). The risk of persistent bleeding following surgery may deter many women and clinicians from its use. Moreover, although data are limited, trachelectomy following SCH may be surgically challenging due to scarring of bowel or bladder to the stump. Despite these disadvantages, if concurrent sacrocolpopexy is planned, SCH may lower mesh erosion rates. However, current data for this are limited and retrospective, and future research is needed.

## ■ Consent

For most women with indications, hysterectomy is a safe and effective treatment that typically leads to an improved postoperative quality of life and psychological outcome (Hartmann, 2004; Kuppermann, 2013). However, pelvic organs may be injured during surgery, and vascular, bladder, ureteral, and bowel injury are most commonly cited. Accordingly, these and the risks of wound infection, blood loss, and transfusion are discussed with the patient before surgery.

Infrequently, unintended adnexectomy may be required, and if bilateral, will create iatrogenic menopause. Importantly, patients should understand the sterilizing effects of hysterectomy.

## Concurrent Adnexal Surgery

Hysterectomy is frequently performed with other operations. Pelvic reconstructive surgeries and bilateral salpingo-oophorectomy (BSO) or salpingectomy are among the most frequent.

Bilateral fallopian tubes and ovaries are prophylactically removed in approximately 40 percent of hysterectomy cases performed for benign indications in the United States (Asante, 2010). In a woman younger than 40 years, ovaries are typically conserved because continued estrogen production is expected until her late 40s. In those older than 50 years, BSO is common. However, for women in their 40s, the decision to prophylactically remove ovaries is controversial.

Proponents of prophylactic BSO between 40 and 50 argue that the procedure lowers future ovarian cancer risk and is estimated to prevent 1000 new cases of ovarian cancer each year (American College of Obstetricians and Gynecologists, 2014b). In addition, patients with retained ovaries may require future surgery for subsequent benign ovarian disease. The risk approximates 3 percent at 10 years posthysterectomy (Casiano, 2013). Specifically, women with endometriosis, pelvic inflammatory disease, and chronic pelvic pain are at greater risk for reoperation. And, if later oophorectomy is required, the risk of ureteral or bowel injury due to adhesions encasing the retained ovary is increased from that with primary BSO. Last, the duration of significant ovarian estrogen production for many will be shortened following hysterectomy. For example, Siddle and coworkers (1987) noted that the mean age of ovarian failure in a group undergoing hysterectomy was 45 years. This was significantly lower than the mean age of 49 years in a control group not receiving surgery.

However, arguments for ovarian conservation are convincing as well. If ovaries are retained during hysterectomy, ovarian cancer risk is still decreased 40 to 50 percent by the hysterectomy itself (Chiaffarino, 2005; Rice, 2013). Additionally, conservation delays the long-term effects of hypoestrogenism (Chap. 21, p. 474). Parker and colleagues (2013) noted higher ovarian and slightly elevated breast cancer rates but a lower all-cause mortality rate in women after hysterectomy with ovarian conservation compared with those electing BSO without estrogen replacement therapy (ERT). Although these rates became nearly equal in those electing BSO

and then receiving postoperative ERT, concerns regarding ERT compliance have been noted. Castelo-Branco and coworkers (1999) found that after 5 years following hysterectomy and BSO, only one third of patients still continued their ERT. Most stopped due to cancer concerns. In addition to loss of estrogen, ovarian androgen production is removed, and its importance in later life has not been entirely delineated (Olive, 2005). The American College of Obstetricians and Gynecologists (2014b) recommends strong consideration of ovarian retention in premenopausal women who are not at increased genetic risk for ovarian cancer. Trends in the United States show a significant decline in BSO rates for those younger than 55 (Novetsky, 2011; Perera, 2013).

Even if ovaries are conserved, the Society of Gynecologic Oncology (2013) encourages consideration of concurrent bilateral salpingectomy during hysterectomy. This practice is hoped to lower peritoneal serous carcinomas (Chap. 35, p. 738). That said, the degree of compromise of ovarian blood supply and long-term function by this resection is not fully known, and discussion of this point should be part of preoperative consenting.

## ■ Patient Preparation

Because of the risk of postoperative wound and urinary tract infection following hysterectomy, patients typically receive antibiotic prophylaxis with either a first- or second-generation cephalosporin (American College of Obstetricians and Gynecologists, 2014a). These and suitable alternatives are found in Table 39-6 (p. 835). As noted in Chapter 39 (p. 834), preoperative mechanical bowel preparation may be implemented depending on anticipated surgical circumstances. Fortunately, the risk of bowel injury with hysterectomy in general is low, and thus many forego evacuation measures for their patients. Laparotomy dictates venous thromboembolism prophylaxis, and options are found in Table 39-8 (p. 836).

## INTRAOPERATIVE

### ■ Surgical Steps

#### □ Anesthesia and Patient Positioning.

Abdominal hysterectomy is typically performed under general or regional anesthesia. The patient is often supine. But if concomitant vaginal procedures are planned, the patient is placed in low lithotomy position in adjustable booted stirrups. After anesthesia induction, hair in the planned incision path is clipped if needed; a Foley catheter is inserted; and abdominal preparation is completed.

**FIGURE 43-12.2** Round ligament ligation.

□ **Abdominal Entry.** Either a transverse or a vertical incision may be used for hysterectomy, and clinical factors influence selection (p. 926).

□ **Exposure.** Following entry into the abdomen, a self-retaining retractor such as an O'Connor-O'Sullivan or a Balfour retractor is placed. The pelvis and abdomen are visually and manually explored, and the bowel is packed from the operating field. The uterus is grasped and elevated from the pelvis. If extensive adhesions are present, normal anatomic relationships are restored. Hysterectomy may be performed by one surgeon, but commonly two surgeons are present, with each typically operating on his or her side of the uterus.

□ **Round Ligament Transection.** Curved Kelly (pean) clamps are placed immediately lateral to each uterine cornu to permit uterine manipulation. Hysterectomy begins with division of one round ligament at its midpoint (Fig. 43-12.2). This provides entry into the retroperitoneal space for ureter identification and access to the uterine artery and cardinal ligament for later transection. The round ligament is grasped with tissue forceps and elevated. A transfixing stitch using 0-gauge delayed-absorbable suture is placed approximately 1 cm lateral to the planned division site. The first bite of this stitch passes through an avascular site of the mesoteres beneath the round ligament, whereas the transfixing bite pierces the round ligament medial to first bite. This prevents hematoma formation between the transfixing stitch and pelvic sidewall. A second simple stitch of similar suture is placed 1 to 2 cm medial to the first and through an avascular site in the mesoteres and beneath the round ligament. These sutures prevent bleeding from Sampson artery and aid tissue manipulation. Once secured, sutures are held by hemostats and directed outward to create

**FIGURE 43-12.3** Opening of broad ligament anterior leaf.

tension along the interposed ligament. The round ligament is then divided, and the incision line is directed deeply into the first 1 to 2 cm of the broad ligament.

□ **Anterior Broad Ligament Leaf.** With this action, the broad ligament separates to create anterior and posterior leaves. Between them, loose areolar connective tissue is seen. To incise the anterior leaf, the round ligament sutures are placed on tension. Metzenbaum scissors are introduced between the anterior leaf and underlying loose connective tissue. Both scissor tips are directed upward to be seen through the peritoneum as they advance. Gentle opening and closing of scissor blade tips during advancement separates the peritoneum from the underlying connective tissue. The tented anterior leaf is then incised sharply. The line of incision curves inferiorly and medially to the level of the vesicouterine

fold, which generally lies just below the uterine isthmus (Fig. 43-12.3).

Next, to further open the retroperitoneal space, the drape of peritoneum lying between the round ligament and infundibulopelvic (IP) ligament is grasped with smooth forceps and placed on tension. This peritoneum is incised with Metzenbaum scissors and with the same undermining technique used for the anterior leaf (Fig. 43-12.4). Lateral and parallel to the IP, the incision is extended cephalad toward the pelvic sidewall.

□ **Ureter Identification.** This is accomplished by localized blunt dissection that is advanced downward with gentle cephalad and caudad strokes into gauzy retroperitoneal tissue above the presumed ureter path (Fig. 43-12.5). Dissection is directed downward, medially, and slightly cephalad toward the medial aspect of the posterior peritoneal

**FIGURE 43-12.4** Peritoneal incision extension.

**FIGURE 43-12.5** Ureter identification.

leaf, along which the ureter courses. Small vessels are coagulated as they are found.

#### □ **Posterior Broad Ligament Leaf.**

With the ureter directly visualized, the posterior peritoneal leaf is incised to create a window. If ovarian preservation is planned, this window is made beneath the uteroovarian ligament alone. If oophorectomy is planned, the posterior leaf of the broad ligament is incised parallel to the IP ligament. The incision is extended toward the pelvic brim and medially toward the uterus just below the uteroovarian ligament. This delineates the IP for ligation (Fig. 43-12.6).

□ **Adnexectomy.** If the adnexa are to be removed, the fallopian tube and ovary are

grasped with a Babcock clamp and elevated medially to place the IP ligament on mild tension for improved delineation (Fig. 43-12.7). With the ureter visualized, a curved Heaney clamp can be placed around this ligament with its arc curving upward. The tips of the clamps are placed through the previously created peritoneal window. A Kelly clamp is placed medial to this and closer to the adnexa.

With clamps secured, the IP ligament is sharply transected above the Heaney clamp. A free tie of 0-gauge delayed-absorbable suture is placed around the Heaney clamp.

As the knot of this suture is secured, the Heaney clamp is quickly opened and closed, that is, “flashed.” A transfixing stitch is then sutured below the clamp but above and distal to the first free tie. As the knot is cinched, the Heaney clamp is removed.

The adnexa is now freed from the pelvic sidewall, and its increased mobility may obstruct the surgeon’s view. Accordingly, the adnexa can be tied to the Kelly clamp still located on the cornu. Alternatively, adnexa can be simply excised and removed.

□ **Ovarian Conservation.** With the leaves of the broad ligament now open, if the ovary is to be preserved, then salpingectomy alone is now completed. This is fully described in Section 43-8 (p. 939). In summary, the mesosalpinx is serially clamped, cut, and ligated. Each clamp incorporates approximately 2 cm of mesosalpinx, and resection progresses from the fimbria to its union with the uterus.

To preserve the ovary, one Kelly clamp is already positioned at the cornu and across the uteroovarian ligament. A Heaney clamp is positioned lateral to this, and its arc faces the uterus (Fig. 43-12.8).

The intervening segment of uteroovarian ligament is incised between the Heaney and Kelly clamps. Ligation of the ligament is carried out as in Step 8. That is, a free tie of 0-gauge delayed-absorbable suture is placed around the Heaney clamp. As the knot is secured, the clamp is flashed. A transfixing stitch is then placed around the same clamp but distal to the first free tie. As the knot is cinched, the Heaney clamp is removed. The ovary is now freed from the uterus and can be placed laterally near the pelvic sidewall. The

**FIGURE 43-12.6** Posterior peritoneal window.

**FIGURE 43-12.7** Infundibulopelvic ligament transection during oophorectomy.

**FIGURE 43-12.8** Uteroovarian ligament transection for ovarian conservation.

Kelly clamp is left in place at the cornu to prevent bleeding and allow uterine manipulation.

□ **Bladder Flap.** Steps 4 through 9 are completed bilaterally, and attention is next turned to the bladder. To avoid urinary tract injury, the bladder is moved caudad and away from the cervix. This is accomplished by first opening the vesicouterine space, the potential space between the bladder and cervix. Several techniques may be used, and at our institution, sharp dissection is preferred (Fig. 43-12.9). This method is particularly beneficial for patients with prior cesarean deliveries who may have scarring between the bladder and cervix. Alternatively, gentle blunt pressure from fingers or sponge stick can be used. Such pressure is directed beneath the bladder, against the cervix, and caudad. With

either dissection method, taut uterine elevation creates helpful tension across the tissue planes to be separated. Tension is created by pulling upward on the Kelly clamps, previously placed at the cornua.

The peritoneum at the vesicouterine fold was previously incised bilaterally in Step 5. During dissection in the vesicouterine space, this peritoneum is grasped with atraumatic tissue forceps and elevated to create tension between it and the underlying cervix. Only loose connective tissue strands lie in this space, and they are easily cut with Metzenbaum scissors. Incision of these bands is kept close to the cervix to avoid cystotomy. Dissection in the midline minimizes laceration of vessels that

course within the vesicocervical ligaments, colloquially termed *bladder pillars*. Once the correct plane is entered, the pearly white cervix and anterior vaginal wall are clearly differentiated from reddish bladder fibers.

The bladder is ideally dissected off the anterior vaginal wall at least 1 cm below the lower margin of the cervix. This averts incorporating bladder fibers within sutures or clamps placed during cuff closure. Thereby, bladder and distal ureteral injury, and later genitourinary fistulas, are prevented.

① **Uterine Arteries.** The uterine artery and vein(s) are identified laterally along the uterus. At the level of the isthmus, some posterior peritoneum and loose areolar tissue still surrounds these vessels. Incising and removing such tissue from around any vessel is termed *skeletonizing*. This ultimately creates a smaller vascular pedicle and minimizes risks for vessel retraction during ligation.

To skeletonize, a surgeon individually grasps excess strips of perivascular connective tissue with fine smooth forceps and gently retracts them laterally and away from the uterine artery or vein. Metzenbaum scissors incise this tissue close to and parallel to the vessel, beginning superiorly and proceeding inferiorly. During this process, the remaining posterior broad ligament peritoneum is similarly incised parallel and close to the uterus (Fig. 43-12.10). Importantly, this step further “drops” the ureter away from the path of subsequent clamps.

Once skeletonized, the uterine vessels are clamped by a curved Heaney clamp at the uterine isthmus level. The clamp tips are placed horizontally across the vertical uterine vessels (Fig. 43-12.11). A Kelly clamp is placed medial and more vertical to the first

**FIGURE 43-12.9** Dissection within vesicouterine space.

**FIGURE 43-12.10** Uterine artery skeletonization.

**FIGURE 43-12.11** Clamps across uterine artery.

clamp and hugs the lateral uterus to prevent bleeding from severed vessels. Tissue between the clamps is then cut.

A simple stitch of 0-gauge delayed-absorbable suture is placed below the Heaney clamp's tip, and the suture ends are wrapped to the clamp's heel. As the knot is cinched, the Heaney clamp is slowly opened and removed. The Kelly clamp remains.

**12 Fundal Amputation.** After bilateral uterine artery ligation, if the uterus is large and bulky, the uterine fundus may be sharply severed from the cervix. After removal of the corpus, Kocher clamps are placed on the anterior and posterior walls of cervix for manipulation.

If supracervical hysterectomy is planned, no further transection is required. In premenopausal women, the upper endocervical canal is coagulated or removed by wedge resection to help avoid postoperative cyclic bleeding. The cervical stump is closed and rendered hemostatic with figure-of-eight stitches using 0-gauge delayed-absorbable suture. Each stitch passes through the posterior peritoneum, the posterior wall of the cervix, and then the anterior wall of the cervix before ligation. Conversely, if the cervical stroma is hemostatic, no suturing may be required.

**13 Cardinal and Uterosacral Ligament Transection.** These ligaments lie lateral to the uterus and inferior to the uterine vessels. A straight Heaney clamp is positioned across the cardinal ligament adjacent to the cervix and medial to the uterine artery pedicle (Fig. 43-12.12). As the Heaney clamp initially grasps the ligament, it is oriented parallel to the lateral side of the uterus. As the clamp is slowly closed, it is angled slightly away from the vertical axis of the cervix. A scalpel is

**FIGURE 43-12.12** Clamp across cardinal ligament.

used to transect the portion of the cardinal ligament medial to the clamp. A transfixing stitch of 0-gauge delayed-absorbable suture is placed below the clamp, and the clamp is removed as the knot is cinched. For smaller bites through the cardinal ligament, a simple stitch without transfixion may suffice.

Depending on the ligament length, the above step may be repeated several times. In this manner, the cardinal ligament is transected and ligated from its superior to inferior extent down the lateral aspect of the cervix to the level of the upper vagina. When this is near completion, the uterosacral ligaments remain as final support structures attached to the cervix. These ligaments are more easily felt and seen by placing upward traction on the uterus. In most benign cases, these liga-

ments are incorporated within instruments used to clamp across the lower cardinal ligament and proximal vagina.

**14 Vagina Transection.** For this step, the surgeon's hand palpates through the anterior and posterior vaginal walls to identify the most inferior level of the cervix. Here, a curved Heaney clamp incorporates the uterosacral ligament and is placed across the anterior and posterior vaginal walls just below the cervix on one side. This is repeated on the other side, and the tips often meet in the midline (Fig. 43-12.13). Importantly, the bladder must be sufficiently mobilized away from this point to prevent injury.

The vaginal tissue above the level of these clamps is then transected. This procedure

**FIGURE 43-12.13** Clamp incorporating uterosacral ligament and proximal vagina.

**FIGURE 43-12.14** Clamps across proximal vagina. Two transfixing stitches for cuff closure.

**FIGURE 43-12.15** Circumferential vaginal incision.

frees the uterus from the pelvis. Transfixing sutures are placed below the Heaney clamps, and the clamps are removed (Fig. 43-12.14).

**15 Vaginal Entry.** During some cases, the cervix may be poorly appreciated between the vaginal walls. To avoid shortening the vagina or leaving cervix behind, the vagina can be entered to identify the cervix. For this, a small longitudinal incision is made in the midline of the upper anterior vaginal wall. A finger is inserted to palpate the cervical margin. Once this level is known, one blade of Jorgensen scissors is inserted into the vagina and positioned just below the cervix (Fig. 43-12.15). At this level, the vagina is then circumferentially cut. Kocher or Allis clamps are placed along the free cut vaginal edge as it forms.

**16 Vaginal Cuff Closure.** For support, a 0-gauge delayed-absorbable suture may be placed to suspend the vaginal apex to the uterosacral ligament pedicle on either side (Fig. 43-12.16). This stitch incorporates the anterior and posterior vaginal walls with the distal portion of the uterosacral ligament and helps prevent vaginal cuff prolapse following surgery.

These sutures are kept long and held by hemostats. Upward and lateral traction elevates the vaginal cuff. The full thicknesses of the incised anterior and posterior vaginal walls are then reapproximated with a running suture line using 0-gauge delayed-absorbable suture or with several figure-of-eight sutures. The peritoneum overlying the

posterior vaginal margin should be included in this closure to lessen the risk of postoperative oozing. Anteriorly, the bladder should be kept clear of the suture line. Once the vaginal cuff is hemostatic, the lateral suspending cuff sutures are cut.

**17 Wound Closure.** The abdominal incision is closed as described in Section 43-1 or 43-2 (p. 928).

## POSTOPERATIVE

Postoperative care follows that for laparotomy, although sexual intercourse is usually delayed until 6 weeks after surgery to permit satisfactory vaginal cuff healing (p. 928).

Febrile morbidity is common following abdominal hysterectomy and exceeds that seen with vaginal or laparoscopic approaches (Peipert, 2004). Frequently, fever is unexplained. But, pelvic infections are common, and other sources of postoperative fever should be evaluated (Chap. 42, p. 919). Because of the high rate of unexplained fever, which resolves spontaneously, observation for 24 to 48 hours for mild temperature elevations is reasonable. Alternatively, antibiotic treatment may be initiated, and appropriate choices are found in Table 3-20 (p. 79). Additional testing, including transvaginal sonography or computed tomography (CT), may be indicated if a pelvic hematoma or abscess is suspected.

**FIGURE 43-12.16** Vaginal cuff closure incorporating uterosacral ligament.

## 43-13

## Vaginal Hysterectomy

In general, this approach is chosen by surgeons if the uterus is relatively small, extensive adhesions are not anticipated, no significant adnexal pathology is expected, and some degree of pelvic organ descent is present. Compared with abdominal hysterectomy, patients undergoing vaginal hysterectomy usually benefit from faster recovery and from reduced hospital stays, costs, and postoperative pain. During selection of hysterectomy approach described on page 950, if all factors are equal, then vaginal hysterectomy is preferred.

## PREOPERATIVE

Patient evaluation, consenting, and patient preparation are similar to that for abdominal hysterectomy (p. 950).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** After adequate general or regional anesthesia is administered, the patient is placed

in standard dorsal lithotomy position (Fig. 40-4, p. 845). The vagina is surgically prepared, and the bladder is drained. Some surgeons may prefer to wait until the anterior peritoneum is entered before inserting a Foley catheter. This permits a gush of urine to signal inadvertent bladder laceration. Along the posterior vaginal wall, a short Auvar weighted vaginal speculum is placed, and a right-angle or other suitable retractor is placed anteriorly.

□ **Vaginal Wall Incision.** To begin, one Lahey-thyroid clamp is used to grasp the anterior cervical lip, while a second one holds the posterior lip. For a smaller cervix, one clamp may easily grasp both lips together. The junction between the cervix and the anterior and posterior vaginal walls can be seen and palpated by in-and-out displacement of the cervix. Just proximal to this junction, a circumferential incision is made around the cervix and is guided by anatomy (Fig. 43-13.1). For example, if the cervix is flush with the vagina, then incision lies close to the remaining cervix to avoid rectal injury. In general, the incision is kept at a depth superficial to the cervical stroma to avert dissection into the cervix. To minimize blood loss during dissection, 10 to 15 mL of a dilute saline solution containing vasopressin (20 U diluted in 30–100 mL of saline) or 0.5-percent lidocaine and epinephrine (1:200,000 dilution) may be injected circumferentially along the incision path.

□ **Posterior Entry.** Although described first here, the sequence of anterior and posterior entry is based on surgeon preference and intraoperative findings. The Lahey-thyroid clamp and cervix are lifted anteriorly to expose the posterior vaginal vault, and an Allis clamp is placed below the circumcised edge of the posterior vaginal wall. Downward traction on the Allis clamp creates tension across the incision. Curved Mayo scissors positioned across the incision line cut to enter the cul-de-sac of Douglas (Fig. 43-13.2). The posterior peritoneum may be affixed centrally to the posterior vaginal wall incision with a single stitch of delayed-absorbable suture. This approximation will assist with closure of the peritoneum at the procedure's end. The short Auvar speculum is replaced by one with a longer blade, which enters the cul-de-sac.

□ **Anterior Peritoneal Entry.** This is generally considered the most challenging step of vaginal hysterectomy. First, the anterior vaginal wall is grasped near the circumferential incision in the midline and elevated with an Allis clamp. Tension is concurrently created by outward traction on the cervical Lahey-thyroid clamps. This traction reveals fibrous connective tissue bands connecting the bladder and cervix. These bands fill the vesicocervical space, which is typically 3 cm long (Balgobin, unpublished data). Although the proximal part of this space contains loose areolar tissue, the distal portion contains

FIGURE 43-13.1 Circumferential cervical incision.

FIGURE 43-13.2 Entry into the cul-de-sac of Douglas.

**FIGURE 43-13.3** Sharp dissection of vesicouterine septum from two views.

thicker fibers. This knowledge permits calm, persistent dissection through this dense tissue rather than prematurely reorienting dissection, which risks “digging” into the cervix.

At our institution, sharp dissection is preferred (Fig. 43-13.3). This method is particularly beneficial for patients with prior cesarean deliveries, who may have scarring between the bladder and cervix. With traction established, the fibers are incised in the midline with Metzenbaum scissors. Tips are kept close and almost parallel to the cervix as dissection is extended cephalad. Bleeding vessels are frequently encountered during initial dissection and are coagulated. After the initial fibers are transected, gentle palpation with the index finger should indicate whether the upper part of the vesicocervical space has been reached. In the absence of scar tissue, these fibers are easily broken, and gentle blunt dissection is advanced cephalad until the vesicouterine fold is palpated. Alternatively, the entire vesicocervical space dissection can be completed with gentle blunt pressure from an index finger covered in surgical gauze. Such pressure is directed against the cervix and cephalad toward the vesicouterine fold.

This fold is a thin and transparent transverse peritoneal fold at the upper border of the cervix. With palpation, this smooth layer glides against the uterine serosa. This peritoneum is grasped with atraumatic tissue forceps, placed on tension, and incised (see Fig. 43-13.3). In cases with difficult anterior entry, the surgeon may enter the posterior cul-de-sac and wrap an index finger anteriorly to palpate and accentuate the vesicouterine fold for anterior entry.

Following vesicouterine fold incision, an index finger explores the opening to confirm peritoneal entry, exclude cystotomy, and identify unanticipated pelvic pathology. This finger then guides a curved Deaver retractor

into the opening to elevate the bladder and anterior vaginal wall.

**Transection of Uterosacral and Cardinal Ligaments.** Outward traction on the Lahey-thyroid clamps pulls the supporting uterine ligaments into view. Such traction, along with upward bladder displacement, helps prevent ureteral injury. The uterosacral and cardinal ligaments are identified, clamped with a curved Heaney clamp, transected, and ligated with 0-gauge delayed-absorbable suture using a transfixing stitch (Fig. 43-13.4). Once the knot of this pedicle is tied, the suture ends are not cut but kept long for later identification. This step is then repeated on the opposite side.

Depending on the cardinal ligament length, similar clamping, cutting, and suturing may

need to be repeated. Advancement is cephalad, and along each side and parallel to the cervix. Each sequential clamp is placed medial to the prior pedicle to reduce ureteral injury risk.

**Uterine Arteries.** The uterine artery is identified on one side and clamped with a curved Heaney clamp. The clamp is placed nearly perpendicular to the long axis of the uterus and medial to the prior cardinal ligament pedicle (Fig. 43-13.5). The tips should firmly abut the uterus to ensure enclosure of entire artery and vein(s) within the clamp. A more laterally placed clamp may not be completely enclose the artery. Following pedicle transection, a simple stitch is placed around the clamp and is secured at the clamp heel as the instrument is removed. Uterine arteries are ligated bilaterally.

**Cornua.** Progressing cephalad, curved Heaney clamps are next placed across the round and uteroovarian ligaments and fallopian tube (Fig. 43-13.6). After transection, a simple stitch of 0-gauge delayed-absorbable suture is placed proximally around the clamp. As the knot is secured, the Heaney clamp is quickly flashed. A transfixing stitch is then sutured around the clamp and positioned distal to the first stitch. As this knot is cinched, the Heaney clamp is removed. This transection is repeated bilaterally. With ovarian preservation, these sutures are cut short after confirming pedicle hemostasis. However, for adnexectomy, the transfixing suture tails may be kept long to allow gentle traction to bring the adnexa toward the vagina.

For the above step, if the uterus is larger, the uteroovarian ligament and tube may be

**FIGURE 43-13.4** Clamp incorporating uterosacral and cardinal ligaments.

**FIGURE 43-13.5** Clamp across uterine vessels.

**FIGURE 43-13.6** Clamp across uteroovarian ligament and fallopian tube.

difficult to reach and clamp. For this, the uterine corpus may be delivered through the posterior colpotomy incision to better expose these. To deliver the fundus, a tenaculum is placed on the upper posterior uterine wall, and it gently pulls the fundus into the vagina. Excessive traction may result in tissue avulsion and bleeding. Conversely, if the uterus is small and descent is adequate, the uteroovarian

and round ligaments and fallopian tube may be combined together in one curved Heaney clamp (Fig. 43-13.7). The pedicle is doubly ligated with a simple suture first placed proximally and then with a transfixing stitch placed distally.

With ovarian preservation, some recommend consideration of bilateral salpingectomy to lower high-grade peritoneal and

ovarian serous carcinoma rates. However, during vaginal hysterectomy, complete resection of the tube is typically more challenging than during abdominal approaches, and iatrogenic bleeding may lead to oophorectomy or conversion to laparotomy. If tube removal is desired, then adjunctive laparoscopic salpingectomy may be considered to ease safe removal of the entire tube.

□ **Morcellation.** In some cases, the uterine fundus may be too large to deliver, and uterine debulking is required prior to ligation of the cornual attachments. This is performed only after both uterine artery pedicles have been secured.

One technique bisects the uterus using curved Mayo scissors, beginning at the cervix and moving toward the fundus. Near completion, fingers placed through the anterior colpotomy incision and behind the fundus help prevent scissor injury to adjacent organs (Fig. 43-13.8). Once completed, one half is elevated out of the operating field and into the pelvic cavity, whereas the other is brought into view for clamp placement across the uteroovarian and round ligaments and fallopian tube (Fig. 43-13.9). Other methods either enucleate individual large leiomyomas or involve cervix-to-fundus central coring to remove volume (Fig. 43-13.10). Once bulk is diminished, a Heaney clamp may be placed around the cornual structures as described in Step 7.

□ **Adnexectomy.** For this, the adnexa is grasped with a Babcock clamp and gently pulled inferiorly and toward the contralateral side of the incision. This creates mild tension

**FIGURE 43-13.7** Fundal inversion to permit cornual structure clamping.

**FIGURE 43-13.8** Uterus bisected.

**FIGURE 43-13.9** Clamp across cornual structures.

on the infundibulopelvic (IP) ligament for improved delineation. To expand the operating field, a right-angle or similar retractor is positioned deep into the incision for vaginal sidewall retraction. This is coupled with upward traction from the originally placed anterior wall retractor.

A curved Heaney clamp is placed around the IP ligament, and its blades cover the entire pedicle width. For difficult angles, the surgeon's contralateral hand can push the ligament into correct position within the clamp. Prior to clamp closure, the surgeon confirms that no bowel or omentum is incor-

porated and that the entire ovary lies distal to the clamp. A moist sponge stick and slight Trendelenburg positioning can push the bowel away from the operative field.

The IP ligament is then clamped and transected ([Fig. 43-13.11](#)). First, a free tie of 0-gauge delayed-absorbable suture is placed

**FIGURE 43-13.10** Coring of central uterine bulk.

**FIGURE 43-13.11** Clamp across infundibulopelvic ligament.

**FIGURE 43-13.12** Vaginal cuff closure.

around the Heaney clamp. As the knot is secured, the clamp is flashed. A transfixing stitch is then placed around the same clamp but distal to the first free tie. As the knot is cinched, the Heaney clamp is removed. Excess traction on this pedicle is avoided to prevent avulsion or retraction of the ligament from the clamp. In such cases, resultant retroperitoneal bleeding may be difficult to control vaginally. Once hemostasis is ensured, the suture is cut. The opposite IP ligament is similarly clamped and transected.

□ **Evaluation of Hemostasis.** Following removal of the uterus, the surgical pedicles are inspected for bleeding. Electrosurgical coagulation or figure-of-eight sutures will typically control bleeding from discrete points. If indicated or preferred, a McCall culdoplasty may be performed (Section 45-22, p. 1116).

⑩ **Vaginal Cuff Closure.** The anterior and posterior vaginal walls are usually reapproximated by a horizontal suture line with

interrupted or continuous running stitches of 0-gauge delayed-absorbable material. If short vaginal length is a concern, walls can be closed by a vertical suture line.

To help prevent later vaginal apex prolapse, the uterosacral ligament pedicles are incorporated within the cuff closure. For this, the interrupted or continuous running closure suture is initially passed through the anterior vaginal wall, through the ligament, through the posterior peritoneum, and finally through the posterior vaginal wall on one side (Fig. 43-13.12). This is repeated on the other side. Suturing then progresses from each side to the midline, or a single running suture may close the entire cuff line. During cuff closure, full thickness bites through the vaginal wall are taken. Also, the posterior peritoneum is incorporated with the closure to minimize risks of bleeding and cuff hematoma.

## POSTOPERATIVE

In general, patients who undergo vaginal hysterectomy compared with abdominal hysterectomy, typically have faster return of normal bowel function, easier ambulation, and decreased analgesia requirements. Although diet and most activities are advanced quickly, intercourse is delayed for 6 weeks to permit vaginal cuff healing. Evaluation and treatment of postoperative complications mirrors that for abdominal hysterectomy.

## 43-14

## Trachelectomy

For many women who have had supracervical hysterectomy, later surgical removal of the cervix, termed *trachelectomy*, is often indicated for complaints of vault prolapse, persistent cyclic bleeding, or preinvasive cervical lesions (Pasley, 1988). Hilger and associates (2005) reported on 335 women who underwent trachelectomy between 1974 and 2003. In half of them, trachelectomy was performed, on average, 26 years after supracervical hysterectomy. Of surgical indications, prolapse and pelvic mass are the most frequent. Bleeding accounts for nearly 10 percent of cases (Hilger, 2005; Kho, 2011).

The cervix may be removed either vaginally or abdominally, but for most women without concurrent pelvic pathology, vaginal trachelectomy is preferred (Pratt, 1976). With the resurgence of supracervical hysterectomy, now performed via laparoscopy, rates of trachelectomy for benign causes may rise.

Trachelectomy for benign indications is described here. Radical trachelectomy for invasive cervical cancer is gaining acceptance and is described in Chapter 30 (p. 670).

## PREOPERATIVE

## ■ Patient Evaluation

As with hysterectomy, women require preoperative Pap test screening to exclude cervical cancer. Microscopic examination of cervicovaginal secretions will identify infections that merit treatment before surgery.

## ■ Consent

As with vaginal hysterectomy, patients are at risk for urinary tract and bowel injury. Similarly, postsurgical vaginal cuff complications may include hematoma, abscess, and cellulitis. Fortunately, complications are infrequent for most. Although Pratt and Jeffries (1976) noted complications in 91 of 262 patients, complication rates in several series range below 10 percent (Riva, 1961; Welch, 1959).

## ■ Patient Preparation

Entry into the peritoneal cavity is common during trachelectomy. Accordingly, as with vaginal hysterectomy, prophylaxis against postoperative infection and venous thromboembolism is warranted. Appropriate choices

are found in Tables 39-6 and 39-8 (p. 835). Enemas the evening prior to surgery aid in evacuation of the rectum.

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Trachelectomy is performed as an inpatient procedure under general or regional anesthesia. The patient is placed in a standard dorsal lithotomy position, the vagina is surgically prepared, and a Foley catheter is placed.

□ **Incision and Extraperitoneal Dissection.** The beginning steps of trachelectomy mirror those for vaginal hysterectomy (Step 2, p. 957). However, unlike vaginal hysterectomy, because the cervical stump lies outside the peritoneum, entry into the peritoneal cavity is not required for trachelectomy. Accordingly, once circumcision of the vaginal wall around the cervix is completed, dissection proceeds to the vesicouterine fold but without peritoneal entry.

In many cases, the bladder is more densely adhered to the anterior cervix, and the clear tissue planes often encountered during vaginal hysterectomy are absent. Moreover, if at completion of the original hysterectomy, the peritoneum was reapprox-

imated to cover the cervical stump, then the bladder may be draped over and scarred to the apex of the stump as well. For this reason, dissection of the vaginal wall, bladder, and rectum from the surface of the cervix typically requires sharp rather than blunt dissection (Fig. 43-14.1). As with vaginal hysterectomy, outward traction on the cervix in combination with counter traction of the vaginal wall aids dissection. To avoid cystotomy and proctotomy, scissor blades and dissecting pressure are directed against the cervix.

□ **Transection of Uterosacral and Cardinal Ligaments.** Once dissected free from the vaginal wall, the uterosacral and cardinal ligaments are clamped and ligated as with vaginal hysterectomy (Fig. 43-14.2). The cervical branches of the uterine artery are typically clamped and ligated with the cardinal ligament. Depending on cervical length, serial transection and ligation of the cardinal ligament is continued cephalad until the stump apex is reached.

□ **Stump Excision and Cuff Closure.** Once the apex is reached, sharp dissection across the top of the stump will free it from the vagina (Fig. 43-14.3). Next, incorporation of the uterosacral ligaments and reapproximation of the vaginal walls follows that for vaginal hysterectomy (Step 11, p. 961).

FIGURE 43-14.1 Extraperitoneal dissection.

**FIGURE 43-14.2** Uterosacral and cardinal ligament transection.

**FIGURE 43-14.3** Stump excision.

### POSTOPERATIVE

As with hysterectomy, a significant number of women will have unexplained febrile morbidity following trachelectomy. Pasley

(1988) in his series of 55 cases noted a rate of 9 percent. Similar to hysterectomy, patients with persistent or high-degree fevers require evaluation and possible antibiotic treatment (Chap. 42, p. 919).

## 43-15

## Sharp Dilatation and Curettage

This procedure is a primary tool for diagnostic evaluation and treatment of abnormal uterine bleeding. However, the indications for dilatation and sharp curettage (D & C) have decreased with the development of less invasive methods such as plastic endometrial samplers and transvaginal sonography (Chap. 8, p. 184).

For evaluation of abnormal uterine bleeding, sharp curettage may be used alone or more commonly in combination with hysteroscopy for those women with persistent bleeding despite normal findings with sonography and endometrial biopsy. In some, mechanical cervical dilatation followed by curettage may be required to gain access to the uterine cavity when a stenotic cervical os prohibits in-office endometrial sampling. Also, if uterine malignancy is suspected and initial biopsy is incomplete, D & C may permit a more thorough removal and interrogation of endometrial tissue.

In the treatment of severe acute menorrhagia, D & C may be used to remove hypertrophic endometrium if bleeding must be stopped promptly or if bleeding is refractory to medical management. Although suction curettage is used more commonly for removal of first-trimester pregnancy products, sharp D & C may also be an option (Chap. 6, p. 152). Finally, in women with suspected ectopic pregnancy, D & C sometimes is used to document the absence of intrauterine trophoblastic tissue (Chap. 7, p. 167).

### PREOPERATIVE

#### Consent

For most women, sharp dilatation and curettage poses only a small risk of complication, and rates are typically below 1 percent (Radman, 1963; Tabata, 2001). Infection and uterine perforation are among the most frequent. With uterine perforation, concern for adjacent organ injury may require diagnostic laparoscopy or laparotomy and injury repair. Although rare, the possibility of hysterectomy is also discussed.

#### Patient Preparation

Because the indications for sharp D & C are diverse, diagnostic testing prior to evacuation will vary. Sonography is a frequent evaluation

tool, and images are reviewed preoperatively to reorient the surgeon to uterine inclination and pathology.

Prophylactic antibiotic administration is typically not required when sharp D & C is performed for gynecologic indications. However, because pelvic infection may follow this procedure when performed in an obstetric setting, antibiotics are usually prescribed postoperatively. Doxycycline, 100 mg orally twice daily for 10 days, is a frequent choice (American College of Obstetricians and Gynecologists, 2014a). The risk of bowel injury or venous thromboembolism (VTE) with this procedure is rare. Thus, preoperative enema or VTE prophylaxis in those without additional risk factors is not mandatory.

### INTRAOPERATIVE

#### Surgical Steps

**Anesthesia and Patient Positioning.** Dilatation and curettage is typically performed as an outpatient procedure under general or regional anesthesia or with local nerve blockade combined with intravenous sedation. The patient is placed in standard dorsal lithotomy position, the vagina is surgically prepared, and the bladder drained.

A bimanual examination to determine uterine size and inclination is performed prior to introduction of vaginal instruments. Information obtained from this examination helps avoid uterine perforation. With insertion of instruments along the long axis of the uterus, there is less chance of injury.

**Uterine Sounding.** Suitable vaginal exposure can be achieved with either a Graves speculum or individual vaginal retractors. The anterior lip of the cervix is grasped with a single-tooth tenaculum to stabilize the uterus during dilatation and curettage. A Sims uterine sound is then held like a pencil with the thumb and first two fingers (Fig. 43-15.1). The sound is slowly guided through the cervical os, into the uterine cavity, and to the fundus. To minimize perforation risks, instruments are not forced and are kept in the midline.

Once gentle resistance is met at the fundus, the distance from the fundus to the external os is measured by score marks along the length of the sound. Knowledge of the depth to which dilators and curettes can safely be inserted also decreases perforation risk.

At times, cervical stenosis may preclude easy access to the endocervical canal. In these cases, smaller caliber tools, such as a lacrimal duct probe, can be guided into the external cervical os to define the canal path. Sonography may be helpful when done simultaneously with D & C in these situations. Sonographic visualization of instruments as they are being passed may help assure proper placement (Christianson, 2008). In addition, pretreatment with the prostaglandin E<sub>1</sub> analogue misoprostol (Cytotec) may allow adequate cervical softening for instrument passage. Commonly used dosing options include 200 or 400 µg vaginally or 400 µg orally or sublingually once 12 to 24 hours prior to surgery. Song and coworkers (2014) noted equal efficacy but a patient preference for oral administration. Common side effects include cramping, uterine bleeding, or nausea.

**Uterine Dilatation.** After the uterus is sounded, dilators of sequentially increasing caliber are inserted to open the endocervical canal and internal cervical os. A Hegar, Hank, or Pratt dilator, as shown on page 967, is held by the thumb and first two fingers, while the fourth and fifth fingers and heel of the hand rest on the perineum and buttock. Each dilator is gently and gradually advanced through the internal cervical os. Serial dilatation continues until the cervix will admit the selected curette (Fig. 43-15.2).

During sounding or dilatation, uterine perforation may occur and is suspected when the instrument travels deeper than previously measured. Because of the blunt, narrow shape of these tools, risk of significant uterine or abdominal organ injury is low. In such cases, if significant bleeding is absent, reassessment of uterine inclination and completion of the D & C is reasonable. Alternatively, surgery may be terminated and repeated at a later date to allow myometrial healing. Importantly, lateral perforation may create a broad ligament hematoma, which if suspected merits

FIGURE 43-15.1 Sims uterine sound.

**FIGURE 43-15.2** Uterine curettes.

laparoscopic evaluation or postoperative surveillance of hemodynamic status.

□ **Uterine Curettage.** Prior to curettage, a sheet of nonadherent wound dressing material (Telfa pad) is spread out in the vagina beneath the cervix. The uterine curette is then inserted and advanced to the fundus, following the long axis of the corpus. The concave curve of the curette loop has a sharp edge, which allows curettage. On reaching the fundus, the sharp surface is positioned to contact the adjacent endometrium (Fig. 43-15.3). Pressure is exerted against the endometrium as the curette is pulled toward the internal cervical os.

After reaching the os, the curette is redirected to the fundus and positioned immediately adjacent to the path of the first curettage pass. After several passes, tissue accumulated in the isthmic region is scraped out onto the Telfa pad. In this fashion, the entire uterine cavity is sequentially and circumferentially curetted. The collected specimen is sent for pathologic evaluation.

As with dilatation, the uterus may be perforated during curettage. In contrast to the

**FIGURE 43-15.3** Uterine curettage.

metal sound or dilator, the sharp curette has the potential to lacerate bowel, vessels, and other abdominal organs. Accordingly, diagnostic laparoscopy is considered to evaluate for such injuries.

□ **Uterine Exploration.** Uterine polyps, both large and small, may be missed with sharp curettage. As described in Chapter 8 (p. 187), hysteroscopy is a more accurate means to diagnose and remove focal lesions and is often coupled with D & C. In areas without these resources or expertise, uterine exploration with Randall kidney stone forceps can be used to secure and remove polyps. For this, closed forceps are inserted into the endometrial cavity. Upon reaching

the fundus, forceps are opened against the uterine walls, closed, and then pulled away from the endometrium. With this technique, anterior, posterior, proximal, and distal cavity surfaces are explored. With capture of a polyp within the jaws, a tug against the closed forceps is felt as they are pulled away from the uterine wall. Firm traction typically frees the polyp. Removed tissue is sent for pathologic evaluation.

## POSTOPERATIVE

Recovery from sharp D & C is typically fast and without complication. Light bleeding or spotting is expected, and patients may resume normal activities at their own pace.

## 43-16

## Suction Dilatation and Curettage

Suction dilatation and curettage (D & C) is the most frequently used method to remove first-trimester products of conception. Vacuum aspiration, the most common form of suction curettage, requires a rigid plastic cannula attached to an electric-powered vacuum source. Alternatively, manual vacuum aspiration uses a similar cannula that attaches to a handheld syringe for its vacuum source (Lichtenburg, 2013).

## PREOPERATIVE

## Patient Evaluation

For most women, dilatation and curettage is preceded by transvaginal sonography. As discussed in Chapter 6 (p. 141), this imaging modality aids in documenting pregnancy nonviability, location, and size as well as uterine inclination. Images are reviewed preoperatively to reorient the surgeon to this information. In addition, complete blood count and blood typing results are reviewed. For women with significant preoperative bleeding, resuscitation as described in Chapter 40 (p. 864) is completed. Most molar pregnancies are treated with evacuation, and special preparation is described in Chapter 37 (p. 783). For Rh-negative women, administration of anti-D immune globulin intramuscularly within 72 hours of pregnancy termination can lower the risk of alloimmunization in future pregnancies. Doses of 300  $\mu$ g (1500 IU) can be given for all gestational ages. Alternatively, dosing may be graduated, with 50  $\mu$ g given IM for pregnancies  $\leq$  12 weeks and 300  $\mu$ g given for those  $\geq$  13 weeks.

## Consent

Suction D & C is a safe and effective method of uterine evacuation (Tunçalp, 2010). Short-term complication rates are low and have been cited at 1 to 5 percent (Hakim-Elahi, 1990; Zhou, 2002). Complications include uterine perforation, retained products, infection, and hemorrhage, and rates increase after the first trimester. Accordingly, sharp or suction curettage is ideally performed before 14 to 15 weeks' gestation.

The incidence of uterine perforation associated with uterine evacuation varies. Important determinants are surgeon skill, uterine position, and uterine size. Rates of perforation increase with a retroverted or large uterus and

with a less experienced surgeon. Accidental uterine perforation usually is recognized when the instrument passes without resistance deep into the pelvis. Observation may be sufficient if the uterine perforation is small, as when produced by a uterine sound or narrow blunt dilator. Considerable intraabdominal damage, however, can be caused by instruments—especially suction cannulas and sharp curettes—passed through a uterine defect into the peritoneal cavity. Because unrecognized bowel injury can cause severe peritonitis and sepsis, laparoscopy or laparotomy to examine the abdominal contents is often the safest course of action in these cases.

Rarely, women may develop cervical incompetence or intrauterine adhesions following D & C. Those undergoing this procedure should understand the potential for these rare but significant complications.

## Patient Preparation

Suction D & C may be performed for cases of incomplete or inevitable abortion and require no cervical dilatation for procedure completion. However, other settings require physical dilatation of the cervical os with metal dilators, a procedural step closely associated with uterine perforation and patient discomfort. Therefore, to obviate this need, hygroscopic dilators may be placed in the endocervical canal to the level of the internal os. These dilators draw water from cervical proteoglycan complexes, which dissociate and thereby allow the cervix to soften and dilate.

Two dilator types are currently available in the United States. One type originates from the stems of *Laminaria digitata* or *Laminaria japonica*, a seaweed. The stems are cut, peeled, shaped, dried, sterilized, and packaged according to their hydrated size—small, 3 to 5 mm diameter; medium, 6 to 8 mm; and large, 8 to 10 mm (Fig. 43-16.1). Another type, Dilapan-S, is an acrylic-based hydrogel rod.

**FIGURE 43-16.1** Hygroscopic dilators, dry and expanded. **A.** Laminaria. **B.** Dilapan-S.

For dilator placement, the cervix is cleansed with povidone-iodine or similar solution and grasped anteriorly with a tenaculum. A laminaria of appropriate size is then inserted using a uterine packing forceps so that the tip rests at the level of the internal os (Fig. 43-16.2). After 4 to 6 hours, the laminaria will have swollen to dilate the cervix sufficiently and allow easier D & C. Cramping frequently accompanies expansion of the device.

In addition to mechanical tools, various prostaglandin preparations have been investigated as cervical “ripening” agents. Misoprostol has been used effectively to induce uterine evacuation in properly selected patients. However, studies investigating its preoperative use to ease cervical dilatation prior to pregnancy evacuation show inconsistent results (Mittal, 2011; Sharma, 2005). Moreover, in comparison, laminaria prove more effective than misoprostol for ripening (Burnett, 2005; Firouzabadi, 2011).

**FIGURE 43-16.2** **A.** Correct laminaria placement. **B.** Expanded laminaria.

**FIGURE 43-16.3** Karman cannulas (sizes 8 to 12 mm). Inset: Cannula tip.

Antibiotic prophylaxis is provided at the time of transcervical surgical pregnancy evacuation. Based on review of 11 randomized trials, Sawaya and associates (1996) concluded that perioperative antibiotics decreased the infection risk by 40 percent. Although no regimen appears superior, a convenient, inexpensive, and effective one is doxycycline, 100 mg orally twice daily for 10 days. Table 39-6 (p. 835) lists alternatives.

## INTRAOPERATIVE

### ■ Instruments

Suction D & C requires an electric suction unit; stiff, translucent, large-bore sterile suction tubing; and sterile Karman suction cannulas (Fig. 43-16.3). Plastic suction cannulas are available in varying diameters. They also have a straight or slightly bent shaft, which can be selected to conform to uterine cavity inclination. Choosing the most appropriately sized cannula balances competing factors. Small cannulas risk postoperative retention

of intrauterine tissue, whereas large cannulas risk cervical injury and greater discomfort. For most first-trimester evacuations, a no. 8 to 12 Karman cannula is sufficient.

### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** In the absence of maternal systemic disease, abortion procedures do not require hospitalization. When abortion is performed outside a hospital setting, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available. Anesthesia or analgesia used varies and includes general anesthesia, paracervical block plus intravenous sedation, or intravenous sedation alone. After delivery of anesthesia or analgesia, the patient is placed in standard dorsal lithotomy position. Bimanual examination to determine uterine size and inclination is performed prior to introduction of vaginal instruments. Information obtained from this examination helps avoid uterine perforation. The vulva

and vagina are then surgically prepared, and the bladder is drained.

□ **Uterine Sounding and Cervical Dilatation.** A Graves speculum or other suitable vaginal retractor(s) is positioned in the vagina to allow cervical access. A single-tooth tenaculum is placed on the cervical lip to provide gentle countertension during instrument passage. First, a Sims uterine sound (Fig. 43-15.1, p. 964) is placed through the cervical os and into the uterine cavity to measure the depth and inclination of the uterine cavity prior to dilatation.

If the cervix is closed or incompletely dilated, metal Pratt, Hegar, or Hank dilators (Fig. 43-16.4) of sequentially increasing diameter are placed through the external and internal os to gently open the cervix. The uterus is especially vulnerable to perforation during this step. Accordingly, the metal dilator is grasped as one would a pencil. The heel of the hand and fourth and fifth fingers rest

**FIGURE 43-16.4** Hank dilators of serially increasing diameter.

**FIGURE 43-16.5** Uterine dilatation.

**FIGURE 43-16.6** Suction cannula inserted into cavity and amniotic sac.

**FIGURE 43-16.7** Suction cannula movement during curettage.

**FIGURE 43-16.8** Removal of uterine contents.

**FIGURE 43-16.9** Sharp curettage.

on the perineum and buttock. Gentle pressure from only the thumb and first two fingers is used to push the dilator through the cervical os (Fig. 43-16.5).

□ **Uterine Evacuation.** Through the now opened cervix, the Karman cannula is inserted into the endometrial cavity (Fig. 43-16.6). The suction unit is then turned on. The cannula is moved toward the fundus, then back toward the os, and is slowly turned circumferentially to cover the entire surface of the uterine cavity (Fig. 43-16.7). A gush of clear fluid into the tubing often heralds entry of the cannula into the gestational sac. This collapses the sac and

draws the placenta and membranes closer to the cannula for more expedient removal. Uterine contents are thereby removed (Fig. 43-16.8).

Tissue is collected in an attached container at the distal end of the tubing and is sent for pathologic evaluation. Occasionally, the Karman cannula may become obstructed with excess tissue. For this, the suction unit is turned off prior to cannula removal. Once the cannula opening is cleared of obstructing tissue, it may be reinserted, suction reestablished, and curettage completed.

□ **Sharp Curettage.** Although no more tissue is aspirated, a gentle sharp curettage

is often completed to remove remaining placental or fetal fragments (Fig. 43-16.9). This is fully described in Section 43-15 (p. 964).

## POSTOPERATIVE

Recovery from suction D & C is typically fast and without complication. Patients may resume normal activities as they desire, but abstinence from coitus is usually encouraged during the first week following surgery. Ovulation may resume as early as 2 weeks after an early pregnancy ends. Therefore, if contraception is desired, methods are initiated soon after abortion.

## 43-17

## Hymenectomy

Imperforate hymen results from failure of the hymen to canalize during the perinatal period. Following menarche, menstrual blood accumulates behind this vaginal obstruction. Distention of the vagina and uterus with blood are *hematocolpos* and *hematometra*, respectively. For this reason, many cases are diagnosed after patients have become symptomatic, usually during adolescence. Accordingly, the indications for hymenectomy may include complaints of amenorrhea, pain, abdominal mass, and urinary and defecation dysfunction (Chap. 18, p. 415).

An asymptomatic imperforate hymen may also be found early, during childhood. If there is no associated mucocele, lesions can be managed expectantly. Elective hymenectomy can then be performed during puberty, when tissues are estrogenized, but prior to menarche to avoid hematometra or hematocolpos. The presence of estrogen aids surgical repair and healing.

### PREOPERATIVE

#### ■ Consent

Hymenectomy is a simple gynecologic procedure, and most patients recover with no short- or long-term complications. Uncommonly, the hymeneal edges may reepithelialize, and a repeat procedure may be required (Liang, 2003).

#### ■ Patient Preparation

Bowel preparation and antibiotic or venous thromboembolism prophylaxis are not required for this brief surgery.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Hymenectomy is typically performed as a day surgery procedure using general anesthesia. The patient is placed in standard dorsal lithotomy position, the bladder is drained, and a sterile perineal prep is performed.

□ **Hymen Incision.** To avert injury to the urethra anteriorly and to the rectum posteriorly, the surgeon avoids creating pure vertical and horizontal incisions. Instead, a cruciate incision is made anteroposteriorly from 10 to

4 and from 2 to 8 o'clock into the hymeneal membrane (Fig. 43-17.1). Immediately, a stream of dark menstrual blood in the case of hematocolpos or mucoid fluid with muco-colpos will follow. The hymeneal leaflets are then sharply trimmed from the hymeneal ring. These are not excised too closely to the vaginal epithelium to avoid increased scarring at the hymeneal ring.

□ **Irrigation.** The vagina is copiously irrigated using a sterile saline solution with either a red rubber catheter or bulb syringe. Intraoperative evaluation or manipulation of

the upper vagina, cervix, and uterus is discouraged, as the walls of these organs may have been greatly thinned by hematocolpos or hematometra and are at risk for perforation.

□ **Suturing.** The cut edges of the leaflet bases are then oversewn with interrupted stitches using 3-0 or 4-0 gauge delayed-absorbable suture, thus creating a ring of sutures (Fig. 43-17.2). A running interlocking suture line is avoided to minimize circumferential narrowing of the introitus.

Some use an alternative to sharp trimming and suturing of the leaflets. Instead,

FIGURE 43-17.1 Hymenal leaflet trimming.

FIGURE 43-17.2 Suturing of leaflets' bases.

hemostats are placed across each leaflet base for approximately a minute to crush and seal fine vessels. After clamp removal, an incision with electrosurgical blade or scissors is carried through the crush line, excises distal leaflet tissue, and eliminates the need for suturing.

## POSTOPERATIVE

Following surgery, the patient may use oral analgesics and topical anesthetics such as lidocaine ointment. Local wound care includes twice-daily sitz baths. The patient is

counseled that retained fluid may continue to drain from the uterus and vagina for several days following the procedure. The patient is seen 1 to 2 weeks following surgery, at which time the introitus is inspected for patency and assessment of healing.

## 43-18

## Bartholin Gland Duct Incision and Drainage

Bartholin gland duct cysts and abscesses are vulvar masses encountered routinely in office gynecology (Chap. 4, p. 97). Bartholin duct cysts typically measure 1 to 4 cm in diameter and are frequently asymptomatic. Patients with larger cysts, however, may complain of vaginal pressure or dyspareunia. In contrast, patients with gland duct abscesses typically complain of rapid unilateral vulvar enlargement and significant pain. Classically, a fluctuant mass is found on one side of the introitus, external to the hymenal ring, and at the lower aspects of the vulva.

Bartholin cysts or abscesses result from ductal opening obstruction followed by accumulation of mucus or pus within the gland duct. Bartholin gland abscesses are polymicrobial infections, and *Bacteroides* species, *Peptostreptococcus* species, *Escherichia coli*, and *Neisseria gonorrhoeae* are frequently found from culture of purulent drainage. Less typically, *Chlamydia trachomatis* may be involved (Bleker, 1990; Kessous, 2013).

Incision and drainage (I & D) alone may give immediate but sometimes only temporary relief. Often, unless a new duct ostium is created, the incised edges following I & D will seal and mucus or pus will reaccumulate. Therefore, I & D with subsequent steps to create a new ostium are surgical goals.

Permanent resolution of the cyst or abscess is the norm following either marsupialization or I & D with Word catheter placement. However, if obstruction recurs, repeating either of these procedures is preferable to gland excision for most cases. Bartholinectomy, described on page 975, carries significantly greater morbidity than either of these two less invasive procedures.

### PREOPERATIVE

#### Consent

Repeated obstruction of the Bartholin gland duct following initial incision and drainage (I & D) is not uncommon during the weeks and months following drainage. Patients are informed of the possible need to repeat the procedure should the duct obstruct again. Dyspareunia is an infrequent long-term sequela, but patients are counseled regarding this potential. Rarely, deep tissue infection or rectovaginal fistula may develop postoperatively.

**FIGURE 43-18.1** Word catheter. (Photograph contributed by Steven Willard.)

### INTRAOPERATIVE

#### Instruments

The goal of Bartholin gland duct I & D is to empty the cystic cavity and create a new accessory epithelialized tract for gland drainage. For the latter, a Word catheter is used (Word, 1964). This is constructed of a 1-inch-long latex tube stem that has an inflatable balloon at one end and a saline-injection hub at the other (Fig. 43-18.1).

#### Surgical Steps

##### Analgesia and Patient Positioning.

Most procedures are performed as an outpatient procedure in the office or emergency room. Rarely, if the abscess is large or if adequate patient analgesia cannot be obtained, then I & D in the operative room may be required. The patient is placed in standard dorsal lithotomy position, and the ipsilateral labial skin is cleaned with a povidone-iodine solution or other suitable antiseptic agent.

Local analgesia is sufficient for most cases and can be obtained by infiltrating the skin overlying and adjacent to the planned incision with an aqueous 1-percent lidocaine solution. This may be augmented with mild intramuscular or intravenous analgesia.

**Drainage.** A 1-cm incision is made using a scalpel with a no. 11 blade to pierce the skin and underlying cyst or abscess wall (Fig. 43-18.2). The incision is made atop the cyst, is placed just outside and parallel to the hymen at 5 or 7 o'clock (depending on the side involved), and is positioned medial to Hart line. This position mimics the normal anatomy of the gland duct opening and avoids creation of a fistulous tract to the outer labium majus (Hill, 1998). To minimize scalpel injury, some recommend use of a small Keyes punch biopsy to instead create a hole simultaneously through the skin and cyst wall.

General bacterial culture as well as samples specific for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* identification can be obtained from spontaneously extruded pus.

**FIGURE 43-18.2** Abscess or cyst incision.

Mucus drained from a Bartholin cyst need not be cultured. Following drainage, the cavity is explored with a small cotton swab tip to open potential pus or mucus loculations. Probing is gentle to avoid perforation through the duct wall and into the nearby and highly vascular vestibular bulb (Fig. 38-26, p. 819). Cyst wall biopsy following cavity drainage to exclude rare Bartholin gland carcinoma is considered for women older than 40 years, for cysts with solid components, or for multiple cyst recurrences.

□ **Word Catheter Placement.** A deflated Word catheter tip is placed into the empty cyst cavity. A syringe is used to inject 2 to 3 mL of sterile saline through the catheter hub to inflate the balloon. Inflation should reach a diameter sufficient to keep the catheter from falling out of the incision (Fig. 43-18.3). Alternatively, a nonlatex 14F Foley catheter is a suitable substitute for those with latex allergy or in settings without a Word catheter. In either case, insufflation with saline rather than air is preferred, as the latter is associated with premature balloon deflation. The hub end of the Word catheter can then be tucked inside the vagina to prevent it from being dislodged by traction from normal perineal movement.

## POSTOPERATIVE

Bartholin gland duct cyst drainage does not require antibiotic treatment. In contrast,

abscesses are typically surrounded by significant cellulitis, and in such cases, antibiotics are warranted. Suitable choices include trimethoprim-sulfamethoxazole (Bactrim DS, Septra DS), doxycycline, or cephalexin (Keflex), prescribed for 7 to 10 days. At our institution, affected immunocompromised women are admitted for intravenous antibiotic therapy until fever or erythema improves.

Patients are encouraged to soak in warm tub baths twice daily. Coitus is avoided for patient comfort and to prevent Word catheter displacement. Ideally, the catheter is left in place for 4 to 6 weeks. Often, however, a catheter will be dislodged before this time. There is no need to try and replace the catheter if displaced, and attempts to reinsert it are typically not possible due to cavity closure.

**FIGURE 43-18.3** Word catheter in place.

## 43-19

## Bartholin Gland Duct Marsupialization

As noted earlier (p. 971), a new duct ostium must be created following I & D of a Bartholin duct abscess to prevent the incised edges from adhering and allowing pus to reaccumulate. For this reason, marsupialization was developed as a means to create a new accessory tract for gland drainage.

With introduction of the Word catheter, however, use of marsupialization for cyst or abscess has declined. Word catheter placement offers several advantages over marsupialization, and recurrence rates are equal (Blakely, 1966; Jacobson, 1960). Marsupialization requires a greater degree of analgesia, a larger incision, placement of sutures, and longer procedure time. That said, this procedure may be selected for those with large abscesses or cysts, those with recurrences after Word catheter failures, or those with latex allergy.

### PREOPERATIVE

#### ■ Consent

The patient consenting discussion for marsupialization mirrors that for Bartholin gland duct I & D. Thus, patients are informed of possible abscess or cyst recurrence. Uncommon postoperative complications are dyspareunia, deep tissue infection, or rectovaginal fistula.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Marsupialization is an outpatient procedure typically performed in an operating suite using a unilateral pudendal nerve block or general anesthesia. Some authors, however, have described performance of the procedure in an emergency room setting (Downs, 1989). The patient is placed in standard dorsal lithotomy position, and the vulva and vagina are surgically prepared.

□ **Skin Incision.** A vertical or elliptical incision measuring 2 cm is made across the skin overlying the cystic bulge using a scalpel with either a no. 10 or 15 blade. The incision is made atop the cyst, is placed just outside and parallel to the hymen at 5 or 7 o'clock (depending on the side involved), and is positioned medial to Hart line. This position mimics the normal gland duct opening anat-

FIGURE 43-19.1 Skin incision.

omy and avoids creation of a fistulous tract to the outer labium majus (Fig. 43-19.1).

□ **Cyst Incision.** A second vertical incision then opens the underlying cyst wall, and pus or mucus under pressure spills out. Pus may be cultured as described on page 971. Allis clamps are then placed on the superior, inferior, right, and left lateral cyst wall edges and fanned out.

Following drainage, the cavity is explored with a small cotton swab tip to open potential fluid loculations. Probing is gentle to

avoid perforation through the duct wall and into the nearby and highly vascular vestibular bulb (Fig. 38-26, p. 819). In addition, cyst wall biopsy following cavity drainage to exclude rare Bartholin gland adenocarcinoma is considered if the patient is older than 40 years or if solid components accompany the cyst.

□ **Wound Closure.** The edges of the cyst wall are sutured to adjacent skin edges with interrupted sutures using 2-0 or 3-0 gauge delayed-absorbable suture (Fig. 43-19.2).

FIGURE 43-19.2 Cyst wall sutured open.

## POSTOPERATIVE

Bartholin gland duct cyst drainage does not require antibiotic treatment. In contrast, abscesses are typically surrounded by significant cellulitis, and in such cases, antibiotics are warranted. Suitable choices include trimethoprim-sulfamethoxazole, doxycycline, or cephalexin, prescribed for 7 to 10 days.

At our institution, affected immunocompromised women are admitted for intravenous antibiotic therapy until fever or erythema improves.

Cool packs during the first 24 hours following surgery can minimize pain, swelling, and hematoma formation. After this time, warm sitz baths, one or two times daily, are suggested for pain relief and wound hygiene. Activities are resumed quickly,

although intercourse is delayed until healing is complete.

Patients may be seen within the first week following surgery to ensure that ostium edges have not adhered to each other (Novak, 1978). Within 2 to 3 weeks, the wound shrinks to create a duct opening typically 5 mm or less. Recurrence rates following marsupialization are low. Jacobson (1960) noted only 4 recurrences in his series of 152 cases.

## 43-20

## Bartholin Gland Duct Cystectomy

Most Bartholin gland duct cysts can be managed with incision and drainage (I & D) and Word catheter placement or with marsupialization. Symptomatic cysts, however, which repeatedly recur and refill following I & D or marsupialization are typical candidates for excision. Others best managed with excision are cysts with solid components, which increases the concern for malignancy; massive cysts; or multilocular cysts, which may be incompletely drained by I & D. Bartholin gland duct abscesses are not suitable for excision and are instead incised and drained (p. 971).

Many had previously suggested excision of all Bartholin gland cysts in women older than 40 to exclude cancer. However, a study by Visco and Del Priore (1996) suggests that the morbidity of gland excision may not be justified for this rare cancer (Chap 4, p. 97). Instead, they recommend cyst I & D with cyst wall biopsy.

### PREOPERATIVE

#### ■ Consent

Complications are usually not encountered during bartholinectomy, but if the rich venous plexus of the nearby vestibular bulb is entered, bleeding can be significant (Fig. 38-26, p. 819). Additionally, gland excision can be associated with other morbidities such as postoperative wound cellulitis, hematoma

formation, or pain from postoperative scarring. Rarely, recurrence from failure to remove the entire cyst wall, rectal injury, or rectovaginal fistula has been described.

#### ■ Patient Preparation

No special antibiotic or venous thromboembolism prophylaxis is typically needed for this brief day surgery.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Analgesia and Patient Positioning.** Excision of most Bartholin gland duct cysts is performed as an outpatient procedure, in an operative suite, and under general anesthesia. The patient is placed in standard dorsal lithotomy position, and the vagina and perineum are surgically prepared.

□ **Skin Incision.** A gauze sponge held by a ring forceps is placed inside the vagina by an assistant, and pressure is directed outward along the back wall of the cyst. This pushes the full extent of the cyst forward. The surgeon's fingers retract the labium minus laterally to expose the medial surface of the cyst.

A vertical incision that extends the length of the cyst is made on the medial surface of the labium minus. Care is taken to incise the skin but avoid puncture of the underlying cyst wall. Allis clamps are placed on the medial incision edge, which is fanned out medially and toward the contralateral labium.

□ **Cyst Dissection.** To summarize the steps as an overview, dissection begins along the cyst's medial border, then along the lat-

eral border, and finally deep vessels are ligated and transected to free the cyst. The greatest vascular supply to these cysts is located at their posterosuperior aspect. Accordingly, dissection of each border begins at the lower cyst pole and is directed superiorly.

To begin, medial traction on the Allis clamps and lateral fingertip traction against the cyst creates tension across connective tissue bands between the cyst wall and surrounding tissue. These bands are divided, and in this fashion, the inferomedial cyst wall is bluntly and sharply dissected free. Dissection planes are kept close to the cyst wall to avoid bleeding from the vestibular bulb and to avoid incision into the rectum (Fig. 43-20.1). Because the lowermost pole of a Bartholin gland cyst may extend to lie adjacent to the rectum, the rectum can be entered accidentally during dissection. Placing a finger at times into the rectum can help orient the surgeon to the spatial relationship between the two.

Following medial border dissection, Allis clamps are next placed on the lateral skin edges and fanned out laterally. Dissection then begins near the inferolateral cyst wall and moves superiorly.

During dissection, bleeding from the vestibular bulb can be troublesome. Most cases can be managed with ligation of individual vessels (if identified), placement of hemostatic sutures within the general bleeding area, closure of dead space, or a combination of these techniques.

□ **Vessel Ligation.** As dissection is completed superiorly, the main deep vascular bundle to the cyst is identified and clamped with a hemostat (Fig. 43-20.2). The bundle is cut and ligated with 3-0 gauge delayed-absorbable or chromic suture.

FIGURE 43-20.1 Cyst dissection.

FIGURE 43-20.2 Vessel ligation.

□ **Wound Closure.** The remaining cyst bed is closed in layers with running or interrupted suture line of 3-0 gauge delayed-absorbable suture. Typically, two layers are required prior to skin closure. However, with large or vascular cyst beds, additional layers may be required. The skin is approximated

with a running subcuticular suture line of 4-0 gauge delayed-absorbable suture.

## POSTOPERATIVE

Cool packs during the first 24 hours following surgery can minimize pain, swelling, and

hematoma formation. After this time, warm sitz baths, one or two times each day, are suggested for pain relief and wound hygiene. Intercourse is delayed for several weeks to permit wound healing, and then resumption is typically dictated by patient comfort.

## 43-21

## Vulvar Abscess Incision and Drainage

A patient with a vulvar abscess may typically present with pain, vulvar edema and erythema, and a fluctuant mass that should be differentiated from Bartholin gland duct abscess (Fig. 43-21.1). In some cases, the abscess may be draining spontaneously, and treatment consists of antibiotics to resolve surrounding cellulitis. In other cases, small abscesses measuring approximately 1 cm or less may be treated with local warm compresses or baths and oral antibiotics. Those with larger abscesses typically require incision and drainage (I & D) for infection resolution.

### PREOPERATIVE

#### ■ Patient Evaluation

In most cases, this is a visual diagnosis, and for those without comorbidities, no specific laboratory testing or imaging is needed. In obese patients, a serum glucose level is considered. Clear cases of necrotizing fasciitis require immediate debridement. However, in suspicious but not convincing cases, expeditious computed tomography can be useful (Chap. 3, p. 81).

#### ■ Consent

Incomplete drainage and persistence of the abscess may follow initial incision and drainage, particularly if the abscess contains

loculations. The abscess may also reform after drainage. Although uncommon, progression to or already coexisting necrotizing fasciitis may complicate the infection course.

#### ■ Patient Preparation

For large abscesses or in the immunosuppressed, intravenous antibiotics are given preoperatively, and coverage for methicillin-resistant *Staphylococcus aureus* (MRSA) is considered. Turman (2008) and Kilpatrick (2010) and their coworkers found MRSA to be a common pathogen in vulvar abscesses (43 and 64 percent, respectively).

FIGURE 43-21.2 Digital exploration and disruption of abscess loculations.

FIGURE 43-21.1 Vulvar abscess incision.

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Many patients with smaller abscesses can undergo incision and drainage in an ambulatory setting. In contrast, to attain adequate analgesia, larger abscesses often require drainage in the operating room under regional analgesia or general anesthesia.

The patient is placed in standard dorsal lithotomy position, and the involved area of the vulva is cleaned with povidone-iodine solution or other suitable antiseptic. If drainage is completed with local analgesia, the skin overlying the abscess is injected with a 1-percent lidocaine solution to achieve a field effect.

□ **Drainage.** A 1- to 2-cm incision is made with a no. 11 scalpel blade into the site where the abscess wall is most thinned and is likely attempting to drain spontaneously. The incision penetrates into the abscess cavity with resultant extrusion of abundant pus. Aerobic and anaerobic cultures are obtained at this time. The abscess cavity is explored to bluntly dissect loculations within the cavity (Fig. 43-21.2). Digital or gentle cotton swab exploration is preferred to that with a pointed surgical instrument, which may tear vestibular bulb veins to create significant bleeding or hematoma.

□ **Procedure Completion.** Depending on surgeon preference, a drain may be placed in the abscess cavity and brought out through a separate incision. The edges of the primary incision are then reapproximated with

**FIGURE 43-21.3** Drain placement and incision closure.

delayed-absorbable suture (Fig. 43-21.3). Alternatively, the wound may be packed with iodoform gauze. With a small abscess, the incision may simply be left open to allow for spontaneous healing.

### POSTOPERATIVE

For small abscesses, the patient may be discharge following I & D, and reevaluation or wound repacking in 48 to 72 hours is reasonable. Appropriate antibiotic coverage are continued for several days, and trimethoprim-sulfamethoxazole (Bactrim, Septra) is a first-line oral agent against MRSA. Women with larger abscesses or greater surrounding cellulitis often warrant admission for pain control and intravenous antibiotic therapy. For MRSA, clindamycin or vancomycin is an effective intravenous choice. Most women with significant immunosuppression or diabetes also require hospital admission for antibiotic administration and comorbidity management. Specifically, Kilpatrick and colleagues (2010) noted that coexistent diabetes was significantly related to hospitalization for more than 7 days, reoperation, and progression to necrotizing fasciitis.

In those without gauze packing, warm sitz baths, one or two times each day, may aid pain relief and wound hygiene. With resolving fever and surrounding cellulitis, the drain is removed. For those with gauze packing, it may be changed once or twice daily until the cavity is nearly closed. In all cases, perineal hygiene and avoidance of labial shaving is emphasized.

## 43-22

## Vestibulectomy

Anatomically, the vestibule extends along the inner labia minora, from the clitoris to the fourchette (Fig. 38-25, p. 818). Additional borders include the hymenal ring and Hart line, which lies along the inner labia minora and demarcates the boundary between keratinized and nonkeratinized epithelium. For some women, inflammation in this region can lead to vulvodynia and dyspareunia.

Most cases of vulvodynia are managed conservatively, but for refractory cases, three surgeries have been employed: vestibuloplasty, vestibulectomy, and perineoplasty (Edwards, 2003). Vestibuloplasty involves denervation of the vestibule by incising, undermining, and then closing the vulvar skin, but without excising the painful epithelium. It generally has been found to be ineffective (Bornstein, 1995).

Alternatively, vestibulectomy incorporates excision of vestibular tissue (Fig. 43-22.1). Incisions extend from the periurethral area down to the superior edge of the perineum and include the fourchette. The lateral incisions are carried along Hart line, and the medial incisions are placed so as to excise the hymen. In sum, mucous membrane, hymen, minor vestibular glands are removed, and Bartholin ducts are transected. Following excision, the vaginal mucosa is mobilized and pulled distally to cover the defect. In certain

cases, a modified vestibulectomy is sufficient and extends only partially up the inner labia minora, well short of the periurethral area (Lavy, 2005).

Perineoplasty is the most extensive of the three procedures and extends from just below the urethra to the perineal body, usually terminating above the anal orifice (see Fig. 43-22.1). Similarly, following tissue resection, the vaginal epithelium is advanced to cover the defect. Although used to treat vulvodynia, perineoplasty may also treat fissuring and associated pain caused by lichen sclerosis (Kennedy, 2005; Rouzier, 2002).

## PREOPERATIVE

## Patient Evaluation

The most important factor for surgical success in treating vulvar pain is identifying the proper candidate (Chap. 4, p. 99). For example, vaginismus coexists in approximately half of patients with vulvodynia and is associated with lower rates of postsurgical pain relief (Goldstein, 2005).

Prior to anesthesia administration, the patient undergoes testing with a cotton swab to map areas of pain. These are marked with permanent marker prior to surgery to delineate the extent of excision (Haefner, 2005). Importantly, all sensitive areas are removed, even those adjacent to the urethra. If not, tender foci that should have been resected as part of the primary operation may remain (Bornstein, 1999).

## Consent

Operative treatments are effective in treating vulvodynia, and pain either resolves or significantly improves in nearly 65 and 80 percent of patients, respectively (Tommola, 2010). Complications are infrequent but may include bleeding, infection, wound separation, Bartholin duct cyst formation, anal sphincter weakness, vaginismus, vaginal stenosis, and failure to alleviate pain (Goetsch, 2009; Haefner, 2000).

## Patient Preparation

Antibiotic prophylaxis is typically not required for this procedure. Venous thromboembolism prophylaxis may be required depending on anticipated surgical length and coexistent patient risk factors (Tables 39-7 and 39-8, p. 836). A preoperative enema may be employed to avoid immediate postoperative stool and thereby improve wound hygiene.

## INTRAOPERATIVE

## Surgical Steps

## Anesthesia and Patient Positioning.

In most cases, vestibulectomy is an outpatient procedure, conducted using general or regional anesthesia. The patient is placed in standard dorsal lithotomy position, and the vulvovaginal area is surgically prepared.

**Surgical Excision.** The primary incision, which is the lateral border, is made to a depth of 2 to 5 mm along Hart line. It is extended inferiorly to the fourchette. The medial incision is placed just proximal to the hymenal ring. The amount of tissue removed anteroposteriorly varies according to sensitivity mapping. Traditionally, it begins in the periurethral area and extends from the openings of the Skene ducts to the fourchette. Accordingly, care is taken to avoid urethral injury.

## Vaginal Mucosal Advancement.

Following tissue excision, the incised edge of the vaginal mucosa is undermined 1 to 2 cm cephalad and then pulled distally to cover the defect (Fig. 43-22.2). To prevent hematoma and wound separation, hemostasis is achieved prior to final suturing.

**Wound Closure.** A deep closure layer using interrupted 3-0 gauge delayed-absorbable sutures approximates the vaginal wall to its new site covering the vestibular defect. The superficial incision between the skin and vaginal epithelium is closed in an interrupted fashion with 4-0 gauge delayed-absorbable suture.

**FIGURE 43-22.1** Incisions for vestibulectomy (red line) and for perineoplasty (blue line).

**FIGURE 43-22.2** Vaginal mucosal advancement.

## POSTOPERATIVE

Cool packs are used to relieve immediate discomfort, and sitz baths are initiated after the first 24 hours. Recovery is typically fast and without complications, and wound healing takes 4 to 8 weeks. Patients usually meet with their surgeon during this time and are instructed to gradually resume intercourse 6 to 8 weeks following surgery (Bergeron, 2001).

## 43-23

## Labia Minora Reduction

When outstretched, most labia minora span 5 cm or less from their base to lateral edge. In some women, this span may be greater and may cause aesthetic dissatisfaction, discomfort with tight clothing, pain with exercise, and insertional dyspareunia. As a result, some elect to have their labia minora surgically reduced. Of note, many women seeking this surgery solely for aesthetic improvement have labial lengths well within normal standards (Crouch, 2011).

In appropriate candidates, goals of surgery include reduction in labial size and maintenance of normal vulvar anatomy. Early reductive procedures involved anteroposterior excision along the base of the labia and reapproximation of the surgical edges. Drawbacks to this approach include a marked color contrast at the suture line, where the labia minora's dark outer surface abuts the lighter inner surface. Moreover, the labial edge is often replaced by a stiff suture line. To reduce these effects, alternate techniques have incorporated labial V-, S-, Z- or W-plasty incisions, and surgeries are increasingly performed by plastic surgeons (Mirzabeigi, 2012).

### PREOPERATIVE

#### ■ Consent

Labia minora reductive surgery is a safe and effective means to remove excess labial tissues. As with any aesthetic procedure, women who are seeking cosmetic correction should have realistic expectations as to the final size, shape, and color of the labia. Wound complications such as hematoma, cellulitis, or incisional dehiscence are rare but should be discussed during counseling. Similarly, postoperative dyspareunia is uncommon but should be noted in the consenting process.

#### ■ Patient Preparation

No specific radiologic imaging is needed for this condition or surgery. Antibiotic or venous thromboembolism prophylaxis is not required for this brief procedure in those without specific risks.

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Labia minora reduction may be performed as an outpatient procedure using general or regional anesthesia. After anesthesia has been delivered, the patient is placed in standard dorsal lithotomy position, and the vulva is surgically prepared.

□ **Labial Marking.** Excessive tissue removal is avoided because aggressive reduction may create anteroposterior narrowing and discomfort during subsequent intercourse. For this reason, during surgical marking, the surgeon may choose to place several fingers into the vagina to distend its caliber. The labia minora are then outstretched laterally.

The desired lateral span of each labium will vary between women, but most surgeons strive to create a final span of 1 to 2 cm. Asymmetry between labia is common, and surgical marking helps to even this difference. With a surgical marker, the surgeon draws a V-shaped wedge on the ventral and dorsal surfaces of the labia minora, demarcating the tissue for excision (Fig. 43-23.1, *left*). In other cases, a simple curved incision may suffice (*right*).

□ **Wedge Excision.** The labia minora have a rich blood supply. To decrease bleeding, the incision may be infiltrated with a solution of 1-percent lidocaine and epinephrine in a 1:200,000 dilution. The tissue wedge or line is then sharply excised. Hemostasis may be achieved using electrosurgical coagulation and is important in avoiding hematoma formation.

□ **Incision Closure.** For wedge incisions, the subcutaneous layers of the labia are reapproximated beginning proximally at the tip of the wedge (Fig. 43-23.2, *left*). Interrupted stitches of 4-0 gauge delayed-absorbable

**FIGURE 43-23.1** Incision lines. **A.** Wedge excision technique (left). **B.** Distal trimming technique (right).

**FIGURE 43-23.2** Wedge incision closure (left) and final suture line (right).

suture are then added outward toward the lateral base to close the remainder of the wound. For linear incisions, dead space between skin edges is closed with interrupted stitches of similar suture. With either incision, the skin is reapproximated with 5-0 gauge delayed-absorbable suture in a running subcuticular or interrupted fashion ([Fig. 43-23.2, right](#)).

## POSTOPERATIVE

Cool packs are used to relieve immediate discomfort, and sitz baths are initiated after the first 24 hours. Perineal hygiene is emphasized during the initial weeks following surgery. Exercise and intercourse may resume after wound healing.

## 43-24

## Vaginal Septum Excision

As described in Chapter 18 (p. 404), incorrect embryologic development may lead to transverse or longitudinal septa at various levels of the vagina. Some septa have small fenestrations or are open ended to allow menstrual blood egress. Those without openings may lead to hematocolpos and hematometra.

Like the McIndoe procedure, vaginal septum excision is best performed in a mature adolescent or young adult rather than in a child. First, estrogen production following puberty can improve healing. Moreover, transverse vaginal septum excision requires some degree of postoperative vaginal dilatation to avoid stricture, and regimen compliance may be limited in young girls. Unfortunately, not all cases can be delayed. Patients may have persistent pain from hematocolpos and hematometra, and these are accompanied by an increased risk of endometriosis.

### PREOPERATIVE

#### ■ Patient Evaluation

Septa are frequently associated with other müllerian defects. Thus, anatomy and anomalies are usually preoperatively defined with sonography or more commonly with magnetic resonance imaging (Chap. 18, p. 416).

#### ■ Consent

Risks of septum excision mirror those associated with the McIndoe procedure. However, skin grafting and its attendant risks are usually avoided except in cases with a thick vaginal septum. Vaginal stricture following excision is a significant risk. In their small series, Joki-Erkkilä and Heinonen (2003) found that two of three adolescents required reexcision of scar tissue following initial septum removal.

#### ■ Patient Preparation

Antibiotic prophylaxis similar to that for hysterectomy is typically administered (Table 39-6, p. 835). Venous thromboembolism prophylaxis may be warranted for cases with greater anticipated length and complexity (Table 39-8, p. 836). Bowel preparation aids rectal decompression to permit greater vaginal distention for visualization. Also, digital rectal examination may be needed at times during surgery to direct septum excision and avoid

rectal laceration. Accordingly, an empty rectal vault may minimize wound contamination.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** After administration of general anesthesia, the patient is placed in standard dorsal lithotomy position, and the perineum and vagina are surgically prepared. A Foley catheter serves as a guide to avoid urethral injury during septum excision.

□ **Transverse Septum Incision.** First, retractors are placed to reveal the upper extent of the vagina. With higher-level septa, diagnostic needle aspiration of the suspected hematocolpos can help to locate the upper vagina to determine the direction of dissection (Fig. 43-24.1). The septum is then incised transversely at its center to avoid laceration of the urethra, bladder, or rectum.

A finger is placed through the transverse incision and is directed cephalad to delineate the upper vaginal walls and the circumferential margins of the septum. Similarly, the Foley catheter or a finger in the rectum may assist with orientation.

□ **Excision.** Once the septal perimeter is defined, the initial transverse incision is

extended laterally to the vaginal wall margins. The septum is widely excised circumferentially along its base to minimize postoperative stricture (Fig. 43-24.2).

□ **Wound Closure.** If the septum was thin, a simple circumferential ring of interrupted stitches is constructed using 2-0 gauge delayed-absorbable suture to reapproximate vaginal mucosal edges (Fig. 43-24.3). For thicker septa, the span between cephalad and caudad vaginal mucosal edges is greater. Accordingly, the mucosa may be undermined both cephalad and caudad to permit mucosal edge reapproximation without tension at the suture line. If the vaginal septum is thick and mucosal reapproximation is not possible, a skin graft can be taken and applied in a manner similar to the McIndoe procedure (p. 985). Finally, in all cases, a soft cylindrical stent is placed into the vagina to prevent stricture.

□ **Unobstructed Longitudinal Septum.** With this septum, a soft tissue sheet attaches to and extends between the anterior and posterior vaginal walls. This divides the vaginal into right and left cylinders. To excise the anterior wall attachment, sharp or electrosurgical cutting is kept close to the union line of the septum and vaginal wall. This incision is extended cephalad until the attachment is freed or the cervix is reached. Incision stops short of the cervix to avoid its injury. The

**FIGURE 43-24.1** Diagnostic needle aspiration to direct dissection.

**FIGURE 43-24.2** Transverse septum excision.

posterior wall attachment is similarly transected. For a lower partial septum, these two steps will free it. For high septa that extend between two cervices, a final anteroposterior incision across the septa and in front of the cervices will release it proximally.

□ **Obstructed Longitudinal Septum.** With an oblique obstructive septum, its proximal end often originates between the two cervices of a uterine didelphys. The caudal end attaches to the lateral vaginal wall to

block outflow and distend the hemivagina. For this, a longitudinal incision is made centrally along the septum. Old blood is typically released with this. A finger is then placed through the incision to delineate the vaginal wall boundaries and identify the occult cervix. The Foley catheter tube in the urethra or a finger in the rectum may also assist with orientation. Once the septal perimeter is defined, the initial longitudinal incision is extended outward in an elliptical path to the vaginal wall margins.

**FIGURE 43-24.3** Vaginal mucosa reapproximation.

□ **Wound Closure.** With either longitudinal septum type, a simple line of interrupted stitches of 2-0 gauge delayed-absorbable suture is placed to reapproximate incised vaginal mucosal edges.

## POSTOPERATIVE

The Foley catheter may be removed on the first postoperative day. The remaining postoperative care mirrors that for the McIndoe procedure, described next.

## 43-25

## McIndoe Procedure

Creation of a functional vagina is the treatment goal for many women with congenital vagina agenesis. Although several surgical and nonsurgical approaches have been used, the McIndoe procedure is the most commonly employed in the United States (Chap. 18, p. 420). With this technique, a canal is formed between the urethra and urinary bladder anteriorly and the rectum posteriorly (McIndoe, 1938). A skin graft obtained from the patient's buttock or thigh is then wrapped around a soft mold and placed into the newly created vagina to allow epithelialization. Alternatively, other materials have been used to line the neovagina. These include buccal mucosa, cutaneous and myocutaneous flaps, amniotic membrane, and absorbable adhesion barrier (Creatsas, 2010; Fotopoulou, 2010; Li, 2014; Motoyama, 2003).

Vaginal stricture can be a significant complication following the McIndoe procedure. Thus, adherence to a postoperative regimen of vaginal dilatation is mandatory. For this reason, surgery may be postponed until the patient has reached the level of maturity needed to comply (American College of Obstetricians and Gynecologists, 2013a).

## PREOPERATIVE

## ■ Patient Evaluation

Vaginal agenesis may be an isolated anomaly but is frequently associated with other müllerian defects. Thus, anatomy and anomalies are usually preoperatively defined with sonography or more commonly with magnetic resonance imaging (Chap. 18, p. 418).

## ■ Consent

Prior to surgery, patients are informed of overall success rates with this procedure. In a Mayo Clinic series of 225 patients, the McIndoe procedure provided a functional vagina to afford "satisfactory" intercourse in 85 percent of patients. In this review, the cumulative complication rate was 10 percent and included vaginal stricture, pelvic organ prolapse, graft failure, postcoital bleeding, and fistulas involving either the bladder or rectum (Klinge, 2003). Additionally, complications at the skin graft harvest site involved keloid formation, wound infection, and postoperative dysesthesias.

## ■ Patient Preparation

Antibiotic prophylaxis similar to that for hysterectomy is typically administered, and venous thromboembolism prophylaxis is planned (Tables 39-6 and 39-8, p. 835). Bowel preparation aids rectal decompression to permit greater room for blunt neovagina development. Also, digital rectal examination may be needed at times during surgery to direct dissection and avoid rectal laceration. An empty rectal vault may minimize wound contamination.

## INTRAOPERATIVE

## ■ Instruments

## Electrodermatome

The skin grafts used to line the neovagina are harvested from the donor site with the aid of an electrodermatome, which is able to shave grafts of varying size and depth. Both split-thickness and full-thickness skin grafts have been used in the McIndoe procedure, and the electrodermatome settings are adjusted to shave the desired depth.

## Vaginal Mold

Following graft harvesting and neovagina formation, a stent is needed to apply the graft to the vaginal walls and hold it in place. Both soft and rigid forms have been used. Unfortunately, rigid or semirigid stents have led to graft loss, fibrosis, contracture, and pressure-related bladder or rectal fistulas.

Use of soft stents has decreased the number of these complications. Inflatable rubber stents or condoms filled with foam rubber or other soft compressible materials are examples (Adamson, 2004; Barutcu, 1998). The vagina graft produces abundant exudates, and poor drainage may lead to graft maceration, sloughing, and graft detachment. Accordingly, suction is attached to the soft

stents to aid drainage of the neovagina (Yu, 2004).

## ■ Surgical Steps

## □ Anesthesia and Patient Positioning.

General anesthesia is administered, and the patient is initially positioned prone for skin graft harvesting from the buttock. Alternatively, skin may be obtained from the thigh or hip. Choosing a location that has minimal hair growth and is cosmetically discreet is desired. The assistance of a plastic surgeon may be enlisted for skin graft procurement.

□ **Skin Graft.** The surgeon first marks the outline of the wound on the donor site skin, enlarging it by 3 to 5 percent to allow for skin shrinkage immediately after excision. The surgeon uses the electrodermatome to remove a single strip of skin that is typically 0.018 inch thick, 8 to 9 cm wide, and 18 to 20 cm long (Fig. 43-25.1). Alternatively, two smaller strips of 5 cm × 10 cm can be obtained from each buttock.

Following excision, the graft is placed in a pan of sterile saline. The harvest sites on the buttocks are sprayed with a topical hemostatic agent and dressed with a clear occlusive dressing (Tegaderm).

□ **Perineal Incision.** The patient is then placed in standard dorsal lithotomy position, perineal cleansing is performed, and a Foley catheter inserted.

The lower edge of each labium minus is grasped with Allis clamps and extended laterally. A third Allis clamp is placed on the vestibular skin below the urethra and is lifted superiorly. A dimple in the vestibule is typically identified below the urethra, and a 2- to 3-cm transverse incision is made across the depression. Allis clamps are then placed on the superior and inferior edges of this incision and are retracted.

FIGURE 43-25.1 Skin graft harvest.

**FIGURE 43-25.2** Neovaginal dissection.

□ **Neovaginal Dissection.** With neovagina development, the goal is to create a canal that is bounded anteriorly by the pubovesical fascia that supports the urethra and bladder, posteriorly by the rectovaginal fascia and rectum, and laterally by the puborectalis muscles. Initially, two canals are created on either side of the median raphe, which is a midline collection of dense connective tissue bands that stretch between the urethra and bladder above and the rectum below (Fig. 43-25.2). The canals are initially formed using a spreading and gentle pushing motion with blunt-tipped scissors. Fingers are then insinuated into the forming tunnels, and pressure is exerted cephalad to extend the tunnel depth. To widen the canals, finger pads are rolled outward, and lateral pressure is applied. Posterior pressure should be avoided to prevent entering the rectum. Each canal is created to reach a depth of approximately 12 cm. Entering the cul-de-sac of Douglas is also avoided.

During dissection, several points are noteworthy. First, with initial caudal dissection,

the surgeon may meet greater resistance than with the more cephalad tissues. Second, remaining in the correct dissection plane can be difficult. Accordingly, the surgeon's finger may be placed into the rectum to identify its location and avert perforation. Similarly, the Foley catheter tubing may serve as an orienting tool anteriorly.

To expand the space, retractors can be placed along the lateral walls of the forming tunnels and stretched outward. Moreover, incising the medial fibers of the puborectalis muscles can add further width. These muscles are cut along the lateral aspect of each canal and at a level midway along the anteroposterior length of the canals.

Cephalad, the tunnel is extended to within 2 cm of the cul-de-sac of Douglas.

This leaves a layer of connective tissue affixed to the peritoneum. The skin graft will attach more effectively to this connective tissue than to a smooth peritoneal surface. Rates of subsequent enterocele formation are also lowered by this technique.

□ **Cutting the Median Raphe.** Once the formation of the two tunnels is completed, the median raphe is cut. The final single canal measures approximately 10 to 12 cm deep and three fingerbreadths wide.

□ **Hemostasis.** As collections of blood can separate the skin graft from the canal bed, hemostasis is required prior to mold insertion.

□ **Mold Preparation.** The vaginal mold may now be covered with the harvested skin. The graft is removed from the saline bath. One end of the graft is placed at the base of one side of the mold with the skin's keratinized surface facing the mold. The long axis of the graft is laid parallel to the long axis of the mold. The graft is then draped up and over the mold tip (Fig. 43-25.3). Last, the lateral edges of the skin graft are approximated on either side of the mold using interrupted stitches of 3-0 catgut.

□ **Mold Customization.** Adapting the mold to the size of the created neovaginal canal is essential. If the mold is too wide, pressure necrosis or inadequate drainage may result. Moreover, at the time of post-operative mold removal, a mold that is too

**FIGURE 43-25.3** Mold creation.

**FIGURE 43-25.4** Skin graft and mold in place.

large and snugly fitted into the neovagina may pull the graft loose. Once appropriately sized and constructed, the mold is then inserted (Fig. 43-25.4).

□ **Perineal Sutures.** The edges of the skin graft at the distal end of the mold are then reapproximated to the distal circumferential opening of the neovagina using interrupted stitches of 4-0 or 5-0 gauge delayed-absorbable suture.

The labia minora, if sufficiently long, can be sutured together along the midline with 2-0 silk sutures to help hold the mold in place for the first 7 postoperative days. An elastic compression dressing is placed on the perineum.

## POSTOPERATIVE

The soft stent and Foley catheter are left in place for 7 days following surgery. To minimize mold dislodgement and wound contamination, a low-residue diet and loperamide, 2 mg orally twice daily, is used to limit defecation.

At the time of mold removal, an operating room, general anesthesia, and standard dorsal lithotomy position are employed. Stitches in the labia minora are cut, and the mold is removed. To lessen the risk of graft avulsion, irrigation is used to reduce adherence between graft and mold.

Several schedules for postoperative dilatation have been described. Commonly, the size of the mold placed at surgery is too large for maintenance use. Therefore, a smaller dilator may initially be used and then gradually replaced with larger ones as the vagina stretches.

For the first 6 weeks following surgery, the dilator is worn continuously except during defecation. During the subsequent 6 weeks, it is used only at night. Following these initial 3 months, patients are then instructed to either wear the dilator at night or engage in intercourse at least twice each week.

## 43-26

## Treatment of Preinvasive Ectocervical Lesions

### LOOP ELECTROSURGICAL EXCISION PROCEDURE (LEEP)

In the United States, use of LEEP for cervical intraepithelial neoplasia (CIN) is popular and often preferred over cryotherapy or laser ablation. This procedure, also known as *large loop excision of the transformation zone (LLETZ)*, uses electric current through a monopolar wire electrode to either cut or coagulate cervical tissues. As such, these thin, semicircular electrodes allow clinicians to excise cervical lesions with minimal patient discomfort, cost, and complications. Moreover, unlike ablative procedures, LEEP permits submission of a surgical specimen for additional evaluation.

### PREOPERATIVE

#### ■ Patient Evaluation

In the United States, women typically receive colposcopic evaluation and histologic interpretation of cervical biopsies prior to LEEP. Less commonly, a “see and treat” approach is also acceptable for specific settings outlined in Chapter 29 (p. 637) (Numnum, 2005). With this, treatment is immediate and relies on initial diagnostic colposcopic findings rather than biopsy results.

For LEEP, part of patient evaluation includes her suitability for an in-office or an operating room procedure. Although office procedures offer lower cost and fewer anesthetic risks, several patient factors favor anesthesia in an operating room. First, markedly relaxed vaginal sidewalls may require significant and potentially uncomfortable retraction for adequate visualization. Second, a lesion or transformation zone that lies near the cervix periphery may risk vaginal or bladder injury during electrode-pass completion, especially if the patient moves unexpectedly. Last, patient comorbidities or anxiety and an inability to remain relatively motionless during an office procedure favor greater anesthesia and patient monitoring.

#### ■ Consent

This procedure is associated with low morbidity, and overall complication rates approximate

10 percent (Dunn, 2004). Major complications are rare (0.5 percent) and may include bowel or bladder injury and hemorrhage (Dunn, 2003; Kurata, 2003). Short-term complications such as abdominal pain, heavier vaginal bleeding, and bladder spasm are treated symptomatically. Light vaginal bleeding or discharge is expected, and patients are so counseled.

Long-term complications include cervical stenosis and failure to completely treat the neoplasia. Persistent disease is typically noted in the initial surveillance Pap smear and in human papillomavirus (HPV) testing following LEEP. However, such treatment failure rates are low (approximately 5 percent) and are positively correlated with initial excised lesion size (Mitchell, 1998). Cervical stenosis is estimated to complicate less than 6 percent of cases. Risk factors include the presence of an endocervical lesion and excision of a large tissue volume (Baldauf, 1996; Suh-Burgmann, 2000).

The effects of LEEP with regard to obstetric outcomes are unclear. Several studies have shown that pregnancy does not appear to be adversely affected by LEEP, whereas others have noted increased risks of premature labor and premature rupture of membranes (Conner, 2014; Heinonen, 2013; Werner, 2010).

#### ■ Patient Preparation

Ideally, LEEP is performed after completion of menses. This decreases the chance of a coexistent early pregnancy and allows cervical healing prior to the next menstrual cycle. With surgery prior to menses, abnormal postprocedural bleeding may be masked, and postsurgical swelling can block menstrual flow and intensify cramping. A normal bimanual examination is confirmed prior to surgery. If

there is a possibility of pregnancy,  $\beta$ -hCG testing precedes treatment. Perioperatively, LEEP excision in general does not require antibiotic or venous thromboembolism prophylaxis. Similarly, bowel preparation is not needed.

### INTRAOPERATIVE

#### ■ Instruments

Tissue excision during LEEP requires an electrosurgical unit, wire loop electrodes, insulated speculum, and smoke evacuation system. Electrosurgical units used in LEEP procedures generate high-frequency (350–1200 kHz), low-voltage (200–500 V) electric current. Because of the risk for electric burns to the patient from stray current, grounding pads are placed on conductive tissue that is close to the operative site (Chap. 40, p. 858).

Similarly, an insulated speculum is used to limit the risk of stray current conductance to the patient. The insulated speculum has a port for smoke evacuation tubing, which assists in clearing smoke from the operating field to improve visualization and lower inhalation risks. Surgical smoke plumes can contain benzene, hydrogen cyanide, formaldehyde, and viruses, and thus local smoke evacuation systems are recommended (National Institute for Occupational Safety and Health, 1999). That said, transmission of infectious disease through surgical smoke has not been documented (Mowbray, 2013).

Electric current is directed to tissue via a 0.2-mm stainless steel or tungsten wire-loop electrode. These are available in various sizes to customize treatment according to lesion dimensions (Fig. 43-26.1). These instruments are disposable and discarded after each patient procedure.

**FIGURE 43-26.1** Various loop electrosurgical excision procedure (LEEP) electrodes.

**FIGURE 43-26.2** Single-pass loop electrosurgical excision.

## ■ Surgical Steps

### □ Anesthesia and Patient Positioning.

The patient is placed in standard dorsal lithotomy position, and the electrosurgical grounding pad is placed on the upper thigh or buttock. The insulated speculum is inserted into the vagina, and smoke evacuation tubing is attached. The application of Lugol solution outlines lesion margins before starting the procedure (Chap. 29, p. 638).

For in office anesthesia, vasoconstricting solutions of either: (1) vasopressin in a 1-percent lidocaine solution (10 units Pitressin in 30 mL of lidocaine) or (2) 1-percent lidocaine with epinephrine (1:100,000 dilution) may be selected. A 25- to 27-gauge spinal needle is used to circumferentially inject 5 to 10 mL of either solution 1 to 2 cm deep into the cervix outside the area to be excised. Cervical blanching usually follows.

□ **Single-pass Excision.** Ideally, the cervical transformation zone and CIN lesion is excised, and the appropriately sized loop is selected for this goal. If colposcopy is satisfactory, the correct loop diameter incorporates the transformation zone to a depth of 5 to 8 mm. The electrosurgical unit is set to cutting mode, and typically 30 to 50 W is used depending on the loop size. Larger loops require higher wattage.

To excise the transformation zone, a loop is positioned 3 to 5 mm outside the lateral perimeter of the area (Fig. 43-26.2). Current through the loop is activated prior to tissue contact, during which electric sparks at the loop tip may be seen. The loop is introduced to the cervix at a right angle to ectocervix. Once a 5 to 8-mm depth is reached, the loop is then drawn parallel to the surface until a point 3 to 5 mm outside the opposite border of the transformation zone and of the CIN lesion is reached. The loop is then withdrawn slowly, positioning it again at right angles to the surface. Current is stopped as soon as the loop exits the tissue. Following

excision, the specimen is placed in formalin for pathologic evaluation.

□ **Multiple-pass Excision.** Less commonly, bulky lesions may require multiple passes using a combination of loop electrode sizes (Fig. 43-26.3).

□ **Control of Bleeding Sites.** Despite use of vasoconstrictors, bleeding following LEEP is common. Sites of active bleeding may be controlled using a 3- or 5-mm ball electrode, and the electrosurgical unit switched to coagulation mode. Alternatively, Monsel paste can be applied with direct pressure to bleeding sites.

## POSTOPERATIVE

A watery vaginal discharge that develops after treatment usually requires light sanitary pad use, but tampons are discouraged.

Vaginal spotting is expected and can persist for weeks. During the first few days following LEEP, patients may complain of diffuse mild lower abdominal pain or cramping for which nonsteroidal antiinflammatory drugs (NSAIDs) typically provide relief. Patients abstain from intercourse during the 4 weeks following surgery. Depending on patient symptoms, work and exercise may resume following treatment.

## CERVICAL CRYOTHERAPY

For appropriate patients, cryotherapy has been used for decades to safely and effectively ablate the cervix transformation zone and CIN lesion. This method uses compressed gas to create extremely cold temperatures that necrose cervical epithelium. For this, the *cryoprobe*, an interfacing tip made of silver or copper, allows contact with and conduction of extreme cold across the cervix surface. When nitric oxide gas is used, probe temperatures can reach  $-65^{\circ}\text{C}$ . Cell death occurs at  $-20^{\circ}\text{C}$  (Gage, 1979).

As the cervical epithelium is cooled, an expanding layer of ice, called the *iceball*, forms beneath the center of the cryoprobe and grows circumferentially outward and past the probe margins. The expanding iceball grows in depth as well as circumference during treatment. The portion of the iceball in which temperatures fall below  $-20^{\circ}\text{C}$  is termed the *lethal zone*. This zone spans from the center of the cryoprobe to a perimeter 2 mm *inside* the outer iceball edge. Past this perimeter, tissue temperatures are warmer, and necrosis may be incomplete. Thus,

**FIGURE 43-26.3** Multiple-pass excision.

when cryotherapy is performed, the iceball is allowed to enlarge until it reaches a mark 7 mm distal to the probe margin, that is, a 5-mm lethal zone and a 2-mm zone of indeterminate tissue death (Ferris, 1994).

Although some use these iceball dimensions to direct therapy, the World Health Organization (2014) recommends a double-freeze method for cryotherapy, described in the steps below. Importantly, a single-freeze method is not sufficient, and dysplasia recurs frequently in the first year following this treatment (Creasman, 1984; Schantz, 1984).

The specific indications and long-term rates of success for cryotherapy are discussed in Chapter 29 (p. 643). As reported in a national consensus guideline, randomized trials comparing different treatment modalities show similar efficacy (Massad, 2013). In general, cryotherapy is appropriate for squamous CIN that does not extend into the endocervical canal, does not span more than two quadrants of the ectocervix, is not associated with unsatisfactory colposcopic examination or abnormal glandular cytology, and is covered by the selected cryoprobe. Moreover, cryosurgery is generally not favored for treating CIN 3 due to higher rates of disease persistence following treatment and lack of a histologic specimen to exclude occult invasive cancer (Martin-Hirsch, 2013). Last, cryosurgery and other ablative techniques are not favored for women with CIN and human immunodeficiency virus (HIV) infection due to high failure rates (Spitzer, 1999).

## PREOPERATIVE

### ■ Patient Evaluation

As with LEEP, women in the United States undergo colposcopy and histologic review of colposcopic biopsies prior to cryotherapy. Presurgical patient preparation mirrors that for LEEP (p. 988).

### ■ Consent

Intraoperative complications are uncommon, and hemorrhage is rare (Denny, 2005). Infrequently, women may experience a vasovagal reaction during treatment, and care is supportive. Perioperatively, patients are counseled that spotting, watery discharge, or cramping are typical, but infection is not. Long-term risks include cervical stenosis, squamocolumnar junction (SCJ) retraction into the endocervical canal, and treatment failure. Of these, treatment failures for CIN I and II have been cited at 6 to 10 percent (Benedet, 1981, 1987; Jacob, 2005; Ostergard, 1980). Last, infertility and pregnancy complications have not been associated with this treatment modality (Weed, 1978).

**FIGURE 43-26.4** Cryotherapy. **A.** Cryotip applied to cervix. **B.** Creation of advancing iceball. (Used with permission from Dr. Claudia Werner.)

## INTRAOPERATIVE

### ■ Instruments

Cryotherapy typically requires a tank of refrigerant gas plus a cryogun, connecting tubing, pressure gauge, and cryoprobe. Nitric oxide and carbon dioxide are frequently used refrigerant gases. Gas moves through connecting tubing, into the barrel of the cryogun, and then to the cryoprobe tip. Circumferential grooves at the cryoprobe base allow it to be screwed securely to the end of the cryogun.

Selection of an appropriate probe is individualized but should cover the transformation zone and lesion. Flat-faced probes are used for lesions located on the cervical portion. Advantageously, this shape has less of a tendency to push the resulting SCJ toward the endocervical canal, and it decreases the risk of unsatisfactory colposcopic examination following treatment.

□ **Analgesia and Patient Positioning.** Cryotherapy may be performed in an office setting and requires no significant analgesia. However, to help attenuate associated uterine cramping, women are often given an NSAID prior to therapy.

The patient is positioned in standard dorsal lithotomy position, and a vaginal speculum is placed. No vaginal cleansing prep is required. The appropriate-sized cryoprobe is attached onto the end of the cryogun barrel. A water-based lubricant jelly is applied to the end of the cryoprobe to ensure even tissue contact.

□ **Iceball Formation.** The probe is then pressed firmly against the cervix (Fig. 43-26.4). The cryogun trigger is squeezed, a light hissing

sound is typically heard, and frost begins to cover the probe. The trigger is held for 3 minutes as the iceball extends past the outer margin of the cryoprobe.

The cryoprobe should not contact the vaginal sidewalls. If this is identified, gas delivery is stopped to allow probe warming. The probe is then gently teased away from the wall, after which the procedure is continued.

□ **First Thaw.** After the first freeze, the trigger is released. The probe quickly warms and can be removed from the cervix. Attempts to remove the probe prior to complete defrosting can cause patient discomfort and bleeding. The surface of the cervix is allowed to thaw during the following 5 minutes.

□ **Second Cycle.** Subsequently, the freezing cycle is repeated for an additional 3 minutes. At completion of the second cycle, the cryoprobe and speculum are removed. Because vasovagal responses can be seen with this procedure, patients are assisted to a sitting position slowly.

## POSTOPERATIVE

As noted, watery vaginal discharge that can persist for weeks, vaginal spotting, and cramping that responds to NSAIDs are expected. Infrequently, severe pain and cramping may result from necrotic tissue obstructing the endocervical canal. Removal of the obstructing tissue typically resolves symptoms.

Because a large area of the cervix is denuded after cryotherapy, the potential for infection is increased. Accordingly, patients abstain from intercourse during the 4 weeks following surgery. If abstinence is

not feasible, then condom use is encouraged. Depending on patient symptoms, work and exercise may resume following treatment.

## CARBON DIOXIDE LASER CERVICAL ABLATION

The carbon dioxide (CO<sub>2</sub>) laser produces a beam of infrared light that produces heat at its focal point sufficient to boil intracellular water and vaporize tissue. Indications and success rates are discussed more fully in Chapter 29 (p. 643). In general, laser ablation may be used for cases in which the entire transformation zone can be seen with satisfactory colposcopy. There should be no evidence of microinvasive, invasive, or glandular disease, and cytology and histology should positively correlate.

Although research has shown laser ablation to be an effective tool in treating CIN, its popularity has declined. Laser units are significantly more expensive than those used for cryotherapy and LEEP. Moreover, lesions are destroyed with ablation, and unlike LEEP, the opportunity for additional pathologic evaluation of surgical margins is lost. Last, physician and staff training and maintenance of certification are typically required for safe, effective use of laser equipment.

## PREOPERATIVE

### Consent

Laser ablation is considered a safe and effective means to treat CIN. As with any treatment of cervical dysplasia, patients should be counseled on the risks of disease persistence and recurrence following treatment. These risks and surgical complications are low and comparable with those for LEEP (Nuovo, 2000).

## INTRAOPERATIVE

### Instruments

Carbon dioxide lasers suitable for cervical ablation are mobile, self-contained units. Tissue effects vary depending on the interval at which energy bursts are released. As a result, continuous waves (cutting) or pulsed energy (coagulation) can be released. Laser guidance is accomplished through attachment to a colposcopic sled device.

**FIGURE 43-26.5** Cervical bed following laser ablation. (Used with permission from Dr. Eddie McCord.)

Because laser light is reflective, protective eyewear is required for the patient and all participants, and a sign is posted on the suite door warning that a laser procedure is in progress. For this same reason, a matte-surface speculum is necessary. As with LEEP, noxious smoke is generated, and a smoke evacuation system is required.

## Surgical Steps

### Anesthesia and Patient Positioning.

Laser ablation for many women is an outpatient procedure and performed in either an operating suite or an office, depending on laser equipment location and patient characteristics. In most cases, local analgesia combined with a vasoconstrictor is sufficient, and administration mirrors that used for LEEP (p. 989). The patient is placed in standard dorsal lithotomy position. A matte-surfaced speculum is inserted, and smoke evacuation tubing is attached to a port on the speculum. Misdirected laser energy can burn surrounding tissues and ignite paper drapes. Therefore, moistened cloth towels are draped outside the vulva to absorb misdirected energy. To delineate the area of excision, Lugol solution is applied.

**Laser Settings.** The colposcope-laser assembly is brought into position and focused on the ectocervix. The laser is set to achieve a power density (PD) of 600 to 1200 W/cm<sup>2</sup> in a continuous wave mode. Average PD =

$100 \times W / D^2$ . In this formula, D is the spot diameter in mm at 10 W at 0.1 sec pulse. Thus, a power of 10 W with a spot diameter of 1 mm will yield a PD of 1000 W/cm<sup>2</sup>.

**Ablation.** Initially, four dots are ablated at 12, 3, 6, and 9 o'clock positions on the perimeter of the cervix to surround the entire lesion. These dots serve as landmarks and are connected in an arching pattern to create a circle. Once encircled, the area is ablated to a depth of 5 to 7 mm (Fig. 43-26.5)

**Endocervical Eversion.** To help prevent postoperative retraction of the SCJ cephalad into the endocervical canal, the tissue immediately surrounding the endocervix is ablated less deeply. This allows an apparent eversion of the endocervical lining and retention of the SCJ on the ectocervix.

**Hemostasis.** Bleeding is common during CO<sub>2</sub> laser vaporization. A defocused laser beam and a lower power setting in a super pulse wave mode will coagulate vessels and aid hemostasis. Bleeding present at the end of surgery may also be controlled with an application of Monsel paste.

## POSTOPERATIVE

Cramping is common following surgery, and light bleeding may persist for a week. Postoperative patient counseling is similar to that for LEEP (p. 989).

## 43-27

## Cervical Conization

Cervical conization removes ectocervical lesions and a portion of the endocervical canal by means of a conical tissue biopsy (Fig. 43-27.1). It is a safe, effective means to treat CIN, carcinoma in situ (CIS), and adenocarcinoma in situ (AIS). Moreover, cervical conization is a standard treatment for women with unsatisfactory colposcopy and biopsies suggestive of high-grade CIN, those with positive endocervical curettage, or those with discordant cytologic and histologic findings. Excision may be completed via scalpel, termed *cold-knife conization*. Alternatively, laser or LEEP conization may be performed. Success rates for these excisional methods in the treatment of CIN are equivalent. However, LEEP conization has gained popularity because of its ease of use and cost effectiveness.

## PREOPERATIVE

## Patient Evaluation

Prior to conization, patients will have undergone colposcopic examination and histologic evaluation of biopsies.  $\beta$ -hCG testing is

**FIGURE 43-27.1** Cone-shaped tissue biopsies.

warranted prior to conization if pregnancy is suspected. If pregnancy is confirmed and invasion is not suspected colposcopically, postpartum patient management is reasonable. Conization during pregnancy has great morbidity because of increased vascularity and intraoperative bleeding.

## Consent

Risks associated with conization mirror those for LEEP excision of ectocervical lesions. However, cold-knife conization has a greater risk of bleeding compared with that of laser and LEEP conization. Moreover, cold-knife and laser conizations carry higher risks of cervical stenosis compared with LEEP conization (Baldauf, 1996; Houliard, 2002). Increasing age and depth of endocervical excision are significant cervical stenosis risks. Penna and coworkers (2005) noted a lower risk of stenosis in postmenopausal women using estrogen replacement therapy compared with postmenopausal nonusers.

Cervical conization for CIN treatment has been associated with adverse outcomes in subsequent pregnancies that include preterm delivery, low-birthweight neonates, incompetent cervix, and cervical stenosis (Kristensen, 1993a,b; Raio, 1997; Samson, 2005). Although there is no major difference in obstetric outcome among the three techniques, increased cone biopsy size has been shown to positively correlate with rates of preterm delivery and premature membrane rupture (Mathevet, 2003; Sadler, 2004). Cold-knife conization generally removes more cervical stroma than other excisional methods.

## COLD-KNIFE CONIZATION

## Surgical Steps

**Anesthesia and Patient Positioning.** For most women, cold-knife conization is a day-surgery procedure performed under general or regional anesthesia. Following administration of anesthesia, the patient is placed in the standard dorsal lithotomy position. The vagina is surgically prepared, the bladder drained, and vaginal sidewalls retracted to reveal the cervix. Areas of planned excision may be more easily identified following Lugol solution application.

**Injection of Vasoconstrictors.** Associated bleeding during cold-knife conization can be brisk and obscure the operating field. Accordingly, preventative steps can be taken. First, vasoconstrictors as described for LEEP are injected circumferentially into the cervix (p. 989). Additionally, descending cervical branches of the uterine arteries, which supply

**FIGURE 43-27.2** Beaver blade.

the cervix, can be ligated with figure-of-eight stitches using nonpermanent suture. These are placed along the lateral aspects of the cervix at 3 and 9 o'clock. After the knots are secured, the sutures are kept long and held by hemostats to manipulate the cervix.

**Conization.** A uterine sound or small-caliber uterine dilator is placed into the endocervical canal to orient the surgeon as to the depth and direction of the canal. Using a no. 11 blade, the surgeon initiates the incision on the lower lip of the cervix. This limits blood from running downward and obscuring the planned incision path. Alternatively, a Beaver blade, which is a triangular-shaped knife blade with a 45-degree bend, may be used (Fig. 43-27.2). With either blade, a circumscribing incision creates a 2- to 3-mm border around the entire lesion (Fig. 43-27.3). The 45-degree angle of the blade is directed centrally and cephalad to excise a conical specimen. Toothed forceps or tissue hooks may be used to retract the ectocervix during cone creation. After incision of the ectocervix, a scalpel or Mayo scissors cuts the deep tip of the cone and releases the specimen. A suture is placed on the site of the specimen that corresponds to its 12 o'clock position in situ. The location of this suture is noted on the pathology requisition form and allows the pathologist to report positive and negative margin sites relative to their clock position.

**Endocervical Curettage.** Following removal of the cone specimen, endocervical curettage is performed to evaluate for presence of residual disease proximal to the excised cone apex. This is sent as a separate specimen for evaluation.

**Hemostasis.** With excision of the specimen, bleeding is common and can be controlled with individual suturing of isolated vessels, with electrosurgical coagulation, or with Sturmdorf sutures. In addition, a topical hemostatic agent such as absorbable methylcellulose mesh can be placed in the cone bed.

With placement of Sturmdorf sutures, a running locked suture line closes the cone

**FIGURE 43-27.3** Conization incision.

bed by circumferentially folding the cut ectocervical edge inward toward the endocervix. This technique is less favored due to increased rates of postoperative dysmenorrhea, unsatisfactory postoperative surveillance Pap smears, and concerns that the flap might conceal residual disease (Kristensen, 1990; Trimbos, 1983).

### LOOP ELECTROSURGICAL EXCISION PROCEDURE (LEEP) CONIZATION

#### ■ Surgical Steps

The surgical steps for this more extensive LEEP mirror those used for excision of ectocervical lesions (p. 989). However, to

remove a portion of the endocervical canal, a deeper pass must be made through the cervical stroma. This may be accomplished with a single deeper pass using a larger loop. Alternatively, in an effort to minimize the volume of tissue excised, a tiered or *top hat* technique can be selected. With this method, an initial pass is made to remove ectocervical lesions as previously described (see Fig. 43-26.2, p. 989). To remove endocervical canal tissue, a second smaller loop is passed more deeply into the cervical stroma (Fig. 43-27.4). As a result, the tissue is excised in two pieces, and both are sent for evaluation. Similar to cold-knife conization, the specimen is marked with suture to note its 12 o'clock position in situ.

### LASER CONIZATION

Excision of a laser cone biopsy specimen uses techniques similar to those described for laser ablation (p. 991). However, rather than ablating the involved tissue, laser energy is directed to cut and remove the cone-biopsy specimen. A higher power density is used to create a cutting effect, for example, 25 W with a 1-mm spot size ( $PD = 2500 \text{ W/cm}^2$ ). A cone-shaped specimen is then excised. During excision of the cone specimen, non-reflective tissue hooks may be needed to retract the ectocervical edge away from the

**FIGURE 43-27.4** Loop electrosurgical excision procedure (LEEP) “top hat” cervical conization procedure transverse (upper row) and coronal (lower row) views. **A.** Excision of ectocervical portion of lesion. **B.** Appearance of cervix following ectocervical excision. **C.** Excision of endocervical portion of lesion. **D.** Appearance of cervix upon procedure completion.

laser beam path and to create tissue tension along the plane of incision.

## POSTOPERATIVE

Recovery following all excisional methods is rapid and follows that for other surgeries of the cervix previously described (p. 989).

However, due to the greater incision, postoperative bleeding can develop more commonly and is treated with Monsel paste or other topical hemostat. Patients require postoperative surveillance for identification of disease persistence or recurrence, and this is described in detail in Chapter 29 (p. 644).

## 43-28

## Treatment of Vulvar Intraepithelial Neoplasia

### WIDE LOCAL EXCISION

With high-grade vulvar intraepithelial neoplasia (VIN), treatment goals include prevention of invasive vulvar cancer and when possible, the preservation of normal vulvar anatomy and function. For more widespread VIN, simple vulvectomy may be appropriate treatment and is described in Section 46-24 (p. 1208). However, less extensive methods such as wide local excision of lesions, ablative modalities, and medical treatments have also been evaluated as alternative options (Chap. 29, p. 649) (Hillemanns, 2006).

Of these, wide local excision of lesions is favored by many. It removes the preinvasive lesion, offers a tissue specimen for exclusion of invasive disease and evaluation of surgical margins, and compared with simple vulvectomy, lowers patient morbidity. In cases where excision involves the clitoris, urethra, or anus, a combined surgical excision and laser ablation approach is sometimes helpful. The combined technique uses CO<sub>2</sub> laser vaporization at sites where excision might lead to dysfunction or poor cosmesis (Cardosi, 2001).

### PREOPERATIVE

#### ■ Patient Evaluation

Prior to excision, full evaluation of the lower reproductive tract for evidence of invasive disease is completed as outlined in Chapter 29 (pp. 637 and 648). Importantly, vulvar biopsies are obtained during this evaluation and should exclude invasive disease, which would warrant more extensive excision (Chap. 31, p. 684).

#### ■ Consent

Wide local excision of high-grade VIN successfully treats disease, and progression to invasive vulvar cancer is low (3 to 5 percent) (Jones, 2005; Rodolakis, 2003). However, VIN recurrence is common, and even in those patients with tissue margins negative for disease, recurrence ranges from 15 to 40 percent (Kuppers, 1997; Modesitt, 1998).

In the immunocompetent, surgical and postoperative risks are few and typically include wound infection or separation, chronic vulvodinia, dyspareunia, and scarring or altered

vulvar appearance. Any vulvar operation requires thorough preoperative counseling regarding expectations for anatomic outcome and for sexual function.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** The choice of anesthesia or analgesia will vary depending on the location and size of the treated lesion. Whereas smaller labial or perineal lesions may easily be excised using local analgesia in an office setting, larger lesions or those involving the urethra and/or clitoris may require general or regional anesthesia. The patient is placed in standard dorsal lithotomy position, pubic hair at the surgical site is clipped, and the vulva is surgically prepared.

□ **Lesion Identification.** The area of excision should be well demarcated. For this, colposcopic examination following application of 3- to 5-percent acetic acid to the vulva will aid identification of lesion margins. Most recommend a 5-mm circumferential surgical margin surrounding the lesion (Joura, 2002). In the past, toluidine blue has been used to stain nuclear chromatin and enhance vulvar lesions. However, normal tissue can also absorb the stain and distort true disease margins, and use of toluidine blue is therefore not recommended.

□ **Incision.** As shown here, a scalpel with a no. 15 surgical blade is used to incise smaller

FIGURE 43-28.1 Vulvar incision.

lesions, whereas a no. 10 blade may be suitable for larger excisions (Fig. 43-28.1). An elliptical incision is preferred and aids wound reapproximation. Most VIN lesions fail to extend deeper than 1 mm on non-hair-bearing areas such as the labia minora. However, in hair-bearing areas of the vulva, VIN may extend to the deepest hair follicles. Thus, incision depth will vary depending on lesion location (Shatz, 1989). Once the incision is completed, Adson forceps or skin hooks can elevate and retract the skin margin away from the incision line. Dissection beneath the lesion begins at the incision periphery and progresses toward the center of the proposed excision area and then to the opposite incision margin.

Disease recurrence is related to the presence or absence of disease-free surgical margins. Thus, frozen sections of the specimen margins can be evaluated intraoperatively.

□ **Margin Undermining.** Reapproximation of the wound edges without tension decreases the risk of postoperative superficial separation. Accordingly, a surgeon may need to sharply undermine the skin at the wound margins with fine scissors to mobilize the skin and immediate underlying subcutaneous tissue.

□ **Wound Closure.** Prior to edge reapproximation, the wound bed is rendered hemostatic to minimize hematoma formation and subsequent wound separation. The edges of the skin are then reapproximated with interrupted stitches using 3-0 or 4-0 gauge delayed-absorbable sutures.

## POSTOPERATIVE

Without complication, recovery from wide local excision is typically rapid, and patients may resume normal activities as desired. Sitz baths and oral analgesics are usually recommended for the first week following surgery. Intercourse is delayed until wounds have fully healed, and this time will vary depending on wound site and size. Superficial wound separation is not uncommon, and sites of separation will heal by secondary intention.

Because of the significant risk for VIN recurrence, postprocedural surveillance is essential. Colposcopic vulvar examination is completed every 6 months for 2 years and then annually thereafter.

## CAVITATIONAL ULTRASONIC SURGICAL ASPIRATION (CUSA)

Indications for use and mechanism of action of cavitation ultrasonic surgical aspiration are discussed more fully in Chapter 40 (p. 859). Briefly, cavitation causes fragmentation and disruption of tissue, which is then aspirated and collected. Thus, the tissue, although fragmented, can be sent for histologic or cytologic evaluation.

Treatment of high-grade VIN with CUSA usually produces excellent cosmetic results, and complications such as scarring and dyspareunia are rare. However, the recurrence rate is high, as it is with other treatment modalities for VIN, and especially in treated hair-bearing areas (Miller, 2002). Thus, it is generally reserved for vulvar skin without hair. Although the procedure allows for tissue evaluation, tissue disruption may preclude adequate examination of all parts of the specimen and their associated relationships. Cost is greater than for excisional therapy and is similar to the cost of laser therapy. Depending on lesion size, CUSA can be more time consuming compared with excision or laser ablation. However, compared with laser therapy, CUSA lacks a smoke plume and avoids the risks associated with radiant energy.

In addition to VIN treatment, CUSA works well for condyloma acuminata, particularly bulky or multifocal condyloma or condyloma that are refractory to topical treatment. Information regarding cavitation therapy for condyloma acuminata is included in this section due to the similarity of treatment for VIN.

## PREOPERATIVE

### Patient Evaluation

The same principles apply as for excisional treatment of VIN. Specifically, a full evaluation of the lower genital tract is indi-

cated to exclude an invasive process. Although condyloma acuminata are often diagnosed and treated on the basis of clinical appearance, a complete evaluation of the lower genital tract should likewise be undertaken preoperatively.

### Consent

Risks of cavitation therapy for VIN or condyloma are few and are similar to those of wide local excision. Postoperative healing is by secondary intention and may take several weeks.

## INTRAOPERATIVE

### Instruments

The CUSA unit consists of a console, an operative hand piece, and a foot pedal, by which the system is activated (Fig. 43-28.2). The console allows control of amplitude or intensity, irrigation, and aspiration. Amplitude determines the relative amount of tissue fragmentation. A setting at 1 will produce cellular fragmentation to a depth of 30  $\mu$ m, whereas a setting at 10 will produce cellular fragmentation to a depth of 300  $\mu$ m. Fragmentation of a specific tissue is dependent on its water content. Therefore, less power is required for tissues with high water content such as skin and condyloma. Irrigation is used to control the considerable heat generated by the vibrating titanium tip (23 kHz) of the hand piece and to suspend the fragmented tissue for suction removal. The tip has a hollow 2-mm diameter and will remove tissue within a 1- to 2-mm radius of the tip. Vaporized and fragmented tissue is aspirated through the hollow tip of

**FIGURE 43-28.2** Operative handpiece of the cavitation ultrasonic surgical aspiration (CUSA) unit.

the hand piece and collected in a tissue trap. Each console setting may be varied depending on the needs of the operator.

### Surgical Steps

**Anesthesia and Patient Positioning.** CUSA is performed in the operating room under regional or general anesthesia. The patient is placed in standard dorsal lithotomy position. The vulva and the perianal region, if involved with disease, are surgically prepped.

**Lesion Identification.** The same colposcopic identification techniques used prior to wide local excision apply for CUSA (p. 995). In Figure 43-28.3A, two areas of VIN are evident even prior to application 3- to 5-percent acetic acid. The larger of the two is located in the midportion of the right labium minus, and the smaller is more anterior and toward the clitoris.

**Console Settings.** For treatment of VIN and condyloma acuminata, an amplitude setting of 5 to 6 produces cellular fragmentation to a tissue depth of 150  $\mu$ m to 180  $\mu$ m and should allow adequate removal of tissue without significant thermal injury. However, some studies have used amplitude settings at 6 to 8 for treatment of VIN (Miller, 2002). Irrigation and aspiration rates may be varied depending on the need of the operator. For example, if tissue fulguration is desired, a decrease in the irrigation rate will permit additional heat production at the hand-piece tip. Aerosolization can be minimized with proper balance of irrigation and aspiration rates.

**Ablation.** As with wide local excision, the area of treatment should extend at least 5 mm beyond the identified lesion(s). The hand-piece tip is moved over the vulva in a back-and-forth motion. Only close contact with the skin of the vulva is required; no pressure is necessary. Repeat movements of the tip over the involved area dictate the depth of tissue removal. However, depth of destruction is often difficult to assess. Collagen bundles and elastic fibers become visible in the reticular dermis (Reid, 1985). Tissue destruction beyond this point increases the likelihood of scarring. For treatment of VIN, depth of treatment may vary between 1.5 and 2.5 mm (Miller, 2002; Rader, 1991). For condyloma acuminata, depth of treatment need not extend beyond the basement membrane (Ferenczy, 1983). Bleeding, if any, is usually minor and is controlled with pressure. Figure 43-28.3B shows the end result for the same patient shown in part A.

**FIGURE 43-28.3** **A.** Vulvar intraepithelial neoplasia (VIN) involving the right labium minus. **B.** Cavitation ultrasonic surgical aspiration (CUSA) treatment of VIN completed.

## POSTOPERATIVE

A 1-percent silver sulfadiazine cream may be applied to the vulva immediately following ablative therapy and continued once or twice daily for a short time. Oral analgesics and sitz baths are helpful in pain management following therapy. Patients may be seen for reevaluation 2 to 4 weeks postoperatively.

## CARBON DIOXIDE LASER VAPORIZATION OF VIN

The CO<sub>2</sub> laser has been used for decades for treatment of VIN (Baggish, 1981). Success rates vary, however, and depend on factors such as length of patient surveillance, number of therapy courses, specific area of treatment, and total area of treated disease. In theory, the CO<sub>2</sub> laser is an ideal means to treat VIN. When used with the colposcope, the laser can accurately eradicate disease while preserving normal tissue structure and function. Associated bleeding is scant, healing is usually excellent, and scarring is minimal. Rates of significant complications are generally low. CO<sub>2</sub> laser vaporization may also be considered as an addition to an excisional procedure. One example is if there is multifocal disease involving both hair-bearing and non-hair-bearing areas, such as the clitoris, where excision may not be ideal. That said, Reid and colleagues (1985) recommend that only those surgeons experienced with CO<sub>2</sub> lasers attempt VIN vaporization by this method. Indeed, there is literally a thin margin between the depth of therapy needed to eradicate disease and a depth that may produce delayed healing, scarring, and a poor cosmetic result.

As with other destructive techniques, before laser vaporization is performed, invasive disease must be excluded. Since VIN is often multifocal, a thorough examination of the vulva and the lower genital tract with biopsy of any abnormal-appearing area is imperative. No tissue sample will be available for analysis following CO<sub>2</sub> laser vaporization.

## PREOPERATIVE

### Consent

As with other VIN treatment methods, recurrence or persistence following CO<sub>2</sub> laser vaporization is possible, and the patient is counseled on the need for postoperative surveillance. Pain, infection, fever, skin depigmentation, alopecia, scarring, and dyspareunia may result from treatment. Healing is generally complete in 4 to 6 weeks but may be delayed if treatment extends significantly into the dermis (Wright, 1987).

## INTRAOPERATIVE

### Instruments

A general description of the CO<sub>2</sub> laser is found on page 991. Recommendations regarding its use for cervical ablation of CIN are likewise appropriate for treatment of VIN.

### Surgical Steps

**Anesthesia and Patient Positioning.** Laser ablation of VIN is nearly always performed as an outpatient procedure either in an office setting or in an operative suite depending on laser availability. The procedure

may be performed under general, regional, or local anesthesia. Ferenczy and associates (1994) used disease greater than 6 cm<sup>2</sup> as a criterion for general anesthesia. The patient is placed in standard dorsal lithotomy position. To lessen the risk of injury from misdirected laser energy to tissues beyond those being treated, wet towels are positioned around the operative field. Paper drapes are avoided due to risk of fire. A moistened sponge is placed inside the rectum to prevent passage of flatus into the surgical field and possible gas ignition.

**Laser Settings.** The laser is coupled to the colposcope, and the assembly is brought into focus on the vulva. A power density (PD) of 600 to 1200 W/cm<sup>2</sup> delivered in continuous mode is sufficient for therapy. However, Reid and associates (1985) caution that PD > 600 W/cm<sup>2</sup> may be difficult to control on the vulva. Calculation of power density is described on page 991.

**Examination of Treatment Area.** After a soaking application of 3- to 5-percent acetic acid solution is applied to the vulva, the area to be treated is examined colposcopically to delineate the zone of vaporization. This may be marked with the laser beam, incorporating a margin of 3 to 5 mm or upward to 1 cm of normal-appearing tissue (Helmerhorst, 1990; Hoffman, 1992).

**Ablation.** The location of VIN will determine the needed depth of laser beam penetration for treatment. As hair root sheaths may harbor VIN up to a depth of 2.5 mm, involved hairy areas of the vulva will require laser penetration into the reticular dermis (Mene, 1985). Wright and Davies (1987) recommend a depth of 3 mm for hair-bearing

areas and consider this depth to correspond well with destruction into the third surgical plane as described by Reid and coworkers (1985). Non-hair-bearing areas contain no adnexal structures and therefore, if laser is used, do not require deeper treatment. One millimeter or less of laser penetration is adequate for treatment of VIN in these areas, that is, no deeper than the basement membrane.

□ **Reexamination.** After lasering, carbonized debris is removed, and 3- to 5-percent acetic acid solution is applied to the vulva,

which is again examined colposcopically to confirm no remaining areas of disease.

## POSTOPERATIVE

Care should be taken to avert adhesion formation (labial coaptation) of treated areas. Avoidance of restricting clothing and separation of the labia at least daily are recommended. Sitz bath two to three times per day is cleansing and frequently gives temporary relief of postoperative vulvar discomfort. Other measures that may be helpful include

application of 1-percent silver sulfadiazine cream two to three times per day and oral analgesics. The patient should refrain from sexual activity until healing is complete.

The first postoperative visit may be scheduled at 4 to 6 weeks following the laser vaporization procedure. An acceptable schedule for surveillance of persistent or recurrent VIN is examination every 6 months for 2 years and then yearly thereafter. More frequent visits, particularly in the first year after treatment, may be warranted depending on individual patient characteristics.

44-1

Diagnostic Laparoscopy

Diagnostic laparoscopy provides a minimally invasive surgery (MIS) option for thorough evaluation of the peritoneal cavity and pelvic organs. It is often performed to evaluate pelvic pain or causes of infertility, to diagnose endometriosis, or to ascertain the extent of adhesive disease or qualities of a pelvic mass. Importantly, systematic evaluation of the peritoneal cavity is performed during every laparoscopy, either diagnostic or operative.

PREOPERATIVE

Consent

During the consenting process for diagnostic laparoscopy, a surgeon reviews procedure goals, including diagnosis and possible treatment of identified pathology. Among others, this includes permission for lysis of adhesions, peritoneal biopsy, and excision or ablation of endometriosis. Importantly, a patient is counseled that diagnostic laparoscopy may not reveal any apparent pathology. Laparoscopy is typically associated with few complications. Of these, organ injuries caused by puncture or by electrosurgery tools are the most common major complications and are summarized in Chapter 41 (p. 877). Patients

are also counseled regarding possible need to complete the diagnostic evaluation via laparotomy. Reasons for conversion during diagnostic laparoscopy include failure to gain abdominal access, organ injury during entry, or extensive adhesions. Overall, the conversion risk to laparotomy is low and approximates 5 percent.

Patient Preparation

In general, laparoscopy is associated with lower rates of postoperative infection and venous thromboembolism (VTE) compared with laparotomy. For diagnostic laparoscopy, antibiotics are typically not required, and VTE prophylaxis is implemented for those with risk factors (Table 39-8, p. 836). In addition, for most patients, bowel preparation is not

administered. However, if extensive adhesiolysis is anticipated and the risk of bowel injury is thereby increased, bowel preparation can be considered.

## INTRAOPERATIVE

### ■ Instruments

Several instruments are especially helpful during diagnostic laparoscopy, and most are found in a standard laparoscopy instrument set. Of these, a blunt probe and atraumatic grasper are valuable to manipulate abdominal organs. A uterine manipulator that allows for chromopertubation is also considered if performing diagnostic laparoscopy for infertility evaluation. If this is planned, indigo carmine dye or methylene blue can be diluted and used. However, current indigo carmine shortages may favor methylene blue use. Either agent is diluted into 50 to 100 mL of sterile saline for injection through the cervical cannula.

### ■ Surgical Steps

#### □ Anesthesia and Patient Positioning.

Most laparoscopic surgery is performed in an operating room and requires general anesthesia. Much less commonly, in-office microlaparoscopy using 2- to 3-mm microlaparoscopes has been reported for second-look evaluation of cancer treatment, sterilization, and pelvic pain and infertility evaluation (Franchi, 2000; Mazdisnian, 2002; Mercurio, 2008; Palter, 1999).

In most cases, following anesthesia induction, the patient is placed in low dorsal lithotomy position in booted support stirrups to permit manipulation of the uterus. The patient's arms are tucked at her sides. Correct patient positioning is critical to avoid nerve injury and is discussed in Chapter 41 (p. 879). A bimanual examination is completed to determine uterine inclination. Inclination will direct positioning of the uterine manipulator, if used. The vagina and abdomen are surgically prepared, and the bladder is drained. If a longer procedure is anticipated, a Foley catheter may be required as a full bladder can obstruct the operating view or increase the risk of bladder injury.

#### □ Uterine Manipulator Placement.

Although not mandatory, a uterine manipulator may be placed to move the uterus during evaluation of the pelvis. Examples are shown in Chapter 41 (p. 881). For manipulator placement, a surgeon is gowned and doubly gloved. A Graves speculum or vaginal retractors are used to display the cervix. To stabilize the cervix, a single-tooth tenacu-

lum is placed on the anterior cervical lip. A Cohen or other uterine manipulator is then inserted into the external os. Alternatively, after measurement of the uterine cavity with a uterine sound, the balloon end of an endometrial cavity manipulator may be threaded into the endometrial cavity, and the balloon inflated. The outer pair of surgical gloves is removed, and the surgeon moves to either side of the patient.

□ **Primary Trocar Entry.** Abdominal access may be attained by any of the four basic techniques described in Chapter 41 (p. 889). These include Veress needle insertion, direct trocar insertion, optical-access insertion, or open entry methods. For diagnostic laparoscopy, no one method is superior to the others. The umbilicus is usually chosen as the site for abdominal entry. However, if a patient's history suggests periumbilical adhesions, then entry at Palmer point may be preferred. A 5-mm or 10-mm umbilical port will house a suitable laparoscope for diagnostic examination. Generally, starting with a 5-mm incision and laparoscope will allow for adequate visualization of the abdominopelvic cavity. Should improved optics be desired, this can be easily changed to a 10-mm size. Once safe initial entry is confirmed, the abdomen is insufflated to reach an intraabdominal pressure of 15 mm Hg or less.

□ **Additional Port Site Selection.** Often during diagnostic laparoscopy, additional operative cannulas are needed. If minimal tissue manipulation is required, a suprapubic port may suffice. However, bilateral lower quadrant ports may be desired if lysis of adhesions or greater tissue manipulation is required. These are placed under direct laparoscopic visualization as described in Chapter 41 (p. 895).

□ **Upper Abdomen Evaluation.** All laparoscopic procedures begin with a systematic and thorough diagnostic inspection of the entire peritoneal cavity, including the pelvis and upper abdomen. Once safe initial entry is confirmed, the area directly below the primary trocar entry site is evaluated for bleeding or other signs of entry trauma. Prior to Trendelenburg positioning, the upper abdomen is examined. Specifically, the liver surface, gallbladder, falciform ligament, stomach, omentum, and right and left hemidiaphragms are inspected. The ascending, transverse, and descending colon are also viewed. During inspection of the ascending portion, the appendix is identified. After Trendelenburg positioning, bowel and omentum fall toward the upper abdomen to expose the retroperitoneal structures. Now free of intestines, the area directly beneath the initial entry site is

examined again. Previously unappreciated trauma to this area from initial abdominal entry might then be seen.

□ **Examination of Pelvis.** After examination of the upper abdomen, attention is turned to the pelvis. First, the uterus is retroflexed with the aid of the uterine manipulator to provide clear viewing of the anterior cul-de-sac. Then, the manipulator tilts the uterus up and to the right to permit left pelvic sidewall inspection. The uterus is then ante flexed to provide access to the posterior cul-de-sac. Last, the uterus is tilted to the left, and the right pelvic sidewall is viewed. Peritoneal surfaces are thereby sequentially and methodically inspected. During this, endometriotic implants, peritoneal defects or windows, adhesions, fibrosis, or studding concerning for malignancy are sought.

Next, both ureters are visualized coursing from the pelvic brim, along the pelvic sidewall, and to the cervix. Both peristalsis and caliber are assessed. Uterine size, shape, and texture are also noted. To examine both fallopian tubes and ovaries, a surgeon may place a blunt probe into the cul-de-sac and sweep the probe forward and laterally. In doing so, the tubes and ovaries are lifted from the posterior cul-de-sac or ovarian fossa for inspection.

#### □ Indicated Laparoscopic Procedures.

After visual assessment of the pathology found, indicated procedures are then performed. If adhesions are encountered, they may be divided as described in Chapter 41 (p. 900).

#### □ Abdomen Deflation and Port Removal.

At laparoscopy completion, carbon dioxide (CO<sub>2</sub>) insufflation is halted, and the gas tubing is disconnected from the primary cannula. The gas ports on all cannulas are opened to deflate the abdominal cavity. To prevent diaphragmatic irritation from retained CO<sub>2</sub>, manual pressure is placed on the abdomen to help expel remaining gas. During this process, all secondary cannulas are removed using laparoscopic visualization. This allows exclusion of bleeding from punctured vessels that may have been tamponaded by these cannulas. Additionally, it prevents herniation of bowel or omentum up through the cannula track and into the anterior abdominal wall. Of note, pneumoperitoneum can also act as an intraoperative tamponade. Accordingly, potential bleeding sites are reinspected as the pneumoperitoneum is released. Next, the primary cannula is removed while leaving the laparoscope in the abdomen. Last, the laparoscope is slowly removed to visualize the abdomen and entry site for any evidence of bleeding and to prevent viscera from being pulled into the port site.

□ **Incision Closure.** Depending on their size, incisions may require deep fascial stitches. To prevent incisional hernia formation, fascial closure is often recommended whenever trocars measuring  $\geq 10$  mm are employed (Lajer, 1997). Nonbladed trocars may decrease this risk (Liu, 2000). For closure, interrupted or running suture line using 0-gauge delayed absorbable suture is suitable.

If open entry was used, then sutures originally placed in the fascia are unthreaded

from the trocar. Each of these sutures then is brought to the midline of the incision, and square knots are tied to close the fascial defect.

Skin incisions are closed with a subcuticular stitch of 4-0 gauge delayed-absorbable suture. Alternatively, the skin may be closed with cyanoacrylate tissue adhesive (Dermabond Topical Skin Adhesive) or skin tape (Steri-Strips) (Chap. 40, p. 847).

After incision closure, the uterine manipulator is removed.

## POSTOPERATIVE

Depending on the procedure performed, most patients can be discharged home on the same day as surgery. For most, physical activities and diet can be resumed according to patient comfort.

## 44-2

## Laparoscopic Sterilization

Approximately 650,000 tubal sterilization procedures are performed annually in the United States. Approximately half of these follow pregnancy delivery or termination, but the others are performed independent of pregnancy and are termed *interval sterilization* (Chan, 2010). Most interval procedures are performed laparoscopically, and most frequently they involve tubal occlusion by electrosurgical coagulation, by mechanical clips, by Silastic bands, or by suture ligation (Pati, 2000).

Current sterilization practices will likely change with recommendations now encouraging consideration of prophylactic salpingectomy at the time of sterilization, abdominal or pelvic surgery, or hysterectomy for women at average risk of ovarian cancer (American College of Obstetricians and Gynecologists, 2015). The rationale for this practice change to help decrease rates of certain epithelial ovarian cancers is described in Chapter 35 (p. 738).

### PREOPERATIVE

#### ■ Patient Evaluation

Several preventive steps can avoid sterilization procedures in women with early, undiagnosed pregnancies. Providing contraception well in advance of surgery, scheduling surgery in the follicular phase of the menstrual cycle, and preoperative serum  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG) level testing are effective methods to prevent or detect early pregnancy (American College of Obstetricians and Gynecologists, 2013a).

Patients who require treatment of advanced cervical epithelial abnormalities and who desire sterilization may choose hysterectomy rather than tubal occlusion as a means to serve both needs. For this reason, women ideally have cervical cancer screening results reviewed prior to surgery.

#### ■ Consent

During the consenting process, patients are counseled regarding other reversible methods of contraception; other permanent methods, such as male sterilization; and the possibility of future regret (American College of Obstetricians and Gynecologists, 2009). Tubal sterilization is effective and should be considered a permanent procedure by the patient. Tubal sterilization is safe and associated complications are few. In general,

**FIGURE 44-2.1** Filshie clip may fall away following fibrosis of fallopian tube ends.

the risks of laparoscopic sterilization mirror those of laparoscopy (Chap. 41, p. 877).

Sterilizing clips and bands routinely fall from around the tube once occluded ends necrose and fibrose (Fig. 44-2.1). Most ectopic clips are incidental findings without untoward patient effects, but less commonly they can incite local foreign body reactions. Rarely, cases of clip migration to sites such as the bladder, uterine cavity, and anterior abdominal wall have been reported (Gooden, 1993; Kesby, 1997; Tan, 2004).

Contraceptive failure and pregnancy rates related to each procedure are also discussed with the patient (Chap. 5, p. 116). Overall, these rates are low, and tubal sterilization is an effective method of contraception. If pregnancy does occur, however, there is a greater risk of ectopic pregnancy. Bipolar coagulation has the highest risk for this complication compared with that of clips or bands (Malacova, 2014; Peterson, 1996). Accordingly, amenorrhea following any sterilization procedure should prompt serum  $\beta$ -hCG testing to aid in identifying ectopic pregnancies.

#### ■ Patient Preparation

For sterilization procedures, antibiotics and bowel preparation are typically not administered. VTE prophylaxis is implemented only for those at increased risk as listed in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Most laparoscopic tubal sterilization procedures are performed using general anesthesia.

To reduce postoperative pain, investigators have evaluated the adjunctive use of bupivacaine solution injected or dripped onto the tubal serosa or delivered transcervically through balloon uterine manipulators into the fallopian tube lumen. Though results have varied, one metaanalysis suggests some benefit in diminishing immediate postoperative pain with these practices (Brennan, 2004; Harrison, 2014; Schytte, 2003; Wrigley, 2000).

To begin, the patient is placed in the low dorsal lithotomy position, and patient arms are tucked at the side. A bimanual examination is completed to determine uterine size and inclination. Uterine size will affect placement of the accessory trocar, and inclination will direct positioning of the uterine manipulator, if used. The vagina and abdomen are surgically prepared, and the bladder is drained. Most sterilization procedures are brief, and a Foley catheter is seldom required. Often, a uterine manipulator or sponge stick is then placed to provide uterine ante flexion or retro flexion during evaluation of the pelvis (p. (Chap. 41, p. 881).

□ **Abdominal Entry and Accessory Ports.** For all of the sterilization procedures described, the initial steps of laparoscopic abdominal entry are performed as described in Chapter 41 (p. 889). In most instances, one accessory port is required and is placed suprapubically in the midline to provide an equal reach to both fallopian tubes. For a normal-sized uterus, this port is placed 2 to 3 cm above the symphysis pubis. However, for a larger uterus, this position is moved cephalad as needed to access both tubes. Once ports are in place, inspection of the abdomen and pelvis is completed prior to the planned procedure.

□ **Filshie Clip.** The titanium Filshie clip is applied with the aid of a customized metal applicator that houses the clip within its single-action jaw. The applicator requires an 8-mm port for insertion into the abdominal cavity. As the jaw is closed, the shorter upper rim of the clip is forced beneath the longer lower clasp, and the clip is thereby locked into place around the fallopian tube.

□ **Fallopian Tube Manipulation.** To begin, a blunt probe or atraumatic grasping forceps is placed through the accessory port. To aid clip positioning, the surgeon stretches the fallopian tube out horizontally and laterally. Concurrently, a uterine manipulator can be used to tilt the uterus laterally and in the opposite direction. The blunt probe is then removed from the single port for insertion of the clip applicator.

□ **Applicator Insertion.** At the beginning of clip application, a Filshie clip is held within its applicator and inserted through the accessory cannula into the abdomen. A surgeon half closes the applicator's upper jaw to insert it and the clip through the cannula. The handle of the applicator is not gripped tightly, as this may prematurely close and lock the clip (Penfield, 2000).

Once the Filshie clip emerges through the cannula, the applicator is opened slowly. The jaw of the applicator has the potential to spring open more quickly than the clip can open. This can result in the clip falling off the applicator and into the abdomen. Fallen clips are preferably retrieved, but if an open

clip becomes lost and hidden by loops of bowel, laparotomy is typically not required for retrieval.

□ **Filshie Clip Placement.** After the clip is completely open, the clip and applicator are positioned with one jaw above and one below the fallopian tube at a site along the isthmus portion of the tube and 2 to 3 cm from the uterine cornu (Fig. 44-2.2). The entire width of the tube should lie across the base of the clip. The distal hooked end of the lower jaw should be visible through the mesosalpinx.

□ **Filshie Clip Application.** Once satisfied that the clip is positioned correctly, a surgeon slowly squeezes the finger bar handle to its full limit, back toward the handle backstop. With this action, the upper ridge of the clip is slowly compressed and locked under the lower hooked end of the clip (Fig. 44-2.3). This flattens the entire tube within the clip (Fig. 44-2.4). As the applicator jaws are slowly opened, the clip releases automatically from the applicator as it has locked onto the tube. These steps are repeated on the opposite fallopian tube. If there is any doubt regarding proper clip placement, a second clip is applied correctly to the same tube.

Rarely, a fallopian tube may be transected by the clip. This is usually associated with a large fallopian tube, which has been clipped too quickly. For sterilization completion, a clip is applied to both ends of the transected tube.

□ **Bipolar Electrosurgical Coagulation.** For this method, the fallopian tube is identified and grasped in the isthmus region at least 2 to 3 cm lateral to the cornu (Fig. 44-2.5). Placement here is important as pressure from retrograde menstrual flow against a coagulated stump that has been placed too close to the cornu can increase the risk of stump recanalization and fistula formation. Leaving a 2- to 3-cm segment allows ample space for absorption of intra-uterine fluid without creating excess pressure against the stump.

□ **Electrocoagulation.** The coagulating paddles of the bipolar forceps should span the tube. Overextending their grasp may lead to partial coagulation of the mesosalpinx and incomplete coagulation of the entire tube width. Before current is applied, the tube is slightly elevated and pulled away from other adjacent structures to prevent thermal injury to these. As current is applied, the tube swells and fluid often bubbles and pops from the tissue. Current is delivered until the tube is completely desiccated. Failure to reach this end point has been linked with higher contraceptive failure rates (Soderstrom, 1989). Because visual inspection of the tube is typically inadequate to assess complete desiccation, an ammeter is incorporated with most bipolar generators. Water conducts current through tissues. Thus, completely desiccated tissues are unable to conduct current. For this reason, current is maintained during coagulation until zero current flow across the tube is registered by the ammeter. The tube is then released.

A second site that is lateral but contiguous with the first coagulated segment is grasped and similarly coagulated. A total of three contiguous sites are serially coagulated. This occludes a total span of 3 cm along the tube's length (see Fig. 44-2.5). Coagulation of shorter distances along the tube can lead to recanalization and contraceptive failure (Peterson, 1999). These steps are then repeated on the opposite fallopian tube.

Occasionally following coagulation, the tube may stick to the bipolar paddles. To free the tube, the paddles are slowly opened and gently twisted to the right and then the left. Additionally, gentle fluid irrigation of the desiccated area may help release the tube.

□ **Falope Ring (Silastic Band).** With this method, a Silastic Falope ring is applied with the aid of a custom metal applicator. To summarize the process, applicator tongs draw a portion of tube up into an inner sheath, and an outer sheath then pushes a Silastic band of the inner sheath and onto the fallopian tube loop.

**FIGURE 44-2.2** Open Filshie clip within applicator.

**FIGURE 44-2.3** Clip application around fallopian tube.

**FIGURE 44-2.4** Closed clip around the tube.

**FIGURE 44-2.5** Bipolar electrocoagulation.

**⑪ Ring Loading.** Prior to its insertion into the abdomen, a Falope ring is stretched around the distal tip of the inner applicator sheath by means of a special ring loader and ring guide (Fig. 44-2.6).

**⑫ Ring Placement.** Once inserted through the accessory port, the applicator's tongs are opened and placed completely around the fallopian tube approximately 3 cm from the cornu. Tongs grasp the mesosalpinx directly at its attachment to the tube. This prevents excess mesosalpinx from being drawn into the inner sheath (Fig. 44-2.7).

**⑬ Ring Application.** A trigger on the applicator retracts the tongs and draws a

loop of tube approximately 1.5 cm into the inner sheath. The total length of tube contained within the inner sheath is thus 3 cm (Fig. 44-2.8).

The outer sheath is then advanced toward the loop's base. This outer sheath pushes the Silastic band of the inner sheath and onto the loop base (Fig. 44-2.9). The loop base will blanch from ischemia following band

placement (Fig. 44-2.10). These steps are repeated on the opposite fallopian tube.

**⑭ Special Circumstances.** Tubal transection is uncommon, and a Falope ring can be applied to each of the divided segments. Vessels of the mesosalpinx can occasionally tear and bleed as the tongs and tube are drawn into the inner sheath. The Silastic

**FIGURE 44-2.6** Falope ring (left) and ring stretched around applicator (right).

**FIGURE 44-2.7** Falope ring applicator placement.

**FIGURE 44-2.8** Tube drawn into inner sheath.

band, once applied to the loop base, will control bleeding in most instances. Thus, electrocautery to achieve hemostasis is infrequently needed.

**15 Hulka Clip Application.** The plastic Hulka clip is also generically known as a spring clip because of the stiff outer metal spring that locks the clip into place. Required equipment includes the clips themselves and a custom metal applicator, which holds the clip during application.

**16 Fallopian Tube Manipulation.** To begin, a blunt probe or atraumatic grasping forceps is placed through the accessory port. The fallopian tube is outstretched horizontally and laterally to aid clip application. Concurrently, a uterine manipulator can be used to tilt the uterus laterally and in the opposite direction.

**17 Clip Loading.** Before the applicator and its clip are inserted through the accessory trocar, the trigger of the applicator is gently squeezed by the surgeon's thumb. This action advances the outer rod of the applicator down and over the top of the clip. This closes the jaws of the clip to within 1 mm

of each of other. This is an unlocked position yet allows the clip and applicator to be threaded down the accessory cannula.

**18 Clip Application.** Once inside the abdomen, the applicator trigger is drawn backward, the outer rod retracts, and the upper jaw of the clip reopens. Held within the applicator jaws, the open clip is positioned across the narrow isthmus portion of the fallopian tube, 2 to 3 cm from the cornu, and perpendicular to the long axis of the tube (Fig. 44-2.11). The jaws are positioned around the tube in a manner that directs the tube deeply into the crux of the clip jaws. This aids in total occlusion of the tube as it is flattened across the base of the closing clip. Additionally, the applicator tip and clip are positioned such that when closed, the clip incorporates a small portion of adjacent mesosalpinx.

**19 Clip Closure.** Once the applicator jaws are appropriately positioned, the thumb-action trigger is slowly squeezed to push

**FIGURE 44-2.9** Outer sheath forces the Falope ring off the inner sheath (inset) and onto the fallopian tube.

**FIGURE 44-2.10** Falope ring in place.

**FIGURE 44-2.11** Hulka clip application.

forward the outer rod of the applicator and close the clip around the tube (Fig. 44-2.12). The clip application is inspected to ensure that it has completely encompassed the tube.

If placement is deemed correct, the trigger is fully depressed. This forces the center rod of the applicator forward against the butt of the clip's stiff metal spring (Fig. 44-2.13). The spring is pushed out and around the plastic frame of the clip to compress and lock the

upper and lower clip jaws in place. One clip is placed on each tube. If a clip is misapplied, a second clip can be placed lateral to the first.

**20 Pomeroy with Endoscopic Loop.** This procedure can be used as a sterilization technique but is more commonly used to excise fallopian tube ectopic pregnancies. A description and figures can be found in Section 44-3 (p. 1012).

**FIGURE 44-2.12** Hulka clip closure.

## 21 Wound Closure

Subsequent surgery completion steps follow those of diagnostic laparoscopy (p. 1005).

## POSTOPERATIVE

Postoperatively, patients are given instructions similar to those following diagnostic laparoscopy. Sterilization is immediate, and intercourse may resume at the patient's discretion.

**FIGURE 44-2.13** Inner rod forces the metal spring down and around the plastic clip to secure it.

## 44-3

## Laparoscopic Salpingectomy

With surgical treatment of ectopic pregnancy, goals include hemodynamic support of the patient, removal of all trophoblastic tissue, repair or excision of the damaged tube, and preservation of fertility in those who desire it. For most women, the preferred surgical approach for ectopic pregnancy management is laparoscopic. It provides a safe and effective treatment of the affected fallopian tube while offering the advantages of laparoscopy. For some, laparoscopic salpingostomy is desired to treat and retain the affected tube. However, if fertility is not a consideration or if tubal damage or bleeding does not permit fallopian tube salvage, then laparoscopic salpingectomy may be selected due to its lower risk of persistent trophoblastic tissue.

Salpingectomy may also be used to remove hydrosalpinges in women undergoing in vitro fertilization. In this case, pregnancy rates are improved if such tubes are excised (Chap. 9, p. 224). Total salpingectomy can be used as a method of sterilization. This may be especially attractive if a primary sterilization technique has failed or if an ovarian cancer risk-reducing strategy is adopted (p. 1006). Last, in women with *BRCA* gene mutations, early bilateral salpingectomy followed by postmenopausal oophorectomy is one strategy to lower epithelial ovarian cancer risks yet provide extended estrogen benefits (Chap. 35, p. 738).

### PREOPERATIVE

#### Consent

The general risks of laparoscopic surgery are discussed in Chapter 41 (p. 877). With

salpingectomy, injury to the ipsilateral ovary is possible. Thus, the potential for oophorectomy and its effects on fertility and hormone function are discussed. Prior to cases for ectopic pregnancy, a patient's desire for future fertility is investigated. If she has completed her childbearing or has failed a prior sterilization procedure, then contralateral tubal ligation or bilateral salpingectomy may be acceptable at the time of surgery.

Following any surgical treatment of ectopic pregnancy, trophoblastic tissue can persist. The risk of this is lower with salpingectomy compared with salpingostomy and is discussed more fully on page 1013.

#### Patient Preparation

Baseline complete blood count (CBC),  $\beta$ -hCG level, and Rh status are routinely assessed. If salpingectomy is performed in the setting of an ectopic pregnancy, substantial bleeding may be encountered. Thus, the patient is typed and crossmatched for packed red blood cells and other blood products as indicated. Salpingectomy is associated with low rates of infection. Accordingly, preoperative antibiotics are usually not administered. For those undergoing laparoscopic salpingectomy for ectopic pregnancy, VTE prophylaxis is typically indicated due to the hypercoagulability associated with pregnancy (Table 39-8, p. 836). For prophylaxis in those with active bleeding, intermittent pneumatic compression devices are preferred.

### INTRAOPERATIVE

#### Instruments

Most instruments required for salpingectomy are found in a standard laparoscopy instrument set. However, a suction irrigation system is commonly needed during salpingectomy to remove blood from a ruptured ectopic

pregnancy. Depending on the size of the ectopic pregnancy or hydrosalpinges, an endoscopic retrieval bag may also be needed. For salpingectomy, the fallopian tube and mesosalpinx require ligation and excision. This may be accomplished using bipolar instruments, Harmonic scalpel, or laparoscopic suture loop (Endoloop). These may not be readily available in all operating suites, and desired tools are requested prior to surgery.

#### Surgical Steps

**Anesthesia and Patient Positioning.** The patient is prepared and positioned for laparoscopic surgery (Chap. 41, p. 879).

**Abdominal Entry.** The abdomen is entered with laparoscopic techniques, and typically two or three accessory trocar sites are added (Chap. 41, p. 889). Depending on the size of the ectopic pregnancy, at least one 10-mm or larger accessory port may be needed to allow specimen removal at surgery's end. Once ports are in place, inspection of the abdomen and pelvis is completed prior to the planned procedure.

**Mesosalpingeal Incision.** The affected fallopian tube is lifted and held with an atraumatic grasping forceps. Kleppinger bipolar electrode forceps are placed across a proximal portion of the fallopian tube. A cutting current at 25 W should suffice (Fig. 44-3.1). When zero amperage of flow is noted, scissors can then cut the desiccated, blanched tube (Fig. 44-3.2).

The Kleppinger forceps are then advanced across the most proximal portion of mesosalpinx. Similarly, current is applied, and the desiccated tissue cut. This process serially moves from the proximal mesosalpinx to its distal extent under the tubal ampulla. As the distal mesosalpinx is cut, the tube is freed.

FIGURE 44-3.1 Fallopian tube desiccation.

FIGURE 44-3.2 Mesosalpinx incision.

**FIGURE 44-3.3** Endoscopic loop ligation.

Other energy sources also work well. Monopolar scissors themselves may be attached to current. In this technique, vessels within the mesosalpinx are first electro-surgically coagulated and then cut. Advanced bipolar technologies (LigaSure, ENSEAL), laser energy, and Harmonic scalpel are suitable options. A surgeon's expertise with a particular modality dictates selection. One or more of these may be preferred based on the surrounding pelvic pathology or adhesions. The major concern with any of these tools is the amount of thermal spread to surrounding tissues.

□ **Endoscopic Loop Ligation.** Alternatively, the vascular supply to the fallopian

tube within the mesosalpinx can be ligated. **Figure 44-3.3** shows an endoscopic suture loop encircling a loop of fallopian tube that contains an ectopic pregnancy. Absorbable and delayed-absorbable suture loops are available, and either is suitable for ligation. Two or three suture loops are sequentially placed, and the tube distal to these ligatures is then cut free with scissors (**Fig. 44-3.4**).

□ **Tissue Removal.** Most tubal ectopic pregnancies are small and pliant. Thus, they can be held firmly by grasping forceps and drawn up into one of the accessory site cannulas. The cannula, grasping forceps, and

**FIGURE 44-3.4** Looped portion of tube excised.

ectopic tissue can then be removed together. Larger tubal ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic port site. Alternatively, larger ectopic pregnancies can be morcellated with scissors within an enclosed bag. Tissue removal techniques are presented on page 1019 and are also illustrated in Chapter 41 (p. 896).

□ **Irrigation.** To remove all trophoblastic tissue, the pelvis and abdomen are irrigated and suctioned free of blood and tissue debris. Slow and systematic movement of the patient from Trendelenburg positioning to reverse Trendelenburg can also assist in dislodging stray tissue and fluid, which is then suctioned and removed from the peritoneal cavity.

□ **Wound Closure.** Subsequent surgery completion steps follow those of diagnostic laparoscopy (p. 1005).

## POSTOPERATIVE

As with most laparoscopic surgeries, patients can resume presurgical diet and activity levels according to their comfort, typically within days.

If salpingectomy is performed for ectopic pregnancy, Rh-negative patients are given a single 50- or 300- $\mu$ g (1500 IU) Rh<sub>0</sub>(D) immune globulin dose intramuscularly within 72 hours. To identify patients in whom trophoblastic tissue may persist, serial serum  $\beta$ -hCG levels are monitored until undetectable (Seifer, 1997). Spandorfer and associates (1997) compared serum  $\beta$ -hCG levels 1 day postoperatively with those drawn prior to surgery. They found a significantly lower percentage of persistent trophoblastic tissue if the  $\beta$ -hCG level fell more than 50 percent and noted no cases if the level declined by greater than 77 percent. Until levels are undetectable, contraception is used to avoid confusion between persistent trophoblastic tissue and a new pregnancy. Ovulation may resume as early as 2 weeks after an early pregnancy ends. Therefore, if contraception is desired, methods are initiated soon after surgery. Last, patients are counseled regarding their increased risk of future ectopic pregnancy.

## 44-4

## Laparoscopic Salpingostomy

For patients with ectopic pregnancy, laparoscopic linear salpingostomy offers the surgical advantages of laparoscopy and an opportunity to retain fertility by preserving the involved fallopian tube. Accordingly, suitable candidates are women with an unruptured isthmic or ampullary ectopic pregnancy and desiring future pregnancies. Success is mainly affected by the amount of bleeding, by the ability to control it, and by the degree of tubal damage.

### PREOPERATIVE

#### Consent

Risks of laparoscopic salpingostomy mirror those for laparoscopic salpingectomy (p. 1011). Importantly, with salpingostomy, a patient is counseled regarding the possible need for salpingectomy if the tube is irreparably damaged or bleeding from the tube cannot be controlled. Also, rates of persistent trophoblastic disease are higher with salpingostomy compared with removal of the entire affected tubal segment.

#### Bleeding

Because trophoblastic tissue is vascular, disruption during ectopic pregnancy removal can lead to severe hemorrhage. The ability of tubal muscularis to contract is minimal, and thus, bleeding during salpingostomy must be controlled with external modalities such as electrocautery. Many devices are appropriate, and the microbipolar device is effective for achieving hemostasis while creating minimal thermal spread. At times, bleeding may be extensive and persistent and necessitate salpingectomy.

To improve hemostasis, vasoconstrictive agents such as vasopressin have been evaluated. Dilutions of 20 U of vasopressin in 30 to 100 mL of saline are suitable. The mesosalpinx is then infiltrated with approximately 10 mL of solution. Because of the potential systemic vasoconstrictive effects of vasopressin, intravascular injection is avoided. Another approach is to inject the solution into the portion of the tube to be incised. This is dictated by surgeon preference. Additional complications and contraindications to vasopressin use are discussed on page 1023. Benefits to vasopressin include less frequent use of electrocautery, shorter operating time, and lower conversion rates to laparotomy for surgery completion.

To avoid vasopressin's cardiovascular complications, Fedele and colleagues (1998) diluted 20 U of oxytocin in 20 mL of saline and similarly injected the mesosalpinx. Oxytocin is purported to contract the smooth muscle fibers of the tube and cause vasoconstriction of mesosalpinx vessels. These researchers noted easier pregnancy enucleation, less bleeding, and less frequent use of electrocautery.

#### Persistent Trophoblastic Tissue

During treatment of ectopic pregnancy, trophoblastic tissue can persist in as many as 3 to 20 percent of cases. Remnant implants typically involve the fallopian tube, but extratubal trophoblastic implants have been found on the omentum and on pelvic and abdominal peritoneal surfaces. Peritoneal implants typically measure 0.3 to 2.0 cm and appear as red-black nodules (Doss, 1998). Severe postoperative bleeding is the most serious complication of this persistent tissue (Giuliani, 1998).

The risk of persistent trophoblast tissue is highest following laparoscopic salpingostomy, especially in women in whom small, early pregnancies are removed. In these pregnancies, the cleavage plane between the invading trophoblast and tubal implantation site is poor. This may lead to a more difficult dissection and failure to completely remove all products of conception. For all cases, preventive recommendations include irrigation and complete suctioning of the abdomen, limitation of Trendelenburg position to limit blood and tissue flow to the upper abdomen, and use of endoscopic bags for removal of larger ectopic pregnancies (Ben-Arie, 2001).

### INTRAOPERATIVE

#### Instruments

Specific tools needed for salpingostomy mirror those for salpingectomy and should be available if salpingectomy is required (p. 1011).

#### Surgical Steps

**Anesthesia and Patient Positioning.** The patient is prepared and positioned for laparoscopic surgery as described in Chapter 41 (p. 879).

**Abdominal Entry.** The abdomen is accessed with laparoscopic techniques, and typically two or three accessory port sites are used. Depending on the ectopic pregnancy size, at least one 10-mm or larger accessory port may be necessary to allow specimen removal at surgery's end. Once cannulas are in place, systematic inspection of the abdomen and pelvis is completed prior to the planned procedure.

**Salpingostomy.** The fallopian tube is lifted and held with atraumatic grasping forceps. By means of a 22-gauge needle through one of the accessory ports or through a separate abdominal wall needle puncture, a solution of vasopressin is injected into the mesosalpinx beneath the ectopic pregnancy. If the serosal layer overlying the ectopic tissue is injected instead, then a smaller 25-gauge needle may be used.

A monopolar needle tip electrode is set at a cutting voltage and used to create a 1- to 2-cm longitudinal incision (Fig. 44-4.1). The

FIGURE 44-4.1 Salpingostomy.

**FIGURE 44-4.2** Hydrodissection.**FIGURE 44-4.3** Coagulation of incision edges.

incision is positioned opposite the mesosalpinx and on the maximally distended portion of the tube that overlies the pregnancy. Laparoscopic scissors, CO<sub>2</sub> laser, bipolar needle, and Harmonic scalpel have also been used.

□ **Pregnancy Removal.** For this step, atraumatic grasping forceps hold one edge of the incision while a suction-irrigation probe tip is insinuated into the tissue plane between the tubal wall and ectopic pregnancy (Fig. 44-4.2). Hydrodissection is performed on one side of the tube and then the other. A combination of high-pressure hydrodissection and gentle blunt dissection with the suction irrigator tip is used to remove the entire conceptus from the tube. Alternatively, the pregnancy or its fragments may require extraction by smooth grasping forceps.

□ **Hemostasis.** Bleeding points can be controlled with monopolar or bipolar electro-surgical coagulation (Fig. 44-4.3). The tubal incision is left open to heal by secondary

intention. Tulandi and Guralnick (1991) found no differences in subsequent fertility and adhesion formation between salpingotomy with or without tubal suturing. Use of topical fibrin products for hemostasis has been evaluated in limited studies and warrants further investigation with regard to adhesion prevention and future pregnancy effects (Mosesson, 1992).

□ **Specimen Extraction.** Most ectopic pregnancies are small and pliant. Accordingly, they can be held firmly by grasping forceps and drawn up into one of the accessory canulas. The cannula, grasping forceps, and ectopic tissue can then be removed together. Larger ectopic pregnancies may be placed in an endoscopic sac to prevent fragmentation as they are removed through the laparoscopic trocar site.

□ **Irrigation.** To prevent persistent trophoblastic tissue postoperatively, the pelvis and abdomen are irrigated and suctioned free of blood and tissue debris.

□ **Adhesion Prevention.** Adjuvants are available that can be used for the prevention of postoperative adhesion formation. However, although adhesion formation is lessened, no substantial evidence documents that their use improves fertility, decreases pain, or prevents bowel obstruction (American Society for Reproductive Medicine, 2013).

□ **Wound Closure.** Subsequent surgery completion steps follow those of diagnostic laparoscopy (p. 1005).

## POSTOPERATIVE

As with most laparoscopic surgeries, patients can resume presurgical diet and activity levels according to their comfort, typically within days. Postoperative topics specific to ectopic pregnancy include Rh<sub>0</sub> [D] immune globulin administration, surveillance for persistent trophoblastic disease, provision of contraception if desired, and counseling on future ectopic pregnancy risk as described on page 1012.

## 44-5

## Laparoscopic Ovarian Cystectomy

Many studies have attested to the efficacy and safety of laparoscopic cystectomy for the management of ovarian cysts. Moreover, because of recovery-associated benefits, a laparoscopic technique is advocated by many as the preferred approach in women with ovarian cysts and a low risk of malignancy (Chap. 9, p. 216).

### PREOPERATIVE

#### ■ Patient Evaluation

Sonography is the primary tool used to diagnose ovarian pathology, and the sonographic characteristics of a cyst aid in determining preoperatively the malignant potential of a given lesion (Chap. 9, p. 217). In those patients with indeterminate ovarian cysts following sonography, magnetic resonance (MR) imaging may enhance discrimination.

The serum tumor marker cancer antigen 125 (CA125) is typically obtained preoperatively in postmenopausal patients and in any woman whose tumor displays other risk factors for ovarian epithelial cancer (Chap. 35, p. 742). Additionally, serum alpha-fetoprotein (AFP), lactate dehydrogenase (LDH), inhibin, and  $\beta$ -hCG levels may be measured to exclude germ cell or sex cord-stromal ovarian neoplasms, if these are suspected (Chap. 36, pp. 761 and 768).

#### ■ Consent

Prior to surgery, patients are informed of the unique complications associated with laparoscopy itself (Chap. 41, p. 877). Specific to ovarian cystectomy, the risks of oophorectomy due to bleeding or extreme ovarian damage are discussed. Depending on the amount of oocyte-containing ovarian stroma that is stripped away with the cyst, diminished ovarian reserve is also a risk. Obviously, because many cysts are removed due to concerns of potential malignancy, patients should be familiar with the steps involved in the surgical staging of ovarian cancer.

#### ■ Patient Preparation

Rates of pelvic and wound infection following ovarian cystectomy and laparoscopy are low, and antibiotic prophylaxis is typically not required. Bowel preparation is not usually required, but may be considered if extensive adhesions are suspected. VTE prophylaxis is

typically not recommended for laparoscopic cystectomy. However, those with a greater risk of malignancy, with risks for VTE, or with an increased chance for conversion to laparotomy may benefit from these measures (Table 39-8, p. 836).

### INTRAOPERATIVE

#### ■ Instruments

Most instruments required for ovarian cystectomy are found in a standard laparoscopy instrument set. A suction irrigation system is commonly needed to remove cyst contents if rupture occurs. An endoscopic retrieval bag is also frequently used. Once contained in the sac, the cyst in some cases may be decompressed with a laparoscopic aspiration needle.

If oophorectomy is required, the infundibulopelvic ligament is ligated. This may be accomplished using bipolar instruments, Harmonic scalpel, laparoscopic suture loop, or stapler. These may not be readily available in all operating suites, and desired tools are requested prior to surgery.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** The patient is prepared and positioned for laparoscopic surgery (Chap. 41, p. 879). A bimanual examination is completed to determine ovarian size and position and uterine inclination. Ovarian information will affect placement of the accessory ports, and uterine inclination will direct positioning of the uterine manipulator if used. A uterine

manipulator may assist with moving the uterus and adnexa (p. 881). In anticipation of possible hysterectomy as a part of ovarian cancer staging, the vagina and abdomen are surgically prepared, and a Foley catheter is inserted. The patient is then draped to allow sterile access to the vagina and abdomen.

□ **Abdominal Entry.** Primary and secondary trocars are placed as described in Chapter 41 (p. 889). For insertion of most endoscopic sacs, at least one 10-mm or larger accessory trocar may be necessary to allow specimen removal at surgery's end. Typically, two or three accessory trocars are required for cystectomy.

Once the abdomen is entered, a diagnostic laparoscopy is performed, inspecting the pelvis and upper abdomen for signs of malignancy such as ascites and peritoneal implants or for evidence of endometriosis. Suspicious areas are biopsied, and those concerning for cancer are sent for intraoperative analysis. Prior to ovarian cystectomy, adhesions are divided to restore proper anatomic relationships.

□ **Ovarian Incision.** A blunt probe is placed under the uteroovarian ligament and posterior ovarian surface to elevate the ovary. An atraumatic grasping forceps then steadies the ovary, and the blunt probe is removed (Fig. 44-5.1). A monopolar needle tip electrode set at a cutting voltage is used to incise the ovarian capsule that overlies the cyst. Other suitable devices for incision include a monopolar scissor blade or Harmonic scalpel. This incision is ideally on the antimesenteric surface of the ovary to minimize dissection into extensive vascularity at the

FIGURE 44-5.1 Ovarian incision.

FIGURE 44-5.2 Dissection initiated.

ovarian hilum. The incision is extended into the ovarian stroma to the level of the cyst wall but ideally does not rupture the cyst.

□ **Cyst Dissection.** A space between the ovary and cyst wall is created using blunt forceps or dissecting scissors (Fig. 44-5.2). Atraumatic grasping forceps are used to hold one edge of the incision, while a blunt probe or suction-irrigation probe tip is insinuated in the tissue plane between the ovarian capsule and cyst wall (Fig. 44-5.3).

Blunt or hydrodissection is performed on one side of the cyst and then the other. Depending on the adherence of the cyst to its surrounding ovarian tissue, cystectomy may at times require sharp dissection with scissors. During dissection, points of bleeding may be coagulated, or isolated vessels may be grasped and coagulated (Fig. 44-5.4).

□ **Cyst Removal.** Following enucleation from the ovary, the cyst is placed into an endoscopic bag (Fig. 44-5.5). The opening of the sac is closed and brought up to the anterior abdominal wall (Fig. 44-5.6). Depending on its size, the cyst and endoscopic bag may be removed in toto through one of the accessory cannulas. In this setting, the laparoscopic cannula is removed first, followed by the cyst contained within the sac.

Alternatively, with larger cysts, the cannula is removed, and the entire pursed opening of the bag is drawn up through the trocar incision and fanned out onto the skin surface. The open edges of the bag are pulled upward

FIGURE 44-5.3 Hydrodissection.

to lift and press the cyst up against the incision. A needle tip is then directed into the incision and pierces the cyst contained within the endoscopic bag. An attached syringe is used to aspirate contents. Alternatively, the cyst may be ruptured by a toothed Kocher

clamp placed through the skin incision and into the sac (Fig. 44-5.7). Thereby, cyst fluid is retained within the endoscopic sac. The endoscopic sac and decompressed cyst wall are then removed together through the incision (Fig. 44-5.8). During removal, care is

FIGURE 44-5.4 Following cyst enucleation, ovarian capsule edges are coagulated.

**FIGURE 44-5.5** Cyst placed in endoscopic sac.

taken to ensure that the endoscopic bag is not inadvertently punctured or torn, and all measures are used to prevent spillage of cyst contents into the abdomen or port site.

□ **Cyst Rupture.** Not uncommonly during the dissection of the cyst away from the ovary, the cyst may rupture. The cyst wall is then removed using a “stripping” technique

(Fig. 44-5.9). With this, both the cyst wall and cyst capsule can be grasped near the dissection plane by atraumatic forceps. Traction and countertraction can separate filmy connective

**FIGURE 44-5.6** Endoscopic bag cinched and brought up to anterior abdominal wall.

**FIGURE 44-5.7** Cyst ruptured by toothed Kocher clamp within the endoscopic sac.

**FIGURE 44-5.8** Sac and collapsed cyst are removed together.

**FIGURE 44-5.9** Stripping of collapsed cyst from ovarian capsule.

tissue between these to advance the dissection plane. As a result, the grasping forceps strip the cyst wall away from the underlying ovarian stroma. To prevent damage to the underlying healthy ovary, the dissection plane between the cyst and stroma should be clearly delineated by traction on each side to

prevent tearing. Injection of dilute vasopressin into this space may also help delineate the dissection plane and minimize bleeding. Histologically, Muzii and colleagues (2002) showed that this technique in nonendometriotic lesions spared ovarian tissue and did not strip away normal ovarian tissue and follicles.

□ **Ovary Closure.** Because of increased adhesion formation risk, technical difficulty, and time associated with laparoscopic suturing, in general the ovarian capsule is not sutured closed following cyst removal. Several studies show that leaving the capsule open does not lead to increased adhesion formation (Marana, 1991; Wiskind, 1990). Application of an adhesion barrier such as oxidized regenerated cellulose may be considered to prevent adhesion formation (Franklin, 1995; Wiseman, 1999). However, no substantial evidence documents that their use improves fertility, decreases pain, or prevents bowel obstruction (American Society for Reproductive Medicine, 2013).

□ **Wound Closure.** If concerning for malignancy, the specimen is submitted in most cases for immediate frozen section analysis. If benign findings are noted, then steps toward surgical closure begin. If malignancy is found, then surgical staging should ensue. Of note, if a large mass was removed and the port site was likely extended during the removal, one should consider fascial closure to prevent port-site hernias. The finishing laparoscopic steps are similar to those for diagnostic laparoscopy (p. 1005).

## POSTOPERATIVE

Following laparoscopic ovarian cystectomy, instructions similar to those for diagnostic laparoscopy are given (p. 1005).

## 44-6

## Laparoscopic Salpingo-oophorectomy

Laparoscopy can be used to safely remove many adnexa and in most cases, offers a faster recovery and less postoperative pain compared with laparotomy. As discussed in Chapter 9 (p. 202), indications for adnexectomy vary but may include torsion, ovarian cyst rupture, suspicion of ovarian malignancy, and symptomatic ovarian remnant. In addition, prophylactic oophorectomy is often considered in women with or at genetic risk for cancers involving the breast, ovary, and colon (Chap. 35, p. 738).

Laparoscopy is a preferred approach when possible and can be safely performed in pregnancy, preferably in the early second trimester. However, for all patients, laparotomy may be preferred in certain clinical settings. These include a high suspicion of cancer, anticipation of extensive pelvic adhesions, and large ovarian size.

### PREOPERATIVE

#### ■ Patient Evaluation

Salpingo-oophorectomy is typically performed to remove ovarian pathology and sonography is the primary tool used for diagnosis. In cases in which anatomy may be unclear, MR imaging may add additional information. As discussed on page 1015, tumor markers may be drawn prior to surgery if malignancy is suspected.

#### ■ Consent

Prior to surgery, patients are informed of the unique complications associated with laparoscopy (Chap. 41, p. 877). Specific to salpingo-oophorectomy, the risk of ureteral injury is discussed. Many adnexa are removed due to concerns of potential malignancy, and patients should be familiar with the steps involved in the surgical staging of ovarian cancer.

#### ■ Patient Preparation

Unless an ovarian abscess is identified, laparoscopic salpingo-oophorectomy does not require antibiotic prophylaxis (American College of Obstetricians and Gynecologists, 2014b). If hysterectomy is required during ovarian staging, antibiotics may be given intraoperatively. Bowel preparation is not

usually required but may be considered if extensive adhesions are suspected. VTE prophylaxis is typically not recommended for laparoscopic cystectomy. However, those with a greater risk of malignancy, with underlying VTE risks, or with an increased chance for conversion to laparotomy may benefit from these measures (Table 39-8, p. 836).

### INTRAOPERATIVE

#### ■ Instruments

Most instruments required for ovarian cystectomy are found in a standard laparoscopy instrument set. However, a suction irrigation system is commonly needed to remove cyst contents if rupture occurs. An endoscopic retrieval bag is also frequently used. During oophorectomy, the infundibulopelvic ligament is ligated. This may be accomplished using bipolar instruments, Harmonic scalpel, laparoscopic suture loop, or stapler. These may not be readily available in all operating suites, and desired tools are requested prior to surgery.

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

The patient is prepared and positioned for laparoscopic surgery as described in Chapter 41 (p. 879). A bimanual examination is completed to determine ovarian size and position and uterine inclination. Ovarian information will affect placement of the accessory ports, and uterine inclination will direct positioning of the uterine manipulator if used. Because of possible hysterectomy as a part of ovarian cancer staging, the vagina and abdomen are surgically prepared, and a Foley catheter is inserted. A uterine manipulator may also be placed to assist with manipulation of the uterus and adnexa (p. 883).

##### □ Abdominal Access.

Primary and secondary trocars are placed as described in Chapter 41 (p. 889). Typically, two or three accessory ports are required. For insertion of most endoscopic sacs, at least one 10-mm or larger accessory port may be necessary to allow specimen removal at surgery's end.

##### □ Pelvic Inspection and Washings.

Once the abdomen is entered, a diagnostic laparoscopy is performed, inspecting the pelvis and upper abdomen for signs of malignancy such as ascites and peritoneal implants (p. 1004). Cellular washings from these areas are obtained and saved until frozen section analysis of the specimen has excluded malignancy. Similarly, identified peritoneal implants from these areas are biopsied and sent for intraoperative evaluation. Prior

to adnexectomy, adhesions are divided to restore proper anatomic relationships.

□ **Ureter Location.** The ureter lies close to the infundibulopelvic (IP) ligament, and its course should be noted. If the location of the ureter is not clear, the peritoneum lateral to the ureter is incised, and retroperitoneal isolation of the ureter is completed (Fig. 44-6.1).

##### □ Infundibulopelvic Ligament Coagulation.

Ligation of the ovarian vessels within the IP ligament can be completed with endoscopic loop ligatures, electro-surgical coagulating devices, Harmonic scalpel, or stapler depending on surgeon preference (see Fig. 44-6.1). Once these vessels are occluded, the IP is severed distally.

##### □ Opening of the Broad Ligament.

After transection of the IP, the fallopian tube and ovary are gently elevated with atraumatic forceps. Incision of the broad ligament's posterior leaf is then extended to the round ligament (Fig. 44-6.2).

##### □ Uteroovarian Ligament Coagulation.

The uteroovarian ligament and proximal fallopian tube are identified posterior to the round ligament. Similarly to the IP, these may be coagulated, stapled, or ligated (Fig. 44-6.3). Distal to this occlusion, the uteroovarian ligament and fallopian tube are transected, and the adnexum is freed.

##### □ Adnexum Removal.

Various endoscopic bags are available for tissue removal (Chap. 41, p. 883). The specimen is dropped into the sac, which is closed and brought up to the anterior abdominal wall. Depending on its size, the adnexum and endoscopic bag may be removed in toto through one of the accessory port sites. In this setting, the laparoscopic cannula is removed first, followed by the specimen contained within the sac.

Alternatively, with larger cystic ovaries, the cannula is removed, and the entire pursed opening of the bag is drawn up through the incision and fanned out onto the skin surface. As illustrated in Section 44-5 (p. 1017), the open edges of the bag are pulled upward to lift and press the ovary against the incision. A needle tip is directed through the incision and into the sac. The ovary is pierced and aspiration drainage is completed by an attached syringe. Alternatively, the cyst may be ruptured by a toothed Kocher clamp placed through the skin incision and into the sac. Thereby, cyst fluid is retained in the endoscopic sac. The endoscopic sac and decompressed cyst wall are then removed together through the incision. During removal, care is taken to ensure that the endoscopic is

**FIGURE 44-6.1** Infundibulopelvic ligament coagulation.

bag is not inadvertently punctured or torn, and all measures are used to prevent spill of cyst contents into the abdomen or port site. Additionally, to prevent spill or to remove a larger solid mass, one may remove the adnexa through a minilaparotomy incision or a col-

potomy incision as described on page 1031 and illustrated in Chapter 41 (p. 896).

□ **Wound Closure.** If malignancy is suspected, the specimen is submitted for immediate frozen section analysis. If benign

**FIGURE 44-6.2** Opening of the broad ligament.

findings are noted, then steps toward surgical closure begin (p. 1005). If malignancy is found, then surgical staging should ensue. Of note, if a large mass was removed and the port site was likely extended during the removal, one should consider fascial closure to prevent port-site herniation.

## POSTOPERATIVE

Advantages to laparoscopy include a rapid return to normal diet and activities, and postoperative complication rates are low. If both adnexa are removed, then hormone replacement therapy is considered in appropriate candidates (Chap. 22, p. 494).

**FIGURE 44-6.3** Fallopian tube and uteroovarian ligament coagulation to free the specimen.

## 44-7

## Ovarian Drilling

Ovarian drilling is a technique of puncturing the ovarian capsule with a laser beam or an electrosurgical needle using a laparoscopic approach. Similar to ovarian wedge resection, this procedure's end goal is to reduce the amount of androgen-producing tissue in women with polycystic ovarian syndrome (PCOS). However, in wedge resection, a long cortical incision is required for this degree of resection. As a result, infertility secondary to adhesions complicates many postoperative courses (Buttram, 1975; Toaf, 1976). To minimize this risk and avoid the need for laparotomy, ovarian drilling techniques using laparoscopy were developed in the early 1980s.

Compared with gonadotropin stimulation to achieve pregnancy, ovarian drilling has lower rates of ovarian hyperstimulation syndrome (OHSS) and of multifetal gestation (Farquhar, 2012). Disadvantages include the surgical risks of laparoscopy, risks of pelvic adhesion formation, and concerns regarding long-term effects on ovarian function (Donesky, 1995; Farquhar, 2012). For these reasons, ovarian drilling is viewed as a second-line therapy. It can be useful in patients who fail to ovulate with clomiphene citrate, who are at risk for OHSS, or who desire to minimize their risk for multifetal gestation.

### PREOPERATIVE

#### ■ Consent

There appear to be relatively few complications that arise immediately after ovarian drilling. Hemorrhage, infection, and thermal bowel injury are infrequent. Similarly, ovarian atrophy following drilling is rare but has been reported (Dabirashrafi, 1989).

Adhesion formation following this procedure, however, is common. Most of these adhesions at second-look laparoscopy have typically been graded as minimal or mild (Gürkan, 1991). Moreover, researchers have described only a minimal, if any, decline in fertility from these adhesions (Gürkan, 1992; Naether, 1993). This risk, however, is discussed with the patient prior to surgery.

### INTRAOPERATIVE

#### ■ Instruments

Ovarian drilling has been described using monopolar or bipolar electrosurgical energy

or using various lasers, all with the goal of causing focal damage to the ovarian stroma and cortex. Currently, no studies support the superiority of one modality (Strowitzki, 2005).

#### ■ Number of Ovarian Punctures

Punctures into the ovarian capsule are typically 2 to 4 mm wide and 4 to 10 mm deep. Although techniques using as few as four or as many as 40 punctures per ovary have been described, few studies have investigated the optimum number of punctures (Farquhar, 2004). For example, Malkawi and Qublan (2005) showed that five punctures per ovary compared with 10 resulted in equally improved pregnancy rates and similarly low rates of post-procedural OHSS and multifetal gestation.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Patient positioning and anesthesia mirror those for other laparoscopic procedures (Chap. 41, p. 879).

□ **Abdominal Entry.** Three incisions are used for this laparoscopic procedure. In addition to an umbilical incision, two bilateral lower abdominal incisions are made. These incisions serve as entry sites for the electrosurgical needle tip and grasping forceps.

□ **Ovarian Drilling.** The ovary is elevated with a blunt grasper. The electrosurgical current is set at 30 to 60 W cutting mode. A monopolar electrosurgery needle tip is used to puncture the ovary perpendicular to the cortical surface and to pierce the follicular cysts that are characteristic of PCOS. Four to five punc-

tures are placed symmetrically on the antimesenteric surface of the ovary (Fig. 44-7.1). Drilling is avoided on the lateral surfaces of the ovaries to minimize adhesions to the pelvic sidewall and is avoided at the ovarian hilum to limit bleeding risks. The needle is inserted to a depth of 4 to 10 mm. Electrical current is applied for 3 to 4 seconds. The ovarian surface can be irrigated with saline or lactated Ringer solution to cool it (Strowitzki, 2005).

□ **Adhesion Barriers.** Because of the risk for adhesion formation, some investigators use adhesion barrier products following ovarian drilling. Greenblatt and Casper (1993), however, showed no improvement in adhesion prevention following this procedure using Interceed adhesion barrier. No other studies have addressed the efficacy of other adhesion prevention products.

□ **Wound Closure.** Subsequent surgery completion steps should follow those of diagnostic laparoscopy (p. 1005).

### POSTOPERATIVE

Postoperatively, patients are given instructions similar to those following diagnostic laparoscopy (p. 1005).

FIGURE 44-7.1 Ovarian drilling.

## 44-8

## Laparoscopic Myomectomy

Myomectomy involves surgical removal of leiomyomas from their surrounding myometrium, and accepted indications include selected cases of abnormal uterine bleeding, pelvic pain, infertility, and recurrent miscarriage. Historically, removal of serosal and intramural tumors required laparotomy. However, laparoscopic excision may be performed by those with advanced skills in operative laparoscopy and laparoscopic suturing. Robotic myomectomy has also increased in popularity for this indication (Visco, 2008).

In general, removal of subserosal and intramural leiomyomas are most appropriate for a laparoscopic approach. Submucous leiomyomas are best treated via hysteroscopic resection (p. 1040). The choice of abdominal or laparoscopic myomectomy is based on various factors that include tumor number, size, and location. Surgical experience and comfort with laparoscopic dissection, tissue extraction, and suturing are other requisites.

### PREOPERATIVE

#### ■ Patient Evaluation

Because of their impact on preoperative and intraoperative planning, leiomyoma size, number, and location are evaluated prior to surgery with sonography, MR imaging, and/or hysteroscopy, as described in Chapter 9 (p. 206). Specifically, leiomyomas may be small and buried within the myometrium. Therefore, accurate information as to tumor number and location ensures complete excision. Moreover, with a laparoscopic or robotic approach, the ability to palpate and appreciate smaller deep tumors may be compromised. In these cases, preoperative MR imaging may best assist with leiomyoma location and surgical planning. Last, multiple large masses or those that are located in the broad ligament, are near the cornua, or involve the cervix may increase the risk of conversion to hysterectomy, and patients are so counseled. Studies have also suggested that there is an increased risk of complications with the following: more than three leiomyomas, tumor size > 5 cm, and intraligamentary location (Sizzi, 2007). Accounting for these factors, a surgeon's expertise is the most important factor in determining approach to myomectomy.

#### ■ Consent

Myomectomy can cause significant bleeding that requires transfusion. Moreover, uncontrolled hemorrhage or extensive myometrial injury during tumor removal may necessitate hysterectomy. Patients are also counseled regarding the risk of conversion to an open procedure, which ranges from 2 to 8 percent (American College of Obstetricians and Gynecologists, 2014a).

Postoperatively, serosal adhesions can form and leiomyomas can recur. In some series, the risk of leiomyoma recurrence after laparoscopic myomectomy appears to be higher than in conventional myomectomy (Dubuisson, 2000; Fauconnier, 2000). As one explanation, with laparoscopic myomectomy, small, deep intramural leiomyomas may be missed because a surgeon's tactile sensation is diminished.

The use of electrosurgical energy on the uterus and challenges of laparoscopic multilayer hysterotomy closure also heighten concerns regarding uterine rupture during a subsequent pregnancy (Hurst, 2005; Parker, 2010; Sizzi, 2007). Women undergoing myomectomy who do plan to have future pregnancies are counseled regarding the possible need for cesarean delivery based on the extent of myometrial disruption during the myomectomy.

#### ■ Patient Preparation

**Hematologic Status and Tumor Size.** Many preparatory steps prior to myomectomy address associated patient anemia, anticipated intraoperative blood loss, and tumor size. First, many women who undergo this surgery are often anemic secondary to associated menorrhagia. Correction prior to surgery may include oral iron therapy, gonadotropin-releasing hormone (GnRH) agonist administration, or both. In anticipation of blood loss, a CBC and type and cross-match for packed red blood cells is obtained. Autologous blood donation or cell saver devices may be considered if great blood loss is expected. In addition, uterine artery embolization may be performed the morning of surgery for large uteri to minimize blood loss. However, this is most often used prior to laparotomy for significantly sized uteri.

GnRH agonists may be considered to decrease leiomyoma size, lower intraoperative blood loss, and decreased adhesion rates. However, loss of pseudocapsule planes around the tumors and greater risk of recurrence due to missed smaller leiomyomas is the trade-off. A fuller evidence-based discussion of these same preoperative options is found in Section 43-10 (p. 945).

#### Prophylaxis

Few studies have addressed the benefits of preoperative antibiotic use. Iverson and coworkers (1996), in their analysis of 101 open myomectomy cases, found that although 54 percent of patients received prophylaxis, infectious morbidity was not lowered compared with patients in whom antibiotics were not used.

In cases of myomectomy performed for infertility, because of the potential for tubal adhesions associated with pelvic infection, antibiotic prophylaxis is commonly used. For those in whom prophylaxis is planned, 1 g of a first- or second-generation cephalosporin is appropriate (Iverson, 1996; Periti, 1988; Sawin, 2000).

The risk of bowel injury with this procedure is low, and bowel preparation is typically not required unless extensive adhesions are anticipated. Because the risk of conversion to hysterectomy is present, vaginal preparation immediately prior to surgical draping is performed. With laparoscopic gynecologic surgery, the decision to provide VTE prophylaxis factors patient- and procedure-related VTE risks (Gould, 2012). Thus, if longer operating times are anticipated or preexisting VTE risks are present, then prophylaxis as outlined in Table 39-8 (p. 836) is reasonable.

### INTRAOPERATIVE

#### ■ Instruments

Many instruments required for laparoscopic myomectomy are found in a standard laparoscopy instrument set. However, a laparoscopic injection needle may be required for vasopressin injection, and a suction irrigation system is frequently needed to remove blood following tumor enucleation. A myoma screw or tenaculum is helpful to create needed tissue tension and countertension for enucleation. After tumor excision, removal may be accomplished by several techniques described on page 1031. Thus, required endoscopic bags or morcellators are assembled preoperatively.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** As with most laparoscopic procedures, the patient is placed in low dorsal lithotomy position in booted support stirrups after adequate general anesthesia has been delivered. A bimanual examination is completed to determine uterine size to aid port placement. Because of the risk of hysterectomy and because colpotomy may be used for tumor removal, both the vagina and abdomen are surgically prepared. A Foley catheter is

inserted. A uterine manipulator may also be placed, including one that will allow chromotubation at the procedure's end (p. 881). If planned, indigo carmine or methylene blue dye is mixed with 50 to 100 mL of sterile saline for injection through the cervical cannula.

□ **Trocar and Laparoscope Insertion.** Primary and accessory trocars are placed as described in Chapter 41 (p. 889). Port placement is customized to assist uterine manipulation, leiomyoma excision, and hysterotomy repair. Depending on uterine height, the primary port may need to be placed supra-umbilically. In general, a distance of at least 4 cm above the level of the fundus is helpful to provide a global view of the uterus. Typically, at least three accessory ports are required. If use of an electric morcellator is planned, one of the cannulas should be at least 12 mm to accommodate the morcellator. After the abdomen is safely entered, a diagnostic laparoscopy is performed, and the serosal uterine surface should be inspected to identify leiomyomas to be removed. Correlating with preoperative imaging, the surgeon selects the optimal uterine incision to minimize myometrial disruption and to remove the maximum number of tumors thorough one incision.

□ **Use of Vasopressin.** 8-Arginine vasopressin (Pitressin) is a sterile, aqueous solution of synthetic vasopressin. It is effective

in limiting uterine blood loss during myomectomy because of its ability to cause vascular spasm and uterine muscle contraction. Compared with placebo, vasopressin injection has been shown to significantly decrease blood loss during myomectomy (Frederick, 1994).

Each vial of vasopressin is standardized to contain 20 pressor units/mL. Suitable doses for myomectomy include 20 U diluted in a range from 30 to 100 mL of saline (Fletcher, 1996; Iverson, 1996). Vasopressin is typically injected along the planned serosal incision(s), between the myometrium and leiomyoma capsule (Fig. 44-8.1). A laparoscopic needle placed through one of the accessory ports or a 22-gauge spinal needle placed directly through the abdominal wall is suitable for injection. Needle aspiration prior to injection is imperative to avoid intravascular injection of this potent vasoconstrictor. The anesthesiologist is informed of vasopressin injection, as a sudden increase in patient blood pressure may potentially occur following injection. Blanching at the injection site is common. The plasma half-life of this agent is 10 to 20 minutes. For this reason, injection of vasopressin is discontinued 20 minutes prior to uterine repair to allow evaluation of bleeding from myometrial incisions (Hutchins, 1996).

The main risks associated with local vasopressin injection result from inadvertent intravascular infiltration and include transient increases in blood pressure, bradycardia, atrioventricular block, and pulmonary edema (Hobo, 2009; Tulandi, 1996). For these

reasons, patients with a medical history of cardiac or pulmonary disease may be poor candidates for vasopressin use.

□ **Serosal Incision.** Because of postoperative adhesion formation risks, surgeons minimize the number of serosal incisions and attempt to place incisions on the anterior uterine wall. Tulandi and colleagues (1993) found for open myomectomy that posterior wall incisions result in a 94-percent adhesion formation rate compared with a 55-percent rate for anterior incisions.

After vasopressin injection, hysterotomy may be performed using a Harmonic scalpel, monopolar electrode, or laser. For most patients, an anterior midline vertical uterine incision allows removal of the greatest number of leiomyomas through the fewest incisions. The length should accommodate the approximate diameter of the largest tumor. The incision depth should afford access to all leiomyomas (Fig. 44-8.2).

□ **Tumor Enucleation.** Once the hysterotomy is created, the myometrium will generally retract, and the first leiomyoma may be grasped with a laparoscopic single-toothed tenaculum. Alternatively, a leiomyoma screw can also retract tissue to create tension between the myometrium and mass (Fig. 44-8.3). Using a blunt tool or suction-irrigator tip, blunt dissection of the pseudocapsule surrounding the leiomyoma frees the tumor from the

FIGURE 44-8.1 Vasopressin injection beneath serosa.

FIGURE 44-8.2 Serosal incision overlying leiomyoma.

**FIGURE 44-8.3** Tumor enucleation.

adjacent myometrium. Areas requiring sharp dissection from the myometrium may be freed with any of the electrosurgical instruments that were used for the uterine incision.

□ **Bleeding.** Hemorrhage during myomectomy primarily develops during tumor enucleation and positively correlates with preoperative uterine size, total weight of leiomyomas removed, and operating time (Ginsburg, 1993). Approximately two to four main arteries feed each leiomyoma and enter the tumor at unpredictable sites. For this reason, surgeons must watch for these vessels, coagulate them prior to transection when possible, and be ready to immediately fulgurate remaining bleeding vessels (Fig. 44-8.4). To avoid myo-

metrial damage, the surgeon applies electrosurgical energy only when necessary.

□ **Myometrial Closure.** Following removal of all tumors, redundant serosa may be excised. Laparoscopic suturing techniques described in Chapter 41 (p. 897) are used during incision reapproximation. The same general principles of myometrial closure for abdominal myomectomy are employed during laparoscopic myomectomy. In one method, for deep myometrial closure, a needle driver can be used with 0-gauge delayed-absorbable suture on a CT-2 needle in a continuous running fashion. Smaller internal myometrial incisions are closed first. The primary incision(s) is then closed in layers to

**FIGURE 44-8.4** Coagulation of vascular attachments between the leiomyoma and the myometrium.

improve hemostasis and prevent hematoma formation (Fig. 44-8.5). A gauge of sufficient strength to prevent breakage during muscle approximation is selected, typically 0 to 2-0 gauge. Alternatively, barbed sutures can close myometrial defects during laparoscopic myomectomy. These obviate the need for knot tying and yield consistent wound opposition (Einarsson, 2010; Greenberg, 2008).

□ **Serosal Closure.** Closure of the serosal incision using a running suture line with 4-0 or 5-0 gauge monofilament delayed-absorbable suture may help to limit adhesion formation (Fig. 44-8.6). Moreover, absorbable adhesion barriers have been shown to reduce the incidence of adhesion formation following myomectomy and may be introduced through laparoscopic ports (Ahmad, 2008). However, no substantial evidence documents that adhesion barrier use improves fertility, decreases pain, or prevents bowel obstruction (American Society for Reproductive Medicine, 2013).

□ **Tissue Extraction.** Once amputated, the myomas must be removed, and options include minilaparotomy, colpotomy, and tissue morcellation. These are fully described in Section 44-10 (p. 1031) and illustrated in Chapter 41 (p. 896).

□ **Laparoscopically Assisted Myomectomy (LAM).** Another MIS technique that may allow for safe and efficient myomectomy is LAM. The procedure is initiated as described above, and abdominal cavity assessment, uterine inspection, and incision of the serosa and myometrium are performed

**FIGURE 44-8.5** Myometrial closure.

**FIGURE 44-8.6** Serosal closure.

laparoscopically. To aid in the laparoscopically challenging steps of myomectomy, LAM offers a hybrid approach. Specifically, tumor enucleation and uterine closure are completed through a 2- to 4-cm minilaparotomy incision placed suprapubically. With this, the pneumoperitoneum and visualization through the laparoscope are lost. Instead, application of a wound retractor system such as the Alexis or Mobius retractor provides visual access to the operative field. The uterus and leiomyoma are brought to the surface of the anterior abdominal wall and through the laparotomy incision. The tumors are then enucleated and divided through this incision (Fig. 44-8.7). This open incision also allows for conventional suturing techniques and aids suturing of large defects that require a multilayer closure (Fig. 44-8.8).

Advantages include decreased operative time, technical simplicity, improved tactile sensation to detect deep intramural leiomyomas, and easier removal of very large tumors (Prapas, 2009; Wen, 2010). Disadvantages stem mainly from the larger abdominal wall incision.

### POSTOPERATIVE

Following abdominal myomectomy, postoperative care follows that for any major laparoscopic surgery. Hospitalization typically varies from 0 to 1 days, and febrile morbidity and return of normal bowel function usually dictate this course (Barakat, 2011). Postoperative activity in general can be individualized, although vigorous exercise is usually delayed until 4 weeks after surgery.

### Fever

Febrile morbidity of greater than 38.0°C is common following myomectomy (Iverson, 1996; LaMorte, 1993; Rybak, 2008). Purported causes include atelectasis, myometrial incisional hematomas, and factors released with myometrial destruction. Although fever is common following myomectomy, pelvic infection is not. LaMorte and colleagues (1993) noted only a 2-percent rate of pelvic infection in their analysis of 128 open myomectomy cases.

### Subsequent Pregnancy

There are no clear guidelines as to the timing of pregnancy attempts following myomectomy. Darwish and colleagues (2005) performed sonographic examinations on 169 patients following open myomectomy. Following myometrial indicators, they concluded that wound healing is usually completed within 3 months. There are no clinical trials that address the issue of uterine rupture and therefore route of delivery of pregnancies occurring after myomectomy (American College of Obstetricians and Gynecologists, 2014a). Management of these cases requires sound clinical judgment and individualization of care. In general, large incisions or those entering the endometrial cavity favor cesarean delivery.

## 44-9

## Laparoscopic Hysterectomy

Several laparoscopic techniques have been developed for hysterectomy and vary depending on the degree of laparoscopic dissection versus vaginal surgery required to remove the uterus (Garry, 1994). These include:

- Diagnostic laparoscopy prior to vaginal hysterectomy (VH)
- Vaginal hysterectomy assisted by laparoscopy, that is, lysis of adhesions and/or excision of endometriosis prior to VH
- Laparoscopically assisted vaginal hysterectomy (LAVH): laparoscopic dissection down to, but not including, uterine artery transection
- Laparoscopic hysterectomy (LH): laparoscopic dissection, including uterine artery transection, but completion of hysterectomy vaginally
- Total laparoscopic hysterectomy (TLH): complete laparoscopic excision of the uterus.

The laparoscopic approach offers advantages over traditional total abdominal hysterectomy (TAH). These include significant lower analgesia requirements, shorter hospital stays, rapid recovery, greater patient satisfaction, and lower rates of wound infection and hematoma formation (Kluivers, 2007; Schindlbeck, 2008). Disadvantageously, surgical time is lengthened, although the learning curve may be a factor. TLH offers fewer advantages compared with VH. Thus, in most cases, TLH should be an alternative to TAH (American College of Obstetricians and Gynecologists, 2011; Marana, 1999; Nieboer, 2009).

For all the hysterectomy types described in the following sections, plans for concurrent bilateral salpingo-oophorectomy (BSO) or for prophylactic salpingectomy are individualized. A detailed discussion of the surgical BSO is found in Chapter 43 (p. 951), whereas the advantages of risk-reducing salpingectomy are outlined in Chapter 35 (p. 738).

### PREOPERATIVE

#### ■ Patient Evaluation

A thorough pelvic examination and history reveal factors that help determine the optimal surgical route. Poor candidates for a vaginal approach include patients with minimal uterine descent, extensive abdominal or pelvic adhesions, a large uterus not amenable

to tissue extraction methods, adnexal pathology, and a restricted vaginal vault or contracted pelvis. Patients with these findings are generally considered for TAH and also for TLH (Schindlbeck, 2008).

Of factors, uterine size and mobility are important. There is no agreed-upon size that precludes LH. However, a wide bulky uterus with minimal mobility may make it difficult to visualize vital structures, to manipulate the uterus during surgery, and to remove it vaginally. Once a patient has been deemed eligible for a laparoscopic approach, the same preoperative evaluation as for abdominal hysterectomy applies (Section 43-12, p. 950).

#### ■ Consent

Similar to an open approach, possible risks of hysterectomy include increased blood loss and need for transfusion, unplanned adnexectomy, and injury to other pelvic organs, especially bladder, ureter, and bowel. The ureters are also at greater risk during LH compared with other hysterectomy approaches (Harkki-Siren, 1997, 1998). Kuno and colleagues (1998) evaluated ureteral catheterization to prevent such injury but found no benefit. Complications related specifically to laparoscopy include injury to the major vessels, bladder, and bowel during trocar placement (Chap. 41, p. 877).

The risk of conversion to an open procedure is also discussed. In general, conversion to laparotomy may be necessary if exposure and organ manipulation is limited or if bleeding is encountered that cannot be controlled laparoscopically.

Concurrent salpingectomy during hysterectomy may be considered to lower future rates of some epithelial ovarian cancers. For this, complete rather than partial salpingectomy is preferred. Operating time is minimally lengthened, but complication rates are not increased. Notably, the American College of Obstetricians and Gynecologists (2015) has emphasized that the planned route of hysterectomy should not be changed to complete prophylactic salpingectomy.

#### ■ Patient Preparation

A blood sample is typed and crossmatched for potential transfusion. If considered, bowel preparation prior to laparoscopy may assist with colon manipulation and pelvic anatomy visualization by evacuating the rectosigmoid. Alternatively, enemas prior to surgery may be as effective for this goal. Antibiotic prophylaxis is administered within the hour prior to skin incision, and appropriate antibiotic options are listed in Table 39-6 (p. 835). Overall, the likelihood of VTE

during laparoscopic hysterectomy is significantly reduced when compared to abdominal hysterectomy (Barber, 2015). Thus, the decision to provide VTE prophylaxis should factor patient- and procedure-related VTE risks (Gould, 2012). If longer operating times are anticipated, conversion to laparotomy is a concern, or preexisting VTE risks are present, then prophylaxis as outlined in Table 39-8 (p. 836) is reasonable.

### INTRAOPERATIVE

#### ■ Instruments

Vessel occlusion is an important component of any hysterectomy. For this, suitable instruments include monopolar or bipolar instruments, Harmonic scalpel, stapling devices, traditional sutures, and suturing devices. Several of these can be used for dissection and hemostasis. The Harmonic scalpel is frequently used for its ability to cut with minimal smoke plume and little surrounding thermal tissue damage, although it should only be used to seal vessels up to 5 mm. Several advanced bipolar devices also offer improved vessel sealing. With various instruments, vessels measuring up to 5 mm (LigaSure, Gyrus Plasma Kinetic) and up to 7 mm (ENSEAL) can be coagulated with minimal thermal spread (Lamberton, 2008; Landman, 2003; Smaldone, 2008).

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

For most women, these procedures are performed in an inpatient setting under general anesthesia. The patient is placed in a low dorsal lithotomy position in booted support stirrups. A bimanual examination is completed to determine uterine size and shape to aid port placement. The abdomen and vagina are surgically prepared, a Foley catheter is inserted, and orogastric or nasogastric tube is placed. Uterine manipulators can assist with visualization. These are considered in cases in which anatomic distortion is anticipated or in those with large uteri.

##### □ Initial Steps.

The introductory steps for LH mirror that for other laparoscopic procedures (Chap. 41, p. 889). The number of ports and their caliber may vary, but in general, LH requires a 5- to 12-mm optical port placed at the level of the umbilicus or higher for larger uteri. Left upper quadrant entry is considered in cases of suspected peri-umbilical adhesions. For larger uteri, if the uterine fundus is close to or above the level of the umbilicus, the optical port is placed approximately 3 to 4 cm above the fundus for optimal viewing.

**FIGURE 44-9.1** The ureter is first identified. With ovarian conservation, the round ligament is transected, and the fallopian tube is then grasped for transection.

Two or three accessory ports are also placed through the lower abdominal wall. Specifically, two ports are positioned beyond the lateral borders of the rectus abdominis muscle, whereas a third may be positioned centrally and cephalad to the uterine fundus.

□ **Pelvic Evaluation.** With the ports and laparoscope inserted and the patient in Trendelenburg position, a blunt laparoscopic probe can aid organ manipulation. The pelvis and abdomen are visually explored. At this point, the decision is made whether to continue with LH or convert to laparotomy. If needed, adhesions are lysed to restore normal anatomy. The bowel is displaced from the pelvis into the abdomen to expand available operating space and viewing.

□ **Ureter Identification.** Irrigating fluids and CO<sub>2</sub> used for insufflation can, with time, create edema of the peritoneum and hinder viewing of retroperitoneal structures. For this reason, the ureters are identified early. The ureters can often be seen easily beneath the pelvic peritoneum, or the peritoneum may be open to identify these. In such situations, the peritoneum medial to the infundibulopelvic (IP) ligament is grasped and tented using atraumatic forceps and incised with scissors. Hydrodissection techniques may be employed. The opening in the peritoneum

then is extended caudally and cephalad along the length of the ureter. Through this peritoneal window, the ureter is identified, and peristalsis should be noted (Fig. 44-9.1) (Parker, 2004).

□ **Round Ligament Transection.** The proximal round ligament is grasped and divided.

□ **Ovarian Conservation.** If ovarian preservation is planned, proximal portions of

**FIGURE 44-9.2** Uteroovarian ligament transection.

the fallopian tube and uteroovarian ligament are also desiccated and transected (Figs. 44-9.1 and 44-9.2). With this, the tube and ovary are freed from the uterus and can be placed in the ovarian fossa.

□ **Oophorectomy.** If removal of the ovaries is desired, the IP ligament is grasped and pulled up and away from retroperitoneal structures. The presence and path of the ureter is identified. The IP ligament is isolated and dissected away from the ureteral course. The pedicle is coagulated, desiccated, or stapled, and then divided (Fig. 44-9.3).

□ **Broad Ligament Incision.** Following transection of the round ligament, the leaves of the broad ligament fall open and

**FIGURE 44-9.3** Infundibulopelvic ligament transection.

**FIGURE 44-9.4** Anterior leaf of broad ligament incised caudally.

loose gauzy connective tissue is found between these leaves. The anterior leaf is incised sharply (Fig. 44-9.4). This incision is directed caudally and centrally to the midline above the vesicouterine fold. The posterior leaf requires incision caudally to the level of the uterosacral ligament. The loose areolar tissue separating the anterior and posterior leaves is dissected as well. Ultimately, opening the broad ligament provides access to lateral uterine anatomy, which is important for subsequent uterine artery ligation.

□ **Bladder Flap Development.** After broad ligament incision bilaterally, the vesicouterine fold is grasped with atraumatic forceps, elevated away from the underlying bladder, and incised (Fig. 44-9.5). This exposes connective tissue between the bladder and underlying uterus in the vesicouterine space. Loosely attached connections can be bluntly divided by gently pushing against the cervix and caudally to move the bladder caudad (Fig. 44-9.6). Denser tissue in the vesicouterine space is better divided sharply. With this, the tissue is elevated, and the

**FIGURE 44-9.6** Bladder moved caudally.

**FIGURE 44-9.5** Vesicouterine fold incised.

scissors are kept close to the surface of the cervix to minimize inadvertent cystotomy risk. As this tissue is dissected, the vesicouterine space is opened. Electrosurgery may be needed to coagulate small bleeding vessels. Creating cephalad traction on the uterus with the uterine manipulator may also help with this dissection. Development of this space allows the bladder to be moved caudally and of the lower uterus and upper vagina. This mobilization of the bladder is necessary for final colpotomy and uterus removal. Of the hysterectomy types, MIS approaches have the highest risk of bladder injury, and injury occurs most frequently to the dome during this sharp or blunt dissection (Harkki, 2001). This risk is increased if prior cesarean delivery or endometriosis has left scarring.

□ **Uterine Artery Transection.** After the uterine arteries are identified, the areolar connective tissue surrounding them is grasped, placed on tension, and incised. This

skeletonizing of the vessels leads to superior occlusion of the uterine artery and vein. The arteries then are then coagulated and transected (Fig. 44-9.7). Alternatively, surgeons may elect to terminate the laparoscopic portion prior to uterine artery transection and complete artery ligation and complete artery transection from a vaginal approach (LAVH).

⑪ **Vaginal Hysterectomy.** With LH, after the uterine arteries are transected, the surgical approach is converted to that for vaginal hysterectomy and is completed as outlined in Section 43-13 (p. 957). In this transition, the patient is repositioned from low dorsal lithotomy to standard lithotomy position.

⑫ **Abdominal Inspection.** After vaginal completion of the hysterectomy, attention is redirected to laparoscopic inspection of the pelvis for signs of bleeding. Before returning to the abdomen, surgeons will replace their

**FIGURE 44-9.7** Uterine artery coagulation.

surgical gloves. Copious irrigation of the abdominopelvic cavity and confirmation of hemostasis is performed. During this inspection, intraabdominal pressures are lowered to better identify sources of bleeding. The laparoscopic procedure is terminated as outlined in Section 44-1 (p. 1005).

## POSTOPERATIVE

Following LH, patient recovery mirrors that for vaginal hysterectomy. In general, compared with those undergoing abdominal hysterectomy, LH patients have faster return of normal bowel function, easier ambula-

tion, and decreased analgesia requirements. A clear liquid diet can be initiated the day of surgery and advanced quickly as tolerated. Postoperative complications in general mirror those for abdominal hysterectomy with the exception that superficial surgical site infection rates are lower.

## 44-10

## Laparoscopic Supracervical Hysterectomy

Laparoscopic supracervical hysterectomy (LSH) differs from total laparoscopic hysterectomy (TLH) in that the uterine corpus is amputated, but the cervix remains. Once freed, the corpus either is delivered through a posterior colpotomy or minilaparotomy incision or undergoes enclosed morcellation. Advantageously, the uterosacral and cardinal ligaments, which are important to pelvic support, are retained. It is also an excellent alternative for cases complicated by extensive scarring. Specifically, adhesions between the bladder and the lower uterine segment in the vesico-uterine space or those in the cul-de-sac may make removal of the cervix difficult. Related to this, ureteral and bladder injury rates are decreased by avoiding difficult dissection.

Certain contraindications to preserving the cervix are excluded prior to selecting supracervical hysterectomy. Examples include Pap test findings of high-grade cervical dysplasia; endometrial hyperplasia with atypia or endometrial cancer; or a patient at risk for noncompliance with routine cervical cancer screening.

### PREOPERATIVE

#### ■ Patient Evaluation

A thorough pelvic examination and history reveal factors that help determine the optimal surgical route. Uterine size and mobility are important, although there is no agreed-upon size that precludes LSH. That said, a large bulky uterus with minimal mobility may be difficult to adequately manipulate, may limit exposure during surgery, and may be challenging to extract. Once a patient has been deemed eligible for a laparoscopic approach, the same preoperative evaluation as for an abdominal hysterectomy applies (Section 43-12, p. 950).

#### ■ Consent

Similar to an open approach, possible risks of LSH include blood loss and need for transfusion, unplanned adnexectomy, and injury to other pelvic organs, especially bladder, ureter, and bowel. Complications related specifically to laparoscopy include injury to the major vessels, bladder, and bowel during trocar placement (Chap. 41, 877).

Postoperatively, endometrium within the lower uterine segment may be retained with

LSH. As a result, the risk of cyclic long-term bleeding is a potential consequence. Rates quoted in early studies are as high as 24 percent but are lower in more recent investigations and range from 5 to 10 percent (Okaro, 2001; Sarmini, 2005; Schmidt, 2011; van der Stege, 1999). Techniques that resect more of the lower uterine and proximal endocervical tissue appear to decrease these long-term bleeding risks (Schmidt, 2011; Wenger, 2005).

In some case, secondary excision of the cervical stump may later be required. Termed trachelectomy, this excision may be indicated if refractory long-term bleeding or significant subsequent cervical neoplasia develops postoperatively. Trachelectomy has the additional indication for residual persistent infection, although this is more anecdotal and not quoted with a consistent incidence. Overall rates of trachelectomy appear to mimic the bleeding rates above and are on a downward trend.

The risk of conversion to an open procedure is also discussed. In general, conversion to laparotomy may be necessary if exposure and organ manipulation are limited or if bleeding is encountered that cannot be controlled with laparoscopic tools and techniques.

#### ■ Patient Preparation

A blood sample is typed and crossmatched for potential transfusion. If considered, bowel preparation prior to laparoscopy may assist with colon manipulation and pelvic anatomy visualization by evacuating the rectosigmoid. Enemas prior to surgery may be as effective for this goal. Antibiotic prophylaxis is administered within the hour prior to skin incision, and appropriate antibiotic options are listed in Table 39-6 (p. 835). With laparoscopic gynecologic surgery, the

decision to provide VTE prophylaxis factors patient- and procedure-related VTE risks (Gould, 2012). Thus, if longer operating times are anticipated, conversion to laparotomy is a concern, or preexisting VTE risks are present, then prophylaxis as outlined in Table 39-8 (p. 836) is reasonable.

### INTRAOPERATIVE

#### ■ Instruments

During cervical amputation, blunt scissors, Harmonic scalpel, laser, or monopolar needle or scissors may be used to excise the corpus. Vessel occlusion is an important component of any hysterectomy. For this, suitable instruments include monopolar or bipolar instruments, Harmonic scalpel, stapling devices, traditional sutures, and suturing devices. Many of these instruments may not be readily available in all operating suites, and desired tools should be requested prior to surgery. After tumor excision, removal may be accomplished by several techniques described in Steps 3, 4, and 5. Thus, required endoscopic bags or morcellators are assembled preoperatively.

#### ■ Surgical Steps

□ **Initial Steps.** The initial surgical steps for LSH mirror those for LH, including coagulation of the uterine vessels as described in Section 44-9, Steps 1 through 10 (p. 1026).

□ **Uterine Amputation.** The corpus is amputated from the cervix at a point just below the internal cervical os and superior to the uterosacral ligaments (Fig. 44-10.1). To limit the possibility of residual endometrium, the incision is conical and extends

**FIGURE 44-10.1** Incision initiated above uterosacral ligaments.

**FIGURE 44-10.2** Incision extended posteriorly.

**FIGURE 44-10.3** Cone-shape incision extended anteriorly.

down into the cervix (Figs. 44-10.2 through 44-10.4). Following amputation, adjunctive coring or ablation of the endocervical canal also may be performed to decrease the risk of postoperative cyclic bleeding (Fig. 44-10.5).

□ **Tissue Extraction.** Once amputated, the uterine corpus must be removed, and options include minilaparotomy, colpotomy, and enclosed morcellation. Although

described here for the uterine corpus, these methods translate to surgical removal of other specimens.

First, for smaller specimens, a minilaparotomy incision ranging from 1 to 4 cm can be made to extract the corpus. Typically, a small Pfannenstiel incision is made, although a small midline vertical incision is also suitable. Both incisions are illustrated in Chapter 43 (p. 927).

For larger uteri, the addition of a tissue retrieval bag and self-retaining retractor can create a closed environment for manual morcellation. For this, a retrieval bag is initially placed into the abdomen. The bag containing the excised specimen is then brought to the surface and is fanned open outside and around the minilaparotomy incision. A self-retaining circular retractor is placed into the bag's interior and simultaneously opened within the incision (see Fig. 44-8.7). This creates a closed environment where the specimen can be sharply divided manually with scissors or knife. Long-term data on safety and efficacy are not currently available.

**FIGURE 44-10.4** Excision completion.

**FIGURE 44-10.5** Endocervical canal coagulated.

□ **Colpotomy.** As another option, a posterior colpotomy can be created similar to that for vaginal hysterectomy and shown in Figure 41-27 (p. 896). To enter the posterior cul-de-sac, attention is turned to the vagina, and handheld retractors are placed to expose the cervix and posterior fornix. The uterine manipulator is used to anteflex the uterus, and an Allis clamp is placed on the posterior vaginal wall 2 to 3 cm from the posterior cervicovaginal junction. The Allis clamp is pulled downward to create tension across the posterior vaginal wall. The posterior vaginal vault is then cut with curved Mayo scissors, and the cul-de-sac of Douglas is entered.

Alternatively, a colpotomy may be created laparoscopically by incising the posterior cul-de-sac with a monopolar instrument, a harmonic scalpel, or Endo Shears near the cervicovaginal junction. A uterine manipulator is used to reflect the uterus anteriorly to create space for the colpotomy, and a sponge stick may be used vaginally to help delineate the space. As Figure 41-28 illustrates, care is taken to avoid damage to the rectosigmoid and to the ureters, which lie lateral to the planned colpotomy.

With colpotomy, pneumoperitoneum is lost immediately. If a laparoscopic instrument is already holding the specimen, this can be passed through the colpotomy and removed vaginally.

For larger uteri, the addition of a tissue retrieval bag during tissue extraction can create a closed environment for scissor morcellation (Fig. 41-29). This reduces the risk of inadvertent tissue dissemination during fragmentation, although long-term safety data are needed (Cohen, 2014; Einarsson, 2014).

Following extraction, the vaginal incision is closed with interrupted stitches or a running suture line using 0-gauge delayed-absorbable suture. If colpotomy is used for specimen removal, a single prophylactic dose of antibiotics is administered. Suitable agents are listed in Table 39-6 (p. 835).

□ **Morcellation.** A third method, enclosed power morcellation, is still being studied. For this, a large containment bag that can house the insufflation gas, can conform to the abdominal cavity, and can flatten against the intraperitoneal organs is introduced into the abdomen. Once in the abdomen, it is unfolded to allow the specimen and gas to be contained. Depending on the pathology, the bag may be

exteriorized through one abdominal port or incision or may function simply as a liner that catches any disseminated tissue during power or manual morcellation (Einarsson, 2014).

During power morcellation, the corpus specimen is grasped securely with a toothed instrument such as a tenaculum and brought to the anterior abdominal wall. Because of the potential for surrounding organ injury, morcellators should not be moved toward the grasped tissue, but rather, those tissues should be brought to it (Fig. 44-10.6) (Milad, 2003). Importantly, the morcellator tip is always kept in laparoscopic view. A peeling rather than coring technique is used to pare down the mass. During this, the tenaculum holding the corpus is drawn up into the morcellator cylinder and well past the edge of the morcellating blade. This avoids metal-to-metal contact, which dulls the blade. In cases of prolonged morcellation, such as with large uteri, the blade may dull. For this, the generator allows a reverse in the blade's rotary direction. Improved cutting is usually restored with this step and generally offers enough blade life to complete the procedure.

Following morcellation, the gas is released, and bag and tissue fragments are removed.

**FIGURE 44-10.6** Uterine corpus morcellation.

Limitations of currently available retrieval bags involve pouch size, working aperture diameter, tensile strength of the bag, and bag permeability.

□ **Hemostasis.** Points of bleeding are coagulated, and the surgeon may elect to reapproximate the anterior vesical and posterior cul-de-sac peritoneum to cover the cervical stump using 2-0 or 0-gauge delayed-absorbable suture. Alternatively, absorbable adhesion barriers (Interceed, Seprafilm) can be placed at the hemostatic surgical stump.

□ **Laparoscopy Final Steps.** Completion of the procedure follows that for general laparoscopic procedures (p. 1005).

## POSTOPERATIVE

Advantages of laparoscopy include a rapid return to normal diet and activities. With supracervical hysterectomy, there is no vaginal cuff that requires extended healing. Sexual intercourse, however, is delayed for 2 weeks following surgery to allow adequate internal healing.

## 44-11

## Total Laparoscopic Hysterectomy

Total laparoscopic hysterectomy (TLH) is similar to LAVH, LSH, and LH with the exception that the procedure is completed entirely from a laparoscopic approach. After detachment, the specimen is removed vaginally or by tissue extraction techniques described on page 1031.

If all factors are equal, vaginal hysterectomy is considered for women undergoing hysterectomy. Ideal candidates for TLH are those not suitable for vaginal hysterectomy (American College of Obstetricians and Gynecologists, 2011). As such, TLH is viewed as a less invasive alternative to TAH. Compared with TAH, TLH benefits include rapid recovery, shorter hospitalizations, fewer minor complications of the wound or abdominal wall, and less blood loss (Nieboer, 2009; Walsh, 2009). These benefits are dependent on a learning curve and may not be readily apparent (Schindlbeck, 2008). Moreover, longer operative times and higher rates of urinary tract injuries are negative balancing factors.

### PREOPERATIVE

#### ■ Patient Evaluation

A thorough pelvic examination and history reveal factors that help determine the optimal surgical route. Uterine size and mobility are important, although there is no agreed-upon size that precludes TLH. That said, a wide bulky uterus with minimal mobility may be difficult to adequately manipulate, may limit exposure during surgery, and may be challenging to extract. Once a patient has been deemed eligible for a laparoscopic approach, the same preoperative evaluation as for an abdominal hysterectomy applies (Section 43-12, p. 950).

#### ■ Consent

Similar to an open approach, possible risks of this procedure include increased blood loss and need for transfusion, unplanned adnexectomy, and injury to other pelvic organs, especially bladder, ureter, and bowel. Complications related to laparoscopy include entry injury to the major vessels, bladder, and bowel (Chap. 41, p. 877). The ureters are also at greater risk during laparoscopic hysterectomies compared with other hysterectomy approaches (Harkki-Siren, 1998). Kuno and colleagues (1998) evaluated the

use of ureteral catheterization to prevent such injury but found no benefit.

The risk of conversion to an open procedure is also discussed. In general, conversion to laparotomy may be necessary if exposure and organ manipulation is limited or if bleeding is encountered that cannot be controlled with laparoscopic tools and techniques.

#### ■ Patient Preparation

A blood sample is typed and crossmatched for potential transfusion. If considered, bowel preparation prior to laparoscopy may assist with colon manipulation and pelvic anatomy visualization by evacuating the rectosigmoid. Alternatively, enemas prior to surgery may be as effective for this goal. Antibiotic prophylaxis is administered within the hour prior to skin incision, and appropriate antibiotic options are listed in Table 39-6 (p. 835). With laparoscopic gynecologic surgery, the decision to provide VTE prophylaxis factors patient and procedure-related VTE risks (Gould, 2012). Thus, if longer operating times are anticipated, conversion to laparotomy is a concern, or preexisting VTE risks are present, then prophylaxis as outlined in Table 39-8 (p. 836) is indicated.

### PREOPERATIVE

#### ■ Instruments

The same instruments that are used for the LH or LSH can be used for this procedure. In addition, a uterine manipulator that has a cupping device for delineating the cervicovaginal junction is helpful for colpotomy and also for final tissue extraction. If these are not available, a low-cost alternative is a right-angle retractor to delineate the anterior and posterior fornices for colpotomy.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** For most women, TLH is performed as an inpatient procedure under general anesthesia. The patient is placed in low dorsal lithotomy position in booted support stirrups. A bimanual examination is completed to determine uterine size and shape to aid port placement. The abdomen and vagina are surgically prepared, a Foley catheter is inserted, and an orogastric or nasogastric tube is placed.

□ **Uterine Manipulator.** A uterine manipulator with its attached cervical cup (VCare or KOH Cup with RUMI manipulator) is placed vaginally to assist uterine manipulation and delineate the cervicovaginal junction for colpotomy. To accomplish placement, the

cervical diameter and thickness are assessed. From this information, the manipulator-cup size, which is small, medium, or large, is selected. To permit manipulator insertion, the cervical os is dilated to accept a no. 8 cervical dilator. The uterus is also sounded to determine cavity depth for correct manipulator placement. The surgeon tests the balloon at the manipulator's end for patency by filling it with air via a port at the opposite end. Once again deflated, it is passed through the cervical os to the fundus and then reinflated to hold the manipulator in place (Fig. 44-11.1A). Two stay sutures of 0-gauge delayed-absorbable suture are placed at 6 and 12 o'clock or at 3 and 9 o'clock, depending on surgeon preference. To securely anchor the cup and cervix, stitches enter the ectocervix and exit just lateral to the endocervix. Each suture end is then passed through openings in the cup base (Fig. 44-11.1B). They are then tied firmly to the cervix on the outside face of the cup (Fig. 44-11.1C). Once in position, the proximal rim of the cup will delineate the cervicovaginal junction. With the VCare, the blue vaginal cup is then advanced to join the interior cup and is locked in place by a locking knob at the manipulator's distal end (Fig. 44-11.1D). If the KOH Cup is used, then a pneumo-occluding balloon is positioned behind the colpotomy cup.

□ **Initial Laparoscopic Steps.** The introductory steps for LH mirror those for other laparoscopic procedures (Chap. 41, p. 889). The number of trocars and their caliber may vary, but in general, TLH requires a 5- to 12-mm optical port, usually at the umbilicus, and two or three accessory ports placed through the lower abdominal wall. Specifically, two trocars are placed beyond the lateral borders of the rectus abdominis muscle, whereas a third may be positioned centrally and cephalad to the uterine fundus. Left upper quadrant entry is considered for initial entry in cases with suspected periumbilical adhesions.

□ **Pelvic Evaluation.** With the cannulas and laparoscope inserted and the patient in Trendelenburg position, a blunt laparoscopic probe aids bowel displacement. The pelvis and abdomen are thoroughly explored. At this point, the decision to continue with TLH or convert to laparotomy is made. If necessary, adhesions are lysed to restore normal anatomy.

□ **Ureter Identification.** Irrigating fluids and CO<sub>2</sub> used for insufflation can with time create edema of the peritoneum and hinder visualization of structures beneath it. For this reason, the ureters are identified early. The ureters are often easily seen retroperitoneally, or the peritoneum may be opened to locate

**FIGURE 44-11.1** Uterine manipulator placement. **A.** Manipulator tip inserted into uterine cavity. **B.** Balloon tip inflated (left). Colpotomy cup sutured to cervix (right). **C.** Colpotomy cup sutured in place. **D.** Blue pneumo-occluding cup advanced and locked in place.

them. In such situations, the peritoneum medial to the infundibulopelvic (IP) ligament is grasped and tented using atraumatic forceps and incised with scissors. An irrigating probe is used to force water beneath and elevate the peritoneum for easier incision. The opening in the peritoneum then is extended a short distance caudally and cephalad over the suspected path of the ureter. Through this peritoneal window, the ureter is identified (see Fig. 44-9.1, p. 1027) (Parker, 2004).

**□ Round Ligament, Adnexa, and Uterine Artery.** The initial steps for TLH mirror those for LH, described in Section

44-9, Steps 5 through 10 (p. 1027). These steps include transection of the round ligament, conservation or excision of the adnexa, caudad displacement of the bladder, and coagulation of the uterine vessels.

**□ Cardinal Ligament Transection.** Following uterine artery coagulation, the cardinal ligaments are transected on each side to reach the level of the uterosacral attachments (Fig. 44-11.2).

**□ Colpotomy.** Incision at the cervicovaginal junction may be performed with Harmonic scalpel, monopolar scissors,

monopolar hook, or plasma kinetic needle point. Prior to incision, the uterine manipulator is pushed cephalad to allow the cervical cupping device to displace the ureters laterally and expose the optimal location for colpotomy. Additionally, dissection within the vesicouterine space should be sufficient to mobilize the bladder caudad and away from the planned colpotomy site.

With these preparatory steps completed, colpotomy is begun by placing the incising tool at the posterior cervicovaginal junction, which is delineated by the cervical cup. If a colpotomy cup is not used, a simple tool such as a right-angle retractor or sponge on a stick placed vaginally in the posterior fornix can also assist with delineating the cervicovaginal junction. The posterior vaginal wall is opened first (Fig. 44-11.3). By extending this incision, the uterosacral ligament is next transected (Fig. 44-11.4). The opposite uterosacral ligament is then divided close to the cervix. Last, the anterior colpotomy incision is created (Fig. 44-11.5). To minimize twisting and specimen disorientation, the lateral vaginal cuff points are transected last (Fig. 44-11.6). Hemostasis is generally maintained using this technique. To prevent vaginal tissue thermal damage and subsequent cuff dehiscence, surgeons use the minimum necessary amount of electrosurgery on the vaginal cuff.

**□ Removal of Uterus.** The uterus is removed intact through the vaginal vault using the manipulator, unless uterine size limits this (Fig. 44-11.7). In the case of large uteri, the uterus is removed using tissue extraction techniques described on page 1031.

**□ Repair of the Vaginal Cuff.** The cuff is closed laparoscopically with a running closure of absorbable suture, with interrupted figure-of-eight sutures, or with a suturing device. For this, delayed-absorbable material is preferred, and the uterosacral ligament is incorporated into the closure for vaginal cuff support (Fig. 44-11.8). If traditional suture is used, one must maintain tension to sufficiently close the cuff. If using barbed suture, the procedure is modified by manufacturer's recommendations to loosen stitch tension between the approximated cuff tissues. Moreover, if barbed suture is used, it is recommended to throw at least two bites in the opposite direction to the original direction of suture line closure to maintain tissue tension. For example, if closure is performed from right to left, the surgeon will reach the far left end and then will place two additional stitches in the left-to-right direction prior to final suture cutting. It is advisable to cut the suture flush with the tissue to decrease bowel damage risk from the barbed end. Confirmation of full-thickness closure is necessary to prevent

**FIGURE 44-11.2** Cardinal ligament incised.

**FIGURE 44-11.3** Posterior colpotomy.

later cuff dehiscence. Alternatively, for those less proficient with laparoscopic suturing, the cuff may be closed vaginally after removal of the uterus as described in Section 43-13 (p. 961).

After cuff closure, irrigation and confirmation of hemostasis is performed. Intra-abdominal pressures are lowered during this inspection to better identify sources of bleeding.

**⑩ Laparoscopy Final Steps.** Completion of this operation follows that for diagnostic laparoscopy (p. 1005).

### POSTOPERATIVE

The advantages of a laparoscopic approach include a rapid return to normal diet and activities. Generally, the evening of the surgery, the Foley catheter is removed, diet is

**FIGURE 44-11.4** Right uterosacral ligament transected, and colpotomy extended toward the left.

**FIGURE 44-11.5** Anterior colpotomy.

**FIGURE 44-11.6** Joining anterior and posterior colpotomy incisions.

**FIGURE 44-11.7** Uterus and manipulator removal.

advanced, and the patient is allowed to ambulate. Oral analgesics are quickly adopted in place of parenteral options. The usual precautions for abdominal hysterectomy in regard to limitation of stress on the abdominal cavity by heavy lifting are followed. Delay of sexual activity mirrors that for abdominal hysterectomy, which is typically 6 weeks.

Vaginal cuff dehiscence is a serious post-operative complication that more frequently follows laparoscopic hysterectomy approaches compared with VH or TAH (Agdi, 2009; Walsh, 2007). In most cases, the precipitating event is sexual activity in premenopausal women and increased intraabdominal pressure coupled with a weak, atrophic vagina in postmenopausal women (Lee, 2009). Patients present with vaginal bleeding or evisceration. Typical treatment includes debridement of vaginal cuff edges, reapproximation with delayed-absorbable suture, and administration of antibiotic prophylaxis. However, compromised bowel may require more extensive surgeries to repair.

Preventatively, sound initial surgical technique strives to minimize electrosurgical damage during colpotomy creation and limit undue desiccation of the vaginal cuff. Approximation of all tissue planes, particularly full-thickness closure of the vaginal wall, should also be ensured. Reapproximation includes an adequate amount of viable tissue that is free of thermal effect. In addition, a two-layer closure may have an advantage over a single-layer figure-of-eight closure (Jeung, 2010).

**FIGURE 44-11.8** Vaginal cuff closure.

## 44-12

## Diagnostic Hysteroscopy

Hysteroscopy allows an endoscopic view of the endometrial cavity and tubal ostia. Indications are varied and include evaluation of abnormal uterine bleeding, infertility, or a sonographically identified uterine cavity mass. Contraindications to surgery include pregnancy and current reproductive tract infection.

### PREOPERATIVE

#### ■ Consent

Risks with diagnostic hysteroscopy are infrequent. Those described in Chapter 41 (p. 903) include uterine perforation and volume overload. Gas embolism is rare.

#### ■ Patient Preparation

Infectious and VTE complications following hysteroscopic surgery are also rare. Accordingly, prophylaxis is typically not required (American College of Obstetricians and Gynecologists, 2013c, 2014b).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Diagnostic hysteroscopy can be performed in an outpatient setting under local anesthesia with or without intravenous sedation. Alternatively, a day-surgery setting and general anesthesia may be selected.

The patient is placed in standard lithotomy position, the vagina is surgically prepared, and the bladder is drained. Because diagnostic hysteroscopy is a short procedure with little if any blood loss, CO<sub>2</sub> or saline is typically selected for uterine distention. Trendelenburg positioning should be avoided to prevent the risk of gas embolism.

□ **Hysteroscope Assembly.** For assembly, the hysteroscope is placed within its outer sheath and locked into place. The light source is then attached to the endoscope. By convention, during hysteroscope insertion, the light source is kept pointing toward the floor. The distention media tubing port is attached to a port that typically lies 180 degrees away from the light source connection.

□ **Hysteroscope Introduction.** For most diagnostic hysteroscopic procedures, cervical

dilatation is not required to admit the 4- to 5-mm hysteroscope. Uterine sounding is not recommended by many because information regarding uterine depth and cavity inclination is provided by direct visualization during hysteroscope insertion. Moreover, the sound may disrupt the endometrium. This may alter endometrial anatomy prior to inspection and may cause obscuring bleeding.

For diagnostic purposes, a hysteroscope equipped with a 0-, 12-, or 30-degree forward oblique-view lens is suitable. A single-toothed tenaculum is placed on the anterior cervical lip, the flow of distention medium is begun, and the hysteroscope is introduced into the endocervical canal. Pressure exerted by the medium opens the endocervical canal and allows entry of the hysteroscope.

If using an angled lens, the surgeon should keep in mind that a panoramic image with a dark hole directly in the middle of the view is incorrect. The desired image would have the cervical canal at the bottom of the monitor if the light cord is directed downward, thus implying that the hysteroscope is in fact in the center of the cervical canal (Fig. 41-37, p. 902).

□ **Hysteroscopic Evaluation.** As the hysteroscope is inserted, the endocervical canal is examined for abnormalities. Upon entering the cavity, the hysteroscope is held at the distal portion of the cavity to allow a panoramic evaluation. Systematically, the hysteroscope is moved to the fundus and then to the left and right to permit inspection of the tubal ostia (Fig. 44-12.1). If an angled lens is employed, the hysteroscope may remain just beyond the internal cervical os and the light cord moved in a 180-degree rotational arc to obtain a global assessment of the endometrial cavity. Some surgeons also advocate keeping the hysteroscope in the cav-

**FIGURE 44-12.1** Hysteroscopic photograph of normal tubal ostia. (Used with permission from Dr. Kevin Doody.)

ity, evacuating it of distention medium, and evaluating the cavity in this decompressed stage. This helps identify lesions that may have been obliterated or flattened by the increased pressure of the distention medium.

□ **Specific Procedures.** Following complete cavity inspection, if specific lesions are identified, they are typically biopsied under direct visualization with hysteroscopic forceps. If intrauterine device (IUD) removal is planned, most are grasped by the string or stem with hysteroscopic grasping forceps and are easily extracted as the entire hysteroscope is removed. However, embedded or fragmented devices may require removal in pieces. In these instances, a sturdy portion of the IUD is firmly grasped and traction on the forceps is exerted toward the vagina. For cases in which the IUD is deeply embedded, laparoscopy can assist in identifying uterine perforation and in determining whether the device is best removed hysteroscopically or laparoscopically.

□ **Procedure Completion.** At the end of the procedure, the flow of distending medium is stopped, and the hysteroscope and then tenaculum are removed. A critical step at this point, and throughout the procedure, is to note the amount of distention fluid used and the amount retrieved. These values are used to calculate the fluid deficit, which is included in the operative report.

### POSTOPERATIVE

Patient recovery is typically rapid and without complication and mirrors that following dilatation and curettage. Diet and activities may be resumed as desired by the patient. Spotting or light bleeding is not uncommon and typically stops within days.

## 44-13

## Hysteroscopic Polypectomy

Indications for endometrial polyp removal include abnormal uterine bleeding, infertility, and risk of malignant transformation (Chap. 8, p. 188). Hysteroscopic excision of these growths may be completed by incision of the polyp base with hysteroscopic scissors or resectoscope loop, avulsion of the polyp with hysteroscopic forceps, or retrieval using suction and morcellation. Of these, the resectoscope and morcellator offer the most versatility in managing lesions, both large and small.

### PREOPERATIVE

#### ■ Patient Evaluation

In many women undergoing polypectomy, preoperative transvaginal sonography or saline infusion sonography examinations have been completed. Information regarding the size, number, and location of polyps is reviewed prior to surgery. Rarely, MR imaging may be indicated to fully distinguish a presumed polyp from a submucous leiomyoma. This often helps determine if myomectomy is instead required.

#### ■ Consent

The complication rates for this procedure are low and mirror that for hysteroscopy in general (Chap. 41, p. 903). Thus, bleeding, infection, and uterine perforation, and rare fluid overload and gas embolism are described.

#### ■ Patient Preparation

As with most hysteroscopic procedures, polypectomy is ideally performed during the follicular phase of the menstrual cycle, when the endometrial lining is thinnest and polyps would be most easily identified. Preoperative endometrial biopsy is optional but is generally considered part of abnormal uterine bleeding evaluation for those with endometrial cancer risks (Chap. 8, p. 184). Preoperative antibiotics or VTE prophylaxis is typically not required (American College of Obstetricians and Gynecologists, 2013c, 2014b).

### INTRAOPERATIVE

#### ■ Instruments

A resectoscope with a 90-degree loop electrode is ideal for polyp excision. Alternatively, an intrauterine morcellator has a hollow cannula that is attached to suction and can quickly

excise small to large growths. For smaller polyps, polyp forceps may also be used through the 5F channel of the operative port.

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Although simple polypectomy procedures under local analgesia in an office setting have been described, most cases are outpatient procedures performed under general or regional anesthesia. The complexity of fluid management, particularly with the use of hypotonic fluids, warrants a degree of safety that can be best provided in the operating suite. Following adequate anesthesia administration, the patient is placed in standard lithotomy position, the vagina is surgically prepared, and a Foley catheter is inserted.

##### □ Media Selection.

Hysteroscopic morcellation may be performed with a physiologic saline solution. However, if a monopolar resectoscope is used, then a nonelectrolyte solution is required. Because of the risks for hyponatremia with sorbitol and glycine, many prefer 5-percent mannitol. Alternatively, selection of a bipolar resecting system (Versapoint) allows performance within an isotonic electrolyte medium. The basics of medium selection are further described in Chapter 41 (p. 903). As with any hysteroscopic procedure, fluid volume deficits are calculated and noted regularly during surgery.

##### □ Cervical Dilatation.

The larger diameter of an 8- or 10-mm resectoscope or morcellator typically requires dilatation up to

9 mm with Pratt or similar dilators (Chap. 43, p. 967).

□ **Resection.** Medium flow is begun, and the resectoscope is inserted into the endocervical canal under hysteroscopic visualization. Upon entering the cavity, a panoramic inspection is completed to identify the location and number of polyps. The resectoscope loop is then extended to reach behind the polyp. Electrosurgical current is applied as the loop is retracted toward the cervix to cut the polyp base. During resection, the loop should remain in view. The freed polyp is then grasped and delivered through the cervical os. This is similar to myoma excision, shown on page 1041.

In cases in which the polyp is large, several passes with the loop electrode may be required for complete excision. Passes begin at the polyp tip and progress until the base is reached. The uterus is not emptied after each pass. This practice maintains visualization of the polyp and minimizes the gas embolism and perforation risks associated with multiple introductions and reintroductions of instruments into the cavity. Instead, resected segments are allowed to float within the cavity as resection continues. Once the entire polyp is excised, then the fragments are collected on a Telfa sheet as they flow out of the cavity along with the distending medium. For larger polyps, the number of floating fragments will accrue. Thus, the cavity may need to be emptied prior to complete resection to permit an unobstructed view during resection.

##### □ Morcellation.

As with loop resection, distention medium flow is begun, and the morcellation unit is inserted. During morcellation,

**FIGURE 44-13.1** Hysteroscopic polypectomy.

it is important to work from the polyp tip toward the base (Fig. 44-13.1). Moreover, the mass is kept between the morcellator opening and the optics of the camera.

The morcellator also has suction action. It is used to clear blood, tissue debris, and clots during resection of large growths. Better visual acuity and the continuous retrieval of the tissue are two of the advantages to this approach.

□ **Control of Bleeding.** Bleeding sites may be coagulated with the same resection

loop using a coagulating current. Alternatively, for heavy bleeding, a Foley catheter balloon may be inflated to tamponade vessels. It can be left in for several hours depending on bleeding severity. It is later removed, and vaginal bleeding is reassessed.

□ **Instrument Removal.** The resectoscope or morcellator is removed, and the surgical specimen is sent for pathologic evaluation. At the end of the procedure, the flow of distending medium is stopped, and the hysteroscope

and then tenaculum are removed. A critical step at this point, and throughout the procedure, is to note the amount of distention fluid used and retrieved to calculate the fluid deficit.

## POSTOPERATIVE

Recovery following polypectomy is rapid, is typically without complication, and follows that for other hysteroscopic procedures (p. 1037).

## 44-14

## Hysteroscopic Myomectomy

For symptomatic women with submucous leiomyomas, hysteroscopic resection of these tumors may provide relief of symptoms in most cases. Candidates may include those with abnormal uterine bleeding, with dysmenorrhea, or with infertility in which leiomyomas are suspected to be contributory. Tumors selected for resection should be either submucous or intramural with a prominent submucous component. During surgery, pedunculated submucous leiomyomas may be excised similarly to polyps (p. 1038). However, tumors with an intramural component require resection with a resectoscope, morcellator, or laser.

### PREOPERATIVE

#### ■ Patient Evaluation

Hysteroscopic myomectomy is a safe and effective option for most women. Contraindications to surgery, however, include pregnancy, potential endometrial cancer, current reproductive tract infection, and medical conditions sensitive to fluid volume overload.

Specific leiomyoma characteristics such as great size, large number, and greater degree of intramural penetration can increase the technical difficulty, complication rate, and clinical failure rate of this procedure (Di Spiezio Sardo, 2008). Thus, prior to resection, women typically undergo transvaginal sonography, saline infusion sonography (SIS), or hysteroscopy to evaluate leiomyoma characteristics. Alternatively, MR imaging can also accurately document uterine anatomy, but its expense and availability may limit its routine use.

During the evaluation by SIS or hysteroscopy, leiomyomas may be grouped according to criteria developed by Wamsteker and associates (1993) and adopted by the European Society for Gynaecological Endoscopy (ESGE).

Class 0: complete submucosal location

Class I: greater than 50-percent submucosal component

Class II: some submucosal involvement but greater than 50-percent myometrial component.

These criteria help predict which leiomyomas are suitable for hysteroscopic resection. A more recent classification has also been proposed by Lasmar and coworkers (2005, 2011). Similar to the ESGE system, their evaluation

grades the degree of tumor penetration into the myometrium. But, in addition, larger tumor size, wider tumor base, tumors in the upper portion of the cavity, or those found along the lateral wall receive higher scores. For higher scores, a nonhysteroscopic technique may be the safest and most successful.

Large or predominantly intramural tumors decrease clinical success rates, increase surgical risks, and increase the need for more than one surgical session to complete resection. For these reasons, many choose to resect only type 0 and I tumors and those measuring less than 3 cm (Vercellini, 1999; Wamsteker, 1993). More recent studies have reported resection of larger leiomyomas, although many need a two-step procedure and require a longer recovery (Camanni, 2010).

#### ■ Consent

Complications of this procedure mirror that for hysteroscopy in general, and rates of 2 to 3 percent have been reported. Hysteroscopic myomectomy is associated with a greater risk of uterine perforation. This complication may follow cervical dilatation, but more frequently results during aggressive resection into the myometrium. Because of this risk, women are also consented for laparoscopy to assess and treat uterine or abdominal organ damage if perforation occurs.

Additionally, patients planning to seek pregnancy should be aware of possible intra-uterine adhesion formation following resection and of rare uterine rupture during subsequent pregnancies (Batra, 2004; Howe, 1993).

During hysteroscopic myomectomy, distending medium is absorbed through venules that are opened during myometrial resection. Media is also absorbed across the peritoneum as the fluid flows in a retrograde direction through the fallopian tubes. Thus, resection of type I or II tumors or removal of large leiomyomas may be halted due to advancing fluid volume deficits. Patients are counseled that a second surgery may be required to finish resections in these cases. Fortunately, because of newer hysteroscopic morcellating tools, operating times and thus fluid deficits are decreased, even with large tumors.

Last, myomectomy is effective treatment, but 15 to 20 percent of patients will eventually require reoperation. This may be hysterectomy or repeat hysteroscopic resection at a later time for either persistent or recurrent symptoms (Derman, 1991; Hart, 1999).

#### ■ Patient Preparation

GnRH agonists can preoperatively shrink leiomyomas to enable resection of large tumors or allow patients to rebuild their red

cell mass before surgery (Chap. 9, p. 208). However, disadvantages include preoperative hot flashes, difficulty in cervical dilatation, increased risk of laceration or perforations, and reduced intracavitary volume, which limits instrument mobility. Thus, GnRH agonist use is individualized.

To allow easier cervical dilatation and resectoscope insertion, misoprostol (Cytotec) can aid cervical softening. This practice is supported in some but not all studies, and postmenopausal women may benefit less from this pretreatment (Ngai, 1997, 2001; Oppegaard, 2008; Preutthipan, 2000). Commonly used dosing options include 200 or 400 µg vaginally or 400 µg orally once 12 to 24 hours prior to surgery. Common side effects include cramping, uterine bleeding, or nausea. Another alternative for cervical preparation prior to dilation is the use of dilute vasopressin (0.05 units/mL). Twenty milliliters of diluted vasopressin can be injected in divided doses intracervically at 4 and 8 o'clock. This method has the advantage of working rapidly at the time of surgery if the need for preoperative preparation was not anticipated (Phillips, 1997). Precautions with this potent vasoconstrictor are outlined in Step 3 on page 1023.

Although the risk of postoperative infection is low, because pelvic infections can have devastating effect on future fertility, most recommend antibiotic prophylaxis prior to extensive hysteroscopic resections, as with myomectomy. Suitable agents are found in Table 39-6 (p. 835).

#### ■ Concurrent Ablation

In those women with menorrhagia and with no desire for future fertility, endometrial ablation may be concurrently performed (p. 1043) (Lofler, 2005). However, because leiomyoma resection alone resolves abnormal bleeding in most women, we do not routinely perform concomitant endometrial ablation unless the patient desires hypomenorrhea.

### INTRAOPERATIVE

#### ■ Instruments

Hysteroscopic myomectomy can be performed using a resectoscope or hysteroscopic morcellator. Both procedures are described.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** For most cases, hysteroscopic myomectomy is an outpatient procedure performed under general anesthesia. The patient is placed in standard lithotomy position, the vagina is surgically prepared, and a Foley catheter is inserted.

**FIGURE 44-14.1** Hysteroscopic resection.

□ **Medium Selection.** The choice of distending medium is dictated by the resecting tool used. Resection using a morcellator, bipolar electrosurgical loop, or laser can be performed in saline solution. Alternatively, cases using a monopolar electrosurgical loop require an electrolyte-free solution. Solution differences are discussed in Chapter 41 (p. 903).

□ **Cervical Dilatation.** Using Pratt or other suitable dilators, the surgeon dilates the cervix as shown in Chapter 43 (p. 967).

□ **Instrument Insertion.** The distending medium flow is begun, and the resectoscope or morcellator is inserted into the endocervical canal under direct visualization. Upon entering the endometrial cavity, a panoramic inspection is first performed to identify and assess leiomyomas.

□ **Resection.** The electrosurgical unit is set to a continuous-wave mode (cutting). The resectoscope loop is advanced to lie behind the leiomyoma, and electric current is applied before the loop contacts the tissue. To minimize thermal injury and perforation, current is applied only as the loop is retracted and not when it is being extended. During resection, the loop should remain in view. Upon contact, the loop electrode is retracted toward the resectoscope (Fig. 44-14.1). To ensure a clean cut and complete excision of the shaved strip, current is not stopped until the entire loop is retracted. The shaved strip

of smooth muscle floats within the endometrial cavity.

The shaving process is repeated serially toward the myoma's base until the tumor is removed. Although strips can be removed from the cavity after each pass, this results in a repetitive loss of uterine distention. Repeated removal and reinsertion of a resectoscope increases the risk of perforation, gas embolism, and fluid intravasation. Thus in most cases, pushing removed strips to the fundus will help to adequately clear the operative field. However, if the view becomes obstructed, a pause in resection may be required to remove these strips.

□ **Morcellation.** Morcellators currently available include Hologic's MyoSure, Smith & Nephew's TruClear system, and Boston Scientific's Symphion system. In general, sharp moving blades are contained within a hollow, rigid tube. By means of a vacuum source connected to the hollow tube, tissue is suctioned into the window opening at the device tip and is shaved off by the moving blade (Fig 44-14.2). Suction also removes morcellated tissue fragments through the device cylinder and allows collection for pathologic analysis.

In retrospective comparisons, hysteroscopic morcellation is faster than resectoscopy

**FIGURE 44-14.2** Hysteroscopic morcellator. **A.** Morcellator blade retracted. Suction draws tissue into the fluted opening. **B.** Blade partially advanced. The blade rapidly rotates as it is advanced and retracted. **C.** Blade is fully advanced and slices tissue drawn into the opening.

and appears easier to perform. It is associated with fewer fluid-related complications and has a shorter learning curve compared with conventional resectoscopy (Emanuel, 2005).

□ **Intramural Leiomyomas.** During removal of leiomyomas with an intramural component, uterine perforation risks are increased if resection extends below the level of the normal myometrium. Therefore, when resection reaches this level, the surgeon should pause and wait for the surrounding myometrium to contract around the now smaller tumor. This delivers deeper portions of the leiomyoma into the uterine cavity. Diminishing the intrauterine pressure, by decreasing the fluid inflow pressure, can also help to deliver the myoma.

□ **Fluid Volume Deficit.** Because of the hypervolemia risk during hysteroscopic myomectomy, fluid volume deficits are care-

fully monitored throughout the procedure. The final fluid deficit is noted in the operative report.

□ **Hemostasis.** Bleeding is common during myomectomy and will often cease as the myometrium fibers contract due to the reduction in intracavitary volume. Vessels that are more actively bleeding may be coagulated with the edge of the resecting loop, and the electrosurgical unit set to a modulating (coagulating) current. At times, a ball electrode may be required to increase the surface area over which current is delivered. Global endometrial ablation offers a similar treatment in the case of multiple bleeding sites but is not suitable for patients desiring fertility. Rarely, bleeding may be poorly controlled with electrosurgical tools. In such cases, mechanical pressure applied to bleeding vessels by a Foley balloon inflated with 5 to 10 mL of saline may be required. This

can be left in for several hours depending on bleeding severity. The catheter is later removed, and vaginal bleeding is reassessed.

## POSTOPERATIVE

Recovery following myomectomy is quick and typically without complication. Patients may resume diet and activities as tolerated. Spotting or light bleeding may follow surgery for 1 to 2 weeks.

For patients desiring pregnancy, conception may be attempted in the menstrual cycle after the resection, unless the leiomyoma was broad-based or had a significant intramural component. In these patients, barrier contraception is advised for three cycles. For women who fail to conceive or continue to have abnormal bleeding following resection, postoperative hysterosalpingography or hysteroscopy is recommended to evaluate for intrauterine synechiae.

## 44-15

## Endometrial Ablation Procedures

Endometrial ablation broadly describes a group of hysteroscopic procedures that destroys or resects the endometrium and leads to eumenorrhea. For many women, ablation serves as a minimally invasive and effective treatment of abnormal uterine bleeding. Within the ablation group, techniques are defined as first- or second-generation depending on their temporal introduction into use and the need for hysteroscopic skills. First-generation tools require advanced hysteroscopic skills and longer operating times and can be associated with distention medium complications, such as volume overload. These techniques include endometrial vaporization with the neodymium:yttrium-aluminum-garnet (Nd-YAG) laser, rollerball electrosurgical desiccation, and endometrial resection by resectoscope.

Comparing first-generation methods, it appears that all three produce similar outcomes in terms of bleeding and patient satisfaction. However, resection methods have been associated with more surgical complications, and thus desiccation methods may be preferred for women without intracavitary lesions (Lethaby, 2002; Overton, 1997).

To reduce risks and required specialized training of these early ablative tools, second-generation nonresectoscopic methods have been introduced during the past 10 years. These tools use various modalities to destroy the endometrium but do not require direct hysteroscopic guidance. Modalities include thermal energy, cryosurgery, electrosurgery, and microwave energy.

### PREOPERATIVE

#### ■ Patient Evaluation

Prior to ablation, complete evaluation of abnormal uterine bleeding should be completed. Accordingly, the possibility of pregnancy, endometrial hyperplasia or endometrial cancer, and active pelvic infection is excluded. During evaluation of bleeding, transvaginal sonography (TVS), saline infusion sonography (SIS), and hysteroscopy may be used solely or in combination (Chap. 8, p. 188). However, many second-generation ablation techniques require a normal endometrial cavity, and endometrial pathology, if identified, can be treated concurrently by several of these ablative methods. Thus, SIS and hysteroscopy are more sensitive than TVS for focal lesions, and either is preferred

for preoperative evaluation. In addition, several second-generation techniques are not appropriate for large endometrial cavities. Thus, uterine depth is also assessed preoperatively by uterine sounding or sonography.

Myometrial thinning from prior uterine surgery may increase the risk of damage to surrounding viscera during ablation. Therefore, women with prior transmural uterine surgery are evaluated for type and location of uterine scar. A history of prior classical cesarean delivery or of abdominal or laparoscopic myomectomy may be considered a relative contraindication to ablation. Some experts advocate the sonographic evaluation of myometrial thickness to determine whether a patient is a candidate for ablation, although no specific thickness has been established (American College of Obstetricians and Gynecologists, 2013b).

#### ■ Consent

Patients selecting ablation should be aware of success rates relative to other treatment options for abnormal bleeding (Chap. 8, p. 197). In general, rates of decreased menstrual flow range from 70 to 80 percent and of amenorrhea, from 15 to 35 percent (Sharp, 2006). Eumenorrhea, rather than amenorrhea, is considered the treatment goal. Therefore, a patient should not undergo ablation if guaranteed amenorrhea is desired. In addition, endometrial ablation effectively destroys the endometrium and is contraindicated in those who desire future fertility.

Endometrial tissue has tremendous regenerative capabilities. Therefore, premenopausal women are counseled before surgery regarding the need for adequate postoperative contraception. If pregnancy does occur, complications after ablation include prematurity, abnormal placentation, and perinatal morbidity. For this reason, many providers recommend concomitant tubal sterilization at the time of endometrial ablation (American College of Obstetricians and Gynecologists, 2013b).

However, in women with tubal sterilization, cornual hematometra or postablation tubal sterilization syndrome (PATSS) can develop from bleeding from regenerated or remnant endometrium. With cornual hematometra, blood is trapped between the postoperative cornual synechiae. With PATSS, blood collects between the occluded proximal tubal stump and synechiae to cause proximal hematosalpinx. Both conditions cause associated cyclic pain. Hysterectomy is commonly required for resolution (McCausland, 2002).

Following ablation, later evaluation of the endometrium for recurrent abnormal bleeding can be challenging. Namely, a Pipelle may not reach remnant endometrium, and endometrial stripe measurements may be less accurate. The American Society for Reproductive

Medicine (2008) advises against endometrial ablation in postmenopausal women because excluding malignancy in these women can be more difficult. Women with risks for endometrial cancer pose similar sampling challenges.

Complications associated with ablation mirror those with operative hysteroscopy, although the risk of fluid volume overload is avoided with second-generation tools.

#### ■ Patient Preparation

During hysteroscopic surgeries, bacteria in the vagina may gain access to the upper reproductive tract and peritoneal cavity. However, postablation infection is rare, and preoperative prophylactic antibiotics are generally not indicated. Because the endometrium can thicken from only a few millimeters in the early proliferative phase to deeper than 10 mm in the secretory phase, all first-generation techniques and some of the second-generation ones are ideally performed in the early proliferative phase. Otherwise, drugs that induce endometrial atrophy such as GnRH agonists, combination oral contraceptives, or progestins may be used for 1 to 2 months prior to surgery. Alternatively, curettage may be performed immediately prior to ablation.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Endometrial ablation is typically a day-surgery procedure, performed under general anesthesia. Some studies state that second-generation techniques may be satisfactorily completed in an outpatient setting with intravenous sedation, local anesthetic blockade, or both (Sambrook, 2010; Varma, 2010). The patient is placed in dorsal lithotomy position, and the perineum and vagina are surgically prepared.

□ **Selection of Distending Medium.** With first-generation procedures, distending medium is required and selected based on the destructive energy used as described in Chapter 41 (p. 903). In general, saline may be used for laser and bipolar electrical current, whereas monopolar tools require non-electrolyte solutions.

□ **Neodymium: Yttrium-Aluminum-Garnet Laser.** Introduced in the 1980s, the Nd-YAG laser was the first ablative tool. Under direct hysteroscopic observation and uterine distention with saline, a Nd-YAG laser fiber touches the endometrium and is dragged across the endometrial surface. This creates furrows of photocoagulated tissue that are 5 to 6 mm deep (Garry, 1995; Goldrath, 1981).

□ **Transcervical Resection of the Endometrium (TCRE).** In addition to less expense, because of the larger loop diameter, TCRE can be completed more quickly than laser fiber ablation. The shorter procedure duration can reduce the risk of excess media absorption.

This method uses a resectoscope with monopolar or bipolar electrical current to excise strips of endometrium. The resection technique is similar to that described for hysteroscopic myomectomy (p. 1040). The excised tissue strips are sent for pathologic evaluation. In cases with concurrent intra-uterine pathology such as endometrial polyps or submucous leiomyomas, TCRE can excise these lesions in addition to the endometrium.

However, TCRE has been associated with higher rates of perforation, especially at the cornua, where the myometrium is thinner. For this reason, many use a rollerball electrosurgical electrode in combination with TCRE, with the rollerball used in the cornua (Oehler, 2003).

□ **Rollerball.** A 2- to 4-mm ball-shaped or barrel-shaped electrosurgical electrode can be rolled across the endometrium as an effective means of vaporizing the tissue (Vancaille, 1989). Advantages to rollerball ablation compared with TCRE include shorter operating time, less fluid absorption, and lower perforation rates. Unfortunately, it is not effective in the treatment of intracavitary lesions, and pathology specimens are not obtained.

□ **Thermal Balloon Ablation.** Several thermal balloon ablation systems are now currently used worldwide (Fig. 44-15.1). Of these, only the ThermoChoice III Uterine Balloon Therapy System is approved for use in the United States. Other balloon systems available in other countries include the Cavaterm Plus system or the Thermablate Endometrial Ablation System.

The ThermoChoice III Uterine Balloon Therapy System is a software-controlled device designed to destroy endometrial tissue using thermal energy. After cervical dilation to 5.5 mm, the ThermoChoice device is inserted into the uterine cavity. Once inside the cavity, a 5-percent dextrose and water solution is instilled into a disposable silicone balloon at the tip and heated to coagulate the endometrium. During the treatment, the contained fluid within the balloon is circulated to maintain a temperature of 87°C (186°F) for 8 minutes. The balloon can be introduced without hysteroscopic assistance into the uterine cavity, and when inflated, it conforms to the cavity contour.

All hot-liquid balloon devices require no advanced hysteroscopic skills, and complication rates are low (Gurtchef, 2003; Vilos, 2004). One disadvantage is the requirement for an anatomically normal uterine cavity.

**FIGURE 44-15.1** ThermoChoice III Uterine Balloon Therapy System. (©Ethicon, Inc. Reproduced with permission.)

Some studies, however, have demonstrated successful use in patients with submucosal leiomyomas (Soysal, 2001). Another limitation is the required pharmacologic thinning prior to thermal ablation. Alternatively, mechanical thinning can be accomplished with dilatation and curettage prior to ablation.

□ **Hysteroscopic Thermal Ablation.** Several second-generation ablation procedures require a normal uterine cavity. However, the HydroThermAblator (HTA) system allows treatment of the endometrium concurrent with submucous leiomyomas, polyps, or abnormal uterine anatomy. Another advantage of this system is that it is

performed under direct hysteroscopic visualization, allowing the surgeon to observe the endometrium being destroyed. However, the risk of external burns from circulating hot water appears to be higher using this method compared other second-generation methods (Della Badia, 2007).

This tool is designed to ablate the endometrial lining of the uterus by heating an uncontained saline solution to a temperature of 90°C and recirculating it through the uterus for 10 minutes (Fig. 44-15.2). Spill through the fallopian tubes is avoided because hydrostatic pressure during the procedure remains below 55 mm Hg, which is well below pressures needed to open the tubes to the peritoneal

**FIGURE 44-15.2** Hysteroscopic thermal ablation.

**FIGURE 44-15.3** Impedance-controlled electrocoagulation.

**FIGURE 44-15.4** Cryoablation.

cavity. Similarly, the water seal created between the hysteroscope and internal cervical os prevents leakage of fluid into the vagina. For this reason, care is taken not to dilate the cervix to a diameter greater than 8 mm.

Initially, a hysteroscope is inserted into the 7.8-mm diameter disposable HTA sheath. This combination is introduced into the endometrial cavity to enable viewing while room-temperature saline is instilled into the uterine cavity. The fluid flow is then gradually heated and circulated to treat the endometrium. At the completion of the treatment phase, cool saline replaces the heated fluid, and the instrument is then removed (Glasser, 2003).

**Impedance-controlled Electrocoagulation.** The NovaSure endometrial ablation system consists of a high-frequency (radiofrequency) bipolar electrosurgical generator and a single-use, fan-shaped device constructed of metal mesh. The mesh fan is designed to contour to the shape of the endometrial cavity. During treatment, an attachment provides suction to draw the endometrium and myometrium up against the mesh electrode for improved contact and to remove generated vapor (Fig. 44-15.3). The treatment time of 2 minutes results in desiccation of the endometrium. An advantage of this system is that it does not require preoperative endometrial preparation. Although Food and Drug Administration (FDA) approval studies evaluated the system in normal uterine

cavities, it has been used successfully in patients with small submucosal leiomyomas and polyps (Sabbah, 2006).

**Cryoablation.** In addition to thermal damage, endometrial ablation can be achieved with extreme cold using the Her Option cryoablation system. Similar to the physics of cervical cryotherapy, gases compressed under pressure with this unit can generate temperatures of  $-100^{\circ}$  to  $-120^{\circ}\text{C}$  at the cryoprobe tip to produce an iceball. As an iceball grows, its leading edge advances through tissue, and cryonecrosis develops in those tissues reaching temperatures below  $-20^{\circ}\text{C}$  (Chap. 43, p. 989).

The Her Option cryoablation system contains a metal probe, which is covered by a 5.5-mm disposable cryoprobe. After dilatation of the cervix, the cryoprobe's 1.4-inch cryotip is placed against one side of the endometrial cavity and advanced to one uterine cornu (Fig. 44-15.4). Concurrent transabdominal sonography is required to ensure accurate cryotip placement and surveillance of the increasing iceball diameter, which is seen as an enlarging hypoechoic area. The first freeze is terminated after 4 minutes or sooner, if the advancing iceball reaches to within 3 mm of the uterine serosa. The cryotip is allowed to warm, is moved from the cornu, and is redirected into the contralateral cornu. A second freeze is performed for 6 minutes or less based on iceball advancement.

**Microwave Ablation.** The microwave endometrial ablation (MEA) technique uses microwave energy to destroy the endometrium. During the procedure, a microwave probe is inserted until the tip reaches the uterine fundus. Once placed, the probe tip is maintained at  $75^{\circ}$  to  $80^{\circ}\text{C}$  and moved slowly from side to side. Microwave energy is spread with a maximum penetration of 6 mm over the entire uterine cavity surface. Speed is an advantage, with the entire treatment completed in 2 to 3 minutes (Cooper, 1999). Due to complications of bowel burns in patients without evidence of uterine perforation, to obtain FDA approval, the manufacturers of the MEA system recommend preoperative myometrial thickness assessment to document at least a 10-mm thickness throughout the uterus (Glasser, 2009; Iliodromiti, 2011). MEA was FDA-approved in 2003, but Microsulis discontinued worldwide sales of the MEA device in 2011.

## POSTOPERATIVE

Advantages to endometrial ablation include rapid patient recovery and low incidence of complications. Patients may resume normal diet and activities as tolerated. Patients may expect light bleeding or spotting during the first postoperative days as necrotic endometrial tissue is shed. A serosanguinous discharge follows for 1 week and is replaced by a profuse and watery discharge for another 1 to 2 weeks.

## 44-16

## Transcervical Sterilization

Hysteroscopic sterilization is a minimally invasive, transcervical method to perform surgical sterilization. Currently, only two forms of transcervical sterilization are approved by the FDA. These are the *Essure Permanent Birth Control* system and *Adiana Permanent Contraception* system (Chap. 5, p. 117). However, the Adiana System is no longer manufactured, although not because of safety or efficacy concerns.

Essure employs a coil device, termed a *microinsert*, which is inserted into the proximal section of each fallopian tube. Once in place and released from its delivery catheter, the microinsert expands to anchor itself within the fallopian tube (Fig. 44-16.1). Over time, synthetic fibers within the microinsert incite a chronic inflammatory response and a local tissue ingrowth from the surrounding tube. This ingrowth leads to complete tubal lumen occlusion, which is documented by hysterosalpingography (HSG) at 3 months following surgery.

As with any permanent birth control method, candidates should be confident in their decision for sterilization. Contraindications include pregnancy or pregnancy termination within the prior 6 weeks, recent pelvic infection, known tubal occlusion, and for Essure, allergy to radiographic contrast medium or nickel.

### PREOPERATIVE

#### ■ Patient Evaluation

Pregnancy is excluded prior to sterilization using a serum or urine  $\beta$ -hCG test.

#### ■ Consent

For many women, hysteroscopic sterilization is a safe and effective method of birth control. Efficacy rates are comparable with current laparoscopic sterilization rates, although long-term data are limited (Magos, 2004). With proper placement, Essure appears to have similar or superior contraceptive efficacy compared with other methods of sterilization (Levy, 2007).

Effective bilateral tubal occlusion or insert placement may not be possible in all patients due to tubal ostium stenosis or spasm or an inability to visualize the ostia (Cooper, 2003). Rates of successful placement average 88 to 95 percent (Kerin, 2003; Ubeda, 2004).

In general, complications of transcervical sterilization are similar to those of hysteroscopy. However, rates of fluid volume overload are low because in most cases procedure lengths are short (15 to 30 minutes) and opening of endometrial vascular channels is minimal. Uterine or tubal perforation has been noted. Rates approximate 1 to 2 percent, and in most cases, these are clinically insignificant (Cooper, 2003; Kerin, 2003). A perforated Essure insert may need to be removed from the peritoneal cavity to prevent complications. Chronic pelvic pain and insert erosion or migration can also occur.

#### ■ Patient Preparation

Because menstrual bleeding and a thick endometrium can impair identification of tubal ostia, this procedure is typically performed during the early proliferative phase of the menstrual cycle. This also decreases the chance of an unidentified luteal-phase pregnancy. Preoperative analgesia may be considered and typically consists of a nonsteroidal antiinflammatory drug given 30 to 60 minutes

before the procedure. Prophylactic antibiotics are not required.

### INTRAOPERATIVE

#### ■ Instruments

The Essure system is disposable and comes individually wrapped. It contains a handle, delivery catheter, release catheter, delivery wire, and microinserts. Each microinsert is attached to the end of a delivery wire, which is housed within a release catheter. In turn, the release catheter is surrounded by a delivery catheter.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Transcervical sterilization can be performed in an outpatient setting under local anesthesia with or without intravenous sedation. Alternatively, a day-surgery setting using general anesthesia may be selected. The patient is placed in the standard lithotomy position, and the vagina is surgically prepared.

□ **Media Selection.** For the Essure system, electrosurgery is not required, and therefore, 0.9-percent saline is commonly used to avoid the increased expense and risk of hyponatremia associated with nonelectrolyte solutions. As with any hysteroscopic procedure, accurate calculation of fluid volume deficits during the procedure is essential. The final deficit is recorded within the operative note.

□ **Hysteroscope Insertion.** Vaginal retractors or speculum provides access to the cervix, and a tenaculum may be used for adequate cervical traction to insert the hysteroscope. Depending on the diameter of the operative hysteroscope, standard cervical dilatation may or may not be required. A 12- to 30-degree hysteroscope is preferred to provide easy visualization of the cornua, and a 5F operating channel is needed.

□ **Essure Microinsert Delivery.** Requisite for completion of the procedure, both tubal ostia must be visualized. To begin delivery, the outermost catheter of the system, the *delivery catheter*, is threaded through the operating channel of the hysteroscope. Its tip is inserted into one tubal ostium. This delivers the tightly coiled, collapsed insert into the ostium. The delivery catheter is then retracted into the Essure device handle, and an inner cannula, which is the *release catheter*, is now seen. As the release catheter is retracted, the microinsert begins to uncoil. Ideally, if correctly placed, three to eight coils of the microinsert trail into the endometrial cavity (Fig. 44-16.2). As a final step, a guide

FIGURE 44-16.1 Microinsert placement and ingrowth of tissue.

**FIGURE 44-16.2** Hysteroscopic photograph of Essure microinsert coils within the tubal ostium. (Reproduced with permission from Bayer.)

wire that is attached to the distal end of the microinsert is detached and retracted. These steps are repeated at the opposite ostium.

### POSTOPERATIVE

Patients typically resume normal diet and activity within the first 24 hours following surgery. Cramping is common within the first few days, and light spotting or bleeding may be noted during the week following surgery.

To document complete tubal occlusion, HSG is performed at 3 months following

insertion (Fig. 44-16.3). Until this time, an alternative method of contraception should be used. Rarely, in those with correct placement, tubal occlusion may not be complete at 3 months, and a second HSG at 6 months may be required to document sterilization. Of note, although Essure microinserts are radiopaque with fluoroscopy, the Adiana silicone implant is not visible. Microinserts can be expelled. Thus, if no Essure device is identified during HSG or if 18 or more of its coils are seen trailing into the uterine cavity, then the microinsert should be replaced or

**FIGURE 44-16.3** Hysterosalpingography displaying correct Essure microinsert placement. (Reproduced with permission from Bayer.)

an alternative method of contraception used (Magos, 2004).

Essure microinserts conduct thermal energy, and this is factored into future surgery across the proximal fallopian tube. Also, synechiae after endometrial ablation can obscure Essure HSG. Thus, ablation and Essure insertion are not performed concurrently. However, following HSG confirmation, Novasure, HTA, and Thermachoice III are thermal methods that can be performed with Essure inserts in place (Aldape, 2013). Last, MR imaging can safely be completed in those with Essure inserts.

## 44-17

## Hysteroscopic Septoplasty

Most uterine septa form from incomplete regression of the medial portion of the müllerian ducts during their fusion (Fig. 44-17.1) (Chap. 18, p. 406). These septa rarely result in infertility. However, they have been associated with malpresentation and increased rates of first- and second-trimester spontaneous abortion. This serves as the main indication for septoplasty.

Before the popularity of operative hysteroscopy, septoplasty was performed abdominally and with a hysterotomy incision. Fortunately, hysteroscopic septoplasty affords MIS with decreased morbidity to the patient and uterus. *Septoplasty* refers to central division of the septum in a caudad-to-cephalad direction, generally with the use of hysteroscopic scissors. Bleeding is minimal due to the relative avascularity of the septum's fibroelastic tissue, which retracts upon incision. *Septum resection* is performed for broader, larger septa that have wider bases. A loop resectoscope or morcellator may be preferred for this.

### PREOPERATIVE

#### ■ Patient Evaluation

Diagnosis of a septate uterus follows guidelines outlined in Chapter 18 (p. 422) and includes HSG, SIS, and transvaginal sonography. Because of the frequent association between renal and müllerian anomalies, intravenous pyelography is also performed. Finally, although a septate uterus is associated with infertility and pregnancy loss, evaluation for other causes of these two conditions is completed prior to septum excision. Contraindications to septoplasty include

**FIGURE 44-17.1** Hysteroscopic photograph of uterine septum. The dark uterine cavity is seen on either side.

pregnancy and active pelvic infection, and these should be excluded.

#### ■ Consent

Hysteroscopic septoplasty is a safe and effective treatment for recurrent pregnancy loss, and postoperative live birth rates approximate 85 percent (Fayez, 1987). In general, complications mirror those for operative hysteroscopy, although the risk of uterine perforation appears increased. For this reason, concurrent laparoscopy in some cases is recommended to help inform a surgeon as to the proximity of the uterine serosa. As the hysteroscope nears the fundal serosa, transillumination of the hysteroscopic light indicates the potential for uterine perforation. Accordingly, a patient may also be consented for concurrent diagnostic laparoscopy as outlined on page 1003.

#### ■ Patient Preparation

Infectious and VTE complications following hysteroscopic surgery are rare. Accordingly, preoperative antibiotics or VTE prophylaxis is typically not required (American College of Obstetricians and Gynecologists, 2013c, 2014b). Misoprostol may be used preoperatively to ease cervical dilatation (p. 901).

### INTRAOPERATIVE

#### ■ Instruments

Septum incision or resection can be completed using hysteroscopic scissors, resectoscope loop, Nd-YAG laser, or mechanical morcellators. Selection is according to septum dimensions and surgeon preference.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Hysteroscopic septoplasty is typically a day-surgery procedure performed under general anesthesia. A woman is placed in standard

**FIGURE 44-17.2** Septum incision.

lithotomy position, the vagina is surgically prepared, and a Foley catheter inserted. If surveillance laparoscopy is planned, then the abdomen is also prepared.

□ **Medium Selection.** The choice of distending medium is dictated by the incising tool used. Sharp incision with scissors, Nd:YAG laser, or bipolar instrument is commonly selected and can be performed in any liquid medium. Monopolar technology will require a hypotonic nonconductive medium.

□ **Concurrent Laparoscopy.** If planned concurrently, placement of the laparoscope follows the steps described in Chapter 41 (p. 889).

□ **Cervical Dilatation.** A tenaculum is placed on the anterior cervical lip. Using a Pratt or other suitable dilator, the surgeon serially dilates the cervix.

□ **Instrument Insertion.** The distending medium flow is begun, and the operative hysteroscope is inserted into the endocervical canal under direct visualization. Upon entering the endometrial cavity, a panoramic inspection is first performed to identify the septum.

□ **Septum Incision.** If scissors are used, a surgeon attempts to keep the line of incision in the anteroposterior midline. Transection begins caudally, at the septum apex, and continues cephalad toward the fundus. Bites with the scissors are taken bilaterally and are directed toward the horizontal midline (Fig. 44-17.2). During incision of the septum, drifting from the vertical midline is common. Incisions typically drift posteriorly in an anteverted uterus and anteriorly in a retroverted one. Thus, a surgeon may pause and reorient periodically.

During septoplasty, incision rather than complete resection of the septum is sufficient. Septal stumps are retracted into the myometrium as the septum is transected. In most cases, the septum is relatively avascular, and cutting at its midpoint causes little bleeding. Signs that transection is complete include increasing tissue vascularity, serosal transillumination of the hysteroscope at the uterine fundus, and reaching a level in line with the tubal ostia.

□ **Septum Resection.** In some cases, the septum is broad, wide, and difficult to simply incise. Thus, to achieve the desired uterine cavity, a surgeon must completely excise or resect the septum. In general, scissors may be used, but in some instances, vaporizing electrodes, loop electrodes, or morcellators are more useful. Instruments are selected according to surgeon skill and preference.

### □ Procedure Completion

After incision completion, the hysteroscope and tenaculum are removed. The final fluid deficit is noted in the operative report. Final steps of laparoscopy, if performed, follows those outlined in Chapter 41 (p. 1005).

## POSTOPERATIVE

Recovery following septoplasty is rapid and typically without complication. Light bleed-

ing or spotting may last 1 week or more. Patients may resume normal diet and activities as desired. Following resection, symptoms such as dysmenorrhea ultimately are greatly decreased.

To stimulate endometrial proliferation and prevent adhesion reformation, oral estrogen administration has proved effective. Although several regimens can be used, we prescribe 2 mg of estradiol, orally for 30 days.

Attempts at conception are delayed for 2 to 3 months following surgery. If septum resection appeared incomplete at the time of surgery or if recurrent miscarriage or amenorrhea develops, then postoperative HSG or a second hysteroscopy may be performed. Complete removal of the septum or adhesiolysis may be required (p. 1052). With subsequent pregnancy, if the myometrium was not entered, cesarean delivery is required only for obstetric indications.

## 44-18

## Proximal Fallopian Tube Cannulation

Proximal fallopian obstruction may result from pelvic inflammatory disease, intratubal debris, congenital malformations, tubal spasm, endometriosis, tubal polyps, and salpingitis isthmica nodosa. It is generally diagnosed during evaluation of infertility when documentation of tubal patency is sought. Therapeutic options have the goal of a successful pregnancy. Therefore, approaches to occlusion in this portion of the tube include tubal cannulation, surgical tubocornual anastomosis, and in vitro fertilization (IVF) (Kodaman, 2004). During cannulation, attempts are made to flush debris from within the tubes and perform chromotubation.

Proximal fallopian tube cannulation may be used to treat up to 85 percent of proximal tubal obstructions, but the occlusion may recur following the surgery. It may be performed as an outpatient radiologic procedure using fluoroscopy (Papaioannou, 2003). Alternatively, cannula placement may be completed with hysteroscopic guidance (Confino, 2003). If a hysteroscopic approach is selected, laparoscopy is typically used concurrently. This allows evaluation and treatment of both proximal and distal tubal disease and provides identification of tubal perforation by the cannulating guide wire if this occurs.

### PREOPERATIVE

#### ■ Patient Evaluation

Proximal tubal occlusion is typically identified with HSG during evaluation of female infertility. To avoid disrupting an early pregnancy, preoperative  $\beta$ -hCG testing is warranted in most patients. Although this procedure may be performed at any time during the menstrual cycle, the early proliferative phase offers the advantage of a thinner endometrium to allow easy identification of tubal ostia and avoids disruption of an early luteal-phase pregnancy.

#### ■ Consent

In addition to general complications associated with hysteroscopy and laparoscopy, patients undergoing proximal tubal cannulation are informed of the small risk of tubal perforation. Fortunately, because the guide wire measures only 0.5 mm in diameter, tubal damage is rarely significant and can be

assessed by concurrent laparoscopic examination of the perforated tube.

In most cases, patients with combined proximal and distal tubal disease are best managed with IVF. As discussed in Chapter 9 (p. 224), hydrosalpinges, when present, can lower IVF success rates and are typically removed. Thus, consideration of and consent for salpingectomy should accompany plans for proximal tubal cannulation.

#### ■ Patient Preparation

The risk of pelvic infection is low. However, because adhesions following such infection can have damaging effects on fallopian tube health, patients are given either a first- or second-generation cephalosporin prior to surgery. In addition, misoprostol may be used preoperatively to aid cervical softening and hysteroscope insertion.

### INTRAOPERATIVE

#### ■ Instruments

Fallopian tubes may be cannulated with a catheter system displayed in [Figure 44-18.1](#). This system contains an outer cannula, inner cannula, and inner guide wire. The preset bend of the outer cannula aids placement of both the inner cannula and guide wire into the tubal ostium. Once the inner cannula has been threaded into the proximal fallopian tube, the guide wire is removed. The inner cannula, now emptied of the guide wire, can be used to flush debris from the fallopian tube and allow chromotubation, which is visualized laparoscopically ([Fig. 19-9, p. 441](#)).

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Hysteroscopic tubal cannulation with

concurrent laparoscopy is typically an outpatient procedure performed under general anesthesia. The patient is placed in standard lithotomy position, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted.

□ **Medium Selection.** No electrosurgery is required for tubal cannulation, thus saline is the preferred medium.

□ **Laparoscopy.** The laparoscope is inserted as described in Chapter 41 (p. 889).

□ **Cervical Dilatation.** Because a smaller diameter operative hysteroscope is required for tubal cannulation, cervical dilatation may not be required. If needed, it is performed as described in Chapter 43 (p. 967).

□ **Hysteroscope Insertion.** The flow of saline is begun, and a 0- or 30-degree hysteroscope is inserted. A panoramic inspection of the entire cavity is performed, and the tubal ostia are identified.

□ **Tubal Cannulation.** The catheter system is threaded through an operating port of the hysteroscope. Under direct visual guidance, the outer catheter is advanced and placed at one of the tubal ostia. The inner catheter is then threaded approximately 2 cm into the proximal fallopian tube ([Fig. 44-18.2](#)). The guide wire is removed.

□ **Tubal Flushing.** The inner catheter is flushed with water-soluble dye. Indigo carmine dye or methylene blue can be diluted and used. However, current indigo carmine shortages may favor methylene blue use. Either agent is diluted into 50 to 100 mL of sterile saline for injection. The laparoscope is positioned to allow inspection of the distal tube to note the presence or absence of dye spill.

**FIGURE 44-18.1** Hysteroscopic tubal cannulation catheter.

**FIGURE 44-18.2** Tubal cannulation.

□ **Concurrent Procedures.** If distal tubal adhesions are noted, laparoscopic lysis of adhesions may be concurrently performed.

□ **Procedure Completion.** Following cannulation, the hysteroscope and cervical tenaculum are removed. Laparoscopy is completed as described in Chapter 41 (p. 1005).

## POSTOPERATIVE

Recovery from hysteroscopic tubal cannulation and laparoscopy is typically quick and uncomplicated. Patients may resume diet, activity, and attempts at conception as desired.

## 44-19

## Lysis of Intrauterine Adhesions

Intrauterine adhesions, also called *synechiae*, may develop following uterine curettage (Fig. 44-19.1). Less commonly, they may result from pelvic radiation, tuberculous endometritis, or endometrial ablation. The presence of these adhesions, also termed *Asherman syndrome*, may lead to hypo- or amenorrhea, pelvic pain, and infertility or pregnancy loss.

Treatment goals include surgical re-creation of normal intrauterine anatomy and prevention of adhesion reformation. Surgery involves hysteroscopic transection rather than excision of adhesions. Thus, thin adhesions can usually be lysed using only gentle blunt force from the hysteroscopic sheath. However, dense adhesions usually require hysteroscopic division with scissors or laser.

Postsurgical pregnancy and live delivery rates are markers of surgical success, and these rates vary depending on the thickness of adhesions and degree of cavity obliteration. For this reason, various adhesion classification systems are useful to help predict the success of adhesiolysis for a given woman (Al-Inany, 2001).

### PREOPERATIVE

#### ■ Patient Evaluation

Although hysteroscopy and saline infusion sonography (SIS) can both accurately identify adhesions, HSG is preferred initially,

because it allows concurrent assessment of tubal patency. However, after adhesions have been noted, diagnostic hysteroscopy is recommended to assess the thickness and density of these bands (Fayez, 1987). Additionally, completion of fertility assessment, including semen analysis and assessment of ovulation, is recommended prior to surgery to help predict chances of conception following the procedure.

#### ■ Consent

In general, hysteroscopic adhesiolysis is an effective tool to correct menstrual disorders and improve fertility in women with uterine adhesions (Valle, 2003). Although overall cumulative delivery rates in those with no other fertility factors ranges from 60 to 70 percent, lower rates generally are associated with more severe disease (Pabuccu, 1997; Zikopoulos, 2004). In addition, pregnancies following surgery may be complicated by placental implantation abnormalities or by preterm labor (Dmowski, 1969; Pabuccu, 2008).

The complications mirror those for operative hysteroscopy. However, the risk of uterine perforation may be increased. For this reason, patients should also be consented for diagnostic laparoscopy.

#### ■ Patient Preparation

Infectious and VTE complications following hysteroscopic surgery are rare. Accordingly, preoperative antibiotics or VTE prophylaxis is typically not required (American College of Obstetricians and Gynecologists, 2013c, 2014b). Additionally, intraoperative intra-cervical dilute vasopressin or preoperative misoprostol may be used to soften the cervix and ease dilatation (Chap. 41, p. 901).

**FIGURE 44-19.1** Hysteroscopic photograph of intrauterine adhesions. (Used with permission from Dr. Kevin Doody.)

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Hysteroscopic lysis of adhesions is typically a day-surgery procedure performed under general anesthesia. The patient is placed in standard lithotomy position, the vaginal is surgically prepared, and a Foley catheter inserted.

##### □ Medium Selection.

The choice of distending medium is dictated by the tool used. Sharp transection with scissors, Nd:YAG laser, or bipolar instrument can be performed in any liquid medium. However, thick adhesions often require resection rather than division, and they are severed close to the myometrium. Thus, the potential for creation of large denuded areas and fluid intravasation is great. Accordingly for many surgeons, 0.9-percent saline is preferred because hyponatremia less likely if fluid overload does develop.

##### □ Concurrent Laparoscopy.

There is an increased risk of uterine perforation in those with more severe obliteration of the cavity. Thus, adjunctive laparoscopy may guide surgeons as to instrument proximity to the uterine serosa. The decision to use a laparoscope is individualized, and its placement follows the steps described in Chapter 41 (p. 889).

□ **Cervical Dilatation.** Using Pratt or other suitable dilators, the surgeon serially dilates the cervix as described in Chapter 43 (p. 967).

□ **Instrument Insertion.** The distending medium flow is begun, and the operative hysteroscope is inserted into the endocervical canal under direct visualization. Upon entering the endometrial cavity, a panoramic inspection is first performed to identify adhesions.

□ **Approach to Lysis.** In general, a systematic approach to adhesiolysis begins with either blunt or sharp disruption of the most central adhesions and moves gradually to reach the most lateral. The size and qualities of adhesions may vary. Thin endometrial adhesions can usually be disrupted with gentle blunt force from the hysteroscopic sheath alone. More commonly, myofibrous and fibrous adhesions are denser and may require complete resection.

Adhesiolysis is continued until the endometrial cavity is restored to normal and the tubal ostia are seen. Importantly, procedures may require termination prior to this, if significant fluid volume deficits are reached.

□ **Chromotubation.** At completion of adhesiolysis, transcervical chromotubation

is performed to document tubal patency. Chromotubation may be performed by injecting dye into the uterine cavity through a uterine manipulator during simultaneous laparoscopy. Alternatively, tubal cannulation as described previously may be performed to establish tubal patency (p. 1050).

□ **Mechanical Uterine Cavity Distention.** This option has been used to prevent treated areas from adhering following surgery. Either a copper IUD, placed for 3 months, or an 8F pediatric Foley catheter balloon, used for 10 days, may be chosen. In a comparison of the two, Orhue and colleagues (2003) noted fewer new adhesions

and greater pregnancy rates in women using the balloon. If a Foley balloon is placed, antibiotic prophylaxis with either doxycycline 100 mg orally twice daily or other appropriate antibiotic is recommended.

## POSTOPERATIVE

Recovery from hysteroscopic resection is rapid and typically without complication. Patients may resume normal activities and diet as tolerated.

To stimulate endometrial proliferation and prevent reformation of adhesions, oral estrogen administration has proved effective. Although several regimens can be used, we

prescribe 2 mg of estradiol, orally for 30 days following adhesiolysis. Conjugated equine estrogen (Premarin) 1.25 mg may also be used. Following IUD insertion, 6 to 8 weeks of oral estrogen supplementation is given.

New adhesions can form following adhesiolysis. In their early stages, these bands are thinner and thus more amenable to successful resection. For this reason, another hysteroscopy or HSG is typically performed at 3 months following the initial resection. If significant new adhesions are found, a second surgical lysis of adhesions is planned. To allow adequate uterine healing, attempts at pregnancy by the patient are delayed for 2 to 3 months.

### 45-1

## Diagnostic and Operative Cystoscopy and Urethroscopy

During gynecologic surgery, the lower urinary tract may be injured. Thus, diagnostic cystoscopic evaluation is often warranted following procedures in which the bladder and ureters

have been placed at risk. Additionally, operative cystoscopy is within the scope of many gynecologists for the passage of ureteral stents, lesion biopsy, and foreign-body removal. Of these, ureteral stenting may be indicated to delineate the ureter's course during cases with abnormal pelvic anatomy or to assess ureteral patency following gynecologic surgery.

Rigid and flexible cystoscopes are available, although in gynecology, a rigid scope is typically used. A cystoscope is composed of an outer sheath, bridge, endoscope, and obturator. The sheath contains one port for

fluid infusion and a second port for fluid egress. For office cystoscopy, a sheath measuring 17F affords greater comfort. However, for operative cases, a 21F or wider-diameter cystoscope is preferred to allow rapid fluid infusion and easier instrument and stent passage. The sheath's end tapers, and in women—with a narrow urethral meatus, an obturator can be placed inside the sheath to create a rounded tip for smooth introduction. In selected instances, gentle dilation of the external urethral opening using narrow cervical dilators is needed prior to sheath introduction. The next piece,

**FIGURE 45-1.1** Cystoscopic optical views.

the bridge, attaches to the proximal portion of the sheath and allows coupling between the endoscope and sheath. Additional ports are present on the bridge and are generally used to introduce stents or instruments.

Several endoscope viewing angles are available and include 0-, 30-, and 70-degree optical views (Fig. 45-1.1). Zero-degree endoscopes are used for urethroscopy. For cystoscopy, a 70-degree endoscope is superior for providing the most comprehensive view of the lateral, anterior, and posterior walls; trigone; and ureteral orifices. To achieve a comparable view, a 30-degree endoscope requires additional manipulation. However, a 30-degree endoscope does offer advantages and allows surgeons greater flexibility as it can be used for either urethroscopy or cystoscopy during a given examination. For operative cystoscopic cases in which instruments are passed down the sheath, a 30-degree endoscope should be used because with 0- and 70-degree endoscopes, operative instruments generally lie outside the field of view.

## PREOPERATIVE

Prior to office cystoscopy, urinary tract infection (UTI) is excluded to avoid upper tract infection. If diagnostic cystoscopy is performed properly, complications are rare. Of these, infection is the most common and results from the significant incidence of bacteriuria following cystoscopy.

## INTRAOPERATIVE

### Surgical Steps

□ **Anesthesia and Patient Positioning.** Cystoscopy may be performed in low or

standard lithotomy position with the legs positioned in stirrups. For office cystoscopy, 2-percent lidocaine jelly is instilled into the urethra 5 to 10 minutes prior to cystoscope insertion. For operative procedures, an additional 50 mL of 4-percent lidocaine solution may be instilled via catheter into the bladder. The perineum and urethral meatus are surgically prepared prior to urethral manipulation.

□ **Distention Media.** The bladder must be adequately distended to fully visualize all surfaces, and for diagnostic purposes, saline or sterile water is suitable. To ensure adequate medium flow, an infusion bag is elevated significantly above the level of the symphysis. The volume needed may vary but is reached when bladder walls are not collapsing inward. Overdistending the bladder is also avoided as it may result in temporary urinary retention. If the bladder is distended beyond its capacity, excess fluid will leak out the urethral meatus and around the cystoscope rather than rupturing the bladder, which is rare.

□ **Indigo Carmine.** If intraoperative cystoscopy is performed to document ureteral patency,  $\frac{1}{2}$  to 1 ampule of indigo carmine is administered intravenously prior to the procedure to aid visualization of urine jets. Less commonly, methylene blue may be used instead but carries the risk of methemoglobinemia in patients with glucose-6-phosphate dehydrogenase deficiency. However, its use may increase given current shortages of indigo carmine (American Urogynecologic Society, 2014a).

□ **Cystoscopy.** The anterior urethral wall is sensitive, and discomfort may result if the sheath's tapered edge is directed anteriorly. Thus, the sheath is inserted into the urethral meatus with the bevel directed posteriorly. Immediately following insertion into the external urethral opening, medium flow is begun.

The cystoscope is advanced toward the bladder under direct visualization. Often, in women with anterior wall prolapse, the urethra slopes downward, and the scope tip is similarly directed. During the procedure, the cystoscope can be steadied with one hand holding the sheath near the urethral meatus (Fig. 45-1.2).

□ **Bladder Inspection.** Upon entry into the bladder, the cystoscope is slowly withdrawn until the bladder neck is identified. The cystoscope is then advanced and rotated 180 degrees so that the light-source cable is pointing down. In this position, an air bubble is noted at the dome, which provides orientation for the remainder of the cystoscopic examination. When a 70- or 30-degree scope is used, the cystoscope is angled upward to view this bubble. To maintain orientation during rotation, the camera is held static while the light cord and cystoscope are rotated (Fig. 45-1.3).

As the distended bladder assumes a spherical shape, it is systematically inspected on each side from apex to internal urethral opening. First, to view the entire left side of the bladder, the cystoscope and light cable are rotated

**FIGURE 45-1.2** Cystoscope steadied during procedure.

**FIGURE 45-1.3** Orientation during cystoscopy is maintained by holding the camera steady while the light cord and cystoscope are rotated.

approximately 90 degrees in a clockwise fashion. The surgeon's left hand is used to prevent awkward hand crossing. To examine the bladder wall from 12 to 3 o'clock positions, the cystoscope is initially angled upward and then pans down to the 3 o'clock position, at which point the scope is parallel to the floor. Next, inspection from 3 to 6 o'clock requires gradual downward angling of the cystoscope. The left ureteral orifice is generally found at the 5 o'clock position, approximately 3 to 4 cm proximal to the internal urethral opening. During bladder inspection, especially the base or posterior wall, digital elevation of the anterior vaginal wall to lift the bladder floor and orifices to a more anatomically correct position is beneficial if pelvic organ prolapse is present. Moreover, accentuated angling may be needed. Once the left orifice is noted, further subtle clockwise rotation of the cystoscope along the interureteric ridge permits isolation of the right ureteral orifice.

The cystoscope is again rotated so that the light-source cable is again pointing downward and the bubble at the dome is again identified. For the right side, counterclockwise movement of the cystoscope and light cord with the surgeon's right hand averts awkward hand crossing. The right wall of the bladder is then similarly examined.

While horizontal to the floor, the cystoscope is withdrawn to the bladder neck and then angled downward to provide a second view of the trigone and both ureteral orifices and to document ureteral patency. Brisk urine flow, with or without indigo carmine, should be seen from each orifice. Peristalsis of the ureteral orifice alone, without flow, is insufficient to document patency. Moreover, scant flow may indicate partial ureteral obstruction and merits further evaluation.

The average time to efflux approximates 10 minutes but can be longer. After 20 minutes, absent jets bilaterally more often reflect hypovolemia and resolve with fluid bolus.

Following this bolus, 10 to 20 mg of furosemide (Lasix) can be added as needed to promote diuresis. Underlying renal disease may also delay efflux. During inspection, a unilateral jet is more concerning for ureteral injury. To evaluate, the surgeon can attempt to thread a stent through the ureteral orifice and into the ureter, as described in Step 8. Repair of ureteral injury is described in Chapter 40 (p. 868).

**Operative Cystoscopy.** For this procedure, the operative instrument (biopsy or grasping forceps or scissors) is introduced through the operating port, until viewed at the end of the cystoscope. Prior to instrument insertion, a rubber adapter cap is positioned over the operating port to create a watertight seal with the operative instrument. Once in view, the instrument and cystoscope are moved together as a unit toward the area of interest.

**Ureteral Stenting.** Ureteral stents may be placed at several junctures during surgery. They may be inserted at the beginning of surgery and left through its duration to define anatomy in cases in which the ureter is at high surgical risk of injury. Alternatively, they may be threaded intraoperatively to document ureteral patency and exclude injury. Finally, ureteral stents may be positioned and left in place at the conclusion of surgery if ureteral injury is suspected or identified. Duration of postoperative stenting is variable and based on indications.

Ureteral stents are available in various sizes, and those ranging from 4 to 7 F are commonly used. Stents vary in length from 20 to 30 cm, and a 24-cm length is appropriate for most adults. Generally, open-ended or whistle-tip stents are used to delineate anatomy or to exclude obstruction. Double- or single-pigtail stents are used in situations that require prolonged ureteral drainage.

**To Exclude Ureteral Obstruction.** A 4F to 6F open-ended or whistle-tip stent is threaded through the operating channel of a 30-degree cystoscope and into the field of view. By advancing both the stent and cystoscope toward the orifice, the stent is passed into the ureteral orifice. After the stent has entered the opening, it is manually threaded and advanced. Alternatively, an Albarrán bridge may be used. This specialized bridging sheath allows deflection and guidance of a stent into an orifice.

Once inserted, a stent is advanced past the level of suspected obstruction. If a stent threads easily, obstruction is excluded. In most gynecologic surgery, this would not be higher than the pelvic brim, which should be 12 to 15 cm from the ureteral orifice in adults. When passing a stent, undue pressure is avoided during advancement to avoid ureteral perforation. Efflux should be documented after stent removal.

If ureteral transection or stricture is suspected from the above steps, a cone-tip ureteral catheter is inserted, and dye is injected into the distal ureter to locate extravasation or point of narrowing. This is done intraoperatively with fluoroscopic guidance. If dye flows to the renal pelvis easily and no extravasation noted, ureteral injury is unlikely.

If gross blood issues from an orifice prior to ureteral manipulation, the ureter may be partially transected. Even if good efflux is noted, many insert and maintain a double-J stent for approximately 4 weeks. In such cases, a computed tomography (CT) urogram or renal sonogram is completed 4 to 12 weeks after stent removal to exclude stricture.

After the above interrogations, absent efflux from one orifice may uncommonly reflect a long-standing unilateral nonfunctioning kidney. For this, postoperative CT and nuclear scan can be selected.

**To Delineate Anatomy.** For this purpose, the stent is advanced until resistance is met, which indicates that the renal pelvis has been reached. The stent is tied securely to the transurethral catheter and drains into the cystoscopy drape. At the conclusion of surgery, the stent is removed.

**Ureteral Stenting.** In cases in which a ureteral stent is required postoperatively, a double-pigtail stent is used. The proximal coil of the stent prevents renal pelvis injury, and the distal coil secures placement in the bladder.

For placement, a guide wire is first threaded into the ureteral orifice and passed to the renal pelvis. The pigtail stent is then placed over the guide wire and advanced by a pusher device until the distal end enters the bladder. The guide wire is removed, allowing the ends to coil in the renal pelvis and

bladder, respectively. Correct upper coil positioning is confirmed intraoperatively using fluoroscopy or plain film radiograph. Stents are usually kept for 2 to 8 weeks depending on the injury identified or suspected. They are generally removed in the office with cystoscopic guidance.

#### ⑩ Biopsy and Foreign Body Removal.

Mucosal lesions can be biopsied with minimal risk or discomfort to the patient. A biopsy instrument is introduced into the cystoscope's operating port and brought into the operative field. With the instrument in view, the cystoscope is moved directly to the lesion. Biopsy is performed, and the cystoscope and instrument are withdrawn through the urethra together. In this way, a biopsy specimen is not pulled through the sheath and possibly lost. Bleeding is usually minor and will stop by itself. For brisk bleeding, electrosurgical coagulation can be used if a nonconducting solution was selected as the distention medium. As described in Chapter 41 (p. 903), electrolyte solutions such as saline cannot be used with monopolar electrosurgery. These solutions conduct current, thus dissipating the energy and thereby rendering the instrument useless.

Foreign bodies, such as stones, are removed using the same technique as biopsy. The instrument is used to grasp the foreign body and then removed together with the cystoscope.

**⑪ Suprapubic Teloscopy.** This is a technique used to visualize the bladder through an abdominal approach. We have found suprapubic teloscopy to be valuable when the ureters must be assessed during a difficult cesarean delivery or during a laparotomy in which a woman has not been positioned to allow easy cystoscopic access to the urethra.

The bladder is distended using the transurethral Foley catheter until the bladder wall is tense. A wide purse-string using 2-0 gauge absorbable suture is then placed

FIGURE 45-1.4 Suprapubic teloscopy.

at the bladder dome, taking deep bites into the bladder muscularis (Fig. 45-1.4). The two suture ends are elevated but held loosely. A small stab incision is then made in the purse-string's center, and a cystoscope is introduced into the bladder. This incision is preferably made in the retropubic or extraperitoneal portion of the bladder dome to minimize risk of fistula formation. For suprapubic teloscopy, a 30-degree cystoscope is most effective. The two suture ends are then pulled up and held tightly to prevent the escape of distending fluid. To allow visualization of the trigone and ureteral orifices, the Foley bulb is deflated but left in place. Indigo carmine or methylene blue is given if necessary to document ureteral efflux. If the ureteral orifices still cannot be visualized, the bladder incision is extended inferiorly into the retropubic portion to allow direct visualization. At the conclusion

of teloscopy, the cystoscope is removed, and the purse-string suture is tied, closing the cystotomy.

#### POSTOPERATIVE

Office cystoscopy does not require specific postoperative management except for prophylactic antibiotics to cover common urinary tract pathogens. At our institution, we prescribe a single perioperative dose. With operative cystoscopy, hematuria may develop, but it generally clears within a few days and is considered significant only if associated with symptomatic anemia.

With long-term ureteral stenting, additional complications may include ureteral spasm, which typically presents as back pain. Stone formation and stent fragmentation are less common but can occur if length of catheterization exceeds 8 weeks.

## 45-2

## Burch Colposuspension

Abdominal antiincontinence procedures attempt to correct stress urinary incontinence (SUI) by stabilizing the anterior vaginal wall and urethrovesical junction in a retropubic location. Specifically, the Burch procedure, also known as *retropubic urethropexy*, uses the strength of the ilipectineal ligament (Cooper ligament) to stabilize the anterior vaginal wall and anchor the wall to the musculoskeletal framework of the pelvis (Fig. 38-24, p. 817).

The Burch colposuspension is usually performed through a Pfannenstiel or Cherney incision. In the past 20 years, some have introduced laparoscopic approaches that use suture or mesh to affix the paravaginal tissues to Cooper ligament (Ankardal, 2004; Zullo, 2004). Compared with open Burch colposuspension, laparoscopic approaches offer similar postoperative rates of subjective cure, despite some evidence for poorer objective outcomes (Carey, 2006; Dean, 2006). Longer-term results will also define its role.

### PREOPERATIVE

#### ■ Patient Evaluation

Prior to surgery, patients undergo complete urogynecologic evaluation. Although not required for uncomplicated demonstrable SUI, urodynamic testing can help differentiate stress and urgency incontinence and assess bladder capacity and voiding patterns (Chap. 23, p. 526).

Many women with SUI may also have associated pelvic organ prolapse. For this reason, other indicated pelvic reconstructive surgeries commonly accompany Burch colposuspension. A required hysterectomy does not appear to improve or worsen Burch procedure success rates (Bai, 2004; Meltomaa, 2001).

#### ■ Consent

For most women with SUI, Burch colposuspension offers a safe, effective long-term treatment for incontinence. In one systematic review, overall continence rates ranged from 85 to 90 percent at 1 year and declined to 70 percent by 5 years (Lapitan, 2012). Surgical risks compare similarly with other surgeries for SUI (Green, 2005; Lapitan, 2003). Intraoperative complications are rare and may include ureteral injury, bladder or urethral

perforation, and hemorrhage (Galloway, 1987; Ladwig, 2004).

Complications following surgery, however, are not uncommon and may include urinary tract or wound infection, voiding dysfunction, de novo urinary urgency, and pelvic organ prolapse—primarily enterocele formation (Alcalay, 1995; Demirci, 2000, 2001; Norton, 2006). Overcorrection of the urethrovesical angle has been suggested as a cause of these long-term urinary and prolapse complications.

#### ■ Patient Preparation

The American College of Obstetricians and Gynecologists (2014) recommends antibiotic prophylaxis prior to urogynecologic surgery, and appropriate choices mirror those for hysterectomy (Table 39-6, p. 835). For all patients undergoing major gynecologic surgery, thromboprophylaxis is also recommended (Table 39-8, p. 836). Bowel preparation is based on surgeon preference and on concurrent surgeries planned.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Burch colposuspension may be performed under general or regional anesthesia as an

inpatient procedure. The patient is placed supine with legs in booted support stirrups in low lithotomy position. The abdomen and vagina are surgically prepared, and a Foley catheter is inserted.

□ **Abdominal Incision.** A low Pfannenstiel or Cherney incision is performed (Section 43-2, p. 929). Surgery in the space of Retzius (retropubic space) is easier to accomplish if the incision is placed low on the abdomen, approximately 1 cm above the upper border of the pubic symphysis. If hysterectomy, culdoplasty, or other intraperitoneal procedure is planned, the peritoneum is entered and concurrent surgery completed prior to colposuspension. If the procedure is done in isolation, fascia of the anterior abdominal wall muscles and then transversalis fascia are incised, but entry into the peritoneal cavity is not required to reach the retropubic space.

□ **Entry into the Space of Retzius.** Between the lower anterior abdominal wall peritoneum and pubic bone lies an avascular plane, that is, the space of Retzius. To enter this retropubic space, the fingers of one hand gently dissect along the cephalad surface of the pubic bone. Alternatively, gentle sponge dissection can be used to open this space (Fig. 45-2.1). Loose areolar tissue is found behind the symphysis within this space and easily separates from the bone. However,

FIGURE 45-2.1 Entry into the space of Retzius.

entry into the wrong tissue plane risks bleeding and bladder injury. Direct exposure of the back of the pubic bone ensures that the correct space has been entered. The bladder and urethra are gently pulled downward and away from the pubic bone, and the space of Retzius opens.

In those with prior surgery, sharp dissection is generally required. Dissection begins with the curved tips of Metzenbaum scissors placed directly on the pubic bone and progresses dorsally until the space is exposed. Sutures can be used to control bleeding from torn paravaginal vessels.

During space of Retzius dissection, the obturator canal is identified early to avoid neurovascular injury to the obturator vessels and nerves. The canal is typically found 1.5 to 2.5 cm below the upper border of the iliopectineal ligament and approximately 5 to 7 cm from the midline of the upper border of the symphysis pubis (Drewes, 2005). Accessory obturator vessels that commonly pass over Cooper ligament to enter the obturator canal are also identified. These can be lacerated during pronounced retraction to expose Cooper ligament.

#### □ **Exposing the Anterior Vaginal Wall.**

After opening this space, fingers of the surgeon's nondominant hand are placed intravaginally at the vagina's midlength and just behind the pubic bone. With one on each side, the finger pads straddle the urethra and push the vagina ventrally. Working within the retropubic space and beginning at the lateral borders of the urethra, gentle downward and lateral pressure against the finger pad bluntly dissects away fat. This exposes the pearly white periurethral tissue between the arcus tendineus fascia pelvis (ATFP), which lies laterally, and urethra, which is medial. If necessary, a surgeon can use a Kittner (peanut) sponge or gauze sponge stick. Importantly, to protect the delicate urethral musculature, this dissection remains lateral to the urethra.

Aggressive dissection or Burch sutures may lacerate vessels within the Santorini plexus of paravaginal veins and risk significant bleeding (Fig. 38-24, p. 817). This is easily controlled with upward pressure from the vaginal fingers. Identified vessels can then be ligated.

□ **Urethrovesical Junction.** Identifying this site aids correct suture placement. To isolate the urethrovesical junction, the surgeon's vaginal hand positions the Foley catheter balloon at the bladder neck. Undue

**FIGURE 45-2.2** Suture placement.

tension on the Foley catheter is avoided as this can drag the bladder into the operative field and increase the risk of sutures entering the bladder.

□ **Suture Placement.** For exposure, the surgeon's vaginal finger presses upward, and the bladder neck is gently displaced by an assistant to the contralateral side by a narrow retractor. To suspend tissue, a double-armed suture of 2-0 gauge nonabsorbable material is placed laterally on each side of the urethra. A first suture is placed 1.5 to 2 cm lateral to the proximal third of the urethra. The needle point is directed toward the vaginal finger, and a thimble may be used to avoid needle-stick injury. For this suturing, a figure-of-eight stitch is used and incorporates vaginal wall while excluding epithelium. A second suture is then placed 1.5 to 2 cm lateral to the urethrovesical junction. Identical sutures are placed on the opposite side of the urethra (Fig. 45-2.2).

Both ends of each suture are then placed through the nearest point of the ipsilateral iliopectineal ligament. Slack is removed from each suture, and knots are tied above the ligament. With knot securing, suture bridges are expected, and these should stabilize but not elevate the anterior vaginal wall and urethrovesical junction. The vaginal wall is stabilized approximately at the level of the distal portion of the ATFP and not significantly higher. Greater elevation of the bladder neck risks postoperative voiding dysfunction.

□ **Cystoscopy.** Following suture ligation, cystoscopy is performed. This allows identification and removal of any errant sutures that may traverse the bladder or urethral mucosa. Moreover, it enables a surgeon to inspect the ureteral orifices and document efflux.

□ **Catheterization.** After colposuspension, the Foley catheter may remain to drain the bladder. Alternatively, a suprapubic catheter may be placed. Investigators comparing the two have found no differences in antiincontinence procedure success rates, length of hospitalization, or rates of infection. Urethral catheterization, however, was linked with a shorter duration of catheterization but also greater patient discomfort (Dunn, 2005; Theofrastous, 2002).

□ **Incision Closure.** The anterior abdominal wall peritoneum is generally closed to prevent displacement of small bowel into the retropubic space. The remaining abdominal wall incision is closed as described in Section 43-2 (p. 930).

## POSTOPERATIVE

In general, recovery follows that associated with laparotomy and varies depending on concurrent surgeries and incision size. A voiding trial as described in Chapter 42 (p. 917) is performed prior to hospital discharge.

## 45-3

## Tension-Free Vaginal Tape

The tension-free vaginal tape procedure (TVT) is the most commonly performed operation worldwide for stress urinary incontinence. The procedure is one of the most widely studied incontinence operations, and cure rates up to 17 years approximate 80 percent (Holmgren, 2005; Nilsson, 2013; Song, 2009). The TVT procedure has also become the prototype for a host of other incontinence operations, which include the TOT (transobturator tape), TVT-O (tension-free vaginal tape obturator), and single-incision midurethral slings (“mini-slings”). These are all considered midurethral slings (MUS) and are based on the concept that midurethral support is vital to continence.

Tension-free vaginal tape placement is indicated for SUI that is secondary to urethral hypermobility or intrinsic sphincteric deficiency (Chap. 23, p. 522). It is used for primary cases and for women who have had prior antiincontinence procedures.

During TVT, a permanent sling material is placed underneath the midurethra, traverses the periurethral tissue, passes behind the pubic bone through the space of Retzius, and exits through the anterior abdominal wall. Once positioned, tissue ingrowth ultimately holds the mesh in place. During placement, the TVT needle is directed blindly through the space of Retzius and can lacerate vessels there to create significant bleeding. A modification of the TVT, the TOT was developed to avoid hemorrhage in this space and to decrease bladder and bowel perforation risks (p. 1063). However, the TVT remains the primary standard operation for SUI.

The TVT device consists of a permanent polypropylene mesh covered with a plastic sheath that is removed after the mesh is positioned. The plastic sheath is believed to prevent bacterial contamination of the mesh as it passes through the vagina and to protect the mesh from being damaged during passage. Once these plastic sheaths are removed, the mesh remains fixed in position. The mesh is attached to two metal disposable needles that are connected to a reusable metal introducer during placement. A metal catheter guide is used to displace the urethra away from the needle during the procedure.

### PREOPERATIVE

#### ■ Patient Evaluation

Prior to TVT procedures, a diagnosis of SUI must be made as described in Chapter 23

(p. 523). Importantly, in some women, SUI can be occult and masked by pelvic organ prolapse that kinks and partially obstructs the urethra. Accordingly, prolapse replacement to reestablish more normal anatomy during urodynamic testing may help unmask this potential SUI. Also of note, caution is exercised in patients who are Valsalva voiders. These women void with abdominal straining rather than with detrusor contraction and urethral relaxation. Most incontinence procedures prevent leakage by closing the urethra during cough or Valsalva maneuver. Therefore, these surgeries, when performed in women who rely on the Valsalva maneuver to urinate, will often result in voiding dysfunction. This tenet applies to all midurethral sling procedures.

#### ■ Consent

The consenting process for TVT should include an honest discussion of outcomes. At best, the 5-year cure rate is 85 percent, with another 10 percent significantly improved. However, some patients will develop postoperative urgency incontinence, and others will develop bothersome voiding dysfunction. Additionally, with time and aging, incontinence may recur secondary to factors not related to urethral support.

As for all antiincontinence procedures, prior to surgery, the patient is provided surgical success rates from the literature and those of the individual surgeon. Moreover, the definition of “outcome success” varies from woman to woman. For example, in a patient with severe incontinence and 20 leakage episodes per day, improvement to one leakage episode every other day would be considered successful. However, in a woman with rare leakage, it may be more difficult to achieve an outcome considered satisfactory. Therefore, patient’s expectations are discussed prior to surgery.

The short-term complications of the TVT procedure include incomplete bladder emptying requiring drainage with Foley catheter or intermittent self-catheterization for several days. A small percentage of patients will develop long-term urinary retention requiring reoperation for tape division or excision (p. 1072). In these women, continence rates decrease. The TVT procedure is associated with a learning curve, and urinary retention rates decline as the number of cases a physician performs accrues. Postoperatively, vaginal mesh erosion may develop as an early or late complication. This is managed by simple excision of the piece of eroding tape and vaginal wall revision. Of note, the American Urogynecologic Society (2014b) considers the mesh used for this sling to be safe and effective.

Intraoperative complications include hemorrhage, bladder perforation, and rarely, bowel injury. Major vessels are injured in less than 1 percent of cases.

#### ■ Patient Preparation

The American College of Obstetricians and Gynecologists (2014) recommends antibiotic prophylaxis prior to urogynecologic procedures, and appropriate choices mirror those for hysterectomy (Table 39-6, p. 835). For all patients undergoing major gynecologic surgery, thromboprophylaxis is recommended (Table 39-8, p. 836). Bowel preparation is based on surgeon preference and mainly on concurrent surgeries planned.

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

The procedure was initially described as an ambulatory surgical procedure performed under local anesthesia. However, it can also be performed with regional or general anesthesia. If performed solely, TVT in most cases is a day-surgery operation. The procedure is performed in standard lithotomy position. The vagina is surgically prepared, and an 18F Foley catheter, which allows passage of a rigid catheter guide, is inserted to assist in deflection of the urethra during needle passage.

□ **Abdominal Incisions.** To begin, two ½-cm skin incisions are made at the level of the upper border of the symphysis, and each lies no further than 2 cm from the midline. More lateral placement risks ilioinguinal nerve injury (Geis, 2002).

□ **Vaginal Incisions.** A midline incision is made sharply in the vaginal epithelium and superficial vaginal muscularis beginning 1 cm proximal to the external urethral opening and is extended 1.5 to 2 cm cephalad. Allis clamps are placed on the edges of the vaginal incision for traction. Using Metzenbaum scissors, bilateral periurethral tunnels are created beneath the vaginal epithelium on either side of the urethra. These tunnels extend several centimeters toward the inferior pubic rami to allow placement of the TVT needle just behind the pubic bone.

□ **Catheter-guide Placement.** A rigid guide is placed through the 18F Foley catheter. During passage of TVT needles, a surgical assistant uses the catheter guide to deflect the urethra to the contralateral side to lower urethral injury risks.

**FIGURE 45-3.1** Needle placed through periurethral tunnel.

□ **Mesh Placement.** The TVT needle and mesh are attached to the introducer. The needle is placed through one of the periurethral tunnels so that its point touches the front surface of the ipsilateral pubic ramus (Fig. 45-3.1). A hand placed in the vagina then carefully guides the needle around the back of the ramus. The needle is then curved upward toward the ipsilateral abdominal incision, perforates the periurethral tissue just behind the pubic bone, and enters the

retropubic space (Rahn, 2006). During this, the needle is always directly behind the pubic bone. Pressure is applied to the introducer handle with the other hand, but the vaginal hand controls the needle's direction. The handle of the introducer always remains parallel to the ground to avoid lateral excursion into major vessels and obturator nerve (Fig. 45-3.2). Additionally, after the needle passes around the pubic ramus and behind the symphysis, its tip is always directed

**FIGURE 45-3.2** Correct and incorrect introducer positioning. **A.** Dark introducer, correct position. The tip is directed in the midline to a position behind the pubic bone. The handle is parallel to the ground. **B.** White introducer, incorrect position. The tip is directed laterally.

toward the abdominal wall incisions. The bladder may be perforated if excessive pressure is applied and if the needle is aimed cephalad rather than toward the abdominal wall (Fig. 45-3.3). Small changes in the position of the hand applying handle pressure can lead to bladder perforation.

□ **Cystourethroscopy.** After the needle perforates the abdominal wall, the Foley and catheter guide are removed, and cystourethroscopy is performed with a 70-degree cystoscope. The bladder is distended with 200 to 300 mL of fluid, and inspection for cystotomy is completed. Generally, perforation will be obvious, and the TVT needle will be seen entering and exiting the bladder. In this situation, the needle is removed and redirected, and correct placement is confirmed by cystoscopy. Inspection of the urethra is also essential and can be performed with the same 70-degree angle scope. Alternatively, a 0-degree or 30-degree endoscope may be used. Iatrogenic trocar bladder injury, if identified intraoperatively does not appear to influence continence outcomes or increase postoperative voiding dysfunction or infection rates (Zyczynski, 2014).

In contrast to bladder perforation, urethral perforation theoretically carries a risk of urethrovaginal fistula. Thus, if urethral perforation is noted, most surgeons abort the procedure and postpone until several months later.

After cystoscopy, the introducer is unscrewed from the needle. The needle is brought through the abdominal wall. The needle is then cut from the mesh, and the mesh is held with a hemostat. Next, the other TVT needle is attached to the introducer and is placed on the other side of the urethra in a similar fashion. Cystourethroscopy is then repeated.

□ **Setting Mesh Position.** A hemostat or similar instrument is placed between the suburethral tissue and the tape to act as a spacer and create distance between the mesh and urethra (Fig. 45-3.4). This spacing avoids excessive mesh tension and lowers the risk for postoperative urinary retention and voiding dysfunction.

Prior to sheath removal, the vaginal sulci are inspected to exclude perforation of the vaginal epithelium occurring during needle guidance. If perforated mesh is seen, the tape is removed, and the TVT needle is again passed through a newly created periurethral tunnel that lies slightly medial to the original. The vaginal perforation defect is repaired with one or two simple interrupted delayed-absorbable sutures.

□ **Sheath Removal.** Once the tape is satisfactorily positioned, an assistant then removes the plastic covering around the

**FIGURE 45-3.3** Correct (dark introducer) and incorrect (light introducer) hand and introducer positioning.

mesh, while the surgeon holds the mesh at the desired distance from the urethra using the spacer instrument. The plastic covering is lifted away from both sides with minimal tension to avoid mesh stretching or undue

urethral elevation. With ideal positioning, a few millimeters of free space separate the suburethral tissue and mesh. The mesh is trimmed just below the skin at the abdominal incisions (Fig. 45-3.5).

□ **Wound Closure.** The vaginal incision is closed in a running fashion with 2-0 gauge delayed-absorbable suture. The abdominal incisions may be closed with Dermabond or with a single interrupted 4-0 gauge delayed-absorbable skin suture.

## POSTOPERATIVE

Prior to discharge from a day-surgery unit, an active voiding trial is performed (Chap. 42, p. 917). If the patient fails this trial, a Foley catheter is replaced and kept for 1 to 3 days prior to a second voiding trial. Alternatively, a patient can be taught self-catheterization. This is continued until postvoid residual volumes fall below about 100 mL.

Normal diet and activity can resume during the first postoperative days. Intercourse, however, is postponed until the vaginal incision is healed, usually at 6 weeks. The time to resumption of exercise and strenuous physical activity is controversial. A standard recommendation has been to delay these at least 2 months, although there are no data supporting this. However, logic would suggest that this is reasonable for adequate healing.

**FIGURE 45-3.4** Setting mesh position.

**FIGURE 45-3.5** Sheath removal and tape trimming.

## 45-4

## Transobturator Tape Sling

The transobturator tape (TOT) sling procedure is a variation of the midurethral sling procedures, which began with tension-free vaginal tape (TVT) (p. 1063). With the TOT procedure, a permanent sling material is inserted bilaterally through the obturator foramen and extends underneath the midurethra. As a result, the space of Retzius is avoided and thereby minimizes the potential for associated bladder and bowel injuries. Bleeding in the space of Retzius is a primary TVT complication, and avoiding this space is an attractive TOT feature. Additionally, in patients who have had prior incontinence procedures and have scarring in the space of Retzius, bladder perforation may be averted by avoiding dissection in this space.

The procedure has several important differences from TVT, and there are also several modifications of the TOT procedure itself. Several companies produce kits containing required mesh and placement needles for TOT. The two major types of TOT procedures are defined by whether needle placement begins inside the vagina and is directed outward, termed an *in-to-out approach*, or starts outside the vagina and is directed inward, called an *out-to-in approach*. Limited data do not show superiority of one over the other (Debodinance, 2007). Currently, the out-to-in technique is more commonly performed and is described here.

Generally, TOT is indicated for primary SUI secondary to urethral hypermobility (Chap. 23, p. 525). In patients with SUI secondary to intrinsic sphincteric deficiency, the value of TOT is unclear, as results are conflicting and data are limited (Rechberger, 2009; Richter, 2010).

### PREOPERATIVE

#### ■ Patient Evaluation

Evaluation and preparation prior to TOT mirrors that for TVT (p. 1063).

#### ■ Consent

As with other surgeries for incontinence, the major risks of this procedure are voiding dysfunction, urinary retention, development of urgency incontinence, and failure to correct SUI. Groin and thigh pain appear to be another potential postoperative problem. Long-term complications may be associated

with the supporting mesh and include mesh erosion (Schimpf, 2014).

Intraoperatively, there is some risk of bladder or urethral perforation, although this is believed to be significantly less than that with TVT. Inappropriate TOT trocar placement rarely can lead to significant hemorrhage or neurologic deficits if obturator nerve and vessel branches are damaged in the thigh compartment.

### INTRAOPERATIVE

#### ■ Instruments

A TOT kit will contain two TOT needles and synthetic mesh tape. The TOT needle is designed to navigate the path from the entry point around the pubic rami to the midurethral vaginal wall incision. A plastic sheath surrounds the mesh tape and allows the mesh to be pulled into position smoothly. However, once these plastic sheaths are removed, the mesh remains fixed in position.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** If performed solely, a TOT procedure in most cases is a day-surgery procedure. It is performed in standard lithotomy position under general, regional, or local anesthesia. The vagina is surgically prepared, and a Foley catheter is placed to assist in determination of urethral location.

□ **Vaginal Incisions.** A midline incision is made sharply in the vaginal epithelium and superficial muscular layer beginning 1 cm proximal to the external urethral opening

and is extended 2 to 3 cm cephalad. Allis clamps are placed on the edges of the vaginal incision for traction. Using Metzenbaum scissors and blunt finger dissection, bilateral periurethral tunnels are created beneath the vaginal epithelium on either side of the urethra. These tunnels extend up to and behind the ischiopubic rami.

□ **Thigh Incisions.** A 0.5- to 1-cm entry incision is made bilaterally in the thigh-crease skin (genitocrural fold), 4 to 6 cm lateral to the clitoris, and at the point where the adductor longus insertion can be palpated. This muscle arises from the superior ramus of the pubis and inserts medially at the mid-length of the femur.

To summarize the needle's path, insertion starts along the lateral edge of the ischiopubic ramus just below the insertion of the adductor longus tendon and arches around the ramus. During this arc, the needle sequentially penetrates the gracilis, adductor brevis, and obturator externus muscles, obturator membrane, obturator internus muscle, and periurethral endopelvic fascia and exits through the vaginal incision.

□ **Mesh Placement.** The TOT needle is grasped, and the tip is placed in one of the thigh incisions (Fig. 45-4.1). The tip is directed cephalad until the obturator membrane is perforated, and a “popping” sensation is felt. A vaginal finger is placed in the ipsilateral vaginal tunnel and is positioned up to and behind the ischiopubic ramus. Using the curve of the TOT needle, the surgeon then directs the needle tip to the end of his finger and passes the needle into the vagina (Fig. 45-4.2). At this time, the vaginal sulcus is inspected to exclude perforation.

FIGURE 45-4.1 Needle introduction.

**FIGURE 45-4.2** Needle passage.

**FIGURE 45-4.3** Tape placement.

If the needle has perforated the sulcus epithelium, it is removed and reinserted correctly. Next, the TOT covered mesh is attached to the needle end, and the needle retraces its original path as it is withdrawn back through the thigh incision. With this, the covered mesh is threaded into position. The mesh is then removed from the needle. The procedure is repeated on the other side (Fig. 45-4.3).

□ **Setting Mesh Position.** A hemostat or similar instrument is placed and opened between the urethra and mesh to act as a spacer and create distance between the mesh and the urethra (Fig. 45-4.4). This spacing avoids excessive urethral elevation and lowers postoperative urinary retention risks. Prior to sheath removal, the vaginal sulci are again

inspected to exclude perforation. If mesh is seen in a sulcus, the tape is removed and reinserted on the affected side.

□ **Sheath Removal.** An assistant surgeon then removes the plastic covering of the mesh from each of the thigh incisions. Concurrently, the surgeon holds the mesh at the desired distance from the urethra using the spacer instrument. The plastic covering is removed with minimal tension to avoid mesh stretching. The mesh is trimmed just inside thigh incisions.

□ **Wound Closure.** The vaginal incision is closed in a running fashion with 2-0 gauge delayed-absorbable suture. The thigh incisions may be closed with a single interrupted subcuticular suture with 4-0 gauge delayed-

absorbable suture or with other suitable skin closure methods (Chap. 40, p. 847).

□ **Cystourethroscopy.** The procedure is marketed as one in which cystoscopy is not necessary. However, because the bladder and urethra can be injured, we recommend post-procedural cystoscopy.

## POSTOPERATIVE

Prior to discharge from a day-surgery unit, an active voiding trial is performed (Chap. 42, p. 917). If significant residuals persist, a Foley catheter remains. A second voiding trial can be repeated in a few days or at the surgeon's discretion. Alternatively, a patient can be taught self-catheterization. T is continued until postvoid residuals fall below approximately 100 mL.

Normal diet and activity can resume during the first postoperative days. Intercourse, however, is delayed until the vaginal incision is healed. The time to resumption of exercise and strenuous physical activity is controversial. A standard recommendation delays these at least 2 months. Data to support this are lacking, however, logic would suggest that this is reasonable to allow adequate healing.

**FIGURE 45-4.4** Setting mesh position.

## 45-5

## Pubovaginal Sling

Pubovaginal sling is a standard procedure for SUI. It has traditionally been used for SUI stemming from intrinsic sphincteric deficiency (Chap. 23, p. 522). In addition, this procedure may also aid patients with prior failed antiincontinence operations. It is generally not employed in a woman having her first surgery for incontinence.

In the past, different materials had been used for the sling, however, autologous fascia is currently preferred. Generally, this fascia is obtained from the patient's rectus sheath, although fascia lata from the thigh may alternatively be harvested. With this surgery, a strip of fascia is placed at the proximal urethra through the space of Retzius, and ends are secured either to each other or to the rectus fascia above the rectus abdominis muscle.

In contrast to midurethral slings, which generally employ premade kits and standardized procedural steps, the technical aspects of autologous fascia pubovaginal slings have greater variability. These include size and location of harvested tissue, anchoring method of the sling to the rectus fascia, and technique for determining mesh tension across the proximal urethra. Steps for the rectus fascial sling are described here.

### PREOPERATIVE

#### ■ Patient Evaluation

As with other antiincontinence procedures, patients require urogynecologic evaluation,

including urodynamic testing to confirm SUI and intrinsic sphincteric deficiency. Additionally, SUI often accompanies pelvic organ prolapse. Thus, the need for concurrent repair of associated prolapse is assessed prior to surgery (Chap. 24, p. 545).

#### ■ Consent

In addition to general surgical risks, patients are counseled regarding the risk of recurrent incontinence, urinary retention, and voiding dysfunction following surgery (Albo, 2007). Overall, traditional slings seem to be as effective as minimally invasive slings but have higher rates of adverse effects (Rehman, 2011).

#### ■ Patient Preparation

Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835). Bowel preparation is based on surgeon preference and mainly on concurrent surgeries planned.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Pubovaginal sling may be performed under general or regional anesthesia as an inpatient procedure. The patient is placed in standard lithotomy position, with lower extremities positioned in candy-cane or booted support stirrups. The abdomen and vagina are surgically prepared, and a Foley catheter is inserted.

□ **Graft Harvest.** A transverse skin incision is made 2 to 4 cm above the symphysis and is

large enough to allow removal of a transverse fascial strip that measures, at minimum, 1.5 cm wide  $\times$  6 cm long. The incision is carried down through subcutaneous tissue to the fascia.

The fascia to be harvested is outlined and then incised, sharply dissected away from the underlying rectus muscle bellies, and removed. Following removal, the strip is cleaned of fat and adventitial tissue. A helical stitch using 0-gauge polypropylene suture is then placed through the fascia at each end of the strip. This stitch is repeated at the other end. These sutures are not tied. The fascial incision is then closed in a running fashion with 0-gauge delayed-absorbable suture.

□ **Vaginal Incision.** At a point 2 cm proximal to the external urethral orifice, a 3- to 5-cm midline vertical incision is made sharply in the anterior vaginal wall and extended cephalad. Alternatively, a U-shaped incision is made at the level of the bladder neck. Sharp and blunt dissection is used to separate the vaginal epithelium from the underlying fibromuscular layer. The space of Retzius is then entered with a combination of sharp and blunt dissection bilaterally by penetrating the periurethral connective tissue (Fig. 45-5.1). Entry into this space is confirmed by the surgeon's finger palpating the dorsal surface of the pubic bone (Fig. 45-5.2). During entry, Santorini's venous plexus can be lacerated, and bleeding is controlled with compression or stitches of 2-0 gauge absorbable suture.

□ **Fascia Placement.** A 0.5- to 1-cm long fascial incision is made no further than 2 cm from the midline on each side. These are placed caudal to the prior harvest incision and just above the pubic bones. A long

FIGURE 45-5.1 Entry into the space of Retzius.

FIGURE 45-5.2 Palpation of pubic bone.

**FIGURE 45-5.3** Passing of dressing forceps.

dressing or packing forceps or needle ligature carrier is placed into one of these incisions and from above, perforates the rectus tendon. The instrument is placed against the back of the pubic bone and advanced toward the vagina. Concurrently, the surgeon guides the instrument to his finger within the space of Retzius and advances it into and through the vaginal incision (Fig. 45-5.3). At this time, cystourethroscopy is performed to exclude bladder or urethral perforation.

The suture ties at one end of the fascial strip are grasped with the perforating forceps and threaded up through the abdominal incision on one side of the urethra. With the other end of the sling, this step is repeated on the other side of the urethra. As a result, the fascial sling lies positioned below the bladder neck (Fig. 45-5.4). Usually four 2-0 gauge delayed-absorbable sutures may be used to fix the proximal and distal edges of the sling beneath the bladder neck to prevent displacement during sling positioning. Stitches are placed lateral to the urethra.

**Setting Sling Position.** Within the laparotomy incision, sutures attached to the sling ends from each side meet and are tied together above the rectus sheath. During knot tying, a space of two to three fingerbreadths is left between the knot and fascia to pre-

vent bladder neck obstruction and urinary retention. In addition, a hemostat is placed between the suburethral tissue and the fascial sling to create distance between the sling and urethra (see Fig. 45-4.4). After the knot

is secured, there should be no upward angulation of the urethra or bladder neck, and a few millimeters of free space should be noted between the fascial sling and the bladder neck.

**Cystourethroscopy.** Cystoscopy is again performed to exclude bladder or urethral perforation. In addition, excessive resistance noted during passage of the cystoscope into the bladder may suggest undue sling tension, which can lead to postoperative obstructive symptoms. If such resistance is noted, the sling is loosened.

**Vaginal Incision.** The vaginal incision is closed with 2-0 gauge delayed-absorbable suture in a running fashion. A Foley catheter is left in place. In the past, suprapubic tube insertion was common practice. However, with a trend toward tying the fascial sling with less tension, the risk of prolonged urinary retention is lowered, and suprapubic drainage is therefore not typically required.

**Abdominal Incision.** The two prior 1-cm fascial incisions are closed with an interrupted stitch of delayed-absorbable suture. The remaining abdominal incision is closed as described in Section 43-2 (p. 930).

## POSTOPERATIVE

In general, recovery follows that associated with laparotomy and is heavily dependent on incision size. A voiding trial as described in Chapter 42 (p. 917) is performed prior to hospital discharge.

**FIGURE 45-5.4** Fascial sling placed and sutured in place on vaginal side.

## 45-6

## Urethral Bulking Injections

Injection of bulking agents into the urethral submucosa is one method available to treat SUI that results from intrinsic sphincter deficiency (ISD) (Chap. 23, p. 522). Although mechanisms are not completely clear, effectiveness may result from expansion of the urethral walls, which allows them to better approximate or *coapt*. As a result, intraluminal resistance to flow is increased and continence is restored. Alternatively, injections elongate the functional urethra, and this may allow more even distribution of abdominal pressures across the proximal urethra to resist opening during stress (Monga, 1997).

Although traditionally recommended for treatment of SUI solely due to ISD, some evidence suggests it can be used to treat SUI resulting from combined ISD and urethral hypermobility (Bent, 2001; Herschorn, 1997; Steele, 2000).

Urethral injection offers a cystoscopically assisted, minimally invasive treatment of SUI. It can be performed in an office under local anesthesia and is associated with a low risk of complications. For these reasons, it is often chosen for women who wish to avoid surgery or who are not surgical candidates due to other comorbidities. Urethral injections can be performed both peri- and transurethrally. The transurethral approach is more often used and allows for more accurate placement of the bulking agent (Faerber, 1998; Schulz, 2004). Currently available agents in the United States approved for use include autologous fat and several synthetic agents described later.

### PREOPERATIVE

#### ■ Patient Evaluation

Complex urodynamic testing with assessment of urethral structure and function is completed. To assess for ISD, maximum urethral closure pressure or leak point pressure are specifically evaluated (Chap. 23, p. 527). Additionally, urethral mobility is assessed.

#### ■ Consent

Procedure efficacy is discussed, and success rates in general are lower than those for surgery. Specifically, 1-year rates of curing or improving SUI range from 60 to 80 percent (Bent, 2001; Corcos, 2005; Lightner, 2002, 2009; Monga, 1995). Continence

rates diminish with time, as would be intuitive, with the breakdown of collagen and fat. However, Chrouser (2004) found similar rates of decline with time even when synthetic material was compared with collagen. Accordingly, these injections are viewed as a nonpermanent treatment of SUI, and sustained continence is found in only 25 percent of patients at 5 years following injection (Gorton, 1999).

One major advantage to urethral injection is its low associated risk of complications. Side effects of injection are generally transient and may include vaginitis, acute cystitis, and voiding symptoms. Of these, urinary retention for a few days postprocedure is the most frequent. Long-term retention, however, is not a significant risk. A more serious complication is persistent *de novo* urgency, which may develop in as many as 10 percent of women following injection (Corcos, 1999, 2005).

#### ■ Patient Preparation

Prior to urethral injection, UTI and anatomic pathology such as urethral diverticula are excluded. Anecdotally, we have seen bulking agent migration into such diverticula. As noted, UTI can commonly follow urethral injection. Therefore, a single dose of an antibiotic to cover uropathogens is administered orally after procedure completion. Tromboprophylaxis is not typically required for this brief office procedure.

### INTRAOPERATIVE

#### ■ Choice of Bulking Agent

In the United States, currently used agents for urethral injection are carbon-coated synthetic microspheres (Durasphere), calcium hydroxylapatite particles (Coaptite), and polydimethylsiloxane (Macroplastique). These synthetic agents are effective. However, no randomized trials compare results among these three, and long-term data are lacking (Shah, 2012; Zoorob, 2012).

Of agents no longer used, autologous fat provided limited success for SUI due to rapid degradation and reabsorption (Haab, 1997; Lee, 2001). A bovine collagen product (Contigen) was commonly selected, but manufacturing ceased due to an inadequate supply of medical-grade collagen. Ethylene vinyl alcohol copolymer (Uryx/Tegress) was withdrawn due to urethral erosion complications.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Urethral injection for most patients can be

performed in an office setting with cystoscopic capability. The patient is placed in the dorsal lithotomy position, the vulva is prepared and draped, and the bladder drained. Two-percent lidocaine jelly is instilled into the urethra 10 minutes prior to the procedure. If necessary, topical 20-percent benzocaine can be used as an analgesic on the vulva, and 4 mL of 1-percent lidocaine can be injected in divided doses at the 3 and 9 o'clock positions of the external urethral orifice.

□ **Transurethral Approach to Needle Placement.** A cystoscope is positioned within the distal urethra, so that the midurethra, proximal urethra, and bladder neck are viewed simultaneously. A 22-gauge spinal needle attached to a syringe carrying the bulking agent is introduced through the cystoscopic sheath. With the bevel pointing toward the urethral lumen, the needle is directed at a 45-degree angle to the lumen and inserted through the urethral wall at the 9 o'clock position and at the level of the midurethra. After the needle tip penetrates the urethral wall, the bevel is no longer seen. The needle is then advanced parallel to the urethral lumen for 1 to 2 cm. This positions the needle at the level of the proximal urethra.

□ **Injection.** The bulking agent is injected under constant pressure, and the submucosal lining begins to rise (Fig. 45-6.1). The needle is withdrawn slowly to bulk the proximal and midurethra. Bulking agent is administered until coaptation of the mucosa has developed (Fig. 45-6.2). In general, 1 to 2 syringes (2.5 to 5 mL) of agent are used per procedure. These steps are then repeated at the 3 o'clock position.

Ideally, the number of needle holes made into the urethral wall is minimized to avoid leakage of bulking agent through these punctures. Thus, if a second syringe of agent is required to achieve coaptation, the originally positioned needle remains in place, and a second syringe of agent is attached.

□ **Cystoscope Removal.** Once coaptation of the mucosa is achieved, the cystoscope is removed, taking care not to advance proximal to the injection site. This avoids forceful compression of the deposited agent by the cystoscope tip and loss of coaptation.

### POSTOPERATIVE

Women are discharged home following their first postinjection void, and single-dose oral antibiotic prophylaxis is prescribed. Women abstain from intercourse for 10 days following injection but may otherwise resume usual activities.

**FIGURE 45-6.1** Injection of bulking agent.

**FIGURE 45-6.2** Corresponding cystoscopic views of urethral coaptation as bulking agent is injected, as shown in Figure 45-6.1.

If urinary retention develops, then intermittent self-catheterization is begun and continued until retention resolves. For those unable to self-catheterize, a temporary Foley catheter is placed. However, catheter placement can potentially compress deposited bulking agent and diminish urethral coaptation.

Two weeks following injection, we assess treatment success. If a patient fails to achieve desired degrees of continence, additional injections are planned to improve urethral coaptation.

## 45-7

## Urethrolysis

Urethrolysis is the loosening or release of a prior urethral suspension repair. This release is used in women with urethral obstruction symptoms including urinary retention and voiding dysfunction following suspension. It can be performed either vaginally or abdominally. A vaginal approach is predominantly used. An abdominal approach, however, may afford a better opportunity to mobilize the bladder from the pubic symphysis and may also be selected in instances in which the initial surgery was performed via laparotomy.

Debate exists as to the need of a concurrent antiincontinence procedure to compensate for urethral support lost with urethrolysis. However, in many cases, residual scarring prevents SUI, and our belief is to avoid repeating a second potentially obstructing procedure. Accordingly, this decision is individualized.

## PREOPERATIVE

## ■ Patient Evaluation

In women with bladder neck obstruction, symptoms usually begin soon after initial surgery. Objective assessment with urodynamic testing is performed to determine the cause of voiding dysfunction and differentiate between a hypotonic bladder and obstruction. Obstruction may result from bladder neck obstruction or

pelvic organ prolapse. Thus, a thorough examination for prolapse is completed.

## ■ Consent

In addition to usual surgical risks, bleeding may be a significant complication due to vascularity in the space of Retzius. Additionally, dissection of dense scarring around the urethra and bladder may place these structures at risk of laceration.

Due to scar tissue reformation, initial obstruction improvement can worsen over time, as scar tissue may variably reform. In contrast, postoperative incontinence may follow deconstruction of prior antiincontinence support or from denervation injury during extensive periurethral dissection.

## ■ Patient Preparation

As with all genitourinary procedures, UTI is excluded prior to surgery. Antibiotic prophylaxis is administered prior to surgery to decrease risks of postoperative wound and urinary tract infection (Table 39-6, p. 835). Tromboprophylaxis is provided as outlined in Table 39-8 (p. 836).

## INTRAOPERATIVE

## ■ Surgical Steps—Vaginal Approach

□ **Anesthesia and Patient Positioning.** Urethrolysis may be performed under general or regional anesthesia. The patient is placed

in standard lithotomy position with lower extremities in candy-cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter is inserted into the bladder.

□ **Vaginal Incision.** Traction is placed on the Foley catheter to identify the bladder neck and assess the degree of scarring. A 2- to 3-cm long incision, either vertical midline or U-shaped, is made in the anterior vaginal wall. The incision site will vary along the vaginal length depending on the location of the original sling or sutures (Fig. 45-7.1). Sharp dissection is used to separate the vaginal epithelium from underlying fibromuscular tissue and is extended bilaterally toward the inferior edge of each pubic rami.

Dissection frees the urethra by dividing scar tissue or prior sling material or sutures that lie between the urethra and pubic rami (Fig. 45-7.2). If prior supporting material is identified, it may be incised or if necessary, excised. Bleeding is frequently encountered and can be controlled with direct pressure or vessel ligation.

After this lateral dissection, the periurethral tissue is perforated, and the space of Retzius is entered. Careful blunt dissection within this space and at the back of the pubic symphysis will additionally mobilize the proximal urethra. Dissection is kept close to the dorsal surface of the pubic bone to avoid cystotomy in a bladder that is generally densely adhered to the pubic bone.

□ **Incision Closure.** Following adequate mobilization of the urethra, the vaginal incision

FIGURE 45-7.1 Vaginal incision.

FIGURE 45-7.2 Periurethral dissection.

**FIGURE 45-7.3** Dissection in the space of Retzius.

**FIGURE 45-7.4** Intentional cystotomy to aid bladder and urethral dissection.

is reapproximated with a running closure using 2-0 gauge delayed-absorbable suture.

### ■ Surgical Steps— Abdominal Approach

□ **Anesthesia and Patient Positioning.** As with a vaginal approach, urethrolisis may be completed under general or regional anesthesia. For an abdominal approach, booted support stirrups and low lithotomy positioning are preferred. This positioning allows vaginal access for the surgeon's hand during dissection and for cystoscopy. The abdomen and vagina are surgically prepared, and a Foley catheter is inserted into the bladder.

□ **Abdominal Incision.** A low transverse incision is typically preferred for this procedure to permit easy access to the space of Retzius. Either Pfannenstiel or Cherney incisions are usually selected (Sections 43-2 and 43-3, p. 929). If the procedure is done in isolation, fascia of the anterior abdominal wall muscles and then transversalis fascia are incised, but entry into the peritoneal cavity is not necessary to reach the space of Retzius.

□ **Entry into the Space of Retzius.** The correct plane of dissection to enter the space of Retzius lies directly behind the pubic bone. Loose areolar tissue is gently dissected downward in a mediolateral fashion with fingers or sponge, beginning immediately behind the pubic bone. If the correct plane is entered, this potential space opens easily. However, women requiring urethrolisis have typically had prior surgery within this space. As a result, tissue can be densely adhered and sharp downward dissection along the dorsal surface of the symphysis may be preferred to enter this space (Fig. 45-7.3).

□ **Bladder Dissection and Urethrolisis.** The bladder is also typically densely adhered to the back of the symphysis. Sharp dissection with the curved surface of scissors facing the symphysis is directed against the symphysis to minimize cystotomy risk. At times, however, an intentional cystotomy may be required so that a finger can be placed inside the bladder to aid dissection (Fig. 45-7.4).

Sharp dissection is continued inferiorly and laterally down the inner surface of the symphysis and pubic bones to free the bladder and eventually also the proximal urethra.

Bleeding is common during dissection and may be controlled with absorbable sutures.

□ **Abdominal Closure.** The abdomen is closed in a standard fashion (Sections 43-2 or 43-3, p. 930).

### POSTOPERATIVE

An active bladder test is performed following catheter removal. If large residual volumes are found, intermittent self-catheterization or Foley catheter replacement is required. If cystotomy was performed, the duration of catheterization is dependent on cystotomy size and location. For example, small cystotomies in the bladder dome typically require drainage for 7 days or less. For larger cystotomies at the bladder base, however, drainage for several weeks may be needed. Antibiotic suppression is not required with this catheter use.

Normal diet and activity can resume during the first postoperative days. With a vaginal approach, however, intercourse is postponed until the vaginal incision is well healed. Recovery from an abdominal approach follows that for laparotomy (Section 43-1, p. 928).

## 45-8

## Midurethral Sling Release

Symptoms of voiding obstruction may develop following urethral sling procedures, specifically TVT and TOT procedures. For most patients, postoperative urinary retention resolves in days or 1 to 2 weeks. However, voiding dysfunction requiring surgery develops in up to 3 percent and generally is identified days to weeks after surgery (Jonsson Funk, 2013; Nguyen, 2012; Richter, 2010). If obstruction is diagnosed soon after the index procedure, surgical release is performed and involves simple cutting of the sling material.

### PREOPERATIVE

#### ■ Patient Evaluation and Preparation

Inability to fully empty the bladder may stem from urethral obstruction or a hypotonic bladder. New-onset urinary retention after a midurethral sling procedure (TVT or TOT) is usually due to sling tightness. However, other factors can be involved, such as preexisting or de novo bladder hypotonia. Thus, prior to TVT urethrolisis, urodynamic testing is often performed to prove that symptoms are due to obstruction rather than to bladder hypotonicity. Additionally, tape may erode into the bladder or urethra in cases of obstruction, and cystoscopy allows exclusion of this complication.

Perioperatively, no specific patient preparation is required, as midurethral sling release is a minor surgical procedure.

#### ■ Consent

Associated with midurethral sling release, the risks of incontinence recurrence, failure to adequately relieve retention, fistula formation, and intraoperative bladder or urethral injury are discussed during consenting.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** This surgery can be performed with local,

regional, or general anesthesia as an outpatient procedure. A patient is placed in standard lithotomy position within candy-cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter is inserted.

□ **Vaginal Incision and Tape Identification.** A midline suburethral incision that follows the prior primary surgical incision is made sharply. Careful dissection is used to expose the sling material and to define the urethral borders. Alternatively, with prior TOT, tight tissue bands may be palpated in the sulci. In this case, the vagina can be incised at one sulcus, and the tape transected or partially excised here.

Often because of increased sling tension, sling material is stretched and measures only half its expected width. Additionally, there is usually extensive tissue ingrowth into the sling material, and identification and mobilization can be difficult. Occasionally, a sling may migrate to the proximal urethra. In these instances, the vaginal incision may require cephalad extension.

□ **Incision of Sling Material.** Following mobilization of the material, a hemostat is opened between the sling and urethra.

Metzenbaum scissors are used to cut the sling material. In general, incision leads to immediate retraction of sling ends (Fig. 45-8.1, top inset). If retraction does not follow, a 1-cm segment of material is then excised (see Fig. 45-8.1, bottom inset). If the sling is deeply embedded and near the urethral lumen, one to two imbricating layers are placed through the vaginal muscularis following sling excision using 2-0 or 3-0 gauge delayed-absorbable suture.

□ **Incision Closure.** After vigorous irrigation, the vaginal epithelium is closed in a continuous running fashion using 2-0 gauge delayed-absorbable suture.

### POSTOPERATIVE

Prior to discharge, an active voiding trial is performed (Chap. 42, p. 917). If a Foley catheter remains, a second voiding trial can be repeated in a few days or at the surgeon's discretion. If a woman is performing self-catheterization, this is continued until postvoid residuals fall below approximately 100 mL. Normal diet and activity can resume during the first postoperative days. Intercourse, however, should be postponed until the vaginal incision is healed.

**FIGURE 45-8.1** Mesh transection through vaginal incision. Inset top: Mesh incision and retraction. Inset bottom: Partial mesh excision.

## 45-9

## Urethral Diverticulum Repair

The approach to urethral diverticulum repair varies and depends on diverticular sac location, size, and configuration. For those near the bladder neck, partial ablation is often chosen to avoid damage to the bladder neck and continence mechanism. For midurethral diverticula, simple diverticulectomy is typically performed. For those located at the external urethral orifice, again, simple diverticulectomy is preferred to the Spence procedure. The latter is rarely performed and can alter final urethral orifice anatomy. Last, for those with a complex diverticulum that may surround the urethra, a combination of techniques may be necessary. Of these options, complete vaginal excision of the urethral diverticulum is preferred (Antosh, 2011).

### PREOPERATIVE

#### ■ Patient Evaluation

As described in Chapter 26 (p. 585), urethral diverticula can be difficult to diagnose due to their often varied and nonspecific presentations. Once identified, accurate information regarding diverticular anatomy is essential to surgical planning and patient counseling. Compared with transvaginal sonography or voiding cystourethrography, magnetic resonance (MR) imaging is a superior radiographic study to delineate diverticular configuration, especially with complex diverticula (Ockrim, 2009).

Additionally, cystoscopy is valuable in locating sac openings along the urethral length and demonstrates high specificity, as transurethral visualization of an ostium is unlikely to be associated with other diagnoses. That said, our frequency of urethral diverticulum detection (sensitivity) was only 39 percent (Pathi, 2013).

Women with diverticulum can present with urinary incontinence. In such cases, we typically perform baseline urodynamic testing but generally defer antiincontinence procedures until after postoperative reevaluation.

#### ■ Consent

With diverticular repair, damage to urethral continence mechanism may lead to postoperative incontinence. Alternatively, urethral stricture or stenosis or urinary retention may develop depending on the extent and location of surgery. Additionally, urethrovaginal

fistula and bladder injury can result. Recurrence rates of 10 to 25 percent have been reported, especially with a horseshoe or circumferential configuration or previous surgical intervention (Antosh, 2011; Ingber, 2011). Failures are believed secondary to incomplete diverticulum excision. Moreover, urethral pain can persist or arise after diverticulectomy (Ockrim, 2009). Recurrent UTI can also persist. Last, with the Spence marsupialization technique, a distal diverticulum and urethral orifice are sharply opened together to form a large single meatus. Thus, external urethral orifice anatomy is usually altered, and a spraying pattern with urination may result.

#### ■ Patient Preparation

Any acute diverticular infection or cystitis is treated prior to surgery. Preventatively, antibiotic and venous thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

### INTRAOPERATIVE

#### ■ Surgical Steps—Diverticulectomy

□ **Anesthesia and Patient Positioning.** Diverticulum excision is typically performed as an inpatient procedure under general or regional anesthesia. A patient is placed in standard lithotomy position within candy-

cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter containing a 10-mL balloon is placed in the bladder to assist in identifying the bladder neck.

□ **Cystourethroscopy.** This procedure is performed at the procedure's onset to attempt diverticular opening identification and exclude other abnormalities.

□ **Vaginal Incision.** To begin, a midline or U-shaped incision is made on the anterior vaginal wall over the diverticulum, and the vaginal epithelium is dissected sharply off the fibromuscular layer of the vaginal wall (Fig. 45-9.1). Ample epithelium is freed to allow adequate exposure and to permit final tissue approximation without suture-line tension.

□ **Diverticulum Exposure.** Next, the fibromuscular layer of the vagina and urethra is incised with a longitudinal or transverse incision to reach the diverticular sac. Anatomically, the distal vaginal and urethral walls are fused, and it may be difficult or impossible to separate tissue planes. Thus, sharp dissection is needed to completely mobilize the diverticular sac away from the vaginal and urethral fibromuscular layer and to the level of the diverticular sac neck (Fig. 45-9.2). During dissection, the sac may be inadvertently or intentionally entered. With this, the diverticular walls can be grasped with Allis clamps to create tension across the connective tissue fibers between the diverticular

FIGURE 45-9.1 Vaginal incision.

FIGURE 45-9.2 Diverticular sac dissection.

walls and the vaginal fibromuscular layer to aid dissection. Similarly, an index finger placed within the sac can recreate sac fullness to stretch these same connective tissue fibers. Dissection is then continued until the diverticulum's communication with the urethra is isolated. Caution and awareness of urethral location are essential to avoid damage.

□ **Diverticulum Excision.** At its neck, the diverticulum is excised from the urethra (Fig. 45-9.3).

□ **Urethral Closure.** The urethral defect is closed with interrupted 4-0 gauge delayed-absorbable sutures over the Foley catheter (Fig. 45-9.4). Fibromuscular layers of the

FIGURE 45-9.3 Diverticulum excision.

urethra and vagina are then reapproximated off tension in two or more layers. For this closure, a vest-over-pants method with 2-0 gauge delayed-absorbable suture is preferred when possible to avoid overlapping suture lines (Fig. 45-9.5). Redundant vaginal epithelium is trimmed, and the epithelium is closed in a running fashion with 2-0 gauge delayed-absorbable suture.

### ■ Surgical Steps—Partial Diverticular Ablation

If extensive dissection is required around the trigone, consideration is given to leaving the proximal portion of the sac in place to avoid direct injury or denervation injury. In addition, ureteral stents may be beneficial during the dissection.

□ **Vaginal Incision.** Again, a midline or U-shaped incision is made on the anterior vaginal wall over the diverticulum, and the vaginal epithelium is dissected sharply off the fibromuscular layer of the vaginal wall. Ample epithelium is freed to allow adequate exposure and later defect closure off tension. The Foley catheter and balloon can be placed on gentle tension to aid in identifying the bladder and bladder neck to avoid injury.

□ **Diverticulum Exposure.** A longitudinal incision is made through the fibromuscular layer to the diverticular sac, and sharp dissection is used to completely mobilize and expose the sac. The diverticulum is opened,

FIGURE 45-9.4 Urethral defect closure.

**FIGURE 45-9.5** Fibromuscular layer reapproximation.

and the communication with the urethra is identified. To avoid injury to the proximal urethra and bladder neck, the diverticular sac, but not the neck of the diverticulum, is sharply excised. As much of the sac as can be accessed is removed.

□ **Sac Closure.** The base of the sac is then sutured side to side with 3-0 gauge delayed-absorbable suture to cover the urethral defect. A second, and possibly a third, imbricating layer using the vaginal muscularis is

created with similar suture. Excess vaginal epithelium that had previously covered the diverticulum is excised. The vaginal epithelium is closed in a running fashion with a 2-0 gauge delayed-absorbable suture.

### ■ **Surgical Steps—Spence Marsupialization**

□ **External Urethral Orifice Incision.** Tips of Metzenbaum scissors are inserted

into the urethral orifice and vagina. An incision is made that incorporates and simultaneously incises the posterior urethral wall, entire thickness of the diverticulum, and distal anterior vaginal wall. By this incision, the external urethral orifice ring is opened and its communication into the diverticular sac is enlarged.

□ **Marsupialization.** For marsupialization, cut edges of the diverticular sac are reapproximated to the vaginal epithelium in a running pattern using 4-0 gauge delayed-absorbable suture. Ultimately, the urethral orifice is widened by this incorporation of the diverticular sac diameter.

## **POSTOPERATIVE**

Catheter management is an important aspect of postoperative care. Although no consensus guidelines exist, most experts recommend catheter placement for 5 to 7 days. Surgeries of increasing complexity may require longer duration. Antibiotic suppression is not required with this catheter use. Normal diet and activity can resume during the first postoperative days. Intercourse, however, is postponed until the vaginal incision is well healed.

## 45-10

## Vesicovaginal Fistula Repair

Vesicovaginal fistulas may be repaired either vaginally or abdominally. A vaginal approach is preferred for most fistulas seen in the United States, which are posthysterectomy, apical fistulas. This approach offers comparable success rates, lower morbidity, and faster patient recovery. Of vaginal methods, the one most commonly performed by gynecologists is the Latzko technique. With this, surrounding vaginal epithelium is reflected away from the fistulous tract. The tract is then resected, but the portion into the bladder is not excised. This avoids a large bladder defect, which can develop with resection of even relatively small fistulas. Following excision, layered closure of the vaginal incision seals the leak. If performed for fistulas at the vaginal apex, then both anterior and posterior vaginal wall epithelia are reflected for tract access. In this location, the final layered closure simulates the steps of colpocleisis, and thus the Latzko technique for apical fistulas is often likened to a proximal partial colpocleisis (p. 1120).

Alternatively, in some cases, the fistulous tract can be completely excised vaginally, and a layered repair of the bladder and then vaginal wall follows. This is preferred by many if the fistulous opening is less than 5 mm in diameter and distant from ureteral orifices.

At times, an abdominal approach may be necessary for women in whom fistula location prohibits effective surgical access or in whom prior vaginal repairs have been unsuccessful. The most commonly described abdominal approach, termed the O'Connor technique, is outlined here and involves bisecting the bladder wall to enter the fistulous tract. Modifications to this as well as an extravesical approach have been described, especially during laparoscopic or robotic routes to fistula repair (Miklos, 2015). With any abdominal approach, omentum or peritoneum can be mobilized and interposed between the bladder and vagina in an attempt to prevent recurrence.

One principle of fistula repair dictates that a repair be performed in noninfected and noninflamed tissues. A second states that tissue must be approximated without excess tension. Last, a multilayer, watertight closure aids reestablishment of bladder integrity. If these guidelines are followed, success rates are typically good and approximate 95 percent (Rovner, 2012). In the United States, most fistulas follow hysterectomy for benign

causes, and repair of these fistulas is associated with high cure rates. In contrast, fistulas associated with gynecologic cancer and radiation therapy may require adjunctive surgical procedures such as vascular or myocutaneous flaps. These flaps provide supportive blood supply to defects that develop in poorly vascularized or fibrotic tissue. Even with these measures, success rates are lower.

### PREOPERATIVE

#### ■ Patient Evaluation

Prior to repair, a fistula should be well characterized, and complex fistulas with multiple tracts or a primary or concomitant ureterovaginal fistula should be identified. Proper evaluation typically includes cystoscopy and imaging that displays the upper and lower urinary tract such as CT urography (pyelography) or intravenous pyelography (IVP) (Fig. 26-2, p. 580). Ureterovaginal fistulas are usually associated with upper tract abnormalities such as hydroureter and hydronephrosis. Therefore, normal IVP or CT findings are reassuring that ureteral involvement is absent. Additionally, this imaging complements cystoscopy in ascertaining the proximity of ureters relative to a fistula for surgical planning. In general, routine posthysterectomy vesicovaginal fistulas develop midline at the vaginal apex and usually away from the ureters, which enter the bladder at the midlength of the vagina. However, lateral fistulas raise concern for ureteral involvement or proximity.

Whether or not surgery can be performed vaginally largely depends on the ability to adequately expose the fistula. Thus, during physical examination, a surgeon assesses if a fistula can be brought down into the surgical field and if a patient's pelvis affords adequate space. Some degree of prolapse of the vaginal apex is helpful for fistula repair. However, a final decision on the repair route is sometimes made intraoperatively, when muscle relaxation from anesthesia allows better assessment of access.

Additionally, tissue infection or inflammation is sought, and if it is identified, fistula repair is delayed until resolution. Fistulas recognized within a few days following hysterectomy may be repaired immediately, prior to the brisk inflammatory response. However, if surgical repair is not undertaken within a few days following the initial surgery, a delay of approximately 6 weeks is recommended to permit tissue inflammation abatement.

#### ■ Consent

Fistulas may redevelop following repair, and patients are counseled that initial surgery may not be curative. With the Latzko

procedure, the vagina is moderately shortened in most cases. Thus, the risk of postoperative dyspareunia is included during surgical consenting. However, a recent study showed that fistula repair improves sexual function and quality of life, with no attributed difference between vaginal and abdominal routes (Mohr, 2014).

#### ■ Patient Preparation

Immediately prior to surgery, intravenous antibiotics and thromboprophylaxis are commonly administered (Tables 39-6 and 39-8, p. 835). The necessity of bowel preparation for this procedure is unclear, and administration is individualized.

### INTRAOPERATIVE

#### ■ Surgical Steps—Vaginal Repair

□ **Anesthesia and Patient Positioning.** In most cases, repair is performed with general or regional anesthesia, and postoperative hospitalization is individualized. The patient is placed in standard dorsal lithotomy position, and the vagina is surgically prepared. If ureters lie close to a fistula, ureteral stents are placed (p. 1059). Cystoscopy is required during the procedure to document ureteral patency and assess bladder integrity.

□ **Delineating a Fistulous Tract.** Initially, the course of a fistulous tract is identified. If a tract is wide enough to accept a pediatric catheter, the tube is threaded through the fistulous tract, and the balloon is inflated within the bladder. If a tract cannot be delineated in this manner, then lacrimal duct probes, ureteral stents, or other suitable narrow dilators are used to trace the tract course and direction. Subsequently, attempts are made to dilate the tract and place a pediatric catheter.

□ **Exposure.** For repair, the fistula is brought into the operative field. If catheterization of the tract is possible, tension on the catheter will allow this. Alternatively, four sutures can be placed in the vaginal wall surrounding the fistula and used to pull the fistula into the operative field (Fig. 45-10.1). Some advocate performing a mediolateral episiotomy to gain exposure, although this is not our practice.

□ **Vaginal Incision.** A vaginal incision is made circumferentially approximately 1 to 2 cm around the fistulous tract (Fig. 45-10.2). Vaginal epithelium surrounding the tract is sharply mobilized laterally and away from vaginal fibromuscular wall and then excised with Metzenbaum scissors.

**FIGURE 45-10.1** Stay sutures in the vaginal wall improve fistula access.

**FIGURE 45-10.2** Vaginal epithelium incision.

□ **Tract Excision.** The fistula tract may or may not be totally excised to the level of the bladder. As noted earlier, complete tract excision creates a larger bladder defect for repair. Also, we prefer not to excise a fistulous tract lying near a ureteral orifice to avert potential ureteral injury and need for reimplantation (Blaivas, 1995).

□ **Fistula Closure.** If a tract is totally excised, the bladder mucosa is reapproximated with 3-0 gauge delayed-absorbable suture in an interrupted or running fashion. Following this closure, the bladder is retrograde filled with at least 200 mL of fluid to exclude leaks. If a defect is found, additional reinforcing sutures are placed until a water-tight repair is achieved.

Regardless of whether the tract is completely or partially excised, anterior and posterior bladder and vaginal muscular layers are then approximated over the fistula site. For this, an interrupted or running suture line of 3-0 or 2-0 gauge delayed-absorbable sutures is created (Fig. 45-10.3). Beginning proximally and adding distally, sequential suture lines are layered (Fig. 45-10.4).

After muscular layers of the bladder and vaginal walls are closed, the vaginal epithelium is closed in a continuous running fashion using 3-0 or 2-0 gauge delayed-absorbable suture.

□ **Cystoscopy.** Cystoscopy is again performed to document ureteral patency and to inspect the incision site.

### ■ Surgical Steps— Abdominal Repair

□ **Anesthesia and Patient Positioning.** In most cases, abdominal repair is performed under general anesthesia. The patient is placed in low lithotomy position within booted support

stirrups. With the patient's thighs parallel to the ground and the legs separated, access to the vagina is maximized. The abdomen and vagina are surgically prepared, and a Foley catheter is inserted.

□ **Abdominal Incision and Bladder Entry.** A low transverse or midline abdominal

**FIGURE 45-10.3** First-layer closure over fistula.

**FIGURE 45-10.4** Second fibromuscular layer closure over fistula and vaginal epithelium reapproximation.

entry incision can be used. If mobilization of the omentum is anticipated, a vertical midline incision can provide greater access to the upper abdomen. A Maylard or Cherney incision may alternatively be selected (Section 43-3, p. 931). After the peritoneum is entered, the abdomen is explored, bowel is packed from the operating field, and a self-retaining abdominal wall retractor is placed. The space of Retzius is opened using the technique

described on page 1061. Next, a vertical midline extraperitoneal incision is made into the bladder dome. Prior to this incision, pushing the Foley balloon up or filling the bladder helps avoid grasping and then cutting the posterior bladder wall.

**□ Fistulous Tract Delineation and Excision.** After cystotomy, the fistula and ureteral orifices are seen from within the bladder. If the fistulous tract is near the orifices, ureteral stents are placed. From the dome, the cystotomy incision is extended over the top and then back of the bladder to reach the circular fistulous opening (Fig. 45-10.5). A lacrimal probe or catheter may be placed into the fistulous tract to delineate its course. The tract is then excised.

In contrast and less commonly, if a fistula tract lies close to the trigone, extension of the bladder incision to the fistulous tract may not be desired, as the resulting bladder defect would be extensive. In these cases, the entire fistulous tract is directly excised using only the bladder dome incision. However, vascular flap interposition with this approach is limited as the bladder wall is not significantly dissected off the vaginal wall.

**□ Separation of the Bladder and Vagina.** In cases with bladder bisection, sharp dissection is used to separate the vagina away from the bladder in the area of the fistula (Fig. 45-10.6). Scarring may be extensive, and sharp rather than blunt dissection is preferred. To assist, the rounded tip of an end-to-end anastomosis (EEA) sizer can be placed in the vagina to manipulate and accentuate the dissection plane (Fig. 46-21.4, p. 1202). The vagina is widely separated from the bladder to allow omentum or peritoneal flap placement between the two.

**FIGURE 45-10.5** Bladder incision.

**FIGURE 45-10.6** Separation of the bladder and vagina.

**FIGURE 45-10.7** Vaginal closure.

□ **Vaginal Closure.** The vagina is closed in one or two layers with 2-0 gauge delayed-absorbable suture and running or interrupted stitches (Fig. 45-10.7). The EEA sizer or fingers within the vagina can accentuate the vaginotomy margins to aid closure.

□ **Bladder Closure.** The entire bisecting bladder incision is closed in two or three layers using running sutures of 3-0 gauge absorbable suture (Fig. 45-10.8). As with the vaginal approach, after the first layer, the bladder is retrograde filled with at least

200 mL, and incision-line leaks are sought. If defects are noted, additional reinforcing sutures are placed to achieve a watertight repair. During bladder closure, each subsequent layer is imbricated such that the preceding suture line is covered and tension is released (Fig. 45-10.9).

If the bladder is not bisected and the fistulous tract is directly excised solely through the bladder dome cystotomy, then the muscular wall of vagina is first repaired in one or two layers as in Step 5. Second, the bladder wall at the fistula excision site is closed in one or two

layers using a running stitch of 3-0 absorbable suture. Next, the bladder mucosa is reapproximated with a single-layer running stitch of 3-0 absorbable suture. Last, the entry bladder dome incision is closed similarly, except the bladder mucosa is reapproximated first and followed by bladder wall closure in layers.

□ **Omental or Peritoneal Interposition.** As described in Section 46-14 (p. 1186), the omentum can be mobilized to create a J-flap. The omentum is then sutured to the anterior wall of the vagina to cover the incision

**FIGURE 45-10.8** First-layer bladder closure.

**FIGURE 45-10.9** Second-layer bladder closure.

**FIGURE 45-10.10** Omentum interposition.

**FIGURE 45-10.11** Peritoneum interposition.

line (Fig. 45-10.10). This provides a tissue layer between vagina and bladder, increases vascular flow to the area, and may improve tissue healing. Alternatively, if the omentum

cannot be mobilized, peritoneum, although less vascular, can be interposed and creates another barrier layer between the bladder and vagina (Fig. 45-10.11).

□ **Cystoscopy.** Cystoscopy is performed to document ureteral patency and inspect the incision site.

□ **Incision Closure.** The abdominal incision is closed as described in Chapter 43 (p. 931).

## POSTOPERATIVE

The bladder is drained postoperatively to prevent overdistention and suture disruption. Either transurethral or suprapubic catheter placement will ensure adequate drainage in the immediate postoperative period. At our institution, we generally continue catheterization for at least 2 weeks following vesicovaginal fistula repair. Antibiotic suppression is not required with this catheter use.

## 45-11

## Martius Bulbocavernosus Fat Pad Flap

This vascular graft contains the fat pad overlying the bulbospongiosus (formerly called bulbocavernosus) muscle and brings a supportive blood supply to repairs involving avascular or fibrotic tissue. As such, this graft is commonly used in complex urethral diverticulum excisions or in complex rectovaginal or vesicovaginal fistula repairs. However, of these indications, there is some evidence supporting successful repair of certain recurrent fistulas without vascular graft interposition (Miklos, 2015; Pshak, 2013).

During graft placement, one end of the bulbocavernosus fat pad is dissected free and subsequently brought to the repair site through the primary vaginal incision. Thus, due to its anatomic origin and limited length, this fat pad, when indicated, is selected for defects involving the low to mid-vagina.

### PREOPERATIVE

#### ■ Patient Evaluation

In most instances, graft placement is anticipated for those with prior radiation or with fistula recurrence. Thus, preoperative planning includes assessment of tissue vascularity, connective tissue strength, and ability to adequately mobilize vaginal tissues to create a multilayered repair closure. For this procedure, a woman must have adequate labial fat, which is also assessed prior to surgery.

#### ■ Consent

During consenting, women are informed of the potential for postoperative vulvar numbness, pain, paresthesias, or hematoma. Because one of the labia majora is repositioned as the graft, patients are counseled regarding the cosmetic consequences.

#### ■ Patient Preparation

Because of the risk of poor wound healing in these complicated repairs, antibiotic prophylaxis listed in Table 39-6 (p. 835) is warranted. T romboprophylaxis is given as outlined in Table 39-8 (p. 836). The necessity of bowel preparation for this procedure is unclear, and administration is individualized based on concomitant procedures.

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning

In most cases, a Martius flap graft and fistula repair can be performed with general or regional anesthesia, and the need for postoperative hospitalization is individualized. The patient is positioned in standard lithotomy position, the vagina is surgically prepared, and a Foley catheter is inserted.

□ **Fistula or Diverticulum Repair.** The specific defect is repaired as outlined in its respective section of this chapter.

□ **Labial Incision.** After repair completion, the lateral margin of one labium majus is incised (Fig. 45-11.1). The length of the incision is tailored to specific labial anatomy

and graft size needed. In many cases, a 6- to 8-cm incision is made beginning below the level of the clitoris and is extended inferiorly.

□ **Mobilization of the Fat Pad.** The vulvar incision edges are retracted laterally, and sharp dissection is used to free the labial fat pad (Fig. 45-11.2). This tissue is vascular, and vessels ideally are ligated or coagulated prior to transection. For rectovaginal fistulas, a broad base is left inferiorly, and the fat pad is detached superiorly. For vesicovaginal and urethrovaginal fistulas or urethral diverticula, the broad base of the pad is maintained superiorly, while the fat pad is detached inferiorly. In each instance, releasing the pad with this specific polarity anatomically permits the largest possible graft to cover the repair site. Occasionally, bilateral fat pads are needed.

□ **Graft Placement.** After the pad is freed, a tunnel is created by bluntly dissecting with a hemostat that travels from the vulvar incision, underneath the vaginal epithelium, and to the vaginal incision at the repair site. The tunnel must be sufficiently broad to avoid vascular compression and graft necrosis. A suture is placed at the graft tip and used to pass the graft through the tunnel and into the vagina (Fig. 45-11.3).

□ **Graft Fixation.** The graft is secured to the vaginal muscularis overlying the repair site with several interrupted stitches using 3-0 gauge delayed-absorbable suture (Fig. 45-11.4).

□ **Incision Closure.** With hemostasis established, the vulvar incision is closed along its length using continuous or interrupted stitches of 3-0 gauge delayed-absorbable

FIGURE 45-11.1 Labial incision.

FIGURE 45-11.2 Mobilization of the fat pad.

**FIGURE 45-11.3** Graft placement.

**FIGURE 45-11.4** Graft fixation.

sutures. For a deep cavity at the harvest site, fatty tissue may be reapproximated in layers to close this space with several interrupted 2-0 or 3-0 gauge delayed-absorbable sutures. Alternatively, a drain may be placed in the cavity. The vaginal epithelium overlying the defect repair is closed in a continuous running

fashion using 3-0 gauge delayed-absorbable suture.

### POSTOPERATIVE

Care after surgery is predominantly dictated by the associated defect repair. Ideally, the

vaginal and perineal sites are kept dry rather than wet, and baths are avoided during the first 6 weeks. After each void or stool, patients rinse with a water-filled squirt bottle and gently pat dry.

## 45-12

## Sacral Neuromodulation

Sacral neuromodulation or sacral nerve stimulation (SNS) electrically stimulates the sacral nerves to modulate reflexes that influence the bladder, sphincters, and pelvic floor (Noblett, 2014). Currently, the InterStim System is the only implantable SNS device that is Food and Drug Administration (FDA)-approved for the following primary indications: urgency-frequency, urgency urinary incontinence, nonobstructive urinary retention, and fecal incontinence. Although not FDA-approved for chronic pelvic pain, interstitial cystitis/painful bladder syndrome, or chronic idiopathic constipation, it may sometimes be used if these symptoms coexist with the previously listed primary indications. This surgery is typically offered to women who have failed to adequately improve with multiple other conservative therapies. The mechanism of action is unclear, but one explanation describes modulation of reflex neural pathways involved with bladder storage and emptying and with innervation of the pelvic floor. Of these, pudendal afferent somatic fibers are thought to play an important role (deGroat, 1981; Gourcerol, 2011).

SNS is generally completed in two phases. First, during a test phase, a slender, 30-cm long permanent lead that conducts electrical impulses to its tip is placed into one posterior sacral foramen and adjacent to a sacral nerve root, most commonly S3. This lead is connected to a temporary external pulse generator to permit an efficacy trial lasting 1 to 2 weeks. If symptoms are decreased by at least 50 percent, then the patient is deemed a suitable candidate for permanent generator implantation. During the second or implantation phase, the lead is connected to a permanent implantable pulse generator (IPG), and the IPG is tucked within a subcutaneous pocket created in the buttock. This staged approach is illustrated in these atlas pages.

A variation of these classic steps, termed percutaneous nerve evaluation (PNE), inserts a *temporary* lead through the S3 foramen in the office, under local anesthesia, and generally without fluoroscopic guidance. However, despite these advantages, the trial period with PNE is brief (3 to 7 days), and the less securely anchored temporary lead more easily migrates away from the target nerve.

### PREOPERATIVE

#### ■ Patient Evaluation

Preoperative testing will vary depending on the indication. For urinary symptoms, women undergo full evaluation including urodynamic testing, voiding diary, cystoscopy, and other selected tests described in Chapter 23 (p. 523). For fecal incontinence, colonoscopy, endoanal sonography, manometry, and possibly pudendal nerve testing, described in Chapter 25 (p. 564), are completed during evaluation.

#### ■ Consent

Failure to significantly improve symptoms may follow either SNS phase. However, approximately 70 percent of those who undergo permanent IPG implantation achieve a greater than 50-percent symptom improvement (Van Kerrebroeck, 2012). Pain at the IPG site and superficial wound infection may also complicate either phase. Long-term adverse changes include altered bowel or bladder function, undesirable sensations, neurostimulator site numbness, lead migration, and surgical device revision, replacement, or required removal. The IPG device is a relative contraindication for MR imaging, although certain IPG models permit head imaging.

#### ■ Patient Preparation

A single prophylactic antibiotic dose may or may not be administered according to surgeon preference. Although not rigorously studied, prophylaxis is recommended by some due to needle passage from skin

to perineural tissue in the presacral space. Tromboprophylaxis is typically not required given the procedure's short duration.

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Although the procedure can be performed using local anesthesia and intravenous sedation, we prefer general anesthesia for the test phase. Importantly, neuromuscular blockade prohibits adequate motor response evaluation and is contraindicated. The patient is positioned prone on a Wilson frame or with a pillow under the lower abdomen to flex the hip 30 degrees for easier access to the sacrum. Pillows are also placed under the shins to allow the toes to move freely during test stimulation. The drape is positioned to permit inspection of the pelvic floor and soles for muscle responses. The area from the lower back to the perineum is surgically prepared. A Foley catheter is typically not required due to the surgery's brevity.

##### □ Identification of S3 Foramina.

These landmarks for lead placement are located approximately 9 cm above the coccyx and 1 to 2 cm lateral to the midline (Fig. 45-12.1). Fluoroscopy is currently the most common method of identifying the necessary bony landmarks intraoperatively. The fluoroscopic C-arm is draped and moved into the anteroposterior (AP) position to allow mapping of the sacral region including foramina. With this, the skin overlying the S3 foramina is outlined with a surgical marker.

FIGURE 45-12.1 Foramen needle insertion.

**FIGURE 45-12.2** Correct lead positioning.

□ **Foramina Needle Insertion.** An insulated foramen needle is inserted through the skin at a site approximately 2 cm lateral to the midline, 2 cm superior to the sciatic notch, and cephalad to the inked outline of the foramen. The needle is guided at a 60-degree angle caudally until the S3 foramen is penetrated. Optimally, the needle is placed into the medial and superior aspect of the S3 foramen. The needle penetrance depth, which is usually 2.5 to 4.0 cm, is confirmed and adjusted with fluoroscopic guidance by a laterally positioned C-arm.

Once in place, the needle is used to conduct electrical test impulses to the S3 nerve. This nerve contracts the levator ani muscles to create an inward retraction or “bellows” movement. S3 stimulation also causes the great toe to flex downward, that is, plantar flexion. In anesthetized patients, a sensory response cannot be elicited, but evidence suggests that motor responses may be more or at least as predictive of success (Cohen, 2006; Govaert, 2009; Peters, 2011). The typical patient sensation with S3 stimulation is a tapping or vibration in the vagina, rectum, or perineum. Once the desired S3 motor reflexes are obtained (“bellows and toe”), lead placement is initiated. If these are absent, needle depth or angle is adjusted to achieve the desired responses. Also, a needle in the contralateral foramen or in a foramen up or down one vertebral space may be tried.

□ **Lead Placement.** Once positioned, the stylet present within the foramen needle is removed and replaced with a guide wire to the appropriate depth. The foramen needle is then removed while holding the guide wire in place. A small incision is made on either side of the guide wire, and a combined introducer sheath/hollow dilator tool is then slid over the guide wire to occupy the foramen needle’s former position. The hollow dilator is unscrewed from the introducer sheath, and the dilator and guide wire are removed together. This leaves only the introducer sheath in place.

Next, using fluoroscopy, the long, flexible lead is passed down the introducer sheath into the S3 foramen. To aid threading, the lead contains a temporary stiff inner stylet. A recently introduced curved stylet better follows anatomic contours to position the lead close to the nerve root (Jacobs, 2014). The lead also contains four circumferential electrode bands arranged in series at its tip, and proximal to these lie four plastic barbs or tines to ultimately anchor the lead within soft tissues (Fig. 45-12.2).

With correct lead positioning as shown, the most proximal of the four electrode bands are fluoroscopically visible just anterior to the sacrum. All four electrodes on the lead should conduct pulses and elicit S3 motor responses. If necessary, the lead can be repositioned within the foramen. Once correctly positioned, the introducer sheath and

then the curved lead stylet are removed. As the introducer sheath is removed, the four tines or barbs lock into place. Thus, the lead cannot be retracted after this point. All four electrodes are again tested to confirm the previously observed responses.

If lead advancement is needed, its stylet is replaced and the lead advanced. Retraction is more problematic. The lead is removed using gentle traction, and Steps 3 and 4 are repeated. The desired range of stimulation amplitude to achieve desired motor responses is 1 to 2 milliamps. Responses at lower amplitudes may indicate that the lead lies too close to the nerve, whereas requisite higher amplitudes can decrease battery longevity.

□ **Pulse Generator Incision and Lead Passage.** Several centimeters below the iliac crest, a 4-cm transverse incision is made over the lateral portion of the buttock that is ipsilateral to the selected foramen. Sharp and blunt dissection is used to create a deep pocket that can house the extension device for the temporary external pulse generator and eventually, the permanent IPG. The pocket should remain above the gluteal muscle fascia but is made sufficiently deep to accommodate the final IPG.

After the pocket is created, a pointed passing device is used to create a narrow tunnel between the lead and the pocket (Fig. 45-12.3). The core of the passing device is removed, leaving a hollow straw within the tunnel (inset). The lead is then manually threaded laterally

**FIGURE 45-12.3** Pulse generator incision and lead passage.

**FIGURE 45-12.4** Within pocket, lead joins extension wire that extends to temporary pulse generator.

**FIGURE 45-12.5** Final implanted pulse generator.

through this straw and into the pocket. The straw is then removed laterally.

□ **Placement of the Extension Device (First Phase).** Within the subcutaneous pocket, the lead is next connected to an extension wire that serves to join the lead to the temporary pulse generator (Fig. 45-12.4). A stab incision is then created lateral to the pocket. The passing device is again used and, this time, guides the extension wire through a second tunnel between the pocket and stab incision. The subcutaneous tissue is then closed over the connector in the pocket with 2-0 gauge delayed-absorbable suture in an interrupted or running fashion. The skin is closed with a subcuticular stitch using 4-0 gauge delayed-absorbable suture or with other suitable skin closure methods. Similarly, the stab incision is closed. Last, the extender wire is joined to a temporary external pulse generator, which is used for 1 to 2 weeks (see Fig. 45-12.4).

□ **Implantable Pulse Generator Placement (Second Phase).** If significant symptom relief is obtained, the permanent IPG is placed 1 to 2 weeks after initial surgery. The procedure is performed with the patient prone and usually with general anesthesia for airway control. The buttock incision is opened down to the connector. The connector and extension wire are removed. The permanent IPG is connected to the lead, and then placed into the subcutaneous pocket (Fig. 45-12.5). The incision is closed again as in Step 6.

## POSTOPERATIVE

Pain or erythema at the incision site suggests cellulitis, abscess, or seroma. These symptoms are evaluated as soon as possible, and antibiotics are instituted if needed. Unusual pain is also evaluated immediately as this could suggest lead malfunction. A woman can turn the device off by herself if necessary. Primary symptoms are continually assessed postoperatively, and the IPG is reprogrammed as needed. Reprogramming the device or changing leads will often lead to symptom improvement.

## 45-13

## Anterior Colporrhaphy

The anterior vaginal wall is the most frequent site of clinically recognized prolapse (Brincat, 2010). One method to correct this is anterior colporrhaphy, which reapproximates attenuated fibromuscular tissue between the vagina and bladder to elevate the bladder to a more anterior and anatomically normal position. Anatomic success rates following this surgery are modest at 1 year (Altman, 2011; Weber, 2001). Thus, strategies to improve these colporrhaphy rates include: (1) concurrent vaginal paravaginal defect repair (PVDR), (2) concurrent apical support surgeries, or (3) synthetic or biologic mesh placement instead of or in addition to colporrhaphy.

Of these, PVDR attempts to provide lateral support to the anterior vaginal wall. However, the vaginal PVDR is less favored as its required dissection creates a large defect within tissue that carries significant nerves and vessels. Also, efficacy data are lacking.

Synthetic mesh placement is associated with improved anterior prolapse anatomic outcomes (61 versus 35 percent) (Altman, 2011). But this disparity in anatomic success does not always reflect symptom success rates (Chmielwesi, 2011). Symptom improvement rates for mesh range from 75 to 96 percent compared with ranges of 62 to 100 percent for native tissue (Lee, 2012). Moreover, mesh use significantly increases risks of mesh erosion, vaginal lumen narrowing, and pelvic abscess (Maher, 2013). These may be associated with dyspareunia, urinary complaints, and chronic pelvic pain (Food and Drug Administration, 2011). Currently, few data guide patient selection for mesh placement, which may be best reserved for those with recurrent prolapse or those with medical comorbidities that preclude alternative procedures (American College of Obstetricians and Gynecologists, 2011). Moreover, surgeons using mesh need adequate training and experience, and patients are educated regarding risks and benefits. Alternatively, cadaveric fascia has been similarly used, but surgical success using this tissue is not significantly improved compared with colporrhaphy alone (Gandhi, 2005).

Last, increasing data suggest that vaginal apex support plays a critical role in anterior vaginal wall suspension (Lowder, 2008; Summers, 2006). Thus, anterior colporrhaphy is now often complemented by apical support procedures.

## PREOPERATIVE

### ■ Patient Evaluation

As stated, women with anterior wall prolapse often have other compartment defects, and a complete POP-Q examination, described in Chapter 24 (p. 540), aids surgical planning. In addition, anterior vaginal wall prolapse is frequently associated with stress urinary incontinence (SUI) (Borstad, 1989). Even those who are continent, however, may have occult SUI unmasked following prolapse correction. Thus, preoperative urodynamic evaluation is often recommended. During this evaluation, the prolapse is reduced to its anticipated postoperative position to mimic pelvic floor anatomy and dynamics following surgery (Chaikin, 2000; Yamada, 2001). The decision to perform a concurrent prophylactic antiincontinence procedure is then dictated by individual urodynamic findings and adequate patient counseling.

### ■ Consent

For most women, anterior colporrhaphy has low complication rates. Of these, recurrence of the anterior vaginal wall defect is one of the most frequent. De novo SUI described earlier, prolonged catheter use for urinary retention, and voiding dysfunction are also discussion points. Although infrequent, postoperative dyspareunia is another cited complication. However, preoperative symptoms related to sexual function in general improve with anterior colporrhaphy (Weber, 2001). Uncommonly, serious hemorrhage, cystotomy, or ureteral injury may occur intraoperatively.

If mesh is used, these latter risks may be increased, and bowel or ureteral injury is possible. Accordingly, intraoperative cystoscopy is recommended. Less common short-term postoperative mesh complications include wound infection or hematoma. Long-term data from randomized trials show mesh erosion rates that range from 5 to 19 percent; chronic pain, up to 10 percent; and dyspareunia, 8 to 28 percent (American College of Obstetricians and Gynecologists, 2011).

### ■ Patient Preparation

Bowel preparation is generally not indicated for isolated anterior colporrhaphy but may be recommended at the surgeon's discretion if other compartmental repairs are planned. Antibiotic prophylaxis with a first- or second-generation cephalosporin is recommended immediately prior to surgery as cystoscopy is also performed. Tromboprophylaxis is given as outlined in Table 39-8 (p. 836).

## INTRAOPERATIVE

### ■ Surgical Steps

#### □ Anesthesia and Patient Positioning.

After adequate general or regional anesthesia is administered, a patient is placed in standard lithotomy position, the vagina is surgically prepared, and a Foley catheter inserted. A short Auvard weighted speculum may be positioned to retract the posterior vaginal wall.

□ **Concurrent Surgery.** Anterior colporrhaphy can be performed with the uterus in situ or alternatively, following hysterectomy. If other reconstructive surgeries are required, they may precede or follow anterior colporrhaphy.

□ **Vaginal Incision.** In those with prior hysterectomy and adequate apical support, two Allis clamps are placed on each side of the midline, 1 to 2 cm distal to the vaginal apex or at the upper extent of the anterior vaginal wall prolapse (Fig. 45-13.1) Clamps are gently pulled laterally to create tension, and the vaginal wall between them is incised transversely. If hysterectomy precedes the repair, the two Allis clamps are placed at the opened cuff edge on either side of midline.

A third clamp is placed in the midline vaginal wall, 3 to 4 cm distal to the apical transverse incision. All three clamps are held, creating gentle outward tension. Metzenbaum scissors tips are insinuated beneath the epithelium in the midline of the previously made transverse incision and directed away from the vaginal apex. Scissor blades are opened and closed, while the surgeon exerts gentle

**FIGURE 45-13.1** Tissue plane dissection.

**FIGURE 45-13.2** Vaginal wall incision.

forward pressure that is parallel to and within the plane beneath the vaginal epithelium. This technique allows separation of the epithelium from the fibromuscular layer. This dissection continues caudad to reach the distal, midline Allis clamp. The undermined vaginal wall is then incised in the midline longitudinally. The midline Allis clamp is then replaced more distally, and the process continues until the vaginal epithelium has been divided to within 2 to 3 cm of the external urethral opening (Fig. 45-13.2). This ending spot corresponds to a midpoint along the length of the urethra. If the anterior wall prolapse does not extend distally beyond the bladder neck, then the distal epithelial incision terminates at the neck. In addition, if a concurrent midurethral sling is planned, the colporrhaphy incision terminates just proximal to the bladder neck to allow a separate incision for sling placement.

□ **Lateral Dissection.** Along the freed epithelial edges, additional Allis or Allis-Adair clamps are placed to create gentle outward tension, while the vaginal epithelium is dissected laterally off the vagina's fibromuscular wall (Fig. 45-13.3). This is accomplished with one finger placed behind the epithelium to accentuate the dissection plane, while scissors are held parallel to the vagina and cut connective tissue fibers between the epithelium and fibromuscular layer. Once the desired tissue plane is entered, a combination of sharp and blunt dissection readily separates the layers. Simultaneous countertraction on the fibromuscular layer by an assistant using tissue forceps or a gauze-covered finger can aid dissection. This separation is extended laterally toward the pelvic walls until substantial fibromuscular tissue is exposed to permit mid-

**FIGURE 45-13.3** Separation of epithelium from fibromuscular layer.

line plication. The steps are then repeated on the contralateral side.

□ **Traditional Anterior Colporrhaphy.** Plication of the fibromuscular layer to the midline is then begun. For this, an interrupted stitch of 2-0 gauge delayed-absorbable suture is placed on one side of the midline beginning nearest the apex. This same needle and suture are carried to the other side of the midline, and a mirror stitch is placed the same distance from the apex. To plicate tissue, the bites of each stitch are generously spaced to bring together the wide lateral

span of attenuated tissue. However, excessive tension is avoided to prevent sutures from pulling through the fibromuscular tissue or from significantly narrowing the vagina. As sutures are tied, the midline bladder bulge is elevated by the surgeon gently upward and away from the incision line. Such plication creates a firm fibromuscular wall layer to support the bladder and if indicated, the urethra (Fig. 45-13.4).

□ **Vaginal Paravaginal Defect Repair.** If vaginal PVDR is to be performed, the vaginal dissection described above is extended

**FIGURE 45-13.4** Midline plication completed.

**FIGURE 45-13.5** Vaginal paravaginal defect repair.

laterally to the pelvic side walls at the level of the arcus tendineus fascia pelvis (ATFP) (Chap. 38, p. 808). Dissection also generally extends from the dorsal surface of the pubic bones to the ischial spines. Blunt dissection is typically used to enter the space of Retzius. If a paravaginal defect is present, the space is easily entered. Visualization of the pelvic sidewall is aided by Breisky-Navratil and lighted retractors. If present, the ATFP appears as a white line running from pubic bone's dorsal surface to the ischial spine. In some cases, the ATFP is attenuated and indistinct, and stitches are instead anchored to the obturator internus muscle's investing

fascia. For repair, a series of four to six 2-0 gauge permanent sutures are placed in the ATFP or obturator fascia and attached to the paravaginal connective tissue (Fig. 45-13.5).

□ **Incision Closure.** Depending on the size of the original anterior wall defect, some redundant vaginal wall will likely be present and require trimming (see Fig. 45-13.4). Liberal trimming, however, can place the vaginal wall incision on excessive tension, affect wound healing, and narrow the vagina. The vaginal epithelium is reapproximated in a running fashion with a 2-0 gauge delayed-absorbable suture.

□ **Mesh Placement.** Various marketed mesh kits are available, and full descriptions for placement are provided by individual manufacturers. In general, a broad mesh sling supports the proximal anterior vaginal wall and has mesh arms that extend and anchor to the sacrospinous ligaments (SSLs) to provide apical support. Concurrently, the distal extent of the mesh ends at the level of the bladder neck.

For placement of anterior and apical mesh repair kits, the paravesical space is entered by lateral dissection similar to the steps for vaginal PVDR (Step 6). The ATFP and the ischial spines are palpated. A finger also slides medially over the SSL. The recommended fixation point on this ligament is 2 to 3 cm medial to the ischial spine, which is similar to the fixation point for the traditional SSL fixation procedure (p. 1112).

□ **Cystoscopy.** Kwon and coworkers (2002) performed cystoscopy following 346 anterior colporrhaphy procedures and found unexpected injury in 2 percent of cases. These each required suture removal and replacement. Accordingly, cystoscopy is warranted to document integrity of the ureteral orifices, bladder, and urethral lumen.

## POSTOPERATIVE

For most women, recovery following anterior colporrhaphy is rapid and associated with few complications. Urinary retention or UTI, however, is common. Prior to discharge, an active voiding trial is performed. If a Foley catheter remains, a second voiding trial can be repeated in a few days or at the surgeon's discretion.

As with other vaginal surgery, diet and activity can be advanced as tolerated. Women, however, abstain from intercourse until wound healing is complete, typically at 6 to 8 weeks following repair.

## 45-14

## Abdominal Paravaginal Defect Repair

Paravaginal defect repair (PVDR) is a prolapse procedure that aims to correct lateral defects in the anterior vaginal wall. The procedure involves attachment of the lateral vaginal wall to the arcus tendineus fascia pelvis (ATFP) (Fig. 38-24, p. 817). This procedure is rarely performed alone and is more often combined with other prolapse procedures, especially abdominal sacrocolpopexy. PVDR is ineffective treatment for stress urinary incontinence (SUI). That said, abdominal PVDR may be performed in conjunction with the antiincontinence Burch colposuspension if a lateral anterior wall defect and prolapse complaints coexist with SUI. PVDR can also be performed laparoscopically or robotically by those with advanced skills. If sutures can be placed the same as in the abdominal approach, the results are expected to be equivalent, but data are limited.

### PREOPERATIVE

#### ■ Patient Evaluation

Demonstration of lateral vaginal wall defects on physical examination is required prior to surgery. If significant anterior wall prolapse is identified, evaluation for SUI or occult SUI is pursued. In women who have a paravaginal defect, other pelvic support defects such as apical or posterior vaginal prolapse commonly coexist. Thus, attempts to identify these defects precede surgery.

#### ■ Consent

Paravaginal defect repair provides support to the lateral vaginal walls, but as with other prolapse procedures, long-term success rates may diminish with time. The procedure involves surgery in the space of Retzius, which has the potential for significant blood loss. In particular, risks of bleeding and bladder injury are generally greater in patients with prior space of Retzius surgery as dense adhesions between bladder and pubic bone are common. Inaccurate suture placement can result in injury to the bladder and/or ureters, although this is infrequent.

#### ■ Patient Preparation

As with most abdominal urogynecologic surgeries, antibiotic prophylaxis is given to pre-

vent wound infection (Table 39-6, p. 835). Bowel preparation may be implemented at the surgeon's discretion if additional procedures are planned. Tromboprophylaxis is given as outlined in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** When performed in conjunction with apical or other repairs, this surgery is typically performed as an inpatient procedure under general anesthesia. Following administration of anesthesia, the patient is placed in low lithotomy position in booted support stirrups. Adequate exposure to the vagina is vital because a vaginal hand is used to elevate and dissect the paravaginal/paravesical space. The abdomen and vagina are surgically prepared, and a Foley catheter with a 10-mL balloon is inserted.

□ **Abdominal Incision.** A low transverse incision placed 1 to 2 cm cephalad to the symphysis pubis affords the best exposure to the space of Retzius. This procedure is typically done in conjunction with abdominal sacrocolpopexy, and the abdominal cavity is entered (Section 43-2, p. 929). If performed in isolation or with a Burch colposuspension, entry into the peritoneal cavity is not necessary to open the space of Retzius.

□ **Entering the Space of Retzius.** After incision of the fascia, the rectus muscles are separated in the midline and retractors are used to hold them apart. To open the space of Retzius, the correct dissection plane lies directly behind the pubic bone, deep to the transversalis fascia but superficial to the perito-

neum. Loose areolar tissue is gently dissected in a lateral-to-medial fashion with atraumatic forceps or scissors beginning immediately behind the pubic bone (Fig. 45-14.1). If the correct plane is entered, this avascular potential space opens easily and without significant hemorrhage. Small bleeding vessels within the loose areolar tissue are coagulated as encountered. If significant bleeding does occur, the wrong tissue plane has likely been entered. From prior surgery in this space, the bladder often adheres to the pubic bone and anterior abdominal wall and thus sharp dissection is indicated.

After the medial portion of the space of Retzius is opened, the obturator canal is identified bilaterally so that its associated vessels and nerve can be avoided. The canal is generally found 5 to 6 cm lateral from the pubic symphysis midline and 1 to 2 cm below the iliopectineal line. The ischial spine is then palpated 4 to 6 cm below and posterior to the obturator canal. The remainder of the paravaginal space is opened with gentle blunt dissection using a gauze sponge. This dissection is generally directed lateromedially, that is, from obturator fascia to lateral bladder border, to expose the ATFP and paravaginal tissue. To assist, a vaginal hand pushing up into the space creates a firm surface to dissect against. In addition, a malleable retractor gently displaces the bladder to the contralateral side.

Large paravaginal blood vessels are often noted along the lateral vaginal wall. Bleeding from these vessels can be controlled by upward pressure of the vaginal hand while hemostatic sutures are placed.

□ **Identification of the Arcus Tendineus Fascia Pelvis.** The ATFP runs along the pelvic sidewall between the pubic bone and

**FIGURE 45-14.1** Dissection in the space of Retzius.

FIGURE 45-14.2 Placement of paravaginal sutures.

FIGURE 45-14.3 Final suture placement.

the ischial spine as a white connective tissue condensation. In those with defects, it may be attenuated, torn in the middle, or completely avulsed from the sidewall. Even in these cases, the distal third of the ATFP is generally preserved and easily identified.

□ **Placement of Paravaginal Sutures.** One or two fingers of the surgeon's nondominant hand are placed in the vagina to elevate the lateral vaginal wall on the planned side of defect repair. At the same time, a medium-sized malleable retractor is used to reflect the bladder medially and protect it and the ureter from inadvertent suture placement or entrapment.

Usually four to six interrupted 2-0 gauge permanent sutures placed approximately 1 cm apart are needed to obliterate the paravaginal defect. The ultimate suture line extends from the level of the ischial spine to the level of the bladder neck or proximal

urethra (Fig. 45-14.2). Each suture passes through the paravaginal tissue just lateral to the bladder wall and through the ATFP or obturator internus fascia and tied. A vaginal finger covered by a thimble for protection presses upward against the lateral vaginal wall to help isolate the paravaginal tissue and assess suture penetration. If a suture punctures the vaginal lumen, it is removed, discarded, and replaced by a more superficial stitch. If bleeding follows, the suture may be tied to constrict involved vessels. Prior to suture placement, the obturator canal and neurovascular bundle are identified and avoided. After all sutures are placed, the procedure is repeated on the other side of the vagina (Fig. 45-14.3).

□ **Cystoscopy.** This is performed to note efflux from both ureteral orifices and to exclude bladder-perforating sutures. A

misplaced suture might be seen as a dimple in the bladder wall. If found, sutures entering the bladder are removed abdominally and properly placed.

□ **Incision Closure.** After vigorous irrigation of the space of Retzius, the abdomen is closed in a standard fashion (Section 43-2, p. 930). If the peritoneum was opened, closure is recommended to prevent small bowel adhesions in the space of Retzius.

## POSTOPERATIVE

In general, recovery follows that associated with laparotomy or endoscopy and varies depending on concurrent surgeries and incision size. A voiding trial as described in Chapter 42 (p. 917) is performed prior to hospital discharge.

## 45-15

## Posterior Colporrhaphy

Posterior colporrhaphy, also colloquially termed posterior repair, is traditionally used to repair prolapse of the posterior vaginal compartment. Specifically, posterior colporrhaphy techniques attempt to reinforce the fibromuscular tissue layer between the vagina and rectum to prevent prolapse of the rectum into the vaginal lumen. The tissue plicated in the midline is often reapproximated distally to the level of the hymen and here includes reapproximation of the perineal body tissue. This is especially important for women who display “perineal descent” during preoperative evaluation. Women with such poor perineal strength may often reinforce (or splint) the perineal body to aid defecation. For these women, perineorrhaphy is often carried out concurrently. Often, the posterior vaginal wall apex must also be suspended to obtain successful repair and prevent recurrence. The apex may be suspended vaginally to the uterosacral or sacrospinous ligament or abdominally to the anterior longitudinal ligament of the sacrum. Thus, a careful preoperative evaluation is essential to restore anatomy.

There are three current transvaginal repairs of posterior wall prolapse. First, traditional midline plication of levator ani muscles, also known as levator myorrhaphy or levatorplasty, plicates the puborectalis muscle in the midline (Francis, 1961). Second, midline vaginal wall plication without levator myorrhaphy brings together the vaginal wall muscularis and adventitial layers in the midline. Tissue previously referred to as “rectovaginal fascia” is in fact these muscularis and adventitial layers, as histologic studies of normal anatomy illustrate a lack of true fascia between the vagina and rectum. Last, defect-directed, also called site-specific, repair reapproximates attenuated vaginal wall at specific bulge sites rather than rotely in the midline. Among these, evidence suggests that midline plication without levator myorrhaphy has superior objective outcomes compared with site-specific repair and has lower dyspareunia rates than levator myorrhaphy (Karram, 2013). For these reasons, midline plication without levator myorrhaphy is the procedure of choice for posterior compartment prolapse except perhaps in select cases, such as women with large genital hiatus undergoing colpocleisis.

Importantly, compared with these methods, a biologic or synthetic graft in the posterior compartment does not improve anatomic

or functional outcomes (Maher, 2013; Paraiso, 2006; Sung, 2012). Well-designed studies that demonstrate efficacy and safety of newly developed grafts are needed before surgeons incorporate these materials into their practices.

## PREOPERATIVE

## ■ Patient Evaluation

A detailed discussion of symptoms begins every patient evaluation prior to colporrhaphy. Often, patients may associate all of their bowel symptoms to a posterior wall bulge, but the two may not be related. Specifically, if constipation is a major complaint, further evaluation and trial of nonsurgical treatment is typically indicated (Chap. 25, p. 569). Symptoms most likely to be cured or improved by posterior repair include the sensation of vaginal bulge and the need to digitally compress the rectal vault for defecation. Also termed vaginal splinting, compression involves placing fingers in the vagina and pushing downward over the defect or sweeping forward to help empty bowel. As another compensatory action, a digit may be inserted in the rectum to scoop out stool.

Posterior wall prolapse commonly accompanies other support defects, and patients undergo a complete pelvic organ prolapse examination. If concurrent anterior vaginal wall or vaginal apex prolapse is present, these are also repaired.

## ■ Consent

In addition to standard surgical risks, this procedure may be associated with failure to correct symptoms or anatomy. Accordingly, a patient and surgeon identify treatment goals and clarify expectations. In the few completed randomized studies, current techniques give a less than optimal anatomic repair, and success rates approximate 70 percent. Another frequent postoperative risk is dyspareunia, which is more common following the levator ani muscle plication discussed earlier. Accordingly, levator plication is not recommended in women who desire to preserve coital function. Injury to the rectum or rectovaginal fistula is another rare but potential complication.

## ■ Patient Preparation

Depending on surgeon preference, patients may be instructed to take in only clear liquids the day prior to surgery and complete one or two enemas that night or the morning of surgery. Ballard and associates (2014), however, noted no distinct advantage to

this. Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** If done in isolation, posterior colporrhaphy is typically a day-surgery procedure for healthy women and performed under general or regional anesthesia. A patient is placed in standard lithotomy position in candy-cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter inserted.

□ **Concurrent Surgery.** Posterior colporrhaphy can be performed with the uterus in situ or alternatively, following hysterectomy. If other reconstructive surgeries are required, they may precede or follow posterior colporrhaphy. Notably, completion of the posterior repair prior to vaginal apex suspension permits the plicated and thus more substantial tissue to be anchored to selected ligaments during apical suspension.

□ **Vaginal Incision and Dissection.** Two Allis clamps are placed on the posterolateral wall of the distal vagina on either side of the midline. Clamps are gently pulled laterally to create tension, and the vaginal wall between them is incised transversely at or just proximal to the level of the hymen and superficial to the perineal body. A third Allis clamp is placed in midline and 3 to 4 cm proximal to the introitus. All three clamps are held, creating gentle outward tension. Metzenbaum scissors tips are insinuated beneath the epithelium in the midline of the previously made transverse incision and directed cephalad (Fig. 45-15.1). Scissor blades are opened and closed, while the surgeon exerts gentle forward pressure that is parallel to and within the plane beneath the vaginal epithelium. This technique allows separation of the epithelium from the fibromuscular layer. This dissection continues cephalad to reach the proximal midline Allis clamp. The undermined vaginal epithelium is then incised in the midline longitudinally.

The midline Allis clamp is then replaced further cephalad, and the process continues until the vaginal epithelium has been divided to the level of the vaginal apex. If a concurrent hysterectomy has been performed, the colporrhaphy incision generally extends to the cuff incision. In either case, if only a simple discrete distal to mid-vagina defect is present, then the midline colporrhaphy incision stops just cephalad to that defect's proximal border.

**FIGURE 45-15.1** Vaginal incision and dissection.

**FIGURE 45-15.2** Rectal examination.

□ **Lateral Dissection.** Along the freed epithelial edges, additional Allis or Allis-Adair clamps are placed to create gentle outward tension, while the vaginal epithelium is dissected laterally off the vagina's fibromuscular wall. This is accomplished with one finger placed behind the epithelium to accentuate the dissection plane. Scissors are held parallel to the vagina and cut connective tissue fibers between the epithelium and fibromuscular layer.

During this early lateral dissection, the perineal body is fused with the vaginal wall fibromuscular layer, and scarring may be present from prior episiotomy. Thus, clear tissue planes are not typically present, and sharp dissection is required. Cephalad to the perineal body, once the desired tissue plane is entered, a combination of sharp and blunt dissection readily separates the layers. Simultaneous countertraction on the fibro-

muscular tissue by an assistant using tissue forceps or a gauze-covered finger can aid dissection. Separation in the correct tissue plane is essential. Deep dissection can enter rectum, whereas superficial dissection can create holes in the vaginal epithelium, often called "button holes."

This tissue separation is extended laterally toward the pelvic walls until substantial fibromuscular tissue is exposed to permit

**FIGURE 45-15.3** Midline defect.

**FIGURE 45-15.4** Midline plication.

**FIGURE 45-15.5** Distal defect.

**FIGURE 45-15.6** Defect-directed repair.

midline plication. The steps are then repeated on the contralateral side.

□ **Rectal Examination.** Rectal examination is performed to exclude rectal injury and to help identify the edges of the fibromuscular wall to be plicated (Fig. 45-15.2).

□ **Midline Plication.** A series of interrupted 2-0 gauge delayed-absorbable sutures are used to plicate the vaginal muscularis and perineal body tissue along the length of the posterior vaginal wall (Figs. 45-15.3 and 45-15.4). As noted, levator plication is avoided in patients who desire to preserve coital function as the risks of vaginal lumen narrowing and dyspareunia may be higher. To plicate tissue, an interrupted stitch of 2-0 gauge delayed-absorbable suture is placed on one side of the midline beginning nearest the apex. This same needle and suture are carried to the other side of the midline, and a mirror stitch is placed the same distance from the apex. The bites of each stitch are generously spaced to bring together the wide lateral span of attenuated tissue. Such plication creates a firm fibromuscular wall layer to support the rectum and if indicated, the perineal body. However, excessive tension is avoided to prevent sutures from pulling through the

fibromuscular tissue or from significantly narrowing the vagina. As sutures are tied, the midline rectal bulge is gently pushed downward by the surgeon and away from the incision line.

Rectal examination is again performed after all sutures are placed to exclude inadvertent suture placement into the rectum. If identified, these are removed and correct suture placement completed.

□ **Defect Assessment.** In some instances, a discrete defect is identified in the posterior fibromuscular layer after the initial dissection. Defects may be lateral, midline, apical, or perineal (Figs. 45-15.5 and 45-15.6). Repair focuses solely on the defect, which is closed by interrupted stitches of 2-0 gauge delayed-absorbable sutures. This is generally a one-layer closure. This repair may be complemented by a midline plication if significant tissue attenuation is still noted.

□ **Indicated Apical Suspension.** If indicated, apical suspension is performed after vaginal wall plication. The proximal posterior vagina is affixed to either the uterosacral or sacrospinous ligament, as described on page 1107. If perineorrhaphy is planned, it is also completed prior to incision closure.

**9 Incision Closure.** Following plication, redundant vaginal wall often remains and requires trimming. Liberal trimming, however, can narrow the vagina and can place the vaginal wall incision on excessive tension that impairs wound healing. The vaginal mucosa is reapproximated in a running fashion using a 2-0 gauge delayed-absorbable suture. Widely positioned sutures are avoided as they can create accordion-type bunching of the vaginal epithelium and subsequent vaginal shortening when the final suture is tied.

## POSTOPERATIVE

Patients are instructed on perineal hygiene. Constipation and straining are avoided, and stool softeners are usually prescribed. As with other vaginal surgery, diet and activity can be advanced as tolerated. Women, however, abstain from intercourse until wound healing is complete, typically at 6 to 8 weeks following repair. Some women have urinary retention after posterior repairs, even without an antiincontinence procedure. If unable to void spontaneously by the time of discharge, a patient can go home with a catheter and be seen again within a week for removal.

## 45-16

## Perineorrhaphy

The perineal body serves as core support of the distal vagina, rectum, and pelvic floor. Therefore, a damaged or weakened perineal body may contribute to distal prolapse. Reinforcement of this structure, that is, *perineorrhaphy*, is often performed in conjunction with other reconstructive procedures, such as posterior colporrhaphy. To reestablish distal support, perineorrhaphy lengthens the anteroposterior dimension of a shortened perineal body, while the genital hiatus is concurrently narrowed.

## PREOPERATIVE

## ■ Patient Evaluation

During assessment, the length of the genital hiatus is measured in centimeters both at rest and with Valsalva maneuver from the external urethral opening at 12 o'clock to the posterior aspect of the hymeneal ring at 6 o'clock. The perineal body is measured from the hymeneal ring at 6 o'clock to the mid-anus.

With perineorrhaphy planning, the degree to which the perineal body is lengthened can be tailored according patient symptoms, surgical goals, and clinical findings. With typical perineorrhaphy, the degree of perineal body lengthening is minimized to create or maintain a genital hiatus wide enough to preserve comfortable intercourse. Moreover, in sexually active postmenopausal women whose partners have decreased erectile tone, entry into the vagina may be difficult if the introitus is too narrow. Thus, following perineorrhaphy, 2 to 3 fingers ideally comfortably pass through the introitus.

For women with "perineal descent" who have to splint to defecate or in those with distal defects and attenuated perineal body tissue, perineorrhaphy may be coupled with posterior colporrhaphy. As described on page 1093, the distal extent of the plicated rectovaginal wall can be reattached to the perineal body. This reestablishes continuity of connective tissue support in the posterior vaginal compartment.

In some women, pelvic support takes precedence, and coital function is also not desired. With "high" perineorrhaphy, the superior-to-inferior extent of the perineal body is lengthened and generally accompanied by plication of the levator ani muscle fascia at the superior aspect of the perineal body. The result of this extensive perineorrhaphy is a shorter genital hiatus length and narrower introitus and vaginal lumen. This may be an advanta-

geous adjunct to colpocleisis. However, data showing improved colpocleisis outcomes by adding levator myorrhaphy are limited (Gutman, 2009).

## ■ Consent

A patient preparing for perineorrhaphy is counseled regarding risks of postoperative dyspareunia, prolapse recurrence, or wound complications, such as a stitch abscess. Bleeding from perineal skin tearing during intercourse may also result and require minor surgical revision.

## ■ Patient Preparation

Because of the surgical site's close proximity to the anus and also because bowel injury is possible, antibiotic prophylaxis is administered prior to surgery to minimize wound infection risks (Table 39-6, p. 835). Bowel preparation, which may employ clear liquid diet and enemas, mirrors that for posterior repair (p. 1093). Tetracycline prophylaxis is given as outlined in Table 39-8 (p. 836).

## INTRAOPERATIVE

## ■ Surgical Steps

## □ Anesthesia and Patient Positioning

Perineorrhaphy is typically performed under general or regional anesthesia, and this choice is often dictated by concurrent surgeries planned. The patient is placed in standard lithotomy position in candy-cane or booted support stirrups. A vaginal and rectal examination under anesthesia is again performed to assess the size of the perineal body and defects of the posterior vaginal wall, which may also require repair. The vagina is surgically prepared, and a Foley catheter inserted.

□ **Concurrent Surgery.** If concurrent surgeries have been included, perineorrhaphy is the final procedure in most cases.

□ **Incision.** To determine the approximate appearance of the final repair, Allis clamps are placed on the posterolateral walls of the vagina at or just proximal to the hymen. These are brought together in the midline and 2 or 3 fingers should easily pass through the intended genital hiatus. If the resulting opening is too narrow, both Allis clamps are moved closer to the midline, and the above steps are repeated. With this technique, a surgeon can judge the final size of the introitus and perineal body. Because scarring and retraction can develop, it is prudent to err on the side of leaving the genital hiatus larger rather than smaller. To begin, a diamond-shape incision

is made with its cephalad tip extending 2 to 3 cm into the vagina and the caudal tip extending to a point approximately 2 cm above the anus.

□ **Removal of Skin and Mucosa.** For traction, Allis clamps are placed at each corner of the diamond. Metzenbaum scissors are used to excise the perineal skin and vaginal epithelium within the diamond away from the underlying tissue. During dissection, the scissor tips are held parallel to the perineal and vaginal tissues, respectively.

Sharp dissection must be performed over the perineal body. This area contains a normal condensation of tissue, and scarring may also be present. As a result, development of good tissue planes is often not possible. A dilute vasopressin solution may be injected to decrease bleeding from extensive venous sinuses that are typically encountered in this region from obstetric or vaginal delivery scars. Frequent rectal examination during dissection may be required to assess the amount of tissue present between the anal and vaginal epithelium to prevent entry into the rectum.

□ **Suture Placement.** One centimeter caudal to the hymeneal ring, a 0-gauge delayed-absorbable suture on a CT-1 needle is used to approximate the connective tissue surrounding the perineal muscles (bulbospongiosus and superficial transverse perineal muscles) in the midline. In suturing this tissue, a wide lateral bite is taken, and suture is directed first in an inward-to-outward and then outward-to-inward sequence (Fig. 45-16.1). This suture technique ultimately buries knots below the plicated muscles. However, initially, the first suture is held and not tied.

Downward traction is placed, and a second suture is placed approximately 1 cm cephalad. This suture ideally reapproximates the separated ends of the perineal membrane. As with the first, this suture is not tied. A third suture can be placed 1 cm further cephalad to this, if necessary. In a similar fashion, one to two stitches are placed 1 cm apart and caudad to the primary suture. These lower stitches plicate the connective tissue surrounding the superficial transverse perineal muscles and upper extent of the external anal sphincter muscle in the midline. The sutures are then progressively tied beginning with the lowermost. In some cases, a second, more superficial layer is placed in the perineal body for additional support.

□ **Vaginal and Perineal Closure.** Starting at the vaginal apex, the vaginal epithelium is closed in a running fashion using 2-0 gauge delayed-absorbable suture (Fig. 45-16.2). When creating a running suture line in the

**FIGURE 45-16.1** Suture placement.

**FIGURE 45-16.2** Wound closure.

vagina, stitches are placed close together. If suture bites are placed far apart during epithelial closure, the vagina can be shortened.

The running suture reapproximates the hymeneal ring and then is brought into the perineal area. The same suture may be used in a running mattress method to reapproximate the subcutaneous tissue to the end of the incision, near the anus. The skin is then reapproxi-

mated in an interrupted or running fashion using 3-0 gauge delayed-absorbable suture.

### POSTOPERATIVE

Patients are instructed on perineal hygiene. Constipation is avoided and stool softeners are usually prescribed. As with other vaginal surgery, diet and activity can be advanced as

tolerated. Women, however, abstain from intercourse until wound healing is complete, typically at 6 to 8 weeks following repair. Some women have urinary retention after perineorrhaphy, even without an antiincontinence procedure. If unable to void spontaneously by the time of discharge, a patient can go home with a catheter and be seen again within a week for removal.

## 45-17

## Abdominal Sacrocolpopexy

Abdominal sacrocolpopexy (ASC) using graft material is a widely accepted transabdominal prolapse operation, and many consider it the preferred procedure to correct advanced apical prolapse. Grafts of autologous, cadaveric, or synthetic materials may be used, but permanent (synthetic) mesh has the best success rate and is selected unless otherwise contraindicated (Culligan, 2005). The graft augments native tissue and suspends the upper third of the vagina to the anterior longitudinal ligament of the sacrum. In addition to correcting apical prolapse, the graft also covers proximal portions of the anterior and posterior vaginal walls. As such, ASC also corrects apical segment prolapse of the anterior vagina wall (“apical” or “transverse” cystoceles) and of the posterior vaginal wall (enteroceles and “high” rectoceles). A modification of the procedure, sacrocolpoperineopexy, is used if concomitant perineal descent is present and believed to contribute to patient symptoms (Cundiff, 1997).

One advantage to ASC is its durability, and long-term success rates for apical suspension approximate 90 percent. It may be used as a primary procedure or alternatively as a repeat surgery for patients with recurrences after other prolapse repair failures. In addition, ASC is often chosen for women believed to be at high risk for recurrence and for whom mesh would augment their own tissue. Examples include those with connective tissue disease, history of recurrent hernia, obesity, or chronically increased intraabdominal pressure such as chronic obstructive pulmonary disease or chronic constipation. Abdominal synthetic mesh aids durability, but its use is balanced against the potential for complications, as discussed later.

Although the vaginal apex can also be successfully suspended with vaginal approach procedures such as sacrospinous ligament fixation (p. 1112) and uterosacral ligament suspension (p. 1107), ASC offers distinct advantages. First, ASC maintains or lengthens the vagina, in contrast to vaginal approaches, which may shorten it. Second, the use of synthetic “permanent” mesh with multiple attachment sites to the vagina has a very low risk of apical failure. Finally, unlike vaginal approaches, in which the vaginal apex is directly affixed to a structure such as the uterosacral or sacrospinous ligament, ASC repositions the vaginal apex to its nearly normal anatomic position using intervening graft material. Thus, the apex typically

remains mobile, which possibly lowers dyspareunia rates.

Sacrocolpopexy can be performed by laparotomy, by conventional laparoscopy, and with robotic assistance. If minimally invasive surgery (MIS) is performed in the same manner as the open operation, similar results can be expected (p. 1103). However, only limited data are currently available on long-term success rates with these MIS approaches (Freeman, 2013; Maher, 2013; Paraiso, 2011).

### PREOPERATIVE

#### ■ Patient Evaluation

Prolapse of the vaginal apex often coexists with other prolapse sites along the vagina. Accordingly, a careful preoperative search is performed for other prolapse sites. If necessary, ASC can be completed concurrently with paravaginal defect repair, posterior repair, or other prolapse surgeries. Beer and Kuhn (2005) found that approximately 70 percent of ASC procedures were performed with other pelvic reconstructive operations. With the technique we describe, a concurrent enterocele will be repaired by the colpopexy, and other enterocele repairs are thus unnecessary.

Prior to ASC, patients with symptoms of urinary incontinence undergo simple or complex urodynamic testing to clarify the type of incontinence and determine if an antiincontinence procedure will be beneficial. For those with SUI, a concurrent antiincontinence operation is generally performed. Because prolapse correction can unmask occult SUI in some women, clinicians also test those without incontinence while manually reducing the prolapse. Last, apical suspension can predispose to later development of anterior vaginal wall prolapse and SUI. Thus, stress-continent women undergoing ASC may elect a prophylactic SUI procedure. To evaluate this practice, the CARE (Colpopexy After Reduction Efforts) trial found that continent women undergoing ASC *plus* a prophylactic urethropexy had a 2-year postoperative SUI incidence of 32 percent. Without preventive urethropexy, SUI rates following ASC were 45 percent (Brubaker, 2006, 2008). Importantly, adding an antiincontinence procedure decreases, but does not eliminate, the risk of later *de novo* SUI. At this time, it is unclear how best to extrapolate these findings to women who elect to have sacrocolpopexy and midurethral sling procedures.

#### ■ Consent

Recurrent prolapse is common following any corrective surgery. Thus, a surgeon should be aware of recurrence rates quoted in the literature and his or her own personal

rates. Although apical prolapse recurrence is infrequent, later prolapse of the anterior and posterior vaginal walls is more common. An extension of the CARE trial used a clinically based definition of anatomic failure. It showed that by 5 years, nearly one third of women met the composite definition of failure (Nygaard, 2013). However, 95 percent had no retreatment for their prolapse.

Mesh erosion develops in 2 to 10 percent of cases. It is generally found at the apex and occurs more often if hysterectomy is performed concurrent with ASC. Erosion may arise soon after surgery or years later (Beer, 2005; Nygaard, 2004, 2013). Many technical points described in the following steps aim to prevent this complication.

#### ■ Patient Preparation

Bowel preparation will vary depending on surgeon preference. Patients can be instructed to take only clear liquids the day prior to surgery and complete one or two enemas that night or the morning of surgery. Alternatively, a mechanical bowel preparation using agents listed in Chapter 39 (p. 835) may be preferred. Ballard and associates (2014), however, noted no distinct advantage to this for urogynecologic operations. Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

For postmenopausal women, vaginal estrogen cream use during the 6 to 8 weeks prior to surgery has been routinely recommended. Estrogen treatment is thought to enhance vascularity and thereby increase tissue strength and promote healing. Although this is logical and commonly practiced, no data suggest that preoperative vaginal estrogen cream decreases mesh erosion or prolapse recurrence rates.

### INTRAOPERATIVE

#### ■ Instruments and Materials

The upper vagina must be elevated and distended by a vaginal manipulator to allow adequate dissection and delineation of the vaginal wall fibromuscular layers for mesh placement. The manipulator may be a cylindrical Lucite rod or a large EEA (end-to-end anastomosis) sizer, which is present in most operating rooms and shown in Figure 46-21.4 (p. 1202).

The ideal bridging material for this procedure is permanent, nonantigenic, easily cut or customized, and readily available. The ideal mesh has a large pore size to allow host tissue ingrowth, is monofilament to decrease bacterial adherence, and is flexible. Currently, polypropylene mesh is the most common synthetic graft used (American Urogynecologic Society, 2013, 2014b).

## ■ Surgical Steps

### □ **Anesthesia and Patient Positioning.**

Following administration of general anesthesia, the patient is positioned in a modified supine position with thighs parallel to the ground and legs in booted support stirrups. Correct positioning prevents nerve injury and allows access to the vagina for manipulation and examination, to the bladder for cystoscopy, and to the abdomen for proper self-retaining retractor placement. The buttocks are positioned at the table edge or slightly distal to allow full range of vaginal manipulator motion. The vagina and abdomen are surgically prepared, and a Foley catheter is inserted.

□ **Incision.** A vertical or transverse abdominal incision may be used, and selection is directed by a woman's body habitus and by planned concurrent procedures. A Pfannenstiel incision generally provides adequate access to the sacrum and deep pelvis. If a Burch colposuspension, paravaginal defect repair, or other surgery in the space of Retzius is planned, then a low transverse incision that is positioned closer to the symphysis may be preferred.

□ **Bowel Packing.** A self-retaining retractor, preferably a Balfour type, is placed, and the bowel is packed up and out of the pelvis with moist laparotomy sponges. Bowel packing attempts to shift the sigmoid colon farther to the patient's left, thereby permitting access to the midline and right aspects of the sacrum.

□ **Concomitant Hysterectomy.** Some data suggest that hysterectomy at the time of ASC leads to higher mesh erosion rates (Culligan, 2002; Griffis, 2006). To reduce erosion risks at the cuff, some surgeons advocate supracervical hysterectomy, theorizing that the cervical stump may act as a barrier to prevent ascending infection and erosion (McDermott, 2009). If a total abdominal hysterectomy is performed, the vaginal apex is closed with absorbable suture such as 0-gauge polyglactin 910 (Vicryl) in a running or interrupted fashion. A second imbricating layer using the same suture may be placed to reduce potential mesh erosion. Another preventive measure is avoiding mesh fixation near the cuff suture line. Specifically, a 1-cm margin from this suture line may avert early mesh erosion during the cuff's healing phase.

□ **Identification of Pelvic Anatomy.** Important boundaries during presacral space dissection are identified beneath the peritoneum prior to the posterior peritoneal incision. These include the aortic bifurcation, iliac vessels, right ureter, right uterosacral ligament, medial border of the rectosigmoid

colon, and sacral promontory, which is the upper anterior surface of the S1 vertebra. An understanding that the right ureter, right common iliac artery, and left common iliac vein all lie within 3 cm of the sacral promontory's midline may lower rates of their injury during surgery in the presacral space (Good, 2013b; Wieslander, 2006). Moreover, both ureters are threatened during dissection of the bladder off the anterior vaginal wall and during suturing of the anterior mesh strip.

□ **Peritoneal Incision.** The rectosigmoid colon is gently retracted to the left with a malleable ribbon or similar retractor. The peritoneum overlying the sacral promontory, between the rectosigmoid colon's medial border and the right ureter, is elevated with tissue forceps and incised sharply. The incision is extended caudally into the posterior cul-de-sac of Douglas. As the incision approaches the deeper portion of the cul-de-sac, it is kept between the medial border of the rectum and the right uterosacral ligament. A vaginal manipulator directed ventrally to create tension aids dissection. The incision may then be continued to the posterior vaginal wall and toward the vaginal apex.

Maintaining proper orientation is critical during this step as inadvertent deviation can cause ureteral or iliac vessel injury on the right, or colon injury on the left. Similarly, if the initial peritoneal incision is extended above the sacral promontory, the left common iliac vein should be identified and avoided. This vessel can lie less than 1 cm from the promontory and is generally difficult to visualize or palpate due to its absent pulsatility and decreased tone. Final closure of this peritoneal incision allows the mesh to lie retroperitoneally. This may lower the risk of bowel-to-mesh adhesions and of bowel obstruction from small-bowel loops entrapped below the bridging mesh strip.

□ **Identification of Anterior Longitudinal Ligament.** Following peritoneal incision, the loose connective tissue between the peritoneum and the sacrum is sharply and bluntly dissected to expose the anterior longitudinal ligament lying along the sacrum's vertical midsection. Generally, this presacral space dissection is started at the promontory and continued 3 to 4 cm inferiorly to the upper extent of the S2 vertebra. Within the connective tissue of the presacral space, fibers of the superior hypogastric nerve plexus, right and left hypogastric nerves, and the inferior mesenteric and superior rectal artery and vein are embedded (Fig. 38-23, p. 816). Of these, the right hypogastric nerve is the most common structure identified during dissection. Below the aortic bifurcation, this midline cordlike nerve courses laterally and at the lower sacral levels,

reaches the right pelvic sidewall. Transection of this nerve is ideally avoided.

Also of seminal importance, the middle sacral vessels typically adhere to the anterior surface of the ligament. Once found in the area exposed for mesh attachment, middle sacral vessels can be avoided, ligated, or coagulated depending on surgeon's preference and operative findings. The middle sacral vein also forms anastomoses with the lateral sacral veins that contribute to the sacral venous plexus. Vessels of this plexus can be extensive, especially in the lower part of the sacrum.

□ **Presacral Space Hemorrhage.** Careful exposure of the anterior longitudinal ligament and overlying vessels helps prevent bleeding during suture placement. Despite these efforts, laceration of the sacral venous plexus can lead to rapid and substantial blood loss, and several steps are critical to its control. First, pressure is applied immediately and held for several minutes. This may be particularly effective for venous bleeding. Sutures and clips may be useful, but tearing of small veins frequently worsens with suturing. Additionally, as vessels retract into the bone, isolation and ligation becomes difficult. Sterile thumbtacks directed through lacerated vessels and pushed into the sacrum can effectively compress such vessels. Unfortunately, these tacks are not routinely found in many operating rooms.

Alternatively, various topical hemostatic agents have been used to control bleeding refractory to these initial steps (Table 40-5, p. 861). Of these, the fibrin sealant family allows conformation to irregular wounds, which is a distinct advantage for presacral space hemorrhage. In refractory cases, vascular surgery consultation may be prudent. Also, injury to the iliac vessels or aorta necessitates immediate consultation.

□ **Sacral Suture Site Selection.** To anchor the suspending mesh strips proximally, a surgeon must decide whether to place sutures through the anterior longitudinal ligament at higher or lower sacral levels. Suture placement at the S3 or S4 vertebral bodies increases the risk of sacral venous plexus laceration, and this practice has largely been abandoned. Suture placement above the sacral promontory risks left common iliac vein injury and penetration of the L5-S1 disc, which may lead to painful discitis or osteomyelitis (Good, 2013a; Wieslander, 2006). However, this disc is the most protuberant structure in the presacral space, and mesh is commonly affixed here, especially during the learning phase of ASC (Abernathy, 2012).

For correct sacral promontory identification, the steep angle of descent between L5 and S1 can be used. That said, even correct suture placement at S1 and the sacral

**FIGURE 45-17.1** Placement of sacral sutures.

promontory still risks middle sacral vessel laceration. However, at S1, the middle sacral vessels are visible and can be easily isolated and avoided or when necessary, clipped or coagulated. Additionally at S1, the anterior longitudinal ligament is thicker and stronger than at lower sacral levels (White, 2009). Affixing sutures here minimizes suture avulsion risks. Finally, attachment of the mesh at S1 may result in a more anatomic suspension of the vaginal apex (Balgobin, 2013).

For these reasons, we prefer to affix mesh to the anterior surface of S1, with the most cephalad suture placed at or just below the sacral promontory. If safe suture placement over the S1 vertebra is prohibited, then the level of the L5-S1 disc is an alternative. Shallow tissue “bites” are needed here to avoid the disc as the anterior longitudinal ligament is only 1 to 2 mm thick.

□ **Sacral Suture Placement.** Typically, three or four serial permanent sutures are used to affix the sacral portion of mesh to the anterior longitudinal ligament. These stitches can be placed first, as described here, or later after vaginal mesh attachment. Needle passage moves from right to left with each stitch, and sutures are aligned vertically. Starting with the lowest suture, they are spaced approximately 0.5 to 1 cm apart. With suturing, 2-0 gauge permanent material, each double-armed with SH needles, is passed through the full thickness of the anterior longitudinal ligament (Fig. 45-17.1). During this, based on findings, suture “bites” either encompass or avoid vessels. Once completed, sutures are held by a hemostat

and not tied. Their needles are covered with a surgical towel to avoid stick injuries.

⑩ **Anterior Vaginal Wall Dissection.** Prior to mesh attachment, the peritoneum and bladder must be dissected off the proximal vagina. Dissection of the bladder from the upper third of the anterior vaginal wall is aided by the vaginal manipulator. The cervical stump or vaginal apex is displaced cephalad and dorsally, and its covering peritoneum is incised transversely and proximal to the bladder’s cephalad margin. With prior hysterectomy, careful identification of the vaginal apex and superior extent of bladder is critical to avoid cystotomy. This is especially important in women with short vaginal lengths or vesicovaginal adhesions. In these cases, retrograde bladder filling and Foley bulb identification may help delineate the upper bladder margin. With cystotomy, several options are possible. If the cystotomy is small and close to the bladder dome, then a two- to three-layered bladder closure, followed by an interposition flap (omental or peritoneal), may be considered. However, if the cystotomy is large or nears the trigone, an alternative approach to vault suspension using native tissue may be considered to minimize mesh erosion into the bladder or fistula formation. Alternatively, the cystotomy can be repaired, and ASC deferred for a later time.

Once the correct vesicovaginal space is entered, the bladder is sharply dissected from the anterior vaginal wall for a distance of approximately 4 to 6 cm caudad to create an extensive surface for mesh fixation. However, the extent of this dissection varies depending

**FIGURE 45-17.2** Dissection of the anterior vaginal wall.

on intraoperative anatomy. Sharp rather than blunt dissection is preferred in the vesicovaginal space (Fig. 45-17.2). Electrosurgical energy use is minimized to reduce risks of delayed thermal bladder injury. Dissection progresses at a depth above the fibromuscular layer of the vaginal wall. Entry into this proper plane lowers the rate of incidental entry into the vagina, which may increase future mesh erosion risks. If the vaginal lumen is entered, the opening is irrigated copiously and closed in two imbricated layers using 2-0 or 3-0 gauge delayed-absorbable suture.

#### ⑪ **Posterior Vaginal Wall Dissection.**

To expose an area of adequate size for mesh fixation, the rectovaginal space is entered, and the rectum is separated from the posterior vagina. For this, the vaginal manipulator now displaces the vaginal apex ventrally. The reflection of the rectum against the posterior vaginal wall is identified, and the peritoneum is incised transversely 2 to 3 cm proximal to this reflection line. The right and left uterosacral ligaments are used as lateral dissection boundaries. With gentle outward traction on the peritoneum, the rectovaginal space is developed with a combination of sharp and blunt dissection. In the absence of adhesions or fibrosis, the rectovaginal space easily opens inferiorly to the superior margin of the perineal body, which lies 3 to 4 cm above the hymen. Identification of loose gauzy connective tissue fibers usually indicates dissection in the correct plane. Also, the white, glistening posterior vaginal wall provides another visual clue, and dissection is kept close to this tissue to avoid inadvertent rectal entry.

**FIGURE 45-17.3** Posterior mesh secured and draped forward. Initially placed sacral sutures are seen in the background.

**FIGURE 45-17.4** Anterior and posterior mesh in place.

In contrast, fatty tissue or excessive bleeding generally indicates incorrect plane dissection and potential proximity to the rectum.

**13 Graft Principles.** Whether two separate strips of self-cut mesh or a commercially pre-formed Y-shaped mesh is used, several surgical principles are generally followed. First, depending on the extent of dissections, six to 12 sutures on the anterior and a similar number on the posterior vaginal wall are placed through the mesh and the vaginal wall muscularis. Sutures ideally do not enter the vaginal lumen because epithelial healing over the stitches may be incomplete, especially with braided suture. However, if the fibromuscular layer is thin, this may not be possible. In this setting, many select monofilament, delayed-absorbable suture, which has a greater propensity for epithelialization postoperatively.

Second, sutures are tied down loosely to avoid tissue strangulation and vaginal wall necrosis, which may lead to mesh or suture erosion. Third, the lower extent of the mesh does not abut the bladder or rectal reflections to minimize potential risks of pelvic organ dysfunction or mesh erosion of into these organs. Last, mesh is positioned symmetrically across the width of both the anterior and posterior vaginal walls.

At our institution, we fashion the two mesh strips only after vaginal dissection is completed. The broader area of each strip will cover the dissected anterior vaginal surface and posterior vaginal surface, respectively. Each strip also has a narrowed portion that will extend to the sacrum and be affixed to the anterior longitudinal ligament. This

narrowed portion reduces mesh bulk, especially near the rectum on the left and the iliac vessels and ureter on the right, to lower mesh erosion rates. However, excessive narrowing may compromise overall repair strength (Balgobin, 2011). Generally, the narrow portion of mesh measures approximately 2 cm. Lengthwise, the proximal end of mesh is initially left long to allow correct positioning to the sacrum and later is trimmed.

**14 Mesh Placement.** To begin, the vaginal manipulator is pushed cephalad and ventrally to fully expose the dissected posterior vaginal wall and stabilize the vagina for suturing. The mesh is commonly attached to the posterior vaginal wall with two to four rows of 2-0 gauge permanent or delayed-absorbable sutures, and rows are placed approximately 1.5 cm apart (Fig. 45-17.3). Depending on the vaginal width and the lateral extent of dissection, each row consists of two to three sutures spaced 1 to 1.5 cm apart. The inferior and lateral extents of the dissected vagina are adequately exposed prior to suture placement to avoid incorporation of rectum into a stitch.

For the anterior vaginal wall, mesh is sutured in exactly the same fashion as was performed on the posterior wall (Fig. 45-17.4).

**15 Mesh Sizing and Sacral Attachment.** For this step, the prior sacral dissection is again exposed, and the two proximal portions of each mesh strip are held together by a right-angle clamp for maneuvering. The vaginal manipulator is removed and replaced by surgeon fingers. Then, by digital pressure directed cephalad, the cuff is gently elevated,

and the proximal portions of mesh are extended to the earlier placed sacral sutures. Alternatively, the cuff can be gently elevated by the vaginal manipulator. With correct positioning, apical suspension reduces prolapse of the apex and the apical segments of the anterior and posterior vaginal walls. Moreover, the mesh segment between the vagina and sacrum should be tension free. Once the desired mesh position and length are determined, the excess mesh above the most cephalad sacral suture is trimmed off. This avoids mesh contact with the right ureter, iliac vein, and other vascular structures that all lie within 1 to 2 cm of the fixation site (Kohli, 1998; Nygaard, 2004).

The six needles of the three double-armed sacral sutures are then passed through the proximal portions of both mesh strips (Fig. 45-17.5). Each of the three sutures is then tied to secure the proximal mesh to the anterior longitudinal ligament (Fig. 45-17.6). To prevent air knots while the lowest sacral suture is secured, the surgeon gently pushes the vaginal apex against the lower part of the sacrum with the vaginal manipulator.

**16 Peritoneal Closure.** Reapproximation of the peritoneum over the mesh can be accomplished in a running or interrupted fashion using 3-0 or 2-0 gauge absorbable suture (Fig. 45-17.7). Placing this mesh retroperitoneally theoretically may lower the risk of bowel obstruction, but this complication has been reported despite peritoneal reapproximation (Pilsgaard, 1999). During closure, the right ureter is kept in constant view to avoid kinking or direct injury.

FIGURE 45-17.5 Mesh attachment to the sacrum.

FIGURE 45-17.6 Final mesh placement.

**17 Cystoscopy.** Cystoscopy is routinely performed prior to laparotomy closure to document ureteral integrity and absence of bladder sutures or injury. Urethral examination is important if an antiincontinence procedure is also performed.

**18 Abdominal Closure.** The abdomen is closed in a standard fashion (Section 43-1 or 43-2, p. 928).

## POSTOPERATIVE

### ■ Patient Care

Postoperative in-hospital management is similar to that for other intraabdominal surgeries.

Specific to ASC, a passive or active voiding trial can be performed on postoperative day 1 or 2, depending on the patient's condition and extent of dissection. Some women have urinary retention after apical suspension, even without an antiincontinence procedure. If unable to void spontaneously by the time of discharge, a patient can go home with a catheter and be seen again within a week for removal. A stool softener is prescribed when regular diet is tolerated, and constipation and straining are ideally avoided.

At routine postoperative visits, the patient is evaluated for prolapse recurrence and mesh or suture erosion. Symptoms of pelvic floor dysfunction are also elicited. Anatomic suc-

cess does not always correlate with functional success, and vice versa. Thus, continual evaluation of surgical results is based on anatomy and on symptoms such as urinary incontinence, defecatory dysfunction, pelvic pain, and sexual dysfunction.

### ■ Complications

Following ASC, the graft material or its attaching sutures can erode through the vaginal epithelium. On average, symptoms develop 14 months following surgery, and vaginal bleeding and discharge are classic symptoms (Kohli, 1998). The diagnosis is generally straightforward, as mesh or sutures can be seen directly during speculum examination.

Mesh erosion through the vaginal mucosa may initially be treated with a 6-week or longer course of intravaginal estrogen cream. For those with exposed mesh and symptoms, surgical removal in an operating suite may be performed vaginally. Epithelium around the erosion site is sharply dissected from the mesh and undermined. The mesh is grasped, placed on gentle tension, dissected off the overlying tissue, and as much mesh as can be identified is resected. The vaginal epithelial edges are then trimmed to freshen edges and reapproximated in a running or interrupted fashion using 2-0 gauge delayed-absorbable suture. Failure of these wounds to heal is interpreted as a sign of graft or tissue infection, and more extensive or complete removal of the graft is considered. Sutures that are eroding into the vagina may be cut and removed in the office. Fortunately, removal of sutures or portions of eroding mesh does not generally compromise prolapse correction.

FIGURE 45-17.7 Peritoneal closure.

## 45-18

## Minimally Invasive Sacrocolpopexy

Sacrocolpopexy (SC) is increasingly being performed with a minimally invasive approach using conventional laparoscopy or robot-assisted laparoscopy. The basic procedural steps are the same as for laparotomic ASC and differ mainly by abdominal entry method and instruments used. Steps are outlined here, but a fuller discussion is found in Section 45-17.

Although not as extensively studied as abdominal sacrocolpopexy (ASC), limited data suggest that minimally invasive SC has similar short-term functional and anatomic results, shorter hospitalization, but longer operating times and greater cost (Judd, 2010; Siddiqui, 2012). Several randomized trials have compared outcomes and costs of laparoscopic sacrocolpopexy (LSC) with robotic sacrocolpopexy (RSC) (Anger, 2014; Paraiso, 2011). Compared with LSC, RSC carries increased cost, operative time, and higher pain scores, but short-term anatomic and functional outcomes and complications are similar. Data also show a longer robotic learning curve to achieve proficiency. That said, as robotic technology and training continues to develop, operative time, costs, and complications will likely decline.

### PREOPERATIVE

#### ■ Patient Evaluation

Candidates for minimally invasive SC undergo the same prolapse and incontinence evaluation as for ASC (p. 1098). As discussed in Chapter 41 (p. 874), factors influencing approach include patient overall health, restrictions to prolonged anesthesia, body habitus, intraabdominal adhesions, and surgeon skill.

#### ■ Consent

Consent considerations mirror those for ASC. Additionally, with the minimally invasive approach, patients are counseled and consented for laparotomy if surgery cannot be completed by MIS. In addition, complications more common to laparoscopy are discussed (Chap. 41, p. 877). These include puncture injury to organs and vessels during abdominal entry, positioning neuropathies, and delayed thermal injury to intraabdominal organs from electrosurgical tools.

#### ■ Patient Preparation

This mirrors preparation for ASC and covers antibiotics and thromboembolism prophylaxis and bowel preparation options (p. 1098).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Following administration of general anesthesia, the patient is positioned for laparoscopy in booted support stirrups as fully described in Chapter 41 (p. 879). The buttocks are positioned slightly distal to the table edge to compensate for mild upward patient migration that often occurs in the steep Trendelenburg position needed for laparoscopy. Correct positioning decreases nerve injury rates, provides access to the vagina, and allows full rotation of vaginal manipulator and laparoscopic instruments. The vagina and abdomen are surgically prepared, and a Foley catheter is inserted.

##### □ Incision and Trocar Placement.

A full description of minimally invasive entry is found in Chapter 41 (p. 889). For LSC, four ports are generally used (Fig. 45-18.1). A 10-mm umbilical port houses the laparoscope; one 5-mm port is placed subcostally and lateral to the rectus abdominis muscle on either side for tissue manipulation; and two 10-mm ports, one in each lower quadrant, allow needle-bearing sutures to be threaded into the abdomen. Knots are tied using an extracorporeal technique, illustrated in Chapter 41 (p. 899).

For RSC, five ports are placed in a shallow “W” formation. One 12-mm umbilical port houses the laparoscope; one 8- or 10-mm assistant port is placed subcostally lateral to the rectus abdominis muscle on the right; and three 8-mm robotic ports are positioned in bilateral lower quadrants, with two on the left and one on the right. We dock the robotic cart on the patient’s left to permit manipulation of the vagina. Knots are tied using intracorporeal knot-tying techniques.

FIGURE 45-18.1 Port placement.

□ **Concomitant Hysterectomy.** The same considerations described for ASC apply to minimally invasive SC. An additional concern with minimally invasive total hysterectomy is the use of electrosurgery to amputate the uterus and its potential for greater cuff dehiscence and mesh erosion rates (Chap. 44, p. 1036). Moreover, limited data currently suggest that total hysterectomy at the time of minimally invasive sacrocolpopexy significantly increases the mesh erosion risk (Tan-Kim, 2011). Accordingly, in appropriately selected patients, supracervical hysterectomy (SCH) is preferred. During the final steps of SCH, to prepare for subsequent sacrocolpopexy, the serosal edges of the cervix may be reapproximated over the exposed endocervical canal using three to five interrupted 2-0 or 0-gauge polyglactin 910 (Vicryl) sutures.

□ **Pelvic Anatomy Delineation.** To begin sacrocolpopexy, the bowel is gently swept out of the pelvis and above the pelvic brim. With LSC, the rectosigmoid epiploicae may be sutured to the left pelvic sidewall to aid presacral space visualization. With RSC, to accomplish the same goal, an atraumatic grasper used through the third robotic port gently displaces the rectosigmoid laterally. Next, the aortic bifurcation and iliac vessels are identified, and the sacral promontory is visualized and probed in the midline. With RSC, promontory palpation using conventional laparoscopic instruments prior to robot docking is important. This provides tactile anatomic information that is not obtainable robotically. Last, other structures and boundaries are identified as described for ASC.

□ **Peritoneal Incision.** The peritoneum overlying the sacral promontory in the midline is elevated with tissue forceps and incised sharply with endoscopic scissors (Fig. 45-18.2). The incision is extended caudally into the posterior cul-de-sac of Douglas and then to the vaginal apex (Fig. 45-18.3). Upward and outward traction on the right and left peritoneal edges aids with dissection. Monopolar energy delivered through the scissors is intermittently used for peritoneal dissection and to control small-vessel bleeding.

##### □ Anterior Longitudinal Ligament Identification.

Following peritoneal incision, the loose connective tissue between the peritoneum and the sacrum is sharply and bluntly dissected to expose presacral space anatomy similar to that for ASC. Gentle dissection with scissors or atraumatic tissue forceps removes fat and areolar tissue from the sacrum. Beneath these tissues, the shiny white anterior longitudinal ligament is seen overlying the bone in the midline. A gauze sponge introduced through the assistant port

**FIGURE 45-18.2** Peritoneal incision overlying the sacrum.

**FIGURE 45-18.3** Peritoneal incision extended caudad.

or a laparoscopic Kittner can assist this dissection.

During dissection, significant hemorrhage can occur. To apply bleeding site pressure, a gauze sponge and atraumatic forceps can be introduced through an assistant port. Bleeding management otherwise follows that during ASC (Step 8, p. 1099).

□ **Sacral Suture Site Selection.** This is completed in a similar manner to that described for ASC. The anterior surface of S1 may be poorly seen with a 0-degree laparoscope due to this vertebral surface's steep angle of descent. In these cases, switching from a 0-degree to a 30-degree scope and directing it downward improves viewing.

□ **Anterior Vaginal Wall Dissection.** A vaginal manipulator is placed to elevate the vaginal apex, and the peritoneum covering it is incised transversely. Sharp and blunt dissection is used to separate the peritoneum and bladder from the anterior vaginal wall (Fig. 45-18.4). The use of electrosurgery during dissection is limited in an effort to minimize delayed thermal injury to the bladder or ureters.

□ **Posterior Vaginal Wall Dissection.** The cervical stump or vaginal apex is next directed cephalad and ventrally. The peritoneum covering the posterior vaginal wall is incised transversely at a level proximal to the reflection of the rectum against the posterior vaginal wall (Fig. 45-18.5). The right and left uterosacral ligaments are used as lateral dissection boundaries. With gentle outward

traction on the peritoneum, the rectovaginal space is entered and developed with a combination of sharp and blunt dissection similar to that with ASC.

During minimally invasive procedures, with patients positioned in steep Trendelenburg, angling a straight vaginal manipulator may be difficult and thus may limit posterior wall exposure. Access can be

improved by instead using a medium-sized Deaver retractor in the vagina with its tip directed anteriorly.

□ **Mesh Placement.** Affixing mesh to the posterior proximal vagina mirrors that in ASC. One strip of mesh is threaded into the peritoneal cavity through one of the 8- or 10-mm assistant cannulas. With graspers

**FIGURE 45-18.4** Dissection of the anterior vaginal wall.

**FIGURE 45-18.5** Dissection of the posterior vaginal wall.

placed through a contralateral operating port, the mesh is guided into place and held against the dissected portion of posterior vaginal wall. The same sutures and suturing principles used for ASC are used for minimally invasive sacrocolpopexy (Fig. 45-18.6). Sutures are placed through the mesh and the vaginal wall using laparoscopic or robotic needle drivers. However, with LSC, the knots are secured using the extracorporeal knot tying technique, but with RSC, the intracorporeal technique is used. Accordingly, long sutures, usually 30 to 36 inches, are used for LSC,

but short sutures, approximately 6 inches, are used for RSC.

With the vaginal manipulator serving as a support, a second strip of mesh is sutured to the anterior vaginal wall in the same manner as on the posterior vaginal wall (Figs. 45-18.7 and 45-18.8).

**⑪ Mesh Sizing and Sacral Attachment.** For this step, the prior sacral dissection is again exposed, and the two proximal portions of mesh are held together by an atraumatic tissue forceps for maneuvering.

Using the vaginal manipulator, the cuff is gently elevated, and the proximal portions of mesh are extended to the earlier exposed ligament over the S1 vertebra. With correct positioning, apical suspension reduces prolapse of the apex and the apical segments of the anterior and posterior vaginal walls. Moreover, the mesh segment between the vagina and sacrum should be tension free.

**⑫ Sacral Suture Placement.** Once desired mesh position and length are determined,

**FIGURE 45-18.6** Posterior mesh placement.

**FIGURE 45-18.7** Anterior mesh placement.

**FIGURE 45-18.8** Anterior mesh sutured.

**FIGURE 45-18.9** Mesh attachment to the sacrum.

**FIGURE 45-18.10** Peritoneal closure.

excess fabric above the planned most cephalad sacral suture is trimmed off. The sacral portion of the mesh is then secured to the anterior longitudinal ligament with three to four stitches that ultimately are aligned vertically along the S1 vertebra. For this, the proximal portions of both mesh strips are held against the ligament, and each stitch travels from right to left. The lowest stitch is placed first, and the needle enters the right side of the mesh, drives through the longitudinal ligament under direct visualization, and exits on the mesh's left side. To prevent air knots as the lowest sacral suture is secured, the surgeon elevates the vaginal manipulator to gently push the vaginal apex closer to and against the lower part of the sacrum.

Two or three additional sutures are next placed in the same fashion, each at a

more cephalad level. Ideally, each suture lies approximately  $\frac{1}{2}$  cm from the previous one, and the most cephalad suture is at or just below the level of the promontory (Fig. 45-18.9).

**13 Peritoneal Closure.** The peritoneum is closed over the intervening and sacral portions of the mesh with 2-0 delayed-absorbable suture in a running fashion (Fig. 45-18.10). If desired, the peritoneum over the vaginal apex is closed over the exposed mesh in a similar fashion.

**14 Return to Supine Position.** With RSC, the robot is undocked at this point. With both RSC and LSC, the patient is returned to a supine position, and the abdomen deflated prior to cystoscopy.

**15 Cystoscopy.** This is routinely performed prior to port closure to document ureteral integrity and exclude bladder sutures or injury. Urethral examination is important if an anti-incontinence procedure is also performed.

**16 Wound Closure.** Subsequent surgery completion steps follow those of laparoscopy (Chap. 41, p. 897).

## POSTOPERATIVE

Patients are usually discharged from the hospital on postoperative day 1. As with other minimally invasive surgery, diet is advanced as tolerated and early ambulation is encouraged. Other postoperative management specific to sacrocolpopexy mirrors that for ASC.

## 45-19

## Vaginal Uterosacral Ligament Suspension

The vaginal apex can be effectively suspended with various vaginal or abdominal surgeries. Of these, suturing the apex to the high (proximal) portion of each uterosacral ligaments (USL), that is, uterosacral ligament suspension (USLS), is more commonly performed vaginally, although abdominal and laparoscopic approaches are suitable. Although often modified, the ultimate USLS goal is vaginal apex support restoration by affixing the anterior and posterior vaginal walls to the uterosacral ligaments at and above the level of the ischial spines. The steps described here outline our preferred approach, which is a modification of the USLS procedure described by Shull and associates (2000).

Another vaginal apical suspension procedure, sacrospinous ligament fixation (SSLF), also strives to correct apical prolapse. However, if USLS and SSLF are compared, USLS maintains the normal vaginal axis orientation and was thought to lower rates of dyspareunia and anterior vaginal wall prolapse. However, authors of the Operations and Pelvic Muscle Training in the Management of Apical Support Loss (OPTIMAL) trial compared outcomes of these two and found that after 2 years, both showed equal composite success scores nearing 60 percent (Barber, 2014). These rates are lower than the 70- to 90-percent success rates generally reported for these apical suspension procedures, but retreatment rates remained low at 5 percent (Margulies, 2010). Of complications in the OPTIMAL trial, neurologic pain persisted in 4 percent of SSLF cases, but ureteral obstruction was more frequent after USLS and approximated 3 percent.

In addition to apical prolapse correction, vaginal USLS effectively repairs apical enteroceles, and thus other enterocele repairs are unnecessary. However, apical prolapse commonly develops in conjunction with anterior and posterior compartment prolapse. Thus, vaginal USLS is often performed with other surgeries such as colporrhaphy and perineorrhaphy to correct these defects.

### PREOPERATIVE

#### ■ Patient Evaluation

As just noted, apical prolapse often coexists with other sites of prolapse, and a careful preoperative assessment is performed.

Also prior to vaginal USLS, patients with urinary incontinence symptoms undergo

simple or complex urodynamic testing to clarify the type of incontinence. For those with SUI, a concurrent antiincontinence operation is generally performed. Because prolapse correction can unmask occult incontinence, clinicians also test continent women while manually reducing the prolapse with a moderately full bladder. Women with such occult SUI are carefully counseled and may also elect to also undergo antiincontinence surgery. Last, fully continent women undergoing vaginal prolapse surgery are also at risk for later development of postoperative SUI.

To evaluate whether a prophylactic midurethral sling (MUS) placed during apical and anterior vaginal prolapse surgery reduces this risk in stress-continent women, the OPUS (Outcomes Following Vaginal Prolapse Repair and Midurethral Sling) trial was conducted. Investigators concluded that prophylactic MUS in these asymptomatic women leads to a 27-percent postoperative SUI incidence at 1 year compared with a 43-percent rate without concomitant prophylactic MUS (Wei, 2012). These results support earlier findings of the CARE trial (p. 1098). Importantly, adding an antiincontinence procedure decreases, but does not eliminate, the risk of de novo SUI.

As another preoperative step, some suggest that estrogen may increase the vaginal wall thickness for easier dissection and suture placement. However, randomized controlled trials analyzing this treatment for reducing suture erosion or prolapse recurrence risks are lacking.

#### ■ Consent

Recurrent prolapse is common following any corrective surgery. Thus, a surgeon should be aware of recurrence rates quoted in the literature and his or her own personal rates. As noted in the prior section, urinary incontinence or voiding or defecatory dysfunction may follow USLS. Also, USLS fixes the upper vagina to the USL and has a potential to shorten the vaginal canal. Accordingly, dyspareunia is another postoperative risk. Moreover, sacral plexus nerve injury with subsequent neuropathy ensues in up to 7 percent of women following vaginal USLS (Barber, 2014; Montoya, 2012). Thus, women are counseled regarding the possible need for suture release if severe buttock pain that radiates to the posterior thigh develops postoperatively. Mild buttock pain without associated radiation and without motor deficits generally resolves during several weeks of expectant management that incorporates analgesics. Last, apical suspension suture erosion and vaginal granulation tissue are frequently reported complications (Barber, 2014).

#### ■ Patient Preparation

Bowel preparation will vary depending on surgeon preference. Patients can be instructed to take only clear liquids the day prior to surgery and complete one or two enemas the night prior to or the morning of surgery. Alternatively, a mechanical bowel preparation, listed in Chapter 39 (p. 835), may be preferred. Ballard and associates (2014), however, noted no distinct advantage to this for urogynecologic operations. Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

#### □ Anesthesia and Patient Positioning.

Vaginal USLS is typically performed under general anesthesia. The patient is placed in standard lithotomy position using candy-cane or booted support stirrups. Examination under anesthesia assesses the degree of prolapse and confirms the need for planned surgeries. The vagina and abdomen are surgically prepared, and a Foley catheter is inserted.

□ **Vaginal Apex Incision.** The initial incision can be made in various ways. If complementing vaginal hysterectomy, the vaginal cuff is already open, and each USL transfixing suture is already held by a hemostat. However, if the patient has previously undergone hysterectomy, the vaginal apex is grasped with Allis clamps, and the overlying epithelium is incised vertically or horizontally depending on circumstances. For example, for concurrent colporrhaphy, a midline vertical apical incision that extends distally along the anterior and/or posterior vaginal wall is preferred.

Alternatively, in patients with large apical enteroceles and redundant apical tissue, a diamond-shaped portion of epithelium can be excised and a new apex created. However, excessive tissue excision that may result in vaginal shortening is avoided. Stitches may then be placed at the lateral boundaries of the intended new apex for later identification. With enterocele, epithelial dissection at the apex typically reveals a peritoneal sac, which is incised to allow peritoneal cavity entry. Last, if a clear dissection plane is not identified, USLS can be performed by an extraperitoneal approach, or SSLF may be performed instead.

#### □ Packing, Retraction, and Identification.

Bowel must be adequately packed away for proper USL visualization to avoid bowel injury when high uterosacral sutures are placed. First, a Deaver retractor displaces the bladder upward. Then, a right-angle retractor or two fingers in the posterior cul-de-sac gently displace the posterior peritoneum and underlying rectum downward to avoid

**FIGURE 45-19.1** Vaginal view of sutures placed into uterosacral ligaments and vaginal walls.

peritoneum tearing, which creates bleeding and difficult USL identification. Two moist laparotomy sponges tied together are then gently threaded into the posterior cul-de-sac to pack bowel into the upper pelvis. The Deaver retractor is then repositioned to cover the laparotomy sponges. Gentle upward retractor traction exposes the mid and proximal USL portions and the deep posterior cul-de-sac close to the sacrum.

Two Allis clamps are next placed at approximately 5 and 7 o'clock positions on the posterior vaginal wall and incorporate the posterior peritoneum. Gentle downward Allis clamp traction tenses the USLs, which are then traced with the contralateral index finger. The strong ligament fibers can be traced from their distal attachments in the vagina to their proximal sacral attachment. Concurrently, the ischial spines, which protrude from the lateral pelvic walls and lie anterolateral to the USLs, are palpated. Ureters are usually indistinct to touch, but they course anterolateral to the USLs. A lighted Breisky-Navratil retractor is useful for retracting the rectum medially to further expose the USLs. A second similar retractor is often positioned on the opposite side for improved visualization of the proximal USL.

□ **Suture Placement into the Uterosacral Ligament.** Following adequate exposure, two to three sutures are placed through one USL. Sutures are equally spaced along

the mid to proximal length of each ligament. Long, straight needle drivers are useful for this. The sutures are individually tagged as they are placed, preferably with labeled clamps numbered 1 through 3 for one side and 4 through 6 for the other. Sutures are then loosely secured to the ipsilateral surgical drape. For the most distal stitch, we use a 2-0 gauge delayed-absorbable suture (*black*) with a swaged on SH needle. For the more proximal stitch(es), a similar gauge permanent material (*blue*) is selected instead (Fig. 45-19.1).

To begin, the distal absorbable suture perforates the USL at its midlength, which lies at approximately the level of the ischial spine. The subsequent, more proximal sutures are placed approximately 0.5 cm to 1 cm cephalad from each prior suture. Two or three sutures are placed on each side, and this number is guided by surgeon preference, the extent of USL exposed, and vaginal cuff width.

With each stitch placement, the needle tip ideally passes through the most medial portion of the ligament in a lateral-to-medial direction. These specifics attempt to minimize ureteral entrapment or kinking risks. Moreover, to lower rectal injury rates, an assistant retracts the rectum to the contralateral side, and suture purchases do not extend too medial, that is, beyond the ligament width. Similarly, suture bites that are too deep risk injury to internal iliac vessels or sacral nerves (Wieslander, 2007). At comple-

tion, gentle traction on each suture should confirm correct placement and incorporation of adequate USL tissue. Excess laxity during such USL traction usually indicates insufficient tissue to provide adequate apical support, and the suture is replaced.

Hematomas form occasionally following inadvertent laceration of pelvic sidewall veins. Application of pressure with a sponge stick will typically control bleeding.

□ **Other Procedures.** Once all the suspensory sutures are placed through each USL, colporrhaphy is completed if indicated. If a perineorrhaphy or midurethral sling procedure is planned, we defer these until the USLS operation is completed.

□ **Vaginal Wall Suture Placement.** Vaginal packing is first removed, and ultimately, four to six sutures (two or three from each USL) are placed along the vaginal cuff width. If one begins on the patient's left side, the free end of the left distal absorbable USLS suture (suture 1) is threaded into a Mayo needle. The needle and suture then pierce the left lateral anterior vaginal wall at the apex. The other needle-bearing suture end similarly penetrates the posterior wall (see Fig. 45-19.1). Each suture strand traverses the full vaginal wall thickness, including the epithelium.

Next, the proximal (permanent) USLS suture(s) are similarly passed through the anterior and posterior vaginal walls, each medial to the previous suture. To lower suture erosion rates, permanent sutures traverse the full thickness of the fibromuscular layer but not the epithelium. However, a substantial thickness of fibromuscular wall is incorporated to prevent tissue tearing, which can create suture bridges that are bowel obstruction risks. The same steps are then repeated on the right.

Ultimately, on each side, the most cephalad USLS sutures (sutures 3 and 6) are placed most medially on the vaginal cuff. The most distal USLS sutures (sutures 1 and 4) are placed most laterally on the vaginal cuff. For organization, all completed sutures are held within numbered clamps on their respective sides.

At this point, indigo carmine or methylene blue dye is given intravenously in preparation for cystoscopy that follows knot tying. Knots are secured starting with most medial cuff sutures (sutures 3 and 6) and ending with the most lateral (sutures 1 and 4) (Fig. 45-19.2). The vaginal wall is confirmed to approximate the USLs. Both this approximation and the order in which sutures are tied may prevent suture bridges. All sutures are held with their corresponding numbered clamps after tying until cystoscopy is completed.

□ **Cystoscopy.** This is performed to document ureteral patency and exclude bladder

**FIGURE 45-19.2** Lateral view of sutures placed into the left uterosacral ligament.

sutures or cystotomy. The ureter lies closest to the lower portion of the USL. Thus, if ureteral obstruction is suspected, the most distal USLS suture on the ipsilateral side is released first, and cystoscopy is repeated. If no flow is noted, the next most proximal suture is released, and this is continued cephalad in a stepwise fashion until efflux is seen.

□ **Rectal Examination.** The rectum is digitally explored to confirm approximation of the cuff against the USLs and exclude sutures entering the rectum.

□ **Closure of the Vaginal Cuff.** The suspension suture ends are now cut, and the vaginal cuff is reapproximated in a running

fashion with 2-0 gauge delayed-absorbable suture. Alternatively, four interrupted 2-0 absorbable sutures are placed through the full thickness of the anterior and posterior vaginal cuff prior to tying of the USL sutures and held for later cuff closure. This practice aids cuff closure with high suspensions, in which vaginal edges may be inaccessible without pulling that in turn disrupts the repair.

## POSTOPERATIVE

Following vaginal USLS, postoperative care mirrors that for vaginal surgery. Postoperative activity in general can be individualized, although intercourse is usually delayed until after 6 weeks following surgery. A voiding trial can be completed on postoperative day 1, depending on the patient's condition and general progress. Some patients have urinary retention after apical suspension, even without an antiincontinence procedure. If unable to void spontaneously by the time of discharge, the patient can be discharged with a catheter and followed up within a week for removal. Patients are screened for lower extremity neuropathy prior to discharge. Suture erosion with granulation tissue can be a short- or long-term complication and is managed as described on page 1102.

## 45-20

## Abdominal Uterosacral Ligament Suspension

Uterosacral ligament suspension (USLS) is more commonly performed vaginally (p. 1107). But for some situations, an abdominal approach, either via laparotomy or laparoscopy, offers advantages. For example, with advanced apical prolapse, many consider abdominal sacrocolpopexy (ASC) the preferred procedure. However, limited data suggest that total hysterectomy concurrent with ASC leads to higher mesh erosion rates. Thus, with total abdominal hysterectomy, abdominal USLS represents an ASC alternative to reduce graft erosion. A second possible indication is the setting of iatrogenic cystotomy during ASC. In this case, to minimize mesh erosion into the bladder or fistula formation, ASC can be aborted and USLS performed instead (p. 1102). Last, although not evidence-based, for women with concurrent pelvic cancer, mesh placement may not be ideal, and thus, USLS may be preferred.

During abdominal USLS, the mid to proximal span of both USLs is sutured to the anterior and posterior vaginal walls at the vaginal apex. Because of this suspension, enteroceles are effectively closed. Abdominal USLS is effective, and limited data show that success rates for the apical suspension approximate 90 percent (Lowenstein, 2009; Rardin, 2009). However, as with other apical procedures, subsequent anterior or posterior compartment defects are later risks.

### PREOPERATIVE

Before surgery, patients are examined to identify other prolapsed sites, which could be concurrently repaired. Similarly, overt or occult SUI is excluded. In addition, consenting includes a discussion regarding prophylactic antiincontinence surgery. As with other apical suspension procedures, and as described fully on page 1098, even stress-continent women may benefit in many cases from a prophylactic antiincontinence procedure performed concurrently. However, for abdominal USLS, data on this prophylactic practice are lacking and must be extrapolated from ASC and vaginal USLS studies. Last, as another preoperative step, some suggest that estrogen aids dissection and suture placement, as the vaginal wall thickness is increased (Rahn, 2014, 2015). However, no randomized controlled trials have analyzed

this treatment's ability to improve dissection or reduce suture erosion or prolapse recurrence risks.

Consenting mirrors that for vaginal USLS (p. 1107). Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835). Bowel preparation is selected according to surgeon preference as for vaginal USLS.

### INTRAOPERATIVE

#### Surgical Steps

□ **Anesthesia and Patient Positioning.** Following administration of general anesthesia, the patient is positioned in a low lithotomy position with thighs parallel to the ground and legs in booted support stirrups. The vagina and abdomen are surgically prepared, and a Foley catheter is inserted.

□ **Incision.** A midline vertical or low transverse abdominal incision is suitable, and a self-retaining retractor and bowel packing clears the operative field. With a laparoscopic approach, port placement is similar to that described for laparoscopic sacrocolpopexy (p. 1103).

□ **Ureter Identification.** The ureters are identified early, as these can be trapped during suture placement through the USL and can be kinked with suture tying. Thus, frequent confirmation of ureter location and cystoscopy after the suspension sutures are tied are essential steps.

□ **Identification of Uterosacral Ligaments.** Prior to hysterectomy, a surgeon identifies each USL by applying contralateral and upward uterine traction. With this technique, the USLs are stretched and more easily seen or palpated. In women with prior hysterectomy, the vaginal cuff is similarly elevated and deviated by a vaginal manipulator. The USLs run medial and posterior to the ureters, and their proximity explains the significant ureteral injury rate, which can reach 11 percent with vaginal USLS (Barber, 2000). The USL midpoint generally lies at the level of the ischial spines, which are located anterolateral to the USLs. In women with normal support, the cervix and upper vagina are located roughly at the level of these spines. Thus, this bony landmark is generally chosen as the site for the most distal USL suture. However, this site may be modified according to vaginal length and intraoperative findings.

□ **Uterosacral Ligament Suture Placement.** Following adequate exposure, two to three sutures are placed through one USL. Sutures are equally spaced along the mid to proximal length of each ligament. During suture placement, the vaginal cuff is elevated to accentuate the USLs. For the most distal stitch, we use a 2-0 gauge delayed-absorbable suture (*black*) with a swaged-on SH needle. For the more proximal stitch(es), a similar gauge permanent material (*blue*) is selected instead (Fig. 45-20.1).

To begin, the distal absorbable suture perforates the USL at its midlength, which lies approximately at the level of the ischial spine.

FIGURE 45-20.1 Uterosacral ligament suture placement.

**FIGURE 45-20.2** Vaginal cuff suture placement.

**FIGURE 45-20.3** All sutures secured.

The subsequent, more proximal sutures are placed approximately 0.5 to 1 cm cephalad from each prior suture. Two or three sutures may be placed on each side, and this number is guided by surgeon preference, the extent of USL exposed, and vaginal cuff width.

With stitch placement, each needle tip ideally passes through the most medial portion of the ligament in a lateral-to-medial direction. Moreover, the assistant retracts the rectum to the contralateral side, and suture purchases do not extend too medial, that is, beyond the ligament width. Similarly, suture bites that are too deep risk injury to internal iliac vessels or sacral nerves (Wieslander, 2007). At completion, gentle traction on each suture should confirm correct placement and incorporation of adequate USL tissue. If not, the suture is replaced.

Following each placement, sutures with needles still attached are then individually tagged, preferably with labeled clamps, and are loosely secured to the ipsilateral drape. This series is repeated on the other side.

□ **Hysterectomy.** These suspensory sutures may be placed through the USL before or after hysterectomy based on surgeon preference and intraoperative findings (Fig. 45-20.2). If sutures are placed prior to hysterectomy, they are held by numbered hemostats and not tied. Their needles are covered with a surgical towel to avoid stick injuries. Hysterectomy is then completed, and the cuff is closed.

□ **Vaginal Wall Suture Placement.** Ultimately, four to six sutures (two or three

from each USL) are placed along the vaginal cuff width. An EEA sizer or similar blunt manipulator is placed in the vagina for cuff movement. If one begins on the patient's left side, the free end of the left distal absorbable USLS suture (suture 1) is threaded into a Mayo needle. The needle and suture then pierce the left lateral anterior vaginal wall at the apex. The other needle-bearing suture end similarly penetrates the posterior wall (see Fig. 45-20.1). Each suture strand may traverse the full vaginal wall thickness, including the epithelium.

Next, the proximal (permanent) USLS sutures are passed through the anterior and posterior vaginal walls, each medial to the previous suture on the cuff. To lower suture erosion rates, permanent sutures traverse the full thickness of the fibromuscular walls but not the epithelium. However, a substantial thickness of fibromuscular wall should be incorporated to prevent tissue tearing, which can create suture bridges that are bowel obstruction risks. The same steps are repeated on the right side of the cuff.

Ultimately on each side, the most cephalad USLS suture (suture 3 or 6) is placed most medially along the vaginal cuff width. The most distal USLS suture (suture 1 or 4) is placed most laterally on the vaginal cuff. For organization, all completed sutures are held within numbered clamps on their respective sides.

At this point, knots are secured starting with the most medial sutures (sutures 3 and 6) and ending with the most lateral (sutures 1 and 4). The vaginal wall is confirmed to

approximate the ULSs (Fig. 45-20.3). Both this approximation and the order in which sutures are tied may prevent suture bridges. All sutures are held with their corresponding numbered clamps after tying until cystoscopy is completed.

□ **Cystoscopy.** To document ureteral patency and exclude bladder sutures or cystotomy, cystoscopy is performed after all suspension sutures are tied. The ureter lies closest to the lower portion of the USL. Thus, if ureteral obstruction is suspected, the most distal USLS suture on the ipsilateral side is released first, and cystoscopy is repeated. If no flow is noted, the next most proximal suture is released, and this is continued cephalad in a stepwise fashion until efflux is seen.

□ **Rectal Examination.** This is performed to confirm approximation of the cuff to the USLs and exclude sutures entering the rectum.

□ **Incision Closure.** The abdomen is closed in a standard fashion (Chap. 43, p. 928).

① **Concurrent Procedures.** If necessary, a paravaginal defect repair or other abdominal antiincontinence procedure may be performed prior to incision closure. If posterior repair or vaginal antiincontinence surgery is required, these will follow incision closure.

## POSTOPERATIVE

Following abdominal USLS, postoperative care mirrors that for abdominal sacrocolpopexy (p. 1102).

## 45-21

## Sacrospinous Ligament Fixation

Extending between the ischial spine and lower sacrum, the sacrospinous ligament (SSL) lies deep to the coccygeus muscle and adds significant stability to the bony pelvis. Fixation of the vaginal apex to this coccygeus-sacrospinous ligament (C-SSL) complex—namely, sacrospinous ligament fixation (SSLF)—is often selected for apical prolapse repair. Although there are many SSLF modifications, apex fixation to the right ligament is most often described, likely due to the left-sided location of the rectosigmoid (Goldberg, 2001; Kearney, 2003).

Gaining access to the SSL also varies. In a more traditional approach, the pararectal space and SSL are accessed through a posterior colporrhaphy incision, and only the right aspect of the apical posterior vaginal wall is attached to the ligament. Alternatively, in the *Michigan four-wall modification*, the SSL is accessed through an apical incision, dissection to the SSL remains extraperitoneal, and both anterior and posterior vaginal walls are directly affixed to the SSL by four points that span the vaginal apex width. Advantageously, this technique may avoid anterior enterocele, contralateral vaginal wall descent, and the need for bilateral suspension (Larson, 2013). A modification of the original Michigan approach is described here (Morley, 1988).

Success rates are comparable to those for other vaginal approaches for vault suspension (Barber, 2014; Maher, 2013). However, SSLF compares less favorably with abdominal sacrocolpopexy. But, SSLF averts abdominal surgery and is associated with shorter operating times and quicker recovery. For these reasons, it is often preferred for women with comorbidities. Additionally, this approach allows other concurrent support defects to be repaired vaginally as well.

### PREOPERATIVE

#### ■ Patient Evaluation

Before surgery, patients are examined to identify other prolapsed sites, which could be concurrently repaired. Similarly, overt or occult SUI is excluded. In addition, consenting includes a discussion regarding prophylactic antiincontinence surgery. As with other apical suspension procedures, and as described fully on page 1098, even stress-continent women may benefit in many cases from a prophylactic antiincontinence procedure performed

concurrently. Last, as another preoperative step, some suggest that estrogen aids dissection and suture placement, as the vaginal wall thickness is increased (Rahn, 2014, 2015). However, no randomized controlled trials have analyzed this treatment's ability to improve dissection or reduce suture erosion or prolapse recurrence risks.

#### ■ Consent

Because the vagina is fixed and laterally deviated with SSLF, dyspareunia is one postoperative risk. Also, recurrent prolapse is common following any corrective surgery. Although the apical prolapse rate following SSLF is below 10 percent, anterior vaginal wall prolapse rates can approach 30 percent (Barber, 2009). If anterior prolapse is attributed to the exaggerated posterior deflection of the vaginal axis, which exposes the anterior vaginal wall to greater intraabdominal stresses than other apical suspensions (Weber, 2005). Despite this theoretical vulnerability, the OPTIMAL trial cited earlier (p. 1107) compared SSLF and vaginal USLS 2-year outcomes and found equal composite success scores nearing 60 percent (Barber, 2014). These percentages are lower than the 70- to 90-percent success rates generally reported for these procedures. In addition, actual retreatment rates remained low at 5 percent (Margulies, 2010).

For most women, SSLF has low associated risks for serious complications, but neurovascular injury can occur. First, low-pressure vessel bleeding encountered during dissection and exposure of the pararectal space is generally attributed to retractor or needle injury of the extensive venous plexus that drains the rectum and vagina. If bleeding can usually be controlled with sustained pressure from pararectal space packing. Second, arterial bleeding may follow aggressive retraction and subsequent middle rectal artery avulsion or laceration. The internal pudendal and inferior gluteal arteries are also at risk if a needle inadvertently extends past the proximal SSL border. Arterial bleeding is best controlled by vessel ligation or clipping. An internal iliac ligation for such bleeding is ineffective due to extensive collateral circulation in the pelvis.

The pudendal nerve and lower sacral nerves such as S3 and S4 can also be damaged if the needle exits or enters past the ligament's proximal (upper) margin. Sutures that are placed too close to the sacrum risk injury to S4 or the nerve to the levator ani muscles (Roshanravan, 2007). Even sutures that are placed in the recommended mid and lower aspect of the SSL can entrap or lacerate the nerve to the levator ani muscles. Pelvic floor muscle spasms, buttock pain, and dyspareunia may be manifestations.

Moreover, sacral plexus nerve injury with subsequent neuropathy has followed vaginal SSLF. As described on page 1107, persistent neurologic pain was noted in 4 percent of SSLF cases in the OPTIMAL trial. Accordingly, women are counseled that additional surgery for suture release may be needed if severe buttock pain that radiates to the posterior thigh persists postoperatively. Mild buttock pain without associated radiation or without motor deficits is common and generally resolves within several weeks and with expectant management that incorporates analgesics. If buttock pain is generally attributed to entrapment of the nerve to the levator ani muscle.

Of other complications, ureteral and rectal injuries and ileus are rare, mainly because this procedure is extraperitoneal. In addition, as with any apical suspension procedure, voiding and defecatory dysfunction can develop.

#### ■ Patient Preparation

Bowel preparation will vary depending on surgeon preference. Patients can be instructed to take only clear liquids the day prior to surgery and complete one or two enemas that night or the morning of surgery. Alternatively, a mechanical bowel preparation using agents listed in Chapter 39 (p. 835) may be preferred. Ballard and associates (2014), however, noted no distinct advantage to this for urogynecologic operations. As with most vaginal surgery, because of the risk posed by the normal vaginal flora for postoperative wound cellulitis and abscess, preoperative antibiotics are warranted. Typical agents are found in Table 39-6 (p. 835). Additionally, thromboprophylaxis is provided as outlined in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Instruments

Suture placement into the SSL can be performed with various ligature carriers and include the Deschamps ligature carrier, Miya hook, Capio ligature carrier, and Endo Stitch. Alternatively, a Mayo needle and long, straight needle driver can be used. Using the Deschamps ligature carrier, a surgeon threads the suture through an eye at the needle-shaped carrier tip. Arcs and curves constructed into the instrument aid ease of suture placement. Once the tip of the Deschamps carrier passes through the ligament, the suture is retrieved with a nerve hook, as shown in atlas Step 4. Disadvantages to this device, however, include the relative thickness of the needle tip, which may be difficult to drive through the ligament. Alternatively, disposable devices have become popular, in particular the Capio ligature carrier. This device is easier to manipulate

**FIGURE 45-21.1** Coccygeus-sacrospinous ligament complex and surrounding pelvic anatomy. Vaginal apex diamond or “T” incisions.

**FIGURE 45-21.2** Entry into right pararectal space through rectal pillar.

than the Miya hook. Also, its design aids placement of sutures using ligament palpation and thus obviates the need for extensive dissection. To expose the ligament, Deaver and Breisky-Navratil retractors are commonly used.

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** After general anesthesia has been administered, a woman is placed in standard lithotomy position. The vagina is surgically prepared, and a Foley catheter is inserted. Initially, vaginal vault prolapse is reduced to place the vagina in a normal anatomic position.

□ **Vaginal Wall Incision.** *In the setting of vaginal cuff prolapse*, the apex is grasped and brought to the level of the ligament to confirm adequate vaginal length or need for redundant tissue excision. With advanced prolapse, a new apex site is required and most often lies posterior to the former hysterectomy scar (Kearney, 2003). When indicated, excess vaginal tissue will be excised. At the planned apex, four points in a diamond configuration are grasped with Allis clamps, are directed inward, and individually brought to lie against the SSL. This ensures fixation off tension and correction of any anterior and posterior vaginal wall redundancy. These points include one midline anterior, one midline posterior, and two lateral ones. Once determined, the diamond-shaped redundant vaginal wall within these four Allis clamps is incised to a depth reaching the underlying loose preperitoneal connective tissue (Fig 45-21.1). If this diamond lies posterior to the prior cuff scar, the peritoneum is generally easily identified and the enterocele sac may be entered intentionally or inadvertently. If this diamond lies anterior to the prior cuff, then

dissection proceeds more superficially to avoid bladder entry.

If vaginal shortening is a concern, then a transverse incision is made at the new apex site and no tissue is excised. Next, a vertical incision that extends several centimeters posteriorly from this transverse incision's midpoint creates a “T” incision that aids access into the pararectal space (Fig. 43-21.1, dotted line). With either incision configuration, the intended apex site is marked with sutures or clamps to maintain proper orientation during fixation.

*In the setting of concomitant vaginal hysterectomy*, after hysterectomy completion, the lateral edges of the anterior and posterior vaginal walls are grasped with Allis clamps and brought into direct contact with the SSL to similarly assess for excess tension or redundancy. A vertical incision is then made through the midline posterior vaginal wall at the open cuff and extended 2 to 3 cm distally. The extraperitoneal space between the vaginal wall and the peritoneum is entered. Then, the pararectal space is entered as described next.

□ **Access to the Right Sacrospinous Ligament.** Whether the SSL is accessed through the apex (Michigan modification) or through the posterior vaginal wall (traditional approach), the same retroperitoneal spaces are entered. Namely, the rectovaginal space and then the pararectal space are entered sequentially to reach the SSL (Fig. 45-21.2). Following entry into the rectovaginal space, traction on the vaginal epithelium with an Allis clamp and countertraction on peritoneum with tissue forceps are applied, while sharp or blunt dissection is directed toward the right ischial spine. Important anatomic structures during entry into the right pararectal space include the rectum, which lies medially and is retracted leftward to avoid injury; blood vessels and peritoneum, which lie ventrally and superiorly; and the levator ani muscles, which

are found dorsal and laterally. To enter the pararectal space, the rectal pillars, also known as deep uterosacral ligament fibers, are perforated as shown by the *arrow* in Figure 45-21.2. This tissue is typically attenuated in women with advanced prolapse and thus easier to perforate. In some cases, perforation with a hemostat or similar instrument is needed. Once in the pararectal space, the ischial spine tip is palpated, and the index finger moves gently medially toward the lower, lateral border of the sacrum to delineate the C-SSL complex (Fig. 45-21.3). This step also allows blunt digital dissection of loose connective tissue from the ligament's midportion.

□ **Retractor Positioning.** Two to three retractors are positioned to adequately expose the C-SSL complex (Fig. 45-21.4). We prefer a small Deaver to displace the peritoneum and blood vessels superiorly, a Breisky-Navratil retractor to displace the rectum medially, and a second Breisky-Navratil retractor to displace the levator muscles inferiorly and further expose the ligament's lower portion. Retraction is gentle to avoid vessel or rectal injury. A rectal examination at this point aims to exclude rectal laceration. During dissection and retractor positioning, vessels in the area may be lacerated, and hemostasis is obtained with direct pressure, electrosurgical coagulation, or ligatures.

□ **SSL Suture Placement.** Once the C-SSL complex is delineated, sutures are placed approximately two fingerbreadths or 2 to 3 cm medial to the ischial spine, which roughly corresponds to the SSL midportion (Roshanravan, 2007; Walters, 2007). Sutures placed too close to the spine risk injury to the pudendal nerves or vessels. Needle entry or exit points ideally remain within the mid to lower portion of the ligament. This lowers injury risk to the inferior gluteal vessels and pudendal

**FIGURE 45-21.3** Anatomy delineated.

or sacral nerves, which course in close proximity to the upper SSL margin.

We use the Deschamps ligature carrier or a tapered Mayo needle with a half-circle radius to ultimately pass four sutures (two absorbable and two permanent) through the ligament (see Fig. 45-21.4). To begin, two long sutures, one delayed-absorbable (*black*) and one permanent (*blue*) are threaded through the carrier eye. For the absorbable sutures, we select either 2-0 or 0-gauge polydioxanone (PDS II), and for the permanent sutures, we use similar-gauge polypropylene (Prolene). Thus, with a single ligament penetration, four suture ends are available. Alternatively, four delayed-absorbable sutures using 0-gauge polydioxanone can be used.

When the Deschamps ligature carrier is used, sutures are retrieved using a nerve hook, as shown. Once the suture ends are retrieved, suture traction is applied to test their anchorage. Firm resistance during traction confirms proper placement. Laxity indicates superficial placement through the coccygeus muscle or overlying fascia, and the sutures are replaced deeper into C-SSL. At this point, the four suture ends are paired by color, tagged by individually numbered hemostats, and loosely secured to the surgical drape.

The second carrier pass is then completed approximately 1 cm medial to the first. Based on intraoperative findings, the order of the carrier passes may be reversed, that is, the lateral suture is placed second. Adequate anchorage

**FIGURE 45-21.4** Retractor exposure and ligature placement.

is similarly confirmed, and these sutures are then paired and tagged. Ultimately, these two carrier passes result in four suture pairs that will later be sutured to the anterior, posterior, and lateral vaginal walls.

Adequate suture labeling (1 through 4) avoids suture tangling and later suture bridging at the fixation site. The delayed-absorbable suture (*black*), which is placed most laterally on the ligament is labeled “1” and will be placed through the right lateral aspect of the vaginal cuff. The delayed-absorbable suture (*black*) placed most medial on the ligament is labeled “4” and will be placed through the left lateral aspect of the vaginal cuff. Sutures 3 and 4 correspond to the permanent sutures (*blue*). These ultimately will be placed through the medial portion of the cuff.

If indicated, anterior colporrhaphy is performed at this time. If performed, the anterior vaginal wall is reapproximated with 2-0 or 3-0 gauge absorbable suture to the level of the cuff. Rectoceles are often corrected with SSLF, and posterior colporrhaphy is not frequently required. If a posterior midline plication, perineorrhaphy, or midurethral sling is planned, we prefer to complete this after apical suspension.

□ **Vaginal Apex Suturing.** The SSL sutures are then sequentially anchored to the anterior and posterior fibromuscular walls of the vagina apex along the vaginal cuff width. To begin, the two ends of suture 1 are grasped. The end that is most cephalad on the ligament is threaded through the Mayo needle eye. This is then driven through the full thickness of the lateral right anterior vaginal wall including the epithelium, at the site of the initial intended-apex marking suture. The other end of suture 1 is then driven through the lateral right posterior wall. Similar steps are subsequently repeated on the cuff’s left side with delayed-absorbable suture 4 (Fig. 45-21.5). Suture ends are not tied but instead held on their respective sides by a hemostat.

Attention is then directed to the permanent sutures (2 and 3). First and medial to those of suture 1, the ends of suture 2 are driven through the anterior and posterior fibromuscular vaginal walls at a point right of the cuff midline. To lower suture erosion rates, permanent sutures traverse the full thickness of the fibromuscular walls but not the epithelium. However, a substantial fibromuscular wall thickness is incorporated to prevent tissue tearing, which can create suture bridges and incomplete healing of the vaginal wall to the ligament. Second and medial to those of suture 4, the ends of suture 3 are driven through the anterior and posterior fibromuscular vaginal walls at a point left of the cuff midline.

□ **Suspension of the Vaginal Vault.** At this point, knots are secured starting with suture 4 and ending with suture 1. A pulley

**FIGURE 45-21.5** Lateral apex suturing.

**FIGURE 45-21.6** Permanent suture placement (blue strands).

stitch may be used for the permanent sutures. With this stitch, a knot is secured on the vaginal wall (posterior wall in this case) (Fig. 45-21.6). As shown in Figure 45-21.7, traction on the other suture end (anterior dashed strand) pulls the tied wall (posterior) to the SSL. However, with the four-wall modification, this type of stitch is not necessary. Each suture is tied down to ensure direct apposition of the vaginal walls to the SSL (Fig. 45-21.8). Both this snug approximation and the order in which sutures are tied may prevent suture bridges. All sutures are held with their corresponding numbered clamps after tying until cystoscopy is completed. Rectal examination confirms apposition of the vaginal cuff to the SSL and excludes rectal injury.

□ **Cuff closure.** If needed, the remainder of the vaginal cuff may be closed in a running fashion using 2-0 gauge delayed-absorbable suture.

### POSTOPERATIVE

Following SSLF, postoperative care mirrors that for vaginal surgery. Postoperative activity in general can be individualized, although intercourse is usually delayed until after 6 weeks following surgery. A voiding trial can be completed on postoperative day 1, depending on the patient's condition and general progress. Some patients have urinary retention after apical suspension, even without an antiincontinence procedure. If unable to void spontaneously by the time of discharge, the

patient can be discharged with a catheter and followed up within a week for removal.

Patients are screened for lower extremity neuropathy prior to discharge. Mild gluteal pain is common and typically resolves within several weeks. Severe gluteal pain that radiates down the posterior thigh and leg is a sign of sacral nerve entrapment and is generally treated by prompt suture release. Dyspareunia is commonly attributed to the posterolateral deflection of the vaginal axis. However, given the anatomic position of the nerves to the coccygeus and levator ani muscles, entrapment of these nerves may possibly lead to transient or sustained muscle spasm and dysfunction (Roshanravan, 2007). If levator muscle tenderness is identified, physical therapy may be helpful.

**FIGURE 45-21.7** Pulley stitch.

**FIGURE 45-21.8** Vaginal apex approximated to ligament.

## 45-22

## McCall Culdoplasty

Culdoplasty techniques are used to obliterate the posterior cul-de-sac of Douglas and prevent herniation of small bowel into the vaginal wall, that is, enterocele. Thus, culdoplasty usually complements procedures that further expose the posterior cul-de-sac to enterocele, such as retropubic urethropexy procedures. However, evidence-based studies have not borne out these benefits, and current concepts of specific pelvic-support defect repair have decreased the popularity of culdoplasty. Nevertheless, this procedure is still performed and may have value when completed in conjunction with other prolapse procedures.

Of these, McCall culdoplasty is most commonly performed during vaginal hysterectomy to close the cul-de-sac, add support to the posterior vaginal apex, and possibly prevent enterocele formation. With traditional McCall culdoplasty, two to three horizontal *internal* rows using permanent sutures are placed from one uterosacral ligament (USL) to the other to obliterate the posterior cul-de-sac (McCall, 1957). The term *internal* denotes that these sutures remain totally intraabdominal and do not penetrate into the vaginal lumen. In addition, one to two rows of absorbable *external* sutures are similarly placed through the USLs, but these pass through the posterior vaginal cuff.

Several modifications aim to provide better vaginal apex support. These include the Mayo/McCall culdoplasty and the modified McCall culdoplasty. The steps described next outline our approach. Importantly, if significant vaginal apex prolapse or enterocele is already present, then we prefer an apical suspension procedure such as sacrocolpopexy, sacrospinous ligament fixation, or vaginal uterosacral ligament suspension, as more data support their efficacy.

## PREOPERATIVE

## ■ Patient Evaluation

McCall culdoplasty is generally performed following vaginal hysterectomy in patients with enterocele or preventively in those without. Because the degree of pelvic organ prolapse will dictate reconstructive surgeries planned, a thorough prolapse evaluation is performed.

## ■ Consent

As with any pelvic reconstructive surgery to correct prolapse, the risk of enterocele

formation or recurrence is discussed. In addition, because this procedure involves placement of sutures through the uterosacral ligaments, risks similar to uterosacral ligament suspension procedures are addressed and include dyspareunia, ureteral or bowel injury, and sacral plexus nerve damage (p. 1107). Suture erosion risks are low.

## ■ Patient Preparation

Bowel preparation will vary depending on surgeon preference and is typically dictated by concurrent surgery planned. Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** McCall culdoplasty is typically performed under general anesthesia, although epidural or spinal regional methods may also be appropriate in select cases. The patient is placed in standard lithotomy position using candy-cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter is inserted. Vaginal hysterectomy is completed as described in Section 43-13 (p. 957), but the vaginal cuff is left open for culdoplasty completion. Excess peritoneum or vaginal wall may be excised at this time if indicated.

□ **Packing.** After vaginal hysterectomy, a moist pack is placed into the posterior cul-de-sac to prevent descent of bowel or omentum.

□ **Identification of Uterosacral Ligaments and Ureters.** This mirrors that described for the vaginal uterosacral ligament suspension procedure (p. 1107). Briefly, a Deaver retractor displaces the bladder upward, and gentle upward retractor traction exposes the distal to mid-USL portions. Two Allis clamps are next placed at approximately 5 and 7 o'clock positions on the posterior vaginal wall and incorporate the posterior peritoneum. Gentle downward Allis clamp traction tenses the USLs, which are then traced with the contralateral index finger from their distal attachments in the vagina toward the sacrum. Ureters are typically indistinct to touch, but they course anterolateral to the USLs. Lighted Breisky-Navratil retractors are useful on either side to further expose the USLs.

□ **Suture Placement.** For the internal McCall sutures, we use 2-0 gauge permanent

suture with a swaged-on SH needle. For the external McCall sutures, a similar-gauge delayed-absorbable material is selected. The number of suture rows placed is guided by cul-de-sac depth, vaginal cuff width, and surgeon preference. Generally, two to three internal and one to two external rows are placed.

Of the internal sutures, the first suture row is the most distal of these, and each subsequent row is placed progressively cephalad across the posterior cul-de-sac. Each row begins with a stitch into one USL. The needle tip pierces the most medial portion of the left USL and travels in a lateral-to-medial direction. As with other USL suspension procedures, these specifics attempt to minimize ureteral entrapment risks. Moreover, to reduce rectal injury rates, the rectum is retracted to the contralateral side, and suture purchases do not extend too medial, that is, beyond the ligament width. The needle then travels through the cul-de-sac peritoneum or rectal serosa with intervening suture bites and exits through the opposite USL. Each row is spaced approximately 0.5 cm to 1 cm cephalad from the previous one. The internal McCall sutures are tagged, held, and tied only after placement of the external McCall sutures.

Following these internal rows, the first external suture is placed through the full thickness of the posterior vaginal wall and incorporates the posterior peritoneum and USL (Fig. 45-22.1). Progressive left-to-right bites are then taken serially through the rectal serosa to reach the opposite uterosacral ligament (Fig. 45-22.2). Finally, the suture enters the opposite uterosacral ligament, passed through the posterior peritoneum, and exits through the full vaginal wall thickness to reenter the vagina.

□ **Suture Tying.** The internal sutures are tied first. These sutures are sequentially tied beginning with the most proximal sutures and progressing caudad. The external sutures are then tied, and again the most cephalad of these is tied first.

□ **Rectal Examination.** The rectum is digitally explored to exclude sutures entering the rectum.

□ **Cystoscopy.** This is performed after all McCall culdoplasty sutures are tied to document ureteral patency and exclude bladder sutures or cystotomy.

□ **Vaginal Cuff Closure.** Upon completion of McCall culdoplasty, the remaining steps of vaginal hysterectomy will follow as described in Section 43-13 (p. 961).

**FIGURE 45-22.1** Uterosacral ligament suture placement.

**FIGURE 45-22.2** Suture reenters the vagina prior to securing.

## POSTOPERATIVE

Following vaginal hysterectomy and McCall culdoplasty, postoperative care mirrors that for vaginal surgery. Activity in general is

individualized, although intercourse is usually delayed until 6 weeks. As with other uterosacral ligament suspension procedures, patients are screened for lower extremity neuropathy prior to discharge. Suture ero-

sion with granulation tissue can be a short- or long-term complication and is managed as described on page 1102.

## 45-23

## Abdominal Culdoplasty Procedures

Included in this group are the Moschcowitz and Halban operations. As with other culdoplasty techniques, the goal is posterior cul-de-sac obliteration to prevent enterocele. However, evidence-based studies have not borne out these benefits, and the popularity of culdoplasty has declined. Nevertheless, this procedure is still performed and may have value when completed with other prolapse procedures.

Selection of either the Halban or Moschcowitz procedure is based on surgeon preference and concurrent abdominal or vaginal pathology. Permanent sutures are generally used to close the cul-de-sac, and procedures differ by the orientation of suture placement. No trials have compared these techniques' efficacy head-to-head.

### PREOPERATIVE

#### ■ Patient Evaluation

Culdoplasty is typically performed with other prolapse surgeries. Thus, thorough pelvic organ prolapse evaluation is performed, and all prolapse sites are considered when planning surgical correction. As with other prolapse procedures, patients are evaluated for existing or occult urinary incontinence.

#### ■ Consent

As with any pelvic reconstructive surgery to correct prolapse, the risk of enterocele recurrence following abdominal culdoplasty is discussed. Additionally, risks of ureteral and bowel injury are included in the consenting process. During Halban and Moschcowitz culdoplasty, the rectosigmoid is plicated to the posterior vaginal wall. Accordingly, defecatory dysfunction and technical difficulty in performing subsequent colonoscopy have been reported following these culdoplasty procedures. Adhesion formation and difficulty with dissection in this space during subsequent operation may also be encountered.

#### ■ Patient Preparation

Bowel preparation will vary by surgeon preference. Patients can drink only clear liquids the day before surgery and complete one or two enemas the night prior to or the morning of surgery. Alternatively, mechanical bowel

preparation, listed in Chapter 39 (p. 835), may be selected. Antibiotics and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Abdominal culdoplasty is typically performed under general anesthesia. Patient positioning mirrors that described more fully for ASC on page 1099. Thus, following administration of general anesthesia, the patient is positioned in a low lithotomy position with thighs parallel to the ground and legs in booted support stirrups. The vagina and abdomen are surgically prepared, and a Foley catheter is inserted.

##### □ Surgical Incision.

Either transverse or vertical incision may be used for culdoplasty. Incision choice is dependent on concurrent surgeries planned. A self-retaining abdominal retractor is placed and concurrent surgeries such as hysterectomy and vault suspension are performed.

##### □ Special Considerations.

Following completion of initial procedures, the cul-de-sac is exposed and evaluated for suture placement. Additionally, an end-to-end anastomosis (EEA) sizer may be placed within the vagina or rectum to identify borders of the

posterior cul-de-sac and allow correct suture placement. Prior to culdoplasty, both ureters are identified again.

In the past, these procedures have focused on suturing peritoneal and serosal surfaces. However, it is currently believed that a more effective approach incorporates deep bites into the muscularis of the vagina and rectosigmoid but avoiding entry into bowel and vaginal lumens. Also, adjacent rectosigmoid veins are protected to avert hematomas from needle sticks. If bleeding develops, direct vascular compression provides effective control in most instances.

##### □ Halban Culdoplasty.

Several rows of 2-0 gauge permanent sutures are placed longitudinally through the serosa and muscularis of the rectosigmoid (Fig. 45-23.1). Rows are placed approximately 1 cm apart. The same sutures are then advanced through the peritoneum of the deep cul-de-sac and up toward the apex of the posterior vaginal wall. As much of the cul-de-sac as possible is obliterated, but to avoid ureteral injury, sutures are not placed lateral to the uterosacral ligaments.

##### □ Moschcowitz Culdoplasty.

Concentric 2-0 gauge permanent sutures are placed in the cul-de-sac beginning at the base and are directed upward almost to the level of the vaginal apex (Fig. 45-23.2). During placement, sutures are placed through the posterior vaginal wall and then advanced through the right uterosacral ligament, the rectosigmoid colon muscularis, and finally the left uterosacral

FIGURE 45-23.1 Halban culdoplasty.

**FIGURE 45-23.2** Moschcowitz culdoplasty.

ligament. The number of concentric rings required depends on the cul-de-sac depth, and usually three to four rings are sufficient. Rings are positioned 1 to 2 cm apart. As with

the Halban procedure, to reduce ureteral kinking, the lateral extent of the each suture ring should incorporate only the medial width of the uterosacral ligament.

□ **Rectal Examination.** This is performed to exclude sutures entering the rectum.

□ **Cystoscopy.** Cystoscopy is performed after all culdoplasty sutures are tied to document ureteral patency.

□ **Incision Closure.** The abdominal incision is closed as described in Chapter 43 (p. 928).

## POSTOPERATIVE

Following culdoplasty, postoperative care follows that for any major abdominal surgery. Hospitalization typically varies from 1 to 3 days, and return of normal bowel function usually dictates this course. Postoperative activity in general can be individualized, although intercourse is usually delayed until 6 weeks.

## 45-24

## Colpocleisis

Pelvic organ prolapse surgery can broadly be grouped as reconstructive or obliterative. Colpocleisis, also known as colpectomy, vaginal extirpation, and vaginectomy, is an obliterative surgery for advanced vaginal or uterovaginal eversion. To correct prolapse, all obliterative procedures close the vaginal canal and thus are only indicated in symptomatic women who do not desire to preserve vaginal anatomy or coital function or who are medically unsuitable for reconstructive surgery. Specifically, this operation may be performed quickly with general, regional, or local anesthesia.

The two main obliterating surgeries are partial colpocleisis and complete colpocleisis. With the partial procedure, also called LeFort colpocleisis, central rectangular sections of vaginal epithelium are dissected from the anterior and posterior vaginal walls, and the denuded fibromuscular layers are apposed and sewn together. This elevates the prolapse back into the pelvic cavity effectively and closes the vagina. The remaining lateral epithelial strips are fashioned into drainage tracts on either side for genital tract fluid egress. Thus, this surgery is appropriate for women with or without a uterus (Fig. 45-24.1).

In contrast, with total or complete colpocleisis, the entire circumference of vaginal epithelium is resected before vaginal walls are approximated. Drainage tracts are lacking, thus, it is typically used for posthysterectomy vault prolapse. If the uterus is present, concurrent total vaginal hysterectomy and closure of the peritoneum and vaginal cuff are performed prior to complete colpocleisis.

Obliterative procedures are effective, and success rates range from 91 to 100 percent (Abassy, 2010; Fitzgerald, 2006; Weber, 2005). However, these rates are interpreted in the context of patients' shorter life expectancies, limited activity levels, and variable outcome definitions. Anatomic success following colpocleisis is likely due to the amount of vaginal tissue sutured together to create a shelf of support. Several studies evaluating symptom improvement have also found high rates of patient satisfaction and functional improvement yet low rates of regret for sexual function loss (Barber, 2007; Fitzgerald, 2008; Gutman, 2009; Hullfish, 2007).

SUI following colpocleisis is common, thus prophylactic antiincontinence surgery is considered. Additionally, high perineorrhaphy (p. 1096) or levator myorrhaphy (p. 1093) is recommended to narrow the genital hiatus and potentially decrease the recurrent prolapse risk. Last, concurrent hysterectomy eliminates the risk of uterine or cervical cancer and of postoperative hemato- or pyometra.

However, patient morbidity, including greater blood loss, increased transfusion risk, and longer procedure time, is increased with hysterectomy. Also, support success rates following colpocleisis are similar whether or not the uterus is removed (Abassy, 2010; Fitzgerald, 2006; Weber, 2005). Thus, hysterectomy is selected based on a woman's general health, surgical goals, and comorbid genital tract disease risks.

## PREOPERATIVE

## Patient Evaluation

Because access to the cervix and endometrial cavity is not possible following this procedure, preinvasive lesions should be excluded. Specifically, a normal cervical cancer screening result is documented prior to surgery, and evaluation of the endometrium with either endometrial biopsy or sonography is recommended.

The full extent of prolapse should be defined prior to surgery. Importantly, colpocleisis is difficult in women with good distal support of either the anterior or posterior vaginal walls.

Women with advanced prolapse often do not display SUI because the urethra is kinked by prolapsing organs. However, with replacement of the prolapse, many with occult SUI do manifest symptoms. Thus, cough stress test or urodynamic testing has traditionally been performed with the prolapse elevated and replaced to search for occult SUI. Urinalysis and a postvoid residual measurement are also evaluated. For those who demonstrate SUI or occult SUI, antiincontinence surgery is recommended. However, even without SUI, a prophylactic antiincontinence procedure is considered to prevent later de novo SUI. Still, benefits of an additional procedure are weighed against the potential risk of urinary retention. For SUI, midurethral slings or urethral bulking agents are suitable options.

Last, women with global prolapse frequently have some degree of ureteral kinking and obstruction. Thus, preoperative pyelography, CT urography, or renal sonography may be elected to identify or exclude ureteral obstruction. Alternatively, preoperative or intraoperative cystoscopy prior to the colpocleisis can be used to document ureteral patency. Known preexisting obstruction will assist with interpretation of cystoscopy findings performed at the procedure's end. Also, with known ureteral obstruction, preoperative stent placement is considered to potentially assist with ureter identification during surgery. Colpocleisis ideally will unkink the ureter, and this can be documented during intraoperative cystoscopy after prolapse correction.

**FIGURE 45-24.1** Prolapse correction following placement of serial sutures.

## ■ Consent

Women considering this procedure must be fully aware that future vaginal intercourse is not possible. Thus, a patient's partner is ideally included in the decision and consenting process. Patients expressing hesitation or doubt are excluded as candidates.

First, as with any prolapse surgery, prolapse recurrence risk is discussed, although this risk is low with colpocleisis. Of note, later de novo rectal prolapse is disproportionately prevalent, and this unique complication was reported in 4 percent of women in one study (Collins, 2007). Second, as discussed, urinary incontinence may develop postoperatively. In addition, ureteral injury has been described. Third, in the unlikely situation that cervical or uterine malignancy develops after LeFort partial colpocleisis, the diagnosis may be potentially delayed. Finally, postoperative morbidity and mortality are especially pertinent in the elderly, and risks for cardiac, thromboembolic, pulmonary, or cerebrovascular events approximate 5 percent (Fitzgerald, 2006).

## ■ Patient Preparation

Bowel preparation, if any, will vary depending on surgeon preference. Patients can be instructed to take only clear liquids the day before surgery and complete one or two enemas the night prior to or the morning of surgery. Alternatively, a mechanical bowel preparation, listed in Chapter 39 (p. 835), may be elected. Antibiotic and thromboprophylaxis are given as outlined in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

### ■ Anesthesia and Patient Positioning

General or regional anesthesia is preferred, although colpocleisis can be performed under local anesthesia. A patient is placed in standard lithotomy position using candy-cane or booted support stirrups, the vagina is surgically prepared, and a Foley catheter is inserted.

### ■ Surgical Steps—LeFort Partial Colpocleisis

As noted, LeFort partial colpocleisis may be performed in women with or without a uterus, but the following description outlines steps in women without prior hysterectomy.

□ **Vaginal Marking.** Throughout the descriptions of both colpocleisis procedures, *proximal* and *distal* will describe prolapsed anatomy rather than final prolapse-corrected anatomy. To begin, the rectangular areas of vaginal mucosa on the anterior and poste-

rior vaginal walls are outlined with a surgical marker or electrosurgical blade. The size of these areas to be removed is determined by the length and width of vaginal walls. On the anterior wall, the proximal edge of the rectangle extends to within 1 to 2 cm of the bladder neck. On the posterior wall, the proximal rectangle edge extends to within 1 to 3 cm of the posterior hymenal ring. The distal rectangle edges reach to within 1 to 2 cm of the cervicovaginal junction both anteriorly and posteriorly. The lateral edges of each rectangle are drawn to leave approximately 2-cm wide lateral epithelial borders on either side. These will be fashioned into lateral channels of adequate caliber to conduct drainage.

□ **Vaginal Infiltration.** The rectangular areas of the vaginal wall to be removed may be thoroughly infiltrated with 50 mL of a dilute hemostatic solution. One example is 20 units of synthetic vasopressin (Pitressin) in 60 mL of saline. This infiltration extends beyond the anticipated incision boundaries. Without infiltration, bleeding can be significant during epithelial excision.

Needle aspiration prior to injection is imperative to avoid intravascular injection of this potent vasoconstrictor. The anesthesiologist is also informed of vasopressin administration, as patient blood pressure may suddenly rise following injection. Blanching at the injection site is common.

Due to the vasoactive effects of vasoconstrictors, patients with certain comorbidities may not be suitable candidates for their

use. These can include a history of angina, myocardial infarction, cardiomyopathy, congestive heart failure, uncontrolled hypertension, migraine, asthma, and severe chronic obstructive pulmonary disease.

□ **Vaginal Dissection.** Previously outlined areas are sharply incised down to the fibromuscular layer. If the anterior dissection is performed first, the vaginal wall epithelium within the previously marked anterior rectangle is dissected off the underlying vaginal wall fibromuscular layer using both sharp and blunt dissection (Fig. 45-24.2). Dissection in the correct plane will prevent inadvertent bladder or bowel entry. One effective technique places a finger behind the vaginal wall, while cephalad dissection with Metzenbaum scissors advances parallel to the vaginal wall epithelium. Bleeding during dissection can generally be controlled with pressure and electrosurgical coagulation. Occasionally, figure-of-eight stitches of 2-0 gauge absorbable suture are needed if large venous sinuses are cut. Next, the vaginal wall epithelium within the previously marked posterior rectangle is similarly dissected off the fibromuscular layer on the posterior vaginal wall (Fig. 45-24.3). Of note, some prefer to dissect posteriorly first to avoid obscuring blood from the anterior wall that may ooze into the surgical field.

□ **Apical and Lateral Channels.** After these rectangles are removed, a row of interrupted stitches using 2-0 gauge delayed-absorbable suture are placed through the

FIGURE 45-24.2 Anterior vaginal wall incision.

**FIGURE 45-24.3** Posterior vaginal wall incision.

**FIGURE 45-24.4** Initial suture placement.

anterior and posterior distal transverse epithelial edges (Fig. 45-24.4). These will effectively close the fibromuscular layer over the cervix and create the apical channel. Next, lateral channels on each side are formed and connect with this apical channel. For this, the lateral anterior and posterior epithelial edges are approximated along their full length (Fig. 45-24.5). This lateral row of

sutures begins distally and progresses proximally to the original proximal transverse incision near the bladder neck. The lateral channels can be created in a stepwise fashion, alternating from one side to the other.

□ **Anterior-to-Posterior Vaginal Wall Approximation.** With the lateral canals now fashioned, the uterus can be sequentially

elevated into the pelvic cavity. For this, a surgeon places progressive rows of interrupted 2-0 gauge permanent or delayed-absorbable sutures that approximate the anterior and posterior fibromuscular layers along the distal prolapsed-tube width (Fig. 45-24.6). Successive transverse tiers of sutures are placed approximately 1 cm apart until the proximal transverse incision is reached (Fig. 45-24.7). These rows create a tissue septum that elevates and supports the uterus (see Fig. 45-24.1).

□ **Cystoscopy.** With either colpocleisis procedure, cystoscopy is performed to exclude urinary tract injury and document ureteral patency.

□ **Closure of the Vaginal Epithelium.** This layer is then reapproximated in a running fashion with 2-0 or 3-0 gauge delayed-absorbable suture (Fig. 45-24.8). Importantly, the ostia of the bilateral drainage tracts remain patent.

□ **Concurrent Surgery.** At this point, an antiincontinence procedure may be completed as needed. Perineorrhaphy may be performed before or after vaginal wall closure (p. 1096).

### ■ Surgical Steps—Complete Colpocleisis

□ **Vaginal Infiltration.** The vaginal cuff is placed on traction, and a vasoconstrictive agent may be injected in a similar fashion

**FIGURE 45-24.5** Creation of lateral drainage canals.

**FIGURE 45-24.6** Second row of sutures.

**FIGURE 45-24.7** Subsequent row of sutures.

to that described for the LeFort partial colpocleisis.

□ **Vaginal Incision and Dissection.** To begin, the borders of planned dissection are marked circumferentially with a pen or electrocautery blade. When redundant tissue is present, marking three to four smaller rectangles over the entire prolapsed vaginal tube helps maintain orientation during dissection.

First, the vaginal epithelium is incised anteriorly at a point 1 to 2 cm distal to the bladder neck. Ultimately, this will be a point that lies approximately 1 cm proximal to the neck. Incision placement here will prevent

downward displacement of the bladder neck and the proximal urethra during apposition of the anterior and posterior vaginal walls. Additionally, it will allow room for the midurethral sling if one is planned. As the incision is swept circumferentially around the prolapse tube, a 1- to 2-cm distance is maintained distal to the hymeneal ring.

The vaginal epithelium is sharply and bluntly dissected off the underlying

fibromuscular layer (Figs. 45-24.9 and 45-24.10). Dissection is kept close to the epithelium to avoid inadvertent bladder or rectal entry. Once the desired plane is identified, sharp and blunt dissection can proceed quickly until the entire vaginal epithelium is removed. One technique for sharp dissection involves positioning a finger behind the vaginal wall and dissecting with Metzenbaum scissors parallel to the vaginal wall and close

**FIGURE 45-24.8** Vaginal mucosa closure.

**FIGURE 45-24.9** Anterior vaginal wall incision.

**FIGURE 45-24.10** Posterior vaginal wall incision.

**FIGURE 45-24.11** Circumferential suturing.

to the epithelium. After entry into the correct plane, blunt dissection with a gauze-covered index finger may allow rapid and wide development of this avascular space. There are areas where dissection may be difficult. For example, upon reaching the prolapsed vaginal apex and uterosacral ligament remnants, extensive scarring may be present that requires sharp dissection. The entire vaginal epithelium is removed from the prolapsed vaginal tube.

□ **Suture Placement.** To plicate the vaginal walls together and elevate the everted vagina, a surgeon places a series of circumferential purse-string sutures around the vaginal tube. With 2-0 gauge permanent or delayed-absorbable suture, stitches incorporate the

**FIGURE 45-24.12** A. Cephalad pressure against telescoping vaginal tube as serial sutures are secured. B. Completely inverted vaginal tube.

fibromuscular layer but avoid deep penetration into the bladder, ureter, or rectum (Fig. 45-24.11).

The first purse-string suture is placed approximately 1 cm from the cuff, and tied while the cuff is inverted with atraumatic forceps or a hemostat (Fig. 45-24.12). The cut suture tails are held with a clamp and the second suture is placed 1 cm proximally. The hemostat tip inverts the vagina while the second suture is tied, and used again to tag the second suture. Progressive purse-string sutures are placed similarly 1 cm apart until the proximal edge of cut vaginal epithelium is reached. These serial steps telescope the prolapsed vaginal tube cephalad and toward the pelvic cavity. Depending on the size of the prolapse, approximately six to eight suture rings are needed to completely invert the prolapsed vaginal tube.

□ **Finishing Steps.** Final steps are similar with both colpocleisis procedures. First, cystoscopy is performed to exclude urinary tract injury and document ureteral patency. The vaginal epithelium is then reapproximated in a running fashion with 2-0 or 3-0 gauge

delayed-absorbable suture. At this point, an antiincontinence procedure may be performed. Perineorrhaphy may be performed before or after vaginal wall closure (p. 1096).

## POSTOPERATIVE

Hospital admission is often prudent given the usual older age and comorbidities of these patients. A normal diet can be given immediately. Oral analgesics are usually sufficient. A voiding trial is performed prior to discharge as all patients can experience urinary retention from a levator myorrhaphy or perineorrhaphy. Patients with urinary retention can return within a week for a subsequent voiding trial and catheter removal.

In general, recovery with colpocleisis is quick and typically without complication. Postoperative bleeding is not anticipated, save for spotting from the surgical site. As with any prolapse procedure, constipation is avoided to protect repair strength during healing. Thus, stool softeners are recommended. Resumption of normal activities is encouraged with the exception of heavy lifting for several months.

## 45-25

## Anal Sphincteroplasty

External anal sphincter (EAS) and/or internal anal sphincter (IAS) repair is most commonly performed in patients with acquired fecal incontinence (FI) and an anterior sphincter defect. One of two methods may be selected for sphincter repair and include an end-to-end technique or an overlapping method. The end-to-end technique is most often used by obstetricians at delivery to reapproximate torn anal sphincter ends. However, in women remote from delivery, the overlapping technique is often selected, and with this, disrupted ends are overlapped and then sutured.

In cases remote from delivery, the overlapping method is preferred. However, the optimal technique or suture material for repair and the effects of pudendal neuropathy on treatment outcome are not well known (Madoff, 2004). With the overlapping method, short-term continence rates up to 85 percent were previously reported (Fleshman, 1991; Sitzler, 1996). However, newer reports show significant deterioration of FI during long-term postoperative surveillance (Bravo Gutierrez, 2004; Zutshi, 2009).

In cases at delivery, no evidence shows that either method yields superior results (Fitzpatrick, 2000; Garcia, 2005). Moreover, overlapping repair requires increased technical skills and carries the potential for increased blood loss, operating time, and pudendal neuropathy. Accordingly, the end-to-end technique is likely to remain the standard method for sphincter reapproximation at delivery until further data from randomized controlled trials are available.

### PREOPERATIVE

#### ■ Patient Evaluation

Because the etiology of FI in patients with documented sphincter defects may be multifactorial, careful preoperative evaluation attempts to distinguish underlying sources. Evaluation for structural gastrointestinal (GI) tract pathology typically involves colonoscopy and/or barium enema. Additionally, radiographic bowel transit studies can be used to diagnose slow transit time, which may be related to defecatory dysfunction.

Specific to the anorectum, endoanal sonography can accurately define structural disruption of the EAS and IAS (Fig. 25-7, p. 568) and is generally performed prior to sphincter repair. Exceptions are cloacal-like defects or chronic fourth-degree lacerations.

In these, the absent anterior portion of the sphincter(s) is easily identified clinically.

Anal manometry and pudendal nerve conduction studies may identify physiologic dysfunction such as neuropathy. Although these tests provide additional information and can be used during counseling, they are not necessary in patients with FI and a documented sphincter defect. In fact, the relationship of pudendal nerve function, typically assessed by determining pudendal nerve terminal motor latency, to sphincteroplasty outcome remains controversial (Madoff, 2004). One study found no association between pudendal nerve status and long-term anal continence (Malouf, 2000).

Clinicians have attempted to improve success rates by selecting only those women who may benefit most from surgery. Patient age, preoperative anal manometry readings, and pudendal nerve motor function have been evaluated as possible outcome predictors. However, research findings are conflicting, and none of these consistently predicts outcome (Bravo Gutierrez, 2004; Buie, 2001; El-Gazzaz, 2012; Gearhart, 2005).

#### ■ Consent

Although many women may have improved FI immediately following anal sphincteroplasty, repair durability is poor. For example, 3 to 5 years following correction, only approximately 10 percent of women are fully continent of solid and liquid stool (Halverson, 2002; Malouf, 2000). Retrospective data show that no patients are continent 10 years following sphincteroplasty (Zutshi, 2009). However, despite FI based on validated questionnaires, the quality of life in these patients notably did not decline.

Reasons for worsening continence following initial improvement remain unknown but may include aging, scarring, and progressive pudendal neuropathy either from initial injury or from the sphincter repair (Madoff, 2004). In addition, skeletal muscle repair is thought to have poor success because resting muscle tone places incision lines on constant tension. Thus, preoperative counseling informs that most individuals will improve after the procedure, but continence is rarely perfect and deteriorates over time.

In addition to persistent FI, sphincteroplasty is associated with other surgical risks. More common serious complications are wound dehiscence and fistula formation. Ha and coworkers (2001) noted a wound complication in 12 percent and fistula formation in 4 percent. Dyspareunia is a risk, especially if levator myorrhaphy (p. 1093) is concomitantly performed in sexually active women. Moreover, we believe levator myorrhaphy is

a nonanatomic repair and do not perform it with sphincteroplasty.

#### ■ Patient Preparation

Because of the high associated risk of wound complications, antibiotic prophylaxis is warranted to minimize wound infection following surgical contamination from vaginal and rectal flora. We use a combination of ciprofloxacin and metronidazole to obtain broad bacterial coverage. Additionally, we often continue this same antibiotic coverage orally for approximately 7 days postoperatively to help reduce wound complications (Maldonado, 2014). Although benefits from mechanical bowel preparation have not been demonstrated, some form of bowel preparation is typically administered the day or night before surgery. Options are listed in Chapter 39 (p. 835). Tromboprophylaxis is also provided as outlined in Table 39-8 (p. 835).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

After administration of either general or regional anesthesia, a woman is placed in standard lithotomy position using candy-cane or booted support stirrups. The vagina and perineum are surgically prepared and draped, and a Foley catheter is inserted.

□ **Incision and Dissection.** A downward-arching curvilinear incision is placed between the fourchette and anus, and this connects with a midline posterior vaginal wall incision (Fig. 45-25.1). The vaginal incision edges are placed on tension with Allis clamps. Along the distal 3 to 4 cm of the posterior vaginal wall, the vaginal epithelium is then sharply dissected off its underlying fibromuscular layer and off the perineal body.

On the perineum, dissection continues distally and laterally with Metzenbaum scissors. Advancement is kept just deep to the perianal skin and progresses until the scarred and usually retracted edges of the EAS are identified within the ischioanal fossa. Dissection proceeds until the EAS muscle is sufficiently mobile to ensure a tension-free overlapping repair.

As the inner arch of the EAS is sharply separated from the anal submucosa, care is taken to avoid anal lumen entry. To assist, a surgeon's index finger within the anus can guide dissection depth, and concomitant upward traction by an assistant on the sphincter's scarred ends helps accentuate the best dissection plane. Internal pudendal vessel branches

**FIGURE 45-25.1** Vaginal dissection.

can be lacerated or inferior rectal nerve injured, especially if lateral dissection extends beyond the 3 and 9 o'clock positions. Thus, if extensive lateral dissection is anticipated, the end-to-end method of repair is preferred.

Scarring in the midline may be cut but is not excised. This fibrous tissue adds strength to the sphincter muscle approximation. However, with extensive scarring, sphincter muscle fibers may be difficult to isolate. A nerve stimulator or a needle tip electro-surgical blade can assist in delineating these fibers. Current will often contract them.

□ **Suture Placement within the Internal Anal Sphincter.** The IAS contributes significantly to the anal canal resting tone, and its reapproximation is included in the repair. Grasped in [Figure 45-25.2](#), the IAS is a smooth, rubbery, thickened white sheet lying deep to the EAS and superficial to the anal mucosa and submucosal layers. This muscle usually retracts laterally when severed.

For suturing, we prefer monofilament, delayed-absorbable suture. First, because both the IAS and EAS muscles are under constant contraction, direct tissue reapproximation by these longer-acting sutures in theory allows adequate scar formation during the critical first 3 months of postoperative healing. Second, use of permanent suture for sphincteroplasty has been associated with high rates of suture erosion and wound dehiscence (Luck, 2005).

**FIGURE 45-25.2** Internal anal sphincter identification.

With suturing, the disrupted IAS edges are approximated in a continuous or interrupted fashion using 3-0 or 2-0 gauge monofilament, delayed-absorbable sutures such as polydioxanone PDS II ([Fig. 45-25.3](#)). Sutures

are spaced approximately 0.5 cm apart. As the distal extent of the IAS is generally several millimeters cephalad to the distal extent of the EAS, reapproximation of the IAS ends above the anal verge. Suture placement and

**FIGURE 45-25.3** Following internal anal sphincter reapproximation, the external anal sphincter is identified and grasped.

**FIGURE 45-25.4** Overlapping sphincteroplasty.

exposure of the IAS is aided by a finger in the rectum.

In many cases when an IAS defect is diagnosed remote from delivery, both the IAS and the EAS are usually identified as a unit. This unit is repaired en-bloc as described next.

□ **Overlapping External Anal Sphincteroplasty.** The overlapping repair of the EAS or EAS/IAS muscle unit is accomplished by placing two rows of mattress stitches using 2-0 or 3-0 gauge monofilament, delayed-absorbable suture. Within each row, the first stitch is the most cephalad, and more caudal stitches are added sequentially. The first row of mattress sutures begins at a distance (1 to 1.5 cm) from the severed edge of the overlying muscle. These then travel through the distal end of the underlying muscle (Fig. 45-25.4). A final upward pass again through the overlying muscle completes the stitch. To aid viewing, the suture ends in this row are held until the second suture row is placed. The second row of stitches then traverses through and through to secure the free end of the overlying muscle to the underlying muscle.

With the overlapping method, either the right or left dissected end of the muscle can be used as the overlying muscle based on intraoperative findings. If significant mobilization cannot be achieved due to scarring or missing sphincter, then an end-to-end repair is performed.

□ **End-to-End External Anal Sphincteroplasty.** When performed for FI remote from delivery, each end of the disrupted

EAS and surrounding scar tissue is identified and grasped with an Allis clamp (see Fig. 45-25.3). The ends of the EAS and its surrounding fibrous tissue are brought to the midline and reapproximated using three to four interrupted stitches of delayed-absorbable, monofilament suture (Fig. 45-25.5).

□ **Perineal Body Reconstruction.** Patients with anal sphincter defects often have a deficient perineal body. In these cases, perineal body reconstruction is performed following reapproximation of the IAS and EAS muscles. This mirrors Step 4 of perineorrhaphy in Section 45-16 (p. 1096). For this, the connective tissue surrounding the separated ends of the bulbospongiosus and superficial transverse perineal muscles are identified and reapproximated. A combination of 2-0 and 0-gauge absorbable sutures is used for this repair. Deep suture bites at the level of the hymen also reunite the perineal membrane, which attaches to both the vaginal walls and the perineal body at the level of the hymen.

□ **Incision Closure.** Excision of excess perineal skin and/or vaginal epithelium may be required prior to closing the incision. Vaginal epithelium and then perineal skin is reapproximated in a running or interrupted

**FIGURE 45-25.5** End-to-end sphincteroplasty.

fashion using 2-0 or 3-0 gauge absorbable suture, again similar to perineorrhaphy.

## POSTOPERATIVE

Pain varies postoperatively, and some women can be discharged home on postoperative day 2, whereas others require longer hospitalization. The Foley catheter is removed on postoperative day 1 or 2. An active voiding trial is performed, and some women may have difficulty voiding due to pain, inflammation, and levator ani muscle spasm. To limit trauma to the healing repair, we try to delay defecation for several days. Although data are lacking, we encourage patients to forego food and drink on day 1. They are subsequently advanced to clear liquids for 3 or 4 days. Stool softeners are given when a solid diet is begun and are continued for at least 6 weeks. Diet or agents that add bulk to the stool are discouraged as this may increase the repair breakdown risk. Local wound care involves perineal cleansing with a plastic water bottle following urination or defecation. Ambulation is encouraged, but physical exercise and sexual intercourse are delayed for 8 weeks. The first postoperative visit is typically 4 weeks following surgery.

## 45-26

## Rectovaginal Fistula Repair

In general, rectovaginal fistulas (RVFs) encountered by gynecologists are those complicating obstetric events and develop in the distal third of the vagina just above the hymen. Surgical management of these “low” RVFs varies by the condition of the external anal sphincter (EAS) but is usually achieved by a transvaginal or transanal approach. Midlevel RVFs are found in the middle third of the vagina and are also usually due to obstetric trauma. These can often be repaired transvaginally or transanally by a tension-free layered closure. High RVFs may follow hysterectomy or radiation therapy and lie close to the cervix or the vaginal cuff, and these are most commonly repaired abdominally.

Fistulas identified during or shortly after delivery are suitable for immediate repair. However, fistulas are not repaired in the setting of inflammation, induration, or infection. Moreover, fistulas that are associated with radiation therapy and recurrent fistula, due to poor tissue vascularity, often require interposition of a vascular flap.

Outcomes vary depending on the underlying cause and repair method. Success rates following obstetric injury repair range from 78 to 100 percent (Khanduja, 1999; Tsang, 1998). However, in cases with episiotomy, the reported success rate is 74 percent, and in those repaired by rectal advancement flap, rates reach only 40 to 50 percent (Mizrahi, 2002; Sonoda, 2002). Fistulas from radiation, cancer, or active inflammatory bowel disease are more difficult to treat successfully. In general, success rates are highest with the first surgical attempt at repair (Lowry, 1988).

### PREOPERATIVE

#### ■ Patient Evaluation

As outlined in Chapter 25 (p. 574), a thorough evaluation is necessary to assess the etiology and delineate the full extent of a fistula. Unless RVFs are obviously from a prior obstetric event, fistulous tract biopsy is indicated to exclude malignancy or inflammatory conditions. Proctoscopy or colonoscopy is warranted if inflammatory bowel disease, malignancy, or gastrointestinal infection is suspected. If there are questions regarding the etiology, complexity, or number of fistulas, then imaging may be needed. At times, pinpoint fistulas are difficult to identify and

may require examination under anesthesia with lacrimal duct probing. Coexisting anal incontinence is assessed, as this may be related to sphincter damage or other etiologies and is likely to persist after fistula repair.

#### ■ Consent

Specific risks following rectovaginal fistula repair include fistula recurrence, dyspareunia, and vaginal narrowing or shortening. Fecal incontinence can follow some repairs if the anal sphincter is disrupted during surgery, as with episiotomy, or if coexistent sphincter defects are not recognized and repaired.

#### ■ Patient Preparation

A rigorous bowel preparation is preferred to clear all stool from the rectal vault. Accordingly, a mechanical bowel preparation is advised the day prior to surgery, and options are listed in Chapter 39 (p. 835). If stool is still present in the rectum at the beginning of surgery, then a povidone-iodine (Betadine) flush with a Malecot drain may be needed. Antibiotic prophylaxis is given concurrent with surgery, however, additional doses during the days before surgery are not indicated. We use a combination of ciprofloxacin and metronidazole to obtain broad bacterial coverage. Additionally, thromboprophylaxis is provided as outlined in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Position.

Rectovaginal fistula repair is typically an inpatient procedure, performed under general or regional anesthesia. A patient is placed in standard lithotomy position in candy-cane or booted support stirrups. The vagina is surgically prepared, and a Foley catheter is inserted.

□ **Fistula Identification.** The fistula is identified and its course is traced with a probe or dilator. Small fistulas may be dilated to improve identification of the tract.

□ **Vaginal Incision.** For a midlevel or low RVF not involving the external anal sphincter, a circular incision is made in the vaginal epithelium surrounding the fistula (Fig. 45-26.1). The incision is made sufficiently wide to permit tract excision and generous mobilization of surrounding tissues for closure without excess suture-line tension (Fig. 45-26.2). Remember that tenets of proper fistula repair emphasize tension-free, multilayered closure, and excellent hemostasis. The entire fistula tract is then excised (Fig. 45-26.3). This creates an anal or rectal opening that is often significantly larger than that found preoperatively.

□ **Closure of the Rectal Wall.** Using 3-0 gauge delayed-absorbable suture, the edges of the anal mucosal defect are reapproximated

FIGURE 45-26.1 Vaginal incision.

**FIGURE 45-26.2** Mobilization of surrounding vaginal mucosa.

**FIGURE 45-26.3** Fistulous tract excision.

in a running or interrupted fashion. Each bite or suture is spaced no more than 5 mm apart (Fig. 45-26.4). Although absorbable sutures can be placed into the rectal lumen, we prefer to reapproximate the submucosal tissue without needle or suture entering the rectum. One or two additional layers of the same gauge suture are placed in the anal or rectal wall muscularis to reinforce the submucosal closure. If the internal anal sphincter (IAS) but not the EAS is involved, the above additional layers incorporate the torn IAS edges.

This step ideally reduces the postoperative anal incontinence risk.

Alternatively, with very small RVFs, a purse-string suture can be placed to encircle the anal defect, and its perimeter lies a few millimeters from the resected fistulous tract rim. This suture is tied and inverts the defect's edges into the bowel lumen. Additional reinforcing layers are then placed as described above.

□ **Closure of the Vaginal Fibromuscular Layer.** The fibromuscular layer of the vagina

is next reapproximated with 2-0 gauge delayed-absorbable sutures in a running or interrupted fashion (Fig. 45-26.5). If possible, two layers are completed to minimize incision tension and reinforce the repair. With anovaginal fistulas, these additional layers also reapproximate perineal body tissue.

If the fistula involves the EAS, an episiotomy—that is, conversion of the defect into a fourth-degree laceration—can be elected. Following excision of the fistulous tract and mobilization of surrounding tissue, repair of the episiotomy is similar to the layered repair of an obstetric fourth-degree laceration. Briefly, the anal submucosa is reapproximated with 3-0 gauge

**FIGURE 45-26.4** Closure of the rectal wall.

**FIGURE 45-26.5** Closure of the fibromuscular layer.

absorbable suture in a running or interrupted fashion. Repair of the IAS, EAS, and perineal body reconstruction mirror that for anal sphincteroplasty (p. 1125).

□ **Martius Bulbocavernosus Fat Pad Graft.** In cases in which avascular or fibrotic tissue is extensive, a Martius graft may be

placed between the fibromuscular layer and vaginal epithelium (p. 1083).

□ **Vaginal Wall Closure.** Excess vaginal mucosa is trimmed, and the vaginal mucosa is closed in a continuous running fashion using 3-0 gauge absorbable or delayed-absorbable suture.

## POSTOPERATIVE

Normal activity can resume during the first postoperative days. Intercourse, however, is delayed at least 6 weeks or until the vaginal incision is healed. To limit trauma to the healing repair, dietary modifications are instituted similar to those for sphincteroplasty (p. 1127).

46-1

Radical Abdominal  
Hysterectomy  
(Type III)

The five “types” of hysterectomy are defined in Chapter 30 (p. 669). Of these, radical

hysterectomy differs from simple hysterectomy in that the parametrium, paravaginal tissue, and their lymphatics are widely resected to achieve negative tumor margins. Described in this section, type III (radical) hysterectomy is chiefly indicated for stage IB1 to IIA cervical cancer or small central recurrences following radiation therapy, or for clinical stage II endometrial cancer when tumor has extended to the cervix (Koh, 2015).

Type III radical hysterectomy is increasingly being performed by minimally invasive approaches (p. 1142). With these techniques, the principles of the abdominal operation are still applied. Namely, radical hysterectomy is a dynamic operation that requires a focused, consistent surgical approach but also significant intraoperative decision making. Familiarity with its concepts continues to be critically important in developing expertise in complex pelvic surgery.

## PREOPERATIVE

### ■ Patient Evaluation

Radical hysterectomy is not appropriate for women with higher-stage cancers. Thus, accurate clinical staging is critical prior to selection of this surgery. Pelvic examination under anesthesia with cystoscopy and proctoscopy is not mandatory for smaller cervical cancer lesions, but the clinical staging described in Chapter 30 (p. 663) should be completed before proceeding surgically. To refine patient selection, for most patients with grossly visible cervical tumors, abdominopelvic computed-tomography (CT) or magnetic resonance (MR) imaging is also performed to identify nodal metastases or undetected local tumor extension. That said, there are limitations on what can be reliably detected preoperatively (Chou, 2006).

### ■ Consent

Women undergoing hysterectomy are specifically counseled regarding the loss of fertility. In those considering bilateral salpingo-oophorectomy (BSO), a discussion of menopause and hormone replacement is included and detailed in Chapter 43 (p. 951). The tone of the consenting process should reflect the extent of the operation required to hopefully cure or at least begin treatment of the malignancy. Moreover, a patient must be advised that the procedure may be aborted if metastatic disease or pelvic tumor extension is found (Leath, 2004).

Radical abdominal hysterectomy can result in significant morbidity from short- and long-term complications. These complications may develop more frequently in women with obesity, prior pelvic infections, and previous abdominal surgery, in whom surgery may be more difficult (Cohn, 2000). Of potential intraoperative complications, the most common is acute hemorrhage. Blood loss may reach 500 to 1000 mL, and transfusion rates are variable, but high (Estape, 2009; Naik, 2010). Subacute postoperative complications may include significant postoperative bladder or bowel dysfunction from surgical denervation (20 percent), symptomatic lymphocyst formation (3 to 5 percent), and uretero-vaginal or vesicovaginal fistula (1 to 2 percent) (Franchi, 2007; Hazewinkel, 2010; Likic, 2008). With any cancer surgery, risk for venous thromboembolism (VTE) is also increased. Additionally, long-term effects on sexual function and other body functions are candidly reviewed and are detailed on page 1139 (Jensen, 2004; Serati, 2009).

### ■ Patient Preparation

For this, a blood sample is typed and cross-matched for potential transfusion. Pneumatic compression devices or subcutaneous heparin or both is planned because of the typically longer surgery and postoperative recovery times and the increased VTE risk associated with cancer (Table 39-8, p. 836) (Martino, 2006).

Bowel preparation with a polyethylene glycol-electrolyte solution (GoLYTELY) is no longer commonly used. Inadvertent bowel injury is rare unless extenuating circumstances are identified. However, it may be helpful to empty the colon to limit fecal spill if extensive pelvic adhesions are anticipated due to prior infection, endometriosis, or radiation therapy.

Suitable perioperative antibiotic prophylaxis to prevent most surgical site infection is found in Table 39-6 (p. 835). Typically, a third-generation cephalosporin is given intravenously at spaced intervals. Compared with simple hysterectomy, the high-volume blood loss during radical hysterectomy clears antibiotics more rapidly from the operative site, and longer surgery may extend past the antibiotic half-life. Both necessitate the additional doses (Bouma, 1993; Sevin, 1991).

### ■ Concurrent Surgery

Early-stage cervical cancer most frequently spreads via the lymphatics. Thus, adjunctive lymph node removal seeks to identify occult metastases. Pelvic lymphadenectomy is typically completed just before or immediately after radical hysterectomy, and paraaortic lymphadenectomy may also be indicated in some circumstances (p. 1169) (Angioli, 1999).

Spread to the adnexa is much less common than via the lymphatics. Thus, the decision for BSO depends on a woman's age and potential for metastases (Shimada, 2006). If ovaries are preserved, then salpingectomy alone is recommended to reduce future risk of some epithelial ovarian cancers (Society of Gynecologic Oncology, 2013). In candidates for ovarian preservation, transposition of ovaries out of the pelvis may be considered in young women if postoperative radiation is anticipated. However, ovarian function may be short-lived. Also, in transposed ovaries, symptomatic periaxonal cysts are commonplace (Buekers, 2001). Oocyte and ovarian cryopreservation techniques have advanced and may soon be a more widespread option (Chap. 20, p. 466).

## INTRAOPERATIVE

### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** General anesthesia is mandatory, but epidural

placement may be considered for postoperative pain control (Leon-Casasola, 1996). Bimanual examination is performed in the operating room before scrubbing to reorient a surgeon to the patient's individual anatomy. The patient is positioned supine. After anesthesia administration, hair in the path of the planned incision is clipped if needed; a Foley catheter is placed; and abdominal preparation is completed.

□ **Abdominal Entry.** A midline vertical abdominal incision provides excellent exposure, but typically prolongs hospital stays and increases postoperative pain. Alternatively, Cherney or Maylard incisions offer postoperative advantages found with transverse incisions and allow access to the lateral pelvis (Chap. 43, p. 931). However, upper para-aortic nodes are not readily accessible through these transverse incisions. A Pfannenstiel incision offers limited exposure and is reserved only for selected patients (Orr, 1995).

□ **Exploration.** After abdominal entry, a surgeon first thoroughly explores the abdomen for obvious metastatic disease. Firm, enlarged lymph nodes and any other suspect lesions are removed or biopsied. Confirmation of metastases or pelvic tumor extension leads to a decision on whether to proceed or abort an operation based on overall intraoperative findings and clinical situation (Leath, 2004).

□ **Entering the Retroperitoneal Space.** The uterus is placed on traction with curved Kelly clamps at the cornua. The round ligament is sutured with 0-gauge delayed-absorbable suture as laterally as possible, and the tie is held on tension to aid entry into the retroperitoneal space. Lateral round ligament transection later aids excision of the parametrium out to the pelvic sidewall. Once the round ligament is divided, the broad ligament beneath separates into thin anterior and posterior leaves that contain loose areolar connective tissue between.

Similar to simple hysterectomy, the anterior leaf of the broad ligament is placed on traction and is sharply dissected to the vesicouterine fold. The posterior leaf of the broad ligament is then placed on traction and sharply dissected along the pelvic sidewall parallel to the infundibulopelvic (IP) ligament.

□ **Ureter Isolation.** Loose areolar connective tissue of the retroperitoneal space is bluntly dissected in the area lateral to the IP until the external iliac artery is palpated just medial to the psoas major muscle. The index and middle fingers are placed on either side of the artery, and the areolar connective tissue is bluntly finger dissected toward the patient's head using a backward "walking" motion (Fig. 46-1.1).

**FIGURE 46-1.1** Finding the ureter.

To permit further cephalad inspection, the medial portion of the broad ligament's posterior leaf is elevated. This permits direct identification of the common iliac artery bifurcation and origins of the external and internal iliac arteries. Here, the ureter crosses over the bifurcation. To isolate the ureter at this site, the surgeon bluntly dissects with a finger or suction tip in a sweeping motion from top to bottom along the medial peritoneal leaf to identify and sufficiently mobilize the lateral surface of the ureter.

To free the medial surface, a Babcock clamp grasps the ureter, and Mixter right-angle clamp tips are opened and closed parallel to the ureter to develop an avascular space between it and its medial peritoneal attachment. Through this space, clamp tips are then passed beneath the ureter to grasp a quarter-inch-wide Penrose drain. The drain is then pulled through this space to surround and isolate the ureter. This assists in identifying its location throughout the remainder of surgery.

□ **Creating Spaces.** The parametrium that will be removed with the hysterectomy specimen lies between the paravesical and pararectal spaces. Thus, creation of these spaces is needed to isolate the parametrium for transection. The pararectal space is developed by gently placing the right index finger lateral to the IP and between the internal iliac artery and ureter. The finger tracks in a gentle swirling motion at a 45-degree angle downward toward the midline and aiming for the coccyx (Fig. 46-1.2). Once formed, this space is bordered by the rectum and ureter medially, internal iliac artery laterally, cardinal ligament anteriorly, and the sacrum posteriorly.

In contrast, the paravesical space is formed by holding the lateral tie of the round ligament and bluntly following the external iliac artery caudally to the pubic ramus. The index and middle finger of the right hand then sweep intervening avascular areolar tissue deeply and medially toward the midline. The developed paravesical space is bounded by the bladder and superior vesical artery medially, the external iliac vessels laterally, the pubic symphysis anteriorly, and the cardinal ligament posteriorly. Once paravesical and pararectal spaces are created, the parametrium is now isolated between these two openings.

□ **Adnexa.** With hysterectomy, ovaries may be retained or removed. If uninvolved with cancer, indications are similar to those for benign hysterectomy (Chap. 43, p. 951). If ovarian preservation is planned, the surgeon performs salpingectomy by serially clamping, cutting, and ligating the mesosalpinx (Section 43-6, p. 939). The uteroovarian ligament is then clamped, cut, and ligated close to the uterus. The ovary is tucked laterally during hysterectomy completion. Alternatively, if BSO is planned, the IP ligament is doubly clamped, cut, and ligated. The uteroovarian ligament is left intact and the adnexa are ultimately removed with the uterine specimen.

□ **Uterine Artery Ligation.** For this step, lateral reflection of the broad ligament's lateral leaf just distal to the round ligament will reveal the superior vesical artery. This vessel is bluntly dissected to better define its location and is grasped with a Babcock clamp and placed on lateral traction. A right-angle clamp is used to develop an avascular space beneath the vessel that should accommodate a

**FIGURE 46-1.2** Opening the pararectal space.

narrow curved Deaver retractor. Lateral traction on the superior vesical artery prevents its inadvertent ligation and aids in identification of the uterine artery (Fig. 46-1.3).

Next, a surgeon's left hand is inserted into the pelvis with the middle finger placed in the paravesical space, the index finger in the pararectal space, and the uterus with attached Kelly clamps cupped in the palm. The uterus is held on firm medial traction to expose the lateral pelvic sidewall. To visualize the uterine artery, a surgeon sharply dissects parametrial attachments and intervening areolar connective tissue beginning at the internal iliac artery and continuing caudad to the superior vesical artery. The origin of the uterine artery is found during this caudal dissection.

Tissues surrounding the uterine artery are bluntly dissected, and a right-angle clamp is placed beneath this artery to retrieve a 2-0 gauge silk suture. The uterine artery tie is placed as close as possible to its origin from the internal iliac artery. The process is repeated to place a separate silk suture far enough medial to enable vessel transection. Black silk ties help identify the proximal and distal portions of the uterine artery throughout the remainder of the operation. A small vascular clip (Hemoclip) can also be placed lateral to the silk tie on the proximal uterine artery for additional security of hemostasis. The uterine artery is then cut. The underlying uterine vein may also then be isolated, clipped or tied, and cut.

□ **Uniting Paravesical and Pararectal Spaces.** The parametrial tissues have been pressed together by development of the paravesical and pararectal spaces. Parametrial resection to unite the upper (ventral) portion

**FIGURE 46-1.3** Ligating the uterine artery.

**FIGURE 46-1.4** Uniting the spaces by parametrial resection.

of these spaces begins near the sidewall, moves medially, and can be performed by several methods. These include: (1) clamping, cutting, and suturing, (2) stapling with gastrointestinal anastomosis (GIA) stapler, (3) electrothermal blade dissection in which a right-angle clamp elevates and isolates parametrial tissue, or (4) use of an electrothermal bipolar coagulator (LigaSure) (Fig. 46-1.4). Dissection is continued until the parametrium overlying the ureter is mobile.

□ **Ureter Mobilization.** In this same area of the pelvis, tips of a right-angle clamp are positioned between the ureter and peritoneal leaf. As previously described, opening and closing the tips downward and parallel to the ureter develops an avascular plane to

bluntly dissect the ureter from the medial peritoneal leaf. The ureter is placed on gentle lateral traction by grasping the previously placed Penrose drain with the left hand. The right index finger carefully sweeps the ureter downward and laterally until a “tunnel” through the paracervical tissue can be palpated ventromedially as the ureter enters this tissue (Fig. 46-1.5). Additional parametrial dissection is often required to ensure that the uterine artery and surrounding soft tissue has been lifted medially and off the ureter.

① **Bladder Dissection.** Electrosurgical dissection is performed to free the bladder distally from the cervix and onto the upper vagina. This may need to be repeated several times as the tunnel is progressively unroofed and the

ureter is more directly visible. To allow adequate vaginal margins, the bladder will eventually need to be dissected so that it lies several centimeters distal to the cervical portio and onto the upper vagina.

② **Unroofing the Ureteral Tunnel.** The uterus is placed on lateral traction, and the proximal ureter is held on traction to straighten it by gently pulling on the Penrose drain. The previously created tunnel opening is palpated. Concurrently, a right-angle clamp is inserted with its tips directed upward, while direct visualization of the underlying ureter is confirmed. The tips are then directed medially toward the cervix, “pop” through the paracervical tissue, and create a new distal opening (Fig. 46-1.6). One tip of a second

**FIGURE 46-1.5** Mobilizing the ureter.

**FIGURE 46-1.6** Unroofing the ureteral tunnel.

FIGURE 46-1.7 Uterosacral ligament transection.

FIGURE 46-1.8 Vaginal transection.

clamp is placed through the tunnel and then through the new distal opening. The clamp then closes around the paracervical tissue that lies above and lateral to the ureter.

Within the tunnel, the ureter is bluntly dissected and pushed posteriorly toward the tunnel floor. It should be visible below before cutting the overlying paracervical tissue. Delayed-absorbable 3-0 suture ties are used to secure the paracervical tissue pedicles that are held by the right-angle clamps, but significant bleeding is commonplace during these steps. The same procedure may be repeated several times caudally to completely unroof the tunnel and expose the ureter. The dissection proceeds in a proximal to distal fashion with direct visualization of the ureter at all times to prevent injury. After being unroofed, the ureter is retracted upward, and filmy attachments between the it and tunnel bed are sharply divided.

**13 Uterosacral Resection.** Posterior radical dissection is often best performed near the operation's end because exposed retroperitoneal tissues typically ooze until the vaginal cuff is closed. The cervical external os is palpated, and at this level, the electrosurgical blade is used to superficially incise or "score" the peritoneum between the uterosacral ligaments. This score line joins the incision line of the previously cut posterior broad ligament peritoneum.

Between the uterosacral ligaments, a plane is developed by gently pressing a finger toward the vaginal wall without poking through and into the vaginal vault. This

rectovaginal plane is developed by gentle pressure toward the sacrum and enlarged laterally until three fingers can be comfortably inserted. This maneuver frees the rectosigmoid from the uterosacral ligaments and prevents inadvertent bowel injury. Remaining peritoneal attachments are sharply dissected to fully expose the rectovaginal space. The exposed uterosacral ligaments can be visualized, palpated, clamped at the pelvic sidewall, then cut, and ligated with 0-gauge delayed-absorbable suture (Fig. 46-1.7). This procedure may need to be repeated to complete transection of the uterosacral ligament and adjacent supportive tissues.

**14 Vaginal Resection.** At this point in the operation, the radical hysterectomy specimen is held in place only by the paracolpium and vagina. The bladder and ureters are further bluntly and sharply dissected free until at least 3 cm of upper vagina will be included with the resected specimen. Curved clamps are placed on the lateral paracolpium. The ureter should be lateral and directly visible. Tissue is then cut and suture ligated with 0-gauge delayed-absorbable suture.

The upper vagina can then be: (1) clamped, cut, and suture ligated, (2) stapled, or (3) sharply transected with electrosurgical blade and suture ligated (Fig. 46-1.8). The specimen is carefully examined to ensure an adequate upper vaginal segment and grossly negative margins.

**15 Suprapubic Catheter Placement.** This catheter may aid postoperative voiding

trials in carefully selected, motivated patients (Pikaart, 2007).

**16 Ovarian Transposition.** For those in whom ovarian function preservation is desired, transposing adnexa out of the anticipated pelvic radiation field is an option. A distal portion of the ovary is grasped with a Babcock clamp. Using traction, dissection is performed to mobilize the IP ligament so that the ovary can be lifted into the upper abdomen. For future radiography or CT interpretation, a large vascular clip is placed on the residual uteroovarian ligament stump to serve as an ovarian location marker. For transposition, a 0-gauge silk suture is placed at this stump site and tied. Its needle is covered but remains attached to the suture.

A handheld abdominal retractor is then used to expose an area of the lateral posterior peritoneum as high as possible in the abdomen. The silk suture needle is then uncovered and placed through the peritoneum, and the ovary is elevated by this "pulley-stitch" and tied. The lateral pelvic defect is closed with a continuous running stitch using 0-gauge delayed-absorbable suture to prevent internal herniation, that is, entrapment of bowel within the peritoneal defect. Ovaries are inspected before abdominal closure to exclude vascular compromise by transposition.

**17 Final Steps.** Active bleeding should be immediately controlled when the radical hysterectomy specimen has been removed. A dry laparotomy sponge may be held firmly deep

in the pelvis for several minutes to tamponade raw surfaces. Topical hemostatic agents may be employed (Table 40-5, p. 861). With bleeding controlled, a surgeon then assesses the vascular support to the ureter and other sidewall structures. To structures that appear particularly devascularized, an omental J-flap may provide additional blood supply (Section 46-14, p. 1186) (Fujiwara, 2003; Patsner, 1997). Routine pelvic suction drainage and closure of the peritoneum are not necessary (Charoenkwan, 2014; Franchi, 2007).

## POSTOPERATIVE

Immediate postoperative care following radical hysterectomy in general follows that for laparotomy. Early ambulation after radical hysterectomy is especially important to prevent thromboembolic complications (Stentella, 1997). Moreover, following laparotomy for cancer, anticoagulants are continued for 2 to 4 weeks postoperatively (American College of Obstetricians and Gynecologists, 2013). Early feeding, including rapid initiation of a clear liquid diet, may also shorten the hospital stay (Kraus, 2000).

Bladder tone returns slowly, and a major cause is thought to be partial sympathetic and

parasympathetic denervation during radical dissection (Chen, 2002). Thus, Foley catheter drainage is commonly continued until a patient is passing flatus because improving bowel function typically accompanies resolving bladder hypotonia. Removal of the catheter or clamping of the suprapubic tube should be followed by a successful voiding trial (Chap. 42, p. 917). A voiding trial may be attempted prior to hospital discharge or at the first postoperative visit. Patients with adequate function are instructed to press gently on the suprapubic area for several days afterward to help completely empty the bladder during voiding and prevent retention. Successful voiding may take several weeks to achieve. In addition to urinary retention, tenesmus and constipation are frequent immediate symptoms that should improve significantly over months or years (Butler-Manuel, 1999; Sood, 2002). Postoperative stool softeners are often prescribed.

Nerve-sparing radical hysterectomy is a method demonstrating improved postoperative bladder function (Raspagliesi, 2006). However, many patients have preexisting abnormal urodynamic findings that are simply exacerbated by radical hysterectomy (Lin, 1998, 2004). In the 3 percent of women

who develop long-term bladder hypotonia or atony, intermittent self-catheterization is preferred to indwelling urinary catheterization (Chamberlain, 1991; Naik, 2005).

For cervical cancer patients undergoing BSO, estrogen replacement therapy is not contraindicated and may be initiated in the hospital at the discretion of the treating oncologist. Cervical cancer survivors treated with radical hysterectomy have much better sexual functioning than those who receive radiation therapy. Despite this, more than half of surgical patients postoperatively report a worse sex life (Butler-Manuel, 1999). Severe orgasmic problems, uncomfortable intercourse due to reduced vaginal length, and severe dyspareunia may develop but often resolve within 6 to 12 months. However, persistent lack of sexual interest and poor lubrication may be long-term or permanent changes (Jensen, 2004). Disturbed vaginal blood flow response during sexual arousal may account for much of the reported constellation of symptoms (Maas, 2004). Eventually, patients treated by surgery alone can expect a quality of life and overall sexual function similar to peers without a history of cancer (Frumovitz, 2005).

## 46-2

## Modified Radical Abdominal Hysterectomy (Type II)

Four procedural differences distinguish a modified radical hysterectomy (type II) hysterectomy from the more radical type III procedure (Section 46-1, p. 1134). First, the uterine artery is transected where it crosses the ureter (rather than at its origin from the internal iliac artery). Second, only the medial half of the cardinal ligament is resected (instead of division at the sidewall). Additionally, the uterosacral ligament is divided halfway between the uterus and sacrum (rather than at the sacrum). And last, a smaller margin of upper vagina is removed. These modifications serve to reduce surgical time and associated morbidity, while still enabling complete resection of smaller cervical tumors (Cai, 2009; Landoni, 2001).

Clear indications for modified radical hysterectomy are few and controversial (Rose, 2001). Stage IA1 (with lymphovascular space invasion) or IA2 cervical cancer are the most common diagnoses (Koh, 2015). Type II hysterectomy is also performed on occasion for: (1) preinvasive or microinvasive disease when a more invasive lesion cannot be excluded, (2) selected stage IB1 disease with < 2 cm lesions, and (3) small central postirradiation recurrences (Cai, 2009; Coleman, 1994; Eisenkop, 2005). In addition, a variation of this operation may be performed if

more extensive dissection is required for known benign disease. Anatomic landmarks that distinguish a type II hysterectomy are somewhat vague, and thereby allow a surgeon to sculpt the procedure to a patient's specific situation (Fedele, 2005). Similar to the type III radical procedure, modified radical hysterectomy is increasingly being performed using a minimally invasive approach.

### PREOPERATIVE

Preparation for surgery should proceed with the same care and discretion that is essential for the success of radical (type III) abdominal hysterectomy (Section 46-1, p. 1135).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Modified radical hysterectomy is performed under general anesthesia with the patient supine. Bimanual examination is performed in the operating room before scrubbing to reorient a surgeon to a patient's individual anatomy. The abdomen is surgically prepared, and a Foley catheter is placed.

□ **Abdominal Entry.** Modified radical hysterectomy may be safely performed through a midline vertical or low transverse incision (Fagotti, 2004).

□ **Retroperitoneal Dissection.** The initial steps of modified radical (type II) hysterectomy mirror those of the type III procedure.

The retroperitoneum is opened to identify structures, the ureter is mobilized, and the paravesical and pararectal spaces are developed to exclude the possibility of parametrial tumor extension before proceeding with this less radical operation (Scambia, 2001). As with radical hysterectomy, adnexa may be spared or removed (p. 1135).

□ **Uterine Artery Ligation.** At this point, type II hysterectomy begins to differ from the radical type III procedure. The superior vesical artery does not have to be identified, nor does the entire extent of the internal iliac artery need to be dissected free of adventitial tissue. The ureteral tunnel opening is palpated, and the uterine vessels divided at that location (Fig. 46-2.1). Ligation of the uterine artery as it crosses the ureter allows preservation of distal ureteral blood supply.

□ **Cardinal Ligament Resection.** The bladder is mobilized distally off the cervix and onto the upper vagina. Parametrial tissue at the sidewall does not require mobilization over and off the ureter (as in a type III hysterectomy). Posterolateral attachments of the ureter remain intact, and only the medial halves of the cardinal ligaments are resected by successive clamping, cutting, and suture ligation of the paracervical tissue that lies medial to the ureter (Fig. 46-2.2). In contrast to the type III hysterectomy, the ureter is not dissected out of the tunnel bed, but is rolled laterally to expose the medial cardinal ligament.

□ **Uterosacral Resection.** Posterior dissection is also modified. Uterosacral ligaments are only clamped halfway to the pelvic sidewall (instead of "at" the pelvic sidewall)

FIGURE 46-2.1 Uterine artery ligation.

FIGURE 46-2.2 Cardinal ligament transection.

**FIGURE 46-2.3** Uterosacral ligament transection.

and transected (Fig. 46-2.3). The uterus and adjacent parametrium can then be lifted well out of the pelvis and any additional tissues also clamped, cut, and ligated.

□ **Vaginal Resection.** At this point, the modified radical hysterectomy specimen is held in place only by the paracolpium and vagina. The bladder and ureters are further

bluntly and sharply dissected free until at least 2 cm of upper vagina will be included in the specimen (instead of 3 to 4 cm). Curved clamps are placed on the lateral paracolpium, cut, and suture ligated.

The upper vagina can then be: (1) clamped, cut, and suture ligated, (2) stapled, or (3) sharply transected with electro-surgical blade and suture ligated. The specimen is carefully examined to ensure an adequate upper vaginal segment and grossly negative margins.

## POSTOPERATIVE

In general, postoperative care follows that for radical hysterectomy, but the incidence of complications is lower (Cai, 2009). Partial sympathetic and parasympathetic denervation should be much less extensive with a modified radical hysterectomy. Thus, bladder dysfunction is much less likely than following a type III radical hysterectomy, and successful voiding begins much earlier (Landoni, 2001; Yang, 1999). Foley catheter drainage may be discontinued on the second postoperative day and is followed by a voiding trial (Chap. 42, p. 917). In addition, bowel and sexual dysfunction should also be less pronounced.

## 46-3

## Minimally Invasive Radical Hysterectomy

Since the 1990s, experience with this procedure has accrued, and rates of both laparoscopic and robotic radical hysterectomy have increased (Wright, 2012). Compared with laparotomy, a minimally invasive surgery (MIS) approach appears to offer comparable cancer survival rates and has similar rates of most surgical complications (Lee, 2010; Yan, 2011). With MIS, less intraoperative blood loss and shorter hospital stays are noted, but operative times can be longer depending on surgeon proficiency (Soliman, 2011).

Whether radical hysterectomy with pelvic lymphadenectomy is completed via laparotomy or with MIS, the cancer indications and surgical steps are the same. Thus, compared with simple hysterectomy (type I), greater resection of parametrial and paracolic tissue and their lymphatics is essential to help ensure tumor-free surgical margins. This degree of resection requires significantly more retroperitoneal dissection, during which the ureter and major vessels must be identified to aid resection and avoid injury.

### PREOPERATIVE

#### ■ Patient Evaluation

Thorough preoperative pelvic examination reveals factors that help determine the optimal surgical approach for a given patient. For example, a large broad or bulky uterus may be difficult to manipulate during MIS, may block views, and may be too large for vaginal removal. Importantly, morcellation is avoided with any gynecologic malignancy.

General challenges to MIS, such as obesity, are described in Chapter 41 (p. 874). That said, laparoscopy can be a successful option for many obese patients and offers lower rates of postoperative wound infection, which is often a major complication after laparotomy in these patients (Park, 2012). Once a patient is deemed eligible for an MIS approach, the same preoperative evaluation as for an open procedure applies (p. 1135).

#### ■ Consent

Risks of MIS radical hysterectomy mirror those listed for radical abdominal hysterectomy (p. 1135). Patient factors that contribute include older age, previous abdominal surgery, and prior radiotherapy (Chi, 2004).

General complications related to MIS are discussed in Chapter 41 (p. 877). With minimally invasive radical hysterectomy specifically, there is also increased concern for nerve injury from a longer operation in lithotomy and steep Trendelenburg position. Additionally, the risk of conversion to an open procedure is discussed. This risk may be increased if exposure and organ manipulation are limited.

#### ■ Patient Preparation

Preoperative preparation is the same as for an open procedure (p. 1135). Thus, antibiotics and VTE prophylaxis are warranted (Tables 39-6 and 39-8, p. 835). Benefits of mechanical bowel preparation can be debated and are individualized. If considered, an evacuated rectosigmoid may improve colon manipulation and pelvic anatomy visualization. Options are found in Chapter 39 (p. 835).

#### ■ Concurrent Surgery

Pelvic lymphadenectomy is typically completed just before or immediately after radical hysterectomy, and paraaortic lymphadenectomy may also be indicated in some circumstances. An MIS approach to lymph node removal in these areas is described in Section 46-12 (p. 1176).

Planned oophorectomy should depend on a woman's age and potential for metastases (Hu, 2013). Ovarian metastasis is rare with early-stage cervical cancer, and particularly with squamous cell carcinoma. Thus, if preservation is chosen, the ovary can be transposed with MIS techniques to the upper abdomen. This is done to help extend ovarian function if later radiotherapy is required. However, ovarian longevity may be shortened postoperatively, and symptomatic ovarian cysts are common. Moreover, advancements in oocyte and ovarian cryopreservation may soon provide suitable alternatives.

Regardless of ovarian preservation, salpingectomy is now encouraged for all women undergoing hysterectomy (Society of Gynecologic Oncology, 2013). As explained in Chapter 35 (p. 738), this practice is hoped to lower rates of high-grade ovarian and peritoneal serous carcinomas.

### INTRAOPERATIVE

#### ■ Instruments

Basic MIS tools for laparoscopic or robotic surgery are required. Important instruments for radical hysterectomy include 5- and 12-mm trocars, combined irrigation/suction device, vaginal probe, and energy devices for cutting and vessel sealing. For the

latter, several electrosurgical and ultrasonic energy-based devices are adapted for either laparoscopic or robotic cases. These include Harmonic scalpel, electrosurgical monopolar instruments, and electrothermal bipolar coagulator devices (LigaSure, ENSEAL, PK Dissecting Forceps). For laparoscopy, the argon-beam coagulator is another option. While operating in the pelvis, a 0-degree laparoscope can be used, although a laparoscope with a 30-degree lens system may also be advantageous in certain circumstances to provide superior lateral views.

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

The patient is initially supine for general endotracheal anesthesia induction. For VTE prophylaxis, lower extremity compression devices are placed. Legs are then positioned in adjustable booted support stirrups in low lithotomy to permit adequate perineal access. Positioning should permit a transvaginal uterine manipulator to move easily in all directions. As described in Chapter 41 (p. 879), appropriate positioning of legs within the stirrups and arms at the side is crucial to reduce nerve injury risks.

Bimanual examination is performed in the operating room before scrubbing to reorient a surgeon to the patient's individual anatomy. The abdomen, perineum, and vagina are then surgically prepared, and a Foley catheter is inserted. To avoid stomach puncture by a trocar during primary abdominal entry, an orogastric or nasogastric tube is placed to decompress the stomach.

During MIS radical hysterectomy, a manipulator is frequently placed to aid uterine repositioning and help acquire adequate vaginal surgical margins. Several uterine manipulators are described and illustrated in Chapter 44 (p. 1033). Popular options include a RUMI manipulator/KOH ring combination or a V-Care device. However, in cervical cancer cases, if a bulky cervical lesion is present, a blunt vaginal probe in the vaginal fornix may be all that can be inserted.

□ **Port Placement.** An illustrated description of MIS entry into the abdominal cavity is found in Chapter 41 (p. 889). Suitable entry methods include the open technique, direct trocar insertion, or transumbilical insertion of a Veress needle. For gynecologic oncology cases, the open technique is often used to minimize vascular or bowel puncture risk. With primary entry, an umbilical or supraumbilical site is preferred. Following entry, a 10- or 12-mm Hassan trocar with a blunt obturator is placed into the abdominal cavity and is secured to the fascia.

**FIGURE 46-3.1** Port placement for minimally invasive radical hysterectomy.

Through the trocar, the obturator is removed and replaced by a 10-mm laparoscope.

After abdominal insufflation, the abdomen and pelvis are thoroughly inspected to assess the extent of disease and adhesions. At this point, confirmation of metastatic disease or pelvic tumor extension should prompt a surgeon to decide whether to proceed or abort the operation based on intraoperative findings and clinical situation. Moreover, the decision is made to proceed laparoscopically or convert to laparotomy.

For laparoscopy, the surgeon stands on one side of the patient, whereas one assistant occupies the opposite side and another stands between the patient's legs. To proceed, other ports are placed under direct laparoscopic visualization. Anatomic landmarks are identified to guide port placement and avert vascular puncture injuries. For complex MIS gynecologic procedures, four port sites are preferred (Fig. 46-3.1). Additional ports are placed according to surgeon preference. These ideally have a minimum of 8 cm between them to allow ample range of motion and for robotic cases, to avoid arm collision.

□ **Opening the Retroperitoneum.** This is the initial step to opening the paravesical and pararectal spaces bilaterally and identifying the ureter. Development of these spaces allows the parametrial tissue to be isolated and later resected.

First, the assistant angles the uterus to the contralateral side of dissection using a uterine manipulator and/or a grasper holding one cornu. This creates tension across the round ligament, which is divided at its midpoint. Transection may be accomplished using any of the energy-based devices previously listed.

**FIGURE 46-3.2** Opening the broad ligament leaf.

Once the round ligament is transected, the broad ligament beneath it separates into thin anterior and posterior leaves, with loose areolar connective tissue between them. The anterior leaf is tented upward by graspers and sharply incised with monopolar scissors or other energy-based device. Incision extends caudally and medially toward the vesicouterine fold and halts near the midline.

To further expand the retroperitoneal opening, the drape of peritoneum lying between the divided round ligament and infundibulopelvic (IP) ligament is elevated with smooth graspers. Incision of this tented peritoneum is extended cephalad toward the pelvic brim but remains

lateral and parallel to the IP (Fig. 46-3.2). This exposes the external iliac vessels and provides access to the ureter.

□ **Ureteral Identification.** This is accomplished by precise sharp and blunt dissection just lateral to the medial leaf of the opened peritoneum. For this, a blunt probe or the closed tips of a grasper may be selected. Dissection is advanced downward, medially, and slightly cephalad with gentle back-and-forth cephalad-caudad strokes into the gauzy retroperitoneal tissue and over the presumed ureter path (Fig. 46-3.3). The ureter is identified and traced along the medial leaf of the peritoneum.

**FIGURE 46-3.3** Locating the ureter.

**FIGURE 46-3.4** Opening the pararectal space.

**FIGURE 46-3.5** Opening the paravesical space.

□ **Creating Spaces.** The uterus remains deviated to the contralateral side to develop the pararectal space. This avascular space is bounded by the rectum and ureter medially, the internal iliac artery laterally, the cardinal ligament and uterine artery caudally, and sacrum cephalad. Within these borders, the tips of closed scissors or other blunt tip push downward and medially through loose connective tissue (Fig. 46-3.4). The surgeon directs dissection downward toward the midline, aims for the pelvic floor, and stops once the levator ani muscles are reached.

For the paravesical space, boundaries are the external iliac vessels laterally, the bladder and obliterated umbilical ligament medially, the pubic symphysis caudally, and the cardinal ligament cephalad. To open this space, the previously incised edge of the broad ligament's anterior leaf is lifted at a point between the bladder and pelvic sidewall. Superficial loose connective tissue lies medial to the external iliac vessels and is bluntly dissected with closed scissors or grasper (Fig. 46-3.5). Staying medial to the external iliac vein and lateral to the superior vesicle/obliterated umbilical artery, dissection is directed caudally until the curve of the pubic ramus is reached.

Once the paravesical and pararectal spaces are opened, the parametria is now isolated between these two spaces for later resection. This dissection also helps to mobilize the bladder, discussed next, and to expose the external iliac vessels, which will aid later pelvic lymphadenectomy.

□ **Bladder Mobilization.** During radical hysterectomy, the bladder is dissected free from the cervix and upper vagina. The mobile

bladder is moved caudad and protected during final vaginal transection. To mobilize the bladder, the peritoneum at the vesicouterine fold is grasped with atraumatic graspers and elevated to create tension between it and the underlying cervix (Fig. 46-3.6). The vesicouterine space, the potential space between the bladder and cervix, is opened using sharp and blunt dissection. Only loose connective tissue fibers lie in this space and are easily cut. Incision of these bands is kept close to the cervix to avoid cystotomy. Dissection in the midline minimizes laceration of vessels that course within the vesicocervical ligaments, colloquially termed bladder pillars. Once the

correct plane is entered, the pearly white cervix and anterior vaginal wall below are clearly differentiated from the more opaque bladder.

Ultimately, the bladder is moved sufficiently caudad to permit excision of up to 3 cm of proximal vagina at the procedure's end. This aids acquisition of tumor-free surgical margins. Generous dissection also avoids incorporating bladder fibers into the cuff closure, which could lead to bladder injury or to later genitourinary fistula.

□ **Uterine Artery Ligation.** For this step, the pelvic sidewall vessels are exposed. By visually moving from the common iliac artery

**FIGURE 46-3.6** Dissection in the vesicovaginal space.

**FIGURE 46-3.7** Uterine artery ligation.

toward its bifurcation, a surgeon can identify the internal iliac artery. The first anterior branch of the internal iliac artery is the umbilical artery. The uterine artery is the second branch and courses medially and over the ureter.

Alternatively, to isolate the uterine artery, the superior vesical artery is identified by blunt dissection on the medial border of the paravesical space. The vessel is followed cephalad to identify the uterine artery origin. In most instances, the uterine artery originates from the internal iliac artery and is identified by its medial course toward and over the ureter.

To isolate the uterine artery for ligation at its origin from the internal iliac artery, tips of a grasper are positioned beneath the vessel. Opening and closing the grasper tips, while directing dissection downward, develops an avascular plane around the artery. Importantly, the uterine vein lies just beneath the artery, and its injury can compromise visibility from brisk bleeding. Once isolated, the uterine artery is coagulated using a vessel-sealing device and divided (Fig. 46-3.7). The artery ends are then elevated to identify the uterine vein, which is similarly isolated, coagulated, and divided.

**□ Ureteral Mobilization and Parametrial Dissection.** Ultimately, during a radical procedure, the ureter is freed in stages from surrounding tissue until its insertion into the bladder is reached. This dissection allows the ureter to be reflected laterally and protected during the wide parametrial excision required for radical hysterectomy.

During early dissection, atraumatic graspers tent up the medial posterior peritoneal leaf to which the ureter is attached. The tips of a right-angle grasper are then positioned between the ureter and peritoneum. Opening and closing

**FIGURE 46-3.8** Lifting the parametrium off the ureter.

the tips downward and parallel to the ureter develops an avascular plane to dissect the ureter free.

Such dissection continues caudally until parametrial tissue surrounding the ureter is met. This tissue is confined between the paravesical and pararectal spaces, contains the divided uterine vessels, and will be dissected medially and up and off the ureter. For this, connective tissue around the medial coagulated end of the uterine artery is grasped laterally and then lifted up and medially (Fig. 46-3.8). Loose connective tissue bands holding the artery and vein and surrounding parametria to the pelvic floor are coagulated and sharply transected. Dissection is

continued medially until the lateral border of the ureter is reached.

For ureterolysis, caudally directed tips of a Maryland grasper are insinuated and opened within the avascular space overlying the ureter. This exposes tissue pedicles on the ureter's lateral aspect, which are then coagulated and cut. The uterine vessels and parametrium are then pulled medially and reflected off the ureter. They will be removed with the final specimen.

During continued caudal ureterolysis, the ureter is seen to enter a “tunnel” within the pubocervical ligament (Fig. 46-3.9). To open this tunnel and free the ureter, the ureter is retracted downward and laterally. Within the tunnel, caudally directed grasper

**FIGURE 46-3.9** Unroofing the ureter.

tips are insinuated and opened within the space overlying the ureter. Tips of an energy-based tool then elevate the tunnel roof above and away from the ureter. The pubocervical ligament roof and the veins within it are then transected. The roof is divided in small increments caudally until completely opened. At this point, the ureteral insertion into the bladder can be identified. The ureter can then be bluntly rolled off the tunnel “floor” and moved laterally with an atraumatic tool to allow later cardinal ligament transection without ureteral injury.

**□ Adnexectomy or Ovarian Preservation.** The IP ligament or the uteroovarian ligament will be transected depending on whether the ovary is removed or retained, respectively. Steps for both mirror those with benign hysterectomy and are fully illustrated in Section 43-12 (p. 953). For these steps, a window is made in the posterior broad ligament below the IP ligament. The window can be made bluntly or with an energy-based tool, and the window is then enlarged. The incision is opened parallel to the IP ligament and is extended cephalad toward the pelvic brim and medially toward the uterosacral ligament. The ureter should be clearly identified to avoid its injury.

For adnexectomy, the IP ligament is divided with a vessel-sealing device followed by cutting. In contrast, if the ovary is to be preserved, then salpingectomy alone is first completed. For this, the mesosalpinx is divided with a vessel-sealing and cutting device, and resection progresses from the fimbria to its union with the uterus. Next, the uteroovarian ligament is transected with the same device, and the ovary is tucked over to the sidewall until hysterectomy completion.

If ovarian preservation is chosen, the ovary can be transposed laparoscopically. With this, the IP ligament is further dissected cephalad by extending the peritoneal incision on both the medial and lateral sides of the IP ligament. This mobilizes the ovary, whose uteroovarian ligament stump is then sutured to the lateral peritoneum in the upper abdomen as described on page 1138. Importantly, following transposition, the ovary is inspected to confirm adequate blood supply. A clip can be placed at the uteroovarian stump so that it can be delineated on future imaging studies.

At this point, steps 3 through 9 are completed on the contralateral side.

**□ Rectovaginal Space.** Developing this potential space moves the rectum downward to isolate the uterosacral ligaments for wide resection. It also permits adequate excision of the proximal vagina for tumor-free margins without rectal injury. First, the uterus

**FIGURE 46-3.10** Incising the posterior peritoneum.

is retracted upward in the midline, and the peritoneum between the uterosacral ligaments is incised at the level of the external cervical os (Fig. 46-3.10). The peritoneal edge closer to the rectum is then grasped and tented outward with atraumatic graspers, and the rectovaginal space is open with a blunt dissector moved side to side. This exposes connective tissue bands and small vessels between the rectum and vagina. These bands are cauterized and transected close to the vagina with an energy-based device (Fig. 46-3.11). Dissection continues 4 cm caudally to ultimately allow a 3-cm vaginal resection.

**⑪ Uterosacral Ligament Transection.**

The uterosacral ligaments, which are now isolated, can then be ligated as close to the sacrum as possible with an energy-based tool (Fig. 46-3.12). Before division of the ligament, the ureter is retracted laterally for protection.

**⑫ Cardinal Ligament Division.**

Next, the lateral attachments of the cervix to the pelvic sidewalls are coagulated and transected with an energy-based device in a caudal direction (Fig. 46-3.13). During this step, the deep uterine vein is usually encountered and should be sufficiently sealed and divided. Also, the

**FIGURE 46-3.11** Opening the rectovaginal space.

**FIGURE 46-3.12** Uterosacral ligament transection.

plane of transection stays at or slightly below the level of the ureter. This avoids extensive autonomic pelvic plexus damage, which exacerbates bladder and possibly bowel and sexual dysfunction.

**13 Vaginal Resection.** With complete mobilization of the bladder and rectum, the anterior and posterior vagina should be easily identified. The radical hysterectomy specimen is now held in place only by the paracolpium and vagina. The goal of radical hysterectomy

resection is to remove approximately 3 cm of the upper vagina. For this, transverse anterior and posterior colpotomy incisions are made and extended circumferentially around the cervix (Fig. 46-3.14). Delineating marks on the uterine manipulator can help direct colpotomy.

The uterus, cervix, vaginal margin, and parametrial tissue are then freed. The specimen is removed intact through the vagina. The final specimen is labeled “radical hysterectomy specimen” and includes cervix,

uterus, vaginal margin, and parametrial tissue (Fig. 46-3.15).

**14 Vaginal Cuff Closure.** Closure of the vaginal cuff can be performed by multiple methods. As noted earlier, one option is cuff closure from a vaginal approach as done during simple vaginal hysterectomy (Section 43-13, p. 961). Alternatively, suitable endoscopic closure techniques are described and detailed in Section 44-11 (p. 1034). Following cuff closure, lymphadenectomy is begun and is described in Section 46-12 (p. 1176).

Both the ureters and bladder can be injured during these procedures. If injury is suspected, cystoscopy at the end of the procedure can aid injury recognition (Section 45-1, p. 1057).

**15 Port Removal and Fascial Closure.** Once procedures have been completed, an inspection for hemostasis is performed. Ports are then removed under direct visualization. All fascial defects larger than 10 mm are closed with 0-gauge delayed-absorbable suture to avoid hernia development at the site. Various methods of skin closure are described in Chapter 40 (p. 847).

## POSTOPERATIVE

Immediate postoperative care following minimally invasive radical hysterectomy in general mirrors that for other minimally invasive procedures. Diet is advanced more quickly than with open procedures, and

**FIGURE 46-3.13** Paracolpium transected.

**FIGURE 46-3.14** Colpotomy created.

**FIGURE 46-3.15** Anterior view of a radical hysterectomy specimen including uterus, cervix, portion of vagina, and parametria.

most patients will tolerate a regular diet early on postoperative day 1. Patients are often discharged home on postoperative day 1 or 2 since their pain is well controlled. As with open radical procedures, the same principles for retaining a Foley catheter do apply. Therefore, many patients will be sent home with the Foley catheter and return to clinic for a voiding trial (Chap. 42, p. 917).

Following minimally invasive radical hysterectomy, patients may be at increased risk for vaginal cuff dehiscence compared with an open approach. In one series, the rate was 1.7 percent and was similar whether surgery was completed laparoscopically or robotically (Nick, 2011). The closure technique of the vaginal cuff is the suggested cause. Thus, many advocate vaginal rather than endoscopic cuff closure to decrease this risk (Fanning, 2013; Uccella, 2011).

46-4

Total Pelvic Exenteration

Total pelvic exenteration removes the bladder, rectum, uterus (if present), and surrounding tissues. It is generally indicated for curative situations when less radical surgery, chemotherapy, or radiation options have been exhausted. The most common indication is centrally persistent or recurrent cervical cancer after radiation therapy. Less frequent indications include some instances of recurrent endometrial adenocarcinoma, uterine sarcoma, or vulvar cancer; locally advanced carcinoma of the cervix, vagina, or endometrium when radiation is contraindicated such as prior radiotherapy or malignant fistula; and melanoma of the vagina or urethra (Berek, 2005; Goldberg, 2006; Maggioni, 2009). Palliative exenterations may be of benefit on rare occasions when selected patients have severe, unremitting symptoms (Guimarães, 2011).

Because exenteration commonly follows radiation therapy, the uterus and cervix usually have lost their distinct tissue architecture and boundaries. As a result, traditional hysterectomy steps and anatomic landmark identification are typically not possible. Minimally invasive exenterative procedures have been reported and may rarely be indicated in highly selected patients (Martinez, 2011; Puntambekar, 2006).

Total pelvic exenterations are subclassified based on the extent of pelvic floor muscle and vulvar resection (Table 46-4.1) (Magrina, 1997). Supralevator (type I) exenteration may be indicated when a lesion is relatively small and does not involve the lower half of the vagina. Most total pelvic exenterations will be infralevator (type II). This type is selected if vaginal contracture, prior hysterectomy, or the inability to otherwise achieve adequate margins is present. Rarely, tumor extension warrants an infralevator exenteration with vulvectomy (type III).

PREOPERATIVE

■ Patient Evaluation

Initially, biopsy confirmation of recurrent invasive disease is performed. With confirmation, the single most important preoperative challenge is to search for metastatic disease that would abort plans for surgery. Chest radiography is mandatory. Abdominopelvic CT is also routinely indicated, but a positron emission tomography (PET) scan may be particularly helpful (Chung, 2006; Husain, 2007). Hydroureter and hydronephrosis are not absolute contraindications unless they are due to obvious pelvic sidewall disease.

Patients often initially reject the entire concept of this operation even when faced with the knowledge that it represents their only chance for cure. Counseling is essential, and overcoming denial may take several visits. Regardless, not all eligible women will wish to proceed.

■ Consent

The consenting process is the ideal time to finalize plans for the type and location of urinary conduit, plans for colostomy or low rectal anastomoses, and need for vaginal reconstruction or other ancillary procedures. A patient is also advised that the procedure may need to be aborted based on intraoperative findings.

For those who undergo exenteration, the perioperative mortality rate approaches 5 percent (Marnitz, 2006; Sharma, 2005). However, the mortality rate from progressive cancer would otherwise be 100 percent. Patients should be prepared for admission to an intensive care unit (ICU) postoperatively. Infection, wound breakdown, bowel obstruction, and venous thromboembolic events are common short-term complications. Additionally, intestinal fistulas or anastomotic leaks or strictures may develop. Reoperation may be required. Most women will experience significant morbidity and unforeseen complications (Berek, 2005; Goldberg, 2006; Maggioni, 2009). Preexisting medical problems, morbid obesity, and malnutrition increase these risks.

Long-term effects on sexual function and other body functions are candidly reviewed. Patients with two ostomies have a lower quality of life and poorer body image. However, in those who retain vaginal capacity, quality of life and sexual function is reportedly improved compared with those without reconstruction. Thus, counseling regarding vaginal reconstruction is part of the preoperative dialogue (Section 46-9, p. 1165). In general, a woman returns to baseline functioning within a year postoperatively, but quality of life is often affected by worries regarding tumor progression (Hawighorst-Knapstein, 1997; Rezk, 2013). Patients should be aware that more than half will develop recurrent disease despite exenterative surgery (Benn, 2011; Westin, 2014).

■ Patient Preparation

Prior to surgery, stoma sites are marked, the consent form is reviewed, and final questions are answered. To minimize fecal contamination during bowel excision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is mandatory. Ileus is common following exenteration and nutritional demands are increased. Thus, total parenteral nutrition (TPN) is often initiated as early as possible when needed. In addition, routine antibiotic prophylaxis has been shown to decrease infectious complications (Goldberg, 1998). Pneumatic compression devices or subcutaneous heparin is particularly important due to the anticipated long operation and extended postoperative recovery. Patients are typed and crossmatched for potential blood product replacement. Critical care team consultation may be indicated, and an ICU bed is requested.

INTRAOPERATIVE

■ Instruments

To prepare for complicated resections, a surgeon should have access to all types and sizes of bowel staplers. These include end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers. Additionally, an electrothermal bipolar coagulator (LigaSure) may speed pedicle ligation while decreasing blood loss (Slomovitz, 2006).

■ Surgical Steps

□ **Anesthesia and Patient Positioning.** General anesthesia with or without epidural placement for postoperative pain management is mandatory. An arterial line for monitoring is typically added as a necessary precaution. Bimanual examination is performed to

TABLE 46-4.1. Differences among Type I (Supralevator), Type II (Infralevator), and Type III (with Vulvectomy) Pelvic Exenterations

Pelvic Structure	Degree of Resection		
	Type I	Type II	Type III
Viscera	Above levator	Below levator	Below levator
Levator ani muscles	None	Limited	Complete
Perineal membrane	None	Limited	Complete
Vulvoperineal tissues	None	None	Complete

reorient a surgeon to a patient's individual anatomy. The abdomen, perineum, and vagina are surgically prepared, and a Foley catheter is inserted. Legs should be positioned in low lithotomy in booted support stirrups to permit adequate perineal access.

□ **Abdominal Entry.** The type of abdominal entry may be dictated by an intended rectus abdominis flap, which requires a low transverse incision. Otherwise, a midline vertical incision is ideal. A less commonly employed option is to initially assess by laparoscopy a patient's suitability for exenteration. This minimally invasive approach may avoid unnecessary laparotomy in up to half of candidate patients (Kohler, 2002; Plante, 1998).

□ **Exploration.** The most common reason that exenterations are aborted is the presence of metastatic peritoneal disease (Miller, 1993). Thus, following positioning of an abdominal self-retaining retractor, a surgeon thoroughly explores for disseminated disease that may not have been suspected preoperatively. Typically, numerous adhesions must also be lysed to inspect and palpate abdominal contents. Suspicious lesions are removed or biopsied.

□ **Lymph Node Dissection.** A significant number of exenterations will be aborted intraoperatively due to identification of lymph node metastases (Miller, 1993). For this reason, pelvic and paraaortic node sampling and frozen section analysis is performed to exclude metastatic disease before proceeding. Additionally, retroperitoneal dissection provides a surgeon with a sense of the degree

of pelvic sidewall fibrosis, which may render the vessels, ureters, and other important structures virtually indistinguishable from the surrounding soft tissue.

□ **Pelvic Sidewall Exploration.** As described in Section 46-1 (p. 1135), the retroperitoneum is entered and the external iliac and internal iliac artery bifurcation is bluntly dissected free of overlying areolar connective tissue. The ureter is placed on a Penrose drain for identification. The paravesical and pararectal spaces are developed.

Parametrial tumor extension is the third most common reason for aborting exenteration (Miller, 1993). Thus, the pelvic sidewall should be verified to be clinically free of disease by inserting one finger into the paravesical space, another into the pararectal space, and palpating the intervening tissue down to the levator plate. There must be a grossly negative margin at the pelvic sidewall to proceed. Tissues may be biopsied and frozen section analysis performed to confirm this impression. Often, it is difficult to know with absolute certainty whether the margins are clear due to the varying extent of retroperitoneal fibrosis encountered.

□ **Bladder Mobilization.** The bladder blade is removed from the self-retaining retractor to permit entry into the space of Retzius and blunt reflection of the bladder from the back of the pubic symphysis. To achieve this, downward traction on the bladder and urethra will expose filmy attachments that may be electrosurgically incised (Fig. 46-4.1). Laterally positioned false

ligaments of the bladder are divided between clamps or transected with an electrothermal bipolar coagulator. This joins the retropubic and paravesical spaces. The bladder should be floppy in the pelvis from loss of its supporting pelvic attachments and is completely freed ventrally. However, the urethra is still attached to the bladder.

□ **Rectal Mobilization.** Following mobilization of the bladder, the ureters are held laterally, and the overlying peritoneum at the pelvic brim is divided on each side in a medial direction up to the sigmoid colon mesentery. By inserting a finger into each pararectal space and sweeping medially, it should be possible to develop the avascular plane between the rectosigmoid and the sacrum (retrorectal space).

Surgeons should be confident that there is no sacral tumor invasion and that they will be able to lift the rectosigmoid out of the pelvis to achieve a posterior margin that is tumor free. This is the last decision to be made before dividing the bowel and beginning steps of the operation that are irreversible.

Once all the tumor boundaries have been assessed, exenteration proceeds by dividing the sigmoid colon with a GIA stapler and dividing the intervening mesenteric tissue (Section 46-21, p. 1201). The proximal sigmoid colon is then packed into the upper abdomen. The distal rectosigmoid is held ventrally and cephalad while a hand is inserted posteriorly to bluntly dissect the adventitial tissue between the rectum and sacrum in the midline (Fig. 46-4.2). This maneuver is continued distally to the coccyx

FIGURE 46-4.1 Mobilizing the bladder.

FIGURE 46-4.2 Mobilizing the rectum.

**FIGURE 46-4.3** Dividing the cardinal ligaments.

to develop the retrorectal space and isolate the laterally located rectal pillars.

□ **Cardinal Ligament Division.** The mobilized bladder and distal rectum with uterus (if present) are held together on contralateral traction, while a hand is placed with one finger in the paravesical space and the other in the pararectal space to isolate the lateral pelvic attachments. The cardinal ligaments, internal iliac vessels, and ureter are often not distinguishable in a typically radiated field, but lie within this tissue.

Beginning anteriorly, these fibrous attachments are serially divided at the pelvic sidewall (Fig. 46-4.3). Vascular clips should be available in case of tissue slippage or inadvertent bleeding.

□ **Internal Iliac Vessels and Ureter Division.** As the pelvic sidewall dissection continues dorsally, the anterior branches of the internal iliac artery, venous channels, and distal ureter ideally are individually located and ligated to optimize hemostasis (Fig. 46-4.4). However, blood vessels and

**FIGURE 46-4.4** Dividing the hypogastric vessels and ureter.

ureters frequently will lie within fibrous tissue and may be relatively indistinguishable. Thus, clamps or the electrothermal bipolar coagulator are placed around smaller pedicles to minimize the possibility of inadvertent blood loss. At minimum, the ureter is located, isolated, and divided as distally as possible to provide extra length for reaching the urinary conduit. Later, any damage at the distal tip can be trimmed as needed to ensure healthy tissue for urinary conduit creation. A large vascular clip is placed on the proximal end of the ureter to distend the lumen

**FIGURE 46-4.5** Dividing the rectal pillars.

**FIGURE 46-4.6** Suprlevator exenteration: dividing the urethra.

**FIGURE 46-4.7** Supralelevator exenteration: dividing the rectum.

**FIGURE 46-4.8** Supralelevator exenteration: appearance of the pelvic floor.

and aid later anastomosis into the planned conduit. Dissection is then repeated on the contralateral side, and any remaining lateral attachments along the levator ani muscles are divided as the pelvic floor curves toward the perineum.

□ **Rectal Pillar Division.** The exenteration specimen is now chiefly tethered by the rectal stalks and distal mesenteric attachments posteriorly. These can be skeletonized with a right-angle clamp and divided along the pelvic floor (Fig. 46-4.5). This maneuver is continued distally to expose the entire posterior pelvic floor. The exenteration specimen is then circumferentially inspected and additional dissection is performed to completely release it from all attachments leading through the levator ani muscles. At this point, steps diverge depending on whether supralelevator or infralelevator exenteration is planned.

⑪ **Supralelevator Exenteration: Final Steps.** Removal of the specimen above the levator muscles begins by posterior traction on the bladder. The Foley catheter should be palpable within the urethra, and all surrounding tissue should already be dissected away. An electrocautery blade is used to transect the distal urethra (Fig. 46-4.6). The distal opening does not require closure and may function as a natural orifice drain postoperatively. Next, the vagina is transected and then closed with 0-gauge delayed-absorbable suture in a running fashion. The transverse anastomosis (TA) or curved cutter stapler

(Contour) is placed across the distal rectum and fired (Fig. 46-4.7). This completes detachment of the specimen, which includes bladder, uterus, rectum, and surrounding tissue. The pelvic floor is then carefully assessed to identify bleeding points (Fig. 46-4.8). A laparotomy pad is packed firmly into the pelvis to tamponade any surface oozing, while the exenteration specimen is inspected to confirm grossly negative margins.

⑫ **Infralelevator Exenteration: Perineal Phase.** With infralelevator exenteration, once abdominal dissection reaches the levator muscles, a second surgical team begins the perineal phase. The use of two teams typically shortens operative time and reduces bleeding. The planned perineal resection is outlined to encompass the tumor. As shown in Figure 46-4.9, resection may require infralelevator exenteration with or without vulvectomy.

The perineal incision ideally begins concomitantly with division of the levator muscles

by the abdominal team. At the perineum, a skin incision is first performed, followed by use of an electrocautery blade to dissect through the subcutaneous tissues surrounding the urethra, vaginal opening, and anus.

⑬ **Infralelevator Exenteration: Partial Resection of the Levator Muscles.** Within the abdomen, the primary surgical team places the specimen on traction. Electrocautery blade dissection is used to circumferentially incise the levator muscles lateral to the area of tumor extension (Fig. 46-4.10). The dissection proceeds distally toward the perineum.

⑭ **Infralelevator Exenteration: Connecting the Perineal and Abdominal Spaces.** After the perineal incision has reached the fascial plane, four spaces are developed: subpubic space, left and right vaginal spaces, and retrorectal space. It is helpful to have the abdominal surgeon place a hand deep into

**FIGURE 46-4.9** Infralelevator exenteration: perineal phase incisions.

**FIGURE 46-4.10** Infralelevator exenteration: partial resection of the levator muscles.

**FIGURE 46-4.11** Infralelevator exenteration: connecting the perineal and abdominal spaces.

the pelvis and guide the electrosurgical dissection by the perineal team (Fig. 46-4.11). Five pedicles are identified that separate these avascular spaces: two pubourethral pedicles, two rectal pillar pedicles, and the midline posterior anococcygeal pedicle. Electrosurgical dissection that is directed by the abdominal surgeon's finger is performed to open the intervening spaces. From below, the five vascular pedicles are divided and ligated using the electrothermal bipolar coagulator.

**15 Infralelevator Exenteration: Removal of the Specimen.** Circumferential dissection will result in complete detachment of the specimen that can be removed either vaginally or abdominally (Fig. 46-4.12). Hemostasis is

then achieved with a series of sutures, vascular clips, or clamps and ties. Finally, the pelvic floor and pedicle sites are carefully reinspected (Fig. 46-4.13).

**16 Infralelevator Exenteration: Simple Closure.** If vaginal reconstruction is not planned, the most straightforward and quickest way to close the perineum is for the second team to perform a layered closure of the deep tissues with 0-gauge delayed-absorbable suture (Fig. 46-4.14). The perineal skin is

closed with the same type of delayed-absorbable suture in a running fashion.

**17 Final Steps.** A dry laparotomy pad may be held firmly deep in the pelvis to tamponade surface oozing, while the conduit, colostomy or bowel anastomosis, other surgical procedures, or vaginal reconstruction are performed. In some instances, intraoperative radiation therapy may be a useful adjunct for an obviously positive or clinically suspicious resection margin (Backes, 2014; Foley, 2014; Koh,

**FIGURE 46-4.12** Infralelevator exenteration: removal of the specimen.

**FIGURE 46-4.13** Infralelevator exenteration: pelvic floor.

**FIGURE 46-4.14** Infralevator exenteration: simple perineal closure.

2015). An omental J-flap may provide additional blood supply to the irradiated, denuded pelvic floor (Section 46-14, p. 1186). The type of postoperative suction drainage may be dictated by these ancillary procedures but should be used judiciously (Goldberg, 2006).

**POSTOPERATIVE**

The morbidity of total pelvic exenteration depends on various factors, which include preoperative health of the patient, intraoperative events, extent of the procedure, ancil-

lary procedures, and postoperative vigilance. Hospitals that treat a relatively high volume of such patients report lower surgical in-hospital mortality rates (Maggioni, 2009). However, unlike a few decades ago, few institutions perform this operation on a regular basis.

The immediate life-threatening concerns are massive bleeding, acute respiratory distress syndrome, pulmonary embolism, and myocardial infarction (Fotopoulou, 2010). Every effort is made to encourage early ambulation as soon as the patient is stable. A prolonged ileus or partial small bowel obstruction will typically respond to expectant management but may require TPN for weeks. Intestinal fistulas and leaks are more common when using mesh to cover the pelvic floor or when performing low rectal anastomoses. Omental pedicle grafts and rectus abdominis or gracilis myocutaneous flaps may prevent such complications. Pelvic abscess and septicemia are additional subacute complications that develop commonly (Berek, 2005; Goldberg, 2006; Maggioni, 2009).

## 46-5

## Anterior Pelvic Exenteration

Removal of the uterus, vagina, bladder, urethra, distal ureters, and parametrial tissues with preservation of the rectum is meant to be a less morbid operation than total pelvic exenteration (Section 46-4, p. 1149). Patients are carefully selected for this more limited procedure to still achieve negative surgical margins. Women who have previously had a hysterectomy are not usually good candidates, because a complete resection of a central recurrence involving the vaginal cuff would typically require removal of both bladder and rectosigmoid colon. The most common indications include small recurrences confined to the cervix or anterior vagina after pelvic radiation. In gynecologic oncology, up to half of all exenterations performed are anterior (Berek, 2005; Maggioni, 2009).

### PREOPERATIVE

The preoperative evaluation is similar to that described for total pelvic exenteration (Section 46-4, p. 1149). Although preservation of the rectum is planned, patients are advised that potentially unforeseen clinical circumstances may dictate bowel resection and colostomy or low rectal anastomosis. Accordingly, a complete bowel preparation is still mandatory.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Initial Steps.** Anterior exenteration is technically similar to total pelvic exenteration, described earlier. Patients are positioned in low lithotomy in booted support stirrups, the appropriate skin incision is made, the abdomen is explored, lymph nodes are removed, and spaces are developed to exclude metastatic or unresectable disease. The procedure begins to differ after the bladder has been mobilized. A surgeon then makes the final decision to leave the rectum intact and proceed with anterior pelvic exenteration.

□ **Developing the Rectovaginal Space.** Instead of mobilizing the rectum and dividing the sigmoid colon, the rectovaginal space is developed much as in a type III radical hysterectomy. The uterosacral ligament and the entire length of the rectal pillars are divided to free the exenteration specimen posteriorly.

□ **Lateral Pelvic Attachments.** The mobilized bladder and uterus are held medially to

**FIGURE 46-5.1** Removal of the specimen.

aid in isolation of the cardinal ligaments, internal iliac vessels, and ureter. These structures are successively divided with an electrothermal bipolar coagulator (LigaSure) or clamped, cut, and individually ligated.

□ **Removal of the Specimen.** After the anterior pelvic exenteration specimen has been completely mobilized, the urethra and vagina are divided (Figs. 46-5.1 and 46-5.2). The urethra is left open, and the vaginal cuff is closed with 0-gauge delayed-absorbable suture in a running fashion.

□ **Final Steps.** Typically, the lesion is small and lies above the levator ani muscles, thus a perineal phase is not required. For

this reason, placement of a myocutaneous flap for vaginal reconstruction may be more problematic in these patients due to limited space in the pelvis.

### POSTOPERATIVE

Morbidity of anterior pelvic exenteration is comparable with that of total pelvic exenteration (Section 46-4, p. 1149) (Sharma, 2005). Ideally, the operation is shorter and restoration of bowel function is more rapid. Some patients will experience tenesmus or long-term rectal symptoms that likely stem from interruption of the autonomic nervous system in surrounding tissue.

**FIGURE 46-5.2** Appearance of the pelvic floor.

## 46-6

## Posterior Pelvic Exenteration

Removal of the uterus, vagina, rectum, and parametrial tissues with preservation of the ureters and bladder is meant to be a less morbid operation than total pelvic exenteration (Section 46-4, p. 1149). Patients are carefully selected for this more limited procedure to still achieve negative surgical margins. For this reason, women who have previously had a hysterectomy are not usually good candidates. The most common indications include small postirradiation recurrences primarily involving the posterior vaginal wall or coexisting with a rectovaginal fistula. In gynecologic oncology, fewer than 10 percent of exenterations are posterior (Berek, 2005; Maggioni, 2009).

### PREOPERATIVE

Preoperative evaluation is largely identical to that described for total pelvic exenteration (Section 46-4, p. 1149). A surgeon's judgment and experience are critical in deciding to proceed with a more limited operation. However, patients are advised that potentially unforeseen clinical circumstances may dictate resection of the ureters and bladder with formation of a urinary conduit.

### INTRAOPERATIVE

#### Surgical Steps

□ **Initial Steps.** Posterior pelvic exenteration is technically similar to a type III radical hysterectomy but with the addition of rectosigmoid resection and a more extended vaginectomy (Section 46-1, p. 1134). The operation begins as a total pelvic exenteration. Patients are positioned in low lithotomy in booted support stirrups, the appropriate skin incision is made, the abdomen is explored, lymph nodes are removed, and spaces are developed to exclude metastatic or unresectable disease (Section 46-4, p. 1150).

FIGURE 46-6.1 Incising the levator muscles.

A surgeon then makes the final decision to leave the bladder intact and proceed with posterior exenteration.

□ **Ureteral Dissection.** As with type III radical hysterectomy, the retroperitoneum is entered, ureters are mobilized, uterine arteries are ligated at their internal iliac artery origin, and parametrial tissue is divided at the pelvic sidewall. The bladder is then mobilized away from the cervix and vagina, and ureters are unroofed from the paracervical tunnels. The lateral attachments are then divided all the way to the levator ani muscles. However, typically these steps are much more tedious in a previously irradiated field because of tissue fibrosis and scarring.

□ **Mobilizing the Rectum.** The sigmoid colon is divided with the mesentery and peritoneal attachments, as described for low anterior resection (p. 1201). The retrorectal space is bluntly dissected to mobilize the rectum and enable transection of the rectal pillars and uterosacral ligaments.

□ **Removal of the Specimen.** The entire specimen may then be placed on traction to aid placement of the transverse anastomosis (TA) or curved cutter stapler (Contour) and

division of the rectum. The rectum is divided below the tumor to leave grossly negative margins.

To encompass the tumor for removal, dissection is continued circumferentially to (or through) the levator ani muscles (Fig. 46-6.1). The distal vagina is transected and sewn closed in a running fashion with 0-gauge delayed-absorbable suture. The specimen is removed.

□ **Final Steps.** Typically, the lesion is small and lies above the levator ani muscles, and thus a perineal phase is usually not required. As a result, placement of a myocutaneous flap for vaginal reconstruction may be more problematic in such patients due to limited space in the pelvis.

### POSTOPERATIVE

Morbidity of posterior pelvic exenteration is comparable with that of total pelvic exenteration (Section 46-4, p. 1149) (Sharma, 2005). Ideally, the operation is shorter and urinary complications are less frequent. However, posterior exenteration in a previously irradiated patient frequently results in a contracted bladder and intractable urinary incontinence.

## 46-7

## Incontinent Urinary Conduit

Removal of the bladder during total or anterior exenteration is the main indication for an incontinent urinary conduit. Less commonly, an otherwise irreparable postirradiation vesicovaginal fistula may warrant urinary diversion. Following cystectomy, an isolated resected segment of bowel that maintains its mesenteric connection and vascular supply is used as the new urine reservoir. A stoma is crafted using one end of the bowel segment and an opening in the anterior abdominal wall. Ureters are reimplanted into the opposite end of this isolated bowel segment.

Various techniques are available to create such urinary conduits, and these are categorized as *incontinent diversions* or *continent diversions*. An incontinent diversion is the simplest to create, but postoperatively a patient must continuously wear an ostomy bag. These conduits are often preferable for medically compromised patients, the elderly, and anyone with a short life expectancy. Alternatively, a continent urinary reservoir can be created that is emptied by intermittent patient self-catheterization of the bowel stoma.

Of incontinent diversions, an *ileal conduit* has historically been the most common urinary diversion used in gynecologic oncology (Goldberg, 2006). However, this bowel segment and distal ureters invariably lie within a previously irradiated field. Conduit construction with radiation-damaged bowel may lead to higher rates of stenosis or leakage at the ureteral anastomotic sites (Pycha, 2008). More recently, the *transverse colon conduit* has proven to be a very successful alternative for previously irradiated patients (Segreti, 1996b; Soper, 1989). *Sigmoid* conduits are generally less desirable due to preexisting radiation damage and proximity to a concurrent colostomy site. The *jejunal conduit* is another rarely used option that typically lies outside the radiation field.

The basic principles of constructing an incontinent urinary conduit are the same, regardless of the intestinal segment used. First, healthy-appearing bowel with a good blood supply is selected. Second, wide-caliber ureterointestinal anastomoses and stenting are essential to minimize the risk of anastomosis stenosis. Third, sufficient mobility of the ureters and bowel segment is important to prevent tension that might lead to anastomotic leaks. Fourth, creation of a straight tunnel through the abdominal wall helps prevent bowel kinking and obstruction.

### PREOPERATIVE

#### ■ Patient Evaluation

The preoperative evaluation is usually dictated by the preceding exenterative procedure. The specific decision is whether to plan for an incontinent or continent urinary conduit. Patients are extensively counseled regarding the differences. The type of conduit selected should be considered permanent, although later conversions are possible (Benezra, 2004).

#### ■ Consent

Patients are advised that intraoperative findings may dictate revision of an original surgical plan. Postoperatively, urinary infections with or without pyelonephritis are very common with any type of conduit. Anastomotic leaks are less frequent with routine ureteral stent placement but can contribute to a prolonged ileus, the need for CT-guided drainage, or potentially, surgical reexploration with revision. Episodes of small bowel obstruction are possible and often develop at the site where the bowel segment was harvested and the remaining bowel ends were reanastomosed. In the long term, ureteral strictures or stenosis may compromise renal function. Infrequently, reoperation is necessary for complications that do not respond to conservative management (Houvenaeghel, 2004).

#### ■ Patient Preparation

Bowel preparation is mandatory, but preparation is typically dictated by the preceding exenterative surgery (Section 46-4, p. 1149). Ideally, an enterostomal therapist is available to mark a conduit stoma site, typically on the patient's right side, that is unobstructed in the supine, sitting, and standing positions.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Initial Steps.** To avoid unnecessary traction on its anastomoses, the incontinent urinary conduit is constructed as the last major intraabdominal step during exenterative surgery. Hemostasis is achieved before beginning the conduit. Anesthesia, patient positioning, and skin incisions are typically dictated by the preceding operation.

□ **Exploration.** The bowel segment for the planned conduit is carefully inspected. It must be healthy appearing, not tethered, and lie close to the distal ureters. The final decision is now made regarding which type of incontinent conduit is best for the circumstances. If the distal ileum has the typical

leathery, pale, mottled appearance of radiation injury, a conduit should be prepared from the transverse colon. Overlooking the importance of this decision can lead to various otherwise preventable complications intraoperatively and postoperatively.

□ **Ileal Conduit: Preparing the Bowel Segment.** The ileocecal junction is located, and the ileum is elevated to identify a bowel segment with the most mobility to reach the right side of the anterior abdominal wall where the stoma will be located. Ideally, the proximal end of the segment lies 25 to 30 cm from the ileocecal valve. At the selected site, the mesentery is scored on each side with an electrosurgical blade to aid insertion of a hemostat directly beneath the bowel loop. A Penrose drain is pulled through to mark this proximal end along the ileum that will eventually become the distal part of the conduit and will form the abdominal wall stoma.

The conduit length depends on subcutaneous tissue depth and ileum mobility but should measure approximately 15 cm. The conduit's butt end will house the ureteral anastomoses and is selected by measuring the ileum that lies distal to the Penrose drain, and again the mesentery is scored. The gastrointestinal anastomosis (GIA) stapler is then inserted to divide the distal bowel segment (Fig. 46-7.1). The point of division should ideally be at least 12 cm from the ileocecal valve. The conduit is remeasured prior to dividing the proximal ileum, to account for possible shrinkage of the intervening segment and to again ensure sufficient length.

Once the bowel is stapled and divided, the conduit mesentery is also carefully divided on each end of the segment. This tissue division is angled inward and toward the base of the mesentery near its insertion to the posterior abdominal wall. This provides adequate mobility. The vasculature may be compromised if too much mesentery is divided, whereas too little will result in tension on the conduit. A perfect balance is required.

When convenient, intestinal continuity, minus the excised segment, is reestablished anterior to the conduit. This is completed by end-to-end small-bowel reanastomosis using the GIA and TA staplers as described in Section 46-20 (p. 1198).

□ **Ileal Conduit: Preparing the Ureters.** The staple line is excised from the stomal end of the conduit, and the conduit is irrigated into a basin. The ureters should now be engaged from the vascular clips placed earlier during exenteration. The distal end of the ureters should have a stay suture placed for traction. To prevent focal necrosis that may impede successful anastomosis, ureters are never directly grasped with forceps

**FIGURE 46-7.1** Ileal conduit: preparing the bowel segment.

**FIGURE 46-7.2** Ileal conduit: ileal incision.

or roughly handled. They are sharply freed from their retroperitoneal attachments so that they easily reach past the point of their planned anastomosis into the conduit. The left ureter is brought *under* the inferior mesenteric artery (IMA) to prevent acute angulation and kinking. This ureter ultimately exits from beneath the base of the sigmoid colon mesentery to reach the conduit.

□ **Ileal Conduit: Ureteral Anastomoses.** Adson forceps are used to grasp a small

section of the ileal serosa to which the left ureter will reach. This site is ideally approximately 2 cm from the butt end of the conduit on the anterior side of the antimesenteric surface. Metzenbaum scissors remove a small, full-thickness section of bowel wall (Fig. 46-7.2). The ileal mucosa should be easily visible.

The distal tip of the left ureter is cut at a 45-degree angle just behind the vascular clip placed during exenteration. If the distal ends of the ureters exhibit fibrosis, they are trimmed to reach healthy-appearing tissue. The prior distal stay-suture is removed with this trimming. Urine will drain into the abdomen while a 4-0 delayed-absorbable stay suture is placed outside-to-in through

the ureter's distal tip. The needle is left on this traction stitch since it will be the final suture in the anastomosis. Fine tip scissors are used to spatulate the ureter for approximately 1 cm, but the length is customized depending on the caliber of the ureteral lumen (Fig. 46-7.3). This maneuver helps to reduce the possibility of future ureteral stenosis.

The first suture is placed at the apex of the spatulation with a full-thickness bite through the ureteral wall and bowel mucosa (Fig. 46-7.4). Two or three adjoining mucosa-to-mucosa sutures are placed. A 7F ureteral stent is then placed through the stomal end of the conduit and advanced through the anastomosis into the left renal pelvis. The stent is held against the wall of the midsection of

**FIGURE 46-7.3** Ileal conduit: spatulating the ureter.

**FIGURE 46-7.4** Ileal conduit: suturing ureter and ileal segment.

**FIGURE 46-7.5** Ileal conduit: stoma with stents carefully pulled through abdominal incision.

the conduit with one hand and secured with a 3–0 or 4–0 gauge chromic catgut suture through the entire bowel wall and around the stent to hold it in place. The left ureteral anastomosis is completed with additional circumferential sutures to achieve a watertight closure (Fig. 46-7.5).

The anastomotic site for the right ureter is selected at least 2 to 3 cm distal to that of the left along the length of the conduit. The entire procedure is then repeated. Saline with methylene blue dye is used to fill the conduit and observe for watertight integrity. Any anastomotic leaks must be reinforced

with additional sutures and retested. If leakage persists or if there is concern about the mucosa-to-mucosa apposition, then the entire anastomosis should be redone.

The butt end of the conduit is next secured to the sacral promontory, iliopsoas muscle, or posterior peritoneum with two or three delayed-absorbable sutures through the seromuscular layer of the conduit. Stabilizing the conduit in this way will prevent undue tension on the ureteral anastomoses when the patient is upright and gravity allows the intestines to slide into the pelvis.

**□ Ileal Conduit: Stoma Creation.** The skin at the proposed stoma site is elevated with a Kocher clamp. An electro-surgical blade, set on cutting mode, is used to excise a small circle of skin. The subcutaneous fat is separated by blunt dissection until the fascia is visible. A cruciate incision is made with an electro-surgical blade (Fig. 46-7.6). The rectus abdominis muscle is split longitudinally and another cruciate incision is created in the peritoneum. The opening is bluntly expanded until it easily accommodates two fingers.

The stoma and stents are carefully pulled through the incision until at least 2 cm of ileum protrudes through the skin. The mesentery may need to be trimmed or the abdominal wall opening further dissected to accommodate the conduit. The mucosal edge of the bowel is everted. The stoma is completed with 3–0 gauge delayed-absorbable “rosebud” stitches that include the ileal mucosa, intervening bowel serosa, and skin dermis (Fig. 46-7.7). Circumferential sutures

**FIGURE 46-7.6** Ileal conduit: making the stoma.

**FIGURE 46-7.7** Ileal conduit: suturing the stoma.

**FIGURE 46-7.8** Transverse colon conduit: preparing the bowel segment.

are placed. Both stents are trimmed to fit in the stoma bag. To enable correct identification postoperatively, the right ureteral stent is cut at a “right” angle. Individual silk sutures placed through each stent may be secured at the skin to prevent stent dislodgment over the first few postoperative days.

□ **Transverse Colon Conduit.** For this type of conduit, the hepatic and splenic flexures of the transverse colon are fully mobilized. In addition, the omentum is detached. Division points are marked with Penrose drains and transected (Fig. 46-7.8). The transverse mesocolon is then divided, as shown by the dotted lines, to provide sufficient mobility while preserving the middle colic artery. When performed in the usual setting of an exenteration with left lower quadrant colostomy, the bowel segment must measure approximately 20 cm to reach the right lower quadrant. Often, this requires incorporation of the hepatic flexure into the conduit and yields an antiperistaltic orientation, that is, urine ultimately flows through the conduit in the opposite direction that fecal waste would normally be propelled. Thus, the proximal bowel segment (nearest the cecum) will be the end of the conduit that eventually is brought through the abdominal wall.

Ureters are sufficiently mobilized in the retroperitoneal space, and both are brought out through a commodious peritoneal opening to reach the conduit. The left ureter will need to be brought across the aorta *proximal* to the IMA (unlike the ileal conduit). The ureteral anastomoses are then completed, ideally at the teniae coli, over stents. To prevent postoperative sliding and tension on the anastomoses, the conduit’s butt end is secured to the sacrum, iliopsoas muscle, or posterior peritoneum with interrupted

delayed-absorbable suture. Intestinal continuity is reestablished anterior to the conduit by a functional end-to-end anastomosis using EEA and TA staplers, as described in Section 46-18 (p. 1195). The stoma can be made at the preselected site, but it can be repositioned almost anywhere that the conduit will comfortably reach. The stomal end of the conduit is brought through the anterior abdominal wall and secured (Fig. 46-7.9).

□ **Final Steps.** Mesenteric defects require closure to prevent internal hernias but not so tightly as to compromise blood supply. A suction drain may be placed if integrity of the anastomoses and leakage is a concern. If the stoma appears dusky, the abdominal wall tunnel may be too tight, the mesentery may be twisted or placed on too much tension, or the blood supply may not be

sufficient. The last circumstance is the worst, and it generally requires trimming of the distal end of the bowel or occasionally redoing the entire conduit. Either is preferable to avoid problematic retraction, stricture, or necrosis.

## POSTOPERATIVE

The stoma is regularly checked for viability during the immediate postoperative recovery period. Both stents should be functioning. A dry stent that does not respond to irrigation should prompt an imaging study to exclude ureteral obstruction. Urinary fistulas and ureteral obstruction are uncommon but are potentially life-threatening if not addressed with percutaneous drainage or reoperation. Prolonged bowel dysfunction may indicate an anastomotic urine leak or small-bowel obstruction.

Patients often are readmitted within a few weeks of surgery due to partial small bowel obstruction, urinary infection, wound separation, or other relatively minor complications of exenteration. These typically resolve with targeted supportive care. Long-term complications include ureteral stenosis and renal loss. Renal function may deteriorate due to chronic infection and reflux. When patients cannot be otherwise managed, they may require long-term percutaneous nephrostomy tubes, indwelling stents, or reoperation and conduit or stoma revision.

Predictably, the overall morbidity of creating an incontinent conduit is much higher in previously irradiated patients (Houvenaeghel, 2004). Tissue quality and mobility are especially important in these patients.

**FIGURE 46-7.9** Transverse colon conduit: final appearance.

## 46-8

## Continent Urinary Conduit

Removal of the bladder during total or anterior exenteration is the main indication for a continent urinary conduit. Vesicovaginal fistulas and disabling incontinence following radiation therapy are other less common reasons. Following cystectomy, urine is diverted into a reservoir created from a resected bowel segment. Depending on their construction, these diversions may render a woman continent or incontinent. An incontinent conduit reservoir chronically drains into an ostomy bag, whereas that of a continent conduit does not leak urine. Patients empty the reservoir by intermittent self-catheterization.

Continent conduits, however, may not be appropriate for all patients. The operation is more complex than an incontinent diversion procedure and may lead to more postoperative complications (Karsenty, 2005). It also requires a highly motivated patient who is capable of long-term self-catheterization. An ideal candidate for a continent conduit is a young, otherwise healthy woman without a colostomy.

There are several continent diversion methods. In gynecologic oncology, the continent ileocolonic urinary reservoir (Miami pouch) has become the most popular choice (Salom, 2004). This pouch is technically straightforward to construct and uses tissues that characteristically lie in nonirradiated areas (Penalver, 1998).

A Miami pouch includes a distal ileum segment, the ascending colon, and a portion of transverse colon. The basic steps involve opening the colon segment along the length of the tenia and folding it onto itself. The walls of the ascending and transverse colon are then sewn together to achieve a reservoir with low intraluminal pressure. The ileal segment is tapered and purse-string sutures are placed at the level of the ileocecal valve to achieve continence. The free ileal segment end is then exteriorized as a stoma to allow catheterization (Penalver, 1989).

### PREOPERATIVE

#### ■ Patient Evaluation

Preoperative evaluation is usually dictated by the preceding exenterative procedure. The specific decision is whether to plan for an incontinent or continent urinary conduit. Patients are extensively counseled regarding the differences. The presence of a permanent

colostomy removes the apparent advantage of a continent conduit and an abdominal wall without draining stomas. Catheterization may be more problematic in very obese women. In addition, some patients with prior high-dose radiation or chronic bowel disease may also not be good candidates due to poor tissue quality and increased associated risks of anastomotic leaks, ureteral stricture, or fistula.

#### ■ Consent

Patients are advised that intraoperative findings such as poor bowel appearance and dense adhesions may dictate a change in surgical plans. In addition, complications are common and should be reviewed. Even in experienced centers, half of patients will have one or more early pouch-related complications: ureteral stricture with obstruction, anastomotic leak, fistula, difficulty in catheterization, pyelonephritis, or sepsis. One third will develop late complications beyond 6 weeks. Ten percent of patients will ultimately require reoperation to revise the Miami pouch (Penalver, 1998). As a result, many patients would not choose the continent urinary conduit again (Goldberg, 2006).

#### ■ Patient Preparation

Bowel preparation is mandatory but generally is dictated by the preceding exenterative surgery. Ideally, an enterostomal therapist is

available to mark a conduit stoma site in the right lower abdomen that is unobstructed in the supine, sitting, and standing positions.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Initial Steps.** To avoid unnecessary traction on anastomoses, the continent urinary conduit is constructed as the last major intraabdominal procedure during exenterative surgery. Before beginning the conduit, hemostasis should be achieved. Anesthesia, patient positioning, and skin incisions are typically dictated by the preceding operation.

□ **Exploration.** The conduit bowel segment is carefully inspected. It must be healthy appearing and lack severe radiation injury. At this point, the final decision to proceed with creation of a Miami pouch is made.

□ **Preparing the Bowel Segment.** The right colon is freed along the white line of Toldt from the cecum, around the hepatic flexure, to the proximal transverse colon. The white line of Toldt marks the lateral attachment of ascending and descending colon's peritoneum to the posterior abdomen's parietal peritoneum. The conduit will require approximately 25 to 30 cm of colon and at least 10 cm of ileum. With these

FIGURE 46-8.1 Preparing the bowel segment.

**FIGURE 46-8.2** Detubularizing the bowel.

measurements in mind, a surgeon selects sites to divide the bowel.

The mesentery is scored with an electro-surgical blade, and a Penrose drain is placed around the sections to be divided. Within the mesentery, the underlying vasculature is reviewed to ensure sufficient conduit blood supply. A gastrointestinal anastomosis (GIA) stapler is used to divide the bowel at both sites marked with the Penrose drains (Fig. 46-8.1).

The mesenteries are incised down through the avascular areas to the posterior peritoneum. At this point, intestinal continuity is reestablished by a functional end-to-end stapled ileotransverse enterocolostomy using the GIA and transverse anastomosis (TA) staplers. The mesenteric defect is closed with 0-gauge delayed-absorbable suture in a running fashion to prevent internal herniation.

□ **Detubularizing the Bowel.** The conduit staple lines on both ends of the bowel segment are removed with Metzenbaum scissors, and the bowel is irrigated into a basin. Of this bowel segment, the entire colonic portion is opened with an electro-surgical blade along the tenia of the antimesenteric border to “detubularize” the bowel (Fig. 46-8.2). This is extended to remove the appendix.

□ **Creating the Pouch.** The colon segment is folded in half and four delayed-absorbable stay sutures are placed at the

corners to begin creation of the pouch. The lateral edge is closed in two layers with 2-0 and 3-0 gauge delayed-absorbable suture in a running fashion (Fig. 46-8.3).

□ **Tapering the Ileum.** A 14F red rubber catheter is inserted through the terminal ileum segment into the pouch. Two purse-string, 0-gauge delayed-absorbable sutures are placed 1 cm apart at the ileocecal junction. The ileum is elevated with Babcock clamps, and a GIA stapler is used to taper the terminal ileum on its antimesenteric border over the

catheter (Fig. 46-8.4). An anterior abdominal wall opening is made in the right lower quadrant so that the ileal segment of the conduit can be pulled through to approximate its final position.

□ **Ureteral Anastomoses.** Both ureters are further mobilized from their retroperitoneal attachments and brought into position under the ascending mesocolon using a 4-0 gauge delayed-absorbable stay suture at the tip. Manipulation with this suture avoids crush injury by forceps and subsequent

**FIGURE 46-8.3** Creating the reservoir.

**FIGURE 46-8.4** Tapering the ileum.

**FIGURE 46-8.5** Ureteral anastomoses.

necrosis. As in the transverse colon conduit, the left ureter is brought over the aorta and *above* the origin of the inferior mesenteric artery (IMA).

The ureteral anastomotic sites to the pouch are selected based on ureter length and their ability to have a straight course to the pouch. One ureter is usually brought through on either side of the pouch suture line. The ureters are trimmed and spatulated (see Fig. 46-7.3, p. 1158). In creating the openings for the ureters, the bowel mucosa is incised at sites away from the suture line. A hemostat is poked through the bowel wall, grasps the ureteral stay suture, and thereby pulls 2 cm of each ureter into the pouch.

Each ureter is secured to the bowel mucosa with interrupted stitches of 4-0 gauge delayed-absorbable suture (Fig. 46-8.5). Single-J ureteral stents (7F) are inserted and sutured to the bowel wall with 3-0 gauge chromic to stabilize their placement. To enable correct identification postoperatively, the right ureteral stent is cut at a “right” angle.

□ **Closing the Pouch.** A large Malecot catheter is brought into the pouch through an incision made away from the ileocecal valve. The ureteral stents are brought out through the pouch next to the Malecot (Fig. 46-8.6). Here, where the catheters exit the pouch, a watertight purse string using 3-0 plain catgut suture is placed. Absorbable

suture is used for this purse string, as the Malecot catheter will be removed only 2 to 3 weeks postoperatively.

The remaining edges of the pouch are closed with two layers of 2-0 and 3-0 gauge

delayed-absorbable suture in a running fashion. Continence may be tested by inserting a red rubber catheter through the plicated ileum, filling the pouch with 250 to 300 mL of saline, removing the red rubber catheter, and gently squeezing the pouch. Additional purse-string sutures may be placed at the ileocecal valve if incontinence is demonstrated. The completed pouch (Fig. 46-8.7) is now ready to be brought to the abdominal wall.

□ **Final Steps.** The two stents and Malecot drain are brought out through a separate stab wound on the abdominal wall away from the stoma site. The Malecot drain is individually fixed to the skin with nylon sutures. The ileal segment is pulled through the abdominal wall and may require trimming to sit flush. The pouch is stabilized by suturing it to the under-surface of the abdominal wall, and the stoma is created by placing interrupted stitches of 3-0 gauge delayed-absorbable suture between the dermis and ileal mucosa as described in Section 46-7, Step 6 (p. 1159). A red rubber catheter is inserted and withdrawn to make sure that the pouch can be easily accessed. A Jackson-Pratt (JP) drain is then placed near the pouch to monitor for urine leakage and is brought out through a separate stab wound away from the stoma.

## POSTOPERATIVE

The Miami pouch initially requires more care than an incontinent urinary conduit. Mucus will be produced by the colonic bowel

**FIGURE 46-8.6** Closing the reservoir.

**FIGURE 46-8.7** Final steps.

segment. Therefore, the Malecot catheter is irrigated every few hours to permit urine drainage. In contrast, the ureteral stents are irrigated only if one of the catheters becomes obstructed. Two to 3 weeks postoperatively, an intravenous pyelogram (IVP) and gravity pouchogram are performed. The IVP excludes anastomotic leaks, ureteral stricture, and fistulas. The pouchogram involves retrograde filling of the conduit to search for leaks. If these tests are normal, the ureteral stents, Malecot catheter, and JP suction drainage tube may all be removed. The hole in the conduit that housed these tubes will heal secondarily.

A patient is taught self-catheterization using an 18F to 22F red rubber catheter and antiseptic technique. The interval between catheterizations is progressively increased over weeks to reach 6 hours during the day and span sleep hours at night. In addition, the pouch requires periodic irrigation to remove mucus. An IVP, pouchogram, and serum electrolyte and creatinine level measurement are performed at 3 months postoperatively and then every 6 months to evaluate the pouch, renal function, and upper urinary tracts.

More than half of patients will have a conduit-related complication postoperatively. Fortunately, most may be successfully managed conservatively without the need for reoperation (Ramirez, 2002). The most common urinary complications are ureteral stricture or obstruction, difficult catheterization, and pyelonephritis (Angioli, 1998; Goldberg, 2006). The gastrointestinal complication rate attributed to Miami pouch is less than 10 percent and includes fistulas (Mirhashemi, 2004).

## 46-9

## Vaginal Reconstruction

Patients undergoing exenterative surgery are typical candidates for creation of a new vagina. Other less common indications include congenital absence of the vagina, postirradiation stenosis, and total vaginectomy. There are innumerable ways to perform the procedure, and the type of reconstruction is typically determined by both the surgeon's personal experience and the patient's clinical circumstances.

Vaginal reconstruction at the time of exenteration is a very personal choice. Not every woman will desire a new vagina, and others will be unhappy with the functional result (Gleeson, 1994a). Moreover, reconstruction may significantly prolong an already lengthy operation and lead to additional perioperative morbidity (Mirhashemi, 2002). However, proponents suggest that filling the large pelvic defect and bringing in a new source of blood supply may actually prevent postoperative fistula or abscess formation (Goldberg, 2006; Jurado, 2000).

To create a functional neovagina, one of the following is performed: (1) surrounding skin and subcutaneous tissue is mobilized and positioned into the defect (skin flap), (2) skin from another part of the body is harvested and transferred to replace the vaginal mucosa (split-thickness skin graft), or (3) skin and underlying tissue outside the radiated field are mobilized on an attached section of muscle with its dominant blood supply (myocutaneous flap). Of the three choices for vaginal reconstruction, skin flaps, such as *rhomboid flaps*, *pudendal thigh fasciocutaneous flaps*, and *advancement* or *rotational flaps*, are technically the easiest to perform (Burke, 1994; Gleeson, 1994b; Lee, 2006). *Split-thickness skin grafts (STSG)* provide the ability to cover large surfaces if primary closure is not possible. However, these require that most of the native subcutaneous tissue has been retained at the neovagina site and require months of stenting with a vaginal mold to prevent stricture (Kusiak, 1996). *Rectus abdominis myocutaneous (RAM) flaps* and *gracilis myocutaneous flaps* are technically more challenging and take longer to perform, but they demonstrate the most satisfying functional results (Lacey, 1988; Smith, 1998). Importantly, RAM flaps may be inappropriate in those with a prior Maylard incision or any other procedure that resulted in ligation of the inferior epigastric artery, which is the dominant blood supply to this type of flap.

**FIGURE 46-9.1** Raising the perineal flaps.

Regardless of reconstruction technique, sexual function is often significantly impaired in women after pelvic exenteration (Hockel, 2008; Ratliff, 1996). Other techniques are used less commonly and are not covered in this section.

### PREOPERATIVE

#### ■ Patient Evaluation

The surgeon should have an open discussion with the patient regarding the risks and benefits of vaginal reconstruction. Some women may have unrealistic expectations that are important to address preoperatively. Others may not wish to incur additional morbidity. The patient should also be aware that intraoperative complications may dictate a change of plans and the need to abort reconstruction.

#### ■ Consent

The potential morbidity of the neovagina depends on the type of reconstruction. Flap necrosis, prolapse, wound separation, or other complications may require reoperation and/or lead to an unsatisfying end result. Postoperative patient concerns are expected and include self-consciousness about being seen in the nude by their partner and vaginal dryness or discharge (Ratliff, 1996).

#### ■ Patient Preparation

The preceding exenterative surgery typically dictates preoperative preparation. Modifications may be required, depending on the type of neovaginal reconstruction. For example, the legs may need to be surgically

prepared beyond the knees for a gracilis flap or a suitable donor site identified for STSG.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** General anesthesia is required for vaginal reconstruction. The abdomen, perineum, and vagina have been surgically prepared, and a Foley catheter inserted. Legs are positioned in standard lithotomy in booted support stirrups to permit adequate perineal access.

□ **Pudendal Thigh Fasciocutaneous Flap.** From a perineal approach, the planned incisions are marked along the skin from the non-hair-bearing areas just lateral to the labia majora. Flaps are roughly  $15 \times 6$  cm. The most inferior skin margin should be level with the lower part of the gaping perineal defect. The skin incision is begun at the superior flap margin and dissected to include the underlying subcutaneous tissue and fascia lata (Fig. 46-9.1). The posterior labial artery, a branch of the internal pudendal artery, provides blood supply (Fig. 38-28, p. 822).

The flap's edges are approximated in a running, subcuticular suture line with 4-0 gauge delayed-absorbable suture. The edges both marked "A" in the figure are joined, as are both edges marked "B." The tubular neovagina is inserted into the perineal defect such that the end labeled with letters becomes the new vaginal apex. The incision sites are closed with interrupted stitches of 3-0 gauge delayed-absorbable suture, and bilateral JP drains are placed beneath these suture lines. The perineal defect requires sculpting of

**FIGURE 46-9.2** Perineal flap closure.

tissue folds and suturing to form a functional end result (Fig. 46-9.2). The apex of the neovagina may then be abdominally sutured to the hollow of the sacrum as in a traditional sacrocolpopexy (Section 45-17, p. 1098). Intraabdominally, the neovagina is then covered with an omental J-flap to provide additional neovascularization.

□ **Split-Thickness Skin Graft with Omental J-Flap.** Modification of the omental flap, which is normally used to close off

the pelvic inlet after exenteration, can create a cylinder for a new vagina. Notably, in thin patients, a thin, poorly vascularized, attenuated omentum may be inadequate to form a substantial cylinder and cover the mold.

From an abdominal approach, the omentum is detached from the stomach with a ligate-divide-staple (LDS) device or electrothermal bipolar coagulator (LigaSure). Resection is usually from right to left, until it will comfortably reach the pelvis as a J-flap (Section 46-14, p. 1186). Only three quarters of the omentum

is divided, so as to preserve the left gastroepiploic artery for blood supply. The distal omentum is rolled into a cylinder and sutured together with interrupted stitches of 3–0 gauge delayed-absorbable suture (Fig. 46-9.3).

The proximal end can be closed abdominally with similar interrupted sutures or the transverse anastomosis (TA) stapler without dividing it entirely. From the perineal side, the omental cylinder is then sutured to the vaginal introitus.

Next, the STSG is harvested from the donor site and sutured over a vaginal mold with 4–0 gauge delayed-absorbable suture in a manner similar to the McIndoe procedure described in Section 43-25 (p. 985). The mold is placed into the neovaginal space and sutured into place at the introitus (Fig. 46-9.4). Each of the remaining smaller perineal defects, now above and below the neovagina, is closed in the midline with interrupted stitches of 3–0 gauge delayed-absorbable suture.

□ **Gracilis Myocutaneous Flap.** From a perineal approach, a reference line is drawn on the medial thigh from the pubic tubercle to the medial tibial plateau following the adductor longus muscle. Inferior to this line, an island of skin, its associated subcutaneous tissue, and the gracilis muscle will serve as the flap. The planned elliptic incision is marked, and a full-thickness skin incision through the

**FIGURE 46-9.3** Raising the omental J-flap.

**FIGURE 46-9.4** Insertion of the split-thickness skin graft.

**FIGURE 46-9.5** Gracilis myocutaneous flap.

reference line is continued through the subcutaneous fat and the fascia lata. The belly of the gracilis muscle is isolated at its distal margin and divided. The remainder of the incision is completed around the marked skin island margin. The gracilis muscle is fully mobilized with blunt and sharp dissection from distal to proximal. This preserves the dominant vascular pedicle—a branch of the medial femoral circumflex artery—as it enters the deep anterior belly of the muscle 6 to 8 cm from the pubic tubercle.

Through the operative site on the thigh, a subfascial tunnel is bluntly developed medially to the open perineal defect. The left gracilis muscle flap is rotated *clockwise* against the thigh, that is, rotated first posteriorly and then medially. It is placed through the tunnels and allowed to hang freely between the patient's legs. The right flap is rotated *counterclockwise* and similarly positioned (Fig. 46-9.5).

Beginning at the distal tip, the tubular gracilis neovagina is constructed by suturing the skin edges of the right and left skin islands together with interrupted stitches using 4–0 gauge delayed-absorbable suture. The proximal opening should accommodate two or three fingers. The neovagina is rotated cephalad into the pelvis and posteriorly anchored to the levator plate abdominally with interrupted stitches of 0-gauge delayed-absorbable suture to prevent vaginal prolapse. Redundant flap skin is trimmed, and the proximal skin is sutured to the introitus with interrupted stitches of 3–0 gauge delayed-absorbable suture.

Each of the remaining smaller perineal defects, now above and below the neovagina, is closed in the midline with interrupted stitches of 3–0 gauge delayed-absorbable suture. Each thigh incision is similarly closed.

□ **Rectus Abdominis Myocutaneous (RAM) Flap.** A skin and muscle island

can be harvested from any location on the abdominal wall as long as the base of its shape is at the umbilicus. Typically, a 10 × 15 cm skin island is marked. At the superior border of the island, which will ultimately form the vaginal opening, the skin, subcutaneous tissue, and anterior rectus sheath are incised. One belly of the rectus abdominis muscle is freed with blunt dissection from the posterior sheath. The belly is divided proximally, and its anastomotic vessels connecting to the superior epigastric system are ligated.

The remaining borders of the skin island are incised through the anterior rectus sheath to the arcuate line. The subcutaneous fat is mobilized along the lateral and medial margins of the rectus muscle belly. The rectus muscle is then bluntly dissected from the posterior sheath until reaching the arcuate line, which is the caudal margin of this sheath. Next, the posterior peritoneum is cut inferiorly along the full length of the midline incision well beyond the flap. The RAM flap is now fully detached, but it needs to be further mobilized on its vascular pedicle to be able to swing into the pelvis. At the distal portion of the skin island, the rectus muscle is then bluntly dissected inferiorly from the anterior sheath to its insertion onto the pubic bone.

The flap, consisting of skin, subcutaneous tissue, anterior sheath, and rectus belly, is coiled around a syringe to form a tube (Fig. 46-9.6). The skin edges are approximated with 4–0 gauge delayed-absorbable suture. The syringe is removed, and the tube is placed into the pelvis. The pelvic end of the tube is closed. The RAM flap must be put into the pelvis without tension to prevent occlusion of its dominant vascular supply from the inferior epigastric artery.

The open end of the neovagina is brought out under the pubic symphysis to the perineum where it is attached to the vulvar defect using interrupted vertical mattress stitches using 0-gauge delayed-absorbable

**FIGURE 46-9.6** Rectus abdominis myocutaneous flap.

suture. An omental J-flap may also be prepared to provide additional blood supply.

Each of the remaining smaller perineal defects, now above and below the neovagina, is closed in the midline with interrupted stitches of 3–0 gauge delayed-absorbable suture. Abdominal wall posterior rectus fascia is reapproximated with no. 1 polydioxanone monofilament (PDS). Skin is closed with staples.

## POSTOPERATIVE

The presence of a vagina significantly improves quality of life for many women, as well as reducing sexual problems after exenteration (Hawighorst-Knapstein, 1997). Reconstruction may be beneficial to a woman's self-image, and the knowledge that intercourse is possible may be reassuring even if she chooses not to be sexually active postoperatively. Morbidity from the procedure largely depends on the type of neovagina.

Pudendal thigh flaps are reliable and easy to harvest, but perhaps are the most likely to be nonfunctional. Long-term sequelae may include vulvar pain, chronic vaginal discharge, hair growth, and protrusion of the flaps. These symptoms may discourage patients and their partners from attempting sexual activity (Gleeson, 1994b).

STSG neovaginas may become infected at the donor or recipient site. Graft sloughing due to vascular compromise or development of a seroma is another common complication. Postoperatively, patients must initially be immobilized to aid healing, and stenting with a vaginal mold is required for months to prevent vaginal stenosis or contracture (Fowler, 2009).

Gracilis myocutaneous flaps may be difficult to pass into the pelvis during the procedure and have the potential for partial or complete tissue loss due to necrosis from an inherently tenuous blood supply (Cain, 1989). Flap loss is significantly more

common if rectosigmoid anastomosis is performed concurrently during exenteration (Soper, 1995). Long-term prolapse is another relatively common problem. Residual scarring on the legs is a frequent, albeit relatively minor, complaint postoperatively.

Rectus abdominis muscle flaps are perhaps the best choice for vaginal reconstruction at the time of pelvic exenteration (Jurado, 2009). Ideally, they fill pelvic dead space, reduce the risk of fistulas, and provide fulfilling sexual activity (Goldberg, 2006). However, the donor site may be difficult to close primarily or may lead to a postoperative hernia or dehiscence. The operating time is also increased because, unlike a gracilis flap where the abdominal team can be proceeding with exenteration while the perineal team is beginning the reconstruction, two surgical teams are not possible when performing a RAM flap. Flap necrosis, enterocutaneous fistula, and vaginal stenosis are other frequent complications (Soper, 2005).

## 46-10

## Pelvic Lymphadenectomy

Pelvic lymph node removal and evaluation is a fundamental tool in accurate cancer staging. As such, it is commonly indicated in women undergoing surgery for uterine, ovarian, or cervical cancer. Also, in those with grossly involved nodes, pelvic lymphadenectomy may serve to optimally debulk tumor burden.

The aim of lymphadenectomy is bilateral *complete* removal of all fatty lymphatic tissue from the areas predicted to carry nodal metastases (Cibula, 2010). These nodes lie within well-defined anatomic boundaries that include: the midportion of the common iliac artery (cephalad), deep circumflex iliac vein (caudad), psoas muscle (laterally), ureter (medially), and obturator nerve (dorsally) (Whitney, 2010). Ideally, the procedure yields numerous pelvic nodes from multiple sites within these boundaries (Huang, 2010). Groups specifically sampled are the external iliac artery, internal iliac artery, obturator, and common iliac artery nodal groups. Removal of at least four lymph nodes from each side (right and left) is a minimum requirement to validate that an “adequate” lymphadenectomy has been performed (Whitney, 2010). In general, the extent of pelvic lymphadenectomy will depend on the clinical circumstances, such as degree of associated scarring and patient habitus.

Additional definitions are commonly used in association with lymphadenectomy. For example, pelvic lymph node “sampling” is a more limited procedure within the same anatomic boundaries and is particularly intended to remove any enlarged or suspicious nodes (Whitney, 2010). Sampling is limited to easily accessible pelvic regions and does not address all nodal groups (Cibula, 2010). Pelvic lymph node “dissection” is a vague term that may range from sampling to lymphadenectomy.

Pelvic lymphadenectomy can be performed via laparotomy or a minimally invasive abdominal approach (p. 1176). In contrast, although the pelvic lymph nodes lie retroperitoneally, a lateral abdominal wall approach to reach these without entering the peritoneal cavity, that is, *extraperitoneal pelvic lymphadenectomy*, is not commonly performed (Larciprete, 2006). Last, emerging advancements in lymphatic mapping and sentinel node techniques are designed to limit the short- and long-term complications associated with extensive lymphatic resection.

### PREOPERATIVE

#### ■ Patient Evaluation

Imaging studies such as CT, MR, or PET imaging may suggest pelvic lymphadenopathy and help guide a surgeon to suspicious areas. However, the ability to preoperatively detect microscopic metastases is limited.

#### ■ Consent

With proper technique, pelvic lymphadenectomy is a straightforward procedure with relatively few complications. These include postoperative lymphocele, nerve and vascular injury, acute hemorrhage, infection, and chronic lymphedema.

#### ■ Patient Preparation

Bleeding is a common problem with pelvic lymphadenectomy and may be exacerbated with obese patients, grossly enlarged or densely adhered lymph nodes, and pelvic vessel anatomic variants. Accordingly, units of packed red blood cells are typed and cross-matched. Topical hemostatic agents may also prove valuable.

Routine bowel preparation and antibiotic prophylaxis are not required for lymphadenectomy but may be indicated for other concurrent surgeries. Prevention of VTE is warranted, and options are listed in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** This surgery may be performed under general or regional anesthesia with a patient supine. A Foley catheter is placed, and the abdomen is surgically prepared.

□ **Abdominal Entry.** A midline vertical or low transverse abdominal incision that allows access to the previously noted anatomic boundaries is appropriate for this procedure. A Pfannenstiel incision offers limited exposure and is reserved for only selected patients.

□ **Abdominal Exploration.** Pelvic and paraaortic lymph nodes are routinely inspected during initial abdominal exploration. Unexpected grossly positive nodes may indicate that a proposed operative plan should be abandoned (for example, radical hysterectomy for cervical cancer) or revised (Whitney, 2000).

□ **Retroperitoneal Exploration.** The retroperitoneal space has typically already

been entered through the round ligament during preceding surgical procedures. However, to extend retroperitoneal access, a surgeon may further incise the anterior and posterior leaves of the broad ligament.

Palpation of the external iliac artery pulsation just medial to the psoas major muscle is the starting point. Its identification permits a surgeon to locate relevant anatomy, as vascular anomalies are regularly encountered. Blunt dissection is then performed cephalad to see the common iliac artery bifurcate into the external and internal iliac arteries. The ureter is isolated as previously described (p. 1135). The remaining pelvic sidewall structures are covered with fatty-lymphoid tissue and are not yet easily visible.

To summarize the planned en bloc specimen excision, dissection begins proximally along the psoas major muscle and external iliac artery and proceeds distally to reach the inguinal ring where the nodal specimen is reflected medially and off the external iliac vein. Next, dissection along the internal iliac artery begins cephalad and moves caudad, and last enters the obturator space for nodal dissection here. The entire nodal bundle is lifted and removed. Separately, nodes excised from along the distal common iliac artery can be included in the final specimen.

□ **External Iliac Nodes.** For this nodal group, an index finger is placed atop the psoas major muscle and lateral to the external iliac artery at a point distal to the common iliac artery bifurcation. The finger bluntly dissects caudally and parallel to the external iliac artery to separate the lateral preperitoneal fat from the fatty-lymphoid tissue covering the external iliac vessels (Fig. 46-10.1). The general absence of lateral branches from these vessels enables more aggressive blunt separation to be performed unless there is significant fibrosis. The genitofemoral nerve, which is visible parallel to the external iliac artery, can often be spared with careful dissection. Injury to this nerve results in ipsilateral labium majus and proximal thigh numbness.

Next, forceps traction is typically required to lift all adventitial tissue up and above the external iliac artery beginning at the common iliac artery bifurcation. This countertraction helps maintain the correct dissection plane moving distally as bands between nodal tissue and the artery are divided using electro-surgical cutting (Fig. 46-10.2).

As dissection continues caudally, the distal self-retaining retractor blade may be temporarily removed to allow resection of all pelvic nodes heading toward the inguinal canal. For this, the fatty nodal tissue overlying the caudal portions of the psoas major muscle and external iliac artery is grasped with forceps. With an incision made parallel and superficial

**FIGURE 46-10.1** Mobilizing the lateral nodal tissue.

**FIGURE 46-10.2** Medial dissection over the vein.

to the artery, distal nodal tissue is freed. Mobilization of this tissue exposes the deep circumflex iliac vein, which crosses laterally over the distal external iliac artery. The deep circumflex iliac vein originates from the distal part of the external iliac vein and serves as the caudal boundary for this nodal group.

The mobilized nodal tissue is next reflected medially to reveal the entire external iliac artery. Medial traction is applied with forceps, and fine adventitial bands that connect the nodes to the underlying external iliac vein are transected using electrocautery cutting or Metzenbaum scissors. Once completed, this external iliac nodal group dissection later permits safe entry into the obturator space, outlined in Step 7.

□ **Internal Iliac Nodes.** Next, ureterolysis, if not previously performed, is completed (Section 46-1, Step 5, p. 1135). The ureter is moved and held medially by a Penrose drain or narrow retractor for protection and improved pelvic sidewall visualization. Spatially, nodes that have been dissected off the external iliac vessels and the fatty nodal tissue bridging the external iliac vein and the internal iliac artery lie in the same plane. Beginning at the common iliac artery bifurcation, the free nodal bundle is elevated and placed on tension. Initial sharp dissection of the internal iliac nodal group continues caudally along the internal iliac vessels and then along the superior vesical artery. As dissection approaches the distal aspect of the superior vesical artery, the nodal attachments are fine and enable electrocautery dissection without the need for clips or ligatures. At this point, both the external iliac and internal iliac nodes are completely dissected and can be submitted as one specimen or combined with obturator fossa lymph nodes, depending on surgeon preference.

□ **Obturator Fossa Node Group.** To reach this nodal group, an index finger is gently inserted between the psoas major muscle and external iliac artery, and blunt dissection progresses downward to the obturator fossa. Lateral arterial or venous branches may need vascular clip application and transection. During this dissection, nodal tissue may be identified behind the external iliac vessels and added to the specimen.

As a result, the external iliac vein is mobilized and can be retracted upward and laterally by a vessel retractor to expose the obturator fossa (Fig. 46-10.3). If present, nodal tissue along the inferomedial wall of the external iliac vein is transected with blunt and electrocautery blade dissection. Also, accessory venous branches may be identified and clipped.

With the vein retractor in place, the obturator nodal tissue is grasped with forceps. This nodal bundle lies deep to the external iliac vein but superficial to the obturator

nerve. With upward traction applied, blunt forceps or a suction tip moved gently side-to-side disrupts nodal tissue attachments to the obturator nerve. The blunt dissection is performed in the center of the fossa to minimize injury to surrounding deep pelvic vasculature. This also clears off tissue to permit obturator nerve identification.

Once this nerve is localized, dissection should purposely remain superficial to it. Firm fibrotic attachments may be electrosurgically transected under direct visualization. As the caudal end of the bundle is reached, it is usually tethered to the sidewall. To free it, a vascular clip is placed distal to the bundle, and the tethered attachment is divided proximal to the clip. At the cephalad end of the bundle, nodes are carefully separated sharply from the inferior aspect of the external iliac vein while avoiding obturator nerve injury.

Nodal tissue deep to the obturator nerve is not routinely removed since the obturator artery and vein traverse this area. Laceration of

**FIGURE 46-10.3** Obturator fossa dissection.

**FIGURE 46-10.4** Distal common iliac dissection.

either vessel can result in retraction and catastrophic hemorrhage that is difficult to control.

#### □ **Distal Common Iliac Lymph Nodes.**

To remove this group, the upper retractor blade is readjusted to expose the distal half of the common iliac artery. The colon may require mobilization using electro-surgical dissection along the white line of Toldt. Once this line is incised, bowel can then be retracted sufficiently to allow access to the common iliac nodes. The ureter is further mobilized medially before beginning node dissection.

Lateral fatty-lymphoid tissue may be removed by first grasping and elevating with forceps and using electro-surgical dissection to establish a plane. Blunt dissection to further separate the nodal tissue from the artery is continued cephalad. Electro-surgical coagulation or clips plus sharp incision are used to detach these nodes (Fig. 46-10.4). Laterally, the nodes are dissected off the psoas major muscle. Importantly, on the patient's right side, the common iliac vein and inferior vena cava (IVC) lie beneath the lateral margin of the common iliac artery, and thus, careful dissection is warranted. Further dissection

is performed atop the distal common iliac artery, which serves as the medial border of dissection for this nodal group.

□ **Final Steps.** Gauze sponges may be opened and tightly placed into the obturator fossa and medial to the external iliac vein to tamponade any surface oozing while additional procedures are performed. Topical hemostatic agents are employed as needed (Table 40-5, p. 861). Closing the retroperitoneal space and using suction drainage does not minimize hematoma or lymphocele development (Charoenkwan, 2014).

## POSTOPERATIVE

Neurologic injuries involving the obturator, ilioinguinal, iliohypogastric, genitofemoral, or femoral nerves may result from direct surgical trauma, stretch injury, suture entrapment, or retractor placement (Cardosi, 2002). Their specific neurologic deficits and management are described in Chapter 40 (p. 843). Notably, transection of the obturator nerve is ideally immediately noted intraoperatively and an epineural repair performed (Vasilev, 1994).

Surgical blunt dissection techniques decrease the risk of inadvertent vessel or nerve injury, but these may increase the chance of postoperative lymphocele formation. Also known as lymphocyst, these usually asymptomatic and transient lymph collections may form a thick fibrotic wall. Postoperative pelvic hematomas are also not uncommon.

## 46-11

## Paraaortic Lymphadenectomy

Removal of paraaortic lymph nodes typically follows pelvic lymphadenectomy to surgically stage women with uterine and ovarian cancer because of these cancers' unpredictable lymphatic dissemination patterns (Burke, 1996; Negishi, 2004). Moreover, removal of enlarged paraaortic nodes may provide optimal debulking of ovarian cancer and may also confer a survival benefit in selected endometrial and cervical cancer patients (Cosin, 1998; Havrilesky, 2005).

Paraaortic lymphadenectomy implies bilateral complete removal of all nodal tissue from within an area with well-defined anatomic boundaries: inferior mesenteric artery (cephalad), midlength of common iliac artery (caudad), ureter (lateral), and aorta (medial). The completeness of the procedure will vary by clinical setting, but an adequate dissection requires that lymphatic tissue at least be demonstrated pathologically from both the right and left sides (Whitney, 2010).

Paraaortic lymphadenectomy can be performed via laparotomy or minimally invasive approach (p. 1176). The proximal dissection is usually only extended to the inferior mesenteric artery (IMA), unless a "high" lymphadenectomy is indicated (Whitney, 2010). With this modification, a surgeon extends dissection to reach the renal veins. Most often, this is performed during ovarian cancer staging or in high-risk endometrial cancer cases to debulk tumor and more accurately stage these cancers (Mariani, 2008; Morice, 2003).

### PREOPERATIVE

#### ■ Patient Evaluation

As described earlier (p. 1169), imaging studies may help guide a surgeon to the most suspicious lymph nodes but are not entirely reliable in identifying small nodal metastases.

#### ■ Consent

Paraaortic lymphadenectomy is not routinely performed worldwide due to the procedure's technical difficulty and potential for complications (Fujita, 2005). Of these, acute hemorrhage and postoperative ileus occur most often. Other complications should be infrequent. In obese women, operative visibility is hindered, and thus, procedure complexity and operative times are considerably greater.

#### ■ Patient Preparation

Bleeding is a common problem with this lymphadenectomy. Accordingly, units of packed red blood cells are typed and cross-matched. Topical hemostatic agents may also prove valuable. Routine bowel preparation and antibiotic prophylaxis are not typically required. However, other concurrent surgeries may dictate their use. Prevention of VTE is warranted, and options are listed in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Lymphadenectomy may be performed under general or regional anesthesia with a patient supine. A Foley catheter is placed, and the abdomen is surgically prepared.

□ **Abdominal Entry.** A midline vertical abdominal incision that allows access to the previously noted anatomic boundaries is appropriate for this procedure. Low transverse incisions offer limited exposure and are reserved for only selected patients.

□ **Abdominal Exploration.** Paraaortic lymph nodes are routinely palpated during initial abdominal exploration. A hand is placed beneath the small bowel mesentery to palpate the aorta. The index and middle fingers are then used to straddle the aorta and palpate for lymphadenopathy. Suspicious or grossly positive paraaortic nodes are typically removed as an initial step. Unexpected positive nodes may indicate that the proposed operative plan should be abandoned or revised (Whitney, 2000). For most instances, in which no adenopathy is present, the dissection is usually performed last due to the possibility of triggering catastrophic bleeding that might otherwise limit further surgery.

□ **Visualization.** Exposure and proper retractor positioning is perhaps the most important part of this procedure. Thus, a self-retaining retractor is positioned to allow access to the aorta. The sigmoid colon and descending colon are gently retracted in a lower left direction, whereas small bowel and transverse colon are packed into the upper abdomen by laparotomy sponges. Modified Trendelenburg patient positioning is also helpful to shift bowel from the operative field. Additional sharp dissection along the right paracolic gutter peritoneum (white line of Toldt) may be necessary to sufficiently mobilize and move the cecum from the dissection field. Once bowel has been cleared, the peritoneum overlying the aorta and right

common iliac artery should be visible. Both vessels are palpated before proceeding. Also, as described on page 1135, the ureter is isolated and held laterally on a Penrose drain to avoid its injury.

□ **Opening the Retroperitoneal Space.** Beginning atop the midportion of the right common iliac artery, a right-angle clamp is used to guide electrosurgical blade incision of the posterior parietal peritoneum. Following each vessel's course, the incision moves cephalad and medially over the right common iliac artery and then cephalad atop the aorta (Fig. 46-11.1). Staying directly above these arteries is recommended to avoid inadvertent laceration of the right common iliac vein or IVC. Continuing cephalad in the midline, sharp incision of the peritoneum is extended through the caudal and then left lateral aspect of the duodenal peritoneal reflection to mobilize the duodenum cephalad. An upper midline self-retaining retractor blade is repositioned to retract this bowel.

□ **Right Paraaortic Nodes.** With the ureter still held laterally, the surgeon first establishes the medial border of the right paraaortic nodal group. Atop the midportion of the right common iliac artery, the lymph node bundle is elevated with forceps to reveal fibrous bands connecting it to the artery. A right-angle clamp is placed beneath these bands, which are then sharply divided to free the distal bundle from the artery. Using electrosurgical cutting atop the right common iliac artery, cephalad and slightly medial dissection continues following the vessel course. Once the aortic bifurcation is reached, cephalad dissection progresses atop the right lateral border of the aorta to reach the level of the IMA. Small perforating vessels may be encountered and are coagulated.

To establish the lateral border of this nodal group, the ureter is again held laterally. Blunt cephalad dissection with a suction tip atop the iliopsoas muscle separates the retroperitoneal fat from the right border of the IVC. The upper right abdominal retractor blade may need to be repositioned to improve visibility.

At this point, the right paraaortic node bundle has been largely detached medially, distally, and laterally. Next, the bundle is again grasped distally with forceps and elevated as gentle sharp dissection beneath this bundle in the midline is directed cephalad. Delicate perforating veins along the IVC warrant meticulous dissection to reduce bleeding. One of these, the "fellow's vein," is routinely encountered near the level of the aortic bifurcation and is occluded with a vascular clip for hemostasis (Fig. 46-11.2). Upon reaching the level of the IMA, the

**FIGURE 46-11.1** Opening the retroperitoneal spaces.

nodal bundle can be removed by placing large vascular clips across the cephalad end and transecting it before the clip. Once excised, this right nodal bundle is sent as a separate specimen.

□ **Repair of Venous Bleeding.** A surgeon should prepare for small lacerations in the wall of the IVC or common iliac veins caused by inadvertent avulsion of perforating venous tributaries. Hemorrhage may be

copious and immediate. Initially, pressure is applied with a sponge-stick or finger, and anesthesia staff is informed of the potential for increased blood loss. Second, exposure is assessed. Blood is suctioned from the abdominal cavity, retractors are repositioned, and incisions are extended if necessary. Last, proper vascular instruments are obtained. Lacerated veins can usually be simply repaired with vascular clips (Fig. 46-11.3).

□ **Left Paraortic Nodes.** The medial border of this nodal group is developed using electrosurgical dissection that begins at the IMA. To advance, the medial side of the bundle is elevated with forceps to create tension across fibrous bands connecting it to the aorta. These fibers are sharply divided and free the proximal bundle. Moving caudally, continued similar dissection progresses atop the left border of the aorta toward its bifurcation. Upon reaching the bifurcation, dissection then advances caudally and slightly lateral to follow atop the left common iliac artery's course. This artery's midlength marks the caudad border.

Once this medial dissection is completed, fibrovascular attachments between the sigmoid colon mesentery and left side of the distal aorta are sharply transected. This aids access to laterally located paraortic nodes.

To develop the lateral border of this nodal group, fingers or suction tip carefully separate the lateral fatty lymphoid tissue from the overlying sigmoid colon mesentery and from the underlying ovarian vessels and

**FIGURE 46-11.2** Removal of right paraortic nodes.

**FIGURE 46-11.3** Repair of venous bleeding.

**FIGURE 46-11.4** Removal of left paraaortic nodes.

**FIGURE 46-11.5** Completed high paraaortic lymphadenectomy.

ureter. Opening this potential space allows clear identification of the ureter and the ovarian vessels, which lie medial to the ureter. A handheld vein retractor is positioned to gently lift up the sigmoid colon mesentery, its adjoining vessels, and ureter.

Establishing these medial and lateral borders delineates the left paraaortic lymph node bundle for removal. To free this bundle caudally, nodal tissue over the common iliac artery is elevated on traction with forceps. A vascular clip is placed across the bundle's caudal end, which is transected before the clip and freed. The distal nodal bundle is next elevated and lifted cephalad (Fig. 46-11.4). Fibrovascular attachments between the bundle and the medial aorta and lateral iliopsoas muscle are transected with electro-surgical blade or with vascular clips and Metzenbaum scissors as dissection moves progressively cephalad to the level of the IMA. Importantly, dissection into the lumbar vessels, which originate from the aorta's posteromedial aspect, is avoided. At the level of the IMA, the cephalad end of the left paraaortic lymph node bundle is clipped and transected. The entire nodal group is removed in toto and submitted as an individual specimen.

□ **Interiliac Nodes.** Optionally, additional lymph nodes may be removed by excising the fatty tissue between the common iliac vessels. For this, the posterior peritoneum at the aortic bifurcation is grasped, and electro-surgical incision is extended caudally atop

the inner side of both common iliac arteries. The crossing left common iliac vein is visible directly beneath.

The peritoneum is reflected caudally, and the fatty tissue beneath is grasped and placed on tension. Sharp dissection is performed along the surface of both common iliac veins, which have very few small perforating vessels. Once mobilized between the common iliac vessels, the triangle-shaped area of fatty-lymphoid tissue is freed by electro-surgical division of bands connecting it to the sacrum.

□ **High Paraortic Lymphadenectomy.** For this extended lymph node removal, anatomic boundaries begin caudally at the level of the IMA and reach cephalad to the entry level of the right ovarian vein and left renal vein (Whitney, 2010). To begin, the former midline peritoneal incision atop the aorta is incised further cephalad, and the duodenal loop is bluntly dissected off the aorta. Repositioning of the retractor blade to move this loop cephalad aids exposure.

On the aorta's right side, the caudal end of the high paraaortic nodal bundle is grasped with blunt forceps, and dissection atop the right lateral border of the aorta is continued cephalad until the right ovarian vein, before its insertion into the IVC. Here, the nodal bundle can be clipped, divided, and incorporated within the specimen.

On the left side, high paraaortic node dissection begins with identification, clipping, and

cutting of the IMA between ties, which allows access to upper nodal tissue. The mesenteric circulation has an extensive collateral network that permits IMA ligation without subsequent bowel ischemia. Alternatively, the IMA may be preserved if adequate exposure is available. This avoids potential bowel ischemia in those with poorly developed collateral vessels.

Dissection continues cephalad atop the left border of the aorta and reaches the left renal vein, which was exposed by prior cephalad displacement of the duodenum. Removal of the left paraaortic nodes includes elevation of the distal nodal bundle and sharp dissection to isolate and electro-surgically divide lymphatic attachments. At the left renal vein, the bundle is clipped and transected (Fig. 46-11.5).

#### ⑪ Retroaortic Lymphadenectomy.

This more extended dissection is optional and begins after left-sided paraaortic lymphadenectomy has been completed. The left-sided lumbar arteries can be seen branching directly from the aorta. These vessels may be clipped and cut to allow manual rolling of the aorta from left to right, which provides access to the retroaortic nodal chain. Typically, this procedure is performed when imaging studies have demonstrated suspicious nodes in the region.

⑫ **Final Steps.** Gauze sponges may be opened and gently placed in areas of nodal

dissection to tamponade any surface oozing. Closing the retroperitoneal space or routinely using suction drainage does not minimize hematoma or lymphocele development (Morice, 2001).

## POSTOPERATIVE

The postoperative course following paraaortic lymphadenectomy in general follows that after laparotomy. However, the incidence of

postoperative ileus is increased due to longer operative time, increased bowel manipulation, incision extension, and additional blood loss. As with pelvic lymphadenectomy, lymphoceles and hematomas may develop.

## 46-12

## Minimally Invasive Staging for Gynecologic Malignancies

Minimally invasive surgery (MIS) can often be used for surgical staging that includes pelvic and paraaortic lymph node excision and sometimes omentectomy and peritoneal biopsy. Also, for those without comprehensive staging at their primary surgery, MIS may allow a less morbid completion of cancer staging. Specific MIS qualities that are suited to lymphadenectomy include expanded magnified views within deep or narrow spaces and the ability to achieve fine dissection. In terms of landmarks and fields of dissection, MIS lymphadenectomy procedural steps are the same as those with the open abdominal approach described on pages 1169 and 1172. However, with an MIS approach to cancer staging, paraaortic lymphadenectomy is typically completed first. The needed pneumoperitoneum gradually distends bowel, and thus surgery higher in the abdomen is performed early to permit adequate bowel manipulation and displacement.

### PREOPERATIVE

#### ■ Patient Evaluation

A thorough pelvic examination and history reveal factors that help determine the optimal surgical route for an individual patient. As described in Chapter 41 (p. 874), when considering MIS, patients with suspected extensive adhesive disease, morbid obesity, or significant cardiopulmonary disease may be poor candidates. Regardless of approach, preoperative imaging studies prior to lymphadenectomy may help guide the surgeon to suspicious lymph nodes.

#### ■ Consent

General complications related to MIS are discussed in Chapter 41 (p. 877) and include entry injury to the major vessels, bladder, ureters, and bowel. More specific to MIS staging, acute hemorrhage is the most commonly associated complication. Additionally, ureteral damage, postoperative lymphocele, and nerve injuries can occur, particularly to the obturator and genitofemoral nerve. In addition, the risk of conversion to an open procedure is discussed. Conversion to laparotomy may be necessary if exposure and

organ manipulation are limited or if acute hemorrhage cannot be controlled with MIS techniques. Finally, port-site metastasis is a rare but possible complication.

#### ■ Patient Preparation

As mentioned, bleeding is a frequent problem with pelvic lymphadenectomy and may be exacerbated by retroperitoneal fibrosis. Accordingly, units of packed red blood cells are typed and crossmatched. Topical hemostatic agents may also prove valuable. Routine bowel preparation and antibiotic prophylaxis are not required for lymphadenectomy but may be indicated for other concurrent surgeries. Thromboembolism prophylaxis is warranted because of the VTE risk associated with cancer. Options are listed in Table 39-8 (p. 836).

### INTRAOPERATIVE

#### ■ Instruments

Important basic MIS tools for laparoscopy include blunt graspers and scissors, whereas the EndoWrist monopolar scissors and the EndoWrist bipolar Maryland grasper are used with the robot. Additional instruments needed for lymphadenectomy include a combined irrigation/suction device, which clears fluid and bluntly dissects; endoscopic bag for node removal; two to three 5-mm instrument ports; 10-mm laparoscope port; 12-mm endoscopic-bag port; and energy devices for cutting and vessel sealing. For the last, several electrosurgical and ultrasonic energy-based devices are adapted for either laparoscopic or robotic cases. These include Harmonic scalpel, electrosurgical monopolar instruments, and electrothermal bipolar coagulator devices (LigaSure, ENSEAL, PK Dissecting Forceps). For laparoscopy, the argon-beam coagulator is another option. Laparoscope selection varies by surgeon, and a 0-degree scope is frequently used. For others, a 30-degree scope permits greater visibility in tight or angulated spaces.

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Laparoscopic lymphadenectomy is performed under general anesthesia. For VTE prophylaxis, lower extremity compression devices are placed, and legs are then positioned in adjustable booted support stirrups. Typically, low lithotomy position is selected due to concurrent hysterectomy, although supine may be appropriate for restaging procedures. As described in Chapter 41 (p. 879), appropriate positioning of legs within the stirrups and

arms at the side is crucial to reduce nerve injury risks. Also, the patient is secured to the bed by means of a gel pad or bean bag with appropriate protective padding. This keeps the patient from sliding when placed in steep Trendelenburg position, which is needed to reflect bowel for retroperitoneal access.

To avoid stomach puncture by a trocar during primary abdominal entry, an orogastric or nasogastric tube is placed to decompress the stomach. To avert similar bladder injury, a Foley catheter is inserted. The abdomen is then surgically prepared. If hysterectomy is planned, then vaginal preparation is also done.

□ **Port Placement.** As described in Section 46-3 (p. 1142), a 10-mm primary trocar for the laparoscope is placed either at or approximately 1 to 2 cm above the umbilicus using an open abdominal entry method. For paraaortic dissection, this port is placed far enough cephalad to permit visualization of the lower aorta. Accessory ports include a right and left lateral abdominal trocar and one above one of the anterior superior iliac spines, as shown in Figure 46-3.1 (p. 1143).

Additional ports are placed according to surgeon preference or clinical circumstances. All ports ideally have a minimum of 8 cm between them to allow ample range of motion and for robotic procedures, to avoid arm collision.

□ **Visual Inspection.** Following insertion of the laparoscope, lymph nodes are grossly inspected during initial abdominal exploration. Unexpected positive nodes may alter a proposed operative plan in certain cases, particularly with cervical cancer. In addition, a decision is made to proceed with the MIS approach or convert to laparotomy.

□ **Paraaortic Lymphadenectomy: Opening the Retroperitoneal Space.** With the patient in steep Trendelenburg position, the small bowel is gently moved into the right and left upper quadrants. The first landmarks identified are the aortic bifurcation and right common iliac artery. The peritoneum over the midlength of the right common iliac artery is grasped, elevated, and sharply incised. This peritoneal incision is extended superiorly atop the right common iliac artery and then atop the aorta. Following each vessel's course, the incision progresses to the curve of duodenum overlying the aorta (Fig. 46-12.1). Once the peritoneum is opened at this level, it is held anteriorly and cephalad by an assistant surgeon using graspers. Blunt and sharp dissection is performed by the surgeon to lift and displace the duodenum cephalad to expose the aorta. This small bowel is progressively lifted until the level of the inferior mesenteric artery

**FIGURE 46-12.1** Opening peritoneum over common iliac artery and aorta.

**FIGURE 46-12.2** Dissection over the inferior vena cava.

(IMA) is reached as it exits from the aorta on the left.

□ **Ureter Identification.** For this, the lateral peritoneal cut edge atop the right common iliac artery is grasped and elevated. Blunt dissection beneath this peritoneum progresses laterally until the right ureter is located as it crosses the common iliac artery. Once identified, the ureter is directed laterally with gentle blunt traction. This lowers ureteral injury risks during the remaining nodal dissection.

□ **Right Paraortic Lymph Nodes.** To summarize lymphadenectomy within this anatomic area, the caudal end of the fatty, lymph node-containing tissue bundle is freed first. The surgeon then develops medial, lateral, and deep bundle margins and last frees the cephalad tip to permit bundle removal.

To begin, with the ureter held laterally and the inferolateral peritoneal edge elevated, the surgeon first develops the caudal border of this nodal group. Dissection begins at the midlength of the right common iliac artery and atop this artery's lateral border. Within the overlying fatty tissue, small spaces are bluntly developed to create fibrous pedicles that can be lysed or coagulated and divided. In doing so, the distal end of the nodal bundle is progressively freed from the artery and can be elevated and brought cephalad.

Dissection then follows the artery's course and moves medially atop its lateral border. During this dissection, small fibrous bands

between the nodal bundle and the right common iliac artery are sequentially transected. Crossing the IVC and reaching the lower aorta, dissection continues atop the right lateral margin of the aorta until reaching the level of the IMA.

To establish the lateral border of this nodal group, the surgeon revisits the dissection's starting point at the right common iliac artery's midlength. Here, a plane is bluntly developed between the lateral border of the IVC and psoas major muscle. Blunt dissection in this plane frees the retroperitoneal fat and is extended cephalad to the level of the IMA.

At this point, the right paraortic node bundle has been largely detached medially, distally, and laterally, and division of the deep bundle attachments can be performed. The nodal tissue is elevated and separated from the underlying IVC with gentle blunt dissection progressing cephalad. This dissection moves proximally atop the IVC to reach the level of the IMA (Fig. 46-12.2). During this progression, small pedicles that often contain minor vessels are developed. These pedicles and their multiple perforating vessels are sequentially isolated, clipped or coagulated, and divided. Typically, this is the most difficult part of the dissection because inadvertently avulsed vessels may bleed profusely. For control, hemostatic clips or coagulation can be used. Moreover, a small gauze sponge can be prophylactically placed into the abdomen to provide quick tamponade if required.

At the level of the IMA, the nodal bundle can be excised by placing large vascular clips across the cephalad end and transecting it before the clip. Lymph nodes are extracted intact using an endoscopic bag through a 12-mm port. Once removed, this right nodal bundle is sent as an individual specimen.

□ **Left Paraortic Lymph Nodes.** Acquisition of the left paraortic lymph nodes begins atop the aorta at the level of the IMA. As on the right side, after the initial bundle tip is freed, the medial, lateral, and deep margins are developed. However, dissection moves caudally rather than cephalad and ends at the left common iliac artery's midlength.

The cephalad end of this nodal group is first developed using sharp or electrosurgical dissection that begins just below the IMA (Fig. 46-12.3). Small spaces within the fatty tissue are bluntly opened to create fibrous pedicles that can be lysed or coagulated and divided. This frees the proximal end of the nodal bundle.

To advance, the lateral peritoneal edge and colon mesentery are elevated to the left on tension, and fibrovascular attachments to left side of the distal aorta are sharply transected. This permits lateral retraction of the colon mesentery for exposure. The medial side of the bundle is next elevated with forceps to create tension across fibrous bands connecting the nodal bundle and aorta. These fibers are sharply divided. Similar dissection continues caudally atop the left border of the

**FIGURE 46-12.3** Dissection over the aorta.

**FIGURE 46-12.4** Dissection to the level of the inferior mesenteric artery.

aorta toward its bifurcation. Upon reaching the bifurcation, dissection then moves caudally and slightly laterally atop the left common iliac artery's lateral border to finish at this artery's midlength.

To access the lateral border of this nodal group, a blunt tip carefully sweeps laterally to separate the lateral fatty lymphoid tissue from the overlying sigmoid colon mesentery and from the underlying ureter. The ureter serves as the lateral boundary of this nodal group. Opening this potential space allows the ureter and the ovarian vessels, which lie medial to the ureter, to be clearly identified. A blunt probe is then repositioned to gently lift the colon mesentery, its adjoining vessels, and ureter. With this lateral border now developed, dissection of nodal attachments continues caudad, staying medial to the ureter and reaching the midlength of the left common iliac artery.

After establishing the medial and lateral boundaries of the left paraaortic nodal group, the caudad tip of the nodal bundle is again grasped and elevated. From the midlength of the left common iliac artery, dissection beneath the bundle moves cephalad while transecting deep attachments between it and the lateral aorta and between it and the psoas major muscle (Fig. 46-12.4). Upon reaching the level of the IMA, the cephalad end of the fatty tissue is clipped and transected. The entire nodal group bundle is removed in toto within an endoscopic bag through the 12-mm port. It is submitted as an individual specimen.

#### □ High Paraaortic Lymphadenectomy.

In some instances, a surgeon may elect an extended laparoscopic dissection. The anatomic boundaries of a high paraaortic lymphadenectomy begin distally at the IMA and reach proximally to the entry level of the right ovarian vein and left renal vein into the IVC, respectively (Whitney, 2010). Typically, this extension is possible only in selected patients with favorable anatomy, such as thin body habitus. Otherwise, upper abdominal exposure is problematic. Other helpful maneuvers include having a second surgical assistant and placing additional right and left upper quadrant trocars. In contrast, robotic paraaortic lymphadenectomy stops at the level of the IMA. High paraaortic dissection to the level of the renal vein is technically difficult and infrequently performed. Reasons include poor visualization, limitations in spanning the distance with the robotic arms, and inability to turn the patient around without undocking and placing additional ports.

To begin laparoscopically, the peritoneum overlying the aorta at the level of the IMA is grasped and elevated cephalad to displace small intestine into the upper abdomen and provide exposure to the aorta. The surgeon dissects retroperitoneally atop the aorta to further mobilize the duodenum and displace it cephalad. Often a laparoscopic fan retractor positioned in the retroperitoneal space aids exposure of the upper aorta.

To develop the medial border of the right high paraaortic nodal group, the nodal

bundle overlying the IVC is regrasped and held on traction to dissect and divide the fibrous attachments from the aorta's anterior surface and right border. This begins caudally at the level of the IMA and ends cephalad at the right ovarian vein.

For the lateral border of this nodal group, the right ureter is identified and again retracted to the right. The lateral portion of the nodal bundle is then bluntly separated from the psoas muscle in a proximal direction. The ovarian vein will be encountered and may be individually sealed and divided depending on its proximity to lymph nodes slated for removal.

With both lateral and medial borders defined, the deep middle attachments of this nodal bundle are freed by gentle cephalad dissection over the IVC until the level of the right ovarian vein is reached. Last, the proximal border of the nodal bundle is detached and removed as described earlier.

Dissection of the high left paraaortic nodal group begins by placing laparoscopic clips on the IMA and dividing between using a vessel-sealing device. Alternatively, the IMA may be preserved if adequate exposure is available. This avoids potential bowel ischemia in those with poorly developed collateral vessels. The left ureter is again identified as the lateral border of this high nodal group and is held laterally by an assistant.

The surgeon performs blunt dissection with intermittent coagulation and division of fibrous or vascular pedicles to detach the nodal

bundle in a cephalad direction. Dissection continues until it reaches the left renal vein, where the bundle is detached and removed.

□ **Pelvic Lymphadenectomy: Retroperitoneal Entry.** For this nodal resection, lymphoid tissue is removed within the area bounded by the psoas major muscle (lateral), the superior vesical artery (medial), the midlength of the common iliac artery (cephalad), and the deep circumflex iliac vein (caudad). To begin, the round ligament is transected, and the peritoneal leaf between the round and infundibulopelvic (IP) ligament is grasped, elevated, and incised parallel to the IP. Gentle traction is again applied to the round ligament, and the broad ligament's anterior peritoneal leaf is opened to reach the vesicouterine fold in the midline. If radical hysterectomy is planned after pelvic lymphadenectomy, then pararectal and paravesical spaces are completely developed as described on page 1144 prior to pelvic lymph node removal.

□ **Pelvic Lymphadenectomy: Distal Common Iliac Nodes.** Bowel is first retracted sufficiently to allow access to the distal half of the common iliac artery. To remove this nodal group, the prior peritoneal incision atop the common iliac artery is extended from its midlength caudally to expose the artery. Ureterolysis, if not previously performed, is completed as described in Section 46-3, Step 4 (p. 1143). The ureter is

then bluntly retracted medially before beginning node dissection.

Lateral fatty lymphoid tissue may be removed by first elevating it with a blunt grasper and using electrosurgical dissection atop the common iliac artery's lateral margin to establish a plane between the nodal bundle and artery. Blunt dissection to further separate the nodal tissue from the artery is continued caudad. Electrosurgical coagulation plus sharp incision is used to detach these nodes. Importantly, on the patient's right side, the common iliac vein and inferior vena cava lie beneath the common iliac artery's lateral margin, and thus careful node excision is prudent. Further dissection is performed atop the distal common iliac artery, which serves as the medial border for this nodal group. Upon reaching the common iliac artery bifurcation, lymphatic tissue excision continues caudally to incorporate the external iliac nodal group.

⑩ **External Iliac Nodes.** Removal of this lymph node group starts by freeing its lateral border. Tissue previously resected along the common iliac artery is elevated and placed on tension. Dissection then extends caudally along the lateral side of the external iliac artery until reaching the deep circumflex iliac vein. This vein crosses the distal external iliac artery and serves as the caudal boundary of this nodal group. Along this path, dissection bluntly develops a plane between medially located lymphoid tissue and lateral preperitoneal fat found above the psoas major muscle

(Fig. 46-12.5). During dissection, the genitofemoral nerve running atop the psoas major muscle is ideally identified and protected.

Next, grasper traction is typically required to lift the nodal bundle above the external iliac artery beginning at the common iliac artery bifurcation. During caudal dissection, a blunt tool gently pushes into the fibrofatty tissue to create distinct pedicles that attach the nodal bundle to the artery. These pedicle attachments can then be coagulated and divided. Electrosurgery can be also used to obtain hemostasis as the lymph node bundle is progressively excised caudally.

The mobilized nodal bundle is next reflected medially to reveal the entire external iliac artery (Fig. 46-12.6). Medial traction is applied with forceps, and fine adventitial bands that connect nodes to the underlying external iliac vein are transected using electrosurgical cutting. In contrast to open surgery, the pneumoperitoneum and Trendelenburg position used during laparoscopy result in vein collapse. As a result, the external iliac vein is harder to distinguish and can be easily injured. Once completed, this external iliac nodal group dissection later permits safe entry into the obturator space, outlined in Step 13.

⑪ **Internal Iliac Nodes.** The ureter is moved and held medially by a blunt instrument for protection and improved pelvic sidewall visualization. Beginning at the distal aspect of the superior vesical artery, the free

**FIGURE 46-12.5** Dissection between the external iliac artery and psoas major muscle.

**FIGURE 46-12.6** Dissection off the external iliac vessels.

**FIGURE 46-12.7** Dissection off the internal iliac artery.

**FIGURE 46-12.8** Dissection above the obturator artery.

nodal bundle is again elevated and placed on tension. Initial sharp excision of the internal iliac nodal group continues cephalad along the superior vesical artery and then along the internal iliac vessels (Fig. 46-12.7). As dissection approaches the common iliac artery bifurcation, the nodal attachments are fine and allow blunt disruption. At this point, both the external iliac and internal iliac nodes are completely dissected and can be submitted as one specimen or combined with obturator fossa lymph nodes, depending on surgeon preference.

**13 Obturator Fossa Nodes.** With the assistant surgeon holding medial traction on the superior vesical artery, the obturator fossa can be exposed. This fossa may be entered medially, between the external iliac artery and the psoas major muscle. Thereafter, the external iliac vessels are retracted medially so that the obturator space can be accessed from a lateral approach. Or, the obturator space can suitably be entered medially.

If present, nodal tissue along the inferomedial wall of the external iliac vein is transected with blunt and electrosurgical dissection. Also, accessory venous branches may be identified and coagulated.

Within the exposed fossa, obturator nodal tissue is grasped with forceps. This nodal bundle lies deep to the external iliac vein but superficial to the obturator nerve. With upward traction applied, blunt forceps or a suction/irrigation device tip moved gently

side-to-side disrupts nodal tissue attachments to the obturator nerve (Fig. 46-12.8). This blunt dissection is performed in the center of the fossa to minimize injury to surrounding deep pelvic vasculature. This is also clears off tissue to permit obturator nerve identification.

Once this nerve is localized, dissection should purposely remain superficial to it. Firm fibrotic attachments may be electrosurgically transected under direct visualization. As the caudal end of the bundle is reached, it is usually tethered to the sidewall and freed sharply. At the cephalad end of the bundle, nodes are carefully separated sharply from the inferior aspect of the external iliac vein while avoiding obturator nerve injury. Nodal tissue deep to the obturator nerve is not routinely removed since the obturator artery and vein traverse this area. Laceration of either vessel can result in retraction and catastrophic hemorrhage that is difficult to control.

Pelvic lymph nodes are then removed in toto via endoscopic bag. The identical procedure is performed on the contralateral side.

**14 Completion of Laparoscopic Staging and Omentectomy.** The staging procedure for ovarian cancer includes obtaining multiple peritoneal biopsies from the cul-de-sac, pelvic sidewalls, and pelvic gutters, and from the diaphragm bilaterally. This can be performed with a blunt grasper and laparoscopic scissors, with or without electrosurgical coagulation. The surgical staging for ovarian cancer and for certain histologic

subtypes of endometrial cancer (papillary serous and clear cell carcinoma) also includes omentum removal.

A laparoscopic omentectomy is performed by identifying and elevating the omentum away from the transverse colon. Avascular windows are created within the proximal omentum. The intervening vascular attachments are then ligated with a vessel-sealing energy tool or endoscopic stapler. Once completely dissected, the omentum is placed in an endoscopic bag and removed through a transabdominal 12-mm port. In many women, the omentum is large and therefore is brought through the vagina if a laparoscopic hysterectomy is performed. All specimens undergo minimal manipulation and are removed through an endoscopic bag to help decrease the risk of port-site or intraabdominal tumor implantation.

**15 Port Removal and Fascial Closure.** Once procedures are completed, areas are inspected for bleeding. Topical hemostatic agents may be used and are listed in Table 40-5 (p. 861). If hemostasis is achieved, trocars are removed and port sites closed. Fascial defects larger than 10 mm are sutured to decrease the risk of herniation at those sites. Interrupted stitches of 0-gauge delayed-absorbable suture are placed to reapproximate this fascia. Alternatively, a dedicated trocar-site closure device, described in Chapter 41 (p. 897), can be used. Regardless of technique, the defect is palpated to confirm adequate closure.

## POSTOPERATIVE

The postoperative course following MIS staging lymphadenectomy generally follows that after other major laparoscopic surgery. Patients usually are able to tolerate clear liquids quickly, followed by a regular diet and discharge on postoperative day 1. With their pain typically controlled with oral pain medication, patients ambulate early.

Postoperative complications may include pelvic lymphocele formation, neurologic injuries, or trocar-site herniation. One long-term potential complication of pelvic lymphadenectomy is lymphedema. The exact incidence is unknown, but estimates range from 1 to 27 percent after surgical staging for endometrial cancer (Todo, 2010). The risk increases if more lymph nodes are removed

or if pelvic radiation is administered after surgery. Treatments, which may or may not be successful, often include compression stockings, lower extremity wrapping, and massage therapy to manipulate lymph channels. Although generally not associated with an adverse outcome, this complication can significantly lower a patient's quality of life postoperatively.

## 46-13

## En Bloc Pelvic Resection

Ovarian cancer with contiguous encasement of the reproductive organs, pelvic peritoneum, cul-de-sac, and sigmoid colon is the main indication for en bloc pelvic resection. Also known as radical oophorectomy, this effective technique aids a maximal cytoreductive surgical effort. As a result of removing all microscopic and infiltrative peritoneal tumor in the pelvis, improved survival rates can be expected in patients with advanced epithelial ovarian cancer (Aletti, 2006b). Moreover, pelvic recurrence rates are low and reflect the completeness of pelvic tumor eradication (Hertel, 2001). Many of the principles of en bloc pelvic resection mirror those of other procedures in gynecologic oncology.

## PREOPERATIVE

## ■ Patient Evaluation

Pelvic examination may reveal a relatively immobile mass, and abdominopelvic CT images typically demonstrate a pelvic mass and ascites. With the presumed diagnosis of advanced ovarian cancer, patients are prepared for anticipated cytoreductive surgery. However, the need for en bloc resection is usually dictated by intraoperative findings rather than preoperative testing.

## ■ Consent

In general, women with advanced ovarian cancer undergoing cytoreductive surgery are at significant risk for complications. Minor postoperative problems such as incisional cellulitis, superficial wound dehiscence, urinary tract infection, or ileus are common. Major postoperative complications of en bloc resection include anastomotic leaks and various fistulas (Bristow, 2003; Park, 2006).

## ■ Patient Preparation

Primary anastomosis without colostomy is typical for most patients. Thus, bowel preparation is commonplace for any type of cytoreductive ovarian cancer surgery, but particularly if en bloc pelvic resection is a possibility. One or more bowel resections may be required to achieve optimal debulking, and often, preoperative determination of the exact location of tumor infiltration is not entirely accurate. The combination of pneumatic compression devices and subcutaneous

heparin is particularly important due to the anticipated longer operation length, coagulability risk associated with malignancy, and possibility of extended postoperative recovery. Moreover, patients are routinely typed and crossmatched for packed red blood cell replacement, as transfusions are frequently indicated (Bristow, 2003).

## INTRAOPERATIVE

## ■ Instruments

En bloc pelvic resection requires access to multiple sizes of bowel staplers, including gastrointestinal anastomosis (GIA), transverse anastomosis (TA), and end-to-end anastomosis (EEA) staplers. Additionally, a ligate-divide-staple (LDS) device or electrothermal bipolar coagulator (LigaSure) may be used to divide vascular tissue pedicles.

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Bimanual examination under general anesthesia is especially important to confirm the need for low lithotomy leg positioning in booted support stirrups. Access to the perineum is crucial any time the EEA device may need to be placed in the rectum. Sterile preparation of the abdomen, perineum, and vagina is performed, and a Foley catheter is placed.

□ **Abdominal Entry.** Typically, a vertical incision is selected for ovarian cancer debulking surgery since the extent of disease cannot

be precisely known beforehand and upper abdominal disease requires excision. At first, the incision extends up to the umbilicus. After exploration and determination of tumor resectability, it can be lengthened as needed.

□ **Exploration.** The abdomen is thoroughly explored to first determine whether all gross disease can be safely removed. For example, unresectable upper abdominal tumor makes the prospect of a radical pelvic operation less attractive.

Frequently during exploration, it is difficult to distinguish uterus, adnexa, and adjacent tumor. As shown in Figure 46-13.1, both ovaries may be grossly enlarged with tumor and densely fixed into the posterior cul-de-sac with contiguous involvement of the uterus, rectosigmoid, and lateral sidewalls. Moreover, superficial implants often coat the fallopian tubes, the vesicouterine fold, and much of the surrounding pelvic peritoneum. En bloc pelvic resection will allow removal of all this gross disease.

□ **Lateral Pelvic Dissection.** For cases in which the round ligaments cannot be located with certainty, the lateral peritoneum is grasped with an Allis clamp, and an electrosurgical blade is used to enter the retroperitoneum (Fig. 46-13.2). The loose areolar connective tissue of this space is bluntly dissected and the overlying peritoneum is sharply incised to create an opening in which the external iliac artery can be palpated. This artery is bluntly followed to the bifurcation with the internal iliac artery. The medial peritoneal leaf of the

FIGURE 46-13.1 Extensive ovarian cancer.

**FIGURE 46-13.2** Lateral pelvic dissection.

broad ligament is elevated to identify the ureter, around which a one-quarter inch Penrose drain is looped.

The infundibulopelvic (IP) ligament will typically not be entirely distinguishable due to induration and anatomic distortion by tumor. A window is bluntly opened just superior to the ureter as it crosses above the pelvic brim to isolate a tissue pedicle that will include the IP ligament. The ligament is isolated, clamped, cut, and tied with 0-gauge delayed-absorbable suture. The entire sequence is repeated on the contralateral side. The ureter may then be mobilized distally, and the anterior portion of the broad ligament is incised toward the vesicouterine fold using an electrosurgical blade. The round ligament will be identified during this dissection and separately divided.

□ **Vesicouterine Dissection.** The anterior broad ligament dissection is continued with a right-angle clamp guiding the electrosurgical blade (Fig. 46-13.3). The peritoneum is typically edematous and thick. En bloc removal of tumor implants within the vesicouterine fold will require a wide excision of the peritoneum over the bladder dome. Thus, the proximal end of the vesicouterine fold may be held on traction, and an electrosurgical blade used to sharply dissect in a caudal direction toward the cervix while encompassing the tumor. The bladder mucosa is typically not entered, but it may be simply repaired if an inadvertent cystotomy occurs (Chap. 40, p. 867). After removal of this peritoneum, the bladder may then be advanced distally in the usual manner as for simple hysterectomy. The whitish cervix will be visualized

**FIGURE 46-13.3** Vesicouterine dissection.

through the anterior vaginal wall. The ureters are held laterally while the uterine vessels are freed of surrounding connective tissue (skel-tonized), clamped, cut, and ligated.

□ **Dividing the Sigmoid Colon.** This step mirrors those in Steps 5 and 6 of low anterior resection, illustrated on page 1201. First, the ureters are held laterally, while a right-angle clamp guides an electrosurgical blade during posterior peritoneum incision. This incision moves medially on each side to reach the midline sigmoid colon mesentery. The sigmoid colon segment that lies proximal to the tumor is selected, and the underlying mesentery is superficially incised on each side with the electrosurgical blade. A GIA stapler is then inserted to divide the bowel.

After colon division, the remaining mesentery is scored superficially with the electrosurgical blade and divided with the electrothermal bipolar coagulator. Larger pedicles, such as those including the inferior mesenteric vessels, will need to be clamped, cut, and ligated separately. As during total pelvic exenteration, the avascular retrorectal space between the rectum and the sacrum may then be bluntly dissected to completely mobilize the rectosigmoid down to the cervix (Fig. 46-13.4).

□ **Retrograde Hysterectomy.** The bladder is separated from the upper vagina with sharp electrosurgical blade dissection. The anterior vaginal wall distal to the tumor margin is grasped with a Kocher clamp. The anterior vaginal wall is then incised at 12 o'clock with the electrosurgical blade, and the incision is extended laterally to the right

and left. The cervix is grasped with a Kocher clamp and retracted to expose the posterior vaginal wall. An electrosurgical blade is used to incise this wall transversely and enter the rectovaginal space. Two Allis clamps grasp the upper vagina to apply caudad traction and aid further dissection. A retrorectal hand is placed to assess whether the tumor extends into the rectovaginal septum beyond the cervix. With large masses, distal dissection may be required into the rectovaginal septum to reach a point distal to the tumor's leading edge. If so, further distal vaginal wall excision may be needed to reach tumor-free margins. Alternatively, smaller tumors may allow proximal dissection in the rectovaginal septum. This gains additional rectal length distal to the tumor and allows for creation of a higher colon reanastomosis. Finally, the remaining uterosacral and cardinal ligaments are clamped, analogous to that during radical hysterectomy, but in a retrograde fashion. With this, distal portions of the cardinal ligament are transected first, and then more cephalad portions are clamped, cut, and ligated. For protection, ureters are held laterally (Fig. 46-13.5).

□ **Distal Rectal Division.** The mucosa of the rectal segment distal to the tumor is circumferentially dissected free of mesenteric attachments and rectal pillars by constant traction on the en bloc specimen. The TA or contour cutting (Contour) stapler is inserted into the pelvis and fired to transect the rectum (Fig. 46-13.6, dotted line). The specimen, which contains the uterus, adnexa, rectosigmoid, and surrounding peritoneum,

**FIGURE 46-13.4** Dividing the rectosigmoid.

**FIGURE 46-13.5** Retrograde hysterectomy.

is then lifted out of the pelvis. The vaginal opening is closed in a running fashion with 0-gauge delayed-absorbable suture. The final appearance [Fig. 46-13.7](#) is shown with completed rectosigmoid anastomosis, which is described in Section 46-21 (p. 1200).

□ **Final Steps.** A surgeon then proceeds with additional procedures if necessary to complete the ovarian cancer debulking surgery. A colostomy or rectosigmoid anastomosis may require mobilization of the splenic flexure and is performed near the end of

surgery. Postoperative drains may be placed at the surgeon's discretion. Occasionally, the bladder may also be retrograde filled to exclude cystotomy during vesicouterine dissection. All pedicles sites are reexamined for hemostasis.

**FIGURE 46-13.6** Rectosigmoid resection.

**FIGURE 46-13.7** Final appearance.

POSTOPERATIVE

En bloc pelvic resection of primary and recurrent ovarian cancer permits a high rate of complete debulking with acceptable

morbidity and mortality rates (Park, 2006). Urinary tract infection, pneumonia, deep-vein thrombosis, wound cellulitis, and postoperative ileus are relatively common events following major abdominal surgery for ovar-

ian cancer. Reoperation for anastomotic breakdown or postoperative hemorrhage specific to en bloc pelvic resection is uncommon (Bristow, 2003; Clayton, 2002).

## 46-14

## Omentectomy

The omentum is typically removed for two reasons: (1) tumor debulking or (2) cancer staging. First, patients who present with advanced ovarian cancer almost invariably have metastases to the omentum. The extent of this “omental cake” may be massive and involve the upper gastrocolic ligament, anterior abdominal wall, splenic hilum, and transverse colon (Fig. 35-14, p. 748). Thus, a surgeon is prepared to encompass the entire tumor with an adequate resection. Second, omentectomy is routinely indicated for staging patients with ovarian cancer or with uterine papillary serous carcinoma who do not have obvious metastatic disease (Boruta, 2009; Koh, 2014; Whitney, 2010).

As a reminder, the proximal omentum has two leaves. Its anterior leaf attaches to the greater curvature of the stomach via the gastrocolic ligament. Its posterior leaf attaches to the caudal margin of the transverse colon. The lesser omental sac lies between these two proximal leaves. *Infracolic omentectomy* describes transection of the anterior leaf (gastrocolic ligament) at a level below the transverse colon. This is sufficient for most clinical circumstances. Supracolic (total) omentectomy describes transection of the anterior leaf (gastrocolic ligament) at a level above the transverse colon and close to the stomach’s greater curvature. It may be indicated for a large omental cake.

Omentectomy may be completed by laparotomy, as described here. It is also amenable to a MIS approach, as described in Section 46-12, Step 14 (1180).

## PREOPERATIVE

## ■ Patient Evaluation

Imaging studies may suggest an omental cake, but its extent is difficult to ascertain until exploration in the operating room.

## ■ Consent

Although bleeding may follow inadequate vessel ligation, complications from omentectomy are rare. Obesity and intraabdominal adhesive disease, however, may increase these risks. Obesity results in a much thicker omentum that has thicker vascular pedicles, which may slip from clamps or ligatures. Additionally, prior upper abdominal surgery—particularly gastric bypass—may cause adhesions and a more difficult resection. In addition to these risks, women with an

omental cake are informed of a possible need for bowel resection, splenectomy, or other radical debulking procedures to remove the entire tumor.

## ■ Patient Preparation

The risk of infection following omentectomy is low, however, this surgery is typically performed with other gynecologic procedures that warrant antibiotics and VTE prophylaxis, as listed in Tables 39-6 and 39-8 (p. 835). The decision to administer a bowel preparation regimen is individualized by surgeon preference and clinical setting. Suitable options are found in Chapter 39 (p. 835).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Omentectomy is typically performed as an inpatient procedure under general anesthesia. A patient is positioned supine, a Foley catheter is placed, and the abdomen is surgically prepared.

□ **Abdominal Entry.** Infracolic omentectomy may be performed through any type of incision. However, because of the uncertain extent of disease that accompanies these cases, a midline vertical incision is most commonly selected. If only a portion of the omentum needs to be removed for staging purposes, the incision does not necessarily need to be extended above the umbilicus since the omentum is often accessible. In all other situations, the incision is extended cephalad to provide sufficient exposure.

□ **Exploration.** Palpation of the omentum is often the first step in exploring the abdomen. This organ is directly beneath a midline vertical incision and should be readily visible. Omentectomy is typically the first procedure performed in women with an omental cake and presumed ovarian cancer. The omentum can usually be quickly removed and sent for frozen section analysis while a surgeon places a self-retaining retractor and proceeds with the remainder of a planned operation.

□ **Visualization.** A surgeon gently grasps the infracolic omentum and pulls it out of the abdomen through the incision. The borders of any omental cake can be seen directly or palpated. The extent of resection can then be determined, and the abdominal wall incision extended if necessary.

□ **Entrance into the Lesser Sac.** The posterior leaf of the omentum is best accessed

by flipping the omental drape cephalad. Filmy adventitial tissue with some traversing small vessel tributaries joins this leaf and colon, and these attachments are electrosurgically cut and vessels divided by a ligate-divide-staple (LDS) device or an electrothermal bipolar coagulator (LigaSure). Dissection generally begins as far to the right as possible and continues as far to the left as possible. A right-angle clamp is opened beneath the omentum to guide the direction of the electrosurgical blade (Fig. 46-14.1). Once the posterior leaf is transected, the lesser sac is entered.

Entrance into the lesser sac mobilizes the colon and provides access to the tumor-free proximal gastrocolic ligament.

□ **Gastrocolic Ligament Division.** Next, attention turns to the anterior omental leaf, and the omental drape is now flipped caudad. For an infracolic omentectomy, dissection of the omentum is performed inferior to the level of the transverse colon. Dissection again generally begins on the far right and moves to the left. Numerous vertically coursing vessels can be seen, but others are covered by fatty tissue and difficult to appreciate. A right-angle clamp is used by the surgeon to “pop” through an avascular portion of the gastrocolic ligament that is near, but safely distal to, the colon. The clamp is then opened in a vertical direction (parallel to the vessels) and held in place to guide the LDS or electrothermal bipolar coagulator in safely and quickly dividing the tissue (Fig. 46-14.2).

This procedure is continued across the entire gastrocolic ligament, and the omental specimen is handed off. However, if a J-flap is planned instead of an omentectomy, then only three quarters of the omentum is divided from right to left. This preserves the left gastroepiploic artery for blood supply. The distal tip of the flap is brought into the pelvis and tacked to adjoining peritoneum with 2-0 or 3-0 gauge delayed-absorbable suture to provide additional blood supply wherever desired. Regardless of whether removing the infracolic omentum or fashioning a J-flap, the drape will need to be rotated back and forth intermittently to make certain that dissection remains away from the colon.

□ **Supracolic Omentectomy.** In cases in which an omental cake has extended proximally, a supracolic (total) omentectomy is indicated. This procedure requires a midline vertical incision to provide better exposure to the upper abdomen. Resection may simply involve transecting the omentum at a higher level in the gastrocolic ligament. Alternatively, anatomic boundaries of resection may need to be extended to the hepatic flexure, the stomach, and the splenic flexure to encompass the entire tumor.

**FIGURE 46-14.1** Posterior omental leaf transection to enter the lesser sac.

**FIGURE 46-14.2** Anterior ligation of gastrocolic ligament.

Dissection again proceeds from right to left, detaching the posterior leaf of the omentum from its attachment to the transverse colon. Mobilization of the ascending colon around the hepatic flexure may be necessary to perform a gastrocolic omentectomy. The right gastroepiploic artery is ligated, and the dissection is continued to the left by dividing the short gastric vessels until the lateral-most portion of the tumor is reached. Mobilization of the descending colon and takedown of

the splenic flexure may be required if tumor extends that far laterally.

□ **Incision Closure.** The remaining omentum should be reexamined at the completion of surgery before closing the abdomen. Occasionally, small bleeding vessels or a hematoma will need to be addressed with additional ligation. The abdominal entry incision is then closed as described in Section 43-1 (p. 928).

## POSTOPERATIVE

Nasogastric tube placement is required only if a total omentectomy has been performed. Decompression of the stomach for 48 hours protects the ligated gastric vessels from postoperative dislodgement due to gastric dilation. The remaining postoperative course follows that for laparotomy or for other specific concurrent surgeries performed.

## 46-15

## Splenectomy

In gynecologic oncology, removal of the spleen is occasionally required to achieve optimal surgical cytoreduction of metastatic ovarian cancer. Most commonly, tumor is found directly extending from the omentum into the splenic hilum during primary debulking surgery. Splenectomy and other extensive upper abdominal resection techniques have been shown to improve survival with acceptable morbidity (Chi, 2010; Eisenhauer, 2006). However, the number of patients who will actually have their spleen removed during their initial operation ranges from 1 to 14 percent (Eisenkop, 2006; Goff, 2006). Splenectomy is also indicated for selected patients with isolated parenchymal recurrences to assist optimal secondary surgical cytoreduction of ovarian cancer (Manci, 2006). In some instances, a laparoscopic or hand-assisted approach may be possible (Chi, 2006). Last, intraoperative splenic trauma is the least common indication and usually is unanticipated (Magtibay, 2006).

## PREOPERATIVE

## ■ Patient Evaluation

Preoperative diagnosis of splenic involvement is often difficult to predict with certainty prior to primary cytoreduction. Typically, in such cases, an omental cake is seen on CT images, but its proximity to the spleen is difficult to ascertain. Splenic involvement is more commonly distinguishable at the time of secondary cytoreduction. Ideally, relapsed patients have isolated disease and have had an extended progression-free survival of at least 12 months before they are considered for splenectomy.

## ■ Consent

Patients with presumed advanced ovarian cancer are consented for possible splenectomy, but the decision to perform the procedure will only be finalized intraoperatively. Although removal of the spleen results in a longer operative time, greater blood loss, and longer hospital stay, it may ultimately determine whether tumor is optimally debulked or not (Eisenkop, 2006). Possible serious complications include hemorrhage, infection, and pancreatitis.

## INTRAOPERATIVE

## ■ Surgical Steps

## □ Anesthesia and Patient Positioning.

Splenectomy is performed under general anesthesia and with the patient supine. The abdomen is surgically prepared, and a Foley catheter is inserted.

## □ Abdominal Entry and Exploration.

During laparotomy, splenectomy requires a vertical incision for adequate exposure. Following entry, a surgeon carefully assesses the entire abdomen and pelvis to confirm the ability to resect all gross disease. Ideally, splenectomy is performed only if optimal tumor debulking can thereby be achieved. The spleen is grasped to assess its mobility, degree of tumor involvement, and potential difficulty in removal. As a brief review, the spleen has ligamentous attachments to its surrounding organs. These include the gastrosplenic, splenocolic, and splenophrenic ligaments. All are transected during splenectomy.

## □ Entrance into the Lesser Sac.

The gastrosplenic ligament, which lies between the stomach's greater curvature and the transverse colon, is opened to the left of midline by dividing vascular pedicles as described in Section 46-14, Step 6 (p. 1186). Dissection is continued in two directions (Fig. 46-15.1). For one, dissection moves along the superior transverse colon with mobilization of the

entire splenic flexure of the colon to reach the splenocolic ligament. For the other, dissection progresses upward to the greater curvature of the stomach toward the gastrosplenic ligament. The intervening portion of omentum is often involved with tumor and is removed.

## □ Mobilization of the Spleen.

The spleen is grasped, elevated, and pulled medially to expose the splenophrenic ligament. A surgeon uses alternating electrocautery blade and blunt finger dissection to further mobilize the spleen. Additional blunt and sharp dissection is then performed circumferentially to free the spleen from the gastrosplenic and splenocolic ligaments. Notably, the gastrosplenic is the most vascular and contains the short gastric arteries. These are carefully ligated and divided. To avoid pancreatic injury, it is important to continually review the anatomy.

## □ Ligating the Splenic Vessels.

The spleen is elevated into the incision, and the peritoneum overlying the splenic hilum is carefully incised. To aid this approach, a left index finger is held against the spleen, and the pancreatic tail, which lies close to the splenic hilum (often within 1 cm), is displaced medially with the left thumb.

Blunt dissection parallel to the expected course of the splenic artery and vein aids identification of these vessels. The artery, vein, and vascular tributaries are individually ligated. The artery is first isolated to prevent splenic engorgement (Fig. 46-15.2). A

FIGURE 46-15.1 Mobilizing the spleen.

**FIGURE 46-15.2** Vessel ligation.

right-angle clamp is placed beneath the artery, and a 2–0 silk suture is pulled through and tied. A second silk tie is placed more distally, directly at the hilum. The proximal end of the artery is again tied or occluded with a vascular clip. The artery is then divided, and the procedure is repeated for the splenic vein. Vascular tributaries are similarly divided. The remaining peritoneal attachments are incised with an electrosurgical blade to remove the spleen.

□ **Final Steps.** The distal pancreas is carefully inspected to exclude injury. The splenic

vessels are also reexamined prior to abdominal closure. Suspicion of pancreatic trauma or bleeding usually prompts placement of a suction drain in the splenic bed. Otherwise, drainage is not routinely required. A nasogastric tube is placed to decompress the stomach and prevent displacement of gastric vessel staples.

### POSTOPERATIVE

Hemorrhage is the most serious immediate complication and typically, originates from

the short gastric or splenic vessels. Bleeding can be profuse, and thus the initial 12 to 24 postoperative hours require particular vigilance (Magtibay, 2006).

The most common postoperative “complication” is left lower lobe lung atelectasis. This will typically resolve with ambulation, pulmonary therapy, and time. Development of a postoperative intraabdominal abscess usually results from inadvertent injury to the stomach, splenic flexure, or distal pancreas.

Excessive pancreatic manipulation or laceration may lead to pancreatitis or leaking. When a distal pancreatectomy is required due to tumor adherence or injury, approximately one quarter of patients will develop a pancreatic leak. According to one set of criteria, this leak is defined by a left upper quadrant collection of fluid seen on imaging after postoperative day 3, and this fluid contains an amylase level > 3 times that of serum amylase. If a drain has been placed, fluid may be sent to the laboratory if this complication is suspected. Pancreatic leak usually presents early in the postoperative period and can be managed conservatively with percutaneous drainage (Kehoe, 2009).

Patients undergoing splenectomy will be at lifelong risk for episodes of overwhelming sepsis. Accordingly, the pneumococcal and meningococcal vaccines are recommended and the *Haemophilus influenzae* type b is considered postoperatively (Kim, 2015). Importantly, these vaccines may be given together but are not administered earlier than 14 days following splenectomy. In addition, patients are instructed to seek immediate medical attention for fevers, which may rapidly progress to serious illness.

## 46-16

## Diaphragmatic Surgery

Patients with advanced ovarian cancer will often have tumor implants or confluent plaques involving the diaphragm. The right hemidiaphragm is most frequently affected. Implants are typically superficial, but invasive disease can extend through the peritoneum to the underlying muscle. Accordingly, gynecologic oncologists are prepared to perform diaphragmatic ablation, stripping (peritonectomy), or full-thickness resection. These surgical procedures increase the rate of optimal tumor debulking and correlate with improved survival (Aletti, 2006a; Tsolakidis, 2010).

### PREOPERATIVE

#### ■ Patient Evaluation

Imaging studies may suggest diaphragmatic nodularity, but the extent is difficult to ascertain until exploration in the operating room.

#### ■ Consent

Patients with presumed advanced ovarian cancer are informed of the possible need for extensive upper abdominal surgery to achieve optimal cytoreduction. Pulmonary complications after diaphragmatic surgical techniques most commonly include atelectasis and/or pleural effusion. However, empyema, subphrenic abscess, and pneumothorax are also possible (Chereau, 2011; Cliby, 2004).

### INTRAOPERATIVE

#### ■ Instruments

It is generally advisable to have a cavitation ultrasonic surgical aspiration (CUSA) system and/or argon beam coagulator (ABC) available for ovarian cancer debulking procedures, since one or both can be useful in eradicating diaphragmatic disease. These tools are discussed further in Chapter 40 (p. 859).

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** As with other major intraabdominal surgeries, diaphragmatic surgery requires general anesthesia. The patient is positioned supine, the abdomen is surgically prepared to accommodate an incision to the sternum, and a Foley catheter is inserted.

□ **Abdominal Entry.** Diaphragmatic surgery requires a vertical midline incision that has been extended to the sternum, passing to the right side of xiphoid process, for maximum exposure. Following abdominal entry, a surgeon carefully assesses the entire abdomen and pelvis to confirm the ability to resect all gross disease. Ideally, diaphragmatic surgery is performed only if optimal tumor debulking can thereby be achieved.

□ **Diaphragmatic Ablation.** A few scattered, small tumor implants on the surface of the right or left hemidiaphragm can usually be easily ablated with the CUSA or ABC. This simple technique may be all that is required.

□ **Diaphragmatic Stripping.** Confluent plaques of tumor or extensive implants indicate the need for resection of the peritoneum. For this, the right side of the anterior rib cage is retracted sharply upward. The liver is manually retracted downward and medially to aid division of the falciform ligament, right coronary ligament, and right triangular ligament of the liver with sharp dissection using an electro-surgical blade. This maneuver significantly mobilizes the liver and allows it to be held medially away from the diaphragm.

Dissection begins on the right side of the diaphragm, where the diaphragmatic peritoneum meets the anterior abdominal wall. Allis clamps are used to grasp the peritoneum above the tumor plaque and place it on tension. The peritoneal incision is created transversely above the tumor with an electro-surgical blade, and a plane is developed with blunt dissection to separate the peritoneum from the underlying muscle fibers of the

diaphragm. The free peritoneal edge is placed on tension with Allis clamps to maintain traction. The incision is then extended medially and laterally to encompass the implants (Fig. 46-16.1). The specimen eventually becomes large enough to grasp with a left hand to aid in “stripping” the peritoneum off the diaphragm. Electro-surgical blade dissection proceeds dorsally until all implants are contained within the peritoneal specimen. At this point, it can be detached.

□ **Diaphragmatic Resection.** Occasionally, tumor has penetrated through the peritoneum, and a plane cannot be developed to strip the diaphragm. In these circumstances, full-thickness diaphragmatic resection is required. A self-retaining retractor is placed, and the liver mobilized. A transverse peritoneal incision is made above the tumor plaque, and at this point, the inadequacy of stripping is determined.

The ventilator is temporarily turned off to avoid lung parenchymal injury, and an electro-surgical blade is used to cut through the diaphragmatic muscle into the pleural cavity above the tumor. Ventilation may then be resumed while Allis clamps are placed to retract the specimen into the peritoneal cavity. Both pleural and peritoneal surfaces should be visible to aid in complete resection of the disease. After resection, primary mass closure of the diaphragmatic defect is then performed with a running stitch using 0-gauge polydioxanone monofilament (PDS) suture or interrupted stitches of silk suture.

To evacuate the pneumothorax, a red rubber catheter is placed through the defect into the pleural space prior to securing the final

FIGURE 46-16.1 Diaphragm stripping.

knot. The ventilator is turned off at the end of inspiration to maximally inflate the lungs while the catheter is placed on suction. The catheter is removed concomitantly with tying the knot, and mechanical ventilation is resumed (Bashir, 2010). Grafts are not typically needed, even for large defects (Silver, 2004).

□ **Final Steps.** The patient is placed in Trendelenburg position at the completion of stripping or resection to check the integrity of the diaphragmatic closure. The upper abdomen is filled with saline and observed

for air leaks as the patient is ventilated. The presence of air bubbles indicates the need to reintroduce the red rubber catheter through the hole, resuture the defect, and retest the closure. Chest tubes are not routinely required.

## POSTOPERATIVE

Atelectasis is common with any diaphragmatic surgery, and routine postoperative respiratory expansion techniques are appropriate

(Chap. 39, p. 827). Diaphragmatic stripping is associated with an increased incidence of pleural effusion, especially when the pleural space is entered. Fortunately, most will self-resolve, and only a few will require postoperative thoracentesis (Dowdy, 2008). Patients having full-thickness diaphragmatic resection are carefully monitored with chest radiographs for evidence of a pneumo- or hemothorax. Those few who do not resolve with supportive care measures may require chest tube drainage to aid lung reexpansion (Bashir, 2010).

## 46-17

## Colostomy

A colostomy is a surgical anastomosis between created openings in the colon and anterior abdominal wall to divert bowel contents into an external collection bag. Colostomies serve several purposes and may be used: (1) to protect distal bowel repair from disruption or contamination by feces, (2) to decompress an obstructed colon, and (3) to evacuate feces if the distal colon or rectum is excised. In gynecologic oncology, specific indications for performing a colostomy are innumerable. Some of the more common ones include rectovaginal fistula, severe radiation proctosigmoiditis, bowel perforation, and rectosigmoid resection in which reanastomosis is not feasible.

A colostomy may be temporary or permanent, and its duration is dictated by clinical circumstances. For instance, recurrent end-stage cervical cancer with obstruction may warrant a permanent colostomy. In contrast, only temporary diversion is needed to allow healing of an intraoperative bowel injury that occurred during benign gynecologic surgery.

In addition, the location of the stoma and the decision to perform an end or loop colostomy are also clinically based. A loop colostomy is constructed by creating an opening in a loop of colon and bringing both ends through the stoma. Alternatively, an end colostomy stoma contains only the proximal end of the transected colon. The distal end is stapled and left intraabdominally.

Regardless of the clinical circumstances, the same surgical principles apply during colostomy: adequate bowel mobilization, sufficient blood supply, and a tension-free tunnel through the abdominal wall without bowel constriction. Strict attention to these seemingly straightforward steps ensures the best possible outcome. In some circumstances, a laparoscopic colostomy may be possible (Jandial, 2008).

## PREOPERATIVE

## ■ Patient Evaluation

The colostomy site, typically on the patient's left, is ideally marked preoperatively by an enterostomal therapist to ensure that the postoperative stoma will be located in an easily accessible area when sitting and standing.

## ■ Consent

Concerns regarding postoperative quality of life changes are common with this procedure.

Accordingly, a surgeon carefully describes a colostomy's medical purpose and its expected temporary or permanent duration. Much of the fear regarding "wearing a bag" can be assuaged with compassionate preoperative counseling and education. Many times, postoperative results are actually superior to a patient's current symptoms and quality of life.

Perioperative complications may include fecal leakage into the abdomen or retraction of the stoma. Long-term complications involve parastomal hernia, stricture, and the potential need for surgical revision.

## ■ Patient Preparation

To minimize fecal contamination during bowel incision, aggressive bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) may be considered the day prior to surgery unless contraindicated, such as with bowel obstruction or perforation. Additionally, broad-spectrum antibiotics are given preoperatively due to the possibility of stool contamination of the operative site. With stool spill, postoperative antibiotic doses for 24 to 48 hours and a drain near the anastomosis are reasonable.

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Colostomy is performed under general anesthesia with the patient positioned supine. Prior to surgery, the abdomen is surgically prepared, and a Foley catheter is inserted.

□ **Abdominal Entry and Exploration.** Although concurrent surgery may dictate the approach, a midline vertical incision, due to its superior exposure, is generally preferred when colostomy is a possibility. The bowel segment is selected as distally as possible to preserve normal bowel. Dissection and adhesiolysis are performed as necessary to mobilize the bowel to obtain sufficient length before creating the abdominal wall stoma opening. The colon is elevated to ensure that it will reach the selected stoma site without tension. If the bowel fails to reach the selected site without tension despite maximal mobilization, then the proposed stoma site is moved to accommodate the available bowel length.

□ **End Colostomy.** This type of diversion is commonly used for rectovaginal fistulas and severe proctosigmoiditis after radiation. Ideally, a more distal colon site is used since bowel content becomes progressively more solid and less voluminous as it moves from

the cecum to the rectum. As a result, the ostomy bag does not need to be changed as often, and the risk of dehydration or electrolyte abnormalities is reduced. If performing an end sigmoid colostomy, the distal bowel may simply be stapled closed and left in the pelvis (Hartmann pouch). In contrast, a more proximal end colostomy performed for a distal colonic obstruction will require that the distal bowel also be brought to the abdominal wall and opened, either at the same site or as a second ostomy. This distal-bowel-loop ostomy serves as a "mucus fistula" to prevent a closed loop obstruction and subsequent colonic perforation from mucus or gas accumulation.

The stoma site for a sigmoid colostomy is selected based on an imaginary line drawn from the umbilicus to the left-sided anterior superior iliac spine. The site is sufficiently lateral from the midline to allow application of the ostomy appliance. But, it is located sufficiently medial because stoma support from the rectus muscle lowers stoma-site hernia risks.

To begin, a Kocher clamp is used to elevate the skin and an electrosurgical blade, set to a cutting mode, is used to remove a 3-cm circle of skin. The fascia is exposed by blunt dissection. In obese patients, a cone through the subcutaneous fat with its tip at the fascia may need to be removed to prevent bowel constriction. A cruciate incision is made on the anterior sheath. The fibers of the rectus abdominis muscle are bluntly separated, and another cruciate incision is cut on the posterior sheath. The opening is bluntly expanded to accommodate two or three fingers.

After the colon is divided as described in Section 46-21, Step 5 (p. 1201), the proximal bowel is mobilized by incising the peritoneum toward the splenic flexure along the white line of Toldt, which is the reflection of posterior abdominal parietal peritoneum over the mesentery of the descending colon. A Babcock clamp is then placed through the skin opening to grasp the stapled end of bowel and lift it through the abdominal opening (Fig. 46-17.1). The bowel should appear pink, and its mesentery must not be twisted. The primary vertical abdominal incision is then closed.

The stoma is not ordinarily "matured" until the abdominal wall and skin are closed, with a dressing in place. First, the table is tilted to the left to minimize bowel spillage and fecal contamination of the incision site, and then the intestinal staple line is excised. Circumferential interrupted 3-0 and 4-0 gauge delayed-absorbable sutures are placed through the bowel mucosa and skin dermis (Fig. 46-17.2). The ostomy bag appliance may then be attached.

**FIGURE 46-17.1** End-sigmoid colostomy: bowel pulled through abdominal wall incision.

**FIGURE 46-17.2** End-sigmoid colostomy: bowel mucosa sutured to skin.

□ **Loop Colostomy Principles.** The typical indications for this type of procedure include protection of a distal anastomosis, relief of colonic obstruction, and colonic perforation. Accordingly, loop colostomy can be performed at any site along the colon where indicated. A loop colostomy in general is intended to be a temporary or palliative procedure. It is easier to take down, often simpler

to perform, and does not necessarily require designation of loops as distal or proximal. However, fecal matter will eventually pass through to the distal segment. As a result, this type of colostomy is not a permanent solution to a fistula or proctosigmoiditis.

□ **Transverse Loop Colostomy.** As a stand-alone procedure, a transverse loop

colostomy is most often performed to relieve a distal obstruction and can be used in an emergent or palliative setting. This colostomy is performed in the left upper quadrant by creating a 5-cm transverse incision over the rectus abdominis muscle midway between the costal margin and the umbilicus. The anterior and posterior fascia, rectus abdominis muscle, and peritoneum are opened longitudinally by sharp and blunt dissection. The omentum is separated from the underlying transverse colon along enough length to allow the bowel segment to be pulled up through the incision without it. Next, a one-quarter inch Penrose drain is placed through the mesocolon for traction, and the bowel loop is brought through the incision (Fig. 46-17.3). A Hollister

**FIGURE 46-17.3** Transverse loop colostomy: bowel segment elevated.

**FIGURE 46-17.4** Transverse loop colostomy: bowel opened.

bridge or similar device is passed through the mesenterotomy in place of the Penrose drain. The skin incision is then closed around the bowel loop without constricting it.

The bowel is then “matured” by opening the antimesenteric half of the bowel along the tenia with an electrosurgical blade and leaving a 1-cm margin on each end (Fig. 46-17.4). The colostomy edges are sutured to the skin with interrupted stitches of 3-0 gauge delayed-absorbable suture.

□ **Final Steps.** The stoma is carefully inspected and ideally is pink and comfortably positioned. A dusky color may indicate

bowel ischemia, which can lead to sloughing, necrosis, and retraction. Tension on the bowel may be improved with additional colon mobilization. Constriction of a loop colostomy within the abdominal wall opening can be improved by broadening the fascial incision or removing additional subcutaneous fat. With end colostomy, on occasion, the tip may need to be transected further distally to reach a viable bowel segment. All of these steps are cumbersome but are much easier to perform during the operation rather than postoperatively after complications become obvious.

## POSTOPERATIVE

Morbidity is comparable for end and loop colostomies (Segreti, 1996a). Complications may be immediate or not evident for several months. Common complications specific to a colostomy may include wound infection, necrosis, bowel obstruction, hematoma, retraction, fistula, fecal leakage, sepsis, stricture, and parastomal herniation (Hoffman, 1992). Many of these complications are manageable with supportive care and local measures. Dramatic symptoms are infrequent but may require operative revision. Careful attention during initial surgery will prevent most of these morbidities.

## 46-18

## Large Bowel Resection

Partial colectomy is most often performed as part of cytoreductive surgery for ovarian cancer, although other indications include radiation injury and colonic fistula. Surgical principles are similar, whether a bowel segment to be removed is from the ascending, transverse, or descending colon. Rectosigmoid (low anterior) resection is somewhat more complex and is reviewed in Section 46-21 (p. 1200).

Ideally during colectomy, a surgeon will achieve meticulous hemostasis, remove the smallest required length of colon, avoid fecal spill, and confirm bowel continuity by excluding possible sites of proximal or distal intestinal obstruction. In addition, bowel must be sufficiently mobilized to create a tension-free anastomosis that is watertight, large caliber, and supported by adequate blood supply. During surgery planning, insufficient bowel length for reanastomosis, a malnourished patient, questionable vascular supply, or undue anastomosis tension may instead require a permanent or temporary diverting colostomy.

A general familiarity with colonic blood supply is important for partial colectomy. The ascending and transverse colon are supplied by the superior mesenteric artery via the ileocolic, right colic, and middle colic branches. The descending and sigmoid colon are supplied by the left colic and sigmoid branches of the inferior mesenteric artery. As a result, these vessels form an effective anastomotic vascular network that allows large bowel resection at virtually any segment of the colon.

## PREOPERATIVE

## ■ Patient Evaluation

The need for partial colectomy during ovarian cancer cytoreductive surgery is usually decided intraoperatively and is based on clinical circumstances. For example, although preoperative CT images may suggest tumor at multiple sites near the colon, these lesions are often superficial and may be removed without colectomy. Typically, the need for colectomy is more obvious preoperatively for those with radiation damage or fistula. However, the extent of resection will still generally be unclear until the operation is underway.

## ■ Consent

Patients are fully informed of the potential for colostomy, anastomotic leak, and abscess formation. A postoperative ileus should also be anticipated.

## ■ Patient Preparation

To minimize fecal contamination during bowel incision, most surgeons still recommend aggressive bowel preparation. One choice, a polyethylene glycol with electrolyte solution (GoLYTELY), may be considered the day prior to surgery unless contraindicated, such as with bowel obstruction or perforation. However, there is no evidence that patients benefit from this practice, and bowel preparation may not lower the risk of postoperative complications (Guenaga, 2009; Zhu, 2010). If a bowel obstruction is present, then cleansing only the distal colon with enemas is a secondary option. The patient is also marked for a colostomy if that is a possibility. Moreover, if a complicated resection or prolonged recovery is anticipated, postoperative TPN administration is considered. Preoperative antibiotics and perioperative VTE prophylaxis are warranted, and options are listed in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

## ■ Instruments

To prepare for complicated resections, a surgeon should have access to all types and sizes of bowel staplers. These include end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers. Additionally, a ligate-divide-staple (LDS) device or electrothermal bipolar coagulator (LigaSure) may aid in vessel ligation.

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Rectovaginal examination under anesthesia

is mandatory before positioning any patient for abdominal gynecologic cancer surgery. A palpable mass with compression of the rectum or rectovaginal septum indicates the need for low lithotomy with legs comfortably positioned in booted support stirrups to prepare for possible low anterior resection and anastomosis. Supine positioning is otherwise appropriate. Sterile preparation of the abdomen, perineum, and vagina is completed, and a Foley catheter is inserted.

□ **Abdominal Entry.** A midline vertical incision is preferable if partial colectomy is anticipated as this incision provides access to the entire abdomen. Required dissection, adhesiolysis, or other unanticipated findings may render exposure from a transverse incision inadequate.

□ **Exploration.** A surgeon first explores the entire abdomen to lyse adhesions, to “run” the bowel and evaluate its appearance from duodenum to rectum, to exclude other potential sites of obstruction proximally or distally, and to determine the extent of the bowel resection. Colonic blood supply at the splenic flexure, hepatic flexure, and ileocecal valve can be tenuous. As a result, resection boundaries ideally lie beyond these areas if possible. For example, in [Figure 46-18.1](#), because of the known tenuous blood supply at the hepatic flexure, the proximal line of transection includes several centimeters of transverse colon. Similarly, the distal line of transection includes 8 to 10 cm of the terminal ileum because the ileocecal artery is sacrificed. Leaving this terminal ileum would render it vulnerable to necrosis from insufficient remaining vascular support.

**FIGURE 46-18.1** Area of resection encompasses tumor.

Once the segment is selected, a window is made in the mesocolon proximal and distal to the lesion. A one-quarter inch Penrose drain is pulled through each location's opening to provide traction.

□ **Mobilization of the Colon.** The bowel is next mobilized by incising peritoneum along the white line of Toldt and/or along the hepatic or splenic flexures—depending on the resection site. For the case shown in Figure 46-18.1, the right retroperitoneal space is entered at the mid-ascending colon, continued along the white line of Toldt, and extended toward and around the cecum to a site beyond the distal Penrose drain. The entry opening is created with an electro-surgical blade just lateral to the colon. This space is bluntly expanded, and electro-surgical dissection is next guided cephalad past the proximal Penrose drain while providing countertraction on the colon. The bowel segment may be bluntly mobilized medially as necessary. Partial infracolic omentectomy may be required for resections involving the transverse colon.

□ **Resection.** A GIA stapler is inserted to replace one Penrose drain, is positioned around the entire colon diameter, and is fired. This stapler lays two rows of staples and transects interposed bowel. A second stapling and transection is then repeated at the other Penrose drain site. Staying close to the bowel segment's wall, the bowel segment may then be detached from its underlying mesentery, using an LDS device, electrothermal bipolar coagulator, or individual clamps and 0-gauge delayed-absorbable suture ligation. During this process, as much of the mesentery as possible is preserved to provide adequate blood supply to the anastomosis. The specimen is then removed.

□ **Side-to-Side Anastomosis.** The proximal and distal bowel ends are held parallel against each other to estimate their position following anastomosis. Typically, additional mobilization of the bowel by incising adhesions and peritoneum is required using a combination of electro-surgical blade and blunt dissection. The two segments must comfortably approximate antimesenteric borders without tension. For larger resections, the mesentery of each segment may also need to be dissected to achieve sufficient mobility. The proximal and distal stapled bowel ends are skeletonized of fatty tissue to create an anastomosis with maximal mucosa-to-mucosa contact. To accomplish this, the proximal staple line is elevated with two Allis clamps at its lateral edges. DeBakey forceps grasp surrounding fatty tissue and place it on traction, while an electro-surgical blade is used to dissect this tissue away from the bowel serosa. The dissection is then performed on the distal rectal segment in similar fashion.

**FIGURE 46-18.2** GIA stapler creates a side-to-side anastomosis of the ileum (left) and transverse colon (right). Inset: TA stapler line closes the distal end of the anastomosis.

The antimesenteric tip of each staple line is excised with scissors, and the bowel is held vertically by Allis clamps to prevent fecal spill. One or two seromuscular silk stay sutures may be placed distally on each bowel end to help align the correct position and prevent slippage. One fork of the GIA stapler is then inserted as deeply as possible into each of the bowel lumens (Fig. 46-18.2). The bowel segments are evenly positioned, and the device is then fired along the antimesenteric surfaces and removed. The stapler places two staggered rows of titanium staples and simultaneously transects tissue between these rows.

The bowel interior should be examined for bleeding sites, which may be electro-surgically coagulated. The remaining opening may then be stapled across with a TA stapler, and residual bowel tissue above the TA staple line is excised. The mesenteric defect is reapproximated with interrupted or running 0-gauge delayed-absorbable suture to prevent an internal hernia.

□ **Final Steps.** The abdomen is irrigated with copious warmed saline at the conclusion of any bowel resection, especially if feces have spilled during the procedure. Drains are not routinely required and may impair healing.

## POSTOPERATIVE

Morbidity after large bowel resection is significantly increased by various factors,

but especially by preexisting obstruction, malignancy, obesity, radiation damage, or sepsis. Moreover, patients undergoing multiple bowel resections have greater blood loss and longer hospital stay (Salani, 2007). Anastomotic leaks are the most specific complication and typically present as an abscess or fistula, or as peritonitis within days or weeks of surgery. Some localized leaks can be managed with initiation of TPN, CT-guided drainage, antibiotic administration, and bowel rest for a couple of weeks. However, urgent reoperation is indicated for nonlocalized intraperitoneal perforation and its resulting peritonitis. This will usually require temporary colostomy (Kingham, 2009).

Pelvic abscesses may also result from intraoperative fecal spillage or hematoma superinfection. Usually these will resolve with CT-guided drainage and antibiotics. Gastrointestinal hemorrhage should be rare with stapled procedures. In addition, symptomatic anastomotic strictures are infrequent and often present as colonic obstruction. Some strictures can be managed with endoscopic stents, but often they require reoperation. Small or large bowel may also become obstructed by postoperative adhesions or tumor progression. Last, a prolonged ileus can develop and be slow to resolve. Most of these complications will depend primarily on the patient's underlying nutrition and the clinical circumstances prompting the primary surgery.

## 46-19

## Ileostomy

Relatively few patients will require ileostomy for management of a gynecologic malignancy. For those who do, loop ileostomy is usually a temporary procedure that is performed to protect a distal anastomosis (Nunoo-Mensah, 2004). Palliation of a large-bowel obstruction or diversion of a colonic fistula may be other indications (Tsai, 2006). On occasion, ovarian cancer will involve the entire colon, requiring colectomy with a permanent end ileostomy and formation of a Hartmann pouch (Song, 2009).

## PREOPERATIVE

## ■ Patient Evaluation

Stoma placement is particularly important for an ileostomy since the effluent will be more corrosive than that of a colostomy. Ideally, the site is marked preoperatively by an enterostomal therapist.

## ■ Consent

In general, many of the complications from this procedure mirror those of colostomy: retraction, stricture, obstruction, and herniation. Patients are informed that temporary loop ileostomies can be taken down later without a laparotomy.

## ■ Patient Preparation

Bowel preparation is preferred whenever there is a potential for more extensive bowel resection. However, ileostomy can safely be performed in virtually all circumstances without cleansing. Antibiotics and VTE prophylaxis are warranted, and options are listed in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Ileostomy is performed under general anesthesia. Patients are generally supine, but low lithotomy is acceptable.

□ **Abdominal Entry.** A midline vertical incision is preferable for most situations in which an ileostomy is considered.

□ **Exploration.** After abdominal entry, a surgeon first explores the abdomen, lyses

adhesions, “runs” the bowel length to identify obstructive sites, and determines the need for ileostomy. An ileum loop is selected that will reach several centimeters above the skin. Additionally, to reduce the effluent volume, the selected loop is located as distally along the bowel length as possible. On occasion, tethering of small bowel by carcinomatosis or radiation injury will significantly reduce mobility and will require a more proximal diversion.

□ **Loop Ileostomy.** A one-quarter inch Penrose drain is placed through a mesenterotomy at the selected loop’s apex. The loop can then be approximated to the stoma site, which is created to accommodate two fingers as described for an ileal conduit (Section 46-7, p. 1159). The loop is pulled through the abdominal wall opening so that several centimeters protrude above the skin surface. The Penrose drain is removed and replaced with either the cut end of a red rubber catheter or another device that can be sewn to the skin to elevate the loop. The loop should be tension-free and patent. The proximal end of the loop is placed in the lower position to reduce fecal flow into the distal bowel. The skin of the abdominal wall is then closed around the stoma.

The ileostomy is “matured” by longitudinally incising the bowel loop and everting its walls with Allis clamps. Circumferential interrupted stitches of 3–0 and 4–0 gauge delayed-absorbable sutures are placed through the dermis and bowel mucosa (Fig. 46-19.1). An ostomy bag may then be applied.

□ **End Ileostomy.** If a total colectomy is performed or if the bowel is too tethered or the patient too obese for a loop to reach the abdominal wall, the distal ileum may need to be divided instead of brought out as a loop.

FIGURE 46-19.1 Ileal loop opened with cautery.

The segment is selected, a mesenterotomy is made, and the GIA stapler is fired. An appropriate stoma site is identified, and with a few modifications, the end ileostomy is matured as in colostomy (Section 46-17, p. 1192). Typically, the abdominal wall opening will be smaller in diameter. Unless there is a distal colon obstruction necessitating creation of a mucus fistula, the distal bowel segment can be left in the peritoneal cavity.

An attempt is made to evert the single stoma by turning the bowel wall over on itself using Allis clamps. In each quadrant of the stoma, stitches of 3–0 gauge delayed absorbable suture are placed through the dermis, the seromuscular layer of the bowel at the skin level, and a full-thickness bite at the cut edge of the everted bowel.

## POSTOPERATIVE

The stoma is carefully examined postoperatively for its appearance and function. The loop supporting rod may be removed in 1 to 2 weeks, but potentially earlier if the stoma becomes dusky or the loops seem constricted or are obstructed.

Ileostomy may be associated with significant postoperative complications. High-output effluent may result in electrolyte abnormalities that are difficult to correct. In addition, approximately 10 percent of patients will require early reoperation for small-bowel obstruction or intraabdominal abscess (Hallbook, 2002). Specifically, if loop ileostomy is indicated to protect a low anterior anastomosis, it is more commonly associated with bowel obstruction and ileus than is loop colostomy (Law, 2002). Long-term complications such as a peristomal hernia or retraction are also possible.

## 46-20

## Small Bowel Resection

Indications for small bowel resection in gynecologic oncology are numerous and include obstruction, tumor invasion, perforation, intraoperative injury, fistulas, or radiation damage. Unlike the large bowel, where greater attention is required to ensure an adequate blood supply to the anastomotic site, the small intestine has a consistent cascade of vessels that all arise from the superior mesenteric artery. However, unique situations such as radiation damage, obstructive dilatation, and edema can compromise this vasculature dramatically. In these situations, meticulous dissection is especially crucial to prevent inadvertent removal of the bowel serosa, enterotomy, and bowel damage that will impair anastomotic healing. In general, surgical principles with this procedure are much the same as those for large bowel resection (Section 46-18, p. 1195).

## PREOPERATIVE

## Patient Evaluation

Small bowel obstructions (SBOs) that do not resolve with nasogastric suction decompression and bowel rest may result from postoperative adhesions or tumor progression. Patients with recurrent gynecologic malignancy, particularly those with ovarian cancer, are preoperatively imaged by abdominopelvic CT with oral contrast. Numerous sites of obstruction may be suspected that would indicate a woman with end-stage disease who might be better served by placement of a palliative percutaneous draining gastrostomy tube. Patients with an SBO following pelvic radiation often have stenosis at the terminal ileum. This vulnerability stems from its proximity to the radiation field of many gynecologic cancers and its limited mobility compared with other small-bowel segments.

## Consent

Depending on circumstances, patients are counseled regarding the intraoperative decision-making process to decide on anastomosis, bypass, or ileostomy. Leaking, obstruction, and/or fistula formation are possible complications. Less common outcomes include short-bowel syndrome and vitamin B<sub>12</sub> deficiency, both described later.

## Patient Preparation

Aggressive bowel preparation is often contraindicated, particularly in patients with

obstruction. Antibiotics and VTE prophylaxis are provided (Chap. 39, p. 835). If a complex fistula is present or an extensive resection for radiation damage is anticipated, then postoperative TPN may be advisable.

## INTRAOPERATIVE

## Instruments

The surgeon should have access to all types and sizes of bowel staplers, such as end-to-end anastomotic (EEA), gastrointestinal anastomotic (GIA), and transverse anastomotic (TA) staplers, to prepare for complicated resections.

## Surgical Steps

## Anesthesia and Patient Positioning.

Small bowel resection is performed under general anesthesia. Patients are generally supine, but low lithotomy or other positioning with access to the anterior abdominal wall is acceptable.

**Abdominal Entry.** A midline vertical incision is preferable for most situations in which a small-bowel resection is considered.

**Exploration.** The surgeon explores the entire abdomen first to identify the obstruction. Infrequently, an adhesion may be located and lysed to quickly relieve an obstruction, thereby avoiding small bowel resection. More often, an area is discovered that warrants removal. Importantly, the remainder of the bowel must be examined to exclude other obstructive sites.

Peritoneum and adhesions attached to the involved portion of small bowel are dissected to mobilize the bowel. The small intestine can be damaged easily by rough handling and extensive blunt dissection—particularly if the bowel is edematous, densely adhered, or previously irradiated. Trauma is minimized to reduce spillage of intestinal contents by inadvertent enterotomy. Ideally, healthy-appearing serosa for anastomosis is identified at sites both proximal and distal to the lesion while preserving a maximum amount of intestine.

**Dividing Small Bowel.** The involved bowel is brought through the abdominal incision. A one-quarter inch Penrose drain is pulled through a mesenterotomy at the proximal and distal sites to be approximated. A GIA stapler is inserted to replace the Penrose drain and is fired. This is repeated at the other bowel site (Fig. 46-20.1). These staple lines minimize contamination of the abdomen with bowel contents.

A wedge of mesentery then is “scored” by superficially creating a V shape with an electrosurgical blade. The mesentery is divided by a ligate-divide-staple (LDS) device, electrothermal bipolar coagulator (LigaSure), or clamps and 0-gauge delayed-absorbable suture ligatures. Achieving hemostasis will be more difficult with edematous or inflamed tissue, and thus smaller mesentery pedicles should be sequentially divided. The bowel specimen is then removed.

## Performing Side-to-Side Anastomosis.

The proximal and distal bowel segments are elevated with Allis clamps and matched parallel along their antimesenteric borders.

FIGURE 46-20.1 Identifying proximal and distal sites.

**FIGURE 46-20.2** Side-to-side anastomosis.

**FIGURE 46-20.3** Closing the enterotomy.

To help alignment, one or two silk stay sutures are placed through the antimesenteric border of each segment beyond the tip of where the GIA stapler fork will reach. The antimesenteric corner of each segment is excised at the staple line just deeply enough to enter the lumen and sufficiently widely to permit passage of one GIA stapler fork. Massively distended bowel from an obstruction may be decompressed by inserting a pool suction tip into the proximal bowel end.

Allis clamps are replaced on the bowel at the edge of each opening. These clamps and silk stay sutures assist insertion of one fork of the GIA stapler into each segment and aid in bowel positioning (Fig. 46-20.2). The bowel is rotated to bring the antimesenteric borders together, Allis clamps are removed, and the GIA stapler is closed and fired.

The remaining enterotomy is regrasped with three Allis clamps to approximate for closure. The TA stapler is placed around the bowel beneath the Allis clamps and is closed (Fig. 46-20.3). The Allis clamps elevate the enterotomy and assist with correct positioning of the TA stapler. The stapler is fired, excess tissue above the stapler is trimmed sharply, and the stapler is opened and removed. The mesenteric defect may be closed next with running 0-gauge delayed-

absorbable suture to prevent internal herniation—that is, herniation of bowel or omentum through the mesenteric defect.

□ **Final Steps.** The abdomen is copiously irrigated with warmed saline. This is performed at the conclusion of any bowel resection, but particularly if bowel contents spill during the procedure. Drains are not required routinely and may impair healing. In general, it is prudent to place a nasogastric tube to decompress the stomach postoperatively until bowel function has resumed. Palpation of the stomach will confirm correct placement, or else the anesthesiologist can be directed to advance or pull back the tube as needed. If this is overlooked, correct location can only be reliably confirmed postoperatively by chest radiography.

## POSTOPERATIVE

The underlying health of the patient, diagnosis, and indications for small bowel resection will dictate much of the potential postoperative morbidity. Ileus is common. Fistula formation, anastomotic leakage, and obstruction are more serious problems that may require reoperation. Two specific complications are unique to extensive small bowel surgery.

First, short-bowel syndrome may develop. More than half the small intestine can be removed without impairing nutritional absorption as long as the remaining bowel is functional. Accordingly, this syndrome is more likely to develop from extensive radiation damage than from surgical resection. Symptoms include diarrhea and dehydration. Maldigestion, malabsorption, nutritional deficiencies, and electrolyte imbalance are often noted. As a result, home TPN may be required in some patients (King, 1993).

A second complication, vitamin B<sub>12</sub> deficiency, results from inadequate absorption and depletion of available stores. The ileum measures on average 300 cm in length, and vitamin B<sub>12</sub> and bile salts are only absorbed in the ileum's distal 100 cm. Malabsorption in this segment may result from radiotherapy or extensive intestinal resection (Bandy, 1984). If vitamin B<sub>12</sub> deficiency is suspected, a complete blood count (CBC), peripheral blood smear, and serum cobalamin (B<sub>12</sub>) level are collected as part of an initial laboratory assessment. Accepted lower limits of serum vitamin B<sub>12</sub> levels in adults range between 170 and 250 ng/L. One option for replacement is 1 mg intramuscularly weekly for 8 weeks, followed by long-term monthly injections (Centers for Disease Control and Prevention, 2011).

## 46-21

## Low Anterior Resection

Rectosigmoid resection, also known as low anterior resection, is mainly used in gynecologic oncology to achieve optimal cytoreduction of primary or recurrent ovarian cancer (Mourton, 2005). This procedure is distinguished from other types of large bowel resection in that it requires mobilization and transection of the rectum distally, below the peritoneal reflection. Following resection of the involved rectosigmoid segment, proximal and distal bowel ends are usually anastomosed.

Low anterior resection is the most common bowel operation for primary tumor debulking (Hoffman, 2005). For example, en bloc pelvic resection combines low anterior resection with hysterectomy, bilateral salpingo-oophorectomy, and removal of surrounding peritoneum (Section 46-13, p. 1182) (Aletti, 2006b). In addition, total and posterior pelvic exenterations incorporate many of the same principles of tissue dissection to remove centrally recurrent cervical cancer and achieve widely negative soft tissue margins. Other less common indications for low anterior resection are radiation proctosigmoiditis and intestinal endometriosis (Urbach, 1998). Occasionally, additional large or small bowel resections will be performed concomitantly with low anterior resection (Salani, 2007).

## PREOPERATIVE

## ■ Patient Evaluation

Bowel symptoms may or may not be present in women with rectosigmoid involvement of ovarian cancer. However, a surgeon should have greater suspicion if patients describe rectal bleeding or progressive constipation. A rectovaginal examination may help predict a need for low anterior resection. Additionally, CT images may suggest rectosigmoid invasion of tumor. However, prediction prior to surgery is difficult. Many ovarian cancers intraoperatively may be easily lifted away from the bowel, or surface tumors may be removed without resection.

## ■ Consent

Patients should be prepared for the possibility of low anterior resection any time ovarian cytoreductive surgery is discussed. The survival benefit of achieving minimal residual disease warrants the risks of this procedure. However, low anterior resection significantly extends operative time, and hemorrhage may contribute to a need for blood transfusion (Tebes, 2006).

In general, progressively higher complication rates and poorer long-term bowel function follow anastomoses that are more distal and approach the anal verge. However, the operation is designed to encompass the tumor. Thus, an end sigmoid colostomy with Hartmann pouch is another, albeit less attractive, option for very low resections. In general, a protective loop colostomy or ileostomy is not required, but patients are counseled for that possibility in the event of poor nutrition, tenuous bowel blood supply, or anastomosis tension. Anastomotic leaks develop in fewer than 5 percent of procedures (Mourton, 2005).

## ■ Patient Preparation

To minimize fecal contamination during resection, bowel preparation such as with a polyethylene glycol with electrolyte solution (GoLYTELY) is generally considered prior to surgery. Antibiotics and VTE prophylaxis are warranted, and suitable options are found in Tables 39-6 and 39-8 (p. 835).

## INTRAOPERATIVE

## ■ Instruments

All types and sizes of bowel staplers such as end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers should be available. Additionally, a ligate-divide-staple (LDS) device or electrothermal bipolar coagulator (LigaSure) may be used for vessel ligation.

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Low anterior resection via laparotomy requires general anesthesia. Rectovaginal

examination under anesthesia is performed before positioning any patient for abdominal gynecologic cancer surgery. A palpable mass with compression of the rectum or rectovaginal septum prompts patient positioning in low lithotomy with legs safely placed in boot support stirrups. This allows access to the rectum in cases requiring EEA stapler insertion for anastomosis. Alternatively, supine positioning may be appropriate if no mass is palpable by rectovaginal examination. In such cases, if a mass is more proximally located, low rectal anastomosis can be performed entirely within the pelvis.

□ **Abdominal Entry.** A midline vertical incision provides generous operating space and upper abdominal access. This is preferable if low rectal anastomosis is anticipated because the descending colon may need to be mobilized around and beyond the splenic flexure of the colon. Transverse incisions often fail to provide sufficient exposure.

□ **Exploration.** A surgeon first explores the entire abdomen to determine if disease is resectable. If not, then the procedure's benefit is reevaluated. On occasion, imminent bowel obstruction, infection, or other clinical circumstances may dictate resection regardless of residual tumor. The pelvis and rectosigmoid are palpated to mentally plan for the resection and determine whether en bloc pelvic resection or an exenterative procedure is indicated.

□ **Visualization.** The bowel is packed into the upper abdomen, and retractor blades are positioned to allow access to the deep pelvis and the entire rectosigmoid colon. Ureters are identified at the pelvic brim and are held laterally on Penrose drains to expose the peritoneum and mesentery that can next be safely dissected.

FIGURE 46-21.1 Dividing the proximal end.

### □ Dividing the Proximal Sigmoid Colon.

The sigmoid colon is held on traction proximal to the tumor and in the approximate area where it will be divided. The ureter is located, and a right-angle clamp is used to guide superficial electro-surgical blade dissection of the peritoneum and mesentery up to the bowel serosa. A similar dissection is repeated on the other side. Blunt dissection may then be performed to define the entire circumference of the sigmoid colon. Epiploica and adjacent fatty tissue are held with DeBakey forceps and dissected away with an electro-surgical blade from the proposed area of transection. The GIA stapler is placed across the sigmoid colon, fired, and removed (Fig. 46-21.1).

### □ Dividing the Mesentery.

Occasionally, the tumor is small and superficially located, requiring only a wedge resection of underlying mesentery to remove it with the bowel segment. More frequently, the entire mesentery needs to be divided to provide access to the avascular plane between the rectosigmoid and the sacrum (retrorectal space). For this, a right-angle clamp is placed through sections of the mesentery, and an LDS device or electrothermal bipolar coagulator divides this tissue. Dissection is continued caudally to divide the mesentery (Fig. 46-21.2). Typically, one or more pedicles will have a blood vessel that slips out and requires clamping with a right-angle clamp and ligation with 0-gauge delayed-absorbable suture.

Blunt dissection is performed in the pelvic midline to identify the large superior rectal vessels, which are branches of the inferior mesenteric artery. The artery and vein are large and are separately doubly clamped, cut, and ligated with 0-gauge delayed-absorbable suture. From this midline, dissection then progresses laterally on both sides until no tissue is visible between the ureters. The common iliac artery bifurcation and sacrum are entirely visible.

□ **Dividing the Rectum.** The proximal sigmoid colon and attached mesentery are repacked into the upper abdomen to improve pelvic exposure. The rectosigmoid is held superiorly, and blunt dissection is performed caudally in the retrorectal space to mobilize the distal bowel beyond the tumor to define the location of planned resection. The ureters are traced along the pelvic sidewall. Lateral blunt dissection is performed to further mobilize the rectosigmoid. Lateral mesenteric attachments are isolated and divided with an LDS device or electrothermal bipolar coagulator or are grasped between Pean clamps, cut, and ligated. Self-retaining retractor blades may require repositioning as dissection proceeds more distally.

The anterior bowel serosa is generally visible throughout its course beyond the peritoneal

FIGURE 46-21.2 Dividing the distal end.

reflection and into the levator muscles. Lateral and posterior bowel margins are surrounded by fatty tissue, mesentery, and rectal pillars. The distal rectum beyond the tumor is grasped and rotated to aid exposure of these attachments. Attachments are divided using alternating electro-surgical blade dissection and vascular pedicle division and/or right-angle clamping and transection. Division continues circumferentially until the rectal serosa is entirely visible.

The curved cutter stapler (Contour) is a good choice for the limited space of the deep pelvis. The rectosigmoid is held on traction, while the stapler is gently inserted into the pel-

vis around the rectal segment. The ureters and any lateral tissue are pushed safely away, the stapler is fired, and the low anterior resection specimen is removed (see Fig. 46-21.2). The pelvis is irrigated, and a laparotomy sponge is left in place to tamponade any surface oozing.

□ **Mobilization.** The final decision is now made to perform an anastomosis instead of an end sigmoid colostomy. The upper abdominal retractors are removed, and the proximal sigmoid colon is mobilized by incising peritoneum along the white line of Toldt toward and/or around the splenic flexure (Fig. 46-21.3). A combination of electro-surgical

FIGURE 46-21.3 Mobilizing the descending colon.

**FIGURE 46-21.4** Performing end-to-end anastomosis. Inset: The EEA stapler device head.

blade and blunt dissection is typically used. The proximal sigmoid colon is intermittently placed into the deep pelvis to assess the extent of further dissection needed to achieve a tension-free anastomosis. Ideally, the proximal sigmoid colon sits comfortably on top of the distal rectum. To achieve this, mobilization may encompass the entire splenic flexure of the colon. Occasionally, the hepatic flexure may also need to be mobilized. Sufficient mobility is critical to ensure a tension-free anastomosis.

#### □ Preparing the Anastomotic Sites.

The proximal and distal stapled bowel ends now must be cleared of fatty tissue or epiploica to allow sufficient mucosa-to-mucosa contact during anastomosis. The staple line of the proximal sigmoid colon is grasped with two Allis clamps at the lateral edges and elevated. Adson forceps are used to delicately place any surrounding fatty tissue on traction, and an electrocautery blade is used to dissect these away from the bowel serosa. This can be particularly difficult in patients with prominent diverticulosis. A similar dissection may also be required on the distal rectal segment.

□ **Placing the Anvil.** The largest possible EEA circular stapler that will fit the bowel segments, typically the 31-mm size, is used. This provides a commodious anastomosis that will lessen the chances of symptomatic rectal stenosis. The proximal sigmoid colon is again held with Allis clamps, and scissors are used to remove the entire staple line. The Allis clamps are replaced to grasp the mucosa/serosa and hold open the proximal sigmoid colon. Sizing instruments may be used if necessary to decide which EEA instrument is best. The EEA device contains

an anvil that will be placed in the proximal bowel and a stapler that is placed in the distal bowel. Articulation of the anvil and stapler head allows firing of a staple ring at this articulation site to form the anastomosis.

First, the anvil is detached from the stapler, lubricated, and gently inserted by rotating it into the proximal sigmoid colon. Its concave surface faces proximally, away from the anticipated anastomotic site (Fig. 46-21.4 inset). Sequential stitches that pierce through bowel serosa, muscularis, and mucosa create a purse string around the anvil. These “through-and-through” stitches using 2–0 Prolene suture are placed 5 to 7 mm from the mucosal edge. The purse string begins and ends on the outside of the bowel serosa around the anvil spike and is then tied securely. Allis clamps are removed. A quicker alternative is to use a stapler purse-string suture device. Irrigation may be performed if bowel contents have spilled.

⑩ **Placing the Stapler.** The distal rectal stump is reexamined to ensure that all surrounding fatty tissue has been dissected free. The surgical team then reviews the details of using an EEA instrument. A phantom application is helpful. After this, the shaft of the stapler is extended and its spike is attached. The shaft and spike are then retracted into the instrument. The EEA is lubricated and gently inserted into the anus until the circular outline is visible and seen to be gently pressing on the rectal staple line. A wing nut located on the device handle is gently rotated, and this extends the shaft and its spike. This is guided by the abdominal surgeon so that the spike is brought out just posterior to the staple midline. In the abdomen, gentle countertraction against the rectum may be helpful as the sharp

spike tip pops through the entire bowel wall thickness. The shaft subsequently becomes visible and the spike is removed.

⑪ **Stapling.** The abdominal surgeon lowers the proximal sigmoid colon to the distal rectum and connects the hollow tip of the anvil into the metal shaft of the EEA. An audible “click” should be heard to confirm articulation. The tip of the EEA is held perfectly still, while the wing nut is again rotated to retract the shaft back into the EEA until the handle indicator is in the correct position. This draws the anvil into apposition with the stapler head. The safety is released, and the instrument is fired by squeezing and depressing the handles completely. Incomplete squeezing can result in partial stapling. The wing nut is then turned to the specified position to release the staple line. The EEA with its attached anvil is then gently rotated and slowly removed from the rectum. The anastomosis is visualized by the abdominal surgeon throughout the process. Distal retraction of the anastomosis or inability to remove the EEA suggests that the stapler was not completely fired. This situation may be salvaged by gently pulling the EEA through the anus and cutting inside the staple line to release the anastomosis. The anvil is removed from the EEA instrument and inspected to confirm that two completely intact circular “donuts” of rectal tissue are present.

⑫ **Rectal Insufflation.** Warmed saline is irrigated into the pelvis. The integrity of the anastomosis may now be checked by gently inserting a proctoscope or red rubber catheter into the anus, but distal to the anastomosis. Air is then insufflated into the bowel. The abdominal surgeon gently palpates the sigmoid colon to make certain that air is

**FIGURE 46-21.5** Testing the anastomosis.

entering the sigmoid colon proximal to the anastomotic site. No air bubbles are visible if the connection is watertight (Fig. 46-21.5). The appearance of bubbles suggests a leak, but this should be double-checked for authenticity. Occasionally, air is being erroneously pumped into the vagina rather than the rectum due to incorrect placement of the red rubber catheter. If there is any valid suspicion for a leak, the distal rectum should be divided again and the anastomosis redone. Reinforcing interrupted suture to close the

air leak may be attempted in select situations, but this is riskier. Diverting colostomy may also be considered if the problem cannot otherwise be managed.

**14 Final Steps.** All pedicle sites are rechecked for hemostasis, and the pelvis is irrigated. Nasogastric suction is not routinely required. In addition, prophylactic suction drainage of the pelvis does not improve outcome or influence the severity of complications (Merad, 1999).

## POSTOPERATIVE

The most common early postoperative complications are similar to those for other major abdominal operations and include fever, self-limiting ileus, wound separation, and anemia requiring transfusion. Serious events such as bowel obstruction and fistula develop infrequently (Gillette-Cloven, 2001). Long-term, some patients will have a poor functional result, including fecal incontinence or chronic constipation (Rasmussen, 2003).

Low rectal anastomoses have much higher intraperitoneal leakage rates than large bowel anastomoses. Leakage of stool leads to fever, leukocytosis, lower abdominal pain, and ileus. These should prompt abdominopelvic CT imaging with oral contrast. If a leak is present, it may appear as a pelvic abscess, or at times, contrast extravasation can be demonstrated into the fluid collection. Occasionally, this complication can be successfully managed with percutaneous drainage of the abscess, bowel rest, and broad-spectrum antibiotics. Otherwise, a temporary diverting loop ileostomy or colostomy may be required (Mourton, 2005). Risk factors for postoperative leakage include previous pelvic irradiation, diabetes mellitus, low preoperative serum albumin, long surgical duration, and a low anastomosis ( $\leq 6$  cm from the anal verge) (Matthiessen, 2004; Mirhashemi, 2000; Richardson, 2006).

## 46-22

## Intestinal Bypass

This bowel anastomotic procedure typically connects a section of the ileum to the ascending or transverse colon and thereby “bypasses” a portion of diseased bowel. Following anastomosis, the closed, bypassed small-bowel segment remains.

There are relatively few indications for intestinal bypass in gynecologic oncology, and this procedure accounts for less than 5 percent of all bowel operations performed for these cancers (Barnhill, 1991; Winter, 2003). In all circumstances, removal of diseased bowel and end-to-end anastomosis is preferable. However, some patients will have unresectable tumor, dense adhesions, extensive radiation injury, or other prohibitive factors. In these cases, a poor decision to proceed with an aggressive dissection can result in numerous enterotomies, hemorrhage, or other intraoperative catastrophes with major postoperative sequelae. Instead, an intestinal bypass can often quickly be performed with minimal morbidity. Many times a bypass is selected because it is the easiest palliative maneuver for a terminally ill patient. The main purpose is to relieve an obstruction, reestablish an adequate bowel communication, and restore the patient’s ability to take oral nourishment.

## PREOPERATIVE

## ■ Patient Evaluation

The intestinal tract is evaluated by CT scanning. Invariably, pelvic radiation injuries are located at the terminal ileum, but there may be complex fistulas or multiple sites of obstruction to be addressed. In most circumstances in which a bypass is considered, a surgeon should anticipate limitations in adequately exploring the abdomen intraoperatively. Careful analysis of preoperative findings will help ensure that bypass encompasses the entire lesion and does not leave a distal obstruction.

## ■ Consent

Patients usually have a miserable quality of life when bypass is considered, and the operation’s goal is mainly to improve patient symptoms. The counseling process should emphasize that intraoperative judgment will dictate whether a small bowel resection, ileostomy, large bowel resection, colostomy, or bypass is indicated. Many risks are similar to those of other intestinal surgical procedures and include anastomotic leaks, obstruction, abscess formation, and fistula. Blind loop syndrome, discussed

FIGURE 46-22.1 Aligning the bowel.

later, is one long-term complication that is specific to the bypass procedure.

## ■ Patient Preparation

Aggressive bowel preparation with oral agents is usually contraindicated due to bowel obstruction or other dire circumstances. Broad-spectrum antibiotics are given perioperatively due to the possibility of stool contamination, and VTE prophylaxis is provided. If a prolonged recovery is anticipated, postoperative TPN is considered.

## INTRAOPERATIVE

## ■ Instruments

To prepare for complicated resections, bowel staplers such as an end-to-end anastomosis (EEA), gastrointestinal anastomosis (GIA), and transverse anastomosis (TA) staplers should be available.

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Bypass is performed under general anesthesia with the patient positioned supine. Prior to surgery, the abdomen is surgically prepared, and a Foley catheter is inserted.

□ **Abdominal Entry and Exploration.** Colostomy generally requires a midline vertical incision for adequate exposure. A surgeon first explores the entire abdomen to identify bowel lesions. In addition, the remaining bowel is examined to exclude other obstructive sites. Healthy-appearing bowel proximal and distal to the lesion is selected with the intent of preserving the maximal amount of intestine. Typically, the bypass will entail

connecting a section of the ileum to the ascending or transverse colon.

□ **Aligning the Bowel.** The two bowel segments selected for the anastomosis are aligned side-to-side without tension or twisting. The hepatic or splenic flexure of the transverse colon may require mobilization from its peritoneal attachments to achieve a tension-free connection. The antimesenteric borders of the bowel segments are held in position by 2–0 silk stay sutures that are placed approximately 6 cm apart along the length of the aligned bowel segments. Two Adson forceps are used to hold up the small-bowel serosa laterally and transversely on traction. An electro-surgical blade is used to enter the small bowel lumen on its antimesenteric surface (Fig. 46-22.1). The same maneuver is performed on the teniae coli to enter the colon.

□ **Performing the Side-to-Side Anastomosis.** One fork of the GIA stapler is inserted into each bowel segment lumen. The bowel is adjusted, if necessary, to position the antimesenteric surfaces between the stapler forks. The stapler is then closed and fired (Fig. 46-22.2). With stapling, the initial small bowel openings that were cut to admit the stapler forks are fused into one open defect. This opening can be closed with the TA stapler and the excess bowel trimmed. As a result this TA staple line, the diseased bowel loop is also simultaneously sealed.

□ **Final Steps.** Occasionally, small bleeding sites on the staple line will need spot electro-surgical coagulation. The anastomosis is also palpated to verify an adequate lumen. The bowel is reexamined to make certain that the connection is watertight and that there is no tension on the anastomosis.

**FIGURE 46-22.2** Performing side-to-side anastomosis.

### POSTOPERATIVE

Recovery after bypass surgery should be rapid compared with that following a large resection with anastomosis. In general, postoperative ileus will resolve in several days,

and patients may begin oral alimentation. The underlying clinical situation prompting the need for bypass surgery will dictate most of the clinical course. Relatively minor complications such as febrile morbidity and wound infection or wound separation occur

commonly. Fistulas, obstruction, anastomotic leaks, abscesses, peritonitis, and perforation are more difficult to manage and often lead to a prolonged postoperative course or death.

Blind loop syndrome is a condition of vitamin B<sub>12</sub> malabsorption, steatorrhea, and bacterial overgrowth of the small intestine. The usual scenario is a bypass procedure that leaves a segment of nonfunctional, severely irradiated bowel behind. Stasis of the intestinal contents leads to dilatation and mucosal inflammation. Symptoms resemble a partial small bowel obstruction and include nausea, vomiting, diarrhea, abdominal distention, and pain. Bowel perforation is possible. Antibiotics will often alleviate the condition, but recolonization and resumption of the blind loop syndrome is common (Swan, 1974). The only definitive therapy for recurrent episodes is exploration with resection of the bypassed segment. To avoid this syndrome, a surgeon may still perform the side-to-side anastomosis. But, the closed loop can be relieved by creation of a mucus fistula at the abdominal wall.

## 46-23

## Appendectomy

Removal of the appendix may be indicated during gynecologic surgery for various reasons. The need, however, is commonly not recognized until an operation is already underway, as signs and symptoms of benign gynecologic conditions can mimic appendicitis (Bowling, 2006; Fayez, 1995; Stefanidis, 1999).

In addition, malignancies may involve the appendix. Ovarian cancer frequently metastasizes to the appendix, which thereby often warrants removal (Ayhan, 2005). Primary tumors of the appendix are rare but commonly metastasize to the ovaries. Thus, the initial surgical intervention is often performed by a gynecologic oncologist (Dietrich, 2007). Pseudomyxoma peritonei is the classic type of mucinous tumor of appendiceal origin that spreads to the ovaries and may implant throughout the abdomen (Prayson, 1994).

Elective coincidental appendectomy is defined as the removal of an appendix at the time of another surgical procedure unrelated to appreciable appendiceal pathology. Possible benefits include preventing a future emergency appendectomy and excluding appendicitis in patients with chronic pelvic pain or endometriosis. Other groups that may benefit include women in whom pelvic or abdominal radiation or chemotherapy is anticipated, women undergoing extensive pelvic or abdominal surgery in which major adhesions are anticipated postoperatively, and patients such as the developmentally disabled in whom making the diagnosis of appendicitis may be difficult because of diminished ability to perceive or communicate symptoms (American College of Obstetricians and Gynecologists, 2014).

## PREOPERATIVE

Specific preoperative tests or preparations are not required prior to appendectomy. In general, the consenting process for gynecologic surgery includes a discussion of possible “other indicated procedures” such as appendectomy when anticipated intraoperative findings and the potential for performing an appendectomy are uncertain.

Most studies suggest that there is, at most, a small increased risk of nonfatal complications associated with elective coincidental appendectomy at the time of gynecologic surgery, whether performed during laparotomy or during laparoscopy (Salom, 2003). Hematoma formation at the mesoappendix may cause an ileus or partial small bowel obstruction. Perforation of the stump is rare and typically follows insecure suture placement.

## INTRAOPERATIVE

## Surgical Steps

□ **Anesthesia and Patient Positioning.** Appendectomy is performed under general anesthesia in a supine position. Postoperative hospitalization is individualized and is dependent on concurrent surgeries and associated clinical symptoms.

□ **Abdominal Entry.** Appendectomy can be performed through almost any incision. A laparoscopic approach or an oblique McBurney incision in the right lower quadrant of the abdomen is traditionally selected for appendectomy. However, in gynecologic cases, the needs of planned concurrent procedures will commonly dictate incision choice.

□ **Locating the Appendix.** The appendix is located by first grasping the cecum and gently elevating it upward into the incision. Insertion of the terminal ileum should be visible, and the appendix is typically obvious at this point. Infrequently, an appendix is retrocecal or otherwise difficult to identify. In this situation, the convergence of the three teniae coli can be followed to locate the appendiceal base.

□ **Mesoappendix Division.** The appendix tip is elevated with a Babcock clamp, and the cecum is held laterally to place the mesoappendix on gentle traction. The appendiceal artery is usually very difficult to distinguish reliably due to abundant surrounding fatty tissue. Thus, curved hemostats are used to successively clamp the mesoappendix and its vessels to reach the appendiceal base (Fig. 46-23.1).

The first hemostat is placed horizontally—aiming directly toward the base of the appendix. The second hemostat is placed at a 30-degree angle so that the tips meet, but Metzenbaum scissors have room to cut between the two clamps. The mesoappendix pedicle is ligated with 3–0 gauge delayed-absorbable suture. This step is typically repeated once or twice to comfortably reach the base of the appendix. An alternative is to use an electrothermal bipolar coagulator (LigaSure) to divide the mesoappendix.

□ **Appendix Ligation.** At this point, the appendix has been completely isolated from the mesoappendix and is still held vertically by a Babcock clamp. A first hemostat is placed at the appendiceal base, and a second is positioned directly above (Fig. 46-23.2). A third hemostat is closed with a few millimeters of intervening tissue to allow for passage of a knife blade. The knife then cuts between

FIGURE 46-23.1 Clamping the mesoappendix.

FIGURE 46-23.2 Ligation of the appendix.

the second and third clamps, and the appendix is removed. The contaminated knife and appendix are then handed off the field.

A 2–0 silk suture is tied beneath the first hemostat as that clamp is slowly removed. A separate suture is then tied underneath the second hemostat for added security of the appendiceal stump. Gentle electrochemical

coagulation at the stump surface may also be performed.

□ **Final Steps.** There is no need to invert the stump or to place a purse-string suture around it. The cecum may be returned to the abdomen, and remaining concurrent surgeries completed.

## POSTOPERATIVE

Patient care postoperatively is dictated by other surgeries performed. Delayed initiation of oral intake or administration of additional antibiotics is not required for appendectomy alone.

## 46-24

## Skinning Vulvectomy

The term *skinning vulvectomy* implies a wide, superficial resection that encompasses both sides of the vulva, that is, a complete simple vulvectomy. The surgical procedure is straightforward and removes the entire lesion. It is distinguished from a *radical complete vulvectomy* in that skinning vulvectomy removes only the squamous epithelium and dermis and preserves the subcutaneous fat and deeper tissues. A less extensive, unilateral procedure is better referred to as a *wide local excision* or *partial simple vulvectomy* (Section 43-28, p. 995).

The usual indication for skinning vulvectomy is a woman with confluent, bilateral vulvar intraepithelial neoplasia (VIN) 2 to 3 who is not a candidate for directed ablation with carbon dioxide (CO<sub>2</sub>) laser or cavitation ultrasonic surgical aspirator (CUSA) (Section 43-28, p. 996). Fortunately, individuals with such extensive VIN are infrequently encountered. Paget disease without underlying adenocarcinoma and vulvar dys-trophies refractory to standard therapy are other rare indications (Ayhan, 1998; Curtin, 1990; Rettenmaier, 1985).

Despite its less radical resection, skinning vulvectomy can still be disfiguring and psychologically devastating. In addition, the defect is often large and cannot be closed primarily without a split-thickness skin graft (STSG) or other type of flap (Section 46-28, p. 1219).

## PREOPERATIVE

## ■ Patient Evaluation

Colposcopy with directed diagnostic biopsy is required to exclude a squamous lesion with invasion, which would warrant a more radical procedure. Familiarity with an array of possible STSGs or flaps is crucial to planning the operation in the event primary closure is not possible.

## ■ Consent

Patients are informed that other more limited treatment options either have been exhausted or are inappropriate. The surgery may result in significant sexual changes, which may be permanent. Accordingly, surgeons emphasize that all efforts will be made to restore a functional, normal-appearing vulva. Fortunately, most physical complications are minor and include cellulitis or partial wound dehiscence.

FIGURE 46-24.1 Marking the incisions.

## ■ Patient Preparation

Complete bowel preparation is influenced by surgeon preference and only indicated if perianal skin is to be excised. In these cases, bowel preparation may minimize fecal soiling and permit initial wound healing prior to the first stool. Otherwise, enemas are sufficient. Antibiotics and VTE prophylaxis are typically given. Grafts are typically taken from the upper thigh, and donor site selection for STSG is described in Section 46-28 (p. 1219).

## INTRAOPERATIVE

## ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Regional or general anesthesia is generally required. The patient is placed in standard lithotomy position, and adjustments provide access to the entire lesion. Vulvar hair should be clipped. Intraoperative colposcopy may be needed to better delineate VIN lesion margins.

□ **Skin Incision.** The inner and outer incision lines are drawn to encompass the disease with margins of at least a few millimeters (Fig. 46-24.1). As an overview, once final markings are placed, the skin is dissected off one side of the vulva. The skin on the opposite side of the vulva is then removed, and the bridging skin overlying the perineal body is excised last. In performing this, the clitoris may be spared in many cases by making a horseshoe-shaped incision (as shown).

To begin, if preserving the clitoris, the outer incision is started on one side of the

vulva at the anterolateral margin of the clitoris and is continued inferiorly along the length of the labium majus at least halfway to the perineal body. The inner incision on that same side of the vulva is then also taken through the full skin thickness to the same inferior halfway point. Incising the skin in stages reduces blood loss.

□ **Beginning the Dissection.** The specimen edge may then be reflected with an Allis clamp to provide traction as the avascular plane underneath the skin is dissected from the subcutaneous fatty tissue (Fig. 46-24.2). When the anterior skin edge is large enough, a hand is placed underneath to reflect the specimen more firmly and guide dissection inferiorly. The outer and inner skin incision is then extended on that same side downward toward the perineal body. Electrosurgical coagulation is used to achieve hemostasis before repeating the process on the contralateral side.

□ **Removal of the Specimen.** The left and right outer skin incisions are joined in the midline superficial to the perineal body. The posterior vulvar tissue is held with an Allis clamp to provide traction for upward dissection toward the inner incision. The inner incision is made sufficiently proximal to encompass disease. This portion of the skinning vulvectomy is typically performed last because an avascular tissue plane superficial to the subcutaneous tissue is absent, and bleeding can be brisk. The specimen can be removed following detachment from the inner incision.

**FIGURE 46-24.2** Performing the dissection.

**FIGURE 46-24.3** Primary closure.

The skinning vulvectomy specimen is carefully examined to grossly determine margins. A frozen section may be warranted if close VIN margins are suspected, to determine if more tissue requires excision. However, the margins of vulvar Paget disease cannot reliably be judged visually or by frozen-section analysis (Fishman, 1995). A stitch is placed on the specimen and noted on the pathology requisition form to orient the pathologist.

□ **Closure of the Defect.** A dry laparotomy pad is held against the vulvar defect and slowly rolled downward to halt surface bleeding and aid meticulous electro-surgical

coagulation of vessels. The operative site is irrigated and assessed.

If the width of the defect is sufficiently narrow to permit primary closure, the surrounding tissue is mobilized. Lateral undermining may be particularly useful for a tension-free closure. Typically, 0 or 2-0 gauge delayed-absorbable vertical mattress sutures are then placed circumferentially with the knots laterally positioned (Fig. 46-24.3). However, if a split-thickness skin graft is required, the graft is now harvested and placed as described on page 1219.

□ **Final Steps.** A CO<sub>2</sub> laser may be used to vaporize multifocal lesions outside the

operative field. This is described in Section 43-28 (p. 997).

### POSTOPERATIVE

If a primary closure is performed, postoperative care is essentially the same as described for patients undergoing radical partial vulvectomy (p. 1212). Long-term surveillance is mandatory regardless of margin status to identify recurrent or de novo sites of preinvasive disease. The Foley catheter can be removed without regard to urine spill unless a graft is placed or the patient is otherwise immobile.

## 46-25

## Radical Partial Vulvectomy

For vulvar cancer, to reduce the high morbidity associated with radical complete vulvectomy yet avoid sacrificing a cure, a less extensive resection may be used. Patients with well-localized, unifocal, clinical stage I invasive lesions are ideal candidates (Stehman, 1992). *Radical partial vulvectomy* is a somewhat ambiguously defined operation that generally refers to complete removal of the tumor-containing portion of the vulva, wherever it is located, with 1- to 2-cm skin margins and excision to the perineal membrane (Whitney, 2010). *Radical hemivulvectomy* refers to a larger resection that may be anterior, posterior, right, or left. Vulvectomy is typically performed concurrently with inguinofemoral lymphadenectomy to add prognostic information. However, in those with microinvasive disease undergoing wide local excision or skinning vulvectomy, lymphadenectomy is not required.

The chief concern in performing a less extensive operation for vulvar cancer is the possibility of an increased risk of local recurrence due to multifocal disease. However, survival after partial or complete radical vulvectomy is comparable if negative margins are obtained (Chan, 2007; Landrum, 2007; Scheistroen, 2002; Tantipalakorn, 2009). Following radical partial vulvectomy, 10 percent of patients will develop a recurrence on the ipsilateral vulva, and this may be treated by reexcision (Desimone, 2007).

### PREOPERATIVE

#### ■ Patient Evaluation

Biopsy confirmation of invasive cancer is mandatory. An isolated squamous lesion

with less than 1 mm of invasion, that is, microinvasion, may be adequately managed with only wide local excision (Section 43-28, p. 995). Multiple microinvasive lesions may require skinning vulvectomy (p. 1208). In general, patients undergoing radical partial vulvectomy do not require reconstructive grafts or flaps to cover operative defects.

#### ■ Consent

Morbidity after radical vulvar surgery is common. Wound separation or cellulitis develops frequently. Long-term changes may include displacement of the urine stream, dyspareunia, vulvar pain, and sexual dysfunction. Surgeons should be sensitive to these possible sequelae and counsel patients appropriately, emphasizing the curative intent and limited scope of the operation.

#### ■ Patient Preparation

Bowel preparation is influenced by surgeon preference and may be indicated with posteriorly located resections. In such instances, bowel preparation may minimize fecal soiling and permit initial wound healing prior to the first stool. Antibiotics and VTE prophylaxis are typically given prior to incision (Tables 39-6 and 39-8, p. 835).

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** Radical partial vulvectomy has been performed under local anesthesia combined with sedation in medically compromised patients (Manahan, 1997). However, regional or general anesthesia is typically required.

Inguinal lymphadenectomy (p. 1216) is typically performed before vulvar resection. Patients may then be repositioned to

standard lithotomy position to provide full exposure to the vulva. The vulva is surgically prepared, and a Foley catheter is inserted.

□ **Radical Partial Vulvectomy: Variations.** The area of tissue to be removed when radically excising a small cancer depends on the size and location of the tumor. In [Figure 46-25.1](#), the dotted line indicates a planned skin incision for: (A) a 1-cm right labium majus tumor with 2-cm margins, (B) a 2.5-cm periclitoral tumor necessitating anterior hemivulvectomy, and (C) a 2.5-cm midline posterior fourchette tumor requiring posterior hemivulvectomy.

□ **Right Hemivulvectomy: Making the Lateral Incision.** The planned excision is drawn on the vulva with a surgical marking pen to provide 2-cm margins ([Fig. 46-25.2](#)). Tapering the incision anteriorly and posteriorly will aid in a tension-free closure. The lateral skin incision is made with a knife (no. 15 blade) into the subcutaneous fat. Forceps are used to place the skin edges on traction and aid electrosurgical dissection downward until reaching the perineal membrane ([Fig. 46-25.3](#)). An index finger can then be used to develop the plane between the fat pad of the labium majus and the subcutaneous tissue of the lateral thigh.

□ **Right Hemivulvectomy: Completing the Resection.** Tissue medial to this lateral resection border is next mobilized medially by blunt and electrosurgical dissection along the perineal membrane. The skin edge of the specimen is then placed on lateral traction, and the medial (vaginal mucosa) incision is incised from anterior to posterior. The labial fat pad is transected anteriorly, and the entire radical right hemivulvectomy specimen is placed on downward traction to aid final dissection along the mucosal incision in an anterior-to-posterior direction ([Fig. 46-25.4](#)). Notably, the vascular vestibular bulb is

**FIGURE 46-25.1** Radical partial vulvectomy: variations.

**FIGURE 46-25.2** Right hemivulvectomy: outlining the skin incision.

**FIGURE 46-25.3** Right hemivulvectomy: lateral dissection to the fascia lata.

typically encountered as the posterior resection is completed. Suture ligation of bleeding sites is often required.

After completed resection, the specimen is examined to ensure adequate margins. It is marked at 12 o'clock with an orienting stitch, and this is noted on the pathology requisition form.

□ **Right Hemivulvectomy: Defect Closure.** A gauze sponge may be held firmly in the cavity and rolled downward to guide the electrosurgical blade in achieving hemostasis. The defect can then be irrigated and evaluated to determine requirement for a tension-free closure while minimizing anatomic distortion (Fig. 46-25.5). Several pedicles are visible, particularly at the

vaginal margin, where vessels were clamped and tied.

In general, lateral undermining of the subcutaneous tissue will provide sufficient mobility to allow primary closure. Interrupted 0-gauge delayed-absorbable suture is used to create a layered reapproximation of deeper tissues. Interrupted vertical mattress sutures, often alternating 0 and 2-0 gauge suture, with knots placed laterally are used to close the skin (Fig. 46-25.6).

□ **Anterior Hemivulvectomy.** This variation requires removal of the clitoris and partial resection of the labia minora, labia majora, and mons pubis. The most anterior portion of the incision is first created on the mons and carried down to the pubic symphysis. The

specimen is reflected posteriorly to guide dissection. In the midline, the clitoral vessels are separately clamped, divided, and ligated with 0-gauge delayed-absorbable suture.

The posterior incision is made above the urethral meatus, and careful attention to Foley catheter location helps avoid urethral injury. Layers of interrupted 0-gauge delayed-absorbable sutures are used to reapproximate deep tissue. Then, 3-0 gauge absorbable suture is used to close the defect in a direction that places the least tension on the suture line. Usually, the area surrounding the urethral meatus is left to granulate secondarily.

□ **Partial Urethral Resection (Optional).** If an anterior lesion encroaches on the urethral meatus, then a distal urethrectomy may be required to achieve a negative margin. Prior to this, the radical partial vulvectomy should otherwise be almost entirely completed. The

**FIGURE 46-25.4** Right hemivulvectomy: removal of the specimen.

**FIGURE 46-25.5** Right hemivulvectomy: evaluation of the surgical defect.

**FIGURE 46-25.6** Right hemivulvectomy: closure of the surgical defect.

urethra may be transected anywhere distal to the pubic arch. For this, the meatus is held with an Allis clamp, and the specimen placed on traction. The posterior urethra is incised with a knife, and the underlying uroepithelium and mucosa are sewn jointly to the adjacent vestibule skin at the 6 o'clock position with 4-0 gauge delayed-absorbable suture. The urethral incision is extended laterally, followed by additional sutures at 3 and 9 o'clock. The Foley balloon is deflated and removed from the bladder. Transection is completed, and a final stitch is placed at 12 o'clock. The Foley catheter is then replaced. Alternatively, the surgeon may forgo stitch placement altogether and allow the meatus to heal by secondary intent. Although urethral plication may be indicated in selected cases, resection of 1 to 1.5 cm of the distal urethra does not ordinarily result in a significant increase in urinary incontinence (de Mooij, 2007).

□ **Posterior Hemivulvectomy.** This variation entails removal of a portion of the labia majora, Bartholin glands, and upper perineal body. It is generally necessary to compromise the deep margin in this resection because of proximity to the anal sphincter and rectum.

The skin is first incised posteriorly, and a finger is placed into the rectum to guide proximal dissection. The specimen is gradually retracted upward off the sphincter. From the midline, dissection then proceeds laterally on each side until the anterior margin at the introitus can be incised to complete the resection. The perineal body is reinforced with interrupted sutures of 0-gauge delayed-absorbable material to provide bulk and to allow reapproximation of skin edges for a tension-free closure. Rectal examination is performed at the end of surgery to confirm the absence of palpable stitches or stenosis. Incontinence of flatus or stool may develop postoperatively despite efforts to preserve the sphincter.

□ **Final Steps.** Suction drains are not typically required but are at least considered in some circumstances. Copious irrigation is indicated at various times during closure of the defect to minimize postoperative infection. No formal dressing is applied. However, fluffed-out gauze may be placed at the perineum and held in place with mesh underwear to tamponade any subcutaneous bleeding and to promote a clean and dry operative site in the immediate postoperative period.

## POSTOPERATIVE

Meticulous care of the vulvar wound is mandatory to prevent morbidity. The vulva is kept dry by use of a blow dryer or fan. Within a few days, brief sitz baths or bedside irrigation followed by air drying will help keep the incision clean. Patients are instructed not to wear tight-fitting underwear upon discharge from the hospital. Moreover, instructions encourage loose-fitting gowns to aid healing and efforts to minimize wound tension. For posteriorly located defects near the anus, a low-residue diet and stool softeners will prevent straining and potential perineal incision disruption.

Typically, the Foley catheter is removed postprocedure or at least on postoperative day 1. If a distal urethrectomy was performed or extensive periurethral dissection was required, then the catheter is removed within a few days. This permits tissue swelling and obstructive urinary retention concerns to abate. Early removal prevents ascending urinary infection. If immobility is encouraged to aid reconstructive graft or flap healing, then the timing of catheter removal is individualized. Notably, urine that comes in contact with the vulvar incision during normal voiding is of little clinical concern.

Incision separation is the most common postoperative complication and often will involve only a portion of the incision (Burke, 1995). Stitches are removed as needed and affected portions of the wound are debrided. Efforts to keep the site clean and dry are continued. Granulation tissue will eventually allow healing by secondary intention, but recovery time will be significantly extended. Although negative-pressure wound therapy (wound vacuum-assisted closure) may be practical in rare instances, the location of most defects precludes effective device placement.

Sexual dysfunction may stem from a sense of disfigurement. Scarring may also result in discomfort or altered sensation that lowers a woman's sexual satisfaction. Clinician sensitivity to these concerns enables a dialogue to develop that can lead to possible management options (Janda, 2004).

## 46-26

## Radical Complete Vulvectomy

If cancers are so extensive that no meaningful portion of the vulva can be preserved, radical complete vulvectomy is indicated rather than the more limited radical partial vulvectomy (p. 1210). The operation is typically performed concurrently with bilateral inguino-femoral lymphadenectomy (p. 1216). With the radical complete vulvectomy technique currently used, intact skin bridges remain between the three incisions (vulvectomy incision and two lymphadenectomy incisions) to aid wound healing. Traditionally, the en bloc incision, colloquially termed the *butterfly* or *longhorn* incision, removed these skin bridges and the underlying lymphatic channels that potentially harbored tumor emboli “in transit” between the vulvar tumor and nodes (Gleeson, 1994c). However, such recurrences are rare, and the en bloc technique has been largely abandoned (Rose, 1999). Thus, the three-incision procedure is preferred because survival rates are equivalent and major morbidity is dramatically reduced (Helm, 1992).

Removal of an extensive vulvar lesion with an adequate margin and with resection down to the perineal membrane usually creates a large surgical defect. In some cases, wound margins may be primarily closed without tension by undermining and mobilizing adjacent tissues. On other occasions, a split-thickness skin graft, lateral skin transposition, rhomboid flap, or other reconstructive procedure, described on page 1219, will be indicated to reduce the chances of wound separation.

### PREOPERATIVE

#### ■ Patient Evaluation

Biopsy confirmation of invasive cancer should precede surgery. Depending on the location of the tumor, the clitoris-sparing modification of radical complete vulvectomy is an option (Chan, 2004). Frequently, patients are elderly, obese, or have significant coexisting medical problems that must be considered.

#### ■ Consent

Major morbidity is common soon after radical complete vulvectomy, and partial wound separation or cellulitis occurs frequently. Complete wound breakdown is more problematic, and weeks of aggressive hospital care may be required to promote secondary healing. Premature hospital discharge may result in

poor home wound care, and subsequent tissue necrosis often requires readmission and surgical debridement. Thus, meticulous attention to the wound is critical during patient admission and frequent office visits thereafter.

Long-term changes may include displacement of the urine stream, dyspareunia, vulvodynia, and sexual dysfunction. Accordingly, surgeons counsel on these possible sequelae yet emphasize the curative intent of the operation and the need for adequate tumor-free margins to lessen local recurrence risks.

#### ■ Patient Preparation

Bowel preparation is guided by surgeon preference and may be indicated with posteriorly located lesions. In addition, evaluation of potential graft donor sites is completed. Antibiotics and VTE prophylaxis are typically given prior to initial incision (Tables 39-6 and 39-8, p. 835).

### INTRAOPERATIVE

#### ■ Surgical Steps

##### □ Anesthesia and Patient Positioning.

Regional or general anesthesia is required, and inguino-femoral lymphadenectomy is performed first. The patient is then placed in standard lithotomy position. Exposure and surgical preparation of the operative field is planned to accommodate resection and reconstruction. Sites of potential donor graft harvest are also prepared as described on page 1219.

□ **Planning the Skin Incision.** The medial and lateral incisions are drawn to encompass the tumor and provide a 1- to 2-cm margin around the tumor. The clitoris is included if necessary. Tapering the incision

anteriorly and posteriorly will also aid in a tension-free closure (Fig. 46-26.1).

□ **Anterior Dissection.** The skin incision begins anteriorly with the knife (no. 15 blade) cutting into the subcutaneous fat. The incision is extended downward approximately three quarters of its length. The remainder of the posterior skin incision is completed later to decrease blood loss. Much of the anterior dissection is described in the preceding section on radical partial vulvectomy (Section 46-25, step 6, p. 1211). However, use of the Harmonic scalpel or bipolar electrocoagulation device (LigaSure) in this more extensive resection may decrease operative time and blood loss compared with use of a conventional electrosurgical blade (Pellegrino, 2008).

Briefly, the incision is carried down to the pubic symphysis. The specimen is reflected downward on traction to guide dissection. The vascular base of the clitoris is clamped in the midline, transected, and suture ligated with 0-gauge delayed-absorbable suture (Fig. 46-26.2). Electrosurgical or Harmonic scalpel dissection then proceeds dorsally off the pubic bone until the inner incision line is reached anteriorly. The inner anterior incision is made above the urethral meatus to avoid injury to the urethra unless a distal urethrectomy is required (46-25, step 8, p. 1212).

□ **Lateral Dissection.** Blunt finger dissection is performed to establish a plane lateral to the labial fat pads and at a depth to reach the perineal membrane. The vulvectomy specimen is placed on traction to guide dissection medially to reach the vaginal walls. Along the lower lateral sides of the vagina, the vascular vestibular bulb is encountered. Vessels are divided with the Harmonic scalpel or clamped, cut, and ligated with 0-gauge

FIGURE 46-26.1 Incisions.

FIGURE 46-26.2 Anterior dissection.

delayed-absorbable suture to reduce bleeding (Fig. 46-26.3).

□ **Posterior Dissection.** An outer skin incision is completed inferiorly with a knife as the vulvectomy proceeds posteriorly toward the perineal body. A finger is then placed into the rectum to prevent inadvertent injury, and the specimen is now held upward on traction (Fig. 46-26.4). Electrosurgical dissection along the deep fascia plane extends the outer incisions toward the midline. The dissection continues anteriorly away from the

anus until the inner incision can be made. With this, the entire complete radical vulvectomy specimen is detached.

□ **Evaluating the Specimen.** A stitch is placed at 12 o'clock on the specimen and noted on the laboratory requisition form to orient the pathologist. Skin retraction of the specimen will make it appear narrower and smaller than the defect. However, it is carefully inspected to assess its margins. Additional lateral or medial tissue margins can be separately sent if necessary.

Alternatively, a frozen section analysis can be requested to evaluate an equivocal margin.

□ **Closing the Defect.** The wound is copiously irrigated, and hemostasis is achieved with a combination of electrosurgical coagulation and clamping with suturing. The defect is then evaluated to determine the best method of closure (Fig. 46-26.5). Undermining lateral tissues will aid a tension-free primary closure. Deeper tissues are first reapproximated with 0-gauge delayed-absorbable suture and interrupted stitches. The vulvar skin is then

FIGURE 46-26.3 Medial dissection.

FIGURE 46-26.4 Posterior dissection.

FIGURE 46-26.5 Surgical defect.

**FIGURE 46-26.6** Simple closure.

closed with 0-gauge, or alternating with 2–0 gauge, delayed-absorbable vertical mattress sutures (Fig. 46-26.6). No stitches are placed between the skin and urethra if this

displaces the urethra or creates tension on it. Instead, this area can be allowed to heal secondarily by granulation. If a split-thickness skin graft or flap is required to close the inci-

sion, the graft is now harvested and placed as described on page 1219.

□ **Final Steps.** Suction drains do not prevent wound infection or breakdown but may be considered in some cases if the defect is large (Hopkins, 1993). If primary closure is performed, then fluffed-out gauze may be placed at the perineum and held in place with mesh underwear to keep the operative site clean and dry in the immediate postoperative period.

## POSTOPERATIVE

If a primary closure is performed, postoperative care is essentially the same as described for patients undergoing radical partial vulvectomy (p. 1212). Because of a larger operative defect, the likelihood of morbidity is correspondingly increased. Management of reconstructive grafts and flaps is reviewed on page 1220.

## 46-27

## Inguinofemoral Lymphadenectomy

Vulvar cancer staging is the primary indication for removal of groin nodes. Inguinal metastases are the most significant prognostic factor in vulvar squamous cancer, and their detection will necessitate additional therapy (Chap. 31, p. 682) (Homesley, 1991). Occasionally, in patients with ovarian or uterine cancer, suspicion of inguinal metastases will prompt removal.

In general, lymphatic drainage from the vulva rarely bypasses the superficial nodes. Thus, a superficial node dissection is integral. These lymph nodes lie within the fatty tissue along the saphenous, superficial external pudendal, superficial circumflex iliac, and superficial epigastric veins. After superficial nodes are addressed, deep nodes may be removed. These nodes are consistently located just medial and parallel to the femoral vein within the fossa ovalis. To reach these, cribriform fascia preservation is recommended to avoid major morbidity (Bell, 2000).

Generally, for patients with unilateral lesions distant from the midline, ipsilateral lymphadenectomy is usually sufficient (Gonzalez Bosquet, 2007). For bilateral lesions or those that encroach on the midline, bilateral lymphadenectomy is indicated.

Sentinel lymph node mapping is a promising modality that has demonstrated great potential in reducing the radicality of detecting inguinal metastases (Van der Zee, 2008). This minimally invasive strategy is emerging as the future standard for vulvar cancer staging and is described in Chapter 31 (p. 686).

### PREOPERATIVE

#### ■ Patient Evaluation

Clinical palpation is not an accurate means of evaluating the groin nodes (Homesley, 1993). MR imaging and PET scanning are also relatively insensitive (Bipat, 2006; Cohn, 2002; Gaarenstroom, 2003). Fixed, large, clinically obvious groin metastases that appear unresectable are treated preoperatively with radiation before attempting removal.

#### ■ Consent

Patients should understand the need for unilateral or bilateral groin dissection and its relationship to their cancer treatment. They should be prepared for a potentially several-week recovery in which postoperative complications are

common and may include cellulitis, wound breakdown, chronic lymphedema, and lymphocyst formation. These events may develop within a few days, several months, or even years later. In contrast, intraoperative complications are less common, and hemorrhage from the femoral vessels is rarely encountered.

#### ■ Patient Preparation

When both groins are dissected, a two-team approach is ideal to reduce operative time. Prophylactic antibiotics may be administered, but they have not been shown to prevent complications (Gould, 2001). VTE prophylaxis is also provided.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** General or regional anesthesia may be used. Inguinal lymphadenectomy is performed prior to partial or complete radical vulvectomy. Legs are placed in booted support stirrups in low lithotomy position, are abducted approximately 30 degrees, and are flexed minimally at the hip to flatten the groin. Rotation of the thigh a few degrees outward will open the femoral triangle.

□ **Skin Incision.** The groin is incised 2 cm below and parallel to the inguinal ligament starting 3 cm caudal and medial to the anterior superior iliac spine—aiming toward the adductor longus tendon (Fig. 46-27.1). The incision is 8 to 10 cm long and is taken through full skin thickness and 3 to 4 mm into the fat.

□ **Developing the Upper Flap.** Adson forceps elevate and provide traction to the upper skin edge while a hemostat is opened underneath to begin cephalad dissection down

through the subcutaneous fat and Scarpa fascia—aiming for a position in the midline of the incision and 3 cm above the inguinal ligament. Dissection proceeds downward until the glistening white aponeurosis of the external oblique muscle is identified. Adson forceps are then replaced with skin hooks to provide better traction.

A semicircle of fatty tissue is rolled inferiorly and laterally along the aponeurosis using electrosurgical dissection and intermittent blunt dissection. During dissection, the superficial circumflex iliac vessels are divided with a Harmonic scalpel or clamped and ligated. Additionally, superficial epigastric and superficial external pudendal vessels are divided as they are encountered (Fig. 38-29, p. 823). Dissection proceeds until the lower margin of the inguinal ligament is exposed (Fig. 46-27.2).

□ **Developing the Lower Flap.** The posterior skin flap is now raised in a similar manner to the upper flap. Dissection progresses through the subcutaneous fat to the deep fascia of the thigh—aiming approximately 6 cm from the inguinal ligament toward the apex of the femoral triangle. As shown in Figure 46-27.1, the femoral triangle is bordered by the inguinal ligament superiorly, by the sartorius muscle laterally, and by the adductor longus muscle medially. Blunt finger dissection along the inner portion of the sartorius and adductor longus muscles aids development of the lower flap boundaries. The dissection progressively becomes deeper into the subcutaneous tissue of the thigh, but remains superficial to the fascia lata. The tissue exiting at the apex of the femoral triangle is divided. Dissection progresses toward the fossa ovalis in circumferential path (Fig. 38-29, p. 823). Node-bearing tissue is held on traction to aid its dissection. Venous tributaries are ligated as they are encountered.

FIGURE 46-27.1 Incisions.

**FIGURE 46-27.2** Dissection of the upper flap.

#### □ Removal of the Superficial Nodes.

The superficial lymph nodes lie within the fatty tissue just mobilized. The saphenous vein is encountered during the dissection of the medial side of the fat pad. The distal end of this vein is individually transected and ligated with permanent suture for identification. If desired, saphenous vein transection can be avoided, and the vein can be salvaged by dissecting it from the fat pad. Circumferential dissection is next performed to isolate and remove the nodal bundle as it overlies the fossa ovalis (Fig. 46-27.3). The proximal end of the saphenous vein is separately ligated, unless the vessel has been preserved and can be dissected away from the nodal bundle. Remaining attachments are dissected from the cribriform fascia or clamped and cut to remove the specimen.

□ **Removal of the Deep Nodes.** The femoral vein should be visible within the fossa ovalis. The deep groin nodes lie just medial and parallel to this vessel. Of these, Cloquet node is the uppermost. The residual deep femoral nodal tissue is excised by removing any fatty tissue along the anterior and medial surfaces of the femoral vein above the deep limit of the fossa ovalis. The femoral sheath and cribriform fascia remain intact if possible.

If a clinically positive deep node cannot otherwise be reached, the cribriform fascia may be unroofed by making a longitudinal incision distally along the overlying femoral sheath (Fig. 46-27.4). Seven or eight underlying deep inguinal nodes are revealed, and these deep nodes are typically located in

a more orderly fashion than the superficial nodes. Fatty-lymphoid tissue is then dissected from the anterior and medial surfaces of the femoral vein. Following node removal, the femoral sheath edges may then be reapproximated using 3-0 gauge delayed-absorbable suture and/or covered with the sartorius muscle.

□ **Sartorius Muscle Transposition (Optional).** The fascia lata is incised to allow blunt dissection of the sartorius muscle (Fig. 46-27.5). The proximal sartorius muscle is then transected at its insertion to the anterior

superior iliac spine. A finger is wrapped around the upper part of the muscle to aid electrosurgical blade transection directly off the spine. Transection is as high as possible, with care taken to avoid the lateral femoral cutaneous nerve. The muscle is then further mobilized to cover the femoral vessels and sutured to the inguinal ligament with 2-0 gauge delayed-absorbable suture.

□ **Wound Closure.** The surgical defect is carefully examined, made hemostatic, and irrigated. The groin is closed with layers of delayed-absorbable suture, and a

**FIGURE 46-27.3** Dissection of the lower flap and removal of superficial nodes.

**FIGURE 46-27.4** Unroofing the cribriform fascia to remove deep nodes.

**FIGURE 46-27.5** Sartorius muscle transposition.

**FIGURE 46-27.6** Wound closure.

Blake or Jackson-Pratt drain is brought out superolaterally and tied in place with permanent suture (Fig. 46-27.6). Staples are placed to reapproximate skin edges.

### POSTOPERATIVE

Suction drainage enables the incision to heal and the underlying space to be obliterated. Drain tubing is manually milked or stripped three times daily with index finger and thumb toward the suction device to prevent blockage. Drains may be removed when output declines to 20 to 25 mL per day. Typically,

this requires approximately 2 weeks (Gould, 2001). Premature removal may result in a symptomatic lymphocyst that requires drain reinsertion or outpatient needle aspiration.

The groin incision remains uncovered and is regularly examined. Postoperative complications are common, particularly wound cellulitis and breakdown. Preoperative radiation and removal of bulky, fixed nodes increase the risk of these. Unroofing the deep fascia can also unnecessarily expose the femoral vessels to erosion or sudden hemorrhage. A protective sartorius muscle transposition may be especially indicated in these selected

situations to prevent morbidity (Judson, 2004; Paley, 1997).

Chronic lymphedema is another frequent complication of inguinal lymphadenectomy. In most reports, preservation of the saphenous vein has been shown to reduce the incidence (Dardarian, 2006; Gaarenstroom, 2003). Regardless, this condition is typically much more problematic with the addition of groin radiation. Supportive management is meant to minimize the edema and prevent symptomatic progression. Foot elevation, compression stockings, and, on occasion, diuretic therapy may be helpful.

## 46-28

## Reconstructive Grafts and Flaps

Primary closure of a vulvar wound is typically not advised if closure of a large defect would create excessive incision tension or if other untoward factors are present. In these cases, a reconstructive skin graft or flap is preferable to a defect healing by secondary intent. In general, the simplest procedure that will achieve the best functional result should be selected.

The decision to perform a split-thickness skin graft (STSG), lateral skin transposition, or rhomboid skin flap depends on clinical circumstances and surgeon experience. Variations of these techniques are occasionally used in gynecologic oncology (Burke, 1994; Dainty, 2005; Saito, 2009). Typical candidates for a skin graft or flap have undergone a large wide local excision, skinning vulvectomy, or partial or complete radical vulvectomy. Myocutaneous flaps, most commonly using the rectus abdominis and gracilis muscles, are used primarily in patients with prior radiation, very large defects, or a need for vaginal reconstruction (Section 46-9, p. 1167). However, a full description of the innumerable types of local flaps is beyond the scope of this section.

### PREOPERATIVE

#### ■ Patient Evaluation

Fortunately, a broad range of operative procedures are available—each with their advantages and disadvantages (Weikel, 2005). The size of the lesion and the anticipated postsurgical defect will largely dictate reconstructive

options. In some complicated cases, plastic surgery consultation may be indicated.

#### ■ Consent

A woman's body image may be significantly altered following extensive vulvar surgery, and sexual dysfunction may be a problem (Green, 2000). When discussing these effects, patient responses vary widely. Some express minimal concern, whereas others are devastated by the thought of a disfiguring result. Accordingly, counseling is individualized, specifically addressing patient concerns.

In addition, wound separation, infection, and wound healing by secondary intention are common. Moreover, patients are advised that recurrences of their underlying disease may recur within the graft or flap (DiSaia, 1995).

#### ■ Patient Preparation

Prophylactic antibiotics are typically given, and bowel preparation is generally influenced by surgeon preference. Early ambulation may be detrimental to graft or flap healing. Therefore, to prevent VTE, use of pneumatic compression devices or subcutaneous heparin is especially warranted (Table 39-8, p. 836).

For patients undergoing STSG, the hip, buttock, and inner thigh are carefully examined. The selected donor sites should contain healthy skin, should be hidden by a patient's clothing postoperatively, and must be accessible in the operating room. Typically, a graft is taken from the upper thigh.

### INTRAOPERATIVE

#### ■ Surgical Steps

□ **Anesthesia and Patient Positioning.** General or regional anesthesia is required.

The patient will need to be positioned in low lithotomy with complete access to the vulva, upper thighs, and mons pubis. Sterile preparation of the lower abdomen, perineum, thighs, and vagina is performed, and a Foley catheter is placed. Infrequently, the buttock or hip will be selected as the STSG donor site—this will require additional repositioning.

□ **Evaluating the Surgical Defect.** After the vulvar resection has been completed and hemostasis is achieved, the wound is examined to confirm that primary closure is impossible (Fig. 46-28.1). The best graft or flap that will adequately cover a defect is determined.

□ **Split-thickness Skin Graft (STSG).** A dermatome device is required to harvest the graft from the donor site when performing a STSG. At a setting of 18/1000ths to 22/1000ths, normal epithelium is harvested from the donor site (Fig. 43-25, p. 985). The STSG is placed in a basin and moistened with saline. The donor site is then sprayed with thrombin, covered with a transparent film dressing (Tegaderm), and wrapped firmly with gauze.

The recipient site is irrigated with antibiotic solution, and hemostasis must be absolute. The graft is then held over the defect and cut to fit so that there is some overlap. Meticulous care is required to smooth graft wrinkles and avoid graft tension. Edges are then sutured to the skin with interrupted 3-0 gauge nylon suture (Fig. 46-28.2). Moistened gauze or cotton balls are placed over the graft and covered with opened and fluffed gauze squares to provide light pressure. To create a stable dressing, a few ties are usually placed through the covering dressing and lateral to the graft site. Alternatively, fibrin tissue adhesives and/or vacuum-assisted closure devices

FIGURE 46-28.1 Large vulvar surgical defect.

FIGURE 46-28.2 Split-thickness skin graft.

**FIGURE 46-28.3** Lateral skin transposition.

may further augment graft adherence and viability (Dainty, 2005).

□ **Lateral Skin Transposition.** In some cases, the skin lateral to the surgical defect is extensively undermined but still may not be able to cover a large defect and reach the medial skin margin. To perform a lateral skin transposition, a surgeon makes separate curvilinear relaxing upper thigh skin incisions bilaterally. As shown in [Figure 46-28.3](#), the relaxing incisions are each undermined to the dotted line, which represents to lateral boarder of this dissection. The resulting mobility of the intervening vulvar skin bridge should allow for a tension-free primary closure using interrupted vertical mattress sutures. Last, the relaxing incisions are closed with interrupted 0-gauge delayed-absorbable suture.

□ **Rhomboid Flaps.** A rhomboid is a four-sided parallelogram with unequal angles

at its corners. When creating a rhomboid flap from adjacent tissue, a marking pen is used to draw all sides the same length as the short axis of the defect (A-C; [Fig. 46-28.4](#)). This minimizes wound tension and prevents necrosis. The diagonal A-C is continued in a straight line onto the adjacent vulvar skin lateral to the defect, and marked so that the length of AC = CE. The remaining rhomboid sides are drawn in parallel.

Incisions are made through the skin and into the subcutaneous fat. A flap is developed to include underlying fatty tissue and is mobilized medially to cover the surgical defect. In repositioning the flap, (as shown by the arrow), line CE swings medially to appose line AB and is secured with stay sutures at the corners CA and EB. Flap edges are reapproximated with vertical mattress stitches using 0-gauge delayed-absorbable suture ([Fig. 46-28.5](#)). Typically, excess tissue folding at the corners requires significant trimming or

undermining to provide a reasonably smooth contour and is needed to aid closure of the remaining defects above and below the flap. Finally, a suction drain is placed at the donor site to prevent seromas caused by extensive tissue dissection and that could otherwise result in wound dehiscence.

## POSTOPERATIVE

Patients are kept relatively immobile for the first 5 to 7 postoperative days to prevent tension on the reconstruction. Foley catheter drainage is also continued during these initial postoperative days. A low-residue diet, diphenoxylate hydrochloride (Lomotil), or loperamide hydrochloride (Imodium) tablets will aid healing by delaying defecation and preventing straining (Table 25-6, p. 570). Tromboembolic prophylaxis is continued until the patient is ambulatory.

During the first few days postoperatively, the wound is examined frequently to identify signs of hematoma or infection. For STSGs, the transparent dressing may be removed from the donor site after approximately 7 days, and an antibiotic ointment applied. For skin flaps, positioning changes or release of some sutures may be helpful if ischemia is noted at the margins. Suction drains are discontinued when output is less than 30 mL per 24 hours.

Women experience significant sexual dysfunction after vulvectomy. However, the extent of the surgery and need for reconstruction is less important than preexisting depression and hypoactive sexual dysfunction. Accordingly, postoperative psychologic counseling and treatment of depression may be particularly helpful (Green, 2000; Weijmar Schultz, 1990).
