## NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

# DEDICATION

This edition of *Williams Gynecology* is dedicated to David L. Hemsell, MD, who served as Director of the Division of Gynecology at the University of Texas Southwestern Medical Center and Parkland Memorial Hospital for more than 20 years. During this tenure, his national awards have included a Meritorious Achievement award from the Infectious Diseases Society of America and an Outstanding Service award from the American College of Obstetricians and Gynecologists.

Early in his training, Dr. Hemsell joined the Air Force and served our country as a Flight Medical Officer. In these years, he pursued specialty training in reproductive endocrinology with Dr. Paul MacDonald. He joined our faculty as the Division Director of Gynecology in 1977. In addition to his Director role, Dr. Hemsell was the Chief of Gynecology at Parkland Memorial Hospital and Medical Director of the Parkland Obstetrics and Gynecology Emergency Room. In these roles, Dr. Hemsell created an environment in which evidence-based medicine was the standard for care. Accordingly, patients, residents, and junior faculty all benefitted from this scientific health care approach. He also served as Director of the Faculty Sexual Assault Examination and Testimony Program. In that role, he coordinated the examinations of many thousands of sexual assault victims and the collection of legal evidence. As a result of his efforts, Dallas County has a system regarded as among the best in medical and legal care for these victims.

During his academic career, Dr. Hemsell added foundational knowledge regarding the etiology, pathogenesis, and treatment of female pelvic infections, especially those following gynecologic surgeries. With this expertise, he served as journal reviewer for multiple journals. He has added to academic knowledge through his nearly 50 book chapters and 100 peer-reviewed articles on multiple gynecologic topics.

For us in the Department of Obstetrics and Gynecology, Dr. Hemsell plays an important role of mentor and colleague. His experience and clinical expertise are invaluable and provide a valuable sounding board for challenging gynecology cases. On so many levels, we have benefitted greatly from his academic and clinical contributions.

# CONTENTS

Editors..... xiii

Contributors..... xv

Artists ..... xix

Preface ..... xxi

Acknowledgments..... xxiii

SECTION 1

BENIGN GENERAL GYNECOLOGY

1. Well Woman Care .....	2	8. Abnormal Uterine Bleeding.....	180
2. Techniques Used for Imaging in Gynecology .....	22	9. Pelvic Mass .....	202
3. Gynecologic Infection.....	50	10. Endometriosis .....	230
4. Benign Disorders of the Lower Genital Tract .....	86	11. Pelvic Pain .....	249
5. Contraception and Sterilization .....	105	12. Breast Disease .....	275
6. First-Trimester Abortion .....	137	13. Psychosocial Issues and Female Sexuality .....	297
7. Ectopic Pregnancy.....	161	14. Pediatric Gynecology.....	318

SECTION 2

REPRODUCTIVE ENDOCRINOLOGY,  
INFERTILITY, AND THE MENOPAUSE

15. Reproductive Endocrinology .....	334	19. Evaluation of the Infertile Couple .....	427
16. Amenorrhea .....	369	20. Treatment of the Infertile Couple .....	449
17. Polycystic Ovarian Syndrome and Hyperandrogenism .....	386	21. Menopausal Transition .....	471
18. Anatomic Disorders .....	404	22. The Mature Woman .....	492

SECTION 3

FEMALE PELVIC MEDICINE AND  
RECONSTRUCTIVE SURGERY

23. Urinary Incontinence .....	514	25. Anal Incontinence and Functional Anorectal Disorders .....	561
24. Pelvic Organ Prolapse .....	538	26. Genitourinary Fistula and Urethral Diverticulum .....	577

SECTION 4

GYNECOLOGIC ONCOLOGY

27. Principles of Chemotherapy .....	592	33. Endometrial Cancer .....	702
28. Principles of Radiation Therapy .....	610	34. Uterine Sarcoma .....	722
29. Preinvasive Lesions of the Lower Genital Tract .....	624	35. Epithelial Ovarian Cancer .....	735
30. Cervical Cancer .....	657	36. Ovarian Germ Cell and Sex Cord-Stromal Tumors .....	760
31. Vulvar Cancer .....	679	37. Gestational Trophoblastic Disease .....	779
32. Vaginal Cancer .....	694		

## SECTION 5

### ASPECTS OF GYNECOLOGIC SURGERY

38. Anatomy .....	796	41. Minimally Invasive Surgery	
39. Preoperative Considerations.....	825	Fundamentals.....	874
40. Intraoperative Considerations .....	841	42. Postoperative Considerations.....	908

## SECTION 6

### ATLAS OF GYNECOLOGIC SURGERY

<b>43. Surgeries for Benign Gynecologic Disorders .....</b>	<b>926</b>	43-19. Bartholin Gland Duct Marsupialization .....	973
43-1. Midline Vertical Incision .....	926	43-20. Bartholin Gland Duct Cystectomy....	975
43-2. Pfannenstiel Incision .....	929	43-21. Vulvar Abscess Incision and Drainage .....	977
43-3. Cherney Incision .....	931	43-22. Vestibulectomy .....	979
43-4. Maylard Incision .....	932	43-23. Labia Minora Reduction .....	981
43-5. Ovarian Cystectomy .....	933	43-24. Vaginal Septum Excision .....	983
43-6. Salpingo-oophorectomy .....	935	43-25. McIndoe Procedure .....	985
43-7. Interval Partial Salpingectomy .....	937	43-26. Treatment of Preinvasive Ectocervical Lesions .....	988
43-8. Salpingectomy and Salpingostomy ...	939	43-27. Cervical Conization .....	992
43-9. Cornuostomy and Cornual Wedge Resection .....	941	43-28. Treatment of Vulvar Intraepithelial Neoplasia .....	995
43-10. Abdominal Myomectomy .....	945	<b>44. Minimally Invasive Surgery.....</b>	<b>1003</b>
43-11. Vaginal Myomectomy for Prolapsed Leiomyoma .....	948	44-1. Diagnostic Laparoscopy .....	1003
43-12. Abdominal Hysterectomy.....	950	44-2. Laparoscopic Sterilization .....	1006
43-13. Vaginal Hysterectomy .....	957	44-3. Laparoscopic Salpingectomy .....	1011
43-14. Trachelectomy .....	962	44-4. Laparoscopic Salpingostomy .....	1013
43-15. Sharp Dilatation and Curettage .....	964	44-5. Laparoscopic Ovarian Cystectomy ...	1015
43-16. Suction Dilatation and Curettage .....	966	44-6. Laparoscopic Salpingo-oophorectomy .....	1019
43-17. Hymenectomy .....	969	44-7. Ovarian Drilling .....	1021
43-18. Bartholin Gland Duct Incision and Drainage .....	971	44-8. Laparoscopic Myomectomy .....	1022
		44-9. Laparoscopic Hysterectomy .....	1026

44-10. Laparoscopic Supracervical Hysterectomy .....	1030	45-19. Vaginal Uterosacral Ligament Suspension .....	1107
44-11. Total Laparoscopic Hysterectomy .....	1033	45-20. Abdominal Uterosacral Ligament Suspension .....	1110
44-12. Diagnostic Hysteroscopy .....	1037	45-21. Sacrospinous Ligament Fixation.....	1112
44-13. Hysteroscopic Polypectomy .....	1038	45-22. McCall Culdoplasty.....	1116
44-14. Hysteroscopic Myomectomy .....	1040	45-23. Abdominal Culdoplasty Procedures .....	1118
44-15. Endometrial Ablation Procedures ...	1043	45-24. Colpocleisis .....	1120
44-16. Transcervical Sterilization .....	1046	45-25. Anal Sphincteroplasty .....	1125
44-17. Hysteroscopic Septoplasty .....	1048	45-26. Rectovaginal Fistula Repair .....	1128
44-18. Proximal Fallopian Tube Cannulation .....	1050	<b>46. Surgeries for Gynecologic Malignancies .....</b>	<b>1134</b>
44-19. Lysis of Intrauterine Adhesions .....	1052	46-1. Radical Abdominal Hysterectomy (Type III).....	1134
<b>45. Surgeries for Pelvic Floor Disorders .....</b>	<b>1057</b>	46-2. Modified Radical Abdominal Hysterectomy (Type II) .....	1140
45-1. Diagnostic and Operative Cystoscopy and Urethroscopy .....	1057	46-3. Minimally Invasive Radical Hysterectomy.....	1142
45-2. Burch Colposuspension .....	1061	46-4. Total Pelvic Exenteration .....	1149
45-3. Tension-free Vaginal Tape .....	1063	46-5. Anterior Pelvic Exenteration .....	1155
45-4. Transobturator Tape Sling .....	1066	46-6. Posterior Pelvic Exenteration .....	1156
45-5. Pubovaginal Sling .....	1068	46-7. Incontinent Urinary Conduit .....	1157
45-6. Urethral Bulking Injections.....	1070	46-8. Continent Urinary Conduit .....	1161
45-7. Urethrolysis .....	1072	46-9. Vaginal Reconstruction .....	1165
45-8. Midurethral Sling Release .....	1074	46-10. Pelvic Lymphadenectomy.....	1169
45-9. Urethral Diverticulum Repair .....	1075	46-11. Paraaortic Lymphadenectomy .....	1172
45-10. Vesicovaginal Fistula Repair .....	1078	46-12. Minimally Invasive Staging for Gynecologic Malignancies .....	1176
45-11. Martius Bulbocavernosus Fat Pad Flap .....	1083	46-13. En Bloc Pelvic Resection .....	1182
45-12. Sacral Neuromodulation .....	1085	46-14. Omentectomy .....	1186
45-13. Anterior Colporrhaphy .....	1088	46-15. Splenectomy .....	1188
45-14. Abdominal Paravaginal Defect Repair .....	1091	46-16. Diaphragmatic Surgery .....	1190
45-15. Posterior Colporrhaphy.....	1093	46-17. Colostomy.....	1192
45-16. Perineorrhaphy .....	1096	46-18. Large Bowel Resection .....	1195
45-17. Abdominal Sacrocolpopexy .....	1098	46-19. Ileostomy.....	1197
45-18. Minimally Invasive Sacrocolpopexy .....	1103		

46-20. Small Bowel Resection .....	1198	46-25. Radical Partial Vulvectomy .....	1210
46-21. Low Anterior Resection.....	1200	46-26. Radical Complete Vulvectomy.....	1213
46-22. Intestinal Bypass .....	1204	46-27. Inguinofemoral	
46-23. Appendectomy .....	1206	Lymphadenectomy .....	1216
46-24. Skinning Vulvectomy .....	1208	46-28. Reconstructive Grafts and Flaps ....	1219

# PREFACE

The first edition of *Williams Obstetrics* was published over a century ago. Since then, the editors of this seminal text have presented a comprehensive and evidenced-based discussion of obstetrics. Patterned after our patriarch, *Williams Gynecology* provides a thorough presentation of gynecology's depth and breadth. In Section 1, general gynecology topics are covered. Section 2 provides chapters covering reproductive endocrinology and infertility. The developing field of female pelvic medicine and reconstructive surgery is presented in Section 3. In Section 4, gynecologic oncology is discussed.

Traditionally, gynecologic information has been offered within the format of either a didactic text or a surgical atlas. However, because the day-to-day activities of a gynecologist blends these two, so too did we. The initial four sections of

our book describe the evaluation and medical treatment of gynecologic problems. The remaining two sections focus on the surgical patient. Section 5 offers detailed anatomy and a discussion of perioperative considerations. Our final section presents an illustrated atlas for the surgical correction of conditions described in Sections 1 through 4. To interconnect this content, readers will find page references within one chapter that will direct them to complementary content in another.

Although discussions of disease evaluation and treatment are evidence based, our text strives to assist the practicing gynecologist and resident. Accordingly, chapters are extensively complemented by illustrations, photographs, diagnostic algorithms, and treatment tables.

# ACKNOWLEDGMENTS

During the creation and production of our textbook, we were lucky to have the assistance and support of countless talented professionals both within and outside our department.

First, a task of this size could not be completed without the unwavering support provided by our Department Chairman, Dr. Steven Bloom, and Vice-Chairman, Dr. Barry Schwarz. Their financial and academic endorsement of our efforts has been essential. Without their academic vision, this undertaking could not have flourished.

In constructing a compilation of this breadth, the expertise of physicians from several departments was needed to add vital, contemporaneous information. We were fortunate to have Dr. April Bailey, with joint appointments in the Department of Radiology and Department of Obstetrics and Gynecology, add her insight and knowledge as a specialist in radiology. Her many stunning images contribute to the academic richness of this edition. From the Department of Pathology, Dr. Kelley Carrick also shared generously from her cadre of outstanding images. She translated her extensive knowledge of gynecologic pathology into concepts relevant for the general gynecologist. From the Department of Surgery at Johns Hopkins University, Dr. David Euhus lent his considerable knowledge of breast disease to contribute both classic and state-of-the-art information to his truly comprehensive chapter, founded on his broad research and clinical expertise. From the Department of Psychiatry here at the University of Texas Southwestern Medical Center at Dallas and from the University of North Carolina at Chapel Hill School of Medicine, we were lucky to have Drs. Geetha Shivakumar and Anna Brandon provide an extensive discussion of psychosocial issues. They expertly distilled a broad topic into a logically organized, practical, and complete presentation. In addition, Dr. Gretchen Stuart, formerly of our department and now a faculty member at the Department of Obstetrics and Gynecology of the University of North Carolina at Chapel Hill, lent her considerable talents in summarizing contraceptive methods and sterilization techniques. Many warm thanks are extended to Dr. Rajiv Gala, also formerly of our department and now of the Ochsner Clinic. Rajiv masterfully organized and summarized chapters on ectopic pregnancy and perioperative practice. His extensive review of the literature and evidence-based writing shines through these chapters. In this edition, new contributors include Drs. Anthony Russell and Andrea Russo from the Department of Radiation Oncology at Massachusetts General Hospital—Harvard Medical School. In their chapter on radiation therapy, they adeptly provided clear explanations of this therapy's fundamentals and offered extensive suggestions for clinical management of patient complications that may be encountered.

Within our own department, the list is too long and the words are too few to convey our heartfelt thanks to all of our

department members for their generous contributions. From our Gynecology Division, many thanks are extended to Drs. Elysia Moschos and April Bailey, who sculpted a clear and detailed summary of traditional and new gynecologic imaging tools. In this edition, these two authors updated radiologic images as needed to present ultimate examples of normal anatomy and gynecologic pathology. We were also lucky to have experts in the field of preinvasive lesions of the lower genital tract, Drs. Claudia Werner and William Griffith. They crafted an information-packed discussion of this topic. In addition, Dr. Griffith has been a steadfast advocate of our project and has added extensive photographic content to many of our chapters. Drs. David Rahn and Eddie McCord teamed to update the chapter on gynecologic infection. Their extensive patient-care experience and rigorous literature review added greatly to the academic and clinical value of this chapter. We were also fortunate to have the expert writing talents of Drs. Mayra Thompson and Kimberly Kho, who provided a compelling and comprehensive discussion of minimally invasive surgery. Our textbook benefitted greatly from the clinical savvy and teaching-centric information that David Rogers and David Owens provided to their chapter. Also, Dr. Rogers has been a long-time supporter of our textbook. We are indebted to him for many of the classic surgical photographs in this edition. Intraoperative fundamentals were thoroughly and logically presented by Drs. Cherine Hamid and Sunil Balgobin. Their strengths in clinical practice and resident teaching are evident in their well-organized and essential chapter. Once again, blending experience and academic fundamentals, Dr. Mary Jane Pearson offered a comprehensive but concise primer on well care for the gynecologic patient.

Our Reproductive Endocrinology and Infertility Division provided other talented physicians and writers. Dr. Kevin Doody lent his considerable clinical and academic prowess in the treatment of infertility. He penned a chapter that clearly describes the state of the art in this field. Dr. Doody was also a kind benefactor with his spectacular clinical photographs on the topic and contributed these generously to numerous chapters. In addition, Dr. Ellen Wilson brought her wealth of clinical experience to chapters on pediatric gynecology and androgen excess. Drawing from her academic and clinical expertise, she crafted chapters that presented practical, prescriptive, and comprehensive discussions of these topics.

Dr. Marlene Corton is a skilled urogynecologist and has written extensively on pelvic anatomy. We were thrilled to have her create stunning chapters on anatomy and anal incontinence. Also from the Urogynecology and Female Pelvic Reconstruction Division, Drs. Clifford Wai and David Rahn added expanded content to their chapter on urinary incontinence. Dr. Wai also masterfully updated his chapter on

vesicovaginal fistula and urethral diverticulum. Special thanks are extended to Dr. Ann Word and her contributions to our chapter on pelvic organ prolapse. Her expertise in extracellular matrix remodeling of the female reproductive tract added fundamental content to the discussion of prolapse physiology.

Dr. David Miller generously contributed his talents without hesitation, and we are indebted to him for his altruism toward our project. In addition, the Division of Gynecologic Oncology offered a deep bench of talented writers. The topic of vulvar cancer was thoroughly covered by Dr. Jayanthi Lea. Dr. Lea also assisted with updating our atlas and added essential steps for minimally invasive approaches. Her strengths in clinical practice and resident teaching are evident in her well-organized and evidence-based chapters. We also benefitted from Dr. Debra Richardson's comprehensive presentation and clinical discussions of cervical and vaginal cancer in her two chapters. She has been a true advocate of both the text and study guide. Dr. Siobhan Kehoe described with clarity and clinical relevance the care and treatment of women with endometrial cancer. We were appreciative of Dr. Matthew Carlson, who teamed with David Miller to present the varied pathology and treatment of uterine sarcoma.

With this edition, several of our valued authors have turned their efforts to other promising pursuits. We are grateful to Drs. F. Gary Cunningham, Bruce Carr, David Hemsell, Larry Word, and Phuc Nguyen for their prior contributions to *Williams Gynecology*. All with well-known and well-established careers, they generously contributed their academic skills without hesitation. We are indebted to them for their altruism toward our project.

Of these academicians, Dr. F. Gary Cunningham provided the academic vision that led to the creation of this text. Dr. Cunningham has been the senior author for seven editions of *Williams Obstetrics*, spanning over 25 years. As such, we benefited greatly from his writing genius, his meticulous organization, and his tenacity to task. His dedication to evidence-based medicine established the foundation on which our textbook was built. We feel privileged to have learned the craft of clear, concise academic summary from a consummate master.

New beautiful and detailed artwork in our atlas this edition was drawn by Mr. Lewis Calver, here at the University of Texas Southwestern Medical Center at Dallas. Again for this edition, he paired his academic talents with Dr. Marlene Corton to create updated hysterectomy and urogynecologic images. Both of these anatomists committed countless hours in the cadaver laboratory and in the library to create academically new presentations. These renderings were crafted and tailored with the gynecologic surgeon in mind to depict important techniques and anatomy for these surgeries. Dr. Jayanthi Lea joined this gifted duo to add complementary and informative illustrations to her description of minimally invasive cancer surgeries.

We also acknowledge the efforts of our atlas artists from the first two editions: Marie Sena, Erin Frederikson, Jordan Pietz, Maya Shoemaker, SangEun Cha, Alexandra Gordon, Jennie Swensen, Amanda Tomasikiewicz, and Kristin Yang. Additionally, alumni from the Biomedical Communications Program at the University of Texas Southwestern Medical

Center provided seminal pieces. These alumni include Katherine Brown, Thomas "T. J." Fels, Belinda Klein, Anne Matuskowitz, Lindsay Oksenberg, Kimberly VanExel, and faculty member Richard P. Howdy, Jr. Also, Ms. Kimberly Hoggatt Krumwiede graciously provided several image series to help clarify the steps and missteps of reproductive tract development.

Within our text, images add powerful descriptive content to our words. Accordingly, many, many thanks are extended to those who donated surgical and clinical photographs. Of our contributors, many beautiful photographs within our book were taken by Mr. David Gresham, Chief Medical Photographer at the University of Texas Southwestern Medical Center. Dave's eye for detail, shading, and composition allowed even simple objects to shine and be illustrated to their full potential. He has been an advocate and valued consultant. Our pathology images were presented at their best thanks to Mr. Mark Smith, a graphics designer here at the University of Texas Southwestern Medical Center. His expertise with micrographs improved the clarity and visual aesthetic of many of our microscopic images.

The providers in the Obstetrics and Gynecology Emergency Services (OGES) at Parkland Hospital were huge allies in our acquisition of images to illustrate normal and abnormal gynecologic findings. The skilled women's health care nurse practitioners have been true supporters of our efforts, and we sincerely thank them.

We are truly indebted to our administrative staff. For this project, we were lucky to have Ms. Sandra Davis serve as our primary administrative assistant. We are greatly appreciative of her tremendous efforts, professionalism, and efficiency. Ms. Ellen Watkins was a valuable assistant in obtaining needed journal articles. She truly helped to keep our project evidence-based. None of our image and text production would have been possible without the brilliant information technology team in our department. Knowledgeable and responsive, Mr. Charles Richards and Mr. Thomas Ames have supported our project since the first edition. We could not do our job without their expertise.

*Williams Gynecology* was sculpted into its final form by the talented and dedicated group at McGraw-Hill Education. Once again, Ms. Alyssa Fried has brought her considerable intelligence, energetic work ethic, and creativity to our project. Her attention to detail and organizational talents have kept our project on track with efficiency and style. Our words fall well short in expressing our gratitude to her. Ms. Samantha Williams served as assistant to Ms. Fried, and we extend warm thanks for her tremendous support. Her efficiency, professionalism, hard work, accuracy, and positive attitude made coordination of this project a dream. Mr. Andrew Moyer joined our project during its final sculpting. He has taken our project under his care and has adeptly shepherded it to completion with a calm and efficient style. We happily look forward to many future collaborative editions together.

Without the thoughtful, creative efforts of many, our textbook would be a barren wasteland of words. Integral to this process are Armen Ovsepyan, at McGraw-Hill Education, and Alan Barnett of Alan Barnett Design. Mr. Richard Ruzicka served as production supervisor for this edition of our textbook. He adeptly kept our project on track through an array of potential hurdles. Special

thanks are extended to Mr. Joseph Varghese and Dr. Shetoli Zhimomi at Thomson Digital. They and their artistic team assisted us in revising many of our text images. Their attention to detail and accurate renderings added important academic support to our words.

Our text took its final shape under the watchful care of our compositors at Aptara, Inc. Specifically, we thank Ms. Indu Jawwad for her talents in skillfully and expediently coordinating and overseeing composition. Her dedicated attention to detail and organization were vital to completion of our project. Her pleasant professionalism was appreciated daily. Also at Aptara, Mr. Shashi Lal Das served a crucial task of quality control and assisted in creating beautiful chapter layouts to highlight our content aesthetically and informatively. Special thanks go to Ms. Kristin Landon. As copyeditor for now several editions of both *Williams Obstetrics* and *Williams Gynecology*, Kristin has added precision and clarity to our efforts. Her pleasant and patient professionalism has made our text better.

We offer a sincere “thank you” to our residents in training. Their curiosity keeps us energized to find new and effective ways to convey age-old as well as cutting-edge concepts. Their logical questions lead us to holes in our text, and thereby, always help us to improve our work. Moreover, many of the photographs in this textbook were gathered with the help of our many residents.

In addition, the contributors to this text owe a significant debt to the women who have allowed us to participate in their care. The images and clinical expertise presented in this text would not have been possible without their collaborative spirit to help us move medical knowledge forward.

Last, we offer an enthusiastic and heartfelt “thank you” to our families and friends. Without their patience, generosity, and encouragement, this task would have been impossible. For them, too many hours with “the book” left them with new responsibilities. And importantly, time away from home left precious family memories and laughs unrealized. We sincerely thank you for your love and support.

Serving as both specialist and primary care provider, a gynecologist has an opportunity to diagnose and treat a wide variety of diseases. Once problems are identified, clinicians, in consultation with the patient, determine how best to manage chronic medical issues based on their experience, practice patterns, and professional interests. Although some conditions may require referral, gynecologists play an essential role in patient screening, in emphasizing ideal health behaviors, and in facilitating appropriate consultation for care beyond their scope of practice.

Various organizations provide preventive care recommendations and update these regularly. Commonly accessed guidelines are those from the American College of Obstetricians and Gynecologists (ACOG), Centers for Disease Control and Prevention (CDC), U.S. Preventive Services Task Force (USPSTF), and American Cancer Society.

### MEDICAL HISTORY

During a comprehensive well-woman visit, patients are first queried regarding new or ongoing illness. To assist with

evaluation, complete medical, social, and surgical histories are obtained and include obstetric and gynecologic events. Gynecologic topics usually cover current and prior contraceptives; results from prior sexually transmitted disease (STD) testing, cervical cancer screening, or other gynecologic tests; sexual history, described in Chapter 3 (p. 60); and menstrual history, outlined in Chapter 8 (p. 182). Obstetric questions chronicle circumstances around deliveries, losses, or complications. Current medication lists include both prescription and over-the-counter drugs and herbal agents. Also, prior surgeries, their indications, and complications are sought. A social history covers smoking and drug or alcohol abuse. Screening for intimate partner violence or depression can be completed, as outlined on page 18 and more fully in Chapter 13 (p. 298). Discussion might also assess the patient's support system and any cultural or spiritual beliefs that might affect her general health care. A family history helps identify women at risk for familial or multifactorial disease such as diabetes or heart disease. In families with prominent breast, ovarian, or colon cancer, genetic evaluation may be indicated, and criteria are outlined in Chapters 33 (p. 707) and 35 (p. 736). Moreover, a significant family clustering of thromboembolic events may warrant testing, as describe in Chapter 39 (p. 836), especially prior to surgery or hormone initiation. Last, a review of systems, whether performed by the clinician or office staff, may add clarity to new patient problems.

For adults, following historical inventory, a complete physical examination is completed. Many women present to their gynecologist with complaints specific to the breast or pelvis. Accordingly, these are often areas of increased focus, and their evaluation is described next.

### PHYSICAL EXAMINATION

#### ■ Breast Examination

##### Clinical Evidence

Self breast examination (SBE) is an examination performed by the patient herself to detect abnormalities. However, studies have shown that SBE increases diagnostic testing rates for ultimately benign breast disease and is ineffective in lowering breast cancer mortality rates (Kösters, 2008; Thomas, 2002). Accordingly, several organizations have removed SBE from their recommended screening practices (National Cancer Institute, 2015; Smith, 2015; U.S. Preventive Services Task Force, 2009). That said, the American College of Obstetricians and Gynecologists (2014b) and the American Cancer Society (2014) recommend breast self-awareness as another method of patient self-screening.

Self-awareness focuses on breast appearance and architecture and may include SBE. Women are encouraged to report any perceived breast changes for further evaluation.

In contrast, clinical breast examination (CBE) is completed by a clinical health-care professional and may identify a small portion of breast malignancies not detected with mammography. Additionally, CBE may identify cancer in young women, who are not typical candidates for mammography (McDonald, 2004). One method includes visual inspection combined with axillary and breast palpation, which is outlined in the following section.

The American College of Obstetricians and Gynecologists (2014b) recommends that women receive a CBE every 1 to 3 years between ages 20 and 39. At age 40, CBE is completed annually. That said, the USPSTF (2009) and the American Cancer Society report insufficient evidence to recommend routine CBE (Oeffinger, 2015).

### Breast Examination

Initially during CBE, the breasts are viewed as a woman sits on the table's edge with hands placed at her hips and with pectoralis muscles flexed (Fig. 1-1). Alone, this position enhances asymmetry. Additional arm positions, such as placing arms above the head, do not add vital information. Breast skin is inspected for breast erythema; retraction; scaling, especially over the nipple; and edema, which is termed *peau d'orange* change. The breast and axilla are also observed for contour symmetry.

Following inspection, axillary, supraclavicular, and infraclavicular lymph nodes are palpated most easily with a woman seated and her arm supported by the examiner (Fig. 1-2). The axilla is bounded by the pectoralis major muscle ventrally and

**FIGURE 1-1** During visual breast inspection, hands are pressed against the waist to flex the pectoralis muscles. With the patient leaning slightly forward, breasts are visually inspected for breast contour asymmetry or skin dimpling.

**FIGURE 1-2** One method of axillary lymph node palpation. Finger tips extend to the axillary apex and compress tissue against the chest wall in the rolling fashion shown in Figure 1-4. The patient's arm is supported by the examiner.

the latissimus dorsi muscle dorsally. Lymph nodes are detected as the examiner's hand glides from high to low in the axilla and momentarily compresses nodes against the lateral chest wall. In a thin patient, one or more normal, mobile lymph nodes less than 1 cm in diameter may commonly be appreciated. The first lymph node to become involved with breast cancer metastasis (the sentinel node) is nearly always located just behind the midportion of the pectoralis major muscle belly.

After inspection, breast palpation is completed with a woman supine and with one hand above her head to stretch breast tissue across the chest wall (Fig. 1-3). Examination includes breast tissue bounded by the clavicle, sternal border, inframammary crease, and midaxillary line. Breast palpation within this pentagonal area is approached in a linear fashion. Technique uses the finger pads in a continuous rolling, gliding circular motion (Fig. 1-4). At each palpation point, tissues is assessed both superficially and deeply (Fig. 1-5). During CBE, intentional attempts at nipple discharge expression are not required unless a *spontaneous* discharge has been described by the patient.

If abnormal breast findings are noted, they are described by their location in the right or left breast, clock position, distance from the areola, and size. Evaluation and treatment of breast and nipple diseases are described more fully in Chapter 12 (p. 275).

During examination, patients are educated that new axillary or breast masses, noncyclic breast pain, spontaneous nipple discharge, new nipple inversion, and breast skin changes such as dimpling, scaling, ulceration, edema, or erythema should prompt evaluation. This constitutes breast self-awareness. Patients who desire to perform SBE are counseled on its benefits, limitations, and potential harms and instructed to complete SBE the week after menses.

**FIGURE 1-3** Recommended patient positioning and direction of palpation during clinical breast examination.

### ■ Pelvic Examination

This examination is typically performed with a patient supine, legs in dorsal lithotomy position, and feet resting in stirrups. The head of the bed is elevated 30 degrees to relax abdominal wall muscles for bimanual examination. A woman is assured that she may stop or pause the examination at any time. Moreover, each part of the evaluation is announced or described before its performance.

### Inguinal Lymph Nodes and Perineal Inspection

Pelvic cancers and infections may drain to the inguinal lymph nodes, and these are palpated during examination. Following this, a methodical inspection of the perineum extends from the mons ventrally, to the genitocrural folds laterally, and to the anus. Notably, infections and neoplasms that involve the vulva can also involve perianal skin. Some clinicians additionally palpate for Bartholin and paraurethral gland pathology. However, in most cases, patient symptoms and asymmetry in these areas will dictate the need for this specific evaluation.

**FIGURE 1-4** Recommended palpation technique. The finger pads and a circular rolling motion are used to palpate the entire breast.

### Speculum Examination

Both metal and plastic specula are available for this examination, each in various sizes to accommodate vaginal length and laxity. The plastic speculum may be equipped with a small light that provides illumination, whereas metal specula require an external light source. Preference between these two types is provider dependent. The vagina and cervix are typically viewed after placement of either a Graves or Pederson speculum (Fig. 1-6). Prior to insertion, a speculum may be warmed with running water or by warming lights built into some examination tables. Additionally, lubrication may add comfort to insertion. Griffith and colleagues (2005) found that gel lubricants did not increase unsatisfactory Pap

smear cytology rates or decrease *Chlamydia trachomatis* detection rates compared with water lubrication. If gel lubrication is used, a dime-sized aliquot is applied sparingly to the outer surface of the speculum blades.

**FIGURE 1-5** Palpation through several depths at each point along the linear path.

**FIGURE 1-6** Vaginal specula. **A.** Pediatric Pederson speculum. This may be selected for child, adolescent, or virginal adult examination. **B.** Graves speculum. This may be selected for examination of parous women with relaxed and collapsing vaginal walls. **C.** Pederson speculum. This may be selected for sexually active women with adequate vaginal wall tone. (Used with permission from US Surgitech, Inc.)

Immediately before insertion, the labia minora are gently separated, and the urethra is identified. Because of urethral sensitivity, the speculum is inserted well below the meatus. Alternatively, prior to speculum placement, an index finger may be placed in the vagina, and pressure placed posteriorly against the bulbospongiosus muscle. A woman is then encouraged to relax this posterior wall to improve comfort with speculum insertion. This practice may prove especially helpful for women undergoing their first examination and for those with infrequent coitus, dyspareunia, or heightened anxiety.

With speculum insertion, the vagina commonly contracts, and a woman may note pressure or discomfort. A pause at this point typically is followed by vaginal muscle relaxation. As the speculum bill is completely inserted, it is angled approximately 30 degrees downward to reach the cervix. Commonly, the

uterus is anteverted, and the ectocervix lies against the posterior vaginal wall (Fig. 1-7).

As the speculum is opened, the ectocervix can be identified. Vaginal walls and cervix are inspected for masses, ulceration, or unusual discharge. As outlined in Chapter 29 (p. 632), cervical cancer screening is often completed, and additional swabs for culture or microscopic evaluation can also be collected. Screening for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* and other STDs is listed in Table 1-1.

### Bimanual Examination

Most often, the bimanual examination is performed after the speculum evaluation. Some clinicians prefer to complete the bimanual portion first to better identify cervical location prior to speculum insertion. Either process is appropriate. Uterine and adnexal size, mobility, and tenderness can be assessed during bimanual examination. For women with prior hysterectomy and adnexectomy, bimanual examination is still valuable and can be used to exclude other pelvic pathology.

During this examination, a gloved index and middle finger are inserted together into the vagina until the cervix is reached. For cases of latex allergy, nonlatex gloves are available. To ease insertion, a water-based lubricant can be initially applied to these gloved fingers. Once the cervix is reached, uterine orientation can be quickly assessed by sweeping the index finger inward along the ventral surface of the cervix. In those with an anteverted position, the uterine isthmus is noted to sweep upward, whereas in those with a retroverted position, a soft bladder is palpated. However, in those with a retroverted uterus, if a finger is swept along the cervix's dorsal aspect, the isthmus is felt to sweep downward. With a retroverted uterus, this same finger is continued posteriorly to the fundus and then side-to-side to assess uterine size and tenderness.

To determine the size of an anteverted uterus, fingers are placed beneath the cervix, and upward pressure tilts the fundus toward the anterior abdominal wall. A clinician's opposite

**FIGURE 1-7** Uterine positions. **A.** Uterine position may be anteverted, midplane, or retroverted. **B.** As shown here, the uterine fundus can be flexed forward, and this is termed antelexion. Similarly, the fundus may be flexed backward to create a retroverted uterus.

**TABLE 1-1.** Sexually Transmitted Disease Screening Guidelines for Nonpregnant, Sexually Active Asymptomatic Women

Infectious Agent	Screening Recommendations	Risk Factors
Chlamydia trachomatis + Neisseria gonorrhoeae	All < 25 yr: annually Those older with risk factors: annually	New or multiple partners; inconsistent condom use; sex work; current or prior STD
Treponema pallidum	Those with risk factors	Sex work; confinement in adult correction facility; MSM
HIV virus	All 13–64 yr: one time <sup>a</sup> Those with risk factors: periodically	Multiple partners; injection drug use; sex work; concurrent STD; MSM; at-risk partners; initial TB diagnosis
Hepatitis C virus	All born from 1945 to 1965: one time Those with risk factors: periodically	Injection/intranasal drug use; dialysis; infected mother; blood products before 1992; unregulated tattoo; high-risk sexual behavior
Hepatitis B virus	Those with risk factors	HIV-positive; injection drug use; affected family or partner; MSM; multiple partners; originate from high- prevalence country
HSV	No routine screening	

<sup>a</sup>Centers for Disease Control and Prevention (2015) and American College of Obstetricians and Gynecologists (2014d) recommend one-time screening between ages 13 and 64 years. The U.S. Preventive Services Task Force (2014b) uses a 15–65 year age range.

HIV= human immunodeficiency virus; HSV= herpes simplex virus; MSM= men having sex with men; STD= sexually transmitted disease; TB= tuberculosis.

Data from Centers for Disease Control and Prevention (2015) and American College of Obstetricians and Gynecologists (2014d); U.S. Preventive Services Task Force (2004a, 2005, 2014a,b).

hand is placed against the abdominal wall to locate the upward fundal pressure (Fig. 1-8).

To assess adnexa, the clinician uses two vaginal fingers to lift the adnexa from the cul-de-sac or from Waldeyer fossa toward the anterior abdominal wall. The adnexa is trapped between these vaginal fingers and the clinician's other hand, which is exerting downward pressure against the lower abdomen. For those with a normal-sized uterus, this abdominal hand is typically best placed just above the inguinal ligament.

### Rectovaginal Examination

The decision to perform rectovaginal evaluation varies among providers. Some prefer to complete this evaluation on all adults, whereas others elect to perform rectovaginal examination for those with specific indications. These may include pelvic pain, an identified pelvic mass, rectal symptoms, or risks for colon cancer.

Gloves are changed between bimanual and rectovaginal examinations to avoid contamination of the rectum with potential vaginal pathogens. Similarly, if fecal occult blood testing is to be done at this time, the glove is changed after bimanual examination to minimize false-positive results. Initially, an index finger is placed into the vagina and a middle finger into the rectum (Fig. 1-9). These fingers are swept against one another in

a scissoring fashion to assess the rectovaginal septum for scarring or peritoneal studding. The index finger is removed, and the middle finger completes a circular sweep of the rectal vault to exclude masses. If immediate fecal occult blood testing is indicated, it may be performed with a sample from this portion of the examination. As noted later, this single fecal occult blood testing does not constitute adequate colorectal cancer screening.

**FIGURE 1-8** Bimanual examination. Fingers beneath the cervix lift the uterus toward the anterior abdominal wall. A hand placed on the abdomen detects upward pressure from the uterine fundus. Examination allows assessment of uterine size, mobility, and tenderness.

**FIGURE 1-9** Rectovaginal examination.

### ■ Examination Interval

Periodic health evaluation and screening can prevent or detect numerous medical conditions. Moreover, periodic visits also foster a patient-physician partnership to help guide a woman through adolescence, reproductive years, and past menopause.

An initial reproductive health visit is recommended between ages 13 and 15 years (American College of Obstetricians and Gynecologists, 2014e). This visit initiates a discussion between an adolescent and health-care provider on issues of general reproductive health, puberty, menstruation, contraception, and STD protection. Although not mandated, a pelvic examination may be necessary if gynecologic symptoms are described. Adolescents may prefer to include parents in their gynecologic health care. However, as discussed in Chapter 14 (p. 320), adolescents may seek care for STDs, substance abuse, contraception, or pregnancy without parental permission (American College of Obstetricians and Gynecologists, 2014a).

For women older than 21 years, the American College of Obstetricians and Gynecologists (2014f) recommends annual well woman visits, during which physical and pelvic examinations are completed. Pelvic evaluation contains those components listed on page 4, namely, inspection and speculum, bimanual, and rectal examinations. However, evidence neither supports nor refutes the value of annual pelvic evaluation in asymptomatic women. Thus, exclusion of this portion is a shared decision following patient-provider discussion. Women with gynecologic complaints are encouraged to permit this examination.

One topic in this conversation is cervical cancer screening. For many women, the appropriate screening interval may not be annually, and specific screening methods and schedules are discussed in Chapter 29 (p. 634). Second, in the past, endocervical swabs for gonorrhea and chlamydia infection screening during speculum examination were preferred. Now, such screening can be completed with similar accuracy using nucleic acid amplification testing of urine, vaginal, or endocervical samples.

Other professional organizations have also published statements regarding preventive care visits. The Institute of Medicine (2011) recommends at least one annual well woman visit to obtain preventive services, including preconception and prenatal care. However, investigators from the American College of

Physicians (ACP) reviewed pelvic examination benefits and harms in asymptomatic adult women (Qaseem, 2014). These authors describe scarce data to determine the ideal interval for routine pelvic examination. Accordingly, the ACP recommends against screening pelvic examination for asymptomatic, nonpregnant adult women. Thus, again, with each annual visit, a discussion of benefits and risks and an agreement to examination is prudent.

## PREVENTIVE CARE

Gynecologists have an opportunity to evaluate their patients for leading causes of female morbidity and mortality and intervene accordingly. Thus, familiarity with various screening guidelines is essential. In 2014, recommendations by the American College of Obstetricians and Gynecologists (2014f) were updated. The USPSTF (2014) regularly revises its screening guidelines, which can be accessed at [www.USPreventiveServicesTaskForce.org](http://www.USPreventiveServicesTaskForce.org). These, along with other specialty-specific recommendations, offer valuable guidance for clinicians providing preventive care. Many of these topics are covered in other text chapters. Some remaining important subjects are present in the following sections.

### ■ Immunization

The need for new or repeat administration of vaccines should be reviewed periodically. Some vaccines are recommended for all adults, whereas others are indicated because of patient comorbidities or occupational exposure risks. For most healthy adults who have completed the indicated childhood and adolescent immunization schedules, those that warrant consideration are listed in Table 1-2. This table summarizes recommended schedules, precautions, and contraindications for these adult vaccines. As of 2015, a link is provided to the full schedules at: <http://www.cdc.gov/vaccines/schedules/>.

In general, any vaccine may be coadministered with another type at the same visit. Notably, the influenza vaccine is available in several formulations. Vaccines for human papillomavirus infection prevention, Gardasil and Cervarix, are discussed additionally in Chapter 29 (p. 630).

### ■ Cancer Screening

#### Colon Cancer

In the United States, nearly 64,000 new cases of colorectal cancer are predicted, and this malignancy is the third leading cause of cancer death in women, behind lung and breast cancer (Siegel, 2015). Incidence and mortality rates from this cancer have declined during the past two decades, largely due to improved screening tools. However, adherence to colorectal cancer screening guidelines for women is usually less than 50 percent (Meissner, 2006).

Guidelines recommend screening average-risk patients for colorectal cancer beginning at age 50 with any of the methods shown in Table 1-3 (Smith, 2015). Screening is selected from either of two method categories. The first is capable of identifying both cancer and precancerous lesions. The second group of methods primarily detects only cancer and includes the fecal occult blood test, fecal immunochemical test, and stool DNA tests.

Of these, colonoscopy is often the preferred test for colorectal cancer screening. For the patient with average risk and normal findings, testing is repeated in 10 years. In the United States,

<sup>a</sup>Previous anaphylactic reaction to any of a vaccine's components serves as a contraindication for any vaccine.

<sup>b</sup>Moderate to severe illness is a precaution to vaccination. Mild illness is not a contraindication.

<sup>c</sup>Several influenza vaccines are available and listed at: <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6332a3.htm#Tab>.

<sup>d</sup>Full guidelines found at <http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-combined-schedule.pdf>.

<sup>e</sup>A list is found at <http://wwwnc.cdc.gov/travel/yellowbook/2010/table-of-contents.aspx>.

<sup>f</sup>These include acyclovir, famciclovir, valacyclovir.

DM = diabetes mellitus; ESRD = end-stage renal disease; GBS = Guillain-Barré syndrome; HIV = human immunodeficiency virus; HPV = human papillomavirus; IM = intramuscular; IV = intravenous; MCV4 = meningococcal conjugate vaccine; MMR = measles, mumps, rubella; MPSV4 = meningococcal polysaccharide vaccine; PCV = pneumococcal conjugate vaccine; PPSV = pneumococcal polysaccharide vaccine; SC = subcutaneous; Td = tetanus, diphtheria; Tdap = tetanus, diphtheria, activated pertussis.

Data from Kim DK, Bridges CB, Harriman HK, et al: Advisory Committee on Immunization Practices recommended immunization schedule for adults aged 19 years or older: United States, 2015. *Ann Intern Med* 162:214, 2015.

flexible sigmoidoscopy is used less frequently. Its limitations include that only the distal 40 cm of colon are seen, and if lesions are found, then colonoscopy is still needed. A final suitable option—computed tomographic (CT) colonography—is not often covered by insurance plans.

Fecal occult blood testing (gFOBT) is an adequate *annual* screening method when two or three stool samples are self-collected by the patient, and the cards are returned for analysis. This method relies on a chemical oxidation reaction between the heme moiety of blood and alpha guaiaconic acid, a component of guaiac paper. Heme catalyzes the oxidation of alpha guaiaconic acid by hydrogen peroxide, the active component in the developer. This oxidation reaction yields a blue color (Sanford, 2009). Red meat, raw cauliflower, broccoli, members of the radish family, and melons have similar oxidizing ability and may yield false-positive results. Vitamin C may preemptively react with the reagents and lead to false-negative results. All of these are eliminated for 3 days before testing. Additionally, women should avoid nonsteroidal antiinflammatory drugs (NSAIDs) 7 days prior to testing to limit risks of gastric irritation and bleeding. These restrictions are cumbersome for some patients and lead to noncompliance with recommended testing.

Alternatively, the fecal immunochemical test (FIT) relies on an immune reaction to human hemoglobin. Similar to FOBT, the FIT test is performed for annual screening on two or three patient-collected stool samples and does not require pretesting dietary limitations. Advantages to FIT include greater specificity for human blood and thus fewer false-positive results from dietary meat and vegetables and fewer false-negative results due to vitamin C. As another option, screening may be completed with stool DNA (sDNA) testing. One FDA-approved test, Cologuard, screens stool for both DNA and hemoglobin biomarkers that are associated with colorectal cancer (Imperiale, 2014). Positive test results from any of these three warrant further evaluation by colonoscopy.

During patient evaluation of pelvic complaints such as pain, a gynecologist not uncommonly performs gFOBT testing on a single stool sample obtained during digital rectal examination. Although potentially helpful diagnostically, this single stool sample is not considered adequate colorectal cancer screening.

These guidelines are appropriate for those with average risk. High-risk factors include a personal history of colorectal cancer or adenomatous polyps, a first-degree relative with colon cancer or adenomas, chronic inflammatory bowel disease, known or

**TABLE 1-3.** Screening Guidelines for the Early Detection of Colorectal Cancer and Adenomas for Average-risk Women Aged 50 years and Older

Tests That Detect Adenomatous Polyps and Cancer <sup>a</sup>		
Test	Interval	Key Issues for Informed Decisions
Colonoscopy	10 years	Bowel prep required; conscious sedation provided
FSIG	5 years	Bowel prep required, sedation usually not provided Positive findings usually merit colonoscopy
Barium enema (DCBE)	5 years	Bowel prep required; polyps ≥ 6 mm merit colonoscopy
Colonography (CTC)	5 years	Bowel prep required; polyps ≥ 6 mm merit colonoscopy
Tests That Primarily Detect Cancer <sup>a</sup>		
Test	Interval	Key Issues for Informed Decisions
gFOBT	Annually	Two to three stool samples collected at home are needed; a single stool sample gathered during office digital examination is not sufficient screening. Positive results merit colonoscopy
FIT	Annually	Positive results merit colonoscopy
Stool DNA (sDNA)	3 years	Positive results merit colonoscopy

<sup>a</sup>One method from this group is selected.  
CTC = Computed tomographic colonography; DCBE = double-contrast barium enema; FIT = fecal immunochemical test; FSIG = flexible sigmoidoscopy; gFOBT = guaiac-based fecal occult blood test; sDNA = stool DNA test.  
Adapted with permission from Smith RA, Manassaram-Baptiste D, Brooks D, et al: Cancer screening in the United States, 2015: a review of current American Cancer Society guidelines and current issues in cancer screening. *CA Cancer J Clin* 2015 Jan-Feb;65(1):30–54.

suspected hereditary syndrome such as hereditary nonpolyposis colon cancer (Lynch syndrome) or familial adenomatous polyposis (Smith, 2015).

Lung Cancer

In the United States, this cancer is estimated to account for 13 percent of all new cancers diagnosed in women in 2015 (Siegel, 2015). It is now the leading cause of cancer-related death in both men and women. All smokers should be advised of tobacco-use risks and encouraged to stop. A list of potential aids is found on page 11.

Lung cancer screening focuses on those at high risk and referral is considered for individuals with general good health, aged 55 to 74, with at least a 30-pack-year history, and who actively smoke or quit within the past 15 years. One remembers that pack-year determination is calculated by multiplying the number of packs smoked per day by the number of years the person has smoked. By convention, one pack contains 20 cigarettes. For appropriate cases, low-dose helical CT scanning is the preferred test (Smith, 2015). Although a common diagnostic test, chest radiography is not recommended as a lung cancer screening tool.

Skin Cancer

The incidence of skin cancers (melanoma and non-melanomas) has increased in the United States during the past three decades. In 2015, melanoma is expected to account for 4 percent of all cancer deaths in women (Siegel, 2015). Skin cancer risks include prolonged sun exposure, family or personal history of skin cancer, fair skin, light hair or freckling, numerous moles, immunosuppression,

and aging (American Cancer Society, 2013). The USPSTF notes insufficient evidence to recommend whole body screening by physician or patient for skin cancer in the general adult population (Wolff, 2009). It does advise clinicians to use the “ABCD” system— asymmetry, border irregularity, color, and diameter (> 6 mm) to evaluate skin lesions of concern and refer appropriately.

Lifestyle Changes  
Smoking

Cigarette smoking is the single most preventable cause of death in the United States and has been linked with certain cancers, cardiovascular disease, chronic lung diseases, and stroke. Moreover, specific to women’s health, smoking is linked to diminished fertility, pregnancy complications, and postoperative complications. These are discussed in greater detail in their respective chapters.

Despite these known negative health outcomes, in 2003, only 64 percent of smokers who had routine examinations in the United States were advised by a physician to quit smoking (Torrijos, 2006). Guidelines from the U.S. Department of Health and Human Services encourage a brief behavioral patient intervention model found on page 12. Patients can also be referred to the National Cancer Institute’s smoking cessation website: [www.smokefree.gov](http://www.smokefree.gov). This site provides free, evidence-based information and professional assistance to help the immediate and long-term needs of those trying to quit. Unless contraindicated, pharmacologic treatments to aid smoking cessation can be offered to all interested women and

**TABLE 1-4.** Drugs Used for Smoking Cessation

Agent	Brand Name	Initial Dosing	Maintenance	Drug Tapering	Therapy Duration
<b>Nicotine Replacement</b>					
Patch <sup>d</sup>	Habitrol Nicoderm CQ	If > 10 CPD: a 21-mg patch is reapplied daily wk 1–6 If < 10 CPD: 14-mg patch daily for wk 1–6	14-mg patch is used wk 7–8 —	7-mg patch is used wk 9–10 7-mg patch is used wk 7–8	8–12 wk
Gum <sup>d</sup>	Nicorette 2 mg 4 mg (if ≥ 25 CPD)	1 piece every 1–2 hr for wk 1–6 (maximum 24 pieces/d)	1 piece every 2–4 hr for wk 7–9	1 piece every 4–8 hr for wk 10–12	12 wk
Lozenge <sup>b</sup>	Commit 2 mg 4 mg (if smokes < 30 min after waking)	1 piece every 1–2 hr for wk 1–6 (maximum 20 pieces/d)	1 piece every 2–4 hr for wk 7–9	1 piece every 4–8 hr for wk 10–12	12 wk
Inhaler <sup>d</sup>	Nicotrol		6 (average use) to 16 cartridges puffed qd for 12 wk	Use is then tapered	12–24 wk
Nasal spray <sup>d</sup>	Nicotrol		1 dose = 1 spray to each nostril per hr (maximum 5 doses/hr & 40/d)	Use is then tapered starting wk 9	12–24 wk
<b>Nicotine Agonists</b>					
Varenicline <sup>c</sup>	Chantix	0.5 mg PO qd for 3 d, then 0.5 mg PO bid for next 4 d	Then 1 mg PO bid		12 wk
<b>CNS Agents</b>					
Bupropion <sup>c</sup>	Wellbutrin SR Zyban	1–2 wk prior to cessation: 150 mg PO qd for 3 d	Then 150 mg PO bid		7–12 wk; may use for 6 mo.
Nortriptyline <sup>a,d</sup>		25 mg PO qd with gradual increase	75–100 mg PO qd		12 wk; may use for 6 mo.
Clonidine <sup>a,c</sup>	Catapres  Catapres-TTS	0.1 mg PO bid, increase by 0.10 mg/d each wk as needed 0.1-mg transdermal patch is changed weekly	0.15–0.75 mg PO qd  0.1- to 0.2-mg transdermal patch weekly		3–10 wk

<sup>a</sup>Recommended as second-line agents by U.S. Public Health Service clinical guidelines, 2008.

<sup>b</sup>Has not been evaluated by the Food and Drug Administration (FDA) for pregnancy.

<sup>c</sup>Considered an FDA pregnancy category C drug.

<sup>d</sup>Considered an FDA pregnancy category D drug.

bid = twice daily; CNS = central nervous system; CPD = cigarettes per day; PO = orally; qd = daily.

Data from Fiore MC, Jaen CR, Baker TB, et al: Treating tobacco use and dependence: 2008 update. Rockville, U.S. Department of Health and Human Services, 2008.

are listed in [Table 1-4](#). Gynecologists who are proficient in the use of these therapies may prescribe. Referral is also appropriate (American College of Obstetricians and Gynecologists, 2014c).

### Exercise

Exercise has known benefits in preventing coronary artery disease, diabetes, osteoporosis, obesity, depression, insomnia, and

breast and colon cancer (Brosse, 2002; Knowler, 2002; Lee, 2003; Vuori, 2001; Youngstedt, 2005). Many of these associations may result from the effects of exercise to lower blood pressure, decrease low-density lipoprotein cholesterol and triglyceride levels, increase high-density lipoprotein cholesterol levels, improve blood sugar control, and reduce weight (Braith, 2006; Pescatello, 2004; Sigal, 2004).

**TABLE 1-5.** Definitions of Abnormal Weight for Adults and Adolescents Using Body Mass Index

Age Group	Underweight	Overweight	Obese
Adult	< 18.5	25–29.9	≥ 30
Adolescent	< 5th percentile for age	Between 85th and 95th percentile for age	> 95th percentile for age

Despite these known benefits, based on U.S. government thresholds, only 45 percent of women in 2012 were considered sufficiently active (Blackwell, 2014). Recommendations from the U.S. Department of Health and Human Services (2008) include moderate-intensity activity such as walking, water aerobics, or yard work for at least 150 minutes each week *or* vigorous-intensity activities such as running, swimming laps, or aerobic dancing for 75 minutes each week. Activities can be performed in episodes of at least 10 minutes that are apportioned throughout the week. Additional health benefits are gained with physical activity beyond these amounts.

Although exercise programs have traditionally emphasized dynamic, aerobic lower-extremity exercise, research supports complementary resistance training to improve muscular strength and endurance, cardiovascular function, metabolism, coronary risk factors, weight management, and quality of life (Williams, 2007). Accordingly, government guidelines also encourage biweekly muscle-strengthening activities that involve all the major muscle groups. A fuller listing of general physical activities and their intensity description is found in the publication *2008 Physical Activity Guidelines for Americans* at the CDC website: [www.health.gov/paguidelines/guidelines](http://www.health.gov/paguidelines/guidelines).

To change any type of health-related behavior, counseling can be brief yet effective. One method is the five A’s system, which in this example is tailored for exercise (Fiore, 2008).

- Ask: if she is physically active now
- Advise: her about the benefits of regular physical activity
- Assess: her willingness to change and decide if she is in a (1) precontemplation, (2) contemplation phase, (3) preparation, or (4) action phase. Her stage of readiness guides further discussion
- Assist: her by recommending local exercise programs
- Arrange: for follow-up evaluation to assess progress

For those with certain comorbidities, clearance by other health care providers may be indicated. For this, the Physical Activity Readiness Questionnaire helps identify women with risk factors who merit further evaluation and is available at: [www.csep.ca/cmfiles/publications/parq/par-q.pdf](http://www.csep.ca/cmfiles/publications/parq/par-q.pdf).

■ **Obesity**  
**Associated Risks and Diagnosis**

In 2010, nearly 36 percent of women in the United States were obese, and almost twice that many were overweight (Flegal, 2012). Possible consequences of obesity include diabetes mellitus, metabolic syndrome, nonalcoholic fatty liver, cholelithiasis, hypertension, osteoarthritis, nonobstructive sleep apnea, and renal disease. Gynecologic issues related to obesity include abnormal menstruation, risks for endometrial neoplasia, and worsening polycystic ovary syndrome. Moreover, some hormonal contraceptives may have lower efficacy in obese women. Despite these considerable consequences, one study showed

that fewer than half of physicians are comfortable discussing obesity (Schuster, 2008). Even if not trained as weight management specialists, clinicians ideally screen for obesity, provide initial obesity evaluation and management, and refer as needed.

Screening is accomplished with calculation of body mass index (BMI) or less commonly, waist circumference. BMI, although not a direct measure of body fat content, is valuable in assessing the risk for weight-related complications. The following calculations can be used:

$$\text{BMI} = (\text{Wt in lb}/(\text{Ht in inches} \times \text{Ht in inches})) \times 703$$
$$\text{BMI} = \text{Wt in kg}/(\text{Ht in meters} \times \text{Ht in meters})$$

More simply, an online calculator can be found at: [www.cdc.gov/healthyweight/assessing/bmi/adult\\_bmi/english\\_bmi\\_calculator/bmi\\_calculator.html](http://www.cdc.gov/healthyweight/assessing/bmi/adult_bmi/english_bmi_calculator/bmi_calculator.html). For adolescents (and children), BMI is adjusted for age and gender and calculated as a percentile. A BMI calculator for adolescents can be found at <http://apps.nccd.cdc.gov/dnpabmi/.calculator.aspx>. Table 1-5 reflects the definitions for underweight, overweight, and obesity for adolescents and adults.

Waist circumference positively correlates with abdominal fat content, which is a risk factor for poor health outcomes. Waist circumference is measured at the level of the iliac crests at the end of normal expiration. Values greater than 35 inches (88 cm) are considered elevated (National Heart, Lung, and Blood Institute, 2000).

No standard single or panel laboratory test is indicated for an obese woman. Evaluation for comorbidities is tailored to the patient, taking into consideration her family and social histories (Table 1-6). Blood pressure measurement, fasting lipid and glucose screening, and thyroid function testing can all be considered for the obese patient during initial evaluation.

**TABLE 1-6.** Obesity Comorbid Risk Factors

Coronary heart disease (CHD)

Osteoarthritis
Gallstones

Data from National Heart, Lung, and Blood Institute: The practical guide: identification, evaluation, and treatment of overweight and obesity in adults. National Institutes of Health Publication No. 98–4084, Bethesda, 2000.

For a woman with elevated BMIs, a clinician should assess her readiness for change and thereby, provide appropriate guidance, support, or referral. In addition, questions regarding previous attempts at weight loss, social hurdles that impede diet and exercise change, and detrimental eating habits are discussed in a nonjudgmental manner.

## Treatment

Effective weight loss is best obtained with proper nutrition and consistent physical activity. [Table 1-7](#) illustrates recommended guidelines to direct therapy for overweight or obese women. A detailed discussion of dietary weight loss extends beyond this chapter's scope, but several clinician and patient aids can be found in *The Practical Guide to Identification, Evaluation and Treatment of Overweight or Obesity in Adults*, available at: [www.nhlbi.nih.gov/guidelines/obesity/prctgd\\_c.pdf](http://www.nhlbi.nih.gov/guidelines/obesity/prctgd_c.pdf).

In general, for the adult patient, a 10-percent weight loss within 6 months is realistic. According to the American Heart Association, suitable options are diets with 1200 to 1500 kcal/day or diets that incorporate a 500 or 750-kcal/d deficit (Jensen, 2014). No single diet plan is espoused as the gold standard for every patient, and the ideal regimen is one that can be adhered to.

In addition to diet and exercise, pharmacologic or surgical options may be implemented for selected obese patients. Four agents are FDA-approved for long-term obesity treatment. First, orlistat (Xenical) is a reversible inhibitor of gastric and pancreatic lipases and leads to a 30-percent blockage of dietary fat absorption (Henness, 2006). This drug is prescribed as 120-mg capsule taken orally three times daily with meals but is also available over-the-counter in 60-mg capsules (Alli), also taken three times daily. Associated malabsorption can lead to deficiencies of the fat-soluble vitamins A, D, E, and K, and all patients should receive a daily supplement enriched with these vitamins. Severe liver injury has been reported rarely, and new labeling reflects this risk (Food and Drug Administration, 2010).

Another medication, lorcaserin (Belviq) is a serotonin 2C receptor agonist used to suppress appetite (Fidler, 2011; Smith, 2010). One 10-mg tablet is taken orally twice daily. A third agent combines phentermine and topiramate (Qsymia)(Gadde, 2011). Doses begin at 3.75 mg/23 mg orally daily and are gradually titrated upward as needed to a maximum dose of 15 mg/92 mg daily. This drug has fetotoxicity potential and prescribing providers participate in a Qsymia Risk Evaluation and Mitigation Strategy program. Last, liraglutide (Saxenda) is a glucagon-like peptide-1 receptor agonist delivered by subcutaneous injection (Astrup, 2009). Dosing begins at 0.6 mg daily and is gradually escalated weekly to reach a 3-mg daily dose. Important poten-

tial risks include medullary thyroid carcinoma and pancreatitis. These last three agents are indicated for those with BMIs of 30 or greater, or 27 or greater if weight-associated comorbid risks exist.

As another adjunct, bariatric surgery may be selected for those with BMIs of 40 or greater, or with BMIs at or above 35 if other comorbid conditions are present (Jensen, 2014). Of available laparoscopic procedures, three are more commonly performed. Two are considered restrictive (limit intake), whereas bypass surgery promotes malabsorptive weight loss. First of these, gastric banding places an adjustable plastic ring around the stomach to limit food intake. Second, sleeve gastrectomy partitions off the lateral stomach by a staple line, and the remaining smaller stomach has a tubular, sleeve appearance. Last, the Roux-en-Y gastric bypass creates a small stomach pouch that is connected directly to the jejunum to bypass the duodenum. This reduces calorie and nutrient absorption. These surgeries lead to substantial weight loss in individuals with morbid obesity and have been linked with improvement in comorbid risk factors and decreased mortality rates (Hutter, 2011). With these, surgical complications are infrequent but can be serious and include gastrointestinal leaks at staple or suture lines, stomal obstruction or stenosis, thromboembolism, and bleeding (Jackson, 2012).

Following bariatric surgery, patients are advised to delay pregnancy for 12 to 24 months (American College of Obstetricians and Gynecologists, 2013). Rapid weight loss during this time poses theoretical risks for intrauterine fetal-growth restriction and nutritional deprivation. However, as weight is lost, fertility rates overall appear to be improved, and risks for pregnancy increase (Merhi, 2009). Thus, effective contraception is needed. Most contraceptive methods appear to be as effective in women with elevated BMIs compared with normal-weight controls. However, the contraceptive patch (OrthoEvra) is less effective in those weighing more than 90 kg (Zieman, 2002). Specific to those with malabsorptive bariatric surgery types, oral contraception efficacy may be lower due to poor absorption (Centers for Disease Control and Prevention, 2013). Last, due to its risk for associated weight gain, depot medroxyprogesterone acetate (Depo-Provera) may be an unpopular choice in women trying to lose weight.

## ■ Cardiovascular Disease

In 2010, nearly 34 percent of the female population was affected by cardiovascular disease (CVD), and more than 400,000 women died from its complications (Go, 2014). Stratification of CVD predispositions can identify vulnerable patients for management or referral ([Table 1-8](#)). Ideal goals for exercise, glucose and lipid levels, blood pressure, and smoking cessation

**TABLE 1-7.** Treatment Recommendations According to BMI

Treatment	BMI 25–26.9	BMI 27–29.9	BMI 30–34.9	BMI 35–39.9	BMI ≥ 40
Diet, activity, behavioral therapy	WCM	WCM	+	+	+
Pharmacotherapy	—	WCM	+	+	+
Surgery	—	—	—	WCM	+

+ represents the use of indicated treatment regardless of comorbidities; BMI = body mass index; WCM = with comorbidities. Data from Jensen MD, Ryan DH, Apovian CM, et al: 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society. *Circulation* 129(25 Suppl 2):S102, 2014.

are discussed in other sections of this chapter. Specific dietary intake recommendations for women are listed in [Table 1-9](#).

■ **Chronic Hypertension**

Nearly 41 million American women are hypertensive. The risk of hypertension increases with age and is increased for black women compared with those of other races (Go, 2014). Chronic hypertension increases the risks for myocardial infarction, stroke, congestive heart failure, renal disease, and peripheral vascular disease. Moreover, chronic hypertension and its potential therapies may limit contraception choices for some women. Thus, gynecologists should be familiar with criteria used to diagnose hypertension. Although many may choose to refer their patients for treatment of hypertension, gynecologists should be aware of target goals and long-term risks associated with this disease.

For adult screening, the American Heart Association (2014) recommends blood pressure assessment starting at age 20 and evaluation repeated every 2 years if initially normal. For patients with elevated pressures, assessment is at least annually.

**TABLE 1-8.** Classification of Cardiovascular Disease (CVD) in Women

<b>≥ 1 assigns high-risk status</b>	Known CHD or CVD
	Peripheral arterial disease
	Aortic aneurysm
	End-stage renal disease
<b>≥ 1 assigns at-risk status</b>	Diabetes mellitus
	Smoking
	SBP ≥ 120 or DBP ≥ 80 mm Hg, or treated hypertension
	Total cholesterol ≥ 200 mg/dL, HDL < 50 mg/dL, or treated dyslipidemia
	Obesity
	Poor diet
	Physical inactivity
	Family history of premature CVD
	Metabolic syndrome
	Collagen-vascular disease
<b>Ideal, if all present</b>	Prior PIH or gestational DM
	Total cholesterol < 200 mg/dL
	BP < 120/< 80 mm Hg
	Fasting blood glucose < 100 mg/dL
	Body mass index < 25
	Abstinence from smoking
	Physically activity
	Healthy diet: see Table 1-9

BP = Blood pressure; CHD = coronary heart disease; CVD = cardiovascular disease; DBP = diastolic blood pressure; DM = diabetes mellitus; GDM = gestational diabetes; HDL = high-density lipoprotein; PIH = pregnancy-induced hypertension; SBP = systolic blood pressure.

**TABLE 1-9.** Specific Dietary Intake Recommendations for Women

Food	Serving
Fruits/vegetables	≥ 4.5 cups/d
Fish	2/wk
Fiber	30 g/d
Whole grains	3/d
Sugar	≤ 5/wk
Nuts, legumes	≥ 4/wk
Saturated fat	< 7%/total energy intake
Cholesterol	< 150 mg/d
Alcohol	≤ 1/d
Sodium	< 1500 mg/d
trans-Fatty acids	None

Adapted with permission from Mosca L, Benjamin EJ, Berra K, et al: Effectiveness-based guidelines for prevention of cardiovascular disease in women—2011 update: a guideline from the american heart association, *Circulation* 2011 Mar 22;123(11):1243–1262.

With screening, blood pressures are best taken with a woman seated in a chair with the tested arm resting on a table, at the level of the heart. Ideally, the patient has been able to rest quietly for a few minutes prior to measurement and to have refrained from tobacco and caffeine use immediately prior to testing. An appropriately sized cuff is selected, and the cuff bladder should encircle at least 80 percent of the arm. Hypertension is diagnosed if readings are elevated on at least two separate office visits over one or more weeks. *Prehypertension* is diagnosed if readings fall in the range 130–139/80–89 mm Hg. Notably, women with prehypertension are at significantly increased risk of developing hypertension later (Wang, 2004). Additionally, compared with normal blood pressure readings, prehypertension is associated with greater risks for CVD (Mainous, 2004).

If hypertension is diagnosed, further examination should exclude underlying causes of hypertension and resultant end-organ disease ([Table 1-10](#)). With the diagnosis of chronic hypertension, assessment then follows for both modifiable and nonmodifiable CVD risk factors. Thus, routine laboratory tests recommended before initiating therapy include an electrocardiogram, urinalysis, blood glucose, hematocrit, lipid profile, thyroid testing, and serum potassium and creatinine measurement. A more extensive search for identifiable causes is not generally indicated unless hypertension is not controlled with initial treatment (Chobanian, 2003).

For treatment, lifestyle changes that mirror those for CVD are encouraged (see [Table 1-9](#)). However, if blood pressure is significantly elevated or resistant to lifestyle modification alone, then pharmacologic treatment may be needed to decrease long-term complications. Recommendations from the Eighth Joint National Committee (JNC 8) are shown in [Table 1-11](#) (James, 2014).

■ **Stroke**

It is the third leading cause of death in the United States, and in 2010, approximately 425,000 American women suffered a new or recurrent stroke (Go, 2014). Gender-specific risk factors for stroke in women include hypertension, atrial fibrillation, migraines with aura, and oral contraceptive use. Aspirin is recommended

**TABLE 1-10.** Identifiable Causes of Hypertension

Chronic renal disease
Chronic corticosteroid therapy and Cushing syndrome
Coarctation of the aorta
Drug-induced or drug-related
Nonsteroidal antiinflammatory drugs
Cocaine and amphetamines
Sympathomimetics (decongestants, anorectics)
Combination hormonal contraception
Adrenal steroids
Cyclosporine and tacrolimus
Erythropoietin
Licorice
Herbal medicines (ephedra, ma huang)
Pheochromocytoma
Primary aldosteronism
Renovascular disease
Sleep apnea
Thyroid or parathyroid disease

as prevention for stroke in normotensive women aged 65 years or older for whom the lowered risks for ischemic stroke and myocardial infarction outweigh the risks for gastrointestinal bleeding and hemorrhagic stroke (Bushnell, 2014). There is no consensus as to the optimal dose or frequency of aspirin for prevention. Options are 81 mg daily or 100 mg every other day.

## ■ Dyslipidemia

### Hypercholesterolemia

Data support that low-density lipoprotein cholesterol (LDL) is the primary atherogenic agent. Although previously believed merely to collect passively within vessel walls, LDL is now felt to be a potent proinflammatory agent and creates the chronic inflammatory response characteristic of atherosclerosis. Logically, elevated levels of total and LDL cholesterol are associated with increased rates of coronary artery disease, ischemic stroke, and other atherosclerotic vascular complications (Horenstein, 2002; Law, 1994).

Preventively, the National Cholesterol Education Program Adult Treatment Panel-III (ATP-III) (2001) recommends that all adults 20 years and older be screened with a fasting serum lipoprotein profile once every 5 years. This profile includes measurement of total, LDL, and high-density lipoprotein (HDL) cholesterol

**TABLE 1-12.** Interpretation of Cholesterol and Triglyceride Levels

Lipoprotein (mg/dL)	Interpretation
<b>Total cholesterol</b>	
< 200	Optimal
200–239	Borderline elevated
≥ 240	Elevated
<b>LDL cholesterol</b>	
< 100	Optimal
100–129	Near optimal
130–159	Borderline elevated
160–189	Elevated
≥ 190	Very elevated
<b>HDL cholesterol</b>	
< 40	Low
≥ 60	Elevated
<b>Triglycerides</b>	
< 150	Optimal
150–199	Borderline elevated
200–499	Elevated
≥ 500	Very elevated

HDL= high-density lipoprotein; LDL= low-density-lipoprotein. Data from National Cholesterol Education Program: Detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III). National Institutes of Health Publication No.01–3670, Bethesda, 2001.

levels and triglyceride concentrations. Table 1-12 lists interpretation of these levels. Notably, if other comorbid risks for coronary heart disease are present, then LDL goals are more stringent.

Lowering LDL levels has been associated with reduced rates of myocardial infarction and stroke (Goldstein, 2006; Sever, 2003). Initial management usually begins with lifestyle and dietary changes, discussed earlier for CVD, and outlined by the American Heart Association (Eckel, 2014). If these modifications are unsuccessful, this organization recommends lipid-lowering treatment consideration for: (1) those with known CVD, (2) those with LDL cholesterol levels at or above 190 mg/dL, (3) those aged 40 to 75 years with diabetes and LDL cholesterol levels of 70 mg/dL or more, and (4) those

**TABLE 1-11.** Initial Drug Therapy for Adults with Hypertension

Health Status	Goal BP	Treatment
General ≥ 60 yr	< 150/90	Nonblack: thiazide-type diuretic, ACEI, ARB, or CCB Black: thiazide-type diuretic or CCB
General < 60 yr	< 140/90	
Diabetes	< 140/90	
Renal disease	< 140/90	ACEI or ARB

ACEI= angiotensin-converting enzyme inhibitor; ARB= angiotensin-receptor blocker; BP = blood pressure; CCB= calcium-channel blocker.

Data from James PA, Oparil S, Carter BL, et al: 2014 evidence-based guideline for the management of high blood pressure in adults: report from the panel members appointed to the Eighth Joint National Committee (JNC 8). JAMA 311(5):507, 2014.

aged 40 to 75 years with LDL cholesterol levels of 70 mg/dL or higher and an estimated 10-year risk of a cardiovascular event that is at least 7.5 percent (Stone, 2014).

Hypertriglyceridemia

Triglycerides are delivered to tissues by very-low-density lipoprotein (VLDL), which is synthesized and secreted by the liver. T is triglyceride-rich lipoprotein is taken up by adipose and muscle, where triglycerides are cleaved from VLDL. Ultimately, a VLDL remnant is created that is atherogenic. For this reason, triglyceride levels can be used as one marker for atherogenic lipoproteins, and high triglyceride levels have been linked to increases in CVD (Assmann, 1996; Austin, 1998). Its clinical importance is also underscored by its inclusion as one criterion for the metabolic syndrome.

Hypertriglyceridemia is diagnosed based on criteria found in Table 1-12. For most with mild or moderate triglyceride elevation, recommendations from American Heart Association emphasize diet changes and weight loss (Miller, 2011). Alternatively, for those with triglyceride levels of 500 mg/dL or greater, treatment goals focus primarily on triglyceride level lowering to prevent pancreatitis.

■ Diabetes Mellitus

Diabetes is common, and approximately 13.4 million adult women in the United States are diabetic (Centers for Disease Control and Prevention, 2014). T e long-term consequences of this endocrine disorder are serious and include coronary heart disease, stroke, peripheral vascular disease, periodontal disease, nephropathy, neuropathy, and retinopathy.

T e USPSTF (2014b) recommends diabetes screening for asymptomatic adults with blood pressure of 135/80 mm Hg or greater. For normotensive adults, screening is individualized based on risks. However, the American Diabetes Association (2015) recommends that screening be considered at 3-year intervals beginning at age 45, particularly in those with BMIs of 25 or above. Moreover, testing is considered at a younger age or completed more often in those who are overweight and have one or more of the other risk factors shown in Table 1-13.

Diabetes and prediabetes may be diagnosed by various laboratory tests listed in Table 1-14. Laboratory measurement of plasma glucose concentration is performed on venous samples, and the aforementioned values are based on the use of such methods. Capillary blood glucose testing using a blood glucometer is an effective monitoring tool but is not currently recommended for diagnostic use.

For those diagnosed with diabetes, referral to a specialist is usually indicated. Delayed onset and slower progression of many diabetic complications has been shown to follow control of elevated blood glucose levels (Cleary, 2006; Fioretto, 2006; Martin, 2006). Control can be achieved with diet modification alone or combined with oral hypoglycemic agents or injectable insulin. To lower diabetic morbidity, therapy goals for otherwise normal patients include hemoglobin A<sub>1c</sub> levels below 7 percent, preprandial glucose between 80 and 130 mg/dL, blood pressure readings below 120/80 mm Hg, low-density lipoprotein (LDL) levels below 100 mg/dL, HDL levels above 50 mg/dL, triglyceride levels below 150 mg/dL, weight loss, and smoking cessation (American Diabetes Association, 2015).

TABLE 1-13. Adult Risk Factors for Diabetes Mellitus

Age ≥ 45 years
Body mass index ≥ 25
Affected first-degree relative
Physical inactivity
Ethnicity: African-, Hispanic-, Native-, and Asian-Americans; Pacific Islanders
Prior prediabetes-range test values
Prior gestational diabetes mellitus or delivery of a baby weighing > 9 lb
Hypertension: ≥ 140/90 mm Hg
HDL cholesterol ≤ 35 mg/dL and/or triglyceride level ≥ 250 mg/dL
Polycystic ovary syndrome
Conditions associated with insulin resistance
Existing cardiovascular disease

HDL= high-density lipoprotein.  
Data from American Diabetes Association, 2015 American Diabetes Association: Standards of medical care in diabetes—2015. Diabetes Care 38:S1, 2015.

Patients with “prediabetes,” that is, impaired fasting glucose or impaired glucose tolerance, have an increased risk for developing diabetes. To avert or delay diabetes, management includes increased physical activity, weight loss, drugs such as metformin, nutritional counseling, and yearly diabetes screening. Metformin is considered especially for those with BMI above 35, age younger than 60 years, and prior gestational diabetes (American Diabetes Associations, 2015).

TABLE 1-14. American Diabetes Association Criteria

<b>Diagnostic Criteria for Diabetes Mellitus</b>
HbA <sub>1c</sub> ≥ 6.5%
or
Fasting plasma glucose ≥ 126 mg/dL Fasting is no caloric intake for at least 8 hr
or
2-hr plasma glucose ≥ 200 mg/dL during an OGTT
or
Symptoms of diabetes plus random plasma glucose concentration ≥ 200 mg/dL Classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss
<b>Criteria for Increased Diabetes Risk (prediabetes)</b>
Fasting plasma glucose: 100–125 mg/dL
or
2-hr plasma glucose during 75-g OGTT: 140–199 mg/dL
or
HbA <sub>1c</sub> : 5.7–6.4%

HbA<sub>1c</sub> = hemoglobin A<sub>1c</sub>; OGTT= oral glucose tolerance test.  
Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus, Diabetes Care. 2008 Jan;31 Suppl 1:S55–S60.

**TABLE 1-15.** Diagnostic Criteria for Metabolic Syndrome in Women

Criteria	Thresholds
Waist circumference	≥ 88 cm (≥ 35 in)
Triglycerides	≥ 150 mg/dL
HDL cholesterol	< 50 mg/dL
Blood pressure	≥ 130/85 mm Hg
Fasting glucose	≥ 110 mg/dL

Drug treatment for any of these conditions is considered a positive criterion.

HDL= high-density lipoprotein.

Adapted with permission from Grundy SM, Cleeman JI, Daniels SR, et al: Diagnosis and management of the metabolic syndrome: an American Heart Association/National Heart, Lung, and Blood Institute scientific statement, *Circulation* 2005 Oct 25;112(17):2735–2752.

## ■ Metabolic Syndrome

This syndrome is a clustering of major cardiovascular disease risk factors (Table 1-15). At present, a single unifying cause of the metabolic syndrome has not been identified, and it may be precipitated by multiple underlying risk factors. Of these, abdominal obesity and insulin resistance appear important (Grundy, 2005).

This syndrome is common, and in 2010, 22 percent of U.S. women met diagnostic criteria. Although genders appear equally affected, Mexican Americans show the highest prevalence, and incidence appears to increase in all ethnicities with age (Beltrán-Sánchez, 2014). The sequelae associated with metabolic syndrome are significant and include an increased risk of diabetes and mortality from coronary heart disease, CVD, and all causes (Lorenzo, 2003; Malik, 2004; Sattar, 2003). Among those with metabolic syndrome, risks are further increased, by cigarette smoking and elevated LDL cholesterol levels.

Goals of clinical management include reducing risks for clinical atherosclerotic disease and for diabetes. Accordingly, primary therapy for metabolic syndrome focuses on lifestyle modification, particularly weight reduction and increased exercise. During evaluation, each metabolic syndrome component is addressed and treated in accordance with current guidelines, as discussed in earlier sections.

## ■ Thyroid Disease

The risk of thyroid disease increases with age, and dysfunction is more common in women. Accordingly, the American Thyroid Association recommends that adults, especially women, be screened for thyroid dysfunction by measurement of a serum thyroid-stimulating hormone (TSH) concentration. This begins at age 35 years and is repeated every 5 years thereafter (Garber, 2012). Moreover, individuals with clinical manifestations potentially attributable to thyroid dysfunction and those with risk factors for its development may require more frequent testing. People at higher risk for thyroid dysfunction include the elderly and those with prior neck radiation, thyroid surgery, autoimmune disease, affected first-degree relative, psychiatric disorders, or lithium use. In contrast, the U.S. Preventive Service Task Force (2004b) has found insufficient evidence to recommend for or against routine screening in asymptomatic women.

## ■ Geriatric Screening

Women are now living longer, and the current life expectancy for women in the United States is 81 years (Arias, 2014). As a woman moves past menopause, many of her health care needs may not be gynecologic. However, a family may often contact a patient's gynecologist first regarding a member's lack of independent function or memory loss.

Of these, functional status is a patient's ability to perform both basic and complex activities for independent living. Basic activities are grooming and toileting, whereas checkbook balancing, bill paying, and housekeeping tasks are more complex, instrumental activities of daily living (Katz, 1963; Lawton, 1969). Declines in functional status are linked to increased risks of hospitalization, institutionalization, and death (Walston, 2006). Identification of functional status loss may permit early intervention.

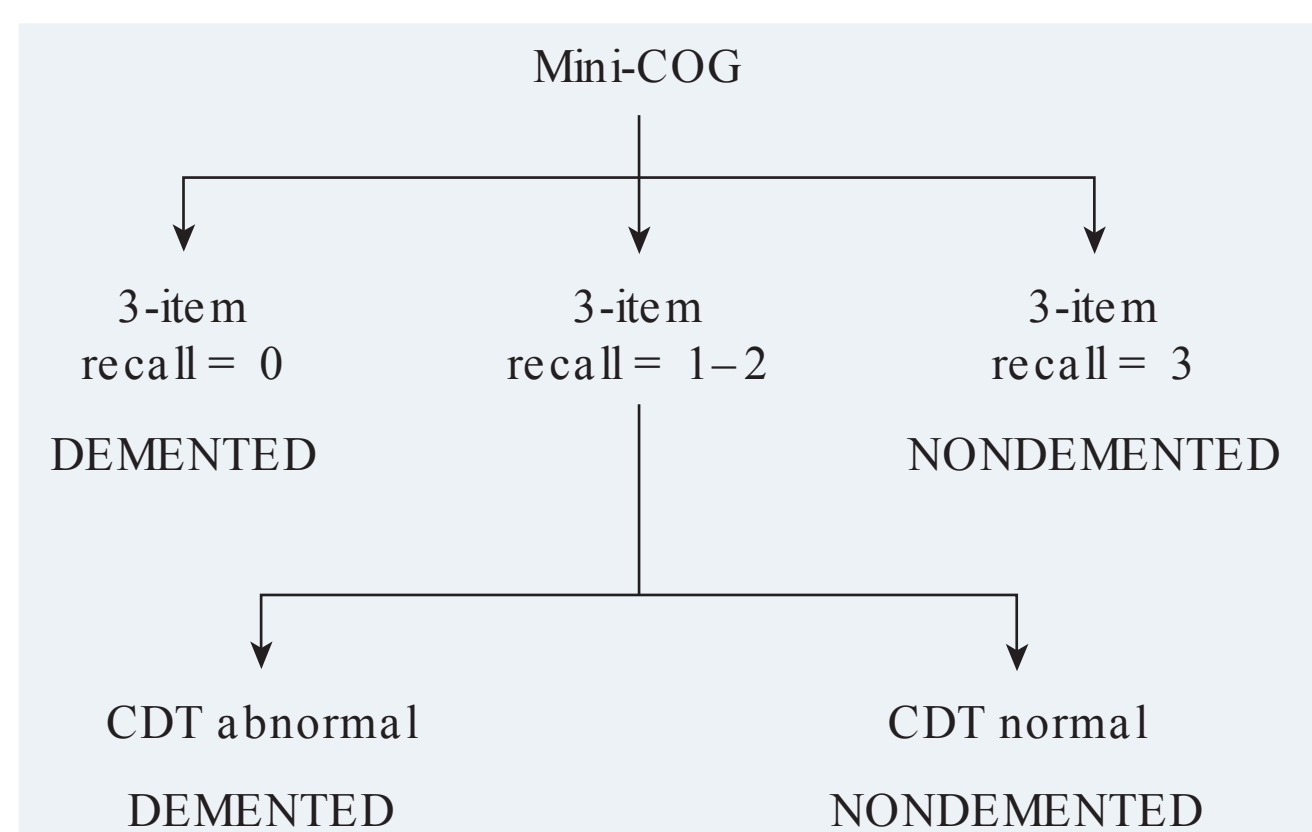

Second, loss of cognitive function may present as short- and long-term memory loss, difficulty with problem solving, or inattention to personal hygiene. Although not expert in recognition of cognitive problems, a gynecologist can perform initial screening and provide results that either reassure the patient and her family or prompt more formal evaluation by a geriatrician or neurologist.

For dementia, the Mini Mental Status Exam or, more recently, the Mini-Cog Test can screen for cognitive impairment in the primary care setting (Borson, 2000, 2006; Folstein, 1975). The Mini-Cog test requires approximately 3 minutes to administer and begins by giving the patient three items to remember early in the interview. Later in discussion, she is asked to recall those three items. For the clock-drawing test, a person is asked to draw a clock with the hands at a specific time, such as 8:30. A correct clock has numbers 1 through 12 labeled correctly in a clockwise fashion, with two arms (of any length) pointing at the correct numbers for the time requested. Any error or refusal to complete the clock is considered abnormal. An algorithm for scoring the Mini-Cog is shown in Figure 1-10. For a Mini-Cog Test result suggestive of dementia, referral to an internist, geriatrician, or neurologist, as available to the patient in that community, is indicated.

## ■ Mental Health

### Depression and Intimate Partner Violence

For women of all ages, these problems are pervasive and account for significant morbidity and mortality. Each is discussed in

**FIGURE 1-10** The Mini-Cog Test. CDT= clock-drawing test. (Modified with permission from Borson S, Scanlan J, Brush M, et al: The Mini-Cog: a cognitive “vital signs” measure for dementia screening in multi-lingual elderly. *Int J Geriatr Psychiatry* 2000 Nov;15(11):1021–1027.)

detail in Chapter 13 and should be routinely screened for at routine health visits. Simple questions such as “During the past 2 weeks, have you felt down, depressed, or hopeless?” and “Have you felt little interest or pleasure in doing things?” are often effective (Whooley, 1997). These two questions constitute the Personal Health Questionnaire-2 (PHQ2), a validated screening tool for depression (Kroenke, 2003). Any positive screening test should prompt further evaluation for depression as outlined in Chapter 13 (p. 298).

For intimate partner violence, American College of Obstetricians and Gynecologists (2012a) guidelines recommend that physicians routinely ask direct, specific questions regarding abuse. General introductory statements such as “Because abuse and violence are so common in women’s lives, I’ve begun to ask about it routinely” can help a health care provider introduce this subject for discussion.

Insomnia

Insomnia is common, and its definition includes: (1) difficulty initiating sleep, (2) trouble maintaining sleep, and (3) early waking. Insomnia may be primary or may be secondary to other conditions such as depression, time-zone travel, restless leg syndrome, stimulant use, and sleep apnea (National Institutes of Health, 2005). Accordingly, historical inventory investigates and treatment addresses these and other secondary causes.

Treatment of primary insomnia is typically cognitive-behavioral or pharmacologic. Cognitive therapy is aimed at changing patients’ beliefs and attitudes regarding sleep. Behavioral therapies are varied and include those that control sleep timing and duration; attempt to improve the bedroom environment; or focus on relaxation or biofeedback techniques (Morgenthaler, 2006; Silber, 2005). Medications may be used to aid sleep, and most agents are of the benzodiazepine family (Table 1-16).

TABLE 1-16. Insomnia Medications Approved by the U.S. Food and Drug Administration

Medication: Brand	Dose
<b>Benzodiazepines</b>	
Temazepam: Restoril	7.5–30 mg
Estazolam: ProSom	0.5–2 mg
Triazolam: Halcion	0.125–0.25 mg
Flurazepam: Dalmane	15–30 mg
Quazepam: Doral	7.5–15 mg
<b>Benzodiazepine-Receptor Agonists</b>	
Eszopiclone: Lunesta	1–3 mg
Zolpidem: Ambien, Ambien CR <sup>a</sup>	5–10 mg 6.25–12.5 mg
Intermezzo <sup>b</sup>	1.75 mg
Zaleplon: Sonata	5–20 mg
<b>Melatonin-Receptor Agonist</b>	
Ramelteon: Rozerem	8 mg

<sup>a</sup>Extended release form.  
<sup>b</sup>Indicated for middle-of-night awakening.

■ Preconceptional Counseling

Value lies in counseling women before conception so that each pregnancy is planned with the goal to achieve the best maternal and fetal outcomes. With this in mind, topics found in Table 1-17 are ideally addressed (American College of Obstetricians and Gynecologists, 2012b; Jack, 2008).

TABLE 1-17. Preconceptional Counseling Topics

Condition	Recommendations for Preconceptional Counseling
Abnormal weight	Calculate BMI yearly. BMI ≥ 25 kg/m <sup>2</sup> : Counsel on diet. Test for DM and metabolic syndrome if indicated BMI ≤ 18.5 kg/m <sup>2</sup> : Assess for eating disorder
Heart disease	Counsel on cardiac risks during pregnancy. Optimize cardiac function, offer effective BCM during this time. Discuss warfarin, ACE inhibitor, and ARB teratogenicity, and if possible, switch to less dangerous agent when conception planned. Offer genetic counseling to those with congenital cardiac anomalies. Review infective endocarditis risks (Nishimura, 2014)
Hypertension	Counsel on specific risks during pregnancy. Assess those with long-standing HTN for ventricular hypertrophy, retinopathy, and renal disease. Counsel women taking ACE inhibitors and ARBs on drug teratogenicity, on effective BCM during use, and on the need to switch agents prior to conception
Asthma	Counsel on asthma risks during pregnancy. Optimize pulmonary function and offer effective BCM during this time. Treat women with pharmacological step therapy for chronic asthma based on ACOG-ACAAI (2000) recommendations
Thrombophilia	Question for personal or family history of thrombotic events or recurrent poor pregnancy outcomes. If found, counsel and screen those contemplating pregnancy. Offer genetic counseling to those with known thrombophilia. Discuss warfarin teratogenicity, offer effective BCM during use, and switch to a less teratogenic agent, if possible, prior to conception

(Continued)

**TABLE 1-17.** Preconceptional Counseling Topics (Continued)

Condition	Recommendations for Preconceptional Counseling
Renal disease	Counsel on specific risks during pregnancy. Optimize blood pressure control and offer effective BCM during this time. Counsel women taking ACE inhibitors and ARBs on their teratogenicity, on effective BCM during use, and on the need to switch agents prior to conception
GI disease	Inflammatory bowel disease: Counsel affected women on subfertility risks and risks of adverse pregnancy outcomes. Discuss teratogenicity of MTX and the other immunomodulators, about which less is known, e.g., mycophenolate mofetil. Offer effective BCM during their use and switch agents, if possible, prior to conception
Liver disease	Hepatitis B: Vaccinate all high-risk women prior to conception (Table 1-2, p. 8). Counsel chronic carriers on transmission prevention to partners and fetus Hepatitis C: Screen high-risk women. Counsel affected women on risks of disease and transmission. Refer for treatment, discuss ramifications of treatment during pregnancy, and offer effective BCM
Hematologic disease	Sickle-cell disease: Screen all black women. Counsel those with trait or disease. Test partner if desired Thalassemias: Screen women of Southeast Asian or Mediterranean ancestry
Diabetes	Advocate good glucose control, especially in periconceptional period to decrease known teratogenicity of overt diabetes. Evaluate for retinopathy, nephropathy, hypertension, etc.
Thyroid disease	Screen those with thyroid disease symptoms. Ensure iodine-sufficient diet. Treat overt hyper- or hypothyroidism prior to conception. Counsel on risks to pregnancy outcome
CT disease	RA: Counsel on flare risk after pregnancy. Discuss MTX and leflunomide teratogenicity. Offer effective BCM during their use and switch agents prior to conception. SLE: Counsel on risks during pregnancy. Optimize disease. Discuss mycophenolate mofetil and cyclophosphamide teratogenicity; offer effective BCM during their use. If possible, switch agents prior to conception
Neurologic and psychiatric disorders	Depression: Screen for symptoms. If affected, counsel on risks of treatment and of untreated illness and high risk of peripartum exacerbation Seizure disorder: Optimize seizure control using monotherapy if possible
Skin disease	Discuss isotretinoin and etretinate teratogenicity, offer effective BCM during their use, switch agents prior to conception
Cancer	Counsel on fertility preservation options prior to cancer therapy and on decreased fertility following certain agents. Offer genetic counseling to those with mutation-linked cancers. Evaluate cardiac function in those given cardiotoxic agents, such as adriamycin. Obtain mammography for those given childhood chest radiotherapy. Discuss SERM teratogenicity, effective BCM during its use, and need to switch agents prior to conception. Review chemotherapy and discuss possible teratogenic effects if continued during pregnancy
Infectious disease	Influenza: Vaccinate all women prior to flu season Malaria: Avoid travel to endemic areas; offer effective BCM or chemoprophylaxis for those planning pregnancy Rubella: Assess immunity; vaccinate as needed and offer effective BCM during next 3 months Tuberculosis: Screen high-risk women and treat Tetanus: Update vaccination, as needed Varicella: Assess immunity; vaccinate as needed and offer effective BCM during next 3 months
STD	Gonorrhea, syphilis, chlamydial infection: Screen per Table 1-1 (p. 6) and treat as indicated HIV: Discuss initiation of treatment prior to conception to decrease perinatal transmission. Offer effective BCM to those not desiring conception HPV: Provide screening per guidelines (Chap. 29, p. 629). Vaccinate as indicated HSV: Provide serological screening to asymptomatic women with affected partners. Counsel affected women on risks of perinatal transmission and of preventive measures during the third trimester and labor

ACAAI = American College of Allergy, Asthma, and Immunology; ACE = angiotensin-converting enzyme; ACOG = American College of Obstetricians and Gynecologists; BCM = birth control method; ARB = angiotensin-receptor blocker; BMI = body mass index; HIV = human immunodeficiency virus; HPV = human papillomavirus; HSV = herpes simplex virus; HTN = hypertension; MTX = methotrexate; NSAID = nonsteroidal antiinflammatory drug; RA = rheumatoid arthritis; SERM = selective estrogen-receptor modulator; SLE = systemic lupus erythematosus; STD = sexually transmitted disease. INTERVENTIONAL RADIOLOGY .....	45
REFERENCES .....	46

Several technical advances made in recent decades currently allow superb imaging of female pelvic structures. As a result, use of sonography in gynecology now equals that in obstetrics. Enhancements to traditional sonography continue to fill important clinical gaps. For example, three-dimensional (3-D) imaging refinements have expanded the gynecologic indications of sonography to rival those of computed tomography (CT) and magnetic resonance (MR) imaging for many conditions. Similarly, application of MR imaging has been extended by MR-guided high-intensity focused ultrasound therapy, used for uterine leiomyoma treatment.

### SONOGRAPHY

#### ■ Physics

In sonography, the picture displayed on a screen is produced by sound waves reflected back from an imaged structure. To begin, alternating current is applied to a transducer containing piezoelectric crystals, which convert electric energy to high-frequency sound waves. A water-soluble gel applied to the skin acts as a coupling agent. Sound waves then pass through tissue layers, encounter an interface between tissues of different densities, and are reflected back to the transducer. Converted back into electric energy, they are displayed on a screen.

Dense material, such as bone, or a synthetic material, such as an intrauterine device (IUD), produces high-velocity reflected waves, also termed *echoes*, which are displayed on a screen as white. These are described as *echogenic*. Conversely, fluid is

*anechoic*, generates few reflected waves, and appears black on a screen. Middle-density tissues variably reflect waves to create various shades of gray, and images are described as *hypoechoic* or *hyperechoic* relative to tissues immediately adjacent to them. Images are generated so quickly—50 to 100 frames/sec—that the picture on the screen appears to move in real time.

Sound reflection is greatest when the difference between the acoustic impedance of two structures is large. This explains why cysts are so well demonstrated with sonography. Strong echoes are produced from the cyst walls, but no echoes arise from the cyst fluid. As more sound traverses the cyst, more echoes are received from the area behind the cyst, a feature known as *through transmission* or *acoustic enhancement* (Fig. 2-1). In contrast, with a dense structure, the sound passing through it is diminished, which creates a band of reduced echoes beyond it, known as *acoustic shadowing* (Fig. 2-2).

The frequency of emitted ultrasound waves is expressed in megahertz (MHz), which means million vibrations per second. The frequency is inversely related to its wavelength, such that transducers emitting pulses of high frequency generate waves of shorter length, which result in higher spatial resolution or sharpness between interfaces but achieve less penetration. Curved transducers provide a wider field of view but often generate lower frequency waves than linear transducers. Higher frequency probes (10 to 15 MHz) are used to image superficial structures, such as breast masses or lost etonogestrel implants in the upper arm. Lower frequencies are required to image deeper structures. For example, transabdominal transducers are typically in the 3- to 5-MHz range, whereas transvaginal transducers are generally 5 to 10 MHz.

#### ■ Examination Techniques

Guidelines for sonographic examination of the female pelvis have been established by The American Institute of Ultrasound in Medicine (2014). These serve as quality assurance standards for patient care and provide assistance to practitioners performing sonography. Guidelines describe equipment and documentation and may be accessed at: <http://www.aium.org/resources/guidelines/femalepelvis.pdf>.

All probes are cleaned after each examination, and vaginal probes are covered by a protective sheath prior to insertion. A female staff member should always chaperone transvaginal sonography. Guidelines describe the examination steps for each organ and anatomic region in the female pelvis. For instance, for the uterus: uterine size, shape, orientation, and description of the endometrium, myometrium, and cervix are documented. The examination and its interpretation are permanently recorded,

**FIGURE 2-1** Transvaginal sonogram of a premenopausal ovary containing a follicular cyst. The cyst fluid appears black or anechoic. Note the white or hyperechoic area under the cyst, a sonographic feature called posterior acoustic enhancement or through transmission.

appropriately labeled, and placed in the medical record. A copy is also kept by the facility performing the study.

### Gray-scale Imaging

Various examination techniques can be used for sonographic study of the female pelvis. Of these, transabdominal evaluation, using a curved-array 3- to 5-MHz transducer, is the first component of general gynecologic examinations because it provides global identification of all pelvic organs and their spatial relationships (American Institute of Ultrasound in Medicine, 2014). In a non-pregnant patient, a full bladder is preferred for adequate viewing, as it pushes the uterus upward from behind the pubic symphysis and displaces small bowel from the field of view. Moreover, the bladder acts as an *acoustic window*, to improve ultrasound wave transmission. In patients with large lesions or masses located superior to the bladder dome, transabdominal sonography provides a panoramic view for greater disease evaluation. Still, endometrial

**FIGURE 2-2** Transvaginal sonogram of an ovarian teratoma demonstrating posterior acoustic shadowing (arrows).

cavity assessment is limited with a transabdominal approach and often requires the transvaginal technique.

*Transvaginal sonography (TVS)* uses higher-frequency (5- to 10-MHz) transducers and is the second component of general gynecologic examinations. Because of its increased sensitivity and spatial image resolution, TVS is ideal for interrogating pelvic anatomy within the confines of the true pelvis. With larger masses, imaging may be incomplete and is complemented by transabdominal sonography.

For TVS, the probe is positioned in the vaginal fornices to place the transducer close to the region of interest and thereby lessen beam attenuation within superficial soft tissues. In contrast to transabdominal imaging, the bladder is emptied prior to a transvaginal study. TVS has few limitations. The only two absolute contraindications are imperforate hymen and patient refusal. A relative contraindication is a patient with a virginal or strictured introitus. These women, however, can usually undergo comfortable examination with proper counseling.

*Transrectal and transperineal techniques* employ transrectal probes and conventional transducers placed over the perineal region, respectively, for image acquisition. Much less commonly used, they are selected for indications such as pelvic floor imaging.

### Harmonic Imaging

This recent modification of sonography is designed to improve tissue visualization and quality by using several frequencies at once from the transmitted ultrasound beam instead of just a single frequency. Newer probes and postprocessing features improve image resolution, particularly at surface interfaces. Visual artifacts that arise from superficial structures such as adipose are also reduced. As such, tissue harmonic imaging is routinely used in our ultrasound examinations.

### Doppler Technology

This ultrasound technique can be performed with either transabdominal or transvaginal sonography to determine blood flow through pelvic organs, based on the red blood cell (RBC) velocity within vessels, especially arteries. Color Doppler captures and characterizes the spectral waveform of flow through certain vessels seen during real-time imaging. Ratios are often used to compare these different waveform components. The simplest is the systolic-diastolic ratio (S/D ratio), which compares the maximal (or peak) systolic flow with end-diastolic flow to evaluate downstream impedance to flow (Fig. 2-3). Of arterial Doppler spectral waveform parameters, the resistance index and pulsatility index are also commonly calculated. These quantitative indices estimate the impedance to RBC velocity within the artery by expressing the differences between the peak systolic and end-diastolic velocities.

A second application is *color Doppler mapping*, in which the color-coded pulsed-Doppler velocity information is superimposed on the real-time gray-scale image. The color is scaled, such that the color brightness is proportional to the flow velocity. Additionally, color Doppler also provides information regarding blood flow direction, and color is assigned to this. Flow approaching the transducer is customarily displayed in red, and flow away from it is shown in blue.

**FIGURE 2-3** Doppler systolic–diastolic waveform indices of blood flow velocity. S represents the peak systolic flow or velocity, and D indicates the end-diastolic flow or velocity. The mean, which is the time-average mean velocity, is calculated from computer-digitized waveforms. (Reproduced with permission from Cunningham FG, Leveno KL, Bloom SL, et al: Williams Obstetrics, 24th ed. New York: McGraw-Hill Education; 2014.)

Color Doppler is not applied during every general gynecologic examination. One frequent indication is adnexal mass. Neovascularity within cancer is composed of abnormal vessels that lack smooth muscle and contain multiple arteriovenous shunts. Consequently, lower-impedance flow is expected with such masses as shown in [Figure 2-4](#) (Kurjak, 1992; Weiner, 1992). Other indications include evaluation of ovarian masses for torsion, improved detection of extrauterine vascularity associated with ectopic pregnancy, and assessment of uterine perfusion in patients with leiomyomas and endometrial disorders (Fleischer, 2005). Due to safety concerns regarding the higher intensities generated by color and spectral Doppler, routine use of Doppler imaging in the first trimester is discouraged, unless needed for an important clinical indication.

**FIGURE 2-4** Complex ovarian mass with irregular cystic areas demonstrating intermediate-impedance [PI= 1.02] flow in a solid component. This mass was found to be a mucinous adenocarcinoma at surgery.

**FIGURE 2-5** Power Doppler evaluation of a gestational sac in the lower uterine segment at the cesarean delivery scar. Circular flow is depicted, consistent with the peritrophoblastic flow of an implanted pregnancy.

*Power Doppler imaging* also maps RBC motion. It detects the energy of Doppler signals generated from moving RBCs using signal-to-noise characteristics of the vessels compared with surrounding tissues. This modality gives no information regarding blood flow direction, and thus data are displayed as a single color, usually yellow or orange. However, power Doppler is more sensitive to low-flow velocities, such as in veins and small arteries. Although employed less often than color Doppler mapping, power Doppler can gather additional information regarding endometrial and ovarian abnormalities ([Fig. 2-5](#)).

### Saline Infusion Sonography

Also called sonohysterography, saline infusion sonography (SIS) displays detailed endometrial cavity anatomy by distending the cavity with sterile saline. It is commonly selected after an endometrial mass or abnormal endometrial thickness is identified during general TVS. SIS can also assist in some infertility investigations and aid viewing of the endometrial thickness if it is poorly imaged because of uterine position or pathology.

After voiding, a woman first undergoes a comprehensive TVS evaluation. A vaginal speculum is then inserted, the vagina and cervix are swabbed with an antiseptic solution, and a catheter primed with sterile saline is advanced into the cervical canal and just past the internal os. We do not routinely use a tenaculum for this. Contact with the uterine fundus is ideally avoided when advancing the catheter to avert pain or vasovagal response. It can also shear away endometrium, causing false-positive results. The speculum is carefully removed to avoid dislodging the catheter, the transvaginal probe is reinserted, and sterile saline is injected through the catheter at a rate based on the patient's tolerance. Usually not more than 20 to 40 mL is required to distend the endometrial cavity ([Fig. 2-6](#)). During this time, the cavity is observed with TVS. The sonographer scans in the longitudinal plane, imaging from one cornu to the other, and in the transverse plane, from the top of the fundus to the cervix. Endometrial surface irregularities are well delineated by the anechoic contrast of saline. At the procedure's

**FIGURE 2-6** Saline infusion sonography of a normal endometrial cavity.

conclusion, the catheter is withdrawn under sonographic visualization. The uterine isthmus, endocervical canal, and upper vagina and vaginal fornices may also be evaluated, and this technique is referred to as *sonovaginography*. On average, the entire procedure lasts 5 to 10 minutes.

Many different catheter systems are available, including rigid systems and flexible catheters with and without attached balloons. We use a 7F SIS balloon catheter set, which tamponades the internal cervical os. This blockade prevents backflow of the distending medium and provides stable filling and adequate distention. We have found it easy to place and well tolerated (Fig. 2-7). Several distending solutions have been described, including saline, lactated Ringer solution, and 1.5-percent glycine. Sterile saline is inexpensive and provides optimal imaging. Alternatively, gel and foam substances have been developed to avoid backflow problems. However, these alternative products have not been extensively investigated and are not used widely in clinical practice.

In the premenopausal woman, SIS is best performed within the first 10 days of the menstrual cycle, and optimally on cycle

days 4, 5, or 6 when the lining is thinnest. This timing is recommended to avoid misinterpreting menstrual blood clots as intrauterine pathology or missing pathology obscured by thick endometrial growth. In addition, such timing usually precludes disturbing a potential pregnancy. For the postmenopausal woman, timing of the procedure is not cycle-dependent.

Complications of SIS are minimal, and the risk of infection is less than 1 percent (Bonnamy, 2002). The American College of Obstetricians and Gynecologists (2014) recommends prophylactic antibiotics for women with prior pelvic inflammatory disease (PID) or identified hydrosalpinges. In these cases, doxycycline 100 mg orally twice daily is prescribed for 5 days. Although not strongly evidence-based, we also routinely give a single dose of doxycycline, 200 mg orally, for infection prophylaxis following SIS to immunocompromised women, such as those with diabetes, cancer, or human immunodeficiency virus infection. Prophylaxis is also given to infertile patients because of the risk for significant tubal damage associated with pelvic infection. Pain is usually minimal. In our experience, women with prior tubal ligation have greater discomfort, likely because fluid is unable to efflux through the fallopian tubes. A nonsteroidal antiinflammatory drug (NSAID) given 30 minutes prior to the procedure will typically minimize discomfort.

Contraindications to SIS include hematometra, pregnancy, active pelvic infection, or obstruction such as with an atrophic or stenotic cervix or vagina. In postmenopausal women with cervical stenosis, we have found the following techniques to be helpful: misoprostol 200 µg tablet orally the evening before and the morning of the procedure; a paracervical block with 1-percent lidocaine without epinephrine; a tenaculum on the cervix for traction; and a sonographically guided sequential cervical dilation with lacrimal duct dilators. Pisal and colleagues (2005) proposed using a 20-gauge spinal needle, inserted into the uterine cavity under sonographic guidance, to overcome severe cervical stenosis.

### Hysterosalpingo-contrast Sonography

In the past, a fallopian tube could be detected with sonography only when distended by fluid, such as with obstruction. Injection

**FIGURE 2-7** A. Saline infusion sonography catheter. B. Saline infusion sonography.

**FIGURE 2-8** Transvaginal image of an ovary with echogenic bubbles adjacent to it (arrows) as seen during hysterosalpingo-contrast sonography (HyCoSy). The air in the saline contrast produces the bright echoes and ring-down artifacts. Visualization of these echoes adjacent to the ovary represents contrast exiting the tube, consistent with tubal patency.

of echogenic contrast during real-time sonography, called sonosalpingography, sonohysterosalpingography, or hysterosalpingo-contrast sonography (HyCoSy), is now an accurate procedure for the tubal patency assessment (Hamed, 2009).

HyCoSy is done in a manner similar to SIS. Fluid egress from the uterine cavity is blocked by a balloon catheter within the cervical canal. Using transvaginal sonography, the fallopian tubes are identified at the point where they join the uterine cornua. A hyperechoic sonographic contrast medium (Echovist, Albunex, or Infuson) is injected through the catheter to fill the cavity and then the fallopian tubes (Fig. 2-8). Alternatively, air coupled with sterile saline solution is another contrast option. With either medium choice, patent tubes appear hyperechoic as they fill with contrast. Color or pulsed Doppler techniques increase the diagnostic accuracy of HyCoSy by showing flow velocity within the tubes (Kupesic, 2007). We use the FemVue Sono Tubal Evaluation System, which simultaneously introduces air and sterile saline in a controlled fashion. The positive pressure flow of the echogenic mixture creates “scintillations” that are visually followed using real-time ultrasound. In patent tubes, flow proceeds from the uterotubal junction, through the length of the tube, and out the fimbriated end. Bubbles then surround the ovary or fill the posterior cul-de-sac. At present no large studies quantitate a risk for post-HyCoSy pelvic infection, and our periprocedural antibiotic prophylaxis mirrors our SIS protocol.

HyCoSy performed in conjunction with SIS provides a comprehensive assessment of the uterine cavity and myometrial anatomy, tubal patency, and adnexal architecture. This allows a cost-effective and time-efficient “one-stop” evaluation (Saunders, 2011). However, HyCoSy does have limitations. We have found that the entire fallopian tube often cannot be visualized due to normal tubal tortuosity. To that end, recent studies have evaluated the combination of 3-D sonography with HyCoSy to more easily view the entire tubal length

(Exacoustos, 2013; Zhou, 2012). Similar to hysterosalpingography (HSG), discussed on page 38, HyCoSy can demonstrate false occlusion from tubal spasm. In addition, a patent tube does not always correlate with normal tubal function. Last, HSG may still be needed for more accurate delineation of tubal anatomy in selected cases (Mol, 1996).

Although comparable to HSG in detecting tubal pathology, it has only recently become routinely used clinically (Heikinen, 1995; Strandell, 1999). In comparison to HSG, HyCoSy can also be performed in an outpatient setting, has lower cost, is well tolerated, avoids x-ray exposure or iodine-related allergic reaction, and provides information on uterine wall and ovarian morphology (Luciano, 2014; Savelli, 2009). The advantages of HyCoSy compared with HSG are equally valid for patient evaluation following sterilization with hysteroscopic devices. Namely, with Essure microinsert coils, tubal blockage confirmation 3 months after sterilization is mandatory (Luciano, 2011). Still, the Food and Drug Administration (FDA) and manufacturer currently recommend HSG to demonstrate tubal occlusion by Essure.

### Three-dimensional Sonography

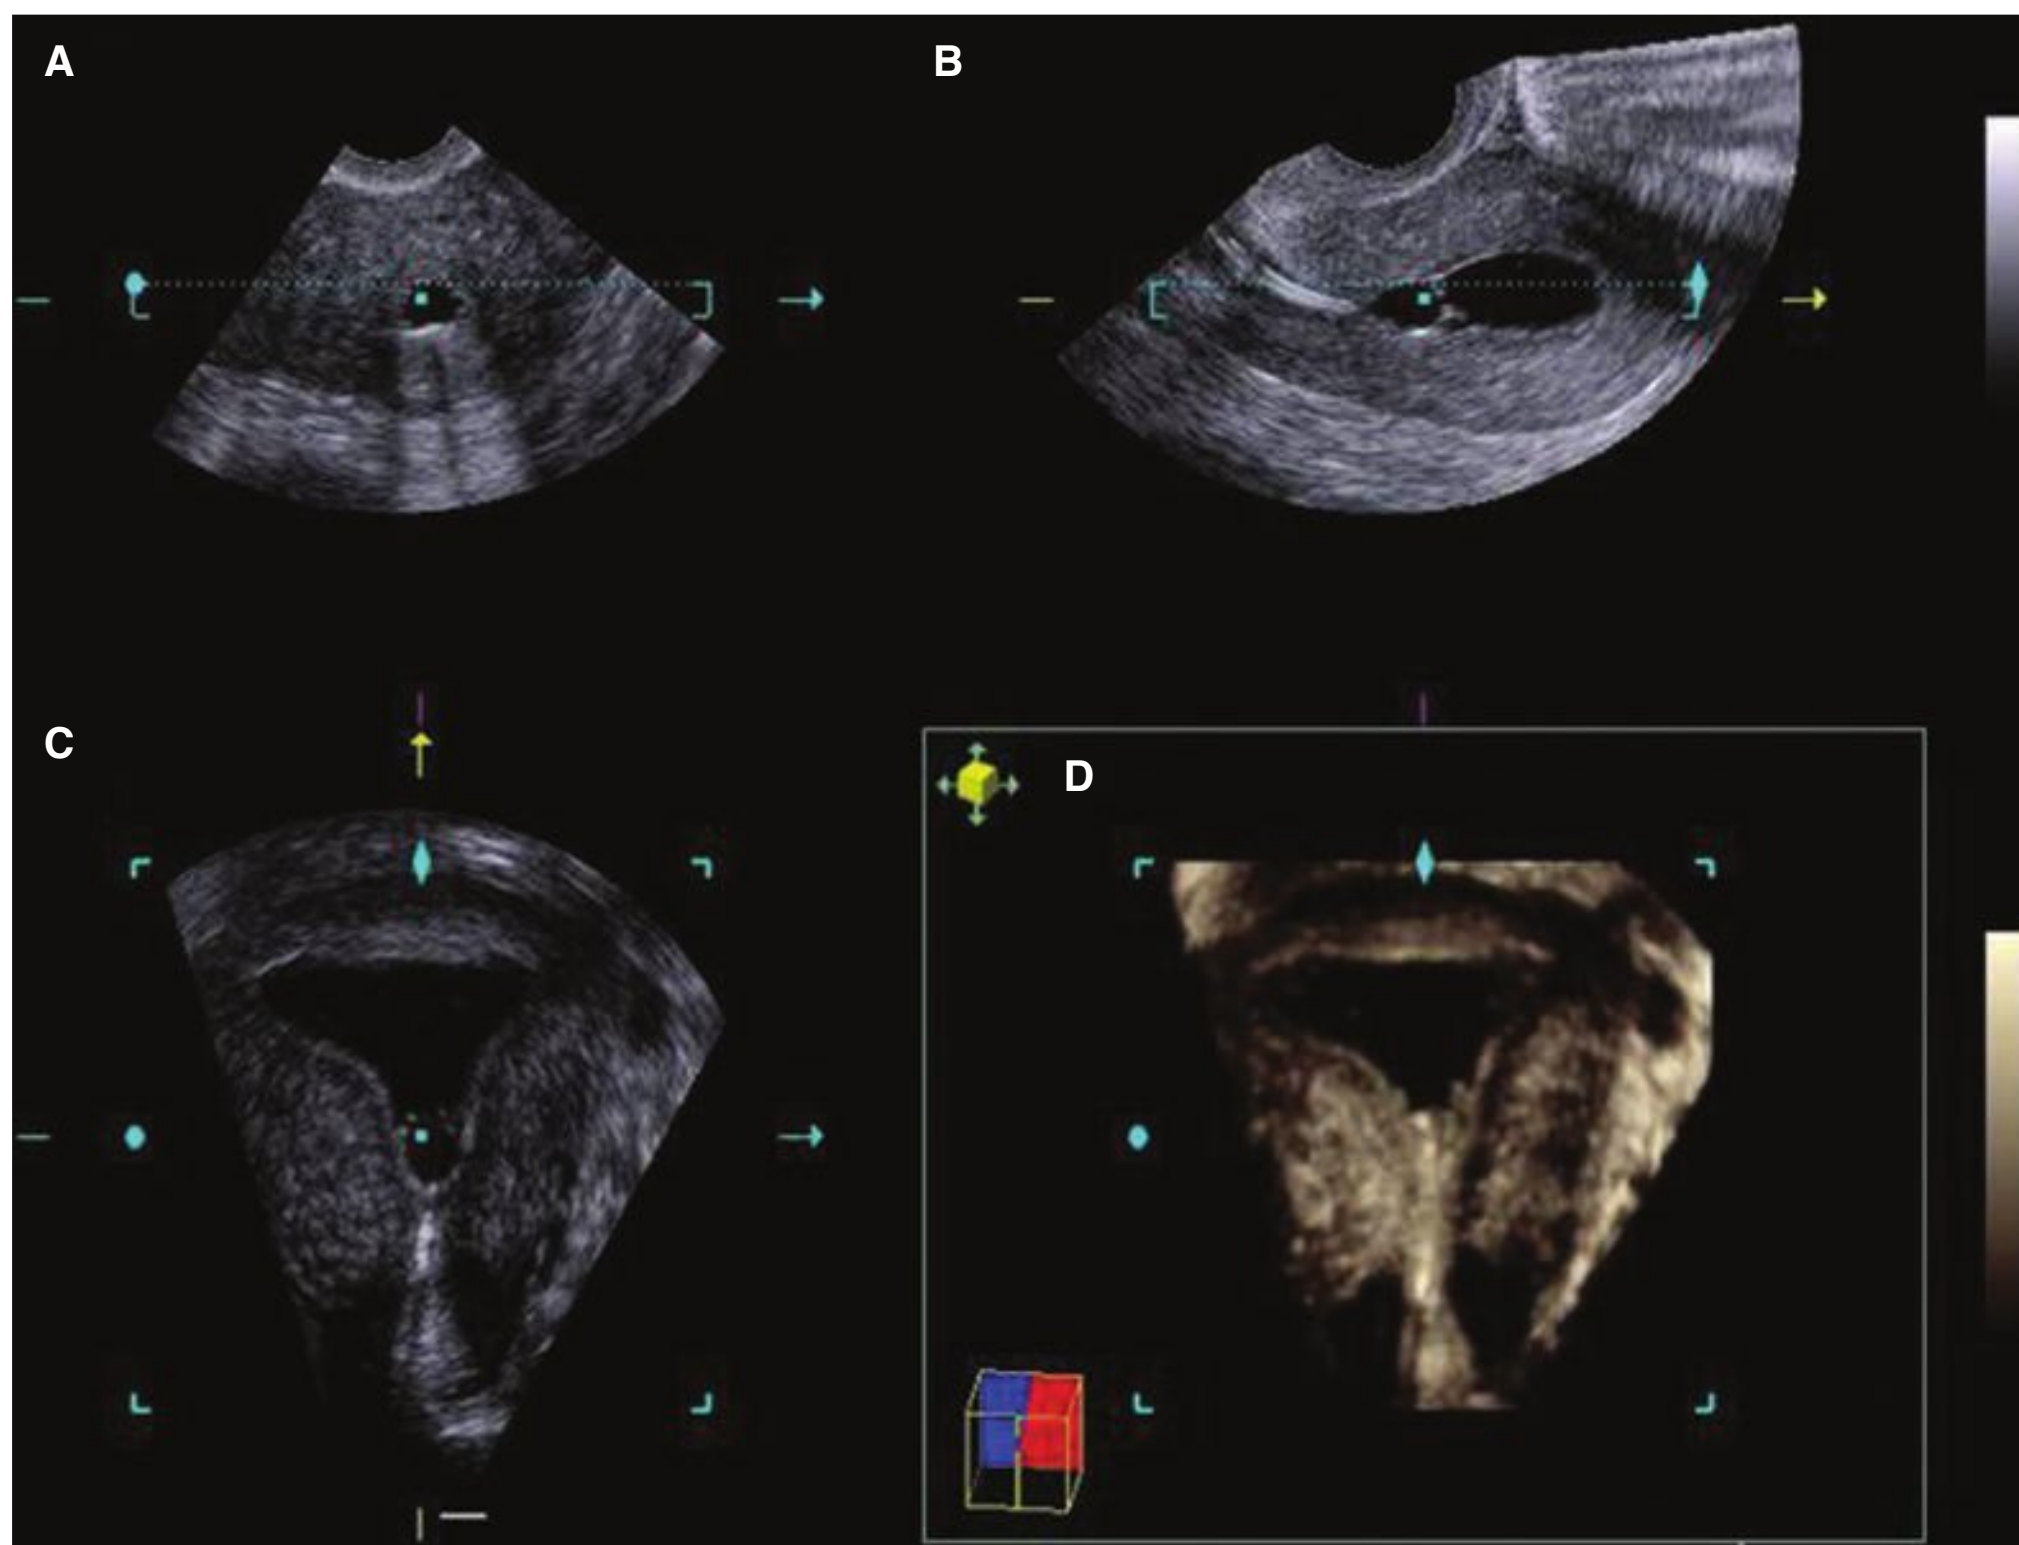

**Technical Aspects.** The ability to obtain certain views of pelvic organs in two dimensions is inherently limited. Transabdominally, the bony pelvis prevents scanning from the pelvic sidewall. Transvaginally, the views obtainable are restricted by the range of vaginal probe mobility. New sonography scanners now allow collection of 3-D data and representation of it on a two-dimensional (2-D) screen. This permits a more detailed assessment of the object studied, without restriction of the number and orientation of the scanning planes. With 3-D imaging, any desired plane through a pelvic organ can be obtained, regardless of the sound beam orientation during acquisition. For example, the “face-on” or coronal plane through the uterus is routinely seen in 3-D imaging but is rarely viewed during 2-D scanning. This view of the uterus is essential for assessing the external contour of the uterine fundus and the shape of the endometrial cavity for congenital uterine anomaly diagnosis.

With 3-D sonography, a volume, rather than a slice, of sonographic data is acquired and stored. The stored data can be reformatted and analyzed in numerous ways, and navigation through the saved volume can show countless planes. At any time, the volume can be retrieved, studied, reconstructed, and reinterpreted as needed. In addition, the level of energy with 3-D sonography is no higher than with 2-D, and manipulations of the obtained volumes are performed “off-line” to avoid additional ultrasound scanning time.

The three main components of 3-D sonography are volume acquisition, processing, and display. First, the preferred method to acquire volumes is automated and uses a dedicated 3-D probe that contains a mechanized drive. When these probes are activated, the transducer elements automatically sweep through the operator-selected region of interest, called a *volume box*, while the probe is held stationary.

After the appropriate volume is acquired, the user can begin to process the volume using the modes available in the ultrasound machine. The acquired volume can be displayed multiple ways. The most common is multiplanar reconstruction,

**FIGURE 2-9** Multiplanar display of a 3-dimensional volume of a uterus and normal endometrial cavity during saline infusion sonography. The views were obtained from a midsagittal reference plane using the Z technique. The planes are as follows: **A**, transverse, **B**, sagittal, **C**, coronal, **D**, rendered image.

in which three perpendicular planes, sagittal (the longitudinal plane that divides the body into right and left sections), axial (the transverse plane that divides the body into cephalad and caudal sections), and coronal (the frontal plane that divides the body into ventral and dorsal sections), are displayed simultaneously. Correlation between the three planes in the multiplanar display is accomplished by placing the planar center dot at the point of interest in one plane and observing the location of the corresponding center dots in the other two planes (Fig. 2-9A-C).

Abuhamad and associates (2006) have described a straightforward postprocessing technique, called the Z technique, that aids in the manipulation of 3-D volumes of the uterus. The anatomic basis of the Z technique is such that, in aligning the midsagittal and midtransverse planes of the uterus parallel to the horizontal axis, the midcoronal plane of the uterus will easily and consistently be displayed. In addition, all or part of the saved volume can be processed into a rendered image that can be shown alone or in correlation with the multiplanar display. A rendered image is a “sum” of all the coronal planar images (Fig. 2-9D). This is the display method that has been publicized in obstetrics, when showing the image of the neonate’s face in utero.

The inverse mode is a rendering technique of the entire volume in which all cystic areas within the volume become digitally opaque and all solid areas become transparent. This technique is useful when trying to see cystic areas that might be hidden in a volume, such as within an ovarian mass. Last, the volume can be displayed in parallel tomographic slices, similar to the displays used by CT and MR imaging.

3-D imaging is not without shortcomings. With 3-D sonography, the same type of acoustic artifacts that occur with 2-D imaging are encountered, such as acoustic shadowing and enhancement, refraction and reverberation, and motion artifacts from bowel peristalsis and vascular pulsation. Another potential pitfall in 3-D imaging of the pelvis involves spatial orientation within the saved volume data. Uterine flexion or version or left versus right may not be readily apparent on review of saved volumes. As such, during the preliminary real-time scanning, the operator must determine the orientation of the area of interest and notate it accordingly.

Another problem commonly encountered in 3-D transvaginal gynecologic imaging is related to the limited size of the volume box. Because of this, the entire uterus is often not acquired in a single volume. In some cases, it may be necessary to acquire two volumes, one for the cervix and a second for the uterine body. Likewise, a very large adnexal mass may not be imaged completely in any single volume of data obtained transvaginally. The size of the volume box provided by the abdominal probe is greater. Thus with 3-D sonography, a large mass may need to be imaged transabdominally instead of transvaginally.

**Clinical Use.** Because it can study organs in numerous scanning planes, 3-D imaging has become invaluable in gynecology to assess the uterine cavity, complex ovarian masses, ovarian fertility reserve, uterine anomalies, and interstitial pregnancies. It also can simultaneously provide anatomic and dynamic information from pelvic floor structures and from mesh implants.

**FIGURE 2-10** Three-dimensional image in the coronal plane of a polyp (calipers) after instillation of saline during saline infusion sonography.

Of these, mapping leiomyoma location relative to the endometrial cavity and surrounding structures is an essential step in triaging patients for treatment as discussed in Chapter 9 (p. 206). For such mapping, 3-D sonography or 3-D SIS can be used in place of conventional SIS or MR imaging. In patients receiving gonadotropin-releasing hormone (GnRH) agonists or following uterine artery embolization (UAE), 3-D sonography can also monitor leiomyoma volume reductions. However, MR imaging is more often used following UAE.

Abnormalities of the endometrium and adjacent myometrium, especially focal endometrial thickenings such as polyps, hyperplasia, and cancer, can be better defined with 3-D technology (Fig. 2-10) (Andreotti, 2006; Benacerraf, 2008). In their comparative study of 36 women with postmenopausal bleeding, Bonilla-Musoles and associates (1997) compared results from 3-D SIS with findings from TVS, 2-D SIS, transvaginal color Doppler, and hysteroscopy. Visualization of the uterine cavity and endometrial thickness with 3-D SIS was comparable to

hysteroscopy and better than the other sonographic techniques. We now routinely implement 3-D imaging for evaluation of abnormal endometria during our transvaginal studies and with all SIS procedures.

Although investigational, 3-D sonography with power Doppler angiography (3D-PDA) has been used to discriminate between benign and malignant endometrial disease in women with postmenopausal bleeding and a thickened endometrium (Alcazar, 2009). 3D-PDA can assess endometrial volume, which may more accurately represent the true tissue amount compared with a 2-D measurement of endometrial thickness. Another tool, 3-D power Doppler imaging enhanced by intravenous (IV) contrast, is also being investigated to differentiate benign endometrial polyps and endometrial cancer (Lieng, 2008; Song, 2009).

IUD positioning within the endometrial cavity can be documented adequately in most cases with traditional 2-D TVS. To be said, 3-D sonography offers improved visualization, especially with the levonorgestrel-releasing IUD (Moschos, 2011). The coronal plane images, which are not possible with 2-D imaging, provide views of both the arms and shaft of the device and the relation of these to the endometrial cavity (Benacerraf, 2009). As such, patients at our institution undergoing gynecologic sonography with an IUD in situ, regardless of the study indication, have both a standard 2-D evaluation and a 3-D volume acquisition of the uterus. The coronal view of the endometrial cavity is reconstructed to establish IUD type, location, and positioning (Fig. 2-11). In addition, although the FDA still mandates a postprocedural HSG following Essure coil placement, TVS has been shown to be an acceptable method of confirmation (Fig. 2-12) (Legendre, 2010).

For adnexal mass interrogation, most agree that 3-D sonography provides detailed internal anatomy (Alcazar, 2003; Bonilla-Musoles, 1995). Moreover, the addition of power Doppler to 3-D evaluation displays the internal architecture and neovascularization also characteristic of malignant neoplasms. However, to date, 3-D power Doppler ultrasound has not shown significantly improved diagnostic accuracy compared with that

**FIGURE 2-11** Intrauterine devices (IUDs). The coronal planes of 3-dimensional sonography best depict the type and positioning of the Copper T 380A IUD (ParaGard) (A) and levonorgestrel-releasing IUD (Mirena) (B) IUDs within the endometrial cavity.

**FIGURE 2-12** Essure contraception. Three-dimensional image in the coronal plane demonstrates the microinsert coils in the bilateral cornua of the uterus, corresponding to proper placement of the devices.

of gray-scale and 2-D power Doppler imaging. Further large, randomized, controlled trials are warranted (Jokubkiene, 2007).

In reproductive medicine, 3-D imaging acquires more precise ovarian volumes and follicle counts than measurements estimated from 2-D imaging. Many predict that it will become the preferred ultrasound technique for infertility ovarian evaluation (Deutch, 2009). Moreover, 3-D sonography can also examine endometrial vascularity to predict endometrial receptivity prior to ovarian stimulation (Wu, 2003).

For congenital müllerian uterine anomalies, 3-D ultrasound is now frequently used to accurately display anatomy (Ghi, 2009; Salim, 2003). It is as sensitive as hysteroscopy and as accurate as MR imaging, and it provides detailed images of both endometrial cavity shape and external fundal contour (Bermejo, 2010). Thus, because the uterine horns and fundal contour are displayed clearly in the same plane, müllerian anomalies can be differentiated (Troiano, 2004). Importantly, 3-D imaging can provide helpful details for preoperative planning.

For pelvic reconstructive surgery indications, 3-D ultrasound has been used to evaluate pelvic floor anatomy, pelvic support, and mesh implants. First, because of its composition, typical polypropylene mesh implants appear as echogenic interwoven interfaces with ultrasound. In contrast, these are poorly depicted with radiography or MR imaging. As a result, 3-D vaginal and perineal sonography is now selected for this evaluation (Dietz, 2012; Fleischer, 2012; Schuettoff, 2006). During implant interrogation, cranial aspects of mesh or retropubic mesh may be poorly imaged. For these patients, MR imaging may be helpful.

As a second indication, postprocessing reconstruction in a coronal plane improves views of the urethra and the periurethral tissue, which are inaccessible with 2-D ultrasound techniques. 3-D images are obtained with abdominal transducers using a translabial-transperineal approach or with transvaginal probes using specialized rotational transducers (Dietz, 2007, 2012; Santoro, 2011).

In women with pelvic floor dysfunction, the reconstructed tomographic ultrasound images afforded by 3-D ultrasound

are particularly useful to quantify the degree of levator ani defects (Dietz, 2010). Perhaps most importantly, 3-D imaging can provide not only anatomic but also dynamic information about pelvic floor structures, as imaging can be executed with the patient performing the Valsalva maneuver or actively contracting the pelvic floor musculature (Fleischer, 2012).

### Contrast-enhanced Sonography

This newer technique couples IV contrast with traditional sonography. With contrast-enhanced sonography, the visible difference between the density (or signal intensity) of a focal lesion is compared with the surrounding normal organ tissue. Enhancement patterns within the mass itself are also assessed.

Ultrasound contrast agents used intravenously are small, stabilized microbubbles, usually 1 to 10  $\mu\text{m}$  in diameter, and composed of perfluorocarbon or nitrogen gas encapsulated in albumin, phospholipid, or polymer shells. The gas-liquid interface contributes to the echogenicity of the microbubbles seen using traditional imaging. The high impedance mismatch between the microbubbles and adjacent RBCs in the blood vessels causes increased scattering and reflection of the ultrasound sound beam. This heightens the ultrasound signal and thereby increases brightness or echogenicity (Hwang, 2010). The degree of echo enhancement depends on many factors, including microbubble size, contrast agent density, compressibility of the bubbles, and the interrogating ultrasound frequency. The greater the size, density, and compressibility of the agent, the more reflection and echogenicity is elicited (Eckersley, 2002).

For ovarian cancer, contrast-enhanced sonography may highlight tumor neovascularization in developing microscopic tumors (Ferrara, 2000). In addition, because vascular channels associated with malignancy are often incompetent, the resultant extravasation of RBCs and contrast agent may be detected sonographically (Fleischer, 2008).

Other promising clinical applications of contrast-enhanced sonography currently under investigation include monitoring tumor and therapeutic angiogenesis, inflammation assessment, evaluation of ischemia and reperfusion injury, early detection of transplant rejection, and targeted drug delivery (Hwang, 2010).

### Sonoelastography

Elastography is an ultrasound imaging technique that measures tissue stiffness in both physiological and pathological states. To obtain an elastographic image, a source of “stress” or “strain” promotes tissue deformation to assess this stiffness (Stoelinga, 2014).

There are three main types of ultrasound elasticity imaging: (1) elastography that tracks tissue movement during compression, typically used to interrogate veins for thrombus; (2) tracking of acoustic shear wave propagation through tissue, often used for prostate evaluation; and (3) the most common method, vibration sonoelastography (Garra, 2007). With vibration sonoelastography, low-amplitude, low-frequency shear waves propagate through the organ of interest, while real-time color Doppler techniques generate an image of tissue movement in response to the external vibrations (Taylor, 2000). For example, if a discrete, hard inhomogeneous mass, such as a tumor, lies within a region of soft tissue, the vibration amplitude is decreased at its location.

Numerous organs and diseases have been evaluated by sonoelastography, and uterine evaluation with this has gained increased attention. Potential areas of investigation include distinguishing endometrial polyps from submucous pedunculated myomas, endometrial cancer from benign endometrial thickening, cervical cancer from normal cervix, and leiomyomas from adenomyosis (Stoelinga, 2014). Moreover, identifying uterine and cervical stiffness during pregnancy may prove valuable for management of preterm or postterm complications (Molina, 2012).

### Focused-ultrasound Therapy

Ultrasound energy during conventional imaging propagates harmlessly through tissue with little energy being absorbed. If energy is deposited as heat but dissipates by the cooling effects of perfusion and conduction. No harmful effects have been recorded at the intensities used for diagnostic purposes (American Institute of Ultrasound in Medicine, 2009).

If, however, the ultrasound beam carries a high level of energy and is brought into tight focus, this energy is rapidly converted into heat. When target spot temperatures rise above 55°C, proteins are denatured, cells die, and coagulative necrosis is incited (Lele, 1977). In contrast, surrounding tissues are warmed but not to lethal temperatures. The current gynecologic use for this modality is treatment of symptomatic leiomyomas and is illustrated in Chapter 9 (p. 211).

## ■ Normal Sonographic Findings

### Reproductive Tract Organs

In the reproductive years, a normal uterus measures approximately 7.5 × 5.0 × 2.5 cm but is smaller in prepubertal, postmenopausal, or hypoestrogenized women. Normal uterine stroma returns low-level, uniform echoes, and the position of the endometrial and endocervical canals is indicated by linear echogenic stripes, representing the interfaces between mucus and mucosa (Fig. 2-13). The cervix is best visualized transvaginally

**FIGURE 2-13** Transvaginal sonogram in the sagittal plane of an anteverted uterine corpus. Calipers demonstrate measurements of the uterine length (+) and the anterior-posterior dimension (x).

**FIGURE 2-14** Transvaginal sonogram in the sagittal plane of a uterine cervix. An endocervical cyst is seen posterior to the thin, echogenic endocervical canal.

with the tip of the probe placed 2 to 3 cm from it. The endocervical canal is a continuation of the endometrial cavity and appears as a thin echogenic line (Fig. 2-14). The vagina is seen as a hypoechoic tubular structure with an echogenic lumen that curves inferiorly over the muscular perineal body at the introitus. The ovaries are ellipsoid and normally lie in the ovarian fossa with their long axes parallel to the internal iliac vessels, which lie posteriorly (Fig. 2-15). Ovarian volume ranges from 4 to 10 cubic centimeters depending on hormonal status (Cohen, 1990). This volume is calculated using the formula for the volume of an ellipse:  $\frac{4}{3}(\pi) \times (A \times B \times C)$ . In this formula, A, B, and C are the ovarian diameters in centimeters, measured in the three different planes. Ovarian follicles appear as spherical anechoic structures within the ovary and may reach a normal size of 3 cm. Normal fallopian tubes are not visible. A small amount of fluid in the posterior cul-de-sac is a normal finding and is often seen with ovulation.

**FIGURE 2-15** Transvaginal sonogram in the sagittal plane of a left ovary (calipers) in a premenopausal woman. The ovary normally lies in the ovarian fossa, anterior to the internal iliac vessel (arrow).

**FIGURE 2-16** Transvaginal sonogram in the sagittal plane of a characteristic trilaminar proliferative endometrium. Calipers demonstrate proper measurement of the “double-layer” thickness made of the alternating hyper-hypo-hyperechogenic lines.

### Endometrium

Functionally, the endometrium has two main layers: the *stratum basale*, which comprises the densely cellular supporting stroma and varies little with the phase of the menstrual cycle, and the *stratum functionale*, which proliferates during each cycle and partially desquamates at menses. These layers cover the entire cavity.

Sonographically, the endometrium’s appearance during the menstrual cycle correlates with the phasic changes in its histologic anatomy. During the follicular phase, when the endometrium is provided estrogen from ovarian folliculogenesis, the stratum basale appears echogenic due to spectral reflections from the mucus-laden glands. In contrast, the stratum functionale is relatively hypoechoic because of the orderly arrangement of glands that lack secretions. The central opposing surfaces of these two endometrial layers manifest as a highly reflective, thin midline stripe. Together, the three echogenic lines create the characteristic trilaminar appearance of the proliferative endometrium (Fig. 2-16).

Measurement of this endometrial thickness extends from the echogenic interface of the anterior basale layer and myometrium to the echogenic interface of the posterior basale layer and myometrium. It thus represents a “double thickness.” The hypoechoic halo outside of and adjacent to the endometrium is not included in the measurement as this is actually the inner compact layer of myometrium. Sonographically, the endometrium is measured from a sagittal or long-axis image of the uterus in the plane where the central endometrial echo is seen contiguous with the endocervical canal and seen distinct from the myometrium. Endometrial thickness correlates approximately with the day of the cycle up to day 7 or 8.

With ovulation and progesterone production from the corpus luteum during the secretory phase, glandular enlargement and secretory vacuoles are seen histologically. During this phase, the endometrium achieves its maximum thickness as the

**FIGURE 2-17** Transvaginal sonogram in the sagittal plane of a secretory endometrium. The endometrium, which is marked by calipers, has become uniformly echogenic.

stroma becomes more vascular and edematous. Sonographically, these changes cause the endometrium to appear echogenic (Fig. 2-17).

With menstruation, the endometrium appears as a slightly irregular echogenic interface from sloughed tissue and blood. The thinnest endometrial measurements are found at conclusion of menses (Fig. 2-18).

With cessation of estrogen stimulation beginning at menopause, the endometrium atrophies, and cyclic sloughing ceases. The postmenopausal endometrium appears thin and uniform (Fig. 2-19).

### Pelvic Floor

With the advent of urogynecology as a specialty, sonography is widely used to evaluate pelvic floor anatomy and function (Dietz, 2012). Various 2-D techniques, including transvaginal,

**FIGURE 2-18** Transvaginal sonogram in the sagittal plane of a menstrual-phase endometrium, which is marked by calipers.

**FIGURE 2-19** Transvaginal sonogram in the sagittal plane of an atrophic postmenopausal endometrium.

transrectal, transperineal, and intraurethral sonography, have been used to investigate urethral anatomy.

Transrectal sonography was the first technique used to assess anal sphincter morphology after childbirth. This method requires special equipment and distention of the anal canal. The technique has limited value in the immediate puerperium and only provides information regarding the anal sphincter. Thus, without levator ani muscle assessment, the posterior compartment is incompletely evaluated. Alternatively, anorectal morphology and the pelvic floor can both be assessed with vaginal sonography using a rotating endorectal probe or standard transvaginal probe. These methods are described further in Chapter 25 (p. 568).

Perineal sonography can also evaluate pelvic floor anatomy. The technique requires filling the bladder with approximately 300 mL of saline. With the woman either supine or erect, a

5-MHz curved-array transducer is placed in sagittal orientation to the perineum. This allows real-time imaging of the pubic symphysis, levator ani muscles, urethra, bladder neck, bladder, vagina, rectal ampulla, and anal canal simultaneously and with little transducer manipulation (Dietz, 2010). Measurements have been standardized by Schaer and coworkers (1995).

3-D ultrasound is increasingly selected to examine pelvic floor anatomy. Specifically, evaluation of pelvic anatomy, support, and mesh implants are some indications, as discussed earlier.

## CLINICAL APPLICATIONS OF SONOGRAPHY

Transvaginal sonography is often preferred for early evaluation of pelvic pain, abnormal uterine bleeding, pelvic mass, early pregnancy complications, infertility practices, and early detection of ovarian and endometrial cancer. Many of these topics and their radiologic characteristics are covered in other chapters. Some remaining important subjects are presented in the following sections.

### ■ Intraabdominal Fluid

During general sonographic evaluation of the pelvis, a small amount of free fluid, as little as 10 mL, is commonly present in the posterior cul-de-sac (Khalife, 1998). If free fluid is seen extending to the fundus of the uterus, it is considered to be moderate in amount. Once identified, moderate free fluid should prompt further evaluation of the paracolic gutters and Morison pouch in the right upper quadrant to assess the extent of free fluid (Fig. 2-20). If fluid fills these areas, then the minimum volume of intraperitoneal fluid approximates 500 mL (Abrams, 1999; Branney, 1995). Large amounts of anechoic free peritoneal fluid generically described as ascites suggest a volume status abnormality or an infectious or inflammatory etiology. Free fluid that contains low-level echoes or echogenic

**FIGURE 2-20** Hemoperitoneum. **A.** In this transvaginal image, a moderate amount of free fluid (arrows) is seen in the posterior cul-de-sac, above the fundus of the uterus, and in the anterior cul-de-sac. **B.** Transabdominal image of Morison pouch in the right upper quadrant. Free fluid, corresponding to the dark anechoic area (arrow), is visualized between the liver edge and the kidney, which suggests a large-volume hemoperitoneum.

debris is consistent with hemoperitoneum with clot, such as with a ruptured hemorrhagic cyst or ectopic pregnancy.

The sensitivity of sonography to detect free fluid has led to its increased use during emergency trauma assessments. Focused assessment with sonography for trauma (FAST) is a limited sonographic examination directed solely at identifying free fluid for the diagnosis of traumatic injury. In the context of trauma, free fluid is usually due to hemorrhage. With FAST, four specific areas are imaged: perihepatic (right upper quadrant), perisplenic (left upper quadrant), pelvis, and pericardium. FAST has significant advantages compared with diagnostic peritoneal lavage and with CT for intraperitoneal fluid identification because it is a rapid, noninvasive, bedside test. However, there is a significant false-negative rate with FAST (Scalea, 1999). This is in part due to the FAST examination being carried out early in the resuscitation phase when only a small amount of free fluid may have collected in the dependent portions of the peritoneal cavity. In addition, as its use has become more widespread, conflicts have developed regarding credentialing and whether radiologists, emergency physicians, or trauma surgeons should be performing this sonographic technique.

### ■ Malignant Ovarian Characteristics

Sonography is commonly the initial and often the only imaging procedure performed during pelvic and ovarian mass evaluation, as most can be correctly categorized based on gray-scale and color or power Doppler ultrasound characteristics. Found in Table 9-3 (p. 217), recommendations from a Society of Radiologists in Ultrasound consensus conference summarizes a reasonable approach to asymptomatic ovarian and other adnexal cysts imaged sonographically (Levine, 2010).

Sonography is the best preoperative diagnostic technique to determine the malignant potential of an ovarian mass (Twickler, 2010). To this end, morphologic scoring systems based on number and thickness of septa, presence and number of papillations, and proportion of solid tissue within the mass have been proposed to standardize the interpretation of findings (DePriest, 1993; Sassone, 1991). When size, morphology, and structure of adnexal masses are combined with color Doppler and spectral analysis of flow signals, the specificity and positive predictive value of sonographic diagnosis is increased (Buy, 1996; Fleischer, 1993; Jain, 1994). In a metaanalysis of 46 studies with 5159 patients, Kinkel and coworkers (2000) reported significantly higher accuracy for combined sonographic techniques compared with that of each individual technique alone. In addition, the International Ovarian Tumor Analysis (IOTA) Group has developed the most accurate mathematic model to date to calculate the malignancy risk of an adnexal mass based on sonographic features (Timmerman, 2005). We use the Ovarian Tumor Index developed by Twickler and colleagues (1999) at our institution.

Neovascularity within a malignant neoplasm produces a significant increase in color Doppler flow signals secondary to angiogenesis. These new vessels are abnormal, lack smooth muscle, and contain multiple arteriovenous shunts. Consequently, lower-impedance flow is expected with such masses as shown in Figure 2-4 (Kurjak, 1992; Weiner, 1992). Moreover, although

most benign tumors appear poorly vascularized, most malignant lesions appear well-vascularized, with flow signals in both peripheral and central regions—including within septations and solid tumor areas. Of Doppler parameters, the color content of the tumor probably reflects tumor vascularity better than any other. The overall impression of this vascularity reflects both the number and size of vessels and their functional capacity. The IOTA group scoring system uses this subjective semiquantitative assessment of flow to describe the vascular features of ovarian masses (Ameye, 2009; Timmerman, 2005). A four-point color score is used to describe tumor blood flow only within septa and solid portions of the mass (Timmerman, 2000).

These observations led many investigators to evaluate the presence, spatial distribution, and prevalence of flow signals within ovarian masses to quantify malignant characteristics. However, because of overlap of vascular parameters between malignant and benign neoplasms, a firm differential diagnosis based on spectral Doppler evaluation alone is not possible (Valentin, 1997).

### ■ Pelvic Inflammatory Disease

In women with acute salpingitis, pelvic sonography is commonly performed. However, large studies evaluating its sensitivity, specificity, or overall usefulness are lacking (Boardman, 1997; Cacciatore, 1992). Sonographic findings vary according to the severity of the disease. In early infection, anatomy may appear normal. With progression, early nonspecific findings include free pelvic fluid, endometrial thickening, endometrial cavity distention by fluid or gas, and indistinct borders of the uterus and ovaries. Enlarged ovaries with increased numbers of small cysts—a “polycystic ovary appearance”—has been shown to correlate with PID. With treatment, this ovarian enlargement resolves (Cacciatore, 1992).

Sonographic findings of the fallopian tubes are the most striking and specific landmarks of PID (Fig. 2-21). Although normal tubes are rarely seen unless surrounded by ascites, tubal wall inflammation allows visualization with sonography. As the

**FIGURE 2-21** Transvaginal sonogram in cross-section of an inflamed, dilated tube demonstrating thickened tubal walls, incomplete septa, and echogenic fluid.

**FIGURE 2-22** “Beads on a string” sign. The echogenic mural nodules shown here (arrows) within this tuboovarian abscess are thought to represent flattened and fibrotic endosalpingeal folds of the inflamed fallopian tube.

lumen occludes distally, the tube distends and fills with fluid. Various appearances result. The tube may become ovoid or pear shaped, filling with fluid that may be anechoic or echogenic. The tubal wall becomes thickened, measuring  $\geq 5$  mm, and incomplete septa are common as the tube folds back on itself. If the distended tube is viewed in cross section it may demonstrate the cogwheel sign, due to thickened endosalpingeal folds (Timor-Tritsch, 1998). Typically, the swollen fallopian tubes extend posteriorly into the cul-de-sac, rather than extending cephalad and anterior to the uterus as large ovarian tumors tend to do. Fluid-debris levels are often visualized in the dilated tubes, and rarely, gas-fluid levels or echogenic bubbles of gas are seen. Color and power Doppler show increased flow from hyperemia in the walls and in incomplete septa of the inflamed tubes (Tinkanen, 1993).

As the disease progresses, the ovary can become involved. When an ovary adheres to the fallopian tube, but is still visualized, it is called a tuboovarian complex. In contrast, a tuboovarian abscess results from a complete breakdown of ovarian and tubal architecture such that the separate structures are no longer identified (Fig. 2-22). If the contralateral side was not affected initially, it may become so. When both tubes are inflamed and occluded, the entire complex typically acquires a U-shape as it fills the cul-de-sac, extending from one adnexal region to the other. The lateral and posterior uterine borders become obscure, and individual tubes and ovaries cannot be distinguished. In women not responding to medical therapy, sonography or CT can be used to guide percutaneous or transvaginal drainage of these lesions.

Findings of chronic PID include hydrosalpinx. As discussed in Chapter 9, several sonographic findings such as its tubular shape, incomplete septa, and hyperechoic mural nodules can help to distinguish a hydrosalpinx from other cystic adnexal lesions (Fig. 9-23, p. 224). If color flow is detected in a hydrosalpinx, it tends to be less exuberant than flow seen in acute PID. Molander and colleagues (2002) found a higher pulsatility

index in patients with a chronic hydrosalpinx ( $1.5 \pm 0.1$ ) than with acute PID ( $0.84 \pm 0.04$ ).

A small number of women with prior PID may have a peritoneal inclusion cyst. These form when ruptured ovarian cyst fluid is trapped around the ovary by adhesions. This diagnosis is suspected if the ovary is surrounded by fluid loculations created by thin septations.

## ■ Infertility

Sonography is employed for four main purposes in the approach to female infertility: (1) to identify abnormal pelvic anatomy; (2) to detect pathology causal or contributory to infertility; (3) to evaluate cyclic physiologic uterine and ovarian changes; and (4) to provide surveillance and visual guidance during infertility treatment.

Sonography can easily demonstrate anatomic uterine defects that may affect both gamete passage and ovum implantation. As discussed, conventional TVS can be used to visualize submucous leiomyomas and polyps, however, relationships of these lesions with the endometrial surface are better seen with SIS (see Figs. 2-6 and Fig. 8-7, p. 187). In those with a history of recurrent abortion, SIS has been used to demonstrate not only müllerian anomalies but various other uterine cavity defects in up to half of patients (Keltz, 1997). As a screening tool for cavity evaluation in this setting, it appears to be twice as accurate as HSG and TVS (Soares, 2000). Intrauterine synechiae can be seen by conventional sonography as hypoechoic lines disrupting the echogenic endometrium. These are more definitively seen during SIS as echogenic bands extending from one endometrial surface to the other (Fig. 2-23).

Transvaginal sonography is used initially to detect congenital uterine anomalies that can cause infertility or early spontaneous abortion. The addition of 3-D techniques can diagnose congenital abnormalities with a test performance similar to that of HSG, laparoscopy, and MR imaging. Thereafter, MR imaging is used to characterize and evaluate cases that are complicated or equivocal, especially preoperatively.

**FIGURE 2-23** Asherman syndrome. Transvaginal saline infusion sonography demonstrates echogenic intrauterine synechiae.

**FIGURE 2-24** Uterus didelphys. Transvaginal sonogram in the transverse plane best depicts the two completely separate uterine horns. A gestational sac is evident in the right uterus.

Of abnormalities, a complete fusion anomaly, such as uterus didelphys, can be accurately diagnosed by sonography. In this setting, two separate and divergent uterine horns are seen to have a deep fundal cleft between the two hemiuteri and to have a wide angle between the two endometrial cavities (Fig. 2-24). In contrast, bicornuate and septate uterine anomalies are less confidently differentiated by traditional 2-D TVS techniques. Ideally, the angle between the two endometrial cavities is  $\geq 105^\circ$  for bicornuate uterus, but  $\leq 75^\circ$  for septate uterus. The fundal contour shows a  $> 1$ -cm notch for bicornuate uterus, but a  $< 1$ -cm notch for septate uterus (Reuter, 1989). However, in many cases, the distinctions among complete bicornuate, partial bicornuate, and septate uteri are subtle. By measuring the relationship of the intracornual line—the line joining both horns of the uterine cavity—to the uterine fundal contour in the 3-D coronal plane, an accurate diagnosis can be made (Fig. 2-25). Similarly, arcuate versus partial septate uteri can be correctly differentiated using quantitative measurements of the depth

**FIGURE 2-26** Unicornuate uterus. The coronal plane of 3-dimensional sonography illustrates the classic “banana” configuration. A gestational sac is seen within the endometrial cavity.

of fundal indentation of the endometrial cavity in the coronal plane. Combining 3-D TVS findings with SIS provides accuracy up to 90 percent to distinguish the two anomalies. Although MR imaging is frequently employed, 3-D sonography is considered by many to be the best noninvasive method for distinguishing between these uterine anomalies (Bermejo, 2010; Salim, 2003).

A unicornuate uterus without a rudimentary horn is seen as a small, well-formed elliptical uterus that deviates to one side and has a single cornu. The fundal shape is concave. With 3-D imaging, the unicornuate uterus has the classic “banana” configuration (Fig. 2-26). In 65 percent of cases, however, the unicornuate uterus is associated with a rudimentary horn, and this is difficult to recognize sonographically (Fig. 18-11, p. 419) (Jayasinghe, 2005). The dilated rudimentary horn is often misdiagnosed as a uterine or adnexal mass. Complete evaluation of these cases often requires MR imaging. With most uterine anomalies, especially if unilateral, proper positioning

**FIGURE 2-25** Three-dimensional (3-D) images of müllerian anomalies in the coronal plane. **A.** Bicornuate uterus. This 3-D rendered image demonstrates a concave external fundal contour that dips below the intercornual line consistent with a bicornuate uterus. Note the pregnancy in the right uterine horn. **B.** Septate uterus. This image depicts the normal uterine serosal contour and the narrow angle between the two small endometrial cavities characteristic of a septate uterus. As the septum ends at the uterine isthmus and does not extend into the cervix, this anomaly is properly termed subseptate. **C.** Arcuate uterus. This image illustrates the normal uterine serosal contour and obtuse angle of the endometrial indentation that is characteristic of an arcuate uterus.

of the kidneys should be documented with transabdominal imaging because of increased rates of associated genitourinary anomalies. Last, in women with complex anomalies associated with vaginal agenesis or imperforate hymen, hematocolpos is commonly seen, often with associated hematometra or hematosalpinx.

Pelvic endometriosis is another frequent cause of infertility. Sonography is the most common imaging procedure to evaluate suspected endometriosis, although it is mostly used to evaluate endometriotic cysts. Endometriomas exhibit a variety of sonographic appearances, the most frequent being a pelvic mass with a thick wall and diffuse low-level echoes within the cyst (Fig. 10-4, p. 236). Magnetic resonance imaging is more specific than sonography for identifying endometriomas, and thus, it is indicated in cases with unclear anatomy sonographically (Fig. 10-8). Sonography's ability to detect small implants and adhesions is limited, but it can be used to identify some cases of deep-infiltrating endometriosis.

One of the most powerful uses of sonography in the infertile patient is treatment surveillance. Sonography is used to monitor folliculogenesis both in normal and stimulated cycles. In natural cycles, observation of a developing follicle and ovulation prediction allow optimal timing for postcoital testing, human chorionic gonadotropin (hCG) administration, intercourse, insemination, and ovum collection. At ovulation, the follicle usually disappears, and fluid is observed in the cul-de-sac. At the follicular site, the corpus luteum appears as an irregular oval containing a small quantity of fluid, internal echoes, and a thick wall. In stimulated cycles, sonographic detection of too many follicles allows withholding of hCG induction to prevent ovarian hyperstimulation syndrome (Fig. 20-4, p. 456). If this develops, sonography is used to grade disease severity through measurements of ovarian size, detection of ascites, and analysis of renal flow resistances. In general, blood flow in the ovulating ovary decreases throughout the menstrual cycle. At ovulation, blood flow velocities dramatically increase in vessels surrounding the corpus luteum because of neovascularization and are seen as low-impedance waveforms. In women undergoing in vitro fertilization (IVF), low ovarian vessel impedance may correlate directly with pregnancy rates (Baber, 1988). Many infertility specialists now incorporate SIS as a first-line screening tool for uterine evaluation before embryo transfer in women undergoing IVF, ovum donation, and IVF-surrogacy (Gera, 2008; Yauger, 2008). Last, sonography can be used to guide interventional maneuvers such as oocyte retrieval and transfer of embryos into the endometrial cavity (Figs. 20-10 and 20-12, p. 464).

### ■ Ultrasound beyond the Pelvis

Ultrasound is used throughout the body. It is often the initial tool in radiologic

evaluation, given its lack of ionizing radiation, low cost, and availability. In the abdomen, common indications for solid organ evaluation include abdominal and flank pain, jaundice, hematuria, organomegaly, or palpable mass. Abnormal blood tests, including elevated liver function tests and creatinine levels, may also be indications for an abdominal ultrasound. Typically, a limited or right upper quadrant ultrasound includes the liver, gallbladder, common bile duct, pancreas, and right kidney. A complete abdominal ultrasound adds the spleen, left kidney, and images of the aorta and inferior vena cava in the upper abdomen. Ideally, a patient has fasted prior to sonographic evaluation of the abdomen to minimize bowel gas and for adequate gallbladder distention. A renal ultrasound focuses on the kidneys, proximal collecting systems, and urinary bladder. Outside of the abdomen and pelvis, a gynecologist may select ultrasound to evaluate superficial structures, like the thyroid gland and breasts. Breast imaging is discussed in Chapter 12 (p. 278).

### Compression Sonography

Compression sonography, often combined with color Doppler sonography, is the initial test currently used to detect deep-vein thrombosis (DVT) (Hanley, 2013). Sonographic evaluation of leg veins is divided into: (1) the groin and thigh examined with the patient supine; and (2) the popliteal region examined with the patient sitting or lying on her side with the thigh abducted and externally rotated. Some institutions also evaluate the calf veins. Impaired visibility, noncompressibility, and the typical echo pattern of a thrombosed vein confirm the diagnosis (Fig. 2-27).

Examination of the femoral, popliteal, and calf trifurcation veins in symptomatic patients is more than 90-percent sensitive and greater than 99-percent specific for proximal DVT (Davis, 2001). Moreover, in 220 patients with suspected DVT, Lensing and coworkers (1989) compared compression sonography with contrast venography, which is the gold standard for DVT

**FIGURE 2-27** Sagittal (**A**) and transverse (**B**) images from a lower extremity. Color Doppler ultrasound study in a woman with popliteal vein thrombosis. **A**. Red arrows demarcate the popliteal vein with no flow suggesting clot in the lumen, which sits above the artery demonstrating normal flow as evidenced by the red color map. **B**. The transverse image shows the large size of the vein due to the thrombus (cursors), as well as normal flow in the artery, evidenced by the red color map.

detection. They found that both the common femoral and popliteal veins were fully compressible—no thrombosis—in 142 of 143 patients who had a normal venogram (99-percent specific). All 66 patients with proximal vein thrombosis had noncompressible femoral or popliteal veins, or both (100-percent sensitive).

For detecting calf vein thrombosis, compression sonography is significantly less reliable. Eventually, isolated calf thromboses extend into the proximal veins in up to a fourth of cases. They do so within 1 to 2 weeks of presentation and thus are usually detected by serial sonographic compression examinations (Bates, 2004). The safety of withholding anticoagulation for those symptomatic patients who have a normal compression examination has been established (Birdwell, 1998; Frieria, 2002). Importantly, normal venous sonographic findings do not necessarily exclude pulmonary embolism (PE) because the thrombosis may have already embolized or because it arose from deep pelvic veins, which are inaccessible to sonographic evaluation (Goldhaber, 2004).

Ultrasound is frequently used for other vascular assessments. Sonographic screening is performed for abdominal aortic aneurysm and to evaluate solid organ vasculature. Also, vascular ultrasound incorporates spectral and color Doppler to assess the lower extremities for venous insufficiencies that may contribute to varicose veins and venous congestion.

## RADIOGRAPHY

Radiographs are used in gynecologic practice in a manner similar to other medical specialties. Of frequently used studies, the *acute abdominal series* includes an upright radiograph of the chest to exclude free air under the diaphragm, an upright film of the abdomen to exclude air-fluid levels within bowel loops, and a supine image to measure bowel loop widths. It is commonly selected as an initial modality if bowel obstruction or perforation is a concern. Importantly, images from those with recent laparotomy or laparoscopy often show expected subdiaphragmatic air. In contrast, a single supine radiograph of the abdomen is called a KUB (kidneys, ureters, and bladder). It may help identify an extrauterine location of a missing IUD or a collecting-system stone.

In women with gynecologic malignancies, radiographs may also be informative. Examples are chest radiographs to screen for pulmonary metastases during cancer staging and during surveillance after initial treatment. As discussed in the next sections, several specialized radiographic procedures are especially useful or specific for gynecology.

### ■ Breast Imaging

Of screening methods, mammography is the only modality clinically proven to decrease breast cancer-related mortality rates in women aged 40 to 74 years. Sensitivity of first mammography ranges from 71 to 96 percent (Humphrey, 2002). For the general population, annual screening mammography is recommended starting at age 40 for women, and a full discussion of screening criteria are found in Chapter 12 (p. 288).

During mammography, breast compression serves to immobilize the breast, to shorten exposure times, and to provide more

uniform tissue thickness. These improve image quality and lower radiation doses (American College of Radiology, 2014). Digital mammography has largely replaced screen-film techniques. This lowers radiation doses, which now only approximate 1.6 mGy (Mettler, 2008). In women with breast implants, mammographic evaluation includes standard and implant-displaced mammographic views. Whether the implant is subpectoral or intramammary, to obtain these additional views, the breast implant is displaced posteriorly toward the patient's chest while the breast tissue is pulled over and in front of the implant.

Different from screening mammography, women with a palpable breast mass or clinical symptom require *diagnostic mammography*. With this, craniocaudal and mediolateral oblique views of each breast are standardly obtained, and additional views are captured as needed to evaluate specific regions of concern. At the same visit, ultrasound evaluation of the breast may add diagnostic information regarding the internal structure of a finding.

If an abnormality is identified during mammography, image-guided aspiration or biopsy is often indicated. If lesions are visible sonographically, ultrasound can guide the radiologist in real time during the biopsy. If the abnormality is not sonographically visible or if concerning calcifications are present, stereotactic and vacuum-assisted core biopsies are obtained using radiographic guidance. During stereotactic breast biopsy, the patient usually lies prone on a specialized table. The breast hangs through an opening and is compressed similar to mammography. Prior to sampling with a biopsy core needle or vacuum-assisted device, two mammographic images are obtained to precisely target the finding, and local anesthetic is administered. With vacuum-assisted biopsy, suction pulls more tissue into the needle for sampling. For abnormalities only detected with MR imaging, MR-guided biopsies are also possible, done with a technique similar to stereotactic biopsy, but performed in the MR scanner using specialized coils, localization grids, and biopsy tools.

Distinct from diagnostic breast MR imaging, *screening* breast MR imaging is reserved for specific patient groups whose lifetime breast cancer risk exceeds 20 to 25 percent as calculated by the Gail model (Chap. 12, p. 287) (Saslow, 2007). For either indication, IV gadolinium contrast is typically administered.

In women with a nipple discharge, a ductogram or galactogram may be informative. The involved duct is cannulated with a fine catheter and a small amount of contrast is injected prior to obtaining additional mammographic views (Fig. 12-7, p. 281). A full discussion of breast disease evaluation is found in Chapter 12.

### ■ Intravenous Pyelography

Excretory urography, also called intravenous pyelography (IVP), is a radiographic study that provides serial imaging of the urinary tract. The initial radiograph, termed a *scout film*, helps identify radiopaque urinary calculi. Intravenous contrast is then administered, and the concentrating function of the proximal tubules renders renal parenchyma radiodense within 1–3 minutes. This *nephrogram phase* allows evaluation of renal size, contour, and axis. Next, a radiograph obtained 5 minutes

after injection depicts contrast excreted into the collecting system. During this *pyelogram phase*, the calyces and proximal ureters are evaluated for symmetry and excretion promptness. Serial imaging is obtained as the more distal collecting system and bladder is opacified by contrast, and a final postvoid radiograph completes the imaging.

Up to 5 to 10 percent of women have an allergic reaction to iodide during IVP, and 1 to 2 percent of reactions are life threatening. In addition, hyperosmolar ionic contrast can be nephrotoxic because of direct tubular insult and ischemic injury. Notably, women with diabetes, renal impairment, and congestive heart failure are at high risk for this contrast nephrotoxicity. As alternatives, nonionic low and isoosmolar iodinated contrast media carry a five- to 30-fold lower incidence of allergic reactions and are less nephrotoxic (Mishell, 1997). Because of this improved safety profile, most centers no longer use intravascular hyperosmolar ionic contrast (American College of Radiology, 2013).

Preoperatively, IVP may be selected to identify urinary anomalies coexistent with reproductive tract congenital defects or confirm lower urinary tract compression by an adjacent pelvic neoplasm. However, many preoperative IVPs have been replaced with multiphasic CT urography protocols performed on multislice CT scanners (Beyersdorff, 2008). For example, although it is not a formal part of cervical cancer staging, many clinicians in the United States substitute CT imaging for IVP in cervical cancer evaluation. Of value, CT allows the cervix, parametria, uterus, adnexa, retroperitoneal lymph nodes, liver, and ureters to be imaged concurrently.

For suspected nephrolithiasis, the American College of Radiology recommends primary evaluation using noncontrast CT given its superior sensitivity for renal stones (Coursey, 2011). To evaluate hematuria, noncontrast combined with contrast-enhanced CT images (CT urography) is most appropriate due to improved sensitivity for renal and urothelial masses. Although IVP has higher in-plane spatial resolution, the current recommendations are to move immediately to initial one-step CT evaluation as CT is frequently needed regardless of IVP results to delineate abnormalities (Cowan, 2007, 2012). That said, IVP may still play a role, especially in resource-poor areas, in postoperative patients, and in those for whom radiation exposure is ideally minimized. Specifically, IVP delivers an average adult effective dose of 1 to 10 mSv, whereas CT urography carries an average adult effective dose of 10 to 30 mSv (Coursey, 2011; Ramchandani, 2008).

### ■ Voiding Cystourethrography and Positive Pressure Urethrography

These radiographic procedures, discussed in Chapter 26 (p. 586), are used to evaluate the female urethra. Voiding cystourethrography (VCUG) is performed by placing a small catheter into the urinary bladder to instill contrast media. For evaluation of prolapse or incontinence, the patient may be asked to Valsalva during examination. After adequate distention of the bladder, the patient is asked to urinate and images are acquired during both bladder filling and urination. If present, diverticula that open into the urethra will fill with contrast. In

cases of suspected vesicovaginal or urethrovaginal fistula, the contrast trail connecting the two involved structures is seen.

In comparison, MR imaging permits superior visualization of urethral abnormalities and is more sensitive than VCUG or positive pressure urethrography (PPUG) for delineating diverticula with complex structure (Chou, 2008; Neitlich, 1998). For this reason, VCUG is currently more often used to evaluate lower urinary tract injury, such as fistulas, and patients with prolonged urinary retention, incontinence, or suspected vesicoureteral reflux.

Described in more detail in Chapter 26 (p. 586), PPUG use has declined. This stems mainly from decreasing numbers of technicians trained to complete the study, difficulty finding appropriate equipment, and the higher sensitivity of MR imaging.

### ■ Hysterosalpingography

This radiographic imaging technique is typically used during infertility evaluations to assess the endocervical canal, the endometrial cavity, and the fallopian tube lumina by injecting radiopaque contrast material through the cervical canal (Chap. 19, p. 438). An average HSG study is performed in 10 minutes, involves approximately 90 seconds of fluoroscopic time, and has an average radiation exposure to the ovaries of 0.01 to 0.02 Gy. As discussed previously (p. 25), hysterosalpingo-contrast sonography is used by some initially in place of HSG to assess tubal patency.

Hysterosalpingography is performed between cycle days 5 and 10. During this time, cessation of menstrual flow minimizes infection and the risk of flushing an ovum from the fallopian tube following ovulation. The test causes cramping, and an NSAID taken 30 minutes prior to the procedure may limit discomfort. To begin, a designated balloon-tipped injection catheter or acorn cannula is introduced just beyond the internal os and in the lower endometrial cavity, as this location is more comfortable for the patient. However, the catheter may also be positioned just cephalad to the external os within the endocervical canal if necessary. A paracervical block may be indicated in selected patients, such as those with cervical stenosis. Because rapid injection may cause tubal spasm, slow contrast injection of usually no more than 3 to 4 mL of contrast medium allows a clear outline of the uterine cavity. Generally, few radiographic views are needed: a preliminary view before injecting contrast, a view showing uterine cavity filling, and the third demonstrating spill of contrast from the fallopian tubes into the peritoneal cavity. An additional image with the catheter deflated and pulled back into the endocervical canal will typically be obtained at the conclusion of the examination to evaluate the lower uterine cavity and internal os.

A normal HSG may have variable appearances (Fig. 19-6, p. 439). The endometrial cavity is usually triangular or sometimes T-shaped in the anteroposterior (AP) projection. In the lateral view, it is oblong. The contour of the endometrium is usually smooth. It occasionally has polypoid filling defects that can be isolated or diffuse and can be difficult to distinguish from endometrial polyps or hyperplasia. Inadvertent injection of air bubbles introduces artifact. In these instances, SIS is often later obtained to further interrogate the endometrial cavity.

Contraindications to HSG include acute pelvic infection, active uterine bleeding, pregnancy, and iodine allergy. HSG complications are rare but can be serious. Of these, the overall risk of acute pelvic infection serious enough to require hospitalization is less than 1 percent but can reach 3 percent in women with prior pelvic infection (Stumpf, 1980). In patients with no history of pelvic infection, HSG is performed without prophylactic antibiotics. If HSG demonstrates dilated fallopian tubes, doxycycline, 100 mg orally twice daily for 5 days, is given to reduce the incidence of post-HSG PID. In patients with a history of pelvic infection, doxycycline can be administered before the procedure and continued if dilated fallopian tubes are found (American College of Obstetricians and Gynecologists, 2014). Pelvic pain, uterine perforation, and vasovagal reactions may also occur. From the contrast, allergic reaction and entry into the vascular system from high injection pressure are potential risks.

### ■ Selective Salpingography

In some cases, it is not possible to distinguish whether tubal blockage seen by HSG is caused by anatomic occlusion or tubal spasm. Hysteroscopic tubal cannulation can further clarify and treat many cases of proximal tubal occlusion as described in Section 44-18 (p. 1050). Alternatively, transcervical selective salpingography and tubal catheterization (SS-TC) under fluoroscopic guidance is another procedure that may be used. It is performed during the follicular phase of the cycle with the catheter forwarded through the cervix and advanced by tactile sensation to the tubal ostium. The position of the catheter is checked fluoroscopically, and if it is satisfactory, water- or oil-soluble contrast is injected. If the obstruction is overcome, the tubal contour is outlined with contrast agent. If the proximal tubal obstruction persists, a guide wire is threaded through the inner cannula of the catheter, advanced toward the obstruction, and gently manipulated to overcome the blockage. The guide wire is then withdrawn, and contrast medium is injected through the catheter to confirm patency. This fluoroscopic tool is effective at diagnosing and treating proximal tubal blockage and is discussed in Chapter 20 (p. 458) (Capitanio, 1991; Turmond, 1991).

### ■ Bone Densitometry

Depending on its mineral density, bone absorbs x-rays to different degrees. Because of this, bone density can be determined, and most measurements provide site-specific information. However, these studies do not assess current or past bone remodeling rates. Thus, sequential density measurements are necessary to monitor rates of bone loss over time (Kaplan, 1995). Currently, two common methods are used. Dual-energy x-ray absorptiometry (DEXA) measures integral bone (cortical and trabecular bone) mineral density in the hip and spine. Quantitative computed tomography (QCT) evaluates bone mineral in high-turnover trabecular bone.

Of these, DEXA is the best technique for axial osteopenia determination (Fig. 21-8, p. 480). It employs two x-ray beams of differing energy levels and accurately measures bone density in the hip and spine—areas most vulnerable to osteoporotic fractures. The spine is commonly scanned between the 1st and 4th lumbar vertebrae. Measurements with DEXA are precise

and accurate; radiation dose is low—less than 5 mrem; and patient acceptability is high because the procedure time is usually only 5 to 15 minutes (Jergas, 1993). The reproducibility of DEXA bone mass measurement to identify a population at high risk for fracture is excellent. DEXA is the preferred method for bone mineral density measurement to diagnose osteoporosis (Chap. 21, p. 479). DEXA instruments that measure bone mass at peripheral sites such as the forearm are also available, but these may not predict hip fractures as accurately as direct hip measurement. Other advantages include a proven effectiveness in monitoring antifracture treatments and being the standard against which other bone imaging measures are evaluated (Blake, 2007). Disadvantageously, DEXA is a 2-D technique that cannot distinguish between cortical and trabecular bone. In addition, bone spurs, aortic calcifications, and arthritis may falsely elevate reported bone density.

Quantitative computed tomography (QCT) uses multiple x-rays to provide a cross-sectional view of the vertebral body. As the rate of turnover in trabecular bone is nearly eight times that in cortical bone, this technique can detect early metabolic changes in this highly vulnerable bone type. It provides a volumetric density, which is an advantage in situations in which DEXA may underestimate bone mineral density (Damilakis, 2007). Although its precision is excellent and it can be used to follow patients undergoing therapy, it has never been validated for World Health Organization (WHO) criteria and is not routinely used as a screening modality. Another technique is quantitative sonography (QUS). This may provide information regarding the structural organization of bone and offers the potential for greater community access to bone mass evaluation (Philipov, 2000; World Health Organization, 1994).

## COMPUTED TOMOGRAPHY

This procedure involves multiple exposures of thin x-ray beams that are translated to 2-D axial images, termed a *slice*, of the particular area of interest. Multiple slices of the target body part are obtained along its length. Multiple-channel helical computed tomography, also called *spiral CT*, allows for continuous acquisition of images in a spiral and the potential for image reformatting in multiple planes. This technique is much faster and permits images to be manipulated for analysis after they have been acquired. Many variables affect radiation dose, especially slice thickness and number of cuts obtained. If a study is performed with multiple phases of contrast, each added phase or acquisition multiplies the total patient dose of radiation.

Intravenous contrast enables superior evaluation of solid organ parenchyma and vasculature. By adding IV contrast, masses become more obvious due to density differences. Dedicated thin slice evaluation of vasculature, termed CT angiography (CTA), can be done throughout the body. Although traditional (fluoroscopic) angiography is still performed, the information that cross-sectional imaging provides and its relative technical ease have increased its use. As discussed earlier, intravenous nonionic low and isoosmolar iodinated contrast media can induce nephrotoxicity and should be used with caution in patients with or at risk for renal insufficiency. Intravenous hydration before and after an examination can

**FIGURE 2-28** Computed tomography (CT) of the female pelvis in the axial plane demonstrates the normal uterus (arrows) as well as cysts in the left ovary (curved arrows).

help reduce contrast-induced nephrotoxicity. One option is 0.9-percent saline at 100 mL/hr beginning 6 to 12 hours before imaging and continuing 4 to 12 hours after the examination (American College of Radiology, 2013).

Oral contrast may enhance CT images if there is concern for gastrointestinal disease or if bowel must be differentiated from adjacent structures. Positive oral contrast is most frequently used and is dense (white) on images. Patients with documented allergies to *intravenous* contrast are rarely allergic to oral contrast. Intraluminal contrast in the rectum or urinary bladder also is dense (white) and can be used to address a specific concern, such as rectovaginal fistula or bladder injury, respectively.

### ■ Normal Pelvic Anatomy

The uterus is identified as a homogenous, soft tissue oval or triangle situated posterior to the bladder (Fig. 2-28). The uterine walls enhance after IV contrast. However, unlike sonography and MR imaging, the endometrium is poorly delineated by CT imaging. The cervix also may not enhance like the remainder of the uterus, and the inner stromal layer typically enhances less than the outer stromal layer (Yitta, 2011). The endocervical canal, which can be identified by MR imaging, is indistinct using CT imaging. The lateral margins of the cervix can typically be differentiated from parametrial fat because of differences in density. However, CT is not sensitive for parametrial involvement in the setting of cervical cancer (Hricak, 2005). Imaging of the vagina and vulva is very limited with CT. Typically, the ovaries are relatively hypodense, vary in appearance and position, and are usually situated lateral to the uterus.

### ■ Imaging Following Gynecologic Surgery

CT is well suited to diagnose potential complications of gynecologic procedures. For ureteral injuries, CT with IV contrast or CT urography is useful. To detect obstruction or injury, CT images are obtained after the kidneys have excreted the contrast and have opacified the collecting systems. High density

(white) contrast that abruptly stops within the ureter suggests obstruction. With ureteral disruption, contrast may flow freely from the injury site or may form an encapsulated collection, a urinoma (Titton, 2003).

For bladder injury, CT cystography may be informative. For this, the bladder is retrograde filled with 300 to 400 mL of dilute iodinated contrast by gravity drip. This is followed by helical CT of the bladder with multiplanar reformations (Chan, 2006). The technique is sensitive and specific for diagnosis of extraperitoneal and intraperitoneal bladder rupture and can also demonstrate vesicovaginal, ureterovaginal, or vesicoenteric fistulas (Jankowski, 2006; Yu, 2004).

CT also outperforms conventional radiography and barium studies for diagnosing bowel complications, such as small bowel obstruction (Maglinte, 1993). For characterizing an abdominal-pelvic fluid collection such as abscess or hematoma, CT with intravenous and oral contrast may be more helpful than other imaging tools (Fig. 3-8, p. 68) (Gjelsteen, 2008).

## ■ Gynecologic Malignancy

In most instances, sonography is the preferred initial method of evaluating the female pelvis. If additional anatomic information is needed, MR imaging is now often preferable to CT imaging because it avoids radiation exposure and iodinated IV contrast, provides excellent soft-tissue contrast, and displays pelvic structures in multiple planes. That said, CT imaging is probably the most frequently used imaging technique for evaluation and surveillance of gynecologic malignancies. Although its sensitivity for intraperitoneal metastases is limited, CT can estimate bulky metastases, such as in women with advanced ovarian cancer.

## MAGNETIC RESONANCE IMAGING

With this technology, images are constructed based on the radiofrequency signal emitted by hydrogen nuclei after they have been “excited” by radiofrequency pulses in the presence of a strong magnetic field. The radiofrequency signal emitted has characteristics called *relaxation times*. These include the T1-relaxation time (longitudinal) and the T2-relaxation time (transverse). The signal intensity of one tissue compared with another, that is, the contrast, can be manipulated by adjusting parameters of the acquisition. For example, by varying the elapsed time between applications of radiofrequency pulses, which is called *repetition time*, and the time between a radiofrequency pulse and sampling the emitted signal, called the *echo delay time*, different tissue weighting can be achieved.

Sequences with a short repetition time and short echo delay time are called *T1-weighted*. Sequences with a long repetition time and long echo delay time are regarded as *T2-weighted*. As examples, the hydrogen molecules in a water-containing area, such as urine in the bladder, have longer relaxation times than those in a solid tissue such as liver. On T1-weighted images, urine in the bladder will appear dark or have low signal intensity. On T2-weighted images, the same urine will appear bright or have high signal intensity. By manipulating multiple parameters and imaging planes, MR imaging is able to achieve superior soft-tissue contrast. The strength of the magnetic field

within the bore of the magnet is measured in tesla (T) (1 tesla = 10,000 gauss). For reference, the earth's magnetic field is approximately 0.5 gauss. Most clinical magnets used for MR imaging are 1.5 to 3 T or 15,000 to 30,000 gauss.

## ■ Technique

The standard imaging technique for the pelvis includes both T1- and T2-weighted sequences that are acquired in at least two planes, usually axial and sagittal. The T2-weighted sequence provides detailed definition of internal organ architecture, such as the zonal anatomy of the uterus and vagina, and aids identification of normal ovaries. T2-weighted images are usually superior in depicting pathologic conditions of the uterus and ovaries. The T1-weighted sequence clearly delineates organ boundaries and surrounding fat, allows optimal visualization of lymph nodes, and is necessary for tissue and fluid content characterization.

To aid accurate diagnosis, highly paramagnetic gadolinium-based contrast agents (GBCAs) are often administered prior to imaging. The most frequently used GBCA types are extracellular agents administered intravenously. Gadolinium shortens the T1 relaxation time of adjacent protons. This increases signal intensity on T1-weighted images to enhance information regarding tissue vascularity (Gandhi, 2006). Side effects are rare, and MR contrast can be used even in those with prior reactions to other contrast agents (American College of Radiology, 2004). MR contrast is given in concentrations and doses significantly lower than that used in CT imaging, undergoes renal excretion within 24 hours, and is safe for patients with mildly compromised renal function. Of note, the FDA recommends caution in administering IV GBCAs to patients with moderate to end-stage renal disease (glomerular filtration rate < 30 mL/min/1.73 m<sup>2</sup>) due to the rare but serious risk of developing nephrogenic systemic fibrosis (NSF). The risks and benefits of using GBCAs are discussed by the requesting physician and radiologist. Written informed consent from the patient is obtained if GBCA use is required for those with a severely diminished glomerular filtration rate. Providing hemodialysis immediately after administration of GBCA for patients in this category of renal compromise for the prevention of NSF has not been proven.

In addition to intravascular GBCAs, water-soluble ultrasound gel can be placed endoluminally (in the vagina and/or the rectum) to better delineate anatomy. This technique can also aid in detection of fistulas and be used to better visualize vaginal septa in the setting of müllerian anomalies (Gupta, 2014).

Additional imaging parameters include fat saturation to detect bulk fat and opposed-phase imaging to highlight microscopic fat. Diffusion-weighted imaging (DWI) with quantitative measurement of apparent diffusion coefficient (ADC) provides information regarding proton movement in tissues. Highly cellular tissues restrict random Brownian motion and yield a high DWI signal and low ADC value. This cellularity information can help identify tumors, abscesses, and lymph nodes (Moore, 2014).

## ■ Safety

The effects from static magnetic fields and gradient magnetic fields generated with MR imaging have been extensively studied.

**TABLE 2-1.** Safety of Magnetic Resonance Imaging with Some Implanted Devices

<b>Biopsy Needles/Markers</b>		
Localization wires	U	U
Biopsy needles	U	U
Coaxial needles	U	U
Breast biopsy markers (e.g., HydroMark)	S	C

To date, harmful or mutagenic effects have not been reported from MR imaging at field strengths used clinically, that is, 3 T or lower. Additionally, the American College of Radiology considers the use of MR imaging in pregnancy to be risk free, regardless of trimester. With its lack of ionizing radiation, MR imaging may be particularly useful in pregnant women for the characterization of pathology for which sonography has provided an inconclusive diagnosis. Using the ALARA (as low as reasonably achievable) principle, imaging during pregnancy is typically limited to 1.5 T. Moreover, GBCAs are not used routinely in pregnancy due to the theoretic risk of toxic gadolinium ion dissociation from its ligand into the amniotic fluid (Kanal, 2013).

Some, but not all, devices preclude MR imaging. For example, many implanted devices unique to women can be safely imaged (Table 2-1). Contraindications to entering the MR environment include mechanically, electrically, or magnetically activated implanted devices such as internal cardiac pacemakers, neurostimulators, cardiac defibrillators, electronic infusion pumps, and cochlear implants. Certain intracranial aneurysm clips and any metallic foreign body in the globe of the eye contraindicate scanning. Before the patient enters the MR environment, radiology personnel should obtain documentation of the

type of patient implant (manufacturer, model, and type) and verify the MR safety rating.

### ■ Use in Gynecology

Although sonography is widely used for suspected gynecologic disease, MR imaging may add information when sonographic findings are equivocal. Specifically, its multiplanar imaging, superior soft-tissue contrast, and large field of view are distinct MR imaging advantages. Accordingly, common indications for MR imaging include distorted pelvic anatomy, large masses that are poorly delineated with sonography, indeterminate cases of adenomyosis, and endometrial disorders in poor surgical candidates. In some instances, pelvic MR imaging may help tailor clinical gynecologic and surgical management (Schwartz, 1994). Also, MR imaging is commonly selected for primary evaluation and subsequent surveillance of pelvic malignancies.

### ■ Normal Findings

The pelvic organs show generally moderate to low signal intensity on T1-weighted images. T2-weighted images of the menstrual uterus depict a high-signal-intensity endometrium; contiguous low-signal-intensity inner myometrium, which is the junctional zone; and a moderate-signal-intensity outer myometrium (Fig. 2-29) (McCarthy, 1986).

The cervix can be distinguished from the uterine body by its prominent fibrous stroma, which has an overall lower signal intensity. The internal architecture of the cervix is seen on T2-weighted images as central high signal intensity (endocervical glands and mucus) surrounded by low signal intensity (fibrous stroma) and peripheral moderate signal intensity (smooth muscle intermixed with fibrous stroma) (Lee, 1985). Similarly, T2-weighted images of the vagina display central high-signal-intensity mucosa and mucus, which is surrounded by a low-signal-intensity muscular wall (Hricak, 1988). Ovaries are normally seen on the T2-weighted sequence as moderately high-signal-intensity stroma containing very high-signal-intensity

follicles (Dooms, 1986). The fallopian tubes are not typically visualized. Hormonal status influences the MR appearance of all structures and reflects associated physiologic changes.

### ■ Benign Disease

#### Leiomyomas

Sonography remains the initial imaging technique for suspected leiomyomas, but its limited field of view, image resolution that declines with increasing patient body fat, and distorted anatomy from large or multiple myomas are potential hindrances (Wolfman, 2006). False-negative rates may reach 20 percent, and tumors < 2 cm are routinely missed by TVS, even when symptomatic (Gross, 1983). Thus, MR imaging is used when TVS findings are equivocal or nondiagnostic (Ascher, 2003). For conservative myoma treatment, the effects of GnRH agonist therapy to shrink tumor volume can be quantified with MR imaging (Lubich, 1991). Moreover, MR imaging is warranted before UAE or focused-ultrasound myoma treatments and often selected prior to hysteroscopic myoma resection. In these cases, imaging verifies leiomyoma location, seeks tumor qualities that portend outcome success or failure, and excludes other causes of patient symptoms such as unsuspected malignancy or indeterminate intracavitary masses (Cura, 2006; Rajan, 2011).

As shown in Figure 2-30, leiomyomas have a variable but characteristic MR appearance and thus can be differentiated from adenomyosis or adenomyoma with 90-percent accuracy (Mark, 1987; Togashi, 1989). This is important when myomectomy is considered. Leiomyomas, even those as small as 0.5 cm, are best seen on T2-weighted images and appear as round, sharply marginated, low-signal-intensity masses relative to the myometrium. Tumors > 3 cm often are heterogeneous because of varying degrees and types of degeneration (Hricak, 1986; Yamashita, 1993). With MR imaging, multiplanar views allow for accurate tumor localization as subserosal, intramural, or submucosal. Moreover, pedunculated myomas and their bridging stalk can be delineated. Of myoma types, intramural or subserosal leiomyomas are frequently circumscribed by a high-signal-intensity rim that represents edema from dilated lymphatics and veins.

Of treatment options, magnetic resonance high-intensity focused ultrasound (MR-HIFU) therapy directs a series of high-power ultrasound pulses—*sonications*—into the myoma. Without MR guidance, focused-ultrasound therapy is hampered by imprecise beam targeting. Fortunately, excellent soft-tissue resolution with MR imaging enables precise tissue targeting. Moreover, MR imaging can measure accurate, near real-time thermometry. This permits power adjustments to reach adequate treatment temperatures yet minimize thermal injury. Pulse duration lasts generally 15 seconds, and a cooling interval is inserted between pulses. The average procedure duration approximates 3½ hours (Hindley, 2004).

MR-HIFU therapy, also called MR-guided focused ultrasound (MRgFUS), is a safe and feasible minimally invasive alternative for leiomyoma treatment (Chen, 2005; Stewart, 2003). Several studies have demonstrated a relatively rapid improvement in patient symptoms, a continued decrease in the leiomyoma size over time, a quicker recovery, and few major adverse events in comparison with UAE or myomectomy

**FIGURE 2-29** Sagittal T2-weighted magnetic resonance (MR) image of a normal uterus and cervix (C). B= bladder; M= myometrium; V= vagina.

**FIGURE 2-30** **A.** Sagittal T1-weighted post-contrast image demonstrates a 5.6-cm enhancing leiomyoma at the uterine fundus. **B.** Sagittal T1-weighted post-contrast image of the same patient 2 months after uterine artery embolization demonstrates lack of enhancement in the fibroid and significant interval decrease in size (now measuring 2 cm).

(Fennessy, 2007; Stewart, 2006, 2007). However, little information is available on long-term results compared with other interventional treatments. Moreover, not all patients are suitable candidates. Obstructions in the energy path such as abdominal wall scars or intraabdominal clips, total uterine size > 24 weeks, a desire for future fertility, or general contraindications to MR imaging are limitations. Moreover, leiomyoma characteristics such as size, perfusion, or location near adjacent organs may limit treatment feasibility. Ongoing investigations of additional MR-HIFU indications include its use in women with symptomatic leiomyomas desiring future fertility, myomas > 10 cm, and adenomyosis (Hesley, 2008; Kim, 2011a,b).

### Congenital Anomalies

As discussed in Chapter 18 (p. 417), müllerian duct anomalies comprise a spectrum of developmental malformations. In the past, full evaluation required laparoscopy, laparotomy, HSG, and hysteroscopy. These invasive techniques were largely replaced by MR imaging, which has an accuracy of up to 100 percent (Carrington, 1990; Fielding, 1996). As discussed earlier, with advances in 3-D sonography techniques, sonographic evaluation with 3-D image reconstruction, with or without saline infusion, can also be used for müllerian anomaly diagnosis (p. 26).

MR imaging is particularly adept at differentiating septate and bicornuate uteri, which is imperative as these two have differing clinical implications and surgical management. Intravenous contrast is not routinely needed, but if a vaginal septum is suspected clinically, then placing ultrasound gel within the vagina prior to imaging may be helpful (Gupta, 2014). T2-weighted images and coronal planes are typically the most informative. With these, the septate uterus generally has a convex fundal contour. The bicornuate uterus typically has a significant fundal notch > 1 cm, although any notch depth within 5 mm of the intercornual line qualifies for bicornuate (Behr, 2012). The endometrial cavities of a bicornuate uterus have a normal width and communicate. Although a less reliable marker, the intercornual distance with a bicornuate uterus typically measures > 4 cm (Carrington, 1990; Fedele, 1989).

With a septate uterus, a fibrous septum divides the two uterine horns. Collagen has low signal intensity on both T1- and T2-weighted images, whereas the intervening myometrium of a bicornuate uterus has high signal intensity on T2-weighted images. The fundal contour of the septate uterus can be convex, flattened, or mildly concave, but if present, the fundal notch lies > 5 mm above the intercornual line (Behr, 2012). Also in contrast to the bicornuate uterus, the intercornual distance of a septate uterus is not increased, and thus each uterine cavity is smaller than usual (Carrington, 1990; Forstner, 1994).

MR imaging is also used for more detailed evaluation of a unicornuate uterus, especially in evaluation for a rudimentary horn (Fig. 2-31). On MR imaging, if endometrial tissue is present within a rudimentary horn, zonal anatomy will be preserved. Moreover, communication of an endometrium-containing

**FIGURE 2-31** Unicornuate uterus. This coronal T2-weighted image demonstrates a protrusion of myometrial tissue from the left lateral uterine body (arrowhead). It is isointense to myometrium but does not demonstrate normal uterine zonal anatomy. Specifically, endometrium (arrow) is noted in the developed right uterine horn but not in the left rudimentary horn.

rudimentary horn is of considerable clinical importance (Chap. 18, p. 420). In a menstruating woman, a noncommunicating horn containing endometrium will often be evident as a hematometra when the cavity becomes distended with blood. MR imaging can also noninvasively identify uterine didelphys, agenesis, and hypoplasia.

### Other Gynecologic Indications

MR imaging is equivalent or superior to sonography to diagnose adenomyosis and has a sensitivity of 88 to 93 percent and a specificity of 66 to 99 percent (Ascher, 1994; Dueholm, 2001; Reinhold, 1996). One principal advantage of MR imaging compared with sonography includes the reliability of MR imaging to diagnose adenomyosis, particularly focal adenomyomas, in the setting of concomitant pathology such as leiomyomas. Another is the reproducibility of MR imaging, which allows for accurate treatment monitoring (Reinhold, 1995).

The thickness of the low-signal-intensity junctional zone (inner myometrium)  $> 12$  mm is diagnostic of adenomyosis on T2-weighted images (Fig. 2-32). A normal junctional zone can measure up to 8 mm, and measurements from 8 to 12 mm are considered indeterminate (Novellas, 2011). Low-signal-intensity areas of adenomyosis often contain internal ovoid and punctate foci of increased signal on both T1- and T2-weighted images. These foci are nests of ectopic endometrium with dilated endometrial glands, with or without hemorrhage (Reinhold, 1995, 1996). Contrast administration does not increase the diagnostic accuracy for adenomyosis (Outwater, 1998).

For polyps and endometrial hyperplasia, TVS and SIS are common diagnostic tools. MR imaging may be helpful if these modalities are nondiagnostic in a patient who is a poor surgical candidate for direct endometrial sampling. That said, differentiation of intracavitary myomas and endometrial polyps can be problematic with MR imaging if necrosis and inflammation are present.

For diagnosing ovarian endometriomas, MR imaging offers similar specificity to TVS (98 percent). These cysts show characteristic “shading” signal loss on T2-weighted images. The

**FIGURE 2-32** Sagittal T2-weighted magnetic resonance image of a uterus with diffuse adenomyosis. Adenomyosis is shown as circumferential thickening of the junctional zone.

correlating hyperintense signal on T1-weighted images originates from old blood products (Chamie, 2011). However, MR imaging differs from TVS in that it can provide evaluation for endometriosis in locations that are not easy to access sonographically or laparoscopically, especially in the setting of advanced disease. For diagnosing deep pelvic endometriosis, MR imaging has a sensitivity of 90 percent, specificity of 91 percent, and accuracy of 91 percent (Bazot, 2004). Additional features used to diagnose endometriosis include stellate margins of fibrotic plaques, tethering, and obliteration of normal pelvic spaces. On T1-weighted images, hyperintense signal foci from old hemorrhagic endometriotic disease aids diagnosis of multifocal endometriosis involving the bladder, rectum, and ureters.

For adnexal masses, MR imaging is useful to further characterize anatomy if sonography is nondiagnostic or inconclusive. MR imaging frequently provides added information regarding soft-tissue composition and the origin and extent of pelvic pathology that may be nongynecologic. Although both sonography and MR imaging are highly sensitive for the detection of adnexal malignancy, MR imaging is slightly more specific (Adusumilli, 2006; Jeong, 2000; Yamashita, 1995).

### Gynecologic Malignancies

For cervical cancer, imaging is not a component of strict clinical staging (Chap. 30, p. 663). That said, MR imaging is an excellent adjunct for preoperative assessment of gynecologic neoplasms. Its superior soft-tissue contrast and ability to image directly in multiple planes allow evaluation for local tumor extension and lymphadenopathy.

Although CT imaging is typically used for assessment of nodal disease and distant metastases, MR imaging consistently outperforms clinical and CT evaluation of cervical cancer in the assessment of local tumor extension (Choi, 2004; Hricak, 1996, 2007). Current recommendations for MR imaging of cervical cancer include tumors with a transverse diameter  $> 2$  cm based on physical examination, endocervical or predominately infiltrative tumors that cannot be accurately assessed clinically, and women who are pregnant or have concomitant uterine lesions that make evaluation difficult (Ascher, 2001; Hricak, 2007). When the extent of parametrial and sidewall invasion is unclear clinically, MR imaging can play an important role as it has a 95- to 98-percent negative predictive value for parametrial invasion (Hricak, 2007; Subak, 1995).

For endometrial carcinoma, surgery is currently the most accurate staging method. Preoperatively, MR imaging may assess the degree of myometrial and cervical extension, which can affect the planned hysterectomy type, extent of lymph node dissection, and decision to provide neoadjuvant intracavitary radiation (Boronow, 1984; Frei, 2000). MR imaging has a 92-percent accuracy in staging endometrial cancer, and an 82-percent accuracy in assessing myometrial invasion depth (Hricak, 1987). Thus, MR imaging is often considered if lymph node metastases are likely. Instances include a high-grade tumor; papillary or clear cell histology; cervical invasion; or need for multifactorial assessment of myometrial, cervical, and lymph node involvement (Ascher, 2001).

For ovarian neoplasms, MR imaging is reserved for evaluation when TVS or CT scanning is nondiagnostic or when

high-risk surgical patients might benefit from further stratification. This stems from its increased cost, decreased availability, and longer imaging and interpretation times (Javitt, 2007). However, in a Society of Radiologists in Ultrasound consensus statement, MR imaging was recommended for simple ovarian cysts > 7 cm, given sonography's limitations in detecting mural nodules in larger ovarian masses (Ekerhovd, 2001; Levine, 2010). MR imaging is also useful to determine adnexal mass origin as uterine, ovarian, or nongynecologic. For those of the ovary, MR imaging helps clarify whether the mass is neoplastic or functional and is malignant or benign. MR imaging of an adnexal mass ideally includes gadolinium-enhanced images to assess tumor vascularity and fat-saturation techniques to differentiate blood from fat (Ascher, 2001). Although histology cannot be diagnosed, findings that are suspicious for malignancy include enhancing solid components, thick septations, nodules, and/or papillary projections.

Sensitivity of MR imaging for detecting adnexal pathology ranges from 87 to 100 percent, which is comparable to sonography and CT scanning (Siegelman, 1999). The advantages of MR imaging compared with CT scanning in the evaluation of suspected ovarian cancer include its superior contrast resolution and increased sensitivity for detecting uterine invasion, extrapelvic peritoneal and lymph node metastases, and tumor extension to omentum, bowel, bone, and vessels (Low, 1995; Tempany, 2000). However, MR imaging has a lower sensitivity for implants < 1 cm compared with CT (Sala, 2013).

## ■ Urogynecology

Pelvic floor evaluations previously performed fluoroscopically are now more often performed with MR imaging. MR imaging provides detailed soft-tissue evaluation of the female urethra, levator ani muscles, and adjacent pelvic structures in patients with incontinence or pelvic organ prolapse (Pannu, 2002). Contrast agents placed in the vagina, rectum, and/or bladder can enhance imaging.

In addition to anatomy, functional data can be obtained. For example, dynamic MR imaging is completed as the patient performs the Valsalva maneuver. With MR defecography, the patient both performs Valsalva maneuver and defecates rectal contrast (ultrasound gel) during rapid cine acquisitions. Protocols vary significantly from center to center, and upright open MR units are not universally available. At our institution, supine MR defecography is preferred to Valsalva alone (Bailey, 2014; Kumar, 2014). MR defecography can evaluate patients with pelvic organ descent, incontinence, constipation, and defecatory dysfunction. It may add information prior to complex pelvic floor reconstruction or after failed previous repairs (Macura, 2006). Grading systems of pelvic organ prolapse and pelvic floor relaxation on dynamic imaging have been developed (Barbaric, 2001; Fielding, 2000).

## ■ NUCLEAR MEDICINE

Nuclear medicine examinations are used similarly in the gynecologic patient as in other medical specialties. Small amounts of radioactive material can be ingested or injected to diagnose, and

at times treat, various diseases. Thyroid studies use radioactive iodine to assess or ablate function. Bone scans may be elected to seek metastatic disease. Various renal scans can offer information regarding renal function, perfusion, and possible obstruction. Ventilation-perfusion (V/Q) scans are often used to identify pulmonary emboli. Controversy remains regarding whether pulmonary artery CTA or V/Q scan is most appropriate in pulmonary emboli evaluation. The V/Q scan does not use nephrotoxic agents and is often preferred in those with renal insufficiency. However, radiopharmaceuticals are not always readily available, and thus pulmonary artery CTA is frequently employed.

Positron emission tomography (PET) uses short-lived radiochemical compounds to serve as tracers for measuring specific metabolic processes suggestive of malignancy or infection (Juweid, 2006). This enables detection of early cancer biochemical anomalies that precede the structural changes identified by other imaging techniques. With FDG-PET, a radiolabeled analogue of glucose, 2-[<sup>18</sup>F]fluoro-2-deoxy-d-glucose (FDG), is injected intravenously and is taken up by metabolically active cells such as tumor cells. PET provides a poor depiction of detailed anatomy, thus scans are frequently read side-by-side or fused with CT scans. The combination allows correlation of metabolic and anatomic data. As a result, current PET scanners are now commonly integrated with CT scanners, and the two scans can be performed during the same session.

PET/CT has become a vital clinical tool, particularly for cancer diagnosis and management. The FDG tracer highlights areas of accelerated glycolysis, which is common in neoplastic cells (Goh, 2003). Several studies have demonstrated high sensitivity and specificity of FDG-PET for the initial staging of cervical cancer, especially in patients with no evidence of extrapelvic metastatic disease by MR or CT imaging (Gjelsteen, 2008; Park, 2005). The ability of FDG-PET imaging to assess nodal status in cervical cancer has both prognostic and therapeutic implications (Fig. 2-33). Prior to lymph node radiation treatment planning, the added anatomic data obtained with PET/CT can be used to guide intensity-modulated radiotherapy (Chap. 28, p. 615). This significantly reduces the amount of radiation delivered to surrounding normal structures (Havrilesky, 2003; Wong, 2004).

## ■ INTERVENTIONAL RADIOLOGY

In gynecology, procedures often provided by interventional radiologists include image-guided biopsy or drainage. In those with advanced cervical cancer, percutaneous nephrostomy may be needed to preserve renal function or to decompress an infected collecting system. Uterine artery embolization is a vascular intervention that employs angiography to delineate the uterine arteries. Once catheterized, each artery is injected with embolic particles to occlude uterine vasculature. As discussed in Chapter 9 (p. 209), UAE can provide definitive independent treatment of uterine leiomyomas as blood flow through the uterine arteries is stopped. This leads to preferential myoma ischemia and necrosis. Although adenomyosis was initially thought to be a contraindication for UAE success, studies are now showing UAE to have durable treatment efficacy in adenomyosis (Kim, 2007). Given the frequent concomitant

**FIGURE 2-33** Positron emission tomography (PET) (**A**) and PET-computed tomography (PET-CT) fusion (**B**) images of a woman with recurrence of ovarian cancer. Arrows demarcate abnormal uptake of tracer in the pelvis that represented a 1-cm lymph node. The biopsy of this lymph node revealed recurrent ovarian cancer. (Images contributed by Dr. Dana Mathews.)

presence of adenomyosis and uterine leiomyomata, treatment success and improvement in symptoms have also been reported in populations with both diseases after UAE (Froeling, 2012). Rarely, UAE may be selected to control severe uterine bleeding in women who are not considered surgical candidates.

NORMAL VAGINAL FLORA

The vaginal flora of a normal, asymptomatic reproductive-aged woman includes multiple aerobic, facultative anaerobic, and obligate anaerobic species (Table 3-1). Of these, anaerobes predominate and outnumber aerobic species approximately 10 to 1 (Bartlett, 1977). These bacteria exist in a symbiotic relationship with the host and are alterable, depending on the microenvironment. They localize where their survival needs are met and have exemption from the infection-preventing destructive capacity of the human host. The function of this vaginal bacterial colonization, however, remains unknown.

Within this vaginal ecosystem, some microorganisms produce substances such as lactic acid and hydrogen peroxide that inhibit nonindigenous organisms (Marrazzo, 2006). Several other antibacterial compounds, termed *bacteriocins*, play a similar role. For protection from many of these toxic substances, a secretory leukocyte protease inhibitor is found in the vagina. This protein protects local tissues against toxic inflammatory products and infection.

Certain bacterial species normally found in vaginal flora have access to the upper reproductive tract. The female upper reproductive tract is not sterile, and the presence of these bacteria does not indicate active infection (Hemsell, 1989; Spence,

1982). Together, these findings do illustrate the potential for infection following gynecologic surgery and the need for antimicrobial prophylaxis. They also explain the potential acceleration of a local acute infection if a pathogen, such as *Neisseria gonorrhoeae*, gains access to the upper tract.

Vaginal pH

Typically, the vaginal pH ranges between 4 and 4.5. Although not completely understood, *Lactobacillus* species contribute by production of lactic acid, fatty acids, and other organic acids. Other bacteria can also add organic acids from protein catabolism, and anaerobic bacteria donate by amino acid fermentation.

Glycogen, which is present in healthy vaginal mucosa, provides nutrients for many vaginal ecosystem species and is metabolized to lactic acid (Boskey, 2001). Accordingly, as glycogen content within vaginal epithelial cells diminishes after menopause, this decreased substrate for acid production leads to a rise in vaginal pH. Specifically, if no pH-altering pathogens are present, a vaginal pH of 6.0 to 7.5 is strongly suggestive of menopause (Caillouette, 1997).

Altered Flora

Changing any element of this ecology may alter the prevalence of various species. For example, postmenopausal women not receiving estrogen replacement and young girls have a lower prevalence of *Lactobacillus* species compared with that of reproductive-aged women. However, for menopausal women, hormone replacement therapy restores vaginal lactobacilli populations, which protect against vaginal pathogens (Dahn, 2008).

Other events predictably alter lower reproductive tract flora and may lead to infection. With the menstrual cycle, transient changes in flora are observed. These are predominantly during the first days of the cycle and are presumed to be associated with hormonal changes (Keane, 1997). Menstrual fluid can also serve as a nutrient source for several bacterial species, resulting in their overgrowth. What role this plays in the development of upper reproductive tract infection following menstruation is unclear, but an association may be present. For example, women symptomatic with acute gonococcal upper reproductive tract infection characteristically are menstruating or have just completed their menses. Last, treatment with a broad-spectrum antibiotic may result in symptoms attributed to inflammation from *Candida albicans* or other *Candida* spp by eradicating other balancing species in the flora.

TABLE 3-1. Lower Reproductive Tract Bacterial Flora

**Aerobes**

- Gram-positive
  - Lactobacillus spp
  - Diphtheroids
  - Staphylococcus aureus
  - Staphylococcus epidermidis
  - Group B Streptococcus
  - Enterococcus faecalis
  - Staphylococcus spp
- Gram-negative
  - Escherichia coli
  - Klebsiella spp
  - Proteus spp
  - Enterobacter spp
  - Acinetobacter spp
  - Citrobacter spp
  - Pseudomonas spp

**Anaerobes**

- Gram-positive cocci
  - Peptostreptococcus spp
  - Clostridium spp
- Gram-positive bacilli
  - Lactobacillus spp
  - Propionibacterium spp
  - Eubacterium spp
  - Bifidobacterium spp
  - Actinomyces israelii
- Gram-negative
  - Prevotella spp
  - Bacteroides spp
  - Bacteroides fragilis group
  - Fusobacterium spp
  - Veillonella spp
- Yeast
  - Candida albicans and other spp

TABLE 3-2. Bacterial Vaginosis Risk Factors

- Oral sex
- Douching
- Black race
- Cigarette smoking
- Sex during menses
- Intrauterine device
- Early age of sexual intercourse
- New or multiple sexual partners
- Sexual activity with other women

an increased risk of BV is associated with sexual contact with multiple and new male and female partners, and condom use lowers the risk (Table 3-2) (Fethers, 2008). Further, rates of STD acquisition are increased in affected women, and a possible role of sexual transmission in the pathogenesis of recurrent BV has been proposed (Atashili, 2008; Bradshaw, 2006; Wiesenfeld, 2003). Successful prevention of BV is limited, but elimination or diminished use of vaginal douches may be beneficial (Brotman, 2008; Klebanoff, 2010).

Bacterial vaginosis is the most common cause of vaginal discharge among reproductive-aged women. Of symptoms, a nonirritating, malodorous vaginal discharge is characteristic, but may not always be present. The vagina is usually not erythematous, and cervical examination reveals no abnormalities.

Clinical diagnostic criteria were first proposed by Amsel and associates (1983) and include: (1) microscopic evaluation of a vaginal-secretion saline preparation, (2) release of volatile amines produced by anaerobic metabolism, and (3) determination of the vaginal pH. A saline preparation, also known as a “wet prep,” contains a swab-collected sample of discharge mixed with drops of saline on a microscope slide. Clue cells are the most reliable indicators of BV and were originally described by Gardner and Dukes (1955) (Fig. 3-1). These vaginal epithelial

■ **Bacterial Vaginosis**

This common, complex, and poorly understood clinical syndrome reflects abnormal vaginal flora. It has been variously named, and former terms are *Haemophilus vaginitis*, *Corynebacterium vaginitis*, *Gardnerella* or anaerobic vaginitis, and nonspecific vaginitis. With bacterial vaginosis (BV), the vaginal flora’s symbiotic relationship shifts for unknown reasons to one in which anaerobic species overgrow and include *Gardnerella vaginalis*, *Ureaplasma urealyticum*, *Mobiluncus* species, *Mycoplasma hominis*, and *Prevotella* species. Bacterial vaginosis (BV) is also associated with a significant reduction or absence of normal hydrogen peroxide-producing *Lactobacillus* species. Whether an altered ecosystem leads to lactobacilli disappearance or whether its disappearance results in the changes observed with BV is unclear.

In evaluating risks for BV, this condition is not considered by the Centers for Disease Control and Prevention (CDC) (2015) to be a sexually transmitted disease (STD). However,

**FIGURE 3-1** Photomicrograph of saline wet preparation reveals clue cells. Several of these squamous cells are heavily studded with bacteria. Clue cells are covered to the extent that cell borders are blurred and nuclei are not visible (arrows). (Used with permission from Dr. Lauri Campagna and Mercedes Pineda, WHNP.)

cells contain many attached bacteria, which create a poorly defined stippled cellular border. At least 20 percent of the epithelial cells should be clue cells. The positive predictive value of this test for BV is 95 percent.

Adding 10-percent potassium hydroxide (KOH) to a fresh sample of vaginal secretions releases volatile amines that have a fishy odor. This is often colloquially referred to as a “whiff test.” The odor is frequently evident even without KOH. Similarly, alkalinity of seminal fluid and blood are responsible for foul-odor complaints after intercourse and with menses. The finding of both clue cells and a positive whiff test result is pathognomonic, even in asymptomatic patients.

Characteristically with BV, the vaginal pH is > 4.5, and this stems from diminished acid production by bacteria. Similarly, *Trichomonas vaginalis* infection is also associated with anaerobic overgrowth and resultant elaborated amines. Thus, women diagnosed with BV should have no microscopic evidence of trichomoniasis.

Last, and used primarily in research studies rather than clinical practice, the Nugent Score is a system employed for diagnosing BV. During microscopic examination of a gram-stained vaginal discharge smear, scores are calculated by assessing bacteria staining and morphology.

Several gynecologic adverse health outcomes have been observed in women with BV. These include vaginitis, endometritis, postabortal endometritis, pelvic inflammatory disease (PID) unassociated with *N gonorrhoeae* or *Chlamydia trachomatis*, and acute pelvic infections following pelvic surgery, especially hysterectomy (Larsson, 1989, 1991, 1992; Soper, 1990). Pregnant patients with BV have an elevated risk of preterm delivery (Flynn, 1999; Leitich, 2007).

Several regimens have been proposed by the 2014 Centers for Disease Control and Prevention BV working group and are for nonpregnant women (Table 3-3). Cure rates with these regimens range from 80 to 90 percent at 1 week, but within 3 months, 30 percent of women have experienced a recurrence of altered flora. At least half have another episode of symptoms associated with this flora change, many of which are correlated with heterosexual contacts (Amsel, 1983; Gardner, 1955; Wilson, 2004). However, treatment of male sexual partners does not benefit women with this recurring condition and is

not recommended. Moreover, other forms of therapy such as introduction of lactobacilli, acidifying vaginal gels, and use of probiotics have shown inconsistent effectiveness (Senok, 2009).

ANTIBIOTICS

These drugs are commonly used in gynecology to restore altered flora or treat various infections. As a group, antibiotics have been implicated in decreasing the efficacy of oral contraceptives. Fortunately, this has been proven in very few, and these are listed in Table 5-9 (p. 124).

■ Penicillins

The heart of all penicillins is a thiazolidine ring with an attached  $\beta$ -lactam ring and a side chain. The  $\beta$ -lactam ring provides antibacterial activity, which is primarily directed against gram-positive aerobic bacteria. Because of the numerous substitutions at the side chain, various antibiotics with altered antibacterial spectra and pharmacologic properties have been synthesized.

Some bacteria produce an enzyme ( $\beta$ -lactamase) that opens the  $\beta$ -lactam ring and inactivates the drug as a primary bacterial defense mechanism. Inhibitors of  $\beta$ -lactamase are clavulanic acid, sulbactam, and tazobactam, and these have been combined with several penicillins to enhance the activity spectrum against a broader variety of aerobic and anaerobic bacteria. Additionally, oral probenecid can be administered separately with penicillins. This drug lowers the renal-tubular secretion rate of these antibiotics and is used to increase penicillin or cephalosporin plasma levels.

Adverse reactions to penicillins may include allergic (e.g., anaphylaxis, urticaria, drug fever), neurologic (e.g., dizziness, seizure), hematologic (e.g., neutropenia, hemolytic anemia, thrombocytopenia), renal (interstitial cystitis), hepatic (elevated transaminases), or gastrointestinal (e.g., nausea, vomiting, diarrhea, pseudomembranous colitis) reactions (Mayo Clinic, 1991). Up to 10 percent of the general population may manifest an allergic reaction to penicillins. The lowest risk is associated with oral preparations, whereas the highest follows those combined with procaine and given intramuscularly. True anaphylactic

TABLE 3-3. Single-agent Bacterial Vaginosis Treatment

Recommended regimens

Metronidazole (Flagyl)	500 mg orally twice daily for 7 days
Metronidazole gel 0.75% (Metrogel vaginal)	5 g (1 full applicator) intravaginally once daily for 5 days
Clindamycin cream <sup>a</sup> 2% (Cleocin, Clindesse)	5 g (1 full applicator) intravaginally at bedtime for 7 days

Alternative regimens

Tinidazole (Tindamax)	2 g orally once daily for 2 days
Clindamycin	1 g orally once daily for 5 days 300 mg orally twice daily for 7 days
Clindamycin ovules <sup>a</sup> (Cleocin)	100 mg intravaginally at bedtime for 3 days

<sup>a</sup>Clindamycin cream and ovules are oil-based and might weaken latex condoms and diaphragms for 5 days after use. Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

reactions are rare, and mortality rates approximate 1 in every 50,000 treatment regimens. If penicillin allergy is noted, yet treatment is still required, desensitization can be performed relatively safely as described by Wendel and coworkers (1985) and outlined at the CDC website: <http://www.cdc.gov/std/treatment/2010/penicillin-allergy.htm>.

Excellent tissue penetration is achieved with these agents. Penicillin remains the primary antibiotic for treatment of syphilis, and this antibiotic family is also useful in treating skin infections, breast cellulitis, and breast abscess. The combination of amoxicillin and clavulanic acid (Augmentin) provides the best oral broad-spectrum antibiotic coverage. Moreover, the ureidopenicillins and those combined with a  $\beta$ -lactamase enzyme inhibitor are effective against acute community-acquired or postoperative pelvic infections. In addition, *Actinomyces israelii* infections, which are an infrequent complication of intrauterine device (IUD) use, are treated with penicillins (Westhoff, 2007).

## ■ Cephalosporins

Cephalosporins also are  $\beta$ -lactam antimicrobials. Substitutions at their side chains significantly alter the spectrum of activity, potency, toxicity, and half-life of these antibiotics. Organization of these qualities has resulted in their division into five generations. This classification does allow grouping based on general spectra of activity.

Rash and other hypersensitivity reactions are the most common and may develop in up to 3 percent of patients. Cephalosporins are  $\beta$ -lactam antibiotics and, if used in those allergic to penicillin, may create the same or accentuated response. Theoretically, this may happen in up to 16 percent of patients (Saxon, 1987). Thus, if an individual developed anaphylaxis with penicillin therapy, cephalosporin administration is contraindicated.

First-generation cephalosporins are used primarily for surgical prophylaxis and in the treatment of superficial skin cellulitis. Their activity spectrum is greatest against gram-positive aerobic cocci, with some activity against community-acquired gram-negative rods. However, there is little activity against  $\beta$ -lactamase producing organisms or anaerobic bacteria. Despite this inactivity against many pathogens of pelvic infection that may be acquired during surgery, there is prophylactic efficacy.

Second-generation cephalosporins have enhanced activity against gram-negative aerobic and anaerobic bacteria, with some diminution in effectiveness against aerobic gram-positive cocci. Their primary use is in surgical prophylaxis or for single-agent therapy of major community-acquired or postoperative pelvic infections, including abscess.

Third-generation cephalosporins provide gram-positive activity, even greater gram-negative coverage, and some anaerobic effects. Fourth-generation agents have a similar profile but are less susceptible to  $\beta$ -lactamases. Last, fifth-generation drugs, such as ceftaroline, share a similar profile but also cover methicillin-resistant *Staphylococcus aureus* (MRSA). All three groups are effective in treatment of major postoperative pelvic infections, including abscess. These agents have documented efficacy as prophylactic agents, but should be reserved for therapy.

## ■ Aminoglycosides

This family of compounds includes gentamicin, tobramycin, netilmicin, and amikacin. Gentamicin is primarily selected because of its low cost and clinical efficacy for pathogens recovered from pelvic infections. For gynecologists, it may be combined with clindamycin with or without ampicillin as a regimen for treatment of serious pelvic infections. Alternatively, gentamicin may be joined with ampicillin and metronidazole. Last, it can be used as adjuvant-agent for outpatient pyelonephritis. Aminoglycoside antibacterial activity is related to its serum/tissue concentration, and the higher the concentration, the greater the potency.

Aminoglycosides have the potential for significant patient toxicity, which can include ototoxicity, nephrotoxicity, and neuromuscular blockade. The inner ear is particularly susceptible to aminoglycosides because of selective accumulation within the hair cells and prolonged half-life within inner ear fluids. Those with vestibular toxicity complain of headaches, nausea, tinnitus, and loss of equilibrium. Cochlear toxicity leads to high-frequency hearing loss. If either of these develops, aminoglycoside administration is stopped promptly. Ototoxicity may be permanent, and risk correlates positively with therapy dose and duration.

Nephrotoxicity is reversible and may develop in up to 25 percent of patients (Bertino, 1993). Risk factors include older age, renal insufficiency, hypotension, volume depletion, frequent dosing intervals, treatment for 3 or more days, multiple antibiotic administration, or multisystem disease. Toxicity leads to a nonoliguric decrease in creatinine clearance and resultant rise in serum creatinine levels.

Neuromuscular blockade is a rare but potentially life-threatening complication and is dose-related. This family of antibiotics inhibits presynaptic acetylcholine release, blocks acetylcholine receptors, and prevents presynaptic calcium absorption. For this reason, aminoglycoside contraindications include myasthenia gravis or concurrent succinylcholine use. Blockade frequently follows rapid intravenous infusion. For this reason, aminoglycosides are ideally given intravenously over at least 30 minutes. Toxicity is usually detected before respiratory arrest, and at its first signs, intravenous calcium gluconate is administered to reverse this form of aminoglycoside toxicity.

Because of these potential adverse reactions, consideration must be given to dosing regimen. In those with normal renal function, aminoglycosides are commonly given parenterally every 8 hours. In those with reduced renal function, doses are reduced, intervals are lengthened, or both. To monitor serum concentration, provide adequate therapeutic levels, and prevent toxicity in patients given multiple daily doses, serum aminoglycoside concentrations are measured at peak (30 minutes after a 30-minute infusion or 1 hour after intramuscular [IM] injection) and at trough (immediately before a next dose). For gentamicin, tobramycin, and netilmicin, peak range ideally is 4 to 6  $\mu\text{g/mL}$ , and troughs are 1 to 2  $\mu\text{g/mL}$ . For amikacin, peaks and troughs are 20 to 30  $\mu\text{g/mL}$  and 5 to 10  $\mu\text{g/mL}$ , respectively.

Once-daily dosing has been evaluated and found to be as or less toxic than multiple daily dosing without sacrificing clinical efficacy (Bertino, 1993). Tulkens and colleagues (1988) reported that once-daily dosing of netilmicin was less toxic than

administration three times daily, without jeopardizing efficacy in the treatment of women with PID. In 1992, Nicolau and associates presented pharmacokinetic data and a nomogram for administering aminoglycosides once daily, which starts with an initial dose based on creatinine clearance and subsequent dosing based on a random serum concentration drawn 8 to 12 hours later.

### ■ Carbapenems

There is a third class of  $\beta$ -lactam antibiotics that differ from penicillins by changes to the thiazolidine ring attached to penicillin. The three antibiotics in this family are imipenem (Primaxin), meropenem (Merrem), and ertapenem (Invanz). Adverse reactions are comparable to those of the other  $\beta$ -lactam antibiotics. As is true with other  $\beta$ -lactams, if patients have experienced a type I hypersensitivity reaction to either a penicillin or cephalosporin, then a carbapenem should not be administered.

These antibiotics are designed for polymicrobial bacterial infections, primarily those with resistant aerobic gram-negative bacteria not susceptible to other  $\beta$ -lactam agents. They should be reserved to preserve efficacy by preventing the development of resistance.

### ■ Monobactam

The marketed monobactam, aztreonam, is a synthetic  $\beta$ -lactam. It has a spectrum of activity similar to that of aminoglycosides, that is, gram-negative aerobic species. Like other  $\beta$ -lactam antibiotics, these compounds inhibit bacterial cell wall synthesis by binding to penicillin-binding proteins or causing cell lysis. Aztreonam has affinity only for the binding proteins of the gram-negative bacteria and lacks affinity for either gram-positive bacteria or anaerobic organisms. For the gynecologist, aztreonam provides coverage for gram-negative aerobic bacteria, which is usually provided by aminoglycosides, for patients with significantly impaired renal function or aminoglycoside allergy.

### ■ Clindamycin

This antibiotic is a workhorse in the treatment of serious gynecologic infections. Clindamycin is primarily active against aerobic gram-positive bacteria and most anaerobic bacteria, with little activity against aerobic gram-negative bacteria. It is also active against *C. trachomatis*. *N. gonorrhoeae* is moderately sensitive, and *G. vaginalis*, which is typically present in BV, is very susceptible to clindamycin. It may be delivered by one of three routes: orally, intravenously, or vaginally (ovules or 2-percent cream).

The principal application of clindamycin for the gynecologist has been its combination with gentamicin and administration to women with serious community-acquired or postoperative soft-tissue infections or pelvic abscess. Its activity against MRSA has increased its use in these cases. Clindamycin is also used as monotherapy vaginally in the treatment of women with BV. Moreover, in women with early stages of hidradenitis suppurativa, some patients improve with long-term topical or oral clindamycin. Because there are parenteral and oral forms of this antibiotic, patients can transition from the more expensive parenteral therapy to oral therapy early.

### ■ Vancomycin

This is a glycopeptide antibiotic that is active only against aerobic gram-positive bacteria. It is primarily used by the gynecologist to treat patients in whom  $\beta$ -lactam therapy is impossible due to a type I allergic reaction. Additionally, an oral dose of 120 mg every 6 hours can be given to patients who have developed antibiotic-associated *Clostridium difficile* colitis and who do not respond to oral metronidazole. Last, vancomycin is often selected for MRSA infections.

Of adverse events, the most remarkable is the “red man” syndrome, which is a dermal reaction developing usually within minutes after initiation of a rapid drug infusion. The reaction, which is a response to histamine release, is an erythematous pruritic rash involving the neck, face, and upper torso. Hypotension also may develop. Intravenous administration over 1 hour or administration of an antihistamine may be protective, if given prior to infusion. Also associated with rapid administration may be painful back and chest muscle spasms.

The most significant of vancomycin’s side effects is nephrotoxicity, which is enhanced with aminoglycoside therapy, as is ototoxicity. Both are associated with high serum vancomycin concentrations. For this reason, serum peak and trough concentrations are recommended and ideally range between 20 and 40  $\mu\text{g/mL}$  and 5 and 10  $\mu\text{g/mL}$ , respectively. The initial dose is 15 mg/kg of ideal body weight. Other side effects include reversible neutropenia that may develop after prolonged use and peripheral intravenous-catheter-related thrombophlebitis.

### ■ Metronidazole

This antibiotic is the principal therapy of trichomoniasis and commonly used for BV. Moreover, it is one of the mainstays of combination antimicrobial therapy given to women with serious postoperative or community-acquired pelvic infections, including pelvic abscess. Since it is active only against obligate anaerobes, metronidazole must be combined with agents effective against gram-positive and gram-negative aerobic bacterial species, such as ampicillin and gentamicin. It is as effective as vancomycin in the treatment of *C. difficile*-associated pseudomembranous colitis.

Up to 12 percent of patients taking oral metronidazole may have nausea, and an unpleasant metallic taste has also been described. Patients should abstain from alcohol use to avoid a disulfiram-like effect and emesis. Peripheral neuropathy and convulsive seizures have been reported, are probably dose-related, and are rare.

### ■ Fluoroquinolones

Also known simply as *quinolones*, these antibiotics have become first-line agents for treating various infections because of their excellent bioavailability with oral administration, tissue penetration, broad-spectrum antibacterial activity, long half-lives, and good safety profile. As with cephalosporins, fluoroquinolones are separated into generations by their development, antibacterial activity, and pharmacokinetic properties.

Quinolones are contraindicated in children, adolescents, and pregnant and breastfeeding women because they may affect

cartilage development. As a family, they are safe, and severe adverse reactions are rare. The side-effect rate ranges from 4 to 8 percent and primarily affects the gastrointestinal (GI) tract following oral administration. Central nervous system (CNS) symptoms such as headache, confusion, tremors, and seizures have been described, and these develop more frequently in patients with underlying brain disorders.

These agents are widely used by gynecologists to treat acute lower urinary tract infections and some sexually transmitted diseases. However, overuse has limited their usefulness in certain infections due to bacterial resistance (Centers for Disease Control and Prevention, 2007). If a less expensive, safer, and equally effective alternative agent is available to treat a given infection, it should be used to preserve fluoroquinolone efficacy.

## ■ Tetracyclines

These bacteriostatic antimicrobials are commonly used orally and inhibit bacterial protein synthesis. Doxycycline, tetracycline, and minocycline are active against many gram-positive and gram-negative bacteria, although their activity is greater against gram-positive species. Susceptible organisms also include several anaerobes, *Chlamydia* and *Mycoplasma* species, and some spirochetes. Accordingly, cervicitis, PID, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale respond to these agents. Moreover, tetracyclines are among treatment options for community-acquired skin and soft-tissue MRSA infections. Specifically, for these infections, minocycline and doxycycline are superior to tetracycline. Tetracycline is active against *Actinomyces* species and is an alternative for treating actinomycosis. Last, these antibiotics also bind specific non-microbial targets, such as matrix metalloproteinases (MMPs), and are potent MMP inhibitors. As such, they provide anti-inflammatory as well as antimicrobial activity for inflammatory conditions such as acne vulgaris and hidradenitis suppurativa.

With oral administration, tetracyclines can produce direct local GI irritation that manifests as abdominal discomfort, nausea, vomiting, or diarrhea. In teeth and growing bones, tetracyclines readily bind calcium, causing deformity, growth inhibition, or discoloration. Accordingly, tetracyclines are not prescribed for pregnant or nursing women or for children younger than 8 years. Sensitivity to sunlight or ultraviolet light may develop with use. Dizziness, vertigo, nausea, and vomiting may be seen with higher doses. In addition, thrombophlebitis frequently follows intravenous administration. Tetracyclines modify the normal GI flora, which can result in intestinal functional disturbances. Specifically, overgrowth of *C. difficile* may lead to pseudomembranous colitis. Vaginal flora also may be altered with resultant *Candida* species overgrowth and symptomatic vulvovaginitis.

## GENITAL ULCER INFECTIONS

*Ulceration* defines complete loss of the epidermal covering with invasion into the underlying dermis. In contrast, *erosion* describes partial loss of the epidermis without dermal penetration. These are distinguished by clinical examination. Biopsies are generally not helpful. But if taken, samples obtained from

the edge of a new lesion are the most likely to be informative. Importantly, biopsy is mandatory if carcinoma is suspected, and Figure 4-2 (p. 88) illustrates technique.

Most young sexually active women in the United States who have genital ulcers will have herpes simplex infection or syphilis, but some will have chancroid, lymphogranuloma venereum, or granuloma inguinale. Essentially all are sexually transmitted and are associated with increased risk for human immunodeficiency virus (HIV) transmission. For this reason, HIV and other STD testing is offered to such patients. Sexual contacts require examination and treatment, and both require reevaluation following treatment.

## ■ Herpes Simplex Virus Infection

Genital herpes is the most prevalent genital ulcer disease and is a chronic viral infection. The virus enters sensory nerve endings and undergoes retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency. Spontaneous reactivation by various events results in anterograde transport of viral particles/protein to the surface. Here virus is shed, with or without lesion formation. It is postulated that immune mechanisms control latency and reactivation (Cunningham, 2006).

There are two types of herpes simplex virus, HSV-1 and HSV-2. Type 1 HSV is the most frequent cause of oral lesions. Type 2 HSV is found more typically with genital lesions, although both types can cause genital herpes. It is estimated that of American females aged 14 to 49 years, 21 percent have suffered a genital HSV-2 infection, and 60 percent of women are seropositive to HSV-1 (Centers for Disease Control and Prevention, 2010; Xu, 2006).

Most women who have been infected with HSV-2 lack this diagnosis because of mild or unrecognized infections. Infected patients can shed infectious virus while asymptomatic, and most infections are transmitted sexually by patients who are unaware of their infection. Most (65 percent) with active infection are women.

## Symptoms

Patient symptoms at initial presentation will depend primarily on whether or not a patient during the current episode has antibody from previous exposure. If a patient has no antibody, the attack rate in an exposed person approaches 70 percent. The mean incubation period is approximately 1 week. Up to 90 percent of those who are symptomatic with their initial infection will have another episode within a year.

The virus infects viable epidermal cells, the response to which is erythema and papule formation. With cell death and cell wall lysis, blisters form (Fig. 3-2). The covering then disrupts, leaving a usually painful ulcer. These lesions develop crusting and heal, but may become secondarily infected. The three stages of lesions are: (1) vesicle with or without pustule formation, which lasts approximately a week; (2) ulceration; and (3) crusting. Virus is predictably shed during the first two phases of an infectious outbreak.

Burning and severe pain accompany initial vesicular lesions. With ulcers, urinary frequency and/or dysuria from direct

**FIGURE 3-2** Genital herpetic ulcers. **A.** Vesicles prior to ulceration. **B.** Punctate (left) or “knife-cut” (right) ulcers are common lesions. (Used with permission from Dr. William Griffith.)

contact of urine with ulcers may be complaints. Local swelling can result from vulvar lesions and cause urethral obstruction. Alternatively or additionally, herpetic lesions can involve the vagina, cervix, bladder, anus, and rectum. Commonly, a woman has other signs of viremia such as a low-grade fever, headache, malaise, and myalgias.

Viral load undoubtedly contributes to the number, size, and distribution of lesions. Normal host defense mechanisms inhibit viral growth, and healing starts within 1 to 2 days. Early treatment with an antiviral medication decreases the viral load. Immune-deficient patients are at increased susceptibility but display diminished response and delayed healing.

For a previously uninfected patient, the vesicular stage is longer. The period of new lesion formation and time to healing are both longer. Pain persists for the first 7 to 10 days, and lesion healing requires 2 to 3 weeks. If a patient has had prior exposure to HSV-2, the initial episode is significantly less severe, with shorter pain and tenderness duration, and time to healing approximates 2 weeks. Virus is shed usually only during the first week.

Recurrence following HSV-2 infection is common, and almost two thirds of patients have a prodrome prior to lesion onset. Heraldic paresthesias are frequently described as pruritus or tingling in the area prior to lesion formation. However, prodromal symptoms may develop without actual lesion formation. Clinical manifestations for women with recurrences are more limited, with only 1 week or less of symptoms.

### Diagnosis

The gold standard for the diagnosis of genital herpes is tissue culture. Specificity is high, but sensitivity is low and declines as lesions heal. In recurrent disease, less than 50 percent of cultures are positive. Polymerase chain reaction (PCR) testing of exudate swabbed from the ulcer is many times more sensitive than culture and will probably replace it. Importantly, a negative culture result does not mean that there is no herpetic infection.

Serologic testing may also add clarity. The herpes simplex virus is surrounded by envelope glycoproteins, and of these, glycoprotein G is the antigen of interest for antibody screening.

Serologic assays can detect antibodies specific to the HSV type-specific glycoprotein G2 (HSV-2) and glycoprotein G1 (HSV-1). Assay specificity is  $\geq 96$  percent, and the sensitivity of HSV-2 antibody testing ranges from 80 to 98 percent. Importantly, with serologic screening, only IgG antibody assays are ordered. IgM testing can lead to ambiguous results as the IgM assays are not type-specific and also may be positive during a recurrent outbreak. Although these tests may be used to confirm herpes simplex infection, seroconversion following initial HSV-2 infection takes approximately 3 weeks (Ashley-Morrow, 2003). Thus, in clinically obvious cases, immediate treatment and additional STD screening can be initiated following physical examination alone. In general, STD screening for a woman found to have any STD typically includes testing directed to identify syphilis, gonorrhea, trichomoniasis, and HIV, chlamydial, and hepatitis B infections.

Serologic screening for HSV in the general population is not recommended. However, HSV serologic testing can be considered for HIV-infected individuals or for women presenting for an STD evaluation, especially for those with multiple partners and for those in demographics with high prevalence (Centers for Disease Control and Prevention, 2015). It can also add management information for couples thought but not confirmed to be discordant for infection (American College of Obstetricians and Gynecologists, 2014b).

### Treatment

Clinical management is with currently available antiviral therapy. Analgesia with nonsteroidal antiinflammatory drugs or a mild narcotic such as acetaminophen with codeine may be prescribed. In addition, topical anesthetics such as lidocaine ointment may provide relief. Local care to prevent secondary bacterial infection is important.

Patient education is mandatory, and specific topics include the natural history of the disease, its sexual transmission, methods to reduce transmission, and obstetric consequences. Notably, HSV can be passed to the neonate during vaginal delivery through an infected field. A comprehensive discussion of obstetric management is found in *Williams Obstetrics*,

24th edition (Cunningham, 2014). For all women, acquisition of this infection may have significant psychological impact, and several websites provide patient information and support. The CDC website can be accessed at <http://www.cdc.gov/std/Herpes/STDFact-Herpes.htm>.

Women with genital herpes should refrain from sexual activity with uninfected partners when prodrome symptoms or lesions are present. Latex condom use potentially reduces the risk for herpetic transmission (Martin, 2009; Wald, 2005).

Currently available antiviral therapy includes acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex). The CDC-recommended oral medications regimens are listed in Table 3-4. Although these agents may hasten healing and decrease symptoms, therapy does not eradicate latent virus or affect future rate of recurrent infections.

For women with established HSV-2 infection, therapy may not be necessary if their symptoms are minimal and tolerated by the patient. Episodic therapy for recurrent disease is ideally

initiated at least within 1 day of lesion outbreak or during the prodrome, if it exists. Patients may be given a prescription ahead of time so that medication is available to begin therapy with prodromal symptoms.

If episodes recur at frequent intervals, a woman may elect daily suppressive therapy, which reduces recurrences by 70 to 80 percent. Suppressive therapy may eliminate recurrences and decreases sexual transmission of virus by approximately 50 percent (Corey, 2004). Once-daily dosing may result in enhanced compliance and decreased cost.

■ Syphilis  
Pathophysiology

Syphilis is an STD caused by the spirochete *Treponema pallidum*, which is a slender spiral-shaped organism with tapered ends. Women at highest risk are those from lower socioeconomic groups, adolescents, those with early onset of sexual activity, and those with a large number of lifetime sexual partners. The attack rate for this infection approximates 30 percent. In 2011, more than 49,000 cases (all stages) of syphilis were reported by state health departments in the United States (Centers for Disease Control and Prevention, 2012).

The natural history of syphilis in untreated patients can be divided into four stages. With *primary syphilis*, the hallmark lesion is the *chancre*, in which spirochetes are abundant. Classically, it is an isolated nontender ulcer with raised rounded borders and an uninfected base (Fig. 3-3). However, it may become secondarily infected and painful. Chancres are often found on the cervix, vagina, or vulva but may also form in the mouth or around the anus. This lesion can develop 10 days to 12 weeks after exposure, with a mean incubation period of 3 weeks. The incubation period is directly related to inoculum size. Without treatment, these lesions spontaneously heal in up to 6 weeks.

With *secondary syphilis*, bacteremia develops 6 weeks to 6 months after a chancre appears. Its hallmark is a maculopapular rash that may involve the entire body and includes the palms, soles, and mucous membranes (Fig. 3-4). As is true for the chancre, this rash actively sheds spirochetes. In warm, moist body areas, this rash may produce broad, pink or gray-white,

**TABLE 3-4.** Oral Agents for Genital Herpes Simplex Infection

**First clinical episode**

Acyclovir 400 mg three times daily for 7–10 days  
or  
Acyclovir 200 mg five times daily for 7–10 days  
or  
Famciclovir (Famvir) 250 mg three times daily for 7–10 days  
or  
Valacyclovir (Valtrex) 1 g twice daily for 7–10 days

**Episodic therapy for recurrent disease**

Acyclovir 400 mg three times daily for 5 days  
or  
Acyclovir 800 mg twice daily for 5 days  
or  
Acyclovir 800 mg three times daily for 2 days  
or  
Famciclovir 125 mg twice daily for 5 days  
or  
Famciclovir 1 g twice daily for 1 day  
or  
Famciclovir 500 mg once, then 250 mg twice daily for 2 days  
or  
Valacyclovir 500 mg twice daily for 3 days  
or  
Valacyclovir 1 g once daily for 5 days

**Suppressive therapy**

Acyclovir 400 mg twice daily  
or  
Famciclovir 250 mg twice daily  
or  
Valacyclovir 0.5 or 1 g once daily

**FIGURE 3-3** Vulvar syphilitic chancre.

**FIGURE 3-4** Secondary syphilis. **A.** Woman with multiple keratotic papules on her palms (arrows). With secondary syphilis, disseminated papulosquamous eruptions may be seen on the palms, soles, or trunk. (Used with permission from Dr. William Griffith.) **B.** Woman with multiple condyloma lata on her labia. Soft, flat, moist, pink-tan papules and nodules on the perineum and perianal area are typical. (Used with permission from Dr. George Wendel.)

highly infectious plaques called *condylomata lata*. Because syphilis is a systemic infection, other manifestations may include fever and malaise. Moreover, organ systems such as the kidney, liver, joints, and CNS (meningitis) can be involved.

During the first year following secondary syphilis without treatment, termed *early latent syphilis*, secondary signs and symptoms may recur. However, lesions associated with these outbreaks are not usually contagious. *Late latent syphilis* is defined as a period greater than 1 year after the initial infection.

*Tertiary syphilis* is the phase of untreated syphilis that may appear up to 20 years after latency. During this phase, cardiovascular, CNS, and musculoskeletal involvement become apparent. However, cardiovascular and neurosyphilis are half as common in females as in males.

### Diagnosis

Spirochetes are too thin to retain Gram stain. Early syphilis is diagnosed primarily by dark-field examination or direct fluorescent antibody testing of lesion exudate. In lieu of this, presumptive diagnosis may be reached with serologic tests that are nontreponemal: (1) Venereal Disease Research Laboratory (VDRL) or (2) rapid plasma reagin (RPR) tests. Alternatively, treponemal-specific tests may be selected: (1) fluorescent treponemal antibody-absorption (FTA-ABS) or (2) *Treponema pallidum* particle agglutination (TP-PA) tests. For population screening, RPR or VDRL testing is appropriate. A positive test result in a woman who has not been treated previously for syphilis or a fourfold titer (two dilutions) increase in a woman previously treated for syphilis should prompt confirmation with treponemal-specific tests. Thus, for *diagnosis confirmation* in a woman with a positive nontreponemal antibody test result or with a suspected clinical diagnosis, FTA-ABS or TP-PA testing is selected. Last, for *quantitative measurement* of antibody titers to assess response to treatment, RPR or VDRL tests are typically used.

Following treatment, sequential nontreponemal tests are performed. During this surveillance, the same type of test should

be used for consistency—either RPR or VDRL. A fourfold titer decrease is required by 6 months after therapy for primary or secondary syphilis or within 12 to 24 months for those with latent syphilis or women with initially high titers ( $> 1:32$ ) (Larsen, 1998). These tests usually become nonreactive after treatment and with time. However, some women may have a persistent low titer, and these patients are described as *serofast*. Moreover, women with a reactive treponemal-specific test will more than likely have a positive test for the remainder of their lives, but up to 25 percent may revert to a negative result after several years.

### Treatment

Penicillin is the first-line therapeutic agent for this infection, and benzathine penicillin is primarily chosen. Specific recommendations for therapy by the CDC (2015) are listed in [Table 3-5](#).

**TABLE 3-5.** Treatment of Syphilis

#### Primary, secondary, early latent (< 1 year) syphilis

Recommended regimen:

Benzathine penicillin G, 2.4 million units IM once

Alternative oral regimens (penicillin-allergic, nonpregnant women): Doxycycline 100 mg orally twice daily for 2 weeks

#### Late latent, tertiary, and cardiovascular syphilis

Recommended regimen:

Benzathine penicillin G, 2.4 million units IM weekly times 3 doses

Alternative oral regimen (penicillin-allergic, nonpregnant women): Doxycycline 100 mg orally twice daily for 4 weeks

Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

For patients with penicillin allergy who cannot be surveilled posttherapy or whose compliance is questioned, skin testing, desensitization, and treatment with IM benzathine penicillin is recommended (Wendel, 1985). For all patients, an acute, self-limited febrile response, termed a Jarisch-Herxheimer reaction, may develop within the first 24 hours after treatment of early disease and is associated with headache and myalgia.

As with other STDs, all patients treated for syphilis and their sexual contacts are screened for other STDs. Patients with evidence of neurologic or cardiac involvement are treated by an infectious disease specialist. After initial treatment, women are seen at 6-month intervals for clinical evaluation and serologic retesting. A fourfold dilution decrease is anticipated. If this does not occur, a patient either has failed treatment or was reinfected and should be reevaluated and retreated. Retreatment recommendations are benzathine penicillin G, 2.4 million units IM weekly for 3 weeks.

■ Chancroid

It is considered one of the classic STDs but is an uncommon infection in the United States. It appears as local outbreaks predominantly in black and Hispanic males. It is caused by a nonmotile, non-spore-forming, facultative, gram-negative bacillus, *Haemophilus ducreyi*. Incubation usually spans 3 to 10 days, and host access probably requires a break in the skin or mucous membrane.

Chancroid lacks a systemic reaction and prodrome. Infection presents initially with an erythematous papule that becomes pustular and ulcerates within 48 hours. Edges of these painful ulcers are usually irregular with erythematous nonindurated margins. The ulcer bases are usually red and granular and, in contrast to a syphilitic chancre, are typically soft. Lesions are frequently covered with purulent material and may become secondarily infected. The most common locations in women include the fourchette, vestibule, clitoris, and labia. Ulcers on the cervix or vagina may be nontender. Concurrently, approximately half of patients will develop unilateral or bilateral tender inguinal lymphadenopathy. If large and fluctuant, they are termed *buboes*. These may occasionally suppurate and form fistulas, the drainage from which will result in other ulcer formation.

Chancroid most commonly imitates syphilis and genital herpes. These may coexist, but uncommonly. Definitive diagnosis requires growth of *H ducreyi* on special media, but sensitivity for culture is less than 80 percent. A presumptive diagnosis can be made with identification of gram-negative, nonmotile rods on a Gram stain of lesion contents. Before obtaining either specimen, superficial pus or crusting ideally is removed with sterile, saline-soaked gauze.

For treatment, the CDC’s (2015) recommended regimens for nonpregnant women include single doses of oral azithromycin (1 g) or IM ceftriaxone (250 mg). Multiple-dose options are ciprofloxacin 500 mg orally twice daily for 3 days or erythromycin base 500 mg orally three times daily for 7 days. Successful treatment leads to symptomatic improvement within 3 days, and objective evidence of improvement within 1 week. Lymphadenopathy resolves more slowly, and if fluctuant, incision and drainage may be warranted. Those with coexisting HIV infection may require longer therapy courses, and treatment failures are more common.

Accordingly, some recommend longer regimens for initial management of known HIV-infected patients.

■ Granuloma Inguinale

Also known as donovanosis, granuloma inguinale genital ulcerative disease is caused by the intracellular gram-negative bacterium *Calymmatobacterium (Klebsiella) granulomatis*. The bacterium is encapsulated and appears as a “closed safety pin” in stained tissue biopsy or cytology specimens. Apparently this disease is only mildly contagious, requires repeated exposures, and has a long incubation period of weeks to months.

Granuloma inguinale presents as painless inflammatory nodules that progress to highly vascular, beefy red ulcers that bleed easily on contact. If secondarily infected, they may become painful. These ulcers heal by fibrosis, which can result in scarring resembling keloids. Lymph nodes are usually uninvolved but can become enlarged, and new lesions can appear along these lymphatic drainage channels. Distant lesions have also been reported.

Diagnosis is confirmed by identification of Donovan bodies during microscopic evaluation of a specimen following Wright-Giemsa staining. Currently, there are no Food and Drug Administration (FDA)-approved PCR tests for *C granulomatis* DNA.

Treatment does stop lesion progression and may be lengthy without formation of granulation tissue in ulcer bases and reepithelialization (Table 3-6). Relapses have been reported up to 18 months after “effective” treatment. A few prospective treatment trials have been published, but these are limited. If successful, improvement will be evident within the first few treatment days.

■ Lymphogranuloma Venereum

This ulcerative genital disease is caused by *trachomatis* serotypes L1, L2, and L3 and is uncommon in the United States. As is true

TABLE 3-6. Oral Treatment for Granuloma Inguinale

<b>Recommended regimen</b>
Azithromycin (Zithromax) 1 g once weekly for at least 3 weeks and until lesions are completely healed
<b>Alternative regimens</b>
Doxycycline 100 mg twice daily as above
or
Ciprofloxacin (Cipro) 750 mg twice daily as above
or
Erythromycin base 500 mg four times daily as above
or
Trimethoprim-sulfamethoxazole DS (Bactrim DS, Septra DS) twice daily as above

DS = double strength.

**FIGURE 3-5** “Groove sign” seen with lymphogranuloma venereum. Enlarged lymph nodes matted together on either side of the inguinal ligament create this characteristic groove. (Reproduced with permission from Morse S, Ballard RC, Holmes KK, et al (eds): *Atlas of Sexually Transmitted Diseases*, 3rd ed. Edinburgh: Mosby; 2003.)

with other STDs, this infection is found in lower socioeconomic groups among persons with multiple sexual partners. Incubation ranges from 3 days to 2 weeks, and its clinical course is divided into three stages: (1) small vesicle or papule, (2) inguinal or femoral lymphadenopathy, and (3) anogenitoretal syndrome. Initial papules appear primarily on the fourchette and posterior vaginal wall up to and including the cervix. Repeated inoculation may result in lesions at multiple sites. These primary lesions heal quickly and without scarring.

During the second stage, sometimes referred to as the inguinal syndrome, inguinal and femoral lymph nodes progressively enlarge. Painful nodes can mat together on either side of the inguinal ligament and create a characteristic “groove sign,” which appears in up to one fifth of infected women (Fig. 3-5). Moreover, enlarging nodes may rupture through the skin and lead to chronically draining sinuses. Women with lymphogranuloma venereum (LGV) commonly develop systemic infection, manifest by malaise and fever. Additionally, pneumonitis, arthritis, and hepatitis have been reported.

In the third stage of LGV, a patient develops rectal pruritus and a mucoid discharge from rectal ulcers. If these become infected, the discharge turns purulent. This presentation stems from lymphatic obstruction that follows lymphangitis and that may result in elephantiasis of external genitalia initially and fibrosis of the rectum. Stenosis of the urethra and the vagina has also been reported. Rectal bleeding is common, and a woman may complain of crampy, abdominal pain with abdominal distention, rectal pain, and fever. Peritonitis may follow bowel perforation.

LGV may be diagnosed following clinical evaluation with exclusion of other etiologies and positive chlamydial testing. Specifically, culture or immunofluorescence or nucleic acid amplification tests (NAAT) testing of samples from genital lesions, affected lymph nodes, or rectum are suitable. Moreover, a chlamydial serologic titer that is  $> 1:64$  can support the diagnosis.

For treatment, the CDC-recommended regimen (2015) is doxycycline, 100 mg orally twice daily for 21 days. Alternatively, one may use erythromycin base 500 mg orally four times daily for the same duration. Sexual contacts exposed to a patient within the prior 60 days are tested for urethral or cervical infection and treated with either standard anti-chlamydial regimen.

## INFECTIOUS VAGINITIS

Symptomatic vaginal discharge most often reflects BV, candidiasis, or trichomoniasis. Bacterial vaginosis typically evokes complaints of foul discharge odor. In contrast, if abnormal discharge is associated with vulvar burning, irritation, or itching, then *vaginitis* is diagnosed. Between 7 and 70 percent of women who have vaginal discharge complaints will have no definitive diagnosis (Anderson, 2004). For those in whom identifiable infection is absent, an inflammatory diagnosis and treatment for infection should not be given. In such instances, a woman may seek reassurance, having concern about a recent sexual exposure, and STD screening may alleviate this.

Importantly, during evaluation, a clinician obtains a complete history regarding prior vaginal infections and their treatment, symptom duration, specifics of self-treatment with over-the-counter (OTC) preparations, and a complete menstrual and sexual history. The salient features of a menstrual history are outlined in Chapter 8 (p. 182). A sexual history typically includes questions regarding age at coitarche, date of most recent sexual activity, number of recent partners, gender of those partners, use of condom barrier protection, method of birth control, prior STD history, and type of sexual activity—anal, oral, or vaginal.

A thorough physical examination of the vulva, vagina, and cervix is also performed. Several etiologies may be identified in the office by microscopic examination of the discharge (Table 3-7). First, a saline preparation, described earlier, can be inspected (p. 51). In contrast, a “KOH-prep” contains a swab-collected sample of discharge mixed with several drops of 10-percent potassium hydroxide (KOH). KOH leads to osmotic swelling and then lysis of squamous cell membranes. This visually clears the microscopic view and aids identification of fungal buds or hyphae. Finally, vaginal pH analysis may add supportive information. Vaginal pH can be estimated using chemical testing paper strips. Appropriate readings are obtained by pressing a test strip directly to the upper vaginal wall and resting it there for a few seconds to absorb vaginal fluid. Once the strip is removed, its color is determined and matched to a color indicator chart on the test strip dispenser. Importantly, blood and semen are alkaline and often will artificially elevate pH. Unfortunately, inexpensive laboratory tests such as these are not as accurate as a clinician would hope (Bornstein, 2001; Landers, 2004).

## ■ Fungal Infection

This infection is most commonly caused by *Candida albicans*, which can be found in the vagina of asymptomatic patients and

**TABLE 3-7.** Characteristics of Common Vaginal Infections

Category	Complaint	Discharge	KOH “Whiff Test”	Vaginal pH	Microscopic Findings
Normal	None	White, clear	—	3.8–4.2	NA
BV	Odor, increased after intercourse and/or menses	Thin, gray or white, adherent, often increased	+	> 4.5	Clue cells, bacteria clumps (saline wet prep)
Candidiasis	Itching, burning, discharge	White, curdy	—	< 4.5	Hyphae and buds (10-percent KOH solution wet prep)
Trichomoniasis	Frothy discharge, odor, dysuria, pruritus, spotting	Green-yellow, frothy, adherent, increased	±	> 4.5	Motile trichomonads (saline wet prep)
Bacterial <sup>a</sup>	Thin, watery discharge, pruritus	Purulent	—	> 4.5	Many WBCs

<sup>a</sup>Streptococcal, staphylococcal, or *Escherichia coli*.  
BV= bacterial vaginosis; KOH = potassium hydroxide; NA= not applicable; WBC = white blood cell.

is a commensal of the mouth, rectum, and vagina. Occasionally, other *Candida* species may be involved and include *C tropicalis* and *C glabrata*, among others. Candidiasis is seen more often in warmer climates and in obese patients. Additionally, immunosuppression, diabetes mellitus, pregnancy, and recent broad-spectrum antibiotic use predispose women to clinical infection. It can be sexually transmitted, and several studies have reported an association between candidiasis and orogenital sex (Bradshaw, 2005; Geiger, 1996).

With candidiasis, pruritus, pain, vulvar erythema, and edema with excoriations are frequent findings (Fig. 3-6). The typical vaginal discharge is described as curdy or cottage cheese-like. Microscopic examination of vaginal discharge with saline and

with 10-percent KOH preparations allows yeast identification. *Candida albicans* is dimorphic, with both yeast buds and hyphal forms. It may be present in the vagina as a filamentous fungus (pseudohyphae) or as germinated yeast with mycelia. Vaginal candidal culture is not routinely recommended. However, it may be warranted for those who fail empiric treatment and for women with evidence of infection yet absence of microscopic yeast.

The CDC classifies vulvovaginal candidiasis (2015) into “uncomplicated” and “complicated.” Uncomplicated candidiasis cases are sporadic or infrequent, mild to moderate in symptom severity, likely caused by *Candida albicans*, and involve nonimmunocompromised women. For both uncomplicated

**FIGURE 3-6** Candidal infection. **A.** Thick white discharge, labial erythema, and edema are seen with candidiasis. (Used with permission from Dr. William Griffith.) **B.** *Candida albicans* in a potassium hydroxide preparation. Serpentine pseudohyphae are seen. and complicated infection, effective treatment formulations are listed in Table 3-8. For uncomplicated infection, azoles are extremely effective, and women warrant specific follow-up only if therapy is unsuccessful.

However, 10 to 20 percent of women have complicated candidiasis, which implies greater symptom severity, perhaps involvement of non-*albicans* species, affected patients with relative immunosuppression, or recurrent disease. By definition, *recurrent disease* reflects four or more candidal infections during a year. For women in these complicated candidiasis categories, cultures are obtained to direct care, and longer therapy may be

needed to achieve clinical cure. Examples include local intra-vaginal therapy for 7 to 14 days.

For recurrent *C albicans* disease, local intravaginal therapy for 7 to 14 days or oral fluconazole (Diflucan) in 100-mg, 150-mg, or 200-mg doses once every third day for a total of three doses (day 1, 4, and 7) are options. Suppressive maintenance regimen for recurrence prevention is oral fluconazole, 100 to 200 mg weekly for 6 months. Non-*albicans* candidal species are not as responsive to topical azole therapy. For non-*albicans* recurrent infection, a 600-mg boric acid gelatin capsule intravaginally daily for 2 weeks has been successful. These

capsules require a compounding pharmacy, and care is taken if children are in the household as accidental oral ingestion of boric acid capsules can be fatal.

Oral azole therapy has been associated with serum liver enzyme elevation. Thus, prolonged oral therapy may not be feasible for that reason or because of interactions with other patient medications such as calcium-channel blockers, warfarin, protease inhibitors, trimetrexate, terfenadine, cyclosporine A, phenytoin, and rifampin. In these cases, local intravaginal therapy once or twice weekly may give a similar clinical response.

## ■ Trichomoniasis

This protozoan infection is the most prevalent nonviral STD in the United States (Van der Pol, 2005, 2007). Unlike other STDs, its incidence appears to increase with patient age in some studies. Trichomoniasis is more often diagnosed in women because most men are asymptomatic. However, up to 70 percent of male partners of women with vaginal trichomoniasis will have trichomonads in their urinary tract.

This parasite is usually a marker of high-risk sexual behavior, and co-infection with other sexually transmitted pathogens is common, especially *N gonorrhoeae*. *Trichomonas vaginalis* has predilection for squamous epithelium, and lesions may increase accessibility to other sexually transmitted species. Vertical transmission during birth is possible and may persist for a year.

## Diagnosis

Incubation with *T vaginalis* requires 3 days to 4 weeks, and the vagina, urethra, endocervix, and bladder can be infected. No symptoms are noted in up to one half of women with trichomoniasis, and such colonization can persist for months

or years. However, in those with complaints, vaginal discharge is typically described as foul, thin, and yellow or green. Additionally, dysuria, dyspareunia, vulvar pruritus, vaginal spotting, and pain may be noted. At times, clinical findings are identical to those of acute PID.

With trichomoniasis, the vulva may be erythematous, edematous, and excoriated. The vagina contains the discharge just described, and subepithelial hemorrhages or “strawberry spots” dot the vagina and cervix. Trichomonads are oval anaerobic protozoa that are slightly larger than a white blood cell (WBC) and have anterior flagella (Fig. 3-7). Microscopic identification of these motile parasites in a saline preparation of the discharge is diagnostic. However, trichomonads are less motile with cooling, and slides ideally are examined within 20 minutes. Inspection of a saline preparation is highly specific, yet sensitivity is only 60 to 70 percent. In addition to microscopy, vaginal pH is often elevated.

The most sensitive diagnostic technique is culture, which is impractical because special media (Diamond media) is required and few laboratories are equipped. NAATs for trichomonal DNA are sensitive and specific but not widely available. Alternatively, the OSOM Trichomonas Rapid Test is an immunochromatographic assay, which has 88-percent sensitivity and 99-percent specificity. It is available for office use, and results are available in 10 minutes (Huppert, 2005, 2007). Trichomonads may also be noted on Pap smear screening and sensitivity approximates 60 percent (Wiese, 2000). If trichomonads are reported from a Pap smear slide, confirmation by microscopic evaluation of a saline preparation is encouraged prior to treatment (American College of Obstetricians and Gynecologists, 2013b). Women with trichomoniasis are tested for other STDs. Additionally, sexual contact(s) are evaluated or referred for evaluation.

**FIGURE 3-7** Trichomonads. **A.** Photomicrograph of a vaginal smear saline preparation containing trichomonads (arrows). One squame and many red blood cells are also present. (Used with permission from Dr. Lauri Campagna and Rebecca Winn, WHNP.) **B.** Drawing depicts anatomic features of trichomonads. Flagella allow this parasite to be motile.

## Treatment

Oral regimens recommended by the CDC (2015) are either metronidazole 2 g once or tinidazole (Tindamax) 2 g once. Although each is effective, some report that an oral 7-day treatment regimen with metronidazole 500 mg twice daily may be more effective in compliant patients. However, compliance may be poor because of longer treatment length and metronidazole side effects (p. 54). Because of drug disulfiram-like effects, patients should abstain from alcohol during use and for 24 hours following metronidazole therapy and for 72 hours after tinidazole.

Affected women are retested within 3 months of treatment. Recurrence occurs in approximately 30 percent of patients. Sex partners are encouraged to seek treatment, and patients are reminded to abstain from sex until they and their partners are cured. Condom use may be protective.

Infrequently, patients may have strains that are highly resistant to metronidazole, but these organisms are usually sensitive to tinidazole. Culture and sensitivity are performed on specimens from patients with frequently recurring infections or from those who do not respond to the initial therapy and who are regimen compliant. Oral tinidazole at doses of 500 mg orally three times daily for 7 days or four times daily for 14 days have been effective in curing patients with resistant organisms (Sobel, 2001). Cases of allergy to these two nitroimidazoles require desensitization by a specialist (Helms, 2008).

## SUPPURATIVE CERVICITIS

### ■ *Neisseria gonorrhoeae*

Many women with cervical *N gonorrhoeae* are asymptomatic. For this reason, women at risk are screened periodically (Table 1-1, p. 6). Risk factors for gonococcal carriage and potential upper reproductive tract infection that merit screening are: age  $\leq$  24 years, prior or current STDs, new or multiple sexual partners, a partner with other concurrent partners, a partner with an STD, lack of barrier protection in those without a monogamous relationship, and commercial sex work (U.S. Preventive Services Task Force, 2014). Screening for women at low risk is not recommended.

## Diagnosis

Symptomatic lower female reproductive tract gonorrhea may present as vaginitis or cervicitis. Those with cervicitis commonly describe a profuse odorless, nonirritating, and white-to-yellow vaginal discharge. Patients may report intermenstrual or postcoital vaginal bleeding, or gentle passage of a cotton swab into the cervical os often produces endocervical bleeding. Gonococcus can also infect the Bartholin and Skene glands, the urethra, and ascend into the endometrium and fallopian tube to cause upper reproductive tract infection (p. 65).

*N gonorrhoeae* is a gram-negative coccobacillus that invades columnar and transitional epithelial cells, becoming intracellular. For this reason, the vaginal epithelium, which is squamous cell, is not involved.

For gonococcal identification, NAATs are available and have replaced culture in most laboratories. Previously, acceptable specimens were recovered only from the endocervix or urethra.

However, newer NAAT collection kits are available for specific collection from the vagina, endocervix, or urine. For women without a cervix following hysterectomy, first-void urine samples are collected. For those with a cervix, vaginal-swab specimens are as sensitive and specific as cervical-swab specimens. Urine samples, although acceptable, are least preferred for those with a cervix (Association of Public Health Laboratories, 2009). However, if selected, the initial urine stream, not midstream, is collected. Of note, these noncultural tests are not FDA-cleared for diagnostic identification of rectal or pharyngeal disease. Thus, cultures are obtained in those screened at these anatomic sites.

All patients with gonorrhea are tested for other STDs, and sexual contacts from the preceding 60 days are evaluated and treated or referred for this. Abstinence is practiced until therapy is completed and until they and their treated sexual partners have symptom resolution.

**Expedited Partner Therapy.** To prevent and control STDs, guidelines for expedited partner therapy (EPT) have been created by the CDC. EPT is the delivery of a prescription by persons infected with an STD to their sexual partners without clinical assessment of the partners or professional counseling. EPT ideally does not replace traditional strategies, such as standard patient referral, when these are available. Although acceptable for treatment of heterosexual contacts with gonorrhea or chlamydial infection, data do not support EPT for trichomoniasis or syphilis. Although sanctioned by the CDC, EPT is not legal in several states within the United States. Moreover, the risk of litigation in the event of adverse outcomes may be elevated when a practice has uncertain legal status or is outside formally accepted community practice standards (Centers for Disease Control and Prevention, 2006). The legal status of EPT in each of the 50 states can be found at: <http://www.cdc.gov/std/ept/legal/default.htm>.

## Treatment

CDC recommendations for single-dose therapy of uncomplicated cervical, urethral, or rectal infection are outlined in Table 3-9. Importantly, widespread quinolone-resistant gonococci in the United States prompted removal of this antibiotic class from the CDC STD guidelines, and declining effectiveness of cefixime has shifted its role to an alternative agent (Centers for Disease Control and Prevention, 2015). Uncomplicated gonococcal pharyngeal infection treatment mirrors the recommended regimen in Table 3-9. Test-of-cure cultures are not usually necessary unless an alternative to ceftriaxone is used. In cases of cephalosporin allergy, one potential option is single oral doses of gemifloxacin 320 mg plus azithromycin 2 g. Another is single doses of gentamicin 240 mg IM plus oral azithromycin 2 g. For azithromycin allergy, ceftriaxone alone suffices. However, if the alternative regimen with cefixime is used, then doxycycline, 100 mg orally twice daily for 7 days, replaces the azithromycin (Centers for Disease Control and Prevention, 2015).

### ■ *Chlamydia trachomatis*

This organism is among the most prevalent of the STD species recovered in the United States, and its highest prevalence is

**TABLE 3-9.** Single-dose Treatment of Uncomplicated Gonococcal Infection of the Cervix, Urethra, or Rectum<sup>a</sup>

<b>Recommended regimen</b>
Ceftriaxone (Rocephin) 250 mg IM <sup>b</sup>
PLUS
Azithromycin (Zithromax) 1 g orally once
<b>Alternative regimen</b>
Cefixime (Suprax) 400 mg orally once
PLUS
Azithromycin 1 g orally once

<sup>a</sup>Test of cure is not required. Persons with persistent symptoms of gonococcal infection or whose symptoms recur shortly after treatment are reevaluated by culture for *N gonorrhoeae*. If positive, isolates are submitted for resistance testing. Suspected treatment failures are reported to the CDC within 24 hours.

<sup>b</sup>Other cephalosporin options include: (1) ceftizoxime (Cefizox) 500 mg IM, (2) cefoxitin (Mefoxin) 2 g IM given with probenecid 1 g orally, or (3) cefotaxime (Claforan) 500 mg IM. Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

found in individuals younger than 25 years. *Chlamydia* prevalence was 4.7 percent overall among sexually active females aged 14 to 24 years based on national survey estimates from 2007 to 2012 (Torrone, 2014). T is increased to 13.5 percent among non-Hispanic black females. Since many with this organism are asymptomatic, women with the same risks that prompt gonococcal screening, listed on page 64, are screening candidates.

T is obligate intracellular parasite is dependent on host cells for survival. It infects columnar epithelial cells, and endocervical glandular infection leads to mucopurulent discharge or endocervical secretions. If infected, the endocervical tissue is commonly edematous and hyperemic. Urethritis can also develop, and dysuria is prominent.

Microscopic inspection of secretions in a saline preparation typically reveals 20 or more leukocytes per high-power field. More specifically, culture, NAAT, and enzyme-linked immunosorbent assay (ELISA) are available for endocervical specimens. Alternatively, combined gonococcal and chlamydial tests are widely used. As with gonorrhea testing, newer NAAT collection kits permit specific collection from the vagina, the endocervix, or urine (p. 64). Vaginal-swab specimens are as sensitive and specific as cervical-swab specimens. Urine samples, although acceptable, are least preferred for women with a cervix. However, for women following hysterectomy, first-void urine samples are preferred. Again, these noncultural tests are not FDA-cleared for diagnostic identification of rectal or pharyngeal disease. If *C trachomatis* is diagnosed or suspected, then screening for other STDs is indicated.

Recommended therapy for *C trachomatis* infection is described in Table 3-10. Azithromycin has the obvious therapeutic compliance advantage of allowing clinicians to observe ingestion at the time of diagnosis. Following treatment, retesting is not

**TABLE 3-10.** Oral Treatments of Chlamydial Infection

<b>Recommended regimen</b>
Azithromycin 1 g once
or
Doxycycline 100 mg twice daily for 7 days
<b>Alternative regimens</b>
Erythromycin base 500 mg four times daily for 7 days
or
Erythromycin ethyl succinate 800 mg four times daily for 7 days
or
Levofloxacin (Levaquin) 500 mg once daily for 7 days
or
Ofloxacin (Floxin) 300 mg twice daily for 7 days

recommended if symptoms resolve. To prevent further infection, abstinence is recommended until a woman and her partner(s) are treated and are asymptomatic. Sexual partner(s) are referred for evaluation, or they are examined, counseled, tested, and treated. As with gonorrhea in heterosexual partners, expedited partner therapy is sanctioned by the CDC for selected patients (p. 64).

■ **Mycoplasma genitalium**

Discovered in 1980, this bacterium’s role in female lower reproductive tract pathology is poorly defined. Most women carriers are asymptomatic, but it has been linked in some but not all studies to urethritis, cervicitis, PID, and later to tubal-factor infertility (Taylor-Robinson, 2011; Weinstein, 2012). T us, in women with persistent or recurrent urethritis, cervicitis, or PID, *M genitalium* may be considered. It has a much more established role in male urethritis (Daley, 2014). As such, gynecologists may more frequently encounter the exposed female partner of an infected male. Currently, the CDC (2015) comments that NAAT testing for exposed women and treatment of subsequently identified infections can be considered. NAATs for this organism are not widely available, but samples from voided urine, the vagina, or the endocervix are appropriate (Lillis, 2011).

For urethritis, cervicitis, or exposure coverage, azithromycin 1 g orally once is recommended. Antibiotic-resistant strains are not uncommon, and for treatment failure, moxifloxacin 400 mg once orally for 7 to 14 days may be used. T is same moxifloxacin regimen for 14 days may be considered for women with PID who fail to respond after 7 to 10 days of standard regimens and in whom *M genitalium* is detected (Centers for Disease Control and Prevention, 2015; Manhart, 2011).

**PELVIC INFLAMMATORY DISEASE**

T is is an infection of the upper female reproductive tract organs. Another diagnosis given to this disease is acute salpingitis. Although all reproductive tract organs may be involved, the

organ of importance, with or without abscess formation, is the fallopian tube. Because of difficulty in accurately diagnosing this infection, its true magnitude is unknown. Many women report that they have been treated for PID when they did not have it, and vice versa. The clinical importance of diagnosing PID is emphasized by its known sequelae, which include tubal-factor infertility, ectopic pregnancy, and chronic pelvic pain. Thus, clinicians ideally carry a low threshold for diagnosing and treating PID.

■ **Microbiology and Pathogenesis**

The exact microbiologic pathogens in the fallopian tube cannot be known for any given patient. Studies have shown that transvaginal culture of the endocervix, endometrium, and cul-de-sac contents reveals different organisms from each site in the same patient. For that reason, treatment protocols are designed so that most potential pathogens are covered by antibiotic regimens.

Classic salpingitis is associated with and secondary to *N gonorrhoeae* infection, and *C trachomatis* is also commonly recovered (Table 3-11). Another species frequently found is *T vaginalis*. The lower reproductive tract flora in women with PID and in those with bacterial vaginosis is predominately anaerobic species. The microenvironment changes produced by BV may aid ascension of the causative organisms of PID (Soper, 2010). However, Ness and colleagues (2004) and others have shown that bacterial vaginosis is not a risk factor for PID development.

Upper tract infection is believed to be caused by bacteria that ascend from the lower reproductive tract. It is assumed that this ascension is enhanced during menstruation due to loss of endocervical barriers. The gonococcus can cause a direct inflammatory response in the human endocervix, endometrium, and fallopian tube and is one of the true pathogens of human fallopian tube epithelial cells. If normal human fallopian tube cells in cell culture are exposed to potential pathogens such as *Escherichia coli*, *Bacteroides fragilis*, or *Enterococcus faecalis*, no inflammatory response follows. If the above bacteria are introduced into a fallopian tube cell culture in which gonococci are present and have caused inflammatory damage, then an exaggerated inflammatory response results.

In contrast, intracellular *C trachomatis* does not cause an acute inflammatory response, and little *direct* permanent damage results from chlamydial tubal involvement (Patton, 1983). However, cell-mediated immune mechanisms may be responsible for subsequent tissue injury. Specifically, persistent chlamydial antigens can trigger a delayed hypersensitivity reaction with continued tubal scarring and destruction (Toth, 2000).

Last, women with pulmonary tuberculosis can develop salpingitis and endometritis. This pathogen is thought to be blood-borne, but ascension may still be a possible route. The fallopian tubes also can be infected by direct extension from inflammatory GI disease, especially ruptured abscess, for example, appendiceal or diverticular.

■ **Diagnosis**

**Silent Pelvic Inflammatory Disease**

Pelvic inflammatory disease can be segregated into “silent” PID and PID. The latter can be further subdivided into acute and chronic.

Silent PID is thought to follow multiple or continuous low-grade infection in asymptomatic women. Silent PID is not a clinical diagnosis. Rather, it is an ultimate diagnosis given to women with tubal-factor infertility who lack a history compatible with upper tract infection. Many of these patients have antibodies to *C trachomatis* and/or *N gonorrhoeae*. At laparoscopy or laparotomy, affected women may have evidence of prior tubal infection such as adhesions, but for the most part, the fallopian tubes are grossly normal. Internally, however, tubes show flattened mucosal folds, extensive deciliation of the epithelium, and secretory epithelial cell degeneration (Patton, 1989). Alternatively, hydrosalpinx may be found. Grossly, these fallopian tubes are distended along their entire length. Their distal ends are dilated and clubbed, and fimbria are replaced by or encased by smooth adhesions (Fig. 9-22, p. 224). Sonographically, a hydrosalpinx tends to be anechoic, tubular, serpentine, and often with incomplete septa (Figs. 9-23). Last, fine adhesions between the liver capsule and anterior abdominal wall may also reflect prior silent disease.

**Acute Pelvic Inflammatory Disease**

**Symptoms and Physical Findings.** The most recent diagnostic criteria presented by the CDC (2015) are for sexually active women at risk for STDs who have pelvic or lower abdominal pain and in whom other etiologies are excluded or unlikely. PID is diagnosed if uterine tenderness, adnexal tenderness, or cervical motion tenderness is present. One or more of the following enhances diagnostic specificity: (1) oral temperature > 38.3°C (101.6°F), (2) mucopurulent cervical discharge or cervical friability, (3) abundant WBCs on saline microscopy of cervical secretions, (4) elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), and (5) presence of cervical *N gonorrhoeae* or *C trachomatis*. Thus, a diagnosis of PID is one typically based on clinical findings.

With acute PID, symptoms characteristically develop during or soon following menstruation. These can include lower

**TABLE 3-11.** Pelvic Inflammatory Disease Risk Factors

Not using mechanical and/or chemical contraceptive barriers
Endocervical testing positive for <i>Ngonorrhoeae</i> or <i>Ctrachomatis</i>

abdominal and/or pelvic pain, yellow vaginal discharge, heavy menstrual bleeding, fever, chills, anorexia, nausea, vomiting, diarrhea, dysmenorrhea, and dyspareunia. Patients also may have complaints suggesting urinary tract infection. Unfortunately, no single symptom is associated with a physical finding that is specific for this diagnosis. Accordingly, other possible sources of acute pelvic pain are considered and listed in Table 11-1 (p. 251).

In women with acute PID, leukorrhea or mucopurulent endocervicitis is common and is diagnosed visually and microscopically. During bimanual pelvic examination, affected women will usually have pelvic organ tenderness. Cervical motion tenderness (CMT) is typically elicited by quickly moving the cervix with examining vaginal fingers. This reflects pelvic peritonitis and can be considered a vaginal “rebound” test. If a woman has pelvic peritonitis secondary to bacteria and purulent debris that has exuded from the fimbriated end of the fallopian tube, this rapid peritoneal movement usually causes a marked pain response. Tapping the cul-de-sac with examining finger(s) will give the examiner similar information. This latter maneuver usually causes a patient significantly less pain because less inflamed peritoneum is stretched.

Abdominal peritonitis may be identified by deep probing and quick release of a hand placed on the abdomen—a test for rebound. Alternatively, an examining hand may be positioned with a palm against a woman’s midabdomen and gently and quickly moved back and forth (shake). This can identify abdominal peritonitis, often with less patient discomfort.

In women with PID and peritonitis, usually only the lower abdomen is involved. However, inflammation of the liver capsule, which can accompany PID, may lead to right upper quadrant pain, a condition known as Fitz-Hugh-Curtis syndrome. Classically, symptoms of this perihepatitis include sharp, pleuritic right upper quadrant pain that accompanies pelvic pain. The upper abdominal pain may refer to the shoulder or upper arm. With auscultation, a friction rub may be heard along the right anterior costal margin. Importantly, during examination, if all abdominal quadrants are involved, suspicion for a ruptured tuboovarian abscess (TOA) is heightened.

**Testing.** In women with lower abdominal pain, tests directed at diagnosing PID or excluding other pain sources are selected. Pregnancy complications can be identified by serum or urine beta-human chorionic gonadotropin testing. A complete blood count (CBC) is selected as a baseline test to exclude hemoperitoneum as the cause of symptoms and identify WBC elevation. In those with significant nausea and vomiting or Fitz-Hugh-Curtis syndrome, liver enzyme values may be normal or mildly elevated. If properly collected, urinalysis findings for infection will be absent. Saline preparation of cervical or vaginal discharge will typically show sheets of leukocytes. In women with suspected acute PID, endocervical testing for both *N gonorrhoeae* and *C trachomatis* is performed as described earlier (p. 64). Screening for other STDs is also completed.

In the opinion of many, an endometrial biopsy (EMB) in women with mucopurulent secretions and suspected PID does not provide useful information to alter the diagnosis or therapy (Achilles, 2005). However, some do recommend EMB to

diagnose endometritis. Polymorphonuclear leukocytes on the endometrial surface correlate with acute endometritis, whereas plasma cells in the endometrium are found with chronic endometritis. However, women with uterine leiomyomas or endometrial polyps but without PID may also often have plasma cells present in the endometrium, as do essentially all women in their lower uterine segment.

**Sonography.** In women with marked abdominal pain and tenderness, appreciation of upper reproductive tract organs during bimanual examination may be limited, and sonography is a primary imaging tool (Fig. 2-21, p. 33). Normal fallopian tubes are rarely imaged. However, with acute tubal inflammation, the tube swells, its lumen occludes distally, it distends, and its walls and endosalpingeal folds thicken. Characteristic findings include: (1) distended, ovoid-shaped tube filled with anechoic or echogenic fluid, (2) fallopian tube wall thickening, (3) incomplete internal septa, and (4) a “cogwheel” appearance when inflamed tubes are imaged in cross section (Timor-Tritsch, 1998). If color or power Doppler is applied, marked vascularity with low-impedance blood flow, which reflects hyperemia, is seen within thickened fallopian tube walls and if present, within septa (Molander, 2001; Romosan, 2013). Sonography may also be used to identify TOA or exclude other pathology as the pain source. If sonography does not lead to a clear diagnosis, computed-tomography (CT) scanning is often selected (Sam, 2002). Magnetic resonance (MR) imaging is a suitable alternative. In women with right upper quadrant pain suggestive of perihepatitis, chest radiography or upper abdominal sonography may be needed to exclude other pathology.

**Laparoscopy.** In Scandinavian countries, women suspected of having acute PID undergo laparoscopy for diagnosis. Tubal serosal hyperemia, tubal wall edema, and purulent exudate issuing from the fimbriated ends of the fallopian tubes, termed *pyosalpinx*, and pooling in the cul-de-sac confirm this diagnosis. Because of this routine practice, Hadgu and coworkers (1986) assembled criteria that preoperatively clinically predicted acute PID and assessed their validity by the absence or presence of disease at laparoscopy. Criteria included: (1) single status, (2) adnexal mass, (3) age < 25 years, (4) temperature > 38°C, (5) cervical *N gonorrhoeae*, (6) purulent vaginal discharge, and (7) ESR ≥ 15 mm/hr. The preoperative clinical diagnosis of PID was 97-percent accurate if a woman met all seven criteria, allowing avoidance of surgery. Thus, due to the risks of laparoscopy, use of clinical findings alone to diagnose PID is reasonable. In those with a less clear presentation, laparoscopy may be needed to exclude other pathology such as appendicitis or adnexal torsion.

### Tuboovarian Abscess

With infection, the inflamed and suppurative fallopian tube can adhere to the ovary. Sonographically, if both tube and ovary are recognizable, the term *tuboovarian complex* is used. If inflammation proceeds, tissue planes and distinction between the two is lost, and the term *tuboovarian abscess* is applied. Tuboovarian abscesses are typically unilateral and may also involve adjacent structures that include bowel, bladder, and contralateral adnexa.

**FIGURE 3-8** Computed tomographic (CT) scan of a tuboovarian abscess undergoing percutaneous needle drainage.

With abscess progression, further structural weakening may lead to abscess rupture and potentially life-threatening peritonitis. Although PID is an important cause of TOA, these may also follow appendicitis, diverticulitis, inflammatory bowel disease, or surgery.

Classically, affected women display signs of PID and a concurrent adnexal or cul-de-sac mass. Sonographically, with TOA, a complex cystic adnexal or cul-de-sac mass with thick irregular walls, areas of mixed echogenicity, septations, and internal echoes from debris is seen (Fig. 2-22, p. 34). If the clinical picture is unclear, CT scanning may add information. A thick-walled, cystic adnexal mass with internal septations and surrounding inflammatory changes is characteristic (Fig. 3-8). Although not routinely used for TOA imaging, MR imaging usually shows a complex pelvic mass with low signal intensity on T1-weighted sequences and heterogeneously high signal intensity on T2-weighted sequences.

Microorganisms frequently cultured include *E coli*, *Bacteroides* spp, *Peptostreptococcus* spp, and aerobic *Streptococcus* spp. (Landers, 1983). Thus, broad-spectrum antibiotic coverage, including that for anaerobes, is selected for initial management of women with unruptured TOA. Most women with TOA will respond to intravenous (IV) antibiotic therapy alone and avoid the need for drainage. Combination antimicrobial regimens will predictably be more successful, and CDC (2015) recommendations for TOA complicating PID include IV regimens in Table 3-12. Parenteral antimicrobial therapy is continued until the patient has been afebrile for at least 24 hours, preferably 48 to 72 hours. In transitioning to oral therapy, doxycycline 100 mg twice daily is combined with either metronidazole 500 mg twice daily or clindamycin 450 mg four times daily to complete a 14-day course.

For those not improved within 2 to 3 days of treatment, prior to attempts at abscess drainage, antimicrobial regimen modification is indicated. Drainage plus antibiotic therapy can be considered as initial treatment for larger abscesses ( $\geq 8$  cm). For this, drainage can be accomplished with or without surgery. Radiologic drainage is minimally invasive and potentially avoids the higher risks associated with general anesthesia and surgery. In general,

**TABLE 3-12.** Recommended Parenteral Treatment of PID

**Recommended regimens**

- { Cefotetan (Cefotan) 2 g IV every 12 hr
- or
- { Cefoxitin (Mefoxin) 2 g IV every 6 hr
- PLUS
- { Doxycycline 100 mg orally or IV every 12 hr
- OR
- { Clindamycin 900 mg IV every 8 hr
- PLUS
- { Gentamicin loading dose 2 mg/kg IV or IM followed by a maintenance dose of 1.5 mg/kg every 8 hr. Single daily dosing at 3 to 5 mg/kg per day may be substituted.

**Alternative regimen**

- Ampicillin/sulbactam (Unasyn) 3 g IV every 6 hr
- PLUS
- Doxycycline 100 mg orally or IV as above

IV= intravenous; PID = pelvic inflammatory disease. Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

pelvic collections can be emptied using transabdominal, transvaginal, transgluteal, or transrectal routes with either CT or sonographic guidance and adequate analgesia. Depending on abscess size and characteristics, contents can be removed with needle aspiration or with pigtail catheter placement and short-term drainage. In cases that are refractory or not amenable to these more conservative measures, exploratory laparoscopy or laparotomy is typically warranted. In those with TOA rupture, emergency surgery is required. Goals of surgery include abscess drainage, excision of necrotic tissues, and peritoneal cavity irrigation.

As is true in all abscesses, drainage is the key to clinical improvement. Although perhaps tempting at laparotomy, removal of the abscess is not necessary unless ovarian parenchyma is involved. This is rare. Electively opening the protective peritoneal and other tissue planes to remove tissues—especially the uterus—in the presence of acute infection does not improve patient outcome compared with percutaneous drainage. As a clinical comparison, infected Bartholin glands are not excised. Rather, they are drained and definitively treated later, when not infected, if necessary.

Infection confined within one organ, such as a pyosalpinx, responds more favorably to antimicrobial therapy because of adequate blood and lymphatic supply. This is true even if attached to an adjacent ovary. A cul-de-sac or interloop abscess is more likely to require drainage, however, because of poor blood and lymphatic supply and a less prompt response to antimicrobial therapy.

Following successful conservative treatment, bilateral adnexal abscesses cannot be equated with guaranteed infertility. In a clinical trial evaluating such patients, 25 percent of women subsequently became pregnant (Hemsell, 1993).

Chronic Pelvic Inflammatory Disease

This diagnosis is given to women who describe a history of acute PID and who have subsequent pelvic pain. Accuracy of this diagnosis clinically is orders of magnitude less than for acute PID. A hydrosalpinx might qualify as a criterion for this diagnosis. Realistically, however, it is a histologic diagnosis (chronic inflammation) made by a pathologist. Thus, the clinical utility of this diagnosis is limited.

■ Treatment of Pelvic Inflammatory Disease

The most successful patient outcomes follow early diagnosis and prompt, appropriate therapy. The primary therapy goal is to eradicate bacteria, relieve symptoms, and prevent sequelae. Tubal damage or occlusion resulting from infection may lead to infertility. Rates following one episode approximate 15 percent; two episodes, 35 percent; and three or more episodes, 75 percent (Westrom, 1975). Also, ectopic pregnancy risk is increased six- to 10-fold and may reach a 10-percent risk for those who conceive. Other sequelae include chronic pelvic pain (15 to 20 percent), recurrent infection (20 to 25 percent), and abscess formation (5 to 15 percent). Unfortunately, women with mild symptoms may remain at home for days or weeks prior to presentation for diagnosis and therapy.

Exactly where a patient is treated remains controversial. There are proposed criteria that predict better outcome for certain patients with in-hospital parenteral antimicrobial therapy (Table 3-13). However, the high cost of in-hospital treatment prevents routine hospitalization for all women given this diagnosis.

Another potential clinical decision involves management of a coexistent IUD. During the first 3 weeks after device insertion, patients have an increased IUD-associated PID risk. After this time, other PID risks are considered causative. With PID, theoretical concerns are that a coexistent IUD might worsen the infection or delay resolution. Although a provider may choose to remove the device, evidence supports leaving an IUD during treatment in those hospitalized with mild or moderate PID (Centers for Disease Control and Prevention, 2015; Tepper, 2013). Severe disease warrants IUD removal. With or without an IUD, women are treated with similar antibiotic regimens. But, if a patient fails to improve within 48 to 72 hours, the device is removed.

TABLE 3-13. Hospitalization Indications for Parenteral Treatment of PID

Pregnant
Adolescents
Drug addicts
Severe disease
Suspected abscess
Uncertain diagnosis
Generalized peritonitis
Temperature > 38.3°C
Failed outpatient therapy
Recent intrauterine instrumentation
White blood cell count > 15,000/mm <sup>3</sup>
Nausea/vomiting precluding oral therapy

PID = pelvic inflammatory disease.

Oral Treatment

In women with a mild to moderate clinical presentation, outpatient treatment and inpatient therapy yield similar results. Clinical treatment with oral therapy is also appropriate for women with HIV infection and PID. These women have the same species recovered compared with non-HIV-infected patients, and their response to therapy is similar.

If women have more than moderate disease, they require hospitalization. Dunbar-Jacob and associates (2004) showed that women treated as outpatients took 70 percent of prescribed doses, and for less than 50 percent of their outpatient treatment days. If patients are treated as outpatients, an initial parenteral dose may be beneficial. Women treated as outpatients are reevaluated in approximately 72 hours by phone or in person. If women do not respond to oral therapy within 72 hours, parenteral therapy is initiated either as an inpatient or as an outpatient if home nursing care is available. This assumes that the diagnosis is confirmed at reevaluation.

Specific treatment recommendations from the CDC are found in Table 3-14. Anaerobes are believed by some to play an important role in upper tract infection and are treated. Hence, metronidazole may be added to improve anaerobic coverage. If patients have BV or trichomoniasis, then metronidazole addition is required, although perhaps not for 14 days.

Parenteral Treatment

Any woman who has criteria as outlined in Table 3-13 is hospitalized for parenteral treatment for at least 24 hours. Following this, if home parenteral treatment is available, this is a reasonable option. Alternatively, if a woman responds clinically and will be appropriately treated by one of the oral regimens in Table 3-14, then she can be discharged on those medications.

Recommendations for parenteral antibiotic treatment of PID are found in Table 3-12. Of these antibiotics, oral and parenteral routes of doxycycline have almost identical bioavailability, but parenteral doxycycline is caustic to veins. Many prospective clinical trials have shown that either of the listed cephalosporins alone, without doxycycline, will result in a clinical cure.

TABLE 3-14. Outpatient Treatment of PID

Ceftriaxone (Rocephin) 250 mg IM once <sup>a,b</sup>
PLUS
Doxycycline 100 mg orally twice daily for 14 days
with or without
Metronidazole (Flagyl) 500 mg orally twice daily for 14 days

<sup>a</sup>Cefoxitin (Mefoxin) 2 g IM with 1 g oral probenecid once may replace ceftriaxone

<sup>b</sup>Other parenteral third-generation cephalosporins IM given in a single dose such as ceftizoxime or cefotaxime may replace ceftriaxone.

IM = intramuscular; PID = pelvic inflammatory disease. Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

For that reason, doxycycline administration could be reserved until the patient can take oral medication. The recommendation is to continue parenteral therapy until 24 hours after the patient clinically improves, and the oral doxycycline 100 mg twice daily is continued to complete 14 days of therapy. Alternatively, if the IV gentamycin/clindamycin regimen is used, then transition to a 14-day oral agent may involve clindamycin orally four times daily or doxycycline 100 mg twice daily.

## INFECTIOUS WARTS AND PAPULES

### ■ External Genital Warts

These lesions are created from infection with the human papillomavirus (HPV), and 86 percent of cases stem from HPV 6 or 11 (Garland, 2009). A fuller discussion of HPV pathophysiology is found in Chapter 29 (p. 627). Genital warts display differing morphologies, and appearances range from flat papules to the classic verrucous, exophytic lesions, termed condyloma acuminata (Fig. 3-9) (Beutner, 1998). Involved tissues vary, and external genital warts may develop at sites in the lower reproductive tract, urethra, anus, or mouth. They are usually asymptomatic but can be pruritic or painful depending on their size and location. Warts are typically diagnosed by clinical inspection, and biopsy is not required unless coexisting neoplasia is suspected (Wiley, 2002). Similarly, HPV serotyping is not required for routine diagnosis.

Condyloma acuminata may remain unchanged or spontaneously resolve, and the effect of treatment on future viral transmission is unclear. However, many women prefer removal, and lesions can be destroyed with sharp or electrosurgical excision, cryotherapy, or laser ablation. In addition, very large, bulky lesions may be managed with cavitation ultrasonic surgical aspiration (CUSA) (Section 43-28, p. 996).

Alternatively, topical agents can be applied to resolve lesions through various mechanisms (Table 3-15). One of these, 5-percent imiquimod cream (Aldara), is a patient-applied, immunomodulatory topical treatment for genital warts. This agent induces macrophages to secrete several cytokines, and of these, interferon- $\gamma$  is probably the most important. For genital

wart clearance, this cytokine stimulates a cell-mediated immune response against HPV (Scheinfeld, 2006). Another topical immune-modulating agent is a 15-percent sinecatechin ointment (Veregen) derived from green tea leaf extracts (Meltzer, 2009). Podophyllin is an antimitotic agent available in a 10- to 25-percent tincture of benzoin solution and disrupts viral activity by inducing local tissue necrosis. Podophyllin resin is no longer a first-line CDC-recommended option due to risks of systemic toxicity if used incorrectly. However, a biologically active extract of podophyllin, podofilox, also termed podophyllo-toxin, is available in a 0.5-percent solution or gel (Condylox) and can be self-applied by the patient. Alternatively, trichloroacetic acid and bichloroacetic acid are proteolytic agents and are applied serially to warts by clinicians. Intralesion injection of interferon is an effective treatment for warts (Eron, 1986). However, its high cost and painful administration render it an alternative option.

Of therapy choices, no data suggest the superiority of one treatment. Thus, in general, treatment is selected based on clinical circumstances and patient and provider preferences. Importantly, no treatment option, even surgical excision, boasts 100-percent clearance rates. Indeed, clearance rates range from 30 to 80 percent. Accordingly, recurrences are common following treatment.

### ■ Molluscum Contagiosum

The molluscum contagiosum virus is a DNA poxvirus that is transmitted by direct human-to-human contact or by infected fomites. An incubation period of 2 to 7 weeks is typical, but can be longer. The host response to viral invasion is papular with central umbilication, giving a characteristic appearance (Fig. 3-10). It may be single or multiple and is commonly seen on the vulva, vagina, thighs, and/or buttocks. Molluscum contagiosum is contagious until lesions resolve.

These papules are typically diagnosed by visual inspection alone. However, material from a lesion can be collected on a swab, applied to a slide, and submitted to a laboratory for diagnostic staining with Giemsa, Gram, or Wright stains. Molluscum bodies, which are large intracytoplasmic structures, are diagnostic.

**FIGURE 3-9** Condyloma acuminata. Multiple exophytic verrucous warts are seen on the labia and perineum.

**FIGURE 3-10** Molluscum contagiosum. Labial lesions are flesh-colored, dome-shaped papules with central umbilication.

**TABLE 3-15.** Recommended Treatment of External Genital Warts

<b>Patient-applied</b> Podofilox 0.5% solution or gel (Condylox). Patients should apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. This cycle may be repeated, as necessary, for up to four cycles. The total wart area treated should not exceed 10 cm <sup>2</sup> , and the total volume of podofilox should be limited to 0.5 mL per day. or Imiquimod 5% cream (Aldara). Patients should apply imiquimod cream once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6 to 10 hours after the application. or Sinecatechिन 15% ointment (Veregen). This extract is applied three times daily (0.5-cm strand to each wart) using a finger to ensure wart coverage. Use is continued until warts are cleared, but not longer than 16 weeks. It is not washed off, and sexual contact is avoided when ointment is present.
<b>Provider-administered</b> Cryotherapy with liquid nitrogen or cryoprobe. Repeat applications every 1 to 2 weeks. or Podophyllin resin 10 to 25 percent in a compound tincture of benzoin. A small amount should be applied to each wart and allowed to air dry. The treatment can be repeated weekly, if necessary. Application should be limited to < 0.5 mL of podophyllin or an area of < 10 cm <sup>2</sup> of warts per session. No open lesions or wounds should exist in the area to which treatment is administered. Some specialists suggest thorough washing 1 to 4 hours after application to reduce local irritation. or Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80 to 90 percent. A small amount should be applied only to the warts and allowed to dry, at which time a white “frosting” develops. This treatment can be repeated weekly if necessary. If an excess amount of acid is applied, the treated area should be powdered with talc, sodium bicarbonate (i.e., baking soda), or liquid soap preparations to remove unreacted acid. or Surgical removal by tangential scissor excision, tangential shave excision, curettage, or electrosurgery.
<b>Alternative regimens</b> Intralesional interferon, photodynamic therapy, topical cidofovir.

Reproduced with permission from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

Most lesions spontaneously regress within 6 to 12 months. If removal is preferred, lesions may be treated by cryotherapy, electrosurgical needle coagulation, or sharp needle-tip curettage of a lesion’s umbilicated center. Alternatively, topical application of agents used in the treatment of genital warts may also be effective treatment for molluscum contagiosum (see Table 3-15).

**PRURITIC INFESTATIONS**

**■ Scabies**

*Sarcoptes scabiei* infect skin and result in an intensely pruritic rash. The mite is crab-shaped, and the female digs into the skin and remains there for approximately 30 days, elongating her burrow. Several eggs are laid daily and begin hatching after 3 to 4 days (Fig. 3-11). The baby mites furrow their own burrows, becoming reproductive adults in approximately 10 days. The number of adult mites present on an affected patient averages a dozen. Sexual transmission is the most likely cause of initial infection, although it can be seen in household contacts. Burrows are thin elevated skin tracks measuring 5 to 10 mm in length. A delayed-type 4 hypersensitivity reaction to the mites,

eggs, and feces develops and results in erythematous papules, vesicles, or nodules in association with skin burrows. Secondary infection, however, may develop and hide these tracks. Most common infection sites include the hands, wrist, elbows, groin, and ankles. Itching in these areas is the predominant symptom.

**FIGURE 3-11** Burrow with *Sarcoptes scabiei*. A mite is seen at the end of a burrow (far right) with seven eggs and smaller fecal particles. (Reproduced with permission from Wolff K, Johnson RA, Saavedra AP: Fitzpatrick’s Color Atlas and Synopsis of Clinical Dermatology, 7th ed. New York: McGraw-Hill; 2013.)

Definitive testing requires scraping across the burrow with a scalpel blade and mixing these fragments in immersion oil on a microscope slide. Identification of mites, eggs, egg fragments, or fecal pellets is diagnostic.

Once diagnosed, 5-percent permethrin cream (Elimite) is a recommended agent. A thin layer is applied from the neck downward with special attention to pruritic areas and the hands, feet, and genital regions. Ideally, all family members are treated with the exception of infants younger than 2 years. Eight to 14 hours after application, a shower or bath is taken to remove the medication. Only one application is necessary. Another option is the oral antihelminth ivermectin (Stromectol) 200 µg/kg once and then repeated 2 weeks later. Bed linens and recently worn clothing are washed to prevent reinfection. A less-preferred option is 1-percent lindane, because it is not recommended in pregnancy or in children younger than 2 years and because seizures have occurred if spread on areas with extensive dermatitis or immediately after showering. If used, a 30-g dose of cream is applied and rinsed off similar to permethrin.

An antihistamine will help reduce pruritus, which can also be treated with a hydrocortisone-containing cream in adults or with emollients or lubricating agents in infants. If these lesions become infected, antibiotic therapy may be necessary.

### ■ Pediculosis

Lice are small ectoparasites that measure approximately 1 mm (Fig. 3-12). Three species infest humans and include the body louse (*Pediculus humanus*), the crab louse (*Phthirus pubis*), and the head louse (*Pediculus humanus capitis*). Lice attach to the base of human hair with claws that vary in diameter between species. It is this claw's diameter that determines the infestation site. For this reason, the crab louse is found on pubic hair and other hair of similar diameter, such as axillary and facial hair, including eyelashes and eyebrows. As is true for mites, the number of lice populating a patient averages a dozen. Lice depend on frequent human blood meals, and pubic lice must travel for new attachment sites. Accordingly, pubic lice usually are sexually transmitted, whereas head and body lice may be transmitted by sharing of personal objects such as combs, brushes, and clothing.

The main symptom from louse attachment and biting is pruritus. Scratching results in erythema and inflammation, which increases blood supply to the area. Patients may develop pyoderma and fever if bites become secondarily infected. Each female adult pubic louse lays approximately four eggs a day, which are glued to the base of hairs. Incubation approximates 1 month. Their attached eggs, termed nits, can be seen attached to the hair shaft away from the skin line as hair growth progresses. These nits usually require a magnifying glass for identification. Moreover, suspicious flecks on pubic hair or in clothing can be examined microscopically to see the characteristic louse. Following diagnosis, patient screening for other STDs is encouraged. Other family members and sexual contacts require evaluation for infestation.

Pediculicides kill not only adult lice, but also the eggs. A single application is usually effective, but a second dose is recommended within 7 to 10 days to kill new hatches. Nonprescription cream rinses or shampoos contain 1-percent permethrin (Nix) or pyrethrins with piperonyl butoxide (Rid, Pronto, R&C). These remain on affected areas for 10 minutes. CDC alternative regimens include 0.5-percent malathion lotion (Ovide) applied for 8 to 12 hours. Also, ivermectin 250 µg/kg orally once can be taken and then repeated in 2 weeks.

In selected cases, 1-percent lindane shampoo can be used, but again, it is less favored due to potential toxicity. Last, eyelash and eyebrow treatment is problematic. These areas are best treated by applying petrolatum (Vaseline) with a cotton swab at night and washing it off in the morning. Bedding and infested clothing are washed and dried with a heat cycle.

In spite of treatment, pruritus may continue and can be relieved by oral antihistamines, antiinflammatory cream or ointment, or both. The patient is reevaluated after 1 week to document louse eradication.

## URINARY TRACT INFECTIONS

Symptomatic acute bacterial urinary tract infections (UTIs) are among the most common bacterial infections treated by clinicians. Cystitis accounts for most of these, whereas acute pyelonephritis treatment accounts for a greater number of

**FIGURE 3-12** *Phthirus pubis*. **A.** Pubic lice are seen attached to hair. In addition, nits are seen as dark dots adhered to pubic hair. (Reproduced with permission from Morse S, Ballard RC, Holmes KK, et al (eds): *Atlas of Sexually Transmitted Diseases*, 3rd ed. Edinburgh: Mosby; 2003.) **B.** Photomicrograph of *Phthirus pubis*. Claw-like legs are ideally suited for clinging to hair shafts. (Used with permission from The Department of Dermatology, Naval Medical Center, Portsmouth, VA)

hospitalizations. Because of their pelvic anatomy, women have many more UTIs than men. Bacteria ascending from the short, colonized urethra easily enter the bladder and perhaps the kidneys. Contributing to contamination, the warm moist vulva and rectum are both in close proximity. Similarly, sexual intercourse increases bladder inoculation.

Infections result from the interaction between bacteria and host. Bacterial virulence factors are important, as they enhance colonization and invasion of the lower and upper urinary tract. The principal virulence factors are increased adherence to either vaginal or uroepithelial cells and hemolysin production. The bacterial species most frequently recovered from infected urine culture is *E coli* (75–95 percent). Other identified species are *Klebsiella pneumoniae*, *Proteus mirabilis*, and *Staphylococcus saprophyticus* (Czaja, 2007; Echols, 1999).

Once within the bladder, bacteria may ascend within the ureters into the renal pelvis and cause upper tract infection. The renal parenchyma also can be infected by blood-borne organisms, especially during staphylococcal bacteremia. *Mycobacterium tuberculosis* gains access to the kidney through this route and also perhaps by ascension.

■ Acute Bacterial Cystitis

The most frequent presenting complaints in otherwise healthy, immunocompetent nonpregnant women are dysuria, frequency, urgency, hematuria, and incontinence. If the patient prefers, most women can be treated with a short course of antibiotics without examination, urinalysis, or urine culture for an isolated episode of acute uncomplicated bacterial cystitis. However, patients are instructed on clinical changes that merit further attention such as fever > 100.4°C and persistence or recurrence of hematuria, dysuria, and frequency despite treatment. Women with these exclusions and others require evaluation to exclude other potential causes of their symptoms (Table 3-16). For example, hematuria in a postmenopausal woman may reflect cervical, uterine, or colonic bleeding evident at the time of urination. Similarly, burning with urination may indicate vulvitis.

As many as 50 percent of women who suffer an uncomplicated acute bacterial episode of cystitis will have another infection within a year. Up to 5 percent have recurring symptoms soon after treat-

ment. When symptoms develop in such women, the likelihood that a true infection is present is greater than 80 percent.

Diagnosis

Thus, for selected women with complicated or recurrent infections or with persistent or new symptoms during treatment, urinalysis and urine culture are mandatory. For a culture specimen to be informative, it must be accurately collected. A “clean catch” midstream voided urine specimen is usually sufficient. A patient is counseled on reasons for and the steps associated with urine specimen collection, which are designed to prevent contamination by other bacteria from the vulva, vagina, and rectum. More than one bacterial species identified in a urine culture usually indicates specimen collection contamination.

Initially, a patient spreads her labia and wipes the periurethral area from front to back with an antiseptic tissue. With labia spread, she begins urinating but does not collect the initial stream. A sample is then collected into a sterile specimen cup. The specimen cup is handled by the patient in such a way to avoid contamination. After collection, a urine specimen is delivered promptly to the laboratory and is plated for culture within 2 hours of collection unless it is refrigerated.

**Culture.** Urine culture allows accurate identification of an inciting pathogen and susceptibility testing of that pathogen to various antibiotics. Classically, significant bacteriuria is defined as  $\geq 10^5$  bacteria (colony-forming units [cfu]) per milliliter of urine. If urine is collected by either suprapubic aspirate or catheterization, colony counts  $\geq 10^2$  cfu/mL are diagnostic. As an exception, Hooton and colleagues (2013) demonstrated that *E coli* in midstream urine is highly predictive of bladder bacteriuria even at very low counts of  $10^2$  cfu/mL.

Although anaerobic bacteria are part of the vaginal, colonic, and skin flora, they rarely cause UTIs. Hence, urine culture reports do not note anaerobes except in rare instances in which the laboratory has been alerted to and specifically requested to look for an anaerobic species. Fungi can be identified on routine bacteria media and are reported but are rare causes of acute cystitis.

Culture is the gold standard, and bacterial species may be identified preliminarily, but a final urine culture report usually is not available for 48 hours. However, rapid test surrogates for culture can support a UTI diagnosis and include microscopy, nitrite testing, and leukocyte esterase testing. Empiric treatment is initially begun but modified, as needed, after culture results are available.

**Culture Surrogates.** *Gram staining* is a simple, rapid, and sensitive method for detecting a concentration  $\geq 10^5$  cfu/mL of a bacterial species. Rapid identification allows appropriate selection of empiric antimicrobial therapy. However, realistically, such testing is typically limited to patients with complicated UTIs or acute pyelonephritis. Instead, *simple microscopic examination* of a urine specimen allows identification of both pyuria and bacteriuria. A specimen is examined expeditiously because leukocytes deteriorate quickly in urine that has not been appropriately preserved. Standards to define pyuria are inadequate, other than gross counts. Accordingly, the rapid test for leukocyte esterase has become a surrogate for the microscopic WBC count.

TABLE 3-16. Exclusions from “Uncomplicated” Cystitis

Diabetes
Pregnancy
Immunosuppression
Symptoms > 7 days
Postmenopausal hematuria
Recent UTI or urologic surgery
Documented urologic abnormalities
Recent hospital or nursing home discharge
Documented temperature above 38°C (100.4°F)
Abdominal and/or pelvic pain, nausea, vomiting
Symptoms of vaginitis (vaginal discharge/vulvar irritation)
Persisting symptoms despite > 3 days of treatment of urinary tract infection

UTI = urinary tract infection.

*Leukocyte esterase testing* measures esterase enzyme found in urinary leukocytes. If used alone diagnostically, this test is most beneficial for its high negative-predictive value, especially with bacterial colony counts  $\geq 10^5$  cfu/mL. If one combines nitrite and leukocyte esterase testing of a clean-catch uncontaminated voided specimen, the specificity of positive test results approaches 100 percent when uropathogen colony counts are  $\geq 10^5$  cfu/mL. The negative predictive value is comparable. However, if these specimens have been contaminated with vaginal or colonic bacteria or with trichomonads, the test result can be falsely positive for uropathogens. In addition, very concentrated urine or urine with significant proteinuria or glucosuria will decrease test accuracy.

*Nitrites* are produced from nitrates metabolized by bacteria. This is most frequently observed in the gram-negative uropathogen family typically responsible for acute UTIs in women. Unfortunately, this test does not identify *Pseudomonas* species or gram-positive pathogens such as staphylococci, streptococci, and enterococci. Moreover, first morning urine specimens are

ideally tested, because more than 4 hours are required for bacteria to convert nitrates to nitrites at levels that are detectable. As a single test, the specificity of a positive nitrite test is very high when uropathogen counts are  $\geq 10^5$  cfu/mL. Its negative predictive value is higher than its positive predictive value. Of note, substances that turn the urine red, such as the bladder analgesic phenazopyridine (Pyridium) or ingestion of beets, can lead to false-positive nitrite test results.

Treatment

During the past two decades, the frequency of infections caused by group B *Streptococcus* and *Klebsiella* species has increased, whereas *E coli* infection rates have diminished. Also, in many locations, sensitivity patterns in *E coli* may warrant a shift in initial empiric treatment (Table 3-17).

For significant dysuria, up to 2 days of a bladder analgesic such as phenazopyridine (Pyridium), 200 mg orally up to three times daily, may give significant relief. However, GI

TABLE 3-17. Treatment of Urinary Tract Infection

Infection Category	Antimicrobial Regimen
<b>Uncomplicated cystitis</b>	
Recommended regimens	Nitrofurantoin macrocrystals/monohydrate (Macrobid) 100 mg twice daily for 5–7 days or Trimethoprim-sulfamethoxazole DS 160/800 mg (Bactrim DS, Septra DS) twice daily for 3 days or Trimethoprim (Bactrim, Septra) 100 mg twice daily for 3 days or Nitrofurantoin macrocrystals (Macrodantin) 100 mg four times daily for 7 days or Fosfomycin tromethamine (Monurol) single 3-g dose once
Alternative regimens	Ciprofloxacin (Cipro) 250 mg twice daily for 3 days or Norfloxacin (Noroxin) 400 mg twice daily for 3 days or Levofloxacin (Levaquin) 250 mg daily for 3 days or Specific $\beta$ -lactams in 3- to 7-day regimens <sup>a</sup>
<b>Outpatient pyelonephritis</b>	
Recommended regimens	Ciprofloxacin 500 mg twice daily for 7 days <sup>b</sup> or Ciprofloxacin 1000 mg daily for 7 days <sup>b</sup> or Levofloxacin 750 mg daily for 5 days <sup>b</sup> or Trimethoprim-sulfamethoxazole DS 160/800 mg twice daily for 14 days <sup>b</sup>
Alternative regimens	Specific $\beta$ -lactams in 3- to 7-day regimens for 7–14 days <sup>a,b</sup>

<sup>a</sup>Suitable agents include amoxicillin-clavulanate, cefdinir, cefaclor, cefpodoxime-proxetil. DS = double strength.  
<sup>b</sup>If the prevalence of fluoroquinolone resistance is thought to exceed 10%, then an initial, single intravenous dose of a long-acting parenteral antimicrobial, such as 1 g of ceftriaxone or a consolidated 24-hr dose of an aminoglycoside, is recommended. Adapted with permission from American College of Obstetricians and Gynecologists: ACOG Practice Bulletin No. 91: Treatment of urinary tract infections in nonpregnant women, Obstet Gynecol 2008 Mar;111(3):785–794.

upset, yellow-orange stained urine and clothing, and hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency are potential side effects.

Following treatment, recurrences may develop. In those recurrently linked with intercourse, low-dose postcoital dosing with agents found in Table 3-17 is usually effective at preventing infection recurrence. A woman with two or more episodes of cystitis within 6 months or three infections within a year is considered for urologic evaluation of her urinary tract. These patients are commonly treated with daily prophylaxis for 6 months, in addition to modification of any risk factors such as diaphragm-spermicide use.

■ **Asymptomatic Bacteriuria**

This is defined as isolation of a specified quantitative count of bacteria in an appropriately collected urine specimen obtained from a person without symptoms or signs referable to urinary infection (Rubin, 1992). In healthy nonpregnant women, the prevalence of this condition increases with age. It is associated with sexual activity and is more common in diabetics. Moreover, one fourth to one half of elderly women in long-term care facilities have bacteriuria, which is seen primarily in those with chronic neurologic illness and functional impairment.

The Infectious Disease Society of America recommends that nonpregnant premenopausal women not be screened or treated for asymptomatic bacteriuria (Nicolle, 2005). The same is true for diabetic women and for older persons living in the community.

■ **Acute Pyelonephritis**

This infection may be divided into mild (no nausea or vomiting, normal to slightly elevated blood leukocyte count, and normal to low-grade fever) and severe (vomiting, dehydration, evidence of sepsis, high leukocyte count, and fever). Other symptoms include those of a lower urinary tract infection and varying degrees of back pain and tenderness to percussion over the region of the kidney(s).

Traditional therapy for this infection has included hospitalization, hydration, and intravenous antibiotic treatment for up to 2 weeks. However, studies in young healthy women with normal urinary tracts indicate that 7 to 14 days of oral therapy are sufficient for compliant women with mild infection (Gupta, 2011). In one study of more than 50 college women with acute uncomplicated pyelonephritis, resistance to trimethoprim-sulfamethoxazole was 30 percent (Hooton, 1997). Accordingly, for outpatient therapy, an oral fluoroquinolone is recommended treatment unless a pathogen is susceptible to trimethoprim-sulfamethoxazole. At initial diagnosis, clinicians may also administer a parenteral dose prior to starting oral therapy (see Table 3-17). Alternatively, if a causative organism is gram-positive, then amoxicillin-clavulanate, cefdinir, cefaclor, or cefpodoxime-proxetil are recommended options (Gupta, 2011).

Hospitalization is warranted for women who display clinical indications at initial evaluation or who fail to improve with outpatient therapy. Appropriate initial IV regimens include a fluoroquinolone; an aminoglycoside with or without ampicillin; an extended-spectrum cephalosporin or extended-spectrum penicillin with or without an aminoglycoside; or a carbapenem.

**TABLE 3-18.** Risk Factors for Postoperative Surgical Site Infection

Smoker
Preoperative anemia
Excessive blood loss
Intraoperative hypothermia
Lower socioeconomic status
Immunocompromised patient
Recent operative site surgery
Obesity (abdominal hysterectomy)
Prolonged surgical procedure (> 3.5 hr)
Foreign body placement (catheter, drain, etc.)
Perioperative HbA1c > 7% or CBG > 250 in diabetics

CBG = capillary blood glucose; HbA<sub>1c</sub> = hemoglobin A<sub>1c</sub>.

The choice among these agents is based on local resistance data and is tailored based on culture-derived susceptibility results.

**POSTOPERATIVE INFECTION**

Development of a postoperative infection can create significant patient morbidity, most seriously sepsis. Risks for postoperative infection are varied and include patient and surgical factors (Table 3-18). Of these, the degree of wound contamination at the time of surgery plays an important role. Because most gynecologic surgeries are elective, a gynecologist has time to decrease microbial inoculum. Thus, BV, trichomoniasis, cervicitis, and active urinary tract or respiratory infections ideally are treated and eradicated prior to surgery.

■ **Wound Classification**

Since 1964, surgical wounds have been classified according to the degree of bacterial contamination of the operative site at the time of surgery. In general, as the number of operative site bacteria (inoculum) increases, so too does the postoperative infection rate.

*Clean wounds* are most commonly found in procedures performed for nontraumatic indications, that are without operative site inflammation, and that avoid the respiratory, alimentary, and genitourinary tracts. No breaks occur in surgical technique. Thus, most laparoscopic and adnexal surgeries are considered to be in this category. Without prophylaxis, infection rates range from 1 to 5 percent. Prophylactic antimicrobial administration does not decrease infection rates following these procedures and is not required.

*Clean contaminated wounds* are those in which the respiratory, gastrointestinal, genital, or urinary tract is entered under controlled conditions, without unusual bacterial contamination. Criteria further define that there is no break in surgical technique. Infection rates range from 5 to 15 percent. This group encompasses many gynecologic procedures including total hysterectomy, cervical conization, and dilatation and curettage (D & C). Of these, hysterectomy is the gynecologic procedure most frequently followed by surgical site infection. These procedures are usually elective, and only hysterectomy and obstetric

D & C require antimicrobial prophylaxis to reduce postoperative infection rates (American College of Obstetricians and Gynecologists, 2014a).

*Contaminated wounds* reflect operations with major breaks in sterile technique or gross GI spillage or incisions in which acute, nonpurulent inflammation is encountered (Mangram, 1999). Infection rates approximate 10 to 25 percent. For this reason, a minimum of 24 hours of perioperative antimicrobial administration is required, and delayed wound closure may be selected. Laparoscopy or laparotomy for acute salpingitis is included in this category.

Dirty wounds are typically old traumatic wounds or those that involve existing clinical infection or perforated viscera. If an abscess is present, these are considered dirty wounds. These operative sites are clinically infected at the time of surgery, and infection rates range from 30 to 100 percent. Accordingly, therapeutic antimicrobial therapy is required, and these wounds typically are allowed to close by secondary intention.

### ■ Surgical Site Infection Classification

The CDC provides definitions of hospital-acquired surgical site infections (SSIs). The Joint Commission currently is emphasizing this morbidity during their hospital accreditation process. Thus, hospitals are more attentive to infection rates and to the rates of individual surgeons.

In classifying SSIs, there are two categories, incisional and organ space (Fig. 3-13). Criteria for each category are detailed in Table 3-19. The incisional group is further subdivided into superficial and deep classes. Organ/space infections develop in

**FIGURE 3-13** Anatomy and classification of surgical site infections (SSI). (Modified with permission from Mangram AJ, Horan TC, Pearson ML, et al: Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee, Infect Control Hosp Epidemiol 1999 Apr;20(4):250–278.)

spaces or organs other than that opened by the original incision or manipulated during the surgical procedure. Specific sites include the vaginal cuff, urinary tract, and intraabdominal sites. Of note, vaginal cuff infections are generally considered in the organ/space class, presuming they meet at least one of these criteria: purulent drainage from the cuff, abscess at the cuff, or pathogens cultured from fluid or tissue obtained from the cuff. Pelvic infections such as adnexal infection, pelvic abscess, or infected pelvic hematoma also fall into the category of organ/space infection.

### ■ Diagnosis

#### Physical Findings

For febrile morbidity, the most frequently used definition is an oral temperature of  $\geq 38^{\circ}\text{C}$  ( $\geq 100.4^{\circ}\text{F}$ ) on two or more occasions, 4 or more hours apart, and 24 or more hours following surgery. This condition is seen most often after hysterectomy, particularly abdominal hysterectomy; usually is not associated with other symptoms or signs of infection; and does not require antimicrobial therapy! It has been reported in up to 40 percent of women following abdominal and almost 30 percent of women after vaginal hysterectomy with antimicrobial prophylaxis. It resolves without antibiotic treatment in the absence of other symptoms or signs of infection.

A remote nonsurgical site may also serve as an origin of fever. These may include pulmonary complications, IV site phlebitis, and UTI. Thus, women who develop recurrent temperature elevation require a thorough history and a careful physical examination by the surgeon, seeking not only surgical but also nonsurgical causes (Fig. 42-2, p. 920).

Operative site pain (incisional, lower abdominal, pelvic, and/or lower back) following surgery is normal. However, those with an operative site infection report increasing pain at the surgery site, and increasing tenderness is present during physical examination. With superficial SSI, pain is superficial and localized to the incision. With pelvic infection, there is deep lower abdominal and/or pelvic pain, and the most common infection sites are the parametria and the vaginal surgical margin. Pelvic abscess or infected pelvic hematoma is least common, and pain is central.

Abdominal palpation is an integral part of SSI diagnosis. Avoiding an abdominal incision if present, a surgeon slowly, gently, and deeply palpates the lower abdomen over the surgical site following hysterectomy and normally elicits patient discomfort. Tenderness does not mean an acute surgical abdomen or infection. In the immediate postoperative period, this tenderness is expected and decreases quickly. Women who develop pelvic cellulitis or cuff cellulitis will have increasing tenderness at gentle depression of the lower abdominal wall over the infected area. Tenderness may be bilateral, but more commonly is more marked on one side. Peritoneal signs are not present. Cellulitis, whether it involves the parametria, adnexa, or vaginal cuff, is not associated with a mass.

In the absence of increasing lower abdominal pain and tenderness, a bimanual examination is not necessary for asymptomatic temperature elevation. However, with a combination of fever, increasing tenderness, and new-onset pain, gentle bimanual examination is required to accurately identify the infection site and to exclude or diagnose a mass. Speculum examination usually

**TABLE 3-19.** Criteria for Defining Surgical Site Infections (SSIs)

**Superficial incisional**

Involves only skin and subcutaneous tissue of the incision  
Develops within 30 days of surgical procedure  
Features at least one of the following:  
Purulent drainage from the superficial incision  
Bacteria in culture obtained aseptically from fluid or tissue from the superficial incision  
Incision deliberately opened by surgeon and is culture positive (or not cultured) and patient has at least one of the following incisional signs or symptoms:  
Tenderness or pain  
Heat or redness  
Localized swelling  
SSI diagnosis made by surgeon or attending physician  
Stitch abscesses are not included in this category  
Diagnosis of “cellulitis,” by itself, does not meet criterion for SSI

**Deep incisional**

Involves the deep soft tissues (muscle and fascia) of the incision  
Develops within 30 days of surgical procedure  
Features at least one of the following:  
Purulent drainage from deep incision of surgical site (but not organ or space component)  
Deep incision that spontaneously dehisces or is deliberately opened by a surgeon and is culture-positive (or not cultured) and patient has at least one of the following signs or symptoms:  
Temperature  $\geq 38^{\circ}\text{C}$  ( $100.4^{\circ}\text{F}$ )  
Localized pain or tenderness  
Abscess or other infection found by reoperation, histopathology, or radiology

**Organ/space**

Involves any body part that was opened or manipulated during the operative procedure, excluding the skin incision, fascia, or muscle layers  
Develops within 30 days of the surgical procedure  
Features at least one of the following:  
Purulent drainage from a drain placed through a stab wound into the organ/space  
Bacteria obtained aseptically from tissue or fluid in that organ/space  
Abscess found by reoperation, histopathology, or radiology  
Vaginal cuff infection with purulence, abscess, and/or positive tissue or fluid culture is included in this category

Reproduced with permission from Centers for Disease Control and Prevention: Procedure-associated module: surgical site infection (SSI) event, 2014.

is not required, and findings are similar with or without an existing infection. As is true for routine pelvic examination, most information at bimanual examination is obtained from the vaginal fingers. If a patient is too tender to allow adequate examination, vaginal sonography is indicated. Bowel function is usually not altered by soft-tissue cellulitis but can be by pelvic abscess or infected pelvic hematoma.

Testing

Pelvic infections following hysterectomy are polymicrobial, and for that reason, it is difficult to identify true pathogens. Research has demonstrated that bacteria recovered transvaginally from the pelves of infected and clinically uninfected women are similar. Accordingly, routine transvaginal culturing of women with cuff or pelvic cellulitis does not add useful information. Moreover, a surgeon should not wait for culture results before starting empiric broad-spectrum antibiotic therapy. However, if initial therapy

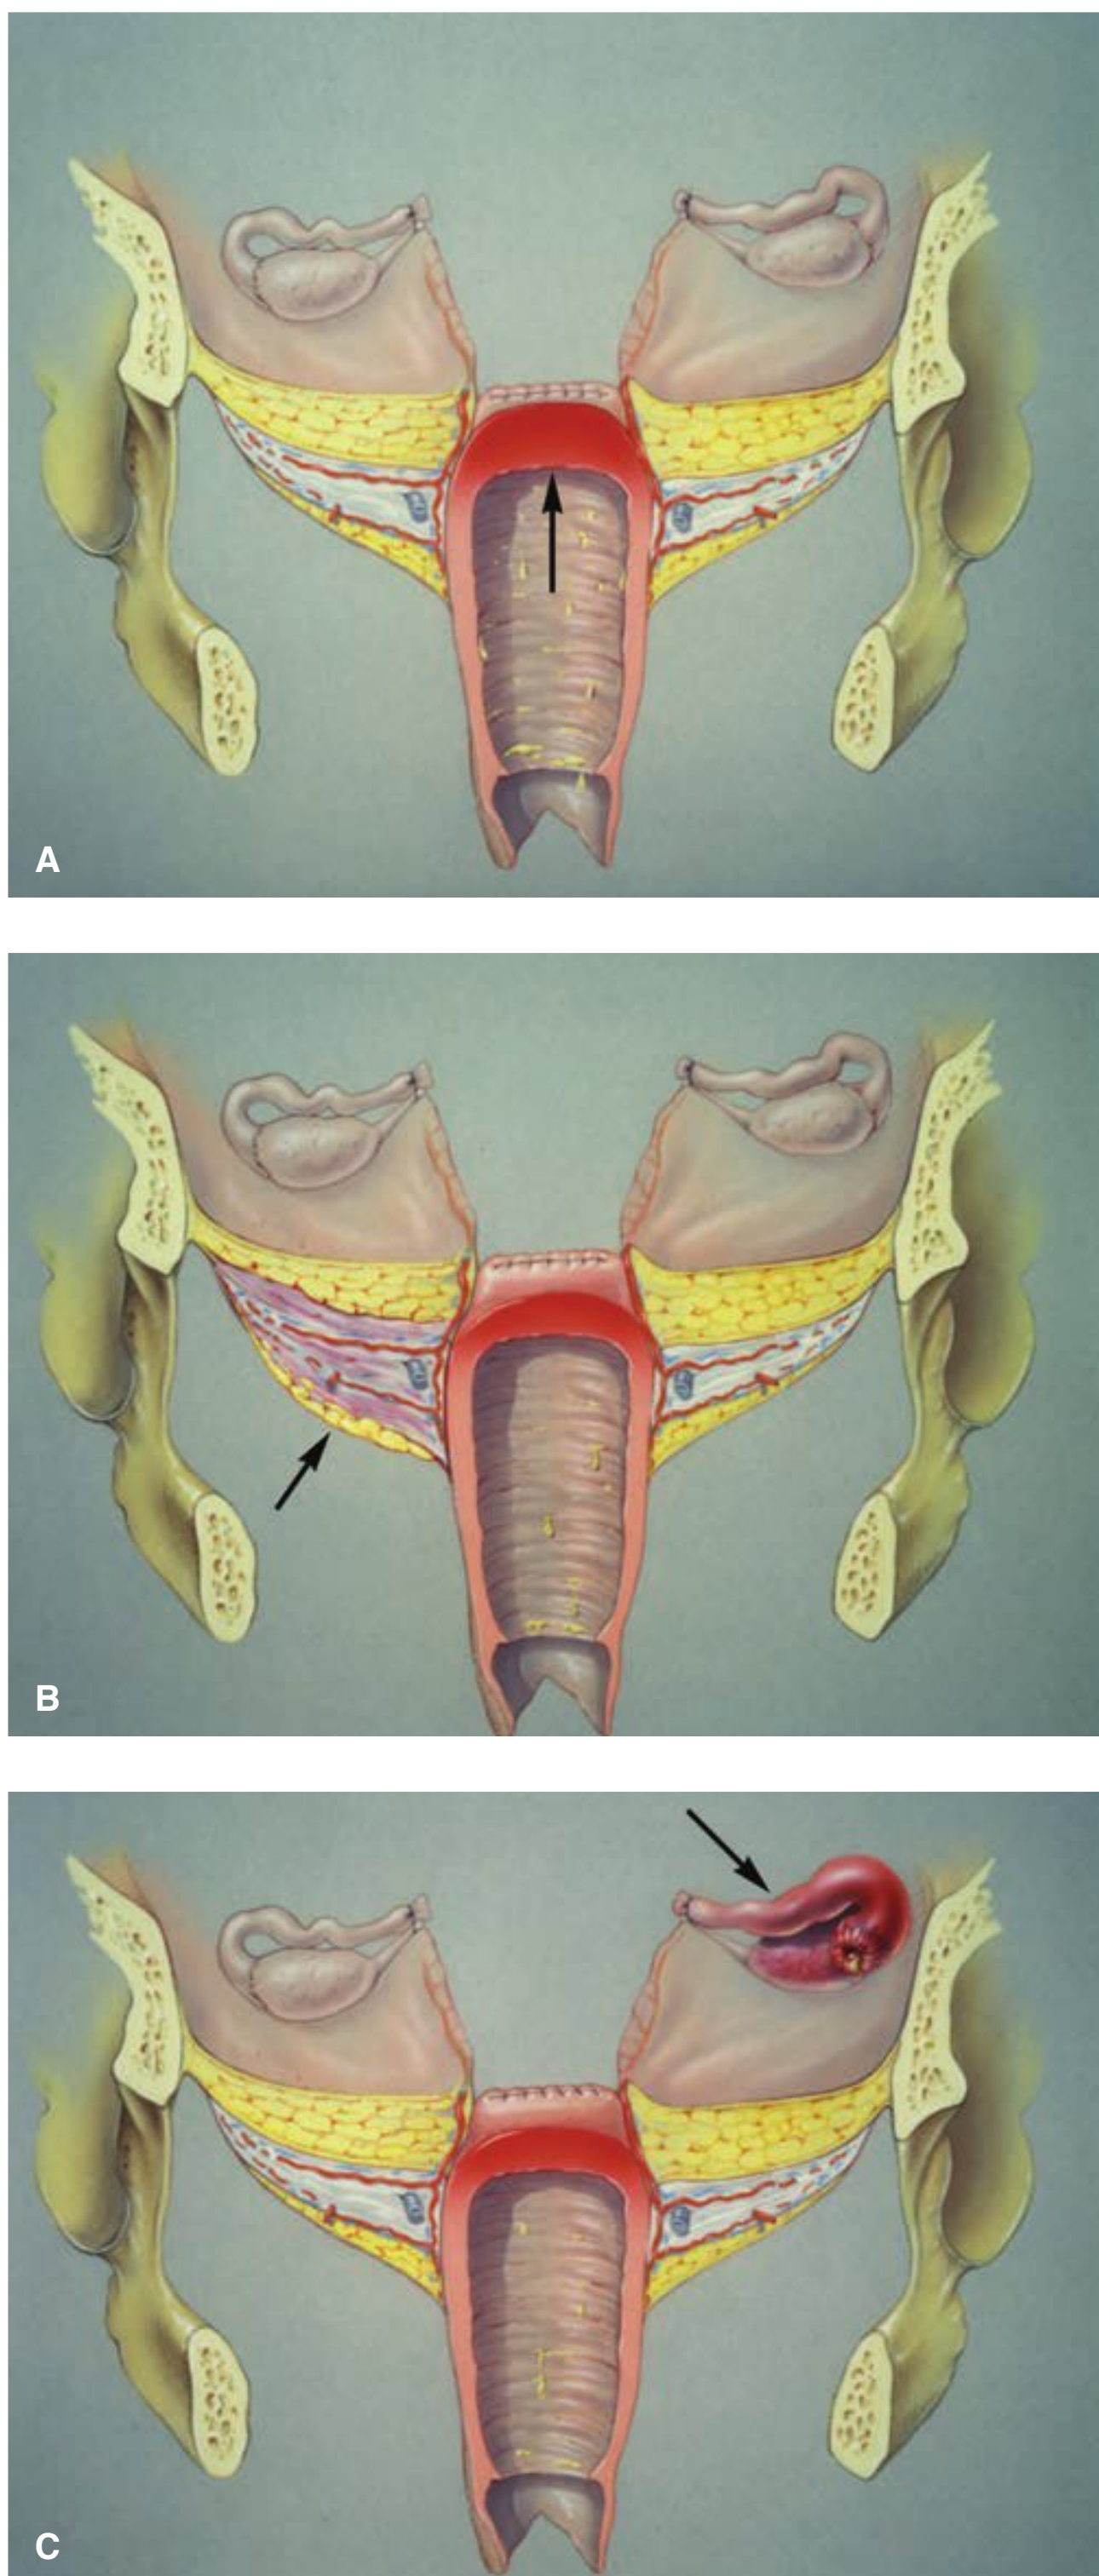

is partially effective or unsuccessful, then a culture will more predictably identify pathogen(s) since therapy will have eradicated other species. The antibiotic regimen should be changed, and culture results may direct this change. In contrast, abscess or infected hematoma fluid are cultured since those species are less likely to be vaginal contaminants. The same is true for any fluid or purulent material present in an abdominal incision.

For many postoperative SSIs, imaging is not mandatory. However, if additional anatomic information is needed, then transvaginal sonography or CT scanning are the most often used, and selection depends on clinical circumstances and suspected etiology.

■ **Specific Infections**  
Vaginal Cuff Cellulitis

Essentially all women develop this infection at the vaginal surgical margin after hysterectomy (Fig. 3-14). Normal response

**FIGURE 3-14** Organ/space infections. **A.** Vaginal cuff cellulitis. The vaginal surgical margin is edematous, hyperemic, and tender, and there are purulent secretions in the vagina. Parametria and adnexa are normal during gentle bimanual examination. **B.** Pelvic cellulitis in the right parametrium. It is indurated and tender to palpation; no mass is present. **C.** Adnexal infection after hysterectomy. The parametria are normal. Tenderness without a mass is appreciated in the adnexal area.

to healing is characterized by small-vessel engorgement, which results in erythema and heat. There is vascular stasis with endothelial leakage resulting in interstitial edema, which causes induration. This area is tender, microscopic evaluation of a wet prep reveals numerous WBCs, and purulent discharge is seen in the vagina. This process usually subsides, does not require treatment, and accordingly, does not require reporting as a SSI. The few women who do require treatment are usually those who present after hospital discharge with mild, but increasing, new-onset lower abdominal pain and have a yellow vaginal discharge. Findings are as above, but the vaginal cuff is more tender than anticipated at this interval from the initial surgical procedure. Oral antimicrobial therapy with a single broad-spectrum agent is appropriate (Table 3-20). A patient is then reevaluated in several days to assess therapeutic efficacy. This may be completed by phone or with an examination if necessary.

### Pelvic Cellulitis

This is a common infection following either vaginal or abdominal hysterectomy. It develops when host humoral and cellular defense mechanisms, combined with preoperative antibiotic prophylaxis, cannot overcome the bacterial inoculum and inflammatory process at the vaginal surgical margin. The inflammatory process spreads into the parametrial region(s) resulting in lower abdominal pain, regional tenderness, and fever, usually during the late second or third postoperative day. There are no peritoneal signs and bowel and urinary function are normal, but the patient may note anorexia.

Patients are discharged on perhaps their first or second postoperative day following vaginal hysterectomy, and affected women may be at home before symptom onset. Hospitalization and treatment with an IV broad-spectrum antibiotic regimen found in Table 3-20 is indicated until a patient has been afebrile for 24 to 48 hours. She then may be discharged home. Most patients requiring hospitalization for IV antibiotic therapy are discharged with a 5- to 7-day oral antimicrobial prescription. Single-agent therapeutic regimens have been shown in prospective randomized trials to be as effective as combination-agent regimens. These infections are polymicrobial, and the regimen selected must have coverage for gram-positive and gram-negative aerobic and anaerobic bacteria.

### Adnexal Infection

This infection is uncommon and presents almost exactly like pelvic cellulitis. The difference is in the location of tenderness during bimanual pelvic examination. The cuff and parametrial areas are not usually tender, but the adnexa are. This infection also may develop after tubal ligation, surgical therapy for ectopic pregnancy, or other adnexal surgery. Empiric antibiotic regimens are identical to those for pelvic cellulitis (see Table 3-20).

### Ovarian Abscess

A rare but life-threatening complication following primarily vaginal hysterectomy is ovarian abscess. Presumably with this infection, surgery is performed in the late proliferative phase of an ovulatory menstrual cycle, and ovaries are in close proximity to the vaginal surgical margin. As expected, physiologic cuff

**TABLE 3-20.** Empiric Antimicrobial Regimens for Postgynecologic Surgery Infections

Regimen	Dose
<b>Single-agent intravenous</b>	
Cephalosporin	
Cefoxitin (Mefoxin)	2 g every 6 hr
Cefotetan (Cefotan)	2 g every 12 hr
Cefotaxime (Claforan)	1–2 g every 8 hr
Penicillin ± $\beta$ -lactamase inhibitor	
Piperacillin	4 g every 6 hr
Piperacillin/tazobactam (Zosyn)	3.375 g every 6 hr
Ampicillin/sulbactam (Unasyn)	3 g every 6 hr
Ticarcillin/clavulanate (Timentin)	3.1 g every 4–6 hr
Carbapenems	
Imipenem/cilastatin (Primaxin)	500 mg every 8 hr
Meropenem (Merrem)	500 mg every 8 hr
Ertapenem (Invanz)	1 g once daily
<b>Combination agent intravenous</b>	
{ Metronidazole (Flagyl) plus	Loading dose 15 mg/kg;
	maintenance 7.5 mg/kg every 6 hr
{ Ampicillin plus	2 g every 6 hr
	Gentamicin 3–5 mg/kg once daily
OR	
{ Clindamycin plus	900 mg every 8 hr
	Gentamicin 3–5 mg/kg once daily
	with or without ampicillin 2 g every 6 hr
<b>Oral agents</b>	
Amoxicillin/clavulanate (Augmentin)	875 mg twice daily
Levofloxacin (Levoquin)	500 mg once daily
Clindamycin	300 mg every 6 hr
Metronidazole	500 mg every 6 hr

cellulitis develops normally, but when ovulation occurs, local bacteria gain access to the ovulation site and the corpus luteum. The corpus luteum often is hemorrhagic, and the blood in this functional cyst provides a perfect medium for bacterial growth.

Affected women have an essentially normal postoperative course until approximately 10 days following surgery. At this time, they experience acute unilateral lower abdominal pain, which then involves multiple quadrants. These symptoms reflect rupture of their abscess and development of generalized abdominal peritonitis. Sepsis commonly follows, and this is a true gynecologic emergency. Immediate exploratory laparotomy is necessary, with IV administration of perioperative broad-spectrum antimicrobials, abscess evacuation, and adnexectomy if easily accessible. At a minimum, necrotic tissues are debrided. After hospital discharge, oral antibiotics are typically continued for an additional 5 to 7 days, and this is variable depending on the clinical course.

Similarly, women rarely may develop a tuboovarian abscess (usually a pyosalpinx) identical to that seen as an end result of acute PID. This process can be managed medically with

IV antimicrobials, and surgery is usually not required unless rupture follows. Combination antimicrobial therapy is continued until a woman has been afebrile for 48 to 72 hours. At this point, IV antibiotics may be replaced by oral agents, which are continued outpatient to complete a 2-week course of therapy. Patients diagnosed with TOA are reevaluated approximately 3 days following hospital discharge and then again 1 and 2 weeks later to document abscess resolution.

### Pelvic Abscess/Infected Pelvic Hematoma

Pelvic abscess not involving an adnexal structure may also uncommonly complicate hysterectomy (Fig. 3-15). This develops from blood, serum, and/or lymph collections following hysterectomy that provide an excellent milieu for the overgrowth of bacteria inoculated into the adjacent tissues during the surgical procedure. An alternative infection can originate within a surgical pelvic hematoma. With hematoma, a postoperative-day-1 hemoglobin classically is significantly lower than that predicted by measured intraoperative blood loss. Reoperation is not required in most instances, and fluid or blood product resuscitation suffices. Unlike women who develop tissue cellulitis following surgery and whose early symptom of infection is pain and not fever, women with an infected hematoma will have low-grade temperature elevation ( $> 37.8^{\circ}\text{C}$ ) as their early finding. Pain is a late symptom for these women. Accordingly, women with

an unexplained postoperative hemoglobin decrease are discharged with instructions to monitor their temperature twice

**FIGURE 3-15** Pelvic abscess or infected hematoma that is extra-peritoneal and cephalad to the vaginal margins.

**FIGURE 3-16** Transvaginal sonogram of an infected pelvic hematoma following hysterectomy. This 11 × 12 cm collection of blood and clot was drained vaginally in the operative room. (Used with permission from Dr. Elysia Moschos.)

daily for approximately 1 week. Temperatures  $\geq 37.8^{\circ}\text{C}$  typically warrant evaluation.

Signs and symptoms of pelvic abscess or infected hematoma are midline, and a mass is discernible centrally. Transvaginal sonography can accurately characterize the dimensions (Fig. 3-16). For both, hospital readmission for therapy is usually necessary. Combination-agent IV antimicrobial therapy is indicated, and selected regimens provide gram-positive and gram-negative aerobic and anaerobic coverage. Additionally, opening the vaginal surgical margin, if possible, to allow drainage will aid treatment and accelerate patient response. This can usually be done in a treatment room early, avoiding return to the operating room. If necessary, these can be drained with sonographic transvaginal guidance or in the operating room. These abscesses or infected hematomas usually remain confined to the extraperitoneal space, and a patient does not usually develop peritonitis. Some patients may develop diarrhea due to the proximity of the rectum, which is usually adjacent to the infected space.

Combination IV antibiotics are administered until a woman has been afebrile 48 to 72 hours. IV antibiotics may then be replaced by oral agents, which are continued outpatient to complete a 2-week course of therapy, if the abscess or hematoma is not drained. If drained, then oral agents continued for 5 to 7 days following IV agents typically is sufficient. Commonly, patients are reevaluated 3 days following hospital discharge and then again 1 and 2 weeks later to document infection resolution.

### Abdominal Incision Infection

The superficial and easily accessible location of this infection aids its diagnosis. Although abdominal incision infection may develop alone or with pelvic infection following abdominal hysterectomy, it develops uncommonly after other gynecologic procedures. Unlike pelvic infection, the incidence of this infection is not altered by antimicrobial prophylaxis. Risk factors include obesity, immunosuppression, diabetes, excessive electrosurgical

coagulation use, passive drains, and coexistent skin inflammation at the time of surgical incision.

Abdominal incisions are usually the most uncomfortable following gynecologic surgery, but pain decreases daily. Erythema and heat are the first physical signs of this infection, which is usually diagnosed on the fourth or fifth postoperative day—again, after discharge from the hospital. A hematoma or seroma may develop in the abdominal wall incision without infection. If these collections are large, opening of the incision and evacuation to prevent infection in those fluids is warranted. Similarly, pus requires incision opening to ensure an intact fascia, as should be done with large seromas or hematomas.

Drainage and local care are usually the basis of successful therapy for abdominal incision infection or for large hematoma or seroma. Wet-to-dry dressings stimulate fibroblastic proliferation and development of healthy granulation tissue. Moistening the dry dressing prior to its removal will ease removal and decrease patient discomfort. At this stage, secondary closure can be considered. Importantly, wounds are irrigated with normal saline. Povidone-iodine, iodophor gauze, hydrogen peroxide, and Daiken solution are avoided as they are caustic to healing tissues. Some recommend their use early but follow with normal saline irrigation. Negative-pressure wound therapy provided by vacuum-assisted wound closure devices is available for more serious or larger wound areas that are slow to respond once the wound has a clean, granulating base (Chap. 42, p. 920).

If there is soft-tissue cellulitis adjacent to the incision, antimicrobial therapy is required. If the initial surgery was a clean procedure, then *Staphylococcus* species predominate. Following clean-contaminated or dirty procedures, isolated organisms commonly include gram-negative bacteria such as *E coli*, *Pseudomonas aeruginosa*, and *Enterobacter* species and gram-positive bacteria, namely, *Staphylococcus* and *Enterococcus* species (Kirby, 2009). Anaerobes are typically not prominent pathogens in these infections but may be present, especially following hysterectomy. Thus, these infections are usually polymicrobial. Antibiotics found in Table 3-20 are suitable regimens.

### Toxic Shock Syndrome

This condition, caused by an exotoxin (TSS toxin-1) produced by *Staphylococcus aureus*, appears approximately 2 days following surgery or menstruation onset. Menstrual-associated toxic shock syndrome (TSS) rates have diminished following changes in tampon composition and use. For TSS, the vagina or wound must be colonized by a toxigenic staphylococcal strain, and the patient must lack the specific antibody that can block the superantigen.

The classic TSS symptoms include fever, malaise, and diarrhea. If postoperative, there are minimal signs of wound infection. A patient has conjunctival and pharyngeal hyperemia without purulence. The tongue is usually reddened, and the skin on the trunk is erythematous but not painful or pruritic. Temperatures are usually above  $38.8^{\circ}\text{C}$ , and orthostatic hypotension or shock may be present. This syndrome results from host cytokines released in response to superantigenic properties of the toxin. The criteria for this diagnosis are presented in Table 3-21.

**TABLE 3-21.** Criteria for Diagnosis of Toxic Shock Syndrome

**Major criteria**

- Hypotension
- Orthostatic syncope
- Systolic BP < 90 mm Hg for adults
- Diffuse macular erythroderma
- Temperature ≥ 38.8°C
- Late skin desquamation, particularly on hands, palms, and soles (1–2 weeks later)

**Minor criteria (organ system involvement)**

- Gastrointestinal: diarrhea or vomiting
- Mucous membranes: oral, pharyngeal, conjunctival, and/or vaginal erythema
- Muscular: myalgia or creatinine level greater than twice normal
- Renal: BUN and creatinine greater than twice normal or > 5 WBCs/hpf in urine, without concurrent UTI
- Hematologic: platelet count < 100,000 per mm<sup>3</sup>
- Hepatic: SGOT, SGPT, and/or bilirubin levels greater than twice normal
- Central nervous system: altered consciousness without focal localizing signs

BP = blood pressure; BUN = blood urea nitrogen; hpf = high-power field; SGOT = serum glutamic oxaloacetic transaminase; SGPT = serum glutamic pyruvic transaminase; UTI = urinary tract infection; WBC = white blood cell.

The wound, if present, is treated like any other wound. It is cultured to confirm presence of *S aureus*. However, results from other cultures (e.g., blood, throat, and cerebrospinal fluid) will be negative. To meet the strict criteria, a woman must have all major and at least three minor criteria. If this is suspected early and therapy is initiated, the complete syndrome may not develop. Serologies for Rocky Mountain spotted fever, measles, and leptospirosis must be negative. Viral infection and group A streptococci can cause a similar presentation.

While awaiting culture results for selection of specific antistaphylococcal antibiotics, empiric therapy covers both methicillin-susceptible and methicillin-resistant *S aureus*. Vancomycin (15 to 20 mg/kg/dose) can be given every 8 to 12 hours, not exceeding 2 g per dose. Some experts argue for the addition of clindamycin, but further evidence is needed. Regardless, the hallmark of therapy is entire system support with large volumes of IV fluids and electrolytes to replace massive body fluid losses from diarrhea, capillary leakage, and insensible loss. These patients may develop significant edema and are best managed in an intensive care unit. Even with appropriate management, the death rate has been reported to be as high as 5 percent because of subsequent acute respiratory distress syndrome (ARDS), disseminated intravascular coagulopathy (DIC), or hypotension unresponsive to therapy with resultant myocardial failure. This syndrome may also follow gynecologic surgical procedures such as D & C, hysterectomy, urethral suspension, and tubal ligation.

**Necrotizing Fasciitis**

Although described in the 1870s, it was not named until 1952, by a Parkland Hospital surgeon (Wilson, 1952). Risk factors for this postoperative incision infection are age older than 50 years, arteriosclerotic heart disease, diabetes mellitus, obesity, debilitating disease, smoking, and previous radiation therapy, all of which are associated with decreased tissue perfusion.

In our clinical service, vulvar infection in obese diabetic women is a prominent risk. Only approximately 20 percent of cases follow surgery, the majority developing after minor injuries or insect bites. Bacteria recovered from women with this infection are similar to those recovered from any postoperative gynecologic infection site, namely predominantly *E coli*, *E faecalis*, *Bacteroides* spp, *Peptostreptococcus* spp, *S aureus*, and groups A and B hemolytic streptococci.

Although this postoperative superficial incisional infection begins like any other postoperative infection with pain and erythema, its hallmark is subcutaneous and superficial fascial necrosis, manifested by excessive tissue edema in adjacent areas. There also may be associated myonecrosis. Blisters or bullae form in tissue that has become avascular and is discolored (Fig. 3-17). Crepitus or induration and edema beyond the region of visible erythema may be present. Tissue destruction is far more extensive than is evident by surface examination. The skin will slip over underlying tissue, and if incised, due to the lack of vascularity, there will be no bleeding but instead usually a thin gray transudate. Severe systemic toxicity and fever may develop. In obvious cases, no imaging is needed, and patients are prepared for surgical debridement. In less-clear cases, radiographs or CT scans, if these can be quickly obtained, may add information by revealing gas in affected tissues produced by clostridial species such as *Clostridium perfringens*.

Although broad-spectrum antibiotic administration is required, the cornerstone of treatment is prompt recognition and immediate surgical removal of necrotic tissue to a level at which viable bleeding tissue is reached. To achieve this, excision of large tissue volumes are often needed. Although this is potentially disfiguring, postponing surgery while waiting for antimicrobial activity only increases the volume of tissue death. Gynecologists may enlist assistance from a general surgeon or gynecologic oncologist if extensive debridement into the posterior perineal triangle, buttock, or inner thigh

**FIGURE 3-17** Vulvar necrotizing fasciitis in an obese, diabetic patient. **A.** Preoperative image of the perineum with notable edema and skin bullae. **B.** The required intraoperative resection was extensive (Used with permission from Dr. Laura Kilmer.)

is anticipated. Early fatality rates for patients with this infection approximated 20 percent in the systematic review of 1463 patients by Goh and associates (2014).

Wounds are left open and treated as wound infections as described earlier with local hydrotherapy or a wound vacuum device. Assistance from a general surgeon for potential grafting is often necessary.

### Methicillin-resistant *Staphylococcus aureus*

Any of the polymicrobial infections discussed in this section may be complicated by MRSA. To cover MRSA, suitable outpatient oral antibiotics for uncomplicated infection include trimethoprim-sulfamethoxazole DS (160 mg/800 mg) twice daily, clindamycin 300 or 450 mg three times daily, doxycycline or minocycline 100 mg twice daily, or linezolid (Zyvox) 600 mg twice daily. For complicated infections, the Infectious Disease Society of America recommends MRSA coverage with IV vancomycin, IV or oral clindamycin, IV or oral linezolid 600 mg twice daily, IV daptomycin (Cubicin) 4 mg/kg once daily, or IV telavancin (Vibativ) 10 mg/kg once daily (Liu, 2011). Newer FDA-approved agents against complicated MRSA infections include ceftaroline (Teflaro), dalbavancin (Dalvance), oritavancin (Orbactive), and tedizolid (Sivextro) (Holmes, 2014). These newer drugs are expensive and may have restricted formulary use to only infectious disease specialists.

## OTHER GYNECOLOGIC INFECTIONS

### ■ Vulvar Abscess

These infections develop similarly to other superficial abscesses but have the potential for significant expansion due to the loose areolar subcutaneous tissue in this area. Risk factors include diabetes, obesity, perineal shaving, and immunosuppression. Common isolates include *Staphylococcus*, group B *Streptococcus*, *Enterococcus* species, *E coli*, and *P mirabilis*. Importantly, Turman (2008) and Kilpatrick (2010) and their coworkers found MRSA in 40 to 60 percent of cultured vulvar abscesses.

In early stages, surrounding cellulitis may be the most prominent finding and only a small or no abscess is identified. In these cases, sitz baths and oral antibiotics are reasonable treatment. When present, smaller abscesses may be treated with incision and drainage, abscess packing if indicated, and oral antibiotics to treat surrounding cellulitis. For uncomplicated infection, suitable oral agents will be broad-spectrum and will cover MRSA. Trimethoprim-sulfamethoxazole may be used alone. Two-drug therapy with clindamycin or doxycycline combined with a second-generation cephalosporin or with a fluoroquinolone is also a suitable choice, among others. However, for those with immunosuppression or diabetes, hospitalization and IV antibiotic therapy is often warranted due to increased risks for necrotizing fasciitis in these individuals. Again, coverage for MRSA is included in IV regimens (Table 3-20).

Large abscesses typically require admission for drainage under anesthesia. This provides adequate pain control for abscess drainage and for abscess cavity exploration to disrupt loculated areas of pus, as described in Section 43-21 (p. 977).

### ■ Bartholin Gland Duct Abscess

This infection is managed primarily by drainage (Fig. 3-18). Drainage can typically be completed in an outpatient setting and is described in Section 43-18 (p. 971). Antibiotics are commonly added to treat surrounding tissue cellulitis. The most common bacteria isolated from these abscesses include anaerobic *Bacteroides* and *Peptostreptococcus* spp and aerobic *E coli*, *S aureus*, and *E faecalis* (Bhide, 2010; Kessous, 2013). Also, *N gonorrhoeae* and *C trachomatis* may be identified (Bleker, 1990). Accordingly, polymicrobial coverage is selected, and suitable single-agent oral outpatient therapy includes, among others, trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, second-generation cephalosporins, or fluoroquinolones, such as ciprofloxacin. In most cases, abscess aerobic cultures are obtained. Depending on patient risks, NAATs for *N gonorrhoeae* and *C trachomatis* and screening for other STDs may be included.

**FIGURE 3-18** Bartholin gland duct abscess with some pus spontaneously draining onto the perineum.

### ■ Actinomyces Infection

*Actinomyces israelii* is a gram-positive, slow-growing, anaerobic bacterium found to be part of the indigenous genital flora of healthy women (Persson, 1984). Some have found it more frequently in the vaginal flora of IUD users, and rates of colonization increase with duration of IUD use (Curtis, 1981). *Actinomyces* is also identified in Pap smears, and Fiorino (1996) cited a 7-percent incidence in IUD users compared with less than 1 percent in nonusers. Pelvic infection and abscess are rare, even in those identified to harbor the bacteria. Accordingly, in the absence of symptoms, the incidental finding of *Actinomyces* on cytology may be managed by: (1) expectant management, (2) extended oral antibiotic treatment with the IUD in place, (3) IUD removal, or (4) IUD removal followed by antibiotic treatment (American College of Obstetricians and Gynecologists, 2013a). In support of conservative observation, reviews by Lippes (1999) and Westhoff (2007) suggest that asymptomatic women may retain their IUDs and do not require antibiotic treatment. With the higher rate of current IUD use, this will no doubt be an increasingly important topic. Importantly, if signs or symptoms of infection develop in women who harbor *Actinomyces*, the device is removed and antimicrobial therapy instituted. Early findings include fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge. *Actinomyces* is sensitive to antimicrobials with gram-positive coverage, notably the penicillins.

REFERENCES . . . . . 102

The lower reproductive tract, comprising the vulva, vagina, and cervix, exhibits a wide spectrum of benign and neoplastic diseases. Disorder characteristics often overlap, and thus differentiating normal variants, benign disease, and potentially serious lesions can be challenging. Lower reproductive tract infection is a frequent cause and discussed in Chapter 3, whereas congenital anomalies and preinvasive neoplasia are infrequent and described in Chapters 18 (p. 404) and 29 (p. 624). The benign lesions highlighted in this chapter are common, and mastery of their identification and treatment is essential.

VULVAR ASSESSMENT

Vulvar skin is more permeable than surrounding tissues because of differences in structure, hydration, occlusion, and friction susceptibility (Farage, 2004). Accordingly, pathology can develop in this area, although frequency estimates are difficult because of patient underreporting and clinician misdiagnosis. Lesions may result from allergen or irritant exposure, infection, trauma, or neoplasia. As a result, symptoms may be acute or chronic and include pain, pruritus, dyspareunia, bleeding, and discharge. Effective therapies are available for most disorders, yet embarrassment and fear may prove significant roadblocks to care for many women.

■ General Approach to Vulvar Complaints

The initial encounter includes reassurance that the patient’s complaints will be investigated thoroughly. Women often

minimize and may be uncomfortable with describing their symptoms. They may relate protracted histories of assorted diagnoses and treatments by numerous providers and may voice frustration and doubt that relief is possible. Patients are not promised a cure but rather that every effort will be made to alleviate their symptoms. This can require multiple visits, tissue sampling, treatment attempts, and even a multidisciplinary plan. A patient-provider partnership approach to management enhances compliance and care satisfaction.

During counseling, the suspected diagnosis, current treatment plan, and recommended vulvar skin care are outlined. Printed materials that explain common conditions, medication use, and skin care are helpful. Patients are often relieved to learn that their complaints and conditions are not unique. Thus, referral to national websites and support groups is usually welcomed.

■ Diagnosis

History

Scheduling adequate time for the initial evaluation is a wise investment, as detailed information is essential. Symptom characterization includes descriptions of abnormal sensations, duration, precise location, and associated vaginal pruritus or discharge. Patients often refer to vulvar pruritus as vaginal, and symptom location should be clarified. A thorough medical history addresses systemic illnesses, medications, and known allergies. Obstetric, sexual, and psychosocial histories and any potentially provocative events around the time of symptom onset often suggest etiologies. Hygiene and sexual practices should be investigated in detail.

Of symptoms, vulvar pruritus is frequent with many dermatoses. Patients may have been previously diagnosed with psoriasis, eczema, or dermatitis at other body sites. Isolated vulvar pruritus may be associated with a new medication. Patients may identify foods that provoke or intensify symptoms, and in such cases, a food diary may be helpful. Most often, vulvar pruritus is due to a contact or allergic dermatitis. Common offenders include strongly scented body soaps and laundry products. Excessive washing and use of wash cloths can result in skin drying and mechanical trauma. Washing often becomes more aggressive with pruritus as patients assume their hygiene is lacking. Any of these practices can create an escalating itch-scratch cycle or exacerbate the symptoms of other preexisting dermatoses. Last, patients frequently use nonprescription remedies for relief of vulvovaginal itching or perceived odor. These products commonly contain multiple known contact allergens, and their use is discouraged (Table 4-1).

**TABLE 4-1.** Common Vulvar Irritants and Allergens

General Categories	Examples of Specific Agents
Antiseptics	Povidone iodine, hexachlorophene
Body fluids	Semen, feces, urine, saliva
Colored or scented toilet paper	
Condoms	Latex, lubricant, spermicide, thiuram
Contraceptive creams, jellies, foams	Nonoxynol-9, lubricants
Dyes	4-Phenylene diamine
Emollients	Lanolin, jojoba oil, glycerin
Laundry detergents, fabric softeners, dryer sheets	
Rubber products	Latex, thiuram
Sanitary baby or adult bathroom wipes	
Sanitary pads or tampons	
Soaps, bubble bath and salts, shampoos	
Topical anesthetics	Benzocaine, lidocaine
Topical antibacterials	Neomycin, bacitracin, polymyxin, framycetin, tea tree oil
Topical corticosteroids	Clobetasol propionate
Topical antifungal creams	Ethylene diamine, sodium metabisulfite

Data from American College of Obstetricians and Gynecologists, 2010; Crone, 2000; Fisher, 1973; Marren, 1992.

### Physical Examination

Examination of the vulva and surrounding skin is completed using adequate lighting, optimal patient positioning, and a magnifying lens or colposcope. Both focal and generalized skin changes are carefully noted, as neoplasia may arise within a field of generalized dermatosis. Abnormal pigmentation, skin texture, nodularity, or vascularity is evaluated. Touch with a small probe such as a cotton swab defines the anatomic boundaries of generalized symptoms and precisely locates focal complaints (Fig. 4-1). A medical record diagram noting vulvar findings and symptoms aids treatment assessment over time.

Vaginal complaints or vulvar conditions without obvious etiology typically prompt vaginal examination. Careful inspection may reveal generalized inflammation or atrophy, abnormal discharge, or focal mucosal lesions such as ulcers. In these

cases, saline preparation of secretions for microscopic evaluation (“wet prep”), vaginal pH testing, and aerobic culture to detect yeast overgrowth are collected. A general skin examination, including the oral mucosa and axillae, may suggest the cause of some vulvar conditions. A focused neurologic examination to evaluate lower extremity sensation and strength as well as perineal sensation and tone may help evaluate vulvar dysesthesias.

### Vulvar Biopsy

Vulvar skin changes are frequently nonspecific and typically require biopsy for accurate diagnosis. Biopsy is strongly considered if the cause of symptoms is not obvious; if initial empiric treatment fails; if the cause of symptoms is not obvious; or if focal, exophytic, or hyper-/hypopigmented lesions are present. During biopsy, ulcerative lesions are sampled at their edges, and hyper- or hypopigmented areas at their thickest region (Mirowski, 2004). Conditions with variable histologic appearance may require multiple biopsies for correct disorder classification.

The steps for vulvar biopsy are shown in Figure 4-2. First, the biopsy site is cleaned with an antimicrobial agent and infiltrated with a 1- or 2-percent lidocaine solution. Biopsy is performed most easily with a Keyes skin punch. The open, circular blade is designed to remove a shallow disc of tissue when gently pressed against the skin and rotated. Keyes punches are available in various diameters, ranging from 2 to 6 mm, and size selection is based on lesion dimensions and on whether sampling or excision is the goal. Vulvar skin and lesion thicknesses are variable, and over-rotation of or undue pressure on the Keyes punch is avoided. Too deep a biopsy will leave a depressed scar. Rotation and pressure should stop when decreased resistance is felt, signaling the dermis has been reached. The tissue disc core is then freed at its base with fine scissors. Larger punch biopsies (4 to 6 mm) may require closure with an absorbable suture.

**FIGURE 4-1** Pain can be assessed and mapped by systematically touching a cotton-tip applicator to the vulva.

**FIGURE 4-2** Vulvar biopsy steps. **A.** A Keyes punch biopsy is placed against the biopsy site. Gentle downward pressure is exerted as the punch is rotated. **B.** A core biopsy is created that extends through the epidermis and into the dermis. **C.** The tip of a fine needle or fine forceps is used to elevate the core, while fine scissors incise its base.

For raised or pedunculated lesions, fine scissors may be used. Occasionally, a No. 15 blade scalpel is selected for larger focal lesions. Tissue is excised parallel to the natural vulvar skin folds, and the defect is sutured to aid healing and minimize scarring. Larger lesions, for which simple closure would create significant incision tension, are best excised by clinicians experienced in more advanced plastic surgery techniques.

Following biopsy, bleeding may be controlled with direct pressure, silver nitrate stick, or Monsel paste. Silver nitrate may permanently discolor the skin, which may upset the patient and confuse subsequent examinations. If needed, simple interrupted stitches using a fine, rapidly absorbable suture provide hemostasis and edge approximation. Nonnarcotic oral analgesics usually suffice to relieve postbiopsy discomfort.

## VULVAR DERMATOSES

The International Society for the Study of Vulvovaginal Disease (ISSVD) provides classification systems for vulvar abnormalities. Their 2006 Classification of Vulvar Dermatoses specifically focuses on dermatoses and divides these based on biopsy-obtained histology. Their more recent terminology and organization system does not supplant the 2006 system. Instead, it classifies a broader group of dermatologic disorders that includes dermatoses, infections, and neoplasias by their similar clinical presentations to aid identification and management (Lynch, 2007, 2012). The next sections describe the more frequently encountered conditions.

### Lichen Simplex Chronicus

An itch-scratch cycle typically leads to chronic trauma from rubbing and scratching (Lynch, 2004). Early examination reveals excoriations within a background of erythema. With chronic trauma, the skin responds by thickening, termed lichenification. Thus, in long-standing cases, vulvar skin is thick with exaggerated skin markings causing a leathery, gray appearance. Skin changes are usually bilateral and symmetric and may extend beyond the labia majora. Intense vulvar pruritus causes functional and psychologic distress, and sleep is often disrupted. Potential pruritus triggers include irritation from clothing, heat, or sweating; chemicals contained within hygiene products and topical medications; laundry products; and even food sensitivities (Virgili, 2003). A detailed history typically leads to the diagnosis.

Treatment involves halting the itch-scratch cycle. First, provocative stimuli are eliminated, and topical corticosteroid ointments help to reduce inflammation. In addition, lubricants, such as plain petrolatum or vegetable oil, and cool sitz baths help to restore the skin's barrier function. Oral antihistamine use, trimmed fingernails, and cotton gloves worn at night can help decrease scratching during sleep. If symptoms fail to resolve within 1 to 3 weeks, biopsy is indicated to exclude other pathology. Histology classically shows thickening of both the epidermis (acanthosis) and the stratum corneum (hyperkeratosis). In these refractory cases, a trial of higher-potency corticosteroid may improve symptoms.

### Lichen Sclerosus

It is classically presents in postmenopausal women, although cases are less often found in premenopausal women, children, and men (Fig. 14-8, p. 323). In a referral dermatologic clinic, lichen sclerosis was found in 1:300 to 1:1000 patients with a tendency toward whites (Wallace, 1971). Others estimate an incidence of childhood lichen sclerosis to be 1 in 900 (Powell, 2001).

The cause of lichen sclerosis remains unknown, although infectious, hormonal, genetic, and autoimmune etiologies have been suggested. Approximately 20 to 30 percent of patients with lichen sclerosis have other autoimmune disorders, such as Graves disease, types 1 and 2 diabetes mellitus, systemic lupus erythematosus, and achlorhydria, with or without pernicious anemia (Bor, 1969; Kahana, 1985; Poskitt, 1993). Accordingly, concurrent testing for these is indicated if other suggestive findings are present.

### Diagnosis

Although sometimes asymptomatic, most individuals with lichen sclerosis complain of anogenital symptoms that often worsen at night. Inflammation of local terminal nerve fibers is suspected. Pruritus-induced scratching creates a vicious cycle that may lead to excoriations and vulvar skin thickening. Late symptoms can include burning and dyspareunia due to vulvar skin fragility and structural changes.

Perianal involvement is frequently seen. The typical white, atrophic papules may coalesce into porcelain-white plaques that distort normal vulvar anatomy. As a result, labia minora regression, clitoral concealment, urethral obstruction, and introital stenosis can develop. The skin generally appears thinned and crinkled. Over time, involvement may extend to the perineum and anus to form a “figure-eight” or “hourglass” shape (Fig. 4-3) (Clark, 1967). Thickened white plaques, areas of erythema, or nodularity should prompt biopsy to exclude preinvasive and malignant lesions. This characteristic clinical picture and histologic findings typically confirm the diagnosis. In long-standing cases, histologic findings may be nonspecific, and clinical suspicion will guide treatment.

### Treatment and Surveillance

Curative therapies are not available for lichen sclerosis. Thus, treatment goals are symptom control and prevention of anatomic distortion. Despite its classification as a nonneoplastic dermatosis, patients with lichen sclerosis demonstrate an

**FIGURE 4-3** Vulvar lichen sclerosis. Note the thin and pale vulvar skin, loss of labia minora architecture, and labia minora fusion beneath the clitoris.

**TABLE 4-2.** Vulvar Care Recommendations

Avoid using gels, scented bath products, cleansing wipes, and soaps, as they may contain irritants
Use aqueous creams to clean the vulva
Avoid using a harsh washcloth to clean the vulva
Dab the vulva gently to dry
Avoid wearing tight-fitting pants
Select white cotton underwear
Avoid washing undergarments in scented washing detergents. Consider using a multirinse process with cold water to remove any remaining detergent
Consider wearing skirts and no underwear at home and at night to avoid friction and aid drying

increased risk of vulvar malignancy. Malignant transformation within lichen sclerosis develops in 5 percent of patients. Histologic cellular atypia may precede a diagnosis of invasive squamous cell carcinoma (Scurry, 1997). Accordingly, lifetime surveillance of women with lichen sclerosis every 12 months is prudent (Neill, 2010). Persistently symptomatic, new, or changing lesions should be biopsied (American College of Obstetricians and Gynecologists, 2010).

As with all vulvar disorders, hygiene recommendations focus on minimizing chemical and mechanical skin irritation (Table 4-2). The chronicity of lichen sclerosis and lack of cure elicits an array of emotions. Support groups dedicated to this condition, such as that found at [www.lichensclerosis.org](http://www.lichensclerosis.org), offer needed psychologic support.

**Corticosteroids.** First-line therapy for lichen sclerosis is an ultrapotent topical corticosteroid preparation such as 0.05-percent clobetasol propionate (Temovate) or 0.05-percent halobetasol propionate (Ultravate). Ointment formulations are preferred by some providers over creams due to their protective and less irritating properties (Table 4-3). Clobetasol propionate offers effective antiinflammatory, antipruritic, and vasoconstrictive properties. Theoretic adrenocorticosuppression and iatrogenic Cushing syndrome may be risks if it is used in large doses for extended periods.

Treatment initiation within 2 years of symptom onset usually prevents significant scarring, but no treatment scheme is universally accepted for topical corticosteroid use. The currently recommended dosing schedule of the British Association of Dermatologists is 0.05-percent clobetasol propionate once nightly for 4 weeks, followed by alternating nights for 4 weeks, and finally tapering to twice weekly for 4 weeks (Neill, 2010). After this initial therapy, recommendations for maintenance therapy vary and range from tapering corticosteroids to “as needed” use to ongoing once- or twice-weekly applications. During initial treatment, some patients may also require oral antihistamines or topical 2-percent lidocaine jelly particularly at night to control itching.

Corticosteroids can also be injected into affected areas, a treatment offered by specialty clinics familiar with techniques and potential complications. One study of eight patients evaluated the efficacy of once-monthly intralesional infiltration

TABLE 4-3. Topical Medication Guide

Steroid Class Potency	Generic Name	Brand Names (available forms)
Low	Alclometasone dipropionate 0.05%	Aclovate (cream, oint.)
	Betamethasone valerate 0.01%	Valisone (cream, lotion)
	Fluocinolone acetonide 0.01%	Synalar (solution)
	Hydrocortisone 1%, 2.5%	Generic OTC versions 1% or 2.5% (cream, oint., lotion)
Intermediate	Betamethasone valerate 0.1%	Valisone (cream, lotion, oint.)
	Desonide 0.05%	DesOwen (cream, oint., lotion)
	Fluocinolone acetonide 0.025%	Synalar (cream, oint.)
	Flurandrenolide 0.025%, 0.05%	Cordran (cream, oint.)
	Fluticasone 0.005%, 0.05%	Cutivate 0.005% (oint.), 0.05% (cream)
	Hydrocortisone butyrate 0.1%	Locoid (cream, oint., solution)
	Hydrocortisone valerate 0.2%	Westcort (cream, oint.)
	Mometasone furoate 0.1%	Elocon (cream, oint., lotion)
	Prednicarbate 0.1%	Dermatop (cream, oint.)
	Triamcinolone 0.025%, 0.1%	Aristocort, Kenalog (cream, oint., lotion)
High	Amcinonide 0.1%	Cyclocort (cream, oint., lotion)
	Betamethasone dipropionate 0.05%	Diprolene, Diprosone (cream)
	Desoximetasone 0.05%, 0.25%	Topicort (cream)
	Diflorasone diacetate 0.05%	Psorcon (cream, oint.)
	Fluocinonide 0.05%	Lidex (cream, gel, oint.)
	Fluocinolone acetonide 0.2%	Synalar-HP (cream)
	Halcinonide 0.1%	Halog (cream, oint., solution)
	Triamcinolone 0.5%	Aristocort, Kenalog (cream, oint.)
Ultrapotent	Betamethasone dipropionate augmented 0.05%	Diprolene (ointment, gel)
	Clobetasol propionate 0.05%	Temovate (cream, gel, oint.)
	Diflorasone 0.05%	Psorcon (cream, oint.)
	Halobetasol propionate 0.05%	Ultravate (cream, oint.)

Oint. = ointment; OTC = over the counter.

of 25 to 30 mg of triamcinolone hexacetonide for a total of 3 months. Severity scores decreased in all categories including symptoms, gross appearance, and histopathologic findings (Mazdisnian, 1999).

**Other Topical Treatments.** *Estrogen cream* is not a primary therapy for lichen sclerosis. However, its addition is indicated for menopausal atrophy, labial fusion, and dyspareunia. Testosterone ointment has failed to show efficacy in trials and is no longer recommended (Bornstein, 1998; Sideri, 1994).

*Retinoids* are reserved for severe, nonresponsive cases of lichen sclerosis or for patients intolerant of ultrapotent corticosteroids. Topical tretinoin reduces hyperkeratosis, improves dysplastic changes, stimulates collagen and glycosaminoglycan synthesis, and induces local angiogenesis (Eichner, 1992; Kligman, 1986a,b; Varani, 1989). Virgili and colleagues (1995) evaluated the effects of topical 0.025-percent tretinoin (Retin-A, Renova) applied once daily, 5 days a week for 1 year. Complete remission of symptoms was seen in more than 75 percent of women. However, more than one quarter of patients experienced skin irritation, which is common with retinoids.

*Topical calcineurin inhibitors* such as tacrolimus (Protopic) and pimecrolimus (Elidel) have antiinflammatory and immuno-

modulating effects. These are indicated for moderate to severe eczema and have been evaluated for lichen sclerosis (Goldstein, 2011; Hengge, 2006). Moreover, these agents, compared with topical corticosteroids, theoretically lower the risk of skin atrophy, since collagen synthesis is unaffected (Assmann, 2003; Kunstfeld, 2003). However, from a double-blind, randomized, prospective study, Funaro and associates (2014) concluded that topical clobetasol propionate was more effective in treating vulvar lichen sclerosis than topical tacrolimus. In the face of recent Food and Drug Administration (FDA) concerns regarding its link to various cancers, clinicians should exercise caution when prescribing tacrolimus for extended periods (Food and Drug Administration, 2010).

Last, *phototherapy* after pretreatment using 5-aminolevulinic acid was investigated in one small series of 12 postmenopausal women with advanced lichen sclerosis. Significant reductions in patient symptoms and short-term improvement for up to 9 months were noted (Hillemanns, 1999).

**Surgery.** Surgical intervention should be reserved for significant sequelae and not for primary treatment of uncomplicated lichen sclerosis. For introital stenosis, Rouzier and coworkers (2002) described marked improvements in dyspareunia and

**FIGURE 4-4** Vulvar contact dermatitis. Contact sites of the offending agent are seen as symmetric erythema on the vulva.

quality of sexual intercourse if perineoplasty was performed (Section 43-22, p. 979). Vaginal dilation and corticosteroids are recommended following most surgical corrections of introital stenosis. For clitoral adhesions, surgical dissection can be used to free the hood from the glans. Reagglutination can be averted using initial nightly application of ultrapotent topical corticosteroid ointment (Goldstein, 2007).

## ■ Inflammatory Dermatoses

### Contact Dermatitis

A primary irritant or allergen creates vulvar skin inflammation, termed *contact dermatitis* (Fig. 4-4). This condition is common, and in unexplained cases of vulvar pruritus and inflammation, irritant contact dermatitis is diagnosed in up to 54 percent of patients (Fischer, 1996).

*Irritant contact dermatitis* classically presents as immediate burning and stinging upon exposure to an offending agent. In contrast, patients with *allergic contact dermatitis* experience a delayed onset and an intermittent course of pruritus and localized erythema, edema, and vesicles or bullae (Margesson, 2004). A detailed history will help distinguish between the two, and an inquiry for potential offending agents can help identify the irritant (see Table 4-1).

With allergic contact dermatitis, patch testing may aid in identifying responsible allergen(s). Alternative conditions, such as candidiasis, psoriasis, seborrheic dermatitis, and squamous cell carcinoma, can be excluded through appropriate use of cultures and biopsy.

Treatments for both entities involve elimination of the offending agent(s), restoration of the natural protective skin barrier, inflammation reduction, and scratch cessation (Table 4-4) (Farage, 2004; Margesson, 2004).

### Intertrigo

Friction between moist skin surfaces produces this chronic condition. Found most often in genitocrural folds, intertrigo can also develop in the inguinal and intergluteal regions.

**TABLE 4-4.** Treatment of Vulvar Contact Dermatitis

1. Stop offending agents and/or practices
2. Correct vulvar skin barrier function
  - a. Sitz bath twice daily with plain water
  - b. Application of plain petrolatum
3. Treat any underlying infection
  - a. Oral antifungal therapy
  - b. Oral antibiotic administration
4. Reduce inflammation
  - a. Topical corticosteroids twice daily for 1–3 weeks
    - i. 0.05% clobetasol propionate ointment
    - ii. 0.1% triamcinolone ointment
  - b. Systemic corticosteroids for severe irritation
5. Break the itch-scratch cycle
  - a. Cool packs (avoid ice packs, which may injure skin)
  - b. Plain, cold yogurt on a sanitary napkin for 5–10 minutes
  - c. Consider an SSRI (sertraline [Zoloft] 50–100 mg) or an antihistamine (hydroxyzine [Vistaril] 25–100 mg)

SSRI = selective serotonin-reuptake inhibitor.

Adapted with permission from Margesson LJ: Contact dermatitis of the vulva *Dermatol Ther* 2004;17(1):20–27.

Superimposed bacterial and fungal infections may complicate the condition.

The initial erythematous phase, if untreated, can progress to intense inflammation with erosions, exudate, fissuring, maceration, and crusting (Mistiaen, 2004). Symptoms typically include burning and itching. With long-standing intertrigo, hyperpigmentation and verrucous changes can develop.

Treatment entails the use of drying agents such as cornstarch and application of mild topical corticosteroids for inflammation. If skin changes do not respond, then seborrheic dermatitis, psoriasis, atopic dermatitis, pemphigus vegetans, or even scabies are considered. If the area is superinfected with bacteria or yeast, appropriate therapy is warranted.

To prevent recurrent outbreaks, obese patients are encouraged to lose weight. Other preventions include light-weight, loose-fitting clothing made of natural fibers, improved ventilation, and thorough drying between skin folds after bathing (Janniger, 2005).

### Atopic Eczema

Classically presenting in the first 5 years of life, atopic dermatitis is a severe pruritic dermatitis that follows a chronic, relapsing course. Scaly patches with fissuring are evident. Individuals with atopic eczema may later develop allergic rhinitis and asthma (Spergel, 2003).

Topical corticosteroids and immunomodulators, such as tacrolimus, can control fares (Leung, 2004). For dry skin, moisturizing with emollients can offer relief.

### Psoriasis

Approximately 1 to 2 percent of the United States' population is affected by psoriasis (Gelfand, 2005). Psoriasis is a T-cell-mediated autoimmune process in which proinflammatory

**FIGURE 4-5** Psoriasis. Raised plaques are seen on the vulva. (Used with permission from Dr. Saly Thomas.)

cytokines induce keratinocyte and endothelial cell proliferation. Thick, red plaques covered with silvery scales are generally found on extensor limb surfaces. Occasionally, lesions involve the mons pubis or labia (Fig. 4-5). Psoriasis can be exacerbated by nervous stress and menses, with remissions experienced during summer months and pregnancy. Pruritus may be minimal or absent, and this condition is often diagnosed by skin findings alone.

Several treatments are available, and topical corticosteroids are widely used because of their rapid efficacy. High-potency corticosteroids are applied to affected areas twice daily for 2 to 4 weeks and then reduced to weekly applications. Diminishing response and skin atrophy are potential disadvantages of long-term corticosteroid use, and recalcitrant cases are best managed by a dermatologist. Vitamin D analogues, such as calcipotriene (Dovonex), although similar in efficacy to potent corticosteroids, are frequently associated with local irritation but avoid skin atrophy (Smith, 2006). Phototherapy offers short-term relief, but long-term treatment plans require a multidisciplinary team (Griffiths, 2000). For moderate to severe psoriasis, several FDA-approved immunomodulating biologic agents are available and include infliximab, adalimumab, etanercept, and ustekinumab (Smith, 2009).

**Lichen Planus**

This uncommon disease involves both cutaneous and mucosal surfaces and affects genders equally between ages 30 and 60 years (Mann, 1991). Although not completely understood, T-cell autoimmunity directed against basal keratinocytes is thought to underlie its pathogenesis (Goldstein, 2005). Vulvar lichen planus can present as one of three variants: (1) erosive, (2) papulosquamous, or (3) hypertrophic. Of these, erosive lichen planus is the most common vulvovaginal form and the most difficult variant to treat. Lichen planus may be drug-induced, and nonsteroidal antiinflammatory drugs,  $\beta$ -blocking agents, methyldopa, penicillamine, and quinine drugs have been implicated.

**Diagnosis.** Table 4-5 summarizes the most common imitators of lichen planus. Women typically complain of chronic

**TABLE 4-5.** Differential Diagnosis of Lichen Planus

Class of Lichen Planus	Mimicking Condition
Erosive lichen planus	Lichen sclerosus
	Pemphigoid vulgaris
	Mucous membrane pemphigoid
	Behçet disease
	Plasma cell vulvitis
	Erythema multiforme major
	Stephen-Johnson syndrome
	Desquamative inflammatory vaginitis
Papulosquamous lichen planus	Molluscum contagiosum Genital warts
Hypertrophic lichen planus	Squamous cell carcinoma

Data from Goldstein, 2005; Kaufman, 1974; Moyal-Barracco, 2004a.

vaginal discharge with intense vulvovaginal pruritus, burning pain, dyspareunia, and postcoital bleeding. On inspection, papules classically are brightly erythematous or violaceous, flat-topped, shiny polygons most commonly found on the trunk, buccal mucosa, or flexor surfaces of the extremities (Goldstein, 2005; Zellis, 1996). Lacy, white striations (Wickham striae) are frequently found in conjunction with the papules and may also be present on the buccal mucosa (Fig. 4-6). Deep, painful erosions in the posterior vestibule can extend to the labia, resulting in agglutination. With speculum insertion, vulvar skin and vaginal mucosa bleed easily. Vaginal erosions can produce adhesions and synechiae, which may lead to vaginal obliteration.

Women with suspected lichen planus require a thorough dermatologic survey looking for extragenital lesions. Nearly one quarter of women with oral lesions will have vulvovaginal

**FIGURE 4-6** Oral lichen planus. Mucosal lesions manifest commonly as lacy, white striations (Wickham striae), although white papules or plaques, erosions, or blisters may also be seen. Oral lesions predominantly affect the buccal mucosa, tongue, and gingiva. (Used with permission from Dr. Edward Ellis.)

involvement, and most with erosive vulvovaginal lichen planus will have oral involvement (Pelisse, 1989). Diagnosis is confirmed by biopsy.

**Vulvar Lichen planus Treatment.** Pharmacotherapy remains the first-line treatment for this condition. Additionally, vulvar care measures, discontinuing any medications associated with lichenoid changes, and psychologic support should be instituted.

Erosive vulvar lichen planus is treated initially with ultra-potent topical corticosteroid ointments, such as 0.05-percent clobetasol propionate applied daily for up to 3 months, and then slowly tapered. Refractory cases are common and may respond to a preparation containing 0.05-percent clobetasol butyrate, 3-percent oxytetracycline, and 100,000 U/g nystatin (Trimovate) (Cooper, 2006). Used in small case series, other beneficial agents include systemic corticosteroids, topical tacrolimus ointment, topical cyclosporine, and oral retinoids (Byrd, 2004; Eisen, 1990; Hersle, 1982; Morrison, 2002).

**Vaginal Lichen planus Treatment.** Commonly prescribed to treat hemorrhoids, corticosteroid suppositories containing 25 mg of hydrocortisone used vaginally are helpful—specifically, if used twice daily and then tapered to maintain symptom remission (Anderson, 2002). For poorly responding patients, compounding pharmacies can provide a 100-mg hydrocortisone suppository. Potent corticosteroids are prescribed judiciously, as systemic absorption may lead to adrenocorticosuppression (Moyal-Barracco, 2004a). Combining local corticosteroid therapy with vaginal dilator use may help restore coital function in patients with moderate vaginal synechiae.

If topical medications fail, systemic treatment with prednisone 40 to 60 mg daily for up to 4 weeks may modulate symptoms (Moyal-Barracco, 2004a). Although no alternative systemic medications have been fully studied, methotrexate, hydroxychloroquine, and mycophenolate mofetil administered by providers familiar with their use are effective within a multidisciplinary approach (Eisen, 1993; Frieling, 2003; Lundqvist,

2002). Surgical adhesiolysis is a last resort. In general, vulvovaginal lichen planus is a chronic, recurrent disease for which symptomatic improvement is possible, but complete control is unlikely.

### Hidradenitis Suppurativa

This chronic disease is manifested by recurrent papular lesions that may lead to abscess, fistula formation, and scarring predominantly in apocrine gland-bearing skin (Fig. 4-7). In order of frequency, affected areas include the axillae; inguinal, perianal, and perineal skin; inframammary regions; and retroauricular skin. Chronic inflammation obstructs skin follicles, with subsequent subcutaneous abscess formation, skin thickening, and deformity. Abscesses typically form sinus tracts, and the resulting disfigurement and chronic purulent drainage can be devastating physically, emotionally, and sexually.

The etiology of hidradenitis suppurativa is unknown. More than one quarter of patients will report a family history of the disease, and an autosomal dominant inheritance pattern has been hypothesized (der Werth, 2000). Although Mortimer and colleagues (1986) found higher plasma concentrations of androgens in women with hidradenitis suppurativa, others have been unable to replicate this finding (Barth, 1996).

Treatment of early cases includes local hygiene and weight reduction in patients who are obese along with topical or oral antibiotics and warm compresses. Used individually, appropriate long-term oral antibiotics and their dosages include: tetracycline, 500 mg twice daily; erythromycin, 500 mg twice daily; doxycycline, 100 mg twice daily; or minocycline, 100 mg twice daily. Topical 1-percent clindamycin solution applied twice daily may also be effective (Jemec, 1998). Additionally, a 10-week course of oral clindamycin, 300 mg twice daily, plus rifampicin, 600 mg twice daily, has shown efficacy (Gener, 2009).

As reviewed by Rhode and associates (2008), an arsenal of other treatment modalities has been reported with varying efficacies. These include cyproterone acetate (an antiandrogen available in Europe), corticosteroids, isotretinoin, cyclosporine, and infliximab. An evidence-based review of pharmacologic

**FIGURE 4-7** Hidradenitis suppurativa. **A.** Axilla shows skin puckering created by scarring from prior infection and inflammation. (Used with permission from Dr. Christine Wan.) **B.** Mons pubis with multiple draining pustules and thickened scarred skin.

interventions provided by Alhusayen (2012) suggests antibacterials and anti-tumor necrosis factor therapy are effective for hidradenitis. In late 2015, the FDA approved Humira (adalimumab) for the treatment of moderate to severe hidradenitis. Nonmedical therapies include laser and phototherapy. Severe, refractory cases may require surgical excision that often involves extensive resection of the vulva and surrounding areas. Plastic surgery techniques are often needed to close these large defects. Unfortunately, postoperative local recurrences can develop.

### Aphthous Ulcers

Nearly 25 percent of women in the second and third decade of life will experience these self-limited mucosal lesions. Classically found on nonkeratinized oral mucosa, aphthous ulcers may also develop on vulvovaginal surfaces. Lesions are painful and can recur every few months. Distinguishing an aphthous ulcer from genital herpes may require appropriate cultures, serologies, and/or biopsies. Histologically, aphthous ulcers are composed of a mononuclear infiltrate with a fibrin coating. Although the etiology is unknown, some theorize the origin to be immune-mediated epithelial cell damage (Rogers, 1997). Other described triggers include stress, trauma, infection, hormonal fluctuation, and nutritional deficiencies of vitamin B<sub>12</sub>, folate, iron, or zinc (Torgerson, 2006). Despite the normally self-limited nature of these ulcers, persistent lesions can lead to painful scarring (Rogers, 2003). Clinicians should consider human immunodeficiency virus testing when aphthae are large and slow to heal.

High-potency topical corticosteroids can be used at the onset of ulceration. Oral corticosteroids may be used to decrease inflammation in cases resistant to topical corticosteroids. Finally, colchicine, dapsone, and thalidomide have been shown to be effective, although they are rarely used.

## VULVAR MANIFESTATIONS OF SYSTEMIC DISEASE

Systemic illnesses may initially manifest on the vulvar or vaginal mucosa as bullous, solid, or ulcerative lesions. Examples include systemic lupus erythematosus, erythema multiforme (Stevens-Johnson syndrome), pemphigus, pemphigoid, and sarcoidosis. A thorough history and physical examination usually suffice to link genital lesions with preexisting conditions. However, biopsy of vulvovaginal lesions may provide a new and unexpected diagnosis if the disorder has not yet become evident elsewhere.

### ■ Acanthosis Nigricans

This condition is characterized by velvety to warty, brown to black, poorly margined plaques. These changes are typically found at skin flexures, especially on the neck, axillae, and genitocrural folds (Fig. 17-6, p. 391).

Acanthosis nigricans is commonly associated with obesity, diabetes mellitus, and polycystic ovarian syndrome. Thus, if signs or symptoms of these are present, appropriate evaluation is warranted. Common to these conditions, insulin resistance with compensatory hyperinsulinemia is thought to promote the

skin thickening of acanthosis nigricans. Insulin binds to insulin-like growth factor (IGF) receptors and leads to keratinocyte and dermal fibroblast proliferation (Hermanns-Le, 2004). Less commonly, acanthosis nigricans is caused by other insulin-resistance or fibroblast growth-factor disorders, as reviewed by Saraiya (2013).

Treatment of acanthosis nigricans has not been evaluated in randomized trials. However, weight loss can ameliorate insulin resistance, which may lead to plaque improvement. In those prescribed metformin for glucose control, improved acanthosis nigricans has been demonstrated (Romo, 2008). Topical keratinolytics and exfoliants may have benefit (Levy, 2012).

### ■ Crohn Disease

Up to one third of women with Crohn disease suffer from anogenital involvement, which may precede gastrointestinal (GI) symptoms and a Crohn disease diagnosis. Vulvar lesions are commonly “metastatic” in that they show typical Crohn disease granulomatous inflammation but are not contiguous with the GI involvement (Sides, 2013). However, vulvar and perianal abscesses and fistulae may extend directly from GI tract lesions. Four manifestation types are vulvar edema (usually asymmetrical), ulceration, hypertrophic lesions, and chronic abscesses (Barret, 2014). Linear “knife-cut” ulcerations and other lesions often affect inguinal, genitocrural, and interlabial folds (Fig. 4-8). All can be asymptomatic but may cause burning or pruritus.

Therapy for gastrointestinal Crohn disease generally benefits external Crohn lesions. Vulvar lesions unrelated to GI disease activity often respond to prolonged courses of oral metronidazole and corticosteroids. Anti-tumor necrosis factor alpha treatments have shown promising efficacy (Barret, 2014). Surgery often can be avoided or delayed with appropriate vulvar care, nutrition, and close collaboration with a gastroenterologist. Used as last resorts, excision of fistulous tracts or other refractory lesions and vulvectomy can be complicated by poor healing and scarring (Sides, 2013). Regardless of management, recurrence is common.

**FIGURE 4-8** Vulvar Crohn disease. Knife-cut ulcers in the genitocrural folds and perineum are commonly seen with vulvar Crohn disease. (Used with permission from Dr. F. Gary Cunningham.)

## ■ Behçet Disease

This is rare, chronic, autoinflammatory, systemic vasculitis most commonly affects patients in their twenties and thirties and those of Asian or Middle Eastern descent. Behçet disease is characterized by mucocutaneous lesions (ocular, oral, and genital) and associated systemic vasculitis. Oral and genital ulcers appear similar to aphthous ulcers and generally heal within 7 to 10 days. Nevertheless, associated pain can be debilitating. Treatment for these lesions mirrors that for aphthous ulcers.

The exact etiology of Behçet disease remains unknown, although genetic and autoimmune etiologies are suspected. Vasculitis dominates the disease process, which may involve the brain, GI tract, joints, lungs, and great vessels. Accordingly, for those suspected of Behçet disease, referral to a rheumatologist for additional testing and treatment is recommended.

## DISORDERS OF PIGMENTATION

Benign variations of vulvar, perineal, and perianal skin pigmentation are commonly encountered, especially in women with darker skin. Diffuse areas of increased pigmentation are usually encountered on the labia minora and fourchette. Areas tend to be bilateral and symmetric and have an even tone and normal texture. With gentle stretching, the color attenuates evenly. This is also seen with pigment variation of chronic inflammatory dermatoses.

Various benign vulvar lesions may appear pigmented. These include benign melanosis, lentigenes, cherry hemangiomas, angiokeratomas, and seborrheic keratosis (Heller, 2013). Focal vulvar abnormalities raise concern for premalignant or malignant conditions, and prompt biopsy avoids diagnostic delay. As discussed in Chapter 29 (p. 648), high-grade intraepithelial neoplasia or invasive cancer can appear white (hyperkeratotic) or hyperpigmented and can present with or without symptoms. Melanoma is discussed in Chapter 31 (p. 688).

## ■ Nevus

Discrete, rounded, pigmented lesions, known as nevi or moles, are easily overlooked on the vulva. These warrant close surveillance as more than half of all melanomas arise from preexisting nevi (Kaufman, 2005). Congenital and dysplastic nevi have the most malignant potential.

Common nevi are classified into three groups: junctional, compound, and dermal, depending on whether the melanotic nevus cells are located at the epidermis-dermis junction, extend into the dermis, or evolve over time to reside entirely within the dermis. Dermal nevi may appear bluish or have normal skin coloration depending on the depth of the nevus cells and may be raised, papillary, or pedunculated.

Recommendations vary regarding biopsy of pigmented vulvar lesions. The American College of Obstetricians and Gynecologists (2008) recommends biopsy of all such lesions. Others suggest nevus-sampling criteria used elsewhere on the body in which asymmetry, uneven pigmentation, irregular borders, diameter > 5 mm, and erosion or fissuring should prompt biopsy (Edwards, 2010). Burning or itching also raises concern. Histologic atypia requires full lesion excision with adequate

FIGURE 4-9 Vulvar vitiligo.

margins. Anatomically challenging biopsies, as with periclitoral lesions, and physical or histologic atypia may prompt referral to clinicians with specialized knowledge and experience with such lesions. Small, bland nevi that are not biopsied warrant a careful descriptive or photographic entry in the medical record and surveillance at least annually until the lesion is deemed stable. Self-examination is encouraged, and changes in lesion or symptoms are important.

## ■ Vitiligo

Loss of epidermal melanocytes can result in depigmented skin, termed vitiligo (Fig. 4-9). No race or ethnicity has greater risks for vitiligo, but the disease may be more disfiguring and distressing for darker-skinned individuals (Grimes, 2005).

Although etiology remains unknown, genetic factors are the most likely cause (Zhang, 2005). Approximately 20 percent of patients have at least one affected first-degree relative. Vitiligo may be mediated by an autoimmune process that destroys melanocytes. Autoimmune diseases such as Hashimoto thyroiditis, Graves disease, diabetes mellitus, rheumatoid arthritis, psoriasis, and vulvar lichen sclerosus are associated with vitiligo (Boissy, 1997; Vrijman, 2012).

Most commonly, depigmentation is symmetric and generalized, although distribution may be acral (limbs, ears) or localized. Depigmentation progression over time is variable. Sometimes confused with the epithelial changes seen with lichen sclerosus, vitiligo preserves normal skin texture and contour and is otherwise asymptomatic. There is no cure for vitiligo, and spontaneous repigmentation is rare. Several treatments for vitiligo include narrowband ultraviolet (UV) B phototherapy, excimer laser therapy, and topical immunomodulators (Baciqalupi, 2012). Most cases are self-limited and explanation of the condition alone is often sufficient.

## SOLID VULVAR TUMORS

Most solid vulvar tumors are benign and arise from local tissue. Less commonly, malignant lesions arise on the vulva and are

**FIGURE 4-10** Vulvar acrochordons (skin tags). Lesions typically are small (arrow) and require no intervention. The larger vulvar acrochordon shown here was excised due to mechanical symptoms from its size.

typically of squamous cell epithelial origin. Rarely, solid vulvar tumors develop as metastatic lesions. Accordingly, many growths warrant biopsy if not confidently diagnosed visually.

### ■ Epidermal and Dermal Lesions

*Acrochordons*, commonly known as skin tags, are benign, soft fibroepithelial lesions. Most often seen on the neck, axilla, or groin, these skin-colored polypoid masses are usually devoid of hair and generally measure 1 to 6 mm in diameter but can grow larger (Fig. 4-10). They are often mistaken for vulvar condylomata, and lack of therapeutic response should prompt removal for histologic analysis. Surgical removal is likewise recommended for chronic irritation or cosmetic concerns. Small lesions are easily removed under local anesthesia in an office setting. Acrochordons have been linked to diabetes mellitus, and insulin-mediated fibroblast proliferation may explain this relationship (Demir, 2002).

*Seborrheic keratosis* may be observed in women with concurrent lesions on the neck, face, or trunk. Sharply circumscribed, slightly raised lesions containing waxy material are typical. The malignant potential of these slow-growing lesions is minimal. Therefore, excision is offered only in cases of discomfort, disfigurement, or unclear diagnosis.

*Keratoacanthoma* is a rapidly growing keratinocyte proliferation originating in a pilosebaceous gland. Rarely developing on the vulva, lesions begin as firm, round papules that progress to a dome-shaped nodule with a central crater. Untreated, the lesion usually spontaneously regresses within 4 to 6 months and leaves only a slightly depressed scar. Controversy surrounds its malignant potential (Ko, 2010; Savage, 2014). Some consider keratoacanthoma benign, whereas others classify it as a well-differentiated squamous cell carcinoma. Nevertheless, its histologic resemblance to this cancer merits surgical excision in most cases with a 4- to 5-mm margin.

*Syringoma* is a benign eccrine (sweat gland) tumor found most frequently on the lower eyelid, neck, and face. Rarely,

**FIGURE 4-11** Vulvar syringoma. Lesions are typically arranged in clusters and may extend the length of the labia majora. Syringomas are flesh-colored or yellow and show no anatomic relationship to adjacent pubic hair follicles.

the vulva may be involved bilaterally with multiple 1- to 4-mm firm papules (Fig. 4-11). The clinical appearance of vulvar syringoma is not pathognomonic. Thus, vulvar punch biopsy will establish the diagnosis and exclude malignancy. Treatment is not required. However, for those with pruritus, mild-potency topical corticosteroids and antihistamines may be helpful. In those with refractory pruritus, surgical excision or lesion ablation may be offered.

### ■ Subcutaneous Masses

*Leiomyoma* of the vulva is a rare tumor felt to arise either from smooth muscle within the vulva's erectile tissue or from transmigration through the round ligament. Surgical excision to exclude leiomyosarcoma is warranted (Nielsen, 1996).

*Fibroma* is a benign tumor rarely arising from deep vulvar connective tissue by fibroblast proliferation. Lesions are primarily found on the labia majora and range from 0.6 to 8 cm in diameter. Larger lesions often become pedunculated with a long stalk and may cause pain or dyspareunia. Surgical excision is indicated for symptomatic lesions or if the diagnosis is unclear.

*Lipoma* is a soft sessile or pedunculated mass composed of mature adipose cells. Similar to fibromas, observation is reasonable in the absence of patient complaints, although symptoms may prompt surgical excision. These lesions lack a fibrous connective tissue capsule. Thus, complete dissection may be complicated by bleeding and require a larger incision.

*Ectopic breast tissue* may develop along the theoretical milk lines, which extend bilaterally from the axilla through the breast and ventrally to the mons pubis. Uncommonly found in the vulva, extramammary breast tissue is hormonally sensitive and may enlarge in response to pregnancy or exogenous hormones. Uncommonly, these typically soft masses may also develop breast pathologies including fibroadenoma, Phyllodes tumor, Paget disease, and invasive adenocarcinoma.

## CYSTIC VULVAR TUMORS

### ■ Bartholin Gland Duct Cyst and Abscess

Mucus produced to lubricate the vulva originates in part from the Bartholin glands. Obstruction of this gland's duct is common and may follow infection, trauma, mucus changes, or congenitally narrowed ducts. However, the underlying cause is often unclear.

In some cases, cyst contents may become infected and lead to abscess formation. These tend to develop in populations with demographic profiles similar to those at high risk for sexually transmitted infections (Aghajanian, 1994). However, a wide spectrum of organisms has been cultured. *Escherichia coli* is the most common isolate, but various other gram-positive and gram-negative aerobes and anaerobes are found (Kessous, 2013; Mattila 1994; Tanaka, 2005). Infrequently, *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is identified.

### Diagnosis and Treatment

Most Bartholin gland cysts are small and asymptomatic except for minor discomfort during sexual contact (Fig. 4-12). With larger or infected cysts, however, patients may complain of severe vulvar pain that precludes walking, sitting, or sexual activity (Fig. 3-18, p. 318).

On physical examination, cysts typically are unilateral, round or ovoid, and fluctuant or tense. If infected, they display surrounding erythema and are tender. The mass is usually located in the inferior labia majora or lower vestibule. Whereas most cysts and abscesses lead to labial asymmetry, smaller cysts may be detected only by palpation. Bartholin abscesses on the verge of spontaneous decompression will exhibit an area of softening, where rupture will most likely occur.

Small, asymptomatic Bartholin gland duct cysts require no intervention except exclusion of neoplasia in women older than 40 years. However, a symptomatic cyst may be managed with one of several techniques. These include incision and drainage (I&D), marsupialization, and Bartholin gland excision, which are described and illustrated in Sections 43–6 through 43–8 (p. 971). Abscesses are treated with I&D or marsupialization.

**FIGURE 4-12** Bartholin gland duct cyst seen as an asymmetrical bulge in the left lower vestibule.

### Malignancy

After menopause, Bartholin gland duct cysts and abscesses are uncommon and should raise concern for neoplasia. However, carcinoma of the Bartholin gland is rare, and its incidence approximates 0.1 per 100,000 women (Visco, 1996). Most are squamous carcinomas or adenocarcinomas (Heller, 2014). Given the rarity of these cancers, Bartholin gland excision is typically not indicated. Alternatively, in women older than 40 years, drainage of the cyst and biopsy of cyst wall sites adequately excludes malignancy (Visco, 1996).

### ■ Urethral Diverticulum and Skene Gland

Ductal occlusion of the Skene gland or paraurethral glands may lead to paraurethral cystic enlargement and possible abscess formation. Their symptoms and treatment are described in Chapter 26 (p. 582).

### ■ Epidermoid Cysts

These cysts, also known as *epidermal inclusion* or *sebaceous cysts*, are commonly found on the vulva, and less so in the vagina. Although histologically similar and lined by squamous epithelium, it is unclear if they represent separate entities. Vulvar epidermoid cysts typically form from plugged pilosebaceous units (Fig. 4-13). However, epidermoid cysts can also follow traumatic implantation of epidermal cells into deeper tissues. These cysts are variable in size, typically round or ovoid, and skin colored, yellow, or white. Generally, cysts are filled with viscous, gritty, or caseous foul-smelling material. Epidermoid cysts are generally asymptomatic and require no further evaluation. If symptomatic or secondarily infected, incision and drainage is recommended.

## VULVODYNIA

In 2003, the ISSVD defined vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder” (Table 4-6)(Moyal-Barracco, 2004b). The term *vestibulitis* was eliminated from ISSVD terminology since inflammatory changes have not been consistently documented. Vulvar pain is described as spontaneous (unprovoked), triggered by physical pressure (provoked), or mixed. Vulvar pain described by most patients as burning, stinging, or a raw irritation is further categorized as localized or generalized.

Limited studies indicate a prevalence of vulvodynia in the general population of 3 to 11 percent (Lavy, 2007; Reed, 2004, 2014). Women from all ethnicities and a wide age range are affected. One study estimated that each year approximately 1 in 50 women will develop vulvodynia (Reed, 2008).

Vulvodynia's underlying cause is likely multifactorial and variable among individuals (Stockdale, 2014). Suspected risk factors, such as oral contraceptive pill use, genetic or immune factors, or infection (chronic yeast or human papillomavirus), remain unsupported by evidence. Whether predominantly physical or psychosocial factors trigger the pain is controversial, with strong arguments on both sides (Gunter, 2007; Lynch, 2008). Most theories propose that some local injury or noxious

**FIGURE 4-13** Epidermal inclusion cysts. **A.** This lesion on the inner labia minora required no intervention. (Used with permission from Vera bell, WHNP.) **B.** This lesion (arrow) on the right labia majora was excised due to patient discomfort. It was filled with tan, clay-like material. (Used with permission from Dr. Shirley Penkar.)

stimulus results in maladaptive local and/or central nervous system responses leading to a neuropathic pain syndrome (Chap. 11, p. 250). Interestingly, patients with vulvodynia have an increased prevalence of other chronic pain disorders, including interstitial cystitis, irritable bowel syndrome, fibromyalgia, and temporomandibular pain (Kennedy, 2005; Reed, 2012).

■ **Diagnosis**

Typically, evaluation and management attempts are delayed for years due to patient embarrassment, attempts at self-treatment, and lack of knowledge that it is a medical condition. Diagnosis

and treatment delays, often by multiple providers, are common (Harlow, 2003, 2014).

An evidence-based algorithm for the diagnosis of vulvodynia is provided in Figure 4-14 (Haefner, 2005). Given that vulvodynia is a diagnosis of exclusion, an extensive history is critical to securing the correct diagnosis (Table 4-7) (American College of Obstetricians and Gynecologists, 2008).

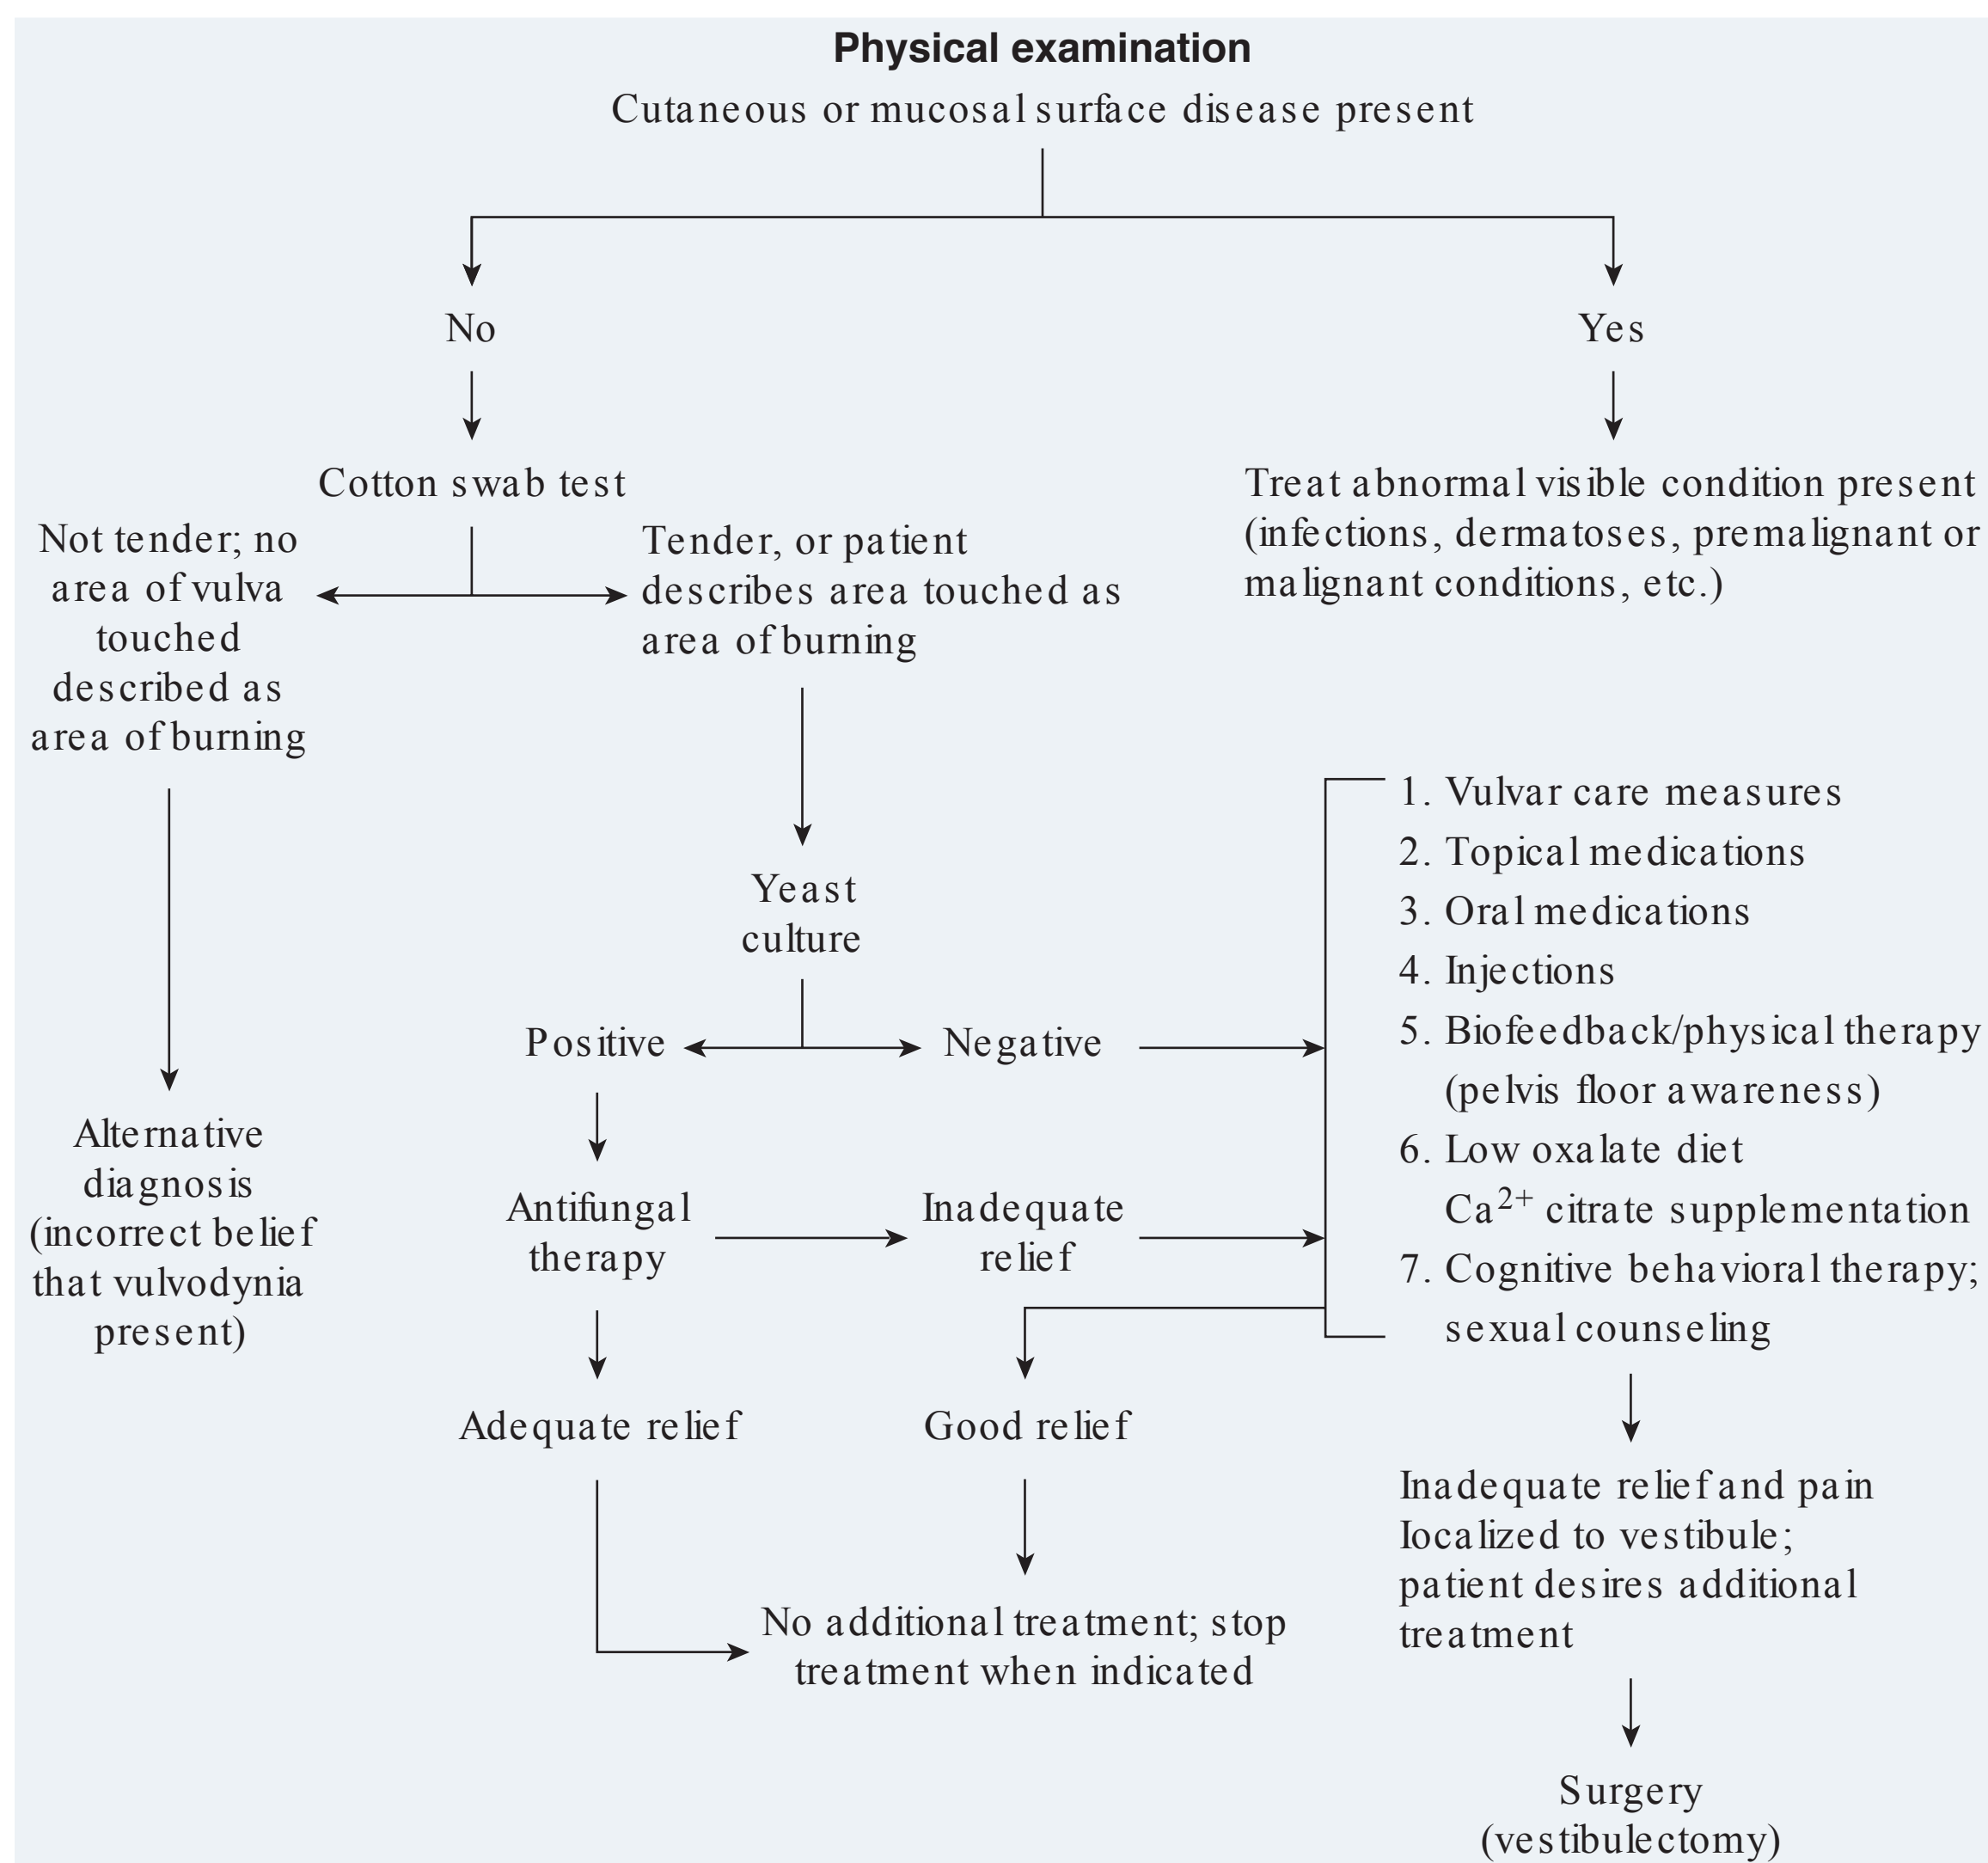

Vulvodynia refers to vulvar discomfort of at least 3 to 6 months duration without an identifiable cause. Generalized or localized vulvodynia is described variably as burning, rawness, itching, or cutting pain within affected areas (Bergeron, 2001). Pain may follow a touch stimulus (allodynia) such as tight clothing, undergarments, sexual contact, or pelvic examination. Sensations may be constant, intermittent, or episodic with exacerbations noted premenstrually (Arnold, 2006).

Questioning seeks to identify frequently associated comorbid conditions or other risk factors. These may include irritable bowel syndrome, interstitial cystitis, psychologic disorders (anxiety, depression, or posttraumatic stress disorder), or a history of infectious diseases such as herpes simplex or zoster. Documentation of past surgical procedures may help identify pudendal nerve injury. A sexual history may reveal clues of past or current abuse, unfavorable coital patterns, and contraceptive modalities that could provoke vulvodynia. Additionally, clinicians inquire about recurrent candidiasis; prior genital trauma, including childbirth-related injuries; and current hygiene practices. Specifically, questions regarding use of feminine hygiene products, panty liners,

TABLE 4-6. ISSVD Terminology and Classification of Vulvar Pain
<b>Vulvar pain related to a specific disorder</b> Infectious Inflammatory Neoplastic Neurologic
<b>Vulvodynia</b> Generalized Provoked Unprovoked Mixed

TABLE 4-7. Appropriate Vulvodynia Questions
When did the pain begin? A precipitating event? Was the onset gradual or sudden? Describe the pain and its intensity. Aggravating factors? Is it provoked or unprovoked? Relieving factors? Prior therapy? Associated symptoms? Urinary? GI? Dermatologic? Does pain lessen quality of life? Limit activities?
GI = gastrointestinal.

**FIGURE 4-14** Algorithm for the diagnosis and treatment of vulvodynia. (Reproduced with permission from Haefner HK, Collins ME, Davis GD, et al: The vulvodynia guideline, J Low Genit Tract Dis 2005 Jan;9(1):40–51.)

laundry and body soaps, bath additives, shaving, and type of undergarment fabric worn can be helpful. Prior therapies are documented to avoid unnecessary treatment repetition.

By definition, vulvodynia lacks specific diagnostic physical signs. Therefore, a thorough examination excludes other possible pathologies. Inspection of the external vulva for lesions or irritation is followed by examination of the vestibule looking for focal, usually mild, erythema at vestibular gland openings. Use of a magnifying lens or colposcope and directed biopsies may be helpful. Of note, Bowen and colleagues (2008) found clinically relevant dermatoses in 61 percent of refractory vulvodynia patients referred to their tertiary care vulvovaginal clinic.

Systematic pain mapping of the vestibule, perineum, and inner thigh is completed, and documentation serves as a reference to assess treatment success (see Fig. 4-1). A cotton swab is used to check for allodynia and hyperesthesia. The swab end can first be unwound to form a cotton-fiber wisp. Subsequently, the wooden stick is broken to form a sharp point to retest the same areas. Pain scale scores are recorded and followed over time.

As a diagnosis of exclusion, no specific laboratory test can confirm vulvodynia, although a saline “wet prep” of vaginal

secretions, vaginal pH testing, and appropriate cultures as clinically indicated for yeast and herpes virus help exclude underlying vulvovaginitis. Focal abnormalities typically prompt biopsy.

## ■ Treatment

Like other chronic pain conditions, vulvodynia is challenging to treat. Approximately one in 10 women with vulvodynia will experience spontaneous remission (Reed, 2008). Due to few well-designed, randomized clinical trials, no specific therapy for vulvodynia has demonstrated superiority. Often, a combination of several therapeutic approaches is required to stabilize and alleviate symptoms (Haefner, 2005; Landry, 2008). Without improvement, surgical excision is a final option. Treatment approaches to vulvodynia are described further by Haefner and associates (2005) and reviewed by Landry and colleagues (2008).

## Behavioral Therapy

The first step in managing all vulvar disorders includes vulvar care as summarized in Table 4-2. Also, accurate medical information

can help resolve some of the fears and questions associated with vulvodynia. The National Vulvodynia Association provides patient information and support and can be accessed online at [www.nva.org](http://www.nva.org).

Vulvodynia is currently seen as more complex than a simple psychosexual problem. Compared with the general population, no differences in marital contentment or psychologic distress are found (Bornstein, 1999). Nevertheless, early counseling includes a basic assessment of the intimate partner relationship and of sexual functioning. Education regarding foreplay, sexual positions, lubrication, and alternatives to vaginal intercourse is offered if potentially helpful.

Back pain, pelvic floor muscle spasm, or vaginismus may coexist with vulvodynia, and pelvic floor muscle examination is described and illustrated in Chapter 11 (p. 257). If coexistent, a physical therapist familiar with treating these concerns may provide internal and external massage, myofascial release techniques, acupressure, joint manipulation, electrical stimulation, therapeutic ultrasonography, and pelvic floor muscle retraining to improve symptoms (Bergeron, 2002).

### Medications

Agents for vulvodynia treatment may be administered topically, orally, or intralesionally. Of topical agents, 5-percent lidocaine ointment applied sparingly to the vestibule 30 minutes prior to sexual intercourse can significantly decrease dyspareunia, and long-term use may promote healing by minimizing feedback pain amplification (Zolnoun, 2003). Numerous other topical anesthetic preparations are reported to have variable success. However, caution is exercised with benzocaine, which is associated with increased rates of contact dermatitis.

Eva and colleagues (2003) found decreased estrogen-receptor expression in women with vulvodynia. However, topical or intravaginal estrogen therapy has yielded mixed results.

As reported by Boardman and coworkers (2008), topical gabapentin cream is well-tolerated, effective, and avoids the potential side effects of systemic gabapentin therapy. In their study, 0.5 mL of a compounded 2-, 4-, or 6-percent gabapentin-containing cream was applied three times daily for at least 8 weeks to affected vulvar areas.

The two major classes of oral medications reported to help vulvodynia are antidepressants and anticonvulsants. However, polypharmacy is avoided by clinicians prescribing one drug at a time, and contraception use is required for reproductive-aged patients. Tricyclic antidepressants (TCAs) have become a first-line agent in the treatment of vulvodynia, and reported response rates may reach 47 percent (Munday, 2001). In our experience, amitriptyline started at doses between 5 and 25 mg orally nightly and increased as needed by 10 to 25 mg weekly yields the best results. Final daily doses do not exceed 150 to 200 mg. Importantly, compliance is encouraged during the nearly 4-week lag required to achieve significant pain relief.

Cases resistant to TCAs may be treated with the anticonvulsants gabapentin or carbamazepine (Table 11-5, p. 259) (Ben David, 1999). Oral gabapentin is initiated at a dosage of 100 mg three times daily and gradually increased over 6 to 8 weeks to a maximal daily dose of 3600 mg. Pain is reassessed every 1 to 2 weeks (Haefner, 2005).

Although topical corticosteroids generally do not help patients with vulvodynia, injections using a combination of corticosteroids and local anesthetics have been used for localized vulvodynia (Mandal, 2010; Murina, 2001). Alternatively, botulinum toxin A injections into the levator ani muscles have been reported effective for vulvodynia-related vaginismus (Bertolasi, 2009).

### Surgery

Women with vulvodynia who fail to improve despite aggressive medical therapy are candidates for surgery. Options include local excision of a precise pain locus, complete resection of the vestibule (vestibulectomy), or resection of the vestibule and perineum (perineoplasty) (Section 43-22, p. 979). Traas and associates (2006) reported high success rates with vestibulectomy among women younger than 30 years. Perineoplasty is the most extensive of the three procedures. Its incision extends from just below the urethra to the perineal body, usually terminating above the anal orifice. This procedure may be selected if significant perineal scarring is suspected to contribute to dyspareunia. Overall, improvement rates for appropriately selected patients are high following vulvar excision procedures. However, surgery is reserved for those with severe, localized, long-standing vestibular pain who have failed significant attempts at conservative management.

## VULVOVAGINAL TRAUMA

### ■ hematoma

It may develop in the relatively vascular vulva following straddle injury, trauma from coitus or assault, or vulvovaginal procedures. Hematomas may develop within subcutaneous tissues or within the superficial perineal pouch of the anterior perineal triangle (Fig. 38-26, p. 819). Within the latter, laceration of the vestibular bulb, clitoral crus, or branches of the internal pudendal vessels may create a sizable mass (Fig. 4-15). Given the protected anatomic location and adipose padding of the labia majora, traumatic vulvar and vaginal injuries are rare in adults. These are much more frequent in children who lack

**FIGURE 4-15** Vulvar hematoma.

such padding, and differentiating straddle injury and sexual abuse in children is often challenging, as injury patterns are not reliably discriminating.

Often requiring a general anesthetic, thorough examination of the vulva and vagina will estimate hematoma stability and the integrity of the surrounding bowel, bladder, urethra, and rectum. If there is no associated organ injury, the venous nature of most vulvar hematomas makes them candidates for conservative management with cool packs followed by sitz baths, pain control, and Foley catheter bladder drainage as needed. In general, vaginal hematomas measuring > 4 cm or rapidly expanding are surgically explored to secure bleeding vessels. However, following incision and clot evacuation, a cavity is often seen without an identifiable bleeding vessel. To prevent reaccumulation, the cavity is closed in layers with absorbable or delayed-absorbable suture using a running or interrupted stitch closure.

### ■ Laceration

Penetrating trauma accounts for most vaginal injuries. Common causes include pelvic fracture, forced inanimate objects, coitus, and hydraulic forces such as those experienced with water skiing. Atrophic vaginal changes can predispose to injury.

With extensive laceration, examination under anesthesia is usually necessary to perform a thorough assessment and to exclude intraperitoneal damage. Moreover, if the peritoneal cavity has been breached, abdominal cavity exploration by laparotomy or laparoscopy is warranted to exclude visceral injury and supraleator or retroperitoneal hematoma.

Treatment goals include hemostasis and restoration of normal anatomy. Irrigation, debridement, and primary repair are key steps during initial management. The vaginal mucosa is typically reapproximated with running or interrupted stitches with absorbable or delayed-absorbable suture. Uncommonly, infection warrants laceration healing by secondary intention. Nonexpanding hematomas may be managed conservatively, whereas expanding masses often require evacuation and isolation of bleeding vessels. With laceration or hematoma, postoperatively, a vaginal pack can help tamponade any continued bleeding.

## VAGINAL CONDITIONS

### ■ Foreign Body

Trauma or chronic irritation from a foreign body placed into the vagina can affect all ages. Objects vary by age group, and small objects may become lodged in a child's vagina during play. An adolescent may be unable to retrieve or may be unaware of a vaginal tampon or piece of a broken condom. In adults, sexual misadventure or abuse can usually explain most objects found.

Three notable items include a retained tampon or contraceptive sponge and the vaginal pessary. Women with a retained tampon or sponge typically complain of foul-smelling vaginal discharge with some associated pruritus, discomfort, or unscheduled bleeding. A history of multiple unsuccessful retrieval attempts may be elicited. In the absence of a leukocytosis, fever, or evidence of endometritis or salpingitis, simple removal

is sufficient treatment. Vaginal lavage to cleanse the vagina is not indicated and may actually increase the ascending infection risk. Toxic shock syndrome has been described with both tampons and contraceptive sponges, and its management is outlined in Chapter 3 (p. 80). Vaginal pessaries are frequently selected to conservatively treat pelvic organ prolapse or incontinence. Associated complications with these devices and their management are described fully in Chapter 24 (p. 553).

### ■ Desquamative Inflammatory Vaginitis

This uncommon, severe form of inflammatory vaginitis develops primarily in perimenopausal women, and white women appear most often affected. Although its etiology is unknown, it may represent a variant of erosive vaginal lichen planus (Edwards, 1988). Possible triggers include diarrhea or antibiotic use (Bradford, 2010). Patients typically complain of copious vaginal discharge, introital burning, and dyspareunia, all of which are refractory to common therapies. On examination, a diffuse, exudative, purulent yellow or green discharge is present on the vaginal walls and varying degrees of vestibular-vaginal erythema are noted. Microscopy reveals many polymorphonuclear and parabasal cells, but pathogens such as trichomonads or yeast forms are absent. The vaginal pH is elevated, and exclusionary test results for gonorrhea and chlamydial infection are negative. The profuse leukorrhea may lead to an erroneous diagnosis of pelvic inflammatory disease or cervicitis, but pelvic tenderness is absent. Although no randomized clinical trials are available, Sobel (2011) reports favorable outcomes with 2-percent intravaginal clindamycin cream or intravaginal hydrocortisone cream or suppositories for 4 to 6 weeks. Whether the efficacy of clindamycin is due to its antibacterial or its antiinflammatory properties is unknown (Bradford, 2010). Patients and clinicians should view this as a chronic condition with expectation of prolonged treatment courses, relapse, and need for retreatment.

### ■ Diethylstilbestrol-induced Reproductive Tract Abnormalities

In the mid-1900s, diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was prescribed to women in the United States for several pregnancy-related problems. Daughters exposed in utero to DES had congenital reproductive tract anomalies and demonstrated increased rates of vaginal clear cell adenocarcinoma (Herbst, 1971). More commonly, *vaginal adenosis*, areas of columnar epithelium within the vaginal squamous mucosa, are found in these women. Vaginal adenosis typically appears as red, granular patches. Symptoms include vaginal irritation, discharge, intermenstrual bleeding, and postcoital bleeding. A fuller discussion of DES-related defects is found in Chapter 18 (p. 423).

### ■ Gartner Duct Cyst

Most vaginal cysts are epidermoid cysts, urethral diverticula, or Gartner duct cysts. The last are uncommon vaginal cysts developing from mesonephric (wolffian) duct remnants (Chap. 18, p. 404). They are typically asymptomatic and found within the lateral vaginal wall during routine examination.

Symptoms, if present, include dyspareunia, vaginal pain, and difficulty inserting tampons. Examination reveals a tense cyst that is palpable or seen to bulge from beneath the vaginal wall. Observation is reasonable in most cases, although marsupialization or excision may be appropriate for symptomatic Gartner duct cysts.

## CERVICAL CONDITIONS

### ■ Eversion

The squamocolumnar junction (SCJ) borders between the columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. As described and illustrated in Chapter 29 (p. 625), endocervical tissue in some women may migrate outward from the endocervical canal in a process termed eversion, thought to be hormonally mediated. As a result, the SCJ lies further distally from the external cervical os. Although eversion is a normal finding, asymmetry of the columnar epithelium surrounding the cervical os can mimic an erosive lesion, and cervical biopsy can aid clarification.

### ■ Nabothian Cyst

Mucus-secreting columnar cells line the endocervical canal. During squamous metaplasia, squamous epithelium may cover functional glandular cells and secretions may accumulate. As this benign process continues, smooth, clear, white or yellow, rounded elevations may form and are visible during routine examination (Fig. 4-16). They also are frequently seen as well-defined anechoic sonolucency along the endocervical canal (Fig. 2-14, p. 30).

Nabothian cysts typically do not warrant therapy. However, if they grow large enough to make Pap testing or cervical examination difficult or cause symptoms, they can be opened with a biopsy forceps and drained. Moreover, if the diagnosis of a cervical mass is uncertain, biopsy for histologic confirmation is obtained.

**FIGURE 4-16** Cervical nabothian cyst (arrow) is seen as a raised, symmetric, smooth, yellow or clear lesion on the ectocervix.

### ■ Endocervical polyp

One of the most common benign neoplasms of the cervix is a hyperplastic projection of endocervical tissue known as an *endocervical polyp* (Fig. 8-8, p. 188). Lesions are usually found during routine pelvic examination. They are generally asymptomatic but may be associated with leukorrhea or postcoital spotting. Additional discussion and treatment options are found in Chapter 8.

### ■ Cervical Stenosis

This narrowing of the cervical canal or opening may be congenital or acquired. Congenital stenosis is rare and likely due to segmental müllerian hypoplasia (Chap. 18, p. 419). In contrast, acquired stenosis is usually iatrogenic due to scarring after cervical excisional procedures such as cold-knife conization and loop electrosurgical excision. This complication is estimated to follow 1 to 2 percent of such procedures. Infection, neoplasia, severe atrophy, and radiation changes are rarer causes.

Diagnosis is based on symptoms and physical findings, as a precise and universally accepted definition is lacking. Symptoms of stenosis in menstruating women include dysmenorrhea, amenorrhea, and infertility. Postmenopausal women are usually asymptomatic until fluid, exudates, or blood accumulates behind the obstruction. The terms hydrometra (fluid), pyometra (pus), or hematometra (blood) are used to describe these conditions and are discussed additionally in Chapter 9 (p. 212). An inability to introduce a dilator into the endocervical canal is generally considered diagnostic. If obstruction is complete, a soft, enlarged uterus from trapped intracavitary fluid is sometimes palpable.

Cervical stenosis is relieved by introduction of dilators of progressively increasing diameter, which may require anesthesia. Preprocedural misoprostol may aid by softening the cervix (Chap. 41, p. 901). In postmenopausal women, pretreatment for several weeks with vaginal estrogen cream may also assist dilatation. Moreover, sonographic guidance can help avert uterine perforation, especially in postmenopausal women (Christianson, 2008). If cervical stenosis is suspected as contributory to infertility, assisted reproduction techniques may be indicated as described in Chapter 20 (p. 461).

## CHAPTER 5

# Contraception and Sterilization

MEDICAL ELIGIBILITY CRITERIA . . . . .	105
TOP-TIER CONTRACEPTIVE METHODS . . . . .	107
SECOND-TIER CONTRACEPTIVE METHODS . . . . .	118
THIRD-TIER CONTRACEPTIVE METHODS . . . . .	128
FOURTH-TIER CONTRACEPTIVE METHODS . . . . .	130
EMERGENCY CONTRACEPTION . . . . .	131
REFERENCES . . . . .	132

Today, an ever-increasing variety of effective methods is available for fertility regulation. Although none is completely without side effects or potential danger, it remains axiomatic that contraception poses fewer risks than pregnancy (Table 5-1). Contraceptive availability is paramount for the care of women, as approximately half of pregnancies in the United States are unintended (Finer, 2014). Moreover, half of these women are using contraception at the time of conception (Henshaw, 1998). These statistics have prompted a reexamination of contraceptive counseling to prevent unplanned pregnancy (American College of Obstetricians and Gynecologists, 2011; Steiner, 2006).

Methods are now grouped according to their effectiveness. *Top-tier* or *first-tier methods* are those that are most effective and are characterized by their ease of use (Fig. 5-1). These methods require only minimal user motivation or intervention and have an unintended pregnancy rate less than 2 per 100 women during the first year of use (Table 5-2). As expected, these first-tier methods provide the longest duration of contraception after initiation and require the fewest number of return visits. Top-tier methods include intrauterine contraceptive devices, contraceptive implants, and various methods of male and female sterilization. A reduction in unintended pregnancies can be better achieved by increasing top-tier method use. Thus, although counseling is provided for all contraceptive methods, common misperceptions regarding some of the top-tier methods—especially intrauterine contraception—can also be dispelled.

*Second-tier methods* include systemic hormonal contraceptives that are available as oral tablets, intramuscular injections, transdermal patches, or transvaginal rings. In sum, their expected failure rate is 3 to 9 percent per 100 users during the first year. This higher rate likely reflects failure to redose at the appropriate interval. Automated reminder systems for

these second-tier methods have been repeatedly shown to have limited efficacy (Halpern, 2013).

*Third-tier methods* include barrier methods for men and women and fertility awareness methods such as cycle beads. Their expected failure rate is 10 to 20 percent per 100 users in the first year. However, efficacy increases with consistent and correct use.

*Fourth-tier methods* include spermicidal preparations, which have a failure rate of 21 to 30 percent per 100 first-year users. The withdrawal method is so unpredictable that some conclude that it does not belong among other contraceptive methods (Doherty, 2009).

### MEDICAL ELIGIBILITY CRITERIA

The World Health Organization (WHO) (2010) has provided evidence-based guidance for the use of all highly effective reversible contraceptive methods by women with various health factors. These guidelines were intended to be modified by individual countries to best serve their populations specific circumstances. Thus, the Centers for Disease Control and Prevention (2010, 2011) published *United States Medical Eligibility Criteria (US MEC)* for contraceptive use in the United States. These US MEC guidelines are available and updated regularly at the CDC website: <http://www.cdc.gov/reproductivehealth/UnintendedPregnancy/USMEC.htm>. In the US MEC, many contraceptive methods are classified into six groups by their similarity: combination oral contraceptive (COC), progestin-only

**TABLE 5-1. Birth-Related or Method-Related Deaths per 100,000 Fertile Women by Age Group**

Method	15–24 Years	25–34 Years	35–44 Years
Pregnancy	5.1	5.5	13.4
Abortion	2.0	1.8	13.4
Intrauterine device	0.2	0.2	0.4
Rhythm, withdrawal	1.3	1.0	1.3
Barrier method	1.0	1.3	2.0
Spermicides	1.8	1.7	2.1
Oral contraceptives	1.1	1.5	1.4
Implants/injectables	0.4	0.6	0.5
Tubal sterilization	1.2	1.1	1.2
Vasectomy	0.1	0.1	0.1

Description	Method examples				Pregnancy per 100 woman years
Most effective	 Implants      IUD      Female sterilization      Vasectomy				<2
Very effective	 Injectables      LAM      Pills      Patch      Vaginal ring				3–9
Effective	 Male condom      Diaphragm      Female condom      Fertility awareness methods				10–20
Least effective	 Spermicides				21–30

**FIGURE 5-1** Contraceptive effectiveness chart. (Adapted with permission from World Health Organization, Johns Hopkins Bloomberg School of Public Health (SHSPH): Family Planning Handbook for Providers. Baltimore and Geneva, 2007.)

pill (POP), depot medroxyprogesterone acetate (DMPA), implants, levonorgestrel-releasing intrauterine system (LNG-IUS), and copper intrauterine device (Cu-IUD). For a given health condition, each method is categorized 1 through 4. The score describes a method’s safety profile for a typical woman with that condition: (1) no restriction of method use, (2) method advantages outweigh risks, (3) method risks outweigh advantages, or (4) method poses an unacceptably high health risk.

■ **Lactation**

Among others, lactation is one factor addressed in the US MEC guidelines. Approximately 20 percent of breast-feeding women will ovulate by 3 months postpartum. Ovulation often precedes menstruation, and these women are at risk for unplanned pregnancy. For women who breast feed intermittently, effective contraception should begin as if they were not breast feeding. Moreover, contraception is essential after the first menses unless pregnancy is planned.

Of available methods, Cu-IUD in breast-feeding women has a category 1 or 2 rating (Table 5-3). Women are counseled that effects of the etonogestrel-releasing contraceptive implant (Nexplanon) or LNG-IUS and breast feeding are not known, but studies have mostly shown no adverse association (Gurtcheff, 2011). Because POPs have little effect on lactation, they are also preferred by some for use up to 6 months in women who are exclusively breast feeding. According to the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (2012), POPs and DMPA may be initiated prior to discharge regardless of breast-feeding status. For the etonogestrel implant, insertion is delayed until 4 weeks postpartum for those exclusively breast-feeding but can be inserted anytime for those not nursing. Combination hormone contraception may begin at 6 weeks following delivery, if breast feeding is well established and the infant’s nutritional status is surveilled. The CDC (2011) revised the US MEC guidelines regarding the use of combined hormonal contraception during the puerperium due to the higher risk of venous thromboembolism (VTE) during these weeks.

**TABLE 5-2.** Contraceptive Failure Rates During the First Year of Method Use in Women in the United States

Method <sup>a</sup>	Perfect Use	Typical Use
<b>Top Tier: Most Effective</b>		
Intrauterine devices:		
Levonorgestrel system	0.2	0.2
T380A copper	0.6	0.8
Levonorgestrel implants	0.05	0.05
Female sterilization	0.5	0.5
Male sterilization	0.1	0.15
<b>Second Tier: Very Effective</b>		
Combination pill	0.3	9
Vaginal ring	0.3	9
Patch	0.3	9
DMPA	0.2	6
Progestin-only pill	0.3	9
<b>Third Tier: Effective</b>		
Condom		
Male	2	18
Female	5	21
Diaphragm with spermicides	6	12
Fertility-awareness		24
Standard days	5	
Two day	4	
Ovulation	3	
Symptothermal	0.4	
<b>Fourth Tier: Least Effective</b>		
Spermicides	18	28
Sponge		
Parous women	20	24
Nulliparous women	9	12
<b>No WHO Category</b>		
Withdrawal	4	22
No contraception	85	85

<sup>a</sup>Methods organized according to tiers of efficacy.

DMPA = depot medroxyprogesterone acetate; WHO = World Health Organization.

Data from Trussell J: Contraceptive efficacy. In Hatcher RA, Trussell J, Nelson AL, et al (eds): Contraceptive Technology, 20th ed. New York, Ardent Media, 2011, p 791.

Concerns regarding contraceptive steroids and use with breast feeding are based on the theoretical and biologically plausible—but unproven—possibility that systemic progestins may interfere with initial breast milk production. Importantly, contraceptive steroids are not purported to harm the quality of breast milk. Minute quantities of the hormones are excreted in breast milk, but no adverse effects on infants have been reported. In two reviews, authors describe the lack of evidence to support a negative impact of hormonal contraception on lactation (Tepper, 2015; Truitt, 2003). The reviewers concluded that all the studies were of poor to fair quality and that randomized trials are needed.

## ■ Adolescence and perimenopause

Females at both ends of the reproductive spectrum have unique contraceptive needs, which are discussed in Chapters 14 (p. 330) and 21 (p. 474). With adolescents, since the mid-1800s, the age of menarche has dropped. Thus, reproductive function is established many years earlier than psychosocial comprehension regarding the consequences of sexual activity. Such early sexual development may result in intermittent spontaneous sexual encounters with a naïve perception of pregnancy and sexually transmitted disease (STD) risks (Sulak, 1993). Importantly, adolescents have unintended pregnancy rates that approach 85 percent (Finer, 2014). Thus, effective contraception counseling ideally is provided *before* the onset of sexual activity. In most states, minors have explicit legal authority to consent to contraceptive services, and in many areas, publicly funded clinics provide free contraception to adolescents (Guttmacher Institute, 2014). Moreover, contraception may be provided without a pelvic examination or cervical cancer screening.

In the perimenopause, ovulation becomes irregular and fertility wanes. However, pregnancies do occur, and in women aged > 40 years, nearly half of all pregnancies are unintended (Finer, 2011). Importantly, pregnancy with advanced maternal age carries an increased risk for pregnancy-related morbidity and mortality. Women in this group may also have coexistent medical problems that may preclude certain contraceptive methods. Finally, perimenopausal symptoms may be present in this group and may be improved with hormonal contraceptive methods.

## TOP-TIER CONTRACEPTIVE METHODS

### ■ Intrauterine Contraception

Fears and concerns with legal liability caused this method to become almost obsolete. However, intrauterine contraception (IUC) has again gained popularity, and IUC use increased from 2 percent in 2002 to 10 percent in 2008 (Fig. 5-2) (Mosher, 2010). Still, this is much lower compared with the worldwide IUC use rate of 14 percent, and specifically with that of China

**FIGURE 5-2** Rates of contraceptive use by method and by method effectiveness for years 2006–2008 in the United States. NFP = natural family planning. (Data from Mosher WD, Jones J: Use of contraception in the United States: 1982–2008, Vital Health Stat 23, 29:1, 2010.)

**TABLE 5-3.** U.S. Medical Eligibility Criteria for Use of Various Contraceptive Methods While Breastfeeding

Method <sup>a</sup>	Category	Comments
<b>Ch Cs<sup>b</sup></b>		
Breastfeeding		Evidence limited. Guidelines based on theoretical concerns
< 1 month	3	
> 1 month	2	
Non-breastfeeding		Theoretical concerns for thrombosis risks. Blood coagulation and fibrinolysis virtually normalized by 3 weeks pp
< 21 days	4	
21–42 days, with risks <sup>c</sup>	3	
21–42 days, with no risks	2	
> 42 days	1	
<b>DMpA, pOps, Implants</b>		
Breastfeeding		Theoretical concerns that early use may diminish breast milk production are not supported by evidence. Limited studies
< 1 month	2	
> 1 month	1	
Non-breastfeeding	1	Limited evidence suggests no adverse side effects
<b>LNG-IUS</b>		
Breastfeeding or not		Theoretical risk of diminished breast milk production. Minimal evidence
< 10 mins	2	
10 mins to ≤ 4 wks	2	
≥ 4 wks	1	
Puerperal sepsis	4	IUD insertion could worsen condition
<b>Cu-IUD</b>		
Breastfeeding or not		IUD placement < 10 min pp is associated with lower expulsion rates compared with later IUD placement up to > 72 hr pp. No comparative data for insertion
< 10 min	1	
10 min to ≤ 4 wks	2	> 72 hr pp
≥ 4 wks	1	At c-section, postplacental placement associated with lower expulsion rate than after vaginal delivery
		No increased risk of infection or perforation associated with pp insertion
Puerperal sepsis	4	IUD insertion could worsen condition

<sup>a</sup>Time reflects time from delivery.  
<sup>b</sup>Combined hormonal contraceptive (CHC) group includes pills, vaginal ring, and patch.  
<sup>c</sup>Associated risks that increase category score include: age ≥ 35, transfusion at delivery, BMI ≥ 30, postpartum hemorrhage, cesarean delivery, smoking, preeclampsia.  
c-section = cesarean delivery; Cu-IUD = copper-bearing intrauterine device; DMPA = depot medroxyprogesterone acetate; LNG-IUS = levonorgestrel-releasing intrauterine system; POPs = progestin-only pills; pp = postpartum.

(40 percent) and northern Europe (11 percent) (United Nations, 2013).

Some barriers to IUC use in the United States include cost, politics, and provider failure to offer or encourage use of this method. To reduce the high proportion of unplanned pregnancies, the American College of Obstetricians and Gynecologists (2013b) encourages use of *long-acting reversible contraceptives (LARC)* for all appropriate candidates, including adolescents. Despite higher up-front costs, the extended span of effective IUC use results in competitive cost effectiveness compared with other contraceptive forms.

Levonorgestrel-releasing Intrauterine System

Three levonorgestrel-releasing intrauterine contraceptives are Food and Drug Administration (FDA)-approved in the United

States. Named Mirena, Skyla, and Liletta, devices are T-shaped polyethylene structures with the stem encased by a cylinder containing polydimethylsiloxane and levonorgestrel (Fig. 5-3). The cylinder has a permeable membrane that regulates continuous daily hormone release. The Mirena is currently approved for 5 years following insertion, but evidence supports use for 7 years (Tonneau, 2008). Liletta and Skyla are currently approved for 3 years. In addition to having a lower dose of progestin, Skyla is also marginally smaller in size. Mirena and Liletta have a length of 32 mm and a width of 32 mm, but with Skyla, these same dimensions measure 28 mm.

There are several progestin-mediated mechanisms by which LNG-IUS may prevent pregnancy. The progestin renders the endometrium atrophic; it stimulates thick cervical mucus that blocks sperm penetration into the uterine cavity; and it may

**FIGURE 5-3** Intrauterine contraceptive devices: Copper-containing ParaGard T 380A (A) and levonorgestrel-releasing Mirena (B).

decrease tubal motility, thereby preventing ovum and sperm union. The progestin may also inhibit ovulation, but this is not consistent (Nilsson, 1984).

Shown in Table 5-4 are the manufacturer's contraindications to use of LNG-IUS. Women who have had a previous

**TABLE 5-4.** Manufacturer Contraindications to IUD Use

#### **paraGard T 380**

Pregnancy or suspicion of pregnancy  
 Uterine abnormality with distorted uterine cavity  
 Acute PID, or current behavior suggesting a high risk for PID  
 Postpartum or postabortal endometritis in last 3 months  
 Known or suspected uterine or cervical malignancy  
 Genital bleeding of unknown etiology  
 Mucopurulent cervicitis  
 Wilson disease  
 Allergy to any component of ParaGard  
 A previously placed IUD that has not been removed

#### **Mirena, Liletta, and Skyla**

Pregnancy or suspicion of pregnancy  
 Uterine abnormality with distorted uterine cavity  
 Use for postcoital contraception  
 Acute PID or history of, unless there has been a subsequent intrauterine pregnancy  
 Postpartum endometritis or infected abortion in the past 3 months  
 Known or suspected uterine or cervical neoplasia  
 Uterine bleeding of unknown etiology  
 Untreated acute cervicitis or vaginitis or other lower genital tract infections  
 Acute liver disease or liver tumor (benign or malignant)  
 Increased susceptibility to pelvic infection  
 A previously placed IUD that has not been removed  
 Hypersensitivity to any component of the device  
 Known or suspected breast cancer or other progestin-sensitive cancer

IUD = intrauterine device; PID = pelvic inflammatory disease. Data from Bayer HealthCare, 2014; Teva Women's Health, 2013.

ectopic pregnancy may be at increased risk for another because of diminished tubal motility from progestin action. In women with uterine leiomyomas, placement of the LNG-IUS may be problematic if the uterine cavity is distorted. In their metaanalysis, Zapata and associates (2010) reported the expulsion rate to be approximately 10 percent in women with coexistent leiomyomas. However, in affected women who retained the device, menstrual blood loss will be lessened in most.

### **Copper-T 380A Intrauterine Device**

Marketed as ParaGard, this device is composed of a stem wrapped with 314 mm<sup>2</sup> of fine copper wire, and each arm has a 33-mm<sup>2</sup> copper bracelet—the sum of these is 380 mm<sup>2</sup> of copper. As shown in Figure 5-3, two strings extend from the base of the stem. The Cu-T 380A is approved for 10 years of continuous use, although it has been shown to prevent pregnancy with continuous use for up to 20 years (Bahamondes, 2005).

The intense local inflammatory response induced in the uterus by copper-containing devices leads to lysosomal activation and other inflammatory actions that are spermicidal (Alvarez, 1988; Ortiz, 1987). In the unlikely event that fertilization does occur, the same inflammatory actions are directed against the blastocyst. And finally, the endometrium becomes hostile for implantation.

### **Counseling for Intrauterine Contraception**

**Infection.** During the modern renaissance of IUC, several improvements have resulted in safer and more effective models. That said, there are still some unwanted side effects and misconceptions surrounding their use.

First, fear of IUD-associated infections precluded use in the past by young women and those of low parity. Improved device design has mitigated these concerns appreciably. In addition, several well-designed studies have shown that sexual behavior and STDs are important risk factors.

With current devices, insertion generally does not increase the risk for pelvic infection. There is no evidence that prophylactic antibiotics are necessary with insertion for women at low risk for STDs (American College of Obstetricians and Gynecologists, 2014b; Walsh, 1998). Of the less than 1 in 100 women who develop an infection within 20 days of IUD insertion, most have a concomitant unrecognized cervical infection. Accordingly, women at higher risk for sexually transmitted lower genital tract infections are screened either before or at the time of IUD insertion (Centers for Disease Control and Prevention, 2015; Faúndes, 1998; Grimes, 2000). Alternatively, a small number of pelvic infections are presumed to be caused by intrauterine contamination with normal flora at the time of insertion. Thus, antibiotics selected for treatment of any pelvic infection within the early weeks following IUD insertion should be broad-spectrum to adequately cover all these organisms.

Long-term IUC use is not associated with an increased pelvic infection rate in women at low risk for STDs. Indeed, these long-term users have a pelvic infection rate comparable with that of COC users. Any pelvic infection after 45 to 60 days is considered sexually transmitted and appropriately treated as described in Chapter 3 (p. 69). For women who develop an infection

associated with an IUD, evidence is insufficient to recommend device removal, although this is commonly done. However, close clinical reevaluation is warranted if an IUD remains (Centers for Disease Control and Prevention, 2015). In women who develop a tuboovarian abscess, the device is removed immediately after parenteral antibiotic therapy is begun.

Special concerns have arisen for women in whom *Actinomyces* species are identified in the lower genital tract, most commonly during Pap smear cytology reporting. Fiorino (1996) noted a 7-percent incidence in the Pap smears of IUD users compared with a 1-percent incidence in nonusers. Symptomatic pelvic actinomycosis is rare but tends to be indolent and severe.

Currently, in the absence of symptoms, incidental identification of *Actinomyces* species in cytologic specimens has uncertain significance. Treatment options reviewed by the American College of Obstetricians and Gynecologists (2013b) include: expectant management, an extended course of antibiotics, IUD removal, or antibiotics plus IUD removal. For women with symptomatic infection, the IUD is removed and intensive antibiotic therapy given. *Actinomyces* is susceptible to antibiotics with gram-positive coverage, notably the penicillins.

**Low parity and Adolescents.** Nulliparous IUD candidates were previously precluded from IUC use because of fears of pelvic infection and induced sterility. Current studies indicate that the pelvic infection rate is not different from that discussed earlier (Lee, 1998; Society of Family Planning, 2010). Moreover, expulsion rates in nulliparas are similar to those in multiparas. A higher proportion of nulliparas will request removal of the device because of pain or bleeding, but overall, this population reports high levels of satisfaction with IUC. Specifically, after the first year, 75 to 90 percent continue use. Revised labeling now places no restrictions on IUC use based on parity. In addition, for the same reasons, *adolescent* IUD candidates may also appropriately select IUC (American College of Obstetricians and Gynecologists, 2014a). Counseling includes clear explanations of the anticipated periprocedural cramping and discomfort.

**human Immunodeficiency Virus-Infected Women.** Intrauterine contraception is appropriate for affected women who are otherwise IUC candidates. Neither device type is associated with higher IUD complication rates if used in this population. Moreover, IUDs do not appear to adversely affect viral shedding or antiretroviral therapy efficacy (American College of Obstetricians and Gynecologists, 2012a).

**postabortal or postpartum placement.** An ideal time to improve successful provision of contraception is immediately following abortion or delivery. For women with an induced or spontaneous first- or second-trimester abortion, IUC can be placed immediately after uterine evacuation.

Insertion techniques depend upon uterine size. After first-trimester evacuation, the uterine cavity length seldom exceeds 12 cm. In these instances, the IUD can be placed using the inserter provided in the package. If the uterine cavity is larger,

the IUD can be placed using ring forceps with sonographic guidance. In women for whom an IUD is placed immediately after induced abortion, the repeat induced abortion rate is only one third of the rate of women not choosing immediate IUD placement (Goodman, 2008; Heikinheimo, 2008). As perhaps expected, the risk of IUC expulsion is slightly higher when placed immediately after abortion or miscarriage, but the advantages of preventing unplanned pregnancies seem to outweigh this (Bednarek, 2011; Fox, 2011; Okusanya, 2014).

Insertion of an IUD immediately following delivery at or near term has also been studied. Placement by hand or by using an instrument has a similar expulsion rate (Grimes, 2010). As with postabortion insertion, expulsion rates by 6 months are higher than those in women whose IUD is placed after complete uterine involution. In one study, the expulsion rate in the former group was nearly 25 percent (Chen, 2010). Even in these circumstances, however, immediate placement may be beneficial because in some populations up to 40 percent of women do not return for a postpartum clinic visit (Ogburn, 2005). Finally, postpartum placement is judged to be category 1 or 2 by the US MEC, that is, its advantages consistently outweigh the risks if puerperal infection is absent (see Table 5-3).

Despite these findings, many choose to delay insertion for several weeks postpartum. Insertion at 2 weeks is quite satisfactory, and in the Parkland System Family Planning Clinics, insertion is scheduled at 6 weeks postpartum to ensure complete uterine involution.

**Menstrual Changes.** Commonly, IUC may be associated with changes in menstrual patterns. Women who choose the Cu-T 380A are informed that increased dysmenorrhea and bleeding with menses may develop. Objectively, no clinically significant hemoglobin changes are generally expected (Tepper, 2013). Treatment with a nonsteroidal antiinflammatory drug (NSAID) will usually diminish the amount of bleeding—even normal amounts—and also relieve dysmenorrhea (Grimes, 2006).

With the LNG-IUS, women are counseled to expect irregular spotting for up to 6 months after insertion and thereafter to expect monthly menses to be lighter or even absent. Specifically, the Mirena device is associated with progressive amenorrhea, which is reported by 30 percent of women after 2 years and by 60 percent after 12 years (Ronnerdag, 1999). As noted in Chapter 8 (p. 195), the LNG-IUS device reduces menstrual blood loss and is an effective treatment for some women with heavy menstrual bleeding (American College of Obstetricians and Gynecologists, 2014e). It is often associated with improved dysmenorrhea.

**Expulsion or perforation.** Approximately 5 percent of women will spontaneously expel their IUD during the first year of use. It is most likely during the first month. Accordingly, a woman is instructed to periodically palpate the marker strings protruding from the cervical os. It can be accomplished by either sitting on the edge of a chair or squatting down and then advancing the middle finger into the vagina until the cervix is reached. Following insertion of either IUD type, women

are reappointed for a visit within several weeks, usually after completion of menses. At this meeting, any side effects are addressed, and IUD placement is confirmed by visualizing the marker strings. Some recommend barrier contraception to ensure contraception during this first month. This may be especially desirable if a device has been expelled previously.

The uterus may be perforated either with a uterine sound or with an IUD. Perforations may be clinically apparent or silent. Their frequency depends on operator skill and is estimated to be approximately 1 per 1000 insertions (World Health Organization, 1987). In some cases, a partial perforation at insertion is followed by migration of the device completely through the uterine wall. Occasionally, perforation occurs spontaneously.

**Marker Strings.** In some cases, the IUD marker strings may not be palpated or seen during speculum examination. During the investigation, a nonpregnant patient should use alternative contraception. Possibilities include that the device was expelled silently, the device has partially or completely perforated the uterus, the woman is pregnant and the enlarging uterus has drawn the device upward, or the marker strings are temporarily hidden within the endocervical canal. An IUD should not be considered expelled unless it was seen by the patient.

Initially, an endocervical brush or similar instrument can be used to gently draw the string out of the cervical canal. If this is unsuccessful, then at least two options are available. After pregnancy has been excluded, the uterine cavity is gently probed using an instrument such as Randall stone forceps or a rod with a hooked end. The strings or device will often be found with this method. If not successful, at this juncture, or possibly as a first choice, transvaginal sonography (TVS) is performed. As described in Chapter 2 (p. 28), 3-dimensional TVS offers improved visualization (Moschos, 2011). If the device is not seen within either the uterine cavity or uterine walls, then an abdominal radiograph, with or without a uterine sound in place, may localize it. Another option includes hysteroscopy.

Management decisions depend upon where the device is located and whether there is a coexistent intrauterine pregnancy. First, a device may penetrate the uterine wall in varying degrees. It should be removed, and this approach varies by IUD location. Devices with a predominantly intrauterine location are typically managed by hysteroscopic IUD removal. In contrast, devices that have nearly completely perforated through the uterine wall are more easily removed laparoscopically.

For women with an intraabdominal IUD, an inert-material device located outside the uterus may cause harm, but not universally. Bowel perforations—both large and small—as well as bowel fistulas have been reported. Once identified laparoscopically, these inert devices can easily be retrieved via laparoscopy or less commonly by colpotomy. Conversely, an extrauterine copper-bearing device induces an intense local inflammatory reaction with adhesions. Thus, they are more firmly adhered, and laparotomy may become necessary (Balci, 2010).

In those with pregnancy and an IUD, early pregnancy identification is important. Up to approximately 14 weeks' gestation, the IUD strings may be visible within the cervix, and if

seen, they are grasped to remove the entire IUD. This action reduces subsequent complications such as late abortion, sepsis, and preterm birth (Alvior, 1973). Tatum and colleagues (1976) reported an abortion rate of 54 percent with the device left in place compared with a rate of 25 percent if it was promptly removed. More recently, a study from Israel by Ganer and coworkers (2009) reported pregnancy outcomes from 1988 to 2007 in 292 women who conceived with a Cu-IUD in place. Outcomes were compared in the two groups of women with and without IUD removal as well as with the general obstetrical population. As shown in Table 5-5, in general, the group of women with an IUD left in place had the worst outcomes. Importantly, however, the group in whom the IUD was removed still had significantly worse outcomes compared with those of the general population. Of special note, Vessey and associates (1979) had previously reported that fetal malformations were not increased in pregnancies in which the device was left in place. In the Ganer study, it is particularly worrisome that this rate was doubled compared with women in whom the device was removed. The distribution of malformations was notable in that 12 percent were skeletal malformations. In contrast, there were no chromosomal anomalies identified in fetuses born to women from the two IUD groups.

Because of these findings, if pregnancy continuation is desired, it is recommended that with early pregnancies the IUD be removed. However, if the strings are not visible, attempts to locate and remove the device may result in pregnancy loss. This risk must be weighed against the risk of leaving the device in place. If removal is attempted, TVS can be used. If attempts at removal are followed by evidence for infection, then antimicrobial treatment is begun and is followed by prompt uterine evacuation.

**Ectopic pregnancy.** The risk of an associated ectopic pregnancy has been clarified over the past few years. IUC is effective in preventing all pregnancies. Specifically, the contraceptive effect of IUC decreases the absolute number of ectopic pregnancies by half compared with the rate in women who do not use contraception (World Health Organization, 1985, 1987). However, the IUC mechanisms of action are more effective in preventing intrauterine implantation. Thus, if IUC fails, a higher proportion of pregnancies are likely to be ectopic (Furlong, 2002).

### Insertion Procedures

Before IUD insertion, the FDA requires that a woman be given a brochure detailing the side effects and apparent risks from its use. Timing of insertion influences the ease of placement as well as pregnancy and expulsion rates. When done toward the end of normal menstruation, when the cervix is usually softer and somewhat more dilated, insertion may be easier, and early pregnancy can be excluded. However, insertion is not limited to this time. For a woman who is sure she is not pregnant and does not want to be pregnant, insertion may be carried out any time during the menstrual cycle. Insertion immediately postpartum or postabortion is also feasible and discussed on page 110.

**TABLE 5-5.** Pregnancy Outcomes in Women Who Conceived with a Copper-Containing IUD in Place

Outcome <sup>a</sup>	IUD in situ (n = 98)	IUD removed (n = 194)	No IUD (n = 141,191)	p value
PROM	10.2	7.7	5.7	.021
Preterm delivery	18.4	14.4	7.3	< .001
Chorioamnionitis	7.1	4.1	0.7	< .001
Fetal growth restriction	1.0	0.5	1.7	NS
Abruption	4.1	2.1	0.7	< .001
Previa	4.1	0.5	0.5	< .001
Cesarean	32	21	13	< .001
Low birthweight				
< 2500 g	11.2	13.4	6.7	< .001
< 1500 g	5.1	3.6	1.1	< .001
Perinatal death	1.0	1.5	1.2	NS
Malformations	10.2	5.7	5.1	< .041

<sup>a</sup>Outcomes shown as percentages.  
IUD = intrauterine device; NS = not significant; PROM = premature rupture of membranes.  
Data from Ganer H, Levy A, Ohel I, et al: Pregnancy outcome in women with an intrauterine contraceptive device. *Am J Obstet Gynecol* 201;381.e1, 2009.

Prior to insertion, a pelvic examination is completed to identify uterine position and size. Abnormalities are evaluated as they may contraindicate the device. Evidence for infection such as a mucopurulent discharge or significant vaginitis is appropriately treated and resolved before insertion.

For pain management, the most effective method of analgesia has not been established, and patient and provider preference directs selection. Options include NSAIDs, topical lidocaine, or paracervical block. Misoprostol is thought to advance cervical softening to mitigate cervical dilatation pain. However, few studies have adequately evaluated these (Allen, 2009).

At the beginning of the insertion procedure, the cervical surface is cleaned with an antiseptic solution, and a tenaculum is placed on the cervical lip. The uterus is sounded to guide correct depth placement. Specific steps for IUD insertion are outlined and illustrated in Figs. 5-4 and 5-5. During insertion, if there is concern for correct IUD positioning, then placement may be checked by inspection or by sonography. If not positioned completely within the uterus, the device is removed and replaced with a new one. An expelled or partially expelled device should not be reinserted.

■ **progestin Implants**

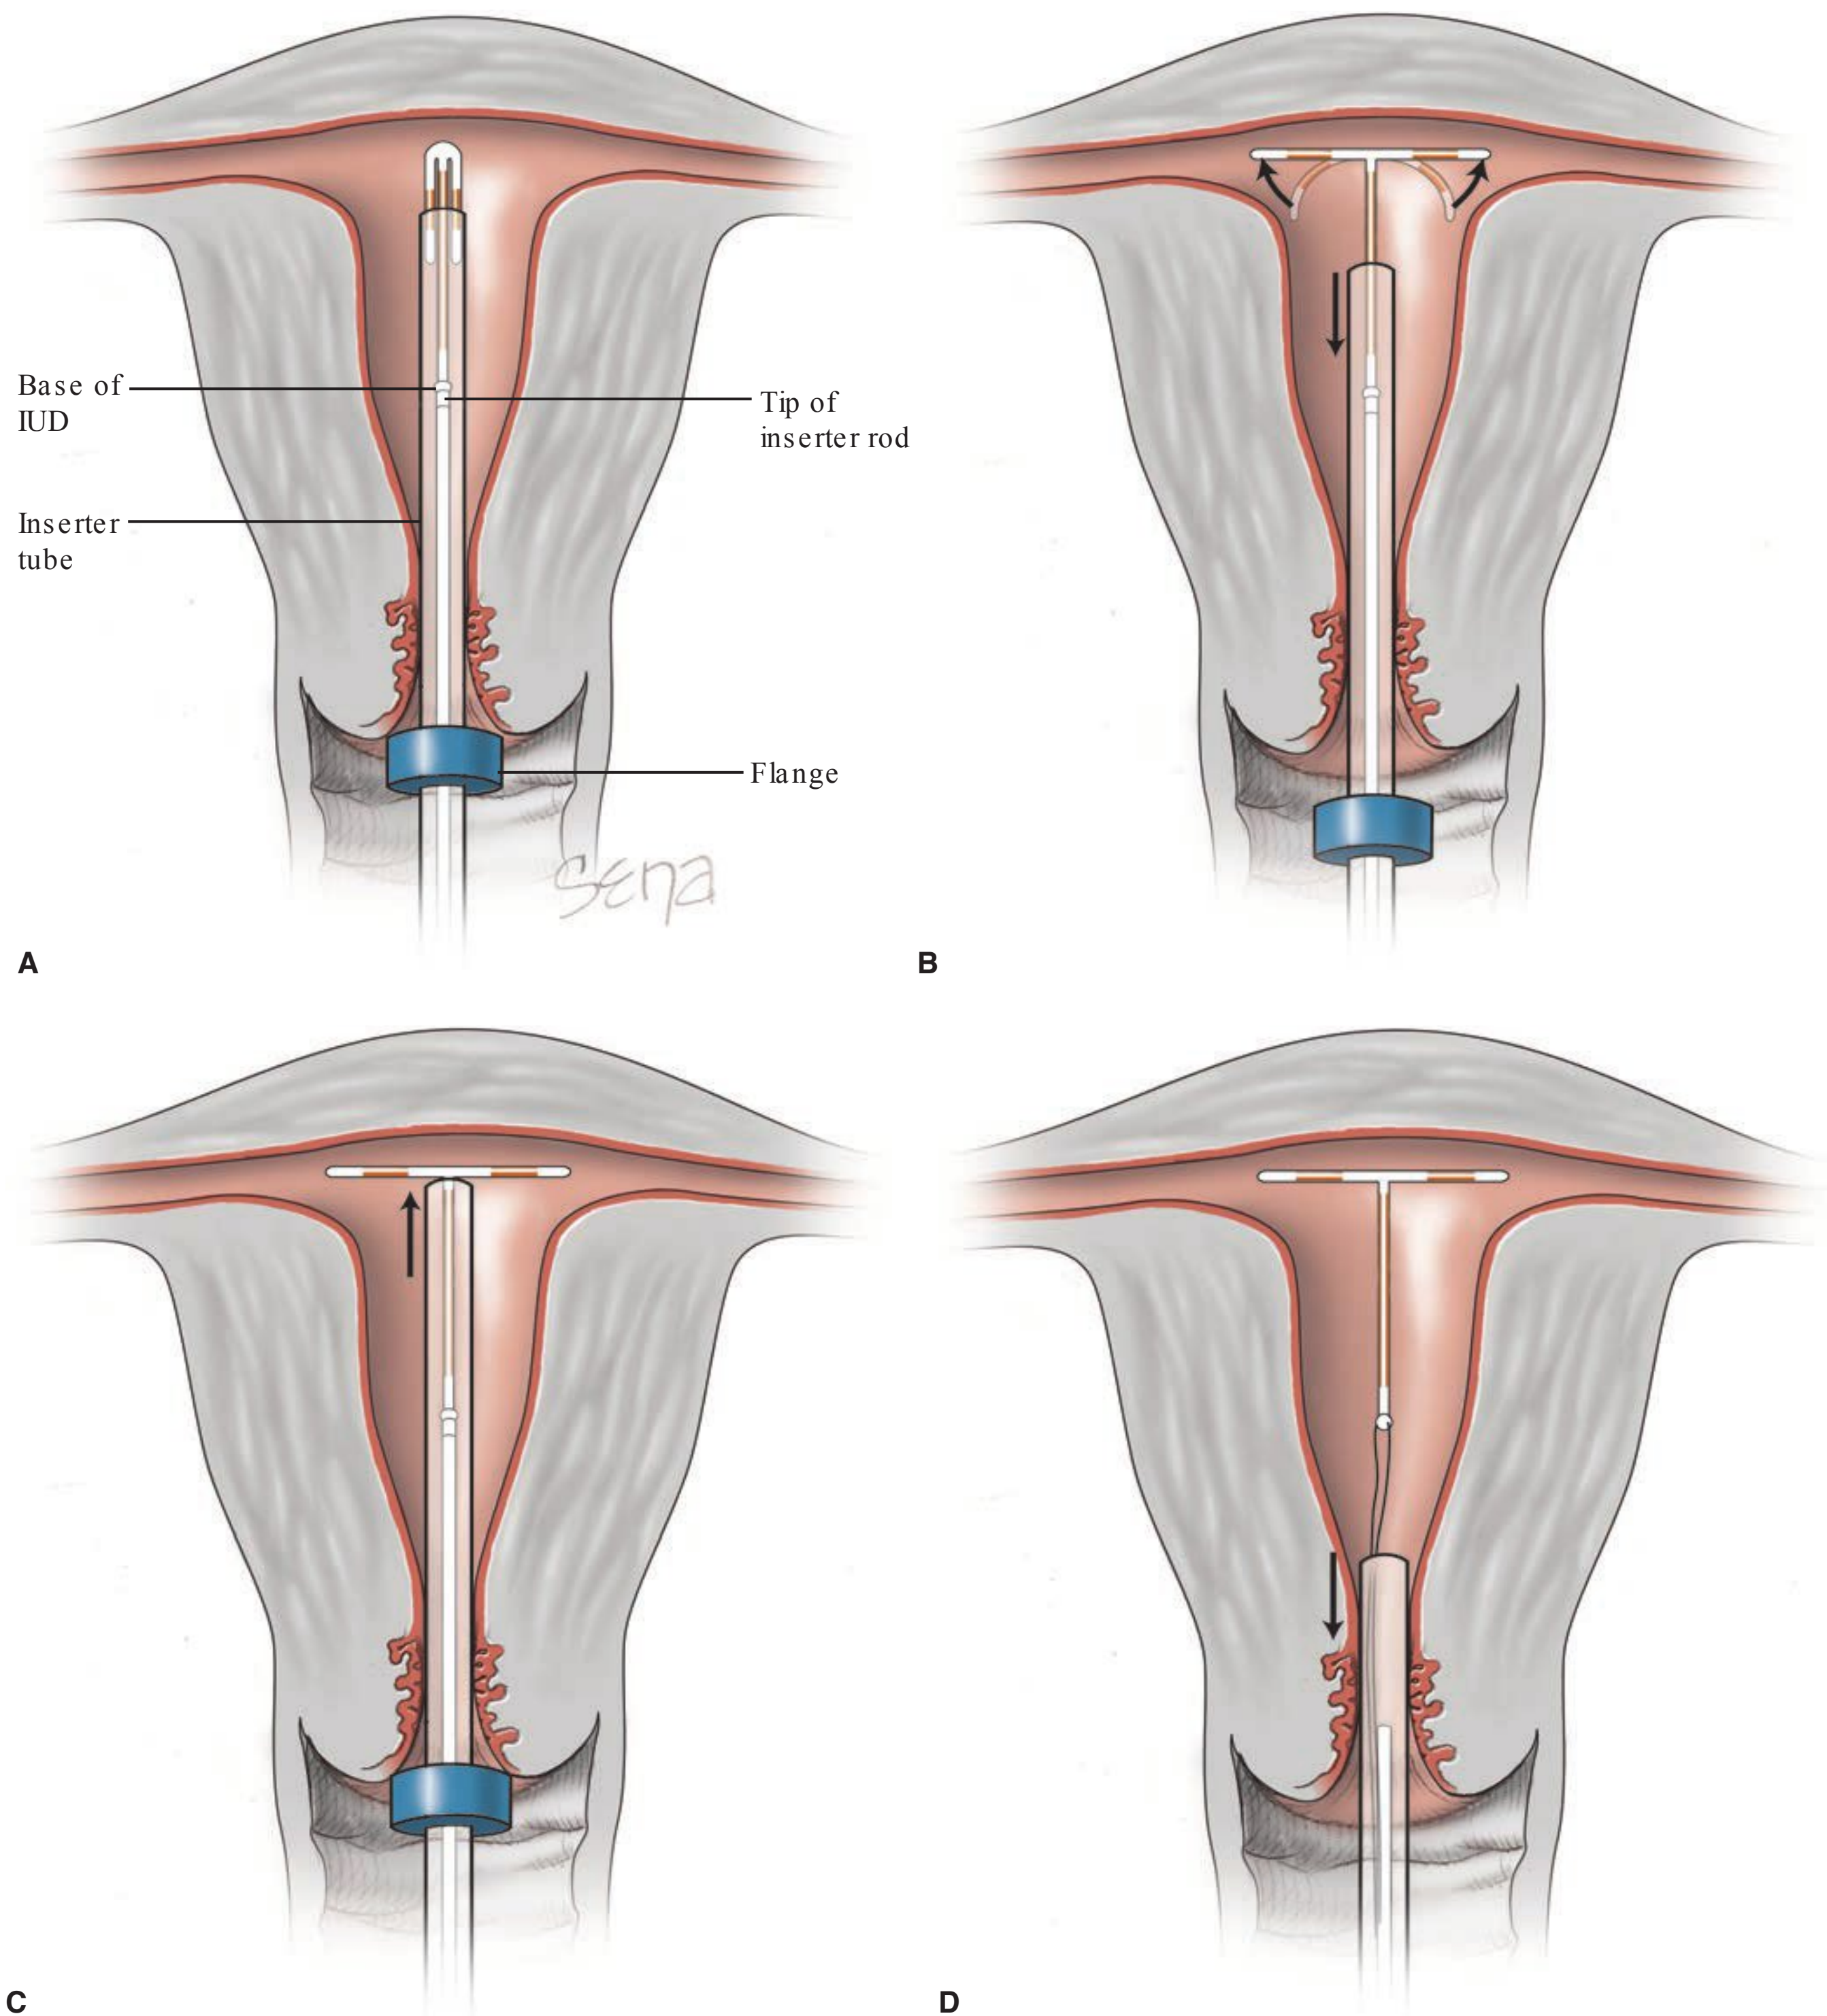

Contraception can be provided by a progestin-containing device that is implanted subdermally and releases hormone over many years. The devices are coated with a polymer to prevent fibrosis. Several systems have been developed, but only one is available in the United States. The initial implant, the Norplant System, releases levonorgestrel from six Silastic rods.

It was withdrawn from the U.S. market, and a fund has been established by the manufacturer to ensure access to patients for removal. Supposedly, the silicone-based rods caused ill-defined symptoms that were reversed with removal. A newer two-rod levonorgestrel system, Jadelle, has received FDA approval but is not marketed or distributed in the United States (Sivin, 2002). Sino-implant II is a structurally and pharmacologically similar system to Jadelle. It is manufactured in China and approved for use by several countries in Asia and Africa (Steiner, 2010).

The implant Nexplanon is currently the only subdermal contraceptive implant marketed in the United States. It is a single-rod subdermal implant containing 68 mg of a progestin—*etonogestrel*—and covered by an ethylene vinyl acetate copolymer. Nexplanon has replaced the earlier etonogestrel implant, Implanon.

For Nexplanon, contraception is provided by progestin released continuously to suppress ovulation, increase cervical mucus viscosity, and induce endometrial atrophy. The etonogestrel implant will provide contraception for up to 3 years. At this time, the device is removed, and another rod may be placed within the same incision site. Contraindications for this device are similar to those cited for other progestin-containing methods. Specifically, these include pregnancy, thrombosis or thromboembolic disorders, benign or malignant hepatic tumors, active liver disease, undiagnosed abnormal genital bleeding, or breast cancer (Merck, 2014). Importantly, patients are counseled that Nexplanon causes irregular bleeding that does not normalize over time. Thus, women who cannot tolerate unpredictable and irregular spotting or bleeding should select an alternative method.

**FIGURE 5-4** Insertion of ParaGard T380A. The IUD is loaded into its inserter tube not more than 5 minutes before insertion. If longer, the malleable arms can retain “memory” of the inserter and remain bent inward. A blue plastic flange on the outside of the inserter tube is positioned from the IUD tip to reflect the uterine depth ascertained during sounding. The IUD arms should lie in the same plane as the flat portion of the blue flange. **A.** The inserter tube, with the IUD loaded, is passed into the endometrial cavity. When the blue flange abuts the cervix, insertion stops. **B.** To release the IUD arms, the solid white rod within the inserter tube is held steady while the inserter tube is withdrawn no more than 1 cm. **C.** The inserter tube is then carefully moved upward toward the top of the uterus until slight resistance is felt. **D.** First, the solid white rod and then the inserter tube are withdrawn individually. At completion, only the threads are visible protruding from the cervix. These are trimmed to allow 3 to 4 cm to extend into the vagina.

**FIGURE 5-5** Insertion of Mirena intrauterine system. Threads from behind the slider are first released to hang freely. The teal-colored slider found on the handle should be positioned at the top of the handle nearest the device. The IUD arms are oriented horizontally. **A.** As both free threads are pulled outward, the Mirena IUD is drawn into the inserter tube. The threads are then moved upward from below and tightly fixed into the handle's cleft. A flange on the outside of the inserter tube is positioned from the IUD tip to reflect the depth found with uterine sounding. **B.** While inserting the Mirena device, the slider is held firmly in position at the top of the handle. Gentle traction is created by outward traction on the tenaculum to align the cervical canal with the uterine cavity. The inserter tube is gently threaded into the uterus until the flange lies 1.5 to 2 cm from the external cervical os to allow the arms to open. While holding the inserter steady, the IUD arms are released by pulling the slider back only to the raised horizontal line on the handle. This position is held for 15 to 20 seconds to allow the arms to fully open. **C.** The inserter is then gently guided into the uterine cavity until its flange touches the cervix. **D.** The device is released by holding the inserter firmly in position and pulling the slider back all the way. The threads will be released automatically. The inserter may then be removed. IUD strings are trimmed to leave approximately 3 cm visible outside the cervix.

**FIGURE 5-6** Nexplanon insertion. A sterile pen marks the insertion site, which is 8 to 10 cm proximal to the medial humeral condyle. A second mark is placed 4 cm proximally along the arm's long axis. The area is cleaned aseptically, and a 1-percent lidocaine anesthetic track is injected along the planned insertion path. **A.** The insertion device is grasped at its gripper bubbles found on either side, and the needle cap is removed outward. The device can be seen within the needle bore. The needle bevel then pierces the skin at a 30-degree angle. **B.** Once the complete bevel is subcutaneous, the needle is immediately angled downward to lie horizontally. **C.** Importantly, the skin is tented upward by the needle as the needle is slowly advanced horizontally and subdermally. **D.** Once the needle is completely inserted, the lever on the top of the device is pulled backward toward the operator. This retracts the needle and thereby deposits the implant. The device is then lifted away from the skin. After placement, both patient and operator should palpate the 4-cm implant.

Nexplanon is inserted subdermally along the biceps groove of the inner arm and 6 to 8 cm from the elbow (Fig. 5-6). Immediately following insertion, the provider and patient should document that the device is palpable beneath the skin. When Nexplanon is removed, this superficial location allows in-office extraction of the implant. Through a small incision large enough to admit hemostat tips, the implant is grasped and removed. If desired, a new rod can be placed through this same incision.

If Nexplanon is not palpable, it can be imaged by radiography, computed tomography (CT), sonography, or magnetic resonance (MR) imaging. Norplant and Jadelle are also radiopaque. This is an advantage compared with Implanon, which is not radiopaque and requires sonography with a 10- to 15-MHz sonographic transducer or MR imaging for identification (Shulman, 2006). In the rare event that an etonogestrel implant cannot be palpated or identified radiologically, the manufacturer can be contacted and arrangements made for etonogestrel level measurement (Merck, 2014).

### ■ permanent Contraception—Sterilization

In 2011 to 2013, surgical sterilization was one of the most commonly reported forms of contraception in childbearing-aged women in the United States (Daniels, 2014). These procedures cannot be tracked accurately because most interval tubal sterilizations and vasectomies are performed in ambulatory surgical centers. However, according to the National Survey of Family Growth, approximately 643,000 female tubal sterilizations are performed annually in the United States (Chan, 2010). The two most commonly employed forms in this country are bilateral tubal ligation—frequently via laparoscopy—and hysteroscopic tubal sterilization. The latter has become popular, and in some settings, it is used in up to half of nonpuerperal female sterilizations (Shavell, 2009).

Over the past 20 years, several important multicenter studies regarding sterilization have been performed by investigators of the Collaborative Review of Sterilization (CREST) and the

Centers for Disease Control and Prevention. Data from many of these studies are subsequently described.

### Female Tubal Sterilization

This is usually accomplished by occlusion or division of the fallopian tubes to prevent ovum passage and fertilization. According to the National Health Statistics Report, 27 percent of contracepting women in the United States use this method (Jones, 2012). Approximately half of tubal sterilization procedures are performed in conjunction with cesarean delivery or soon after vaginal delivery (MacKay, 2001). Accordingly, this is termed *puerperal sterilization*. The other half of tubal sterilization procedures are done at a time unrelated to recent pregnancy, that is, nonpuerperal tubal sterilization. This is also termed *interval sterilization*. In most instances, nonpuerperal tubal sterilization is accomplished via laparoscopy or hysteroscopy.

**Tubal Interruption Methods.** There are three methods, along with their modifications, that are used for tubal interruption. These include application of various permanent rings or clips to the fallopian tubes; electrocoagulation of a tubal segment; or ligation with suture material, with or without removal of a tubal segment. In a Cochrane review, Lawrie and colleagues (2011) concluded that all of these are effective in preventing pregnancy.

*Electrocoagulation* is used for destruction of a segment of tube and can be accomplished with either unipolar or bipolar current. Although unipolar coagulation has the lowest long-term failure rate, it also has the highest serious complication rate. For this reason, bipolar coagulation is favored by most (American College of Obstetricians and Gynecologists, 2013a).

*Mechanical methods* of tubal occlusion can be accomplished with: (1) a silicone rubber band such as the *Falope Ring* or the *Tubal Ring*; (2) the spring-loaded *Hulka-Clemens clip*—also known as the *Wolf clip*, or (3) the silicone-lined titanium *Filshie clip*. The steps to these procedures are described in Section 44-2 (p. 1006) of the surgical atlas. In a randomized trial of 2746 women, Sokal and associates (2000) compared the Tubal Ring

and Filshie clip and reported similar rates of safety and 1-year pregnancy rates of 1.7 per 1000 women. All of these mechanical occlusion methods have favorable long-term success rate.

**Suture ligation** with tubal segment excision is more often used for puerperal sterilization. Methods include Parkland, Pomeroy, and modified Pomeroy, which are illustrated in Section 43-7 (p. 937).

The type of abdominal entry for sterilization is also variable. Laparoscopic tubal ligation is the leading method used in this country for nonpuerperal female sterilization (American College of Obstetrics and Gynecologists, 2013a). This is frequently done in an ambulatory surgical setting under general anesthesia, and the woman can be discharged several hours later. Alternatively, some choose minilaparotomy using a 3-cm suprapubic incision. This is especially popular in resource-poor countries. With either laparoscopy or minilaparotomy, major morbidity is rare. Minor morbidity, however, was twice as common with minilaparotomy in a review by Kulier and associates (2004). Finally, the peritoneal cavity can also be entered by colpotomy through the posterior vaginal fornix, although this approach is infrequently used.

**Counseling.** Indications for this elective procedure for sterilization include a request for sterilization with clear understanding that this is permanent and irreversible. Each woman is counseled regarding all alternative contraceptive options and their efficacy. Each woman is also informed regarding her sterilization options, which include laparoscopic or hysteroscopic tubal occlusion or bilateral total salpingectomy. The risks and benefits of each are thoroughly discussed. Many women may also have questions or misunderstanding about possible long-term outcomes after female sterilization. As with any operation, surgical risks are assessed, and occasionally the procedure may be contraindicated.

**Risk-reducing Salpingectomy.** The Society of Gynecologic Oncology (2013) currently recommends consideration of bilateral total salpingectomy as a preventive measure against serous ovarian and peritoneal cancers. As discussed in Chapter 35 (p. 738), this may be especially relevant for women at greatest risk for these cancers, namely, women with *BRCA1* or *BRCA2* mutation. Most pelvic serous cancers are thought to originate in the distal fallopian tube. Total salpingectomy may confer up to a 34-percent reduction in endometrioid and serous ovarian cancer rates (Erickson, 2013; Sieh, 2013). If risk-reducing salpingectomy is elected in women with BRCA mutations, the pathology requisition form should state this genetic information. This prompts more thorough tubal specimen sectioning to search for cancer and precancerous lesions, which can be found in the tubes of BRCA mutation carriers.

In low-risk women, because the ovarian cancer risk is less than 2 percent, risk-reducing salpingectomy as an isolated procedure is likely unwarranted. However, if surgery such as hysterectomy or tubal sterilization is planned, women are counseled regarding the risks and benefits of complete fallopian tube excision (Anderson, 2013). As advantages, total salpingectomy may decrease risks for subsequent tubal surgery. As disadvantages, operating time may be increased by 10 minutes, and more importantly, the degree of long-term ovarian blood supply disruption with total salpingectomy is not clearly defined (Creinin, 2014).

**Regret.** Invariably, some women will later express regrets about sterilization. From a CREST study, Jamieson and coworkers (2002) reported that by 5 years, 7 percent of women undergoing tubal ligation had regrets. This is not limited to female sterilization, as 6 percent of women whose husbands had undergone vasectomy had similar remorse. The cumulative probability of regret within 14 years of sterilization was 20 percent for women aged 30 or younger at sterilization compared with only 6 percent for those older than 30 years (Hillis, 1999).

No woman should undergo tubal sterilization believing that subsequent fertility is guaranteed either by surgical reanastomosis or by assisted reproductive techniques. These are technically difficult, expensive, and not always successful. Pregnancy rates vary greatly depending upon age, the amount of tube remaining, and the technology used. Pregnancy rates range from 50 to 90 percent with surgical reversal (Defieux, 2011). Of note, pregnancies that result after tubal sterilization reanastomosis are at risk to be ectopic.

**Method Failure.** Reasons for interval tubal sterilization failure are not always apparent, but some have been identified. First, surgical error may occur and likely accounts for 30 to 50 percent of cases. Second, tubal fistula may complicate occlusion methods. Although usually encountered with electrocoagulation procedures, fistulas from inadequate or defective electric current delivery are now less likely because an amp meter is used routinely. In some cases, sterilization failure may follow spontaneous reanastomosis of the tubal segments. With faulty clips, occlusion can be incomplete. Last, luteal phase pregnancy may occur and describes the situation in which a woman is already pregnant when the procedure is performed. This can often be avoided by scheduling surgery during the menstrual cycle's follicular phase and by preoperative human chorionic gonadotropin (hCG) testing.

The overall failure rate reported from the CREST studies was 1.3 percent of 10,685 tubal sterilization surgeries. As shown in Figure 5-7, these rates vary for different procedures.

**FIGURE 5-7** Data from the U.S. Collaborative Review of Sterilization (CREST) shows the cumulative probability of pregnancy per 1000 procedures by five methods of tubal sterilization. (Data from Peterson HB, Xia Z, Hughes JM, et al: The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 174(4):1161, 1996.)

And even with the same operation, failure rates vary. For example, with electrocoagulation, if fewer than three tubal sites are coagulated, the 5-year cumulative pregnancy rate approximates 12 per 1000 procedures. However, it is only 3 per 1000 if three or more sites are coagulated (Peterson, 1999). The lifetime increased cumulative failure rates over time are supportive that failures after 1 year are not likely due to technical errors. Indeed, Soderstrom (1985) found that most sterilization failures were not preventable.

With method failure, pregnancies following tubal sterilization have a high incidence of being ectopically implanted compared with the rate in a general gynecologic population. These rates are especially high following electrocoagulation procedures, in which up to 65 percent of pregnancies are ectopic. With failures following other methods—ring, clip, tubal resection—this percentage is only 10 percent (Peterson, 1999). Importantly, ectopic pregnancy must be excluded when any symptoms of pregnancy develop in a woman who has undergone tubal sterilization.

**Other Effects.** Several studies have evaluated the risk of heavy menstrual bleeding and intermenstrual bleeding following tubal sterilization, and many report no link (DeStefano, 1985; Shy, 1992). In addition, Peterson and coworkers (2000) compared long-term outcomes of 9514 women who had undergone tubal sterilization with a cohort of 573 women whose partners had undergone vasectomy. Risks for heavy menstrual bleeding, intermenstrual bleeding, and dysmenorrhea were similar in each group. Perhaps unexpectedly, women who had undergone sterilization had *decreased* duration and volume of menstrual flow, they reported *less* dysmenorrhea, but they had an *increased* incidence of cycle irregularity.

Other long-term effects have also been studied. It is controversial whether risks for subsequent hysterectomy are increased (Pati, 2000). In a CREST surveillance study, Hillis and associates (1997) reported that 17 percent of women undergoing tubal sterilization subsequently had undergone hysterectomy by 14 years. Although they did not compare this incidence with a control cohort, the indications for hysterectomy were similar to those for nonsterilized women who had undergone a hysterectomy. Women are highly unlikely to develop salpingitis following sterilization (Levgur, 2000). Tubal sterilization appears to have a protective effect against ovarian cancer, but not breast cancer (Westhoff, 2000).

Some psychological sequelae of sterilization were evaluated in a CREST study by Costello and associates (2002). These investigators reported that tubal ligation did not change sexual interest or pleasure in 80 percent of women. In the remaining 20 percent of women who reported a change, 80 percent described the changes to be positive.

## Transcervical Sterilization

**Mechanical Tubal Occlusion.** Various methods of sterilization can be completed using a transcervical approach to reach the tubal ostia. Within each ostium, occlusion is achieved by placing either mechanical devices or chemical compounds.

Mechanical methods employ insertion of a device into the proximal fallopian tubes via hysteroscopy. One system, Essure,

**FIGURE 5-8** Microinsert used in the Essure Permanent Birth Control System.

is FDA-approved for use in the United States. A second system, Adiana Permanent Contraception, was taken off the market in 2013.

The Essure Permanent Birth Control System consists of a microinsert made of a stainless steel inner coil that is enclosed in polyester fibers. These fibers are surrounded by an expandable outer coil made of *nitinol*—a nickel and titanium alloy used in coronary artery stents (Fig. 5-8). Fibroblastic proliferation within the fibers causes tubal occlusion. The Essure technique is described in Section 44-16 (p. 1046). Analgesia provided by intravenous sedation or paracervical block will successfully alleviate pain (Cooper, 2003). In some women, general anesthesia is preferred.

By far, the overwhelming advantage of hysteroscopic sterilization is that it can be performed in the office. In addition, the procedure times average less than 20 minutes. Abnormal anatomy may preclude procedure completion. One year after placement, Essure contraceptive failure rates range from less than 1 percent to 5 percent (Garipey, 2014; Munro, 2014).

Three months following device insertion, hysterosalpingography (HSG) is required to confirm complete occlusion (American College of Obstetricians and Gynecologists, 2012b). Prior to undergoing the procedure, patients are counseled on the importance of HSG compliance as up to half of all unplanned pregnancies after hysteroscopic sterilization may be associated with follow-up noncompliance (Cleary, 2013; Levy, 2007). Other reasons for subsequent unplanned pregnancy include incomplete occlusion (10 percent), incorrect HSG interpretation (33 percent), and an established pregnancy prior to the procedure (1 percent) (Jost, 2013; Munro, 2014). In some women, occlusion is incomplete at 3 months, and the study is then repeated at 6 months postoperatively. Until tubal occlusion is established, another method of contraception is needed. Transvaginal sonography has been investigated as an alternative confirmation tool, but currently HSG is required by the FDA (Veersema, 2011).

Pelvic pain after hysteroscopic sterilization is uncommon. If pelvic pain presents soon after the procedure, symptoms are likely to resolve by 3 months postoperatively, around the same time as the follow-up HSG (Arjona Berral, 2014; Yunker, 2015).

As with all sterilization procedures, Essure placement should be considered permanent. The success rate of subsequent spontaneous pregnancy after microsurgery tubal reversal ranges between 0 and 36 percent (Fernandez, 2014; Monteith, 2014).

**Chemical Tubal Occlusion.** Agents may be placed into the uterine cavity or tubal ostia to incite an inflammatory response to cause tubal occlusion. A method that has been used worldwide in more than 100,000 women consists of using an IUD-type inserter to place quinacrine pellets into the uterine fundus. It is effective, especially considering its simplicity. Pregnancy rates reported by Sokal and colleagues (2008) were 1 and 12 percent at 1 and 10 years, respectively. Although the WHO recommends against its use because of carcinogenesis concerns, it remains an important method for resource-poor countries (Castaño, 2010; Lippes, 2002).

### Hysterectomy

For a woman with uterine or other pelvic disease for which hysterectomy may be indicated, this may be the ideal form of sterilization.

### Male Sterilization

Vasectomy is performed each year in nearly a half million men in the United States (Magnani, 1999). The office procedure is done with local analgesia and usually takes 20 minutes or less to complete. As illustrated in Figure 5-9, a small incision is made in the scrotum, and the lumen of the vas deferens is disrupted to block sperm traveling from the testes. Compared with female tubal sterilization, vasectomy is 30 times less likely to fail and is 20 times less likely to have postoperative complications (Adams, 2009).

Sterility following vasectomy is not immediate nor is its onset reliably predictable. The time until complete expulsion of sperm stored distal to the vas deferens interruption is variable and requires approximately 3 months or 20 ejaculations (American College of Obstetricians and Gynecologists, 2013a). Thus, another form of contraception is used until azoospermia is documented. Although most recommend that semen be analyzed until two consecutive sperm counts are zero, Bradshaw and coworkers (2001) reported that a single azoospermic semen analysis is sufficient.

**FIGURE 5-9** Vasectomy. On the left, the incision site is shown. On the right, a portion of the vas deferens has been excised.

Sterilization by vasectomy has a failure rate less than 1 percent (Michielsen, 2010). Causes include failure from unprotected intercourse too soon after vasectomy, incomplete vas deferens occlusion, or recanalization following suitable separation.

**Fertility Restoration.** After vasectomy, fertility may be restored either by surgical reanastomosis techniques or by sperm retrieval from the testis. Surgical reversal techniques and perioperative evaluation have been reviewed by the American Society for Reproductive Medicine (2008). Sperm retrieval combined with in vitro fertilization techniques avoids such reversal surgeries and is described in Chapter 20 (p. 462). From their review, Shridharani and Sandlow (2010) concluded that microsurgical reversal is cost effective, but comparative trials with sperm retrieval methods are needed.

**Long-term Effects.** Regret of sterilization was discussed on page 116. Other than this, long-term consequences are rare (Amundsen, 2004). However, because antibodies directed at spermatozoa frequently develop in these men, there were initial concerns that these might cause systemic disease. Putative risks were analyzed by Köhler and coworkers (2009) and include cardiovascular disease, immune-complex disorders, psychological changes, male genital cancers, and frontotemporal dementia. Their findings and those of others are not convincing for an increased risk of cardiovascular disease or accelerated atherogenesis from vasectomy (Schwingl, 2000). Moreover, rates of testicular or prostate cancers do not appear increased with this procedure (Holt, 2008; Köhler, 2009).

## SECOND-TIER CONTRACEPTIVE METHODS

Contraceptives considered to be *very effective* are the hormone-containing preparations that include combination oral contraceptives, progestin-only contraceptive pills, and contraceptives with estrogens and/or progestins that are made systemically available by injection, transdermal patch, or intravaginal ring. When used as intended, these methods are highly effective, however, their efficacy is user dependent. Thus, *typical use* considers each woman's compliance with taking a daily pill, changing transdermal patches or rings, or presenting for an injection (see Table 5-2). Such "real world" use significantly diminishes their efficacy, and for women in the United States, these contraceptives have a first-year pregnancy rate of 3 to 9 per 100 users.

### Combined hormonal Contraceptives

These are contraceptives that contain an estrogen and a progestin. As such, several underlying conditions are considered contraindications to their use (Table 5-6). Combined hormonal contraceptives (CHCs) are available in the United States in three formats—oral contraceptive pills, the transdermal patch, and the intravaginal contraceptive ring. Because of limited data for the transdermal and transvaginal methods relative to that for COCs, their use is usually considered along with those of combined oral contraceptives.

### Pharmacology

There are multiple contraceptive actions of CHCs. The most important is to inhibit ovulation by suppression of hypothalamic

**TABLE 5-6.** Contraindications to the Use of Combination Oral Contraceptives

Pregnancy
Uncontrolled hypertension
Smokers older than 35 years
Diabetes with vascular involvement
Cerebrovascular or coronary artery disease
Migraines with associated focal neurologic deficits
Thrombophlebitis or thromboembolic disorders
History of deep-vein thrombophlebitis or thrombotic disorders
Thrombogenic heart arrhythmias or thrombogenic cardiac valvulopathies
Undiagnosed abnormal genital bleeding
Known or suspected breast carcinoma
Cholestatic jaundice of pregnancy or jaundice with pill use
Hepatic adenomas or carcinomas or active liver disease with abnormal liver function
Endometrial cancer or other known or suspected estrogen-dependent neoplasia

gonadotropin-releasing hormone, which prevents pituitary secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Estrogens suppress FSH release and stabilize the endometrium to prevent intermenstrual bleeding—referred to as *breakthrough bleeding* in this setting. Progestins inhibit ovulation by suppressing LH, they thicken cervical mucus to retard sperm passage, and they render the endometrium unfavorable for implantation. Thus, CHCs have contraceptive effects from both hormones and, when taken daily for 3 out of every 4 weeks, provide virtually absolute protection against conception.

Until recently, there were only two estrogens available for use in oral contraceptives in the United States. These were *ethinyl estradiol* and its less commonly used 3-methyl ether, *mestranol*. In 2010, a third estrogen compound—*estradiol valerate*—was approved by the FDA. Most currently available progestins are *19-nortestosterone* derivatives. However, drospirenone is a spironolactone analogue, and the dose of drospirenone in COCs currently marketed has properties similar to a 25-mg dose of spironolactone (Seeger, 2007). Drospirenone displays antiandrogenic activity, and its antimineralocorticoid properties may, in theory, cause potassium retention, leading to hyperkalemia. Thus, drospirenone is not prescribed for those with renal or adrenal insufficiency or with hepatic dysfunction. Moreover, monitoring of serum potassium levels is recommended in the first month for patients chronically treated concomitantly with any drug associated with potassium retention (Bayer HealthCare Pharmaceuticals, 2012). Several studies have shown improvement in symptoms for women with premenstrual dysphoric disorder (PMDD) who use the drospirenone-containing COC, Yaz (Lopez, 2012; Yonkers, 2005). For this pill, the FDA has approved its indications to include treatment of premenstrual syndrome and moderate acne vulgaris for women requesting oral contraception.

Progestins were initially selected for their progestational potency. However, they are often compared, marketed, and prescribed based on their presumed estrogenic, antiestrogenic,

and androgenic effects. However, the doses of progestins used in combined contraceptive formulations are so low that none of these purported negative side effects are actually manifested clinically. In fact, an important effect of CHCs is increased production of sex hormone-binding globulin (SHBG) by the liver and production is promoted mostly by the estrogen component of CHCs. Elevated SHBG levels lower serum free testosterone levels and thereby limit  $5\alpha$ -reductase, the enzyme necessary to convert testosterone to its active form, dihydrotestosterone. For this reason, CHCs can be expected to have salutary effects on androgen-related conditions such as acne (del Marmol, 2004; Rosen, 2003; Torneycroft, 1999).

### Combined Oral Contraceptive Pills

**Formulations.** Hormone-containing contraceptive pills recently had a celebrated 50<sup>th</sup> anniversary in this country. These various preparations—used by approximately 16 million women in the United States in 2013—are popularly known by several names (United Nations, 2013). Among others, these include: *combination oral contraceptives (COCs)*, *birth control pills (BCPs)*, *oral contraceptives (OCs)*, *oral contraceptive pills (OCPs)*, and most simply, *the pill*.

*Combination oral contraceptives* are marketed in a bewildering variety shown in (Table 5-7 and Fig. 5-10). Currently, the daily estrogen content in most COCs varies from 20 to 50  $\mu\text{g}$  of ethinyl estradiol, and most pills contain 35  $\mu\text{g}$  or less. Of note, in 2011, the FDA approved the first pill containing only 10  $\mu\text{g}$  of ethinyl estradiol—*Lo Loestrin Fe*. For current formulations, the lowest acceptable dose is governed by the ability to prevent unacceptable breakthrough bleeding.

With COCs, the progestin dose can be constant throughout the cycle—*monophasic pills*—but the dose frequently is varied—

**FIGURE 5-10** Various combined oral contraceptive (COC) pills.

**A.** Extended-use COCs. Each of the three sequential cards of pills is taken. Placebo pills (peach) are found in the bottom card. **B.** 21/7 triphasic COCs. Active pills are taken for 3 weeks and are followed by seven placebo pills (green). With triphasic pills, the combination of estrogen and progestin varies with color changes, in this case, from white to blue to dark blue. **C.** 24/4 monophasic COCs. Monophasic pills contain a constant dose of estrogen and progestin throughout the pill pack. With 24/4 dosing regimens, the number of placebo pills is decreased to four.

*biphasic* and *triphasic* pills. In some of these, the estrogen dose is also varied during the cycle. *Multiphasic* pills were developed to reduce the amount of total progestin per cycle without sacrificing contraceptive efficacy or cycle control. The reduction is achieved by beginning with a low dose of progestin and increasing it later in the cycle. Theoretically, the lower total dose minimizes the intensity of progestin-induced metabolic

changes and adverse side effects. Disadvantages of multiphasic formulations include confusion caused by the multicolored pills—in some brands there are five colors. Another side effect is breakthrough bleeding or spotting, which likely is increased compared with monophasic pills (Woods, 1992).

In a few COCs, inert placebo pills have been replaced by tablets containing iron. These have the suffix Fe added to their

name. In addition, Beyaz has a form of folate—levomefolate calcium—within both its active and placebo pills.

**Administration.** Ideally, women would begin COCs on the first day of a menstrual cycle, in which case an additional contraceptive method is unnecessary. A more traditional schedule—the *Sunday start*—requires pill initiation on the first Sunday following the onset of menses. If menses begin on a Sunday, then pills are started that day. Last, a *quick start* method may be used in which pills are started on any day of the cycle, commonly the day prescribed. This approach improves short-term compliance (Westhoff, 2002, 2007a). Both Sunday start and quick start methods require use of an additional method for 1 week to protect against conception.

To obtain maximum efficacy and promote regular use, most manufacturers offer dispensers that provide 21 sequential color-coded tablets containing hormones, followed by seven inert tablets of another color (see Fig. 5-10B). Some newer, lower-dose pill regimens continue active hormones for 24 days, followed by 4 days of inert pills (see Fig. 5-10C). The goal of these 24/4 regimens is to improve the efficacy of very low-dose COCs. Importantly, for maximum contraceptive efficiency, each woman should adopt an effective scheme for ensuring daily—or nightly—self-administration.

During COC use, if one dose is missed, conception is unlikely with higher-dose monophasic COCs. When this is recognized, taking that day's pill plus the missed pill will minimize breakthrough bleeding. The remainder of the pill pack is then completed with one pill taken daily.

If several doses are missed, or if a dose is missed with the lower-dose pills, then two pills are taken but an effective barrier technique is added for the subsequent 7 days. The remainder of the pack is completed with one pill taken daily. Alternatively, a new pack can be started and a barrier method added as additional contraception for a week. With any scenario of missed pills, if withdrawal bleeding does not occur during the placebo pills, the pills are continued, but the woman should seek medical attention to exclude pregnancy. Fortunately, CHCs are not teratogenic if taken accidentally during early pregnancy (Lammer, 1986).

### Transdermal System

There is one transdermal system available in the United States—*Ortho Evra patch*. The patch has an inner layer with an adhesive and hormone matrix and an outer water-resistant layer. The patch is applied to the buttocks, upper outer arm, lower abdomen, or upper torso but avoids the breasts. It delivers daily a dose of 150 µg of the progestin norelgestromin and 20 µg of ethinyl estradiol. A new patch is applied each week for 3 weeks, followed by a patch-free week to allow withdrawal bleeding.

In a randomized trial by Audet and associates (2001), the patch was slightly more effective than a low-dose oral contraceptive—1.2 versus 2.2 pregnancies per 100 woman years. Patch replacement was required for either complete—1.8 percent, or partial detachment—2.8 percent. In approximately 3 percent of women, a severe application-site reaction precluded further use.

Pooled data suggest that women who weigh 90 kg or more are at increased risk for pregnancy with the patch (Zieman,

2002). Other metabolic and physiologic effects mirror those seen with low-dose COCs, with the caveat that accumulated experience is limited. The patch is suitable for women who prefer weekly applications to daily dosing and who meet the other criteria for CHC administration.

Concerns have been raised that CHC delivered by the patch may be associated with an increased risk for VTE and other vascular complications. This is followed reports that patch use was associated with increased hepatic synthesis of procoagulants compared with COC or vaginal ring use (Jensen, 2008; White, 2006). Although peak serum estrogen levels were lower with patch versus COC use, total exposure was greater—a relatively increased net estrogen effect (Kluft, 2008; van den Heuvel, 2005). Despite lack of a convincing clinical association, in 2008, the FDA ordered labeling for the patch to state that users *may* be at increased risk for developing VTE. Plaintiff attorneys followed with lawsuits that inevitably curtailed use of the patch method (Phelps, 2009). To date, conclusive evidence for increased morbidity with patch use compared with other CHC use is lacking (Jick, 2006, 2010a,b).

### Transvaginal Ring

There is one intravaginal hormonal contraceptive available in the United States—*NuvaRing*. It is a flexible polymer ring with a 54-mm outer diameter and a 50-mm inner diameter (Fig. 5-11). Its core releases a daily dose of 15 µg ethinyl estradiol and 120 µg of the progestin etonogestrel. These doses effectively inhibit ovulation, and the failure rate is reported to be 0.65 pregnancies per 100 woman-years (Mulders, 2001; Roumen, 2001).

Prior to dispensing, the pharmacy must keep rings refrigerated. Once dispensed, their shelf life is 4 months. The ring is initially inserted within 5 days after the onset of menses. It is removed after 3 weeks for 1 week to allow withdrawal bleeding. After this, a new ring is inserted. Breakthrough bleeding is uncommon. Up to 20 percent of women and 35 percent of men reported being able to feel the ring during intercourse. If bothersome, the ring may be removed for coitus, but it should be replaced within 3 hours.

**FIGURE 5-11** Estrogen- and progestin-releasing vaginal contraceptive ring.

## Extended Cycle Contraception

The use of CHCs continuously for more than 28 days has become increasingly popular. Their benefits include decreased episodes of cyclic bleeding, fewer menstrual symptoms, and lower costs. Several formulations are available (see Table 5-7). Although these prepackaged cycle formulations are available, extended cycle contraception can also be achieved in other ways. The standard 21- or 28-day COC packs, with the placebo pills discarded, can be used continuously. Also, either the transdermal patch or the vaginal ring can be used without the 1-week hormone-free interval.

Several factors unique to extended-cycle CHCs are important. Some of these are shared with continuous progestin contraceptive methods such as implants or injections. The principal change is loss of menstrual normalcy that manifests as less frequent, lighter, and generally unpredictable bleeding episodes. For example, amenorrhea of 6 months or more is reported to affect 8 to 63 percent of extended cycle users. Although considered a benefit by most women, it is far from a guaranteed one. More often, women have fewer bleeding episodes per month. This allows repair of associated anemia in those who had heavy menstrual bleeding prior to extended-cycle use.

However, these characteristics also render some women reluctant to use this method, as it may be considered “unnatural” to miss monthly menses. Some are concerned that amenorrhea may be a sign of pregnancy, may diminish future fertility, or may increase endometrial neoplasia. Rather, findings support a *decreased* risk for endometrial malignancy associated with cyclic CHC use. Thus on a biological basis, it seems reasonable to conclude that this protective effect would also apply to continuous CHC use. Moreover, women who use a continuous CHC method report fewer menstrual symptoms that include headaches, fatigue, bloating, and dysmenorrhea compared with women using cyclic contraceptives (Edelman, 2014). Moreover, hypothalamic-pituitary-ovarian suppression is greater with continuous use and reduces the possibility of escape ovulation caused by delayed start of a new contraceptive cycle.

## Drug Interactions

Interactions between CHCs and various other medications take two forms. First, hormonal contraceptives may interfere with the actions of some drugs shown in Table 5-8. In contrast, some drugs shown in Table 5-9 may decrease the contraceptive

**TABLE 5-8.** Drugs Whose Effectiveness Is Influenced by Combination Oral Contraceptives (COCs)

Interacting Drug	Documentation	Management of the Interacting Drug
<b>Analgesics</b>		
Acetaminophen	Adequate	Possible dose increase needed
Aspirin	Probable	Possible dose increase needed
Meperidine	Suspected	Possible dose decrease needed
Morphine	Probable	Possible dose increase needed
<b>Anticoagulants</b>		
Dicumarol, warfarin	Controversial	
<b>Antidepressants</b>		
Imipramine	Suspected	Reduce dosage about a third
<b>Tranquilizers</b>		
Diazepam, alprazolam	Suspected	Reduce dose
Temazepam	Possible	Possible dose increase needed
Other benzodiazepines	Suspected	Observe for increased effect
<b>Antiinflammatories</b>		
Corticosteroids	Adequate	Watch for increased effect, decrease dose accordingly
<b>Bronchodilators</b>		
Aminophylline, theophylline	Adequate	Reduce starting dose by a third
<b>Antihypertensives</b>		
Cyclopenthiiazide	Adequate	Increase dose
Metoprolol	Suspected	Possible dose decrease needed
<b>Other</b>		
Troleandomycin	Suspected liver damage	Avoid
Cyclosporine	Possible	May use smaller dose
Antiretrovirals	Variable	See manufacturer or other <sup>a</sup>
Lamotrigine	Adequate	With monotherapy or when given with drugs that are not known to alter lamotrigine levels, then avoid COCs

effectiveness of CHCs. Mechanisms for these are multiple and frequently cannot be identified. In some cases, genes coding for cytochrome oxidase system enzymes are either stimulated or suppressed.

Resulting pharmacokinetic changes can decrease serum contraceptive steroid concentrations, but the ultimate effect on ovulation suppression is unknown. However, with current information, these interactions often require that the dose of contraceptive or that of the other drug be adjusted to ensure efficacy.

**Combined Hormonal Contraception and Medical Disorders**

A summary of health benefits associated with CHCs is found in Table 5-10. Despite this, interactions of CHCs with some chronic medical disorders may constitute relative or absolute contraindication to CHC use. These are described in the following sections.

**TABLE 5-10.** Some Benefits of Combination Estrogen plus Progestin Oral Contraceptives

Increased bone density
Reduced menstrual blood loss and anemia
Decreased risk of ectopic pregnancy
Improved dysmenorrhea from endometriosis
Fewer premenstrual complaints
Decreased risk of endometrial and ovarian cancer
Reduction in various benign breast diseases
Inhibition of hirsutism progression
Acne improvement
Prevention of atherogenesis
Decreased incidence and severity of acute salpingitis
Decreased activity of rheumatoid arthritis

**Obese and Overweight Women.** In general, CHCs are highly effective in obese women (Lopez, 2013). However, obesity may result in altered pharmacokinetics of some CHC methods. To that said, data regarding overweight women are conflicting regarding increased pregnancy risk due to decreased CHC efficacy from lowered bioavailability (Brunner, 2005; Edelman, 2009; Holt, 2005; Westhoff, 2010). Importantly, in some women, obesity may be synergistic with other conditions, described next, that may render CHCs a less optimal contraceptive method.

Excessive weight gain is a concern with use of any hormonal contraceptive. Gallo and associates (2014) again concluded in their review that available evidence was insufficient to determine the influence of CHCs on weight gain, although no large effect was obvious.

**Diabetes Mellitus.** Higher-dose COCs were associated with insulin antagonistic properties, particularly those mediated by progestins. However, with current low-dose CHCs, these concerns have been mitigated. In healthy women, large, long-term prospective studies have found that COCs do not increase the risk for diabetes (Rimm, 1992). Moreover, these agents do not appear to increase the risk for overt diabetes in women with prior gestational diabetes (Kjos, 1998). Last, use of these contraceptives is approved for nonsmoking diabetic women who are younger than 35 years and who have no associated vascular disease (American College of Obstetricians and Gynecologists, 2013d).

**Cardiovascular Disease.** In general, severe cardiovascular disorders limit the use of CHCs. For less severe disorders, however, current formulations do not increase associated risks.

First, low-dose CHCs do not appreciably increase the absolute risk of clinically significant hypertension (Chasan-Taber,

1996). However, it is common practice for patients to return 8 to 12 weeks following CHC initiation for evaluation of blood pressure and other symptoms. For those with already established chronic hypertension, CHC use is permissible in those with well-controlled, otherwise uncomplicated hypertension (American College of Obstetricians and Gynecologists, 2013d). Severe forms of hypertension, especially those with end-organ involvement, usually preclude CHC use.

Women who have had a documented *myocardial infarction* should not be given CHCs. That said, these contraceptives do not increase the de novo risk for myocardial ischemia in nonsmoking women younger than 35 years (Margolis, 2007; Mishell, 2000; World Health Organization, 1997). Smoking by itself, however, is a potent risk factor for ischemic heart disease, and CHCs used after age 35 years act synergistically to increase this risk.

**Cerebrovascular Disorders.** Women who have had either an *ischemic* or *hemorrhagic stroke* should not use CHCs. But the incidence of strokes in nonsmoking young women is low, and use of CHCs does not increase the risk for either type of stroke (World Health Organization, 1996). This form of vascular disorder is more commonly encountered in those who smoke, have hypertension, or have migraine headaches with visual aura and who use CHCs (MacClellan, 2007).

*Migraine headaches* may be a risk factor for strokes in some young women. Curtis and coworkers (2002) reported that women using COCs who had *migraine headaches with aura* had a two- to fourfold increased risk for stroke compared with nonusers. Because of this, the WHO (2010) recommends against CHC use in this subset of migraineurs. Alternatively, the American College of Obstetricians and Gynecologists (2013d), because the absolute risk is low, has concluded that CHCs may be considered for young nonsmoking women who have migraine headaches without focal neurologic changes. For many of these women, an intrauterine contraceptive method or a progestin-only pill may be more appropriate (World Health Organization, 2010).

**Venous Thromboembolism.** Early in CHC history, it was apparent that *deep-vein thrombosis* and *pulmonary embolism* risks were significantly increased in women who used these contraceptives (Realini, 1985). These risks were found to be estrogen-dose related and have been appreciably lowered with evolution of low-dose formulations that contain only 10 to 35 µg of ethinyl estradiol (Westhoff, 1998). Of note, a possible increased VTE risk with drospirenone-containing COCs has been shown in two studies, and the FDA has encouraged an assessment of benefits and of VTE risks in users of these pills (Food and Drug Administration, 2012; Jick, 2011; Parkin, 2011).

Mishell and coworkers (2000) concluded that VTE risk is three- to fourfold higher in current COC users compared with nonusers. However, the risk without contraception is low—approximately 1 per 10,000 woman years—and thus the incidence with CHCs is only 3 to 4 per 10,000 woman years. Importantly, these CHC-enhanced risks appear to dissipate rapidly once contraceptive treatment is discontinued. And, of equal importance, these VTE risks are still lower than those

estimated during pregnancy, which has an incidence of 5 to 6 per 10,000 woman years.

Several cofactors increase the incidence of VTE in women using estrogen-containing contraceptives or those who are pregnant or postpartum. These include one or more of the many thrombophilias, which include *protein C* or *S* deficiency or *factor V Leiden mutation* (Chap. 39, p. 836) (Mohllajee, 2006). Other factors that raise VTE risks are hypertension, obesity, diabetes, smoking, and a sedentary lifestyle (Pomp, 2007, 2008).

Older studies indicated a twofold increased risk for perioperative VTE in CHC users (Robinson, 1991). Data are lacking with the low-dose formulations currently used, and thus the American College of Obstetricians and Gynecologists (2013c,d) recommends balancing VTE risks against those of unintended pregnancy during the 4 to 6 weeks required preoperatively for thrombogenic effects of CHCs to dissipate.

**Systemic Lupus Erythematosus.** The use of CHCs in women with otherwise uncomplicated systemic lupus erythematosus (SLE) has been the “poster child” for evidence-based clinical research. In the past, and with good reason, CHCs were contraindicated in women with SLE. This was because of their underlying high risk to develop venous and arterial thrombosis along with the thrombogenic effects of older high-dose COC pills. The safety of the low-dose modern COCs in many women with SLE was shown in two randomized trials (Petri, 2005; Sánchez-Guerrero, 2005). Use of CHCs in women with SLE was reviewed by Culwell and colleagues (2009). Importantly, CHCs are not appropriate in women with SLE who have positive testing for antiphospholipid antibodies or have other known contraindications to CHC use. Affected women with these antibodies have increased clotting risks.

**Seizure Disorders.** Approximately 1 million women of reproductive age in the United States are diagnosed with some form of epilepsy. As shown in Tables 5-8 and 5-9, metabolism and clearance of some CHCs are appreciably altered by some, but not all, of the commonly used anticonvulsants. One mechanism with several antiepileptic drugs is potent induction of cytochrome P450 system enzymes. In turn, this increases contraceptive steroid metabolism, and serum levels of these decrease by as much as half (American College of Obstetricians and Gynecologists, 2013d; Zupanc, 2006).

These metabolic interactions usually do not result in increased seizure activity. One possible exception is combined use of CHCs and monotherapy with the anticonvulsant lamotrigine. Serum anticonvulsant levels are decreased by up to 50 percent, which may increase seizure risks (Gaffeld, 2011).

Evidence-based guidelines for use of contraceptives by women with epilepsy are listed in the US MEC. Use of CHCs in epileptic women is rated as category 3, that is, theoretical or proven risks usually outweigh the method advantages. CHCs used concurrently with anticonvulsants may reduce contraceptive or anticonvulsant effectiveness. Thus, epileptic women using cytochrome P450 enhancing anticonvulsants are counseled regarding alternate contraceptive methods if feasible. If not, a COC containing at least 30 µg of ethinyl estradiol should be used. For those using lamotrigine monotherapy, CHCs are not recommended.

Although they are not CHCs, progestin-only containing preparations are also affected by use of anticonvulsants that induce the cytochrome P450 enzyme system. These result in decreased serum progestin levels and lower rates of effective ovulation suppression and pose an unacceptable risk of unplanned pregnancy.

**Liver Disease.** Both estrogens and progestins have known effects on hepatic function. Cholestasis and cholestatic jaundice, which develop more commonly in pregnancy, are also infrequently induced by CHC use. Because susceptibility is likely due to an inherited gene mutation of bilirubin transport, cholestasis with CHCs is more likely in women affected during a pregnancy. Discontinuing CHCs typically resolves symptoms. Whether these cholestatic effects of CHCs also raise risks for subsequent cholelithiasis and cholecystectomy is unclear. Any increased risk is likely to be small, and the known effects of increasing parity on gallbladder disease must also be considered.

Regarding women with viral hepatitis or cirrhosis, the WHO has provided recommendations (Kapp, 2009b). For women who have active hepatitis, CHCs should not be initiated, but these may be continued in women who experience a flare of their liver disease while already taking CHCs. Use of progestin-only contraception in these women is not restricted. With cirrhosis, mild compensated disease does not limit the use of CHCs or progestin-only methods. However, in those with severe decompensated disease, all hormonal types are avoided.

**Neoplastic Diseases.** Stimulatory effects of sex steroids on some cancers are a concern. It would appear, however, that overall these hormones do not *cause* cancer (Hannaford, 2007). A report from the Collaborative Group on Epidemiological Studies of Ovarian Cancer (2008) verified earlier studies that showed a protective effect against endometrial and ovarian cancers (Cancer and Steroid Hormone Study, 1987a,b). However, this protection wanes as duration from pill discontinuance increases (Tworoger, 2007). Reports concerning possible increased risks for premalignant and malignant changes of the liver, cervix, and breast are conflicting and are presented next.

First, *hepatic focal nodular hyperplasia* and *benign hepatic adenomas* were previously linked with older higher-dose estrogen-containing COCs. However, studies that evaluated women taking contemporary low-dose COCs reported no such association (Hannaford, 1997; Heinemann, 1998). Similarly, earlier correlations between CHCs and hepatocellular carcinoma have been refuted by the multicenter WHO Study (1989) and by Maheshwari and coworkers (2007). For women with known tumors, COCs may be used in those with focal nodular hyperplasia, but avoided in those with benign hepatic adenoma and hepatocellular carcinoma (Kapp, 2009a).

Second, *cervical dysplasia* and *cervical cancer* rates are increased in COC users. These risks increase with duration of use. But, according to the International Collaboration of Epidemiological Studies of Cervical Cancer (2007), if COC use is discontinued, by 10 years the risk becomes comparable with that of never-users. The reasons for this neoplasia risk are speculative and may be related to more frequent human papillomavirus (HPV) exposure because of decreased use of barrier

methods. It may also be related to the more frequent cytologic screening that COC users may have. Moreover, COCs may increase persistence of HPV infection and HPV oncogene expression (de Villiers, 2003). Importantly, if cervical dysplasia is treated, the recurrence rate is not increased in CHC users.

Last, *breast cancer* is stimulated by female sex steroid hormones, but it is still unclear whether CHCs have an adverse effect on tumor growth or development. The Collaborative Group on Hormonal Factors in Breast Cancer (1996) analyzed data from studies that included more than 53,000 women with breast cancer and 100,000 nonaffected women. They found a significant 1.24-fold increased risk for current COC users. This risk decreased to 1.16 for those 1 to 4 years after discontinuing COCs and 1.07 for those at 5 to 9 years. The risks were not influenced by age at first use, duration of use, family history of breast cancer, first use prior to pregnancy, or the dose or type of hormone used. This lack of correlation serves to question any causal role of COCs in breast tumorigenesis.

The Collaborative Group investigators also found that COC-associated breast tumors tended to be less aggressive and that cancers were detected at earlier stages. They suggested that the increased cancer diagnosis may have been because of more intensive surveillance among users. In a case-control study—4575 cases and 4682 controls—there was no relationship found with either current or past COC use and breast cancer (Marchbanks, 2002). Finally, women heterozygous for *BRCA1* or *BRCA2* gene mutations have not been shown to have an increased incidence of breast or ovarian cancer with COC use (Brohet, 2007). With regard to benign breast disease, Vessey and Yeates (2007) reported that COC use apparently *lowered* the relative risk.

**h IV Infections and Antiretroviral Therapy.** Women with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) require special considerations regarding contraceptive use. As outlined by the American College of Obstetricians and Gynecologists (2012a), affected women need highly effective contraception that meets several criteria. It must be compatible with highly active antiretroviral therapy (HAART), should provide a low risk for acquiring STDs, and must not increase their risk of transmitting HIV to their partners.

Although CHCs are safe for use in HIV-positive women, their metabolism may be variably altered by some HAART regimens in current use. Details of various HAART regimen interactions with CHCs are available at the University of California, San Francisco HIV InSite website: <http://hivinsite.ucsf.edu/insite?page=ar-00-02>.

## ■ progestin-Only Contraceptives

Contraceptives that contain only a progestin were developed to obviate the unwanted side effects of estrogens. Progestins can be delivered by several routes that include tablets, injections, intrauterine devices (p. 108), and subdermal implants (p. 112).

### Progestin-Only Pills

Also called *mini-pills*, POPs are taken daily. They do not reliably inhibit ovulation, but instead thicken cervical mucus and

decidualize and atrophy the endometrium. Because mucus changes do not persist beyond 24 hours, to be maximally effective, a pill is ideally taken at the same time daily. Their use has not achieved widespread popularity because of a much higher incidence of irregular bleeding and a slightly higher pregnancy rate than that seen with CHCs (see Table 5-2).

POPs have minimal if any effect on carbohydrate metabolism and coagulation factors. They do not cause or exacerbate hypertension and thus may be ideal for some women at increased risk for other cardiovascular complications. Such women include those with a history of thrombosis or migraine headaches or smokers older than 35 years. Because they do not impair milk production, POPs are suitable for lactating women. When used in combination with breast feeding, POPs are virtually 100-percent effective for up to 6 months (Betrabet, 1987; Shikary, 1987).

POPs should not be taken by women with unexplained uterine bleeding, breast cancer, hepatic neoplasms, pregnancy, or active severe liver disease (Janssen-Ortho, 2014).

Compliance is essential to POP use. If a pill is taken even 4 hours late, an additional form of contraception must be used for the next 48 hours. This may contribute to another major drawback, which is a higher risk for contraceptive failure compared with CHCs. Moreover, with failure, the proportion of pregnancies that are ectopic is increased (Sivin, 1991). POP effectiveness is also decreased by some medications, and in some instances POPs should be avoided (see Tables 5-8 and 5-9).

Another disadvantage is irregular uterine bleeding. This may be characterized by amenorrhea, intermenstrual bleeding, or prolonged heavy menstrual bleeding. As with other progestin-containing contraceptive methods, functional ovarian cysts develop with a greater frequency, although they usually do not require intervention (Hidalgo, 2006; Inki, 2002).

## Injectable Progestins

**Formulations.** There are three injectable depot progesterone preparations that are used worldwide. This method is popular in the United States and is used by approximately 6 percent of women choosing a contraceptive. Injectable progestins have mechanisms of action similar to those for oral progestins and include increased cervical mucus viscosity, creation of an endometrium unfavorable for implantation, and unpredictable ovulation suppression.

Injectable preparations include depot medroxyprogesterone acetate—marketed as *Depo-Provera*. A 150-mg dose is given by intramuscular injection every 90 days. A derivative of DMPA is marketed as *depo-subQprovera 104*, and a 104-mg dose is given subcutaneously every 90 days. Because absorption is slower with subcutaneous injections, the 104-mg dose is equivalent to the 150-mg intramuscular preparation (Jain, 2004). With either method, if the initial dose is given within the first 5 days following menses onset, no back-up contraception is necessary (Haider, 2007). A third injectable depot progestin that is not currently available in the United States is norethindrone enanthate, which is marketed as *Norgest*, and a 200-mg dose is injected intramuscularly every 2 months.

Injectable progestins have contraceptive efficacy equivalent or better than that of COCs. With perfect use, DMPA has

pregnancy rates of 0.3 percent, but typical-use failure rates are as high as 7 percent at 12 months (Kost, 2008; Said, 1986). Depot progesterone does not suppress lactation, and iron-deficiency anemia is less likely in long-term users because of less menstrual bleeding. Progestin injectables should not be taken by women with pregnancy, unexplained uterine bleeding, breast cancer, active or history of thromboembolic disease, cerebrovascular disease, or significant liver disease (Pfizer, 2014).

As with most progestin-only contraceptive methods, DMPA does not significantly affect lipid metabolism, glucose levels, hemostatic factors, liver function, thyroid function, and blood pressure (Dorflinger, 2002). Moreover, these have not been shown to increase the risk for thromboembolism, stroke, or cardiovascular disease (Mantha, 2012; World Health Organization, 1998). Despite this, manufacturer prescribing information often lists thrombosis or thromboembolic conditions as contraindications. However, for individuals with these disorders, US MEC considers progestin-containing methods category 2.

**Notable Effects.** Patients interested in DMPA use should be familiar with its potential effects and side effects. First, as is typical of progestin-only contraception, DMPA usually causes irregular menstrual-type bleeding. Cromer and coworkers (1994) reported that one fourth of women discontinued its use in the first year because of irregular bleeding. Amenorrhea may develop after extended use, and women are counseled about this benign effect.

Prolonged ovulation suppression may also persist after DMPA injections are stopped. In an earlier study by Gardner and Mishell (1970), one fourth of women did not resume regular menses for up to a year. Accordingly, DMPA may not be the best choice for women who plan to use contraception only briefly before attempting conception.

Bone mineral density can also be significantly diminished because of lowered estrogen levels and is most worrisome in long-term users. This loss is particularly relevant for adolescents because bone density increases most rapidly from ages 10 to 30 years (Sulak, 1999). Additionally, decreased bone mineral density may be a concern for perimenopausal women, who will shortly be entering the menopause, a time of known accelerated bone loss. These concerns prompted the FDA in 2004 to require a black-box warning that DMPA “should be used as a long-term birth control method—longer than 2 years—only if other birth-control methods are inadequate.” There are some mitigating factors that balance this concern. First, although bone loss is greatest during the first 2 years, it subsequently slows appreciably. Second, most bone lost during contraceptive use is restored within 5 years after its discontinuance (Clark, 2006; Harel, 2010). In sum, the American College of Obstetricians and Gynecologists (2014c) has concluded that concerns of bone density loss should not prevent or limit use of this contraceptive method.

Of potential cancer risks, cervical carcinoma in situ rates are possibly increased with DMPA use. However, risks for cervical cancer or for hepatic neoplasms are not higher with this method (Thomas, 1995). Advantageously, ovarian and endometrial cancers are decreased (Kaunitz, 1996; World Health Organization, 1991). In addition, Skegg and colleagues (1995)

pooled the results of the New Zealand and WHO case-control studies that included almost 1800 women with breast cancer. Compared with 14,000 controls, DMPA contraceptive use was associated with a twofold cancer risk in the first 5 years of use. However, the overall risk was not increased.

Of other effects, some women report breast tenderness with DMPA use. Depression has also been reported, but a causal link is unproven. Finally, although weight gain is often attributed to depot progestins, not all studies have shown this (Bahamondes, 2001; Mainwaring, 1995; Moore, 1995; Taneepanichskul, 1998). Beksinska and coworkers (2010) reported that adolescents who used intramuscular DMPA gained 2.3 kg more weight during a 4- to 5-year interval compared with weight gained by adolescents who used COCs. Subcutaneous DMPA has also been shown to cause modest weight gain in most women (Westhoff, 2007b). Because women who gain weight in the first 6 months of use are more likely to have long-term progressive weight gain, Le and colleagues (2009) suggest that these women may benefit from early counseling.

### ThIRD-TIER CONTRACEPTIVE METHODS

There are two types of contraceptive methods that are considered as moderately effective. One type includes barrier methods, which are designed to prevent functional sperm from reaching and fertilizing the ovum. The other category consists of fertility awareness methods. Perhaps more so than with other contraceptive methods, moderately effective methods have the highest success rates when used by couples who are dedicated to their use.

#### ■ Barrier Methods

These methods include vaginal diaphragms and male and female condoms. As shown in Table 5-2, the reported pregnancy rate for these methods varies from 2 to 6 percent in the first year of use and is highly dependent on correct and consistent use.

#### Male Condom

Most condoms are made from latex rubber, and various sizes are manufactured to accommodate male anatomy. Less commonly, polyurethane or lamb cecum is used. Condoms provide effective contraception, and their failure rate when used by strongly motivated couples has been as low as 3 or 4 per 100 couple-years of exposure (Vessey, 1982). Generally, and especially in the first year of use, the failure rate is much higher.

The efficacy of condoms is enhanced appreciably with a reservoir tip. Lubricants should be water based because oil-based products destroy latex condoms and diaphragms (Waldron, 1989). Key steps to ensure maximal condom effectiveness include: (1) used with every coitus, (2) placed before penis and vagina contact, (3) withdrawn while penis still erect, (4) its base held during withdrawal, and (5) used with spermicide.

A distinct advantage of condoms is that, when used properly, they provide considerable—not absolute—protection against many STDs. Condoms also help prevent premalignant cervical changes, probably by blocking HPV transmission (Winer, 2006).

For latex-sensitive individuals, alternative condoms are available. Condoms made from lamb intestines—*natural skin*

or *lambskin condoms*—are effective, but they do not provide protection against STDs. Nonallergenic condoms are made with a synthetic thermoplastic elastomer, such as polyurethane, which is also used in some surgical gloves. These are effective against STDs but have significantly higher breakage and slip-page rates compared with those of latex condoms (Gallo, 2006). In a randomized trial of 901 couples, Steiner and associates (2003) documented breakage and slippage with 8.4 percent of polyurethane condoms compared with only 3.2 percent of latex condoms. They also reported that 6-month typical pregnancy probabilities were 9.0 percent with polyurethane condoms but only 5.4 percent with latex ones.

#### Female Condom—Vaginal Pouch

Manufactured by many companies under different names, female condoms prevent pregnancy and STDs. One brand available in the United States is the *FC2 Female Condom*—a polyurethane cylindrical sheath with a flexible polyurethane ring at each end (Fig. 5-12). The open ring remains outside the vagina, and the closed internal ring is fitted behind the symphysis and beneath the cervix like a diaphragm (Fig. 5-13). It should not be used with a male condom because together they may slip, tear, or become displaced. In vitro tests show the female condom to be impermeable to HIV, cytomegalovirus, and hepatitis B virus. As shown in Table 5-2, the pregnancy rate is higher than with the male condom.

#### Diaphragm plus Spermicide

The diaphragm consists of a circular, flexible rubber dome of various diameters supported by a circumferential metal spring (Fig. 5-14). When used in combination with spermicidal jelly or cream, it can be very effective. The spermicide is applied to the cervical surface centrally in the cup and along the rim. The device is then placed in the vagina so that the cervix, vaginal fornices, and anterior vaginal wall are partitioned effectively from the remainder of the vagina and the penis. At the same time, the centrally placed spermicidal agent is held against the

**FIGURE 5-12** Female condom. (Reproduced with permission from The Cervical Barrier Advancement Society and Ibis Reproductive Health.)

**FIGURE 5-13** Female condom insertion and positioning. **A.** The inner ring is squeezed for insertion and is placed similarly to a diaphragm. **B.** The inner ring is pushed inward with an index finger.

cervix by the diaphragm. When appropriately positioned, the rim is lodged deep into the posterior vaginal fornix. Superiorly, the rim lies in close proximity to the inner surface of the symphysis immediately below the urethra (Fig. 5-15). If the diaphragm is too small, it will not remain in place. If too large, it will be uncomfortable when positioned. Because the variables of size and spring flexibility must be specified, the diaphragm is available only by prescription. Because of the requirement for proper placement, the diaphragm may not be an effective choice for women with significant pelvic organ prolapse. The malpositioned uterus can cause unstable diaphragm positioning that results in expulsion.

For use, the diaphragm and spermicidal agent can be inserted well before intercourse, but if more than 2 hours elapse, additional spermicide is placed in the upper vagina for maximum protection. Spermicide is similarly placed before

each episode of coitus. The diaphragm is not removed for at least 6 hours after intercourse. Because toxic shock syndrome has been described following its use, the diaphragm is not left in place for longer than 24 hours.

Proper diaphragm use requires a high level of motivation. Vessey and coworkers (1982) reported a pregnancy rate of only 1.9 to 2.4 per 100 woman-years for compliant users. In a small study, Bounds and colleagues (1995) reported a much higher failure rate of 12.3 per 100 woman years. The unintended pregnancy rate is lower in women older than 35 years compared with younger women.

### Cervical Cap

This reusable, washable, silicone barrier device surrounds the cervix to block sperm passage and is combined with a spermicide. Marketed in the United States, FemCap is currently

**FIGURE 5-14** Group of three diaphragms. (Reproduced with permission from The Cervical Barrier Advancement Society and Ibis Reproductive Health.)

**FIGURE 5-15** A diaphragm in place creates a physical barrier between the vagina and cervix.

**FIGURE 5-16** CycleBeads. During use, the red bead denotes menses onset, and the small black band is advanced, as directed by the arrow, for each day of the menstrual cycle. When the white beads are reached, abstinence is observed until brown beads begin again. (Reproduced with permission from Cycle Technologies.)

available in 22-, 26-, and 30-mm diameters to accommodate differing cervical sizes. It may be inserted any time prior to intercourse and must be left in place for at least 8 hours thereafter. Spermicide dosing and redosing mirrors that with a diaphragm. Other caps formerly manufactured in the United States that might still be in use include Prentif, Vimule, Dumas, and Lea Shield.

### ■ Fertility Awareness-based Methods

This form of contraception is defined by the WHO (2007) as a method that involves identification of the fertile days of the menstrual cycle (Fig. 5-16). The couple may then avoid intercourse or use a barrier method during those days. The comparative efficacy of fertility-based awareness methods remains unknown (Grimes, 2004). Clearly, proper instruction is critical, and complex charting is involved. These charts, as well as detailed advice, are available from the National Fertility Awareness and Natural Family Planning Service for the United Kingdom at: <http://www.fertilityuk.org> and from the Natural Family Site at: <http://www.bygpub.com/natural>.

## FOURTH-TIER CONTRACEPTIVE METHODS

### ■ Spermicides

These contraceptives are marketed variously as creams, jellies, suppositories, aerosol foams, and film (Fig. 5-17). They are used widely in the United States, and most are available without a prescription. Probable users include women who find other methods unacceptable. They are useful especially for women who need temporary protection, for example, during the first week after starting CHC or while nursing.

Spermicidal agents provide a physical barrier to sperm penetration and a chemical spermicidal action. The active ingredient is nonoxynol-9 or octoxynol-9. Importantly, spermicides must be deposited high in the vagina in contact with the cervix shortly before intercourse. Their duration of maximal

**FIGURE 5-17** Vaginal contraceptive film. The film is first folded in half and then folded up and over the tip of the inserting finger. Once inserted near the cervix, the film will dissolve to provide spermicide.

effectiveness is usually no more than 1 hour. Thereafter, they must be reinserted before repeat intercourse. Douching, if practiced, is avoided for at least 6 hours after intercourse.

High pregnancy rates are primarily attributable to inconsistent use rather than to method failure. Even if inserted regularly and correctly, however, foam preparations are reported to have a failure rate of 5 to 12 pregnancies per 100 woman-years of use (Trussell, 1990). If pregnancy does occur with use, spermicides are not teratogenic (Briggs, 2015).

Spermicides that primarily contain nonoxynol-9 do not provide protection against STDs. In randomized trials, Roddy and colleagues (1998) compared nonoxynol-9 with and without condom use and found no additional protective effects against chlamydial or HIV infection or gonorrhea. Long-term use of nonoxynol-9 was reported to have minimal effects on vaginal flora (Schreiber, 2006).

There is currently much interest in combined spermicide-microbicide agents. These have the advantage of protecting against STDs, including HIV (Weber, 2005). Those in the surfactant class have dual action—they destroy the sperm membrane and they also disrupt the outer envelopes or membranes of viral and bacterial pathogens. Second-generation microbicides also fortify natural defenses. Third-generation microbicides work as topical antiretroviral agents.

### ■ Contraceptive Sponge

The contraceptive sponge *Today* was reintroduced into the United States in 2005. Sold over the counter, it consists of a nonoxynol-9-impregnated polyurethane disc that can be inserted for up to 24 hours prior to intercourse (Fig. 5-18). The disc is moistened and placed directly against the cervix. While in place, the sponge provides contraception regardless of the number of coital episodes. For efficacy, it remains in place for 6 hours after intercourse, and to lower irritation and infection risks, it remains no longer than 30 hours (Mayer Laboratories, 2009). Although perhaps more convenient, the sponge is less effective than the diaphragm or condom.

**FIGURE 5-18** Vaginal sponge. When in position, the sponge dimple apposes the cervix surface, and the ribbon loop faces outward to allow easy hooking with a finger for removal.

## EMERGENCY CONTRACEPTION

First popularized by the “morning-after pill” in the 1970s, emergency contraception (EC) is now widely available in other forms. These methods are appropriate for women presenting for contraceptive care following consensual but unprotected sexual intercourse or following sexual assault. There are several methods that, if used correctly, will substantially decrease the likelihood of an unwanted pregnancy in these women. According to the American College of Obstetricians and Gynecologists (2015), methods currently available include sex steroid-containing compounds, antiprogesterone compounds, and the copper-

containing IUD (Table 5-11). Importantly, because duration of use is short, women with conditions that might normally contraindicate hormonal forms may be given these for EC.

Information regarding EC is made available to health care providers or patients by several 24-hour sources:

- American Congress of Obstetricians and Gynecologists: [www.acog.org](http://www.acog.org)
- Emergency Contraception Hotline and website: 1-888-NOT-2-LATE (888-668-2528) and [www.not-2-late.com](http://www.not-2-late.com)
- Reproductive Health Technologies Project: [www.rhtp.org/contraception/emergency/](http://www.rhtp.org/contraception/emergency/)
- Pastillas Anticonceptivas de Emergencia: [www.en3dias.org.mx](http://www.en3dias.org.mx).

## hormone-based Options

### Mechanisms of Action

Hormonal contraceptives have different mechanisms of action depending on which day of the menstrual cycle intercourse occurs and which day the tablets are given (Croxatto, 2003). One major mode is inhibition or delay of ovulation (Marions, 2004). Other suggested mechanisms include endometrial changes that prevent implantation, interference with sperm transport or penetration, and impaired corpus luteum function. Despite these effects, every method used for postcoital contraception will have failures. Pregnancies that develop despite emergency hormonal contraception appear unaffected by this prophylaxis. Moreover, emergency hormonal contraception is not a form of medical abortion. Rather, this method prevents ovulation or implantation. It cannot disrupt a zygote that has implanted.

Except perhaps the copper IUD, other EC methods generally will not prevent pregnancy resulting from subsequent episodes of intercourse during the same cycle. Accordingly, use of a barrier

**TABLE 5-11.** Methods Available for Use as Emergency Contraception

Method	Formulation	Pills per Dose
<b>progestin-Only pill</b>		
Plan B <sup>a</sup>	0.75 mg levonorgestrel	1
Plan B One-Step <sup>b</sup>	150 mg levonorgestrel	1
<b>SPRM pill</b>		
Ella <sup>b</sup>	30 mg ulipristal acetate	1
<b>COC pills<sup>a, c</sup></b>		
Ogestrel	0.05 mg ethinyl estradiol + 0.5 mg norgestrel <sup>d</sup>	2
Lo/Ovral, Cryselle	0.03 mg ethinyl estradiol + 0.3 mg norgestrel <sup>d</sup>	4
Trivora (pink), Enpress (orange)	0.03 mg ethinyl estradiol + 0.125 mg levonorgestrel	4
Aviane, Lessina	0.02 mg ethinyl estradiol + 0.1 mg levonorgestrel	5
<b>Copper-containing IUD</b>		
ParaGard T380A		

<sup>a</sup>Treatment consists of two doses taken 12 hours apart.

<sup>b</sup>Treatment consists of a single dose taken once.

<sup>c</sup>Use of an antiemetic agent before taking the medication will lessen the risk of nausea, which is a common side effect.

<sup>d</sup>Norgestrel contains two isomers, and only one of these isomers is bioactive, namely levonorgestrel. Thus, the amount of norgestrel needed for efficacy is twice that of the levonorgestrel-based regimens. COC = combination oral contraceptive; SPRM = selective progesterone-receptor modulator.

technique is recommended until the next menses. When menstruation is delayed 3 weeks past its expected onset, the likelihood of pregnancy is increased and appropriate testing is instituted.

### Estrogen-Progestin Combinations

Also known as the *Yuzpe method*, these COC-containing regimens shown in Table 5-11 have been approved by the FDA for use as EC (Yuzpe, 1974). Although more effective the sooner they are taken after unprotected intercourse, pills should be taken within 72 hours of intercourse, but may be given up to 120 hours. Initial dosing is followed 12 hours later by a second dose.

Efficacy is defined by the number of pregnancies observed after treatment divided by the estimated number that would have occurred with no treatment. The *prevented fraction* ranges widely between reports and averages approximately 75 percent with COC regimens (American College of Obstetricians and Gynecologists, 2015).

Nausea and vomiting are common with COC regimens because of their high estrogen doses (Trussell, 1998a). An oral antiemetic taken at least 1 hour before each dose may reduce these bothersome symptoms. In randomized trials, a 1-hour pretreatment dose of either 50-mg meclizine or 10-mg metoclopramide was effective (Ragan, 2003; Raymond, 2000). If vomiting occurs within 2 hours of a dose, a replacement dose is given.

### Progestin-only Regimens

A progestin-only method of EC is marketed as *Plan B* and *Plan B One-Step*. Plan B consists of two tablets, each containing 0.75 mg of levonorgestrel. The first dose is taken within 72 hours of unprotected coitus but may be given as late as 120 hours, and the second dose is taken 12 hours later (see Table 5-11). Ngai and associates (2005) also showed that a 24-hour interval between dosing is effective. Plan B One-Step is a single, 1.5-mg levonorgestrel dose, which is taken ideally with 72 hours or up to 120 hours following intercourse.

Most studies, including a multicenter WHO trial, indicate that the progestin-only regimens are more effective than COC regimens to prevent pregnancy (von Hertzen, 2002). The American College of Obstetricians and Gynecologists (2015) cites an approximate 50-percent decreased pregnancy rate with levonorgestrel compared with COCs. Finally, Ellertson and colleagues (2003) reported a 55-percent pregnancy prevention rate even if Plan B was taken as late as 4 to 5 days after unprotected intercourse.

### Antiprogestins and Selective Progestin-receptor Modulators

These agents, described in Chapter 9 (p. 207), have contraceptive activity because they prevent progesterone-mediated endometrial preparation for implantation. There are several mechanisms by which antiprogesterone compounds achieve this. One mechanism is by progesterone-receptor modulation, and two compounds are available.

First, mifepristone (RU 486)—*Mifeprex*—is a progesterone antagonist. It either delays ovulation or impairs secretory endometrium development. Cheng and colleagues (2012) in their Cochrane review noted that mifepristone in single doses of 25 or 50 mg was superior to other hormonal EC regimens.

Mifepristone also had few side effects. In the United States, mifepristone is not used for EC because of its high cost and because it is not manufactured or marketed in an appropriate dose for EC.

A second drug, a selective progesterone-receptor modulator (SPRM), was FDA approved in 2010 for postcoital contraception. Ulipristal acetate—*Ella*—is taken as a single 30-mg tablet up to 120 hours after unprotected intercourse (Brache, 2010). Side effects include nausea and delay of subsequent menses.

### ■ Copper-containing Intrauterine Devices

Insertion of a copper-containing IUD is an effective postcoital contraceptive method. Fasoli and coworkers (1989) summarized nine studies that included results from 879 women who chose this as a sole method of postcoital contraception. The only pregnancy reported aborted spontaneously. Trussell and Stewart (1998b) reported that when the IUD was inserted up to 5 days after unprotected coitus, the failure rate was 1 percent. A secondary advantage is that this method also puts in place an effective 10-year method of contraception.

ABORTION CONSEQUENCES	155
POSTABORTAL CONTRACEPTION	155
REFERENCES	156

The word *abortion* derives from the Latin *aboriri*—to miscarry. Abortion is defined as the spontaneous or induced termination of pregnancy before fetal viability. It is thus appropriate that miscarriage and abortion are terms used interchangeably in a medical context. But, because popular use of abortion by laypersons implies a deliberate intact pregnancy termination, many prefer miscarriage for spontaneous fetal loss. Both terms will be used throughout this chapter.

### TERMINOLOGY

Defining viability has significant medical, legal, and social implications as this definition provides the line that separates

abortion from preterm birth. It is usually defined by pregnancy duration and fetal birthweight for statistical and legal purposes. The National Center for Health Statistics, the Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO) all define *abortion* as any pregnancy termination—spontaneous or induced—prior to 20 weeks' gestation or with a fetus born weighing < 500 g. Confusion may be introduced by state law criteria that define abortion more widely.

Technologic developments have revolutionized current abortion terminology. Transvaginal sonography (TVS) and precise measurement of serum human chorionic gonadotropin (hCG) concentrations help to identify extremely early pregnancies and to clarify intrauterine versus ectopic location. Ubiquitous application of these practices makes it possible to distinguish between a *chemical* and a *clinical* pregnancy. Another term, *pregnancy of unknown location*—*PUL*, aids the goal of early identification and management of ectopic pregnancy (Barnhart, 2011). Management options for ectopic gestation are described in Chapter 7 (p. 161). Of intrauterine pregnancies, those that end in a spontaneous abortion during the first trimester, that is, within the first 12<sup>6/7</sup> weeks of gestation, are also termed *early pregnancy loss* or *early pregnancy failure*.

Approximately half of first-trimester miscarriages are *anembryonic*, that is, with no identifiable embryonic elements. The previous term *blighted ovum* for these pregnancies has fallen out of favor. The remaining pregnancies are *embryonic* miscarriages, which may be further grouped as either those with chromosomal anomalies (*aneuploid abortions*) or those with a normal chromosomal complement (*euploid abortions*).

Common terms used to describe pregnancy losses are listed here and will be discussed in this chapter. They include:

1. Spontaneous abortion—this category includes threatened, inevitable, incomplete, complete, and missed abortion. Septic abortion is used to further classify any of these that are complicated by infection.
2. Recurrent abortion—this term is variably defined, but it is meant to identify women with repetitive spontaneous abortions.
3. Induced abortion—this term is used to describe surgical or medical termination of a live fetus that has not reached viability.

### SPONTANEOUS ABORTION

#### ■ Incidence

More than 80 percent of spontaneous abortions occur during the first 12 weeks of gestation (American College of Obstetricians

and Gynecologists, 2015). With first trimester losses, death of the embryo or fetus nearly always precedes spontaneous expulsion. Death of the conceptus is usually accompanied by hemorrhage into the decidua basalis. This is followed by adjacent tissue necrosis that stimulates uterine contractions and expulsion. An intact gestational sac is usually filled with fluid and may or may not contain an embryo or fetus.

The reported incidence of spontaneous abortion varies with the sensitivity of methods used to identify them. Wilcox and colleagues (1988) studied 221 healthy women through 707 menstrual cycles. They used highly specific assays sensitive to minute concentrations of maternal serum beta human chorionic gonadotropin ( $\beta$ -hCG) and found that 31 percent of pregnancies were lost after implantation. Importantly, two thirds of these early losses were *clinically silent*.

There are factors known to influence clinically apparent spontaneous abortion. However, it is unknown if these same factors affect clinically silent miscarriages. For example, the clinical miscarriage rate nearly doubles with maternal or paternal age greater than 40 (Gracia, 2005; Kleinhaus, 2006). Although it may seem intuitive that this difference would be similar for clinically silent miscarriages, this has not been studied.

■ **Fetal Factors**

As shown in Figure 6-1, approximately half of embryonic first-trimester miscarriages are aneuploid, an incidence that decreases markedly with advancing gestation at the time of pregnancy loss. In general, aneuploid fetuses abort earlier than those with a normal chromosomal complement. Kajii (1980) reported that 75 percent of aneuploid fetuses aborted before 8 weeks, while the rate of euploid abortions peaks at approximately 13 weeks. Almost 95 percent of chromosomal abnormalities in aneuploid fetuses are caused by maternal gametogenesis errors. Thus, only 5 percent are due to aberrant paternal chromosomes (Jacobs, 1980).

**Aneuploid Abortion**

Trisomy describes the condition in which three copies of a given chromosome are present. As shown in Table 6-1, *autosomal trisomy* is the most frequently identified chromosomal anomaly in early miscarriages. Although most trisomies result from

**FIGURE 6-1** Frequency of chromosomal anomalies in abortuses and stillbirths during each trimester. Approximate percentages for each group are shown. (Data from Eiben, 1990; Fantel, 1980; Warburton, 1980.)

**TABLE 6-1.** Chromosomal Findings in Early Abortuses

Chromosomal Studies	Reported Incidence Range (Percent)
<b>Normal (euploid)</b>	
46,XY and 46,XX	45–55
<b>Abnormal (aneuploid)</b>	
Autosomal trisomy	22–32
Monosomy X(45,X)	5–20
Triploidy	6–8
Tetraploidy	2–4
Structural anomaly	2
Double or triple trisomy	0.7–2

Data from Eiben, 1990; Kajii, 1980; Simpson, 1980, 2007.

*isolated nondisjunction*, balanced structural chromosomal rearrangements are present in one partner in approximately 2 percent of couples with recurrent miscarriage (Barber, 2010). Trisomies of all chromosomes have been identified with the exception of chromosome number 1. Trisomies of number 13, 16, 18, 21, and 22 are most common. Based on a study of almost 47,000 women, the baseline risk for fetal aneuploidy was 1.4 percent. One prior miscarriage increased the risk of subsequent fetal aneuploidy to 1.67 percent. Two or three previous miscarriages increased this risk to 1.8 and 2.2 percent, respectively (Bianco, 2006).

*Monosomy X (45,X)* is the single most common specific chromosomal abnormality and is also known as *Turner syndrome*. Cystic hygroma, a multiloculated lymphatic malformation, is a frequent sonographic finding with this syndrome and portends a poor prognosis. Most fetuses with monosomy X spontaneously abort, but some are liveborn females (Chap. 18, p. 411). Conversely, *autosomal monosomy* is rare and incompatible with life.

*Ploidy* describes the number of complete chromosome sets. *Triploidy* is often associated with hydropic or molar placental degeneration (Chap. 37, p. 780). Of hydatidiform moles, partial moles are characteristically triploid. Associated triploid fetuses frequently abort early, and those born later are all grossly malformed. Advanced maternal and paternal ages do not increase the incidence of triploidy. *Tetraploid* fetuses most often abort early in gestation and are rarely liveborn.

*Chromosomal structural abnormalities* infrequently cause abortion. Infants with a balanced translocation who are liveborn usually appear normal but may experience recurrent pregnancy loss as discussed on page 145.

■ **Euploid Abortion**

The causes of euploid abortions are poorly understood, but various maternal medical disorders, genetic abnormalities, uterine defects, and environmental and lifestyle conditions have been implicated. Some of these, such as uterine anomalies or endocrinopathies, would be predicted to cause repetitive losses unless identified and treated. Others, such as genetic abnormalities, are not correctable. Paternal contribution to miscarriage is unclear and is discussed on page 145. Proposed etiologies will be discussed in the following sections, with a somewhat

arbitrary categorization under either the isolated or recurrent pregnancy loss sections.

## ■ Maternal Factors

### Medical Conditions

Pregnancy loss is clearly associated with diabetes mellitus and thyroid disorders (p. 149). Beyond these, few acute or chronic diseases convey early pregnancy risk. Even developing countries report that miscarriages are rarely caused by tuberculosis, malignancies, or other serious conditions.

*Anorexia nervosa* and *bulimia nervosa* are eating disorders reported to cause subfertility, preterm delivery, and fetal growth restriction. However, their association with miscarriages is less studied (Andersen, 2009; Sollid, 2004). *Chronic hypertension* is a common condition associated with increased rates of pre-eclampsia and fetal growth restriction but may not be associated with early pregnancy loss. Inflammatory bowel disease and systemic lupus erythematosus may independently increase the risk (Al Arfaj, 2010; Khashan 2012).

Women who have had multiple miscarriages are significantly more likely to have myocardial infarctions later in life. This perhaps suggests a link with underlying vascular disease (Kharazmi, 2011). Unrepaired cyanotic heart disease is likely an abortion risk, and in some, this may persist after repair (Canobbio, 1996).

Several relatively common genital tract abnormalities—especially those of the uterus—can either prevent pregnancy implantation or disrupt a pregnancy that has implanted. Of these, congenital anomalies are most often implicated, but some acquired anomalies can also cause pregnancy loss. Unless corrected, these defects typically result in repetitive pregnancy losses and thus are considered on page 147.

### Infection

As an overview, only a few organisms are proven to cause abortion. In general, systemic infections likely infect the fetoplacental unit by a blood-borne route. Others may infect locally via maternal genitourinary infection or colonization.

*Chlamydia trachomatis* is suspected and in one study was found in 4 percent of abortuses compared with < 1 percent of controls (Baud, 2011). Oakeshott and coworkers (2002) noted an association between *bacterial vaginosis* and second-but not first-trimester miscarriage. One metaanalysis showed that *Mycoplasma genitalium* infection was significantly associated with spontaneous abortion, preterm birth, and infertility (Lis, 2015).

Data concerning the abortifacient effects of some other infections are conflicting. Namely, roles for *Mycoplasma hominis*, *Ureaplasma urealyticum*, and human immunodeficiency virus (HIV)-1 infection in abortion are unclear (Quinn 1983a,b; Temmerman, 1992; van Benthem, 2000). Moreover in livestock, several infections cause abortion, but data remain inconclusive in humans. These include *Brucella abortus*, *Campylobacter fetus*, and *Toxoplasma gondii* (Feldman, 2010; Hide, 2009).

Last, infections caused by *Listeria monocytogenes*, parvovirus, cytomegalovirus, or herpes simplex virus likely have no abortifacient effects (Brown, 1997; Feldman, 2010; Yan, 2015).

## Surgery

The risk of miscarriage due to a surgical procedure during pregnancy is not well studied. No currently used anesthetic agents have proven teratogenic effects when used at any gestational age. *Uncomplicated* surgical procedures—including abdominal or pelvic surgery—do not appear to increase the risk for abortion (Mazze, 1989). The American College of Obstetricians and Gynecologists (2013c) recommends that elective surgery be postponed until delivery or after. Nonurgent surgery should be performed in the second trimester, when possible, to decrease the theoretical risk for abortion or preterm contractions. Laparoscopy is also suitable, and adaptations for pregnancy are described in Chapter 41 (p. 876) (Pearl, 2011).

Ovarian tumors or cysts can be safely resected without causing pregnancy loss. An important exception involves early removal of the corpus luteum or the ovary in which it resides. If performed prior to 10 weeks' gestation, supplemental progesterone is given. Between 8 and 10 weeks, a single injection of intramuscular 17-hydroxyprogesterone caproate, 150 mg, is given at the time of surgery. If the corpus luteum is excised between 6 to 8 weeks, then two additional 150-mg injections are given 1 and 2 weeks after the first. Other suitable progesterone replacement regimens include: (1) micronized progesterone (Prometrium) 200 or 300 mg orally once daily, or (2) 8-percent progesterone vaginal gel (Crinone), one premeasured applicator vaginally daily plus micronized progesterone, 100 or 200 mg orally once daily. Supplementation is continued until 10 weeks' gestation.

*Trauma* seldom causes first-trimester miscarriage, and although Parkland Hospital is a busy trauma center, this is an infrequent association. Major trauma—especially abdominal—can cause fetal loss but is more likely as pregnancy advances.

## Radiotherapy and Chemotherapy

In utero exposure to radiation may be abortifacient, teratogenic, or carcinogenic depending on the level of exposure and stage of fetal development. Threshold doses that cause abortion are not precisely known but definitely lie within the therapeutic doses used for maternal disease treatment (Williams, 2010). According to Brent (2009), exposure to < 5 rads does not increase the miscarriage risk.

Female cancer survivors who were treated in the past with abdominopelvic radiotherapy may be at increased risk for miscarriage. Wo and Viswanathan (2009) reported an associated two-to eight-fold increased risk for miscarriages, low-birthweight and growth-restricted infants, preterm delivery, and perinatal mortality in women with prior radiotherapy. Hudson (2010) found an associated increased risk for miscarriage in those given radiotherapy and chemotherapy in the past for a childhood cancer.

Regarding chemotherapeutic agents, cases in which women with an early normal gestation are erroneously treated with methotrexate for an ectopic pregnancy are particularly worrisome. In a report of eight such cases, two viable-size fetuses had multiple malformations. An additional three patients spontaneously aborted their pregnancy (Nurmohamed, 2011). In a study of methotrexate treatment for rheumatic disease, the observed incidence of spontaneous abortion and major birth defects was

statistically elevated in the patients receiving methotrexate after conception compared with disease-matched controls or women without autoimmune disease (Weber-Schoendorfer, 2014).

### Medications and Vaccines

Only a few medications have been evaluated regarding the risk for early pregnancy loss. Conclusions have been difficult to derive from these studies based on multiple confounding factors including differences in doses, exposure duration, gestational age, and underlying maternal disease. Nonsteroidal antiinflammatory drugs are not linked to early pregnancy loss (Edwards, 2012). Also, oral contraceptives or spermicidal agents used in contraceptive creams and jellies are not associated with an increased miscarriage rate. When *intrauterine devices* fail to prevent pregnancy, however, the risk of abortion, and specifically septic abortion, increases substantively (Ganer, 2009; Moschos, 2011).

Most routine immunizations can be given safely during pregnancy. Fortunately, evidence to link immunization, even live-virus vaccines, with miscarriage is lacking. Two large metaanalyses clearly demonstrated no harm from the human papillomavirus (HPV) or influenza vaccine in early pregnancy (McMillan, 2015; Wacholder, 2010).

### Nutritional Factors and Weight

*Dietary deficiency* of any one nutrient or moderate deficiency of all nutrients does not appear to be an important cause of abortion. Even in extreme cases—for example, *hyperemesis gravidarum*—abortion is rare. Dietary quality may be important as this risk may be reduced in women who consume fresh fruit and vegetables daily (Maconochie, 2007).

Data also suggest that extremes in weight can be deleterious. *Obesity* is associated with subfertility, increases the risk of miscarriage, and results in a host of other adverse pregnancy outcomes (Boots, 2014). Bellver and associates (2010a) studied 6500 women with in vitro fertilization (IVF)-conceived pregnancies and found that pregnancy and live birth rates were reduced progressively for each body mass index (BMI) unit increase. Although the risks for many adverse late-pregnancy outcomes are decreased after bariatric surgery, any salutary effects on the miscarriage rate are not clear (Guelinckx, 2009). Pregnant women who have undergone bariatric surgery are monitored for nutritional deficiencies (American College of Obstetricians and Gynecologists, 2013d).

Low BMI has also been associated with increased miscarriage risk (Helgstrand, 2005; Metwally, 2010). A cohort of more than 90,000 women demonstrated that the primary modifiable prepregnant risk factors for miscarriage are being underweight, obese, or aged 30 years or older at conception (Feodor Nilsson, 2014).

### Behavior

Of these, alcohol has been well studied in pregnancy. Earlier observations were that both miscarriage and fetal anomaly rates increased with alcohol abuse rates during the first 8 weeks of gestation (Armstrong, 1992; Floyd, 1999). Such outcomes likely are dose related, although safe levels have not been identified. Maconochie (2007) observed a significantly increased

risk only with regular or heavy alcohol use. Low-level alcohol consumption did not significantly increase the abortion risk in two studies (Cavallo, 1995; Kesmodel, 2002). In contrast, Danish National Birth Cohort data suggest an adjusted hazard ratio for first-trimester fetal death of 1.66 with as few as two drinks per week (Andersen, 2012).

At least 15 percent of pregnant women admit to *cigarette smoking*. It seems intuitive that cigarettes could cause early pregnancy loss by several mechanisms that cause adverse late-pregnancy outcomes (Catov, 2008). Some studies link smoking with abortion risk and find a dose-response effect (Armstrong, 1992; Nielsen, 2006). Conversely, several others do not support this association (Rasch, 2003; Wisborg, 2003).

*Excessive caffeine* consumption has been associated with an increased abortion risk. Heavy intake, or approximately five cups of coffee per day—about 500 mg of caffeine—slightly increases the abortion risk (Cnattingius, 2000). Studies of “moderate” intake—less than 200 mg daily—did not demonstrate increased risk (Savitz, 2008; Weng, 2008). Currently, the American College of Obstetricians and Gynecologists (2013b) concludes that moderate consumption likely is not a major abortion risk and that any associated risk with higher intake is unsettled.

The adverse effects of illicit drugs on early pregnancy loss also are unclear. Although cocaine was linked to increased miscarriage in one study, reanalysis refuted this conclusion (Mills, 1999; Ness, 1999).

### Occupation and Environment

Some environmental toxins such as benzene are implicated in fetal malformations, but data regarding miscarriage risk are less clear (Lupo, 2011). Earlier reports implicated arsenic, lead, formaldehyde, benzene, and ethylene oxide (Barlow, 1982). More recently, evidence suggests that DDT—dichlorodiphenyltrichloroethane—may raise miscarriage rates (Eskenazi, 2009). Nevertheless, DDT-containing insecticides are endorsed by the WHO (2011) for mosquito control to prevent malaria.

Few studies assess occupational exposure and abortion risks. Exposure to neither the electromagnetic fields of video display terminals nor to ultrasound increases miscarriage rates (Schnorr, 1991; Taskinen, 1990). An elevated risk has been described for dental assistants exposed to 3 or more hours of *nitrous oxide* per day in offices without gas-scavenging equipment (Rowland, 1995). In their metaanalysis, Dranitsaris and colleagues (2005) found a small incremental risk for spontaneous abortion in women who worked with *cytotoxic antineoplastic chemotherapeutic agents*.

## ■ Clinical Classification

### Threatened Abortion

As a group, abortion can be divided clinically several ways. Commonly used categories include threatened, inevitable, incomplete, complete, and missed abortion. When the products of conception, uterus, and other pelvic organs become infected, the term septic abortion is descriptive.

Of these, *threatened abortion* is presumed when there is a bloody vaginal discharge or bleeding through a closed cervical

**TABLE 6-2.** Increased Incidence of Some Adverse Outcomes in Women with Threatened Abortion

Maternal	Perinatal
Placenta previa	Preterm ruptured membranes
Placental abruption	Preterm birth
Manual removal of placenta	Low-birthweight infant
Cesarean delivery	Fetal growth restriction
	Perinatal death

Data from Johns, 2006; Lykke, 2010; Saraswat, 2010; Wijesiriwardana, 2006.

os (Hasan, 2009). In early pregnancy, bleeding is common and includes that with blastocyst implantation at the time of expected menses. Of pregnant women, approximately one quarter experience first-trimester spotting or heavier bleeding. Of these, 43 percent will subsequently miscarry. Bleeding is by far the most predictive risk factor for pregnancy loss, but this risk is substantially less if fetal cardiac activity is seen sonographically (Tongsong, 1995).

With miscarriage, bleeding usually begins first, and cramping abdominal pain follows hours to days later. There may be low-midline rhythmic cramps; persistent low backache with pelvic pressure; or dull and midline suprapubic discomfort. The combination of bleeding and pain predicts a poor prognosis for pregnancy continuation. Even if miscarriage does not follow early bleeding, the risks for later adverse pregnancy outcomes are elevated (Table 6-2). In a study of almost 1.8 million pregnancies, the risk for many of these pregnancy complications rose threefold (Lykke, 2010).

**Diagnosis.** A woman with an early pregnancy, vaginal bleeding, and pain should be examined. The primary goal is prompt diagnosis of an ectopic pregnancy. Serial quantitative serum  $\beta$ -hCG levels, progesterone levels, and transvaginal sonography, alone or in combination, can help ascertain if the fetus is alive and if it is within the uterus. Repeat evaluations are often necessary as none of these tests has 100-percent accuracy for the diagnosis of pregnancy location or fetal viability. Figure 6-2 depicts composite serum  $\beta$ -hCG level disappearance curves in women with bleeding who went on to have an early miscarriage (Barnhart, 2004). Several predictive models based on serum  $\beta$ -hCG levels done 48 hours apart have been described (Barnhart, 2010; Condous, 2007). Of these, serum  $\beta$ -hCG levels with a robust uterine pregnancy should increase at least 53 to 66 percent every 48 hours (Barnhart, 2004; Kadar, 1982). Seeber and associates (2006) used an even more conservative 35-percent rise after 48 hours.

With serum progesterone levels, those  $< 5$  ng/mL suggest a dying pregnancy. In contrast, values  $> 20$  ng/mL support the diagnosis of a healthy pregnancy. However, progesterone levels often lie between these thresholds, are then considered indeterminate, and thus are less informative.

Transvaginal sonography can document the location and viability of a gestation. If this cannot be done, then pregnancy of unknown location (PUL) is diagnosed. Notably, a consensus

**FIGURE 6-2** Composite curve describing decline in serial human chorionic gonadotropin (hCG) values starting at a level of 2000 mIU/mL following early spontaneous miscarriage. The dashed line is the predicted curve based on the summary of data from all women. The colored area within the dashed lines represent the 95-percent confidence intervals. (Data from Barnhart K, Sammel MD, Chung K, et al: Decline of serum human chorionic gonadotropin and spontaneous complete abortion: defining the normal curve. *Obstet Gynecol* 104:975, 2004.)

conference in 2012 concluded that prior sonographic criteria for fetal viability yielded unacceptably high rates of viable intrauterine pregnancies (IUPs) being falsely diagnosed as nonviable or as PULs (American College of Obstetricians and Gynecologists, 2015; Doubilet, 2014). Such erroneous diagnoses can lead to unnecessary surgical or medical treatment, interruption of a viable IUP, or incorrect assumption that a woman is at recurrent risk for an ectopic pregnancy. They proposed more stringent guidelines for the diagnosis of pregnancy failure (Table 6-3).

One early TVS sign of an IUP is the gestational sac. This anechoic fluid collection represents the exocoelomic cavity. It may be encircled by two echogenic external layers, the *double-decidua sign*, which represent the decidua parietalis and decidua capsularis (Fig. 6-3). The gestational sac can be seen by 4.5 weeks with maternal  $\beta$ -hCG levels between 1500 and 2000 mIU/mL (Barnhart, 1994; Timor-Tritsch, 1988). More recently, Connolly and colleagues (2013) reported that a threshold value of

**TABLE 6-3.** Society of Radiologists in Ultrasound Guidelines for Early Pregnancy Loss Diagnosis

#### Diagnostic Sonographic Findings

- CRL  $\geq 7$  mm and no heartbeat
- MSD  $\geq 25$  mm and no embryo
- Absence of embryo with heartbeat  $\geq 2$  weeks after a scan showed a gestational sac without a yolk sac
- Absence of embryo with heartbeat  $\geq 11$  days after a scan showed a gestational sac with a yolk sac

CRL = crown-rump length; MSD = mean sac diameter.  
Data from Doubilet PM, Benson CB, Bourne T, et al:  
Diagnostic criteria for nonviable pregnancy early in the first trimester, *N Engl J Med* 2013 Oct 10;369(15):1443–1451.

**FIGURE 6-3** Early intrauterine pregnancy. **A.** Sonogram shows the anechoic gestational sac surrounded by two concentric echogenic layers, which are the inner decidua capsularis (arrow) and the peripheral decidua parietalis (arrow). **B.** The drawing shows the anatomy of an early pregnancy. **C.** The yolk sac (arrow) is circular and anechoic, and in this image, it lies to the right of its adjacent embryo.

3500 mIU/mL may be required to detect a gestational sac in 99 percent of cases. Importantly, a gestational sac may appear similar to other intrauterine fluid accumulations such as the *pseudogestational sac* (*pseudosac*) present with ectopic pregnancy (Fig. 7-4, p. 166). A pseudosac may be excluded once a definite yolk sac or embryo is seen inside the sac. The diagnosis of an IUP should be avoided if the yolk sac is not yet seen.

The yolk sac is a circular, 3- to 5-mm-diameter anechoic structure. It is typically seen within the gestational sac at approximately 5.5 weeks' gestation and with a mean sac diameter (MSD)  $\geq 10$  mm. At approximately 6 weeks' gestation, a 1- to 2-mm embryo adjacent to the yolk sac can be found (see Fig. 6-3). Absence of an embryo in a sac with a MSD of 16 to 24 mm is suspicious for pregnancy failure (Doubilet, 2014). Cardiac motion can be detected at 6 to 6.5 weeks' gestation, at an embryonic length of 1 to 5 mm. As shown in Table 6-3, absent cardiac activity at certain stages can be used to diagnose pregnancy failure.

### Inevitable Abortion

Amnionic fluid leaking through a dilated cervix portends almost certain abortion. Either uterine contractions begin promptly or infection develops. Rarely is a gush of vaginal fluid during the first half of pregnancy without serious consequence.

In the rare case, fluid may have collected previously between the amnion and chorion and may not be associated with pain, fever, or bleeding. If documented, then diminished activity with observation is reasonable for some early-to-mid second-trimester gestations. After 48 hours, if no additional amnionic fluid has escaped and if there is no bleeding, cramping, or fever, then a woman may resume ambulation and pelvic rest. With bleeding, cramping, or fever, abortion is considered inevitable, and the uterus is evacuated.

### Incomplete Abortion

Bleeding that follows partial or complete placental separation and that is coupled with dilation of the cervical os is termed incomplete abortion. The fetus and the placenta may remain entirely within the uterus or partially extrude through the dilated os. Before 10 weeks, they are frequently expelled together, but later, they deliver separately. Management options of incomplete abortion include curettage, medical abortion, or expectant management in clinically stable women as discussed on page 152. With surgical therapy, additional cervical dilatation may be necessary before suction curettage. In others, retained placental tissue simply lies loosely within the cervical canal and allows easy extraction with ring forceps. With miscarriage, removed products of conception are sent to pathology for standard histologic analysis. With this, products of conception are confirmed, and gestational trophoblastic disease is excluded.

### Complete Abortion

In some cases, expulsion of the entire pregnancy is completed before a patient presents for care. In such cases, a history of heavy bleeding, cramping, and tissue passage at home is common. Physical examination reveals a closed cervical os. Patients are encouraged to bring in passed tissue, which may be a

complete gestation, blood clots, or a decidual cast. The last is a layer of endometrium in the shape of the uterine cavity that when sloughed can appear as a collapsed sac (Fig. 7-7, p. 168).

If a gestational sac is not identified grossly in the expelled specimen, sonography is performed to differentiate a complete abortion from threatened abortion or ectopic pregnancy. Characteristic findings of a complete abortion include a thickened endometrium without a gestational sac. However, this does not guarantee a recent IUP. Condous and associates (2005) described 152 women with heavy bleeding, an empty uterus with endometrial thickness  $< 15$  mm, and a diagnosis of completed miscarriage. Six percent were subsequently proven to have an ectopic pregnancy. Thus, a diagnosis of complete abortion should not be made unless an intrauterine pregnancy was previously diagnosed sonographically or passage of a gestational sac has been confirmed. In unclear settings, serial serum  $\beta$ -hCG measurements aid correct diagnosis. With complete abortion, these levels drop quickly (Connolly, 2013).

### Missed Abortion—Early Pregnancy Loss

The term *missed abortion* requires clarification. Historically, the term was used to describe dead products of conception that were retained for weeks or months in a uterus with a closed cervical os. Despite this, concurrent early pregnancy findings of amenorrhea, nausea and vomiting, breast changes, and uterine growth appeared normal. To elucidate these disparities, Streeter (1930) studied aborted fetuses and observed that the mean interval from death-to-abortion was approximately 6 weeks.

This historical description of missed abortion is in contrast to that defined currently based on results of serial serum  $\beta$ -hCG assays and TVS (Fig. 6-4). There is rapid confirmation of fetal or embryonic death—even in early pregnancies—and many women choose uterine evacuation when the diagnosis is confirmed. Many classify these as a missed abortion, although the term is used interchangeably with early pregnancy loss or pregnancy wastage (Silver, 2011).

**FIGURE 6-4** Transvaginal sonogram in the sagittal plane showing a gravid uterus. Calipers mark the sac borders of this anembryonic gestation.

### Septic Abortion

Horrible infections and maternal deaths associated with criminal septic abortions have become rare with legalized abortion. Still, perhaps 1 to 2 percent of women with threatened or incomplete miscarriage can develop infection and sepsis syndrome. Elective abortion, either surgical or medical, is also occasionally complicated by severe and even fatal infections (Barrett, 2002; Ho, 2009). Bacteria gain uterine entry and colonize dead conception products. Organisms may invade myometrial tissues and extend to cause parametritis, peritonitis, septicemia, and rarely, endocarditis (Vartian, 1991).

Significant necrotizing infections and toxic shock syndrome have been reported due to *Clostridium perfringens*, *Clostridium sordellii*, and group A streptococcus—*S pyogenes* (Centers for Disease Control and Prevention, 2005; Daif, 2009). Clinical manifestations begin within a few days after the abortion.

Women may be afebrile when first seen with prominent endothelial injury, capillary leakage, hemoconcentration, hypotension, and a profound leukocytosis (Fischer, 2005; Ho, 2009). Maternal deaths from these clostridial species approximate 0.58 per 100,000 medical abortions (Meites, 2010).

Treatment of infected abortion or postabortal sepsis includes prompt administration of broad-spectrum antibiotics. Suitable regimens are found in Table 3-20 (p. 79). For women with septic incomplete abortion or for those with retained fragments, intravenous antimicrobial therapy is promptly followed by uterine evacuation. Most women respond to this treatment within 1 to 2 days and are discharged when afebrile. Continued oral antibiotic treatment is likely unnecessary (Savaris, 2011). Rarely, sepsis causes acute respiratory distress syndrome, acute kidney injury, or disseminated intravascular coagulopathy. In these cases, intensive supportive care is essential.

To prevent postabortal sepsis, prophylactic antibiotics are given at the time of surgical evacuation or induced abortion. The American College of Obstetricians and Gynecologists (2014b) recommends doxycycline, 100 mg orally 1 hour prior to and then 200 mg orally after the procedure.

### ■ Management

Unless there is serious bleeding or infection, management of spontaneous abortion can be individualized. In the case of threatened abortion, bed rest is often recommended but does not improve outcomes. Neither does treatment with a host of medications that include chorionic gonadotropin (Devaseelan, 2010). Acetaminophen-based analgesia will help relieve discomfort from cramping.

For other cases of spontaneous abortion, any of three management options is reasonable—expectant, medical, or surgical. Each has its own risks and benefits. For example, the first two are associated with unpredictable bleeding, and some women will require unscheduled curettage. Nevertheless, expectant management for suspected first-trimester miscarriage results in spontaneous resolution of pregnancy in more than 80 percent of women (Luise, 2002). Whereas surgical treatment is definitive and predictable, it is invasive and not necessary for all women (American College of Obstetricians and Gynecologists, 2015).

**TABLE 6-4.** Randomized Controlled Studies for Management of Early Pregnancy Loss

Study	Inclusion Criteria	No.	Treatment Arms	Outcomes
Nguyen (2005)	Incomplete SAB	149	(1) PGE <sub>1</sub> , 600 µg orally (2) PGE <sub>1</sub> , 600 µg orally initially and at 4 hour	60% completed at 3 d 95% at 7 d; 3% curettage
Zhang (2005)	Pregnancy failure <sup>a</sup>	652	(1) PGE <sub>1</sub> , 800 µg vaginally (2) Vacuum aspiration	71% completed at 3 d; 16% failure 97% successful
Trinder (2006) (MIST Trial)	Incomplete SAB; missed AB	1200	(1) Expectant (2) PGE <sub>1</sub> , 800 µg vaginally ± 200 mg mifepristone (3) Suction curettage	50% curettage 38% curettage 5% repeat curettage
Dao (2007)	Incomplete SAB	447	(1) PGE <sub>1</sub> , 600 µg orally (2) Vacuum aspiration	95% completed 100% completed
Torre (2012)	First-trimester miscarriage <sup>b</sup>	174	(1) Immediate—PGE <sub>1</sub> , 200 µg orally Day 2—400 µg vaginally (2) Delayed—no treatment; TVS days 7 and 14	81% completed 19% curettage 57% completed 43% curettage

<sup>a</sup>Includes anembryonic gestation, embryonic or fetal death, without signs of incomplete SAB.

<sup>b</sup>Includes anembryonic gestation, embryonic or fetal death, or incomplete or inevitable SAB.

SAB= spontaneous abortion; PGE<sub>1</sub>= prostaglandin E<sub>1</sub>; TVS = transvaginal sonography.

With persistent or heavy bleeding, the hematocrit is determined. If there is significant anemia or hypovolemia, then pregnancy evacuation is generally indicated. In cases in which there is a live fetus, some may infrequently choose transfusion and further observation.

Several randomized studies that compared these management schemes were reviewed by Neilson (2013). A major drawback cited for between-study comparisons was varied inclusion criteria and techniques. For example, the success of medical therapy was enhanced in studies that included women with vaginal bleeding compared with those that excluded such women (Creinin, 2006). Selected studies reported since 2005 are listed in in Table 6-4. These permit some generalizations. First, success is dependent on the type of early pregnancy loss, that is, incomplete versus missed abortion. Second, expectant management of spontaneous incomplete abortion has failure rates as high as 50 percent. Medical therapy failure rates with prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) may be related to dose, route, and form, and rates vary from 5 to 40 percent. Last, curettage results in a quick resolution that is 95- to 100-percent successful. Importantly, subsequent pregnancy rates do not differ among these management methods (Smith, 2009).

During spontaneous miscarriage, 2 percent of D-negative women will become isoimmunized if not provided passive isoimmunization. With an induced abortion, this rate may reach 5 percent. The American College of Obstetricians and Gynecologists (2013e) recommends anti-Rh<sub>0</sub>(D)immunoglobulin given as 300 µg intramuscularly (IM) for all gestational ages. Alternatively, dosing may be graduated, with 50 µg given IM for pregnancies ≤ 12 weeks and 300 µg given for those ≥ 13 weeks.

Prophylaxis with a threatened abortion is controversial, and recommendations are limited by scarce evidence-based data

(Hannafin, 2006; Weiss, 2002). Up to 12 weeks' gestation, prophylaxis is optional for women with threatened abortion and a live fetus. At Parkland Hospital, we administer a 50-µg dose to all D-negative women with first-trimester bleeding.

### RECURRENT MISCARRIAGE

Terms used to describe repetitive early spontaneous pregnancy losses include *recurrent miscarriage*, *recurrent spontaneous abortion*, and *recurrent pregnancy loss*, with the last term gaining popularity. The term *habitual abortion* was used in the past and currently is not preferred. Approximately 1 to 2 percent of fertile couples experience recurrent miscarriage, which is classically defined as three or more consecutive losses at < 20 weeks' gestation or with a fetal weight < 500 g. Most women with recurrent miscarriage have embryonic or early fetal loss. Recurrent anembryonic miscarriage or those with consecutive losses after 14 weeks are much less common.

Studies are difficult to compare due to a lack of standard definitions. Some investigators include women with two rather than three consecutive losses, whereas others include women with three nonconsecutive losses. Documentation of pregnancy with β-hCG levels, sonography, and/or pathological examination also varies. At minimum, recurrent miscarriage should be distinguished from sporadic pregnancy loss, which implies intervening pregnancy that reached viability.

As shown in Table 6-5, the success rate of a subsequent viable pregnancy decreases as age increases and as the number of consecutive losses increases (Brigham, 1999). Following more than 150,000 miscarriages, Bhattacharya and coworkers (2010) reported miscarriage rates as they related to the number of prior losses (Table 6-6). In both studies, the risk for subsequent miscarriage was similar following either two or three losses.

**TABLE 6-5.** Predicted Success Rate of Subsequent Pregnancy According to Age and Number of Previous Miscarriages

Age (yr)	No. of Previous Miscarriages			
	2	3	4	5
	Predicted Success of Subsequent Pregnancy (%)			
20	92	90	88	85
25	89	86	82	79
30	84	80	76	71
35	77	73	68	62
40+	69	64	58	52

Data from Brigham SA, Conlon C, Farquhason RG: A longitudinal study of pregnancy outcome following idiopathic recurrent miscarriage. *Hum Reprod* 14(11):2868, 1999.

The American Society for Reproductive Medicine (2013) has proposed that recurrent pregnancy loss (RPL) be defined by two or more failed clinical pregnancies confirmed by either sonographic or histopathologic examination. Each loss should be considered an impetus for further evaluation, and a thorough evaluation is warranted after three losses. Other considerations include maternal age and the interval between pregnancies. Evaluation and treatment are considered earlier in couples with concordant subfertility. This practice is further justified by a recent study of more than 1000 women in which those with two pregnancy losses had a prevalence of abnormal test findings similar to that of women with three or more losses (Jaslow, 2010). Remarkably, the chances for a successful pregnancy are more than 50 percent even after five losses in women younger than 45 years (Brigham, 1999).

## Etiology

Of the many putative causes of early RPL, only three are widely accepted: parental chromosomal abnormalities, antiphospholipid antibody syndrome, and acquired or congenital uterine abnormalities. Other suspected but not proven causes are alloimmunity, endocrinopathies, and environmental toxins. As

**TABLE 6-6.** Predicted Miscarriage Rate with Subsequent Pregnancy Based on Number of Prior Miscarriages<sup>a</sup>

	Previous Pregnancy Losses			
	0	1	2	3
Pregnancies (n)	143,595	6577	700	115
Subsequent risk for miscarriage	7.0%	13.9%	26.1%	27.8%

<sup>a</sup>Nonconsecutive miscarriages showed the same pattern of risk as consecutive miscarriages.  
Data from Bhattacharya S, Townend J, Bhattacharya S: Recurrent miscarriage: are three miscarriages one too many? Analysis of a Scottish population-based database of 151,021 pregnancies. *Eur J Obstet Gynecol Reprod Biol* 150:24, 2010.

discussed on page 139, very few infections are firmly associated with early pregnancy loss. It is even less likely that infections would cause recurrent miscarriage because most are sporadic or they stimulate protective maternal antibodies.

The timing of the recurrent losses may provide a clue to their etiology. For a given individual with RPL, each miscarriage tends to occur near the same gestational age (Heuser, 2010). Genetic factors most frequently result in early embryonic losses, whereas autoimmune or anatomic abnormalities more likely lead to second-trimester losses. Although many causes of RPL parallel those of sporadic miscarriage, the relative incidence differs between the two categories. For example, recurrent first-trimester losses have a significantly lower incidence of genetic abnormalities than observed in sporadic losses. In one series, the products of conception had a normal karyotype in half of recurrent miscarriages but in only a fourth of sporadic losses (Sullivan, 2004).

## Parental Chromosomal Abnormalities

### Parental Karyotype

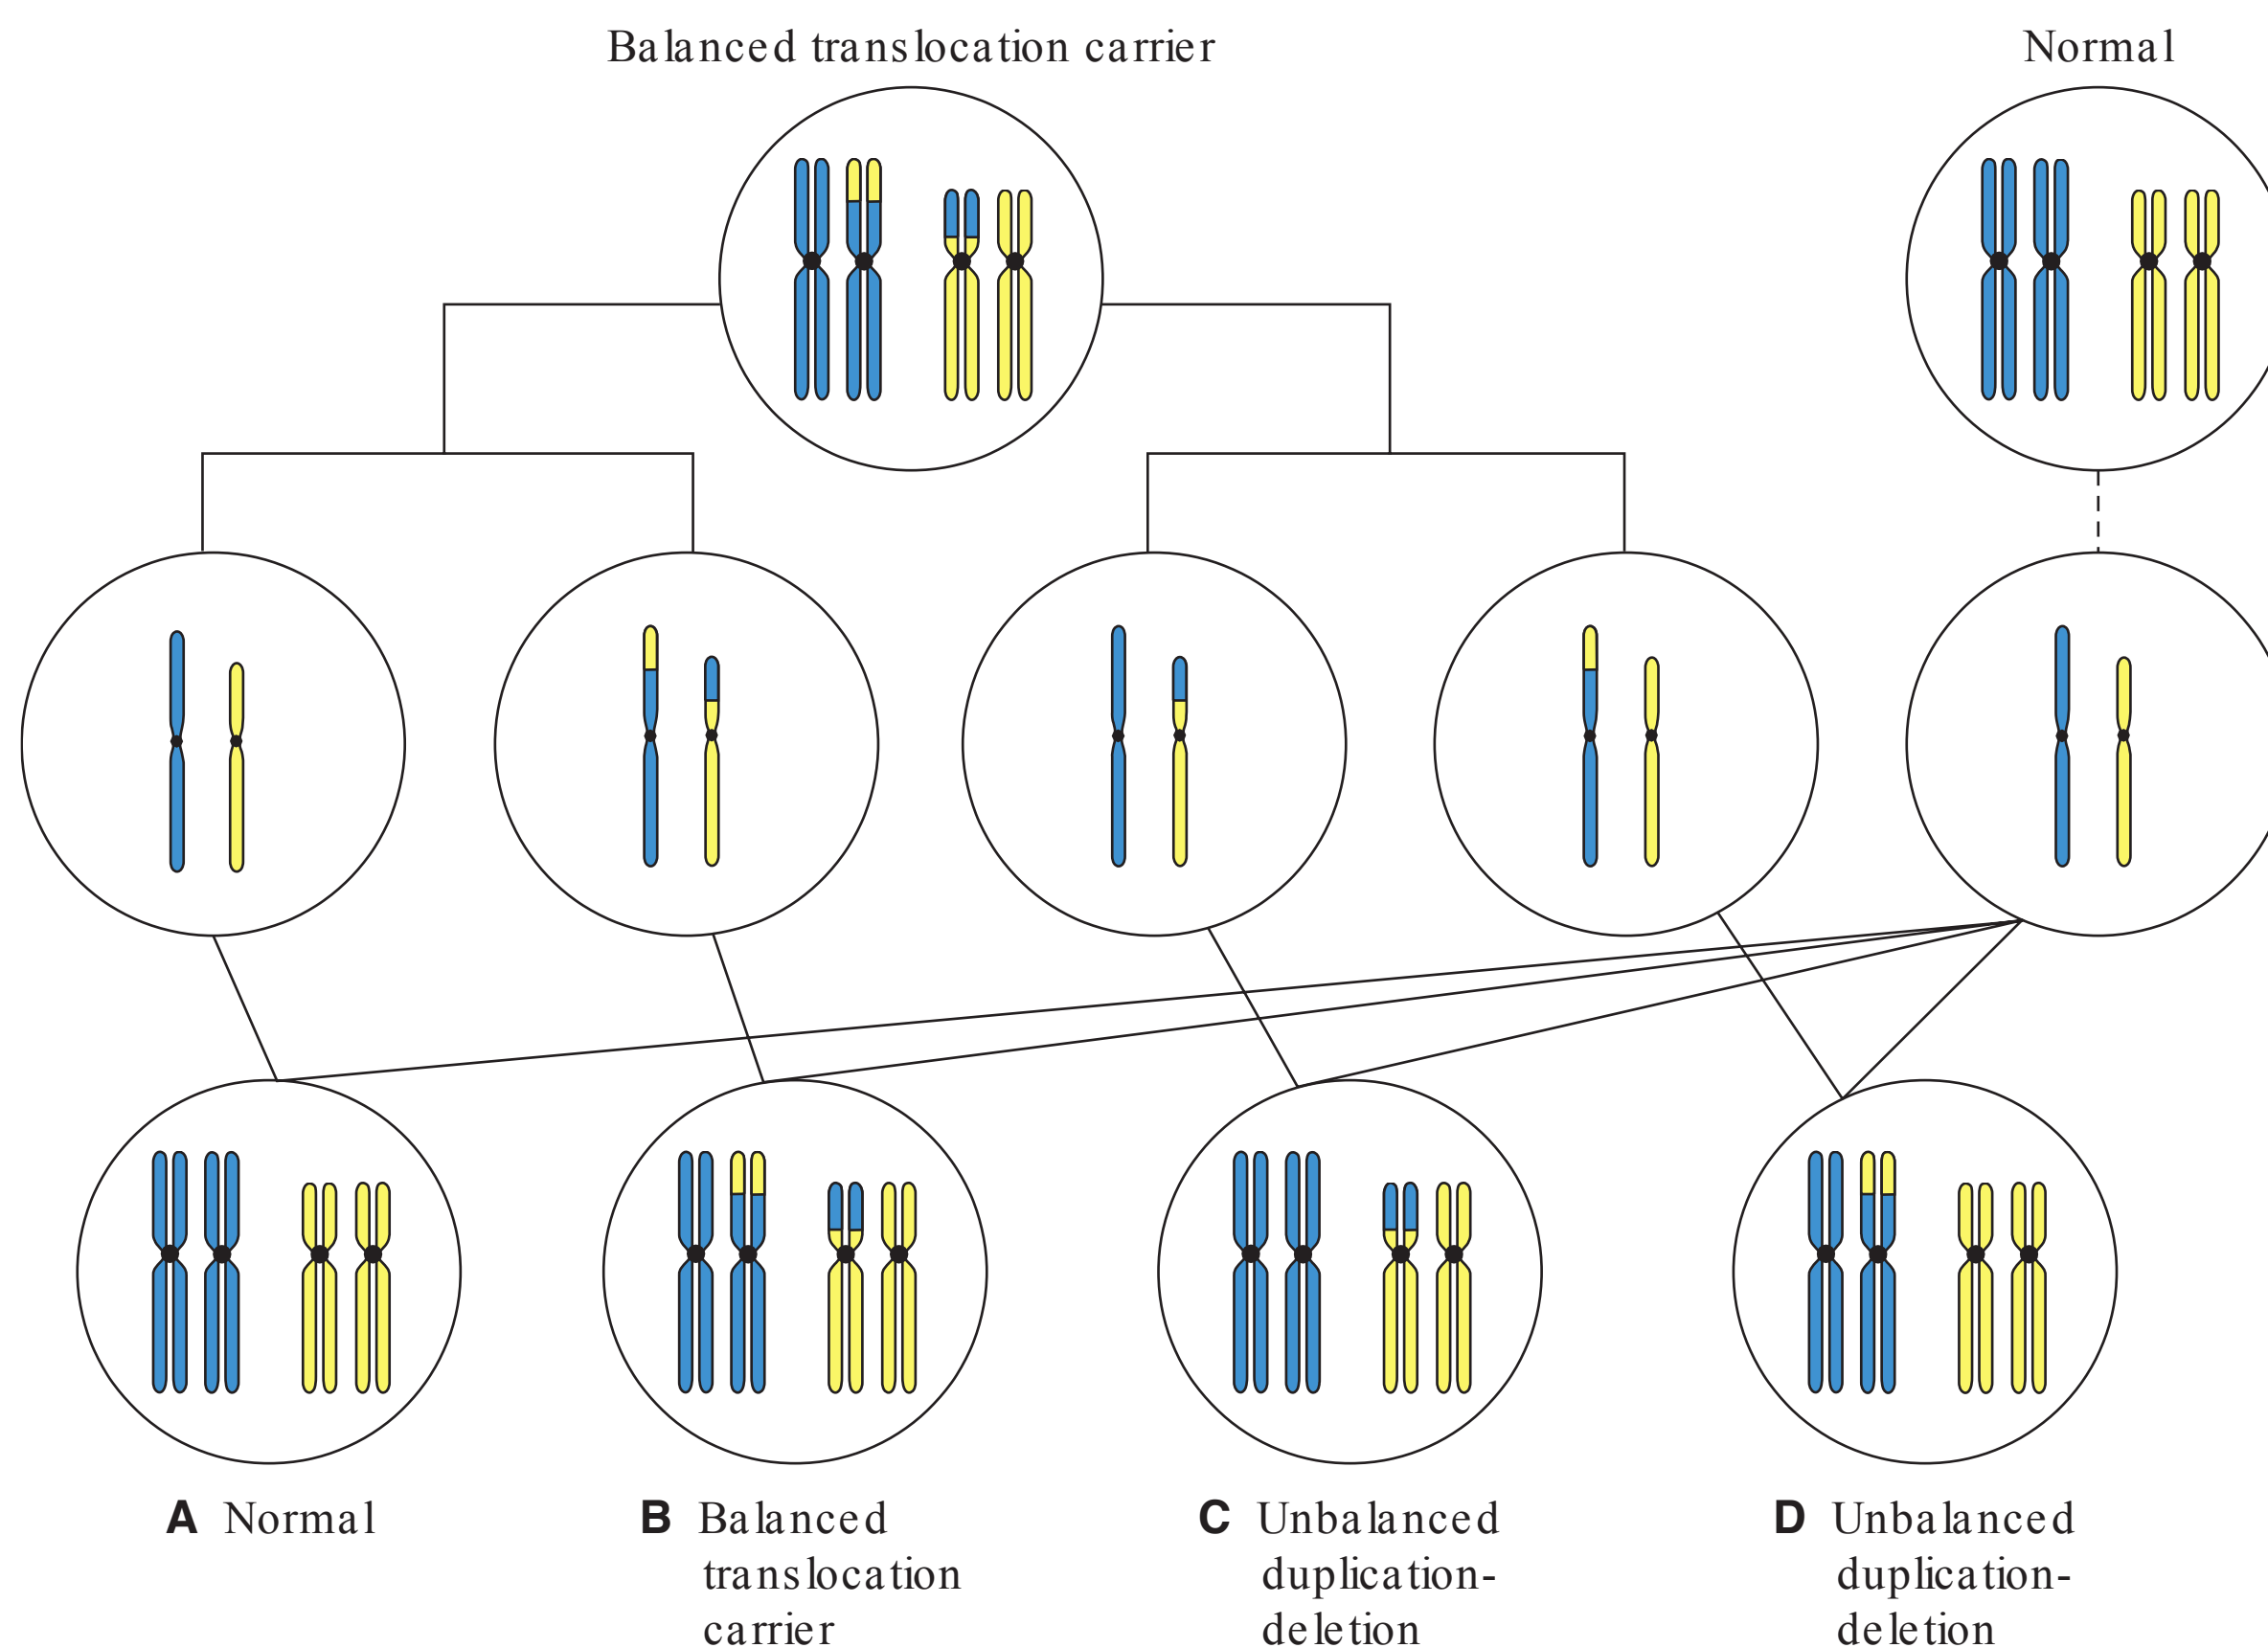

Although these account for only 2 to 5 percent of RPL, karyotype evaluation of both parents is recommended (American Society for Reproductive Medicine, 2012). Data from 8000 couples with two or more miscarriages demonstrated structural chromosomal anomalies in 3 percent—a fivefold greater incidence than observed for the general population. In the parents, balanced reciprocal translocations accounted for 50 percent of identified abnormalities; robertsonian translocations for 24 percent; and X chromosome mosaicism such as 47, XXY—*Klinefelter syndrome*—for 12 percent. Inversions and various other anomalies made up the remainder. The women were twice as likely as the men to harbor the cytogenetic abnormality (Tarapel, 1985). The likelihood of a karyotypic abnormality does not differ between consecutive or nonconsecutive pregnancy losses (van den Boogaard, 2010).

As noted, balanced translocations are the most common structural chromosomal abnormality and result in several possible genetic outcomes in the conceptus: normal, the same balance translocation, or an unbalanced translocation (Fig. 6-5). Offspring who inherit the balanced translocation are likely to also experience recurrent miscarriage. With an unbalanced translocation, the conceptus will either spontaneously abort or produce an anomalous, frequently stillborn fetus. Thus, a history of second-trimester loss or fetal anomaly raises suspicion that one parent may have an abnormal chromosome pattern.

### Sperm DNA Testing

Increasing attention has been directed to sperm aneuploidy and DNA damage as a cause of infertility and RPL. In couples with RPL, some but not all studies report higher rates of aneuploidy and DNA fragmentation in sperm from the male partner (Bellver, 2010b; Ramasamy, 2015; Robinson, 2012). Although unlikely to be as critical as maternal age, increasing paternal age was significantly associated with an increased abortion risk in one study of more than 92,000 births (Kleinhaus, 2006). This risk was lowest before age 25 years, after which it progressively increased at 5-year intervals. A detrimental effect of paternal age on pregnancy outcomes following intrauterine insemination and IVF has also

**FIGURE 6-5** Gametes produced by a balanced translocation carrier. (Reproduced with permission from Cunningham FG, Leveno KL, Bloom SL, et al: Williams Obstetrics, 24th ed. New York: McGraw-Hill; 2014.)

been reported (Belloc, 2008; Robertshaw, 2013). However, semen analysis and assays for DNA integrity are not currently recommended as part of RPL evaluation (American Society for Reproductive Medicine, 2012).

### Screening Products of Conception

Some recommend that fetal tissue be routinely analyzed for chromosomal abnormalities following a second consecutive miscarriage (Stephenson, 2006). One reason cited is that an abnormal karyotype suggests a sporadic loss and therefore does not predict an increased risk for loss with a subsequent pregnancy. Conversely, an abortus with a normal karyotype might suggest an alternative cause and imply the need for earlier evaluation.

Opponents of such routine karyotyping cite its high cost and possibility of misleading results. This applies particularly if the abnormal cells are derived from a pregnancy with placental mosaicism. Moreover, detection of a 46, XX karyotype may simply reflect contamination with maternal tissues. In sum, karyotyping of products of conception may not accurately reflect fetal karyotype. Because of the expense and limited information provided, we do not recommend this practice.

Although the cost effectiveness of karyotyping studies is not universally accepted, some are promoting the use of even more complex and expensive genetic techniques to evaluate couples with RPL (Barber, 2010). These include comparative genomic hybridization, chromosomal microarray, and copy number sequence technologies. These approaches can detect chromosomal

changes below the threshold of sensitivity for conventional cytogenetic analysis (Gao, 2012; Lui, 2015). Currently, we recommend that RPL evaluation should include a standard karyotype of both parents and that more detailed chromosomal evaluation should remain investigational.

### Treatment

Individualized treatment is indicated in couples with a structural genetic abnormality. Approaches include IVF with preimplantation genetic diagnosis (PGD) or the use of donor gametes. These techniques are described in Chapter 20 (p. 466). Depending on the timing of prior losses, chorionic villus sampling or amniocentesis may also be considered. In one retrospective study of couples with known translocations, PGD was found to increase the successful pregnancy rate and decrease the length of time to conception (Fischer, 2010). Even so, the prognosis is generally good without intervention for couples with a balanced translocation. Franssen and colleagues (2006) compared couples with a balanced translocation and non-carrier couples. In both groups, 85 percent of couples had a healthy child, although the risk for miscarriage was higher in the carrier couples.

Some have recommended that PGD screening be done even in couples with normal karyotypes who have idiopathic RPL. Results from a large prospective cohort trial, however, found no support for this practice (Platteau, 2005). At this time, the American Society for Reproductive Medicine (2012) does not recommend PGD in couples who are chromosomally normal.

## ■ Anatomic Factors

Several uterine abnormalities have been implicated in RPL and other adverse pregnancy outcomes, but not infertility (Reichman, 2010). According to Devi Wold and associates (2006), 15 percent of women with three or more consecutive miscarriages will be found to have an acquired or congenital uterine anomaly. The likelihood of identifying an abnormality is similar whether a patient has experienced two, three, or four consecutive miscarriages. This suggests that cavity evaluation after two miscarriages is reasonable (Seckin, 2012).

### Acquired Uterine Defects

Acquired uterine abnormalities associated with pregnancy loss include intrauterine synechiae, leiomyoma, and endometrial polyps. Of these, intrauterine synechiae—known as *Asherman syndrome*—usually result from destruction of large areas of endometrium by curettage or ablative procedures. Characteristic multiple filling defects are seen during hysterosalpingography or saline infusion sonography (Fig. 2-23, p. 34 and Fig. 19-6, p. 439). Directed hysteroscopic lysis of adhesions is preferable to curettage, as discussed and illustrated in Section 44-19 of the atlas (p. 1052). In one study, adhesiolysis decreased the miscarriage rate from 79 to 22 percent and increased successful term pregnancies from 18 to 69 percent (Katz, 1996). Other studies have reported similar outcomes with prognosis correlating with disease severity (Al-Inany, 2001; Goldenberg, 1995).

*Uterine leiomyomas* are found in a large proportion of adult women and can cause miscarriage, especially if located near the placental implantation site. Common sense suggests that detrimental effects should be greater for submucous compared with intramural leiomyomas, and for large versus small tumors. However, uterine cavity distortion is apparently not requisite for bad outcomes, and conclusive data are lacking (Saravolos, 2011). For example, in women undergoing IVF, pregnancy outcomes were adversely affected by submucous but not subserosal or intramural leiomyomas (Jun, 2001; Ramzy, 1998). In contrast, a metaanalysis reported increased adverse pregnancy outcomes—including miscarriage—following IVF in women with intramural myomas (Sunkara, 2010).

Currently, although based on poor-quality data, most agree that consideration be given to excision of submucosal and intracavitary leiomyomas in women with recurrent miscarriage, as discussed in Chapter 9 (p. 205). Uterine artery embolization to treat myomas may increase the risk for subsequent miscarriage and may not be advisable (Homer, 2010). Likewise, hysteroscopic removal of endometrial polyps is generally recommended, although data are scant, particularly in the presence of single or small polyps.

*Incompetent cervix*, also known as cervical insufficiency, may develop following surgical or birth trauma and has also been associated with a molecular defect in collagen synthesis (Dukhovny, 2009). Cervical insufficiency does not cause first-trimester miscarriage but is associated with an increased risk for second-trimester loss following painless cervical dilatation after 16 to 18 weeks' gestation. Cervical incompetence is often treated surgically with cerclage placement. Interested readers

are referred to Chapter 18 of *Williams Obstetrics*, 24th edition (Cunningham, 2014).

### Developmental Anomalies

Congenital malformations of the müllerian ducts also may have adverse pregnancy effects. Anomalies include unicornuate, bicornuate, septate, arcuate, and didelphic uteri. Cited prevalence rates for müllerian anomalies vary widely. This is likely due to differences in the criteria set to define normalcy and in the diagnostic modality employed. Anomalies are often first detected by hysterosalpingography or routine sonography. Further characterization by 3-dimensional (3-D) sonography and magnetic resonance (MR) imaging may be helpful.

In a compilation study of more than 573,000 women, the observed incidence of anomalies was 1 in 600 in fertile women and 1 in 30 in infertile women. The overall incidence was 1 in 200 (Nahum, 1998). Much higher rates have been reported using 3-D sonography, perhaps due to greater sensitivity. Salim and associates (2003) scanned nearly 2500 women using 3-D sonography. Anomalies were identified in 24 percent of women with RPL, but in only 5 percent of controls. In a metaanalysis of publications from 1950 to 2007, Saravolos and coworkers (2008) concluded that uterine anomalies are present in approximately 17 percent of patients with RPL, 7.3 percent of infertile women, and 6.7 percent of women in the general population. The distribution of anomalies and associated loss rates are shown in Table 6-7. Unicornuate, bicornuate, and septate uteri are all associated with increased early miscarriage and second-trimester abortion, fetal malpresentation, and preterm labor (Reichman, 2010).

Demonstration of improved early pregnancy outcome following correction of a uterine anomaly has proven difficult. Nevertheless, in one observational study, pregnancy outcomes were reviewed following hysteroscopic removal of a septum in women with more than two prior miscarriages (Saygili-Yilmaz, 2003). The miscarriage rate decreased from 96 to 10 percent following surgery, and term pregnancy rates increased from zero to 70 percent. A recent metaanalysis reported that hysteroscopic metroplasty was associated with a markedly reduced

**TABLE 6-7.** Estimated Prevalence of Some Congenital Uterine Malformations and Their Associated Pregnancy Loss Rate

Uterine Anomaly <sup>a</sup>	Proportion (%)	SAB Rate (%) <sup>b</sup>
Bicornuate	39	40–70
Septate or unicornuate	14–24	34–88
Didelphys	11	40
Arcuate	7	—
Hypo- or aplastic	4	—

<sup>a</sup>Estimated overall prevalence 1:200 women (Nahum, 1998).

<sup>b</sup>Includes first- and second-trimester spontaneous abortions (SABs).

Data from Buttram, 1979; Nahum, 1998; Reddy, 2007; Valli, 2001.

probability of spontaneous abortion compared with untreated women (Venetis, 2014). Based on these reports and the relative safety of hysteroscopic correction, most experts recommend hysteroscopic resection of a uterine septum in women with recurrent miscarriage, as described in Section 44-17 (p. 1048) (American Society for Reproductive Medicine, 2012).

In contrast, surgical repair of a bicornuate uterus requires laparotomy and full-thickness incision of the uterine wall (Fig. 18-12, p. 422). Disadvantages to metroplasty include the requirement of cesarean delivery to prevent uterine rupture in subsequent pregnancy and the high rate of postoperative pelvic adhesion formation and subsequent infertility. Thus, surgery is generally not recommended except for women who have had a very high number of pregnancy losses. Additional discussion regarding the incidence, clinical impact, and treatment of congenital anatomic abnormalities can be found in Chapter 18 (p. 417). The use of a gestational carrier may be an option in women who are not surgical candidates.

■ Immunologic Factors

Much attention has focused on the role of the immune system in RPL. Yetman and Kutteh (1996) estimated that 15 percent of more than 1000 women with recurrent miscarriages had recognized immunologic factors. Two primary pathophysiologic models are the *autoimmune theory*—immunity against “self,” and the *alloimmune theory*—immunity against antigens from another person.

Autoimmune Factors

It has been appreciated that pregnancy wastage is increased in women with systemic lupus erythematosus (Clowse, 2008). Subsequently, many women with lupus were identified to have antiphospholipid antibodies—a family of autoantibodies directed against phospholipid-binding plasma proteins (Erkan,

2011). Between 5 and 15 percent of women with RPL have clinically significant antiphospholipid antibodies compared with only 2 to 5 percent of controls (Branch, 2010).

The combination of these antiphospholipid antibodies and specific clinical findings is termed *antiphospholipid antibody syndrome*—APS (American College of Obstetrics and Gynecology, 2012). Criteria for its diagnosis are shown in Table 6-8. Positive tests are repeated at a minimum of 12 weeks with strict requirements for acceptable laboratory methods and interpretation (Miyakis, 2006). This is the only autoimmune disorder that has been clearly linked to pregnancy loss. Miscarriage due to APS most often occurs after 10 weeks. APS is more commonly associated with fetal death, preterm delivery, early-onset preeclampsia, and fetal growth restriction from placental insufficiency and placental thromboses (Clark, 2007a,b).

The mechanisms by which antiphospholipid antibodies result in miscarriage are unclear but can be divided into three general categories—thrombosis, inflammation, and abnormal placentation (Meroni, 2010). *Thrombosis* was initially thought to be due to inhibition of prostacyclin secretion by the vascular endothelium and stimulation of thromboxane A production by platelets. These actions result in vasoconstriction and increased platelet aggregation. More recently, it has been proposed that antiphospholipid antibodies act on trophoblast and endothelial surfaces to inhibit the function of annexin A5, a natural anticoagulant that prevents the activation of factor X and prothrombin (Rand, 2010). Antiphospholipid antibodies may also activate complement to intensify hypercoagulability, which leads to recurrent placental thromboses. *Acute local inflammatory responses* at the placental-maternal interface may also be induced by antiphospholipid antibodies. Finally, *placentation* may be directly affected by these antibodies through impaired decidual expression of integrins and cadherins. This can inhibit placental proliferation and syncytial development. Notably, defective decidual trophoblast invasion—not placental thrombosis—is

TABLE 6-8. Clinical and Laboratory Criteria for Diagnosis of Antiphospholipid Antibody Syndrome<sup>a</sup>

Clinical Criteria

- Obstetric:
- One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks
  - or
  - Severe preeclampsia or placental insufficiency necessitating delivery before 34 weeks
  - or
  - Three or more unexplained consecutive spontaneous abortions before 10 weeks
- Vascular: One or more episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ

Laboratory Criteria<sup>b</sup>

- Presence of lupus anticoagulant according to guidelines of the International Society on Thrombosis and Hemostasis
- or
- Medium or high serum levels of IgG or IgM anticardiolipin antibodies
- or
- Anti-β2 glycoprotein-I IgG or IgM antibody

<sup>a</sup>At least one clinical and one laboratory criterion must be present for diagnosis.

<sup>b</sup>These tests must be positive on two or more occasions at least 12 weeks apart.

IgG = immunoglobulin G; IgM = immunoglobulin M.  
Data from Branch, 2010; Erkan, 2011; Miyakis, 2006.

the most common histologic abnormality identified in APS-related early pregnancy loss (Di Simone, 2007).

Several other *antilipid antibody idiotypes* have been described (Bick, 2006). Their measurement is expensive, frequently poorly controlled, and of uncertain relevance in the evaluation of RPL. Results are likewise inconclusive regarding testing for other antibodies including rheumatoid factor, antinuclear antibodies, and those for celiac disease. Currently, testing for these additional antibodies is not recommended during RPL evaluation.

### Antiphospholipid Antibody Syndrome Treatment.

Various treatments have been proposed for women with APS and RPL (Kutteh, 2014). Several studies have compared single-agent or combination therapies using unfractionated heparin, low-molecular-weight heparin, low-dose aspirin, glucocorticoids, or intravenous immunoglobulin (IVIG). Concomitant use of glucocorticoids and heparin is generally not recommended. Compared with single treatment regimens, this combination may increase the maternal fracture risk without improving outcome. IVIG has also been discredited as described in the next section.

For women with APS, one reviewer group concluded that the combination of unfractionated heparin and low-dose aspirin significantly benefitted pregnancy outcome in those with first-trimester pregnancy losses (Ziakas, 2010). They found no improvement with low-molecular-weight heparin (LMWH) and aspirin combinations. Similar conclusions were reached in a Cochrane Database Review through 2011 (Empson, 2012). LMWH plus aspirin is appealing based on its ease of use and improved safety profile. However, until the issue is settled, unfractionated heparin is recommended.

Guidelines from the American College of Obstetricians and Gynecologists (2012) suggest that women with RPL and APS who have not had a thrombotic event receive prophylactic low-dose aspirin—81 mg orally per day—and heparin when pregnancy is diagnosed with continuation until delivery and 6 weeks postpartum. Heparin regimens vary, but unfractionated heparin—5000 to 10,000 units subcutaneously daily—is common. Some experts suggest initiating low-dose aspirin prior to conception (Kutteh, 2014). At a minimum, careful clinical surveillance to ensure early pregnancy detection seems prudent.

### Alloimmune Factors

The immune tolerance of the mother to a semiallogeneic fetus remains incompletely understood (Williams, 2012). An attractive theory suggests that normal pregnancy requires the expression of blocking factors that prevent maternal rejection of paternally derived foreign fetal antigens. The pregnant woman ostensibly will not produce these blocking factors if she shares human leukocyte antigens (HLAs) with the father. Other alloimmune disorders that have been posited to cause recurrent miscarriage include altered natural killer cell activity and increased lymphocytotoxic antibodies. Berger and associates (2010) found that women with mutations of the HLA-G gene experienced recurrent miscarriages more often than women with normal haplotypes.

Various tests and treatment options have been developed to address this issue. None has withstood rigorous scrutiny. In an

attempt to correct the dysregulated response to fetal antigens, proposed therapies include paternal or third-party leukocyte immunization and IVIG. Three randomized clinical trials failed to demonstrate any benefit of IVIG or placebo in patients with idiopathic miscarriage (Stephenson, 2010). Because these treatments have not been adequately tested and are potentially harmful, immunotherapy cannot currently be recommended for RPL.

## ■ Endocrinologic Factors

### Luteal Phase Defect

Arredondo and Noble (2006) estimated that 8 to 12 percent of recurrent miscarriages are the result of endocrine factors. The increased incidence of miscarriage in these disorders is most frequently attributed to abnormal folliculogenesis with subsequent abnormal luteal function. This so-called *luteal phase defect (LPD)* is associated with inadequate endometrial development at implantation. Treatment for presumed LPD has included progesterone supplementation, hCG administration to enhance corpus luteum function, or ovulation induction with agents such as clomiphene citrate to generate additional corpora lutea. For this indication, none have proven beneficial. Although progesterone replacement is controversial for LPD, it is clearly indicated until 8 to 10 weeks in women who have had the supporting corpus luteum removed surgically that pregnancy (p. 139).

### Thyroid Disease

Although the mechanisms by which they may adversely affect early pregnancy remain unclear, several endocrine disorders deserve discussion. These disorders include thyroid disorders, hyperprolactinemia, diabetes mellitus, and polycystic ovarian syndrome (PCOS). Of these, *thyroid disorders* have long been suspected to cause early pregnancy loss and other adverse pregnancy outcomes. Severe iodine deficiency—infrequent in developed countries—is associated with excessive miscarriage rates (Castañeda, 2002). Women suffering from hyperthyroidism have a greater risk for both spontaneous abortion and stillbirth (Andersen, 2014).

Thyroid hormone insufficiency is common, but the degree of insufficiency varies. In pregnancy, although overt hypothyroidism is rare, the incidence of subclinical hypothyroidism approximates 2 percent (Casey, 2005). Autoimmune Hashimoto thyroiditis is a usual cause, and its incidence and severity accrue with age. Despite this common prevalence, any effects of hypothyroidism on early pregnancy loss are still unclear (Krassas, 2010; Negro, 2010). That said, De Vivo (2010) reported that subclinical thyroid hormone deficiency may be associated with very early pregnancy loss.

The prevalence of abnormally high serum levels of antibodies to thyroid peroxidase or thyroglobulin is nearly 15 percent in pregnant women (Abbassi-Ghanavati, 2010; Haddow, 2011). Although most of these women are euthyroid, those with clinical hypothyroidism tend to have higher concentrations of antibodies. Even in euthyroid women, antibodies are a marker for increased miscarriage risk (Chen, 2011; Tangaratinam, 2011).

In sum, symptomatic women should undergo thyroid function testing, and overt hypo- or hyperthyroidism should

be treated to prevent pregnancy complications. Screening all women with pregnancy loss is more controversial. Likewise, it is unclear whether patients with subclinical hypothyroidism or thyroid autoimmunity should receive treatment (Negro, 2006; Vissenberg, 2012).

### Hyperprolactinemia

Cyclic ovulation may become dysfunctional in response to elevated serum prolactin levels such as occurs with prolactinoma. Prolactin may also have direct effects on the endometrium. Hirahara (1998) reported an increase in successful pregnancies in patients with hyperprolactinemia treated with the dopamine agonist bromocriptine. Although data are scarce, many experts still suggest measuring prolactin levels in patients with RPL.

### Diabetes Mellitus

Insulin-dependent diabetes substantively increases risks for spontaneous abortion and major congenital malformations (Greene, 1999). This directly relates to the degree of periconceptional glycemic and metabolic control. Importantly, this risk is greatly mitigated with optimal metabolic control. In fact, the miscarriage rate in women with excellent control rivals that of nondiabetic women (Mills, 1988). Although diabetes itself is a recognized cause of RPL, diabetic women with recurrent loss may also have levels of insulin resistance greater than diabetic women without miscarriages (Craig, 2002). This suggests that ovarian insulin resistance may be in itself contributory, as discussed next.

### Polycystic Ovarian Syndrome

Women with polycystic ovaries have generally been considered to carry an elevated miscarriage risk. However, this association has been questioned (Cocksedge, 2009). Inhibition of serum luteinizing hormone (LH) during a gonadotropin ovulation-induction cycle failed to improve pregnancy outcome in a controlled trial. This is argued against a role for the elevated LH levels seen in PCOS (Clifford, 1996).

Data implicating hyperinsulinemia in pregnancy loss are somewhat stronger. Insulin modulates insulin-like growth factor actions in the ovary, thereby affecting folliculogenesis and steroid production. Retrospective and case-control studies concluded that metformin begun either before or during pregnancy decreases miscarriage rates in women with PCOS (Glueck, 2002; Nawaz, 2010). Metformin (Glucophage) lowers hepatic glucose production and increases insulin sensitivity and thereby lowers insulin levels. However, a systematic review of randomized trials found no improvement in abortion risk with metformin treatment (Palomba, 2009). At this time, routine metformin treatment for women with PCOS solely to treat pregnancy loss is not recommended.

### ■ Thrombophilias

Complexities of the coagulation cascade include several single-gene mutations that affect pro- or anticoagulant proteins. Mutations predisposing to thrombosis—collectively termed *thrombophilias*—are caused by mutations of the genes for factor

V Leiden, prothrombin, antithrombin, and protein C and protein S. These are described further in Chapter 39 (p. 836). In the past, several of these thrombophilias were suspected to cause RPL. However, large prospective cohort studies have refuted these associations, and testing for these abnormalities for this indication is no longer recommended (American College of Obstetrics and Gynecologists, 2014d; American Society of Reproductive Medicine, 2012).

### ■ Evaluation and Treatment

Some considerations for evaluation and management of women with recurrent miscarriage are outlined in Table 6-9. Timing and extent of evaluation is based on maternal age, coexistent infertility, symptoms, and the level of patient anxiety. In our view, after a thorough history and clinical examination, a modicum of testing is done that is directed at likely causes. General testing may include parental karyotyping, uterine cavity evaluation, and testing for APS. There is progressively less support to screen for inherited thrombophilias, endocrine disorders, or luteal phase defect.

Unfortunately, a putative cause will be identified in only about half of couples with RPL. Empiric treatment for unexplained pregnancy loss is discouraged. Even for those with no explanatory findings, couples are cautiously assured that the chances of successfully achieving a live birth are reasonably good (Branch, 2010; Reddy, 2007). The results shown previously in Tables 6-5 and 6-6—while age dependent—forecast a reasonable prognosis for a successful subsequent pregnancy even after five recurrent losses. Although these couples are anxious to try any treatment, the lack of definitive benefits for many of these is carefully considered and appropriate counseling offered.

## INDUCED ABORTION

### ■ Rates

The term *induced abortion* is defined as the medical or surgical termination of pregnancy before the time of fetal viability. Definitions to describe the incidence include the *abortion ratio*, which is the number of abortions per 1000 live births, and the *abortion rate*, which is the number of these per 1000 women aged 15 to 44 years.

In the United States, abortion statistics most likely are underreported. The Guttmacher Institute (2011) found that 1.2 million procedures were performed annually from 2005 through 2008. But for 2011, only about 730,322 elective abortions were reported to the CDC (Pazol, 2014). The calculated abortion ratio was 219 per 1000 live births, and the abortion rate was 13.9 per 1000 women aged 15 to 44 years. Women aged 20 to 29 years accounted for 58 percent of abortions and had the highest abortion rate. Of all abortions, 64 percent were done  $\leq 8$  weeks' gestation; 91 percent  $\leq 13$  weeks; 7 percent at 14 to 20 weeks; and only 1.4 percent were performed at  $\geq 21$  weeks.

Global statistics for abortion rates are reported by the WHO. According to its latest report, approximately 1 in 5 pregnancies were aborted worldwide in 2008 (Sedgh, 2012). Almost half of these procedures were considered unsafe.

**TABLE 6-9.** Tests Used for Evaluation of Couples with Recurrent Pregnancy Loss

Etiology	Diagnostic Evaluation	Possible Therapies
Genetic <sup>a</sup>	Karyotype partners	Genetic counseling, donor gametes
Anatomic <sup>a</sup>	Sonohysterography Hysterosalpingogram MR imaging	Septum transection, myomectomy, or adhesiolysis
Immunologic <sup>a</sup>	Lupus anticoagulant Anticardiolipin antibodies Anti- $\beta$ 2 glycoprotein-I antibody	Heparin + aspirin
Endocrinologic <sup>b</sup>	TSH Prolactin Fasting glucose, Hgb A <sub>1c</sub> Day 3 FSH, estradiol Midluteal progesterone	Levothyroxine Dopamine agonist Metformin Counseling, PGD, donor oocyte IVF Progesterone
Thrombophilic <sup>c</sup>	Antithrombin deficiency Protein C or S deficiency Factor V Leiden mutation Prothrombin mutation Hyperhomocysteinemia	No proven treatment  Folic acid
Toxic	Tobacco, alcohol use Exposure to toxins, chemicals Obesity	Eliminate consumption Behavior modification Weight loss

<sup>a</sup>Testing for these disorders is generally supported by the literature and expert opinion. One or a combination of these tests may be indicated.

<sup>b</sup>Ongoing controversy regarding testing.

<sup>c</sup>Current recommendations against testing. Included for historic reference.

FSH = follicle-stimulating hormone; IVF = in vitro fertilization; MR = magnetic resonance; PGD = pre-implantation diagnosis; TSH = thyroid-stimulating hormone.

Data from Brezina, 2013; Reddy, 2007; Fritz, 2011.

## ■ Classification

Abortions are performed for various indications that include social, economic, or emotional reasons. Although not formal categories, many choose to define induced abortion as: (1) indicated or therapeutic or (2) elective or voluntary.

First, medical and surgical disorders may provide a maternal-health indication for pregnancy termination. These include persistent cardiac decompensation, pulmonary arterial hypertension, advanced hypertensive vascular disease, diabetes with end-stage organ failure, and malignancy. In cases of rape or incest, most consider termination reasonable. The most common indication currently is to prevent birth of a fetus with a significant anatomic, metabolic, or mental deformity. Defining the seriousness of a fetal deformity is complicated by social, legal, and political mores.

The interruption of pregnancy before viability at the request of the woman, but not for medical reasons, is usually termed elective or voluntary abortion. Most abortions done today are elective, and thus, it is one of the most frequently performed procedures. From the Guttmacher Institute, Jones and Kavanaugh (2011) estimate that a third of American women will have at least one elective abortion by age 45.

## ■ Abortion in the United States

### Legality

The legality of elective abortion was established by the United States Supreme Court in the case of *Roe v. Wade*. The Court defined the extent to which states might regulate abortion and ruled that first-trimester procedures must be left to the medical judgment of the physician. After this, the state could regulate abortion procedures in ways reasonably related to maternal health. Finally, subsequent to viability, the state could promote its interest in the potential of human life and regulate and even proscribe abortion, except for the preservation of the life or health of the mother.

Other legislation soon followed. The 1976 Hyde Amendment forbids use of federal funds to provide abortion services except in case of rape, incest, or life-threatening circumstances. The Supreme Court in 1992 reviewed *Planned Parenthood v. Casey* and upheld the fundamental right to abortion, but established that regulations before viability are constitutional as long as they do not impose an “undue burden” on the woman. Subsequently, many states passed legislation that imposes counseling requirements, waiting periods, parental consent or notification for minors, facility requirements, and funding restrictions. One

major choice-limiting decision was the 2007 Supreme Court decision that reviewed *Gonzales v. Carhart* and upheld the 2003 Partial-Birth Abortion Ban Act. This was problematic because there is no medically approved definition of partial-birth abortion. According to the Guttmacher Institute, 41 states set new limits on abortion during 2011 and 2012 (Tanner, 2012). In two strongly worded Committee Opinions, the American College of Obstetricians and Gynecologists (2014a,c) calls for increased advocacy to overturn restrictions, improve access, and codify abortion as a fundamental component of women's health care. The College (2013e) supports the legal right of women to obtain an abortion prior to fetal viability and considers this a medical matter between a woman and her physician.

Training in Abortion Techniques

Because of its inherent controversial aspects, abortion training for residents and postgraduate fellows has been both championed and assailed. The Accreditation Council for Graduate Medical Education mandated in 1996 that Obstetrics and Gynecology residency education include access to experience with induced abortion. The American College of Obstetricians and Gynecologists (2014c) outlines legislative, institutional, and social barriers to abortion training and supports the use of “opt-out” programs. In these, abortion training is integrated as a standard part of the residency schedule, but residents with religious or moral objections can decline to participate. The Kenneth J. Ryan Residency Training Program was established in 1999 to improve residency training in abortion and family planning. By 2013, 59 Ryan programs had been started in the United States and in Canada. Disappointingly, a recent survey of United States residency programs determined that no abortion training was available in 16 percent of programs and that 30 percent continue to use the “opt-in” approach (Turk, 2014).

Other programs teach residents technical aspects through management of early incomplete and missed abortions and through pregnancy interruption for fetal death, severe fetal anomalies, and life-threatening medical or surgical disorders (Steinauer, 2005). Freedman and coworkers (2010) rightly emphasize that abortion training should include discussion of the social, moral, and ethical aspects of the procedure.

Formal fellowships in Family Planning are 2-year postgraduate programs. By 2010, these were located in 22 departments of obstetrics and gynecology at academic centers nationwide. Training includes experience with high-level research and with all methods of pregnancy prevention and termination.

Abortion Providers

The American College of Obstetricians and Gynecologists (2013f) respects the need and responsibility of health-care providers to determine their individual positions on induced abortion. It also emphasizes the need to provide standard-of-care counseling and timely referral if providers have individual beliefs that preclude pregnancy termination. From a mail survey of 1800 obstetrician-gynecologists, 97 percent had encountered women seeking an abortion, but only 14 percent performed them (Stulberg, 2011). Still, most practitioners help women find an abortion provider (Harris, 2011). In any event, any

physician who cares for women must be familiar with various abortion techniques so that complications can be managed or referrals made for suitable care.

Counseling before Elective Abortion

Three basic choices are available to a woman considering an abortion: (1) continued pregnancy with its risks and parental responsibilities; (2) continued pregnancy with arranged adoption; or (3) termination of pregnancy with its risks. Knowledgeable and compassionate counselors should objectively describe and provide information regarding these choices so that a woman or couple can make an informed decision (Baker, 2009; Templeton, 2011).

ABORTION TECHNIQUES

In the absence of serious maternal medical disorders, abortion procedures do not require hospitalization. With outpatient abortion, capabilities for cardiopulmonary resuscitation and for immediate transfer to a hospital must be available.

First-trimester abortion can be performed either medically or surgically by several methods that are listed in Table 6-10. Distinctive features of each technique were reviewed by the American College of Obstetricians and Gynecologists (2009). Results with either surgical or medical methods are comparable with those for spontaneous miscarriage as previously shown in Table 6-4. Both have a high success rate—95 percent with medical and 99 percent with surgical techniques.

With medical therapy, surgery is usually avoided as is the need for sedation (Table 6-11). Medical terminations have lower average costs and may allow for more privacy during the termination. However, medical abortion may extend for days up to a few weeks, bleeding is usually heavier and less predictable, and incomplete abortion is more common with medical versus surgical abortion (Niinimäki, 2009; Robson, 2009). Likely for these reasons, only 10 percent of abortions in the United States are managed using medical methods (Templeton, 2011).

TABLE 6-10. Techniques Used for First Trimester Abortion<sup>a</sup>

Approach	Technique
Surgical	Dilatation and curettage
	Vacuum aspiration
	Menstrual aspiration
Medical	Prostaglandins E <sub>2</sub> , F <sub>2α</sub> , E <sub>1</sub> , and analogues
	Vaginal insertion
	Parenteral injection
	Oral ingestion
	Antiprogesterones—RU 486 (mifepristone) and epostane
	Methotrexate—intramuscular or oral
	Various combinations of the above

<sup>a</sup>All procedures are aided by pretreatment using hygroscopic cervical dilators.

**TABLE 6-11.** Comparison of Medical versus Surgical Abortion

Factor	Medical	Surgical
Invasive	Usually no	Yes
Pain	More	Less
Vaginal bleeding	Prolonged, unpredictable	Light, predictable
Incomplete abortion	More common	Uncommon
Failure rate	2–5%	1%
Severe hemorrhage	0.1%	0.1%
Infection rate	Low	Low
Anesthesia	Usually none	Yes
Time involved	Multiple visits, follow-up exam	Usually one visit, no follow-up exam

Data from American College of Obstetricians and Gynecologists, 2015; Templeton, 2011.

## ■ Surgical Abortion

Surgical pregnancy termination includes a transvaginal approach through an appropriately dilated cervix. Rarely, pregnancies are evacuated transabdominally by either hysterotomy or hysterectomy. Of transvaginal procedures, electric vacuum aspiration is the most commonly used form and is illustrated in Chapter 43 (p. 966). Alternatively, manual vacuum aspiration is done with a similar cannula that attaches to a handheld syringe for its vacuum source.

### Cervical Preparation

For transvaginal evacuation, preoperative cervical ripening softens and slowly dilates the cervix to minimize trauma from mechanical dilatation. This preparation is typically associated with less pain, a technically easier procedure, and shorter operating times (Kapp, 2010). Of methods, hygroscopic dilators draw water from cervical tissues and expand to gradually dilate the cervix. One type is derived from various species of *Laminaria* algae that are harvested from the ocean floor (Chap. 43, p. 966). Another is *Dilapan-S*, which is composed of an acrylic-based gel.

Schneider and associates (1991) described 21 cases in which women who had a hygroscopic dilator placed changed their minds. Of 17 women who chose to continue their pregnancy, 14 carried to term, two delivered preterm, and one miscarried 2 weeks later. None suffered infection-related morbidity, including three untreated women with cervical cultures positive for *Chlamydia trachomatis*. In spite of this generally reassuring report, it seems prudent to presume irrevocability with regard to dilator placement and abortion.

Medications may also be used for cervical preparation. In the metaanalysis by Kapp (2010), efficacy of these medications was found to be similar to that of hygroscopic dilators. The most common is misoprostol (Cytotec), which is used off-label, and patients are counseled accordingly (Tang, 2013). The dose

is 400 to 600 µg administered orally, sublingually, or placed into the posterior vaginal fornix (Meirik, 2012). Marginal benefits ascribed to misoprostol included easier cervical dilatation and a lower composite complication rate.

Another effective cervical-ripening agent is the progesterone antagonist *mifepristone* (Mifeprex). With this, 200 to 600 µg is given orally. Other options include formulations of *prostaglandins E<sub>2</sub>* and *F<sub>2α</sub>*, which have unpleasant side effects and are usually reserved as second-line drugs for cervical ripening (Kapp, 2010).

### Electric Vacuum Aspiration

In this method, also known as dilatation and curettage (D & C), a rigid cannula attached to an electric-powered vacuum source empties the uterus. This may be coupled with sharp curettage. To begin, the surgeon first dilates the cervix. The pregnancy is then evacuated by suctioning out the contents—suction curettage, by mechanically scraping out the contents—sharp curettage, or both. Curettage—either sharp or suction—is recommended for gestations ≤ 15 weeks. According to one review, the use of suction curettage is superior if available (Tunçalp, 2010). Curettage usually requires sedation or analgesia. In addition to intravenously or orally administered sedatives, success has been reported with paracervical lidocaine blockade, with or without other analgesics (Renner, 2012). Perioperative antibiotic prophylaxis is also recommended as described on page 143.

### Menstrual Aspiration

Aspiration of the endometrial cavity within 1 to 3 weeks after a missed menstrual period has been referred to as *menstrual extraction*, *menstrual induction*, *instant period*, *traumatic abortion*, and *mini-abortion*. The procedure is done using a flexible 5- or 6-mm Karman cannula and attached syringe. The primary drawbacks are that the small pregnancy may be missed or an ectopic pregnancy can be unrecognized. To identify placenta in the aspirate, MacIsaac and Darney (2000) recommend that the syringe contents be rinsed in a strainer to remove blood, then placed in a clear plastic container with saline and examined with back lighting. Placental tissue macroscopically appears soft, fluffy, and feathery. A magnifying lens, colposcope, or microscope also can improve visualization. Despite the possibility of missing the products, Paul and coworkers (2002) reported a 98-percent success rate with more than 1000 such procedures.

### Manual Vacuum Aspiration

This procedure is similar to menstrual aspiration but is used for early pregnancy failures or elective termination up to 12 weeks. Some recommend that pregnancy terminations done in the office with this method be limited to ≤ 10 weeks because blood loss rises sharply between 10 and 12 weeks (Masch, 2005; Westfall, 1998). For pregnancies ≤ 8 weeks, preprocedure cervical ripening is usually not necessary. After this time, some recommend that osmotic dilators be placed the day prior to or misoprostol given 2 to 4 hours before the procedure. Paracervical blockade with or without sedation is used. The technique employs a

hand-operated 60-mL syringe and cannula. A vacuum is created in the syringe attached to the cannula, which is inserted transcervically into the uterus. The vacuum produces up to 60 mm Hg suction. Complications are similar to other surgical methods (Goldberg, 2004).

■ Medical Abortion

Throughout history, many natural substances have been given for alleged abortifacient effects. Currently, only three medications for early medical abortion have been widely studied. These are used either alone or in combination and include: (1) the antiprogesterin *mifepristone*, (2) the antimetabolite *methotrexate*, and (3) the prostaglandin *misoprostol*. Mifepristone and methotrexate increase uterine contractility by reversing progesterone-induced inhibition, whereas misoprostol directly stimulates the myometrium. Clark and associates (2006) have reported that mifepristone causes cervical collagen degradation, possibly from increased expression of matrix metalloproteinase. Methotrexate and misoprostol are both teratogens, thus there must be a commitment to completing the abortion once these drugs are given.

With these three agents, several dosing schemes are effective, and some are shown in Table 6-12. For these regimens, misoprostol is either given alone or given with methotrexate or mifepristone. As discussed on page 144 and previously shown in Table 6-4, any of several regimens used for “early pregnancy loss” are also likely to be successful for elective pregnancy interruption (American College of Obstetricians and Gynecologists, 2014e).

For elective termination at ≤ 63 days’ gestation, randomized trials by von Hertzen (2009, 2010) and Winikoff (2008) and their colleagues showed 92- to 96-percent efficacy when one of the mifepristone/misoprostol regimens was used. Similar results were reported from 10 large urban Planned Parenthood clinics (Fjerstad, 2009). In this later study, buccal misoprostol-

oral mifepristone regimens were 87- to 98-percent successful for abortion induction with pregnancies < 10 weeks’ gestation. This rate diminished with advancing gestations. In another study of 122 women at 9 to 12 weeks’ gestation, the success rate was approximately 80 percent (Dalenda, 2010). According to the American College of Obstetricians and Gynecologists (2014e), outpatient medical abortion is an acceptable alternative to surgical pregnancy termination in appropriately selected pregnant women less than 49 days’ menstrual age. After this time, available data—albeit less robust—support surgical abortion as preferable. Bleeding and cramping with medical termination can be significantly worse than menstrual cramps, thus adequate analgesia, usually including a narcotic, is provided.

Administration

With the mifepristone regimens, mifepristone treatment is followed by misoprostol given at that same time or up to 72 hours later. Some prefer that misoprostol be administered on site, after which the woman typically remains for 4 hours. Symptoms are common within 3 hours and included lower abdominal pain, vomiting, diarrhea, fever, and chills/shivering. In the first few hours after misoprostol is given, if the pregnancy appears to have been expelled, an examination is done to confirm expulsion. If the pregnancy has not been expelled, a pelvic examination is performed, and the patient is discharged and appointed to return in 1 to 2 weeks. At this time, if clinical or sonographic evaluation fails to confirm completed abortion, a suction procedure usually is recommended.

With the methotrexate regimens, misoprostol is given 3 to 7 days later, and women are seen again at least 24 hours after misoprostol administration. They are next seen approximately 7 days after methotrexate is given, and sonographic examination is performed. If an intact pregnancy is seen, then another dose of misoprostol is given. Afterward, the woman is seen again in 1 week if fetal cardiac activity is present or in 4 weeks

TABLE 6-12. Regimens for Medical Termination of Early Pregnancy

<b>Mifepristone/Misoprostol</b> <sup>a</sup> Mifepristone, 100–600 mg orally followed by: <sup>b</sup> Misoprostol, 200–600 µg orally or 400–800 µg vaginally, buccally, or sublingually given immediately or up to 72 hours
<b>Methotrexate/Misoprostol</b> <sup>c</sup> Methotrexate, 50 mg/m <sup>2</sup> intramuscularly or orally followed by: <sup>d</sup> Misoprostol, 800 µg vaginally in 3–7 days. Repeat if needed 1 week after methotrexate initially given
<b>Misoprostol Alone</b> <sup>e</sup> 800 µg vaginally or sublingually, repeated for up to three doses

<sup>a</sup>Doses of 200 versus 600 mg are similarly effective.

<sup>b</sup>Oral route may be less effective; possibly more side effects, namely, nausea and diarrhea. Sublingual route has more side effects than vaginal route. Shorter intervals (6 hours) with PGE<sub>1</sub> given after mifepristone may be less effective than when given > 36 hours.

<sup>c</sup>Efficacy similar for routes of administration.

<sup>d</sup>Similar efficacy when given on day 3 versus day 5.

<sup>e</sup>Intervals of 3–24 hours if given vaginally; of 3–4 hours if given sublingually.

Data from Borgatta, 2001; Coyaji, 2007; Creinin, 2001, 2007; Fekih, 2010; Guest, 2007; Hamoda, 2005; Honkanen, 2004; Jain, 2002; Kulier, 2011; Pymar, 2001; Raghavan, 2009; Schaff, 2000; Shannon, 2006; von Hertzen, 2003, 2007, 2009, 2010; Winikoff, 2008.

if there is no heart motion. If abortion has not occurred by the second visit, it is usually completed by suction curettage.

With regimens using solely misoprostol, an initial 800- $\mu$ g dose is repeated every 3 to 24 hr for up to three doses. Importantly, misoprostol-only regimens are associated with significantly higher continuing pregnancy rates (Grossman, 2004).

The American College of Obstetricians and Gynecologists (2014e) recommends that a woman be instructed to contact her provider during these regimens if bleeding soaks two or more pads per hour for at least 2 hours. The provider can then decide whether she needs to be seen. Similarly, patients should contact their health care provider if fever develops.

Unnecessary surgical intervention in women undergoing medical abortion can be avoided by the proper interpretation of follow-up sonographic results. Specifically, if no gestational sac is seen and there is no heavy bleeding, then intervention is unnecessary. This is true even when, as is common, the uterus contains sonographically evident debris. Another study reported that a multilayered sonographic pattern indicated a successful abortion (Tzeng, 2013). Assessment of the clinical course along with bimanual pelvic examination is generally adequate. Routine postabortal sonographic examination is unnecessary (Clark, 2010). Follow-up serum  $\beta$ -hCG levels have shown promise in preliminary investigations (Dayananda, 2013). Increasing evidence suggests that misoprostol is a safe and effective method to fully evacuate the uterus in the case of retained products following spontaneous or surgical abortion (American College of Obstetricians and Gynecologists, 2009).

### Contraindications

In many cases, contraindications to medical abortion evolved from exclusion criteria that were used in initial clinical trials and should rightly be considered relative contraindications. These include: in situ intrauterine device; severe anemia, coagulopathy, or anticoagulant use; and significant medical conditions such as active liver disease, cardiovascular disease, or uncontrolled seizure disorders. Because misoprostol diminishes glucocorticoid activity, women with disorders requiring glucocorticoid therapy are usually excluded (American College of Obstetricians and Gynecologists, 2009). In women with renal insufficiency, the methotrexate dose is modified and given with caution, or preferably, another regimen is chosen (Kelly, 2006).

## ABORTION CONSEQUENCES

Potential short-term morbidity of spontaneous and induced abortion includes retained tissue, hemorrhage, and infection in approximately equal frequency (Niinimäki, 2009; von Hertzen, 2010). In a review of more than 233,000 medical abortions, there were 1530 (0.65 percent) significant adverse events. Most of these were ongoing pregnancy (Cleland, 2013). As might be predicted, complication rates increase with progressing gestation in both spontaneous and induced abortions. For example, retained tissue occurs more frequently following second-trimester loss (40 percent) compared with earlier losses (17 percent) (van den Bosch, 2008).

Of long-term sequelae, abortion-related deaths are likely underreported (Horon, 2005). With this caveat in mind, mortality rates are exceedingly low. Legally induced abortion, performed by trained gynecologists, especially when performed during the first 2 months of pregnancy, has a mortality rate of less than 1 per 100,000 procedures (Grimes, 2006; Pazol, 2014). Moreover, pregnancy-associated mortality is 14-fold greater than abortion-related mortality—8 versus 0.6 deaths per 100,000 (Raymond, 2012). Early abortions are even safer, and the relative mortality risk of abortion approximately doubles for each 2 weeks after 8 weeks' gestation. The CDC identified 10 abortion-related deaths in the United States in 2010 (Pazol, 2014).

Some data suggest that certain adverse pregnancy outcomes are more common in women who have had an induced abortion (Maconochie, 2007). Specifically, several studies note an approximate 1.5-fold increased incidence of preterm delivery at 22 to 32 weeks (Hardy, 2013; Moreau, 2005; Swingle, 2009). One systematic review of 37 studies noted a significantly increased 1.35-fold risk for subsequent low-birthweight and preterm deliveries after one pregnancy termination (Shah, 2009). These risks rose along with an increased number of procedures. Multiple sharp curettage procedures may raise the subsequent risk of placenta previa, whereas vacuum aspiration procedures likely do not (Johnson, 2003). Other studies suggest that subsequent pregnancy outcomes are similar regardless of whether a prior induced abortion was completed medically or surgically (Virk, 2007).

The rates of infertility or ectopic pregnancy do not appear to be significantly increased by prior abortion. There may be exceptions if there are postabortal infections, especially those caused by chlamydial species. It may be reasonable to compare women undergoing a pregnancy termination with those having a first-trimester miscarriage, in whom the 5-year live-birth rate was approximately 80 percent following pregnancy loss (Smith, 2009).

Data relating induced abortion to overall maternal health are limited. In one case-control study, there was no evidence for excessive mental health disorders (Munk-Olsen, 2011). A review by the American College of Obstetricians and Gynecologists (2013a) concluded that there is no causal relationship between prior induced abortion and breast cancer risk.

## POSTABORTAL CONTRACEPTION

Ovulation may resume as early as 2 weeks after an early pregnancy loss, whether spontaneous or induced. Lahteenmaki and Luukkainen (1978) detected LH surges 16 to 22 days after abortion in 15 of 18 women studied. Plasma progesterone levels, which had plummeted after the abortion, increased soon after the LH surges. These hormonal events agree with histological changes observed in endometrial biopsies (Boyd, 1972).

Accordingly, effective contraception should be initiated soon after abortion unless another pregnancy is desired immediately. An intrauterine device can be inserted after the procedure is completed (Bednarek, 2011; Shimoni, 2011). Alternatively, any of the hormonal contraceptive methods discussed in Chapter 5 can be initiated at this time (Madden, 2009; Reeves, 2007).

### EPIDEMIOLOGY

An ectopic or extrauterine pregnancy is one in which the blastocyst implants anywhere other than the endometrial lining of the uterine cavity. Nearly 95 percent of ectopic pregnancies implant in the fallopian tube. Other sites are shown in [Figure 7-1](#), which reflects data from 1800 surgically treated ectopic pregnancies (Bouyer, 2002). Bilateral ectopic pregnancies are rare, and their estimated prevalence is 1 of every 200,000 pregnancies (al-Awwad, 1999).

Reported incidences rates of ectopic pregnancy are less reliable than in the past as outpatient treatment protocols render national hospital discharge statistics invalid. One estimate by Kaiser Permanente of North California was 2.07 percent of total pregnancies from 1997 to 2000 (Van Den Eeden, 2005). Hoover and colleagues (2010) queried a large claims database of privately insured women between 2002 and 2007 and calculated a rate of 0.64 percent. However, this may not accurately reflect the cases in higher-risk, lower-socioeconomic, uninsured populations. Stulberg and coworkers (2014) reviewed 2004 to 2008 Medicaid claims data from 14 states. They reported a rate of 1.4 percent and noted that black women were 46 percent

more likely to experience an ectopic pregnancy than whites in this government-insured group.

Among several factors that help explain the incidence of ectopic pregnancies are: (1) greater sexually transmitted disease prevalence, (2) diagnostic tools with improved sensitivity, (3) tubal factor infertility, (4) delayed childbearing and accompanied use of assisted reproductive technology, and (5) increased intrauterine device (IUD) use and tubal sterilization, which predispose to ectopic pregnancy if the method fails (Ankum, 1996; Li, 2014a; Ljubin-Sternak, 2014).

Ectopic pregnancy remains the leading cause of early pregnancy-related death. Still, current diagnostic and treatment protocols have resulted in substantial declines in fatality rates. One analysis showed a 56-percent decline in the ectopic pregnancy mortality ratio between the 1980 to 1984 epoch and the 2003 to 2007 epoch. During this later span, African-American women were approximately three times more likely to die as a result of ectopic pregnancy complications than whites (Creanga, 2011). Inadequate access to gynecologic and prenatal care may partially explain this trend.

In most of these cases, death is directly related to severe hemorrhage from tubal rupture. Risk factors that increase the likelihood of tubal rupture include ovulation induction, serum  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG) level  $> 10,000$  IU/L, and never having used contraception (Job-Spira, 1999). Appreciation of these characteristics can aid prompt surgical intervention.

### RISK FACTORS

Several risks have been linked with ectopic pregnancy ([Table 7-1](#)). Among these, documented tubal pathology, surgery to restore tubal patency, or tubal sterilization can all lead to obstruction and subsequent ectopic pregnancy. A woman with two prior ectopic pregnancies has a 10- to 16-fold increased chance for another (Barnhart, 2006; Skjeldestad, 1998).

*Smoking*, which may be a surrogate marker for sexually transmitted infections, increases the ectopic pregnancy risk three- to fourfold in women who smoke more than one pack of cigarettes daily (Saraiya, 1998). The increased risk of ectopic pregnancy among smokers undergoing assisted reproductive technology was verified in a metaanalysis by Waylen and associates (2009). In addition, animal studies show that smoking alters oocyte cumulus complex pick-up and embryo transport through its effects on ciliary function and smooth-muscle contraction (Shaw, 2010; Talbot, 2005).

*Assisted reproductive technology (ART)* for sub- or infertile couples has a 0.8-percent incidence of ectopic pregnancy per

**FIGURE 7-1** Various sites and frequency of ectopic pregnancies. (Reproduced with permission from Cunningham FG, Leveno KJ, Bloom SL (eds): Ectopic pregnancy. In Williams Obstetrics, 24th ed. New York, McGraw-Hill Education, 2014.)

transfer and 2.2 percent per clinical pregnancy (Coste, 2000). Interestingly, recent series note significant reductions in ectopic pregnancy rates at the time of in vitro fertilization (IVF) if frozen-thawed embryos (2.2 percent rate) are used rather than those from fresh cycles (4.6 percent) (Fang, 2015; Huang, 2014). In women undergoing IVF, the main risk factors for ectopic pregnancy are tubal factor infertility and hydrosalpinges (Strandell, 1999; Van Voorhis, 2006). Moreover, “atypical” implantation—that is, interstitial, abdominal, cervical, ovarian, or heterotopic—is more common following ART procedures. As a review, heterotopic pregnancy is

an intrauterine pregnancy coexistent with an extrauterine pregnancy.

*Older reproductive-aged women*, specifically women aged 35 to 44 years, carry a threefold risk of ectopic pregnancy compared with those aged 15 to 25 years (Goldner, 1993). These have been attributed to age-related hormonal changes that alter tubal function (Coste, 2000).

*Contraception* lowers overall pregnancy rates and thereby lowers ectopic pregnancy rates. However, if pregnancy does occur, some methods increase the relative incidence of ectopic pregnancy. Examples include the levonorgestrel-releasing intrauterine system (Mirena) and copper IUD (ParaGard). In one study of 61,448 IUD users, 118 contraceptive failures were reported, and 21 of these were ectopic (Heinemann, 2015). Progestin-only contraceptive pills also pose a slightly increased risk because of their effects to diminish tubal motility. With tubal sterilization failure, ectopic pregnancy is a concern. In one study, this risk was 3.5 times greater in women younger than 28 years at the time of sterilization. This may be in part because of age-related fecundity. Of methods, higher ectopic rates were noted with laparoscopic partial salpingectomy and electrodestruction methods (Malacova, 2014).

**PATHOPHYSIOLOGY**

Acute inflammation has been implicated in the tubal damage that predisposes to ectopic pregnancies. Chronic salpingitis and salpingitis isthmica nodosa also contribute (Kutluay, 1994).

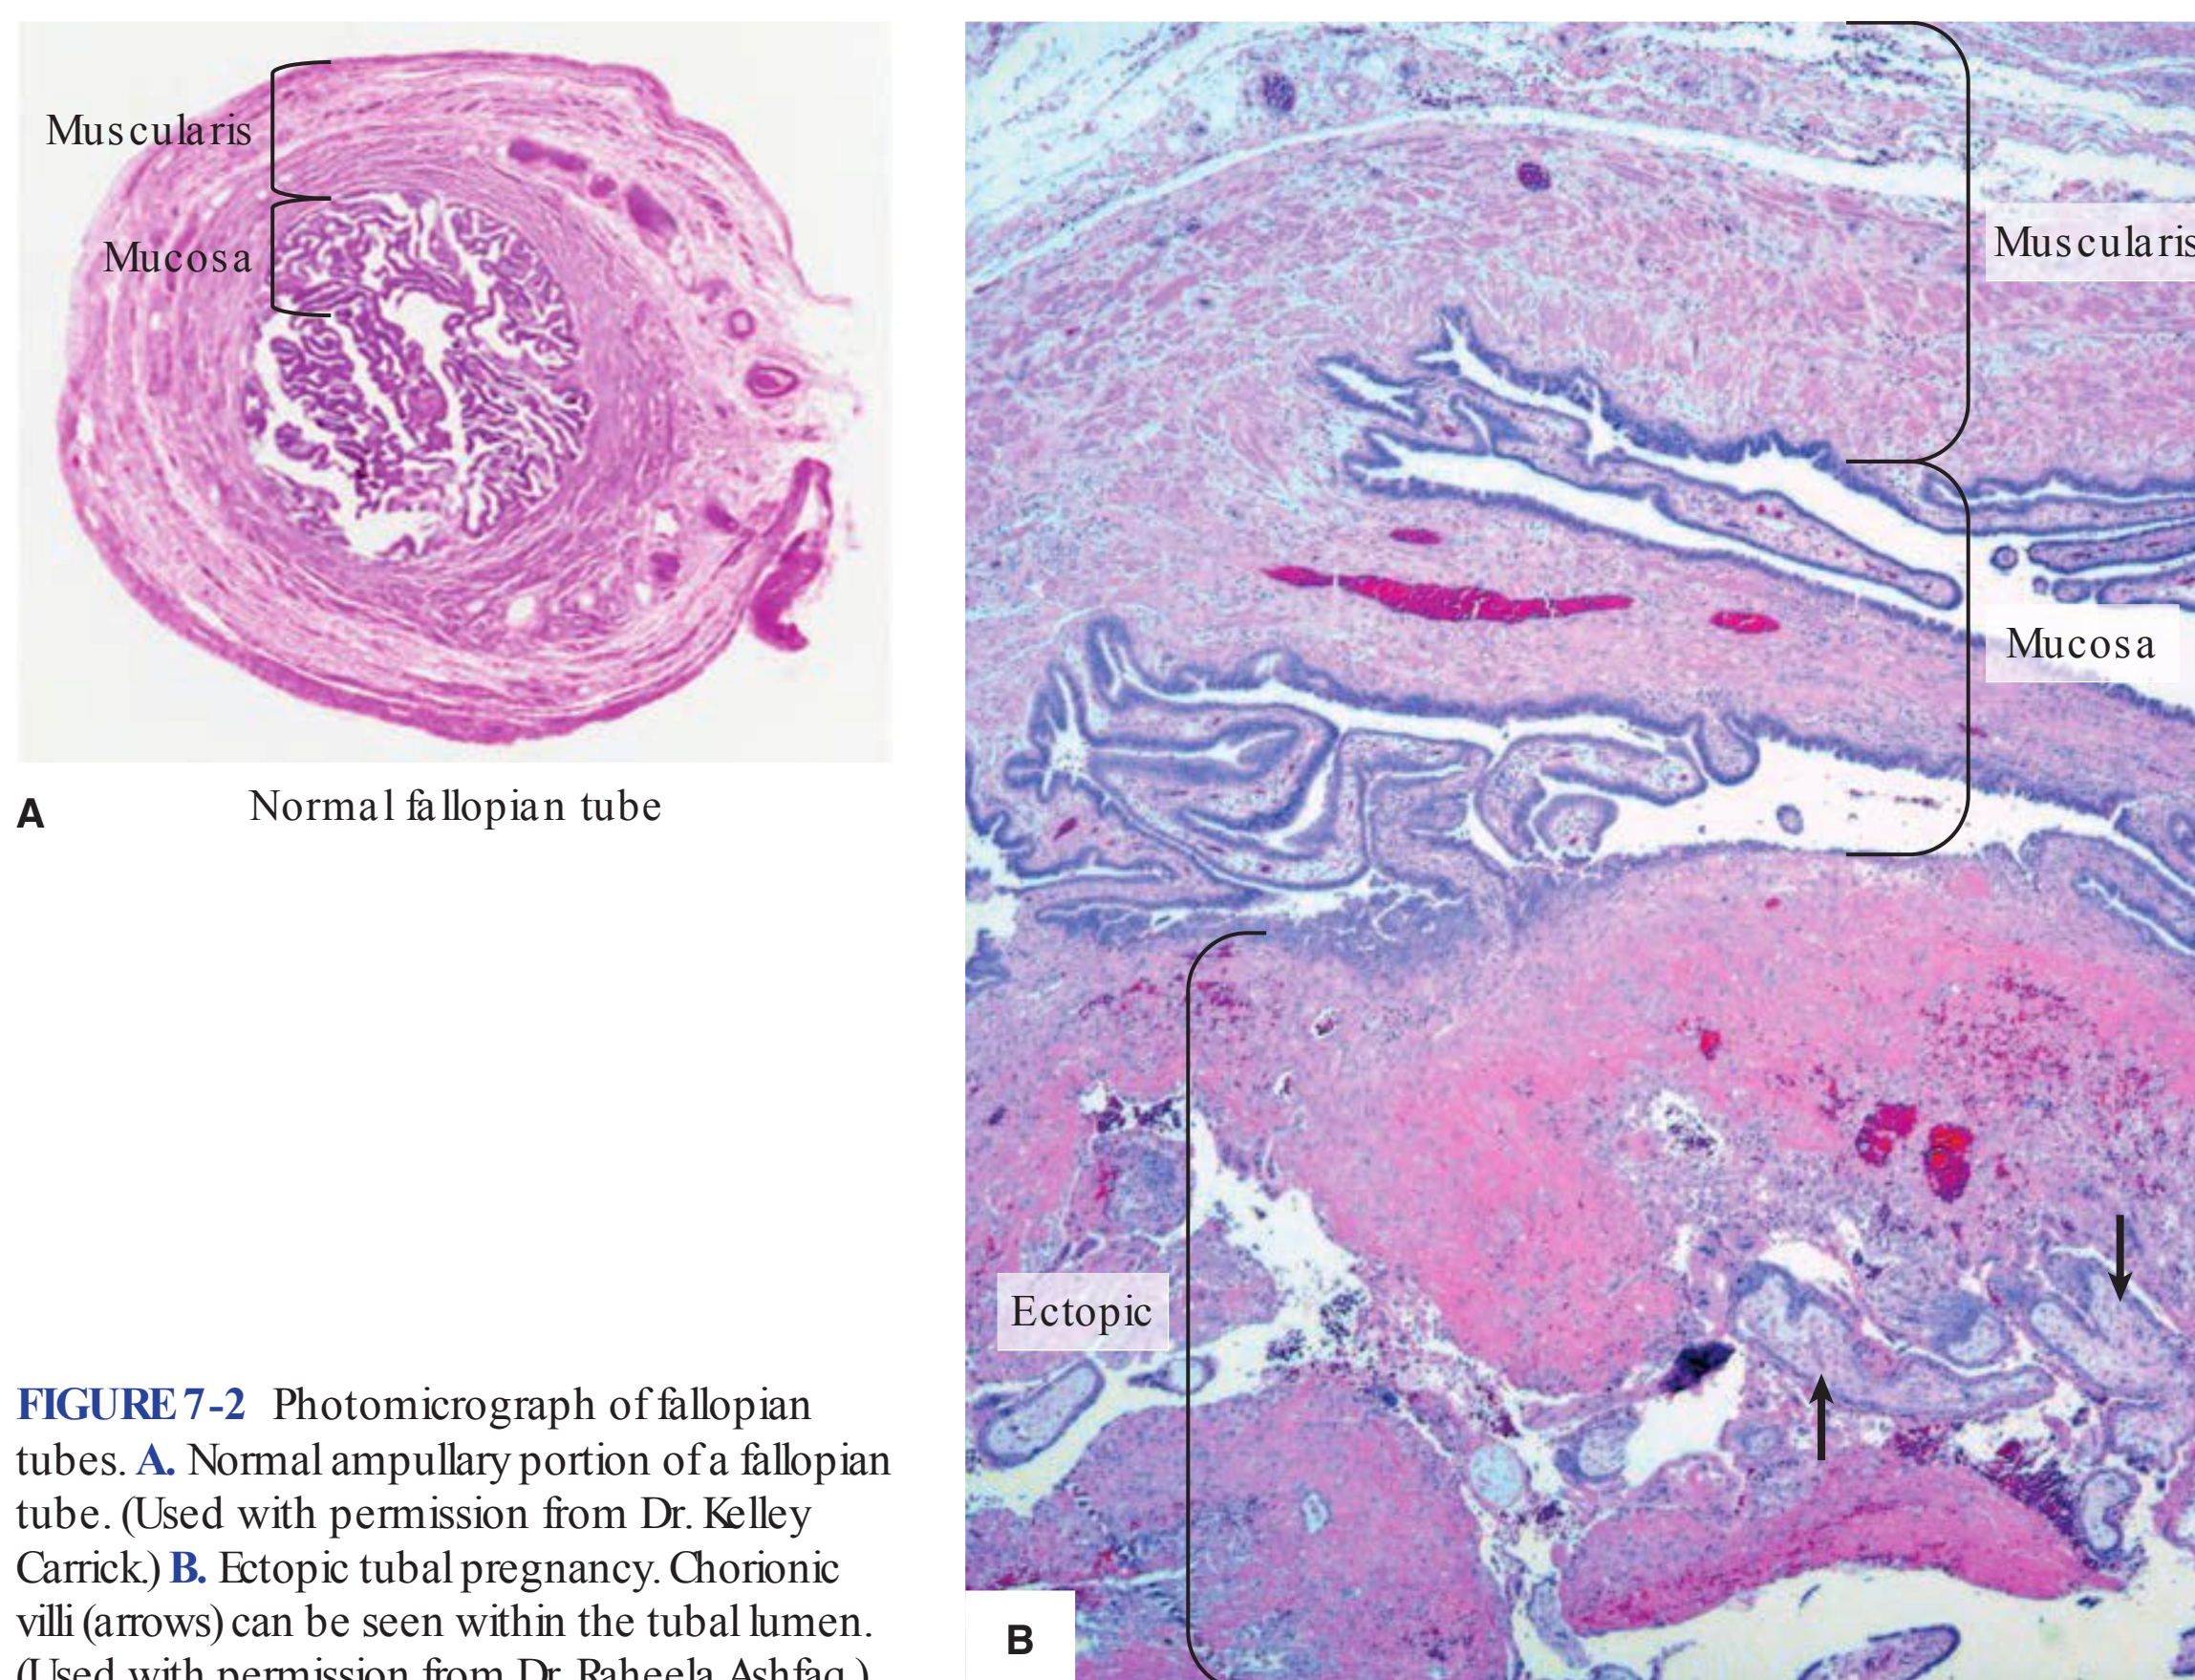

Of suspected agents, recurrent chlamydial infection causes intraluminal inflammation, subsequent fibrin deposition, and tubal scarring (Hillis, 1997). Moreover, persistent chlamydial

**TABLE 7-1.** Risk Factors for Ectopic Pregnancy

Factor	Odds Ratio (95% CI)
Prior ectopic pregnancy	12.5 (7.5, 20.9)
Prior tubal surgery	4.0 (2.6, 6.1)
Smoking > 20 cigarettes per day	3.5 (1.4, 8.6)
PID confirmed by laparoscopy or positive test for Chlamydia trachomatis	3.4 (2.4, 5.0)
≥ 3 prior spontaneous miscarriages	3.0 (1.3, 6.9)
Age ≥ 40 years	2.9 (1.4, 6.1)
Prior medical or surgical abortion	2.8 (1.1, 7.2)
Infertility > 1 year	2.6 (1.6, 4.2)
Lifelong sexual partners > 5	1.6 (1.2, 2.1)
Prior IUD use	1.3 (1.0, 1.8)

IUD = intrauterine device; PID = pelvic inflammatory disease; STD = sexually transmitted disease.  
Data from Bouyer, 2003; Buster, 1999.

**FIGURE 7-2** Photomicrograph of fallopian tubes. **A.** Normal ampullary portion of a fallopian tube. (Used with permission from Dr. Kelley Carrick.) **B.** Ectopic tubal pregnancy. Chorionic villi (arrows) can be seen within the tubal lumen. (Used with permission from Dr. Raheela Ashfaq.)

antigens can trigger a delayed hypersensitivity reaction that promotes continued scarring despite negative culture results (Toth, 2000). Whereas endotoxin-producing *Neisseria gonorrhoeae* causes virulent pelvic inflammation that has a rapid clinical onset, the chlamydial inflammatory response is chronic and peaks at 7 to 14 days.

Inflammation within the fallopian tube can also arrest embryo progress and provide a premature proimplantation signal (Shaw, 2010). Specifically, oviduct interstitial cells of Cajal are specialized pacemaker cells responsible for oviduct motility and egg transport. Infections in mice by *Chlamydia muridarum*, which is similar to human *Chlamydia trachomatis*, lead to absent spontaneous pacemaker activity and may offer another explanation of how *chlamydial infection* increases ectopic pregnancy rates in humans (Dixon, 2009).

Another factor involved with oviductal transport of embryos is the cannabinoid receptor (CB1), which is mediated by endocannabinoid signaling. Chronic exposure to nicotine can affect endocannabinoid levels and lead to fallopian tube dysfunction (Horne, 2008).

The mechanism for ectopic pregnancy in women using ART has been a conundrum because the fallopian tube is typically bypassed. Revel and colleagues (2008) sought to establish the relationship between E-cadherin, an adhesion molecule, and tubal ectopic pregnancy implantation sites. They found E-cadherin strongly localized to the tubal embryo implantation site only in women who underwent IVF. This suggests a biologic rather than mechanical factor accounting for the ectopic pregnancies associated with IVF.

Once normal tubal transport has been disrupted, fallopian tube anatomy plays an important role in tubal pregnancy genesis. Namely, the fallopian tube lacks a submucosal layer beneath its epithelium. Therefore, a fertilized ovum can easily burrow through the epithelium and implant within tube's muscularis layer (Fig. 7-2). As rapidly proliferating trophoblasts erode the muscularis layer, maternal blood pours into the spaces within the trophoblastic or the adjacent tissue.

With this process, the location of a tubal pregnancy may predict the extent of damage. Senterman and associates (1988) studied histologic samples from 84 isthmic and ampullary pregnancies. They reported that half of the ampullary pregnancies were intraluminal, and the muscularis was preserved in 85 percent of these. Conversely, isthmic gestations were found both intra- and extraluminally with greater disruption of the tubal wall. The timing of tubal rupture is also partially dependent on pregnancy location. As a rule, fallopian tubes rupture earlier if implantation is in the isthmic or ampullary portion. Later rupture is seen if the ovum implants within the interstitial portion. Rupture is usually spontaneous but can also follow trauma such as that associated with bimanual pelvic examination or coitus.

After implantation, differences in ectopic pregnancy development explain the typically divergent clinical paths between acute and chronic ectopic pregnancies. *Acute ectopic pregnancies* are those with a high serum  $\beta$ -hCG level at presentation. These high  $\beta$ -hCG levels correlate with the depth of trophoblastic invasion into the tubal wall. Greater invasion promotes concomitant severe ischemic changes and tubal wall rupture (Erol, 2015). Rapid pregnancy growth leads to an immediate diagnosis

from painful tubal distention or from rupture. Indeed, these carry a higher risk of tubal rupture compared with chronic ectopic pregnancies (Barnhart, 2003c).

With *chronic ectopic pregnancy*, minor repeated ruptures or tubal abortion incites an inflammatory response that leads to formation of a pelvic mass. Its abnormal trophoblasts die early. Thus, negative or lower, static serum  $\beta$ -hCG levels are found. Chronic ectopic pregnancies typically rupture late, if at all, but commonly form a complex pelvic mass. In these cases, it often is the mass, rather than pain or bleeding, that prompts diagnostic surgery (Cole, 1982; Uğur, 1996).

CLINICAL MANIFESTATIONS

The classic symptom triad of ectopic pregnancy is amenorrhea followed by vaginal bleeding and ipsilateral abdominal pain. However, as women seek care earlier, the ability to diagnose ectopic pregnancy before rupture—even before the onset of symptoms—is not unusual. Of other symptoms, banal pregnancy discomforts such as breast tenderness, nausea, and urinary frequency may accompany more ominous findings. These include shoulder pain worsened by inspiration, which is caused by phrenic nerve irritation from subdiaphragmatic blood, or vasomotor disturbances such as vertigo and syncope from hemorrhagic hypovolemia.

Of physical findings, some women have orthostatic findings from hypovolemia. Birkhahn and associates (2003) employed the shock index to evaluate the severity of ruptured ectopic pregnancy. This index is the heart rate divided by systolic blood pressure and can assess trauma patients for hypovolemic or septic shock. The normal range lies between 0.5 and 0.7 for

nonpregnant patients. A shock index  $> 0.85$  and a systolic blood pressure  $< 110$  mm Hg are highly suggestive of a potentially life-threatening gynecologic emergency, such as a ruptured ectopic pregnancy (Birkhahn, 2003; Polena, 2015). Despite these findings of advanced hypovolemia, normal vital signs are unreliable to exclude earlier stages of tubal rupture.

Abdominal and pelvic findings may also be notoriously scarce in many women before tubal rupture. With rupture, however, nearly three fourths will have marked tenderness on both abdominal and pelvic examination, and pain is aggravated with cervical manipulation. A pelvic mass, including fullness posterolateral to the uterus, can be palpated in approximately 20 percent of women. Initially, an ectopic pregnancy may feel soft and elastic, whereas extensive intraluminal hemorrhage produces a firmer consistency. Many times, discomfort precludes palpation of the mass, and limiting examinations may help avert iatrogenic rupture.

DIAGNOSIS

Symptoms of ectopic pregnancy can mimic multiple entities (Table 7-2). Early pregnancy complications such as threatened or missed abortion or hemorrhagic corpus luteum cyst may be difficult to differentiate. Moreover, approximately 20 percent of women with normal pregnancies have early bleeding. Several disorders not related to pregnancy can also mimic ectopic pregnancy. In general, a positive test for  $\beta$ -hCG usually excludes these other diagnoses. However, these conditions may exist concurrently with pregnancy—either intrauterine or ectopic. Transvaginal sonography and serial serum  $\beta$ -hCG measurements are the most valuable diagnostic aids to confirm clinical

TABLE 7-2. Conditions That Cause Lower Abdominal Pain

Cause	Abdominal Location	Characteristics	Associated Findings
<b>Pregnancy</b>			
Abortion	Midline or generalized	Crampy, episodic	(+) UCG; vaginal bleeding
Ectopic	Unilateral or generalized	Sharp or aching, continuous	(+) UCG; vaginal bleeding
<b>Uterus and Cervix</b>			
Endomyometritis	Lower, midline	Dull aching	Vaginal discharge, fever
Endometriosis	Lower, midline	Cyclic, aching	Possible adnexal mass
Degenerating myoma	Lower, midline	Dull aching or sharp	Irregular, enlarged uterus
<b>Adnexal Disease</b>			
Salpingitis	Unilateral or bilateral	Severe	Moderate to high fever
Tuboovarian abscess	Unilateral or bilateral	Dull aching or sharp	High fever; adnexal mass
Corpus luteum cyst	Lower, unilateral	Acute onset, sharp	(+ / - ) UCG
Adnexal torsion	Lower, unilateral	Acute onset, sharp, continuous or episodic	Adnexal mass
<b>Other</b>			
Appendicitis	Periumbilical or right lower	Sharp or aching, continuous	Anorexia, nausea, vomiting
Diverticulitis	Left lower	Dull aching	Fever
Cystitis	Midline, suprapubic	Acute, spasms	Dysuria, frequency
Renal calculi	Flank, radiating downward	Severe, episodic	Hematuria

UCG = urinary chorionic gonadotropin test result.

suspicious of an ectopic pregnancy. Additionally, because ectopic pregnancy can lead to significant bleeding, a hemogram is an additional fast and effective initial screen.

## ■ Laboratory Findings

### Serum $\beta$ -hCG Measurements

Human chorionic gonadotropin is a glycoprotein produced by syncytiotrophoblast and can be detected in serum as early as 8 days after the luteinizing hormone (LH) surge. In normal pregnancies, serum  $\beta$ -hCG levels rise in a log-linear fashion until 60 or 80 days after the last menses, at which time values plateau at approximately 100,000 IU/L. Given an interassay variability of 5 to 10 percent, interpretation of serial values is more reliable when performed by the same laboratory.

With a robust intrauterine pregnancy (IUP), serum  $\beta$ -hCG levels should increase at least 53 to 66 percent every 48 hours (Barnhart, 2004; Kadar, 1982). Seiber and associates (2006) used an even more conservative 35-percent rise after 48-hours. Past this 48 hours, allowing time for additional data may better determine the location and viability of the pregnancy. But, this is weighed against the increased chance of ectopic pregnancy rupture during these extra diagnostic days. In hemodynamically stable women, adding a third serum  $\beta$ -hCG level on day 4 or 7 could correct the diagnosis of a pregnancy of unknown location in an additional 7 to 13 percent of patients (Zee, 2013). Nevertheless, inadequately rising serum  $\beta$ -hCG levels indicate only a dying pregnancy, not its location.

Many women present with an unsure last menstrual period, and an educated guess of gestational age is made. In these cases, correlation between the serum  $\beta$ -hCG concentration and transvaginal sonography findings becomes especially important.

### Serum Progesterone Levels

Serum progesterone concentration is used by some to aid ectopic pregnancy diagnosis when serum  $\beta$ -hCG levels and sonographic findings are inconclusive (Stovall, 1992). Serum progesterone concentration varies minimally between 5 and 10 weeks' gestation, thus a single value is sufficient. Mol and coworkers (1998) performed a metaanalysis of 22 studies to assess the accuracy of a single serum progesterone level to differentiate ectopic from uterine pregnancy. They found that results were most accurate when approached from the viewpoint of *healthy versus dying pregnancy*. With serum progesterone levels  $< 5$  ng/mL, a dying pregnancy was detected with *near perfect* specificity and with a sensitivity of 60 percent. Conversely, values of  $> 20$  ng/mL had a sensitivity of 95 percent with specificity approximating 40 percent to identify a healthy pregnancy. Ultimately, serum progesterone levels can be used to buttress a clinical impression, but again they *cannot* reliably differentiate between an ectopic and intrauterine pregnancy (Guha, 2014).

## ■ Sonography

High-resolution sonography has revolutionized the clinical management of women with a suspected ectopic pregnancy. With transvaginal sonography (TVS), a gestational sac is usually visible between 4½ and 5 weeks, the yolk sac appears between

5 and 6 weeks, and a fetal pole with cardiac activity is first detected at 5½ to 6 weeks. With transabdominal sonography, these structures are visualized slightly later. The sonographic diagnosis of ectopic pregnancy rests on visualization of an adnexal mass separate from the ovary (Fig. 7-3).

When the last menstrual period is unknown, serum  $\beta$ -hCG testing is used to define expected sonographic findings. Each institution must define a  $\beta$ -hCG discriminatory value for TVS, that is, the lower limit at which an examiner can reliably visualize an IUP. At most institutions, this value is a concentration between 1500 and 2000 IU/L. Accurate diagnosis by sonography is three times more likely if the initial  $\beta$ -hCG level is above this value. Connolly and colleagues (2013) reported evidence to suggest an even higher threshold. They noted that with live IUPs, a gestational sac was seen 99 percent of the time with a discriminatory level of 3510 IU/L. Even with  $\beta$ -hCG levels above the chosen discriminatory value, technical challenges such as leiomyomas, adenomyosis, multifetal gestation, or IUD can hinder the ability to accurately diagnose an intrauterine gestation (Gurel, 2007; Ko, 2014).

When  $\beta$ -hCG levels are above the set discriminatory value, the absence of an IUP may suggest an abnormal pregnancy. The abnormality may be an ectopic pregnancy, an incomplete abortion, or a resolving completed abortion. For example, despite total passage of products of conception with complete abortion,  $\beta$ -hCG testing may still be positive while original  $\beta$ -hCG is metabolized and cleared. Conversely, when  $\beta$ -hCG values lie below the discriminatory value, sonographic findings are not diagnostic in nearly two thirds of cases (Barnhart, 1999).

In an attempt to unify the language used with sonographic evaluation of early pregnancies, a consensus statement was drafted with five categories: (1) definitive ectopic pregnancy (extrauterine gestational sac with yolk sac and/or embryo), (2) probable ectopic pregnancy (inhomogeneous adnexal mass or extrauterine sac-like structure), (3) probable IUP (intrauterine echogenic sac), (4) definite IUP (intrauterine gestational sac with yolk sac and/or embryo), and (5) pregnancy of unknown location (PUL) (lacking signs of either ectopic pregnancy or IUP) (Barnhart, 2011).

Systematic sonographic evaluation is critical to establish the correct diagnosis. Most begin with the endometrial cavity. In pregnancies conceived spontaneously, identification of an IUP effectively excludes the possibility of ectopic implantation. When ART is employed, however, careful examination of the tube and ovary is performed even with an intrauterine pregnancy because heterotopic pregnancy rates may be as high as 1 per 100 (Tal, 1996). An intracavitary fluid collection caused by bleeding from the decidua can create a *pseudogestational sac*, or *pseudosac*. As shown in Figure 7-4, this one-layer collection lies typically in the midline of the uterine cavity. In contrast, a normal gestational sac is eccentrically located (Dashefsky, 1988). Another intracavitary finding is a trilaminar endometrial pattern, which represents two adjacent proliferative-phase endometrial layers (Fig. 2-16, p. 31) (Lavie, 1996). For the diagnosis of ectopic pregnancy, this finding's specificity is 94 percent but with a sensitivity of only 38 percent (Hammoud, 2005). Endometrial stripe thickness has not been well correlated with ectopic pregnancies. However, Moschos and Twickler (2008b)

Inhomogeneous mass

Mass with empty extrauterine sac

Mass with yolk sac

**FIGURE 7-3** Transvaginal sonographic findings with various ectopic pregnancies. For sonographic diagnosis, an ectopic mass should be seen in the adnexa separate from the ovary and may be seen: (A) as an inhomogeneous adnexal mass (yellow arrows), (B) as an empty extrauterine sac with a hyperechoic ring (arrow), or (C) as a yolk sac and/or fetal pole with or without cardiac activity within an extrauterine sac. LO = left ovary. (Used with permission from Dr. Elysia Moschos.)

**FIGURE 7-4** Transvaginal sonography of a pseudogestational sac (arrow) within the endometrial cavity. Note its ovoid shape and central location, which are characteristic of these fluid collections. (Used with permission from Dr. Elysia Moschos.)

determined that in PULs, none that ultimately proved to be normal IUPs had a stripe thickness  $< 8$  mm.

The fallopian tubes and ovaries are also inspected. Visualization of an extrauterine yolk sac or embryo clearly confirms an ectopic pregnancy, although such findings are less commonly seen (Paul, 2000). In some cases, a *halo* or tubal ring that surrounds an anechoic sac can be seen. According to Burry and associates (1993), this has a positive-predictive value of 92 percent and a sensitivity of 95 percent. Alternatively, an inhomogeneous complex adnexal mass is usually caused by hemorrhage within the ectopic sac or by an ectopic pregnancy that has ruptured into the tube. Overall, approximately 60 percent of ectopic pregnancies are seen as an inhomogeneous mass adjacent to the ovary; 20 percent appear as a hyperechoic ring; and 13 percent have an obvious gestational sac with a fetal pole (Condous, 2005). Brown and associates (1994) conducted a metaanalysis of 10 studies to ascertain the best transvaginal sonographic criteria to diagnose ectopic pregnancy. They reported that the finding of any adnexal mass, other than a simple ovarian cyst, was the most accurate. With this, they found a sensitivity of 84 percent, specificity of 99 percent, positive-predictive value of 96 percent, and negative-predictive value of 95 percent. However, not all adnexal masses represent an ectopic pregnancy, and integration of sonographic findings with other clinical information is necessary.

Differentiating an ectopic pregnancy from a corpus luteum cyst can be challenging. However, Swire and coworkers (2004) observed that the corpus luteum wall is less echogenic compared with both a tubal ring and the endometrium. They found that a spongelike, lacelike, or reticular pattern seen within the cyst is classic for hemorrhage (Fig. 9-16, p. 218). Moreover, a corpus luteum is found within the parenchyma of an ovary, but a markedly asymmetric appearing ovary should raise suspicion of an ectopic pregnancy (Gurel, 2007). With transvaginal color Doppler imaging, placental blood flow within the periphery of the ectopic pregnancy—the *ring of fire*—can be seen (Fig. 7-5). Although this finding can aid ectopic pregnancy diagnosis, a

**FIGURE 7-5** Color Doppler transvaginal sonography of an ectopic pregnancy. The “ring of fire” reflects placental blood flow around the periphery of the pregnancy. This finding, however, may also be seen with corpus luteum cysts.

ring of fire also can be seen with a corpus luteum of pregnancy (Pellerito, 1992). Pulsed-color Doppler sonographic measurement of resistance indices has poor sensitivity and limits its utility (Atri, 2003). Finally, to help characterize a suspicious mass, an examiner can gently palpate an adnexum that is placed between the vaginal probe and the examiner’s abdominal hand during real-time scanning. A mass that moves separately from the ovary suggests a tubal pregnancy, whereas a mass that moves synchronously more likely represents a corpus luteum cyst (Levine, 2007).

During sonographic evaluation of the pelvis, TVS can detect as little as 50 mL of free peritoneal fluid in the cul-de-sac of Douglas. This may be intraabdominal bleeding or physiologic peritoneal fluid. A large volume of fluid or fluid that is echogenic is more worrisome for hemoperitoneum. In addition, transabdominal right-upper-quadrant sonographic imaging helps assess the extent of hemoperitoneum. Blood in the paracolic gutters and Morison pouch indicates significant hemorrhage. Specifically, free fluid in Morison pouch typically is not seen until a hemo-

peritoneum reaches 400 to 700 mL (Branney, 1995; Rodgerson, 2001). Detection of peritoneal fluid in conjunction with an adnexal mass is highly predictive of ectopic pregnancy (Nyberg, 1991). That said, despite technologic advances, the absence of suggestive findings does not exclude ectopic pregnancy.

### ■ Culdocentesis

With a 16- to 18-gauge spinal needle, the cul-de-sac of Douglas may be entered through the posterior vaginal fornix (Fig. 7-6). The aspirate characteristics, in conjunction with clinical findings, may help clarify the diagnosis. Normal-appearing peritoneal fluid is designated as a negative test. If fragments of an old clot or nonclotting blood are found in the aspirate when placed into a dry, clean test tube, then hemoperitoneum is diagnosed. If the aspirated blood clots after it is withdrawn, this may signify active intraperitoneal bleeding or puncture of an adjacent vessel. If fluid cannot be aspirated, the test can only be interpreted as unsatisfactory. Purulent fluid suggests an infection-related cause such as salpingitis or appendicitis. Feculent material may originate from a perforated colon or an inadvertent puncture of the rectosigmoid colon during culdocentesis.

Several studies have challenged the usefulness of this bedside test, and culdocentesis has been largely replaced by TVS (Glezerman, 1992; Vermesh, 1990). Sonography with findings of echogenic fluid to establish hemoperitoneum is more sensitive and specific than culdocentesis—100 and 100 percent versus 66 and 80 percent, respectively. Also, for most women, sonography is better tolerated.

### ■ Endometrial Evidence

Several endometrial changes are associated with ectopic pregnancy. These include decidua found in 42 percent of samples, secretory endometrium in 22 percent, and proliferative endometrium in 12 percent, all with an absence of trophoblasts (Lopez, 1994). Decidua is endometrium that is hormonally prepared for pregnancy, and the degree to which the endometrium is converted with ectopic pregnancy is variable. Thus, in addition to bleeding, women with ectopic tubal pregnancy may pass a

**FIGURE 7-6 A.** Transvaginal sonography of a fluid collection (arrow) in the cul-de-sac of Douglas. (Used with permission from Dr. Elysia Moschos.) **B.** Culdocentesis. With a 16- to 18-gauge spinal needle attached to a syringe, the cul-de-sac of Douglas is entered through the posterior vaginal fornix as upward traction is applied to the cervix with a tenaculum.

**FIGURE 7-7** In this image of a decidual cast, arrows mark the area that conformed to the cornua. (Reproduced with permission from Cunningham FG, Leveno KJ, Bloom SL (eds): Ectopic pregnancy. In Williams Obstetrics, 24th ed. New York, McGraw-Hill Education, 2014.)

*decidual cast*, which is the entire sloughed endometrium that reflects the form of the endometrial cavity (Fig. 7-7). Decidual sloughing may also occur with IUP abortion. Thus, tissue is carefully evaluated visually and then histologically for evidence of a conceptus. If no clear gestational sac is visually seen or if no villi are identified histologically within the cast, then the possibility of ectopic pregnancy must still be entertained.

Before methotrexate treatment is given for ectopic pregnancy treatment, many recommend that the absence of intrauterine trophoblastic tissue be confirmed by curettage (Barnhart, 2002; Chung, 2011; Shaunik, 2011). The presumptive diagnosis of ectopic pregnancy is inaccurate in nearly 40 percent of cases without histologic exclusion of a spontaneous pregnancy loss. Nevertheless, the need, method, and risks of endometrial sampling must carefully be weighed against the limited risks of methotrexate.

Endometrial biopsy with a Pipelle catheter was studied as an alternative to curettage and found inferior. The sensitivity of obtaining chorionic villi ranged from 30 to 63 percent (Barnhart, 2003b; Ries, 2000). By comparison, frozen section of curettage fragments to identify products of conception is accurate in more than 90 percent of cases (Barak, 2005; Li, 2014b; Spandorfer, 1996).

### ■ Summary of Diagnostic Evaluation

Confirmation by diagnostic laparoscopy remains the gold standard for ectopic pregnancy diagnosis (Fig. 7-8). That said, with sensitive diagnostic modalities available, ectopic pregnancy can typically be diagnosed prior to surgery, and use of an evidence-based algorithm can assist. After appropriate clinical evaluation, all reproductive-aged women with any suspicion of pregnancy are tested using a sensitive urine  $\beta$ -hCG assay. Following positive testing, if an IUP is not confirmed by sonography, if no signs of acute intraabdominal hemorrhage are present, and if an ectopic gestation is suspected, then an evaluation such as the one depicted in Figure 7-9 may be used. Gracia and Barnhart (2001) performed a decision analysis of six diagnostic strategies

**FIGURE 7-8** Laparoscopic photograph of ectopic pregnancy. A blunt probe elevates a blue, distended left tubal ampulla. (Used with permission from Dr. Kevin Doody.)

to evaluate which sequence of tests was most efficient in missing the fewest ectopic pregnancies and interrupting the fewest IUPs. They found the best strategy was to include TVS for all women with first-trimester pain or bleeding. If findings are not diagnostic, then serial serum  $\beta$ -hCG levels are measured. Using this strategy, only 1 percent of all potential IUPs were interrupted; no ectopic pregnancies were missed; and the average time to diagnosis was 1.46 days.

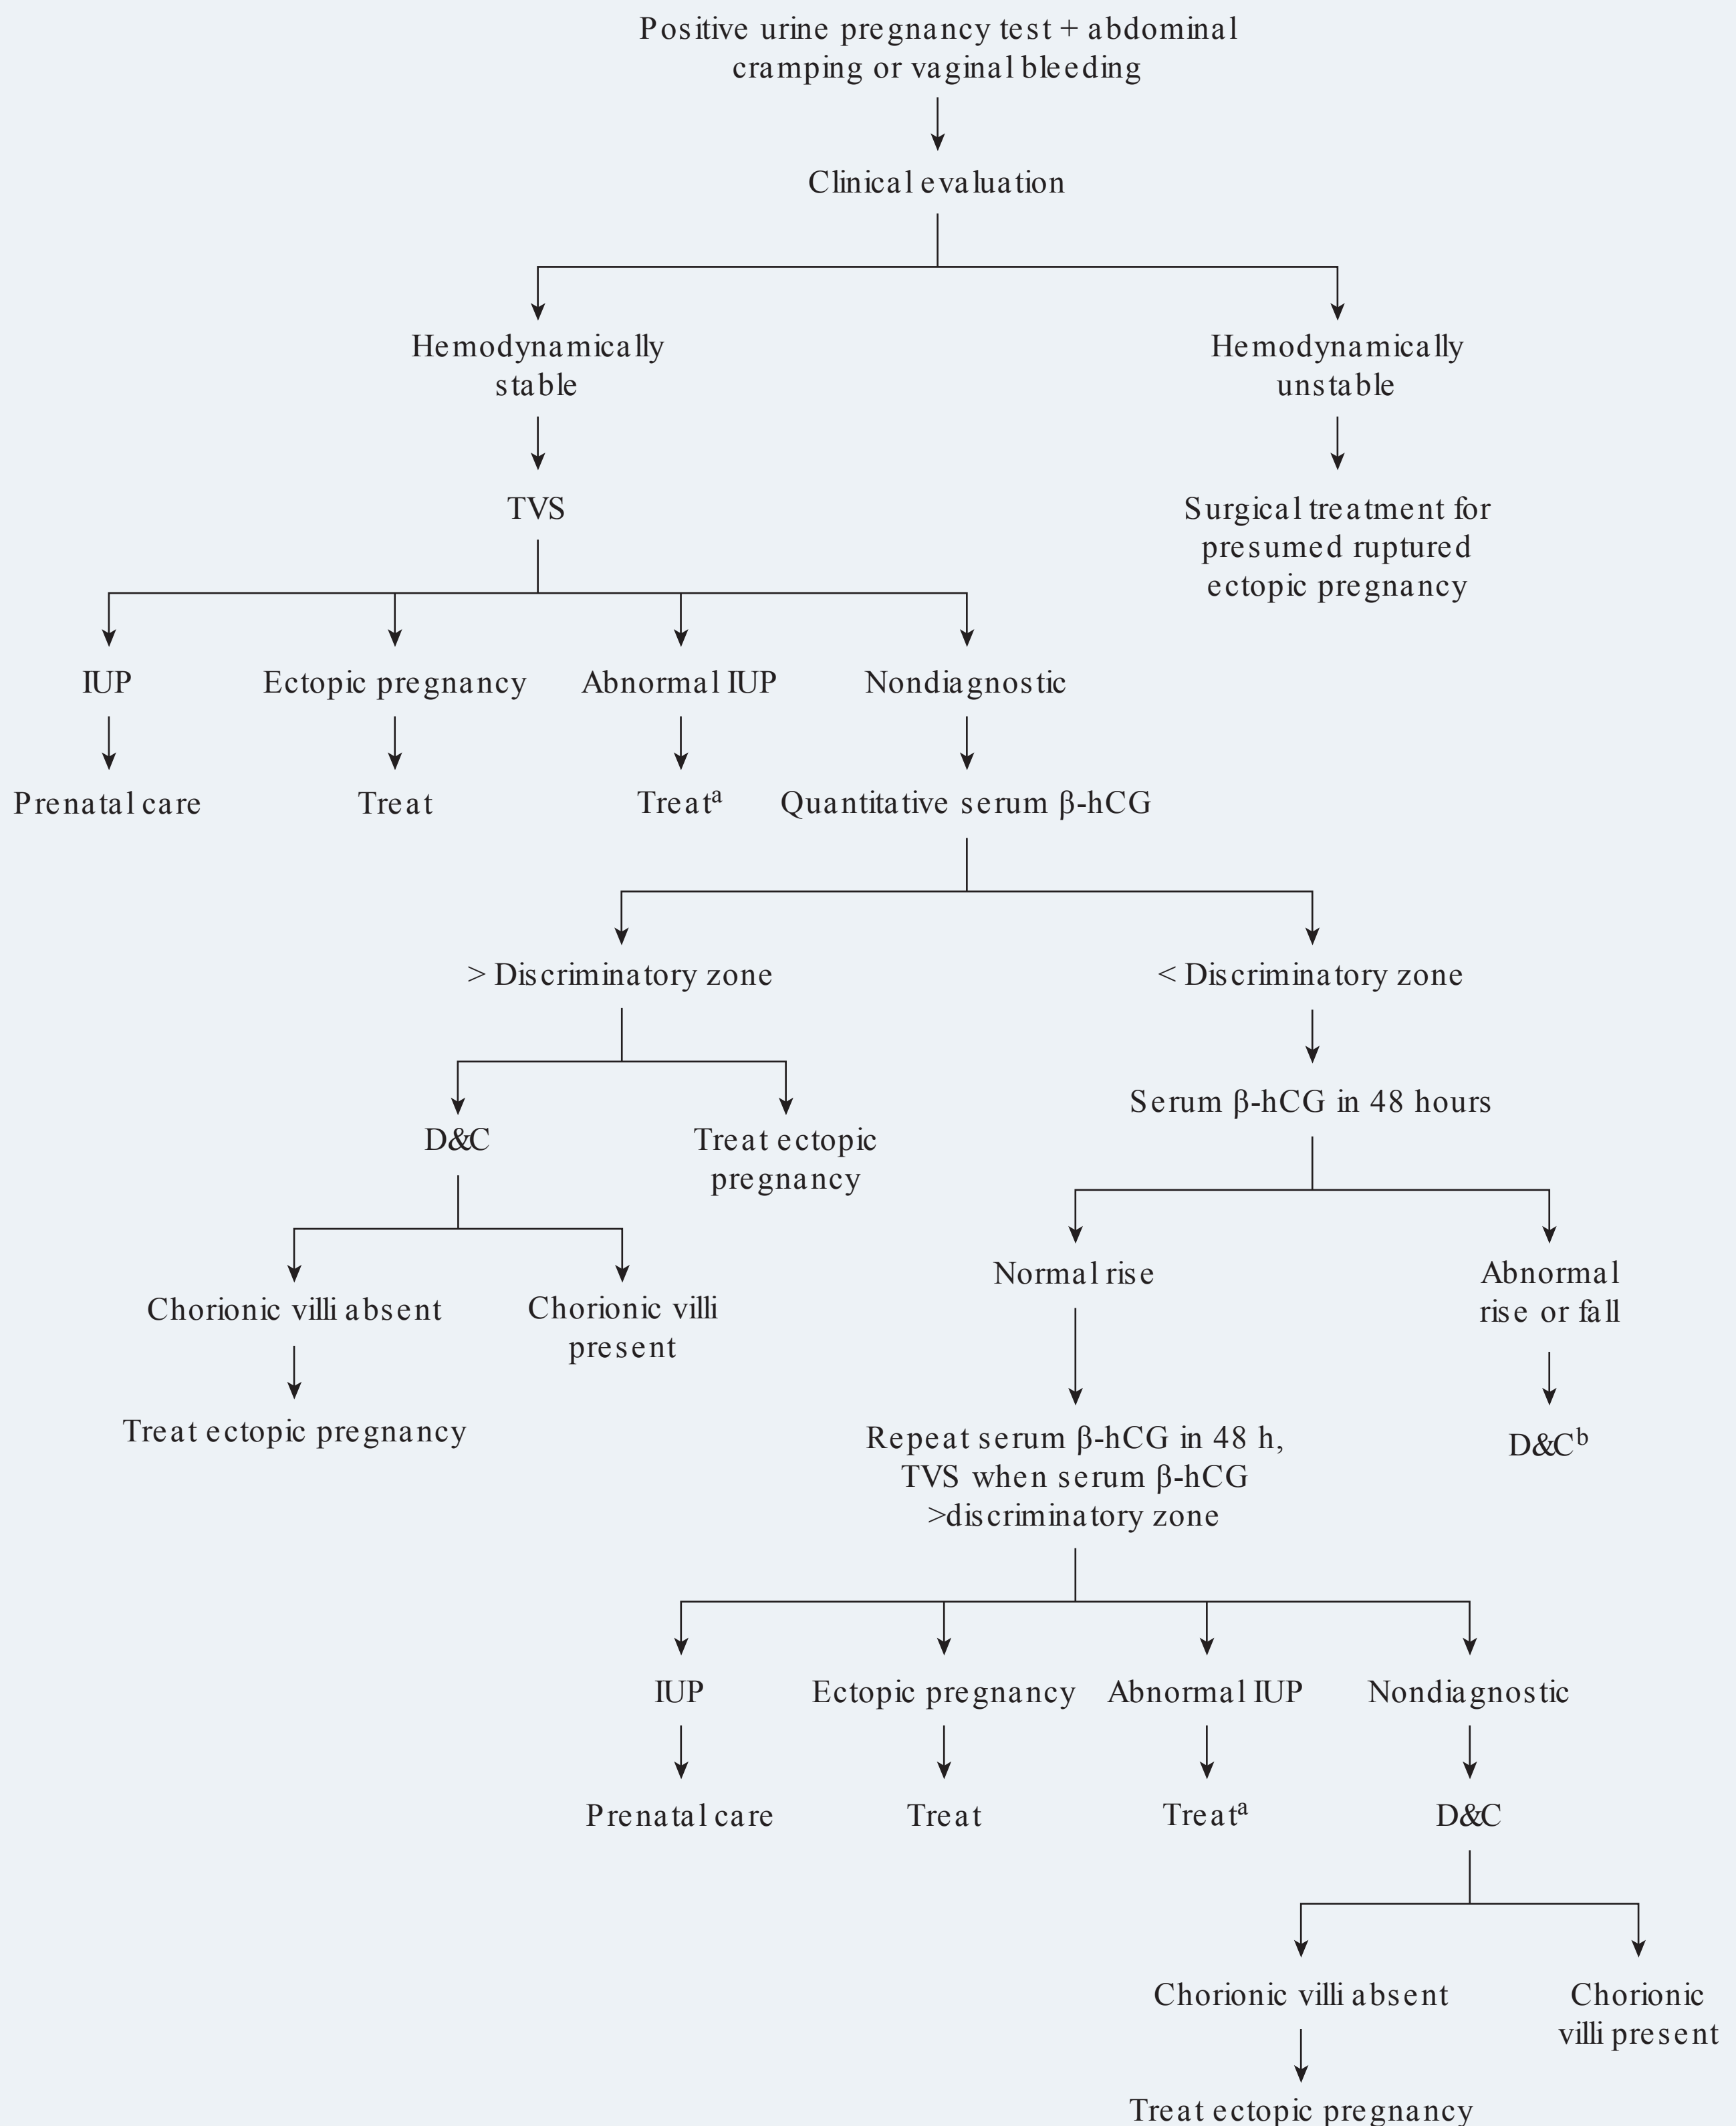

## MANAGEMENT

Without intervention, an ectopic tubal pregnancy can lead to tubal abortion, tubal rupture, or spontaneous resolution. *Tubal abortion* is the expulsion of products through the fimbrial end. This tissue can then either regress or reimplant in the abdominal cavity. With reimplantation, bleeding or pain necessitating surgical intervention is a common complication. *Tubal rupture* is associated with significant intraabdominal hemorrhage. With *spontaneous resolution*, small ectopic pregnancies die and are resorbed without adverse patient effects. As with the ending of any early pregnancy, Rh status is assessed. If a woman is D negative and her partner has a blood group that is either D positive or unknown, then 300  $\mu$ g anti-D immune globulin is given to prevent anti-D isoimmunization.

### ■ Medical Management

Medical therapy is preferred for most ectopic pregnancies, if feasible. Only methotrexate has been extensively studied as an alternative to surgical therapy. The best candidate for medical therapy is a woman who is asymptomatic and motivated and who has resources to be compliant with surveillance. Absolute contraindications for medical therapy with methotrexate include hemodynamic instability and those shown in Table 7-3 (American College of Obstetricians and Gynecologists, 2014; American Society for Reproductive Medicine, 2013). With medical therapy, some classic predictors of success are the initial serum  $\beta$ -hCG level, ectopic pregnancy size, and fetal cardiac activity.

**FIGURE 7-9** Algorithm of ectopic pregnancy evaluation.

<sup>a</sup>Abnormal IUPs may be treated by D & C, medical regimens, or expectant management as outlined in Chapter 6.

<sup>b</sup>Expectant management may be appropriate in a small select group of women with very low β-hCG levels that are dropping as described on page 173.

β-hCG = β-human chorionic gonadotropin; D & C = dilatation and curettage; IUP = intrauterine pregnancy; TVS = transvaginal sonography.

Of these, the  $\beta$ -hCG level is the single best prognostic indicator of treatment success in women given single-dose methotrexate. The prognostic value of the other two predictors may be directly related to their relationship with  $\beta$ -hCG concentrations. According to Lipscomb and colleagues (1999), an initial serum value  $< 5000$  IU/L was associated with a success rate of 92 percent, whereas an initial concentration  $> 15,000$  IU/L had a success rate of 68 percent. In another study, Menon and associates (2007) reported that compared with an initial serum  $\beta$ -hCG level of 2000 to 4999 IU/L, an initial serum  $\beta$ -hCG of 5000 to 9999 IU/L is nearly four times more likely to be associated with methotrexate therapy failure.

The effect of size on success rates with medical therapy has fewer supporting data, although many early trials used “large size” as an exclusion criterion. In one study, the success rate with single-dose methotrexate was 93 percent in cases with ectopic masses  $< 3.5$  cm, whereas success rates were between 87 and 90 percent when the mass was  $> 3.5$  cm (Lipscomb, 1998).

Identification of cardiac activity sonographically is a relative contraindication to medical therapy, although this is based on limited evidence. Most studies report an increased risk of failure if there is cardiac activity, however, a success rate of 87 percent has been reported (Lipscomb, 1998).

Of predictors of treatment failure, extrauterine yolk sac as a predictor of methotrexate failure has conflicting evidence (Lipscomb, 2009). Rapidly rising  $\beta$ -hCG levels both before ( $> 50$  percent) and during methotrexate therapy may also portend an increased failure risk (American Society for Reproductive Medicine, 2013; Dudley, 2004).

Methotrexate

It is folic acid antagonist competitively inhibits the binding of dihydrofolic acid to the enzyme dihydrofolate reductase. It leads to reduced amounts of purines and thymidylate

and thereby an arrest of DNA, RNA, and protein synthesis (Chap. 27, p. 596). It inhibits fast-growing tissue and is used for cancer chemotherapy and for early IUP termination. The drug can be given orally, intravenously, or intramuscularly (IM) or can be directly injected into the ectopic pregnancy sac. Currently, IM methotrexate administration is used most commonly for tubal ectopic pregnancies.

Prior to therapy, serum creatinine and  $\beta$ -hCG levels, a complete blood count, liver function tests, and blood type and Rh status are obtained (American Society for Reproductive Medicine, 2013). Moreover, all except blood typing are repeated prior to additional doses (Lipscomb, 2007). With administration, women are counseled to avoid the following until treatment is completed: folic acid-containing supplements, which can competitively reduce methotrexate binding to dihydrofolate reductase; nonsteroidal antiinflammatory drugs, which reduce renal blood flow and delay drug excretion; alcohol, which can predispose to concurrent hepatic enzyme elevation; sunlight, which can provoke methotrexate-related dermatitis; and coitus, which can rupture the ectopic pregnancy (American College of Obstetricians and Gynecologists, 2014). Importantly, methotrexate is a teratogen and is a Food and Drug Administration pregnancy category X. As such, it can lead to a profound embryopathy that includes intrauterine growth retardation and cardiac, craniofacial, and skeletal abnormalities (Nurmohamed, 2011).

The most common side effects of methotrexate include stomatitis, conjunctivitis, and transient liver dysfunction, although myelosuppression, mucositis, pulmonary damage, and anaphylactoid reactions have been reported with only one dose of 50 to 100 mg (Isaacs, 1996; Straka, 2004). Side effects are seen in as many as a third of women treated, however, they are usually self-limited. In some cases, leucovorin (folinic acid) is given following treatment to blunt or reverse methotrexate side effects. Such therapy is termed *leucovorin rescue* (Chap. 27, p. 597).

TABLE 7-3. Medical Treatment Protocols for Ectopic Pregnancy

	Single Dose	Multidose
<b>Dosing</b>	One dose; repeat if necessary	Up to four doses of both drugs until serum $\beta$ -hCG level declines by 15%
<b>Medication dosage</b>		
Methotrexate	50 mg/m <sup>2</sup> BSA (day 1)	1 mg/kg, days 1, 3, 5, and 7
Leucovorin	NA	0.1 mg/kg days 2, 4, 6, and 8
<b>Serum <math>\beta</math>-hCG level</b>	Days 1, 4, and 7	Days 1, 3, 5, and 7
<b>Indication for additional dose</b>	<ul style="list-style-type: none"><li>• If serum <math>\beta</math>-hCG level does not decline by 15% from day 4 to day 7</li><li>• Less than 15% decline during weekly surveillance</li></ul>	If serum $\beta$ -hCG level declines < 15%, give additional dose; repeat serum $\beta$ -hCG in 48 hours and compare with previous value; maximum four doses
<b>Surveillance</b>	Once 15% decline achieved, then weekly serum $\beta$ -hCG levels until undetectable	
<b>Methotrexate Contraindications</b>		
Sensitivity to MTX	Intrauterine pregnancy	Peptic ulcer disease
Tubal rupture	Hepatic, renal, or hematologic dysfunction	Immunodeficiency
Breast feeding	Active pulmonary disease	

BSA= body surface area;  $\beta$ -hCG =  $\beta$ -human chorionic gonadotropin; NA= not applicable.

The single-dose and multidose methotrexate protocols shown in Table 7-3 are associated with overall resolution rates for ectopic pregnancy that approximate 90 percent. To date, Alleyassin and coworkers (2006) have completed the only randomized trial comparing single and multidose administrations. Although the study was underpowered to detect a small difference in success rates, they did observe that 89 percent in the single-dose group and 93 percent in the multidose group were successfully treated. When analyzed from the standpoint of treatment failure, single-dose therapy had a 50-percent higher failure rate compared with multidose therapy (6/54 versus 4/54). Lipscomb and colleagues (2005) reviewed their institutional experience with methotrexate therapy in 643 consecutively treated patients. They found no significant differences in treatment duration, serum  $\beta$ -hCG levels, or success rates between the multi- and single-dose protocols—95 and 90 percent, respectively. Barnhart and coworkers (2003a) performed a metaanalysis of 26 studies that included 1327 women treated with methotrexate for ectopic pregnancy. Single-dose therapy was more commonly used because of simplicity. It was less expensive, was easily accepted because of less intensive post-therapy monitoring, and did not require leucovorin rescue (Alexander, 1996). The major limitation was that multidose treatment had a fivefold greater chance of success than single-dose therapy. Failures included women with tubal rupture, massive intraabdominal hemorrhage, and need for urgent surgery and blood transfusions. Ultimately, most women received between one and four doses of methotrexate. Interestingly, the initial serum  $\beta$ -hCG value was not a valid indicator of how many doses of methotrexate a patient would need for a successful outcome (Nowak-Markwitz, 2009). In the absence of adequately powered randomized trials comparing single- with multidose therapy, we use single-dose IM methotrexate.

**Single-Dose Methotrexate.** This regimen is the most widely used medical treatment of ectopic pregnancy. Of various doses, the most popular is the 50 mg/m<sup>2</sup> body surface area (BSA) protocol (Stovall, 1993). BSA can be derived using various Internet-based BSA calculators such as: <http://www.globalrph.com/bsa2.htm>.

Close monitoring is imperative. A serum  $\beta$ -hCG level is determined prior to methotrexate administration and is repeated on days 4 and 7 following injection. Levels usually continue to rise until day 4. Comparison is then made between day 4 and 7 serum values. If there is a decline by 15 percent or more, then weekly serum  $\beta$ -hCG levels are drawn until they measure < 2 IU/L. A decline of less than 15 percent is seen in approximately 20 percent of treated women. In such cases, a second 50 mg/m<sup>2</sup> dose is given, and the protocol is restarted. One review of more than 1700 cases showed that if a second dose is needed, then a day 1 serum  $\beta$ -hCG level < 2234 IU/L could be considered a predictor of ultimate treatment success (Cohen, 2014). Approximate time to resolution for all women averages 36 days, but in some, treatment requires as long as 109 days (Lipscomb, 1998). Others have tried, without success, to develop more convenient serum  $\beta$ -hCG monitoring protocols (Kirk, 2007; Thurman, 2010). In the end, the original day-4-to-7 guidelines have been validated.

During the first few days following methotrexate administration, up to half of women experience abdominal pain that can be controlled with mild analgesics. This *separation pain* presumably results from tubal distention caused by tubal abortion or hematoma formation or both (Stovall, 1993). In some cases, inpatient observation with serial hematocrit determinations and gentle abdominal examinations help assess the need for surgical intervention.

**Multidose Methotrexate.** The most common regimen is seen in Table 7-3 and consists of up to four doses of parenteral methotrexate, followed by adjunctive doses of leucovorin 24 hours later. Serial serum  $\beta$ -hCG concentrations are obtained. If there is not a 15-percent decline from the previous value—for example, days 1 to 3—an additional methotrexate/leucovorin dose is given, and the serum  $\beta$ -hCG level is repeated 2 days later. A maximum of four doses are given, and weekly serum  $\beta$ -hCG level surveillance continues until values are undetectable.

A hybrid “two dose” protocol strives to balance the efficacy and convenience of the two most commonly used protocols (Barnhart, 2007). The regimen administers 50 mg/m<sup>2</sup> of methotrexate on days 0 and 4 without leucovorin rescue. Although the protocol is still considered experimental, no safety concerns were noted in the 101 patients treated, and the success rate approached 87 percent. A recent comparison of the single dose and “two dose” methotrexate protocols found equivalent success rates (87 and 90 percent, respectively) with a trend toward increased needs for repeated doses in the single-dose cohort (Gungorduk, 2011).

### Other Medical Options

The bioavailability of oral and parenteral methotrexate is similar, but few trials have evaluated oral methotrexate for ectopic pregnancy treatment. Korhonen and coworkers (1996) randomly assigned women with candidate tubal pregnancies to be managed expectantly or to receive low-dose oral methotrexate, 2.5 mg daily for 5 days. They found no differences in primary treatment success.

Mifepristone is a progesterone antagonist and is effective for evacuation of first-trimester IUPs (Chap. 6, p. 154). Logically, the addition of mifepristone, 600 mg orally, to single-dose methotrexate might improve unruptured ectopic pregnancy resolution. However, in a randomized trial of 212 cases, success rates did not differ if mifepristone was added (Rozenberg, 2003).

Direct injection of methotrexate with sonographic or laparoscopic guidance into an ectopic pregnancy aims to minimize systemic side effects of methotrexate. Pharmacokinetic studies with 1 mg/kg of methotrexate injected either into the sac or by traditional IM injection showed similar success rates. However, fewer drug-related side effects were seen with local injection (Fernandez, 1995).

Direct injection of 50-percent glucose into the ectopic mass using laparoscopic guidance was 94-percent successful in one small prospective trial for women with serum  $\beta$ -hCG levels < 2500 IU/L (Yeko, 1995). Gjelland and coworkers (1995) reported that the treatment success rate was significantly better

in a similar population in which sonographically rather than laparoscopically guided injection was used.

### Surveillance

Posttherapy monitoring assesses treatment success and screens for signs of persistent ectopic pregnancy. Most medical management protocols have well-defined surveillance schedules. In the absence of symptoms, bimanual examinations are deferred to avoid the theoretical risk of manual tubal rupture. Importantly, sonographic monitoring of ectopic mass dimensions can be misleading after serum  $\beta$ -hCG levels have declined to  $< 15$  IU/L. Brown and colleagues (1991) described persistent masses to be resolving hematomas rather than persistent trophoblastic tissue. For this reason, posttherapy sonography is reserved for suspected complications such as tubal rupture. Most recommend contraception for 3 to 6 months after successful medical therapy with methotrexate, as this drug may persist in human tissues for up to 8 months after a single dose (Warkany, 1978).

## ■ Surgical Management

### Laparotomy versus Laparoscopy

At least three prospective studies have compared laparotomy with laparoscopic surgery for ectopic pregnancies (Lundorff, 1991; Murphy, 1992; Vermesh, 1989). In sum, investigators found no significant differences in overall tubal patency determined at second-look laparoscopy. This was despite higher rates of ipsilateral adhesions in the laparotomy group. Each method was followed by a similar number of subsequent intrauterine pregnancies. Fewer repeat ectopic pregnancies were noted in women treated laparoscopically, although this difference was not significant. Laparoscopy offered shorter operative times, less blood loss, fewer analgesic requirements, and shorter hospital stays. Laparoscopic surgery was significantly less successful in resolving the tubal pregnancy, but this was balanced by the just-mentioned benefits of minimally invasive surgery.

With improvements in laparoscopic equipment and with accrued experience, cases previously managed by laparotomy, such as ruptured tubal or intact interstitial pregnancies, can now be considered for laparoscopy in those with commensurate skills (Sagiv, 2001). Among experienced surgeons, shorter operating times and expedited hemorrhage control are both advantages of laparoscopic intervention for ruptured ectopic pregnancies (Cohen, 2013).

Laparotomy offers a potential advantage to laparoscopy if salpingostomy is planned. A metaanalysis using data from two trials concluded that compared with laparotomic salpingostomy, laparoscopic salpingostomy leads to one case of persistent trophoblastic disease for every 12 women undergoing the laparoscopic approach (Mol, 2008).

### Laparoscopy

Two randomized trials have been completed to date to guide the choice between conservative—laparoscopic salpingostomy, and definitive—laparoscopic salpingectomy. The European Surgery in Ectopic Pregnancy (ESEP) study randomly assigned 446 women with a healthy contralateral fallopian tube to salpingectomy or salpingostomy (Mol, 2014). In the DEMETER trial

patients were also randomly selected for either of these surgeries. Similar to the ESEP study, results from the DEMETER trial showed no differences in 2-year subsequent IUP rates (64 versus 70 percent, respectively) whether salpingectomy or salpingostomy was used for ectopic pregnancy removal (Fernandez, 2013). Thus, if the contralateral fallopian tube appears normal, then salpingectomy is a reasonable treatment option that avoids the 5 to 8 percent complication rate caused by persistent or recurrent ectopic pregnancy in the same tube (Rulin, 1995).

For laparoscopic salpingectomy, many techniques have been described, and a surgical description is found in Section 44-3 (p. 1011). Lim and associates (2007) compared electrosurgical coagulation of the tube and mesosalpinx during laparoscopic salpingectomy with laparoscopic suture-loop (Endoloop) ligation. Endoloop use was associated with significantly shorter operating times (48 versus 61 minutes) and lower postoperative pain scores.

For laparoscopic salpingostomy, a woman who is hemodynamically stable and strongly desires to preserve fertility is an appropriate candidate. This applies especially if the other fallopian tube is absent or damaged. Serum  $\beta$ -hCG levels may be a factor in patient selection. One retrospective study found that ectopic resolution rates were lower following salpingostomy in women in whom the initial serum  $\beta$ -hCG level was  $> 8000$  IU/L (Milad, 1998). Supportive evidence for this comes from Natale and associates (2003), who reported that serum  $\beta$ -hCG levels  $> 6000$  IU/L have a high risk of implantation into the tubal muscularis.

As illustrated in Section 44-4 (p. 1013), during salpingostomy, the ectopic tissue can be flushed or grasped from the tubal incision. All free and tubal placental tissue should be meticulously removed, as retained trophoblast in the tube can lead to later invasion and bleeding. Other cases of persistent serum  $\beta$ -hCG levels are explained by trophoblastic tissue that is dropped during ectopic extraction and then subsequently implants intraabdominally (Bucella, 2009).

## ■ Medical versus Surgical Therapy

Several randomized trials have compared methotrexate treatment with laparoscopic surgery. One multicenter trial compared a multidose methotrexate protocol with laparoscopic salpingostomy and found no differences for tubal preservation and primary treatment success (Hajenius, 1997). However, in this same study group, health-related quality of life factors such as pain, posttherapy depression, and decreased perception of health were significantly impaired after systemic methotrexate compared with laparoscopic salpingostomy (Nieuwkerk, 1998).

Evidence is conflicting when single-dose methotrexate is compared with surgical intervention. In two separate studies, single-dose methotrexate was overall less successful in resolving pregnancy than laparoscopic salpingostomy, although tubal patency and subsequent uterine pregnancy rates were similar between both groups (Fernandez, 1998; Sowter, 2001). Krag Moeller and associates (2009) reported during a median surveillance period of 8.6 years that ectopic-resolution success rates were not significantly different between those managed

surgically and those treated with methotrexate. Moreover, cumulative spontaneous intrauterine pregnancy rates were not different between the methotrexate group (73 percent) and the surgical group (62 percent).

Based on these studies, we conclude that women who are hemodynamically stable and in whom there is a small tubal diameter, no fetal cardiac activity, and serum  $\beta$ -hCG concentrations  $< 5000$  IU/L have similar outcomes with medical or surgical management. Despite lower success rates with medical therapy for women with larger tubal size, higher serum  $\beta$ -hCG levels, and fetal cardiac activity, medical management can be offered to the motivated woman who understands the risks of emergency surgery in the event of treatment failure.

### ■ Expectant Management

In select women, close observation, in anticipation that there will be spontaneous resorption of an ectopic pregnancy, is reasonable. Intuitively, it is difficult to accurately predict which woman will have an uncomplicated course with such management. Although an initial serum  $\beta$ -hCG concentration best predicts outcome, the range varies widely. For example, initial values  $< 200$  IU/L predict successful spontaneous resolution in 88 to 96 percent of attempts, whereas values  $> 2000$  IU/L had success rates of only 20 to 25 percent (Elson, 2004; Trio, 1995). Even with declining values, when the initial  $\beta$ -hCG level exceeded 2000 IU/L, the success rate was only 7 percent (Shalev, 1995). Interestingly, in this study, there was no difference in ipsilateral tubal patency or 1-year fertility rates with either success or failure of expectant management.

Close monitoring is warranted because the risk of tubal rupture persists despite low and declining serum  $\beta$ -hCG levels. An argument could be made that the minimal side effects of methotrexate make it preferable to a potentially prolonged surveillance and associated patient anxiety.

### ■ Persistent Ectopic Pregnancy

Incomplete eradication of trophoblastic tissue and its continued growth causes tubal rupture in 3 to 20 percent of women following conservative surgical or medical treatment of ectopic pregnancy (Graczykowski, 1999). Thus, abdominal pain following conservative management prompts immediate suspicion for persistent trophoblast proliferation.

Following salpingostomy, persistent ectopic pregnancy is more likely with very early pregnancies. Specifically, surgical management is more difficult because pregnancies smaller than 2 cm are harder to visualize and completely remove. To obviate this, Graczykowski and associates (1997) administered a prophylactic dose of  $1 \text{ mg/m}^2$  methotrexate postoperatively, which reduced the incidence of persistent ectopic pregnancy and length of surveillance. Again, this is balanced against methotrexate side effects.

The optimal monitoring schedule to identify persistent ectopic pregnancy after surgical therapy has not been determined. Protocols describe serum  $\beta$ -hCG level monitoring from every 3 days to every 2 weeks. Spandorfer and associates (1997) estimated the risk of persistent ectopic pregnancy based on

serum  $\beta$ -hCG levels done on the first postoperative day after salpingostomy. They observed that if serum  $\beta$ -hCG levels fell by  $> 50$  percent compared with presurgical values, then there were no treatment failures within the first 9 days, and thus repeat serum  $\beta$ -hCG determinations 1 week after surgery were appropriate. Conversely, if serum levels fell by  $< 50$  percent, then there was a 3.5-fold increased risk of failure within the first week, thus necessitating earlier postoperative evaluation. Importantly, despite low and falling serum  $\beta$ -hCG concentrations, tubal rupture can still occur (Tulandi, 1991). Currently, standard therapy for persistent ectopic pregnancy is single-dose methotrexate given IM at a dose of  $50 \text{ mg/m}^2$  BSA.

## OVARIAN PREGNANCY

Ectopic implantation of the fertilized egg in the ovary is rare and is diagnosed if four clinical criteria are met. These were outlined by Spiegelberg (1878) and include: (1) the ipsilateral tube is intact and distinct from the ovary; (2) the ectopic pregnancy occupies the ovary; (3) the ectopic pregnancy is connected by the uteroovarian ligament to the uterus; and (4) ovarian tissue can be demonstrated histologically in the placental tissue. A more recent increased incidence in ovarian pregnancy likely is artifactual due to improved imaging. Risk factors are similar to those for tubal pregnancies. In one review, 24 percent of a total of 110 ovarian ectopic pregnancies were in IUD users (Ko, 2012). Nearly a third of women with an ovarian pregnancy present with hemodynamic instability because of rupture. Diagnosis is based on the classic sonographic description of a cyst with a wide echogenic outer ring on or within the ovary (Comstock, 2005). With smaller ectopic pregnancies, ovarian wedging can be considered (Ko, 2012). For larger lesions, oophorectomy is often required.

## INTERSTITIAL PREGNANCY

Interstitial pregnancies implant in the proximal tubal segment that lies within the muscular uterine wall. Swelling lateral to the insertion of the round ligament is the characteristic anatomic finding (Fig. 7-10). Incorrectly, these are sometimes called cornual pregnancies, but this term describes conceptions that develop in the horns of uteri with müllerian anomalies (Lau, 1999; Moawad, 2010). In the past, interstitial pregnancies usually ruptured following 8 to 16 weeks of amenorrhea. This later gestational age at rupture is attributed to the greater distensibility of the myometrium covering the fallopian tube's interstitial segment. Risk factors are similar to others discussed, although prior ipsilateral salpingectomy is a specific risk factor for interstitial pregnancy (Lau, 1999). Because of the proximity of these pregnancies to the uterine and ovarian arteries, hemorrhage with rupture can be severe and is associated with mortality rates as high as 2.5 percent (Tulandi, 2004).

Distinct from interstitial pregnancy, the term *angular pregnancy* describes intrauterine implantation in one of the lateral angles of the uterus and medial to the uterotubal junction and round ligament. This distinction is important because angular pregnancies can sometimes be carried to term but with increased

**FIGURE 7-10** Interstitial pregnancy. **A.** Transvaginal sonogram, parasagittal view shows an empty uterine cavity (white arrows) and a mass lateral to the uterine fundus (red arrow). (Used with permission from Dr. Elysia Moschos.) **B.** Left-sided interstitial pregnancy prior to resection. (Used with permission from Dr. Mario Castellanos.)

risk of abnormal placentation and uterine rupture (Arleo, 2014; Jansen, 1981). Improved imaging modalities, such as 3-dimensional sonography, may help differentiate eccentrically located gestational sacs from an interstitial pregnancy (Singh, 2015; Tanaka, 2014).

For interstitial pregnancies, surgical management involves cornual resection by either laparotomy or laparoscopy (Section 43-9, p. 941). As discussed for suspected tubal pregnancy, interstitial pregnancy can now often be diagnosed early enough to consider conservative medical therapy (Bernstein, 2001). Given its low incidence, no consensus regarding prediction of success using methotrexate has been established. Jermy and colleagues (2004) reported a 94-percent success with systemic methotrexate in 17 women using a dose of 50 mg/m<sup>2</sup> BSA. Their series included four women in whom fetal cardiac activity was verified. Because these women have higher initial serum  $\beta$ -hCG levels at diagnosis, longer surveillance is usually needed. Deruelle and coworkers (2005) advocate adjuvant postmethotrexate uterine artery embolization to help avert hemorrhage and hasten ectopic pregnancy resolution. Of other therapies, uterine artery methotrexate infusion and embolization combined with systemic methotrexate has shown promising results (Hirsch, 2014; Krissi, 2014). Hysteroscopic resection or transcervical suction curettage of interstitial pregnancies has been described (Sanz, 2002; Zhang, 2004).

Following either medical or conservative surgical management, the risk of uterine rupture with subsequent pregnancies is unclear. Thus, careful observation of these women during pregnancy, along with strong consideration of elective cesarean delivery, is warranted.

## CERVICAL PREGNANCY

The incidence of cervical pregnancy is reported to be between 1 in 8600 and 1 in 12,400 pregnancies (Ushakov, 1997). The incidence appears to be rising because of ART, especially IVF and embryo transfer (Ginsburg, 1994; Pattinson, 1994). A risk factor unique to cervical pregnancy is a history of dilatation and

curettage in a prior pregnancy and is seen in nearly 70 percent of cases (Hung, 1996; Pisarska, 1999). Two diagnostic criteria are necessary for cervical pregnancy confirmation: (1) cervical glands are found opposite the placental attachment site, and (2) a portion of or the entire placenta is located below either the entrance of the uterine vessels or the peritoneal reflection on the anterior and posterior uterine surface (Fig. 7-11).

For most hemodynamically stable women with a first-trimester cervical pregnancy, nonsurgical management with systemic methotrexate can be offered and administered as in Table 7-3. Jeng and colleagues (2007) also described 38 cases successfully treated with methotrexate injection into the gestational sac. Resolution and uterine preservation is achieved with methotrexate regimens for gestations < 12 weeks in 91 percent of cases (Kung, 1997). In selecting appropriate candidates, Hung and colleagues (1996) noted higher risks of systemic methotrexate treatment failure in those with a gestational age > 9 weeks,  $\beta$ -hCG levels > 10,000 IU/L, crown-rump length > 10 mm, and fetal cardiac activity. For this reason, many induce fetal death with intracardiac or intrathoracic injection of potassium chloride (Jeng, 2007; Verma, 2009). Uterine artery embolization, either before or after methotrexate administration, may be an additional adjunct to limit bleeding complications (Cipullo, 2008; Hirakawa, 2009).

Although conservative management is feasible for many women with cervical pregnancies, surgical intervention may also be selected. Procedures include suction curettage or hysterectomy. Moreover, in those with advanced gestations or with bleeding uncontrolled by conservative methods, hysterectomy is typically required. Importantly, patients should understand the increased risk of urinary tract injury with hysterectomy due to the close proximity of the ureters to the ballooned cervix. Prior to either procedure, uterine artery embolization may be considered to limit intra- and postoperative bleeding (Nakao, 2008; Trambert, 2005). In addition, before curettage, local methotrexate injection into the amnionic sac, ligation of the descending branches of the uterine arteries, or cerclage placement at the internal os to compress feeding vessels have all been

**FIGURE 7-11** Cervical pregnancy. **A.** Transvaginal sonography, sagittal view of a cervical pregnancy. Sonographic findings with cervical pregnancy may include: (1) an hourglass uterine shape and ballooned cervical canal; (2) gestational tissue at the level of the cervix (black arrow); (3) absent intrauterine gestational tissue (white arrows); and (4) a portion of the endocervical canal seen interposed between the gestation and the endometrial canal. (Used with permission from Dr. Elysia Moschos.) **B.** Hysterectomy specimen containing a cervical ectopic pregnancy from a different case. (Used with permission from Dr. David Rahn.)

described (Davis, 2008; De La Vega, 2007; Mesogitis, 2005; Trojano, 2009). Following curettage, in the event of hemorrhage, a 26F Foley catheter with a 30-mL balloon can be placed intracervically and inflated to effect hemostasis and to monitor uterine drainage (Ushakov, 1997). In addition, uterine artery embolization may be considered.

## HETEROTOPIC PREGNANCY

A uterine pregnancy in conjunction with an extrauterine pregnancy is termed a *heterotopic pregnancy*. In the past, the incidence was estimated to be 1 in 30,000 pregnancies. In pregnancies resulting from ART, the heterotopic pregnancies rate approximates 0.09 percent (Perkins, 2015). For a tubal pregnancy coexistent with a uterine pregnancy, potassium chloride can be injected into the tubal pregnancy sac. Methotrexate is contraindicated due to the detrimental effects on the normal pregnancy (p. 170).

**FIGURE 7-12** Cesarean scar pregnancy. **A.** Transvaginal sonogram of a uterus with a cesarean scar pregnancy (CSP) in a sagittal plane. The diagnosis is suggested by sonographic criteria indicative of CSP. First, an empty uterine cavity is identified by a bright hyperechoic endometrial stripe (white arrow). An empty cervical canal is similarly identified. Last, an intrauterine mass is seen in the anterior part of the uterine isthmus (red arrows). (Used with permission from Dr. Elysia Moschos.) **B.** Hysterectomy specimen containing a cesarean scar pregnancy. (Used with permission from Dr. Sunil Balgobin.)

## CESAREAN SCAR PREGNANCY

Implantation within the scar of a prior cesarean delivery through a microscopic tract in the myometrium is uncommon (Fig. 7-12). Similar to other ectopic pregnancies, it carries significant risks of massive hemorrhage. Reviews cite the incidence of cesarean scar pregnancy (CSP) to approximate 1 in 2000 pregnancies (Sadeghi, 2010). These microscopic tracts can also stem from other prior uterine surgery—curettage, myomectomy, operative hysteroscopy—and perhaps from manual removal of the placenta (Ash, 2007).

Differentiating between a pregnancy with low implantation and a cesarean scar pregnancy can be difficult, and several investigators have described sonographic findings (Jurkovic, 2003;

Moschos, 2008a). According to Godin (1997), four sonographic criteria should be satisfied for the diagnosis: (1) an empty uterine cavity, (2) an empty cervical canal, (3) a gestational sac in the anterior part of the uterine isthmus, and (4) absence of healthy myometrium between the bladder and gestational sac.

Treatment standards are lacking, but options include systemic or locally injected methotrexate, either alone or combined with suction curettage or hysteroscopic removal (Shen, 2012; Timor-Tritsch, 2012; Yang, 2010). Isthmic resection with a double layer closure can be performed open, laparoscopically, or robotically (Hudecek, 2014). With any of the options, uterine artery embolization may be used adjunctively to minimize hemorrhage (Zhuang, 2009). In most cases, the uterus can be preserved, although hysterectomy is also an acceptable and sometimes necessary option (Sadeghi, 2010).

### OTHER ECTOPIC PREGNANCY SITES

Abdominal pregnancy is an implantation in the peritoneal cavity exclusive of tubal, ovarian, or intraligamentous implantations. These are rare and have an estimated incidence of 1 in 10,000 to 25,000 live births (Atrash, 1987; Worley, 2008). Ectopic placental implantations in less expected sites have been described in case reports and include the omentum, spleen, liver, and retroperitoneum, among others (Chin, 2010; Chopra, 2009; Gang, 2010; Martínez-Varea, 2011). Also rare, ectopic pregnancies have been reported in women with prior hysterectomy (Fylstra, 2010). Presumably, a vaginal cuff fistula, a prolapsed fallopian tube, or a cervical stump after supracervical hysterectomy allows sperm to access an ovulated ovum.

### PREVENTION

Prevention is difficult because few ectopic pregnancy risk factors are modifiable (Butts, 2003). Tubal pathology carries one of the highest risks, and pelvic inflammatory disease (PID) plays a major role in tubal adhesions and obstruction. Chlamydial infections constitute nearly half of PID cases, thus efforts have been directed toward screening high-risk populations for asymptomatic infections. These include sexually active women < 25 years or women with risk factors (Table 1-1, p. 6). Such screening programs in Sweden have demonstrated steady declines in both chlamydial infections and ectopic pregnancy rates, especially in women aged 20 to 24 years (Cates, 1999; Egger, 1998).

DEFINITIONS

Abnormal uterine bleeding (AUB) may display several patterns, and descriptive terms have been updated to standardize nomenclature (Munro, 2011). For example, *heavy menstrual bleeding (HMB)* (formerly menorrhagia) defines prolonged or heavy cyclic menstruation. Objectively, menses lasting longer than 7 days or exceeding 80 mL of blood loss are determining values. The term *intermenstrual bleeding* replaces metrorrhagia. Frequently, women may complain of both patterns. The term *breakthrough bleeding* is a more informal term for intermenstrual bleeding that accompanies hormone administration. In some women, there is diminished flow or shortening of menses, *hypomenorrhea*. Women normally menstruate every 28 days ± 7 days. Cycles with intervals longer than 35 days describe a state of *oligomenorrhea*. The term *withdrawal bleeding* refers to the predictable bleeding that results from an abrupt decline in progesterone levels. Finally, *postcoital bleeding* is that prompted by vaginal intercourse.

Assessing HMB in a clinical setting has its limitations. First, patient perception of blood loss and objective measurement often fail to correlate (Chimbira, 1980b). As a result, objective methods to assess blood loss have been investigated. Hallberg and associates (1966) describe a technique to extract hemoglobin from sanitary napkins using sodium hydroxide. Hemoglobin is converted to hematin and can be measured spectrophotometrically. Although used in research, this approach in a clinical setting has obvious constraints.

Other tools used to estimate menstrual blood loss include hemoglobin and hematocrit evaluation. Hemoglobin concentrations below 12 g/dL increase the chance of identifying women with HMB. A normal level, however, does not exclude HMB, as many women with clinically significant bleeding have normal values.

Another method involves estimating the number and type of pads or tampons used by a woman during menses. Warner and colleagues (2004) found positive correlations between objective HMB and passing clots more than 1 inch in diameter and changing pads more frequently than every 3 hours. Attempts to standardize this type of evaluation have led to development of the pictorial blood assessment chart (PBAC) (Fig. 8-1). With a scoring sheet, patients are asked to record daily the number of sanitary products that are lightly, moderately, or completely saturated. Scores are assigned as follows: 1 point for each lightly stained tampon, 5 if moderately saturated, and 10 if completely soaked. Pads are similarly given ascending scores of 1, 5, and 20, respectively. Small clots score 1 point, whereas large clots score 5. Points are then tallied for each day. Totals more than 100 points per menstrual cycle correlate with greater than 80 mL objective blood loss (Higham, 1990).

Menstrual calendars are also frequently used to evaluate abnormal bleeding and its patterns. With this, patients are asked to record dates and blood flow quality throughout the month. These calendars can be used to aid diagnosis and to document improvement during medical treatment.

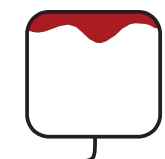

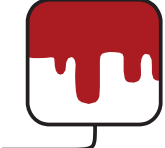

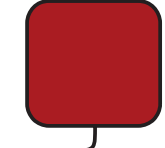

**INCIDENCE**

Abnormal uterine bleeding is common, and etiologies include anatomic changes, hormonal dysfunction, infection, system disease, medications, and pregnancy complications (Table 8-1). As a result, AUB may affect females of all ages. Factors that influence incidence most greatly are age and reproductive status.

Prior to menarche, bleeding is investigated as an abnormal finding. In children, the vagina, rather than the uterus, is more frequently involved. Vulvovaginitis is often the cause, but dermatologic conditions, neoplasms, and trauma by accident, abuse, or foreign body are others. In addition to vaginal sources, urethra bleeding may originate from urethral prolapse or infection. True uterine bleeding usually results from increased estrogen levels, and precocious puberty, accidental exogenous ingestion, and ovarian neoplasm are considered. These are each discussed further in Chapter 14.

In adolescence, AUB results from anovulation and coagulation defects at disproportionately higher rates compared with older reproductive-aged women (Ahuja, 2010). In contrast,

Pads	Points per each	Tampons	Points per each
	1		1
	5		5
	20		10

Large clots	5
Small clots	1

benign or malignant neoplastic growths are less frequent. Pregnancy, sexually transmitted diseases, and sexual abuse are also considered in this population.

Following adolescence, the hypothalamic-pituitary-ovarian (HPO) axis matures, and anovulatory uterine bleeding is encountered less often. With increased sexual activity, rates of bleeding related to pregnancy and sexually transmitted disease rise. The incidences of bleeding from leiomyomas and endometrial polyps also increase with age.

During the perimenopause, as with perimenarchal girls, anovulatory uterine bleeding from HPO axis dysfunction is a more frequent finding (Chap. 21, p. 472). In contrast, the incidences of bleeding related to pregnancy and sexually transmitted disease decline. With aging, risks of benign and malignant neoplastic growth increase.

After menopause, bleeding typically can be traced to a benign origin such as endometrial or vaginal atrophy or polyps. Even so, malignant neoplasms, especially endometrial carcinoma, are found more often in this age group. Less commonly, estrogen-producing ovarian carcinoma may cause endometrial hyperplasia with uterine bleeding. Similarly, ulcerative vulvar, vaginal, or cervical neoplasms can be sources. And rarely, serosanguinous discharge from a fallopian tube cancer may appear as uterine bleeding. Thus, bleeding in this demographic usually prompts evaluation to exclude these cancers.

pathophysiology

The endometrium consists of two distinct zones, the functionalis layer and the basalis layer (Fig. 8-2). The basalis layer lies in direct contact with the myometrium, is beneath the functionalis, and is less hormonally responsive. The basalis serves as a reservoir for regeneration of the functionalis layer following

**Ta BLE 8-1.** Differential Diagnosis of Abnormal Bleeding

<b>Structural</b> Uterine—leiomyoma, adenomyosis, endometrial polyp, endometrial hyperplasia or cancer, uterine sarcoma, AVM Cervix—endocervical polyp, dysplasia, or cancer Vagina—cancer, postoperative granulation tissue Fallopian tube—cancer Ovary—sex cord-stromal tumors Atrophic vaginal, cervical, or endometrial epithelia Partial outflow obstruction—congenital müllerian defect, Asherman syndrome Intrinsic endometrial
<b>anovulation</b> Immature HPO axis or aging ovarian follicles Hypothyroidism Hyperprolactinemia—pituitary or hypothalamic disorder Androgen excess—PCOS, CAH, Cushing syndrome/disease Premature ovarian failure
<b>pregnancy</b> Implantation, abortion, ectopic pregnancy, GTD
<b>Exogenous</b> IUD, foreign body, trauma Medications—sex steroids, anticoagulants, hyperprolactinemia inducing
<b>Infection</b> STD, TB, chronic endometritis, postabortal or postpartum infection
<b>Systemic abnormalities</b> Coagulopathies, hepatic or chronic renal failure, hyperthyroidism, obesity

AVM= arteriovenous malformation; CAH= congenital adrenal hyperplasia; GTD = gestational trophoblastic disease; HPO = hypothalamic-pituitary-ovarian axis; PCOS = polycystic ovarian syndrome; STD = sexually transmitted disease; TB= tuberculosis.

menses. In contrast, the functionalis layer lines the uterine cavity, undergoes dramatic change throughout the menstrual cycle, and ultimately sloughs during menstruation. Histologically, the functionalis has a surface epithelium and underlying subepithelial capillary plexus. Beneath these are organized stroma, glands, and interspersed leukocytes.

Blood reaches the uterus via the uterine and ovarian arteries. From these, the arcuate arteries arise to supply the myometrium. These in turn branch into the radial arteries, which extend toward the endometrium at right angles from the arcuate arteries (Fig. 8-3). At the endometrium-myometrium junction, the radial arteries bifurcate to create the basal and spiral arteries. The basal arteries serve the basalis layer of the endometrium and are relatively insensitive to hormonal changes. The spiral arteries stretch to supply the functionalis layer and end in a subepithelial capillary plexus.

**FIGURE 8-2** Drawing of endometrial anatomy as it varies through the menstrual cycle.

At the end of each menstrual cycle, progesterone levels drop and lead to release of lytic matrix metalloproteinases (MMP). These enzymes break down the stroma and vascular architecture of the functionalis layer. Subsequent bleeding and sloughing of this layer constitute menstruation (Jabbour, 2006). Initially, platelet aggregation and thrombi control blood loss. In addition, the remaining endometrial arteries, under the influence of mediators, vasoconstrict to limit further bleeding (Ferenczy, 2003).

## DIAGNOSIS

### ■ History and Physical Examination

With AUB, the diagnostic goal is exclusion of pregnancy or cancer and identification of the underlying pathology to allow

optimal treatment. During initial evaluation of abnormal bleeding, a thorough menstrual history is collected. Topics typically include age at menarche, date of last menstrual period, birth control method, and the timing and amount of bleeding. Associated symptoms such as fever, fatigue, bulk symptoms, tissue passage, or pain can also direct evaluation. Importantly, medications are reviewed, as abnormal bleeding can accompany use of nonsteroidal antiinflammatory drugs (NSAIDs), anticoagulants, and agents associated with hyperprolactinemia (Table 12-2, p. 281). Less robust evidence implicates herbal supplements such as ginseng, garlic, ginkgo, don quai, and St. John wort (Cordier, 2012).

Most gynecologic disorders do not consistently display a specific bleeding pattern, and patients may complain of HMB or intermenstrual bleeding or both. Thus, the pattern for a particular woman may be of limited value in diagnosing the underlying bleeding cause but can be used to assess improvement with treatment.

Of pain symptoms, dysmenorrhea often accompanies abnormal bleeding caused by structural abnormalities, infections, and pregnancy complications. This seems intuitive because of the role of prostaglandins in both HMB and dysmenorrhea. Painful intercourse and noncyclic pain are less frequent in women with AUB and usually suggest a structural or infectious source.

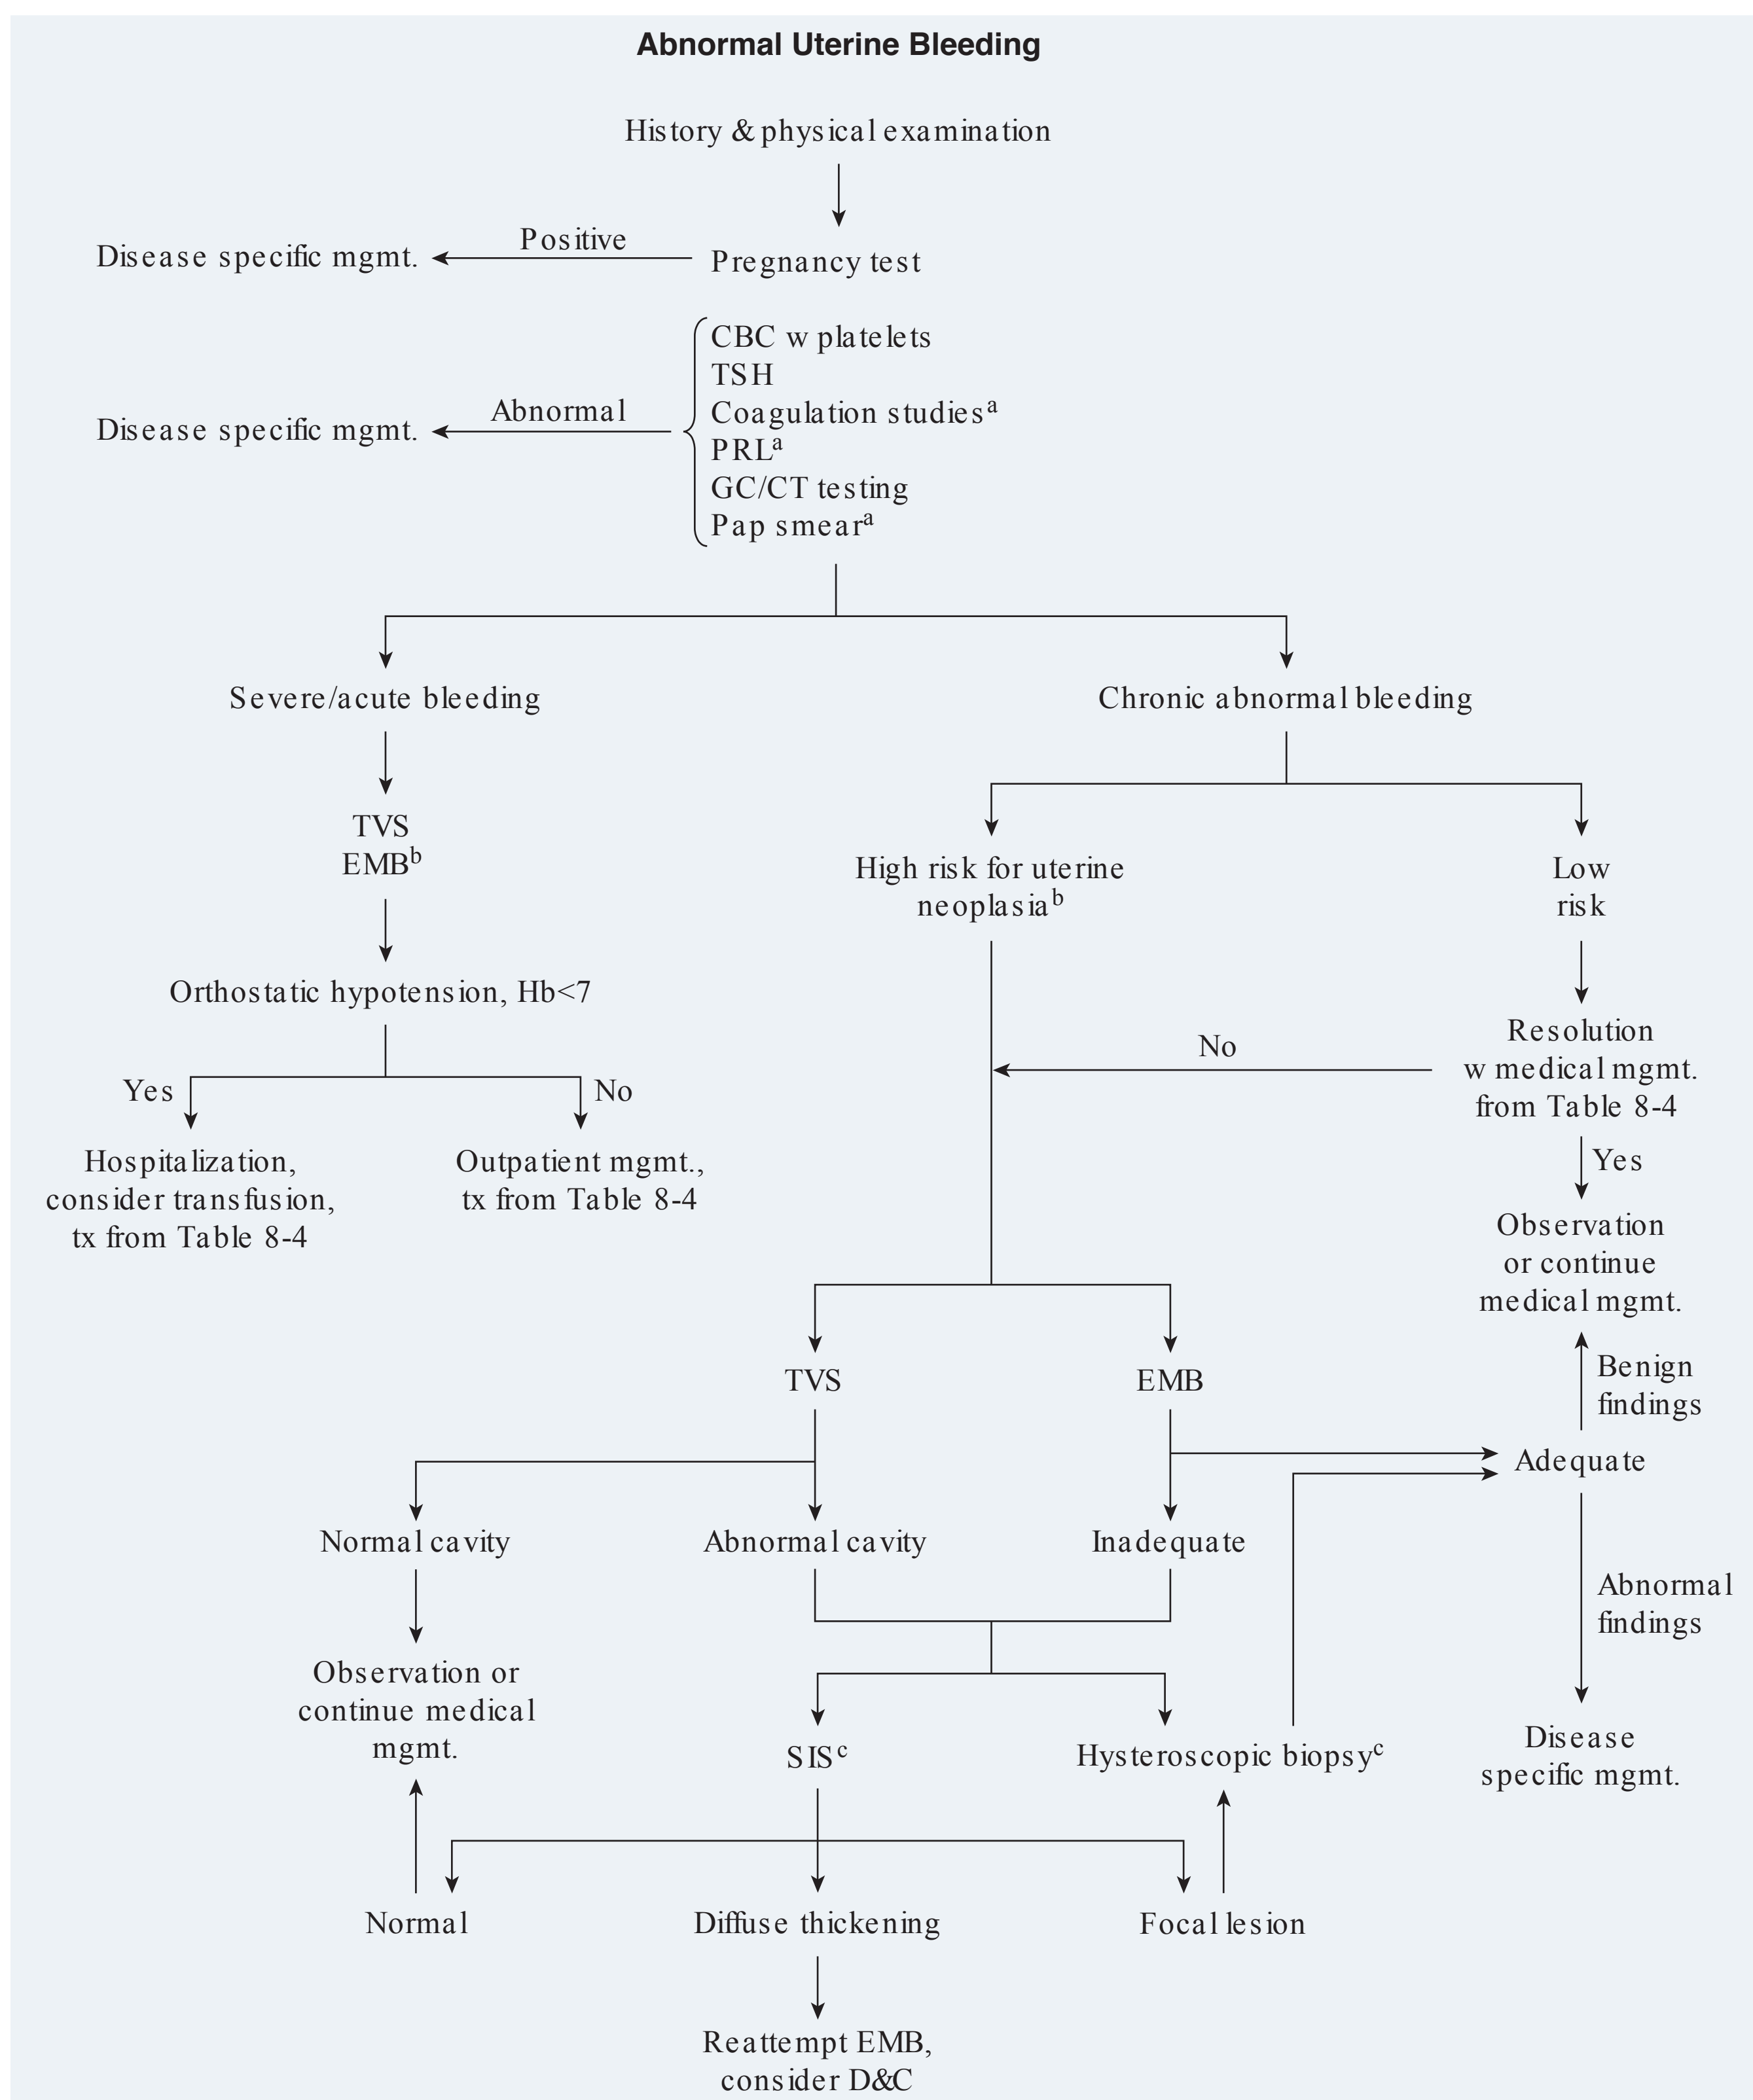

Following a historical inventory, physical examination attempts to identify findings that may suggest an etiology. Moreover, the site of uterine bleeding is confirmed, because vaginal, rectal, or urethral bleeding can present similarly. This is more difficult if there is no active bleeding, and urinalysis or stool guaiac evaluation may be helpful adjuncts.

To complement physical findings, blood tests, cervical cytology, sonography (with or without saline infusion), endometrial biopsy, and hysteroscopy are used primarily (Fig. 8-4). In many cases following history and physical examination, these tools may not be required or may be individually selected based on patient variables, suspected diagnosis, available resources, and/or provider training. Test suitability for a given patient is discussed next.

**FIGURE 8-3** Drawing of uterine blood supply.

<sup>b</sup>Patients with chronic anovulation, obesity,  $\geq 45$  years of age, tamoxifen use, or other risks for endometrial cancer.

<sup>c</sup>Both comparable in sensitivity and specificity. Either or both may be selected depending on patient characteristics and physician preference (p. 186).

CBC = complete blood count; D&C = dilatation and curettage; GC/CT = *Neisseria gonorrhoeae* and *Chlamydia trachomatis*; EMB = endometrial biopsy; Hb = hemoglobin level; mgmt. = management; PRL = prolactin level; SIS = saline infusion sonography; TSH = thyroid-stimulating hormone level; TVS = transvaginal sonography; tx = treatment.

## ■ Laboratory Evaluation

### β-Human Chorionic Gonadotropin and Hematologic Testing

Miscarriage, ectopic pregnancies, and hydatidiform moles may cause life-threatening hemorrhage. Pregnancy complications are quickly excluded with determination of urine or serum β-human chorionic gonadotropin (hCG) levels. This is typically obtained on all reproductive-aged women with a uterus.

Additionally, in women with AUB, a complete blood count (CBC) will identify anemia and the degree of blood loss. With chronic loss, erythrocyte indices will reflect a microcytic, hypochromic anemia and show decreases in mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). Moreover, in women with classic iron-deficiency anemia from chronic blood loss, an elevated platelet count may be seen. In those for whom the cause of anemia is unclear, those with profound anemia, or in those who fail to improve with oral iron therapy, iron studies are often indicated. Specifically, iron-deficiency anemia produces low serum ferritin and low serum iron levels but an elevated total iron-binding capacity. As discussed further on page 192, screening for disordered hemostasis is considered in women and adolescents with HMB and no other obvious cause.

### “Wet Prep” Examination and Cervical Cultures

Cervicitis often causes intermenstrual or postcoital spotting. Accordingly, microscopic examination of a saline preparation of cervical secretions or “wet prep” can be informative. With mucopurulent discharge, sheets of neutrophils (> 30 per high-power field) and red blood cells are typical. With trichomoniasis, motile trichomonads are also found. Cervicitis-related bleeding is frequently reproduced during sampling from an inflamed cervix with a friable epithelium.

The association between mucopurulent cervicitis and cervical infection with *Chlamydia trachomatis* and *Neisseria gonorrhoeae* is well established (Brunham, 1984). Thus, the Centers for Disease Control and Prevention (CDC) (2015) recommend testing for both when mucopurulent cervicitis is found. Moreover, even without frank discharge, these organisms can cause endometritis (Eckert, 2004). Thus, bleeding or spotting alone may merit screening for these two in at-risk populations listed in Table 1-1 (p. 6). Last, herpes simplex virus (HSV) may manifest as diffuse erosive and hemorrhagic ectocervical lesions (Paavonen, 1988). In patients with such findings who lack a known HSV history, directed culture or serologic testing can be obtained.

### Cervical Cytology or Biopsy

Both cervical and endometrial cancers can bleed, and evidence for these tumors may be detected during diagnostic Pap smear evaluation. The most frequent abnormal cytologic results involve squamous cell pathology and may reflect cervicitis, intraepithelial neoplasia, or cancer. Less commonly, atypical glandular or endometrial cells are found. Thus, depending on the cytologic results, colposcopy, endocervical curettage, and/or endometrial biopsy may be indicated as discussed in Chapter 29 (p. 636). Moreover, at times, a visibly suspicious

vaginal or cervical lesion may bleed and warrant direct biopsy with Tischler forceps.

### Endometrial Biopsy

**Indications.** In women with AUB, sampling and histologic evaluation of the endometrium may identify infection or neoplastic lesions such as endometrial hyperplasia or cancer.

AUB is noted in 80 to 90 percent of women with endometrial cancer. The incidence and risk of this cancer increases with age, and most affected women are postmenopausal (National Cancer Institute, 2014). Thus, in postmenopausal women, the need to exclude cancer intensifies, and endometrial biopsy is typically indicated. Of premenopausal women with endometrial neoplasia, most are obese or have chronic anovulation or both. Thus, women with AUB in these two groups also warrant exclusion of endometrial cancer. Specifically, the American College of Obstetricians and Gynecologists (2012) recommends endometrial assessment in any woman older than 45 years with AUB, and in those younger than 45 years with a history of unopposed estrogen exposure such as seen in obesity or polycystic ovarian syndrome (PCOS), failed medical management, and persistent AUB.

**Sampling Methods.** For years, dilatation and curettage (D & C) was used for endometrial sampling. However, because of associated surgical risks, expense, postoperative pain, and need for operative anesthesia, other suitable substitutes were evaluated. In addition, investigators have demonstrated incomplete sampling and missed pathology even with D & C (Grimes, 1982; Stock, 1975).

Initial of these techniques used metal curettes. Endometrial samples that are removed with these curettes show significant positive correlation with histologic results obtained from hysterectomy specimens (Stovall, 1989). Thus, they are deemed adequate sampling methods. However, disadvantages include patient discomfort and rare procedural complications such as uterine perforation and infection.

To minimize these, flexible plastic samplers have been evaluated for endometrial biopsy. Advantageously, samples from these catheters have comparable histologic findings with tissues obtained by D & C, hysterectomy, or stiff metal curette (Stovall, 1991). Moreover, they afford greater patient comfort.

Prior to performing endometrial biopsy, pregnancy is excluded in women of reproductive age. With Pipelle insertion, patients frequently note cramping, which can be allayed by a preprocedural NSAID. For some, slow transcervical intrauterine instillation of 5 mL of 2-percent lidocaine using an 18-gauge angiocatheter can lower perceived pain scores (Kosus, 2014).

After patient education and consent, a speculum is placed, and the cervix is cleansed with an antibacterial solution, such as povidone-iodine solution. In many cases, a single-tooth tenaculum is needed to stabilize the cervix and permit passage of the Pipelle through the cervical os and into the endometrial cavity. When placing the tenaculum on the anterior cervical lip, closing the clamp slowly can decrease discomfort. Some evidence also supports topical anesthetic use. Examples are 10-percent lidocaine spray immediately prior or 5-percent lidocaine/prilocaine

**FIGURE 8-5** Steps of endometrial biopsy. **A.** During biopsy, the Pipelle is inserted through the cervical os and directed to the uterine fundus. **B.** The stilette of the Pipelle is retracted to create suction within the cylinder. **C.** Several times, the Pipelle is withdrawn to the level of the internal cervical os and advanced back to the fundus. The Pipelle is gently turned during its advance and retraction to allow thorough sampling of all endometrial surfaces.

cream (EMLA cream) 10 minutes before tenaculum placement (Davies, 1997; Zullo, 1999).

With sampling, the Pipelle is directed toward the fundus until resistance is met (Fig. 8-5). Markings on the Pipelle allow measurement of uterine depth, and this value is recorded in the procedure note. The inner Pipelle stilette is then retracted to create suction within the cylinder. Several times, the Pipelle is withdrawn to the level of the internal cervical os and advanced back to the fundus. The device is gently turned during its advance and retraction to allow thorough sampling of all endometrial surfaces. Uncommonly, a vagal response can follow Pipelle

insertion. In this instance, the procedure is terminated, and patient support is provided.

Despite its advantages, there are limitations to endometrial sampling with the Pipelle device. First, a tissue sample that is inadequate for histologic evaluation, such as from endometrial atrophy, or an inability to pass the catheter into the endometrial cavity is encountered in up to 28 percent of biopsy attempts (Smith-Bindman, 1998). Cervical stenosis and large submucous leiomyomas are classic obstructions. An incomplete evaluation often necessitates further investigation with D & C, transvaginal sonography with or without saline infusion, or diagnostic hysteroscopy (Emanuel, 1995). Second, endometrial biopsy has a cancer-detection failure rate of 0.9 percent. Thus, a positive histologic result is accurate to diagnose cancer, but a negative result does not definitively exclude it. Therefore, if an endometrial biopsy with normal tissue is obtained, but abnormal bleeding continues despite conservative treatment or if the suspicion of endometrial cancer is high, then further diagnostic efforts are warranted. Finally, endometrial sampling is associated with a greater percentage of false-negative results with focal pathology such as endometrial polyps. In a study of 639 women evaluated by diagnostic office hysteroscopy and endometrial biopsy, Svirsky and colleagues (2008) found that the sensitivity of endometrial sampling for detection of endometrial polyps and submucosal fibroids was only 8.4 and 1.4 percent, respectively. Because of these limitations with endometrial sampling, investigators have evaluated sonography, hysteroscopy, or both to replace or complement endometrial sampling.

## ■ Sonography

### Transvaginal Sonography

With improved resolution, this technology is chosen by many instead of endometrial biopsy as a first-line tool to assess AUB. Advantageously, it allows assessment of both the myometrium and the endometrium. Thus, if AUB stems from myometrial pathology such as leiomyomas, sonography offers anatomic information that is not afforded by hysteroscopy or endometrial biopsy. In addition, transvaginal sonography (TVS) compared with these other two typically offers greater patient comfort and suitable detection of postmenopausal endometrial hyperplasia and cancer (Karlsson, 1995; Van den Bosch, 2008). That said, no tool, including TVS, is recommended for routine endometrial cancer screening in asymptomatic women (Breijer, 2012).

When the endometrium is imaged in a sagittal view, opposed endometrial surfaces appear as a hyperechoic *endometrial stripe* down the center of the uterine body (Fig. 8-6 and Fig. 2-16, p. 31). In postmenopausal women, this endometrial thickness has been correlated with endometrial cancer risk. Although endometrial thickness varies among patients, ranges have been established. Granberg and coworkers (1991) found thickness measurements of  $3.4 \pm 1.2$  mm in postmenopausal women with atrophic endometrium,  $9.7 \pm 2.5$  mm in those with endometrial hyperplasia, and  $18.2 \pm 6.2$  mm in those with endometrial cancer. Subsequent investigations have similarly focused on endometrial thickness as it relates to hyperplasia and cancer risks in postmenopausal women. For endometrial cancer, negative predictive values > 99 percent have been reported using a

**FIGURE 8-6** The sonographic endometrial stripe in a sagittal plane represents the thickness created by the apposed anterior and posterior endometrium. In premenopausal women, stripe thickness will vary during the menstrual cycle as the endometrium gradually thickens and then is sloughed.

measurement of  $\leq 4$  mm (Karlsson, 1995; Tsuda, 1997). Use of hormone replacement therapy (HRT) does not appear to affect the threshold used (Smith-Bindman, 1998). In those using cyclic HRT, completing TVS on day 4 or 5 following cycle bleeding is recommended (Goldstein, 2001). For postmenopausal women, an endometrial thickness  $> 4$  mm typically requires additional evaluation with saline infusion sonography (SIS), hysteroscopy, or endometrial biopsy.

Consensus, however, is lacking regarding the asymptomatic postmenopausal women in whom a thick endometrium is found. The American College of Obstetricians and Gynecologists (2013d) notes that this finding need not routinely prompt evaluation but that further testing is directed by coexistent patient risks. Focal lesions are common in this subgroup and thus may favor SIS or hysteroscopy if additional evaluation is indicated (Schmidt, 2009).

Researchers have also attempted to create endometrial thickness guidelines for premenopausal women. Merz and colleagues (1996) found that the normal endometrial thickness in premenopausal women did not exceed 4 mm on day 4 of the menstrual cycle, nor did it measure more than 8 mm by day 8. However, endometrial thicknesses can vary considerably among premenopausal women, and evidence-based abnormal thresholds that have been proposed range from  $\geq 4$  mm to  $> 16$  mm (Breitkopf, 2004; Goldstein, 1997; Shi, 2008). Thus, a consensus for endometrial thickness guidelines has not been established for this group. At our institution, no additional evaluation is recommended for a normal-appearing endometrium measuring  $\leq 10$  mm in a premenopausal female experiencing AUB if she has no other risk factors to prompt further testing. Risk factors for endometrial carcinoma include extended AUB, chronic anovulation, diabetes mellitus, obesity, and tamoxifen use.

Qualities other than endometrial thickness are also considered because textural changes may indicate pathology. Punctate cystic areas within the endometrium may indicate a polyp. Conversely, hypoechoic masses that distort the endometrium and originate from the inner layer of myometrium most likely are submucous

leiomyomas. Although there are no specific sonographic findings that are characteristic of endometrial cancer, some findings have been linked with greater frequency (Fig. 33-3, p. 705). For example, intermingled hypo- and hyperechoic areas within the endometrium may indicate malignancy. Endometrial cavity fluid collections and an irregular endometrial-myometrial junction have also been implicated. Thus, with these findings, even with a normal endometrial stripe width in postmenopausal patients, endometrial biopsy or hysteroscopy with biopsy is considered to exclude malignancy (Sheikh, 2000).

Although these criteria can safely reduce endometrial biopsy rates for many patients, others consider false-negative rates as too high with this strategy for evaluation of postmenopausal women (Timmermans, 2010). Some advocate hysteroscopy with direct biopsy or D & C to evaluate postmenopausal bleeding (Litta, 2005; Tabor, 2002). In other patient populations, the 4-mm guideline may also be inappropriate. For example, van Doorn and coworkers (2004) reported decreased diagnostic accuracy in diabetic or obese women, and they recommend consideration of endometrial sampling.

A major limitation of TVS is its higher false-negative rate for diagnosing focal intrauterine pathology. This results in part from the physical inability of TVS to clearly assess the endometrium when there is concurrent uterine pathology such as leiomyomas or polyps. In these cases, SIS or hysteroscopy may be informative.

### Saline Infusion Sonography

It is simple, minimally invasive, and effective sonographic procedure can be used to evaluate the myometrium, endometrium, and endometrial cavity (Chap. 2, p. 24). Also known as *sonohysterography* or *hysterosonography*, SIS allows identification of common masses associated with AUB such as endometrial polyps, submucous leiomyomas, and intracavitary blood clots. These masses frequently create nondescript distortion or thickening of the endometrial lining when imaged with TVS. Thus, compared with TVS, SIS typically permits superior detection of intracavitary masses and differentiation of lesions as being endometrial, submucous, or intramural (Fig. 8-7). In addition, Moschos and colleagues (2009) describe a method of endometrial biopsy during SIS using a sonography-guided Pipelle. Although not yet widely used, this technique enables directed histologic sampling of endometrial pathology and has proved superior to blind endometrial biopsy in providing a diagnosis for AUB in peri- and postmenopausal women.

SIS has also been compared with hysteroscopy to detect uterine cavity focal lesions. De Kroon and coworkers (2003) performed a metaanalysis of 24 studies and reported SIS to equal the diagnostic accuracy of hysteroscopy. Importantly, neither hysteroscopy nor SIS can reliably discriminate between benign and malignant focal lesions. Thus, because of the malignant potential of many focal lesions, biopsy or excision of most structural lesions, when identified, is recommended for those with risk factors. For this, operative hysteroscopy is typically used.

SIS has other limitations. First, it is cycle dependent and best performed in the proliferative phase to minimize false-negative and false-positive results. For example, focal lesions may be concealed in a thick, secretory endometrium. Also, the amount of

**FIGURE 8-7** Transvaginal sonography of the uterus in the sagittal plane. **a.** The endometrium is thickened in this postmenopausal patient. **B.** Saline infusion sonography reveals a posterior endometrial mass and further delineates its size and qualities. (Used with permission from Dr. Elysia Moschos.)

endometrial tissue that can develop during the normal secretory phase can be mistaken for a small polyp or focal hyperplasia. Second, SIS usually has more patient discomfort than TVS, and approximately 5 percent of examinations cannot be completed because of cervical stenosis or patient discomfort. As expected, stenosis is more prevalent in postmenopausal women, and the incompleteness rate mirrors that of diagnostic hysteroscopy.

Although accurate for identifying focal lesions, SIS may not add to the value of TVS for evaluation of diffuse lesions such as hyperplasia and cancer. Therefore, in postmenopausal women with AUB, and in whom the exclusion of cancer is more relevant than evaluating focal intracavitary lesions, SIS alone as an initial diagnostic tool may not have advantages over TVS.

### Additional Sonographic Techniques

In selected instances, other imaging modalities can provide information beyond that obtained from TVS and SIS. Of these, color and pulsed Doppler, by demonstrating vascularity, may better highlight suspected focal abnormalities (Bennett, 2011). Similarly, 3-dimensional (3-D) sonography and 3-D SIS are most helpful to clarify focal lesions (Benacerraf, 2008; Makris, 2007). With power Doppler, finding multiple irregularly branching vessels may suggest malignancy (Opolskiene, 2007). 3-D power Doppler has been employed to differentiate malignant and benign endometrium, but its value is still undefined (Alcazar, 2009; Opolskiene, 2010). Last, although preferred to computed tomography (CT), magnetic resonance (MR) imaging is rarely needed for AUB evaluation but can display endometrium in cases in which sonographic views are obstructed.

### ■ hysteroscopy

With this procedure, an endoscope, usually 3 to 5 mm in diameter, is inserted into the endometrial cavity as explained in detail in Section 44-12 (p. 1037). The uterine cavity is then distended with saline or another medium for visualization. In addition to inspection, biopsy of the endometrium allows histologic diagnosis of abnormal areas and has been shown to be

a safe and accurate means of identifying pathology. Also, focal lesions can be diagnosed and completely removed in the same session. In fact, many studies examining the accuracy of TVS or SIS for intracavitary pathology evaluation use hysteroscopy as the “gold standard” for comparison.

The main advantage of hysteroscopy is detection of intracavitary lesions such as leiomyomas and polyps that might be missed using TVS or endometrial sampling (Tahir, 1999). It also permits simultaneous removal of many lesions once identified. Thus, some advocate hysteroscopy as the primary tool for AUB diagnosis. However, the invasiveness and cost of hysteroscopy is balanced against improved diagnostic efficiency. Moreover, although accurate for identifying endometrial cancer, hysteroscopy is less accurate for endometrial hyperplasia. Accordingly, some recommend endometrial biopsy or endometrial curettage in conjunction with hysteroscopy (Ben-Yehuda, 1998; Clark, 2002).

Hysteroscopy has other limitations. Cervical stenosis will sometimes block successful introduction of the endoscope, and heavy bleeding may obscure and hinder an adequate examination. Hysteroscopy is more expensive and technically challenging than TVS or SIS. Costs can be lower with office hysteroscopy rather than that in an operative suite. However, patient discomfort may limit complete examination during some of these procedures. Use of a smaller diameter or flexible hysteroscope may diminish this procedural pain (Cicinelli, 2003). In either arena, associated infection and uterine perforation have been reported, but their incidences are low (Bradley, 2002; Vercellini, 1997). Last, peritoneal seeding with malignant cells may take place during hysteroscopy via retrograde flow through the fallopian tubes in some women subsequently diagnosed with endometrial cancer (Bradley, 2004; Zerbe, 2000). Despite the risk of peritoneal contamination by cancer cells with hysteroscopy, patient prognosis overall does not appear to be worsened (Cicinelli, 2010; Polyzos, 2010). The American College of Obstetricians and Gynecologists (2011) considers hysteroscopy acceptable for AUB evaluation in those without advanced-stage uterine or cervical cancer.

### ■ Summary of Diagnostic procedures

There is no one clear sequence to the use of endometrial biopsy, TVS, SIS, and hysteroscopy when evaluating AUB. None of these will distinguish all anatomic lesions with high sensitivity and specificity. That said, TVS for several reasons is a logical first step. It is well tolerated, is cost-effective, and requires relatively minimal technical skill. Additionally, it can reliably determine stripe thickness and whether a lesion is myometrial or endometrial. Once potential anatomic lesions have been identified, subsequent evaluation requires individualization. If endometrial hyperplasia or cancer is suspected, then endometrial biopsy may offer advantages. Alternatively, possible focal lesions may be best investigated with either hysteroscopy or SIS. Ultimately, the diagnostic goal is to identify and treat pathology and specifically to exclude endometrial carcinoma. Thus, selection of appropriate tests depends on their accuracy in characterizing the most likely anatomic lesions.

### ETIOLOGY CLASSIFICATION

Causes of AUB are numerous and summarized by the acronym PALM-COEIN (Munro, 2011). In this International Federation of Gynecology and Obstetrics (FIGO) classification system, letters reflect Polyp, Adenomyosis, Leiomyoma, Malignancy and hyperplasia, Coagulopathy, Ovulatory disorders, Endometrial dysfunction, Iatrogenic, and those Not yet classified.

Pregnancy is not considered in this system, but AUB is encountered in 15 to 20 percent of pregnancies (Everett, 1997; Weiss, 2004). Although frequently no reason is found, bleeding may reflect early abortion, ectopic pregnancy, cervical infection, hydatidiform mole, cervical eversion, or polyp. Detailed discussions of bleeding associated with these are found in Chapters 6, 7, and 37.

### STRUCTURAL ABNORMALITIES

#### ■ Uterine Enlargement

Structural abnormalities are frequent causes of abnormal bleeding, and of these, leiomyomas are by far the most common. Myomas, adenomyosis, and isthmoceles are presented in Chapter 9. Uterine and cervical neoplasms are discussed in

Chapters 30, 33, and 34. As described in Chapter 18, partially obstructive congenital reproductive tract anomalies may at times cause chronic intermenstrual bleeding. Endometrial and endocervical structural abnormalities such as polyps and arteriovenous malformations are described here.

#### ■ Endometrial polyp

These soft, fleshy intrauterine growths are composed of endometrial glands, fibrous stroma, and surface epithelium. Polyps are common, and their prevalence in the general population approximates 8 percent (Dreisler, 2009a). Moreover, in those with AUB, rates range from 10 to 30 percent (Bakour, 2000; Goldstein, 1997). Intact polyps may be single or multiple, measure from a few millimeters to several centimeters, and be sessile or pedunculated (Fig. 8-8). Estrogen and progesterone have been implicated in their growth, and higher receptor levels are noted within polyps compared with adjacent normal endometrium (Leão, 2013). These hormones elongate endometrial glands, stromal tissue, and spiral arteries, leading to the characteristic polypoid appearance. Others suggest local immune disturbances contribute to polyp formation and to associated AUB and infertility (Al-Jefout, 2009; Kitaya, 2012).

Patient risk factors include increasing age, obesity, and tamoxifen use (Reslova, 1999). Although some studies suggest an association between hormone replacement therapy and polyp formation, others do not (Bakour, 2002; Dreisler, 2009a; Maia, 2004; Oguz, 2005). Use of oral contraceptive pills appear to be protective (Dreisler, 2009b). Similarly, for women taking tamoxifen, the levonorgestrel-releasing intrauterine system (LNG-IUS) was investigated and shown to lower endometrial polyp formation rates, but its ultimate effects on breast cancer recurrence are incompletely defined and a concern (Wong, 2013).

Women with polyps may have no complaints, and polyps are identified during imaging for other indications (Goldstein, 2002). More frequently, heavy cyclic or intermenstrual bleeding is an associated symptom. Bleeding may stem from surface epithelium breaks associated with chronic inflammation and vascular fragility or from apical ischemic tissue necrosis (Ferenczy, 2003). Infertility has been linked indirectly with endometrial polyps. For example, small studies have shown increased pregnancy rates and fewer early pregnancy losses in infertile

women following hysteroscopic excision (Pérez-Medina, 2005; Preutthipan, 2005). The exact mechanisms related to infertility are unknown, although local inflammation may play a role as noted earlier. Also, polyps found near the tubal ostia may hinder ostium function and block sperm migration (Shokeir, 2004; Yanaihara, 2008). Accordingly, many advocate polyp removal in infertile women.

The main diagnostic tools for endometrial polyp evaluation include TVS with applied color Doppler, SIS, and hysteroscopy. Endometrial biopsy may identify polyps but has less diagnostic sensitivity. In premenopausal women, TVS is best performed prior to day 10 of the cycle to lower the risk of false-positive and false-negative findings. With TVS, an endometrial polyp may appear as a nonspecific endometrial thickening or as a round or elongated hyperechoic focal mass within the endometrial cavity. Sonolucent cystic spaces corresponding to dilated endometrial glands are seen within some polyps (Nalaboff, 2001). TVS can be augmented with color or power Doppler. Endometrial polyps typically have only one arterial feeding vessel, whereas submucous leiomyomas generally received blood flow from several vessels arising from the inner myometrium (Fig. 8-9) (Cil, 2010; Fleischer, 2003).

SIS and hysteroscopy are both accurate in identifying endometrial polyps (Soares, 2000). With SIS, polyps appear as echogenic, smooth, intracavitary masses with either broad bases or thin stalks and are outlined by fluid (see Fig. 8-9B). Hysteroscopy identifies nearly all cases of endometrial polyps (see Fig. 8-8). Another advantage of hysteroscopy is the ability to identify and remove the polyp concurrently.

The Pap smear is an ineffective tool to identify polyps. However, it occasionally incidentally leads to their identification. For example, 5 percent of postmenopausal women with benign endometrial cells identified on Pap smear are found to have endometrial polyps (Karim, 2002). Moreover, in postmenopausal women with atypical glandular cells of undetermined significance (AGUS), endometrial polyps were the most frequent underlying pathology found (Obenson, 2000).

**FIGURE 8-9** Transvaginal color Doppler sonography (TV-CDS) of an endometrial polyp. Color flow feature identifies a single feeder vessel, which is characteristic of a polyp. (Used with permission from Dr. Elysia Moschos.)

Most polyps are benign, and premalignant or malignant transformation develops in only approximately 5 percent (Baiocchi, 2009). Thus, operative hysteroscopic polypectomy may be most effective for symptomatic women or those with risk factors for malignant transformation. These risks include postmenopausal status, larger polyp size ( $> 1.5$  cm), abnormal bleeding, and tamoxifen use (Ferrazzi, 2009; Lee, 2010). Hysteroscopically, polyps can be removed by electrosurgical resection or morcellation, as illustrated in Chapter 44 (p. 1038). During hysteroscopic polypectomy, background sampling of the endometrium is considered in those with endometrial cancer risk factors (Rahimi, 2009).

For asymptomatic women with polyps but without malignant transformation risk factors, management can be more conservative. Some advocate removal of all endometrial polyps because premalignant and malignant transformation has been identified in even asymptomatic premenopausal women (Golan, 2010). However, the transformation risk in these patients with small lesions is low, and many of these polyps spontaneously resolve or slough (Ben-Arie, 2004; DeWaay, 2002). If conservative observation is elected, the optimum surveillance for these women remains undefined.

### ■ Endocervical polyp

These lesions represent overgrowths of benign endocervical stroma covered by mucinous columnar epithelium. They typically appear as single, red, smooth elongated masses extending from the endocervical canal. Polyps vary in size and range from several millimeters to 2 or 3 cm. These common growths are found more frequently in multiparas and rarely in prepubertal females. Endocervical polyps are usually asymptomatic, but they can cause intermenstrual or postcoital bleeding or symptomatic vaginal discharge. Many endocervical polyps are identified by visual inspection during pelvic examination. In other instances, they may lie higher in the endocervical canal and be found during TVS (Fig. 8-10). Last, AGUS Pap smear findings may prompt investigation and also lead to identification

**FIGURE 8-10** This transvaginal sonogram shows a sagittal view of the cervix and an endocervical polyp marked by calipers.

**FIGURE 8-11** Transvaginal sonography of an arteriovenous malformation (AVM). **A.** Sagittal image of the uterus (calipers) with an irregular-shape anechoic space within the posterior fundal myometrium. **B.** Color Doppler evaluation of this area in the transverse plane demonstrates the classic mosaic color pattern of an AVM. (Used with permission from Dr. Elysia Moschos.)

of endocervical polyps higher in the endocervical canal (Burja, 1999).

Endocervical polyps are typically benign, and premalignant or malignant transformation develops in less than 1 percent (Chin, 2008; Schnatz, 2009). However, cervical cancer can present as polypoid masses and can mimic these benign lesions. Others in the differential diagnosis include condyloma acuminata, leiomyoma, decidua, granulation tissue, endometrial polyp, or fibroadenoma. Most recommend removal and histological evaluation of all polypoid lesions. However, studies have stratified affected patients by symptoms and cytology. Results showed no preinvasive disease or cancer in polyps of asymptomatic women with normal cervical cytology (Long, 2013; MacKenzie, 2009).

For removal, if the stalk is slender, endocervical polyps are grasped by ring forceps. The polyp is twisted repeatedly about the base of its stalk to strangulate its feeding vessels. With repeated twisting the base will narrow and avulse. Monsel paste (ferric subsulfate) can be applied with direct pressure to the resulting stalk stub to complete hemostasis. Rarely, a thick pedicle is found and may warrant surgical ligation and excision if heavier bleeding is anticipated. Patients are counseled that polyp recurrence rates range from 6 to 15 percent (Berzolla, 2007; Younis, 2010).

### ■ Arteriovenous Malformation

These consist of a mixture of arterial, venous, and small capillary-like channels with fistulous connections. Uterine arteriovenous malformation (AVM) may be congenital or acquired, and vessel sizes can vary considerably. Acquired AVMs are usually large vessels that develop with a cesarean delivery scar or form after trauma from D & C. They can also arise concurrently with cervical or endometrial cancer, with gestational trophoblastic disease, or with intrauterine device use (Ghosh, 1986). Uterine AVMs are rare and more frequently involve the corpus, but they may also be found in the cervix (Lowenstein, 2004). Affected patients often note HMB and perhaps intermenstrual bleeding that is unprovoked or that is triggered by a spontaneous miscarriage, curettage, or other intracavitary uterine surgery.

Symptoms can appear slowly or suddenly with life-threatening bleeding (Timmerman, 2003).

In some cases, AVMs are first visualized with TVS because of its ready availability and widespread use. Sonographic characteristics are nonspecific and may include anechoic tubular structures within the myometrium (Fig. 8-11). Color Doppler or power Doppler ultrasound may provide a more specific image with bright, large-caliber vessels and multidirectional flow (Tullius, 2015). Angiography aids confirmation and can be used concurrently to perform vessel embolization (Cura, 2009). CT scanning with contrast, MR imaging, SIS, and hysteroscopy have also been used to image these (Lowenstein, 2004; Timmerman, 2003).

Arteriovenous malformations are traditionally treated by hysterectomy. However, less invasive, yet effective, approaches include arterial embolization or surgical coagulation of AVM feeding vessels (Corusic, 2009; Ghosh, 1986).

## EXTERNAL SOURCES

### ■ Intrauterine Devices

Of potential exogenous factors, intrauterine devices (IUDs), sex steroid hormone medications, and anticoagulants are typical sources. In contrast, trauma or vaginal erosion from a foreign body is infrequently encountered.

Of these, copper-containing intrauterine devices (ParaGard) can cause heavy or intermenstrual bleeding, and several explanations have been suggested. At the cellular level, prostaglandins are implicated as affecting vascular tone (Coskun, 2011). At the tissue level, endometrial vascularity, congestion, and degeneration result in interstitial hemorrhage, which may lead to intermenstrual bleeding (Shaw, 1979). At the organ level and with either IUD type, malpositioning or less commonly embedding into or perforating through the myometrium can generate AUB (Benacerraf, 2009; Kaislasuo, 2013). TVS and especially 3-D TVS can usually clarify IUD position (Moschos, 2011).

For copper IUD-related bleeding, pregnancy, infection, malpositioned device, or gross structural pathology are first excluded.

Then HMB can be treated or prevented with an empiric trial of NSAIDs taken during menses. Intermenstrual bleeding, however, is typically not improved with these agents (Godfrey, 2013). Limited evidence also supports tranexamic acid for treatment or prevention (Ylikorkala, 1983). Women with persistent or refractory bleeding may have other pathology and are managed similarly to other women with the initial complaint of AUB. However, with TVS, endometrial stripe evaluation may be limited by IUD shadowing. Importantly, endometrial biopsy with small catheters can be performed without device removal (Grimes, 2007).

With the levonorgestrel-releasing intrauterine system (LNG-IUS), marketed as Mirena, Liletta, and Skyla, unscheduled spotting or light bleeding is expected during the first several months and decreases with continued use (Centers for Disease Control and Prevention, 2013). The pathophysiology of this bleeding is not clear, but downregulation of estrogen and progesterone receptors, increased local leukocyte populations, and altered MMP levels are suggested factors (Labied, 2009). The endometrial effects of progestins are thought to predominate, and evidence is accruing that low-dose progestins increase endometrial vascular fragility (Hickey, 2002). Over time, the endometrium atrophies, and these vascular abnormalities gradually resolve at a time thought to coincide clinically with progestin-induced amenorrhea (McGavigan, 2003). Scant data guide specific treatment of problematic LNG-IUS-related bleeding, but options discussed next for other progestin-only contraception can be extrapolated.

## ■ Hormonal Therapy

Other *hormonal birth control methods* can create bleeding disturbances. Overall, menses are typically lighter with these, but intermenstrual bleeding is frequent with progestin-only methods throughout use and with combination oral contraceptive (COC) formulations during early months of use. Chronic COC-related intermenstrual bleeding is typically corrected by changing to a brand with an increased estrogen dose. In contrast, for AUB due to a progestin-only implant or depot medroxyprogesterone acetate (DMPA), bleeding can be lessened by an estrogen supplement such as daily ethinyl estradiol or conjugated equine estrogen (Premarin) or by the addition of a COC (Alvarez-Sanchez, 1996; Díaz, 1990; Said, 1996). These are provided for a few weeks. Alternatively, NSAIDs given for 5 to 7 days is reasonable, but studies show mixed results (Abdel-Aleem, 2013; Centers for Disease Control and Prevention, 2013).

With *hormone replacement therapy*, irregular spotting or bleeding is also a well-known side effect. During the first year of therapy, irregular bleeding is more likely with continuous combined therapy than sequential therapy. However, during the second year, this order is reversed (Lethaby, 2004). With continuous therapy, lower initial doses may cause less bleeding (Archer, 2007). Importantly, intrauterine pathology has been shown to be four times more frequent in patients with continued abnormal bleeding after six months of HRT use, as well as in those who have abnormal bleeding after achieving initial amenorrhea (Leung, 2003).

Of the *selective estrogen-receptor modulators (SERMs)*, raloxifene (Evista) is used to treat osteoporosis. Postmenopausal

bleeding can develop with use but much less frequently and with lower rates of endometrial pathology than with HRT (Neven, 2003). Another SERM, tamoxifen, is used as an adjunct for treatment of estrogen receptor positive breast cancer. Although it diminishes estrogen action in breast tissue, tamoxifen stimulates endometrial proliferation. This SERM has been linked to hyperplasia, polyps, and carcinoma of the endometrium and to uterine sarcomas (Cohen, 2004). Thus, associated AUB warrants evaluation. However, using TVS or endometrial biopsy to screen women who use tamoxifen but who do not have abnormal bleeding has not proved effective (Barakat, 2000). Accordingly, for women without increased endometrial cancer risks but using tamoxifen, such routine surveillance is not recommended (American College of Obstetricians and Gynecologists, 2014).

## ■ Anticoagulants

Although treatment with these confers a risk of major bleeding, menstrual irregularities are also often encountered. Initially, coagulation studies including prothrombin time (PT), partial thromboplastin time (PTT), and platelet count are obtained as bleeding may be related to excess anticoagulant activity. Patients are also queried regarding recent dosage changes or antagonist medications. Physical examination is completed, and AUB evaluation components are performed as indicated.

Management of AUB can be challenging as many traditional treatment options carry thromboembolic risks. For chronic HMB, the LNG-IUS has been found to be an effective treatment in many of women using anticoagulants (Pisoni, 2006). If a surgical approach is ultimately desired, endometrial ablation or hysterectomy can be considered. Anticoagulation reversal for surgery differs depending on whether surgery is urgent or elective, and both instances are described in Chapter 39 (p. 830).

For acute severe HMB, anticoagulation is reversed, and a Foley balloon can be inserted into the intrauterine cavity and inflated to tamponade bleeding. Estrogen-containing hormonal manipulation of the endometrium and tranexamic acid are contraindicated because of their underlying risks for thromboembolism. Moreover, emergent surgery or uterine artery embolization (UAE) is associated with increased rates of intra- and postoperative bleeding or thromboembolic complications.

## ENDOMETRITIS

In addition to cervicitis (p. 184), chronic endometritis has been linked to abnormal bleeding in some but not all studies (Greenwood, 1981; Pitsos, 2009). Underlying infection is often implicated, and agents of bacterial vaginosis, *Mycoplasma* species, *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*, have each been identified. Thus, testing for the latter two pathogens is reasonable in sexually active patients, and positive results prompt treatment per CDC guidelines (2015). That said, vaginal cultures may not always correlate with endometrial culture (Cicinelli, 2008).

In other cases, chronic endometritis is linked to a structural cause such as endometrial polyp, IUD, or submucous leiomyoma. It may follow abortion or pregnancy.

Chronic endometritis is traditionally diagnosed histologically by plasma cell infiltration found in an endometrial sample.

In women undergoing diagnostic hysteroscopy, the diagnosis can also be suggested by endometrial hyperemia, edema, and “micropolyps” measuring < 1 mm (Cicinelli, 2005).

Because infection may or may not underlie all cases of chronic endometritis, deciding whether or not to treat with antibiotics can be challenging. Moreover, few studies have evaluated the efficacy of antibiotics to resolve symptoms. At our institution, patients with documented histologic findings of endometritis are typically given a course of doxycycline, 100 mg orally twice daily for 10 days.

## SYSTEMIC CAUSES

### ■ Kidney, Liver, and Thyroid Disease

Severe *renal dysfunction* often is accompanied by endocrine disturbances that lead to hypoestrogenism and amenorrhea or to normal estrogen levels but anovulation (Matuszkiewicz-Rowińska, 2004). In a study of 100 women with chronic renal failure undergoing dialysis, Cochrane and Regan (1997) reported that 80 percent of those menstruating complained of HMB. Of additional concern, bleeding may worsen the chronic anemia already associated with renal failure.

For AUB from anovulation, renal patients are treated with traditional methods as outlined on page 194 (Guglielmi, 2013). Of specific options, Fong and Singh (1999) report success with the LNG-IUS in renal transplant patients with HMB secondary to uterine leiomyomas. Notably, COCs may be contraindicated with severe hypertension, which commonly complicates renal disease, or with some systemic lupus erythematosus cases. Moreover, in those with renal disease, NSAIDs are avoided because they cause renal artery vasoconstriction that diminishes glomerular function.

If women with renal failure and HMB cannot take or do not respond to medical therapy, then surgical treatments are considered. Of these, Jeong and coworkers (2004) noted decreased bleeding in 87 percent of patients following endometrial ablation.

*Liver dysfunction*, depending on its severity, can lead to menstrual abnormalities (Stellon, 1986). With end-stage liver disease warranting transplantation, menstrual dysfunction is reported by 60 percent (de Koning, 1990). The underlying mechanism for bleeding is not clear, but as in renal failure, HPO axis dysfunction is suggested. Hemostatic dysfunction may also contribute. With the exception of von Willebrand factor, all of the coagulation proteins and most of their inhibitors are synthesized in the liver. Last, thrombocytopenia is common in women with portal hypertension and splenomegaly.

Evidenced directing the HMB treatment in women with liver disease is limited, and hormonal therapy may be inappropriate for some affected women. As outlined by the World Health Organization, in those with chronic viral hepatitis or with mild compensated cirrhosis, hormonal contraceptive use is not restricted. In those with active hepatitis or a flare of their chronic viral disease, progestin-only contraception is acceptable. Estrogen-containing products, if already in use, may be continued, whereas initiation of these is avoided. In those with severe, decompensated cirrhosis, all hormonal contraception is avoided (Kapp, 2009).

Both *hyperthyroidism* and *hypothyroidism* can cause menstrual disturbances ranging from amenorrhea to HMB. In many women, these menstrual abnormalities antedate other clinical findings of thyroid disease (Joshi, 1993). Thus, in most women with chronic AUB, measurement of serum thyroid-stimulating hormone (TSH) level is recommended. With hyperthyroidism, hypomenorrhea and oligoamenorrhea are more frequent complaints (Krassas, 2010). With severe overt hypothyroidism, women commonly present with anovulation, amenorrhea, and anovulatory AUB (p. 194). These women can also display defects in hemostasis. This may be due to decreased coagulation factor levels that have been identified in some hypothyroid patients. With either hypo- or hyperthyroidism, treatment of the underlying thyroid disorder usually corrects AUB (Krassas, 1999; Wilansky, 1989).

### ■ Coagulopathy

Normally, a clot forms from an aggregation of platelets, which is then stabilized by a fibrin net. Thus, many coagulation defects leading to HMB can be broadly categorized as either: (1) dysfunction of platelet adherence or (2) defects in platelet plug stabilization. First, during initial stages of hemostasis, platelets adhere to vessel wall breaks through binding of their receptors to exposed collagen. This bridging is dependent on von Willebrand factor (vWF), a plasma protein. Once bound, platelets are activated and release a potent agonist of their aggregation, thromboxane. Thus, low platelet number, defects in vWF quality or quantity, platelet receptor defects, or thromboxane inhibitors may all lead to poor platelet adherence and HMB. Second, the coagulation cascade leads to fibrin, which stabilizes aggregated platelets. Thus, defects in the clotting factors that make up these cascades may also predispose to abnormal bleeding.

In general, coagulopathies are infrequent causes of gynecologic bleeding. However, in the subset of women with HMB and normal anatomy, the incidence is significantly higher (Philipp, 2005). And in women with known inherited bleeding disorders, HMB is the most common complaint (Byams, 2011).

For diagnosis, a history of easy bruising, bleeding complications with surgery or obstetric delivery, recurrent hemorrhagic ovarian cysts, epistaxis, and gastrointestinal bleeding or a family history of bleeding disorders raises concern for coagulopathy. Laboratory screening includes a CBC with platelets, PT, PTT, and fibrinogen level (American College of Obstetricians and Gynecologists, 2013e). More frequently identified coagulopathies include von Willebrand disease, thrombocytopenia, and platelet dysfunction. Specific screening for each is discussed subsequently. Deficiencies of factor VIII and IX (hemophilia A and B) and other factor deficiencies are uncommon. Acute treatment of these disorders is by factor replacement, and long-term management is similar to that for von Willebrand disease (Mannucci, 2004).

### Platelets

As described, low platelet counts may lead to AUB. *Thrombocytopenia* may be broadly categorized as resulting from disorders that: (1) increase platelet destruction, as with idiopathic thrombocytopenic purpura (ITP), (2) decrease platelet

production, as with hematopoietic malignancy, or (3) increase platelet sequestration, as with splenomegaly.

Alternatively, normal platelet counts may be found, but *platelet dysfunction* leads to poor aggregation. One example is prolonged use of thromboxane inhibitors such as NSAIDs and aspirin. These drugs are often taken by women with AUB due to its close association with dysmenorrhea. Accordingly, patients are queried regarding chronic use of these drugs. Much less often, primary genetic defects in platelet receptors, such as Bernard-Soulier syndrome and Glanzmann thrombasthenia, lead to platelet dysfunction and abnormal bleeding.

As a group, evidenced-based data directing the treatment of platelet-associated HMB are limited. For acute, severe HMB, platelet transfusion is considered for counts  $< 20,000/\mu\text{L}$  or for those  $< 50,000/\mu\text{L}$  with brisk bleeding. For those undergoing procedures, a transfusion threshold of  $\leq 50,000/\mu\text{L}$  is used, and for major surgery,  $\leq 100,000/\mu\text{L}$  (James, 2011). Concurrently, treatment is tailored to the underlying cause of thrombocytopenia. Long-term, with the exception of NSAIDs, treatment options include those described later for AUB secondary to endometrial dysfunction (p. 195).

### Von Willebrand Disease

Von Willebrand factor (vWF) is a glycoprotein synthesized in endothelial cells and in megakaryocytes, which produce platelets. For coagulation, it is integral to platelet adherence at sites of endothelial injury and also prevents clearance of factor VIII. von Willebrand disease (vWD) has several variants, which are characterized by either diminished amount or decreased function of vWF (Table 8-2). This is an inherited bleeding disorder. In general, type 3 vWD displays autosomal recessive transmission, whereas type 1 and most subtypes of type 2 show an autosomal dominant pattern.

The disorder is more common in whites than in African-Americans, and the prevalence of vWD approximates 1 percent in the general population (Rodeghiero, 2001). However, in women with AUB and normal pelvic anatomy, vWD is found in nearly 13 percent (Shankar, 2004). Of women with vWD, nearly 75 percent complain of HMB, which typically begins with menarche (Byams, 2011).

In screening for coagulopathy as described on page 192, women with vWD may display a prolonged PTT or may have normal results. If vWD is suspected clinically, specific tests

include measurement of von Willebrand-ristocetin cofactor activity, vWF antigen concentration, and factor VIII activity (James, 2009b). Of note, factor VIII and vWF levels reach a nadir during menses and are relatively increased in women using COCs. However, testing need not be rescheduled nor COCs halted to complete patient evaluation (James, 2009a). Consultation with a hematologist is often recommended because the diagnosis of vWD, especially in its mild form, can be difficult.

Treatments for women with vWD and chronic HMB mirror that listed for primary endometrial dysfunction (p. 195). Of options, COCs are often used as first-line treatment and have been noted to arrest uterine hemorrhage in 88 percent of affected women (Foster, 1995). Also, Kingman and coworkers (2004) reported that the LNG-IUS effectively decreased blood loss and induced amenorrhea in 56 percent of 16 women with an inherited bleeding disorder. DMPA (Depo-Provera), progestin-only pills, and etonogestrel implant (Nexplanon) are other options for HMB in these women. Additional treatment may also include the antifibrinolytic drug tranexamic acid (Lysteda). Importantly, agents that prevent platelet adhesion, such as aspirin or NSAIDs, are avoided (American College of Obstetricians and Gynecologists, 2013e).

For women with chronic HMB who do not respond to conventional treatment, a hematologist may be consulted for desmopressin or vWF concentrate use (Nichols, 2008). Desmopressin is a vasopressin analogue that promotes release of vWF from endothelial cells. Available in intravenous and nasal forms, its side effects include flushing, transient blood-pressure changes, nausea, or headache, but these rarely limit use. In those with chronic HMB in whom desmopressin is ineffective or contraindicated, a vWF concentrate can be chosen. Available in the United States, Humate-P or Alphanate each contains both vWF and factor VIII.

In those with vWD-related chronic HMB who no longer desire fertility, surgical intervention may be considered. Preliminary success has been found with endometrial ablation for affected women, but long-term success rates are lower than in those without a bleeding disorder (Rubin, 2004). Dilatation and curettage is ineffective long-term to control bleeding and may acutely worsen blood loss in affected women (James, 2009a). Hysterectomy is curative, although rates of bleeding complications from hysterectomy in women with vWD are higher than those of unaffected women (James, 2009c). In preparation for

**Table 8-2.** vWD Classification and Laboratory Values

Condition	Description of vWF deficiency	Bleeding propensity	vWf:RCo (IU/dL)	vWf:Ag (IU/dL)	FVIII activity
Type 1	Quantitative: partial	Mild to Moderate	$< 30$	$< 30$	↓ or Normal
Type 2	Qualitative	Moderate	$< 30$	$< 30\text{--}200$	↓ or Normal
Type 3	Quantitative: virtually complete	High	$< 3$	$< 3$	↓↓↓ ( $< 10$ IU/dL)
Normal			$50\text{--}200$	$50\text{--}200$	Normal

FVIII = coagulation factor VIII; vWD = von Willebrand disease; vWF = von Willebrand factor; vWF:Ag = von Willebrand factor antigen; vWF:RCo = von Willebrand factor:ristocetin cofactor activity.

**Ta BLE 8-3.** Medical Treatment of Acute Heavy Abnormal Uterine Bleeding<sup>a,b</sup>

CEE <sup>c,d</sup>	25 mg IV every 4 hr, up to 3 doses
CEE <sup>d,e</sup>	2.5 mg every 6 hr
COCs <sup>d,e</sup> 30–50 µg	1 pill every 6 or 8 hr, up to 7 d
MPA <sup>e</sup>	10 mg every 4 hr
NETA <sup>e</sup>	5–10 mg every 4 hr
TXA <sup>c</sup>	10 mg/kg IV every 8 hr
TXA	1.3 g every 8 hr for 5 d

<sup>a</sup>Agents given orally except where noted as IV.  
<sup>b</sup>For anemic patients, initiate oral iron supplements.  
<sup>c</sup>If IV forms required, transition patients to oral agents once bleeding is improved.  
<sup>d</sup>Antiemetics may aid nausea.  
<sup>e</sup>Oral hormonal agent dosages are tapered by extending dosing from every 4–6 hr, to every 8 hr, to every 12 hr, and finally to daily. Each new dosing lasts 2 to 7 days depending on the level of concern for rebleeding.  
CEE= conjugated equine estrogen (Premarin); COCs = combination oral contraceptive pills; d = day; hr = hour; IV= intravenous; MPA= medroxyprogesterone acetate; NETA= norethindrone acetate; TXA= tranexamic acid.  
Data from DeVore, 1982; Munro, 2006; James, 2011.

surgical procedures, a hematologist may assist with desmopressin or vWF concentrate dosing.

For severe emergent bleeding, hormonal and antifibrinolytic options shown in Table 8-3 are implemented while clotting factor deficiencies are corrected. In addition, desmopressin can be administered (Edlund, 2002). However, desmopressin is a potent antidiuretic agent. Thus, if multiple doses or shorter dosing intervals are used, concurrent fluid restriction and monitoring for hyponatremia is advised (Rodeghiero, 2008). However, if aggressive fluid resuscitation is needed, then desmopressin may not be appropriate. In this case, vWF concentrates are used instead to quickly raise factor levels (James, 2011). Comprehensive management guidelines for vWD are also available from The National Heart, Lung, and Blood Institute at: <http://www.nhlbi.nih.gov/files/docs/guidelines/vwd.pdf>.

**OVULATORY DYSFUNCTION**

A large percentage of women with AUB have anovulation as the underlying etiology, and the term AUB-O denotes this ovulatory dysfunction. *Dysfunctional uterine bleeding* is currently a less-preferred term for this (American College of Obstetricians and Gynecologists, 2012). With AUB-O, bleeding episodes are variable, and amenorrhea, HMB, and intermenstrual bleeding often interchange. For example, women with anovulation may be amenorrheic for weeks to months followed by irregular, prolonged, and heavy bleeding.

The underlying causes of anovulation are varied and fully described in Chapter 16 (p. 369). Regardless of the reason, if ovulation does not occur, no progesterone is produced, and a proliferative endometrium persists. At the tissue level, a chronic

proliferative endometrium is typically associated with stromal breakdown, decreased spiral arteriole density, and dilated and unstable venous capillaries (Singh, 2005). Because endometrial vessels become markedly dilated, bleeding can be severe. At the cellular level, the availability of arachidonic acid is reduced, and prostaglandin production is impaired. For these reasons, bleeding associated with anovulation is thought to result from alterations in endometrial vascular structure and prostaglandin concentration and from an increased endometrial responsiveness to vasodilating prostaglandins (Hickey, 2000, 2003).

**Chronic Management**

Ideally, AUB-O is reversed by correction of the underlying cause of anovulation. If this is not possible, chronic progestin therapy supplements the physiologic progesterone that is absent with anovulation. For women requiring contraception, COCs, progestin-only contraceptive pills, DMPA, LNG-IUS, and etonogestrel subdermal implant are options. In those not desiring contraception, cyclic monthly progesterone followed by withdrawal will typically regulate menses. Suitable oral daily doses given for 10 days each month include: (1) medroxyprogesterone acetate (MPA [Provera]), 5 or 10 mg; (2) norethindrone acetate (NETA [Aygestin]), 5 or 10 mg; or (3) micronized progesterone, 300 mg (de Lignières, 1999; Munro, 2000). As another but less frequently used choice, gonadotropin-releasing hormone (GnRH) agonists create profound hypogonadism (Chap. 9, p. 208). The induced amenorrhea can be advantageous to permit severely anemic women with HMB to rebuild their red cell volume (Vercellini, 1993). Surgery is rarely indicated for AUB-O, unless medical therapy fails, is contraindicated, or is not tolerated by the patient, or the patient has concomitant significant uterine structural lesions (American College of Obstetricians and Gynecologists, 2013b). Surgical options mirror those for abnormal bleeding associated with endometrial dysfunction, discussed on page 197.

**Acute Hemorrhage Management**

At times, women with anovulatory bleeding may have severe HMB that requires acute intervention. Fluid resuscitation is instituted as described in Chapter 40 (p. 864). Medical treatment is simultaneously administered to slow bleeding (see Table 8-3). As primary choices, equine estrogens can be given intravenously (IV) in 25-mg doses every 4 hours for up to three doses (DeVore, 1982). Once bleeding has slowed, patients can be transitioned to an oral taper using Premarin pills or more commonly COCs. These pill forms can also be selected primarily for less severe bleeding. With any of these high-dose choices, an antiemetic may be needed to control nausea. For COC administration, formulations containing at least 30 µg of ethinyl estradiol are selected, and a complete list is found in Table 5-7 (p. 120). If bleeding is significant, the regimen begins with one pill every 6 hours until the bleeding has stopped or markedly diminished. For most women, bleeding will slow within 24 to 48 hours. After bleeding has diminished, the COC dosage is decreased to one pill every 8 hours for the next 2 to 7 days and then to one pill every 12 hours for 2 to 7 days (James, 2011). A once-a-day dosage is then continued for several weeks, to be followed by withdrawal menses. This

type of dose-diminishing regimen is colloquially known as a “COC taper.” Effective modification of this regimen may include less frequent dosing or smaller doses. Following this taper, COCs may be stopped or continued long-term for cycle control (Munro, 2006).

As an alternative to high-dose estrogen therapy for acute HMB, high-dose MPA (10 mg) or NETA (5 to 10 mg) can be used and administered orally every 4 hours. As with oral COCs, these are then tapered once bleeding has waned. One proposed taper stretches dosing to every 6 hours for 4 days, then every 8 hours for 3 days, then every 12 hours for 2 to 14 days. The progestin is then continued daily (James, 2011). Another primary regimen uses MPA 20 mg orally three times daily combined with DMPA 150 mg intramuscularly. Here, the single depot injection serves as the taper (Ammerman, 2013).

Tranexamic acid (TXA) is also an option, and the usual IV dose is 10 mg/kg every 8 hours. As bleeding declines, transition to an oral dose of 1.3 g given three times a day can be implemented (James, 2011). Cautions for extended TXA use combined with hormonal agents are described on page 196.

With any of these medication regimens, an intrauterine Foley balloon can be inflated for brisk bleeding. This acts to tamponade the endometrial vessels while the above-listed agents exert their control.

Primary Endometrial Dysfunction

This form of AUB is thought to stem predominately from endometrial vascular dilatation alone. For example, women with ovulatory bleeding lose blood at rates three times faster than women with normal menses, but the number of spiral

arterioles is not increased (Abberton, 1999). Thus, in women with ovulatory AUB, vessels supplying the endometrium are thought to have decreased vascular tone and therefore increased rates of blood loss from vasodilatation (Rogers, 2003). Several provocateurs of this change in vascular tone are suggested, especially prostaglandins. Despite these physiologic findings, AUB from endometrial dysfunction (AUB-E) has no clear diagnostic features and currently is a diagnosis of exclusion.

Acute medical treatment of severe AUB-E mirrors that for AUB due to ovulatory dysfunction as shown in Table 8-3. Chronic medical options include LNG-IUS, COCs, sustained progestins, TXA, NSAIDs, androgens, and GnRH agonists (Table 8-4).

Levonorgestrel-releasing Intrauterine System

In addition to providing effective contraception, this device releases sustained progestin levels within the uterine cavity. This atrophies the endometrial lining and reduces menstrual loss by 74 to 97 percent after 3 months’ use (Singh, 2005; Stewart, 2001). The LNG-IUS can be used in most women, including adolescents, as a first-line treatment for HMB. It is particularly useful for reproductive-aged women with AUB-E who wish to retain fertility. Contraindications include an abnormal uterine cavity, untreated breast or reproductive tract cancer, acute liver disease or tumor, and reproductive tract infection or infection risks. Other caveats are listed in Table 5-4 (p. 109).

Of treatments for AUB-E, the LNG-IUS is one of the more extensively researched (Matteson, 2013). In randomized trials, the LNG-IUS proved more effective in decreasing menstrual blood loss than NSAIDs given during menses; than oral progesterone

TABLE 8-4. Chronic Medical Treatment of Abnormal Uterine Bleeding due to Primary Endometrial Dysfunction<sup>a,b</sup>

Agent	Brand	Dosage	Study
LNG-IUS	Mirena	5-yr intrauterine use	Shaaban, 2011
COCs	Table 5-7 <sup>c</sup>	One pill daily	Fraser, 2011
DMPA	Depo-Provera	150 mg IM every 3 mo	Küçük, 2008
NETA	Aygestin	5 mg, 3 times daily, days 5–26 of cycle	Irvine, 1998
TXA <sup>d</sup>	Lysteda	1.3 g, 3 times daily × 5 d	Lukes, 2010
NSAID <sup>d</sup>			
Mefenamic acid	Ponstel	500 mg, 3 times daily × 5 d	Bonnar, 1996
Naproxen	Naprosyn	550 mg on first day, then 275 mg daily	Hall, 1987
Ibuprofen	Motrin	600 mg, daily throughout menses	Makarainen, 1986
Flurbiprofen	Ansaid	100 mg, 2 times daily × 5 d	Andersch, 1988
Danocrine	Danazol	100 mg or 200 mg, daily throughout cycle	Chimbira, 1980b
GnRH agonists	Lupron	3.75 mg, IM each month (up to 6 mo)	Thomas, 1991

<sup>a</sup>All agents are administered orally except GnRH agonists, DMPA, and LNG-IUS.  
<sup>b</sup>For anemic patients, also initiate oral iron supplementation.  
<sup>c</sup>See Table 5-7, p. 120.  
<sup>d</sup>Begin treatment with menses onset.  
COCs = combination oral contraceptive pills; DMPA = depot medroxyprogesterone acetate; GnRH = gonadotropin-releasing hormone; IM = intramuscularly; LNG-IUS = levonorgestrel-releasing intrauterine system; NETA = norethindrone acetate; NSAID = nonsteroidal antiinflammatory drug; TXA = tranexamic acid.

given 21 days each cycle; or than COCs (Irvine, 1998; Reid, 2005; Shaaban, 2011).

However, trials often evaluate HMB more generally and thus several AUB etiologies, in addition to AUB-E, are bundled. For HMB, Gupta and coworkers (2013) noted higher associated quality-of-life scores with LNG-IUS compared with several traditional oral medical options. If compared with endometrial ablation, the LNG-IUS appears to have similar therapeutic effects for HMB up to 2 years after treatment (Kaunitz, 2009). Last, one randomized trial compared LNG-IUS or hysterectomy for HMB and reported equal improvements in health status and quality of life at 1 year and again after 5 years (Hurskainen, 2001, 2004). However, by 5 years, 42 percent of those assigned to the LNG-IUS eventually underwent hysterectomy, and by 10 years, 46 percent (Heliövaara-Peippo, 2013). To summarize its efficacy, compared with most available options, the LNG-IUS provides equivalent or superior improvement in HMB for suitable candidates.

### ■ Combination Oral Contraceptive pills

These hormonal agents effectively treat AUB-E, and when used long term, menstrual blood loss is reduced by 40 to 70 percent (Jensen, 2011; Fraser, 1991, 2011). Advantages to COC use include the additional benefits of reducing dysmenorrhea and providing contraception. Their presumed method of action is endometrial atrophy, although diminished prostaglandin synthesis and decreased endometrial fibrinolysis are other suggested actions (Irvine, 1999).

### ■ Tranexamic acid

TXA is antifibrinolytic drug reversibly blocks lysine binding sites on plasminogen (Fig. 8-12). In women with AUB-E, fibrinolytic activity within the endometrium is increased compared with that of women with normal menses (Gleeson, 1994). Clinically, TXA has been shown to reduce bleeding in women with AUB-E by 40 to 50 percent (Bonnar, 1996; Lukes, 2010). In addition, it requires administration only during menstruation and has few minor reported side effects that are predominantly gastrointestinal and dose-dependent. The recommended dose is two 650-mg tablets orally taken three times daily for a maximum of 5 days during menses.

Although used in other parts of the world for many years, oral TXA was approved by the U.S. Food and Drug Administration (FDA) to treat HMB in 2009. Its U.S. marketed name is Lysteda. The drug has no effect on other blood coagulation parameters such as platelet count, PTT, and PT (Wellington, 2003). Contraindications to TXA include concurrent COC use, a history of or an intrinsic risk for thromboembolic disease, disseminated intravascular coagulation, and color blindness. The last relates to animal studies showing retinal changes with TXA. Associated symptoms may not be appreciated by those with preexisting color blindness.

### ■ Nonsteroidal antiinflammatory Drugs

These well-tolerated oral agents are commonly used to treat AUB-E, and rationale for their use stems from prostaglandin's suspected role in the pathogenesis of this endometrial dysfunction. Because women lose 90 percent of menstrual blood volume

during the first 3 days of menses, NSAIDs are most effective if used with menses onset or just prior to its onset and continued throughout its duration (Haynes, 1977). Thus, one advantage is that they are taken only during menstruation. Another advantage is that frequently associated dysmenorrhea also improves with NSAIDs.

Conventional NSAIDs nonspecifically inhibit both cyclooxygenase-1 (COX-1), an enzyme critical to normal platelet function, and COX-2, which mediates inflammatory response mechanisms. Thus, conventional NSAIDs such as ibuprofen and naproxen may not be ideal considering their inhibitory effects on platelet function. However, no data show an advantage with specific COX-2 inhibitors for HMB compared with conventional NSAIDs. Among conventional NSAIDs, there are no differences in clinical efficacy, but responses to a particular agent may vary among individuals.

Although NSAIDs require only temporal dosing, are cost-effective, and are well tolerated, they often are only moderately effective for AUB-E and reduce menstrual bleeding by approximately

**FIGURE 8-12** Tranexamic acid (TXA) mechanism of action. **A.** Normally, plasminogen binds with tissue plasminogen activator (tPA) to form plasmin. This binding degrades fibrin into fibrin degradation products and leads to clot lysis. **B.** TXA binds to the lysine-binding site on plasminogen. This new conformation blocks plasmin binding to fibrin. Fibrin strands are not broken, and a clot persists to slow bleeding.

25 percent (Lethaby, 2013a). Thus, if greater reductions in blood loss are needed, other agents in this section may prove more beneficial.

### ■ Other hormonal agents

In contrast to AUB-O, AUB-E is relatively unresponsive to cyclic administration of oral progestins (Kaunitz, 2010; Preston, 1995). However, women with AUB-E may respond to longer treatment schedules. NETA, 5 mg, or MPA, 10 mg, each given orally three times daily for days 5 through 26 of each menstrual cycle have proved effective (Fraser, 1990; Irvine, 1998). Unfortunately, prolonged use of high-dose progestins is often associated with side effects such as mood changes, weight gain, bloating, headaches, and atherogenic changes in the lipid profile (Lethaby, 2008). Moreover, patients may find the dosing schedule challenging.

With GnRH agonists, the profound hypoestrogenic state created induces endometrial atrophy and amenorrhea in most women. Side effects include those typical for menopause, and thus associated bone loss precludes their long-term use. This family of drugs, however, may be helpful for short-term use by inducing amenorrhea and allowing women to rebuild their red blood cell mass. Chapter 9 (p. 208) describes available agents and their dosages.

Of androgens, danazol is a derivative of the synthetic steroid 17 $\alpha$ -ethinyl testosterone, and its net effect creates a hypoestrogenic and hyperandrogenic environment to induce endometrial atrophy. As a result, menstrual loss is reduced by approximately half, and it may even induce amenorrhea (Dockeray, 1989). For HMB, suggested dosing is 100 to 200 mg orally daily (Chimbira, 1980a). Unfortunately, this agent has significant androgenic side effects that include weight gain, oily skin, and acne. Thus, some reserve danazol as a second-line drug for short-term use prior to surgery (Bongers, 2004).

Gestrinone is derived synthetically from a 19-nortestosterone steroid nucleus. Its mechanisms of action, side effects, and indications for HMB treatment are similar to those of danazol. The recommended treatment dose is 2.5 mg orally twice weekly (Turnbull, 1990). The drug is used in the United Kingdom and other countries but is not approved for use in the United States.

### ■ Iron Therapy

Women with AUB may become anemic, and care typically is directed toward bleeding abatement and oral iron replacement. Common equivalent replacement regimens include: (1) ferrous sulfate, 325 mg tablet (contains 65 mg elemental iron) three times daily, or (2) ferrous fumarate, 200 mg tablet (contains 64 mg elemental iron) three times daily. Iron supplementation is further discussed in Chapter 39 (p. 830).

### ■ Uterine procedures

For many women, conservative medical management may be unsuccessful or associated with significant side effects. Surgical management of HMB may include procedures to destroy the endometrium or hysterectomy.

Of these, *dilatation and curettage* is rarely used for long-term treatment of AUB because its effects are temporary.

Occasionally, D & C is performed to quickly remove a thickened endometrium and arrest severe HMB refractory to high-dose estrogen administration (American College of Obstetricians and Gynecologists, 2013c). Preprocedural TVS may be prudent as D & C may be ineffective or disadvantageous for women with an already thinned endometrial stripe.

*Endometrial resection or ablation* attempts to permanently remove and destroy the uterine lining. Different types use laser, radiofrequency, electrical, or thermal energies. Methods are considered first- or second-generation techniques according to when they were introduced into use and their need for concurrent hysteroscopic guidance.

Several studies that compared first- and second-generation techniques have shown them equally effective to reduce HMB (Lethaby, 2013b). Similarly equivalent efficacy is seen among the various second-generation options, which are described in Chapter 44 (p. 1043) (Daniels, 2012). After ablation, 70 to 80 percent of women experience significantly decreased flow, and 15 to 35 percent of these develop amenorrhea (Sharp, 2006). Increasing treatment failures due to endometrial regeneration accrue with time, and by 5 years following ablation, approximately 25 percent required additional surgery, in most cases hysterectomy (Cooper, 2011). However, the risk of reoperation following resection and ablation procedures is balanced by their significantly lower complication rates compared with hysterectomy.

After ablation, uterine cavity anatomy is often distorted by uterine wall agglutination and intracavitary scar bands, termed synechiae. This may pose several long-term problems. First, focal hematometra or postablation tubal sterilization syndrome (PATSS) can form from menstrual blood trapped behind synechiae. It can cause severe distention and cyclic pain (Chap. 44, p. 1043). Second, because of distorted anatomy, 33 percent of endometrial sampling attempts may be inadequate, and endometrial stripe evaluation by TVS or hysteroscopic examination may be limited (Ahonkallio, 2009). Accordingly, endometrial ablation is not routinely recommended for patients at high risk for endometrial cancer (American College of Obstetricians and Gynecologists, 2013a). Other contraindications are listed in [Table 8-5](#).

*Uterine artery embolization (UAE)* is more commonly used to treat HMB secondary to uterine leiomyomas and is described in

**Table 8-5.** Contraindications for Endometrial Ablation

Pregnancy
Acute pelvic infection
Endometrial hyperplasia or genital tract cancer
Women at high risk for endometrial cancer <sup>a</sup>
Women wishing to preserve their fertility
Postmenopausal women
Expectation of amenorrhea
Large or distorted endometrial cavity <sup>b</sup>
Intrauterine device in place
Prior uterine surgery—classical cesarean delivery, transmural myomectomy

<sup>a</sup>Risks include obesity, chronic anovulation, tamoxifen use, unopposed estrogen use, and diabetes mellitus.

<sup>b</sup>Each device has specific cavity-size limitations.

Chapter 9 (p. 209). Rarely, this intervention may be considered emergently in women with excessive acute HMB who are not responding to conservative measures, especially those who refuse blood products or who have coagulopathic disorders. However, with the latter, coagulopathy that is severe may preclude safe femoral artery cannulation, which is requisite for UAE.

*Hysterectomy*, despite the above measures, ultimately is chosen by more than half of women with HMB within 5 years of their referral to a gynecologist. In at least a third of these, an anatomically normal uterus is removed (Coulter, 1991). Removal of the uterus is the most effective treatment for bleeding, and overall patient satisfaction rates are high. Disadvantages to hysterectomy include more frequent and severe intraoperative and postoperative complications compared with either conservative medical or ablative surgical procedures. Operating time, hospitalization, recovery times, and costs are also greater. The procedure and its complications are discussed in detail in Section 43-12 (p. 950).

REFERENCES..... 225

Pelvic masses are common and may involve reproductive organs or nongynecologic structures. Affected women can be symptom-free or may complain of pain, pressure, dysmenorrhea, infertility, or uterine bleeding. Treatment varies with patient age and therapeutic goals. Medical management is possible for many with pelvic masses, but for others, procedural interventions offer highest success rates.

DEMOGRAPHIC FACTORS

Of associated factors, pelvic mass rates and underlying pathology change with age. In prepubertal girls, most gynecologic pelvic masses involve the ovary. Even before puberty, ovaries are active, and masses are often functional, rather than neoplastic, cysts (de Silva, 2004). Of neoplastic lesions, most are benign germ cell tumors, especially mature cystic teratomas (dermoid cysts) (Brown, 1993). Malignant ovarian tumors in children and adolescents are rare, and this age group accounts for only 1.2 percent of all ovarian cancers (National Cancer Institute, 2014). Most cancers are germ cell tumors, and among children and adolescents, rates increase with age (American Cancer Society, 2014).

In adolescents, the incidence and type of ovarian pathology in general mirrors that of prepubertal girls. However, with the onset of reproductive function, pelvic masses in adolescence may also include endometriomas and the sequelae of pelvic inflammatory disease (PID) and pregnancy.

In adult women, the differential diagnosis for a pelvic mass expands. Uterine enlargement due to pregnancy, functional ovarian cysts, and leiomyoma are among the most common. Endometrioma, mature cystic teratoma, acute or chronic tubo-ovarian abscess (TOA), and ectopic pregnancies are other frequent causes. Most pelvic masses in this age group are benign, but malignancy rates increase with age.

In postmenopausal women, with cessation of reproductive function, the causes of pelvic mass also change. Simple ovarian cysts and leiomyomas are still frequent. Menopause typically results in leiomyoma atrophy, but some uterine bulk may still persist. Importantly, malignancy is a more frequent cause in this demographic group. Ovarian cancer accounts for nearly 3 percent of new cancers among all women (American Cancer Society, 2014). Uterine tumors, including adenocarcinoma and sarcoma, can enlarge the uterus.

LEIOMYOMAS

Uterine enlargement most frequently reflects pregnancy or leiomyomas. Less often, enlargement is from adenomyosis, hematometra, an adhered adnexal mass, or malignancy. Of these, leiomyomas are benign smooth muscle neoplasms that typically originate from the myometrium. They are often referred to as *uterine myomas*, and they are colloquially called *fibroids*. Their incidence among women is generally cited as 20 to 25 percent, but is as high as 70 to 80 percent in studies using histologic or sonographic examination (Baird, 2003; Cramer, 1990). The health care consequences of these tumors are substantial. From 1998 to 2005, 27 percent of inpatient gynecologic admissions were for uterine leiomyoma care (Whiteman, 2010).

■ Pathophysiology

Pathology

Grossly, leiomyomas are round, rubbery tumors that when bisected display a whorled pattern. They possess a distinct autonomy from their surrounding myometrium because of a thin, outer connective tissue layer (Fig. 9-1). This clinically important cleavage plane allows leiomyomas to be easily “shelled” from the uterus during surgery. Histologically, leiomyomas contain elongated smooth-muscle cells aggregated in dense bundles. Mitotic activity, however, is rare and is a key point in differentiation from malignant leiomyosarcoma.

The typical appearance of leiomyomas may change if smooth muscle is replaced with various degenerative substances

**FIGURE 9-1** The appearance of leiomyomas will vary depending on the degree and type of degeneration present. **A.** In this bisected uterine fundus, a typical off-white, whorled leiomyoma lies distinct from the surrounding myometrium. **B.** Microscopically, leiomyomas (L) are composed of bland, spindled smooth-muscle cells characterized by elongate, blunt-ended nuclei and tapered eosinophilic cytoplasm. The cells are arranged in interlacing fascicles that intersect at right angles. Leiomyomas are usually well-circumscribed, and the interface (asterisk) between the myoma and adjacent myometrium can be seen grossly and microscopically. These tumors are usually more cellular than the surrounding myometrium (M). (Used with permission from Dr. Kelley Carrick.)

following necrosis. This process is collectively termed *degeneration*, and the replacement substances dictate the naming of these degenerative types. Forms include hyaline, calcific, cystic, myxoid, red, and fatty, and these gross changes should be recognized as normal variants. Necrosis and degeneration develop frequently in leiomyomas because of the tenuous blood supply within these tumors. Leiomyomas have a lower arterial density compared with the surrounding normal myometrium. Moreover, their lack of vascular organization leaves some tumors vulnerable to hypoperfusion and ischemia (Forssman, 1976). As discussed later, acute pain may accompany degeneration.

## Pathogenesis

Each leiomyoma is derived from a single progenitor myocyte. Thus, multiple tumors within the same uterus each show independent cytogenetic origins (Townsend, 1970). Several unique defects involving chromosomes 6, 7, 12, and 14 and others correlate with rates and direction of tumor growth (Brosens, 1998). Of specific gene mutations, those involving *MED12* and *HMG42* genes, and less commonly *COL4A5-A6* or *FH* genes, account for most leiomyomas (Mehine, 2014). Of these, fumarate hydratase (*FH*) gene mutations are rare but lead to the *hereditary leiomyomatosis and renal cell cancer (HLRCC) syndrome*. This is characterized by cutaneous and uterine leiomyomas and renal cell cancer (Mann, 2015). Future determination of each mutation's role in leiomyoma formation is anticipated to aid treatment development.

Following their genesis, uterine leiomyomas are estrogen and progesterone sensitive tumors. Consequently, they develop during the reproductive years. After menopause, leiomyomas generally shrink, and new tumor development is infrequent. These sex steroid hormones likely mediate their effect by stimulating or inhibiting transcription or cellular growth-factor production.

Leiomyomas themselves create a hyperestrogenic environment, which appears requisite for their growth and maintenance. First, compared with normal myometrium, leiomyoma cells contain a greater density of estrogen receptors, which results in greater estradiol binding. Secondly, these tumors convert less estradiol to the weaker estrone (Englund, 1998; Otubu, 1982; Yamamoto, 1993). A third mechanism involves higher levels of cytochrome P450 aromatase in leiomyomas compared with normal myocytes (Bulun, 1994). This specific enzyme catalyzes the conversion of androgens to estrogen (Chap. 15, p. 337).

Some conditions also provide sustained estrogen exposure that encourages leiomyoma formation. For example, the increased years of persistent estrogen production found with early menarche and with an increased body mass index (BMI) are each linked with a greater leiomyoma risk (Velez Edwards, 2013; Wise, 2005). Obese women produce more estrogens from increased conversion of androgens to estrogen in adipose tissue by aromatase. They also display decreased hepatic production of sex hormone binding globulin (Glass, 1989). Women with polycystic ovarian syndrome (PCOS) have a higher risk of myoma formation, which may stem from the sustained estrogen exposure that accompanies chronic anovulation (Wise, 2007).

Of other factors, estrogen and progesterone hormone treatment in premenopausal women probably has no significant inductive effect on leiomyoma formation. With few exceptions, combination oral contraceptive (COC) pills either lower or have no effect on this risk (Chiaffarino, 1999; Parazzini, 1992).

Smoking alters estrogen metabolism and lowers physiologically active serum estrogen levels (Soldin, 2011). This may explain why women who smoke generally have a lower risk for leiomyoma formation.

As with estrogen, leiomyomas carry a higher progesterone receptor density compared with their surrounding myometrium. Progesterone is considered the critical mitogen for uterine leiomyoma growth and development, and estrogen functions to upregulate and maintain progesterone receptors (Ishikawa, 2010). Thus, cell proliferation, extracellular matrix

accumulation, and cell hypertrophy, which all lead to leiomyoma growth, are controlled by progesterone directly and in a permissive role by estrogen.

This relationship is supported by evidence that the anti-progestins mifepristone and ulipristal induce atrophy in most leiomyomas (Donnez, 2012a; Murphy, 1993). Moreover, in women treated with gonadotropin-releasing hormone (GnRH) agonists, leiomyomas typically decrease in size. However, if progestins are given simultaneously with GnRH agents, there is typically *increased* leiomyoma growth (Carr, 1993).

Clinically, this relationship may be important when prescribing sex steroid hormones. In postmenopausal women, hormone replacement therapy (HRT) has either a stimulatory or no effect on growth (Polatti, 2000; Reed, 2004). Palomba and associates (2002) found that higher doses of medroxyprogesterone acetate (MPA) were associated with leiomyoma growth and recommended using the lowest possible dose of MPA in these patients.

Of other factors associated with myoma development, race and age are notable risks. Myomas are rare in adolescence but increase with age during the reproductive years. In a study by Baird and coworkers (2003), the cumulative incidence by age 50 years was nearly 70 percent in whites and more than 80 percent in African-American women. Lower rates of leiomyomas are linked with pregnancy. Those who have higher parity, have had a more recent pregnancy, and have breastfed all display lower incidences of myoma formation (Terry, 2010). Leiomyomas are more common in African-American women compared with white, Asian, or Hispanic women. Thus, as noted earlier, heredity and specifically gene mutations play a seminal role in myoma development.

### ■ Uterine Leiomyoma Classification

These tumors are classified based on their location and direction of growth (Fig. 9-2). *Subserosal leiomyomas* originate from myocytes adjacent to the uterine serosa, and their growth is directed outward. When these are attached only by a stalk to

**FIGURE 9-2** Leiomyomas can be categorized as shown. However, the borders of most leiomyomas overlap these distinct regions.

their progenitor myometrium, they are called *pedunculated leiomyomas*. *Parasitic leiomyomas* are subserosal variants that attach themselves to nearby pelvic structures from which they derive vascular support. These myomas then may or may not detach from the parent myometrium. *Intramural leiomyomas* are those with growth centered within the uterine walls. Finally, *submucous leiomyomas* are proximate to the endometrium and grow toward and bulge into the endometrial cavity. For endoscopic resection evaluation, submucous leiomyomas are further classified by their depth of involvement. The European Society of Hysteroscopy and the International Federation of Gynecology and Obstetrics (FIGO) defines leiomyomas as: type 0, if the mass is located entirely within the uterine cavity; type 1, if less than 50 percent is located within the myometrium; and type 2, if greater than 50 percent of the mass is surrounded by myometrium (Wamsteker, 1993). To aid abnormal uterine bleeding research, this numerical classification was expanded by FIGO to similarly assign subclassifying numbers to intramural, subserosal, and parasitic leiomyomas (Munro, 2011).

Of tumors outside the uterine corpus, only about 0.4 percent develop in the cervix (Tiltman, 1998). Leiomyomas have also been found infrequently in the ovary, fallopian tube, broad ligament, vagina, and vulva.

### Leiomyomatosis

Extrauterine smooth-muscle tumors, which are benign yet infiltrative, may develop in women with concurrent or prior uterine leiomyomas, and this condition is termed leiomyomatosis. In such cases, malignant metastases from a leiomyosarcoma must be excluded.

*Intravenous leiomyomatosis* invades and extends serpiginously into the uterine veins, other pelvic veins, vena cava, and even cardiac chambers. As such, this rare tumor may lead to classic leiomyoma complaints or to uncharacteristic ones such as right-sided congestive cardiac symptoms. Tumors are usually amenable to resection. Although these are histologically benign, recurrence rates may reach 28 percent (Wang, 2012).

*Benign metastasizing leiomyomas* derive from morphologically benign uterine leiomyomas that disseminate hematogenously. Lesions have been found most often in the lungs, and less so in lymph nodes, bone, brain, and heart. Classically, these are found in women who have a recent or distant history of pelvic surgery.

*Disseminated peritoneal leiomyomatosis (DPL)* is benign and appears as multiple small peritoneal nodules on abdominal cavity or abdominal organs surfaces. As such, DPL intraoperatively and radiologically looks like widespread peritoneal metastatic malignancy. DPL is usually found in women of reproductive age, and 70 percent are associated with pregnancy or COC use (Bisceglia, 2014).

Last, with the increased use of electromechanical morcellation during minimally invasive myomectomy or hysterectomy, multiple small peritoneal leiomyomas may be found later after the primary surgery. Secondary implantation of myoma remnants is implicated, and these present similarly to parasitic leiomyomas or DPL (Kho, 2009). A full discussion of this topic is found in Chapter 41 (p. 896).

Treatments for all these benign conditions may involve hysterectomy with oophorectomy, tumor debulking, and agents

that lower estrogen and/or progestin levels. Pharmaceutical choices include GnRH agonists, aromatase inhibitors, selective estrogen-receptor modulators, or antiprogestins (Lewis, 2013; Taveira-DaSilva, 2014).

## ■ Symptoms

### Bleeding

Most women with leiomyomas are asymptomatic. However, affected women may complain of bleeding, pain, pressure, or infertility. In general, symptom risk increases with myoma size and number. Bleeding is common, especially heavy menstrual bleeding (HMB), and dilated endometrial venules are implicated. Dysregulation of local vasoactive growth factors is thought to promote this vasodilatation. When engorged venules are disrupted at the time of menstrual sloughing, bleeding from these markedly dilated vessels overwhelms the usual hemostatic mechanisms (Stewart, 1996). For this reason, subserosal, intramural, and submucous tumors all have a propensity to cause HMB (Wegienka, 2003).

### Pressure and Pain

A sufficiently enlarged uterus can cause chronic pressure, urinary frequency, incontinence, or constipation. Rarely, leiomyomas extend laterally to compress a ureter and lead to obstruction and hydronephrosis. Aside from pressure, patient may also note dysmenorrhea, dyspareunia, or noncyclical pelvic pain (Lippman, 2003; Moshesh, 2014).

Acute pelvic pain is a less frequent complaint but is most often seen with a degenerating or prolapsing leiomyoma. Rare tumor complications include torsion of a subserosal pedunculated leiomyoma, acute urinary retention, or deep-vein thromboembolism (Gupta, 2009). With leiomyoma degeneration, tissue necrosis classically causes acute pain, fever, and leukocytosis. This constellation mimics other acute pelvic pain sources. Thus, sonography is typically performed to help identify a cause, and usually a nondescript leiomyoma is found. Computed tomography (CT) may also be obtained, especially if clear interpretation of pelvic anatomy is obscured by multiple large leiomyomas or if appendicitis, nephrolithiasis, diverticulitis, or others are considered. Treatment of myoma degeneration is nonsurgical and includes analgesics and antipyretics as needed. However, broad-spectrum antibiotics are often administered, as differentiating between leiomyoma degeneration and acute endomyometritis can be difficult. In most cases, symptoms improve within 24 to 48 hours. Pain stemming from tumor degeneration classically follows uterine artery embolization (UAE), and treatment with analgesics usually suffices as discussed on page 209.

Women with prolapse of a tumor from the endometrial cavity will typically note cramping or acute pain as the tumor stretches the endocervical canal to pass through. Associated bleeding or serosanguinous discharge is common. Visual inspection is usually diagnostic (Fig. 9-3). However, sonography is often performed to evaluate the size and number of other uterine leiomyomas and exclude other possible sources of pain. Surgical treatment involves severing the leiomyoma from its stalk as described in detail in Section 43-11 (p. 948).

**FIGURE 9-3** This round, hyperemic leiomyoma and its elongated stalk have prolapsed from the uterine cavity, through the cervix, and into the vagina. (Used with permission from Dr. David Rogers.)

### Infertility and Pregnancy Wastage

Leiomyomas can diminish fertility, but only 1 to 3 percent of infertility cases are due solely to leiomyomas (Buttram, 1981; Donnez, 2002). Their putative effects include occlusion of tubal ostia and disruption of the normal uterine contractions that propel sperm or ova. Distortion of the endometrial cavity may diminish implantation and sperm transport. Importantly, leiomyomas are associated with endometrial inflammation and vascular changes that may disrupt implantation (American Society for Reproductive Medicine, 2008).

Of myomas, subfertility is more closely associated with submucous leiomyomas than with tumors located elsewhere. Improved pregnancy rates following hysteroscopic resection have provided most of the indirect evidence for this link (Casini, 2006; Surrey, 2005). In contrast, evidence does not implicate subserosal tumors. For intramural leiomyomas that do not distort the endometrial cavity, the relationship with subfertility is more tenuous. Several investigators have reported equally good in vitro fertilization (IVF) success rates in women with and without leiomyomas that did not distort the endometrial cavity (Oliveira, 2004; Yan, 2014). Others, however, have reported adverse fertility effects from such intramural leiomyomas (Eldar-Geva, 1998; Hart, 2001). Importantly, the strength of this evidence must be weighed against the morbidity associated with myomectomy. Namely, peritubal or intrauterine adhesions can threaten fertility, and myometrial defects risk uterine rupture during subsequent pregnancies.

Both uterine leiomyoma and spontaneous miscarriage are common, and an association between these has not been shown convincingly. Moreover, there is no conclusive evidence that surgical treatment reduces miscarriage rates (American Society for Reproductive Medicine, 2012b; Pritts, 2009).

### Other Clinical Manifestations

Less than 0.5 percent of women with leiomyomas develop *myomatous erythrocytosis syndrome*. This may result from excessive erythropoietin production by the kidneys or by the leiomyomas

themselves (Vlasveld, 2008). In either case, red cell mass returns to normal following hysterectomy.

Leiomyomas occasionally may cause *pseudo-Meigs syndrome*. Traditionally, Meigs syndrome consists of ascites and pleural effusions that accompany a benign ovarian fibroma. However, any pelvic tumor including large, cystic leiomyomas or other benign ovarian cysts can cause this. The presumed etiology stems from discordancy between the arterial supply and the venous and lymphatic drainage from the leiomyomas. If due to myomas, resolution of ascites and hydrothorax follows hysterectomy or myomectomy.

## ■ Diagnosis

Leiomyomas are often detected by pelvic examination with findings of uterine enlargement, irregular contour, or both. In reproductive-aged women, uterine enlargement prompts determination of a urine or serum  $\beta$ -human chorionic gonadotropin (hCG) level. Sonography is initially done to define pelvic anatomy. Transvaginal sonography (TVS) provides superior resolution, but some uteri are so large that transabdominal sonography is needed to image the entire corpus. The sonographic appearances of leiomyomas vary from hypo- to hyperechoic depending on the ratio of smooth muscle to connective tissue and whether there is degeneration (Fig. 9-4). Calcification and cystic degeneration create the most sonographically distinctive changes. Calcifications appear hyperechoic and commonly rim the tumor or are randomly scattered throughout the mass. Cystic or myxoid degeneration typically fills the leiomyoma with multiple, smooth-walled, round, irregularly sized but generally small hypoechoic or anechoic areas.

If HMB, dysmenorrhea, or infertility accompanies a pelvic mass, then the endometrial cavity is evaluated for submucous leiomyomas, endometrial polyps, congenital anomalies, or synechiae. With focal lesions such as submucous leiomyomas, the endometrium appears thick or irregular during TVS, and adjunct imaging tools may help clarify anatomy. Of these, saline infusion sonography (SIS) or hysteroscopy may provide additional cavity information (Figs. 9-5 and 9-6), and their

**FIGURE 9-5** Submucous fibroid is clearly outlined during saline infusion sonography (SIS) (arrowheads). The SIS catheter balloon is seen in the lower uterine cavity (B). (Used with permission from Dr. Elysia Moschos.)

advantages are described in Chapters 2 and 8. Also, three-dimensional (3-D) TVS and 3-D SIS can be valuable (Fig. 9-7). Leiomyomas have characteristic vascular patterns that can be identified by color and power Doppler techniques. A peripheral circumferential rim of vascularity from which a few vessels arise to penetrate into the center of the tumor is a classic finding. As such, Doppler imaging can be used to help differentiate an extrauterine leiomyoma from another pelvic mass or a submucous leiomyoma from an endometrial polyp. For the infertile woman, the endometrial cavity can be evaluated with hysterosalpingography (HSG) or hysterosalpingo-contrast sonography HyCoSy (Chap. 2, p. 25). This offers the advantage to also define tubal patency.

When imaging is limited by body habitus or distorted anatomy, magnetic resonance (MR) imaging may be required. Although used less often for myoma evaluation, this tool allows more accurate assessment of the size, number, and location of

**FIGURE 9-4** Transvaginal sonogram of an intramural leiomyoma. (Used with permission from Dr. Elysia Moschos.)

**FIGURE 9-6** Hysteroscopic photograph of a submucous leiomyoma prior to resection. (Used with permission from Dr. Karen Bradshaw.)

leiomyomas in greater amounts than PR-B (Viville, 1997). Specific agents can competitively bind these receptors. Agents are classified as antiprogestins if they universally prompt antagonist effects. However, agents are termed selective progesterone-receptor modulators (SPRMs) if they exert antiprogestational effects in some tissues but progestational effects in others.

Of antiprogestins, mifepristone, also known as RU-486, diminishes leiomyoma volume by approximately half. Various doses have been used and range from 2.5 to 10 mg given orally daily for 3 to 6 months (Carbonell Esteve, 2008, 2012). Mifepristone therapy, however, has several drawbacks. First, approximately 40 percent of treated women complain of vasomotor symptoms. Second, its antiprogestational effects expose the endometrium to unopposed estrogen. The spectrum of endometrial findings range from simple endometrial hyperplasia to a newer category described as *progesterone-receptor modulator-associated endometrial changes* (Mutter, 2008). The concern for endometrial stimulation currently limits mifepristone's use to 3 to 6 months. As a final concern, mifepristone (Mifeprex) is currently Food and Drug Administration (FDA)-approved solely for early pregnancy termination. It is manufactured only as 200-mg tablets, a dose well above that needed for leiomyoma therapy.

Ulipristal acetate is a SPRM that has similar effects to mifepristone. Currently marketed outside the United States, ulipristal acetate (Esmya), given as 5- or 10-mg oral daily doses, controls leiomyoma-related bleeding in 90 percent of patients. It performs comparably with leuprolide acetate (Donnez, 2012a,b). Again, endometrial concerns currently limit its use solely to that of a preoperative adjunct. Other SPRMs are also under investigation, but none are currently commercially available for leiomyoma treatment.

Other sex steroid hormone options include the androgens, danazol and gestrinone, which shrink leiomyoma volume and improve bleeding symptoms (Coutinho, 1989; De Leo, 1999). Unfortunately, their prominent side effects, which include acne and hirsutism, preclude their use as first-line agents.

### GnRH Receptor Agents

These compounds are synthetic derivatives of the GnRH decapeptide. They are inactive if taken orally, but intramuscular (IM), subcutaneous, and intranasal preparations are available. Leuprolide acetate (Lupron) is FDA-approved for leiomyoma treatment and is available in a 3.75-mg monthly dose or 11.25-mg 3-month dose, both given IM. Less frequently used GnRH agonists include goserelin (Zoladex), administered as a 3.6-mg monthly or 10.8-mg 3-month subcutaneous depot implant; triptorelin (Trelstar), given as a 3.75-mg monthly or 11.25-mg 3-month IM injection; and nafarelin (Synarel), used in a 200- $\mu$ g twice-daily nasal spray regimen. These latter three are not specifically FDA-approved for leiomyoma treatment, but their off-label use has been shown effective.

GnRH agonists shrink leiomyomas by targeting the growth effects of estrogen and progesterone. Initially, these agonists stimulate receptors on pituitary gonadotropes to cause a supra-physiological release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Also called a *flare*, this phase typically lasts 1 week. With their long-term action, however,

agonists downregulate receptors in gonadotropes, thus creating desensitization to further GnRH stimulation. Correspondingly, decreased gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration (Broekmans, 1996).

Results with GnRH agonist treatment include dramatic decreases in uterine and leiomyoma volume. Most women experience a mean decrease in uterine volume of 40 to 50 percent, and most of this occurs during the first 3 months of therapy. Clinical benefits of reduced leiomyoma volumes include pain relief and diminished HMB, usually amenorrhea. During this time, anemic women are given oral iron therapy to rebuild red cell mass and increase iron stores (Filicori, 1983). GnRH agonist treatment typically is continued for 3 to 6 months. Following their discontinuance, normal menses resume in 4 to 10 weeks. Unfortunately, leiomyoma then regrow, and uterine volumes regain pretreatment sizes within 3 to 4 months (Friedman, 1990). Despite regrowth, Schlaff and coworkers (1989) reported symptom relief for approximately 1 year in half of women given GnRH agonists.

GnRH agonists have significant costs, risks, and side effects. Side effects result from the profound drop in serum estrogen levels, mirror those of menopause, and develop in up to 95 percent of women treated with these drugs (Letterie, 1989). Despite this, less than 10 percent of patients terminate treatment secondary to side effects (Parker, 2007). Importantly, 6 months of agonist therapy can result in a 6-percent loss in trabecular bone, not all of which may be recouped following discontinuation (Scharla, 1990). As a result, these agents alone are not recommended for longer than 6 months of use.

To obviate side effect severity, several medications have been added to GnRH agonist treatment. The goal of this “add-back therapy” is to counter side effects—most importantly vasomotor symptoms and bone loss—without mitigating the shrinking action on uterine and leiomyoma volume. This is made possible by the fact that the estrogen level required to improve vasomotor symptoms and minimize bone loss is below the estrogen threshold that would restimulate leiomyomas growth. Mizutani and associates (1998) found that GnRH agonists suppress leiomyoma cell proliferation and induce cell apoptosis at the fourth week of GnRH agonist therapy. They proposed that add-back therapy be withheld until after this time. Because of these and other observations, add-back therapy is typically begun 1 to 3 months following GnRH agonist initiation.

Add-back therapy traditionally includes estrogen combined with a progestin, and those studied have generally been low-dose preparations equivalent to menopausal HRT. An oral regimen of MPA, 10 mg (days 16–25), combined with equine estrogen, 0.3 to 0.625 mg (days 1–25), or a continuous daily regimen of MPA 2.5 mg and equine estrogen 0.3 mg to 0.625 mg may be used.

Add-back therapy with selective estrogen-receptor modulators (SERMs), such as tibolone and raloxifene, has also been shown to prevent bone loss. Advantages of SERMs include the ability to begin them concurrently with GnRH agonist treatment without negating the agonist effects of leiomyoma shrinkage. Unfortunately, a high percentage of women complain of vasomotor symptoms while taking SERMs (Palomba, 1998,

2004). Raloxifene is associated with greater venous thromboembolism risks (Goldstein, 2009).

Because of the limitations of GnRH agonist therapy, the American College of Obstetricians and Gynecologists (2014a) recommends that it not be used longer than 6 months without add-back therapy. Short-term, preoperative GnRH agonist use offers several advantages. Their use decreases HMB and may allow correction of anemia. Decreased uterine size as a result of treatment may allow a less complicated or extensive surgical procedure. For example, hysterectomy or myomectomy may be performed through a smaller laparotomy incision or by vaginal or minimally invasive surgery (MIS) approaches. This advantage may be less robust for GnRH agonist use prior to hysteroscopic myomectomy and is discussed in that section of the atlas (p. 1040).

In contrast to agonists, *GnRH antagonists* are available. Two agents in this class, cetrorelix and ganirelix, are currently FDA-approved for infertility use in women undergoing controlled ovarian hyperstimulation. However, a limitation of these drugs is that they are daily injectables. Also, a depot form of cetrorelix did not provide adequate or consistent suppression of estrogen production or leiomyoma growth (Felberbaum, 1998). A new agent, elagolix, is a nonpeptide oral GnRH antagonist that is currently being evaluated for both endometriosis and leiomyoma treatment (Diamond, 2014).

### Nonhormonal Options

Tranexamic acid (TXA) is an antifibrinolytic agent described fully in Chapter 8 (p. 196). Studies have not evaluated TXA specifically for myoma-related HMB, but subgroup analysis does provide some support for its use for myoma-related bleeding (Eder, 2013).

The benefits of NSAIDs for leiomyoma-related bleeding are less clear, and the few studies have conflicting results (Anteby, 1985; Mäkräinen, 1986; Ylikorkala, 1986). Thus, although NSAIDs are potentially helpful for myoma-related dysmenorrhea, available data do not support their use as sole agents for leiomyoma-related HMB.

Because aromatase levels are higher with myomas, aromatase inhibitors (AIs) for leiomyoma treatment seem logical. However, only a few small studies have evaluated short-term use of the oral nonsteroid AIs, letrozole and anastrozole (Parsanezhad, 2010; Varelas, 2007). As with GnRH agonists, the induced profound systemic hypoestrogenism leads to menopausal symptoms and potential bone loss. Moreover, their use is associated with increased FSH release, which could cause multiple follicular cyst formation. Larger prospective studies are needed to define their clinical role.

### Radiologic Interventions

**Uterine Artery Embolization.** This is an angiographic interventional procedure that delivers polyvinyl alcohol microspheres or other synthetic particulate emboli into both uterine arteries. Uterine blood flow is thereby obstructed, producing ischemia and necrosis. Because vessels serving leiomyomas have a larger caliber, these microspheres are preferentially directed to the tumors, sparing the surrounding myometrium.

During UAE, an angiographic catheter is placed in one femoral artery and advanced under fluoroscopic guidance to

**FIGURE 9-8** Diagram of uterine artery embolization (UAE).

sequentially catheterize both uterine arteries (Figs. 9-8 and 9-9). Failure to embolize both uterine arteries allows existing collateral circulation between the two uterine arteries to sustain leiomyoma blood flow and is associated with a significantly lower success rates (Bratby, 2008).

UAE is a management option for women with documented uterine leiomyomas who have significant symptoms despite medical management and who might otherwise be considered a candidate for hysterectomy or myomectomy. Based on current evidence and discussed later, women who have not completed childbearing may be better served by myomectomy (Gupta, 2012; Mara, 2008). Other patient limitations are listed in Table 9-2, and many are associated with altered vascular anatomy. This is a reason why GnRH agonists are not recommended prior to UAE. In addition, pedunculated submucous tumors are not suitable as these tumors can infarct and slough. Pedunculated subserosal tumors were previously excluded for similar reasons. But based on additional data, the Society of Interventional Radiology removed this caveat (Dariushnia, 2014).

Prior to UAE, a woman undergoes a thorough evaluation by her gynecologist. Components include current cervical cancer screening and negative testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Endometrial biopsy is completed in those with endometrial cancer risk factors (Chap. 8, p. 184). Complete blood count, creatinine level, prothrombin time (PT), and partial thromboplastin time (PTT) are also obtained.

Following UAE, pain management typically requires a 24- to 48-hour hospital admission. After discharge, most patients have pain controlled with NSAIDs and have a rapid return to daily activities. However, as a result of leiomyoma necrosis, approximately 10 percent of patients develop significant postprocedural symptoms and require hospital readmission (Hehenkamp, 2005, 2006). The *postembolization syndrome*, seen in approximately 25 percent of cases, usually lasts 2 to 7 days and is classically marked by pelvic pain, nausea, low-grade fever, mild white blood cell count elevation, and malaise (Edwards, 2007). Symptom intensity varies, and management

**FIGURE 9-9** Fluoroscopic images obtained during uterine artery embolization (UAE). **A.** Before embolization, the leiomyoma can be identified by its numerous, hypertrophied, tortuous arteries wrapping around its periphery and extending within it. **B.** After embolization, most of the blood vessels are occluded by particles and appear truncated. Leiomyomas are again easily visualized and appear dark and smudged as the contrast/particle mixture stagnates within the tumor. (Used with permission from Dr. Samuel C. Chao.)

includes supportive care and analgesia. Because symptoms stem from myoma necrosis, antibiotics are not typically required but may be administered if infectious endomyometritis is an alternative diagnosis.

Embolization is effective for leiomyoma-related symptoms. Several randomized controlled trials have shown high rates of patient satisfaction and symptom improvement (Edwards, 2007; Hehenkamp, 2008). Compared with hysterectomy, UAE is associated with shorter hospitalization, reduced 24-hour pain scores, and earlier return to daily activities. UAE also compares favorably with myomectomy for symptom relief (Goodwin, 2006; Manyonda, 2012). However, some patients do not

achieve adequate improvement. Namely, long-term surveillance reveals that approximately 26 to 37 percent of UAE-treated patients will require a subsequent procedure, which in many cases is hysterectomy (Moss, 2011; Van der Kooij, 2010).

There are several complications associated with UAE. Leiomyoma tissue passage is common and likely is seen only with leiomyomas that initially have contact with the endometrial surface. Necrotic leiomyomas that pass into the vagina usually can be removed in the office. Those that do not pass spontaneously from the uterine cavity or that remain firmly attached to the uterine wall may require dilatation and evacuation (Spies, 2002). Groin hematoma and prolonged vaginal discharge are other frequent complications. Brief amenorrhea and associated transiently elevated FSH levels may last a few menstrual cycles after UAE. Permanent amenorrhea, however, develops occasionally, and more often in older reproductive-aged patients (Hehenkamp, 2007). This complication likely results from concurrent embolization of the ovaries via anastomoses between the uterine and ovarian arteries. Rarely, embolization may incite necrosis in surrounding tissues such as the uterus, adnexa, bladder, and soft tissues.

Pregnancy subsequent to UAE can pose complications. Although the number of evaluable pregnancies is small, consistent problems include increased rates of miscarriage, postpartum hemorrhage, and cesarean delivery (Homer, 2010). Other complications, noted by some but not all studies, are higher rates of preterm delivery, fetal malpresentation, fetal growth restriction, and abnormal placentation (Goldberg, 2004; Pron, 2005; Walker, 2006).

In sum, UAE has typically low major complication rates and high symptom-relief scores. However, these are balanced against the need for ultimate reintervention in a significant number of women.

**Magnetic Resonance-guided Focused Ultrasound (MRgFUS).** This is also called MR-guided high intensity focused ultrasound (MR-HIFU). With this FDA-approved

**TABLE 9-2.** UAE Absolute and Relative Contraindications

Absolute	
Pregnancy	
Active uterine or adnexal infection	
Suspected reproductive tract malignancy <sup>a</sup>	
Relative	Reason
Coagulopathy	Bleeding complications
Renal impairment	Renal effects of contrast
Severe contrast allergy	Allergic reaction
Desire for future fertility	Pregnancy complications
Uterine size > 20–24 weeks	Difficult to embolize
Prior salpingectomy or SO	Altered arterial anatomy
Prior pelvic radiation	Altered arterial anatomy
Large hydrosalpinx	Increased infection risk
GnRH agonist use	Narrows vascularity

<sup>a</sup>Unless performed as an adjunct to treatment.  
GnRH = gonadotropin-releasing hormone; SO = salpingo-oophorectomy; UAE = uterine artery embolization.  
Data from American College of Obstetricians and Gynecologists, 2014a; American Society for Reproductive Medicine, 2008; Dariushnia, 2014; Stokes, 2010.

**FIGURE 9-10** Diagram of magnetic resonance-guided focused ultrasound.

intervention, ultrasound energy is focused to heat and incite coagulative necrosis in selected myomas (Fig. 9-10). Concurrent MR imaging enables precise targeting and provides real-time tissue temperature feedback to limit surrounding thermal injury. During sessions lasting 2 to 3 hours, a patient lies prone within the MR imaging unit, and the bladder is continuously drained. Manufacturer contraindications are general contraindications to MR imaging, pregnancy, and energy-path obstructions such as abdominal wall scars, bowel, or foreign bodies. Other study exclusions have included future fertility desires, current pelvic infection, other uterine pathology, menopause, myoma size > 10 cm, and uterine size > 24 weeks. Also, myomas with poor perfusion characteristics, pedunculated serosal or submucous myomas, or those near vital structures increase failure rates or injury risks. Moreover, each session has limits on total myoma volume treated and on time, which may leave some myomas untreated.

Advantageously, MRgFUS is noninvasive, requires only conscious sedation, and is associated with rapid recovery and return to daily activities. In early prospective studies, MRgFUS improves quality-of-life scores and is well tolerated (Hindley, 2004). Complications have included skin burns, adjacent tissue injury, and venous thromboembolism. Notably, similar to UAE, symptoms relief wanes with time, and  $\geq 12$  months following MRgFUS, 8 to 24 percent of women seek alternative procedures for their symptoms, including hysterectomy (Machtinger, 2012; Okada, 2009). Compared with UAE in one small nonrandomized study, MRgFUS showed superior symptom improvement at 5 years (Froeling, 2013). Results from an ongoing randomized controlled trial comparing these two are awaited.

## Surgery

**Hysterectomy.** For women with persistent symptoms despite conservative therapy, surgery is necessary for many with myomas. Options include hysterectomy, myomectomy, endometrial ablation, and myolysis. Of these, hysterectomy is the definitive and most common surgery. In 2007, nearly 540,000 hysterectomies were performed, and 43 percent of cases had a diagnosis of leiomyoma (Wechter, 2011). Hysterectomy is effective for myoma symptoms, and a study of 418 women undergoing hysterectomy found satisfaction rates greater than 90 percent (Carlson, 1994). There were marked improvements

in pelvic pain, urinary symptoms, fatigue, psychological symptoms, and sexual dysfunction. However, benefits are balanced against the risks of major surgery.

Hysterectomy can be performed vaginally, abdominally, or laparoscopically depending on patient and uterine factors. With hysterectomy, removal of the ovaries may or may not be desired. Prophylactic salpingectomy to lower ovarian cancer risk is another consideration. The decision making for each is presented fully in Section 43-12 (p. 950).

**Myomectomy.** This uterus-preserving surgery excises myomas and is considered for women who desire fertility preservation or who decline hysterectomy. This can be performed hysteroscopically, laparoscopically, or via laparotomy. In general, predominantly intracavitary myomas are resected hysteroscopically, whereas subserosal or intramural myomas require laparotomy or laparoscopy for excision.

Hysteroscopic resection is an incisionless, day-surgery procedure that affords quick recovery. Resection is most effective with type 0 and type 1 tumors, and other surgical evaluation aspects are discussed in Chapter 44 (1040). For myoma-related HMB, long-term effectiveness ranges from 85 to 90 percent (Derman, 1991; Emanuel, 1999). Infertility is improved following removal, as previously described on page 205. However, despite its advantages, hysteroscopic resection is possible for only a small subset of myomas.

For women with subserosal or intramural myomas, surgeons must use a laparotomic or laparoscopic approach to enucleate tumors buried in the muscular uterine walls and then reconstruct normal anatomy. As such, surgical complexity and subsequent risks are increased. This type of myomectomy usually improves pain and bleeding. For example, HMB improves in approximately 70 to 80 percent of patients (Buttram, 1981; Olufowobi, 2004).

When selecting a surgical approach for subserosal or intramural myomas, several factors are weighed. Laparoscopic leiomyoma resection yields successful outcomes and recurrence rates comparable to those for laparotomy (Rossetti, 2001). Advantageously, shorter hospital stays and less febrile morbidity, blood loss, adhesion formation, and pain are found with laparoscopic resection compared with laparotomy (Mais, 1996; Takeuchi, 2002). However, limitations to a laparoscopic approach include myoma size, number, and location, and laparoscopic surgical skills, especially multilayer suturing of the leiomyoma beds following enucleation. In general, large intramural and multiple myomas require higher skill levels. Also, seeding the abdominal cavity with myomatous implants is a concern with intraabdominal morcellation, and tissue extraction options are described in Chapter 41 (p. 896). To overcome some of these limits, minilaparotomy techniques may be selected. However, as with larger laparotomy incisions, minilaparotomy is faster than laparoscopic myomectomy but still underperforms laparoscopy regarding patient pain scores, hospital stay, and blood loss (Alessandri, 2006; Palomba, 2007). Also, robot-assisted myomectomy has been described. In general, this offers similar MIS advantages but longer operating times. Moreover, due to poor tactile feedback from robotic instruments, myomas may be missed and lead to higher recurrence rates (Griffin, 2013).

In sum, for those considering myomectomy, hysteroscopic resection is preferred when possible. For remaining cases, abdominal approach selection varies depending on myoma characteristics and surgeon skill. That said, MIS offers decreased postoperative pain and comparable complication rates, although long-term durability data are limited.

**Myomectomy versus Hysterectomy.** In women not seeking pregnancy, risk and benefits aid the decision between myomectomy and hysterectomy. Again, for intracavitary lesions, hysteroscopic resection is preferred. For intramural or subserosal lesions, open myomectomy compared with open hysterectomy yields similar blood loss, intraoperative injuries, and febrile morbidity (Iverson, 1996; Sawin, 2000). However, if laparoscopic approaches are examined, one study showed laparoscopic myomectomy resulted in greater blood loss, higher rates of transfusion and conversion to laparotomy, but lower risks of bladder injury compared with laparoscopic hysterectomy (Odejinmi, 2015).

Moreover, with all myomectomy approaches, symptom relief may be incomplete and prompt additional interventions. Also, myomas can redevelop. Specifically, recurrence rates following myomectomy range from 40 to 50 percent (Acien, 1996; Fedele, 1995). Last, compared with hysterectomy, myomectomy leads to a greater risk for postoperative intraabdominal adhesions (Stricker, 1994).

**Endometrial Ablation.** There are several tissue-destructive modalities that cause endometrial ablation, and they are discussed in Section 44-15 (p. 1043). These techniques are effective for women with abnormal uterine bleeding from endometrial dysfunction (AUB-E). But when used as a sole technique for myoma-related bleeding, the failure rate approaches 40 percent (Goldfarb, 1999; Yin, 1998). In addition, most of these modalities have limitations regarding cavity length and degree of cavity distortion. That said, studies have shown efficacy if treating submucous myomas measuring  $\leq 3$  cm (Glasser, 2009; Sabbah, 2006; Soysal, 2001).

In other instances, ablation can be used instead as an adjunct following hysteroscopic leiomyoma resection in women with HMB. The few studies that have evaluated this have shown greater improvement in HMB following resection coupled with ablation than with resection alone (Indman, 1993; Loffer, 2005).

**Myolysis and Other Approaches.** Myolysis describes myoma puncture with tools to permit mono- or bipolar cautery, laser vaporization, or cryotherapy. All of these incite myoma necrosis and subsequent shrinkage. Of these, the Acessa system uses a monopolar radiofrequency needle that is inserted transabdominally into each myoma during laparoscopy, as illustrated in Figure 41-11 p. 885). With this newer approach, early evidence shows patient symptom improvement, and a reintervention rate of 11 percent at 3 years. However, data regarding long-term symptom relief, recurrence rates, and effects on fertility and pregnancy are lacking (Berman, 2014).

Another option is laparoscopic uterine artery occlusion (LUAO). This attempts to achieve myoma devascularization and necrosis by surgically sealing both uterine arteries near their origin from the internal iliac artery as well as both ovarian arteries (Ambat, 2009). The reintervention rate at 4 years is

28 percent, similar to UAE (Hald, 2009). For now, the requirement for advanced surgical skills, treatment failure rates, and scarce high-quality data limit this procedure's use.

## HEMATOMETRA

In this condition, menstrual outflow obstruction traps blood and distends the uterus. Depending on the level of the genital tract blockage, blood can variably distend the vagina (hematocolpos), the uterus (hematometra), and fallopian tubes (hematosalpinx). Obstruction may be congenital, and these are described in Chapter 18. Acquired abnormalities such as scarring and neoplasms may also obstruct menstrual flow. As such, hematometra may follow radiation treatment, prolonged hypoestrogenism with atrophy, or surgeries of the endometrial cavity or endocervical canal, particularly endometrial ablation and cervical conization. Other predisposing conditions are Asherman syndrome or malignancies of the uterus or cervix.

Women with hematometra classically complain of cyclic, midline pain. Low back pain and pelvic fullness can also be noted, and with total obstruction, there is amenorrhea. If significant, a large uterus can even compress the bladder or rectum and yield urinary retention or constipation. With partial obstruction, blood may erratically drain around the blockage and can be foul. Last, blood may become infected, and pyometra creates fever and leukocytosis.

Pelvic examination findings include an enlarged, soft, or even cystic midline uterine corpus that may be tender to palpation. These findings mimic early pregnancy, leiomyoma cystic degeneration, leiomyosarcoma, and gestational trophoblastic disease. Thus, urine or serum  $\beta$ -hCG assay is obtained in reproductive-aged women. Importantly, in cases in which the underlying cause is unclear, endocervical and endometrial biopsy are usually indicated to exclude malignancy.

Sonography is a principal diagnostic tool, and imaging shows a smooth, symmetric hypoechoic enlargement of the uterine cavity (Fig. 9-11). Low-level internal echoes are often

**FIGURE 9-11** Sonographic transvaginal sagittal image of hematometra. The uterine walls and proximal cervix are dilated by retained blood, which appears hypoechoic. (Used with permission from Dr. Elysia Moschos.)

present. A hematosalpinx is seen less commonly and is identified as hypoechoic tubular distentions lateral to the uterus. Although typically not required for the diagnosis, MR imaging can be used in some cases to help localize the obstruction and to provide additional anatomic information.

For most cases of hematometra, relief of the obstruction and blood evacuation are the goals. Cervical dilatation in the clinic or operating suite usually relieves the accumulation. Some have described hysteroscopy following dilatation to access blood pockets and to lyse adhesions in cases complicated by uterine synechiae (Cooper, 2000). Congenital abnormalities may require more extensive procedures to correct the obstruction (Chap. 18, p. 415).

## ADENOMYOSIS

### ■ Pathophysiology

Adenomyosis is characterized by uterine enlargement caused by ectopic rests of endometrium—both glands and stroma—located deep within the myometrium. These rests may be scattered throughout the myometrium—*diffuse adenomyosis*, or may form a localized nodular collection—*focal adenomyosis*. Although either form may be suspected clinically, the diagnosis is usually based on histologic findings in surgical specimens. Accordingly, reported incidences in hysterectomy specimens vary depending on the histologic criteria and the degree of sectioning, but range from 20 to 40 percent in large series (Vercellini, 2006). In one gynecology clinic population undergoing TVS, adenomyosis was suspected sonographically in 21 percent of women (Naftalin, 2012).

On gross examination, the uterus is often globally enlarged, but this rarely exceeds that of a 12-week pregnancy. The surface contour is usually smooth, regular, reddish, and soft. The grossly cut uterine surface typically appears spongy and trabeculated with focal areas of hemorrhage (Fig. 9-12). The ectopic foci of glands and stroma that are found in the myometrium in adenomyosis originate from the basalis layer. Because cells

from the basalis layer do not undergo the typical proliferative and secretory changes during the menstrual cycle, hemorrhage within these foci is minimal.

The most widely held theory regarding adenomyosis development describes the downward invagination of the endometrial basalis layer into the myometrium. The endometrial-myometrial interface is unique in that it lacks an intervening submucosa. Accordingly, even in normal uteri, the endometrium commonly invades the myometrium superficially (Benagiano, 2012). Mechanisms that incite deep myometrial invasion are unknown. In some cases, myometrial vulnerability stems from prior pregnancy or uterine surgery. Estrogen and progesterone likely play a role in its development and maintenance. For example, adenomyosis develops during the reproductive years and regresses after menopause. Regardless of the permissive cause, cell migration and invasion proceed.

Parity and age are significant risk factors for adenomyosis (Templeman, 2008). Specifically, nearly 90 percent of cases are in parous women, and nearly 80 percent develop in women in their 40s and 50s (Bird, 1972; Lee, 1984). Adenomyosis is also associated with aromatase expression and higher tissue estrogen levels (Yamamoto, 1993). This similar increase is also seen in leiomyomas, endometrial hyperplasia, and endometriosis, which are often coexistent with adenomyosis (Ferenczy, 1998). However, as discussed in Chapter 10, endometriosis differs epidemiologically from adenomyosis and is thought to arise from another mechanism.

Of other factors, adenomyosis is found more frequently in women taking the selective estrogen-receptor modulator tamoxifen (Parazzini, 1997). COC pill use does not appear to be a risk.

### ■ Diagnosis

Approximately one third of women with adenomyosis have symptoms, and HMB and dysmenorrhea are common. Perhaps 10 percent complain of dyspareunia. Symptom severity correlates with increasing number of ectopic foci and extent of

**FIGURE 9-12** Adenomyosis. **A.** Gross bisected uterine specimen. Note the spongy, trabeculated myometrial texture. (Used with permission from Dr. Raheela Ashfaq.) **B.** In adenomyosis, endometrial glands (G) and their surrounding stroma (S) originate from the endometrial basalis, which dips irregularly into the myometrium (M). (Used with permission from Dr. Kelley Carrick.)

invasion (Levgur, 2000). The pathogenesis of these symptoms is unknown, although myometrial contractility and markers of inflammation are implicated (Guo, 2013; Liu, 2011; Mechsner, 2010). Any link with subfertility is unclear, as data are scarce and of poor quality (Maheshwari, 2012; Tomassetti, 2013).

For many years, the diagnosis of adenomyosis in most cases has been made retrospectively following hysterectomy and histologic examination. Serum measurement of cancer antigen 125 (CA125), one tumor marker, is unhelpful. Although CA125 levels are typically elevated in women with adenomyosis, they may also be elevated in those with leiomyomas, endometriosis, pelvic infection, and pelvic malignancies (Kil, 2015).

Transabdominal sonography does not consistently identify the often subtle myometrial changes of adenomyosis, thus, imaging with TVS is preferred (Bazot, 2001). In comparison, MR imaging may be equal or slightly superior to TVS (Dueholm, 2001; Reinhold, 1996). Thus, MR imaging may be most appropriate when the diagnosis is inconclusive, when further delineation would affect patient management, or when coexisting uterine myomas distort anatomy (American College of Obstetricians and Gynecologists, 2014b). With TVS, findings of diffuse adenomyosis may include: (1) anterior or posterior myometrial wall appearing thicker than its counterpart, (2) myometrial texture heterogeneity, (3) small myometrial hypoechoic cysts, which are cystic glands within ectopic endometrial foci, (4) striated projections extending from the endometrium into the myometrium, (5) ill-defined endometrial echo, and (6) a globally enlarged uterus (Fig. 9-13). With application of color or power Doppler, diffuse vascularity may be seen in affected myometrium. Because these findings are often subtle, operator experience influences diagnostic accuracy more than with other pelvic pathology.

**FIGURE 9-13** Transvaginal sagittal uterine image displaying globular uterine enlargement and heterogeneous myometrial texture. Uterine wall thickening can show anteroposterior asymmetry, and here the posterior wall is thicker. In this image, the endomyometrial junction is also poorly defined. Last, a “shutter blind” effect is thought to reflect endometrial gland invasion into the subendometrial tissue and appears as echogenic linear striations. (Used with permission from Dr. Elysia Moschos.)

Focal adenomyosis appears as a discrete hypoechoic nodule(s) that may sometimes be differentiated from leiomyomas by its poorly defined margins, elliptical rather than globular shape, minimal mass effect on surrounding tissues, lack of calcifications, and presence of anechoic cysts of varying diameter (Levy, 2013).

## ■ Management

The main objective of treatment is relief of pain and bleeding. Although supportive data specific to adenomyosis are scant, conservative therapy for symptomatic adenomyosis is similar to that for endometriosis. First, cyclic NSAIDs are often given with menses. COCs and progestin-only regimens can be used to induce endometrial atrophy and decrease endometrial prostaglandin production to improve dysmenorrhea and HMB. The LNG-IUS is also effective for treatment of adenomyosis-related bleeding (Sheng, 2009). Notably, expulsion rates may be higher in affected women (Youm, 2014). GnRH agonists are another effective choice, although their expense and hypoestrogenic side effects typically limit their long-term use. These agonists may be most helpful for women with adenomyosis-related subfertility or as relief prior to surgical treatment (Fedele, 2008). Although danazol may be considered, it is often a less desirable option due to its androgenic side effects.

Hysterectomy is definitive treatment. As with other conditions, surgical route selection is influenced by uterine size and associated uterine or abdominopelvic pathology. Alternatively, endometrial ablation or endometrial resection using hysteroscopy has successfully treated HMB caused by adenomyosis (Preutthipan, 2010). However, complete eradication of deep adenomyosis is problematic and is responsible for a significant number of treatment failures (Wishall, 2014). Because of this, McCausland and McCausland (1996) recommended sonography or MR imaging prior to ablation to identify these deep lesions and thereby allow better patient selection. Another caveat is that any injury to the endometrial lining, including ablation, may be the initiating insult that activates endometrial tissue to invade the myometrium, thus causing adenomyosis. Adenomyosis has been found in 45 to 65 percent of hysterectomy specimens following failed ablation (Gonzalez Rios, 2015; Shavell, 2012).

UAE has also been used to relieve symptoms for some women with adenomyosis, although study sizes are small (Chen, 2006; Kim, 2007). Investigators following women 1 to 5 years after UAE found 65 percent were still improved (Popovic, 2011). For focal adenomyosis, MRgFUS has been effective in a few small case series (Fukunishi, 2008; Yang, 2009).

## OTHER UTERINE ENTITIES

*Myometrial hypertrophy* is global uterine enlargement without identifiable pathology, especially in those with high parity (Fraser, 1987). Also known as gravid hypertrophy, this condition results from myometrial fiber enlargement and not hyperplasia or interstitial fibrosis (Traiman, 1996). One definition includes uterine weights exceeding 130 g for nulliparas and 210 g for multiparas (Zaloudek, 2011). Symptoms are infrequent, but HMB is a common complaint.

*Uterine or cervical diverticula* are sacculations that communicate with and extend out from the endometrial cavity or endocervical canal. A small number are thought to be congenital anomalies developing from a localized duplication of the distal müllerian duct on one side (Engel, 1984). More often, these are acquired, develop after cesarean delivery, and are thought to arise at sites of partial uterine dehiscence. The terms *cesarean scar defect* or *isthmocoele* are used for these iatrogenic niches in the myometrium. Cesarean scar defects may lead to postmenstrual spotting or intermenstrual bleeding (Bij de Vaate, 2011). Niches can serve as a passive repository for menstrual blood and release it during postmenstrual days. An alternative explanation describes fragile vessels in the niche that cause bleeding (van der Voet, 2014). Rarely, these sacs may become secondarily infected (Ou, 2011).

Although niches can be seen during TVS, defects are best imaged by SIS or HSG (Roberge, 2012). Hysteroscopy can also identify these. Treatment includes hysterectomy, hysteroscopic resection of niche edges, or laparoscopic excision of the involved myometrium followed by reapproximation of muscle edges (Api, 2015; Gubbini, 2011). Data are limited regarding superiority of one over another.

## OVARIAN CYSTS AS A GROUP

Ovarian masses are a frequent finding in general gynecology, and most are cystic (Fig. 9-14). Histologically, ovarian cysts are often divided into those derived from neoplastic growth, *ovarian cystic neoplasms*, and those created by disruption of normal ovulation, *functional ovarian cysts*. Differentiation of these is not always clinically apparent using either imaging tools or tumor markers. Thus, ovarian cysts are often managed as a single composite clinical entity, and the next sections describe this general approach. Later sections discuss discrete pathologies.

The exact mechanisms leading to cyst formation are unclear. Angiogenesis is an essential component of both the follicular and luteal phases of the ovarian cycle. It also is a component of various pathologic ovarian processes, including follicular cyst

**FIGURE 9-14** Intraoperative photograph of a large benign mucinous cystadenoma. The fimbriated end of the fallopian tube is seen above the ovary, and the uterus lies to the right.

formation, PCOS, ovarian hyperstimulation syndrome, and benign and malignant ovarian neoplasms.

The incidence of ovarian cysts varies only slightly with patient demographics and ranges from 5 to 15 percent (Dorum, 2005; Millar, 1993). Functional ovarian cysts make up a large portion. Neoplasms constitute most of the remainder, and these predominantly are benign. In their review of U.S. inpatient hospitalizations for 2010, Whiteman and colleagues (2010) reported that approximately 7 percent of gynecologic admissions were for benign ovarian cysts.

However, despite continuous improvement in diagnostic methods, it is often impossible to clinically differentiate between benign and malignant conditions. Thus, management must balance concerns of performing an operation for an innocent lesion with the risk of not removing an ovarian malignancy.

## Symptoms

Most women with ovarian cysts are asymptomatic. If symptoms develop, pain is common. Dysmenorrhea may indicate endometriosis with an associated endometrioma. Intermittent or acute severe pain with vomiting often accompanies torsion. Other causes of acute pain include cyst rupture or tuboovarian abscess. In contrast, pressure or ache may be the sole symptom and can result from ovarian capsule stretching. In advanced ovarian malignancies, women may note increased abdominal girth and early satiety from ascites or from an enlarged ovary. In some women, evidence of hormonal disruption can be found. For example, excess estrogen production from granulosa cell stimulation may disrupt normal menstruation or initiate bleeding in prepubertal or postmenopausal patients. Increased androgens produced by theca cell stimulation can virilize women.

## Diagnosis

Many ovarian cysts are asymptomatic and found incidentally on routine pelvic examination or during imaging studies for another indication. Findings vary, but typically masses are mobile, cystic, nontender, and found lateral to the uterus.

Serum  $\beta$ -hCG testing is invaluable in the evaluation of adnexal pathology. Detection of serum  $\beta$ -hCG may indicate ectopic pregnancy or a corpus luteum of pregnancy. Less commonly,  $\beta$ -hCG can also serve as a tumor marker in defining germ cell neoplasms.

Tumor markers are typically proteins produced by tumor cells or by the body in response to tumor cells. Of markers used, CA125 is a glycoprotein produced by mesothelial cells that line the peritoneal, pleural, and pericardial cavities. CA125 serum levels are often elevated in women with epithelial ovarian cancer. Unfortunately, CA125 is not a tumor-specific antigen, and concentrations are increased in up to 1 percent of healthy controls. Levels may also rise in women with nonmalignant disease such as leiomyomas, endometriosis, adenomyosis, and salpingitis. Despite these limitations, serum CA125 determinations may be helpful and are often obtained if ovarian cysts are large or have sonographically worrisome signs. Cysts in patients who are postmenopausal or are *BRCA* gene mutation carriers may also warrant CA125 level evaluation (Chap. 35, p. 737). Of other markers, serum alpha-fetoprotein (AFP) levels can be

elevated in those rare patients with an endodermal sinus tumor or embryonal carcinoma. Increased serum levels of  $\beta$ -hCG may indicate an ovarian choriocarcinoma, a mixed germ cell tumor, or embryonal carcinoma. Inhibin A and B are markers for granulosa cell tumors. Last, lactate dehydrogenase (LDH) levels may be increased in those with dysgerminoma, whereas elevated carcinoembryonic antigen (CEA) and cancer antigen 19–9 (CA19–9) levels arise from secretions of mucinous epithelial ovarian carcinomas.

Sonography is a first-line tool to evaluate pelvic masses. Transabdominal scanning is performed first to avoid missing a large cyst that lies outside the pelvis. For lesions confined within the true pelvis, TVS has superior resolution. Characteristic findings for specific types of ovarian cysts have been described and have also been defined to discriminate malignant from benign lesions (Table 9-3).

Traditional gray-scale sonography can be augmented with color flow Doppler. Transvaginal color Doppler sonography (TV-CDS) may add information regarding lesion structure, malignant potential, and possible torsion. However, for assessing simple ovarian cysts and the risk of malignancy, TV-CDS typically provides no significant advantage compared with conventional TVS (Vuento, 1995). CT or MR imaging of an ovarian cyst may clarify situations in which anatomy or patient habitus complicates sonographic imaging. However, in most clinical settings, sonography alone is suitable (Outwater, 1996).

## ■ Management

### Observation

In prepubertal and reproductive-aged women, most ovarian cysts are functional and spontaneously regress within 6 months of identification. For postmenopausal women with a simple ovarian cyst, expectant management may also be reasonable if several criteria are met. These are: (1) sonographic evidence of a thin-walled, unilocular cyst, (2) cyst diameter less than 5 cm, (3) no cyst enlargement during surveillance, and (4) normal serum CA125 level (Nardo, 2003). The American College of Obstetricians and Gynecologists (2013) notes that simple cysts up to 10 cm in diameter by sonographic evaluation may safely be followed even in postmenopausal women.

### Surgery

There is considerable morphologic similarity among cyst types and between those that are malignant and benign. For diagnosis, ovarian cyst aspiration is usually avoided because of possible intraperitoneal seeding by early-stage ovarian cancer. Moreover, nondiagnostic, false-positive and false-negative results are common (Martinez-Onsurbe, 2001; Moran, 1993). Accordingly, for many cases, excision of the cyst serves as the definitive diagnostic tool.

With suspected ovarian cancers, optimal surgical resection and proper staging by a gynecologic oncologist during the primary operation are major factors in long-term patient survival. Thus, women with pelvic masses and preoperative findings suspicious for malignancy are generally referred. The American College of Obstetricians and Gynecologists (2011) and Society of Gynecologic Oncology have jointly presented guidelines

regarding clinical criteria that should prompt preoperative referral to a gynecologic oncologist (Table 9-4).

For the generalist, cysts presumed to be benign may be excised or the whole ovary may be removed. Of these, cystectomy offers the advantage of ovarian preservation, but at the risk of cyst rupture and content spill. With ovarian cancer, such spill and subsequent malignant seeding can worsen patient prognosis. Thus, the decision for one surgical technique in preference over the other is influenced by lesion size, patient age, and intraoperative findings. For example, in premenopausal women, smaller lesions generally require only cystectomy with preservation of reproductive function. Larger lesions may necessitate oophorectomy because of increased risks of cyst rupture during enucleation, difficulty in reconstructing ovarian anatomy following large cyst removal, and the greater risk of malignancy in these bigger cysts. However, in postmenopausal women, oophorectomy is preferred because the risk for cancer is higher and comparative benefits of ovarian salvage are limited (Okugawa, 2001).

Clinical findings of an unexpected malignancy at the time of surgery will dictate further actions. Multiple small lesions studding the peritoneal surface, ascites, and exophytic growths extending from the ovarian capsule should prompt collection of peritoneal fluid for cytologic study and intraoperative frozen section analysis. If cancer is found, gynecologic oncologists are ideally consulted intraoperatively. At minimum, limited clinical staging, as discussed in Chapter 35 (p. 748), can be completed.

The surgical route is also dictated by clinical factors. Laparoscopy has many patient advantages and is safe for cystectomy and oophorectomy in appropriately selected women (Mais, 1995; Yuen, 1997). Thus, if benign disease is anticipated, this is a frequently used approach. However, large cysts may obstruct laparoscopic instrument mobility and may not fit into endoscopic sacs for contained removal.

For medium-sized cysts, laparotomy incisions can usually be minimized. As a result, most who undergo minilaparotomy can be discharged the day of surgery. Although minilaparotomy typically offers shorter operative times, lower rates of cyst rupture, and greater cost savings compared with laparoscopy, this approach can limit a surgeon's ability to lyse adhesions and inspect peritoneal surfaces for signs of ovarian malignancy.

Women with large cysts are best managed by laparotomy. With a greater potential for malignancy, a midline vertical incision provides a surgical field large enough for oophorectomy without tumor rupture and for surgical staging if malignancy is found. In those with a low risk of malignancy and a moderate-sized cyst, laparotomy through a low transverse incision may be appropriate and offer the advantages of this incision (Chap. 43, p. 929).

## FUNCTIONAL OVARIAN CYSTS

These are common, originate from ovarian follicles, and are created during follicle maturation and ovulation. They are subcategorized as either *follicular cysts* or *corpus luteum cysts* based on both their pathogenesis and histologic qualities. They are not neoplasms and derive their mass from accumulation of intrafollicular fluids rather than cellular proliferation. With follicular

**TABLE 9-3.** Recommended Management of Asymptomatic Ovarian Masses Found with Imaging

Type of Ovarian Mass	Recommendation
<b>Cysts with Benign Qualities</b>	
Simple Cyst	Simple cysts, regardless of patient age, are typically benign
Premenopausal	
≤ 3 cm diameter	Normal anatomic finding
≤ 5 cm diameter	No additional treatment required
> 5 but ≤ 7 cm diameter <sup>a</sup>	TVS repeated in 6–12 wks to document resolution; if persistent, then yearly TVS <sup>b</sup>
> 7 cm diameter <sup>a</sup>	MRI or surgical evaluation
Postmenopausal	
≤ 1 cm diameter	Normal anatomic finding
≤ 5 cm diameter <sup>a</sup>	CA125 level; if normal level, then TVS repeated in 6–12 wks; if persistent cyst, then yearly TVS <sup>b</sup>
> 7 cm diameter <sup>a</sup>	MRI or surgical evaluation
Hemorrhagic Cyst <sup>c</sup>	
Premenopausal	
≤ 3 cm diameter CL	Normal anatomic finding
≤ 5 cm diameter	No additional treatment required
> 5 but ≤ 7 cm diameter	TVS repeated in 6–12 wks; if persistent, then consider MRI or surgical evaluation
Early postmenopausal <sup>d</sup>	CA125 level; if normal, then TVS repeated in 6–12 wks; if persistent cyst, then consider MRI or surgical evaluation
Any size	
Late postmenopausal <sup>d</sup>	Surgical evaluation
Any size	
Endometrioma	TVS repeated in 6–12 wks; if persistent, then yearly TVS <sup>b</sup>
Mature cystic teratoma	If not surgically removed <sup>e</sup> , then yearly TVS <sup>b</sup>
Hydrosalpinx	May be observed as clinically indicated
Peritoneal inclusion cyst	May be observed as clinically indicated
<b>Cysts with Indeterminate, but Probably Benign Qualities</b>	
Indeterminate for: hemorrhagic cyst, mature cystic teratoma, endometrioma	
Premenopausal	TVS repeated in 6–12 wks; if persistent cyst, then consider surgical evaluation or MRI
Postmenopausal	Consider surgical evaluation
Thin-walled cyst with single thin septation or focal cyst wall calcification	Same as for simple cyst
Multiple thin septations (< 3 mm)	Consider surgical evaluation
Nodule (non-hyperechoic) without flow	Consider surgical evaluation or MRI
<b>Cysts with Qualities Suggesting Malignancy</b>	
Thick (> 3 mm) irregular septations	Consider surgical evaluation
Nodule with blood flow	Consider surgical evaluation

<sup>a</sup>The American College of Obstetricians and Gynecologists (ACOG) (2013) recommends a threshold up to 10 cm for simple cysts in all age groups.

<sup>b</sup>Shorter time interval may be selected for surveillance as clinically indicated.

<sup>c</sup>Color Doppler as an adjunct is recommended to exclude solid components.

<sup>d</sup>All postmenopausal women with an adnexal mass also undergo breast examination, digital rectal examination, and mammography, if not already performed in the last year due to the high rate of metastasis from other primary tumors to the ovary.

<sup>e</sup>Some studies have found that stable small dermoid cysts may be observed in premenopausal women.

CA125 = cancer antigen 125; CL= corpus luteum; MRI= magnetic resonance imaging; TVS= transvaginal sonography. Data from American College of Obstetricians and Gynecologists, 2013; Harris, 2013; Levine, 2010.

cyst formation, hormonal dysfunction prior to ovulation results in expansion of the follicular antrum with serous fluid. In contrast, excessive hemorrhage from the vascular corpus luteum following ovulation may fill its center to create a corpus luteum cyst. Thus, follicular and corpus luteum cysts differ in their genesis, but symptoms and management are similar.

### ■ Associated Factors

Of potential factors, high-dose COCs suppress ovarian activity and protect against cyst development (Ory, 1974). However, in subsequent studies with low-dose pills, COCs provided only modest protective effects (Holt, 2003; Lanes, 1992). By contrast, the incidence of follicular cysts is increased with many progestin-only contraceptives. Recall that continuous, low-dose progestins do not completely suppress ovarian function. As a result, dominant follicles may develop in response to gonadotropin secretion, yet the normal ovulatory process is frequently disrupted, and follicular cysts develop. Clinically, follicular cysts are found with greater frequency in those using the LNG-IUS and progestin-releasing implants (Hidalgo, 2006; Nahum, 2015).

Both pre- and postmenopausal women treated with tamoxifen for breast cancer have an increased risk for benign ovar-

**FIGURE 9-15** Sonographic transvaginal sagittal image of an ovary (calipers) containing a follicular cyst. Note the smooth walls and lack of internal echoes. (Used with permission from Dr. Elysia Moschos.)

ian cyst formation (Chalas, 2005). Premenopausal women and women with greater BMI are disparately affected. Most are functional cysts that resolve with time whether tamoxifen treatment is continued or discontinued (Cohen, 2003). If small simple cysts are found, sonographic surveillance is reasonable. If clinical signs of malignancy are present, then surgical exploration is indicated, and tamoxifen is discontinued. Of other SERMs, bazedoxifene, raloxifene, and ospemifene do not appear to increase ovarian cyst rates (Archer, 2015).

Several epidemiologic studies have linked smoking with functional cyst development (Holt, 2005; Wyshak, 1988). Although the exact mechanism(s) is unknown, changes in gonadotropin secretion and ovarian function are suspected (Michnovicz, 1986).

### ■ Diagnosis and Treatment

Functional cysts are managed similarly to other cystic ovarian lesions. Consequently, sonography is initially performed. Typical follicular cysts are completely rounded anechoic lesions with thin, regular walls (Fig. 9-15). Conversely, corpus luteum cysts are termed “great imitators” because of their varied sonographic characteristics (Fig. 9-16). Imaging with transvaginal

**FIGURE 9-16** Sonographic transvaginal images of hemorrhagic corpus luteum cysts. **A.** Diffuse low-level echoes, which are commonly associated with hemorrhage, are seen throughout this smooth-walled cyst. **B.** With evolution of the clot, a lacy reticular pattern develops. **C.** As the clot hemolyzes, a distinct line often forms between the serum and retracting clot. With further retraction, the clot may appear as an intramural nodule. (Used with permission from Dr. Elysia Moschos.)

color Doppler typically displays a brightly colored ring because of their increased surrounding vascularity. T is *ring of fire* is also common to ectopic pregnancies (Fig. 7-5 p. 167).

If asymptomatic, women with findings of a functional ovarian cyst may be observed. Evidence does not support the use of COCs to hasten resolution (Grimes, 2014). Surgical excision may be reasonable for large persistent cysts, usually those > 10 cm. Progressively enlarging cysts are typically removed.

■ Theca Lutein Cysts

T ese are an uncommon type of follicular cyst, characterized by luteinization and hypertrophy of their theca interna layer. Bilateral, multiple smooth-walled cysts form and range in size from 1 to 4 cm in diameter. Termed *hyperreactio lutealis*, this condition is thought to be prompted by elevated LH or  $\beta$ -hCG levels. Commonly associated conditions include gestational trophoblastic disease, multifetal gestation, placentomegaly, and ovarian hyperstimulation during assisted reproductive techniques (Fig. 37-4, p. 782). T ese cysts typically resolve spontaneously following removal of the stimulating hormone source. However, prior to this, these bulky ovaries are at risk for torsion.

BENIGN NEOPLASTIC OVARIAN CYSTS

T ese lesions, plus functional ovarian cysts, constitute most ovarian masses. Ovarian neoplasms can be distinguished histologically depending on their cell type of origin. T ese are grouped as epithelial tumors, germ cell tumors, sex cord-stromal tumors, and others shown in Table 9-5. Of benign ovarian neoplasms, serous and mucinous cystadenomas and mature cystic teratoma are the most common (Pantoja, 1975).

■ Ovarian Teratoma

T ese belong to the germ cell family of ovarian neoplasms. Teratomas arise from a single germ cell, and therefore may contain any of the three germ layers—ectoderm, mesoderm, or endoderm. T ese layers are typically disorganized. Teratomas are classified as:

Immature teratoma—T is neoplasm is malignant and described in Chapter 36 (p. 765). Immature tissues from one, two, or all three germ cell layers are found and often coexist with mature elements.

Mature teratoma—T is benign tumor contains mature forms of the three germ cell layers:

- 1. Mature cystic teratoma develops into a cyst, is common, and is also called *benign cystic teratoma* or *dermoid cyst*.
- 2. Mature solid teratoma has elements formed into a solid mass.
- 3. Fetiform teratoma or homunculus forms a doll-shape, as the germ cell layers display considerable normal spatial differentiation.

Monodermal teratoma—T is benign tumor is composed either solely or predominantly of only one highly specialized tissue type. Of the monodermal teratomas, those composed dominantly of thyroid tissue are termed *struma ovarii*.

Of these teratoma types, mature cystic teratoma is by far the most common. T ese benign tumors comprise approximately 10 to 25 percent of all ovarian neoplasms and 60 percent of all benign ovarian neoplasms (Koonings, 1989; Peterson, 1955). T ese cystic tumors are typically slow growing, and most measure between 5 and 10 cm (Comerci, 1994). T ey are bilateral in approximately 10 percent of cases (Peterson, 1955). When sectioned, most cysts appear unilocular and typically contain one area of localized growth, which protrudes into the cystic cavity. Alternatively designated as *Rokitansky protuberance*, *dermoid plug*, *dermoid process*, *dermoid mamilla*, or *embryonal rudiment*, this protuberance can be absent or multiple.

**FIGURE 9-17** **A.** A sectioned mature cystic teratoma following cystectomy. Abundant hair and sebum, characteristic of these neoplasms, is evident. **B.** In this classic histologic example, ectodermal elements include skin (Sk), sebaceous (Se), and eccrine (E) glands, whereas mesodermal elements are smooth muscle (Sm) and adipose (A).

Microscopically, endodermal or mesodermal derivatives may be found, but ectodermal elements usually predominate. The cyst is typically lined with keratinized squamous epithelium and contains abundant sebaceous and sweat glands. Hair and fatty secretions are often found within (Fig. 9-17). At times, bone and teeth are also identified. The Rokitansky protuberance is usually the site where the most varied tissue types are found and is also a common location of malignant transformation. Malignant transformation develops in 0.06 to 2 percent of cases and typically in older women (Choi, 2014; Rim, 2006). Most malignant cases are squamous cell carcinoma.

The diverse tissues found within teratomas do not arise by fertilization of an ovum by sperm. Instead, they are thought to develop from genetic material contained within a single oocyte by asexual *parthenogenesis*. As a result, almost all mature cystic teratomas have a 46,XX karyotype (Linder, 1975).

Mature cystic teratomas can often undergo torsion, but cyst rupture is rare. Presumably, their thick cyst wall resists rupture compared with other ovarian neoplasms. If cysts do spill, acute peritonitis is common, and Fielder and associates (1996) attributed peritonitis to the sebum and hair contents. They showed the benefits of intraoperative lavage to prevent peritonitis and adhesion formation. Chronic leakage of teratoma contents is rare but can lead to granulomatous peritonitis.

Symptoms from these teratomas are similar to those of other ovarian cysts. However, ovarian teratomas can rarely cause immune-mediated encephalitis. Neurologic symptoms stem from antibodies to *N*-methyl-d-aspartate receptors (NMDARs), which have critical roles in synaptic transmission. The teratomas contain primitive neural tissue, which presumably provides the antigen that prompts NMDAR antibody formation. Teratoma resection is essential to resolution, which can often be dramatic. Resection may be combined with immunotherapy. In one large series of 100 patients, 75 percent recovered, but 25 percent died or survived with severe deficits (Dalmau, 2008).

Sonography is the main imaging tool, and mature cystic teratomas display several characteristic features (Fig. 9-18). First,

fat-fluid or hair-fluid levels are seen as a distinct linear demarcation where serous fluid interfaces with sebum, which is liquid at body temperature. When floating, hair forms accentuated lines and dots that represent hair in longitudinal and transverse planes. The Rokitansky protuberance is a rounded mural nodule that measures 1 to 4 cm, is predominantly hyperechoic, and creates an acute angle with the cyst wall. Last, the “tip of the iceberg” sign is created by amorphous echogenic interfaces of fat, hair, and tissues in the foreground that shadow and thus obscure structures behind it (Guttman, 1977). Notably, these findings are not exclusive to mature cystic teratomas. For example, Patel and associates (1998) reported modest positive predictive values for these findings individually. However, they described values of 100 percent when two or more were found within a given lesion.

For most women with mature cystic teratoma, surgical excision provides a definitive diagnosis, affords relief of symptoms, and prevents torsion, rupture, and malignant degeneration.

**FIGURE 9-18** Sonogram revealing characteristics of mature cystic teratoma. (Used with permission from Dr. Elysia Moschos.)

Laparoscopy is appropriate, and surgical route is selected as for other ovarian masses (p. 216). To prevent granulomatous peritonitis, the cyst can be enucleated over laparotomy sponges or an endoscopic bag to capture cyst spill (Kondo, 2010). Moreover, copious pelvic irrigation is a final surgical step. In the past, most recommended that the opposite ovary be explored because of the high frequency of bilateral lesions. However, given the accuracy of current sonographic imaging, these procedures are no longer indicated with a normal-appearing contralateral ovary (Comerci, 1994).

Although most of these masses are surgically removed, a few studies have supported surveillance only for cysts measuring < 6 cm in premenopausal women, especially those desiring future fertility (Alcázar, 2005; Hoo, 2010). These studies document slow tumor growth that averages less than 2 mm/yr. If not removed, sonographic surveillance is recommended every 6 to 12 months initially (Levine, 2010).

### ■ Benign Serous and Mucinous Tumors

These are members of the surface epithelial neoplasia group, and both are lined by cells similar to those lining the fallopian tube. *Benign serous tumors* are typically thin-walled, unilocular cysts filled with serous fluid (Fig. 9-19). They are bilateral in up to 20 percent of cases. *Benign mucinous tumors* are typically thicker-walled, mucoid-containing tumors that may be small but can often attain large diameters. They may be uni- or multilocular.

In categorizing tumors within the epithelial family, benign tumors are designated as *adenomas*; malignant tumors, as *carcinomas*; and those with exuberant cellular proliferation without invasive behavior as *low malignant potential* (Chen, 2003). The prefix *cyst-* describes predominantly cystic neoplasms with intracystic growth. Thus, *serous cystadenoma* describes a benign, mainly cystic tumor of the ovarian epithelial tumor group (Prat, 2009).

## SOLID OVARIAN MASSES

Completely solid ovarian masses typically are benign. That said, these masses are still removed because of the inability to exclude malignancy in these tumors. Ovarian tumors that may present as a solid masses include: sex cord-stromal tumors, Krukenberg tumor, ovarian leiomyoma and leiomyosarcoma, carcinoid, primary lymphoma, and transition cell tumors, also called Brenner tumors (Fig. 9-20). The most common of these are the fibroma and fibrothecoma, both typically benign sex cord-stromal tumors and discussed in Chapter 36 (p. 771).

**FIGURE 9-19** Serous (A,B) and mucinous (C,D) cystadenoma. **A.** This simple cyst has a fibrous wall and is lined by a single layer of benign, columnar tubal-type epithelium with cilia. Surface epithelium invaginations are cut tangentially and give the illusion of smaller subepithelial rests. **B.** High-power view of its ciliated, tubal-type lining. **C.** Mucinous cystadenomas are typically multiloculated cysts lined by a single layer of benign mucin-containing epithelium. Mucinous fluid is secreted by the epithelium and contained within the cystic mass. In this image, it is the amorphous material above the epithelium and is stained pink (asterisk). **D.** High-power view of simple columnar, mucin-containing epithelium. (Used with permission from Dr. Kelley Carrick.)

Solid adnexal masses may also represent nonneoplastic conditions. Ovarian remnant syndrome and ovarian retention syndrome stem from persistent functional ovarian tissue following surgery. These conditions most commonly cause pain and are discussed in detail in Chapter 11 (p. 261). Rarely,

**FIGURE 9-20** Transvaginal sonogram of a benign ovarian fibroma.

congenital accessory ovaries may confuse sonographic findings and are discussed in Chapter 18 (p. 423).

### ADNEXAL TORSION

Torsion involves the twisting of adnexal components. Most often, the ovary and fallopian tube rotate as a single entity. Infrequently, an ovary may alone turn about its mesovarium, and rarely a fallopian tube twists alone about the mesosalpinx. Normal adnexa can twist, but in 50 to 80 percent of cases unilateral ovarian masses are identified (Nichols, 1985; Warner, 1985). Adnexal torsion accounts for 3 percent of gynecologic emergencies. Although this most commonly occurs during the reproductive years, postmenopausal women can also be affected. A disproportionate number of cases of adnexal torsion develop during pregnancy, and these compose 20 to 25 percent of all torsion cases.

Adnexal masses with increased mobility have greater torsion rates. Congenitally long uteroovarian ligaments create excessively mobile mesovaria or fallopian tubes and may increase the risk in even normal adnexa. Similarly, pathologically enlarged ovaries with a diameter > 6 cm will typically rise from the true pelvis. Without these bony confines, mobility and torsion risk are increased. Accordingly, the highest rates of torsion are in adnexal masses measuring 6 to 10 cm (Houry, 2001). Torsion of the adnexa more commonly involves the right adnexa, likely because the mobility of the left ovary is limited by the sigmoid colon (Hasiakos, 2008).

Two key points assist in initially maintaining blood flow to the involved adnexal structures despite twisting of their vascular pedicles. First, adnexa are supplied from the respective adnexal branches of both the uterine and ovarian vessels. During torsion, one of these, but not the other, may be involved. Second, although low-pressure veins draining the adnexa are compressed by the twisting pedicle, high-pressure arteries initially resist compression. As a result of this continued inflow but arrested egress of blood, the adnexa become congested and edematous

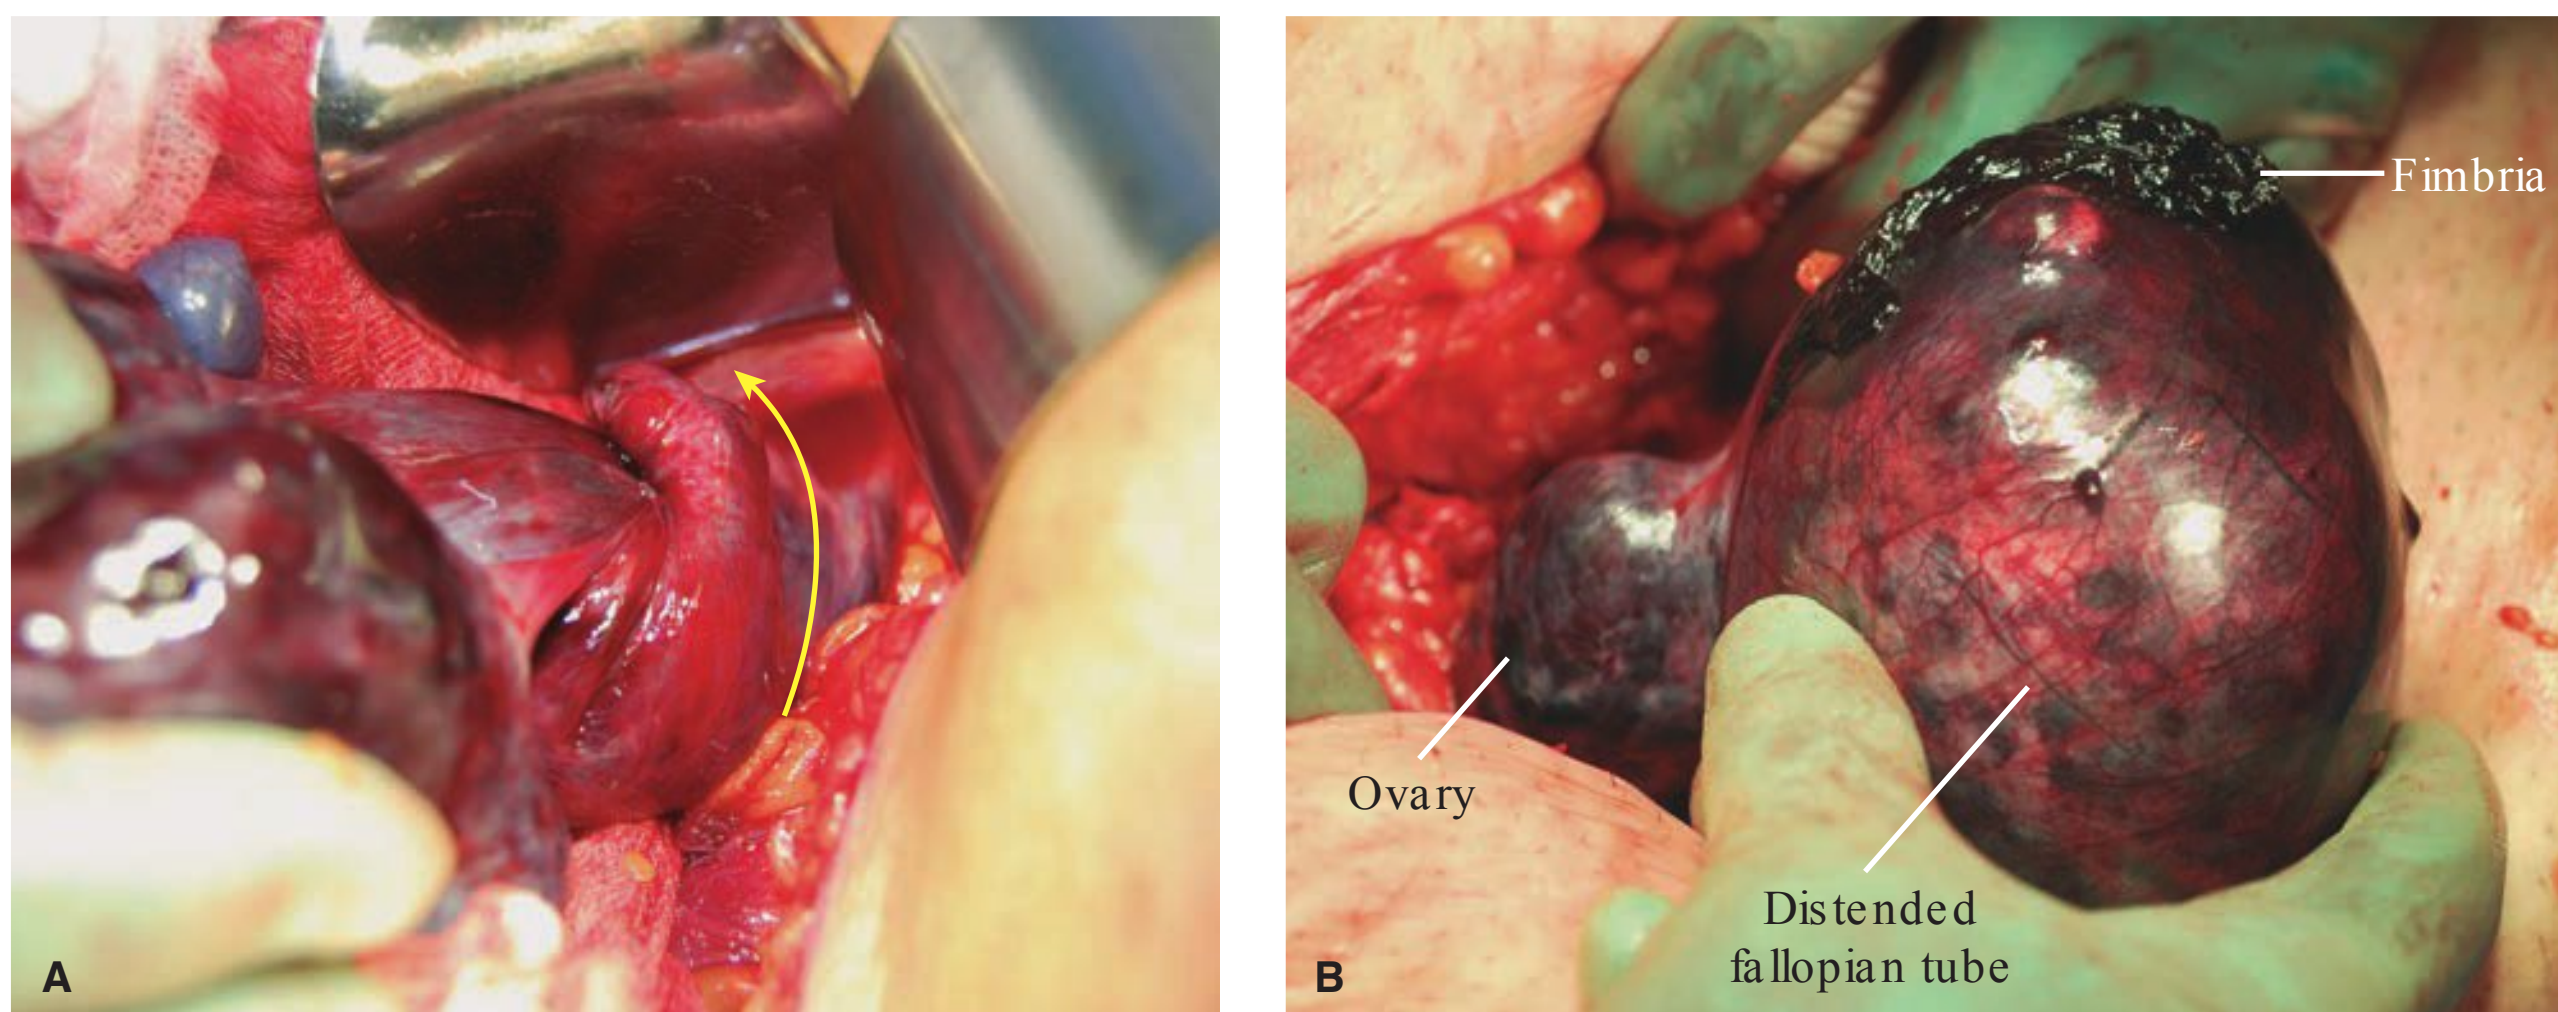

but do not infarct. Because of this, cases of early torsion can often be conservatively managed at the time of surgery. With continued stromal swelling, however, arteries may become compressed, leading to infarction and necrosis that necessitate adnexectomy. Grossly, twisted adnexa are enlarged and often appear hemorrhagic (Fig. 9-21).

### ■ Diagnosis

Classically, the woman with adnexal torsion complains of sharp lower abdominal pain with sudden onset that worsens intermittently over several hours. The pain usually is localized to the involved side, with radiation to the flank, groin, or thigh. Low-grade fever suggests adnexal necrosis. Nausea and vomiting frequently accompany the pain.

Lack of clear physical findings can make diagnosis difficult. An adnexal mass may not be palpable, and during its early stages, significant discomfort may not be elicited during examination. Sonography plays an essential role. However, sonographic findings can vary widely depending on the degree of vascular compromise, the characteristics of any associated intraovarian or intratubal mass, and the presence or absence of adnexal hemorrhage. Sonographically, torsion may mimic ectopic pregnancy, tuboovarian abscess, hemorrhagic ovarian cyst, and endometrioma. Accordingly, rates of correct diagnosis range from 50 to 75 percent (Graif, 1984; Helvie, 1989).

Despite these limitations, specific findings have been described. First, multiple follicles rimming an enlarged ovary reflects ovarian congestion and edema described earlier. The twisted pedicle may also appear as a bull's-eye target, whirlpool, or snail shell, that is, a rounded hyperechoic structure with multiple, inner, concentric hypoechoic rings. In affected women, transvaginal color Doppler sonography may show disruption of normal adnexal blood flow. However, in some cases, incomplete or intermittent torsion may variably display both venous and arterial flow during TV-CDS. Thus, disruption of vascular flow is highly suggestive of torsion. But torsion should

**FIGURE 9-21** Intraoperative photographs of adnexal torsion. **A.** Twisting of the infundibulopelvic ligament leads to strangulation of ovarian vessels within it. **B.** A cyanotic ovary and fallopian tube result and are shown here. Hemorrhage into the tubal walls created this massively dilated fallopian tube. Dusky fimbria are seen at the end of the tube. (Used with permission from Dr. Jason Harn.)

not be excluded on the basis of a normal Doppler study alone, especially with clinically suggestive signs and symptoms.

Last, CT or MR imaging is usually not required. These may be helpful in complicated cases or in those with ambiguous clinical presentation such as seen with incomplete or chronic torsion (Rha, 2002).

## ■ Management

Salvage of the involved adnexa, resection of any associated cyst or tumor, and possible oophoropexy are treatment goals. Findings of adnexal necrosis or rupture with hemorrhage, however, may necessitate removal of adnexal structures.

Torsion may be evaluated by laparoscopy or laparotomy. Previously, adnexectomy was usually done to avoid possible thrombus release and subsequent embolism during untwisting. Evidence does not support this. McGovern and coworkers (1999) reviewed nearly 1000 cases of torsion and found the rare occurrence of pulmonary embolism in only 0.2 percent. These cases of embolism were associated with adnexal excision, and none were linked to untwisting of the pedicle. In a study of 94 women with adnexal torsion, Zweizig and associates (1993) reported no increased morbidity in women undergoing untwisting of the adnexa compared with those undergoing adnexectomy.

For these reasons, detorsion of the adnexa is generally recommended. Within minutes following untwisting, congestion is relieved, and ovarian volume and cyanosis typically diminish. For many, absence of these changes may prompt adnexal removal. A persistently black-bluish ovary, however, is not pathognomonic for necrosis, and the ovary may still recover. Cohen and colleagues (1999) reviewed 54 cases in which adnexa were preserved regardless of their appearance following detorsion. They reported functional integrity and successful subsequent pregnancy in almost 95 percent. Bider and coworkers (1991) observed no increased postoperative infection morbidity in cases similarly managed. Because adnexal necrosis may still occur, conservative management requires postoperative vigilance for fever, leukocytosis, and peritoneal signs.

Following detorsion, there is no consensus as to the management of the adnexa. Specific ovarian lesions should be excised. Cystectomy in a hemorrhagic, edematous ovary, however, may technically be difficult. Therefore, some recommend cystectomy if the mass persists for 6 to 8 weeks after primary intervention (Rody, 2002).

The retorsion rate among fertile women was 28 percent in one review of 38 publications (Hyttel, 2015). To minimize these rates, unilateral or bilateral oophoropexy has been described and may be considered (Djavadian, 2004). Techniques to secure the ovary vary. These include shortening of the uteroovarian ligament with a running stitch through the ligament or suturing of either the ovary or the uteroovarian ligament to the posterior aspect of the uterus, the lateral pelvic wall, or the round ligament (Fuchs, 2010; Weitzman, 2008). However, the effects of this positioning on later ovum uptake and fertility are unclear.

Management during pregnancy does not differ. However, if the corpus luteum is removed before 10 weeks' gestation, progesterational support is recommended until 10 weeks' gestation

to maintain the pregnancy. Suitable regimens include: (1) micronized progesterone (Prometrium) 200 or 300 mg orally once daily; (2) 8-percent progesterone vaginal gel (Crinone) one premeasured applicator vaginally daily plus micronized progesterone 100 or 200 mg orally once daily; or (3) intramuscular 17-hydroxyprogesterone caproate (Delalutin), 150 mg. With the last option, if between 8 and 10 weeks, then only one injection is required immediately after surgery. If the corpus luteum is excised between 6 to 8 weeks, then two additional doses should be given 1 and 2 weeks after the first.

## PARAOVARIAN MASSES

Most paratubal/paraovarian cysts are not neoplastic and are either distended remnants of the paramesonephric duct or mesothelial inclusion cysts. One autopsy series cited a rate of approximately 5 percent of adnexal cysts (Dorum, 2005). The most common paramesonephric cyst is the *hydatid of Morgagni*, which is pedunculated and typically dangles from one of the fimbria. Neoplastic paraovarian cysts are rare and histologically resemble tumors of ovarian origin. They are usually cystadenomas or cystadenofibromas and rarely malignant (Korbin, 1998).

These cysts are most commonly identified in asymptomatic women at the time of surgery or sonography for other gynecologic problems. If symptoms develop, they mimic those of ovarian cysts. They are infrequently associated with complications such as hemorrhage, rupture, or torsion (Genadry, 1977).

Transvaginal sonography is often used as a primary evaluation tool for symptomatic women, and most of these cysts have thin, smooth walls and anechoic centers. However, sonography and MR imaging have limitations in differentiating between paraovarian and ovarian pathology (Ghossain, 2005). Thus, many women are managed as if diagnosed with a comparable ovarian cyst. When surgically managed, cystectomy or, less frequently, drainage and fulguration of the cyst wall are performed. When small and noted as an incidental intraoperative finding, these are generally excised, although this is not an evidence-based practice.

Of solid paraovarian tumors, leiomyomas are the most common and have pathophysiology identical to those within myometrium. Infrequently, congenital anomalies such as an accessory or supernumerary ovary, rudimentary uterine horn, or pelvic kidney may present as a pelvic mass with or without symptoms. One rare solid paraovarian tumor arises as a remnant of the Wolffian duct and has been termed the *female adnexal tumor of probable Wolffian origin* (Devouassoux-Shisheboran, 1999). As described in Chapter 18 (p. 417), Wolffian duct remnants are such that this rare tumor develops within the broad ligament or along the mesosalpinx (Kariminejad, 1973). Other rare paraovarian solid tumors include sarcomas, lymphoma, adenocarcinoma, pheochromocytoma, and choriocarcinoma.

Most paraovarian solid tumors are asymptomatic and identified on routine pelvic examination. Occasionally, there is unilateral pelvic and abdominal pain. Sonography and MR imaging are used to visualize these masses, although accurate differentiation between benign and malignant lesions is typically not possible. Thus, most solid masses are surgically removed.

## FALLOPIAN TUBE PATHOLOGY

### ■ Hydrosalpinx

Fallopian tube neoplasms are rare, and most fallopian tube masses involve ectopic pregnancy or the sequelae of PID. Of these, hydrosalpinx is a chronic cystic swelling of the fallopian tube that forms following distal tubal obstruction. Causes include PID and endometriosis and rarely fallopian tube cancer. Grossly, the fine fimbria and tubal ostia are obliterated and replaced by a smooth, clubbed end (Fig. 9-22). The ballooned, thin walls of the elongated tube are translucent, and the tube is typically distended with a clear serous fluid. The ipsilateral ovary may be adhered to the hydrosalpinx.

Hydrosalpinx may be found in asymptomatic women during pelvic examination or sonography done for other indications. Some women note infertility or chronic pelvic pain. The differential diagnosis mimics that for other cystic pelvic lesions. In general, no laboratory test is helpful, and serum CA125 level testing for presumed ovarian malignancy is typically negative.

Sonographic interrogation shows a thin-walled, hypoechoic cystic fusiform structure with incomplete septa (Fig. 9-23). In some, multiple hyperechoic mural nodules measuring 2 to 3 mm arch around the inner circumference of the tube to create the *beads on a string* sign. These nodules represent fibrotic endosalpingeal folds.

Management varies depending on the conviction of diagnosis, desire for future fertility, and associated symptoms. In asymptomatic women who have completed childbearing, and in whom the sonographic evidence supports the diagnosis of hydrosalpinx, expectant management is typical. In those with pelvic pain or infertility, or in whom the diagnosis is uncertain, diagnostic laparoscopy is often chosen.

For women not wishing to preserve fertility, laparoscopic treatment may include lysis of adhesions and salpingectomy. Conversely, in women who desire fertility, surgical intervention

**FIGURE 9-22** Laparoscopic photograph of a hydrosalpinx. Note the thin-walled ballooned fallopian tube and its clubbed end (arrow) stretching from the cornua and draping around the blunt probe. A typical corpus luteum cyst is seen at the distal end of the ovary. (Used with permission from Dr. Karen Bradshaw.)

**FIGURE 9-23** Transvaginal sonogram of hydrosalpinx. Incomplete septa, which are folds of the dilated tube, are seen within this fusiform, fluid-filled structure. (Used with permission from Dr. Elysia Moschos.)

depends on the degree of tubal damage. As the degree of tubal distortion increases, fertility rates decrease. In women with mild tubal disease, laparoscopic neosalpingostomy has resulted in 80-percent pregnancy rates and is a reasonable approach (Fig. 20-7, p. 459) (Schlaff, 1990). In those with severe tubal disease, IVF may offer a greater chance at conception.

Of note, women with a hydrosalpinx who undergo IVF have approximately half the pregnancy rate of other women (Camus, 1999; Zeyneloglu, 1998). The explanation is unclear, and theories include toxic hydrosalpinx fluid, lowered growth factor concentrations, and mechanical flushing of embryos by excess fluid (Loutradis, 2005; Lu, 2013; Strandell, 2002). If hydrosalpinges are resected prior to IVF, subsequent rates of pregnancy, implantation, and live births are improved (Dechaud, 1998; Johnson, 2010; Strandell, 1999). Thus, the American Society for Reproductive Medicine (2012) recommends such surgery prior to IVF. Some evidence shows that Essure inserts may sufficiently occlude the tube for this purpose (Arora, 2014).

### ■ Benign Neoplasms

These are rare in the fallopian tube. The most common benign tumor is mesothelioma, which is found in less than 1 percent of hysterectomy specimens (Pauerstein, 1968). Previously termed adenomatoid tumors, these 1- to 2-cm, well-circumscribed solid nodules arise in the tubal wall (Salazar, 1972). Tubal leiomyomas are uncommon and derive from the smooth muscle of the tubal muscularis, from the broad ligament, or from vessels in either location.

Microscopically, the epithelium of the fallopian tube contains an intermixing of both ciliated and secretory cells. The secretory cell population increases with age, and cellular outgrowths can be seen histologically that contain only secretory cells (Li, 2013). These benign secretory cell outgrowths (SCOUTs) and their link to serous tubal intraepithelial carcinoma (STIC) and pelvic

serous carcinoma are current research topics (Mehrad, 2010). These are described in Chapter 35 (p. 740).

## ■ Tuboovarian Abscess

This is an inflammatory mass involving the fallopian tube, ovary, and often surrounding structures. If an ovary adheres to the fallopian tube, but is still visualized, it is called a *tuboovarian complex*. In contrast, a *tuboovarian abscess* results from a complete breakdown of ovarian and tubal architecture such that the separate structures are no longer identified. Either is usually a consequence of PID, although occasionally endometritis and pelvic malignancy may be the generative source. Affected women usually have lower abdominal pain, fever, leukocytosis, and unilateral or bilateral adnexal masses. These abscesses and their management are more fully discussed in Chapter 3 (p. 68).

REFERENCES . . . . . 244

Endometriosis is a common benign disorder defined as the presence of endometrial glands and stroma outside of the normal location. Implants of endometriosis are most often found on the pelvic peritoneum, but other frequent sites include the ovaries and uterosacral ligaments. Endometrial tissue located within the myometrium is termed adenomyosis and discussed in Chapter 9 (p. 213). Women with endometriosis may be asymptomatic, subfertile, or suffer varying degrees of pelvic pain. This is an estrogen-dependent disease and thus lends itself to hormone-based treatment. However, in those with disease refractory to medical management, surgery may be required.

INCIDENCE

The incidence of endometriosis is difficult to quantify, as women with the disease are often asymptomatic. Moreover, imaging modalities have low sensitivities for small implants (Wall, 2015). The primary method of diagnosis is laparoscopy, with or without biopsy for histologic diagnosis (Dunselman, 2014). Using this standard, the annual incidence of surgically diagnosed endometriosis was 1.6 cases per 1000 women aged between 15 and 49 years (Houston, 1987). In asymptomatic women, the prevalence of endometriosis ranges from 6 to 11 percent, depending on the population studied and mode of diagnosis (Buck Louis, 2011; Mahmood, 1991). However, because of its link with infertility and pelvic pain, endometriosis is notably more prevalent in subpopulations of women with these complaints. From

studies, the prevalence lies between 20 to 50 percent in infertile women, and in those with pelvic pain, it ranges from 40 to 50 percent (Balasch, 1996; Eskenazi, 2001; Meuleman, 2009). In adolescents, Janssen and coworkers (2013) reported that nearly two thirds of adolescents undergoing diagnostic laparoscopy for pelvic pain had evidence of endometriosis.

Previously, white women were thought to be disproportionately affected. More recent studies have provided variable results. Some show greater rates for whites and Asians, whereas others have found no statistically significant differences in endometriosis prevalence among any racial or ethnic groups (Jacoby, 2010). Of other patient characteristics, lower body mass appears to positively correlate with endometriosis risk (Peterson, 2013; Shah, 2013).

PATHOPHYSIOLOGY

■ Pathogenesis

The definitive cause of endometriosis remains unknown, but theories have been proposed. A more favored one describes retrograde menstruation through the fallopian tubes (Sampson, 1927). These refluxed endometrial fragments invade the peritoneal mesothelium and develop a blood supply for implant survival and growth. Supporting data include a report that surgical obliteration of the outflow tract in baboons induces endometriosis (D’Hooghe, 1997). In correlation, women with outflow tract obstruction also have a high incidence of endometriosis, which often resolves following obstruction relief (Sanfilippo, 1986; Williams, 2014). Importantly however, most women have retrograde menstruation (Halme, 1984). Thus, other factors, such as immunologic and angiogenic components, likely aid implant persistence.

Another hypothesis, the stem cell theory, implicates undifferentiated endometrial cells that initially reside in the endometrium’s basalis layer. These cells differentiate into epithelial, stromal, and vascular cells as the endometrium is routinely regenerated each cycle. If displaced to an ectopic location, such as by retrograde menstruation, these stem cells may give rise to endometriosis (Valentijn, 2013).

Aberrant lymphatic or vascular spread of endometrial tissue has also been implicated (Jerman, 2015). Lymphatic spread of endometriosis to pelvic sentinel lymph nodes is noted in affected women (Mechsner, 2008; Tempfer, 2011). Findings of endometriosis in unusual locations, such as the groin, also bolster this theory (Mourra, 2015). Last, cases in which no peritoneal implants are found, but solely isolated retroperitoneal lesions are noted, implicate lymphatic spread (Moore, 1988).

Another theory concerns coelomic metaplasia and suggests that the parietal peritoneum is pluripotent and can undergo metaplastic transformation to tissue histologically identical to normal endometrium. Because the ovary and the progenitor of the endometrium, the müllerian ducts, are both derived from coelomic epithelium, such metaplasia may help explain endometriosis involving the ovary. This process may also underlie cases of endometriosis in those without menstruation, such as premenarchal girls and males treated with estrogen and orchiectomy for prostate cancer (Marsh, 2005; Taguchi, 2012). Last, a theory purports that müllerian remnants left along their embryonic path undergo abnormal differentiation (Batt, 2013; Signorile, 2012).

### ■ Anatomic Sites

Endometriosis may develop anywhere within the pelvis and on other extrapelvic peritoneal surfaces. Most commonly, endometriosis is found in the dependent areas of the pelvis. As such, the anterior and posterior cul-de-sacs, other pelvic peritoneum, the ovary, and uterosacral ligaments are frequently involved. Additionally, the rectovaginal septum, ureter, and bladder and rarely, pericardium, surgical scars, and pleura may be affected. One pathologic review revealed that endometriosis has been identified on all organs except the spleen (Markham, 1989). Implants may be superficial or they may be *deep infiltrating endometriosis (DIE)*, that is, infiltrative forms that involve vital structures such as bowel, bladder, and ureters (Koninckx, 2012; Vercellini, 2004). Some definitions of DIE also quantify invasion as  $> 5$  mm (Koninckx, 1994).

As just noted, ovarian endometriomas are frequent manifestations of endometriosis (Fig. 10-1). These smooth-walled, dark-brown ovarian cysts are filled with a chocolate-appearing fluid and may be unilocular or, when larger, multilocular. Their pathogenesis is unclear, yet three theories include invagination of ovarian cortex implants, coelomic metaplasia, and secondary involvement of functional ovarian cysts by endometrial implants located on the ovarian surface (Vignali, 2002).

### ■ Molecular Mechanisms

Endometriosis is an estrogen-dependent, chronic inflammatory disease with aberrant growth of ectopic endometrial tissue. In this discussion, *eutopic endometrium* is that which lines the uterine cavity, whereas *ectopic endometrium* describes that outside the cavity. In affected patients, ectopic endometrial implants show molecular differences from the eutopic endometrium of unaffected women. The disturbed molecular mechanisms in this disease are yet to be completely defined. However, suspected underpinnings include an environment of estrogen dominance, estrogen dependence, and progesterone resistance within implants; inflammation; escape from immune clearance; local invasion and neurovascularity development; and genetic predisposition.

### Estrogen and Progesterone

Estrogen plays a causative role in endometriosis formation and is derived from multiple sources. First, most estrogen in women is produced directly by the ovaries. Second, peripheral tissues also produce estrogens through conversion of ovarian and

**FIGURE 10-1** Endometrioma. **A.** Surgical specimen of an ovary containing an endometrioma. **B.** Dark, chocolate-like fluid had filled this cyst. (Used with permission from Dr. Roxanne Pero.) **C.** In ovarian endometriomas, endometrial-type epithelium (E) and subjacent stroma (S) line the cyst, and are bordered peripherally by ovarian stroma (O). The golden brown pigment in the cyst wall (asterisks) is hemosiderin, indicating remote hemorrhage. Debris composed of necrotic and degenerating cells and remote hemorrhage occupies the interior of the cyst (D). It is the remote hemorrhage that confers the chocolate-like color to cyst fluid.

adrenal androgens by the enzyme aromatase. Endometriotic implants express aromatase and 17 $\beta$ -hydroxysteroid dehydrogenase type 1, which are the enzymes responsible for conversion of androstenedione to estrone and of estrone to estradiol, respectively. Implants, however, are deficient in 17 $\beta$ -hydroxysteroid dehydrogenase type 2, which inactivates estrogen (Kitawaki, 1997; Zeitoun, 1998). This enzymatic combination ensures that implants create an estrogenic environment. Moreover, it provides the rationale for aromatase inhibitor use to diminish aromatase activity in refractory clinical cases (p. 241). Last, the endometriotic stromal cell uniquely expresses the full complement of genes in the steroidogenic cascade, which is sufficient to convert cholesterol to estradiol itself (Bulun, 2012).

In addition to an estrogenic environment, normal progesterone effects are attenuated in endometriosis. This is progesterone resistance is thought to stem from an overall low concentration of progesterone receptors within implants (Attia, 2000). Specifically, pathological overexpression of estrogen receptor  $\beta$  in endometriosis suppresses estrogen receptor  $\alpha$  expression. This diminishes estradiol-mediated induction of the progesterone receptor in endometriotic cells (Xue, 2007).

As one consequence of this resistance, survival of refluxed endometrium in affected women may be bolstered. Namely, normal endometrium does not express aromatase and has elevated levels of 17 $\beta$ -hydroxysteroid dehydrogenase type 2 in response to progesterone (Satyaswaroop, 1982). As a result, progesterone antagonizes the estrogen effects in normal endometrium during the luteal phase. Endometriosis, however, manifests a relative progesterone-resistant state, which prevents this antagonism in its implants.

Progesterone resistance may also enhance implantation of refluxed endometrium. Invasion of the mesothelium can be aided by matrix metalloproteinases (MMPs). These are a group of collagenase proteins that can digest and remodel extracellular matrix and are implicated in endometrial turnover during normal menstruation. Of the various MMPs, MMP-3 expression is significantly increased in women with endometriosis compared with healthy controls, and its expression is significantly elevated during the luteal phase (Kyama, 2006). Progesterone represses MMP activity (Itoh, 2012). Thus, in affected patients, progesterone resistance within these implants may augment the MMP activity necessary for implant invasion.

## Inflammation

Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) is the most potent inducer of aromatase activity in endometrial stromal cells (Noble, 1997). Estradiol produced in response to the increased aromatase activity subsequently augments PGE<sub>2</sub> production by stimulating the cyclooxygenase type 2 (COX-2) enzyme in uterine endothelial cells (Gurates, 2003). This creates a positive feedback loop and potentiates the estrogenic effects on endometriosis proliferation. As discussed on page 239, nonsteroidal antiinflammatory drugs (NSAIDs) are used clinically to reduce prostaglandin formation and thereby decrease endometriosis-linked pain.

## Immune System

With retrograde menstruation, refluxed menstrual tissue in most women is usually cleared by macrophages, natural killer

(NK) cells, and lymphocytes. For this reason, immune system dysfunction is one likely mechanism for endometriosis establishment (Seli, 2003). Of these immune cells, macrophages serve as scavengers, and increased numbers are found in the peritoneal cavity of women with endometriosis (Haney, 1981; Olive, 1985b). Although this increased population might logically act to suppress endometrial proliferation, macrophages in these affected women actually stimulate endometriotic tissue (Braun, 1994).

Of other immune system players, NK cells have cytotoxic activity against foreign cells. Although NK cell numbers are unaltered in the peritoneal fluid of affected women, the NK cell cytotoxicity against endometrium is decreased (Ho, 1995; Wilson, 1994).

Cellular immunity may also be disordered in women with endometriosis, and T lymphocytes are implicated. For example, in patients with endometriosis compared with unaffected individuals, total lymphocyte numbers or helper/suppressor subpopulation ratios do not differ in peripheral blood. However, peritoneal fluid lymphocyte numbers are increased (Steele, 1984). Also, the cytotoxic activity of T lymphocytes against autologous endometrium in affected women is impaired (Gleicher, 1984).

Humoral immunity is also altered in affected women and is thought to play a role. Endometrial antibodies of the IgG class are more frequently detected in the sera of women with endometriosis (Odukoya, 1995). One study also identified IgG and IgA autoantibodies against endometrial and ovarian tissues in the sera and in cervical and vaginal secretions of affected women (Mathur, 1982). These results suggest that endometriosis may be, in part, an autoimmune disease.

Cytokines are small, soluble immune factors involved in signaling of other immune cells. Numerous cytokines, especially interleukins, are suspected in endometriosis pathogenesis. Of specific interest, increased levels of interleukin-1 $\beta$  (IL-1 $\beta$ ), IL-6, and IL-8 have been identified in relevant tissues and fluids (Arici, 1998; Mori, 1991; Tseng, 1996).

Other cytokines and growth factors are associated with endometriosis establishment. For example, both monocyte chemoattractant protein-1 (MCP-1) and RANTES (regulated on activation, normal T-cell expressed and secreted) can attract monocytes. Levels of these cytokines are increased in the peritoneal fluid of those with endometriosis and positively correlate with disease severity (Arici, 1997; Khorram, 1993). In addition, vascular endothelial growth factor (VEGF) is an angiogenic growth factor, which is upregulated by estradiol in endometrial stromal cells and peritoneal fluid macrophages. Levels of this factor are increased in the peritoneal fluid of affected women (McLaren, 1996). Although the exact role of these cytokines is unclear, perturbations in their expression and activity further support an immunologic role in endometriosis development.

## Genetics

No mendelian genetic inheritance pattern has been identified for endometriosis. But, the increased incidence in first-degree relatives suggests a polygenic/multifactorial pattern. For example, in population studies, 4 to 8 percent of the female siblings or mothers of affected women had endometriosis (Dalsgaard,

2013). Other research revealed that women with endometriosis and an affected first-degree relative were more likely to have severe endometriosis (61 percent) than women without an affected first-degree relative (24 percent) (Malinak, 1980). Studies also demonstrate concordance for endometriosis in monozygotic twin pairs (Saha, 2015; Treloar, 1999).

To assist with identifying candidate genes, population-based genome-wide association studies (GWASs) have been performed. These studies are founded on the principle that common diseases, such as endometriosis, are caused by genetic variants that are common themselves. With GWAS, a set of several 100,000 common single nucleotide polymorphisms (SNPs or single DNA base-pair changes) are selected to provide the maximum coverage of the genome. Their frequencies are then compared between affected and unaffected groups. From GWASs of endometriosis, several candidate genes and chromosomes have been identified for further study (Burney, 2013).

## CLASSIFICATION

The primary method of endometriosis diagnosis is visualization of endometriotic lesions by laparoscopy, with or without biopsy for histologic confirmation. The extent of endometriosis can vary widely between individuals, and thus, one classification by the American Society for Reproductive Medicine (1997) allows disease to be quantified (Fig. 10-2). With this, endometriosis on the peritoneum, ovaries, fallopian tubes, and cul-de-sac is scored at surgery. At these sites, points are assigned for disease surface area, degree of invasion, morphology, and extent of associated adhesions. Also, endometriotic lesions are morphologically categorized as white, red, or black. In this system, endometriosis is classified as stage I (minimal), stage II (mild), stage III (moderate), and stage IV (severe).

Advantages of this system are its widespread implementation, its ease of use, and its four simple-to-comprehend stages. However, the system has limitations. It correlates poorly with infertility and pain symptoms (Guzick, 1997; Vercellini, 1996). For example, women with extensive disease (stage IV) may note few complaints, whereas those with minimal disease (stage I) may have significant pain or subfertility or both. This poor predictive ability stems in part from scores that are derived from subjective visual examination. Moreover, disease involving ureter, bowel, or other extrapelvic sites is not scored (Adamson, 2013). To address these shortcomings, other systems have been developed but are yet to be widely

used. These include the ENZIAN staging system to better represent DIE and the Endometrial Fertility Index (Adamson, 2010; Haas, 2011).

## SYMPTOMS

### Pain

As noted, women with endometriosis may be asymptomatic, but chronic pelvic pain (CPP) or subfertility is common (Ballard, 2008). Of endometriosis-associated CPP, dysmenorrhea, dyspareunia, and noncyclic pain are frequent types. Less often and described on page 234, affected women may also complain of dyschezia (pain with defecation), dysuria, or abdominal wall pain.

To Be Used with Abnormal Tubes and/or Ovaries

**FIGURE 10-2** Reproduced with permission from American Society for Reproductive Medicine: Revised American Society for Reproductive Medicine classification of endometriosis, Fertil Steril 1997 May;67(5):817-821.

At the molecular level, the underlying cause of pain is unclear, but proinflammatory cytokines and prostaglandins released by endometriotic implants may be one source (Bulun, 2009). Other investigations implicate nerve growth into endometriotic implants (Barcena de Arellano, 2011; McKinnon, 2012). Once established, continued exposure of these sensory nerves to the inflammatory environment within the implants can lead to central sensitization and CPP, as described in Chapter 11 (p. 250) (As-Sanie, 2013; Bajaj, 2003). The variability of implant location and these chemical influences help explain the differing pain manifestations experienced by women with endometriosis. That said, typical pain scoring tools such as the visual analogue scale and the numerical rating scale are suitable for initial assessment and for evaluation of treatment efficacy (Fig. 11-3, p. 255) (Bourdel, 2015).

Of pain types, endometriosis-associated dysmenorrhea typically precedes menses by 24 to 48 hours. Compared with primary dysmenorrhea, this pain is thought to be more severe and is less responsive to NSAIDs and combination oral contraceptives (Allen, 2009; Opoku-Anane, 2012). Presence of DIE also positively correlates with dysmenorrhea severity (Lafay Pillet, 2014).

Endometriosis-associated dyspareunia is often related to rectovaginal septum, uterosacral ligament, or posterior cul-de-sac disease, although other involved sites can cause painful intercourse (Vercellini, 2007, 2012). Tension on diseased uterosacral ligaments during intercourse may trigger this pain (Fauconnier, 2002). Although some women with endometriosis describe a history of dyspareunia since coitarche, endometriosis-associated dyspareunia is suspected if pain develops after years of pain-free intercourse (Ferrero, 2005).

Noncyclic chronic pelvic pain (CPP) is another frequent symptom of endometriosis. Approximately 33 percent of women with CPP are found to have endometriosis at the time of laparoscopy (Howard, 2003). This percentage is higher in adolescents with CPP (Janssen, 2013). Some studies correlate pain severity with advanced-stage disease, whereas other studies do not (Fedele, 1992; Hsu, 2011).

The focus of chronic pain may vary. If the rectovaginal septum or uterosacral ligaments are involved with disease, pain may radiate to the rectum or lower back. Alternatively, pain radiating down the leg and causing cyclic sciatica may reflect sciatic nerve involvement (Possover, 2011). That said, pain may correlate poorly with pelvic disease location (Hsu, 2011).

## ■ Infertility

The incidence of endometriosis in women with subfertility is 20 to 30 percent (Waller, 1993). In addition, although wide variability is reported, patients with infertility appear to have a greater incidence of endometriosis than fertile controls (13 to 33 percent versus 4 to 8 percent) (D'Hooghe, 2003; Strathy, 1982). Furthermore, Matorras and colleagues (2001) noted an increased prevalence of more severe stages of endometriosis in women with infertility.

Adhesions are one intuitive explanation for endometriosis-related infertility. These may impair normal oocyte pick-up and transport by the fallopian tube. Beyond mechanical impairment,

numerous subtle defects also appear to be involved. Such defects include perturbations in follicle development, ovulation, sperm function, embryo quality and development, and implantation (Macer, 2012; Stille, 2012).

A link between infertility and milder forms of endometriosis is less well supported (D'Hooghe, 1996; Schenken, 1980). An association is suggested by the differing prevalence of endometriosis between infertile and fertile women. For example, Rodriguez-Escudero and associates (1988) reported that women with minimal endometriosis had a 12-month cumulative pregnancy rate of 47 percent, which is below that of normal fertile women. Furthermore, a prospective cohort study demonstrated that women with minimal or mild endometriosis had a fecundity similar to that of those with unexplained infertility.

In moderate to severe endometriosis (stage III to IV), tubal and ovarian architecture are often distorted. As a result, impaired fertility would be expected. Few studies report fecundity rates in women with severe endometriosis. One investigation comparing mild, moderate, and severe endometriosis revealed a monthly fecundity rate of 8.7 percent in those with mild disease, 3.2 percent with moderate disease, and no pregnancies with severe disease (Olive, 1985a). In another, women with severe endometriosis undergoing in vitro fertilization (IVF) had poorer implantation and pregnancy rates compared with those with mild disease (Harb, 2013).

## ■ Symptoms from Specific Sites

### Rectosigmoid Lesions

Defecatory pain develops much less often than other types of CPP in affected patients. Complaints may be chronic or cyclic, and they can be associated with constipation, diarrhea, or cyclic hematochezia (Roman, 2013). Thus, gastrointestinal causes of CPP are also entertained during evaluation (Chap. 11, p. 265). The origin of symptoms can be fixation of the rectum to adjacent anatomic structures or rectal wall inflammation.

Symptoms may also stem from DIE of the gastrointestinal tract, which complicates 5 to 12 percent of proven endometriosis cases. Bowel DIE predominantly involves rectosigmoid colon and much less so the small bowel, cecum, or appendix (Ruffo, 2014b). Lesions are usually confined to the subserosa and muscularis propria. Thus, colonoscopy offers poor diagnostic sensitivity (Milone, 2015). Rarely, more severe cases may involve the bowel wall transmurally and lead to intestinal obstruction or a clinical picture suggesting malignancy (Kaufman, 2011; Ruffo, 2014a).

For diagnosis, rectal DIE can be imaged by transvaginal sonography (TVS), and sensitivity approximates 80 percent. However, TVS techniques used to diagnose DIE have a learning curve, and these are predominantly performed at tertiary care centers (Tammaa, 2014). Magnetic resonance (MR) imaging can clarify anatomy and degree of invasion, especially preoperatively (Bazot, 2009; Wall, 2015). Laparoscopy typically provides the definitive diagnosis.

Without obstructing symptoms, women may be considered for conservative management with hormonal therapy. However, treatment is often surgical, and cases often warrant a surgeon skilled in bowel surgery. Variables such as anatomic

site, DIE depth, lesion size, and number of foci influence surgery. Colorectal segment resection may be needed. Less invasive techniques that shave down the lesion without opening the rectum or that excise discrete nodules are also described (Alabiso, 2015).

### Urinary Tract Lesions

Logically, endometriosis should be considered if urinary tract symptoms persist despite negative urine culture results. Symptoms, if present, are more common with bladder disease. These include dysuria, suprapubic pain, urinary frequency, urgency, and hematuria (Gabriel, 2011; Seracchioli, 2010). Costovertebral angle pain may reflect ureteral endometriosis with obstruction and hydronephrosis that can progress eventually to kidney function loss (Knabben, 2015).

In a large series by Antonelli and coworkers (2006), the prevalence of urinary tract DIE was 2.6 percent. In this series of 31 patients, 12 had bladder endometriosis, 15 had ureteral endometriosis, and four had both ureteral and bladder involvement. TVS has suitable accuracy for bladder DIE but is less sensitive for ureteral disease (Exacoustos, 2014a). In unclear cases, MR imaging can add additional anatomic information. In light of associated symptoms with urinary tract DIE, cystoscopy with biopsy can also help clarify the diagnosis.

Treatment is either medical or surgical. If elected, surgery for bladder invasion is typically partial cystectomy. Surgeries for ureteral involvement vary by disease severity and include: (1) freeing the tethered ureter by ureterolysis, (2) segmental resection and reanastomosis, or (3) ureter reimplantation into the bladder, that is, ureteroneocystotomy (Seracchioli, 2010).

### Anterior Abdominal Wall

Some individuals with abdominal pain can have anterior abdominal wall endometriomas. Most of these lesions develop in the abdominal scar after uterine surgery or cesarean delivery, whereas others form unrelated to prior operations (Fig. 10-3) (Ding, 2013). Implants usually are found within the subcutaneous layer, are palpable, and may involve the adjacent fascia. Less often, the rectus abdominis muscle is infiltrated (Mostafa, 2013). Diagnostic tools are variably employed, and abdominal wall sonography, computed tomography (CT), MR imaging, and fine-needle aspiration are options. The decision to perform concurrent TVS is typically guided by whether CPP symptoms coexist.

In most instances, implants are surgically excised for pain relief and diagnosis. For small implants, preoperative imaging may not be needed. But with larger implants and concerns for fascial or rectus abdominis muscle involvement, CT or MR imaging can aid surgery planning (Ecker, 2014). Large fascial defects following excision may require mesh to close the defect.

### Thoracic Lesions

*Thoracic endometriosis* defines implants inside the thoracic cavity that lead to symptoms described as menstrual or synonymously called “catamenial.” These include cyclic chest or shoulder pain, hemoptysis, or pneumothorax, which predominantly occurs on

**FIGURE 10-3** Endometriosis within a Pfannenstiel incision scar. **A.** Preoperative photograph delineates the borders of the mass. **B.** Computed tomography image shows a subcutaneous mass (arrow) extending down to the anterior abdominal wall fascia on the left. **C.** Excised mass. **D.** Bisected mass shows white fibrous scarring within yellow subcutaneous fat. the right (Haga, 2014; Rousset-Jablonski, 2011). Chest CT is preferred imaging (Rousset, 2014). For pneumothorax, minimally invasive thoroscopic surgery is usually indicated. This is often coupled with several months of postoperative gonadotropin-releasing hormone (GnRH) or of progestin therapy identical to that for pelvic endometriosis treatment (Alifano, 2010). Hemoptysis, depending on findings, may be treated hormonally or surgically.

## DIAGNOSTIC EVALUATION

### ■ Physical Examination

For the most part, endometriosis is a disease confined to the pelvis. Accordingly, visual cues are often lacking. Some exceptions include endometriosis within an episiotomy scar or surgical scar, most often within a Pfannenstiel incision (Koger, 1993; Zhu, 2002). Rarely, endometriosis may develop spontaneously within the perineum or perianal region (Watanabe, 2003). Occasionally, blue or red powder-burn lesions are seen on the cervix or the posterior vaginal fornix. These lesions can be tender or bleed with contact. One study found that speculum examination displayed endometriosis in 14 percent of patients diagnosed with DIE (Chapron, 2002).

During bimanual examination, pelvic organ palpation often reveals suggestive anatomic abnormalities. Uterosacral ligament nodularity and tenderness may reflect active disease or scarring along the ligament. An enlarged, cystic adnexal mass may represent an ovarian endometrioma, which can be mobile or adhered to other pelvic structures. A retroverted, fixed, tender uterus and a firm, fixed posterior cul-de-sac are among other findings. Pelvic nodularities secondary to endometriosis may be more easily detected by bimanual examination during menses (Koninckx, 1996). However, examination is generally inaccurate in assessing the extent of endometriosis, especially if the lesions are extragenital. Last, rectal examination may reveal rectovaginal septum nodularity or tenderness.

### ■ Laboratory Testing

Laboratory investigations are often undertaken to exclude other causes of pelvic pain that are listed in Table 11-1 (p. 251). Initially, a complete blood count (CBC), human chorionic gonadotropin assay, urinalysis and urine cultures, vaginal cultures, and cervical swabs may be collected to exclude infections or pregnancy complications. If urinary tract endometriosis is suspected, then renal function can also be assessed by creatinine levels.

Numerous serum markers have been studied as possible diagnostic tools. Cancer antigen 125 (CA125) is a glycoprotein that is found in fallopian tube epithelium, endometrium, endocervix, pleura, and peritoneum. As discussed in Chapter 35 (p. 737), this marker is used in ovarian cancer evaluation and surveillance. Recognized by monoclonal antibody assays, elevated CA125 levels positively correlate with endometriosis severity (Hornstein, 1995a). Unfortunately, the assay has poor sensitivity in detecting mild endometriosis and appears to be a better diagnostic test for stage III or IV endometriosis (Mol, 1998; Santulli, 2015). Although the role of this assay in clinical practice is uncertain, it may be useful in the presence of a sonographically detected ovarian cyst suggestive of an endometrioma.

As for other serum markers, May and colleagues (2010) completed a systematic review of more than 100 putative biomarkers. They were unable to identify a single biomarker or biomarker panel that they felt was clinically useful.

**FIGURE 10-4** Transvaginal sonogram demonstrating ovarian endometrioma. A cyst with diffuse internal low-level echoes is seen.

### ■ Diagnostic Imaging

Many women with endometriosis present with CPP, and TVS is an initial imaging tool. It is accurate in detecting endometriomas and aids exclusion of other causes of pelvic pain. However, imaging of superficial endometriosis or endometriotic adhesions is inadequate. Small endometriotic plaques or nodules may occasionally be seen, but these findings are inconsistent (Wall, 2015).

Endometriomas can be diagnosed by TVS with adequate sensitivity in most settings if they are 20 mm in diameter or greater. Sensitivity and specificity of TVS to diagnose endometriomas range from 64 to 90 percent and from 22 to 100 percent, respectively (Moore, 2002). An endometrioma classically is cystic with homogeneous, low-level internal echoes, often described as “ground glass” echogenicity. There is normal surrounding ovarian tissue (Fig. 10-4). As such, these may have an identical appearance to hemorrhagic corpus luteum cysts. Although endometriomas are most often unilocular, one to four thin septations can be found (Van Holsbeke, 2010). Less typically, these cysts can display thick septations or walls. Also less often, echogenic wall foci that lack flow when color Doppler is applied can be seen and are typically depositions of blood or blood components (Bhatt, 2006). Color Doppler TVS often demonstrates pericystic, but not intracystic, flow. Although endometriomas can be found in postmenopausal women, they are less common and more often are multilocular compared with those in reproductive-aged women.

As noted previously (p. 234), TVS for DIE involving the bowel and bladder has suitable accuracy (Exacoustos, 2014a; Hudelist, 2011). That said, for the diagnosis of rectal endometriosis, TVS is highly operator dependent, and experience is often lacking (Dunselman, 2014). Thus, MR imaging may clarify anatomy for equivocal sonographic findings and offers superior resolution at soft tissue interfaces (Fig. 10-5). In some cases with DIE, MR imaging can assist preoperative planning.

CT scanning plays a limited role in the evaluation of endometriosis. This is because TVS images endometriomas well, and CT has poor sensitivity for small implants and plaques. That said, chest CT is preferred for thoracic endometriosis. CT is

**FIGURE 10-5** Magnetic resonance images of an endometrioma (arrows) just lateral to the rectum. **A.** Consistent with subacute blood, low-intensity signals are found on T-2 weighted sequences. **B.** High-intensity signals are seen on T-1 weighted sequences. (Used with permission from Dr. Diane Twickler.)

suitable for abdominal wall endometrioma evaluation. Also, in selected cases, CT may have a role to evaluate bowel or ureteral endometriosis (Exacoustos, 2014b).

### ■ Diagnostic Laparoscopy

Although imaging can add clinical information, laparoscopy is the primary method used for diagnosing endometriosis (American College of Obstetricians and Gynecologists, 2014b). Surgical findings vary and may include discrete endometriotic lesions, endometrioma, or adhesions. Implants are typically found on pelvic organ serosa and pelvic peritoneum. Lesions are variably colored and can be red (red, red-pink, or clear), white (white or yellow-brown), and black (black or black-blue) (Fig. 10-6). White and red lesions most commonly correlate with the characteristic histologic findings of endometriosis (Jansen, 1986). Dark lesions are pigmented by hemosiderin deposition from trapped menstrual debris. In addition to color differences, endometriotic lesions may differ morphologically. They can appear as smooth blebs on peritoneal surfaces, as holes or defects within the peritoneum, or as flat stellate lesions whose points are formed by surrounding scar tissue. Endometriotic lesions may be superficial or may deeply invade the peritoneum or pelvic organs.

Endometriomas are easily identified during laparoscopy. Laparoscopic visualization of ovarian endometriomas has a sensitivity and specificity of 97 percent and 95 percent, respectively (Vercellini, 1991). Because of this, ovarian biopsy is rarely required for diagnosis.

### ■ Pathologic Analysis

Current guidelines do not require biopsy and histologic evaluation for the diagnosis of endometriosis. However, some suggest

**FIGURE 10-6** Endometriosis diagnosed during laparoscopy. **A.** Several red and clear endometriotic lesions seen on the pelvic peritoneum of the posterior cul-de-sac. **B.** Several brown-black lesions on the ovarian surface. (Used with permission from Dr. David Rogers.)

that relying solely on laparoscopic findings in the absence of histologic confirmation often results in overdiagnosis (Buck Louis, 2011; Wykes, 2004). Specifically, the greatest discordance between laparoscopic and histologic findings is noted in scarred lesions (Walter, 2001). Histologic diagnosis requires both endometrial glands and stroma found outside the uterine cavity (Fig. 10-7). Additionally, hemosiderin deposition is frequently seen. The gross appearance of endometriotic lesions often suggests certain microscopic findings. For example, if examined microscopically, red lesions are frequently vascularized, whereas white lesions more often display fibrosis and few vessels (Nisolle, 1997).

### Treatment

Treatment for endometriosis depends on a woman's specific complaints, symptom severity, location of endometriotic lesions, goals for treatment, and desire to conserve future fertility. As

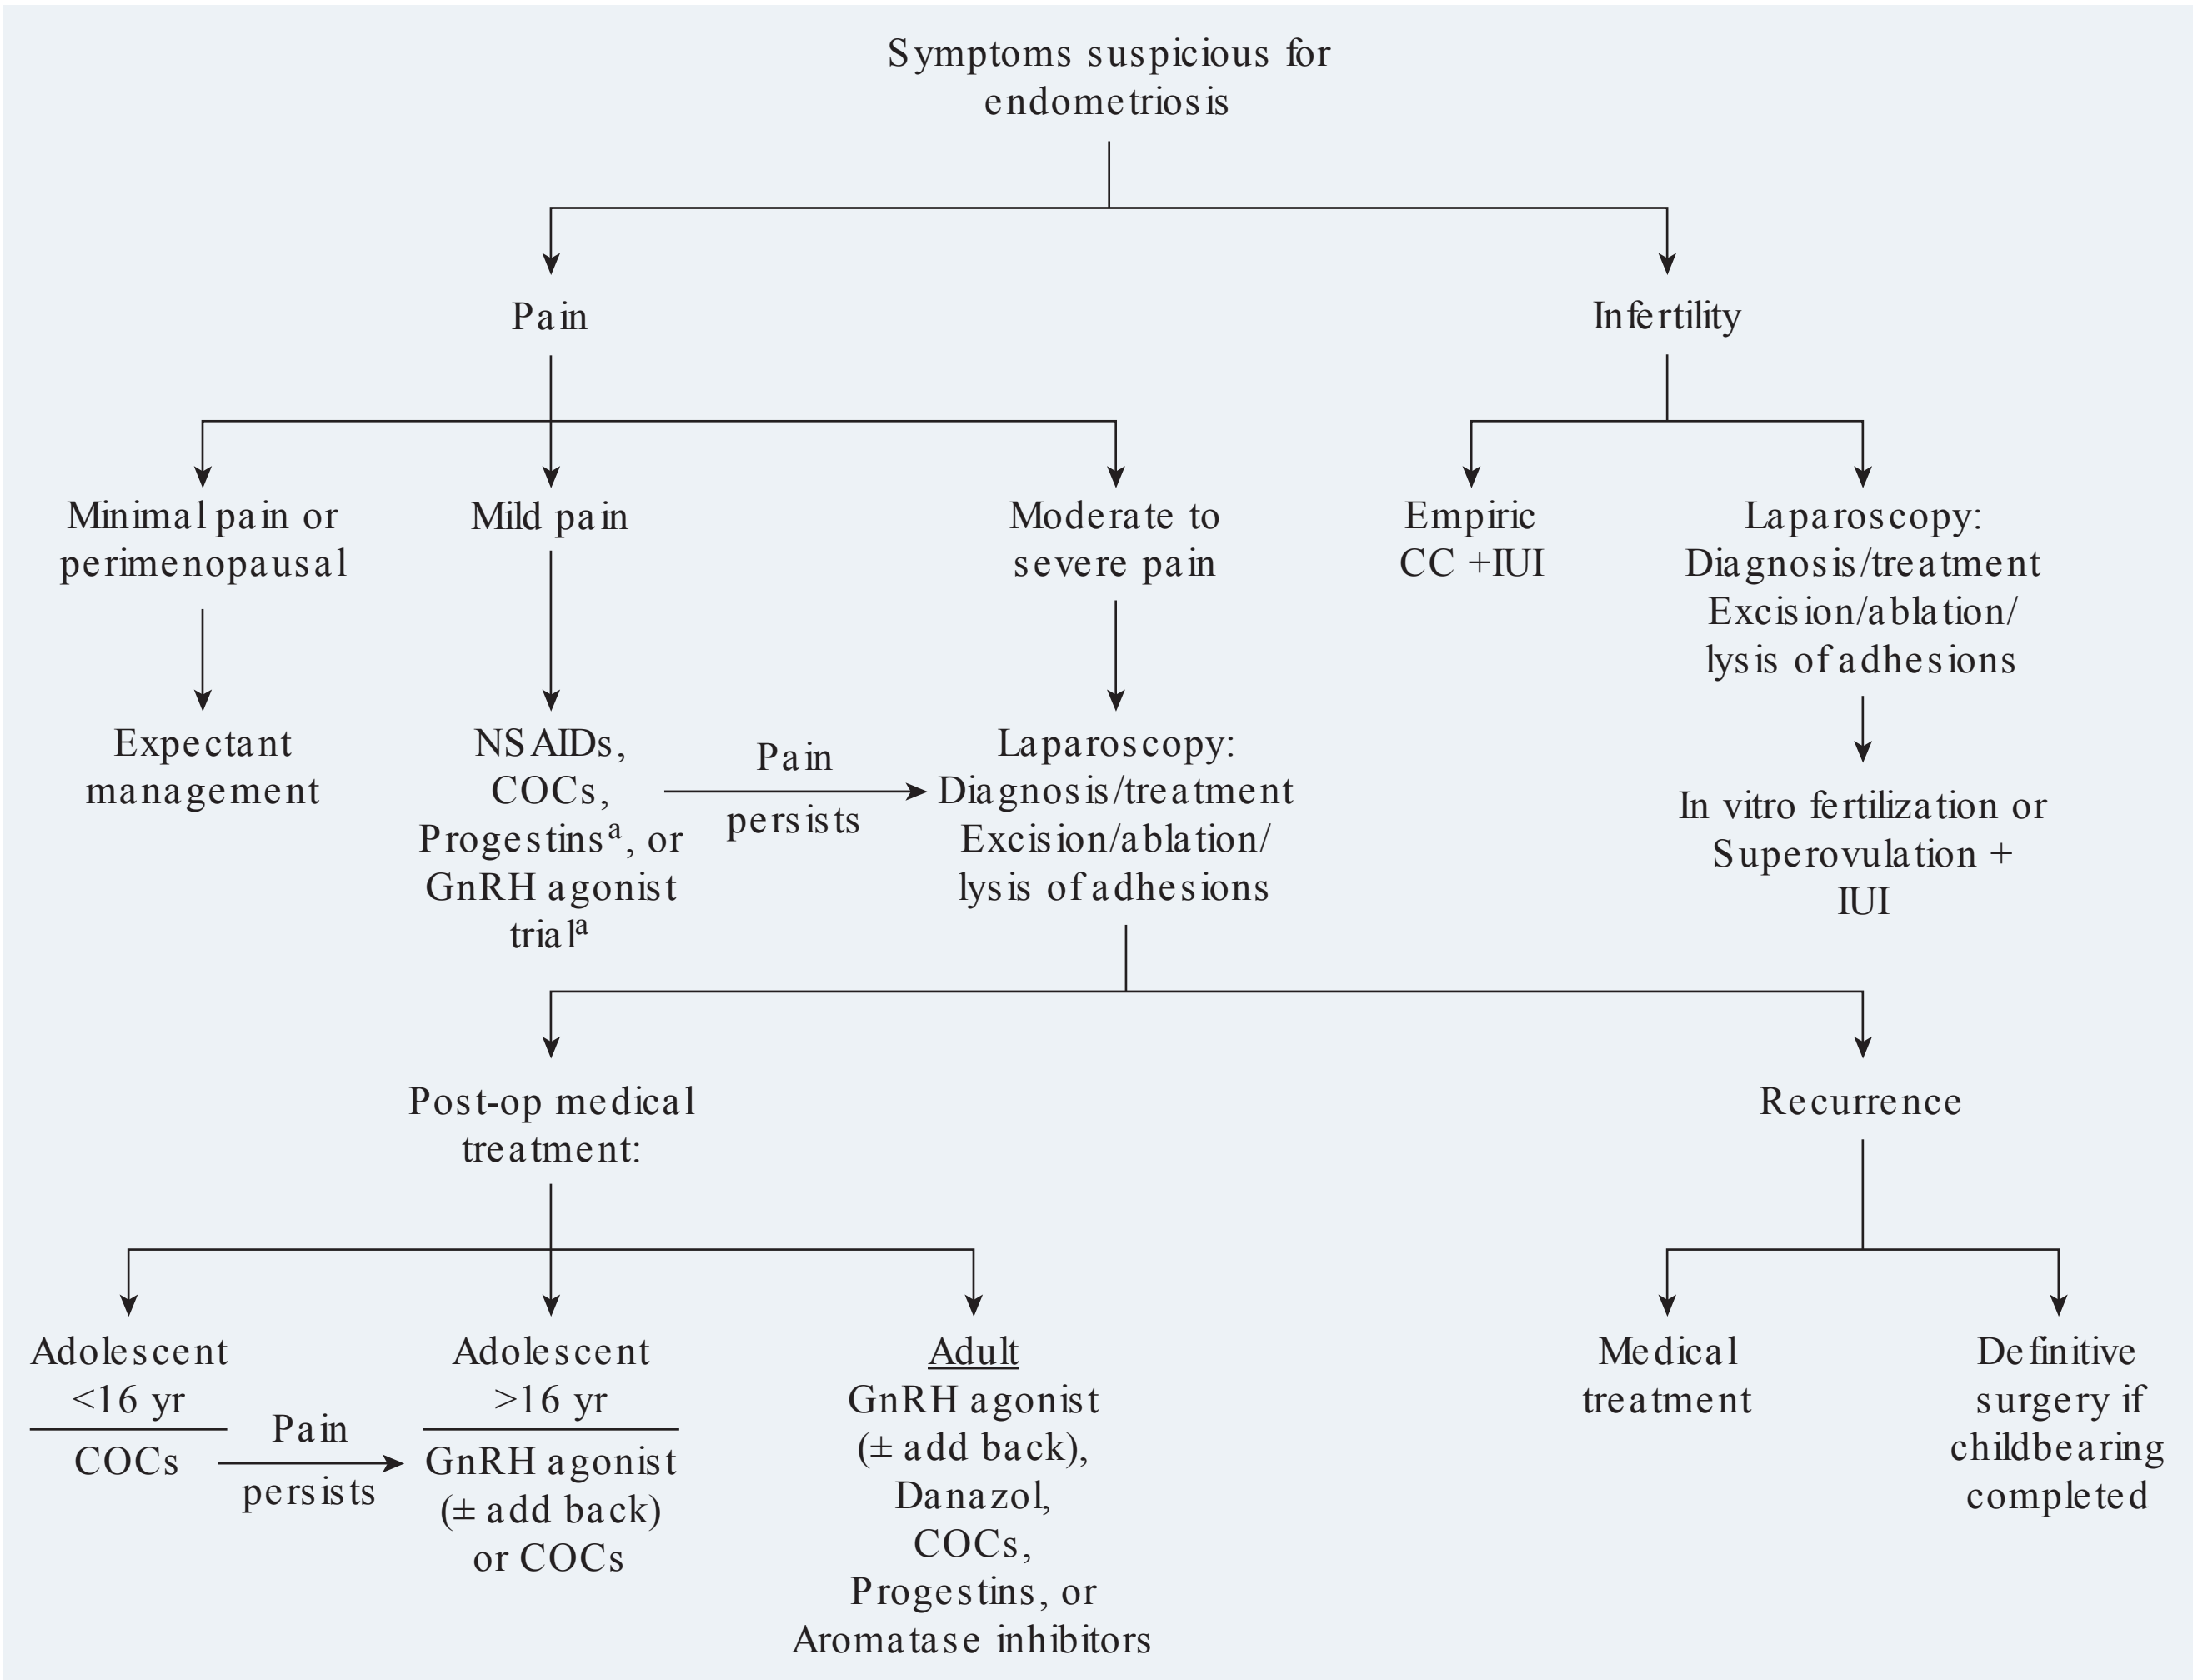

**FIGUR E 10-7** Endometriosis. This focus of endometrial glands and stroma was identified in the abdominal wall at the lateral aspect of a cesarean delivery scar. (Used with permission from Dr. Kelley Carrick.)

shown in [Figure 10-8](#), determining whether a patient is seeking treatment for infertility or pain is essential, as therapy for these two is different.

If pain is prominent and conception is not currently desired, then medical therapy is typically selected. Treatment strives to atrophy ectopic endometrium and diminish disease-associated inflammation. Available agents include NSAIDs, sex steroid hormones, GnRH agents, and aromatase inhibitors. In general, suitable starting regimens are NSAIDs alone or combined with oral contraceptive pills or with a progestin. These agents may be initiated if endometriosis is suspected in a woman with CPP or may be started following diagnostic laparoscopy. If initial therapy fails to control pain following laparoscopy, then use of a different medication is reasonable. If initial empiric therapy is ineffective, then either diagnostic laparoscopy or medication change is suitable (American College of Obstetricians and Gynecologists, 2014b). Of note, although medical treatment improves pain, relapse rates are high with therapy discontinuation.

If infertility is the presenting symptom, then fertility-preserving treatment without ovulation suppression will be required, as outlined on page 243. In contrast, if the patient

<sup>a</sup>Agents not recommended for adolescents younger than 16 years.

has severe, recalcitrant pain and has completed childbearing, definitive surgery may be warranted, as described on page 243.

## ■ Medical Treatment of Pain

### Expectant Management

For many women, symptoms will preclude them from choosing expectant management. However, for those with mild symptoms or for asymptomatic women diagnosed incidentally, expectant management may be appropriate (Moen, 2002). Sutton and associates (1997) expectantly managed patients initially diagnosed by laparoscopy with minimal to moderate endometriosis. At second-look laparoscopy after 1 year, 29 percent of women had disease regression, 42 percent remained unchanged, and 29 percent had disease progression. Other investigators have shown similar rates of disease regression with expectant management (Tommas, 1987). These studies are confined to patients with minimal to moderate endometriosis. There are no well-designed trials examining the effect of expectant management on severe endometriosis.

### Nonsteroidal Antiinflammatory Drugs

Both COX-1 and -2 enzymes promote synthesis of prostaglandins involved in the pain and inflammation associated with endometriosis. Specifically, endometriotic tissue expresses COX-2 at greater levels than eutopic endometrium (Cho, 2010). Accordingly, therapy aimed at lowering these prostaglandin levels plays a role in alleviating endometriosis-associated pain. As such, NSAIDs are often first-line therapy in women with primary dysmenorrhea or pelvic pain with suspected or known endometriosis. That said, study evidence supporting NSAIDs for this disease is scant and is extrapolated from efficacy data in primary dysmenorrhea (Kauppila, 1985; Marjoribanks, 2010).

The NSAIDs listed in Table 10-1 nonselectively inhibit both COX-1 and COX-2 enzymes. In contrast, selective COX-2 inhibitors specifically inhibit the COX-2 isoenzyme. Due to the cardiovascular risks with long-term use of selective COX-2 inhibitors, these medications are used at the lowest possible dose and for the shortest duration necessary (Jones, 2005). Thus, drugs in Table 10-1 are primarily selected.

### Combination Hormonal Contraceptives

These agents are a mainstay for the treatment of endometriosis-related pain. They inhibit gonadotropin release, decrease

menstrual flow, and decidualize implants. As such, abundant study evidence supports use of combination oral contraceptive (COC) pills or the contraceptive patch or ring to relieve endometriosis-related pain (Harada, 2008; Vercellini, 1993, 2010). These provide contraception and other noncontraceptive benefits, which are balanced against risks enumerated in Chapter 5 (p. 119).

COCs can be used conventionally in a cyclic regimen or may be used continuously, without a break for withdrawal menses. The continuous regimen decreases the frequency of painful menses and improves CPP (Guzick, 2011). For endometriosis-related pain, monophasic or multiphasic COCs are both suitable. Additionally, low-dose COCs (containing  $\leq 20 \mu\text{g}$  ethinyl estradiol) have not proved superior to conventional-dose COCs for endometriosis treatment, but lower doses may lead to higher rates of abnormal uterine bleeding (Gallo, 2013).

### Progestins

This family of hormones is often used for endometriosis therapy. Progestational agents are known to antagonize estrogenic effects on the endometrium, causing initial decidualization and subsequent endometrial atrophy. For endometriosis treatment, progestins can be administered as an oral progestin pill, depot medroxyprogesterone acetate (DMPA) (Depo-Provera), norethindrone acetate (NETA), or a levonorgestrel-releasing intrauterine system.

As supporting evidence, one randomized trial compared the effect of oral medroxyprogesterone acetate (MPA) 100 mg daily given for 6 months and placebo. At second-look laparoscopy, partial or total resolution of peritoneal implants was noted in 60 percent of progestin-treated women compared with 18 percent of the placebo group. Furthermore, pelvic pain and defecatory pain were significantly reduced (Telimaa, 1987). Side effects of high-dose MPA included acne, edema, weight gain, and irregular menstrual bleeding. In practice, MPA is prescribed in oral dosages ranging from 20 to 100 mg daily.

Alternatively, MPA may be given intramuscularly in depot form in a dosage of 150 mg every 3 months. In depot form, MPA may delay resumption of normal menses and ovulation and thus is less suitable for women contemplating imminent pregnancy. Subcutaneous formulation of MPA, marketed as Depo-SubQ Provera 104, is also effective (Schlaff, 2006).

As discussed in Chapter 5 (p. 127), the Depo-Provera package insert carries a “black box warning.” This describes that

**TABLE 10-1.** Commonly Used Oral Nonsteroidal Antiinflammatory Drugs (NSAIDs) in the Treatment of Endometriosis-Associated Dysmenorrhea

Generic Name	Trade Name	Dosage
Ibuprofen	Motrin, Advil, Nuprin	400 mg every 4–6 hr
Naproxen	Naprosyn, Aleve	500 mg initially, then 250 mg every 6–8 hr
Naproxen sodium	Anaprox	550 mg initially, then 275 mg every 6–8 hr
Mefenamic acid	Ponstel	500 mg initially, then 250 mg every 6 hr
Ketoprofen	Orudis, Oruvail	50 mg every 6–8 hr

prolonged DMPA use may result in bone density loss, that this loss is greater with increasing duration of use, and that the loss may not be completely reversible. Labeling recommends limiting use to 2 years unless other contraceptive methods are inadequate. Thus, the risks and benefits of treatment are weighed if contemplating long-term DMPA therapy. Bone density surveillance with dual energy x-ray absorptiometry (DEXA) scanning is not recommended (American College of Obstetricians and Gynecologists, 2014a).

NETA is a 19-nortestosterone synthetic progestin that has been used to treat endometriosis. In one study, investigators administered an initial oral dosage of NETA, 5 mg daily, with increases of 2.5 mg daily until amenorrhea or a maximal dosage of 20 mg daily was reached. They found an approximately 90-percent reduction in dysmenorrhea and pelvic pain (Muneyyirci-Delale, 1998). As discussed on page in the next section, NETA is also used as adjunct therapy with GnRH agents to blunt the bone loss linked with those drugs.

Dienogest is another 19-nortestosterone synthetic progestin suitable for endometriosis. In one randomized study, it was significantly more effective than placebo for reducing endometriosis-associated pain when used orally at a dosage of 2 mg daily (Strowitzki, 2010a). Other trials show efficacy equivalent to that of GnRH agonists (Harada, 2009; Strowitzki, 2010b). Currently, this progestin as a sole agent is not available in the United States.

The levonorgestrel-releasing intrauterine system (LNG-IUS) (Mirena) delivers levonorgestrel directly to the endometrium and is effective for up to 5 years. This intrauterine device has traditionally been used for contraception, but data are accruing for endometriosis treatment. One small randomized trial that incorporated second-look laparoscopy showed improved endometriosis stage with both LNG-IUS and the comparator GnRH treatment. Other small randomized trials have shown symptom improvement when compared against expectant management, DMPA, or GnRH agonists (Petita, 2005; Tanmahasamut, 2012; Vercellini, 2003b; Wong, 2010). However, in patients with bowel endometriosis, the LNG-IUS may be ineffective for symptom control (Hinterholzer, 2007). Contraindications to LNG-IUS use are listed in Chapter 5 (p. 109).

Intuitively, the implant that chronically releases the progestin etonogestrel might be considered for endometriosis. Data regarding its efficacy for this indication are limited. One small randomized study comparing the implant and the LNG-IUS reported comparable efficacy (Walch, 2009).

### GnRH Agonists

Endogenous pulsatile release of GnRH prompts secretory activity of the gonadotropes within the anterior pituitary. Gonadotropin release from the pituitary then leads to ovarian steroidogenesis and ovulation. However, continuous, nonpulsatile GnRH administration results in pituitary desensitization and subsequent loss of ovarian steroidogenesis. These features allow pharmacologic use of GnRH agonists for endometriosis treatment. With loss of ovarian estradiol production, the hypoestrogenic environment removes the stimulation normally provided to the endometriotic implants and creates a pseudo-menopausal state during treatment. In addition to their direct

effect on estrogen production, GnRH agonists also reduce COX-2 levels in patients with endometriosis, providing another mechanism of treatment (Kim, 2009).

GnRH agonists are inactive if taken orally, but intramuscular, subcutaneous, and intranasal preparations are available. Leuprolide acetate (Lupron Depot) is available in a 3.75-mg monthly dose or an 11.25-mg 3-month dose, both given IM. Less frequently used GnRH agonists include goserelin (Zoladex) administered as a 3.6-mg monthly or a 10.8-mg 3-month subcutaneous depot implant; triptorelin (Trelstar) given as a 3.75-mg monthly IM injection; and nafarelin (Synarel) used in a 200-mg twice-daily nasal spray regimen. All of these except triptorelin carry specific Food and Drug Administration (FDA) approval for endometriosis treatment.

**Pain Improvement.** Empirically, GnRH agonists may be used *prior to laparoscopy* in women with CPP and clinical suspicion of endometriosis. In a study by Ling and associates (1999), after 3 months of GnRH agonist treatment, pain scores significantly declined compared with those after placebo. Subsequent laparoscopy revealed that 93 percent of these women had surgically diagnosed endometriosis. Similarly, in suspected cases, depot leuprolide acetate may be used empirically *in lieu of laparoscopy* for satisfactory symptom improvement. That said, an empiric GnRH trial is not routinely offered to patients younger than 16 years because GnRH agonist effects on long-term bone mineral density (BMD) have not been adequately studied in this age group.

In those with *surgically confirmed* endometriosis, numerous studies demonstrate the effectiveness of GnRH agonist therapy to improve pain symptoms (Brown, 2010). The GnRH agonists provide greater relief when administered for 6 months compared with 3 months (Hornstein, 1995b). As noted in the prior sections, GnRH agonists compares favorably with other drugs used for endometriosis treatment. Although GnRH is effective, its cost and side effects often favor trials of COCs or progestins first.

**Add-back Therapy.** Concerns regarding the effects of prolonged hypoestrogenism preclude extended treatment with GnRH agonists. Hypoestrogenic symptoms include hot flashes, insomnia, reduced libido, vaginal dryness, and headaches. Moreover, both spine and hip BMD decrease at 3 and 6 months of GnRH agonist therapy, with only partial recovery at 12 to 15 months after treatment (Orwoll, 1994). Because of the increased osteoporosis risk, therapy is usually limited to the shortest possible duration—usually no greater than 6 months.

Estrogen may be added to GnRH agonist therapy to counteract bone loss and is termed add-back therapy. With the addition of such hormonal add-back therapy, a GnRH agonist may occasionally be used longer than 6 months (American College of Obstetricians and Gynecologists, 2014b). The goal of add-back therapy is to supply enough estrogen to minimize GnRH agonist side effects while still maintaining a hypoestrogenic state sufficient to suppress endometriosis. Barbieri (1992) explained that tissues have varied sensitivity to estrogen, and a concentration of estrogen that will partially prevent bone loss may not stimulate endometrial growth. This “estrogen threshold” has not been established but is thought to approximate 30 to 40 pg/mL of estradiol.

Several regimens are suitable and appear equally efficacious (Wu, 2014). In one study, NETA 5 mg orally given daily, with or without conjugated equine estrogen (Premarin) 0.625 mg orally daily, for 12 months provided extended pain relief beyond the duration of treatment and preserved BMD (Hornstein, 1998). Another regimen of transdermal estradiol 25 µg plus daily 5 mg oral MPA showed that the GnRH agonist remained effective in reducing endometriosis pain (Edmonds, 1996). In addition, traditional COCs may be used effectively as add-back agents.

The extent of BMD decline has been evaluated with add-back therapy. Although bone loss was noted in all patients undergoing GnRH agonist treatment, the extent of loss was lower in the add-back group (Edmonds, 1994). Quality of life is also improved with add-back therapy (Zupi, 2004).

Such therapy can be initiated either immediately with the GnRH agonist or after 3 to 6 months of agonist therapy. However, little benefit is gained by deferring add-back therapy, and patients who receive add-back concurrently with agonist therapy have reduced bone loss (Al-Azemi, 2009; Kiesel, 1996). Supplemental calcium as a 1000-mg total daily dose is recommended along with add-back regimens (American College of Obstetricians and Gynecologists, 2014b).

### GnRH Antagonists

GnRH antagonists are a newer category of GnRH analogues capable of suppressing gonadotropin production. Unlike GnRH agonists, GnRH antagonists do not produce an initial release or *flare* of gonadotropins. Thus, suppression of gonadotropins and sex steroid hormones is immediate.

GnRH antagonists are mainly used for suppression of premature ovulation during IVF cycles. They have not been well studied for endometriosis treatment. Küpker and colleagues (2002) evaluated the effect of the antagonist cetrorelix in 15 endometriosis patients. They administered subcutaneous injections of cetrorelix at a dosage of 3 mg weekly for 8 weeks. Patients were symptom free during treatment, and second-look laparoscopy revealed disease regression in 60 percent of study participants. That said, long-term depot forms are not currently available.

Of newer agents, a nonpeptide, orally bioactive GnRH antagonist, elagolix, is undergoing evaluation. One 24-week randomized trial showed similar efficacy between elagolix and DMPA for endometriosis-associated pain (Carr, 2014).

### Aromatase Inhibitors

As noted earlier (p. 231), in endometriotic tissue, estrogen may be produced locally through aromatization of circulating androgens. This may clarify postmenopausal endometriosis or may explain cases in which symptoms persist despite conventional treatment. Hormonal strategies described in prior sections target ovarian estrogen production but have little effect on estrogens produced from other sources. In contrast, the aromatase inhibitors (AIs) block aromatase action and estradiol production in both the ovary and extraovarian sites. As a result, estrogen levels are dramatically suppressed, and AIs have hypoestrogenic side-effect profiles similar to those of GnRH agonists (Pavone, 2012). AIs used clinically include anastrozole (Arimidex) and letrozole (Femara).

In addition to hypoestrogenic side effects, a second concern is ovarian cyst formation. As explained and shown in Figure 20-3 (p. 455), by blocking the conversion of androgens to estrogens in ovarian granulosa cells, AIs reduce the negative feedback at the pituitary–hypothalamus level. This leads to increased GnRH secretion. Resulting elevations in luteinizing hormone (LH) and follicle-stimulating hormone promote increased ovarian follicular development. Therefore, combining AI with a progestin or COCs helps blunt this side effect (Shippen, 2004).

Small studies that combined aromatase inhibitors with NETA or with COCs support this approach for pain relief (Amsterdam, 2005; Ferrero, 2009). However, due to side effects and limited data, such AI combinations are usually prescribed to women after other options for medical or surgical treatment have been exhausted (Dunselman, 2014).

### Selective Progesterone-Receptor Modulators

Progestins produce agonist effects upon binding to progesterone receptors. In contrast, progesterone antagonists and selective progesterone-receptor modulators (SPRMs) are agents that vary in their progesterone-receptor binding. Progesterone antagonists universally bind to and inactivate these receptors. SPRMs, depending on their individual pharmacologic profile, may activate or inactivate progesterone receptors variably within different tissue types (Chap. 15, p. 364). Currently, these are not used in the United States to treat endometriosis.

Of progesterone antagonists, mifepristone (RU-486; Mifeprex) is FDA-approved solely for early pregnancy termination. Studied in women with endometriosis, mifepristone reduced pelvic pain and extent of endometriosis (Kettel, 1996). However, as a side effect, its antiprogesterone effects expose the endometrium to chronic unopposed estrogen. Resulting endometrial changes range from simple endometrial hyperplasia to a new category described as progesterone-receptor-modulator-associated endometrial changes (PAEC) (Mutter, 2008). The clinical significance of PAEC is still unclear.

Of SPRMs, ulipristal acetate is available in the United States for emergency contraception as Ella and in Europe for presurgical treatment of leiomyomas as Esmya. Again, long-term endometrial safety for both eutopic and ectopic endometria is unclear with this SPRM, and this limits its chronic use at this time. Most other SPRMs are still experimental.

### Androgens

These drugs are now used as second-line agents for endometriosis due to their androgenic side effects. Of these, danazol is a synthetic 17α-ethinyl testosterone derivative. Its predominant action suppresses the midcycle LH surge to promote chronic anovulation (Floyd, 1980). Danazol occupies receptor sites on sex hormone-binding globulin (SHBG) and thereby increases serum free testosterone levels. It also binds directly to androgen and progesterone receptors. As a result, danazol creates a hypoestrogenic, hyperandrogenic state that induces endometrial atrophy in endometriotic implants (Fedele, 1990). Regarding efficacy, danazol given orally at dosages of 200 mg three times daily proved superior to placebo to diminish endometriotic implants and pelvic pain symptoms after 6 months of therapy (Telimaa, 1987).

The recommended dosage of danazol is 600 to 800 mg orally daily. Unfortunately, significant androgenic side effects develop and include acne, hot flashes, hirsutism, adverse serum lipid profiles, voice deepening (possibly irreversible), elevation of liver enzyme levels, and mood changes. Moreover, due to possible teratogenicity, this medication should be taken in conjunction with effective contraception. Because of its adverse side-effect profile, danazol is prescribed less frequently, and if administered, its duration is limited.

Gestrinone (ethynorgestrienone; R2323) is an antiprogestational agent prescribed in Europe for endometriosis. It has antiprogestational, antiestrogenic, and androgenic effects. Gestrinone equals the effectiveness of danazol and of GnRH agonists for relief of endometriosis-related pain (Prentice, 2000). Furthermore, during 6 months of treatment, gestrinone was not associated with the bone density loss commonly seen with GnRH agonist use and was more effective in persistently decreasing moderate to severe pelvic pain (Gestrinone Italian Study Group, 1996). Disadvantageously, gestrinone appears to lower high-density lipoprotein (HDL) levels. Gestrinone is administered orally, 2.5 to 10 mg weekly, given daily or three times weekly.

## ■ Surgical Treatment of Endometriosis-related Pain

### Lesion Removal and Adhesiolysis

Because laparoscopy is the primary method for endometriosis diagnosis, surgical treatment at the time of diagnosis is an attractive option. Numerous studies have examined removal of endometriotic lesions, through either excision or ablation. In one randomized trial, diagnostic laparoscopy alone was compared with laparoscopic endometriotic lesion ablation plus uterine nerve ablation. In the ablation group, 63 percent of women attained significant symptom relief compared with 23 percent in the expectant management group (Jones, 2001).

The optimal method to address endometriotic implants for maximal symptom relief is controversial. First, laser ablation does not appear to be more effective than conventional electro-surgical ablation of endometriosis (Blackwell, 1991). Second, ablation and excision both appear to perform suitably. In one randomized trial, ablation was compared with excision of lesions in women with stage I or II endometriosis. At 6 months, similar reductions in pain scores were found (Wright, 2005). Another study showed no significant difference between ablation and excision at 12 months (Healey, 2010). However, at 5 years, the need for further hormonal or analgesic treatment was greater in the ablation group (Healey, 2014). For deeply infiltrative endometriosis, some authors have advocated radical surgical excision, although well-designed trials are lacking (Chapron, 2004).

Unfortunately, recurrence is common following surgical excision. Jones and associates (2001) demonstrated pain recurrence in 74 percent of patients at a mean time of 73 months postoperatively. The median time for recurrence was 20 months. After surgery for pain-related endometriosis, postoperative medical treatment may be elected to extend pain relief or treat residual pain. For this, the most rigorous evidence supports COCs or the LNG-IUS (Somigliana, 2014).

Adhesiolysis is postulated to effectively treat pain symptoms in women with endometriosis by restoring normal anatomy. However, most studies are poorly designed and retrospective. As a result, a definitive link between adhesions and pelvic pain is unclear (Hammoud, 2004). For example, one randomized trial demonstrated no overall pain relief from adhesiolysis compared with expectant management (Peters, 1992). However, within this study, one woman with severe, dense vascularized bowel adhesions experienced pain relief following adhesiolysis.

Adhesion prevention during endometriosis surgery emphasizes sound surgical techniques described in Chapter 40 (p. 841). Of adhesion-prevention agents available in the United States, small studies show lower adhesions reformation rates with use of the cellulose barrier Interceed in endometriosis cases (Mais, 1995a; Sekiba, 1992). But, as noted by the American Society for Reproductive Medicine (2013), although peritoneal instillates and barriers may reduce postoperative adhesions, this has not translated clinically into improved pain, fertility, or bowel obstruction rates.

### Endometrioma Resection

Endometriomas are typically treated surgically to exclude malignancy or treat associated pain. To determine the best technique, total ovarian cystectomy compared against aspiration coupled with cyst wall ablation has been studied. Findings note that cystectomy lowers endometrioma recurrence rates and pain symptoms and improves subsequent spontaneous pregnancy rates (Dan, 2013; Hart, 2008). During surgery, ideally normal ovarian tissue is preserved. Toward this goal, electrosurgical coagulation of bleeding sites should be limited. As alternatives, some have described use of dilute vasopressin or suture (Pergialiotis, 2015; Qiong-Zhen, 2014). Other technical steps are described in Chapter 44 (p. 1015). Despite cystectomy, endometriomas may recur. Liu and coworkers (2007) found an approximately 15 percent recurrence rate at 2 years following initial surgery.

Importantly, women who undergo endometrioma excision may subsequently have a reduced *ovarian reserve*, that is, the capacity to provide ova capable of fertilization (Somigliana, 2012). Additionally, surgery increases risks for adhesion formation. Both effects may diminish future fertility. Accordingly, in a woman who is asymptomatic, has a small endometrioma that displays classic findings, has a known endometriosis diagnosis, and has normal or stable CA125 levels, surveillance is an option (American College of Obstetricians and Gynecologists, 2013, 2014b). This approach may benefit asymptomatic women with recurrent endometriomas, as repeat surgery can again diminish reserve (Ferrero, 2015). Following initial diagnosis of an endometrioma, repeat TVS is recommended 6 to 12 weeks later to exclude a hemorrhagic cyst. Endometriomas may then be sonographically surveilled in asymptomatic women yearly or sooner, at the clinician's discretion (Levine, 2010). The main disadvantage to observation is an inability to exclude ovarian malignancy, and thus patient counseling is essential.

### Presacral Neurectomy

For some women, transection of presacral nerves lying within the presacral space may provide relief of chronic pelvic pain (Fig. 38-23, p. 816). Results from a randomized trial revealed

significantly greater pain relief at 12 months postoperatively in women treated with presacral neurectomy (PSN) and endometriotic excision compared with that from endometriotic excision alone (86 percent versus 57 percent) (Zullo, 2003). However, all of these women had midline pain. One metaanalysis demonstrated a significant decrease in pelvic pain after PSN compared with that following more conservative procedures, but only in those with midline pain (Proctor, 2005). Neurectomy may be performed laparoscopically, but it is technically challenging. Due to involved nerve disruption, postoperative constipation and voiding dysfunction are common (Huber, 2015). For these reasons, PSN is used in a limited manner and not recommended routinely for management of endometriosis-related pain.

### Laparoscopic Uterosacral Nerve Ablation

There is no evidence that laparoscopic uterosacral nerve ablation (LUNA) is effective in treating endometriosis-related pain (Vercellini, 2003a). In a randomized trial of 487 women with chronic pelvic pain lasting longer than 6 months, with or without minimal endometriosis, LUNA did not improve pain, dysmenorrhea, dyspareunia, or quality-of-life scores compared with laparoscopy without pelvic denervation (Daniels, 2009).

### Abdominal versus Laparoscopic Approach

All of the surgical procedures listed above can be completed through open or laparoscopic approaches. First, for benign ovarian masses such as endometriomas, strong evidence supports laparoscopy (Mais, 1995b; Yuen, 1997). Laparoscopic treatment of endometrioma carries an associated 5-percent risk for conversion to laparotomy. However, because of its efficacy and low rates of postoperative morbidity, laparoscopy is a preferred route when feasible (Canis, 2003).

For excision of endometriotic implants, studies also demonstrate effectiveness and low morbidity rates with laparoscopy. Moreover, adhesiolysis is preferred via laparoscopy when safe, and laparoscopy leads to less de novo adhesion formation than laparotomy (Gutt, 2004). Laparoscopic presacral neurectomy appears to be as effective as laparotomy (Nezhat, 1992; Redwine, 1991).

### Hysterectomy

This procedure is the definitive and most effective therapy for women with endometriosis who do not wish to retain fertility. It is appropriate for women with intractable pain, adnexal masses, or multiple previous conservative therapies or surgeries (American College of Obstetricians and Gynecologists, 2014b). Hysterectomy for patients with endometriosis may suitably be completed laparoscopically, abdominally, or vaginally. However, adhesions and distorted anatomy secondary to endometriosis often makes a laparoscopic or vaginal approach difficult. In addition, the need to remove ovaries may make a vaginal approach less feasible. Accordingly, the choice of procedure will depend on equipment availability, operator experience, and extent of disease.

**Oophorectomy.** Prior to hysterectomy for endometriosis, oophorectomy is discussed. A general discussion of risks and benefits is found in Chapter 43 (p. 950). Specific to endometriosis,

the benefits of pain relief and reoperation risks are measured against complications of hypoestrogenism. In one study, of those with hysterectomy and bilateral salpingo-oophorectomy (BSO), 10 percent had recurrent chronic pelvic pain and 4 percent required reoperation. Compared with these women, those choosing ovarian conservation had a sixfold greater risk of recurrent pain and an eightfold greater risk of requiring additional surgery (Namnoum, 1995). In a second study, among all those choosing hysterectomy, ovarian conservation doubled the reoperation rate compared with those undergoing BSO (Shakiba, 2008). Moreover, in a subanalysis of those older than 40, ovary conservation lead to a sevenfold greater reoperation rate than BSO. However, in those younger than 40, reoperation rates did not differ whether ovaries were retained or removed. The American College of Obstetricians and Gynecologists (2014b) notes that ovarian conservation can be considered in patients undergoing hysterectomy if ovaries appear normal.

In epidemiologic studies, women with prior endometriosis have slightly increased ovarian cancer rates and higher proportions of clear cell and endometrioid subtypes (Kim, 2014; Pearce, 2012; Somigliana, 2006). That said, consensus guidelines do not recommend management changes in relation to this cancer risk (Dunselman, 2014).

**Postoperative Hormone replacement.** Women with surgical menopause are usually younger and would likely benefit from estrogen replacement. Options are discussed in Chapter 22. Although evidence is lacking, some suggest that treatment in these women continue until the time of expected natural menopause.

Unopposed estrogen is appropriate for hypoestrogenic women without a uterus, but disease recurrence has been reported with this therapy in women with severe endometriosis first treated with hysterectomy and BSO (Taylor, 1999). Symptoms required repeat surgery and did not recur with adjuvant combined estrogen and progestin regimens. Additionally, cases of endometrial carcinoma have been reported in women with endometriosis who were treated with unopposed estrogen after hysterectomy and BSO (Reimnitz, 1988; Soliman, 2006). This is rare and may arise from incompletely resected pelvic endometriosis. Therefore, adding a progestin to estrogen replacement therapy can be considered in women with severe endometriosis treated surgically (Moen, 2010). Again, the risks of malignancy are balanced against the adverse lipid changes and breast cancer risks associated with adding progesterone to hormone replacement therapy.

The optimal timing for hormone replacement initiation following hysterectomy with BSO is supported by limited data. One small study showed no significant differences in postoperative recurrent pain rates whether hormones were initiated immediately after surgery or were delayed (Hickman, 1998).

### ■ Treatment of Endometriosis-related Infertility

For an asymptomatic woman with infertility, laparoscopy solely to exclude endometriosis is unwarranted (American Society for Reproductive Medicine, 2012). For those with endometriosis-related pain undergoing medical therapy, treatment does not raise fecundity (Hughes, 2007).

For women with infertility and minimal to mild endometriosis, surgical ablation has been suggested to be beneficial, although the effect appears small (Marcoux, 1997). However, other researchers did not report a fertility benefit to surgical ablation for mild to moderate endometriosis (Parazzini, 1999). A metaanalysis of these two studies did demonstrate an advantage for laparoscopic surgery compared with diagnostic laparoscopy (Jacobson, 2010).

Moderate to severe endometriosis may be treated with surgery to restore normal anatomy and tubal function. However, well-designed trials examining the role of surgery for subfertility in women with severe endometriosis are limited (Crosignani, 1996). In infertile women with stage III/IV endometriosis, clinicians can consider operative laparoscopy, instead of expectant management, to increase spontaneous pregnancy rates (Dunselman, 2014). However, after initial unsuccessful surgery for infertility, IVF is preferable to reoperation (Pagidas, 1996).

Alternatively, patients with endometriosis and infertility are candidates for fertility treatments such as controlled ovarian hyperstimulation, intrauterine insemination, and IVF (Chap. 20, p. 449). Logically, age and disease stage factor into treatment decisions.

Pain in the lower abdomen and pelvis is a common complaint. But, pain is subjective and often ambiguous, and thus, difficult to diagnose and treat. To assist, clinicians ideally understand the mechanisms underlying human pain perception, which involves complex physical, biochemical, emotional, and social interactions. Providers are obligated to search for organic sources of pain, but equally important, avoid overtreatment of a condition that is minor or short lived.

### PAIN PATHOPHYSIOLOGY

Pain is a protective mechanism meant to warn of an immediate threat and to prompt withdrawal from noxious stimuli. Pain is usually followed by an emotional response and inevitable behavioral consequences. These are often as important as the pain itself. The mere threat of pain may elicit emotional responses even in the absence of actual injury.

When categorized, pain may be considered *somatic* or *visceral* depending on the type of afferent nerve fibers involved. Additionally, pain is described by the physiologic steps that produce it and can be defined as *inflammatory* or *neuropathic* (Kehlet, 2006). Both categorizations are helpful for diagnosis and treatment.

#### ■ Somatic or Visceral Pain

Somatic pain stems from nerve afferents of the somatic nervous system, which innervates the parietal peritoneum, skin, muscles, and subcutaneous tissues. Somatic pain is typically sharp and localized. It is found on either the right or left within

dermatomes that correspond to the innervation of involved tissues (Fig. 11-1).

In contrast, visceral pain stems from afferent fibers of the autonomic nervous system, which transmits information from the viscera and visceral peritoneum. Noxious stimuli typically include stretching, distention, ischemia, necrosis, or spasm of abdominal organs. The visceral afferent fibers that transfer these stimuli are sparse. Thus, the resulting diffuse sensory input leads to pain that is often described as a generalized, dull ache.

Visceral pain often localizes to the midline because visceral innervation of abdominal organs is usually bilateral (Flasar, 2006). As another attribute, visceral afferents follow a segmental distribution, and visceral pain is typically localized by the brain's sensory cortex to an approximate spinal cord level that is determined by the embryologic origin of the involved organ. For example, pathology in midgut organs, such as the small bowel, appendix, and caecum, causes perceived periumbilical pain. In contrast, disease in hindgut organs, such as the colon and intraperitoneal portions of the genitourinary tract, causes midline pain in the suprapubic or hypogastric area (Gallagher, 2004).

Visceral afferent fibers are poorly myelinated, and action potentials can easily spread from them to adjacent somatic nerves. As a result, visceral pain may at times be referred to dermatomes that correspond to these adjacent somatic nerve fibers (Giamberardino, 2003). In addition, both peripheral somatic and visceral nerves often synapse in the spinal cord at the same dorsal horn neurons. These neurons, in turn, relay sensory information to the brain. The cortex recognizes the signal as coming from the same dermatome regardless of its visceral or somatic nerve origin. This phenomenon is termed *viscerosomatic convergence* and makes it difficult for a patient to distinguish internal organ pain from abdominal wall or pelvic floor pain (Fig. 11-2) (Perry, 2003).

Viscerosomatic convergence explains the dermatomal distribution of some visceral pain. In contrast, *direct intraspinal neuronal reflexes* permit transmission of visceral nociceptive input to other pelvic viscera (viscero-visceral reflex), to muscle (viscero-muscular reflex), and to skin (viscerocutaneous reflex). These intraspinal reflexes may explain why patients with endometriosis or interstitial cystitis manifest other pain syndromes such as vestibulitis, pelvic floor myalgia, or irritable bowel syndrome (IBS). Thus, unless the underlying chronic visceral pain source is identified and properly treated, referred pain and secondary pain syndromes may not be successfully eliminated (Perry, 2000).

#### ■ Inflammatory Pain

With acute pain, noxious stimuli such as a knife cut, burn, or crush injury activate sensory pain receptors, more formally

A

B

**FIGURE 11-1** Dermatome maps. A dermatome is an area of skin supplied by a single spinal nerve. **A.** Body dermatomes. **B.** Perineal dermatomes. (Adapted with permission from Steege JF, Metzger DA, Levy BS (eds): *Chronic Pelvic Pain: an Integrated Approach*. Philadelphia: WB Saunders; 1998.)

termed *nociceptors*. Action potentials travel from the periphery to dorsal horn neurons in the spinal cord. Here, reflex arcs may lead to immediate muscle contraction, which removes and protects the body from harm. Additionally, within the spinal cord, sensory information is augmented or dampened and may then be transmitted to the brain. In the cortex, it is recognized as pain (Janicki, 2003). After an acute stimulus is eliminated, nociceptor activity quickly diminishes.

If tissues are injured, then inflammation usually follows. Body fluids, along with inflammatory proteins and cells, are

**FIGURE 11-2** Viscerosomatic convergence. Pain impulses originating from an organ may affect dorsal horn neurons that are synapsing concurrently with peripheral somatic nerves. These impulses may then be perceived by the brain as coming from a peripheral somatic source such as muscle or skin rather than the diseased viscera. (Reproduced with permission from Howard FM, Perry CP, Carter JE, et al (eds): *Pelvic Pain: Diagnosis and Management*. Philadelphia: Lippincott Williams & Wilkins; 2000.)

called to the injury site to limit tissue damage. Because cells and most inflammatory proteins are too large to cross normal endothelium, vasodilation and increased capillary permeability are required features of this response. Chemical mediators of this process are prostaglandins, which are released from the damaged tissue, and cytokines, which are produced in white blood cells and endothelial cells. Cytokines include interleukins, tissue necrosis factors, and interferons. These sensitizing mediators are released into affected tissues and lower the conduction threshold of nociceptors. This is termed *peripheral sensitization*. Similarly, neurons within the spinal cord and/or brain display increased excitability, termed *central sensitization*. As a result, within inflamed tissues, the perception of pain is increased relative to the strength of the external stimulus (Kehlet, 2006). Normally, as inflammation decreases and healing ensues, the increased sensitivity to stimuli and thus the perception of pain subsides.

## ■ Neuropathic Pain

In some individuals, sustained noxious stimuli can lead to persistent central sensitization and to a permanent loss of neuronal inhibition. As a result, a decreased threshold to painful stimuli remains despite resolution of the inciting stimuli (Butrick, 2003). This persistence characterizes *neuropathic pain*, which is felt to underlie many chronic pain syndromes. During central sensitization, neurons within spinal cord levels above or below those initially affected may eventually become involved. This phenomenon results in chronic pain that may be referred across several spinal cord levels. In addition, some evidence suggests that chronic pain states are also associated with regional brain morphology changes in regions known to regulate pain. This has been described as maladaptive central nervous system (CNS) plasticity in response to prolonged nociceptive input (As-Sanie, 2012). The concept of neuropathic pain helps

explain in part why many patients with chronic pain have discomfort disproportionately greater than the amount of coexistent disease found.

Thus, in assessing patients with chronic pain, a clinician may find an ongoing inflammatory condition. In these cases, inflammatory pain dominates, and treatment is directed at resolving the underlying inflammatory condition. However, for many patients, evaluation may reveal no or minimal current pathology. In these cases, pain is neuropathic, and treatment thus focuses on management of pain symptoms themselves.

## ACUTE PAIN

The definition of acute lower abdominal pain and pelvic pain varies based on duration, but in general, discomfort is present less than 7 days. The sources of acute lower abdominal and pelvic pain are extensive, and a thorough history and physical examination can aid in narrowing the list (Table 11-1). With acute pain, a timely and accurate diagnosis is the goal and ensures the best medical outcome. Thus, although history and examination are described separately here, in clinical settings they often are performed almost simultaneously for optimal results.

### History

In addition to a thorough medical and surgical history, a verbal description of the pain and its associated factors is essential. For example, duration can be informative, and pain with abrupt

onset may be more often associated with organ torsion, rupture, or ischemia. The nature of pain may add value. Patients with acute pathology involving pelvic viscera may describe *visceral pain* that is midline, diffuse, dull, achy, or cramping. One example is the midline periumbilical pain of early appendicitis. Patients may repeatedly shift or roll to one side to find a comfortable position.

The underlying pelvic pathology may extend from the viscera to inflame the adjacent parietal peritoneum. In these cases, sharp *somatic pain* is described, which is localized, often unilateral, and focused to a specific corresponding dermatome. Again using appendicitis as an example, the classic migration of pain to the site of peritoneal irritation in the right lower quadrant illustrates acute somatic pain. In other instances, sharp, localized pain may originate, not from the parietal peritoneum, but from pathology in specific muscles or in isolated areas of skin or subcutaneous tissues. In either instance, with somatic pain, patients classically rest motionless to avoid movement of the affected peritoneum, muscle, or skin.

Colicky pain may reflect bowel obstructed by adhesion, neoplasia, stool, or hernia. It can also stem from increased bowel peristalsis in those with irritable or inflammatory bowel disease or infectious gastroenteritis. Alternatively, colic may follow forceful uterine contractions with the passage of products of conception, pedunculated submucous leiomyomas, or endometrial polyps. Last, stones in the lower urinary tract may cause spasms of pain as they are passed.

Associated symptoms may also direct diagnosis. For example, absence of dysuria, hematuria, frequency, or urgency will exclude urinary pathology in most instances. Gynecologic causes are often associated with vaginal bleeding, vaginal discharge, dyspareunia, or amenorrhea. Alternatively, exclusion of diarrhea, constipation, or gastrointestinal bleeding lowers the probability of gastrointestinal (GI) disease.

Vomiting complaints, however, are less informative, although the temporal relationship of vomiting to the pain may be helpful. In the acute surgical abdomen, if vomiting occurs, it usually follows as a response to pain and results from vagal stimulation. This vomiting is typically severe and develops without nausea. For example, vomiting has been found in approximately 75 percent of adnexal torsion cases (Descargues, 2001; Huchon, 2010). Thus, the acute onset of unilateral pain that is severe and associated with a tender adnexal mass in a patient with vomiting alerts one to the increased probability of adnexal torsion. Conversely, if vomiting is noted prior to the onset of pain, a surgical abdomen is less likely (Miller, 2006).

In general, well-localized pain or tenderness, persisting for longer than 6 hours and unrelieved by analgesics, has an increased likelihood of acute peritoneal pathology.

### Physical Examination

Examination begins with patient observation during initial questioning. Her general appearance, including facial expression, diaphoresis, pallor, and degree of agitation, often indicates the urgency of the clinical condition.

Elevated temperature, tachycardia, and hypotension will prompt an expedited evaluation, as the risk for intraabdominal

**TABLE 11-1.** Etiologies of Acute Lower Abdominal and Pelvic Pain

<b>Gynecologic</b>	
PID	Dysmenorrhea
Tuboovarian abscess	Mittelschmerz
Ectopic pregnancy	Ovarian mass
Incomplete abortion	Ovarian torsion
Prolapsing leiomyoma	Obstructed outflow tract
<b>Gastrointestinal</b>	
Gastroenteritis	Inflammatory bowel disease
Colitis	Irritable bowel disease
Appendicitis	Obstructed small bowel
Diverticulitis	Mesenteric ischemia
Constipation	Malignancy
<b>Urologic</b>	
Cystitis	Urinary tract stone
Pyelonephritis	Perinephric abscess
<b>Musculoskeletal</b>	
Hernia	Abdominal wall trauma
<b>Miscellaneous</b>	
Peritonitis	Sickle cell crisis
Diabetic ketoacidosis	Vasculitis
Herpes zoster	Abdominal aortic aneurysm
Opiate withdrawal	rupture

PID = pelvic inflammatory disease.

pathology increases with their presence. Constant, low-grade fever is common in inflammatory conditions such as diverticulitis and appendicitis, and higher temperatures may be seen with pelvic inflammatory disease (PID), advanced peritonitis, or pyelonephritis.

Pulse and blood pressure evaluation ideally assess orthostatic changes if intravascular hypovolemia is suspected. A pulse increase of 30 beats per minute or a systolic blood pressure drop of 20 mm Hg or both, between lying and standing after 1 minute, is often reflective of hypovolemia. If noted, establishment of intravenous access and fluid resuscitation may be required prior to examination completion. Notably, certain neurologic disorders and medications, such as tricyclic antidepressants or antihypertensives, may also produce similar orthostatic blood pressure changes.

Abdominal examination is essential. Visual inspection of the abdomen focuses on prior surgical scars, which may increase the possibility of bowel obstruction from postoperative adhesions or incisional hernia. Additionally, abdominal distention may be seen with bowel obstruction, perforation, or ascites. After inspection, auscultation may identify hyperactive or high-pitched bowel sounds characteristic of bowel obstruction. Hypoactive sounds, however, are less informative.

Palpation of the abdomen systematically explores each abdominal quadrant and begins away from the area of indicated pain. Peritoneal irritation is suggested by rebound tenderness or by abdominal rigidity due to involuntary guarding or reflex spasm of the adjacent or involved abdominal muscles.

Pelvic examination in general is performed in reproductive-aged women, as gynecologic pathology and pregnancy complications are a common pain source in this age group. The decision to pursue this pelvic examination in geriatric and pediatric patients is based on clinical information.

Of findings, purulent vaginal discharge or cervicitis may reflect PID. Vaginal bleeding can stem from pregnancy complications, benign or malignant reproductive tract neoplasia, or acute vaginal trauma. Leiomyomas, pregnancy, and adenomyosis are common causes of uterine enlargement, and the latter two may also create uterine softening. Cervical motion tenderness reflects peritoneal irritation and can be seen with PID, appendicitis, diverticulitis, and intraabdominal bleeding. A tender adnexal mass may reflect ectopic pregnancy, tuboovarian abscess, or ovarian cyst with torsion, hemorrhage, or rupture. Alternatively, a tender mass may reflect an abscess of nongynecologic origin such as one involving the appendix or colon diverticulum.

Rectal examination can add information regarding the source and size of pelvic masses and the possibility of colorectal pathologies. Stool guaiac testing for occult blood, although less sensitive when not performed serially, is still warranted in many patients (Rockey, 2005). Those with complaints of rectal bleeding, painful defecation, or significant changes in bowel habits are examples.

In emergency departments, women with acute pain may experience waits between their initial assessment and subsequent testing. For these patients, literature supports early administration of analgesia. Fears that analgesia will mask patient symptoms and hinder accurate diagnosis have not been supported (McHale, 2001; Pace, 1996). Thus, barring significant

hypotension or drug allergy, morphine sulfate may be administered judiciously in these situations.

## ■ Laboratory Testing

Despite benefits from a thorough history and physical examination, the sensitivity of these two in diagnosing abdominal pain is low (Gerhardt, 2005). Thus, laboratory and diagnostic testing are typically required. In women with acute abdominal pain, pregnancy complications are common. Thus, either urine or serum  $\beta$ -human chorionic gonadotropin (hCG) testing is recommended in those of reproductive age without prior hysterectomy. Complete blood count (CBC) can identify hemorrhage, both uterine and intraabdominal, and can assess the possibility of infection. Urinalysis can be used to evaluate possible urolithiasis or cystitis. In addition, microscopic evaluation and culture of vaginal discharge may add support to clinically suspected cases of PID.

## ■ Radiologic Imaging

### Sonography

In women with acute pelvic pain, several imaging options are available. However, transvaginal and transabdominal pelvic sonography are preferred modalities if an obstetric or gynecologic cause is suspected (Andreotti, 2011). Sonography provides a high sensitivity for detection of structural pelvic pathology. It is widely available, can usually be obtained quickly, requires little patient preparation, is relatively noninvasive, and avoids ionizing radiation. Disadvantageously, examination quality is affected by the skill and experience of the sonographer.

In most cases, the transvaginal approach offers superior resolution of the reproductive organs. Transabdominal sonography may still be necessary if the uterus or adnexal structures are significantly large or if they lie beyond the transvaginal probe's field of view. Color Doppler imaging during sonography permits evaluation of the vascular qualities of pelvic structures. In women with acute pain, the addition of Doppler studies is particularly useful if adnexal torsion or ectopic pregnancy is suspected (Twickler, 2010). Less common causes of acute pain amenable to sonographic diagnosis are perforation of the uterine wall by an intrauterine device (IUD) or hematometra caused by menstrual outflow obstruction from müllerian agenesis anomalies. For these, 3-dimensional (3-D) transvaginal sonography has become invaluable (Bermejo, 2010; Moschos, 2011).

### Computed Tomography

Computed tomography (CT) and multidetector computed tomography (MDCT) are increasingly used to evaluate acute abdominal pain in adults. CT offers a global examination that can identify numerous abdominal and pelvic conditions, often with a high level of confidence (Hsu, 2005). Compared with other imaging tools, it has superior performance in identifying GI and urinary tract causes of acute pelvic and lower abdominal pain (Andreotti, 2011). For example, noncontrasted renal colic CT has largely replaced conventional intravenous pyelography to search for ureteral obstruction. For appendicitis, one study found that the false-positive diagnosis rate among adults decreased from

24 to 3 percent from 1996 to 2006. Investigators noted that this decrease correlated with the increased rate of CT use during the same interval (Raman, 2008). Appendiceal perforation also decreased from 18 to 5 percent. Considering that the false-positive diagnosis of appendicitis in women is as high as 42 percent, this certainly represents an improvement in clinical outcomes. For evaluation of GI abnormalities such as appendicitis, the combination of both oral and intravenous contrast is preferred.

In addition to its high sensitivity, CT has several advantages for most nongynecologic disorders. It is extremely fast; is not perturbed by gas, bone, or obesity; and is not operator dependent. Disadvantages include occasional unavailability, high cost, inability to use contrast media in patients who are allergic or have renal dysfunction, and exposure to low levels of ionizing radiation (Leschka, 2007).

The debate regarding CT safety and possible overuse is ongoing (Brenner, 2007). Of major concern is the potential increased cancer risk directly attributable to ionizing radiation, which is estimated to be even higher in younger patients and women (Einstein, 2007). Radiation doses from CT are generally considered to be 100 to 500 times those from conventional radiography (Smith-Bindman, 2010). Investigators in a large multicenter analysis found the median effective radiation dose from a multiphase abdomen and pelvic CT scan was 31 mSv, and this correlates with a lifetime attributable risk of four cancers per 1000 patients (Smith-Bindman, 2009). By way of comparison, health care workers are generally limited to 100 mSv over 5 years with a maximum of 50 mSv allowed in any given year (Fazel, 2009). But, in the acute clinical setting, CT imaging benefits frequently outweigh these risks.

### Other Imaging

In some instances, plain film radiography is selected. Although its sensitivity is low for most gynecologic conditions, it still may be informative if bowel obstruction or perforation is suspected (Leschka, 2007). Dilated loops of small bowel, air-fluid levels, free air under the diaphragm, or the presence or absence of colonic gas are all significant findings when attempting to differentiate between a gynecologic and GI cause of acute pain.

Magnetic resonance (MR) imaging is becoming an important tool for women with acute pelvic pain if initial sonography is nondiagnostic. Common reasons for noninformative sonographic evaluations include patient obesity and pelvic anatomy distortion secondary to large leiomyomas, müllerian anomalies, or exophytic tumor growth. As a first-line tool, MR imaging is often selected for pregnant patients, for whom ionizing radiation exposure should be limited. However, for most acute disorders, it provides little advantage over 3-D sonography or CT (Bermejo, 2010; Brown, 2005). Lack of availability can be a disadvantage after hours, on weekends, or in smaller hospitals and emergency departments.

### ■ Laparoscopy

Operative laparoscopy is the primary treatment for suspected appendicitis, adnexal torsion, ectopic pregnancy, and ruptured ovarian cyst associated with ongoing symptomatic hemorrhage. Moreover, diagnostic laparoscopy may be useful if no pathology

can be identified by conventional diagnostics. However, in stable patients with acute abdominal pain, noninvasive testing is typically exhausted before this approach is considered (Sauerland, 2006).

The decision to perform a surgical procedure for acute pelvic pain can be challenging. If the patient is clinically stable, the decision can be made in a timely manner, with appropriate evaluation and consultation completed preoperatively. In a less stable patient with signs of peritoneal irritation, possible hemoperitoneum, organ torsion, shock, and/or impending sepsis, the decision to operate is made decisively unless there are overwhelming clinical contraindications to immediate surgery.

## CHRONIC PAIN

Persistent pain may be visceral, somatic, or mixed in origin. As a result, it may take several forms in women that include chronic pelvic pain (CPP), dysmenorrhea, dyspareunia, dysuria, musculoskeletal pain, intestinal cramping, or vulvodynia. Each of these forms is described here except for vulvodynia, discussed in Chapter 4 (p. 97). The list of pathologies that may underlie these symptoms is extensive and includes both psychological and organic disorders (Table 11-2). Moreover, pathology in one organ can commonly lead to dysfunction in adjacent systems. As a result, a woman with chronic pain may have more than one cause of pain and overlapping symptoms. A comprehensive evaluation of multiple organ systems and psychologic state is essential for complete treatment.

## CHRONIC PELVIC PAIN

This common gynecologic problem has an estimated prevalence of 15 percent in reproductive-aged women (Mathias, 1996). No definition is universally accepted. However, many investigators define chronic pelvic pain as: (1) noncyclic pain that persists for 6 or more months; (2) pain that localizes to the anatomic pelvis, to the anterior abdominal wall at or below the umbilicus, or to the lumbosacral back or buttocks; and (3) pain sufficiently severe to cause functional disability or lead to medical intervention (American College of Obstetricians and Gynecologists, 2010).

Causes of CPP fall within a broad spectrum, but endometriosis, symptomatic leiomyomas, and IBS are often diagnosed. Of these, endometriosis is a frequent cause, but it typically is also associated with cyclic symptoms. It is discussed fully in Chapter 10 (p. 230). Chronic pain secondary to leiomyomas is described in Chapter 9 (p. 205).

The pathophysiology of CPP is unclear in many patients, but evidence supports a significant association with neuropathic pain, described earlier (p. 250). CPP shows increased association with IBS, interstitial cystitis, and vulvodynia, which are considered by many to be chronic visceral pain syndromes stemming from neuropathic pain (Janicki, 2003).

### ■ History

More than with many other gynecologic complaints, a detailed history and physical examination are integral to diagnosis. A pelvic pain questionnaire can be used initially to obtain

**TABLE 11-2.** Diseases That May Be Associated with Chronic Pelvic Pain in Women

<b>Gynecologic</b>		
Endometriosis	Reproductive tract cancer	Chronic PID
Adenomyosis	Pelvic muscle trigger points	Chronic endometritis
Leiomyomas	Intrauterine contraceptive device	Vestibulitis
Abdominal adhesions	Outflow tract obstruction	Pelvic congestion syndrome
Endometrial/endocervical polyps	Ovarian retention syndrome	Broad ligament herniation
Ovarian mass	Ovarian remnant syndrome	Chronic ectopic pregnancy
Adnexal cysts	Pelvic organ prolapse	Postoperative peritoneal cysts
<b>Urologic</b>		
Chronic UTI	Urethral syndrome	Interstitial cystitis
Detrusor dyssynergia	Urethral diverticulum	Radiation cystitis
Urinary tract stone	Urinary tract cancer	
<b>Gastrointestinal</b>		
IBS	Colitis	Celiac disease
Constipation	Inflammatory bowel disease	Chronic intermittent bowel obstruction
Diverticular disease	Gastrointestinal cancer	
<b>Musculoskeletal</b>		
Hernias	Degenerative joint disease	Vertebral compression
Muscular strain	Levator ani syndrome	Disc disease
Faulty posture	Fibromyositis	Coccydynia
Myofascial pain	Spondylosis	Peripartum pelvic pain
<b>Neurologic</b>		
Neurologic dysfunction	Abdominal cutaneous nerve entrapment	Spinal cord or sacral nerve tumor
Pudendal neuralgia	Neuralgia of iliohypogastric, ilioinguinal, lateral femoral cutaneous, or genitofemoral nerves	
Piriformis syndrome

IBS = irritable bowel syndrome; PID = pelvic inflammatory disease; UTI = urinary tract disease.

information. One example is available from the International Pelvic Pain Society and may be accessed at: <http://www.pelvicpain.org/docs/resources/forms/History-and-Physical-Form-English.aspx>. Additionally, a body silhouette diagram can be provided to patients for them to mark specific sites of pain. The McGill Pain Questionnaire and Short Form combines a list of pain descriptors with a body map for patients to mark pain sites (Melzack, 1987). Pain scales can also quantify discomfort and include visual analogue scales (VAS) and verbal descriptor scales (VDS) (Fig. 11-3). At minimum, the series of questions found in Table 11-3 may provide valuable information. As noted, many of these questions focus on gynecologic, surgical, and psychologic risk factors.

First, of gynecologic factors, CPP is more common in women than men and is often worsened by stress and menstruation. Also, pregnancy and delivery can be traumatic to neuromuscular structures and have been linked with pelvic organ prolapse, pelvic floor muscle myofascial pain syndromes, and symphyseal or sacroiliac joint pain. In addition, injury to the ilioinguinal or iliohypogastric nerves during Pfannenstiel incision for

cesarean delivery may lead to lower abdominal wall pain even years after the initial injury (Whiteside, 2003). Following delivery, recurrent, cyclic pain and swelling in the vicinity of a cesarean incision or within an episiotomy suggests endometriosis within the scar itself (Fig. 10-3, p. 235). In contrast, in a nulliparous woman with infertility, pain may stem more often from endometriosis, pelvic adhesions, or PID.

Second, prior abdominal surgery increases a woman’s risk for pelvic adhesions, especially if infection, bleeding, or large areas of denuded peritoneal surfaces were involved. Adhesions were found in 40 percent of patients who underwent laparoscopy for chronic pelvic pain suspected to be of gynecologic origin (Sharma, 2011). The incidence of adhesions increases with the number of prior surgeries (Dubuisson, 2010). Last, certain disorders persist or commonly recur, and thus information regarding prior surgeries for endometriosis, adhesive disease, or malignancy are sought.

Of psychologic risk factors, CPP and sexual abuse are significantly associated (Jamieson, 1997; Lampe, 2000). A metaanalysis by Paras and associates (2009) demonstrated that sexual

<b>Visual analogue scale</b>

abuse is linked with an increased lifetime diagnosis rate of functional bowel disorders, fibromyalgia, psychogenic seizure disorder, and CPP. Additionally, for some women, chronic pain is an acceptable means to cope with social stresses. Thus, patients are questioned regarding domestic violence and satisfaction

**TABLE 11-3.** Questions Relevant to Chronic Pelvic Pain

1. Describe the location, quality, severity, and timing of your pain.
2. When and how did your pain start and how has it changed?
3. What makes your pain better or worse?
4. What other symptoms or health problems do you have?
5. Do you have frequency, urgency, or bloody urine?
6. Do you have nausea or vomiting, diarrhea, constipation, or rectal bleeding?
7. Do you have pain with your periods?
8. Did your pain start initially as menstrual cramps?
9. Have you had surgery? What was the reason?
10. How many pregnancies have you had?
11. How did you deliver? Was there an episiotomy?
12. What form of birth control do you use and have you used in the past?
13. Have you ever been treated for a sexually transmitted disease or pelvic infection?
14. Do you have pain with deep penetration during intercourse?
15. Are you depressed or anxious?
16. Have you been treated for mental illness in the past?
17. Have you been or are you now being abused physically or sexually?
18. What prior evaluations or treatments have you had for your pain?
19. Have any of the previous treatments helped?
20. What medications are you taking now?
21. How has the pain affected your quality of life?
22. What do you believe or fear is causing your pain?

with family relationships. Furthermore, an inventory of depressive symptoms is essential, as depression may cause or result from CPP (Tables 13-3 and 13-4, p. 299). Other conditions bearing similarities to CPP include fibromyalgia, chronic fatigue syndrome, temporomandibular disorder, and migraine. These are referred to as functional somatic syndromes, and CPP can be comorbid with each of these (Warren, 2011).

## Physical Examination

In a woman with chronic pain, even routine examination may be extremely painful. In those with neuropathic pain, mere light touch may elicit discomfort. Therefore, examination proceeds slowly to allow relaxation between each step. Moreover, a patient is reassured that she may ask for the examination to be halted at any time. Terms used to describe examination findings include *allodynia* and *hyperesthesia*, among others. Allodynia is a painful response to a normally innocuous stimulus, such as a cotton swab. Hyperalgesia is an extreme response to a painful stimulus.

## Stance and Gait

Women with intraperitoneal pathology may compensate with changes in posture. Such adjustments can create secondary musculoskeletal sources of pain (p. 267). Alternatively, musculoskeletal structures may be the site of referred pain from these organs (Table 11-4). Thus, careful observation of a woman's posture and gait is integral.

Initially, a woman is examined while standing. Posture is evaluated anteriorly, posteriorly, and laterally. Anteriorly, symmetry of the anterior superior iliac spines (ASISs), umbilicus, and weight bearing is evaluated. If one leg bears most of the weight, the nonbearing leg is often externally rotated and slightly flexed at the knee. Next, the anterior abdominal wall and inguinal areas are inspected for abdominal wall or femoral hernias, described on page 267. Inspection of the perineum and vulva with the patient standing may identify varicosities. These are often asymptomatic or may cause superficial discomfort. Such varicosities may coexist with internal pelvic varicosities, the underlying cause of pelvic congestion syndrome (p. 261).

Posteriorly, inspection for scoliosis and of horizontal stability of the shoulders, gluteal folds, and knee creases is completed. Asymmetry may reflect musculoskeletal disorders.

Lateral visual examination searches for lordosis and concomitant kyphosis. This combination has been noted in some women with CPP and termed *typical pelvic pain posture (TPPP)* (Fig. 11-4) (Baker, 1993). Also, abnormal tilt of the pelvic bones can be assessed by simultaneously placing an open palm on each side between the posterior superior iliac spine (PSIS) and the ASIS. Normally, the ASIS lies one-quarter inch below the level of the PSIS, and greater distances may suggest abnormal tilt. Pelvic tilt may be associated with hip osteoarthritis and other orthopedic problems (Labelle, 2005; Yoshimoto, 2005).

Any observed mobility limitation can be informative. Thus, a patient is asked to bend forward at the waist. Limitation in forward flexion may reflect primary orthopedic disease or adaptive shortening of back extensor muscles. This shortening

TABLE 11-4. Musculoskeletal Origins of Chronic Pelvic Pain

Structure	Innervation	Referred Pain Site(s)
Hip	T12–S1	Lower abdomen; anterior medial thigh; knee
Lumbar ligaments, facets/disks	T12–S1	Low back; posterior thigh and calf; lower abdomen; lateral trunk; buttock
Sacroiliac joints	L4–S3	Posterior thigh; buttock; pelvic floor
Abdominal muscles	T5–L1	Abdomen; anteromedial thigh; sternum
Pelvic and back muscles		
Iliopsoas	L1–L4	Lateral trunk; lower abdomen; low back; anterior thigh
Piriformis	L5–S3	Low back, buttock; pelvic floor
Pubococcygeus	S1–L4	Pelvic floor; vagina; rectum; buttock
Obturator internal/external	L3–S2	Pelvic floor; buttock; anterior thigh
Quadratus lumborum	T12–L3	Anterior lateral trunk; anterior thigh; lower abdomen

Modified with permission from Baker PK: Musculoskeletal origins of chronic pelvic pain. *Diagnosis and treatment. Obstet Gynecol Clin North Am* 1993 Dec;20(4):719–742.

is seen frequently in women with chronic pain and TPPP. In such cases, patients are unable to bend over at the waist to create the normal convex curve.

Muscle weakness may also indicate orthopedic disease. A Trendelenburg test, in which a patient is asked to balance on one foot, can indicate dysfunction of hip abductor muscles or hip joint. With a positive test, when a woman elevates a leg by flexing the hip, the ipsilateral iliac crest droops.

Gait is evaluated by having the patient walk across the room. An *antalgic gait*, known as a limp, refers to a gait that minimizes weight bearing on a lower limb or joint and indicates a higher probability of musculoskeletal pain.

Sitting and Supine

A patient is next invited to sit on the examining table. Myofascial pain syndrome may involve pelvic floor muscles and often leads

to a patient shifting weight to one buttock or sitting toward a chair’s front edge.

With the patient supine, the anterior abdominal wall is evaluated for abdominal scars. These may be sites of hernia or nerve entrapment or may indicate a risk for intraabdominal adhesive disease. Auscultation for bowel sounds and bruits follows. Increased bowel activity may reflect irritable or inflammatory bowel diseases. Bruits prompt investigation for vascular pathology.

While supine, a woman is asked to demonstrate with one finger the point of maximal pain and then encircle the total surrounding area of involvement. Superficial palpation of the anterior abdominal wall by a clinician may reveal sites of tenderness or knotted muscle that may reflect nerve entrapment or myofascial pain syndrome (p. 268). Moreover, pain with elevation of the head and shoulders while tensing the abdominal wall muscles, *Carnett sign*, is typical of anterior abdominal wall pathology. Conversely, if the source of pain originates from inside the abdominal cavity, discomfort usually decreases with such elevation (Tomson, 1991). Moreover, Valsalva maneuver during head and shoulder elevation may display diastasis of the rectus abdominis muscle or hernias. Diastasis recti can be differentiated in most cases from a ventral hernia. Specifically, with diastasis, the borders of the rectus abdominis muscle can be palpated bilaterally along the entire length of the protrusion. Last, deep palpation of the lower abdomen may identify pathology originating from pelvic viscera. Dullness to percussion or a shifting fluid wave may indicate ascites.

Mobility is also evaluated. In most cases, a woman can elevate her leg 80 degrees from the horizontal toward her head, termed a *straight leg test*. Pain with leg elevation may be seen with lumbar disc, hip joint, or myofascial pain syndromes. Additionally, symphyseal pain with this test may indicate laxity in the symphysis pubis or pelvic girdle. Both the obturator and iliopsoas tests may indicate myofascial pain syndromes involving these muscles or disorders of the hip joint. With the obturator test, a supine patient brings one knee into 90 degrees of flexion while the same foot remains planted. The ankle is held stationary, but the knee is gently pulled laterally and then medially to assess for tenderness. With the iliopsoas test, a supine woman with

FIGURE 11-4 Concurrent lordosis and kyphosis are common postural changes associated with chronic pelvic pain. TPPP = typical pelvic pain posture.

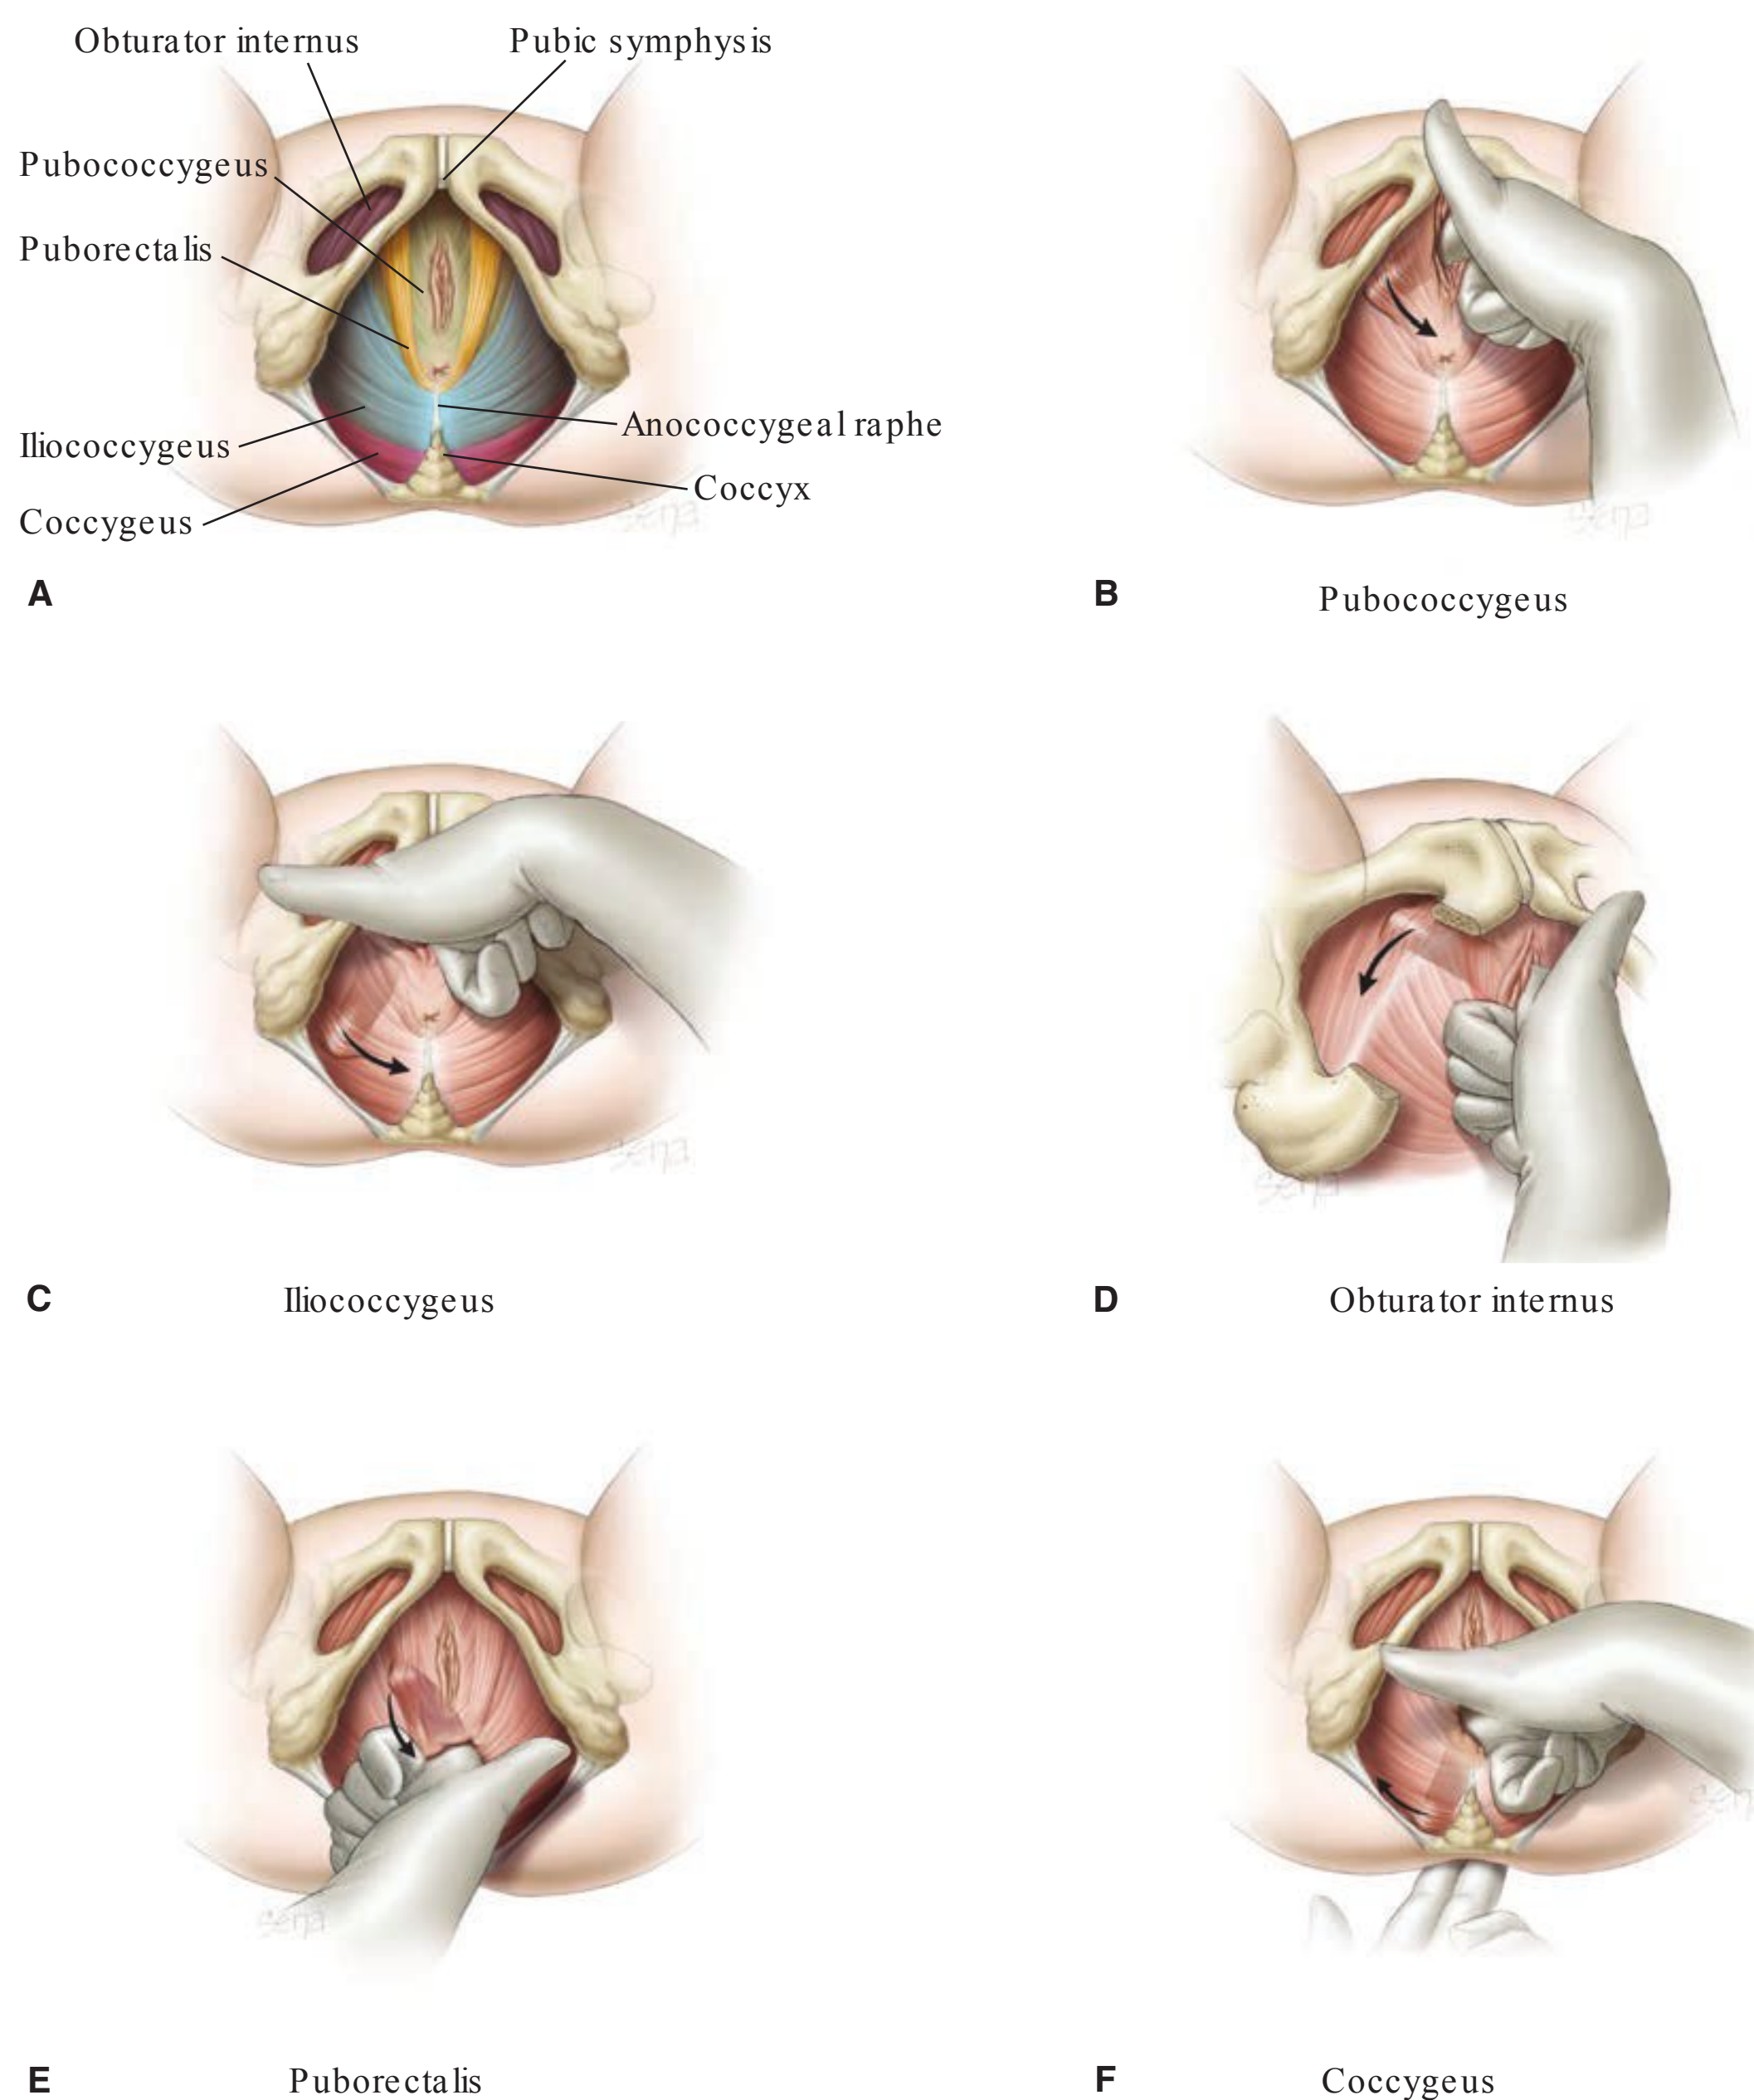

legs extended attempts to flex each hip separately against downward resistance from the examiner's hand placed on the ipsilateral anterior thigh. If pain is described with hip flexion, the test result is positive.

### Lithotomy

Pelvic examination begins with inspection of the vulva for generalized changes and localized lesions. Vulvar erythema often reflects infectious vulvitis, described in Chapter 3 (p. 60), or vulvitis stemming from dermatoses (Chap. 4, p. 88). Vulvar skin thinning may reflect lichen sclerosus or atrophic changes. The vestibular area is also examined. Erythema of the vestibule, with or without punctate lesions, may indicate vestibulitis. Following this inspection, systematic pressure point palpation of the vestibule, as shown in Figure 4-1 (p. 87), is completed

using a small cotton swab to assess for pain (allodynia). Last, the anocutaneous reflex, as described in Chapter 24 (p. 548), may also be performed to assess pudendal nerve integrity.

Prior to speculum examination, a single digit systematically evaluates the vagina. Pain elicited from pressure beneath the urethra may indicate urethral diverticulum. Pain with anterior vagina palpation under the trigone can reflect interstitial cystitis. Systematic sweeping pressure against the pelvic floor muscles along their length may identify isolated taut muscle knots from pelvic floor myofascial syndrome. Of these muscles, the pubococcygeus, iliococcygeus, and obturator internus muscles can usually be reached with a vaginal finger (Fig. 11-5). Next, insertion points of the uterosacral ligaments are palpated. Nodularity is highly suggestive of endometriosis, and palpation may reproduce dyspareunia symptoms. Cervical motion tenderness may be

**FIGURE 11-5** Pelvic floor muscle examination. (Used with permission from Ms. Marie Sena.)

noted with acute and chronic PID. If pain follows gentle movement of the coccyx, then articular disease of the coccyx, termed coccydynia, is suspected. The importance of pelvic examination sequence cannot be overstated, as information from single-digit examination may be lost if preceded by bimanual examination.

Bimanual assessment of the uterus may reveal a large uterus, often with an irregular contour, due to leiomyomas. Globular enlargement with softening is more typical of adenomyosis. Immobility of the uterus may follow scarring from endometriosis, PID, malignancy, or adhesive disease from prior surgeries. Adnexal palpation may reveal tenderness or mass. Tenderness alone may reflect endometriosis, diverticular disease, or pelvic congestion syndrome. Adnexal mass evaluation is outlined in Chapter 9 (p. 202).

Rectal examination and rectovaginal palpation of the rectovaginal septum is included. Palpation of hard stool or hemorrhoids may indicate GI disorders, whereas nodularity of the rectovaginal septum may be found with endometriosis or neoplasia. Myofascial tenderness involving the puborectalis and coccygeus muscles can be noted by sweeping the index finger with pressure across these muscles. Last, stool testing for occult blood may be performed during digital rectal examination at the initial visit. Alternatively, home test kits for occult blood are available and discussed in Chapter 1 (p. 9).

## ■ Testing

For women with CPP, diagnostic testing may add valuable information. Results from urinalysis and urine culture can indicate stones, malignancy, or recurrent infection of the urinary tract as pain sources. Thyroid disease can affect physiologic functioning and may be found in those with bowel or bladder symptoms. Thus, serum thyroid-stimulating hormone (TSH) levels are commonly assayed. Diabetes can lead to neuropathy, and glucose levels can be assessed with urinalysis or serum testing.

Radiologic imaging and endoscopy may be informative, and of these, transvaginal sonography is widely used by gynecologists to evaluate CPP. Sonography of the pelvic organs may reveal endometriomas, leiomyomas, ovarian cysts, dilated pelvic veins, and other structural lesions. In those with suspected pelvic congestion syndrome, transvaginal color Doppler ultrasound is often a primary diagnostic tool (Phillips, 2014). With sonography, patients can be imaged standing, if necessary, and while performing a Valsalva maneuver to accentuate vasculature distention. However, despite its applicability for many gynecologic disorders, sonography has poor sensitivity in identifying endometriotic implants or most adhesions. Of other modalities, CT or MR imaging often adds little additional information to that obtained with sonography. These may be selected if sonography is uninformative or if anatomy is greatly distorted.

In those with bowel symptoms, barium enema may indicate intraluminal or external obstructive lesions, malignancy, and diverticular or inflammatory bowel disease. However, flexible sigmoidoscopy and colonoscopy may offer more information because colonic mucosa can be directly inspected and biopsied if necessary.

Cystoscopy, laparoscopy, flexible sigmoidoscopy, and colonoscopy may each be employed, and patient symptoms will dictate

their use. In those with symptoms of chronic pain and urinary symptoms, cystoscopy is often advised. If GI complaints predominate, then flexible sigmoidoscopy or colonoscopy may be warranted. For many women with no obvious cause of their CPP, laparoscopy is performed. Importantly, intraoperative explanations for CPP are common despite normal preoperative examinations (Cunanan, 1983; Kang, 2007). Laparoscopy allows direct identification and, in many cases, treatment of intraabdominal pathology. Therefore, laparoscopy is considered by many to be a “gold standard” for CPP evaluation (Sharma, 2011).

One laparoscopic approach to CPP is performed under local anesthesia with the patient conscious and available for questioning regarding sites of pain (Howard, 2000; Swanton, 2006). Termed *conscious pain mapping*, this technique has resulted in more targeted treatment and improved postoperative pain scores. However, its clinical use to date has been limited.

## ■ Treatment

### Medical Options

In many women with CPP, an identifying source is found and treatment is dictated by the diagnosis. However, in other cases, pathology may not be identified, and treatment is directed toward dominant symptoms.

Treatment of pain typically begins with oral analgesics such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) listed in Table 10-1 (p. 239). NSAIDs are particularly helpful if inflammatory states underlie the pain. Acetaminophen is a widely used and effective analgesic despite having no significant antiinflammatory properties. Of note, dosing recommendations from the Food and Drug Administration (2011) limit the maximum total daily dose of acetaminophen to 4 g.

If satisfactory relief is not achieved, then opioid analgesics such as codeine or hydrocodone may be added (Table 42-2, p. 910). Importantly, opioid maintenance therapy for CPP is considered only if all other reasonable pain control attempts have failed and if benefits outweigh harms (Chou, 2009; Howard, 2003). Opioids are most effective and least addictive if given on a scheduled basis and at doses that adequately relieve pain. If pain persists, stronger opioids such as morphine, methadone, fentanyl, oxycodone, and hydromorphone can replace milder ones. However, this is balanced against side effects. Close and regular surveillance is essential, and consultation with pain management experts may be beneficial (Baranowski, 2014; Chou, 2009). Unlike classic opioids, tramadol hydrochloride has a mild central opioid effect but also inhibits serotonin and norepinephrine reuptake.

Estrogen support is integral to endometriosis. Thus, an empiric trial of sex-steroid hormone suppression may be considered, especially in those with coexistent dysmenorrhea or dyspareunia and who lack dominant bladder or bowel symptoms. As discussed in Chapter 10 (p. 239), combination oral contraceptives, progestins, gonadotropin-releasing hormone (GnRH) agonists, and certain androgens are effective options.

For many, CPP represents neuropathic pain, and therapy with antidepressants or anticonvulsants has been extrapolated from treatment of such pain in other disorders. Tricyclic antidepressants reduce neuropathic pain independent of their antidepressant effects (Saarto, 2010). Moreover, antidepressants

are a logical choice, as clinically significant depression is commonly comorbid with pain. Amitriptyline (Elavil) and its metabolite nortriptyline (Pamelor) have the best documented efficacy for neuropathic and nonneuropathic pain syndromes (Table 11-5) (Bryson, 1996). Selective serotonin-reuptake inhibitors do not have strong evidence to support their efficacy for CPP (Lunn, 2014). Of anticonvulsants, gabapentin and carbamazepine are most commonly used to reduce neuropathic pain (Moore, 2014; Wiffen, 2014).

Combining drugs with different sites or mechanisms of action may often improve pain. For example, an NSAID

and an opioid may be partnered, especially in conditions in which inflammation is dominant. If muscle spasm underlies pain, then pairing a tranquilizer or a muscle relaxant with an opioid or with an NSAID may improve results (Howard, 2003).

### Surgery

Nerve destruction, termed *neurolysis*, involves nerve transection or injection of a neurotoxic chemical. Nerve transection cuts a specific peripheral nerve or may be performed on an entire nerve plexus.

**TABLE 11-5.** Antidepressants and Antiepileptic Drugs Used in Chronic Pain Syndromes

Drug (Brand name)	Dosage	Side Effects
<b>ANTIDEPRESSANTS</b>		
<b>Tricyclic antidepressants</b>		
Amitriptyline (Elavil) <sup>a</sup> Imipramine (Tofranil) <sup>a</sup>	For both, 10–25 mg at bedtime; increase by 10–25 mg per week up to 75–150 mg at bedtime or a therapeutic drug level	Dry mouth, constipation, urinary retention, sedation, weight gain Tertiary amines have greater anticholinergic side effects
Desipramine (Norpramin) <sup>a</sup> Nortriptyline (Pamelor) <sup>a</sup>	For both, 25 mg in the morning or at bedtime; increase by 25 mg per week up to 150 mg per day or a therapeutic drug level	Secondary amines have fewer anticholinergic side effects
<b>Selective serotonin reuptake inhibitors</b>		
Fluoxetine (Prozac) <sup>a</sup> Paroxetine (Paxil) <sup>a</sup>	For both, 10–20 mg per day; up to 80 mg per day for fibromyalgia	Nausea, sedation, decreased libido, sexual dysfunction, headache, weight gain
<b>Novel antidepressants</b>		
Bupropion (Wellbutrin) <sup>a</sup>	100 mg per day; increase by 100 mg per week up to 200 mg twice daily (400 mg per day)	Anxiety, insomnia or sedation, weight loss, seizures (at dosages above 450 mg per day)
Venlafaxine (Effexor) <sup>a</sup>	37.5 mg per day; increase by 37.5 mg per week up to 300 mg per day	Headache, nausea, sweating, sedation, hypertension, seizures. Serotonergic properties in dosages below 150 mg per day; mixed serotonergic and noradrenergic properties in dosages above 150 mg per day
<b>ANTIEPILEPTIC DRUGS</b>		
<b>First-generation agents</b>		
Carbamazepine (Tegretol)	200 mg per day; increase by 200 mg per week up to 400 mg three times daily (1200 mg per day)	Dizziness, diplopia, nausea, aplastic anemia
Phenytoin (Dilantin) <sup>a</sup>	100 mg at bedtime; increase weekly up to 500 mg at bedtime	Blood dyscrasias, hepatotoxicity
<b>Second-generation agents</b>		
Gabapentin (Neurontin)	100–300 mg at bedtime; increase by 100 mg every 3 days up to 1800 to 3600 mg per day taken in divided doses three times daily	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain
Pregabalin (Lyrica)	150 mg at bedtime for diabetic neuropathy; 300 mg twice daily for postherpetic neuralgia	Drowsiness, dizziness, fatigue, nausea, sedation, weight gain
Lamotrigine (Lamictal) <sup>a</sup>	50 mg per day; increase by 50 mg every 2 weeks up to 400 mg per day	Dizziness, constipation, nausea; rarely, life-threatening rashes

<sup>a</sup>Not approved by the Food and Drug Administration for treatment of neuropathic pain.

*Presacral neurectomy (PSN)* describes interruption of somatic pain fibers from the uterus that course within the superior hypogastric plexus (Fig. 38-13, p. 806). This procedure is performed by incising the pelvic peritoneum over the sacrum and then identifying and transecting the sacral nerve plexus. In women so treated, approximately 75 percent note a greater than 50 percent decline in pain (American College of Obstetricians and Gynecologists, 2010).

However, PSN is technically challenging and requires familiarity with operating in the presacral space. Surgery has been associated with long-term constipation and urinary retention postoperatively. Infrequently, life-threatening hemorrhage may be encountered from the middle sacral vessels, which run in the presacral space.

Alternatively, *laparoscopic uterosacral nerve ablation (LUNA)* involves the destruction of nerve fibers that pass to the uterus through the uterosacral ligament. During LUNA, approximately 2 cm of uterosacral ligament near its attachment to the uterus is excised or obliterated using electrosurgery or carbon dioxide (CO<sub>2</sub>) laser (Lifford, 2002). Based on pelvic innervation, PSN or LUNA is indicated only for treatment of centrally located pelvic pain, and both have been performed to treat refractory endometriosis-related CPP and dysmenorrhea.

Regarding efficacy, in one randomized trial, investigators performed laparoscopy with and without LUNA for 487 patients with CPP but found no difference in pain, dysmenorrhea, dyspareunia, or quality-of-life measures (Daniels, 2009). Similarly, a metaanalysis found no pain improvement difference between those who did and those who did not undergo LUNA (Daniels, 2010). Moreover, comparisons of LUNA and PSN show significantly greater long-term pain relief with PSN (Proctor, 2005). In sum, available evidence does not support frequent use of LUNA.

Hysterectomy and bilateral salpingo-oophorectomy (BSO) at times may serve as definitive management if thorough evaluation is complete and conservative therapies have failed. For many women with CPP, hysterectomy is effective in resolving pain and improving quality of life (Hartmann, 2004; Stovall, 1990). However, pain may not be resolved in a significant number of women. For example, authors of one prospective study monitored 308 women for 1 year after hysterectomy for CPP and found that 75 percent had complete discomfort resolution, 21 percent had persistent but improved pain, and 5 had unchanged or worsening pain. Pain may persist despite hysterectomy more commonly in those who are younger than 30 years, those who have mental illness, or those with no identifiable pelvic pathology (Gunter, 2003). Almost 40 percent of women with no identified pelvic pathology will have persistent pain after hysterectomy (Hillis, 1995).

Failure of hysterectomy to relieve pain may be multifactorial. First, visceral reflexes (p. 249) may produce multiple pain syndromes within the same patient. Second, hysterectomy does not address nongynecologic etiologies for pelvic pain. Last, pain from interstitial cystitis, pelvic floor myofascial syndrome, or musculoskeletal disorders may worsen following surgery due to its potentially negative effects on innervation, musculature, or vasculature.

Accordingly, before hysterectomy is considered, efforts to accurately diagnose CPP causes and to conservatively manage the pain are first exhausted. Women are given reasonable expectations for symptom relief from hysterectomy and informed of the potential for persistent or worsening pain. As with any operation, the anticipated benefits should outweigh potential risks.

If hysterectomy is planned for endometriosis, concurrent BSO is reasonable. This is more fully discussed in Chapter 10, p. 243). In one analysis of 138 women monitored for 58 months after hysterectomy with ovarian conservation for endometriosis, the relative risk for pain recurrence was 6 and relative risk for reoperation approximated 8 (Namnoum, 1995). In contrast, data regarding bilateral oophorectomy efficacy at time of hysterectomy for idiopathic CPP are lacking and are individualized.

## ■ Specific Causes of Chronic Pelvic Pain

### Pelvic Adhesions

Adhesions are fibrous connections between opposing organ surfaces or between an organ and abdominal wall, at sites where there should be no connection. They vary in vascularity and thickness. These fibrous connections are common, and in laparoscopies performed for CPP, adhesions are found in approximately one quarter of cases (Howard, 1993). However, not all adhesive disease creates pain. For example, Thornton and associates (1997) found no relationship between pelvic pain and intraabdominal adhesions.

In those with pain, adhesions are believed to stretch the peritoneum or organ serosa as it moves. This theory is supported by studies using conscious pain mapping, in which filmy adhesions that allowed significant movement between two structures had the highest association with pain, whereas adhesions that prohibited movement had the lowest pain scores. Moreover, adhesions that had a relationship to the peritoneum had a high association with pain (Demco, 2004). Sensory nerve fibers have been identified histologically, ultrastructurally, and immunohistochemically in human peritoneal adhesions obtained at laparotomy, lending additional support to the above theories (Suleiman, 2001).

Risks for adhesions include prior surgery, prior intraabdominal infection, and endometriosis. Less commonly, inflammation from radiation, chemical irritation, or foreign-body reaction may be causes. Pain is typically aggravated by sudden movement, intercourse, or other specific activities.

Laparoscopy is the primary tool used to diagnose adhesions. In general, sonography lacks sensitivity. However, Guerriero and coworkers (1997) noted a positive correlation with ovarian adhesions if the ovarian surface borders appeared blurred or if the ovary appeared immediately adjacent to the uterus and this intimate position persisted despite transducer manipulation of both.

Surgical lysis is often used to treat pain symptoms, and several observational studies have shown pain improvement (Fayez, 1994; Steege, 1991; Sutton, 1990). However, two randomized studies comparing adhesion lysis with expectant management found no difference in pain scores after 1 year (Peters, 1992; Swank, 2003). Others who support the continued judicious

use of adhesiolysis in the treatment of pelvic pain question the statistical methods used in these studies (Roman, 2009). When performed, adhesiolysis is associated with a significant risk of adhesiogenesis, especially in cases involving endometriosis (Parker, 2005). Thus, the decision to lyse adhesions is individualized.

If adhesiolysis is performed, steps are taken to minimize reformation (Hammoud, 2004). Gentle tissue handling, adequate hemostasis, and minimally invasive techniques are essential. Many studies have evaluated the efficacy of various instillates and barriers placed over organs following surgery to minimize adhesion formation. Bioresorbable sheets that are Food and Drug Administration (FDA)-approved and often used in gynecology include brands Seprafilm and Interceed. One peritoneal instillate is icodextrin solution (Adept Adhesion Reduction Solution). Of these options, the American Society for Reproductive Medicine (2013) notes that barrier sheets reduce postoperative adhesions but also state that no substantial evidence shows their use decreases pain. They also report “insufficient evidence to recommend peritoneal instillates.” Similarly, two Cochrane reviews reported insufficient evidence regarding the efficacy of any of these agents (Ahmad, 2014; Hindocha, 2015).

### Ovarian Remnant Syndrome and Ovarian Retention Syndrome

After oophorectomy, remnants of an excised ovary may create symptoms that are termed *ovarian remnant syndrome*. Distinction is made between this syndrome and ovarian retention syndrome, also known as residual ovary syndrome. *Ovarian retention syndrome* involves symptoms stemming from an ovary intentionally left at the time of previous gynecologic surgery (El Minawi, 1999). Although differentiated by the amount of ovarian tissue involved, both syndromes have nearly identical symptoms and are diagnosed and treated similarly.

Although an uncommon cause of CPP, women with symptomatic ovarian remnants most typically complain of chronic or cyclic pain or dyspareunia. Those with BSO performed for endometriosis may be at particular risk (Kho, 2012). The onset of symptoms is variable and may begin years following surgery (Nezhat, 2005). Women with these syndromes may have a pelvic mass palpable on bimanual examination. Sonography is often informative. In those with ovarian remnants, ovaries may be identified in some cases by a thin rim of ovarian cortex surrounding a coexistent ovarian cyst (Fleischer, 1998). Indeterminate cases may require CT or MR imaging. In cases where ureteral compression is suspected, radiographic or CT pyelography or MR imaging may be warranted. Laboratory testing, specifically follicle-stimulating hormone (FSH) levels, can aid diagnosis in reproductive-aged women with prior BSO. If these levels lie in the premenopausal range, then retained ovarian tissue is likely (Magtibay, 2005).

Although medical treatment has included hormonal manipulation to suppress functioning tissue, surgical excision is required in most symptomatic cases (Lafferty, 1996). Because the ureter is commonly intimately involved with adhesions encasing a remnant, laparotomy is prudent in some cases. However, surgeons with advanced skills in minimally invasive surgery can achieve successful outcomes (Nezhat, 2005; Zapardiel, 2012).

### Pelvic Congestion Syndrome

Retrograde blood flow through incompetent valves can often create tortuous, congested ovarian or pelvic veins. Chronic pelvic ache, pressure, and heaviness may result and is termed *pelvic congestion syndrome* (Beard, 1988). Currently, it is not clear whether congestion results from mechanical dilatation, ovarian hormonal dysfunction, or both. Higher rates of ovarian varicosities and pelvic congestion syndrome are noted in parous women. A mechanical theory describes a dramatic increase in pelvic vein diameter during late pregnancy that leads to ovarian vein valve incompetence and pelvic varicosities. Estrogen is implicated in pelvic congestion syndrome in that it acts as a venous dilator. Moreover, pelvic congestion syndrome resolves following menopause, and antiestrogenic medical therapy has been shown to be effective (Farquhar, 1989; Gangar, 1993). Most likely, both factors play roles. The cause of pain with pelvic congestion remains unclear, but increased dilatation, concomitant stasis, and release of local nociceptive mediators have been suggested.

Affected women may describe pelvic ache or heaviness that may worsen premenstrually, after prolonged sitting or standing, or following intercourse. On physical examination, tenderness at the junction of the middle and lateral thirds of a line drawn between the symphysis and anterior superior iliac spine or direct ovarian tenderness may be found. In addition, varicosities in the thigh, buttocks, perineum, or vagina may be associated (Venbrux, 1999).

The left ovarian venous plexus drains into the left ovarian vein, which empties into the left renal vein. The right ovarian vein generally drains directly into the inferior vena cava. Both ovarian veins have numerous trunks, any of which may be involved. Clinical practice guidelines recommend noninvasive sonography or CT or MR venography for suspected cases. Sonographic findings with applied Doppler include a dilated tortuous ovarian vein with a diameter  $\geq 6$  mm, slow blood flow  $\leq 3$  cm/sec, and a dilated arcuate vein in the myometrium that communicates to the pelvic varicosities (Fig. 11-6) (Park, 2004). With positive findings, then retrograde ovarian and internal iliac venography is preferred if intervention is planned (Gloviczki, 2011).

**FIGURE 11-6** Color Doppler transvaginal image of tortuous and dilated pelvic vessels in the right adnexa in a patient with chronic pelvic pain. (Used with permission from Dr. Elysia Moschos.)

Diagnostic laparoscopy can also identify varicosities. However, because all these modalities are performed while a woman is supine or in Trendelenburg position, varicosities often decompress and may be missed. CO<sub>2</sub> insufflation pressure also contributes to the high false-negative rate of laparoscopy to diagnose pelvic varicosities.

Common treatments for pelvic congestion syndrome are hormonal suppression, ovarian vein embolization, or hysterectomy with BSO. First, medical treatment with medroxyprogesterone acetate, 30 mg orally daily, or with a GnRH agonist is effective for some women with pelvic congestion syndrome, although symptoms typically recur after medication is discontinued (Reginald, 1989; Soysal, 2001). Second, embolization appears to afford effective treatment, and pain improves in 70 to 80 percent of women (Hansrani, 2015). Third, Beard and coworkers (1991) studied 36 patients who underwent hysterectomy and BSO for pelvic congestion syndrome and intractable pelvic pain. Although 12 of 36 had residual pain at 1 year, only one patient had pain affecting daily life. They concluded that pain and quality-of-life scores were improved. Importantly, none of these options are definitive, and evidence-based studies supporting their efficacy are limited.

## DYSMENORRHEA

Cyclic pain with menstruation is common and accompanies most menses (Weissman, 2004). This pain is classically described as cramping and is often accompanied by low backache, nausea and vomiting, headache, or diarrhea. The term *primary dysmenorrhea* describes cyclic menstrual pain without an identifiable associated pathology, whereas *secondary dysmenorrhea* frequently complicates endometriosis, leiomyomas, PID, adenomyosis, endometrial polyps, and menstrual outlet obstruction. For this reason, secondary dysmenorrhea may be associated with other gynecologic symptoms, such as dyspareunia, dysuria, abnormal bleeding, or infertility.

Compared with secondary dysmenorrhea, primary dysmenorrhea more commonly begins shortly after menarche. Pain characteristics, however, typically fail to permit differentiation between the two types, and primary dysmenorrhea is usually diagnosed following exclusion of known associated causes.

When other factors are removed, primary dysmenorrhea equally affects women regardless of race and socioeconomic status. However, increased pain duration or severity is positively associated with earlier age at menarche, long menstrual periods, smoking, and increased body mass index (BMI). In contrast, parity appears to improve symptoms (Harlow, 1996; Sundell, 1990).

Pathophysiologically, prostaglandins are implicated in dysmenorrhea. During endometrial sloughing, endometrial cells release prostaglandins as menstruation begins. Prostaglandins stimulate myometrial contractions and ischemia. Women with more severe dysmenorrhea have higher levels of prostaglandins in menstrual fluid, and these levels are highest during the first 2 days of menstruation. Prostaglandins are also implicated in secondary dysmenorrhea. However, anatomic mechanisms are also suspected, depending on the type of accompanying pelvic disease.

## ■ Diagnosis

In women with menstrual cramps and no other associated findings or symptoms, no additional evaluation may be initially required, and empiric therapy can be prescribed (Proctor, 2006). In women at risk for PID, cultures for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are prudent. Moreover, if pelvic evaluation is incomplete due to body habitus, then transvaginal sonography may be informative to exclude structural pelvic pathology.

## ■ Treatment

Of options, NSAIDs are often preferred. Because prostaglandins are suspected in the genesis of dysmenorrhea, NSAID administration is logical, and studies support their use (Marjoribanks, 2010). These drugs and their dosages are found in Table 10-1 (p. 239).

Steroid hormone contraception leads to endometrial atrophy and in turn lower endometrial prostaglandin levels. Of choices, combination hormone birth control methods are believed to improve dysmenorrhea by lowering prostaglandin production. Studies of combination oral contraceptives (COCs) note improved dysmenorrhea in many users (Brill, 1991; Wong, 2009). In addition, extended or continuous administration of COCs, described in Chapter 5 (p. 123), may be helpful for women with pain not controlled by the traditional cyclic pill schedule (Sulak, 1997). Progestin-only contraceptives are also used for dysmenorrhea. Namely, the levonorgestrel-releasing intrauterine system (LNG-IUS), depot medroxyprogesterone acetate injection, and progestin-releasing implanted rods all are reasonable choices (Lindh, 2013).

GnRH agonists and androgens are other options. The estrogen-lowering effects of these lead to endometrial atrophy and diminished prostaglandin production. Although GnRH agonists and androgens such as danazol lessen dysmenorrhea, their substantial side effects preclude their routine and long-term use. A fuller discussion and dosages for these agents and their side effects are found in Chapter 10 (p. 240).

Complementary and alternative medicine has been evaluated for dysmenorrhea. Oral vitamins E, fish oil, low-fat diet, and Chinese herbal medicine have all been shown to improve dysmenorrhea. However, evidence derives from small and typically nonrandomized trials (Barnard, 2000; Harel, 1996; Zhu, 2008; Ziaei, 2001). Additionally, data are limited but positive toward the use of exercise, topical heat, acupuncture, and transcutaneous electrical nerve stimulation (TENS) (Akin, 2001; Brown, 2010; Proctor, 2002; Smith, 2011).

Cases of dysmenorrhea refractory to conservative management are unusual, and in such instances, surgery may be indicated. Hysterectomy is effective in treating dysmenorrhea, but those desiring future fertility may decline it. For these women, presacral neurectomy can be considered.

## DYSPAREUNIA

This is a frequent gynecologic complaint, and in reproductive-aged women in the United States, the 12-month prevalence is 15 to 20 percent (Glatt, 1990; Laumann, 1999). Painful intercourse may be associated with vulvar, visceral,

musculoskeletal, neurogenic, or psychosomatic disorders. Coexistent etiologies may also lead to similar symptoms. For example, women with vulvodynia have been shown in many cases to have coexistent pelvic floor muscle spasm, both of which may cause dyspareunia (Reissing, 2005). Because of the frequent association between dyspareunia and CPP and frequent overlap of etiologies, physical examination and diagnostic testing often follow that for women with CPP (p. 253).

Dyspareunia may be subclassified as *insertional*, that is, pain with vaginal entry, or *deep*, which is associated with deep penetration. Of insertional dyspareunia cases, vulvodynia, vulvitis, and poor lubrication form the majority. Of deep dyspareunia cases, endometriosis, pelvic adhesions, and bulky leiomyomas are frequent causes. In many women, both insertional and deep dyspareunia may be present.

Additional terms include *primary dyspareunia*, which describes the onset of painful intercourse coincident with coitarche, and *secondary dyspareunia*, which is painful intercourse that follows an earlier period of pain-free sexual activity. Sexual abuse, female genital mutilation, and congenital anomalies most frequently lead to primary dyspareunia, whereas sources of secondary dyspareunia are more varied. Last, dyspareunia is clarified as *generalized*, occurring in all episodes of intercourse, or as *situational*, associated with only specific partners or sexual positions. Recent changes in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) have merged dyspareunia and vaginismus into the term *genito-pelvic pain/penetration disorder* (American Psychiatric Association, 2013).

## ■ Diagnosis

During history taking, patients are questioned regarding associated symptoms such as vaginal discharge, vulvar pain, dysmenorrhea, CPP, dysuria, or scant lubrication. Onset of symptoms and their temporal association with obstetric delivery, pelvic surgery, or sexual abuse is often informative. In addition, dyspareunia may be found in those who breast feed, presumably because of hypoestrogenism-derived vaginal atrophy seen with lactation (Buhling, 2006; Signorello, 2001). Psychosocial topics such as relationship satisfaction or depression are also covered.

Inspection of the vulva mirrors that for chronic pain. In particular, generalized erythema, episiotomy scars, or atrophy is sought. Erythema may indicate contact or allergic dermatitis or infection, particularly fungal infection. Accordingly, a historical inventory of potential skin irritants, a saline slide preparation, vaginal pH testing, and vaginal cultures are performed. Specifically, a vaginal fungal culture may be required in some cases as several noncandidal species may be poorly detected if microscopic analysis is solely used (Haefner, 2005).

Some studies, but not all, have found a positive correlation between degree of pelvic organ prolapse and dyspareunia (Burrows, 2004; Ellerkmann, 2001). If noted, its degree is assessed as described in Chapter 24 (p. 548).

Physical examination evaluates the distal, mid-, and proximal vagina. Evaluation may first begin with palpation of the Bartholin and paraurethral glands. Additionally, cotton-swab testing is used to map painful areas (Fig. 4-1, p. 87). Next, insertion of a single digit into the distal vagina may elicit

*vaginismus*, that is, reflex contraction of the muscles associated with distal vaginal penetration (Basson, 2010). The contraction response is normal, but prolonged spasm of the bulbospongiosus, pubococcygeus, piriformis, and obturator internus muscles may cause pain. Spasm is thought to be a conditioned response to current or former physical pain.

With deeper digital examination, midvaginal pain may be triggered. This may be seen with interstitial cystitis, in congenital anomalies, or following radiation therapy or pelvic reconstructive surgeries.

Deep dyspareunia is more commonly caused by disorders that also cause CPP. Focal points of this vaginal examination are discussed on page 257. Similarly, diagnostic testing for deep dyspareunia in large part mirrors that for CPP. Urine and vaginal cultures may indicate infection, and radiologic imaging may reveal structural visceral disease.

## ■ Treatment

Resolution of dyspareunia is highly dependent on the underlying cause. For those with vaginismus, structured desensitization is effective. Patients gradually gain control in comfortably inserting dilators of increasing size into the introitus. Concurrent psychological counseling in such cases is often warranted. Poor lubrication may be countered with education directed toward adequate arousal techniques and use of external lubricants. As discussed in Chapter 22, estrogen cream or the selective estrogen-receptor modulator ospemifene (Osphena) will usually resolve genitourinary syndrome of menopause, which is the new preferred term for vulvovaginal atrophy.

Surgery may be indicated for structural pathologies and may include ablation of endometriosis, lysis of adhesions, and restoration of normal anatomy. For those with dyspareunia confidently attributed to a retroverted uterine position, uterine suspension has been shown, albeit in small studies, to be effective (Perry, 2005).

## DYSURIA

Evaluation of dysuria begins with a careful pelvic inspection to exclude vaginitis, vulvar lesions, and urethral diverticulum. A voiding diary can be informative, and for those with associated dyspareunia, a sexual history is obtained. The most common cause of dysuria is infection, and urinalysis and urine culture are therefore initial tests. Similarly, *C trachomatis* and herpes simplex virus infections are excluded. For those with chronic dysuria, urodynamic studies may help to identify those with detrusor overactivity, significantly decreased compliance, or bladder outlet obstruction (Chap. 23, p. 526). Cystoscopy is used to identify the hallmark mucosal findings of interstitial cystitis and exclude neoplastic growths or stones (Irwin, 2005). Adjunctively, sonography or laparoscopy may be indicated to exclude structural pelvic pathology or endometriosis.

## ■ Interstitial Cystitis/Painful Bladder Syndrome

This chronic inflammatory disorder of the bladder is typified by frequency, urgency, and pelvic pain. With interstitial

cystitis (IC), this triad is found in combination with characteristic mucosal changes and reduced bladder capacity. In contrast to cases with classic IC findings, *painful bladder syndrome* describes chronic IC symptoms in those who lack cystoscopic findings of IC or other bladder pathology (Abrams, 2002).

The prevalence of IC in the United States is variable and cited at 0.5 to 3 percent (Berry, 2011; Jones, 1997). It is diagnosed more commonly in women, in whites, in smokers, and in those in their 40s (Kennedy, 2006; Propert, 2000). There is a strong association between IC and endometriosis. The two conditions share similar symptoms, and many patients evaluated for chronic pelvic pain have been found to have either one or both conditions (Butrick, 2007; Paulson, 2007). In addition, IC is associated with IBS, generalized pain disorders, fibromyalgia, pelvic floor dysfunction, and depression (Aaron, 2000; Clauw, 1997; Novi, 2005; Peters, 2007).

The exact cause of IC is unknown, and current theories include increased mucosal permeability or mast cell activation (Sant, 2007; Warren, 2002). Glycosaminoglycans are an important component of the mucin layer that covers and protects the bladder urothelium. One theory explains that IC symptoms originate from a defect in the protective bladder glycosaminoglycan component. This leads to increased permeability of the bladder mucosa (Parsons, 2003).

## Diagnosis

IC is considered in women with unexplained chronic pelvic pain and voiding symptoms. Warren and colleagues (2006) found that the key descriptor “pelvic pain” fit 100 percent of an affected population. Other relevant descriptors are “pressure” and “discomfort” (Sirinian, 2005). Of voiding complaints, frequency, urgency, nocturia, and pain with bladder filling or emptying are often reported. Dyspareunia and postcoital ache are common. As with most chronic pain syndromes, symptoms may worsen premenstrually. Given the broad spectrum of triggers (alcohol, caffeine, smoking, spicy foods, citrus fruits and juices, carbonated drinks, and potassium), patients may not relate exacerbation of their symptoms to these. Cranberry juice, frequently advised for urinary tract infection, can acutely exacerbate pain from IC.

Single-digit vaginal examination in the patient with IC may demonstrate urethral or anterior vaginal/bladder base tenderness as well as pelvic floor hypertonus, tenderness, or trigger points. The basic laboratory examination includes urinalysis and culture, and unevaluated microhematuria typically prompts cytology, especially in smokers, to exclude neoplasia. Cystoscopy and urodynamic studies may add clarity to complex presentations or exclude other entities that mimic IC. However, consensus on cystoscopic or urodynamic criteria for IC is lacking (Hanno, 2011). Cystoscopically, *Hunner ulcers* are reddish-brown mucosal lesions with small vessels radiating toward a central scar (Fig. 11-7). These ulcers are rare but considered diagnostic for IC. The more common finding is *glomerulations*, which are small petechiae or submucosal hemorrhages. However, these may be present in patients without IC symptoms and undergoing cystoscopy for other indications (Waxman, 1998). Urodynamic testing may reveal sensory urgency at low bladder volumes, decreased compliance, and decreased capacity. The potassium sensitivity test (PST) indicates increased urothelial permeability

**FIGURE 11-7** Cystoscopic photograph displays Hunner ulcers. (Reproduced with permission from Reuter HJ: Bladder. In Atlas of Urologic Endoscopy Diagnosis and Treatment. New York, Thieme Medical Publishers, 1987, p 85.)

but is painful and may trigger a severe symptom flare. Moreover, a negative result does not eliminate suspicion for IC. In one study, 25 percent of patients meeting strict IC criteria had a negative PST result (Parsons, 1998).

Given the broad symptom spectrum, its frequent association with other pelvic pain syndromes, and symptoms that overlap with other pain disorders, diagnosing IC can be challenging. Moreover, uniform consensus on diagnostic criteria is lacking. Thus, the diagnosis of interstitial cystitis remains clinical and is mostly one of exclusion. Not surprisingly, misdiagnosis, underdiagnosis, or delayed diagnosis of IC is common.

## Treatment

The American Urological Association has provided evidence-based guidelines for IC management (Hanno, 2011, 2015). First-line treatment provides patient education and behavioral modification, especially avoidance of bladder irritants. Second-tier options are pelvic floor physical therapy to resolve trigger points or pelvic floor hypertonus or to implement pharmacological management. Suitable agents include amitriptyline, cimetidine, hydroxyzine, or pentosan polysulfate sodium (Elmiron), which is a weak anticoagulant. Also, intravesical therapy may consist of direct bladder instillation of heparin, lidocaine, or dimethyl sulfoxide (DMSO). For patients who do not respond, cystoscopy coupled with short-duration, low-pressure bladder distention and fulguration of Hunner ulcers may afford relief. FDA approval is lacking for treatment with cyclosporin A, intradetrusor botulinum toxin A, or sacral neuromodulation, which is described in Section 45-12 (p. 1085). However, their use may be considered in patients who fail to respond to other therapies. Major surgery such as cystoplasty or urinary diversion is performed rarely for carefully selected

patients in whom all other therapies have failed to provide adequate symptom control.

## GASTROINTESTINAL DISEASE

In numerous cases, GI disease is found as an underlying cause of chronic pelvic pain. GI causes may be organic or functional (see Table 11-1). Thus, initial screening may follow that for CPP. However, symptoms such as fever, GI bleeding, weight loss, anemia, and abdominal mass will prompt a stronger search for organic pathology. Investigations may include sigmoidoscopy or colonoscopy to exclude inflammation, diverticula, or tumors. For those with diarrhea, stool examination for leukocytes or for ova and parasites may be indicated. Moreover, serologic testing for celiac disease can be valuable. When indicated, sonography may aid in distinguishing GI from gynecologic pathology.

### ■ Colonic Diverticular Disease

Colon diverticula are small defects in the muscular layer of the colon through which colonic mucosa and submucosa herniate. Diverticular disease is common and typically affects the sigmoid or descending colon. Chronic symptoms include abdominal pain that localizes to the left lower quadrant, obstipation, and rectal fullness. More seriously, diverticula may cause acute or chronic GI bleeding or may become infected. Clinically, infection can be difficult to distinguish from PID or tuboovarian abscess. In these cases, CT is the preferred imaging technique and has a sensitivity for diagnosis exceeding 90 percent and a specificity approaching 100 percent (Ambrosetti, 1997).

Chronic diverticular disease is usually treated with a high-fiber diet and long-term suppressive therapy with antibiotics. With acute severe infection, hospitalization, parenteral antibiotics, surgical or percutaneous abscess drainage, or partial colectomy may be required. Suspected rupture of a diverticular abscess with peritonitis is an indication for immediate surgical exploration (Jacobs, 2007).

### ■ Celiac Disease

This is an inherited autoimmune intolerance to gluten, which is a component of wheat, barley, or rye. In affected individuals, gluten ingestion creates an immune-mediated reaction that damages the small intestine mucosa and leads to varying degrees of malabsorption. Thus, treatment dictates a gluten-free diet for life (Rubio-Tapia, 2013). Celiac disease is common, and its incidence in the general population approaches 1 percent (Green, 2007). Its incidence is suspected to be even higher if those with GI symptoms are screened. There is a gender bias to the disease, and two to three times as many women as men are affected (Green, 2005).

The most common presenting symptoms are abdominal pain and diarrhea. Other findings include weight loss, osteopenia, and fatigue from anemia, all of which stem from malabsorption. In addition, celiac disease has been associated with infertility, although the mechanism is not understood (Tersigni, 2014).

Celiac disease is suspected in those with characteristic findings and in those with a family history of the disorder. Diagnosis requires both duodenal biopsy and a positive response to a gluten-free diet. However, numerous patients presenting with abdominal pain and diarrhea do not have celiac disease. Thus, to avoid unnecessary biopsy, many physicians will screen with noninvasive serologic tests. Of these, serologic screening for IgA antitissue transglutaminase antibodies is preferred and is performed while patients maintain a gluten-containing diet during testing (Rubio-Tapia, 2013).

### ■ Functional Bowel Disorders

Also known as *functional gastrointestinal disorders (FGIDs)*, this group of functional disorders has symptoms attributable to the lower GI tract and includes those listed in Table 11-6. In defining these chronic conditions, symptoms must have begun more than 6 months previously and have occurred more than 3 days a month during the last 3 months (Longstreth, 2006). The diagnosis always presumes the absence of a structural or biochemical explanation for symptoms (Thompson, 1999).

#### Irritable Bowel Syndrome

This functional bowel disorder is defined as abdominal pain that improves with defecation and is associated with a change in bowel habits. Subtypes are divided by the predominant stool pattern and include constipative, diarrheal, and mixed categories. Although defining criteria are listed in Table 11-6, other symptoms that support the diagnosis include abnormal stool frequency or stool form, straining, urgency, passing mucus, and bloating (Longstreth, 2006).

IBS is common, and its general population prevalence is estimated to approximate 10 percent (Canavan, 2014; Lovell, 2012). The prevalences of diarrhea-predominant and constipation-predominant IBS are equivalent (Saito, 2002).

The pathophysiology of IBS is complex, and neural, hormonal, genetic, environmental, and psychosocial factors are variably involved (Drossman, 2002). The primary mechanism of IBS, however, is thought to stem from poorly regulated interactions between the CNS and the enteric nervous system (ENS). Such brain-gut dysfunction may eventually cause alterations of GI mucosal immune response, intestinal motility and permeability, and visceral sensitivity. In turn, these produce abdominal pain and altered bowel function (Mayer, 2008). Specifically, serotonin (5-hydroxytryptamine, 5-HT) is involved with regulating intestinal motility, visceral sensitivity, and gut secretion and is thought to play an important role in IBS (Atkinson, 2006; Gershon, 2005).

Prior to assigning a diagnosis of IBS, clinicians ideally exclude organic disease. However, for young patients who have typical IBS symptoms and no organic disease symptoms, few tests are required. Testing is individualized, and factors that typically prompt greater evaluation include older patient age, longer duration and greater severity of symptoms, absent psychosocial factors, organic disease symptoms, and family history of GI disease.

**Treatment.** Nonpharmacologic approaches may improve symptoms. First, no specific diet suffices for all patients,

**TABLE 11-6.** Functional Gastrointestinal (GI) Disorders

**Functional Bowel Disorders**

Irritable bowel syndrome (IBS)	Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with 2 or more of the following: (1) improved with defecation; (2) onset associated with a change in stooling frequency; (3) onset associated with a change in form of stool
Functional abdominal bloating	Must include both of the following: (1) recurrent feeling of bloating or visible distention at least 3 days/month in 3 months; (2) insufficient criteria for a diagnosis of functional dyspepsia, IBS, or other functional GI disorder
Functional constipation	Must include two or more of the following: (1) straining during at least 25% of defecations; (2) lumpy or hard stools in at least 25% of defecations; (3) sensation of incomplete evacuation for at least 25% of defecations; (4) sensation of anorectal obstruction/blockage for at least 25% of defecations; (5) manual maneuvers to aid at least 25% of defecations; (6) fewer than three defecations per week Loose stools are rarely present without the use of laxatives There are insufficient criteria for IBS
Functional diarrhea	Loose or watery stools without pain, occurring in at least 75% of stools
Unspecified functional bowel disorder	Bowel symptoms not attributable to an organic etiology that do not meet criteria for the previously defined categories

**Functional Abdominal Pain**

Functional abdominal pain	At least 6 months of: (1) continuous or nearly continuous abdominal pain; and (2) no or only occasional relation of pain with physiologic events (e.g., eating, defecation, or menses); (3) some loss of daily functioning; (4) pain is not feigned (e.g., malingering); (5) insufficient criteria for other functional gastrointestinal disorders that would explain the abdominal pain
Unspecified functional abdominal pain

but foods known to trigger symptoms are logically avoided. Combination probiotics in general improve global IBS symptoms, bloating, and flatulence, although current data limit recommendation of preferred species (Ford, 2014a,c).

Drug therapy is directed toward dominant symptoms. For those with constipation-dominant IBS, commercial soluble fiber analogues or psyllium husk may help if increased dietary fiber is unsuccessful (Bijkerk, 2009). Of these, psyllium husk is gradually titrated to improve tolerability to a dosage of 3 to 5 g orally twice daily. Of note, dietary fiber is effective in treating constipation but is not effective for diarrhea-dominant IBS or for IBS-associated pain (Ruepert, 2011). Another agent, linaclotide (Linzess), a guanylate cyclase agonist, stimulates increased fluid secretion and transit time (Chey, 2012b; Rao, 2012). It is taken orally as a 290-μg capsule once daily. Alternatively, lubiprostone (Amitiza) is a GI chloride-channel activator that is taken orally twice daily as an 8-μg capsule. It also enhances intestinal fluid secretion to improve intestinal motility (Chey, 2012a; Drossman, 2009). No longer available due to cardiovascular adverse events, tegaserod (Zelnorm) was a partial serotonin-receptor agonist (Food and Drug Administration, 2012b).

For those with diarrhea-dominant symptoms, treatments often strive to slow bowel motility because as substances stay longer in the gut, more water is absorbed from fecal matter to bulk stool. Indirect evidence supports loperamide (Imodium), 2 mg orally once or twice daily (Trinkley, 2014; Weinberg,

2014). For those with severe diarrhea, alosetron (Lotronex), a selective serotonin 5-HT<sub>3</sub>-receptor antagonist, interacts with ENS neuron receptors to slow bowel motility. T is drug decreases pain, urgency, and stool frequency (Camilleri, 2000; Chey, 2004). However, due to cases of ischemic colitis associated with its use, alosetron is now available only through a strictly regulated FDA prescribing program (Chang, 2006; Food and Drug Administration, 2012a).

For patients with pain secondary to bowel spasm, antispasmodic agents decrease intestinal smooth muscle activity and are thought to decrease abdominal discomfort. Agents available in the United States include dicyclomine (Bentyl) and hyoscyamine sulfate (Levsin). Dicyclomine is begun at 20 mg orally four times daily and increased after 1 week to 40 mg. Hyoscyamine sulfate is dosed at 0.25 to 0.5 mg orally daily and can be increased as needed up to four times daily. Although having benefits for IBS, the anticholinergic side effects of these agents often limit their long-term use (Ruepert, 2011; Schoenfeld, 2005). Peppermint oil, another effective antispasmodic, can be taken orally as over-the-counter capsules at dosages of 550 mg once daily or 187 mg three times daily (Khanna, 2014).

Tricyclic antidepressants may help patients with IBS both by an anticholinergic effect on the gut and by mood-modifying action. Tricyclic antidepressants may slow intestinal transit time and have been shown to be effective in treatment of diarrhea-dominant IBS (Hadley, 2005). Last, psychological

or behavioral treatments may help some patients (Ford, 2014b).

## MUSCULOSKELETAL ETIOLOGIES

Clinical syndromes involving the muscles, nerves, and skeletal system of the lower abdomen and pelvis are frequently encountered but often overlooked by gynecologists. Importantly, unrecognized musculoskeletal pain may lead to unnecessary surgery or promote development of pelvic pain syndromes.

### ■ Hernia

Defects in anterior abdominal wall or femoral fascia can lead to herniation of bowel or other intraabdominal contents through these rents. Such herniation can create pain locally at the defect site or cause referred pain along the distribution of a compressed sensory nerve. Moreover, if blood supply to the contents is acutely compromised, then bowel obstruction or ischemia will require surgical intervention. Hernias that involve the anterior abdominal wall and pelvic floor are most commonly associated with CPP. Much less frequently, *sciatic hernia*, which is herniation of peritoneum and peritoneal contents through the greater sciatic foramen, and *obturator hernia*, which is that through the obturator canal, are also described sources of acute or chronic pain.

Hernias may develop at sites of inherent anatomic weakness, and common types in women include ventral, umbilical, and incisional hernias. Indirect inguinal, direct inguinal, and femoral hernias are types less often found in females. Spigelian hernias are rare. As shown in Figure 11-8, ventral hernias are caused by fascial defects typically occurring in the midline. Umbilical hernias are those involving defects of the umbilical ring. Indirect inguinal hernias are those in which abdominal contents herniate through the internal inguinal ring and into the inguinal canal. As shown in Figure 11-9, contents may then exit the external inguinal ring. In contrast, contents of a direct inguinal hernia bulge through a fascial defect within Hesselbach triangle. Spigelian hernias can occur anywhere along the lateral border of the rectus abdominis muscle. However, the most frequent location is this border's intersection point with the arcuate line.

Conditions that increase intraabdominal pressure such as pregnancy, ascites, peritoneal dialysis, and chronic cough are known hernia risk factors. Congenital or acquired anatomic weakness or connective tissue disorders are also associated.

For diagnosis, patients with CPP or abdominal pain ideally are examined while standing and also during Valsalva maneuver. Because of the potential risks associated with content herniation and strangulation, hernias are typically repaired once identified. Small ventral, umbilical, or incisional hernias may be repaired

**FIGURE 11-8** Hernias that may involve the anterior abdominal wall. (Used with permission from Mr. T. J. Fels.)

**FIGURE 11-9** Indirect and direct inguinal hernias and femoral hernia. A direct hernia is caused by a fascial defect within Hesselbach triangle. The sides of this triangle are formed by the inguinal ligament, the inferior epigastric vessels, and the lateral border of the rectus abdominis muscle. An indirect hernia forms from intraabdominal contents exiting through the inguinal canal. Femoral hernias form from contents exiting through the femoral ring.

by gynecologic surgeons. In these cases, the hernia sac is excised and fascia reapproximated. Patients with larger hernias, which usually require mesh placement, or hernias in the inguinal area are typically referred to a general surgeon.

### ■ Myofascial Pain Syndrome

Primary musculoskeletal (MS) conditions may lead to CPP (see Table 11-2). In other cases, secondary myofascial pain syndromes can originate from endometriosis, interstitial cystitis, or IBS. Such chronic visceral inflammatory conditions can create pathologic changes in nearby muscles and/or nerves to cause abdominal wall or pelvic floor pain. Thus, awareness of these complex associations allows a physician to more effectively address all components leading to pain, rather than narrowly focusing on an isolated visceral disorder.

With myofascial pain, a hyperirritable area within a muscle promotes persistent fiber contraction (Simons, 1999). The primary reactive area within the muscle is termed a *trigger point* (*TrP*) and is identified as a palpable taut, ropy band. Trigger points are thought to form as the end of a metabolic crisis within a muscle. Dysfunction of a neuromuscular endplate can lead to sustained acetylcholine release, persistent depolarization, sarcomere shortening, and creation of a taut muscle band. Affected fibers compress capillaries and decrease local blood flow. The resulting ischemia leads to release of substances that activate peripheral nerve nociceptors and in turn cause pain (McPartland, 2004). A persistent barrage of nociceptive signals from TrPs may eventually lead to central sensitization and the potential for neuropathic pain (p. 250). Signals may spread segmentally within the spinal cord to cause localized or referred pain (Gerwin, 2005). TrPs can also initiate viscerosomatic convergence that can generate autonomic responses such as vomiting, diarrhea, and bladder spasm.

TrPs can affect any muscle, and those involving muscles of the anterior abdominal wall, pelvic floor, and pelvic girdle can be sources of CPP. The incidence of myofascial disease is unknown. However, in an evaluation of 500 patients with CPP, Carter (1998) found that 7 percent of patients primarily had TrPs as a source of their pain. Moreover, of nearly 1000 women evaluated for CPP, 22 percent were found to have significant tenderness of the levator ani muscles and 14 percent

had piriformis muscle tenderness (Gomel, 2007). Prevalence appears to be greatest at ages between 30 and 50 years. Risk factors are varied, although many trigger points can be traced to a prior specific trauma such as a sports injury or to chronic biomechanical overload of a muscle (Sharp, 2003). Accordingly, a detailed inventory of sports injuries, traumatic injuries, obstetric deliveries, surgeries, and work activities is essential.

### Diagnosis

Having the patient mark painful sites on a body silhouette diagram can be an informative first step. Involvement of specific muscles will often give characteristic patterns. Patients typically describe the pain as aggravated by specific movement or activity and relieved by certain positions. Cold, damp exposure generally worsens pain. Pressure on a trigger point causes pain and produces effects on a target area or *referral zone*. This is specific and reproducible area of referral rarely coincides with dermatologic or neuronal distribution and is the feature that differentiates myofascial pain syndromes from fibromyalgia (Lavelle, 2007).

Muscle examination may be completed by flat palpation, pincer palpation, or deep palpation depending on muscle location. Flat palpation uses fingertips to roll over superficial muscles, which are accessible only at the surface (Fig. 11-10). This technique is commonly used to assess the anterior abdominal wall. In muscles with greater accessibility, pincer palpation grasps the muscle belly between the thumb and fingers. With any of the palpation techniques, spot tenderness and taut muscle bands are sought. Classically, the involved muscle displays weakness and restricted stretch. TrP pressure may also elicit a local muscle twitch response, reproduce a patient's referred pain, or both.

### Specific Muscle Groups

Anterior abdominal wall muscles—that is, the rectus abdominis, the obliques, and transversus abdominis muscles—may all develop TrPs, and somatovisceral pelvic symptoms from these muscles may include diarrhea or urinary frequency, urgency, or retention. Rectus abdominis muscle TrPs are frequently found along the linea semilunaris, which is the term for this muscle's lateral margin (Suleiman, 2001). Additional rectus abdominis TrPs may develop at the muscle's insertion into the pubic bone and also below the umbilicus. Within the external oblique

**FIGURE 11-10** Techniques for trigger point palpation. **A.** With flat palpation, fingertips stroke across the muscle surface. **B.** With pincer palpation, the muscle is grasped and palpation for trigger points is completed as the muscle slips through the fingers.

**FIGURE 11-11** Trigger points and their extensive patterns of referred pain (red shading) **A.** Trigger points in the levator ani and coccygeus muscles. **B.** Trigger point in the obturator internus muscle. (Used with permission from Ms. Marie Sena.)

muscle, trigger points frequently involve its lateral attachment to the anterior iliac crest. Pain usually refers to the pubic bone.

After examination of the anterior abdominal wall, muscles of the pelvis are evaluated. Following careful inspection of the external genitalia, vaginal examination proceeds slowly with the index finger only and initially without a palpating abdominal hand. Muscles within the pelvis include the levator ani, coccygeus, obturator internus, and deep transverse perineal and piriformis muscles, and these are assessed for painful TrPs (see Fig. 11-5) (Vercellini, 2009). TrPs involving these muscles and anal sphincter muscles are frequently associated with poorly localized pain that may be described as involving the coccyx, hip, or back (Fig. 11-11). Dyspareunia is common.

**Levator Ani Syndrome.** Pain stemming from TrPs involving the levator ani muscles has had various names including levator ani spasm syndrome and coccydynia (see Fig. 11-11). Currently, *levator ani syndrome* is preferred. *Coccydynia* is reserved for coccygeal pain originating from skeletal trauma to the coccyx.

The levator ani muscles, including their supporting fascia, overlying parietal peritoneum, and intimately associated visceral peritoneum, are connected by common sensory nerves to the spinal cord. These provide the basis for viscerosomatic convergence (Spitznagle, 2014). Spasm of these muscles can result in lower abdominal pain, low back pain, dyspareunia, and chronic constipation.

### Treatment

Regardless of TrP location, the treatment goal is TrP inactivation, which then allows stretching and release of taut muscle bands. Of methods, TrP point massage or more aggressive ischemic compression massage are effective (Hull, 2009). Biofeedback, relaxation techniques, or psychotherapy may be helpful therapy adjuncts. Analgesics, antiinflammatory drugs, muscle relaxants, or neuroleptics may also be prescribed. Finally, electrical stimulation, TrP dry needling, or TrP injection may be required. In those who are unresponsive to injection of local anesthetic agents, botulinum toxin A injection may be considered (Gyang, 2013). At our institution, as in many other

tertiary referral centers, we often consult pelvic floor physical therapy experts for many of these treatments.

### ■ Peripartum Pelvic Pain Syndrome

Also known as pelvic girdle pain, this condition is characterized by persistent pain that begins during pregnancy or immediately postpartum. Pain is prominent around the sacroiliac joints and symphysis and is thought to originate from injury or inflammation of the pelvic and/or lower spine ligaments. Muscle weakness, postural adjustments of pregnancy, hormonal changes, and weight of the fetus and gravid uterus are all potential contributing factors (Mens, 1996). Pelvic girdle pain is common. Significant pain is estimated to affect approximately 20 percent of pregnant women and 7 percent of those during the 3 months following delivery (Albert, 2002; Wu, 2004). Diagnosis is usually clinical and based on findings during specific orthopedic joint manipulation tests. These are used to recreate or provoke the pain. Treatment includes physical therapy, exercise, and analgesics typically used for CPP (Vermani, 2010; Vleeming, 2008).

## NEUROLOGIC ETIOLOGIES

### ■ Anterior Abdominal Wall Nerve Entrapment Syndromes

Nerve compression can lead to chronic pelvic pain and may involve nerves of the anterior abdominal wall or those within the pelvis. Anterior abdominal wall pain is frequently mistaken for visceral pain. Common causes include entrapment of the anterior cutaneous branches of the intercostal nerves or compression of branches of the ilioinguinal, iliohypogastric, genitofemoral nerves, and lateral femoral cutaneous nerves (Greenbaum, 1994). These peripheral nerves can be compressed either within narrow anatomic canals or rings or beneath tight ligaments, fibrous bands, or sutures. For example, each anterior cutaneous branch of an intercostal nerve traverses anteriorly through the rectus abdominis muscle. Each branch and its corresponding vessels travels through a fibrous ring found within

**FIGURE 11-12** Drawing displays nerve entrapment of the anterior cutaneous branches of one of the intercostal nerves. The nerve is compressed as it traverses the rectus abdominis muscle within a fibrous sheath. (Reproduced with permission from Greenbaum DS, Greenbaum RB, Joseph JG, et al: Chronic abdominal wall pain. Diagnostic validity and costs, Dig Dis Sci 1994 Sep;39(9):1935–1941.)

the lateral aspect of rectus abdominis muscle (Fig. 11-12). Clinically, these nerve branches are those often seen during Pfannenstiel incision creation as the anterior rectus sheath is dissected off each rectus belly (Fig. 43-2.3, p. 930). On crossing the anterior rectus sheath, each nerve branch divides and then courses within the subcutaneous layer. Within the fibrous ring, fat surrounding the neurovascular bundle appears to pad the enclosed structures (Srinivasan, 2002). However, if this bundle receives excessive intra- or extraabdominal pressure, compression of the bundle against the fibrous ring causes nerve ischemia and pain (Applegate, 1997).

Nerve entrapment, injury, or neuroma formation may also involve branches of the ilioinguinal, iliohypogastric, lateral femoral cutaneous, or genitofemoral nerves, as described in Chapter 40 (p. 845). Involvement may follow inguinal hernia repair, low transverse abdominal incisions, and lower abdominal laparoscopic trocar placement. Hypoesthesia is the more common finding with these injuries, but pain may variably develop within months of surgery or after several years.

Criteria for diagnosing nerve entrapment are clinical and include: (1) pain aggravated by patient movement or light skin pinching over the affected area and (2) pain improvement following local anesthetic injection. In general, electromyography is uninformative because it lacks adequate sensitivity (Knockaert, 1996). For local injection, 1- or 2-percent lidocaine and a 40-mg/mL concentration of triamcinolone can be combined in a 1:1 ratio. However, the corticosteroid may be omitted. Less than half a milliliter is injected at each pain site.

Injections of the mixture may be repeated if initially successful. Additional treatments can include oral analgesics, biofeedback, and gabapentin. If conservative options fail to bring sufficient relief, neurolysis with injection of 5- to 6-percent absolute alcohol or phenol, or surgical neurectomy may be required (Madura, 2005; Suleiman, 2001).

### ■ Pudendal Neuralgia

Neuralgia is sharp, severe, shooting pain that follows the distribution of the involved nerve. Pudendal nerve entrapment may create this type of pain on the perineum. The three branches of this nerve are the perineal nerve, the inferior rectal nerve, and the dorsal nerve to the clitoris (Fig. 38-28, p. 822). Thus, pain may involve, alone or in combination, the clitoris, vulva, or rectum. Pudendal neuralgia is rare, is usually unilateral, and typically develops after age 30. In affected individuals, allodynia and hyperesthesia may be extreme to the point of disability. The pain is aggravated by sitting, is relieved by sitting on a toilet seat or standing, and may progress during the day.

The diagnosis of pudendal neuralgia is clinical, and *Nantes criteria* are used by many. As inclusion criteria: pain follows the pudendal nerve innervation path, is worse with sitting, has no associated sensory loss, does not awaken patients, and is relieved by nerve blockade (Labat, 2008). Clinical suspicion may be supported by objective testing. This may include neurophysiologic testing such as pudendal nerve motor latency and electromyography (EMG), both described in Chapter 25 (p. 569). However, abnormal findings with these are not specific for pudendal neuralgia. Rarely, CT or MR imaging may be informative, although these may be performed to exclude other pathology (Khoder, 2014).

Treatment can involve physical therapy; behavioral modification; gabapentin or tricyclic antidepressants; pudendal nerve blockade, with or without corticosteroids; botulinum toxin A injection; and pudendal nerve stimulation. If these are unsuccessful, surgical nerve decompression may be elected.

### ■ Piriformis Syndrome

Compression of the sciatic nerve by the piriformis muscle may lead to buttock or low back pain in the distribution of the sciatic nerve (Broadhurst, 2004). This is termed the *piriformis syndrome*. Proposed mechanisms for compression include: contracture or spasm of the piriformis muscle from trauma, overuse and muscle hypertrophy, and congenital variations, in which the sciatic nerve or its divisions pass directly through this muscle (Hopayian, 2010).

Fishman and associates (2002) estimate the piriformis syndrome to be responsible for 6 to 8 percent of cases of low back pain and sciatica in the United States each year. Symptoms include pain and tenderness involving the buttocks, with or without radiation into the posterior thigh. Pain is worse with activity, prolonged sitting, walking, and internal rotation of the hip (Kirschner, 2009). Dyspareunia has a common but variable association and has been demonstrated in 13 to 100 percent of cases (Hopayian, 2010).

Diagnosis of the syndrome is clinical and based on findings during specific orthopedic joint manipulation tests (Michel, 2013). Nerve conduction and EMG are typically nondiagnostic.

Uncommonly, MR imaging may be helpful by identifying a swollen or enlarged piriformis muscle or anatomic muscle variants (Petchprapa, 2010). Treatment is conservative and includes physical therapy, NSAIDs, muscle relaxants, or neuropathic pain agents such as gabapentin, nortriptyline, or carbamazepine. Therapeutic injections of local anesthetics, with or without corticosteroids, or of botulinum toxin A may be used. Surgery is reserved for refractory cases.

Breast disease in women encompasses a spectrum of benign and malignant disorders, which present most commonly as breast pain, nipple discharge, or palpable mass. The specific causes of these symptoms vary with patient age. Benign disorders predominate in young premenopausal women, whereas malignancy rates increase with advancing age. Evaluation of breast disorders usually requires the combination of a careful history, physical examination, imaging, and, when indicated, biopsy.

### ANATOMY

#### ■ Ductal System

The glandular portion of the breast is composed of 12 to 15 independent ductal systems that each drain approximately 40 lobules (Fig. 12-1). Each lobule consists of 10 to 100 milk-producing acini that empty into small terminal ducts (Parks, 1959). Terminal ducts drain into larger collecting ducts that

merge into even larger ducts, which exhibit a saccular dilation just below the nipple called a lactiferous sinus (Fig. 12-2).

In general, only six to eight openings are visible on the nipple surface. These drain the dominant ductal systems, which account for approximately 80 percent of the breast's glandular volume (Going, 2004). Minor ducts either terminate just below the nipple surface or open on the areola near the base of the nipple. The areola itself contains numerous lubricating sebaceous glands, called Montgomery glands, which are often visible as punctate prominences.

In addition to epithelial structures, the breast is composed of varying proportions of collagenous stroma and fat. The distribution and abundance of these stromal components accounts for a breast's consistency when palpated and for its imaging characteristics.

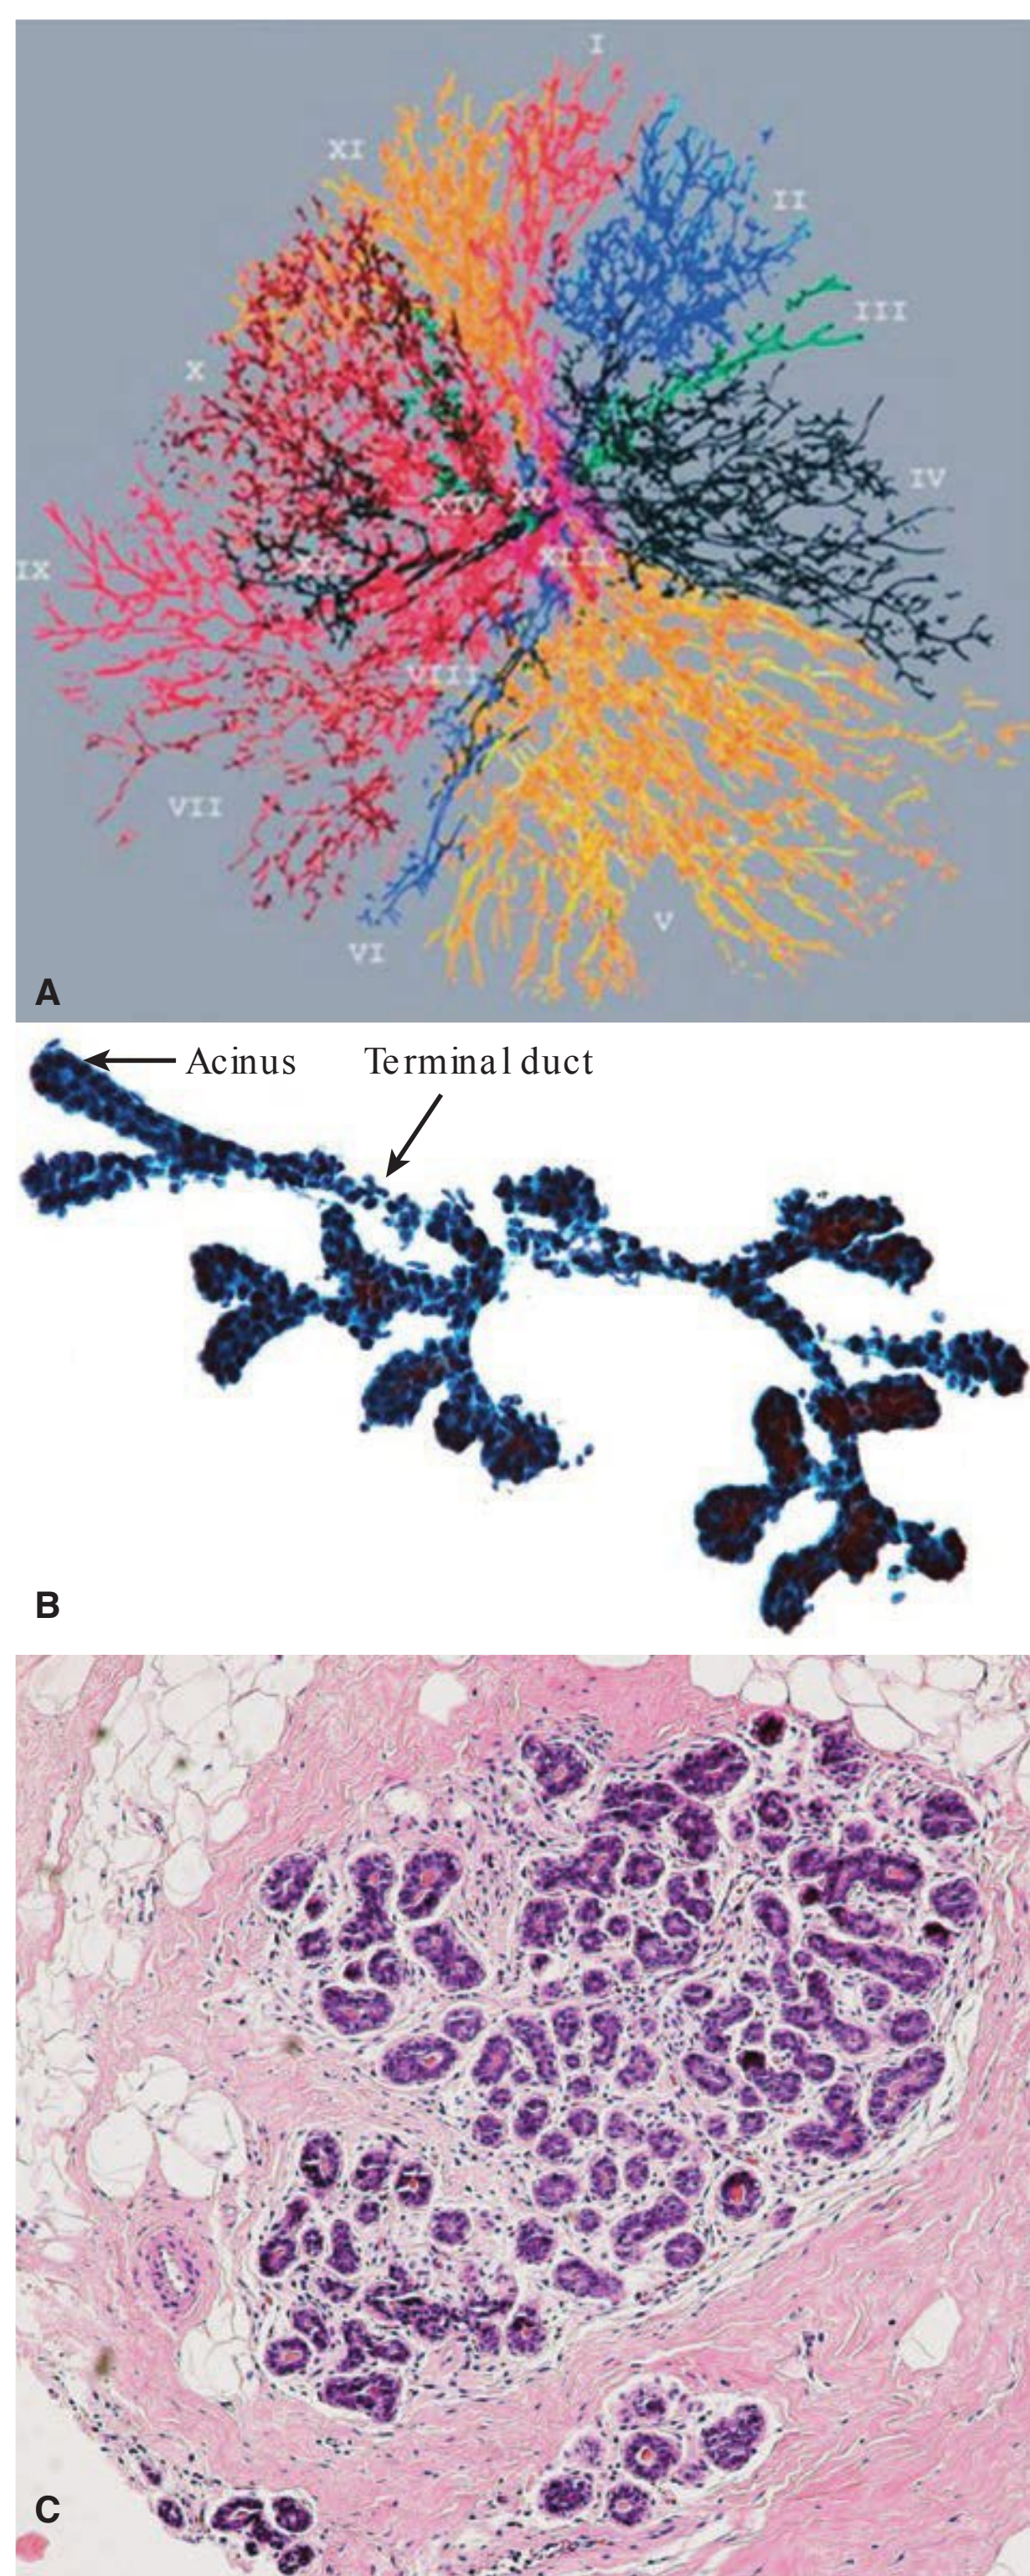

#### ■ Lymphatic Drainage

Afferent lymphatic drainage of the breast is provided by dermal, subdermal, interlobar, and prepectoral systems (Fig. 12-3) (Grant, 1953). Each of these may be viewed as a lattice of valveless channels that interconnect with every other system and that ultimately drain into one or two axillary lymph nodes (the sentinel nodes). Because all of these systems are interconnected, the breast drains as a unit, and injection of colloidal dyes in any part of the breast at any level will result in accumulation of dye in the same one or two axillary sentinel lymph nodes. The axillary lymph nodes receive most of the lymphatic drainage of the breast and consequently are the nodes most frequently involved with breast cancer metastases (Hultborn, 1955). However, there are also alternate drainage pathways that do not appear to interconnect with other networks and that drain directly into internal mammary, supraclavicular, contralateral axillary, or abdominal lymph node basins.

### DEVELOPMENT AND PHYSIOLOGY

During fetal development, the primordial breast arises from the basal layer of the epidermis. Before puberty, the breast is a rudimentary bud composed of a few branching ducts capped with alveolar buds, end buds, or small lobules (Osin, 1998). At puberty, usually between the ages of 10 and 13 years, ovarian estrogen and progesterone cooperate to direct organized communication between breast epithelial cells and mesenchymal cells, resulting in extensive branching of the ductal system and development of lobules (Ismail, 2003). Specific disorders of this development are discussed in Chapter 14 (p. 325). Final differentiation of the breast is mediated by progesterone and

**FIGURE 12-1** **A.** Ductal anatomy of the breast. The terminal duct lobular units are surrounded by loosely cellular intralobular stroma, which consists of dense fibrous tissue admixed with adipocytes.

prolactin and is not completed until the first full-term pregnancy (Grimm, 2002; Ismail, 2003).

During the reproductive years, terminal ducts near the acini and the acini themselves are most sensitive to ovarian hormones and prolactin. Most forms of benign and malignant breast disease arise in these terminal duct-acinar structures. Breast epithelial cells proliferate during the luteal phase of the menstrual cycle when estrogen and progesterone levels are increased, and then undergo programmed cell death at the end of the luteal phase, when levels of these hormones decline (Anderson, 1982; Soderqvist, 1997). This effect is mediated by paracrine signaling induced by estrogen-receptor activation and is associated with an increase in the water content of the extracellular matrix (Stoekelhuber, 2002). This is often recognized as breast fullness and tenderness in the week preceding menses.

At menopause, when ovarian estrogen production ceases, breast lobules involute, and the collagenous stroma is replaced by fat. Because estrogen receptor expression is negatively regulated by estrogen, there is an increase in estrogen receptor expression after menopause (Khan, 1997). Despite a decline in ovarian estrogen production, postmenopausal women continue to produce estrogen through the action of the enzyme aromatase, which converts adrenal androgens to estrogen (Bulun, 1994). Aromatase is found in fat, muscle, and breast tissue.

## EVALUATION OF A BREAST LUMP

It is not possible to distinguish benign from malignant or cystic from solid breast masses by clinical examination. However, findings from clinical examination, interpreted in conjunction with imaging and pathology (the triple test), contribute significantly to management decisions (Hermansen, 1987).

### Physical Examination

The breast is comma shaped, and the comma's tail corresponds to the axillary tail of Spence. This extension can be large, especially during pregnancy and lactation, and is frequently mistaken for an axillary mass.

Clinical examination of the breast begins with inspection of the breast to determine whether there is dimpling, nipple retraction, or skin changes. This examination is described in Chapter 1 (p. 2). The presence and character of expressible nipple discharge is recorded. In addition, the location of a mass is specifically documented according to its clock position and then measured along the long axis using a ruler or caliper (Fig. 12-4). The distance from the center of the nipple to the center of the mass is specified. Since numerous health care providers are typically involved in the evaluation and management of the same breast mass, the most useful entry in the clinical record will define the location and size of the mass (e.g., right breast, 2-cm mass, 3:00, 4 cm from the nipple). Although clinical examination alone can never exclude malignancy, noting that a mass has benign features such as smoothness, roundness, and mobility will factor into the ultimate decision to excise or observe a lesion. Evaluation also includes careful examination of the axillae, infraclavicular fossa, and supraclavicular fossa to identify lymphadenopathy.

**FIGURE 12-2** Breast anatomy. (Reproduced with permission from Seeley RR, Stephens TD, Tate P: *Anatomy and Physiology*, 7th ed. New York: McGraw-Hill; 2006.)

## ■ Diagnostic Imaging

Imaging of a suspected mass may begin with mammography that includes magnification, extra compression, or extra views beyond the usual medial lateral oblique and cranial caudal views that are typically used for screening. Unlike screening

mammography, diagnostic mammography may be appropriate for women of any age. In addition, sonography is invaluable for determining whether a mass is cystic or solid and is a component of most diagnostic imaging algorithms. Certain features of solid masses, such as irregular margins, internal echoes, or

**FIGURE 12-3** Lymphatic drainage of the breast. **A.** Accessory drainage pathways. **B.** Classic axillary drainage pathways. (Reproduced with permission from Grant RN, Tabah EJ, Adair FE: *The surgical significance of the subareolar symph plexus in cancer of the breast*, *Surgery* 1953 Jan;33(1):71–78.)

**FIGURE 12-4** Recording the location of a breast mass as “Left breast, 2.5-cm mass, 10:00, 6 cm FN.” FN = from the nipple.

a width-to-height ratio  $< 1.7$  may suggest malignancy (Stavros, 1995).

Diagnostic imaging results should be summarized according to the Breast Imaging Reporting and Data System (BI-RADS) classification (Table 12-1) (D’Orsi, 2013). Lesions that are graded BI-RADS 5 are highly suggestive of malignancy, and  $\geq 95$  percent of these are ultimately proven to be cancerous. Decreasing numerical grades are associated with diminishing probability of malignancy.

### ■ Breast Biopsy

Evaluation of a solid breast mass is completed by needle biopsy. These biopsies should be performed after an imaging test or a minimum of 2 weeks prior to an imaging test. This is because resulting tissue trauma can produce image artifacts that simulate malignancy (Sickles, 1983). Options include fine-needle aspiration (FNA) biopsy or core-needle biopsy. The trend in recent years favors core-needle biopsy (Tabbara, 2000). Although FNA takes less time to perform and is less expensive than core-needle biopsy, it is less likely to provide a specific diagnosis and has a higher insufficient sample rate (Shannon, 2001). FNA retrieves clusters of epithelial cells that may be interpreted as benign or malignant, but it cannot reliably differentiate between benign proliferative lesions and fibroepithelial neoplasms or between ductal carcinoma in situ and invasive cancer (Boerner, 1999; Ringberg, 2001).

In contrast, core-needle biopsy is performed using an automated device that takes one core at a time or is completed using a vacuum-assisted device that, once initially positioned, delivers multiple cores. Needle biopsy of solid masses should be done prior to excision, as the biopsy results contribute significantly to surgical planning (Cox, 1995).

### ■ Triple Test

The combination of clinical examination, imaging, and needle biopsy is called the *triple test* (Wai, 2013). When all three assessments suggest a benign lesion or all three suggest a breast

cancer, the triple test is said to be concordant. A concordant benign triple test is  $> 99$ -percent accurate, and breast lumps in this category can be followed by clinical examination alone at 6-month intervals. If any of the three assessments suggests malignancy, the lump should be excised regardless of results from the other two. It is always appropriate to offer excision of a fully evaluated breast lump, even after a benign concordant triple test result, as breast lumps can be a source of significant anxiety.

## BENIGN LUMPS AND FIBROEPITHELIAL NEOPLASMS

### ■ Cysts

Most breast cysts arise from apocrine metaplasia of lobular acini. They are generally lined by a single layer of epithelium that ranges from flattened to columnar. One autopsy series that included 725 women reported microcysts in 58 percent and cysts  $> 1$  cm in 21 percent (Davies, 1964). The incidence of breast cysts peaks between 40 and 50 years, and the lifetime incidence of palpable breast cysts is estimated to be 7 percent (Haagensen, 1986).

Breast cysts are diagnosed and classified by sonography. There are three types of cysts: simple, complicated, and complex (Berg, 2003). Simple cysts are sonolucent, have a smooth margin, and show enhanced through-transmission (Fig. 12-5). These lesions do not require special management or monitoring, but they may be aspirated if painful. Recurrent cysts can be reimaged and reaspirated, but recurrent symptomatic cysts are best managed by excision.

Complicated cysts show internal echoes during sonography and can sometimes be indistinguishable from solid masses. Internal echoes are usually caused by proteinaceous debris. Consideration is given to aspirating complicated cysts. The aspirated material may be submitted for culture, if it is purulent, or for cytology, if there are worrisome clinical or imaging features. If the sonographic abnormality does not resolve completely with aspiration, a core-needle biopsy is usually performed.

Complex cysts show septa or intracystic masses during sonographic evaluation. An intracystic mass usually represents a papilloma, but medullary carcinoma, papillary carcinoma, and some infiltrating ductal carcinomas can present as complex cysts. Although some advocate core-needle biopsy for the evaluation of complex cysts, this procedure can decompress a cyst, making it difficult to localize at the time of surgery. Additionally, papillary lesions diagnosed by needle biopsy will require excision. Thus, it seems reasonable to recommend excision of all complex cysts.

### ■ Fibroadenoma

It represents a focal developmental abnormality of a breast lobule and as such is not a true neoplasm. Histologically, fibroadenomas are composed of glandular and cystic epithelial structures surrounded by a cellular stroma. Fibroadenomas account for 7 to 13 percent of breast clinic visits and had a prevalence of 9 percent in one autopsy series (Dent, 1988; Franyz, 1951). They often present in adolescence, are recognized most

**TABLE 12-1.** Breast Imaging Reporting and Data System (BI-RADS)

BI-RADS Category	Description	Examples
0	Additional views or sonography required	Focal asymmetry, microcalcifications, or a mass identified on a screening mammogram
1	No abnormalities identified	Normal fat and fibroglandular tissue
2	Not entirely normal, but definitely benign	Fat necrosis from a prior excision, stable biopsy-proven fibroadenoma, stable cyst
3	Probably benign	Circumscribed mass that has been followed for < 2 years
4A	Low suspicion for malignancy, but intervention required	Probable fibroadenoma, complicated cyst
4B	Intermediate suspicion for malignancy, intervention required	Partially indistinctly margined mass otherwise consistent with a fibroadenoma
4C	Moderate suspicion, but not classic for carcinoma	New cluster of fine pleomorphic calcifications, ill-defined irregular solid mass
5	Almost certainly malignant	Spiculated mass, fine linear and branching calcifications
6	Biopsy-proven carcinoma	Biopsy-proven carcinoma

frequently in premenopausal women, and usually spontaneously involute at menopause.

Fibroadenomas classified as benign concordant by the triple test can be safely followed without excision. Because some fibroadenomas may grow large, and because benign phyllodes tumors are often indistinguishable from fibroadenomas by

imaging and needle biopsy, a fibroadenoma that is growing should be excised.

### ■ Phyllodes Tumors

These are true biphasic neoplasms characterized by epithelial-lined spaces surrounded by cellular stroma. Both the epithelial

**FIGURE 12-5** Sonographic appearance of palpable breast masses. **A.** Simple cyst. **B.** Silicone granuloma. **C.** Fibroglandular ridge. **D.** Solid mass (benign phyllodes tumor). **E.** Complex cystic and solid mass (intracystic papillary carcinoma with low-grade ductal carcinoma in situ). **F.** Suspicious (invasive ductal carcinoma). (Used with permission from Stephen J. Seiler, MD.)

and stromal components can be monoclonal and clonally related (Karim, 2013). Phyllodes tumors are classified as benign, intermediate, or malignant, based on the degree of stromal cell atypia, number of mitoses, tumor margin characteristics, and abundance of stromal cells (Oberman, 1965). Phyllodes tumors account for less than 1 percent of breast neoplasms, and the median age at diagnosis is 40 years (Kim, 2013; Reinfuss, 1996).

Malignant phyllodes tumors can metastasize to distant organs, with lung being the primary site. Chest radiographs or chest computed-tomography (CT) scanning are appropriate staging tests for malignant cases. Phyllodes tumors rarely metastasize to lymph nodes, thus axillary staging is not required unless nodes clinically appear involved (Chaney, 2000).

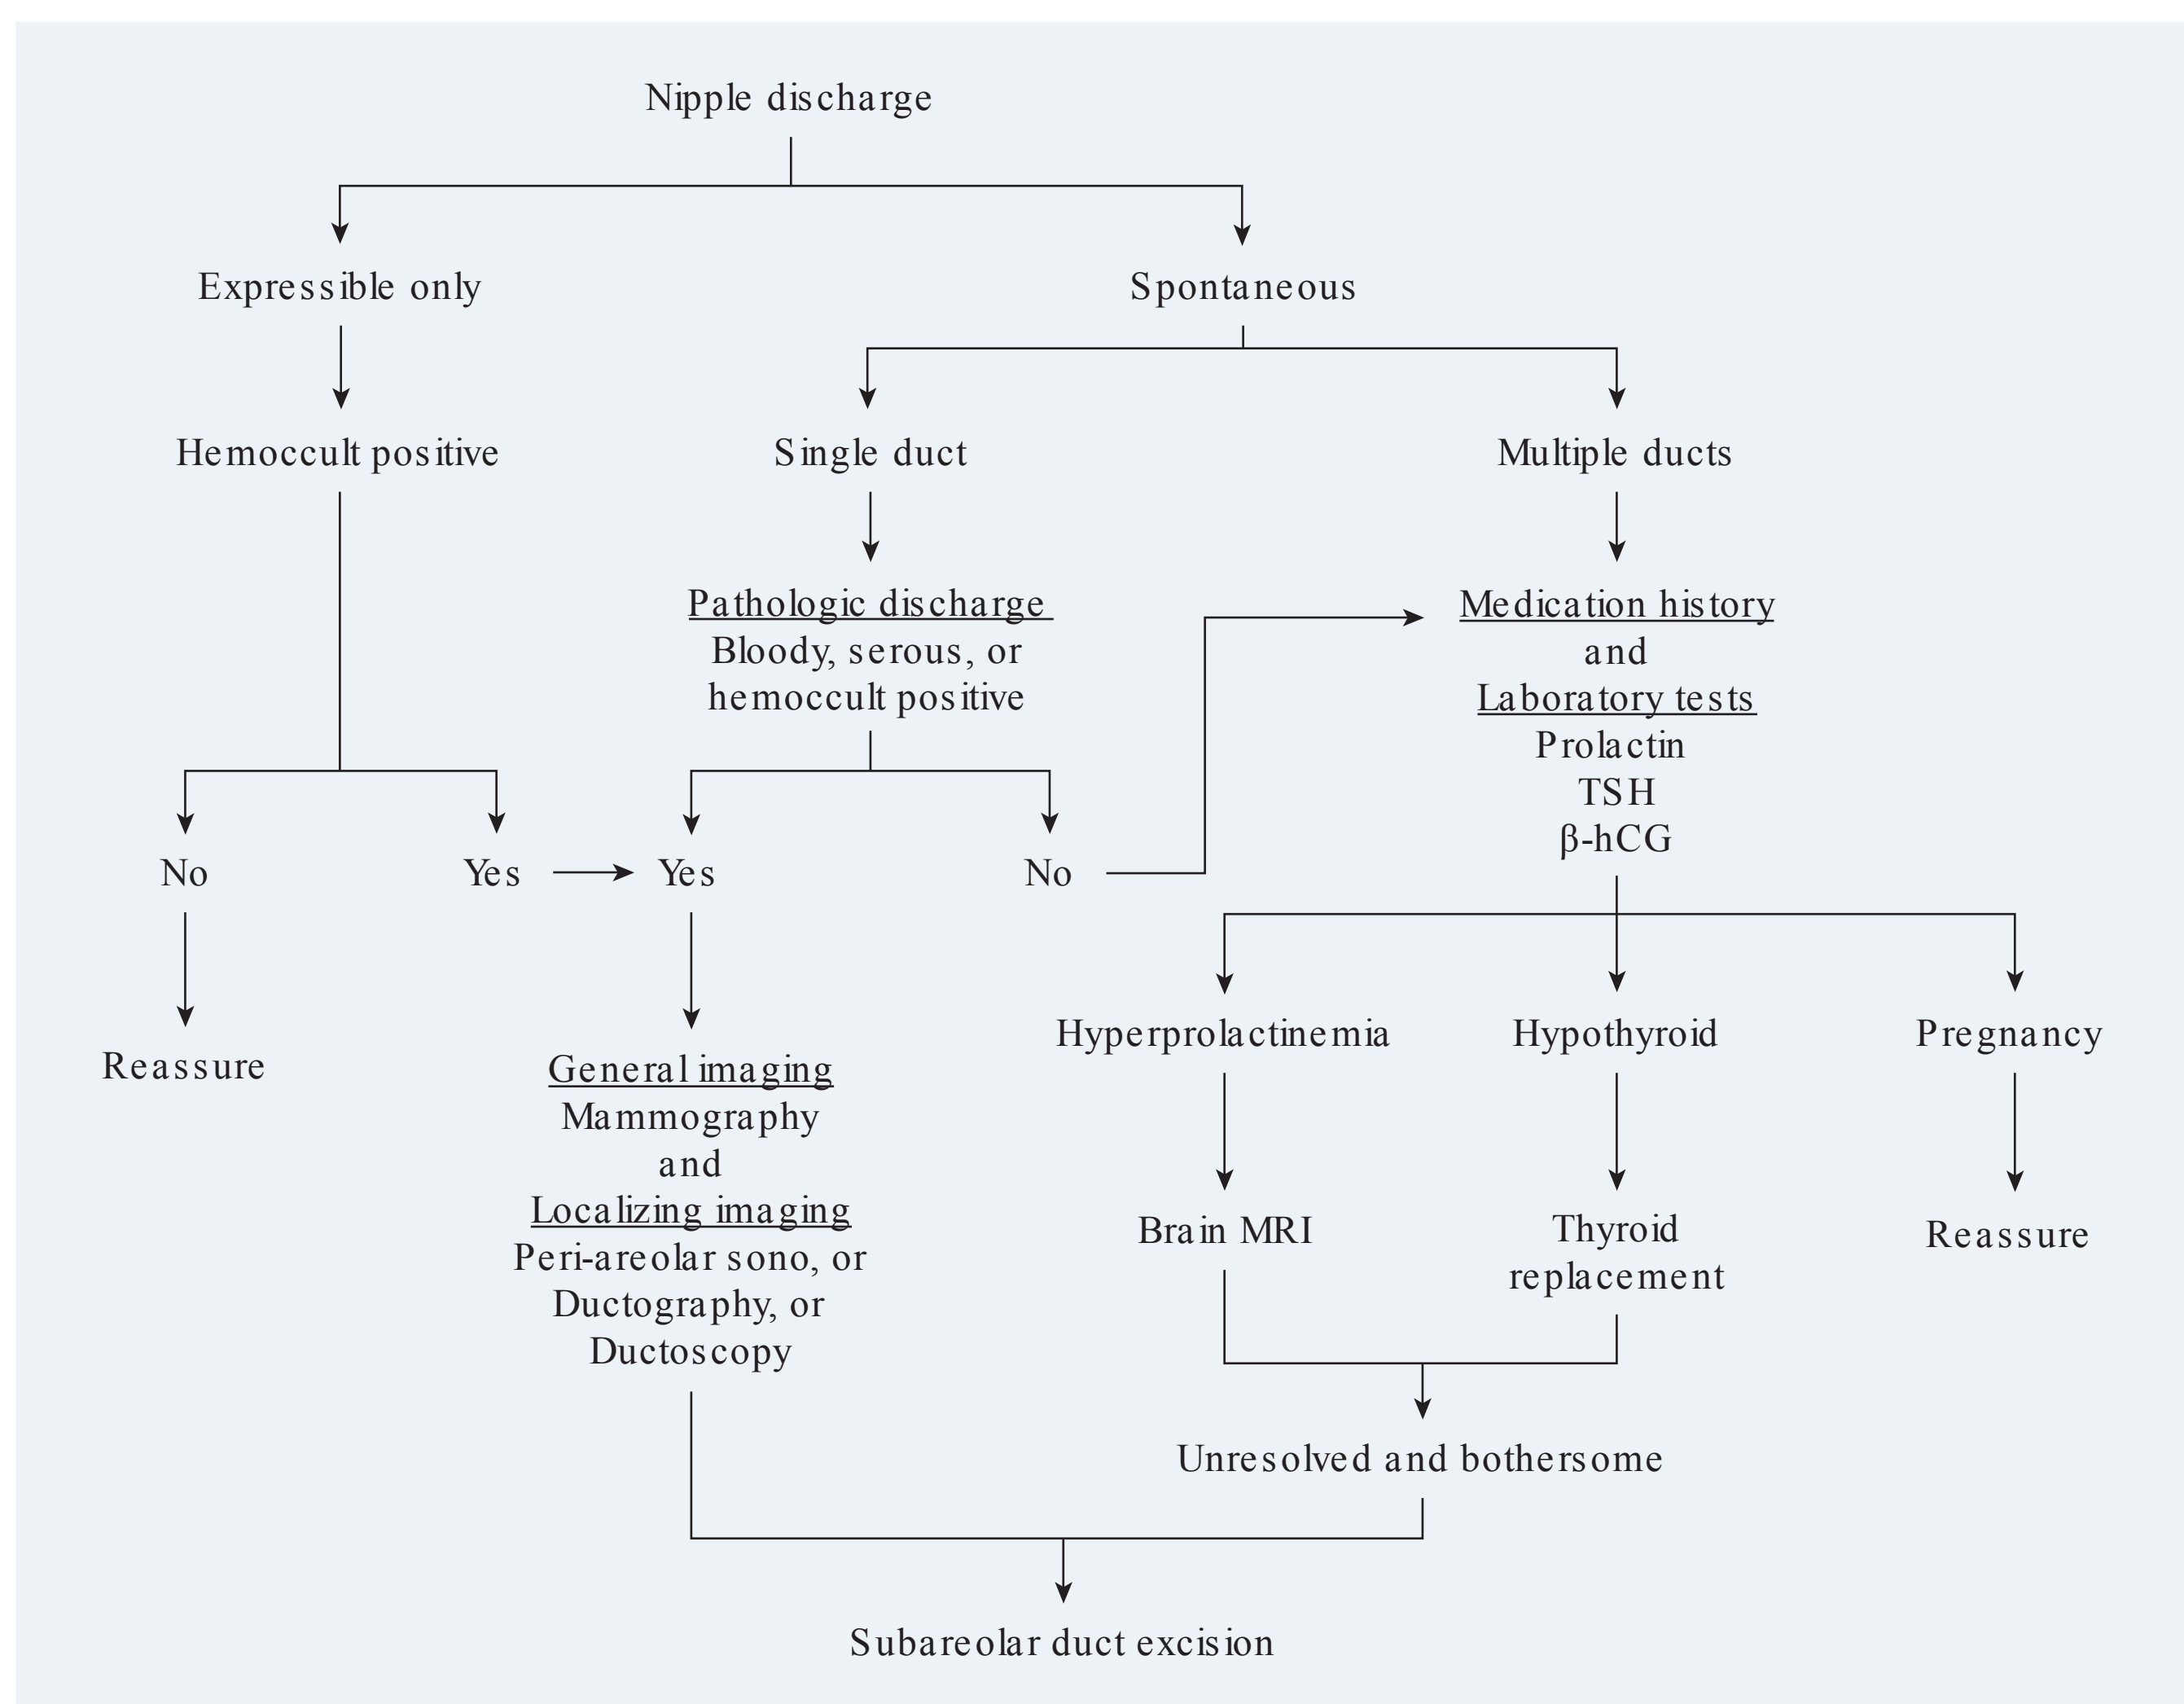

Treatment consists of wide local excision with a minimum 1-cm margin. Mastectomy may be required to achieve this margin, as the median tumor size at presentation is 5 cm. Local recurrence rates for completely excised tumors range from 8 percent for benign lesions to 36 percent for malignant ones (Barth, 1999). Fibroproliferation in the surrounding breast tissue and necrosis are the strongest predictors of recurrence

(Barrio, 2007). Postoperative adjuvant radiation therapy may be indicated for high-risk cases (Barth, 2009).

## NIPPLE DISCHARGE

Fluid can be expressed from the nipple ducts of at least 40 percent of premenopausal women, 55 percent of parous women, and 74 percent of women who have lactated within 2 years (Wrensch, 1990). The fluid generally issues from more than one duct and may range from milky white to dark green or brown. Green coloration is related to the content of cholesterol diepoxides and does not suggest underlying infection or malignancy (Petrakis, 1988).

Multiduct discharges that are elicited only following manual expression are considered physiologic and do not require additional evaluation. However, spontaneous discharges merit evaluation (Fig. 12-6). Spontaneous milky nipple discharge, also called galactorrhea, results from various causes (Table 12-2) (Chap. 15, p. 359). Of these, pregnancy is a frequent cause of new-onset spontaneous discharge, and a bloody multiduct discharge during pregnancy is not uncommon.

**FIGURE 12-6** Diagnostic algorithm to evaluate nipple discharge. hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging; TSH = thyroid-stimulating hormone.

**TABLE 12-2.** Causes of Galactorrhea

<b>Idiopathic</b>	<b>Systemic disorders</b>
<b>Physiologic</b>	Chronic renal failure
Lactation	Hypothyroidism
Breast stimulation	Cirrhosis
Stress	Pseudocyesis
	Seizures
<b>Hypothalamic lesions</b>	Ectopic tumor production
Tumors	<b>Pharmacologic</b>
Infiltrative disorders	Dopamine-blocking agents:
Irradiation	Phenothiazines: chlorpromazine, prochlorperazine
Trauma, surgery	Butyrophenones: haloperidol
Rathke cleft cyst	Thioxanthenes: thiothixene
<b>Pituitary lesions</b>	Benzamides: metoclopramide
Prolactinoma	Risperidone
Other tumors	Dopamine depletors: reserpine, opiates, $\alpha$ -methyldopa
Infiltrative disorders	H <sub>2</sub> antagonists: cimetidine, ranitidine
Lymphocytic hypophysitis	Serotonergic pathway stimulation: amphetamines
Empty sella	Calcium-channel blockers: verapamil
<b>Intercostal nerve stimulation</b>	Antidepressants: MAOI, TCA, SSRI
Chest wall lesions	Estrogen
Chest surgery	
Spinal cord injury	

H<sub>2</sub> = histamine 2; MAOI = monoamine oxidase inhibitor; TCA = tricyclic antidepressant; SSRI = selective serotonin-reuptake inhibitor.

Pathologic nipple discharge is defined as a spontaneous single-duct discharge that is serous or bloody. The rate of underlying malignancy ranges from approximately 2 percent for young women with no associated findings on imaging or physical examination to 20 percent for older women with associated findings (Cabioglu, 2003; Lau, 2005). Most pathologic nipple discharges are caused by benign intraductal papillomas, which are simple milk duct polyps (Urban, 1978). They arise in the major milk ducts, generally within 2 cm of the nipple, and contain a velvety papillary epithelium on a central fibrovascular stalk.

Evaluation of a pathologic nipple discharge begins with breast examination. Careful evaluation can frequently locate a trigger point on the areolar edge that elicits the discharge when pressed. Occult-blood testing and microscopic examination of the discharge can provide additional information. A glass slide that has been touched to the discharge and immediately fixed in 95-percent alcohol may be used for cytologic assessment. Nipple fluid samples are acellular in 25 percent of cases and thus cannot exclude an underlying malignancy (Papanicolaou, 1958). However, malignant cells, if found, are highly correlated with an underlying cancer (Gupta, 2004).

Following these examinations, diagnostic mammography and an assessment of the subareolar ducts by sonography or ductography is indicated. Diagnostic mammography is

**FIGURE 12-7** Imaging for a pathologic nipple discharge. **A.** Ductography shows a single dilated duct with an irregular filling defect (arrow). **B.** Periareolar sonogram demonstrates an irregular intraductal mass with microlobulated margins within the white circle. An excisional biopsy revealed a benign intraductal papilloma. (Used with permission from Stephen J. Seiler, MD.)

usually negative, but it may occasionally identify an underlying ductal carcinoma in situ (DCIS). Mammary ductography, also known as galactography, requires cannulating the affected duct, injecting radiocontrast, and then performing mammography (Fig. 12-7).

An evaluation of the subareolar ducts, as described above, is required to localize an intraductal lesion for subsequent excision. However, pathologic nipple discharge is *definitively* diagnosed and treated by subareolar duct excision, which is also known as microductectomy (Locker, 1988). Subareolar duct excision can also be used to treat bothersome multiduct discharges not associated with pituitary prolactinoma.

## BREAST INFECTIONS

### ■ Puerperal Infections

Breast infections are generally divided into puerperal, which develop during pregnancy and lactation, and nonpuerperal.

Of these, pregnancy-related breast infection is characterized by warm, tender, diffuse breast erythema, associated with systemic signs of infection such as fever, malaise, myalgias, and leukocytosis. The most common organism is staphylococcus, and it is successfully treated with oral or intravenous antibiotics, depending on the severity. However, infection may also progress to form deep parenchymal abscesses that require surgical drainage (Branch-Elliman, 2012). Sonographic examination is highly sensitive for identifying underlying abscesses if mastitis does not improve rapidly with antibiotics or if an abscess is suggested clinically. Women with puerperal mastitis should continue to breast feed or breast pump during treatment to prevent milk stasis, which may contribute to infection progression (Tomsen, 1983). Cracked or excoriated nipples may provide entry for bacteria and are treated with lanolin-based lotions or ointments.

Appropriate antibiotics for puerperal mastitis include those covering staphylococcal species. Group A and B *Streptococcus*, *Corynebacterium*, and *Bacteroides* species and *Escherichia coli* are less frequently isolated. Commonly, cephalexin (Kefex) or dicloxacillin (Dynapen), each given at dosages of 500 mg orally four times daily, or the combination of amoxicillin and clavulanate (Augmentin), 500 mg orally three times daily, may be prescribed for 7 days. Erythromycin, 500 mg orally four times daily, will provide adequate coverage for those with a penicillin allergy. Methicillin-resistant *Staphylococcus aureus* (MRSA) is becoming a more prevalent community-acquired pathogen causing mastitis in pregnancy and the puerperium (Laibl, 2005; Stafford, 2008). If MRSA is suspected or if a patient fails to improve on an initial regimen, then trimethoprim-sulfamethoxazole double strength (Bactrim DS, Septra DS), one or two tablets orally twice daily, or clindamycin, 300 mg orally three times daily, is a suitable choice. In ill patients with extensive infection, hospitalization and intravenous (IV) antibiotics are typically required. In these complicated cases, MRSA coverage may be prudent, and clindamycin, 600 mg IV every 8 hours, or vancomycin, 1 g IV every 12 hours, can be administered. Intravenous antibiotics are typically given until the woman is afebrile for 24 to 48 hours. Oral antibiotics are then continued to complete a 7- to 10-day course.

Focal mastitis may result from an infected galactocele. A tender mass will usually be palpable at the site of skin erythema. Needle aspiration of the galactocele and antibiotics are frequently all that is required, but recurrence or progression may mandate surgical drainage.

## ■ Nonpuerperal Infections

*Uncomplicated cellulitis* in a nonirradiated breast and in a nonpuerperal setting is uncommon. Accordingly, its presence prompts imaging and biopsies to exclude inflammatory breast cancer, described on page 291.

*Nonpuerperal breast abscesses* are generally classified as peripheral or subareolar. Peripheral abscesses usually are skin infections such as folliculitis or infection of epidermal inclusion cysts or Montgomery glands. These abscesses are all adequately treated by drainage and antibiotics discussed in the previous section. In contrast, subareolar abscesses arise from

keratin-plugged milk ducts directly behind the nipple. The abscess itself usually presents under the areola, and fistulous communications between multiple abscesses are common (Kasales, 2014). Simple drainage is associated with a recurrence rate of nearly 40 percent, thus effective treatment requires subareolar duct excision and complete removal of sinus tracts. In general, surgical drainage of nonpuerperal breast abscesses is usually always accompanied by biopsy of the abscess wall, as breast cancer occasionally presents as an abscess (Benson, 1989; Watt-Boolsen, 1987).

*Idiopathic granulomatous mastitis (IGM)* is not a true infection. It is included in this section because the painful masses, fluid collections, skin erythema, ulceration, and draining sinus tracts are often confused with infection. Core biopsy will show noncaseating granulomas, and fluid aspirated from apparent “abscesses” is nearly always sterile. Tissue stains can be used to exclude tuberculosis or mycotic infection. Wegener granulomatosis and sarcoidosis are considered in the initial differential diagnosis. This is a self-limiting condition that may take years to resolve. Procedures should be minimized as they will often result in painful draining sinuses. High-dose corticosteroids or methotrexate have been used for treatment, but it is not clear whether they are effective (Mohammed, 2013; Pandey, 2014).

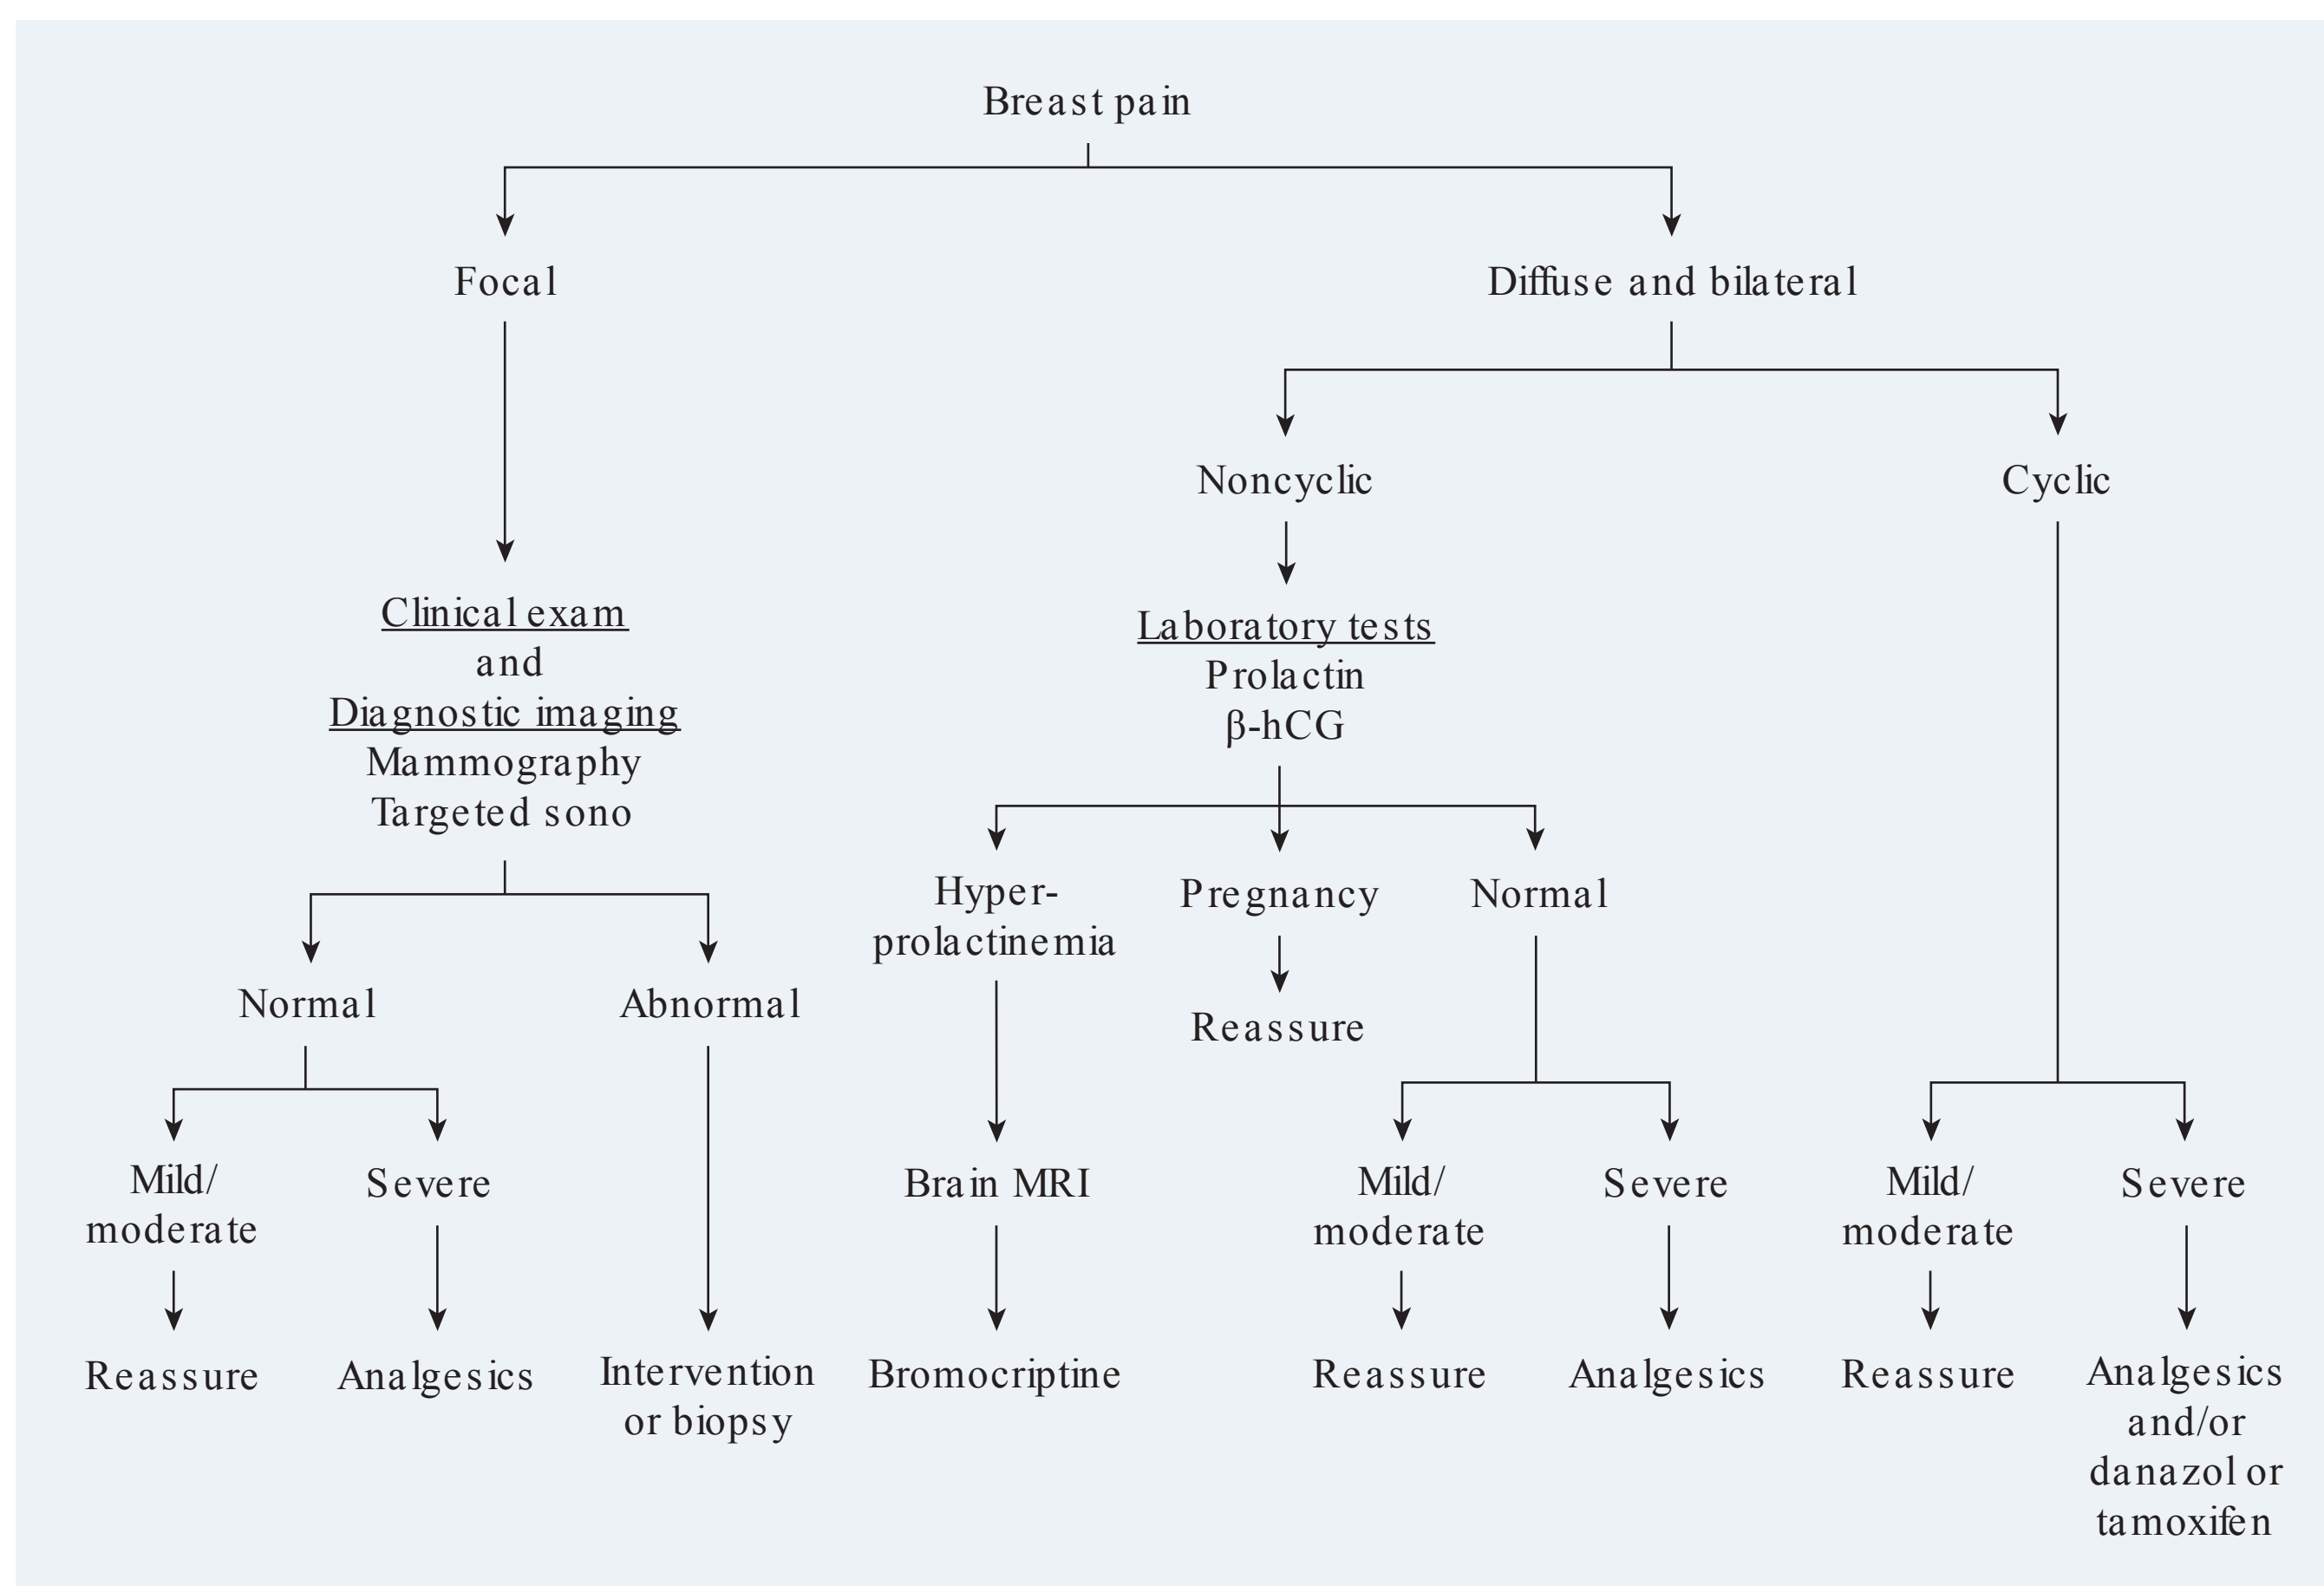

## MASTALGIA

The prevalence of breast pain is 66 percent and is higher for women nearing menopause than for younger women (Euhus, 1997; Maddox, 1989). The precise etiology of mastalgia is unknown, but it is likely related to estrogen- and progesterone-mediated changes in interstitial water content and therefore in interstitial pressure.

Mastalgia is generally classified as cyclic or noncyclic. Noncyclic mastalgia is often focal and shows no relationship to the menstrual cycle. Although focal mastalgia is frequently caused by a simple cyst, breast cancer occasionally presents as focal breast pain. Therefore, this complaint is evaluated by careful clinical examination, targeted imaging, and needle biopsy of any palpable or imaging abnormalities.

In contrast, cyclic mastalgia is usually bilateral, diffuse, and most severe during the late luteal phase of the menstrual cycle (Gateley, 1990). It remits with the onset of menstruation. Cyclic mastalgia requires no specific evaluation and is generally managed symptomatically with nonsteroidal anti-inflammatory agents (Fig. 12-8). Various other treatments have been proposed including bromocriptine, vitamin E, or oil of evening primrose. However, outcomes are no better than placebo in the best randomized clinical trials, except for bromocriptine in the subset of women with elevated prolactin levels (Kumar, 1989; Mansel, 1990). For the most severe cases, several agents are effective when administered during the last 2 weeks of the menstrual cycle. These include: (1) danazol, 200 mg orally daily; (2) the selective estrogen-receptor modifier toremifene (Fareston), 20 mg orally daily; or (3) tamoxifen (Nolvadex), 20 mg orally daily. Pregnancy must first be excluded and then avoided if these medications are used.

**FIGURE 12-8** Diagnostic algorithm to evaluate mastalgia. Oil of evening primrose or vitamin E is frequently used for mild/moderate pain, but the effects are no better than placebo. hCG = human chorionic gonadotropin; MRI = magnetic resonance imaging.

## BENIGN BREAST DISEASE

### ■ Benign Breast Disease without Atypia

The primary tissue components of the breast are fat, fibrous stroma, and epithelial structures. The hormonally responsive component is the epithelium, but considerable paracrine communication exists between the epithelium and stroma. The natural hormonal changes of puberty, pregnancy, lactation, and menopause drive considerable physiologic remodeling of breast tissue during a woman's lifetime, but pathologic remodeling is observed in some. This is initially characterized by acinar dilation and fibrosis, termed *nonproliferative benign breast disease*. Depending on the extent and pattern of these changes, a breast may appear mammographically dense, feel nodular to palpation, or both. The term "fibrocystic change" is often used to refer to palpably nodular breast tissue or to the histologic pattern of dilated ducts and acini invested with dense collagenous stroma. This is not a significant breast cancer risk factor and does not require any special management.

When this change is accompanied by accumulation of luminal epithelial cells (e.g., epithelial hyperplasia), it is called *benign proliferative disease* (Fig. 12-9). This change has been linked to higher levels of estrogen, insulin, and certain inflammatory cytokines, as well as reduced levels of the beneficial adipokine adiponectin (Catsburg, 2014). Benign proliferative

breast disease without atypia is a modest breast cancer risk factor with a relative risk of 1.5 to 1.9 (Dupont, 1993; Hartmann, 2005; Sneige, 2002).

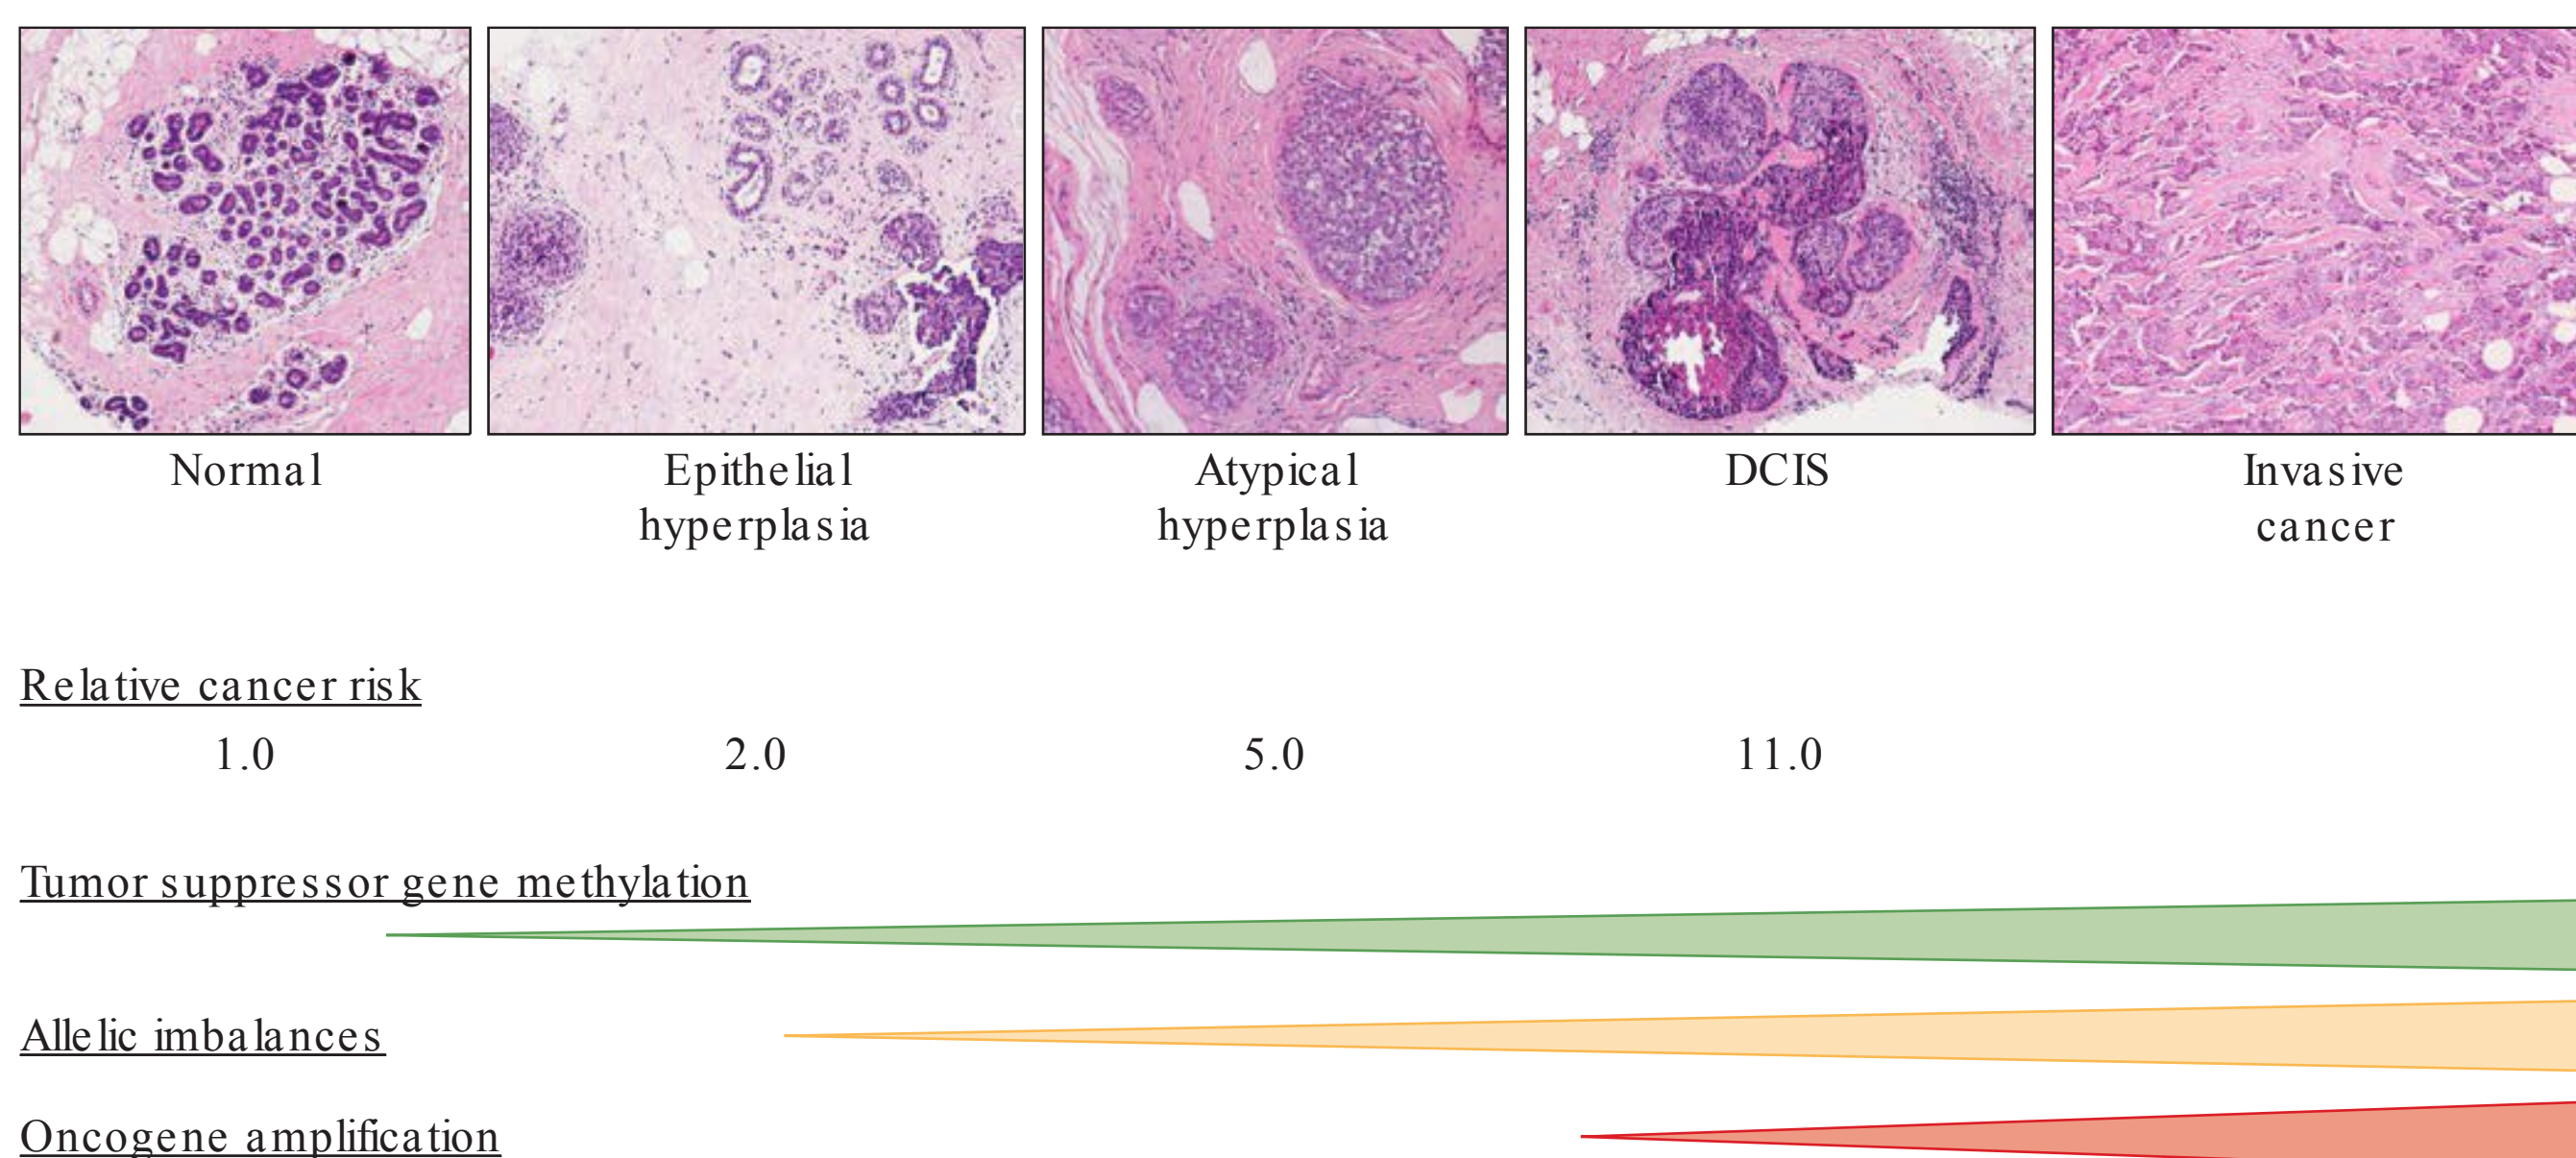

### ■ Benign Proliferative Disease with Atypia

Atypia refers to specific alterations in the size, shape, or nuclear features of individual epithelial cells in combination with the way groups of cells are organized. Atypical proliferation of ductal cells is termed atypical ductal hyperplasia (ADH), whereas similar changes in acinar cells are termed atypical lobular hyperplasia (ALH). As more and more terminal ducts or acini become involved, the condition is recognized as ductal carcinoma in situ or lobular carcinoma in situ, respectively, which are discussed in later sections (Ringberg, 2001).

Benign proliferative disease with atypia historically accounts for 4 percent of benign breast lesions (Hartmann, 2005). However, the incidence has recently decreased coincident to reductions in hormone replacement therapy use (Menes, 2009).

It is important to recognize that the difference between ADH and low-grade ductal carcinoma in situ is based on the area occupied by the proliferative epithelial cells (Vandenbussche, 2013). Accordingly, surgical excision is usually recommended when ADH is diagnosed by core biopsy, as 4 to 38 percent of cases will be upgraded to in situ or invasive cancer.

**FIGURE 12-9** Histologic progression from normal breast tissue to cancer. DCIS = ductal carcinoma in situ.

Chemoprevention is an excellent option for high-risk women with atypical hyperplasia. These lesions are estrogen-driven, and tamoxifen has been shown to reduce breast cancer risk by 52 to 86 percent for these women (Coopey, 2012; Fisher, 1999).

Benign proliferative disease with atypia is a marker of increased breast cancer risk. Relative risks are 4.5 to 5.0, and absolute risks approximate 1 percent per year for 20 to 30 years (Degnim, 2007; Dupont, 1993). This risk is higher for more extensive lesions. Risk does not appear to increase further with hormone replacement use.

### LOBULAR CARCINOMA IN SITU

Similar to proliferative ductal lesion, lobular carcinoma in situ (LCIS) differs from ALH by the greater extent of lobular cell proliferation with LCIS and increased acini distention. LCIS is not associated with any specific mammographic or palpable features and thus is only diagnosed incidentally. Classic LCIS has not traditionally been viewed as a direct precursor of breast cancer, but this view is changing. For example, although LCIS is associated with increased risk for both breasts, women with LCIS most commonly develop carcinoma in the ipsilateral breast (Fisher, 2004b; Ottesen, 1993; Salvadori, 1991). Moreover, infiltrating lobular cancers frequently show associated LCIS, and a clonal relationship between LCIS and subsequent invasive cancer has been demonstrated (Abner, 2000; Andrade, 2012; Sasson, 2001).

As noted, LCIS is also a marker of increased breast cancer risk. The risk of subsequent breast cancer approximates 1 percent per year but is modified upward by early age at diagnosis, family history of breast cancer, and extensive disease (Bodian, 1996).

Surgical excision is recommended if LCIS is diagnosed by needle biopsy, as an associated cancer will be identified in 2 to 25 percent of cases (Buckley, 2014). Excising

to clear margins is not required (Sadek, 2013). These lesions are strongly estrogen receptor positive, and tamoxifen has been shown to reduce breast cancer risk by 56 percent in this setting (Fisher, 1999).

### DUCTAL CARCINOMA IN SITU

DCIS can be understood as a condition in which cancer cells fill portions of a mammary ductal system without invading beyond the duct's basement membrane (Ringberg, 2001). Although DCIS cells have accumulated many of the DNA changes common to invasive breast cancer, they lack certain critical changes that would permit them to persist outside of the duct (Aubele, 2002). Ductal carcinoma in situ is classified as stage 0 breast cancer.

The U.S. incidence of DCIS has increased in parallel with that of invasive breast cancer during the past two decades. But, as with invasive breast cancer, the incidence has plateaued during the past several years (Virnig, 2010). DCIS currently accounts for 25 to 30 percent of all breast cancers in the United States. It is most commonly diagnosed by screening mammography as it is frequently associated with pleomorphic, linear, or branching calcifications (Fig. 12-10).

DCIS is classified by morphologic type, the presence or absence of comedonecrosis, and nuclear grade. The common morphologic types include cribriform, solid, micropapillary, and comedo (Fig. 12-11). Comedonecrosis appears as a necrotic eosinophilic core down the center of a duct packed with cancer cells. Of all of the classifying variables, nuclear grade is the most predictive for associated invasive cancer, extent of disease, and recurrence after treatment (Ringberg, 2001).

Incompletely treated DCIS may recur locally, and 50 percent of recurrences are associated with fully developed invasive breast cancer. The principal treatment of DCIS is wide excision with a negative margin. This may require mastectomy if DCIS is extensive or if there are other contraindications to breast

**FIGURE 12-10** Fine linear-branching calcifications in a segmental distribution associated with ductal carcinoma in situ. (Used with permission from Stephen J. Seiler, MD.)

conservation. When breast conservation is possible, postoperative breast irradiation will reduce the local recurrence rate from 18 percent to 9 percent and is considered standard adjuvant treatment (Fisher, 1993). For those treated with breast conservation and radiation, the breast cancer-specific survival rate is 96 percent (Fig. 12-12) (Solin, 1996).

Axillary staging is generally not included in the management of DCIS, although some have advocated sentinel node biopsy for large, high-grade DCIS diagnosed by needle biopsy and treated by lumpectomy, as occult invasive cancer is diagnosed in 10 percent (Wilkie, 2005). Sentinel lymph node (SLN) biopsy in conjunction with mastectomy is less contro-

**FIGURE 12-12** Cause-specific and overall survival for ductal carcinoma in situ. (Reproduced with permission from Solin LJ, Kurtz J, Fourquet A, et al: Fifteen-year results of breast-conserving surgery and breast irradiation for the treatment of ductal carcinoma in situ of the breast, *J Clin Oncol* 1996 Mar;14(3):754–763.)

versial, as it is not possible to go back and perform SLN biopsy if an occult invasive cancer is diagnosed in this setting.

Five years of tamoxifen is recommended for estrogen-receptor-positive DCIS treated by breast conservation (Fisher, 1999). Although tamoxifen is not associated with a statistically significant improvement in overall survival rates, it does significantly reduce the incidence of ipsilateral invasive cancer and also reduces the risk of contralateral breast cancer.

### ■ Paget Disease of the Nipple

This type of DCIS presents as a focal eczematous rash of the nipple (Fig. 12-13). Ductal carcinoma cells, responding to chemoattractants secreted by cells in the dermis, migrate to the surface of the nipple, inducing skin breakdown (Schelfhout, 2000). The condition is easily diagnosed histologically by punch biopsy or excision of the affected nipple tip after nipple-areolar blockade using local anesthetic. Evaluation also includes careful clinical examination, as an associated mass is identified in approximately 60 percent of cases (Ashikari, 1970). Among those with no palpable abnormalities, mammography will show suspicious densities or calcifications in 21 percent (Ikeda, 1993). An underlying DCIS is identified in about two thirds of cases, and an invasive cancer in approximately one third (Ashikari, 1970).

Treatment includes wide excision with negative margins. Breast conservation, which requires central breast resection including the nipple-areolar complex and all identifiable underlying disease, is followed

A. Cribriform DCIS, low grade

B. Micropapillary DCIS

C. Solid DCIS, high grade

D. DCIS with comedonecrosis

**FIGURE 12-11** Morphologic types of ductal carcinoma in situ (DCIS). (Used with permission from Dr. Sunati Sahoo, Pathology, UTSW Medical Center.)

**FIGURE 12-13** **A.** and **B.** Paget disease of the nipple. **C.** Benign reactive dermatitis. (Used with permission from Dr. Marilyn Leitch.)

by postoperative breast irradiation (Bijker, 2001). Axillary staging by sentinel node biopsy is not required unless an invasive component is identified or total mastectomy is performed.

### BREAST CANCER RISK FACTORS

The most profound breast cancer risk factor is female gender. In addition, the incidence of breast cancer, as for most other cancers, increases with advancing age. Only 12 to 30 percent of breast cancer has a significant familial component, and apart from radiation exposure early in life, convincing environmental causes have not been elucidated (Baker, 2005; Locatelli, 2004). Breast cancer risk factors are listed in Table 12-3, but the strong link between ovarian function and breast tissue remodeling warrants more detailed description. In general, all of these risk factors are more prevalent in developed countries than in those that are less developed. Consequently, breast cancer is more common in industrialized cultures (Parkin, 2001).

#### ■ Reproductive Factors

##### Ovulatory Cycles

Ovulatory menstrual cycles exert stress on the breast epithelium by inducing proliferation in the late luteal phase. If conception does not occur, proliferation is followed by programmed cell death (Anderson, 1982; Soderqvist, 1997). Early age at menarche is associated with earlier onset of ovulatory cycles and increased breast cancer risk (den Tonkelaar, 1996; Vihko, 1986). Conversely, early menopause, whether it is natural or surgical, is associated with a reduced breast cancer risk (Kvale, 1988). Pregnancy generates very high levels of circulating estradiol, which is associated with a transient increase in short-term risk. But pregnancy also induces terminal differentiation of breast epithelium and provides relief from ovarian cycling. Consequently, increasing parity is associated with reduced lifetime risk.

##### Pregnancy

The breast is unique among all human organs in that it exists as a primordium for a decade or more before entering a highly proliferative state at menarche, and then does not fully mature until the first live birth. Immature breast epithelium is more susceptible to carcinogens than postlactational epithelium (Russo, 1996). Therefore, the longer a first live birth is delayed,

the greater the breast cancer risks. Relative to nulliparity, a first live birth before the age of 28 years is associated with reduced breast cancer risk, whereas one occurring later is associated with increased risk (Gail, 1989). Both early age at first live birth and greater numbers of live births are associated with reduced breast cancer risk (Layde, 1989; Pike, 1983).

#### ■ Hormone Replacement Therapy

The postmenopausal use of combined estrogen and progestin hormone replacement therapy is a modest breast cancer risk factor, and relative risks range from 1.26 to 1.76 (Beral, 2011; Hulley, 2002; Rossouw, 2002). The risk is higher with longer durations of use and with a shorter interval between the onset of menopause and the start of the medication (Beral, 2011). Estrogen-only replacement is not convincingly associated with increased breast cancer risk, but there is a relationship with body mass index that yields a lower risk for obese women and higher risk for thin women (Anderson, 2004).

### BREAST CANCER RISK STRATIFICATION AND MANAGEMENT

Approaches for managing breast cancer risk include: (1) lifestyle modification to achieve and sustain ideal body weight, (2) enhanced surveillance that includes screening magnetic resonance (MR) imaging, (3) chemoprevention with a selective estrogen-receptor modifier or an aromatase inhibitor, and (4) prophylactic surgery including oophorectomy or mastectomy for those at highest risk (Cuzick, 2014; Domchek, 2010; Goss, 2011; Heemskerk-Gerritsen, 2007; Vogel, 2010). Beyond beneficial lifestyle modification, each intervention introduces new risks, and thus breast cancer risk quantification is essential for making prevention decisions.

The American Cancer Society has endorsed screening MR imaging for women with a lifetime breast cancer risk that exceeds 20 percent (Saslow, 2010). The Food and Drug Administration (FDA) has approved tamoxifen chemoprevention for women older than 35 years with > 1.7 percent breast cancer risk over 5 years. Similarly, raloxifene (Evista) is approved for increased-risk postmenopausal women. To maximize benefit and minimize harm, breast cancer risk, age, race, and prior hysterectomy all factor into chemoprevention decisions (Freedman, 2011).

**TABLE 12-3.** Common Risk Factors and Their Risk Ratios<sup>a</sup>

Genetic Risk Factors	Risk Ratio
Female gender	114
Age	4–158 <sup>b</sup>
High-penetrance mutations: BRCA1, BRCA2, p53, STK11	26–36
Modest-penetrance mutations: PTEN, p16, PALB2, CDH1, NF1, CHEK2, ATM, BRIP1	2.0–2.7
Family: mother, daughter, sister	1.55–1.8
Family: aunt, niece, grandmother	1.15
Genetic polymorphisms: FGFR2, TNRC9, MAP3K1, LSP1, MRPS30	1.07–1.26
<b>Other Factors</b>	
Mantle radiation	5.6
Acini per lobule in benign breast tissue	
11–20	2.8
21–40	3.23
≥ 41	11.85
Mammographic density	
> 25–50% (scattered)	2.4
> 51–75% (heterogeneous)	3.4
> 75% (dense)	5.3
Biopsy w LCIS	5.4
Biopsy w atypical hyperplasia	5
Increased BMD	2.0–2.5
Age at first birth > 35	1.31–1.93
Obesity (BMI > 30)	1.2–1.8
Any benign breast disease	1.47
Elevated circulating insulin	1.46
5 years of combined HRT	1.26–1.76
Elevated circulating estrogen	1.1–1.7
Nulliparity	1.26–1.55
Alcohol (> 1 drink/day)	1.31
Age at menarche < 12	1.21

<sup>a</sup>Risks listed by genetic or nongenetic and ordered by strength of association with breast cancer.

<sup>b</sup>Risk compared to women aged 20–29. The risk ratio increases approximately by 4 for every year older than 30. BMD = bone mineral density; BMI = body mass index; HRT = hormone replacement therapy; LCIS = lobular carcinoma in situ.

Data from Beral, 2011; Bodian, 1996; Cauley, 1996; Claus, 1994; De Bruin, 2009; Easton, 2007; Freisinger, 2009; Fu, 2007; Gail, 1989; Gunter, 2009; Hankinson, 2005; Howlader, 2013; Hulley, 2002; Kotsopoulos, 2010; Laloo, 2006; Mavaddat, 2010; McKian, 2009; Phipps, 2010; Rossouw, 2002; Santen, 2005; Welsh, 2009; Zhou, 2011.

The foregoing highlights the importance of quantitative breast cancer risk stratification. Several computer models are available for this. The most thoroughly validated is the Gail model, available at <http://www.cancer.gov/bcrisktool/> (Costantino, 1999; Gail, 1989; Rockhill, 2001). Although the most generally applicable model, the Gail model is insufficient when there is a strong family history of breast cancer, male breast cancer, or ovarian cancer (Euhus, 2002). Genetic models such as BRCAPRO, Tyrer-Cuzick, or BOADICEA are more appropriate in these settings (Berry, 1997; Lee, 2014; Tyrer, 2004).

## ■ Breast Cancer Genetics

Twin studies suggest that only 12 to 30 percent of breast cancer is primarily genetic in origin, and modeling studies implicate autosomal dominant inheritance of single genes as the most important mechanism (Lichtenstein, 2000; Locatelli, 2004; Risch, 2001). As such, genetic testing is one of the most powerful risk stratification tools available. It can identify women at very high risk for cancer who could reasonably consider risk-reducing surgery. In breast cancer patients, it can also contribute directly to decisions regarding surgery, radiation, and systemic therapies (Euhus, 2013). Mutations in *BRCA1* or *BRCA2* genes are the most frequently identified germline alterations in familial breast cancer, but the list of predisposition genes is growing (Table 12-4). Commercialized massive parallel sequencing, namely, next-generation sequencing, now allows testing for mutations in a few to dozens of genes simultaneously (Euhus, 2015).

Obtaining a reasonably detailed cancer family history is essential for identifying individuals who may benefit from genetic counseling and testing. At a minimum, the relationship and age at diagnosis is recorded for every cancer in the family. Family histories that may suggest inherited susceptibility include early-onset breast cancer (< 50 years), bilateral breast cancer, male breast cancer, multiple affected relatives in one generation, breast cancer in multiple generations, development of cancers that are known to be associated with a particular syndrome, and two or more cancers in one relative, especially if they develop at an early age.

## ■ Hereditary Breast-Ovarian Cancer Syndrome

This syndrome accounts for 5 to 7 percent of breast cancers in the United States and is most frequently caused by *BRCA1* or *BRCA2* mutation (Malone, 2000). Hallmarks of the form linked with *BRCA1* include early age at breast cancer diagnosis (median 44 years); high-grade, estrogen- and progesterone-receptor negative breast cancers; and associated ovarian cancer (Foulkes, 2004). Other associated cancers are pancreatic cancer and melanoma.

For *BRCA1* mutation carriers, the lifetime breast cancer risk ranges from 45 to 81 percent, and ovarian cancer risk from 16 to 54 percent (Antoniou, 2008; Brohet, 2014; Ford, 1998; King, 2003; Mavaddat, 2013). Individuals who have developed both breast and ovarian cancer have an 86-percent probability of carrying a *BRCA* mutation (Cvelbar, 2005).

Among *BRCA2* carriers, lifetime risk for breast cancer ranges from 27 to 85 percent, and ovarian cancer risk from 6 to 27 percent. Women with *BRCA2* mutations develop breast cancer later in life than *BRCA1* carriers, thus age at diagnosis is not usually a good criterion for recognizing this syndrome (Panchal, 2010). Similar to sporadic breast cancer, most *BRCA2*-associated breast cancers are hormone receptor positive (Lakhani, 2002). Ovarian cancer is an associated cancer but develops less frequently than it does in *BRCA1*-affected families. Five to 13 percent of male breast cancers are associated with *BRCA2* mutations. Lifetime breast cancer risk is estimated at 1.8 percent for men with *BRCA1* mutations and 8.3 percent for *BRCA2* (Tai, 2007).

For affected women, early premenopausal bilateral oophorectomy reduces breast cancer risk by 37 to 72 percent and also lowers breast cancer-specific and all-cause mortality rates (Domchek, 2010; Finch, 2014; Kauff, 2008). This is discussed further in Chapter 35 (p. 736). Bilateral prophylactic mastectomy reduces breast cancer risk by more than 90 percent but has not yet been shown to improve survival rates (Hartmann, 2001; Heemskerk-Gerritsen, 2007; Meijers-Heijboer, 2001).

With the introduction of next-generation sequencing panel tests, clinicians are increasingly confronted with rare syndromes for which there are scarce data to guide management (see Table 12-4) (Euhus, 2015). Involvement of professional genetic counselors and careful assessment of a three-generation family cancer history is essential for estimating and managing cancer risk.

Surgical options for breast cancers that arise in the context of an inherited predisposition syndrome are the same as for sporadic breast cancers (Pierce, 2010). However, patients are counseled that the risk of an ipsilateral second primary breast cancer in a preserved breast can be as high as 3 to 4 percent annually (Haffty, 2002; Seynaeve, 2004). Moreover, lifetime contralateral breast cancer risk is 83 percent for *BRCA1* mutation carriers and 62 percent for *BRCA2* carriers, and growing evidence supports bilateral mastectomy to improve survival rates (Evans, 2013; Mavaddat, 2013; Metcalfe, 2014).

## BREAST CANCER SCREENING

In the United States, digital mammography has largely replaced film-screen mammography, and 3-dimensional (3-D) tomosynthesis is gradually replacing 2-D mammography. This

technique generates hundreds of images as the x-ray source arcs over the top of the breast. Digital reconstruction allows a radiologist to visually scroll through breast images and significantly attenuates overlying breast densities at each level (Kopans, 2013). Compared with 2-D mammography, tomosynthesis reduces the false-positive rate (recall rate) by 15 to 30 percent and increases the cancer detection rate by 10 to 29 percent (Greenberg, 2014; Haas, 2013; Skaane, 2013). This is achieved with slightly higher radiation doses (Feng, 2012).

## ■ The Screening Mammography Controversy

In 2009, the U.S. Preventive Services Task Force recommended biennial screening mammography for women aged 50 to 74 years and individualized screening decisions for women aged 40 to 49. Several influential organizations including the American College of Obstetricians and Gynecologists (2014) and the American College of Radiology suggest that yearly screening mammography begin at age 40 (Lee, 2010). The American Cancer Society recommends yearly screening beginning at age 45, but with an opportunity to begin at age 40. They promote a transition to biennial screening at age 55, although yearly screening may be elected (Oeffinger, 2015). The controversy centers on: (1) the true mortality rate benefit, (2) the harm from false-positive results, and (3) the harm from diagnosing clinically irrelevant breast cancers.

However, most data available for addressing these issues are derived from eight large, but older, randomized prospective trials. The most recent trial was completed in the 1980s. Recent technological advances have significantly improved the sensitivity of mammography, but breast cancer treatment has also advanced, reducing the mortality rate improvement from early detection. Based on 30-year-old data, it is generally agreed that screening mammography starting at age 50 reduces breast cancer mortality rates by approximately 27 percent, and one metaanalysis reported an 18-percent reduction for women aged 40 to 49 (Hendrick, 1997; Kerlikowske, 1997). However, screen-detected breast cancer is a heterogeneous disease. Some cancers will eventually develop clinical metastases no matter how small they are when first detected, and some will never become lethal no matter how long diagnosis is delayed. This latter form is the one most likely to be detected by periodic screening (length time bias).

The practice of screening mammography is based on the assumption that early intervention in some subgroup of tumors will interrupt progression and save lives. Since the introduction of screening mammography more than three decades ago, there has been a large increase in the detection of early-stage breast cancer but only a small decrease in the diagnosis of node-positive or metastatic disease (Bleyer, 2012). This suggests that many breast cancers will never progress (overdiagnosed) and that the fraction of breast cancers whose progression can be interrupted by surgery may be modest.

For now, annual mammography beginning at age 40 as recommended by several professional societies is reasonable, but women are counseled of the risks and benefits. Among 1000 U.S. women aged 50 years who are screened annually for a decade, 0.3 to 3.2 are estimated to avoid a breast cancer death, 490 to 670 will have at least 1 false alarm, and 3 to 14 will be overdiagnosed and treated needlessly (Welch, 2014). There is

no arbitrary age above which screening should cease. Women should have at least 10 years of remaining life to realize a mortality benefit from screening mammography (Lee, 2013).

### ■ Breast Magnetic Resonance Imaging

Breast MR imaging is commonly used as an adjunct to screen high-risk women and to establish disease extent in certain breast cancer patients. It is more sensitive for breast cancer detection than is mammography, but it is expensive and has a high false-positive rate. In addition, some evidence links its use with increased mastectomy rates but without reducing reexcision rates or improving breast cancer outcome (Houssami, 2013, 2014; Pilewskie, 2014; Turnbull, 2010).

Annual screening breast MR imaging is frequently selected for genetically high-risk women and in women with a lifetime breast cancer risk exceeding 20 percent (Saslow, 2010). It increases the diagnosis of smaller, lymph node negative breast cancers but does not improve survival rates (Gareth, 2014; Moller, 2013).

Breast MR imaging is not routinely performed in women with newly diagnosed breast cancer. Its primary value is assessing response to neoadjuvant chemotherapy in women contemplating breast conservation and evaluating women with breast cancer metastatic to axillary lymph nodes from an unknown primary (Morrow, 2011). Additionally, it can aid establishing the extent of disease prior to breast conservation for a subset of patients in whom uncertainty persists after careful clinical examination, mammography, and sonography.

### ■ Other Breast Imaging Modalities

Adding almost any imaging modality to screening mammography will incrementally increase the cancer detection rate but at the cost of an increased false-positive rate and more biopsies. Modalities that are occasionally useful, but not recommended for routine use, include screening sonography, breast-specific gamma imaging, and breast positron emission tomography (PET) (Kalinyak, 2014; Merry, 2014; Rechtman, 2014). These latter two tests are associated with significantly higher radiation exposure. Evidence is accumulating that medical radiation exposure before age 30 can increase breast cancer risk, and thus caution is advised (Berrington de Gonzalez, 2009; Pijpe, 2012).

### ■ Screening Physical Examination

The value of a screening clinical breast examination (CBE) performed by health care providers should not be neglected (Jatoi, 2003). Four of the large, randomized mammography trials mentioned earlier collected information on CBE and found that 44 to 74 percent of the breast cancers were detected by this approach. Sensitivity and specificity were higher for CBE than mammography among young women.

In contrast, enthusiasm for patients to perform breast self-examination (BSE) has diminished after a very large randomized trial from Shanghai, China, found no improvement in mortality rates (Tommas, 2002). Although there is less interest in promoting regimented BSE, encouraging women to remain breast-aware is reasonable.

**FIGURE 12-14** Trends in breast cancer incidence and survival in the United States. Curve of decreasing breast cancer rates in U.S. □ = incidence of invasive breast cancer; ▢ = incidence in situ; ■ = 5-year survival. (Data from Howlader N, Noone AM, Krapcho M, et al: SEER Cancer Statistics Review, 1975–2010, National Cancer Institute. 2013. Available at: [http://seer.cancer.gov/archive/csr/1975\\_2010/](http://seer.cancer.gov/archive/csr/1975_2010/). Accessed August 7, 2014.)

## INVASIVE BREAST CANCER

In the United States, breast cancer is the most common cancer in women and the second most frequent cause of cancer-related mortality (second to lung) (Siegel, 2014). Although the incidence of breast cancer increased steadily in this country through the 1980s and 1990s, it has leveled at approximately 125 cases per year per 100,000 postmenopausal women and is declining for some ethnicities. Concurrently, survival rates steadily improve (Fig. 12-14) (Howlader, 2013).

### ■ Tumor Characteristics

Primary cancers of the breast comprise 97 percent of malignancies affecting the breast, whereas 3 percent represent metastases from other sites. The most common of these, in descending order, are the contralateral breast, sarcoma, melanoma, serous epithelial ovarian cancer, and lung cancer (DeLair, 2013). Cancers of mammary epithelial structures account for most of primary breast cancer. Infiltrating ductal carcinoma is the most common form of invasive breast cancer (□80 percent), and infiltrating lobular carcinoma is the second most frequent (□15 percent). Other malignancies such as phyllodes tumors, sarcoma, and lymphoma form the remainder.

Apart from stage, the primary tumor characteristics that most influence prognosis and treatment decisions are hormone receptor status, nuclear grade, and Her-2/neu expression (Harris, 2007). Approximately two thirds of breast cancers are estrogen- and progesterone-receptor positive. This feature is generally associated with a better prognosis and more treatment options.

Her-2/neu is a membrane tyrosine kinase that cooperates with other Her-family receptors to generate proliferation and survival signals in breast cancer cells. Approximately 25 percent of breast cancers have increased expression of Her-2/neu (Masood, 2005). The list of medications that specifically target HER2 overexpressing breast cancer is growing and includes trastuzumab (Herceptin), trastuzumab emtansine (Kadcyla), pertuzumab (Perjeta), neratinib, and lapatinib (Tykerb) (Tolaney, 2014).

Gene expression profiling has identified several “intrinsic subtypes” of breast cancer with prognostic significance (Caddeo,

TABLE 12-5. Breast Cancer Surgical Staging

T Stage		Stage Grouping

M Stage					
M0	No distant metastases				
M1	Distant metastases				

2013). Multigene assays are now available in the clinic for individualized prediction of prognosis and treatment response, especially for estrogen-receptor positive tumors (Rouzier, 2013).

■ Breast Cancer Staging

Careful breast cancer staging is essential for predicting outcome, planning treatment, and comparing treatment effects in clinical trials. Each patient is assigned both a clinical and a pathologic stage. The clinical stage is based on examination and radiographic findings, whereas the pathologic stage is based on actual tumor measurements and histologic assessments of lymph nodes after primary surgery. Surgical staging of breast cancer is based on the TNM system, which includes primary tumor size (T), regional lymph node involvement (N), and presence of distant metastases (M) (Table 12-5). For patients with a clinically negative axilla, sentinel lymph node biopsy has replaced complete axillary dissection for nodal staging (Lyman, 2014).

The most common distant metastatic site in breast cancer is bone, followed by lung, liver, and brain. Thus, for newly diagnosed breast cancer patients, a complete blood count and liver function tests including alkaline phosphatase are recommended. Whole body screening with CT of the chest, CT or MR imaging of the abdomen and pelvis, and bone scan or whole body PET/CT are only recommended for clinical suspicion of metastases or for patients with clinical stage III disease (National Comprehensive Cancer Network, 2014).

■ Breast Cancer Treatment

Breast cancer is best managed by a multidisciplinary team of breast surgeons, medical oncologists, and radiation oncologists.

Goals of surgery and radiation therapy are elimination of all local or regional tumor in a way that maximizes cosmesis and minimizes the risk of local or regional recurrence. There is some evidence that these local modalities reduce the risk of subsequent metastases and therefore increase survival rates (Darby, 2011). However, a significant proportion of patients with apparently localized disease have tumor cells detectable in their blood or bone marrow at diagnosis (Braun, 2005; Giuliano, 2011a). For these women, systemic treatment with chemotherapy, hormone manipulation, or targeted therapies is the primary approach for reducing metastasis risk and death (Dowsett, 2010; Peto, 2012).

Surgery

Halstead (1894) revolutionized the treatment of breast cancer by demonstrating improved outcome for patients treated with radical mastectomy. However, results from recent randomized clinical trials have appropriately fostered a trend toward less aggressive surgery. Specifically, lumpectomy with postoperative radiation therapy results in the same breast cancer-specific survival rate as total mastectomy (Fisher, 2002).

Axillary dissection, that is, near-complete axillary lymphadenectomy, was also once a standard part of breast cancer staging and treatment, but its role is diminishing (Rao, 2013). The procedure is still indicated for patients with clinically node positive disease at diagnosis. However, it is frequently omitted in selected patients with clinically negative nodes but positive sentinel nodes, because radiation therapy and systemic adjuvant therapies achieve the same low axillary recurrence rate and the same survival rate (Galimberti, 2013; Giuliano, 2010, 2011b). When required, axillary dissection results in lymphedema in

15 to 50 percent of women, depending on how it is measured (Morrell, 2005). Dissection is also associated with persistent shoulder or arm symptoms in up to 70 percent (Kuehn, 2000).

### Radiation Therapy

After breast-conserving surgery, whole breast radiation reduces local recurrence from approximately 5 percent per year to 1 percent per year, although it may be omitted in elderly patients with favorable tumors (Fisher, 2002; Hughes, 2013). Shorter courses of partial breast irradiation may be appropriate in selected patients (Smith, 2009). Postmastectomy chest wall radiation improves survival in women with high-risk lymph node positive breast cancer (Overgaard, 1999; Ragaz, 2005). Recent clinical trial data are driving a marked increase use of extended-field radiation therapy (Early Breast Cancer Trialists' Collaborative Group, 2014).

### Chemotherapy

In the past, adjuvant chemotherapy was reserved for patients with nodal metastases and was always given after definitive surgery. However, randomized prospective trials have shown that adjuvant chemotherapy also improves survival rates for high-risk node-negative patients (Fisher, 2004a). Increasingly, however, the decision for chemotherapy is influenced by specific measures of tumor biology including results from multigene assays (Rouzier, 2013; Sparano, 2008).

If used, adjuvant chemotherapy is usually administered after primary surgery but before radiation therapy. Neoadjuvant chemotherapy is given prior to definitive surgery and is gaining popularity. Neoadjuvant chemotherapy permits assessment of a given tumor's sensitivity to the selected agents, and tumor shrinkage permits less aggressive surgery (von Minckwitz, 2013).

Modern breast cancer chemotherapy often includes an anthracycline such as doxorubicin (Adriamycin), in conjunction with cyclophosphamide (Cytosan) (Trudeau, 2005). The addition of a taxane has been shown to improve outcome (A'Hern, 2013). Platins such as cisplatin (Platinol) or carboplatin (Paraplatin) are increasingly used to replace doxorubicin when other cardiotoxic drugs such as trastuzumab are required and to treat certain tumor subtypes that have defects in homologous recombination. Chemotherapeutic agents are described more fully in Chapter 27 (p. 592).

### Hormonal Therapy and Targeted Therapies

Adjuvant hormonal therapy is used for estrogen-receptor positive tumors. In pre- or postmenopausal women, one option is the selective estrogen-receptor modulator tamoxifen (Jaiyesimi, 1995). As discussed in Chapter 27 (p. 603), important side effects of tamoxifen include menopausal symptoms, increased risks of thromboembolic events, and higher rates of endometrial polyps and endometrial cancer. Although this cancer risk is increased, surveillance of the endometrium with routine transvaginal sonography or endometrial biopsy is not recommended. Endometrial evaluation is reserved for those with abnormal bleeding and follows that outlined in Chapter 8 (p. 184).

In postmenopausal women, aromatase inhibitors may be used. FDA-approved agents include anastrozole (Arimidex), letrozole (Femara), and exemestane (Aromasin) (Kudachadkar,

2005). In postmenopausal women, most circulating estradiol is derived from the peripheral conversion of androgens by the enzyme aromatase. Administration of aromatase inhibitors reduces circulating estradiol to nearly undetectable levels in these women. The addition of an aromatase inhibitor after tamoxifen is associated with a 23- to 39-percent improvement in the disease-free survival rate and a nearly 50-percent reduction in the contralateral breast cancer rate (Geisler, 2006). Although tamoxifen is commonly used as an initial antihormonal therapy in postmenopausal women, transition to an aromatase inhibitor and 10 years of treatment improves outcome (Johnston, 2014).

Unlike tamoxifen, aromatase inhibitors are associated with greater rates of bone loss and fractures. Accordingly, baseline bone mineral density testing and periodic monitoring is recommended. For women with mild or moderate bone loss, exercise and supplementation with vitamin D and calcium are encouraged. Various agents are available for managing severe loss, and a discussion of these drugs is found in Chapter 22 (p. 499).

Bisphosphonates such as zoledronic acid (Zometa) are often used to prevent cancer-treatment-induced bone loss (Hadjji, 2011). In addition, the combination of aromatase inhibitors and zoledronic acid appears to improve outcome in hormone-receptor-positive breast cancer (Coleman, 2013).

Therapies that target specific biological pathways are becoming available. However, only HER2-targeted therapies are currently used routinely in early-stage breast cancer and only in HER2-amplified tumors. Targeting the mTOR pathway with everolimus (Afinitor) is now an FDA-approved strategy for advanced or metastatic hormone-receptor-positive breast cancer and is also being investigated for trastuzumab-resistant HER2-positive breast cancer (Andre, 2014; Dhillon, 2013). Comprehensive molecular profiling of tumors to identify targets for intervention is becoming more common (Frampton, 2013). Biologic agents for targeting cancer are described more fully in Chapter 27 (p. 603).

### ■ Surveillance

Long-term surveillance of breast cancer patients after treatment includes periodic history and physical examination. Women who elected breast conservation are counseled that the remaining breast tissue requires surveillance indefinitely. Ipsilateral, second primary breast cancers develop at a rate of approximately 1 percent per year and contralateral breast cancers at approximately 0.7 percent per year (Fatouros, 2005; Fisher, 1984; Gao, 2003). Laboratory and imaging tests are obtained to further evaluate specific signs or symptoms. Screening tests other than mammography to identify asymptomatic recurrences are not recommended (Khatcheressian, 2013).

### ■ Inflammatory Breast Cancer

Inflammatory breast cancer accounts for 1 to 5 percent of breast cancers (Chang, 1998; Dawood, 2010). This cancer presents with skin changes that can range from a faint red blush to a flaring-red rash associated with skin edema (peau d'orange change) (Fig. 12-15). It is distinguished from a neglected advanced primary breast cancer by its rapid onset and progression within just a few weeks. The cancer spreads rapidly throughout the entire

**FIGURE 12-15** Photographs of inflammatory breast cancer. **A.** Subtle erythematous blush and edema in inflammatory breast cancer. **B.** Classic inflammatory breast cancer. (Used with permission from Dr. Marilyn Leitch.)

breast and creates diffuse induration. As a result, the breast may enlarge to two to three times its original volume within weeks (Taylor, 1938).

Although mastitis or even congestive heart failure can produce a similar clinical appearance, inflammatory breast cancer must be definitively excluded. This always includes diagnostic mammography and punch biopsy of the skin. However, it also may require multiple biopsies and additional imaging such as MR imaging. Treatment begins with induction chemotherapy, followed by modified radical mastectomy (total mastectomy and axillary dissection), and then postoperative chest wall irradiation with or without additional chemotherapy (Cariati, 2005). The 5-year survival rate is 30 to 55 percent, which is significantly worse than for neglected advanced primary breast cancer (Brenner, 2002; Harris, 2003).

Thirty years ago, psychiatrist George Engel coined the term “biopsychosocial model” to describe a developing paradigm for patient care (Engel, 1977). As shown in [Figure 13-1](#), the model encourages treatments that consider the mind and body of a patient as two intertwining systems influenced by a third system—society. This was perhaps the first time a distinction was drawn between “disease” and “illness.” Namely, disease is the pathological process, and illness is the patient’s experience of that process. In keeping with this model, psychological factors have two distinct relationships with women’s reproductive health. At times, they are a consequence (infertility has been linked with psychological distress). At other times, they may be an insidious cause of a health problem (increased hysterectomy rates are noted in women with a low tolerance for the physical discomfort of menstruation).

Years before Engel’s work, Erik Erikson (1963) created a model that describes psychological maturation in stages across the life span. Specifically, adolescents are confronted with identity development; reproductive-aged women with intimacy concerns; peri- and early menopausal women with productivity

issues; and older women with life review. Combining Erikson’s developmental model with Engel’s psychosocial model provides a dimensional perspective to aid the evaluation, diagnosis, and treatment of any patient.

Not only do women use more health care services in general than men in the United States, but more women approach their physicians with psychiatric complaints, and more women have comorbid illness than men (Andrade, 2003; Kessler, 1994). Because primary care is the setting in which most patients with psychiatric illness are first seen, obstetricians and gynecologists often are the first to evaluate a woman in psychiatric distress. The clinical interview in [Table 13-1](#) provides an example of an assessment that includes all three domains from the biopsychosocial model.

### MOOD DISORDERS

Mood, anxiety, and alcohol or substance use disorders are three families of psychiatric disorders commonly seen and often comorbid with reproductive problems. These three groups are defined by specific criteria described by the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) (American Psychiatric Association, 2013). Each family of

**FIGURE 13-1** Biopsychosocial model. (Data from Engel GL: The need for a new medical model: a challenge for biomedicine. *Science* 1977 Apr 8;196(4286):129–136.)

TABLE 13-1. Psychiatric Assessment of Women

Component	Consideration
Present or past psychiatric illness	Relation to reproductive triggers: pregnancy, menses, menopause, etc.
Medications	All medications and supplements; exogenous hormones
Diet	Abnormal eating patterns; diet pills, laxatives, diuretics
Substance use	Covert use, especially of prescription drugs
Family	Including their premenstrual and postpartum mood disorders
Medical	Autoimmune disease, which can present with psychiatric symptoms
Menstrual	Premenstrual or perimenopausal symptoms
Social	Current or past sexual, physical, or emotional abuse. Note sexual preference and current relationship satisfaction
Economic	Ability to meet ongoing financial needs

Data from Burt VK, Hendrick VC: Clinical Manual of Women’s Mental Health. Washington: American Psychiatric Publishing; 2005.

disorders is characterized by predominant features, and each disorder within those families is identified by specific symptoms of that feature.

Of these families, mood disorders are categorized as *depressive disorders* (major depressive disorder, persistent depressive disorder, premenstrual dysphoric disorder, other specified depressive disorder, and unspecified depressive disorder) or as *bipolar and related disorders* (bipolar I, bipolar II, cyclothymic

disorder, other specified bipolar disorder, and unspecified bipolar disorder). For bipolar disorders, defining behaviors include racing thoughts, inflated grandiosity, psychomotor agitation, loquaciousness, and high-risk behavior, among others. These are severe enough to impair occupational or social relationships.

For depressive disorders, symptoms include those in Table 13-2. The lifetime prevalence in the general U.S. population approximates 20 percent (Kessler, 2005). As such, depression is a major cause of disability, and females are 1.6 times more likely than men to suffer from a major depressive episode (Substance Abuse and Mental Health Services Administration, 2013). Women also may experience one or more comorbid psychiatric disorders, most commonly an anxiety disorder and/or substance use disorder.

Self-report questionnaires are generally used to identify individuals who require further psychiatric evaluation (screening measures) and may also assess the frequency and intensity of depressive symptoms (severity measures). The Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR) is one such tool easily implemented for clinical use (Tables 13-3 and 13-4) (Rush, 2003). Further information regarding the instrument is available at [www.ids-qids.org](http://www.ids-qids.org). By patient report, this questionnaire assesses symptom severity required by DSM-5 criteria to diagnosis major depressive disorder. Ultimately, diagnosing mood disorders requires assessment by a trained clinician.

ANXIETY DISORDERS

Anxiety disorders have the highest prevalence rates in the United States. Lifetime rates approximate 30 percent, and similar to depression, women are 1.6 times more likely to be diagnosed than men (Kessler, 2005). Criteria established in the DSM-5 provide guidelines to help distinguish anxiety disorders from normally expected worries (Table 13-5).

TABLE 13-2. Diagnostic Criteria for a Major Depressive Episode

- A.  $\geq 5$  criteria present during the same 2-week period and represent change from previous functioning.**  
**At least one of these is:**  
Depressed mood most of the day, nearly every day  
Markedly diminished interest/pleasure in most activities, most of the day, most days  
**The balance of 5 from these:**  
Significant weight loss/gain, change in appetite, or failure to make expected gains  
Insomnia or hypersomnia nearly every day  
Psychomotor agitation or retardation nearly every day, observable by others  
Fatigue or loss of energy nearly every day  
Feelings of worthlessness or excessive or inappropriate guilt nearly every day  
Diminished ability to think or concentrate or indecisiveness  
Recurrent thoughts of death, recurrent suicidal ideation, plans, or attempt
- B.** Symptoms cause significant distress or impairment in functioning  
**C.** Symptoms are not due to a substance or a general medical condition  
**D.** Symptoms not accounted by other psychiatric disorder  
**E.** No prior mania or hypomania

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

**TABLE 13-3.** The Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report) (QIDS-SR<sub>16</sub>)

**ChECK ThE ONE RESpONSE TO EACH ITEM ThAT BEST DESCRIBES YOU FOR ThE pAST SEVEN DAYS.**

- During the past seven days...**
- 1. Falling Asleep:**
- ☐ 0 I never take longer than 30 minutes to fall asleep.
  - ☐ 1 I take at least 30 minutes to fall asleep, less than half the time.
  - ☐ 2 I take at least 30 minutes to fall asleep, more than half the time.
  - ☐ 3 I take more than 60 minutes to fall asleep, more than half the time.
- 2. Sleep During the Night:**
- ☐ 0 I do not wake up at night.
  - ☐ 1 I have a restless, light sleep with a few brief awakenings each night.
  - ☐ 2 I wake up at least once a night, but I go back to sleep easily.
  - ☐ 3 I awaken more than once a night and stay awake for 20 minutes or more, more than half the time.
- 3. Waking Up Too Early:**
- ☐ 0 Most of the time, I awaken no more than 30 minutes before I need to get up.
  - ☐ 1 More than half the time, I awaken more than 30 minutes before I need to get up.
  - ☐ 2 I almost always awaken at least one hour or so before I need to, but I go back to sleep eventually.
  - ☐ 3 I awaken at least one hour before I need to, and can't go back to sleep.
- 4. Sleeping Too Much:**
- ☐ 0 I sleep no longer than 7–8 hours/night, without napping during the day.
  - ☐ 1 I sleep no longer than 10 hours in a 24-hour period including naps.
  - ☐ 2 I sleep no longer than 12 hours in a 24-hour period including naps.
  - ☐ 3 I sleep longer than 12 hours in a 24-hour period including naps.
- 5. Feeling Sad:**
- ☐ 0 I do not feel sad.
  - ☐ 1 I feel sad less than half the time.
  - ☐ 2 I feel sad more than half the time.
  - ☐ 3 I feel sad nearly all of the time.

- please complete either 6 or 7 (not both)**
- 6. Decreased Appetite:**
- ☐ 0 There is no change in my usual appetite.
  - ☐ 1 I eat somewhat less often or lesser amounts of food than usual.
  - ☐ 2 I eat much less than usual and only with personal effort.
  - ☐ 3 I rarely eat within a 24-hour period, and only with extreme personal effort or when others persuade me to eat.

- OR-**
- 7. Increased Appetite:**
- ☐ 0 There is no change from my usual appetite.
  - ☐ 1 I feel a need to eat more frequently than usual.
  - ☐ 2 I regularly eat more often and/or greater amounts of food than usual.
  - ☐ 3 I feel driven to overeat both at mealtime and between meals.

- please complete either 8 or 9 (not both)**
- 8. Decreased Weight (Within the Last Two Weeks):**
- ☐ 0 I have not had a change in my weight.
  - ☐ 1 I feel as if I have had a slight weight loss.
  - ☐ 2 I have lost 2 pounds or more.
  - ☐ 3 I have lost 5 pounds or more.

- OR-**
- 9. Increased Weight (Within the Last Two Weeks):**
- ☐ 0 I have not had a change in my weight.
  - ☐ 1 I feel as if I have had a slight weight gain.
  - ☐ 2 I have gained 2 pounds or more.
  - ☐ 3 I have gained 5 pounds or more.

- During the past seven days...**
- 10. Concentration/Decision-Making:**
- ☐ 0 There is no change in my usual capacity to concentrate or make decisions.
  - ☐ 1 I occasionally feel indecisive or find that my attention wanders.
  - ☐ 2 Most of the time, I struggle to focus my attention or to make decisions.
  - ☐ 3 I cannot concentrate well enough to read or cannot make even minor decisions.
- 11. View of Myself:**
- ☐ 0 I see myself as equally worthwhile and deserving as other people.
  - ☐ 1 I am more self-blaming than usual.
  - ☐ 2 I largely believe that I cause problems for others.
  - ☐ 3 I think almost constantly about major and minor defects in myself.
- 12. Thoughts of Death or Suicide:**
- ☐ 0 I do not think of suicide or death.
  - ☐ 1 I feel that life is empty or wonder if it's worth living.
  - ☐ 2 I think of suicide or death several times a week for several minutes.
  - ☐ 3 I think of suicide or death several times a day in some detail, or I have made specific plans for suicide or have actually tried to take my life.
- 13. General Interest:**
- ☐ 0 There is no change from usual in how interested I am in other people or activities.
  - ☐ 1 I notice that I am less interested in people or activities.
  - ☐ 2 I find I have interest in only one or two of my formerly pursued activities.
  - ☐ 3 I have virtually no interest in formerly pursued activities.

(Continued)

**TABLE 13-3.** The Quick Inventory of Depressive Symptomatology (16-Item) (Self-Report) (QIDS-SR<sub>16</sub>) (Continued)

<p><b>During the past seven days...</b></p> <p><b>14. Energy Level:</b></p> <ul style="list-style-type: none"><li><input type="checkbox"/> 0 There is no change in my usual level of energy.</li><li><input type="checkbox"/> 1 I get tired more easily than usual.</li><li><input type="checkbox"/> 2 I have to make a big effort to start or finish my usual daily activities (for example, shopping, homework, cooking, or going to work).</li><li><input type="checkbox"/> 3 I really cannot carry out most of my usual daily activities because I just don't have the energy.</li></ul> <p><b>15. Feeling Slowed Down:</b></p> <ul style="list-style-type: none"><li><input type="checkbox"/> 0 I think, speak, and move at my usual rate of speed.</li><li><input type="checkbox"/> 1 I find that my thinking is slowed down or my voice sounds dull or flat.</li><li><input type="checkbox"/> 2 It takes me several seconds to respond to most questions, and I'm sure my thinking is slowed.</li><li><input type="checkbox"/> 3 I am often unable to respond to questions without extreme effort.</li></ul>	<p><b>During the past seven days...</b></p> <p><b>16. ---	---

Modified with permission from Rush AJ, Trivedi MH, Ibrahim HM, et al: The 16-item quick inventory of depressive symptomatology (QIDS), clinician rating (QIDS-C), and selfreport (QIDS-SR): a psychometric evaluation in patients with chronic major depression. *Biol Psychiatry* 2003 Sep 1;54(5):573–583.

**TABLE 13-4.** Quick Inventory of Depressive Symptomatology-Self Report (QIDS-SR<sub>16</sub>) Scoring Instructions

1. Enter the highest score on any one of the four sleep items (items 1 to 4)  
Enter the highest score on any one of the four weight items (items 6 to 9)  
Enter the highest score on either of the two psychomotor items (items 15 and 16)
2. There will be one score for each of the nine Major Depressive Disorder symptom domains
3. Add the scores of the nine items (sleep, weight, psychomotor changes, depressed mood, decreased interest, fatigue, guilt, concentration, and suicidal ideation) to obtain the total score; total scores range from 0 to 27
4. 0–5: no depressive symptoms; 6–10: mild symptoms; 11–15: moderate symptoms; 16–20: severe symptoms; 21–27: very severe symptoms

Modified with permission from Rush AJ, Trivedi MH, Ibrahim HM, et al: The 16-item quick inventory of depressive symptomatology (QIDS), clinician rating (QIDS-C), and selfreport (QIDS-SR): a psychometric evaluation in patients with chronic major depression. *Biol Psychiatry* 2003 Sep 1;54(5):573–83.

**TABLE 13-5.** Diagnostic Criteria for Generalized Anxiety Disorder

- A. Excessive anxiety and worry about a number of events or activities. This occurs more days than not for at least 6 months
- B. The person finds it difficult to control the worry
- C. The anxiety and worry are associated with  $\geq 3$  of the following six symptoms:
  - Easily fatigued
  - Irritability
  - Muscle tension
  - Disturbed sleep
  - Difficulty concentrating
  - Restless or keyed up
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
- E. The disturbance is not due to physiological effects of a substance or another medical condition
- F. Symptoms not better explained by another mental disorder

Data from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

**TABLE 13-6.** Diagnostic Criteria for Substance Use Disorder

<b>A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by two or more of the following, occurring at any time in the same 12-month period:</b>
Consumption of larger amounts or over a longer period than was intended
Desire or unsuccessful efforts to cut down
Increased time spent in activities seeking the substance
Cravings or urges
Failure to fulfill major obligations
Continued use despite recurrent problems
Giving up important social, occupational, or recreational activities
Use in physically hazardous situations
Persistent use despite knowledge of problem
Tolerance develops to the substance
Substance cessation leads to withdrawal symptoms

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

SUBSTANCE USE DISORDERS

In the United States, the lifetime prevalence for alcohol and substance use disorders approximates 15 percent. T is diagnosis is twice as likely in males, although rates in women are increasing (Kessler, 2005). Indicators of substance misuse are found in Table 13-6. Often substance abuse disorders coexist with mood and anxiety disorders. A detailed discussion of these issues is beyond this chapter’s scope, but additional information regarding alcohol and other commonly abused substances, including prescription medications, is found at: <http://www.drugabuse.gov>.

EATING DISORDERS

Specific feeding and eating disorders classified by the DSM-5 and relevant to women’s health care are anorexia nervosa, bulimia nervosa, binge-eating disorder, and unspecified feeding or eating disorder (Tables 13-7 and 13-8). T e core symptoms of both anorexia and bulimia are preoccupation with weight gain and excessive self-evaluation of weight and body shape, accompanied by either restriction of food intake (anorexia) or the use of compensatory behaviors to prevent weight gain after binge eating (bulimia). Binge-eating disorder is differentiated by consuming larger amounts of food, lacking a sense of control

over the eating, but not engaging in subsequent weight-loss behaviors. T ese disorders are 10 to 20 times more common in females than in males, particularly in those aged 15 to 24 years (Mitchell, 2006). In young females, an estimated 4 percent suffer from anorexia, 1 to 1.5 percent from bulimia, and 1.6 percent from binge-eating disorder. While anorexia usually begins early in adolescence and peaks around age 17, bulimia nervosa typically has a later onset than anorexia and is more prevalent over the life span (Hoek, 2006). Pathological eating is also found in older women, particularly binge-eating disorder and unspecified eating disorder (Mangweth-Matzek, 2014).

T e exact etiology of such abnormal consumption is unknown. However, evidence suggests a strong familial aggregation for eating disorders (Stein, 1999). In the restricting type of anorexia, the concordance rate among monozygotic twins approximates 66 percent and 10 percent for dizygotic twins (Treasure, 1989). Various biologic factors have been implicated in eating disorder development. Abnormalities in neuropeptides, neurotransmitters, and hypothalamic-pituitary-adrenal and hypothalamic-pituitary-gonadal axes are reported (Stoving, 2001). In addition, psychological and psychodynamic factors related to an absence of autonomy are thought to influence obsessive preoccupations. Although eating disorders are believed to be a Western culture phenomenon, rates are also increasing in non-Western cultures (Lai, 2013).

**TABLE 13-7.** Diagnostic Criteria for Anorexia Nervosa

<b>A.</b> Refusal to maintain body weight at or above a minimal normal weight for age and height
<b>B.</b> Intense fear of gaining weight or becoming fat, even though underweight
<b>C.</b> Disturbance in the way in which one’s body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low weight
<b>Restricting Type:</b> No binge-eating or purging behaviors
<b>Binge-Eating/purging Type:</b> Binge-eating and self-induced vomiting, or the misuse of laxatives, diuretics, or enemas

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

**TABLE 13-8.** Diagnostic Criteria for Bulimia Nervosa

- A.** Recurrent episodes of binge eating  
Eating, in a discrete period of time, an amount of food definitely larger than most people would eat in a similar period of time under similar circumstances  
A sense of lack of control over eating during the episode
- B.** Recurrent inappropriate compensatory behavior to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise
- C.** Binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months
- D.** Self-evaluation is unduly influenced by body shape and weight
- E.** The disturbance does not occur exclusively during episodes of anorexia nervosa

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

■ **Diagnosis**

*Anorexia nervosa* is divided into two subtypes: (1) a restricting type and (2) a binge-eating/purging type, which is distinguished from bulimia by weighing less than the minimum standard for normal. Symptoms begin as unique eating habits that become more and more restrictive. Advanced symptoms may include extreme food intake restriction and excessive exercise. Up to 50 percent of anorectics also show bulimic behavior, and these types may alternate during the course of anorexic illness. Bulimic-type anorectics have been found to engage in two distinct behavior patterns, those who binge and purge and those who solely purge. The body-mass index percentile, clinical symptoms, degree of disability, and need for supervision determine clinical severity.

Diagnosis of anorexia is initially challenging as patients often defend their eating behaviors upon confrontation and rarely recognize their illness. They increasingly isolate themselves socially as their disorder progresses. Multiple somatic complaints such as gastrointestinal symptoms and cold intolerance are common. In the disorder’s later stages, weight loss becomes more apparent, and medical complications may prompt patients to seek help. Findings often include dental problems, general nutritional deficiency, electrolyte abnormalities (hypokalemia and alkalosis), and decreased thyroid function. Electrocardiogram changes such as QT prolongation (bradycardia) and inversion or flattened T-waves may be noted. Rare complications include gastric dilatation, arrhythmias, seizure, and death.

*Bulimia nervosa* is identified by periods of uncontrolled eating of high-calorie foods (binges), followed by compensatory behaviors such as self-induced vomiting, fasting, excessive exercise, or misuse of laxatives, diuretics, or emetics. Unlike patients with anorexia, those with bulimia often recognize their maladaptive behaviors. Severity is based on the frequency of the inappropriate behaviors, clinical symptoms, and level of disability. Most bulimics have normal weights, although their weight may fluctuate. Physical changes may be subtle and include dental problems, swollen salivary glands, or knuckle calluses on the dominant hand. Termed *Russell sign*, calluses form in response to repetitive contact with stomach acid during purging (Strumia, 2005).

Binge-eating disorder is distinct from anorexia and bulimia. It is characterized by ingesting large amounts of food within a short time and is accompanied by feelings that one cannot control the amount of food eaten. Severity is assessed according

to the number of gorging episodes per week. Binge-eating is associated with obesity. That said, most obese individuals do not necessarily engage in binge episodes and consume comparatively fewer calories than those with the syndrome. Prevalence in the United States approximates 1.6 percent for females and 0.8 percent for males, and in middle-aged women, binge-eating is more common than anorexia or bulimia (Mangweth-Matzek, 2014).

All these are complex disorders that affect both psychological and physical systems and are often comorbid with depression and anxiety. Rates of mood symptoms approximate 50 percent, and anxiety symptoms, 60 percent (Braun, 1994). Simple phobia and obsessive-compulsive behaviors may also coexist. In many cases, patients with anorexia have rigid, perfectionistic personalities and low sexual interest. Patients with bulimia often display sexual conflicts, problems with intimacy, and impulsive suicidal tendencies.

■ **Treatment**

A multidisciplinary approach benefits the treatment of eating disorders. Practice approaches include: (1) nutritional rehabilitation, (2) psychosocial treatment that includes individual and family therapies, and (3) pharmacotherapeutic treatment of concurrent psychiatric symptoms. Online resources for information and support are provided by the National Eating Disorder Association, [www.edap.org](http://www.edap.org) and Academy for Eating Disorders, [www.aedweb.org](http://www.aedweb.org). However, health care providers should also be aware of eating disorder advocacy websites (Norris, 2006).

Data concerning the long-term physical and psychological prognosis of women with eating disorders are limited. Most may symptomatically improve with aging. However, complete recovery from anorexia nervosa is rare, and many continue to have distorted body perceptions and peculiar eating habits. Overall, the prognosis for bulimia is better than for anorexia.

**MENSTRUATION-RELATED DISORDERS**

Frequently, reproductive-aged women experience symptoms during the late luteal phase of their menstrual cycle. Collectively these complaints are termed *premenstrual syndrome (PMS)* or, when more severe and disabling, *premenstrual dysphoric disorder (PMDD)*. Nearly 300 different symptoms have been reported and typically include both psychiatric and physical

complaints. For most women, these are self-limited. However, approximately 15 percent report moderate to severe complaints that cause some impairment or require special consideration (Wittchen, 2002). Current estimates are that 3 to 8 percent of menstruating women meet the strict criteria for PMDD (Halbreich, 2003b).

■ **pathophysiology**

The exact causes of these disorders are unknown, although several different biological factors have been suggested. Of these, estrogen and progesterone, as well as the neurotransmitters gamma-aminobutyric acid (GABA) and serotonin, are frequently studied.

First, estrogen and progesterone are integral to the menstrual cycle. The cyclic complaints of PMS begin following ovulation and resolve with menses. PMS is less common in women with surgical oophorectomy or drug-induced ovarian hypofunction, such as with gonadotropin-releasing hormone (GnRH) agonists (Cronje, 2004; Wyatt, 2004). Moreover, women with anovulatory cycles appear protected. One potential effect stems from estrogen and progesterone’s influence on central nervous system neurotransmitters: serotonin, noradrenaline, and GABA. The predominant action of estrogen is neuronal excitability, whereas progestins are inhibitory (Halbreich, 2003a). Menstruation-related symptoms are believed to be associated with neuroactive progesterone metabolites. Of these, allopregnanolone is a potent modulator of GABA receptors, and its effects mirror those of low-dose benzodiazepines, barbiturates, and alcohol. These effects may include loss of impulse control, negative mood, and aggression or irritability (Bäckström, 2014). Wang and colleagues (1996) noted fluctuations in allopregnanolone across the various menstrual cycle phases. These changes were implicated with PMS symptom severity.

Second, evidence also supports a role for serotonergic system dysregulation in PMS pathophysiology. Decreased serotonergic activity has been noted in the luteal phase. Moreover, trials of serotonergic treatments show PMS symptom reduction (Majoribanks, 2013).

Last, sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS) to alter electrolyte and fluid balance. The antimineralocorticoid properties of progesterone and possible estrogen activation of the RAAS system may explain PMS symptoms of bloating and weight gain.

■ **Diagnosis**

PMDD is identified in the DSM-5 by the presence of at least five symptoms accompanied by significant psychosocial or functional impairment (Table 13-9). PMS refers to the presence of numerous symptoms that are not associated with significant impairment. During evaluation, the revised criteria in DSM-5 recommend that clinicians confirm symptoms by prospective patient mood charting for at least two menstrual cycles. In certain instances, complaints may be an exacerbation of an underlying primary psychiatric condition(s). Thus, other common psychiatric conditions such as depression and anxiety disorders are excluded. Additionally, other medical conditions that have a multisystem presentation are considered. These include hypothyroidism, systemic lupus erythematosus, endometriosis,

**TABLE 13-9.** Diagnostic Criteria for Premenstrual Dysphoric Disorder

- A.** ≥ 5 symptoms below: occur in most cycles during the week before menses onset, improve within a few days after menses onset, and diminish in the week postmenses
- B.** One (or more) of the following symptoms must be present:
  - Marked affective lability
  - Marked irritability or anger or increased interpersonal conflicts
  - Marked depressed moods, feelings of hopelessness, or self-deprecating thoughts
  - Marked anxiety, tension
- C.** One (or more) of the following symptoms must be also present:
  - Decreased interest
  - Difficulty concentrating
  - Easy fatigability, low energy
  - Increase or decrease in sleep
  - Feelings of being overwhelmed
  - Physical symptoms such as breast tenderness, muscle or joint aches, “bloating” or weight gainNote: Criteria A–C must be present for most menstrual cycles in the preceding year
- D.** Symptoms are associated with significant distress or interferences with work, school, relationships
- E.** The disturbance is not merely an exacerbation of another disorder such as major depression, panic disorder, persistent depressive disorder, or a personality disorder
- F.** Criterion A should be confirmed by prospective daily ratings in at least two symptomatic cycles
- G.** The symptoms are not due to physiological effects of a substance or another medical condition

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 5th Edition, DSM-5, Washington, American Psychiatric Association, 2013.

anemia, fibromyalgia, chronic fatigue syndrome, fibrocystic breast disease, irritable bowel syndrome, and migraine.

■ **Treatment**

Therapy for PMDD and PMS include psychotropic agents, ovulation suppression, and dietary modification. Generalists may consider treatment of mild to moderate cases. However, if treatment fails or if symptoms are severe, then psychiatric referral may be indicated (Cunningham, 2009).

Selective serotonin-reuptake inhibitors (SSRIs) are considered primary therapy for psychological symptoms of PMDD and PMS, and fluoxetine, sertraline, and paroxetine are Food and Drug Administration (FDA) approved for this indication (Table 13-10). Standard dosages are administered in either continuous dosing or luteal phase (14 days prior to expected menses) dosing regimens. Several well-controlled trials of SSRIs have shown these drugs to be effective and well tolerated (Shah,

**TABLE 13-10.** List of Common Psychotropic Medications

Drug Class	Indication	Examples <sup>a</sup>	Brand Name	Commonly Reported Side Effects
Selective serotonin-reuptake inhibitors (SSRIs)	Depressive, anxiety, and premenstrual disorders	Fluoxetine <sup>c</sup> Citalopram <sup>c</sup> Escitalopram <sup>c</sup> Sertraline <sup>c</sup> Paroxetine <sup>d</sup> Fluvoxamine <sup>c</sup>	Prozac, Sarafem Celexa Lexapro Zoloft Paxil Luvox	Nausea, headache, insomnia, diarrhea, dry mouth, sexual dysfunction
Serotonin noradrenergic-reuptake inhibitors (SNRIs)	Depressive, anxiety, and premenstrual disorders	Venlafaxine XR <sup>c</sup> Duloxetine <sup>c</sup> Levomilnacipran <sup>c</sup> Desvenlafaxine <sup>c</sup>	Effexor Cymbalta Fetzima Pristiq	Dry mouth, anxiety, agitation, dizziness, somnolence, constipation
Tricyclic and tetracyclic antidepressants	Depressive and anxiety disorders	Desipramine <sup>c</sup> Nortriptyline <sup>d</sup> Amitriptyline <sup>c</sup> Doxepin <sup>c</sup> Maprotiline <sup>b</sup>	Norpramin Pamelor, Aventyl Elavil Sinequan Ludiomil	Drowsiness, dry mouth, dizziness, blurred vision, confusion, constipation, urinary retention and frequency
Benzodiazepines	Anxiety disorders	Alprazolam <sup>d</sup> Clonazepam <sup>d</sup> Diazepam <sup>d</sup>	Xanax Klonopin Valium	Drowsiness, ataxia, sleep changes, impaired memory, hypotension
Others	Depressive disorders	Nefazodone <sup>c</sup>	Serzone	Headache, dry mouth, orthostatic hypotension, somnolence
		Trazodone <sup>c</sup>	Desyrel	
		Bupropion SR, XL <sup>c</sup>	Wellbutrin	
		Mirtazapine <sup>c</sup>	Remeron	
	Anxiety disorders	Vilazodone <sup>c</sup>	Viibryd	Dry mouth, increased appetite, somnolence, constipation Diarrhea, nausea, dry mouth Weight gain, akathisia, extra-pyramidal signs, somnolence
		Aripiprazole <sup>c,e</sup>	Abilify	
		Vertioxetine <sup>c</sup>	Brintellix	
		Buspirone <sup>b</sup>	Buspar	
	Sleep agents	Hydroxyzine <sup>c</sup>	Vistaril, Atarax	Constipation, nausea, vomiting Dizziness, drowsiness, headache
		Zaleplon <sup>c</sup>	Sonata	
		Zolpidem <sup>c</sup>	Ambien, Intermezzo, Edluar, Zolpimist	
		Ramelteon <sup>c</sup>	Rozerem	
		Eszopiclone <sup>c</sup>	Lunesta	Headache, somnolence, amnesia, fatigue

2008). In addition, short-term use of anxiolytics such as alprazolam or buspirone offers added benefits to some women with prominent anxiety. However, in prescribing benzodiazepines, caution is taken in women with prior history of substance abuse (Nevatte, 2013).

Because gonadal hormonal dysregulation is implicated in the genesis of PMS symptoms, ovulation suppression is another option. There is some data to support combination oral contraceptive (COC) pills in general for premenstrual mood symptoms. Moreover, in randomized trials, *Yasmin*, a COC containing the spironolactone-like progestin drospirenone, showed therapeutic

benefits. It carries an FDA indication for PMDD treatment in women who desire contraception (Pearlstein, 2005; Yonkers, 2005). Alternatively, GnRH agonists are another means of ovulation suppression. These agents are infrequently selected due to their hypoestrogenic side effects and risks. If elected for PMDD and used longer than 6 months, add-back therapy, as discussed in Chapter 10 (p. 240), can potentially blunt these side effects. Rarely, symptoms warrant bilateral oophorectomy, and a trial of GnRH agonists prior to surgery may be prudent to determine the potential efficacy of castration. Last, the synthetic androgen danocrine (Danazol) also suppresses

ovulation, but androgen-related acne and hair growth are usually poorly tolerated.

Of other possible agents, prostaglandin inhibitors such as ibuprofen and naproxen offer benefits through their antiinflammatory effects and alleviate cramping and headaches associated with PMS (Table 10-1, p. 239). Diuretics such as combined hydrochlorothiazide and triamterene (Dyazide) and spironolactone (Aldactone) may be prescribed to alleviate fluid retention and leg edema. Monitoring for potential side effects such as orthostatic hypotension and hypokalemia is critical since these can be severe.

Diet—namely, foods and beverages high in sugar and caffeine—can aggravate premenstrual symptoms in some women. Calcium, 600 mg orally twice daily, has shown benefits, theoretically by correcting deficiency-related symptoms such as muscle cramps (Tys-Jacobs, 2000). Vitamins such as pyridoxine (vitamin B<sub>6</sub>) and vitamin E may offer some relief. Pyridoxine is a cofactor to tryptophan hydroxylase, which is the key enzyme in the serotonin synthesis (Wyatt, 1999). The recommended dose of pyridoxine is 50 to 100 mg/day, but doses exceeding 100 mg/day are avoided to prevent pyridoxine toxicity. Magnesium in combination with vitamin B<sub>6</sub> appears to reduce anxiety-related premenstrual symptoms (De Souza, 2000). Of nonpharmacologic alternatives to treatment, there is growing evidence assessing efficacies of acupuncture, bright-light therapy, exercise, and omega fatty acids (Brandon, 2014).

## PERINATAL DISORDERS

In general, psychiatric disorders during pregnancy have a course and presentation similar to that in nonpregnant women. For this reason, there are no distinct diagnostic criteria for psychiatric disorders experienced in the context of pregnancy and the puerperium.

### ■ perinatal Depression

In the revised DSM-5, a major depressive episode, with its onset during pregnancy or within 4 weeks following childbirth, is categorized by a specifier term that notes “with peripartum onset.” Some women experience the first onset of depression during this time, whereas others are vulnerable for relapse (Cohen, 2006a). Etiologic studies have been inconclusive, but both hormonal changes and psychosocial stressors are implicated (Bloch, 2006; Boyce, 2005). Treatment is critical, as suicide is a leading cause of maternal death in developed countries (Centre for Maternal and Child Enquiries, 2011). Accordingly, health professionals are encouraged to thoroughly assess psychiatric and psychosocial history to enable early identification, prevention, and treatment of perinatal depression (Moses-Kolko, 2004). The American College of Obstetricians and Gynecologists (2012) currently notes insufficient evidence for *universal* peripartum depression screening but recommends that evaluation be considered for women with current depression or prior major depression. Other risks include life stress, poor social support (particularly from the partner), and maternal anxiety (Lancaster, 2010).

To screen for and assess severity of peripartum depressive symptoms, the Edinburgh Postnatal Depression Scale (EPDS) is one tool specifically developed for pregnancy (Cox, 1987). Unlike screening measures that score symptoms characteristic of pregnancy itself (appetite, weight change, sleep disturbance, and fatigue), the EPDS inquires about neurovegetative symptoms that are more specific to depression. Available in numerous languages, the EPDS is an efficient way for a clinician to identify patients at risk for perinatal depression. It is available through the American Academy of Pediatrics at: [http://www2.aap.org/sections/scan/practicingsafety/toolkit\\_resources/module2/epds.pdf](http://www2.aap.org/sections/scan/practicingsafety/toolkit_resources/module2/epds.pdf).

### Antepartum

The prevalence of depression during pregnancy has been estimated to be highest (11 percent) in the first trimester, falling to 8.5 percent in the second and third trimesters. For treatment, the American Psychiatric Association and American College of Obstetricians and Gynecologists have issued pregnancy guidelines for depression management that recommend careful risk and benefit analysis of existing treatment (especially medications) (Yonkers, 2009). For major depression, psychotropic medication and psychotherapy have the largest evidence-based support (Stuart, 2014). However, data also note efficacy for several complementary interventions (Deligiannidis, 2013). The FDA (2006, 2011b) recommends careful and transparent risk assessment during pregnancy before prescribing psychotropic medications. On the other hand, women who discontinue antidepressant medication during pregnancy relapse into depression significantly more frequently than women who maintain their pharmacologic treatment (Cohen, 2006a). And as noted, suicide accounts for a significant proportion of pregnancy-associated death. Thus, a clinician must assess the risk of relapse in severely depressed women against potential risk to the newborn of antidepressant medication exposure. Additional guidance is found in *Williams Obstetrics*, 24th edition (Cunningham, 2014). Patients may benefit the most from a combination of treatment options, guided by the information available and the woman's attitudes and preferences regarding potential treatments. Nonpharmacologic and complementary approaches are also potential options for depressive symptoms during pregnancy. These include acupuncture, bright light therapy, exercise, omega fatty acid supplementation, and yoga and massage therapies (Field, 2012; Manber, 2010; Shivakumar, 2011; Su, 2008; Wirz-Justice, 2011).

### Postpartum

Depression after childbirth is largely divided into three categories: “postpartum blues,” postpartum depression, and postpartum psychosis. The strongest predictors of postpartum depression include prior history of depression or anxiety, family history of psychiatric illness, poor marital relationship, poor social support, and stressful life events in the previous 12 months (Boyce, 2005; Sayil, 2007).

*Postpartum blues* describes a transient state of heightened emotional reactivity that can develop in up to 50 percent of women. The onset is 2 to 14 days after childbirth, and its duration is less than 2 weeks (Gaynes, 2005). Blues generally

require no intervention. Rest and social support contribute significantly to remission. However, postpartum blues do constitute a significant risk factor for subsequent depression during the puerperium.

*Postpartum depression*, as noted, includes onset during pregnancy and within 4 weeks following delivery. However, in research and most clinical settings, any depression developing within 12 months following childbirth is considered to have postpartum onset (Sharma, 2014). With this definition, the prevalence of postpartum depression approximates 15 percent of delivered women (Gaynes, 2005). Postpartum depression warrants careful assessment by a mental health professional, and treatment is initiated immediately to minimize impaired caregiving. Infants of depressed mothers exhibit cognitive, temperamental, and developmental differences compared with infants of unaffected mothers (Kaplan, 2009; Newport, 2002). SSRIs are usually first-line agents, although fluoxetine use is discouraged due to relatively high concentrations in breast milk (Sie, 2012). Several psychosocial interventions have also demonstrated efficacy in treating postpartum depression. Of these, the most significant effects have been achieved with interpersonal therapy and cognitive-behavioral therapy (Stuart, 2014). Additionally, Postpartum Support International is an excellent resource of information for both clinicians and patients. Information can be obtained at [www.postpartum.net](http://www.postpartum.net) and MedEd PPD websites (<http://mededppd.org/default2.asp>).

Last, *postpartum psychosis* develops in less than 2 percent of new mothers, and its onset is generally within 2 weeks of childbirth (Gaynes, 2005). The risk for this severe form of depression is increased for women who have had prior mood disorders. Particularly, prior postpartum psychosis increases by 30 to 50 percent a woman's risk with subsequent deliveries (American Psychiatric Association, 2013). Evaluation and antipsychotic pharmacologic treatment is essential for these patients. Hospitalization is often indicated until the safety of mother and infant is assured.

### ■ Other psychiatric Disorders

Clinicians most often focus on mood disorders during the perinatal period. However, other psychiatric illnesses such as anxiety disorders, bipolar disorder, and schizophrenia may also be present. Of these, bipolar disorders and schizophrenia are serious, recurrent psychiatric illnesses that require pharmacologic treatment. Treatment planning is critical with such patients, and decisions are made in collaboration with a psychiatric professional. The FDA (2011a) issued a safety communication alerting health care providers concerning some antipsychotic medications that are associated with neonatal extrapyramidal and withdrawal symptoms similar to the neonatal behavioral syndrome seen in those exposed to SSRIs. Thus, a careful balance must be struck between minimizing medication risk to the fetus and maternal risk from untreated or undertreated disease.

### ■ perinatal Loss

With perinatal loss, many studies have focused on identifying factors that modify grieving styles, and a few have studied inter-

ventions for families after such loss. Health care providers are most helpful if they speak directly, use understandable language, and share information that would provide parents a sense of control over their situation and that would address their fears. Additional time with health professionals and a perception of being a priority are also important (DiMarco, 2001; Flenady, 2014). Since grief is individual, no generalizations can be made concerning clinical treatment in these situations. Thus, a clinician must ask a patient what she needs and wants. Couples therapy may be helpful if mother and father find it difficult to grieve congruently. Family therapy may be indicated if other children need support to process the loss and their parents' grief. Many hospitals provide support groups, and the Hygeia Foundation (<http://hygeiafoundation.org>) offers both useful information and online support.

## MENOPAUSAL TRANSITION AND MENOPAUSE

The menopausal transition has long been investigated as a vulnerable period for emergence of mood symptoms. Anxiety, irritable mood, and sleep problems are more likely to develop in perimenopausal women than in premenopausal counterparts (Brandon, 2008; Freeman, 2006). Moreover, data suggest that rates of new-onset depression during menopausal transition are nearly twice those for premenopausal women (Cohen, 2006b). This risk persists even after adjusting for sleep disturbances and vasomotor symptoms.

Other possible risks for depression and anxiety are a prior history of depression, severe premenstrual distress, hot flashes, and disrupted sleep. Demographic predictors of increased risk during the perimenopause are lower educational status, African-American ethnicity, unemployment, and major life stressors (Bromberger, 2001; Freeman, 2006; Maartens, 2002). Moreover, psychosocial issues include a woman's recognition that her reproductive years are ending and that her children will leave to establish their own lives. Developmentally, many women are transitioning from being family focused to finding new avenues in which to invest time and energy.

Mood vulnerability during menopausal transition is believed to follow erratic physiologic fluctuations in reproductive hormones. Detailed discussion of these hormones as they relate to mood changes during this transition is found in Chapter 21 (p. 485).

### ■ Evaluation and Treatment

Perimenopausal women with psychological symptoms warrant a comprehensive psychosocial inventory and risk factor assessment. Since medical conditions may concurrently develop during this transition, evaluation excludes these before symptoms are considered psychosomatic. In particular, thyroid function is evaluated.

The approach to treating mood symptoms involves both pharmacotherapy and psychotherapy (Brandon, 2008). Recommended psychotropic medications are SSRIs and selective noradrenergic-reuptake inhibitors (SNRIs) such as venlafaxine (Effexor). These agents are good options for women who decline hormone therapy. Additional benefits include alleviation of vasomotor symptoms and sleep disturbance.

Studies suggest that short-term administration of estrogen is an option for perimenopausal women with depressive symptoms (Soares, 2001). However, the psychotropic role of estrogen-progesterone preparations in postmenopausal women remains unclear. Moreover, benefits are weighed against safety concerns raised by the Women's Health Initiative (WHI) Study regarding estrogen use (Chap. 22, p. 492). Of nonpharmacologic alternatives investigated to date for mood disturbance during menopause, yoga and moderate-intensity exercise have demonstrated benefit (Brandon, 2014). However, these studies are small.

## LATE LIFE

According to estimates by the Census Bureau, the number of older people in the United States will significantly increase over the next decade as the "Baby Boomer" generation ages. By 2030, nearly 20 percent of the population will be older than 65 (He, 2005). Psychosocial issues addressed are significantly different for these women. Stressors may include diminished mental and physical function and loss of partner, family, or friends. Erikson identified the task of this final developmental stage of life as one of consolidation and integration. In this model, women retrospectively examine their life. They may manage their last years with integrity and with satisfaction in a life well lived, or may suffer despair, feeling that all was in vain.

According to the 2000 U.S. Census, functionally impairing mental disorders affected 11 percent of adults aged 65 to 74 and 10 percent of those older than 74 (He, 2005). Of these disorders, depression, anxiety, late-onset psychotic and paranoid disorders, and alcoholism are those most likely to be observed in clinical practice. As in the general population, anxiety is the most common psychiatric disorder in the elderly. However, the prevalence of depression is generally thought to be lower in postmenopausal women compared with reproductive-aged women. Moreover, most studies suggest that the gender gap between rates of depression closes in late life (Zarit, 1998).

### ■ Evaluation and Treatment

If a psychiatric disorder is suspected, careful evaluation is required to exclude underlying medical causes for these changes. For example, depression may be a comorbid disorder with or an early symptom of Alzheimer and Parkinson disease (Polidori, 2001). Alternatively, depression, anxiety, and psychosis may also result from a single medication or medication combinations.

Specific screening questionnaires for depression have been developed for the elderly, such as the Geriatric Depression Scale (Brink, 1982). This screening tool is available in various languages at: <http://www.stanford.edu/~yesavage/GDS.html>. In addition, neuropsychologic evaluation is helpful to discriminate between the source and nature of mood symptoms and cognitive impairment. Dementia screening is discussed in Chapter 1 (p. 17).

Recognizing the natural decline in serotonin levels with aging, many gerontologists prescribe SSRIs for their patients. However, communication among all treating physicians to

coordinate medications and minimize interactions is particularly important for elderly patients.

Psychosocial treatments are often helpful for the patient and, where applicable, her caregivers. Cognitive-behavioral therapy and interpersonal therapy have both been found effective with the elderly. Moreover, family therapy can be of great value to those struggling with end-of-life issues, functional impairments, multiple losses, and caregiver burden. Social workers are also of tremendous value if a patient and family need to locate additional care resources.

For depression in older adults, one metaanalysis of 89 studies found that pharmacotherapy or psychotherapy achieved comparable results. In contrast, for anxiety, another analysis of 32 studies found pharmacotherapy slightly more effective than psychotherapy (Pinquart, 2006, 2007). Thus, treatment planning is individualized and assesses patient preference, contraindications, and treatment access.

## SOMATIC SYMPTOM DISORDERS

Recurrent, multiple, often unexplained physical symptoms are hallmark features of *somatic symptom disorders*. These disorders are common, and their estimated prevalence in general clinical practice is 16 percent (de Waal, 2004). Their prevalence may be even higher in specialty clinics such as pain management clinics. Somatic symptom disorders are complex and poorly understood. However, symptoms cause significant distress and/or impairment in various domains of an affected individual's life. Moreover, one in four somatic symptom patients suffer from comorbid anxiety and depressive symptoms. Thus, a multidisciplinary approach is often required to effectively manage these women's symptoms.

## SEXUAL ASSAULT

Sexual assault is a broad term that includes rape, unwanted genital touching, and even forced viewing of or involvement in pornography. Rape is a legal term and in the United States refers to penetration of a body orifice without consent (mouth, vagina, or anus) and with force or the threat of force or incapacity (young or old age, cognitive or physical disability, or drug or alcohol intoxication). The definition of rape includes spousal rape (Linden, 2011). Rape is often motivated by aggression and rage, with the assailant using sexual contact as a weapon for power and control.

For sexual assault, large population-based surveys indicate a lifetime prevalence of 13 to 39 percent among women and 3 percent among men (Tjaden, 2000). Certain populations are at increased risk and include the physically or mentally disabled; homeless persons; persons who are gay, lesbian, bisexual, or transgendered; alcohol and drug users; college students; and persons younger than 24 (Lawyer, 2010).

Well-known sequelae of rape include isolation, depression, anxiety, somatic symptoms, suicide attempts, and posttraumatic stress disorder (PTSD). The experience has a strong effect on the victim's subsequent health and thus is a major public health issue. Importantly, in caring for sexual assault victims, clinicians should be familiar with the complex array of reactions

(emotional and physical), common injuries, and elements of proper evaluation and treatment of these patients.

■ **physical Findings**

Initial evaluation of a sexual assault victim concentrates on identifying serious injuries. Although 70 percent of rape victims sustain no obvious physical injuries, 24 percent sustain minor injuries, and up to 5 percent sustain major nongenital injuries. Common nongenital injuries include bruises, cuts, scratches, and swelling (81 percent); internal injuries and unconsciousness (11 percent); and knife or gunshot wounds (2 percent) (Sommers, 2001). In the genital area, the posterior fourchette is the area most often injured. Although death is rare, the fear of death during an assault is one of the most intense reactions (Deming, 1983; Marchbanks, 1990).

Once life-threatening injuries are excluded, a patient is ideally moved to a quiet, private setting for further evaluation. A systematic, thorough, but compassionate approach to obtaining a history and collecting evidence is essential for appropriate treatment of the victim and for future prosecution of her assailant (American College of Obstetricians and Gynecologists, 2014).

■ **Examination and Documentation**

Although valid evidence may be collected up to 5 days after sexual assault, immediate examination increases the opportunity to obtain valuable physical evidence (Table 13-11). Consent is obtained prior to physical and genital examination and evidence collection. This step helps to reestablish a victim's sense of control and is essential for entry of evidence in a court of law (Plaut, 2004). Providers emphasize that vital information may be lost if evidence is not collected early. Moreover, evidence collection does not commit a victim to pressing criminal charges (Linden,

1999). A patient is also counseled that she may terminate an examination if it is too emotionally or physically painful.

Most states have standardized kits for evidence collection and storage in which kits may be locked to ensure that legal evidence procedures are maintained. Documentation of all physical injuries is essential, and objective evidence of trauma (even minor) is associated with increased chances of successful prosecution. Clothing is collected as a patient undresses on a white sheet and placed in properly labeled bags (Ingemann-Hansen, 2013). Any debris, such as hair, fibers, mud, or leaves, is also collected.

Evidence gathering includes a sample of the patient's saliva and swabs of all involved orifices. A thorough pelvic examination with evidence collection is essential, even if there are no complaints of genital pain. Up to one third of victims can have traumatic genital injuries without symptoms. Common patterns of genital injury include tears of the posterior fourchette and fossa, labial abrasions, and hymenal bruising. Significant genital injuries are more common in postmenopausal or prepubertal victims. Colposcopy is used if available because this technique increases detection of more subtle injuries of the cervix and vagina. Lenahan (1998) reported that the use of colposcopy increased genital trauma recognition from 6 percent to 53 percent. In addition, a Wood's lamp may aid identification of semen on the skin, which then is collected with moistened cotton swabs. A blood sample is collected for typing, to differentiate the blood type of the victim from that of the assailant. After evidence is collected, it is signed, sealed, and locked in a secure place (Mollen, 2012; Rambow, 1992).

■ **Treatment**

**Pregnancy Prevention**

Medication prophylaxis to prevent pregnancy and common sexually transmitted diseases is provided to women following sexual assault. The risk of rape-related pregnancy approximates 5 percent per rape among reproductive-aged victims (Holmes, 1996). Most of these pregnancies, unfortunately, occur in adolescents, often the victims of incest, who never report the incident or receive medical attention. Because of variation in a woman's menstrual cycle, pregnancy prophylaxis, also termed emergency contraception, is offered to all victims with reproductive organs. Prophylaxis can be administered for up to 72 hours after rape but is most effective in the first 24 hours (Table 13-12). Some studies indicate that prophylaxis may be effective for up to 5 days following rape.

A negative pregnancy test to exclude a preexisting pregnancy is confirmed before administering emergency contraception. This is especially true for ulipristal (Ella), a progesterone antagonist, because of fetal loss risks if used in the first trimester. With estrogen/progestin combinations, side effects include nausea and vomiting, breast tenderness, and heavier menstrual period. In comparison, with levonorgestrel (Plan B), the risk of nausea and vomiting is less (Arowojolu, 2002). An antiemetic can be prescribed 30 minutes prior to hormone administration to decrease nausea (Table 42-7, p. 914).

Patients are informed that their next menses may be delayed following this prophylaxis. Although current regimens are 74 to 89 percent effective, women are counseled to return if

**TABLE 13-11.** Important Elements of Physical Examination and Evidence Collection Following Sexual Assault

<b>physical examination</b>
General appearance
Affect/emotional status
Complete examination of head, body, and extremities; record injuries on body diagram
Pelvic examination, with colposcopy if available, to exclude lower reproductive tract trauma
<b>Elements of evidence collection</b>
Clothing collected in labeled paper bags
Swabs and smears of involved orifices and skin surfaces
Blood sample for patient blood typing to compare with assailant's type
Head hair combings; then head hairs cut or pulled from patient for comparison
Pubic hair combings; then pubic hair cut or pulled from patient for comparison
Fingernail scrapings from the patient, if the victim scratched the assailant's skin or clothing

**TABLE 13-12.** Pregnancy and Sexually Transmitted Disease Prevention Following Sexual Assault

**Testing**

- Pregnancy test (urine or serum)
- Serum testing for hepatitis B surface antigen (HBsAg), HIV, and syphilis
- Evaluation for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* from each penetrated site
- Microscopic evaluation of vaginal discharge saline preparation
- If HIV PEP is planned, then CBC, serum liver function tests, and serum creatinine level

**Treatment**

- Levonorgestrel, ulipristal, or Yuzpe method: all dosages in Table 5-11, p. 131
- Ceftriaxone 125 mg intramuscularly, single dose or cefixime 400 mg orally, single dose
- Azithromycin 1 g orally, single dose
- Metronidazole 2 g orally, single dose

**Optional treatment**

- Hepatitis B vaccination (Table 1-2, p. 8).
- HIV protease-inhibitor-based PEP: lopinavir/ritonavir (Kaletra) plus (lamivudine or emtricitabine) plus zidovudine.  
One option: Kaletra 3 tablets orally twice daily with Combivir (lamivudine/zidovudine) 1 tablet twice daily for 28 days

CBC = complete blood count; HIV = human immunodeficiency virus; PEP = postexposure prophylaxis.  
Data from Centers for Disease Control and Prevention: Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States. MMWR 54(2):1, 2005; Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, 2015. MMWR 64(3):1, 2015.

their next menses is more than 1 to 2 weeks late (Task Force on Postovulatory Methods of Fertility Regulation, 1998; Trussell, 1996; Yuzpe, 1982).

**Sexually Transmitted Disease Prevention**

The risk of acquiring sexually transmitted disease (STD) after rape has been estimated. The risk for trichomoniasis approximates 12 percent; bacterial vaginosis, 12 percent; gonorrhea, 4 percent to 12 percent; chlamydial infection, 2 to 14 percent; syphilis, 5 percent; and human immunodeficiency virus (HIV) infection, 0.1 percent (Jenny, 1990; Katz, 1997; Schwarcz, 1990). However, these risks are difficult to predict and vary by geographic location, type of assault, assailant, and presence of preexisting infections. General recommendations describe prophylaxis for hepatitis, gonorrhea, and chlamydia (see Table 13-12).

The fear of contracting HIV after sexual assault is common in survivors and is often the primary concern following rape (Baker, 1990). However, postexposure prophylaxis (PEP) against HIV remains controversial, given the low risk of transmission after a single sexual assault (Gostin, 1994). With regard

to sexual exposures, the per-contact risk of HIV transmission associated with receptive penile-anal exposures is estimated to be 0.5 to 3.2 percent and with receptive penile-vaginal exposures, 0.05 to 0.15 percent (Wieczorek, 2010). Although rare, HIV transmission associated with receptive oral intercourse has been reported. Experts recommend offering PEP to candidates who are at a higher risk of being exposed to HIV and who are willing to complete the full course of medications and comply with surveillance testing (Table 13-13). The risks and side effects of these medications and need for close monitoring is discussed with patients. Nausea is a common side effect with PEP. Thus, a prescription for an antiemetic such as phenergan, to be used as needed, is commonly provided. PEP should begin within 72 hours, if indicated. For sexual assault patients presenting outside of this time frame, information is provided regarding follow-up HIV antibody testing and referral options.

Because of the emotional intensity of the experience, a woman may not recall all the information provided, and thus written instructions are helpful. Survivors are referred to local rape crisis centers and encouraged to visit within 1 to 2 days.

**TABLE 13-13.** HIV PEP after Sexual Assault

- Assess for risk of HIV infection in the assailant and test if possible
- Determine characteristics of the assault that may increase the risk of HIV transmission (i.e., mucous membrane or broken skin in contact with blood, semen, or rectal secretions)
- Consider consulting an HIV specialist or the National Clinicians' Postexposure Prophylaxis Hotline: 888-448-4911
- If patient is at risk for HIV from assault, discuss PEP risks and benefits
- If the patient starts PEP, schedule follow-up within 7 days
- If prescribing PEP, obtain CBC, serum liver function tests, and serum creatinine level
- Check HIV serology at baseline, 6 weeks, and then at 3 and 6 months

CBC = complete blood count; HIV = human immunodeficiency virus; PEP = postexposure prophylaxis.

Sexual assault victims receive subsequent medical evaluation at 1 to 2 weeks, and 2 to 4 months following their rape. During these visits, examination for STDs and blood testing for HIV and syphilis is performed. Remaining hepatitis vaccinations are administered, if needed.

Psychological Response to Sexual Assault

Survivors of sexual assault may display an array of reactions that frequently include anxiety, agitation, crying, or a quiet, calm, and removed affect. In 1974, Burgess and Holmstrom first characterized the “rape trauma syndrome.” They described two response phases to the trauma of sexual assault: (1) the acute disorganization phase, lasting several weeks, and (2) the reorganization phase, lasting from several weeks to years. During the acute phase, shock and disbelief, fear, shame, self-blame, humiliation, anger, isolation, grief, somatic manifestations, and loss of control are common. During the reorganization phase, feelings of vulnerability, despair, guilt, and shame may continue. Symptoms can include nonspecific anxiety, somatic complaints, or depression. Longitudinal data indicate that sexual assault survivors are at increased lifetime risk for PTSD, major depression, and suicide contemplation or attempt (Linden, 2011). Health care providers ideally enlist the input of social workers or rape crisis counselors to help evaluate the patient’s immediate and future emotional and safety needs.

CHILD SEXUAL ABUSE

Sexual abuse is defined as a child engaged in sexual activities that he or she cannot comprehend, for which he or she is developmentally unprepared and cannot give consent, and/or that violate societal laws or social taboos (Kellogg, 2005). Sexual activities can include vaginal/anal intercourse, oral-genital contact, genital-genital contact, fondling, and exposure to pornography or to adults engaging in sexual activity. In the United States, the overall prevalence of child sexual abuse ranges from 11 to 32 percent for females and 4 to 14 percent for males (Sapp, 2005). Thus, indicators that prompt evaluation include: (1) statements by the child or family of abuse, (2) genital or anal

injury without concordant history of unintentional trauma, (3) semen or pregnancy identified, or (4) STD diagnosed beyond the incubation period of vertical (natal mother-to-child) transmission (Bechtel, 2010).

Determining whether genital findings in children are normal variants or indicative of assault can be difficult, and these have been categorized according to their likelihood of associated sexual abuse. An exhaustive list of normal and indeterminate signs has been compiled by Adams and colleagues (2007, 2008), and those considered diagnostic are listed in Table 13-14. A provider completing the examination should have formal training in the evaluation of suspected child sexual abuse. A list of local specialist providers can be found on the American Academy of Pediatrics Section on Child Abuse and Neglect website at <http://www.aap.org/sections/childabuseneglect/>. Importantly, acute injuries associated with child sexual abuse heal and resolve rapidly. Thus, examination is completed as soon as sexual assault is suspected (McCann, 2007). As signs may be subtle, a careful history and full examination are carried out with the aid of photodocumentation, preferably using a colposcope (Price, 2013).

The prevalence of STDs in child victims of sexual abuse is low (Girardet, 2009a). Thus, the decision to obtain specimens from a child is individualized. Situations that typically prompt testing include: (1) signs or complaints of genital penetration or of an STD, (2) suspected assailant with a high risk for STDs, (3) another household member with an STD, (4) abuse by a stranger, or (5) community with a high STD rate (Centers for Disease Control and Prevention, 2015).

If indicated, recommended testing includes: cultures for *Neisseria gonorrhoeae* from the pharynx, anus, and vagina; cultures for *Chlamydia trachomatis* from the anus and vagina; and culture and wet mount evaluation of a vaginal swab specimen for *Trichomonas vaginalis* infection and bacterial vaginosis. Culture rather than nucleic acid amplification tests (NAATs) are preferred. Swab specimens from vagina, rather than endocervix, are recommended for prepubertal girls (Centers for Disease Control and Prevention, 2015). Decisions regarding serologic testing for *Treponema pallidum*, HIV, and hepatitis B virus are individualized.

TABLE 13-14. Findings Diagnostic of Sexual Contact in Suspected Child Sexual Abuse

Acute genital or perianal lacerations or extensive bruising <sup>a</sup>
Perianal or fourchette scarring <sup>a</sup>
An area between 4 and 8 o’clock on the rim of the hymen where it appears to have been torn through to, or nearly to, the base
Positive genital, anal, or pharyngeal culture for <i>Neisseria gonorrhoeae</i> <sup>b</sup>
Confirmed diagnosis of syphilis <sup>b</sup>
Positive culture or saline prep for <i>Trichomonas vaginalis</i> in a child older than 1 year
Positive genital or anal culture for <i>Chlamydia trachomatis</i> in a child older than 3 years
Positive serology for HIV <sup>b</sup>
Pregnancy
Sperm identified in specimens taken directly from a child’s body

<sup>a</sup>If other medical conditions such as Crohn disease, coagulopathy, or labial adhesion not explanatory for findings.

<sup>b</sup>If perinatal transmission, transmission from blood products, and needle contamination have been excluded.

HIV= human immunodeficiency virus.

Data from Adams JA: Guidelines for medical care of children evaluated for suspected sexual abuse: an update for 2008. Curr Opin Obstet Gynecol 2007 Jun;20(3):163-172; Adams JA, Kaplan RA, Starling SP, et al: Guidelines for medical care of children who may have been sexually abused. J Pediatr Adolesc Gynecol 2008 Oct;20(5):435–441.

The general concept that sexually transmissible infections found beyond the neonatal period are evidence of sexual abuse has exceptions. For example, perinatally acquired *C trachomatis* infection has, in some cases, persisted up to age 3 years in girls. Genital warts have been diagnosed in children who have no other evidence of sexual abuse. Finally, most hepatitis B virus infections in children result from household exposure to those chronically infected with the virus (Centers for Disease Control and Prevention, 2015).

Routine STD prophylaxis for children who have been sexually abused is generally not recommended due to lower rates of associated infection and a greater guarantee of scheduled follow-up. However, if the clinical setting dictates or if test results are positive for infection, antibiotics are provided. Rates of HIV transmission following sexual abuse are also very low in children (Girardet, 2009b). However, antiretroviral treatment is well tolerated by children, and PEP can be offered based on the clinical setting (Cybulska, 2012). When considered, antiretroviral PEP is initiated, similar to other prophylaxis, within the first 72 hours. The CDC (2015) recommends consulting professionals who specialize in care of HIV-infected children.

## INTIMATE PARTNER VIOLENCE

The terms *domestic violence (DV)*, *gender-based violence*, and *violence against women* encompass a multitude of abuses directed at women and girls. The United Nations Declaration on the Elimination of Violence against Women (1993) defines violence as acts that cause or have the potential to cause harm. Introduction of the term “gender-based” emphasizes that the act is rooted in inequality between women and men (Krantz, 2005). *Intimate-partner violence (IPV)* refers to harm inflicted by one intimate partner on the other, with the intention of causing pain or controlling the other’s behavior. *Honor-based violence (HBV)* is most prevalent in south Asian and Middle Eastern countries, where acts are committed to maintain family honor in the community. The prevalence of HBV in the United States is increasing with increasing immigration from these areas (Dickson, 2014).

Violence against women varies and includes wife battering, sexual assault, incest, and elder abuse (Burge, 1997; Straka, 2006). Most victims know their assailant and have been assaulted more than once. The average length of victimization is 4 years for repeatedly raped women and for physically assaulted women (Tjaden, 2000).

### Risks

In the United States, nearly one in four women has experienced IPV at some point in her life. Aside from youth and ethnicity, few traits characterize women who are assaulted by violent men. Peters and colleagues (2002) analyzed data from 5298 IPV reports. They found that women aged 16 to 24 years are at greatest risk for IPV, a risk that was more than twice as great as the risk for women aged 25 to 34 years. Rates of IPV decreased throughout the reproductive years and reached a nadir in women aged 65 or older. Hotelling and Sugarman (1986) in their review found only one consistent risk marker

of being an abused wife. Witnessing violence as a child was a significant risk factor in 11 of 15 studies.

Seven to 20 percent of pregnant women may be victims, and homicide is reported as the leading cause of death during pregnancy. Most cases result from partner abuse (Gazmararian, 1996; Shadigian, 2005). Therefore, screening for IPV is an important component of prenatal care.

The social and medical problem of elder abuse is escalating with an aging population. Currently, each year, approximately 1 in 10 older adults are mistreated, and 84 percent of cases are unreported (Hoover, 2014; Jayawardena, 2006). Elder abuse is divided into seven categories by The National Center on Elder Abuse: physical, emotional, and sexual abuse, financial exploitation, neglect, self-neglect, and abandonment. Of these categories, neglect is the most prevalent. It occurs most often in the home and is perpetrated most frequently by family members. Identified risk factors are caregiver stress, patient cognitive impairment, need for assistance with daily life activities, conflicted family relationships, and poor social support (Hoover, 2014).

### Diagnosis

Women who have been assaulted are far more likely to seek help from their medical provider than from legal personnel, mental health professionals, or victim advocates. For years after the assault, victims have an unusually high rate of medical use and may present with psychiatric and somatic complaints (Koss, 1992). Moreover, IPV can adversely affect health, and affected women are more likely to have cardiac disease, asthma, and drink excessively compared with women without prior IPV (Bair-Merritt, 2014).

Although some clinicians may feel awkward asking patients, researchers agree that the single most important thing a physician can do for a battered woman is to ask about violence (Linden, 1999). Additionally, health care providers should ask about violence if they identify symptoms or behaviors that may be associated with victimization (Burge, 1997). These can include bruising, unexplained injuries, depression or anxiety, alcohol or drug abuse, unexplained chronic pain, isolation, inability to cope, limited access to care, noncompliance, husbands with extremely controlling behaviors or intense jealousy, or husbands with substance abuse.

### Management

If a patient discloses IPV, a clinician should validate and normalize a patient’s perspective. Patients are counseled that many women have assault experiences, that most are afraid to confide these, that memories of the experience can be painful, and that a fear of future assaults is a reasonable fear. Following a patient’s disclosure, a clinician expresses concern for the woman’s health and safety and conveys a willingness to discuss relationship issues at any time. Moreover, information describing community resources is offered. The National Domestic Violence Hotline (1-800-799-SAFE (7233)) is a nonprofit telephone referral service with access to more than 5000 women’s shelters nationally.

Battery is a crime, yet few states specifically require reporting of IPV. A small number of states require mandatory arrest of batterers, and a few jurisdictions aggressively pursue cases

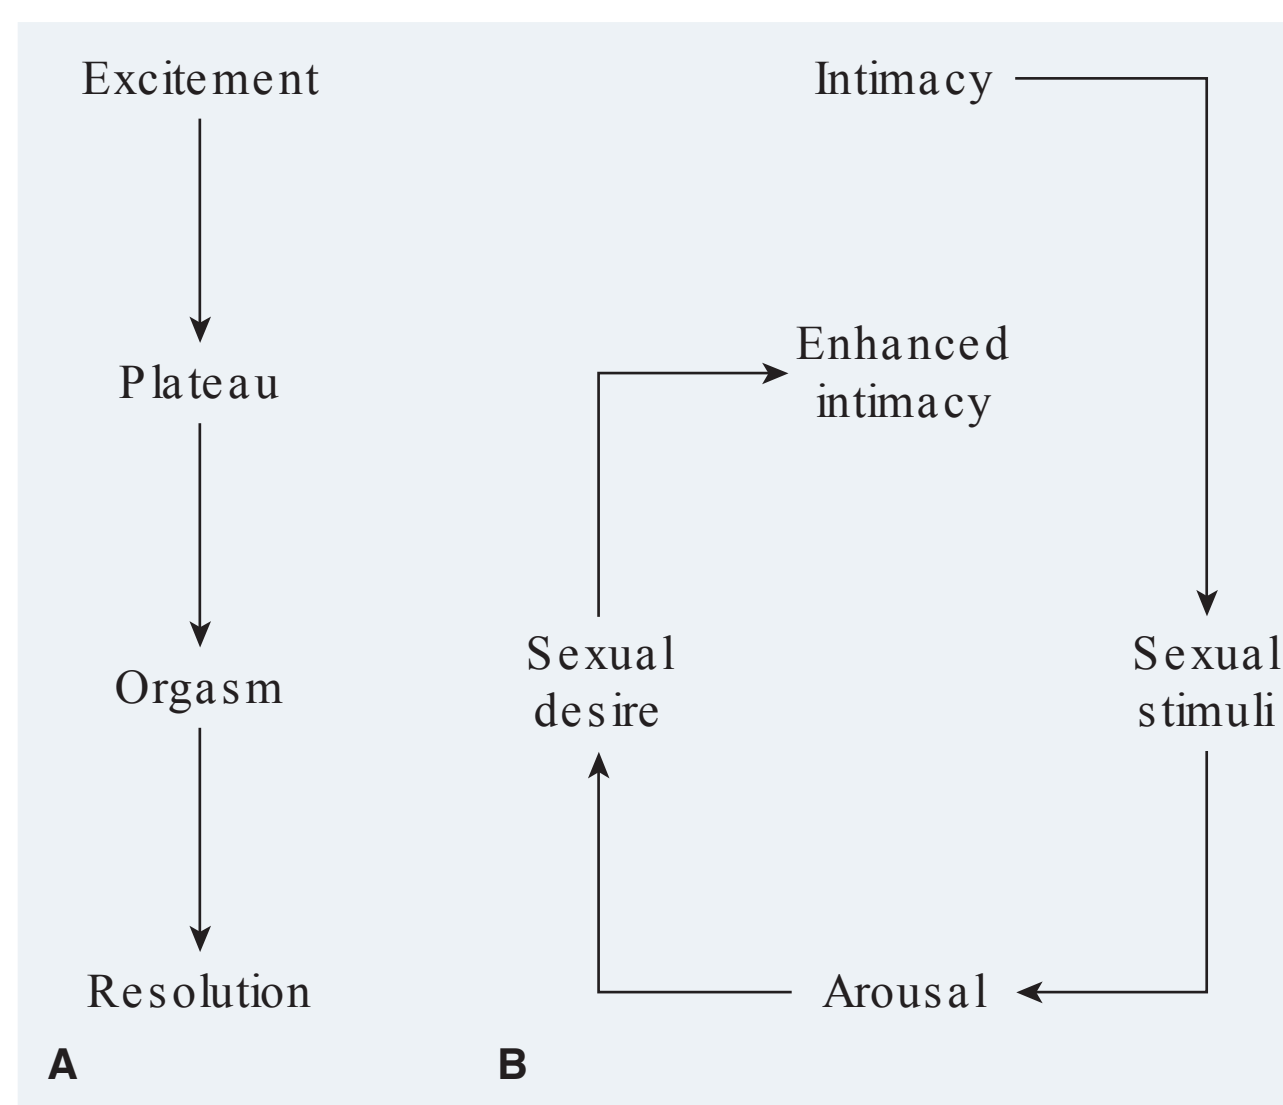

of IPV. Accordingly, each clinician should know their state laws to properly and adequately inform their patients. In addition, providers should thoroughly document physical findings of violence. Such data may be required if criminal charges are pursued.

## FEMALE SEXUALITY

Sexuality is one of the most complex and yet basic components of human behavior. Expressions of sexuality and intimacy remain important throughout life. Although basic sexual drive is biologic, its expression is determined by various psychological, social, environmental, spiritual, and learned factors. Thus, satisfaction is often less dependent on the physical components of sexuality than on the quality of the relationship and the context in which sexual behavior is undertaken.

In describing the sexual response cycle, several models have been proposed to describe normal sexual response (Kingsberg, 2013). Masters and Johnson, in 1966, were the first to offer a theoretical “human sexual response cycle” that was based on their direct observations of the anatomic and physiologic changes experienced by men and women in a laboratory setting. This was a four-stage linear cycle that they labeled as “excitement,” “plateau,” “orgasm,” and “resolution.” The cycle was independently modified by Kaplan (1979) and Leif (1977) to a triphasic model that emphasized desire—in contrast to physiologic genital arousal—as the first stage of sexual response. In 2001, Basson first published her intimacy-based circular model to help explain the multifactorial character of female sexual response (Fig. 13-2). This model includes the interplay of emotional intimacy, sexual stimuli, psychological factors, and relationship satisfaction. This model also introduces the concept of receptive/responsive desire, which is the idea that arousal often precedes desire and that women often begin a sexual encounter from a position of sexual neutrality. It encompasses

**FIGURE 13-2** Models of female sexual response. (Data from Basson R: Human sex-response cycles. *J Sex Marital Ther* 27:33, 2001; Masters WH, Johnson VE: *Human Sexual Response*. Boston, Little Brown, 1966.)

the impact of biologic and nonbiologic factors on a woman’s sexual response, including motivation, interpersonal issues, cultural and religious beliefs, partner’s health status, relationship quality, past sexual abuse, and distractions. Basson’s model (2001, 2006) emphasizes that desire and arousal are difficult to separate, and this serves as the basis for DSM-5 classification changes. Namely, the diagnoses of hypoactive sexual desire disorder and female sexual arousal disorder are now combined and considered as female sexual interest/arousal disorder (American Psychiatric Association, 2013; Kingsberg, 2013).

### ■ Drive/Desire

The basis of desire and perceived arousal in women is poorly understood, but it appears to involve interactions among multiple neurotransmitters, sex hormones, and environmental factors. The biopsychosocial model of desire as outlined by Levine (1984) suggests that desire is composed of three individual but interrelated components: sexual drive, sexual beliefs, and sexual motivation. The biologic component, drive, is spontaneous and includes cravings for sexual activity, sexual dreams, unprompted sexual thoughts, and genital sensations. It is influenced by neuroendocrine mechanisms. The second component reflects a woman’s beliefs and values about sex. The third component, motivation, reflects the emotional willingness to engage in sexual activity with a given partner (or alone). Motivation often carries the most weight among these components and is altered by psychological function, relationship quality, and concerns about health, occupation, or family. The interplay and input of these realms yield one’s sexual interest. Thus, a clinician’s differential diagnosis and assessment must be broad, and treatment incorporates a biopsychosocial/integrative approach.

### ■ Arousal

A woman’s sexual arousal is complex and correlates positively with the sexual stimulus and its emotional context. This subconscious reflex is organized by the autonomic nervous system and processed in the limbic system in response to mental or physical stimuli that are recognized as sexual. Subjective findings of sexual arousal include vaginal and vulvar congestion, increases in vaginal lubrication, and other somatic changes such as blood pressure level, heart rate, muscle tone, respiratory rate, and temperature. However, in sexually healthy women, measurements of genital congestion and subjective arousal vary widely (Everaerd, 2000; Laan, 1995). There are also affective responses to sexual arousal. Feelings of joy and affirmation or feelings of fear, guilt, and awkwardness serve to modulate arousal.

In the basal state, clitoral corporal and vaginal smooth muscles are tonically contracted. After sexual stimulation, neurogenic and endothelial release of nitric oxide (NO) leads to clitoral cavernosal artery relaxation. The resulting arterial inflow increases intracavernosal pressure and clitoral engorgement (Cellek, 1998). The glans clitoris extrudes and sensitivity is enhanced.

In the basal state, the vaginal epithelium reabsorbs sodium from the submucosal capillary plasma transudate. However, after sexual stimulation, several neurotransmitters, including NO and vasoactive intestinal peptide, are released. These

modulate vaginal vascular and nonvascular smooth muscle relaxation (Palle, 1990). Submucosal capillary flow dramatically increases and overwhelms sodium reabsorption. Free to 5 mL of vaginal transudate is produced, and this enhanced lubrication aids pleasurable coitus. Smooth-muscle relaxation of the vagina increases vaginal length and luminal diameter, especially in the distal two thirds of the vagina.

## ■ Release and Resolution

Masters and Johnson (1966) proposed that orgasmic release is a reflex-like response that follows once a plateau of excitement has been reached or exceeded. The actual neurobiology of orgasm is unknown, although it seems to include the mesolimbic dopamine pathways and the pudendal, pelvic, and hypogastric nerves. Orgasm occurs with the release of contraction-producing agents such as serotonin and oxytocin, which lead to rhythmic contraction of the levator plate, uterus, and vagina. The physiologic and behavioral indices of orgasm involve the whole body—facial grimaces, generalized muscle myotonia, carpopedal spasms, and contractions of the gluteal and abdominal muscles. The subjective experience of orgasm includes feeling of intense pleasure with a peaking and rapid, exhilarating release. These sensations are reported to be singular, regardless of the manner in which orgasm is achieved (Newcomb, 1983). Women are unique in their ability to be multiorgasmic, that is, capable of a series of distinguishable orgasmic responses without a lowering of excitement between them.

After orgasm, the anatomic and physiologic changes of excitement reverse. In women, genital vasocongestion diminishes, and the vagina shortens and narrows. A filmy sheet of perspiration covers the body, and elevated heart and respiration rates gradually return to normal. If orgasm has occurred, there is concomitant psychologic and physical relaxation. If orgasm does not occur, a similar physiologic processes occurs, but at a slower rate.

## ■ Normal Variations in the physiologic Response

Sexual function and variations in the physiologic response may be affected by many biologic and psychologic aspects of reproduction and the life cycle. First, during pregnancy, sexual function may change, and a reduction in sexual desire and coital frequency is typical (Hyde, 1996). These changes may stem from fears of causing fetal harm during intercourse or orgasm. In addition, fatigue, physical discomfort, or feeling less physically attractive are other reasons.

Women who suffer recurrent miscarriage or infertility or undergo therapeutic abortion, and even those during a normal puerperium, may have an altered physiologic and psychologic sexual response. In the puerperium, fatigue, hormonal changes, and a healing episiotomy scar may contribute to diminished frequency and enjoyment of intercourse (Srivastava, 2008). Hyde (1996) found that women who are breast feeding report less sexual activity and less satisfaction than those who were not breast feeding. The study failed to demonstrate any marked differences according to the method of delivery, although women who had cesarean delivery were more likely to resume

intercourse 4 weeks postpartum than women who delivered vaginally.

For older women, baseline data from the Study of Women's Health Across the Nation (SWAN) addressed sexual behavior in 3262 women aged 42 to 52 years who were either premenopausal or in early menopausal transition. In early menopausal transition, investigators found few changes in sexual practices or function (Cain, 2003). In a group aged 40 to 69 years, Addis and associates (2006) found that 71 percent were sexually active and 65 percent reported satisfaction. Sexual dysfunction was noted in 45 percent and was associated with having a higher education level, poor health, a significant relationship, and a low mental health score.

Late in menopausal transition and with natural menopause, hormonal changes, as a consequence of the hypoestrogenic state, can interfere with physiologic response (Avis, 2000; Tan, 2012). The prevalence of sexual dysfunction is higher and ranges from 68 to 86 percent (Sarrel, 1990). Masters and Johnson (1966) described a delay in reaction time of the clitoris, delayed or absent vaginal lubrication, decreased vaginal congestion, and reduced duration of contractions with orgasm. Loss of estrogen diminishes genital blood flow, vaginal lubrication, and vaginal tissue structural integrity (Freedman, 2002; Pauls, 2005). That said, estrogen replacement in postmenopausal women improves libido and orgasm (Sarrel, 1990). Others have shown improved vaginal lubrication, blood flow, and vaginal compliance in menopausal women using systemic estrogen replacement, but these were not correlated with subjective improvements in sexual function (Berman, 1999; Semmens, 1982).

With aging, sexuality still plays an important role in physical and mental health. Klausmann (2002) and Dennerstein (2001) both suggest that even many years after menopause, an increase in desire and interest is consistently reported with a new relationship. The opportunity for sexual activity in the form of intercourse, however, is often dependent on partner issues. Both partner availability and partner health begin to shape the frequency with which this form of sexual activity occurs. In general, sexual activity declines with increasing age. Activity is reported in 30 to 78 percent of 60-year-old women, in 11 to 74 percent of those older than 70, and in 8 to 43 percent of 80-year-old women (Morley, 2003). Few data describe sexual function in those older than 80, but as the "Baby Boomer" cohort of a more sexually open group continues to age, the future holds promise for the desire to maintain this quality of life (Morley, 1992).

## SEXUAL DYSFUNCTIONS

Psychiatric sexual dysfunctions are characterized by painful intercourse or disturbances in desire, arousal, orgasm, or resolution that cause marked distress and relationship difficulty (Table 13-15). Sexual dysfunction stemming from dyspareunia may also originate from gynecologic disease and is discussed more fully in Chapters 4 (p. 97) and 11 (p. 262).

Although many studies have investigated female sexual dysfunction, prevalence rates are difficult to establish due to differing criteria and measures of sexual functioning. However,

TABLE 13-15. Sexual Dysfunctions

<b>Female sexual interest/arousal disorder</b> Lack of or significantly reduced sexual interest/arousal for a minimum of 6 months, causing distress, and not explained by severe relationship distress (i.e., violence)
<b>Female orgasmic disorder</b> Persistent or recurrent delay in, or absence of, orgasm following a normal excitement phase taking into account factors such as age, sexual experience, and the adequacy of sexual stimulation she receives, persisting for 6 months
<b>Genitopelvic pain/penetration disorder</b> Recurrent or persistent genital pain in anticipation of, during, or as a result of vaginal intercourse or penetration attempts
<b>In all the above disorders</b> The disturbance causes marked distress or interpersonal difficulty Sexual dysfunction is not better accounted for by another psychiatric disorder and is not due exclusively to the direct physiologic effects of a substance or a general medical condition
<b>Types:</b> Lifelong versus acquired; generalized versus situational

Data from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, DSM-5, Washington, American Psychiatric Association, 2013.

Hayes and colleagues (2006) estimated that 64 percent of women experience low or no sexual desire, 35 percent have difficulty achieving orgasm, and 26 percent experience sexual pain. Most difficulties last less than 6 months, but one third may persist longer.

■ **Diagnosis and Treatment**

Patient history is a primary diagnostic tool. Psychosocial risk factors for sexual dysfunction include comorbid psychological disorders, negative emotions, maladaptive cognitions (such as inaccurate expectations), cultural factors, lack of education regarding sexual functioning, couple distress, and absent physical attraction. Of these, psychiatric disorders such as depression and anxiety are frequently comorbid with sexual disorders. Thus, for most patients who suffer from sexual dysfunction, evaluation does not stop with an organic explanation (Bach, 2001). In accordance with the biopsychosocial approach, diagnosis of sexual disorders begins by judging if dysfunction is caused exclusively by a general medical condition, drug abuse, medication, or toxin exposure. Subsequently, evaluation for a primary psychiatric disorder follows. Assessment typically inventories a woman’s ethnic, cultural, religious, and social backgrounds and includes a frank discussion about her current sexual partner(s) and sexual expectations. Clinical judgment takes into account the patient’s age and sexual experience, symptom frequency and chronicity, and her perception of symptoms. Importantly, a woman is asked if the sexual difficulty is chronic or new-onset and if it persists across all situations or appears only in certain circumstances. Finally, referral to a psychiatrist or psychologist may be indicated for a thorough psychiatric interview.

Multidisciplinary treatment is ideal for patients with sexual dysfunction. A team would typically include the referring physician, gynecologist, psychologist, and a nurse-specialist. In organic disorders, it may be necessary to include specialists in urology, gastroenterology, and anesthesiology. Psychological approaches usually include some combination of sexual education, commu-

nication enhancement, identification of emotional and cultural factors, cognitive-behavioral therapy, and couples therapy.

VAGINAL BLEEDING	327
PRECOCIOUS PUBERTY	327
DELAYED PUBERTY	329
SEXUALITY	329
REFERENCES	331

Pediatric gynecology is a unique subspecialty that encompasses knowledge from various specialties including general pediatrics, gynecology, reproductive endocrinology, as well as pediatric endocrinology and pediatric urology. Treatment of a particular patient may thus require the collaboration of clinicians from one or more of these fields.

Gynecologic disorders in children can differ greatly from those encountered in the adult female. Even the simple physical examination of the genitalia differs significantly. A thorough understanding of these differences can aid in diagnosing the various gynecologic abnormalities seen in this age group.

### PHYSIOLOGY AND ANATOMY

#### ■ Hypothalamic-Pituitary-Ovarian Axis

A carefully orchestrated cascade of events unfolds in the neuroendocrine system and regulates development of the female reproductive system. In utero, gonadotropin-releasing hormone (GnRH) neurons develop in the olfactory placode. These neurons migrate through the forebrain to the arcuate nucleus of the hypothalamus by 11 weeks' gestation (Fig. 16-5, p. 376). They form axons that extend to the median eminence and to

the capillary plexus of the pituitary portal system (Fig. 15-11, p. 345). Gonadotropin-releasing hormone, a decapeptide, is influenced by higher cortical centers and is released from these neurons in a pulsatile fashion into the pituitary portal plexus. As a result, by midgestation, the GnRH "pulse generator" stimulates secretion of gonadotropins, that is, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), from the anterior pituitary. In turn, the pulsatile release of gonadotropins stimulates ovarian synthesis and release of gonadal steroid hormones. Concurrently, accelerated germ cell division and follicular development begins, resulting in the creation of 6 to 7 million oocytes by 5 months' gestation. By late gestation, gonadal steroids exert a negative feedback on secretion of both hypothalamic GnRH and pituitary gonadotropins. During this time, oocyte number decreases through a process of gene-related apoptosis to reach a level of 1 to 2 million by birth (Vaskivuo, 2001).

At birth, FSH and LH concentrations rise abruptly in response to the fall in placental estrogen levels and are highest in the first 3 months of life (Fig. 14-1). The transient rise in gonadotropin levels is followed by an increase in gonadal steroid concentrations, which is thought to explain instances of neonatal breast budding, minor bleeding from endometrial shedding, short-lived ovarian cysts, and transient white vaginal mucous discharge. Following these initial months, gonadotropin levels gradually decline to reach prepubertal levels by age 1 to 2 years.

The childhood years are thus characterized by low plasma levels of FSH, LH, and estradiol. Estradiol levels typically measure  $< 10$  pg/mL, and LH values are  $< 0.3$  mIU/mL. Both may be assessed if precocious development is suspected (Neely, 1995; Resende, 2007). During childhood, ovaries undergo active follicular growth and oocyte atresia. As a result of this attrition, by puberty, only 300,000 to 500,000 oocytes remain (Fritz, 2011).

#### ■ Anatomy

Pelvic anatomy also changes during early childhood. In the neonate, sonographically, the uterus measures approximately 3.5 cm in length and 1.5 cm in width. Because the cervix is larger than the fundus, the neonatal uterus is typically spade-shaped (Fig. 14-2) (Nussbaum, 1986). An echogenic central endometrial stripe is common and reflects the transiently elevated gonadal steroid levels described earlier. Fluid is seen within the endometrial cavity in 25 percent of female newborns. Ovarian volume measures  $\leq 1$  cm<sup>3</sup>, and small cysts are frequently found (Cohen, 1993; Garel, 2001).

**FIGURE 14-1** Variation in oocyte number and hormone levels during prenatal and postnatal periods. (DHEA= dehydroepiandrosterone; FSH= follicle-stimulating hormone; hCG= human chorionic gonadotropin; LH= luteinizing hormone.) (Reproduced with permission from Fritz M, Speroff L: Clinical Gynecologic Endocrinology and Infertility, 8th ed. Baltimore: Lippincott Williams & Wilkins; 2011.)

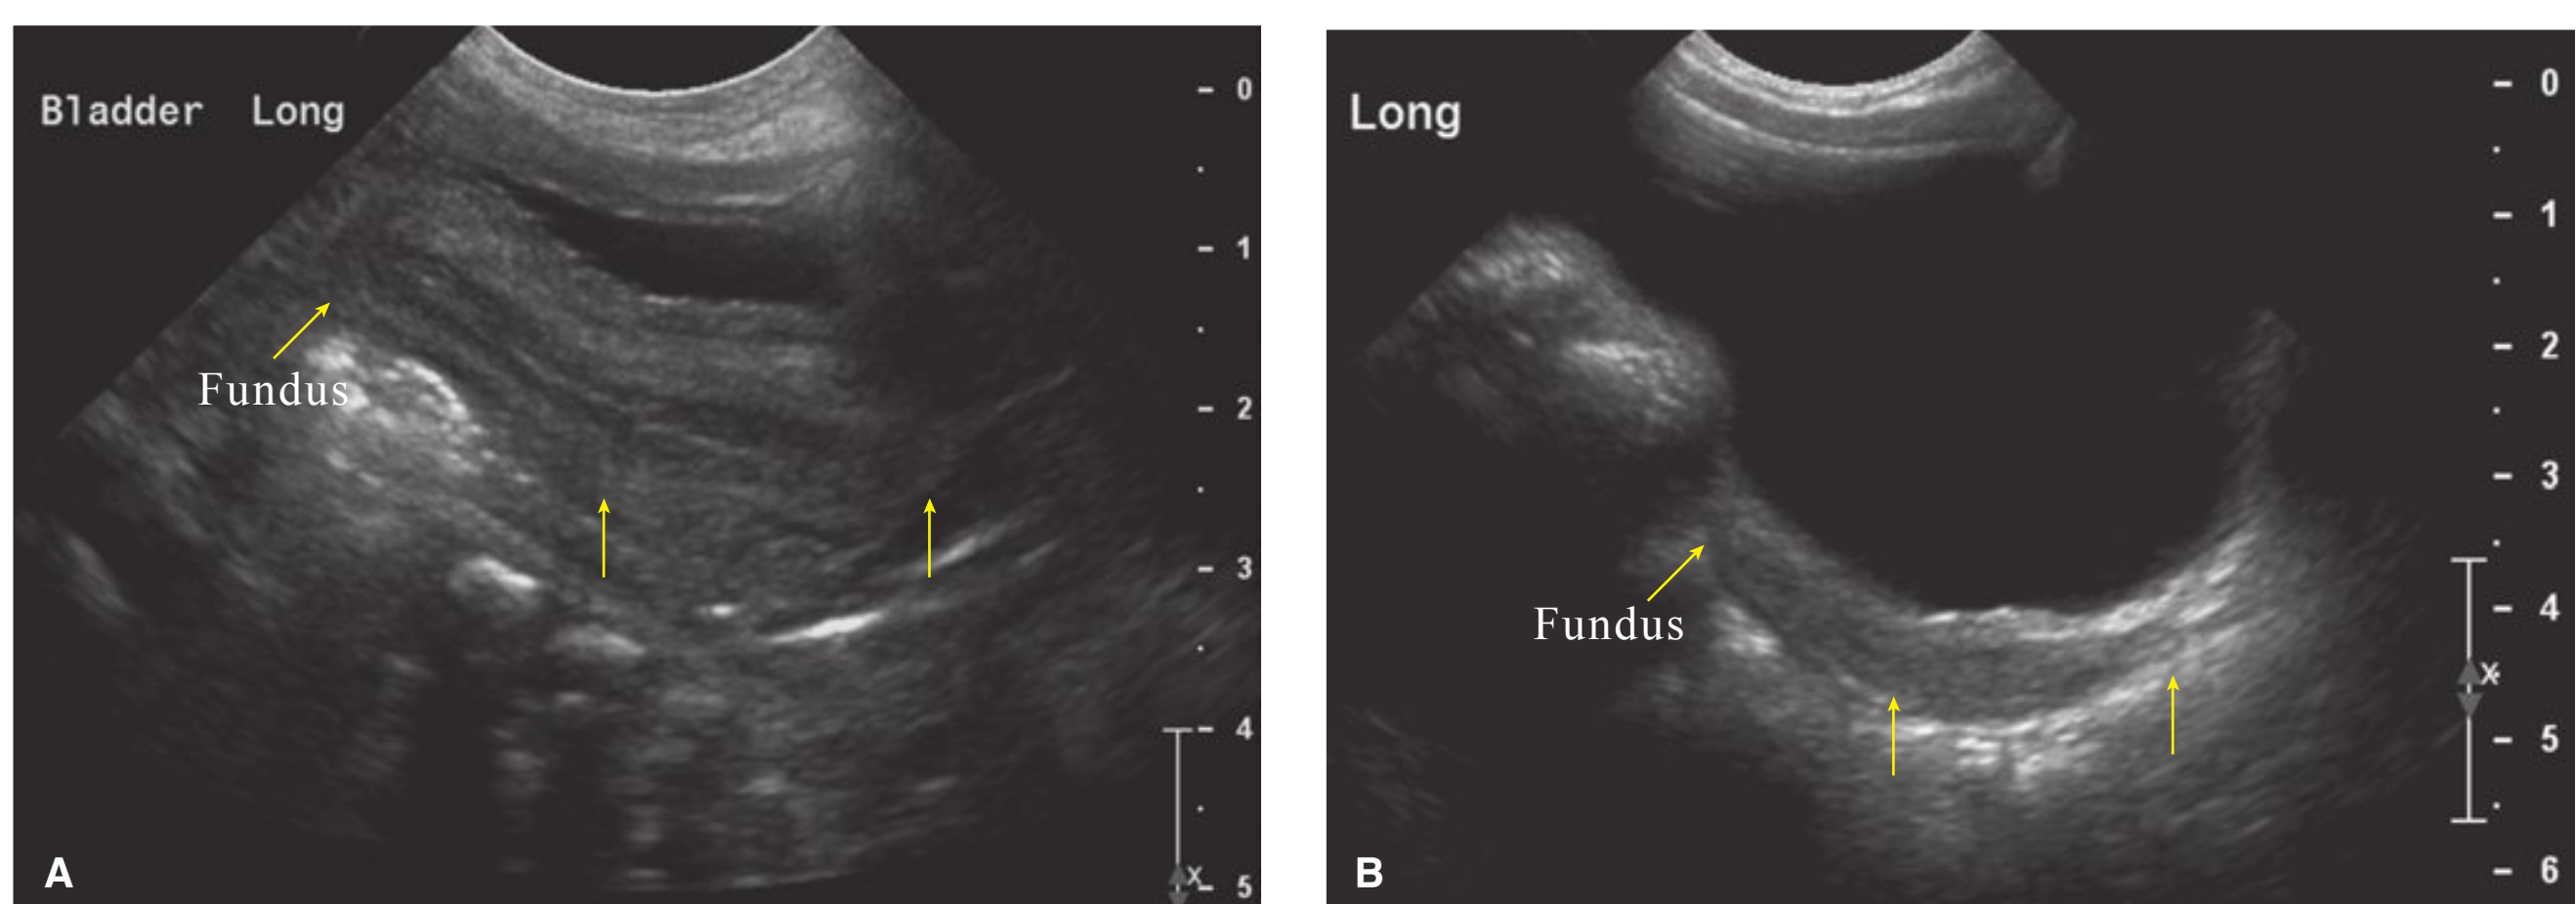

During childhood, the uterus measures 2.5 to 4 cm and is tubular as a result of the cervix and fundus becoming equal size. The ovaries increase in size as childhood progresses, and volumes range from 2 to 4 cm<sup>3</sup> (Ziereisen, 2005).

## Pubertal Changes

Puberty marks the normal physiologic transition from childhood to sexual and reproductive maturity. With puberty, primary sexual characteristics of the hypothalamus, pituitary, and ovaries initially undergo an intricate maturation process. This

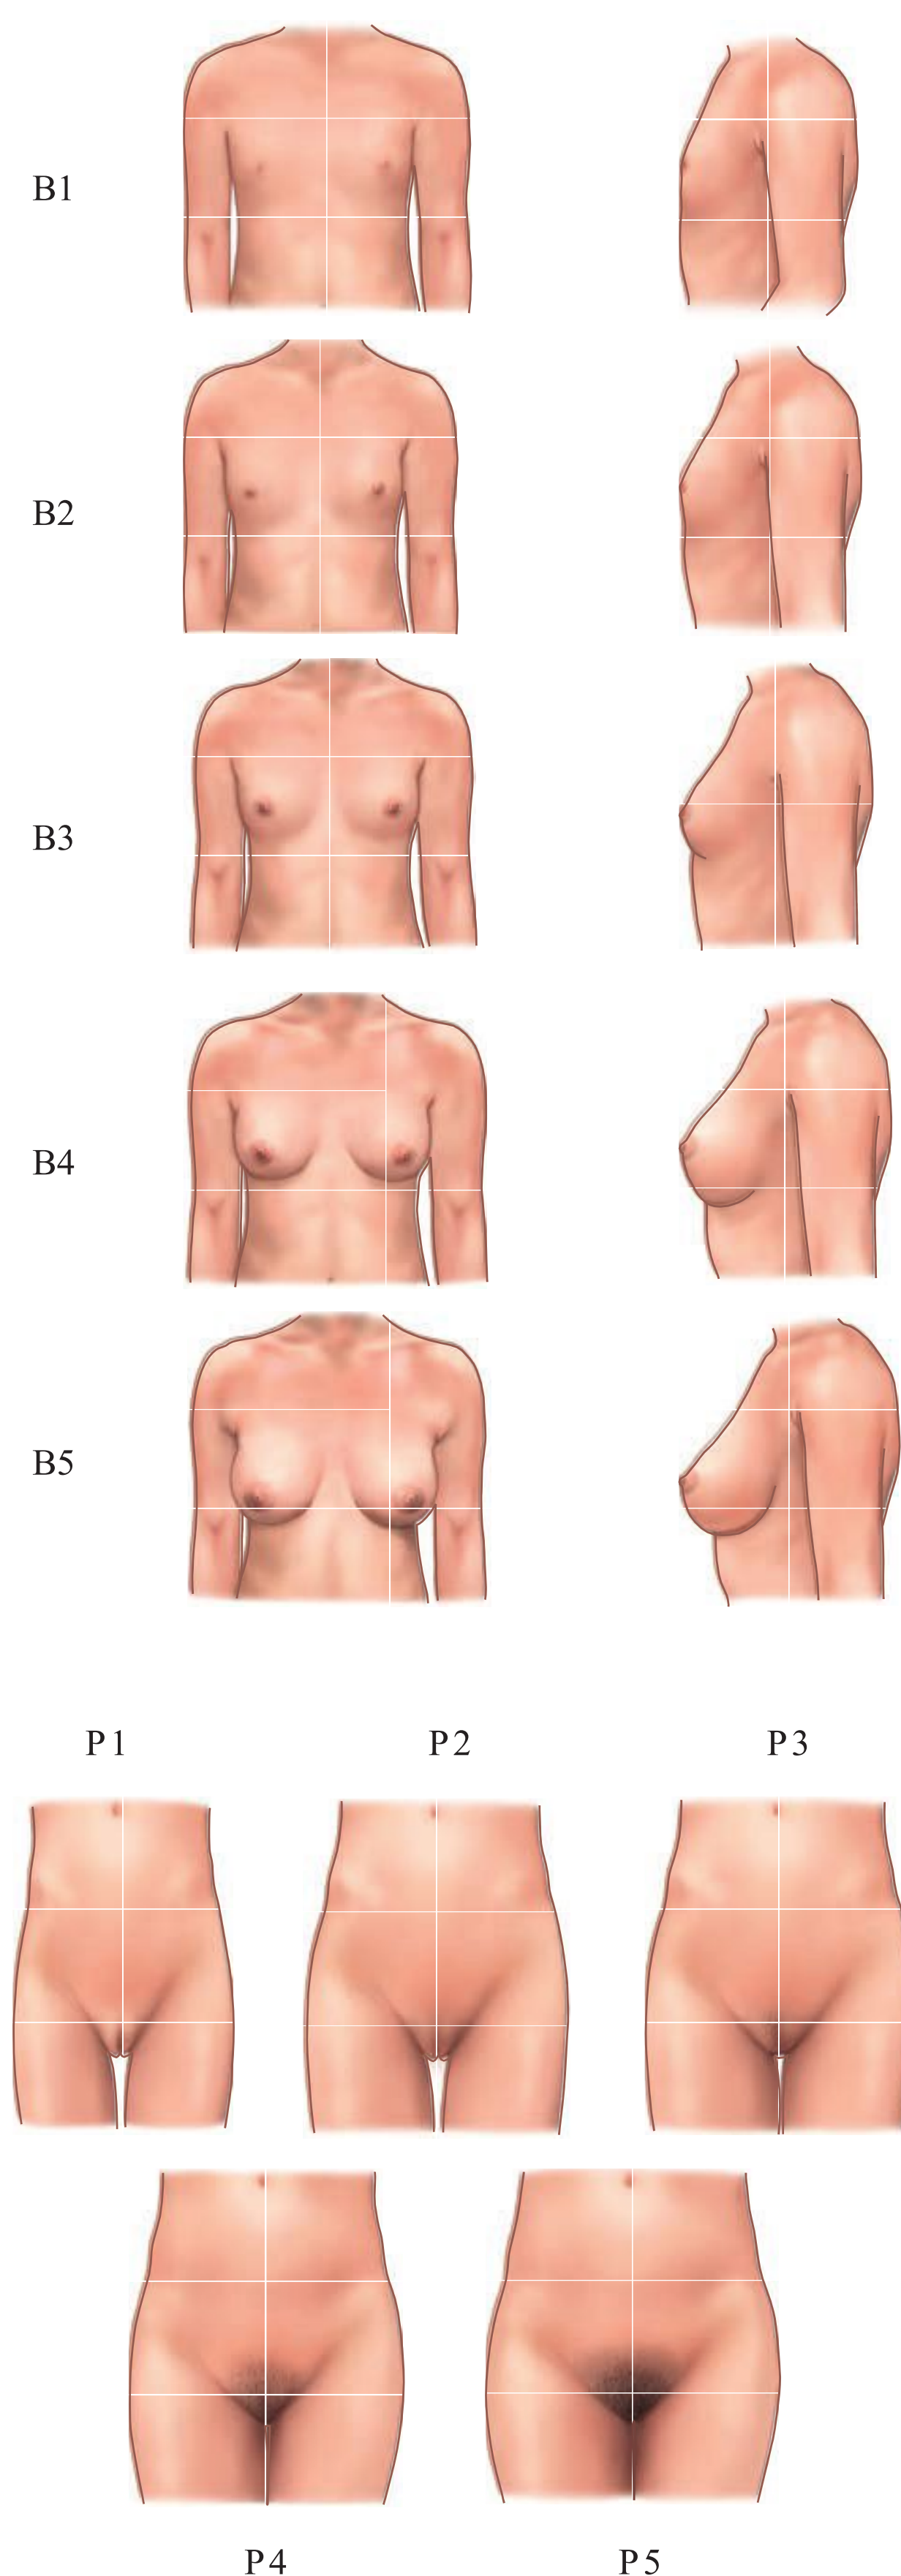

maturation leads to the complex development of secondary sexual characteristics involving the breast, sexual hair, and genitalia, in addition to a limited acceleration in body growth. Each landmark of hormonal and anatomic change during this time represents a spectrum of what is considered “normal.”

Marshall and Tanner (1969) recorded breast and pubic hair development in 192 English schoolgirls and created the *Tanner stages* to describe pubertal development (Fig. 14-3). Initial pubertal changes begin between ages 8 and 13 years in most North American females (Tanner, 1985). Changes before or after are categorized as either precocious puberty

**FIGURE 14-2** Transabdominal pelvic sonograms. **A.** Normal neonatal uterus. Midline longitudinal sonogram of the pelvis in this 3-day-old newborn demonstrates the uterus posterior to the bladder. Yellow arrows mark the fundus, isthmus, and cervix, respectively. The anteroposterior (AP) diameter of the cervix is greater than that of the fundus and creates a spade-shaped uterus. Due to the effect of maternal and placental hormones, a central echogenic endometrial cavity stripe is clearly visible. **B.** Normal prepubertal uterus. Midline longitudinal sonogram of the pelvis in this 3-year-old girl demonstrates the uterus posterior to the bladder. Yellow arrows mark the fundus, isthmus, and cervix, respectively. The uterus is homogeneously hypoechoic. The AP diameter of the cervix is equal to that of the fundus, and this gives the uterus a tubular shape. (Used with permission from Dr. Neil Fernandes.)

**FIGURE 14-3** The Tanner stages of female breast and pubic hair development.

or delayed puberty and warrant evaluation. In most girls, breast budding, termed *thelarche*, is the first physical sign of puberty and begins at approximately age 10 years (Aksglaede, 2009; Biro, 2006). In a minority, pubic hair growth, known as *pubarche*, develops first. Following breast and pubic hair growth, adolescents undergo an accelerated increase in height, termed a *growth spurt*, during a 3-year span from ages 10.5 to 13.5 years.

Since these original population studies, U.S. girls have trended to start thelarche and menarche earlier. Differences in onset timing are also related to race and higher body mass index (BMI) (Biro, 2013; Rosenfield, 2009). For example, higher BMI correlates with earlier pubertal development. The mean age of menarche in white girls is 12.7 years and 6 months earlier, or 12.1, in black girls (Tanner, 1973).

### GYNECOLOGIC EXAMINATION

An adolescent who has reached the age of 18 may consent to medical examination and treatment. Prior to this age, individual state laws govern whether minors can give their own consent for certain kinds of health care. Some examples include: emergency contraception, substance abuse, or sexually transmitted disease treatment. Every state has laws allowing minors to consent to care if they are emancipated, living apart from their parents, or pregnant. The Guttmacher Institute publishes an overview of Minors' Consent Law regularly at [www.agi-usa.org](http://www.agi-usa.org).

A routine yearly examination of a child by her pediatrician generally includes a brief examination of the breasts and external genitalia. Congenital anomalies that are visible externally, such as imperforate hymen, may be identified. Alternatively, if parent or child has a specific complaint regarding vulvovaginal pain, rash, bleeding, discharge, or lesions, a gynecologic examination is directed toward the area of concern.

A parent or guardian should be present at the examination. This allows the child to understand that the examination is sanctioned. Moreover, clinicians can use this opportunity to inform a parent regarding findings and potential treatment. They can also emphasize the concept of inappropriate genital touching by others and parental notification if this occurs. In mid-to-late adolescence, however, a patient may prefer, for privacy reasons, not to be examined with a parent present.

“Child-friendly” objects or pictures and distracting conversation can ease fears and aid examination. Similarly, using an anatomically appropriate doll to explain the steps may decrease anxiety. The examination begins with a less-threatening approach of checking the ears, throat, heart, and lungs. Breasts are inspected. The external genital examination is best performed with the child in a frog-leg or knee-chest position to improve visualization. Occasionally, the patient may feel more comfortable sitting in a parent's lap. Sitting on a chair or examination table, the parent allows the child's legs to straddle the parent's thighs (Fig. 14-4).

Once the child is optimally positioned, each labium may be gently held with a thumb and forefinger and pulled toward the examiner and laterally. In this manner, the introitus, hymen, and lower portion of the vagina are inspected (Fig. 14-5). An

**FIGURE 14-4** Various positions for examination of the pediatric patient (A–D).

**FIGURE 14-5** A. Normal prepubertal genitalia. B. Imperforate hymen.

internal examination is rarely necessary unless a foreign body, tumor, or vaginal bleeding is suspected. This evaluation is best accomplished under general anesthesia. Vaginoscopy may be performed using a hysteroscope or cystoscope to provide illumination as well as irrigation. During vaginoscopy, normal saline is used as the distention medium (Fig. 14-6). The labia majora are manually approximated to occlude the vagina and achieve vaginal distention.

### LABIAL ADHESION

Adhesion between the labia minora begins as a small posterior midline fusion, which is usually asymptomatic. This fusion may remain an isolated minor finding or may progress toward the clitoris to completely close the vaginal orifice. Also termed *labial agglutination*, this adhesion develops in 1 to 5 percent of prepubertal girls and in approximately 10 percent of female infants within the first year of life (Berenson, 1992; Christensen, 1971).

The cause of labial adhesion is unknown, although hypoenestrogenism is implicated. This fusion typically develops in a low-estrogen environment. Namely, it is seen in infants and

**FIGURE 14-6** Photograph taken during vaginoscopy in an 8-year-old female. Typical for prepubertal girls, the cervix is almost flush with the proximal vagina.

young girls and tends to undergo spontaneous resolution at puberty (Jenkinson, 1984). Additionally, erosion of the vulvar epithelium is implicated in some cases of labial adhesion. For example, adhesion can be associated with lichen sclerosus, with herpes simplex viral infection, and with vulvar trauma following sexual abuse (Berkowitz, 1987).

The diagnosis is made visually. The labia majora appear normal, whereas the labia minora are fused with a distinct thin line of demarcation or *raphe* between them (Fig. 14-7). Extensive agglutination may leave only a ventral pinhole meatus between the labia. Located immediately beneath the clitoris, this small opening may lead to urinary dribbling as urine pools behind the adhesion. In these cases, urinary tract infection or urethritis can develop.

Treatment varies according to the degree of scarring and symptoms. In many instances, if the patient is asymptomatic, no intervention is necessary as the adhesion will typically resolve spontaneously with the rise of estrogen levels at puberty. Extensive adhesion with urinary symptoms, however, will require estrogen cream therapy. Estradiol (Estrace) cream or conjugated equine estrogen (Premarin) cream is applied to the fine, thin raphe twice daily for 2 weeks, followed by daily applications for an additional 2 weeks. A generous pea-sized amount of cream is placed with a finger or cotton-tipped applicator onto the raphe. With each application, gentle outward traction is exerted on the labia majora to help separate the adhesion. Similarly, light pressure may also be applied with the cotton applicator itself, as tolerated. After adhesion separation, a petroleum jelly (Vaseline) or vitamins A and D ointment (A&D ointment) may be applied nightly for 6 months to decrease the risk of recurrence. If the adhesion reforms during the subsequent months or years, the process may be similarly

repeated. Occasionally, with overuse of estrogen cream, local irritation, vulvar pigmentation, and minor breast budding may develop, at which time topical treatment is discontinued. These side effects are reversible once treatment is halted. Alternatively, the use of 0.05-percent betamethasone cream applied twice daily for 4 to 6 weeks is another topical option (Mayoglou, 2009; Meyers, 2006).

Manual separation of labial adhesion in an outpatient setting without analgesia is painful and thus generally not advised. In addition, recurrence is much more common. However, if the adhesion persists despite consistent use of estrogen cream, then labia minora separation may be attempted several minutes after applying 5-percent lidocaine ointment to the adhesion raphe.

If separation is not easily accomplished or tolerated, surgical separation is recommended in an operating room under general anesthesia as an outpatient procedure. Midline division of the fused labia, also termed *introitoplasty*, uses an electrosurgical fine tip and does not require suturing. To prevent repeated agglutination after surgery, an estrogen cream is applied nightly for 2 weeks. This is followed by an emollient cream nightly for at least 6 months.

**FIGURE 14-7** Labial adhesion. **A.** Labia minora are agglutinated in the midline. **B.** Resolution and restoration of normal anatomy.

## CONGENITAL ANATOMIC ANOMALIES

Several anatomic and müllerian abnormalities present in early adolescence as obstructions to menstrual outflow. Described in Chapter 18, those most commonly presenting with outlet obstruction include imperforate hymen, transverse vaginal septum, cervical and vaginal agenesis with an intact uterus, obstructed (non-communicating) uterine horn, and the OHVIRA syndrome (obstructed hemivagina with ipsilateral renal agenesis) (Smith, 2007). These are often diagnosed in an adolescent with primary amenorrhea and cyclic pain. Notably, an adolescent with OHVIRA or with an obstructed uterine horn will have menses, but these often become increasingly painful over 6 to 9 months.

## VULVITIS

### ■ Allergic and Contact Dermatitis

Vulvar inflammation may develop in isolation or in association with vaginitis. Allergic and contact dermatitis are common, whereas atopic dermatitis (eczema) and psoriasis are less frequent sources of itching and rash. With allergic and contact dermatitis the underlying pathophysiology varies, but the clinical appearance is usually similar. Vesicles or papules form on bright-red, edematous skin. However, in chronic cases, scaling, skin fissuring, and lichenification may be seen. In response, information regarding the degree of hygiene and continence and exposure to potential skin irritants is sought.

Typical offending agents include bubble baths and soaps, laundry detergents, fabric softeners and dryer sheets, bleach, and perfumed or colored toilet paper (Table 4-1, p. 87). Topical creams, lotions, and ointments used to soothe an area may also be an irritant to some children. For most, removing the offending agent and encouraging once- or twice-daily sitz baths is sufficient. These baths consist of placing two tablespoons of baking soda in warm water and soaking for 20 minutes. If itching is severe, an oral medication may be prescribed, such as hydroxyzine hydrochloride (Atarax) 2 mg/kg/d divided in four doses. Alternatively, a 2.5-percent topical hydrocortisone ointment can be applied twice daily for 1 week. Aside from chemical irritants, children can also develop diaper dermatitis from urine and stool exposure. Corrective measures keep the skin dry by more frequent diaper changes, or they create a moisture barrier by application of emollient creams, such as Vaseline or A&D ointment.

### ■ Lichen Sclerosus

Vulvitis may also be caused by lichen sclerosus. With this, the vulva displays hypopigmentation; atrophic, parchment-like skin; and occasional fissuring. Lesions are usually symmetrical and may form an “hourglass” appearance around the vulva and perianal areas (Fig. 14-8). Occasionally, the vulva develops dark purple vulvar ecchymoses, which may bleed. Over time, if left untreated, the periclitoral area may scar, the labia minora may become attenuated, and the posterior fourchette may fissure and bleed.

Similar to labial adhesion, lichen sclerosus can develop concurrently with hypoestrogenism or with inflammation. Lichen

**FIGURE 14-8** Lichen sclerosus before and after treatment.

**A.** Findings include thin, parchment-like skin on the labia majora, ecchymoses on the labia minora and majora, and mild disease on the perianal skin. Involvement of both the vulva and perianal skin gives a figure-of-eight shape to affected areas. **B.** Skin texture and ecchymoses improved following treatment. (Used with permission from Dr. Mary Jane Pearson.)

sclerosus more commonly affects postmenopausal women and carries risks for vulvar malignancy. This association is not found in affected pediatric patients. The exact pathophysiology of lichen sclerosus is unknown, although an autoimmune process is suspected given its association with Graves thyroiditis, vitiligo, and pernicious anemia. Twin and cohort studies suggest a genetic role (Meyrick Thomas, 1986; Sherman, 2010).

Patients may complain of intense itching, discomfort, bleeding, excoriations, and dysuria. Diagnosis typically relies on visual inspection. However, rarely, a vulvar biopsy may be indicated in children if the classic skin changes are absent.

Treatment consists of topical corticosteroid cream such as 2.5-percent hydrocortisone, applied nightly to the vulva for 6 weeks. If improvement is noted, the dose may be lowered to 1-percent hydrocortisone and continued for 4 to 6 weeks. Thereafter, petroleum-based ointment use and strict attention to hygiene are recommended. Severe cases require a more potent corticosteroid such as 0.05-percent clobetasol propionate

(Temovate), applied twice daily for 2 weeks. The initial dosing is followed by an individualized regimen, which slowly tapers the dose to a once-weekly bedtime application. The long-term prognosis for childhood lichen sclerosus is unclear. Although some cases resolve at puberty, small case series suggest that as many as 75 percent of affected children have disease that persists or recurs following puberty (Berth-Jones, 1991; Powell, 2002; Smith, 2009).

■ Infection

Some common infectious organisms that may cause prepubertal vulvitis include group A beta-hemolytic streptococcus, *Candida* species, and pinworms. With group A beta-hemolytic streptococcus, the vulva and introitus may be bright “beefy” red, and symptoms include dysuria, vulvar pain, pruritus, or bleeding. In most cases, vulvovaginal culture and clinical setting typically lead to diagnosis. Group A beta-hemolytic streptococcus is treated with an oral first-generation penicillin or cephalosporin or other appropriate antibiotic for 2 to 4 weeks.

Candidiasis is rare in prepubertal girls. It more often develops during the first year of life, after a course of antibiotics, or in females with juvenile diabetes or immunocompromise. A reddened, raised rash with well-demarcated borders and occasional satellite lesions is typical. Microscopic examination of a vaginal sample prepared with 10-percent potassium hydroxide (KOH) will help identify hyphae (Fig. 3-6, p. 61). For treatment, antifungal creams such as clotrimazole, miconazole, or butoconazole are applied to the vulva twice daily for 10 to 14 days or until the rash clears.

*Enterobius vermicularis*, also known as *pinworm*, can create intense vulvar itching. Nocturnal pruritus results from an intestinal infection with these 1-cm-long threadlike white worms that often exit the anus at night. Inspecting this area with a flashlight at night, parents may identify worms perianally. The “Scotch-tape test” entails pressing a piece of cellophane tape to the perianal area in the morning, affixing the tape to a slide, and visualizing parasite eggs by microscopy. Treatment is albendazole (Albenza) 200 to 400 mg in a single-dose chewable tablet.

VULVOVAGINITIS

Several months after birth, as estrogen levels wane, the vulvovaginal epithelium becomes thin and atrophic. As a result, the vulva and vagina are more susceptible to irritants and infections until puberty, and vulvovaginitis is a common prepubertal problem. Three fourths of vulvovaginitis cases in this age group are nonspecific, with culture results yielding “normal flora.” Alternatively, several infectious agents, discussed subsequently, may be identified.

With nonspecific vulvovaginitis, the pathogenesis is not well defined, but known instigating factors are included in Table 14-1. Symptoms include itching, vulvar redness, discharge, dysuria, and odor. Most children and those adolescents who are not sexually active tolerate speculum examination poorly. But a vaginal swab for bacterial culture can be comfortably obtained. In cases of nonspecific vulvovaginitis, cultures typically only isolate normal vaginal flora. Culture results that reveal bowel

TABLE 14-1. Causes of Vulvovaginitis in Children

Poor vulvar hygiene
Short distance from the anus to the vagina
Inadequate front-to-back wiping after bowel movements
Lack of labial fat pads and labial hair
Nonestrogenized vulvovaginal epithelium
Vaginal foreign body
Chemical irritants such as soaps
Coexistent eczema or seborrhea
Chronic disease or altered immune status
Sexual abuse

flora suggest contamination with fecal aerobes. Treatment attempts to correct the underlying cause. Itching and inflammation may be relieved with a low-dose topical corticosteroid such as hydrocortisone, 1 or 2.5 percent. Occasionally, severe itching can lead to a secondary bacterial infection that requires oral antibiotics. Oral agents often selected are amoxicillin, an amoxicillin plus clavulanic acid combination, or a similar cephalosporin given during a 7- to 10-day course.

Infectious vulvovaginitis often presents with a malodorous, yellow or green purulent discharge, and vaginal cultures are routinely obtained in these cases. The respiratory pathogen group A beta-hemolytic streptococcus is the most common specific infectious agent found in prepubertal females and is isolated from 7 to 20 percent of girls with vulvovaginitis (Pierce, 1992; Piippo, 2000). Treatment of group A beta-hemolytic streptococcus consists of amoxicillin, 40 mg/kg, taken orally three times daily for 10 days. Less frequently, other respiratory pathogens found include: *Haemophilus influenzae*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*. Enteric pathogens such as *Shigella* and *Yersinia* species may also be found by culture of vaginal discharge. Classically, *Shigella* species incite a mucopurulent bloody discharge, which typically follows diarrhea caused by the same organism. Treatment is with oral trimethoprim-sulfamethoxazole (TMP-SMZ), 6 to 10 mg/kg/d, divided and given every 12 hours (Bogaerts, 1992).

As discussed in Chapter 13, sexual abuse may lead to infections, including those caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, herpes simplex virus (HSV), *Trichomonas vaginalis*, and human papillomavirus (HPV). The clinical presentation of each mirrors the infectious findings in adults. Perinatal vertical transmission and latency may permit some of these to persist into infancy and childhood (Chap. 13, p. 310). Long latency and several possible modes of transmission rendered HPV especially difficult to assign origin (Fig. 14-9) (Unger, 2011). That said, child protective services are notified of any child suspected to be the victim of sexual abuse.

GenITAL Trauma

The prepubertal vulva is less protected from blunt injury due to the lack of labial fat pads. In addition, children are more physically active, thereby increasing the trauma risk. Fortunately, most injuries to the vulva are blunt, minor, and accidental. Sharp-object penetration, however, may cause more serious

**FIGURE 14-9** Surgical excision of extensive perianal and vulvar condyloma in a prepubertal girl.

injury to the vulvovaginal area. Sexual or physical abuse is also considered. Management of vulvovaginal trauma is discussed in more detail in Chapter 4 (p. 100).

## OVARIAN TUMORS

Ovarian masses, typically cysts, are common in childhood. They may be found prenatally during maternal sonographic evaluation or during prepubertal years and adolescence. Although most are benign, approximately 1 percent of all malignant tumors in this age group are ovarian (Breen, 1977, 1981).

Fetal and neonatal ovarian cysts are typically cystic and identified incidentally during maternal sonographic examination. Although the true incidence of fetal ovarian cysts is not known, some cystic development has been reported in 30 to 70 percent of female fetuses (Brandt, 1991; Lindeque, 1988). Most fetal cysts result from maternal hormonal stimulation in utero. Those during the neonatal period and infancy usually develop from the postnatal gonadotropin surge seen with the withdrawal of maternal hormones after birth. They are usually simple, unilateral, asymptomatic, and regress spontaneously by 4 months after birth, whether they are simple or complex. The risk of malignancy is low, although rupture, intracystic hemorrhage, visceral compression, and torsion followed by autoamputation of the ovary or adnexa may be uncommon complications.

For uncomplicated fetal or neonatal cysts measuring less than 5 cm in diameter, appropriate management is observation and sonographic examination every 4 to 6 weeks (Bagolan, 2002; Nussbaum, 1988; Papic, 2014). For simple cysts measuring greater than 5 cm, percutaneous cyst aspiration has been described to prevent torsion (Bryant, 2004; Noia, 2012). Large complex ovarian cysts that do not regress postnatally require surgical excision.

In children, most ovarian masses are cystic and symptoms vary. Asymptomatic cysts may be discovered incidentally during abdominal examination or during sonographic examination for some other indication. Enlarging cysts can increase abdominal girth or cause chronic pain. Hormone-secreting cysts may lead to isosexual or heterosexual precocious puberty, and thus

evaluation for signs of early pubertal development is indicated. Moreover, rupture, hemorrhage, or torsion may precipitate acute abdominal pain, similar to that seen in adults.

For imaging, a prepubertal child will not tolerate sonographic examination with a transvaginal probe. Thus, in this age group, transabdominal pelvic sonography is most frequently used. Computed tomography (CT) is helpful if a mature cystic teratoma (dermoid cyst) is suspected, as fat is better appreciated with this modality. Although magnetic resonance (MR) imaging is preferred for congenital müllerian anomaly evaluation, it is less helpful than pelvic sonography for ovarian mass determination. The most common complex cysts found in childhood and adolescence are germ cell tumors, specifically benign mature cystic teratoma (Panteli, 2009). Rarely, tumors may be malignant germ cell tumors or epithelial ovarian tumors (Schultz, 2006; Tapper, 1983).

As with those of the fetal and neonatal periods, small simple ovarian cysts without septation or internal echoes may be monitored with serial sonographic examination. Most less than 5 cm will resolve within 1 to 4 months (Tind, 1989). Persistent or enlarging cysts warrant surgical intervention, and laparoscopy is preferred. Optimal management includes fertility-sparing ovarian cystectomy with preservation of normal ovarian tissue.

Following puberty, ovarian cysts in adolescents, as in adults, are frequent. Management mirrors that of adnexal masses found in adults as described in Chapter 9 (p. 215).

## BREAST DEVELOPMENT AND DISEASE

Some newborns may have minor breast budding due to transplacental passage of maternal hormones in utero. Similarly, newborn breasts may produce *witches' milk*, which is a bilateral white nipple discharge, also a result of maternal hormone stimulation. Both effects are transient and diminish over several weeks to months.

At puberty, under the influence of ovarian hormones, the breast bud grows rapidly. The epithelial sprouts of the mammary gland branch further and become separated by increasing deposition of fat. Such breast development, termed *thelarche*, begins in most girls between the ages of 8 and 13 years. Thelarche prior to age 8 or lack of breast development by age 13 is considered abnormal and investigated (p. 327).

Breast examination begins in the newborn period and extends through the prepubertal and adolescent years, as abnormalities can develop in any age group. Assessment includes inspection for accessory nipples, infection, lipoma, fibroadenoma, and premature thelarche.

## ■ Polythelia

Accessory nipples, also termed *polythelia*, are common and noted in 1 percent of patients. Most frequently, a small areola and nipple are found along the embryonic milk line, which extends from the axilla to the groin bilaterally. Accessory nipples are usually asymptomatic, and excision is not required. Rarely, however, they may contain glandular tissue that can lead to pain, nipple discharge, or development of fibroadenomas.

## ■ Premature Thelarche

Thelarche may begin before age 8 in some girls and if early, is most commonly seen in girls younger than 2 years. This early breast maturation is termed *premature thelarche*. It differs from precocious puberty in that it is self-limited and develops in isolation, without other signs of pubertal development. Premature thelarche is suspected when minimal breast tissue growth or nipple maturation is noted during surveillance, but the patient's height, which is measured to exclude a growth spurt, falls within established percentile curves. Monitoring body growth and breast changes alone may suffice, but in those with increased height or weight or with other pubertal changes, additional testing for precocious puberty is warranted. Thus, analysis of the patient's growth curve and Tanner stage; a radiographic bone age study; and gonadotropin measurement may be indicated (p. 328).

To explain bone age, as children develop, their bones change in size and shape. These changes can be seen radiographically and can be correlated with chronologic age. Thus, the radiographic "bone age" is the average age at which children in general reach a particular stage of bone maturation. Girls with early estrogen excess from precocious puberty show growth-rate acceleration, rapid bone age advancement, early cessation of growth, and eventual short stature because of this early cessation. Bone age can be determined at many skeletal sites, and the hand and wrist are the most commonly selected.

Premature thelarche is suggested if the bone age is synchronous and thus falls within 2 standard deviations of chronologic age. However, if the bone age is advanced by 2 or more years, puberty has begun and evaluation of precocious puberty is indicated. In those with isolated premature thelarche, serum estradiol levels may be slightly elevated, and this is seen more commonly in those who were very low-birthweight infants (Klein, 1999; Nelson, 1983). In addition, serum gonadotropin levels are in the prepubertal range. In most cases, premature breast development regresses or stabilizes, and treatment consists of reassurance with careful surveillance for other signs of precocious puberty.

## ■ Breast Shape

Growth during early breast development in girls aged 13 to 14 years may be asymmetric. The etiology is not known. However, in some cases, sports injury or surgical trauma during early breast development may lead to asymmetry (Goyal, 2003; Jansen, 2002). Examination seeks to exclude a breast mass such as a fibroadenoma or cyst. If no mass is identified, then yearly breast examinations determine the extent and persistence of asymmetry. In most cases, asymmetry will resolve by the completion of breast maturity (Templeman, 2000). Therefore, a decision toward surgical intervention is not made until full breast growth is attained. Until that time, adolescents may be fitted with padded bras or even prosthetic inserts to ensure symmetry when fully clothed.

Extremely large breasts without concurrent large breast masses can rarely develop in adolescence. Such breast hypertrophy can incite back pain, shoulder discomfort from bra-strap pressure, kyphosis, and psychologic distress. These young women will often seek reduction mammoplasty, but surgery is delayed until breast growth is completed. This is determined by serial breast measurements and is typically between the ages of 15 and 18 years.

**FIGURE 14-10** Comparison of normal and tuberous breast development. (Modified with permission from Grolleau JL, Lanfrey E, Lavigne B, et al: Breast base anomalies: treatment strategy for tuberous breasts, minor deformities, and asymmetry, *Plast Reconstruct Surg* 1999 Dec;104(7):2040–2048.)

Tuberous breasts are another growth variant (Fig. 14-10). With normal development, growth on the breast's ventral surface projects the areola forward, and circumferential peripheral growth enlarges the breast base. In some adolescents, the fascia is densely adhered to the underlying muscle and prohibits peripheral breast growth. Only forward breast growth is permitted, and *tuberous breasts* form. This appearance can also follow exogenous hormone replacement that may be prescribed to girls with a lack of breast development from genetic, metabolic, or endocrine conditions. In these conditions, to avoid tuberous development, hormone replacement is initiated at small dosages and gradually increased over time. For example, transdermal estrogen (estradiol patch), 0.025 mg, may be applied twice a week for 6 months, followed by incremental dose increases every 6 months, through doses 0.05 mg and 0.075 mg, to finally reach 0.1 mg twice a week. Medroxyprogesterone acetate (Provera), 10 mg, is given orally each day for 12 days of the month to prompt withdrawal periods. Once estrogen patch dosing has reached 0.1 mg daily, the patient may alternatively be placed on a low-dose oral contraceptive pill instead.

## ■ Absent Breast Development

Congenital absence of breast glandular tissue, termed *amastia*, is rare. More commonly, a lack of breast development results from low estrogen levels caused by constitutionally delayed puberty, chronic disease, Poland syndrome, radiation or chemotherapy, genetic disorders such as gonadal dysgenesis, or extremes of physical activity. Treatment is based on the etiology. For example, once a competitive athlete completes her career, breast development may begin spontaneously without hormonal treatment. In contrast, to prompt breast development and prevent osteoporosis, patients with gonadal dysgenesis will require some form of hormonal replacement, such as that described in the preceding section.

## ■ Breast Mass or Infection

Breast lump complaints in an adolescent often reflect fibrocystic changes. These are characterized by patchy or diffuse,

bandlike thickenings. For discrete breast masses, sonography is selected to distinguish cystic from solid mass and to define cyst qualities (Garcia, 2000). In contrast, mammography has a limited role. Its limited sensitivity and specificity in young developing dense breast tissue yields high rates of false-negative results (Williams, 1986).

Actual breast cysts are found on occasion and will usually resolve spontaneously over a few weeks to months. If a cyst is large, persistent, or symptomatic, a fine-needle aspiration may be performed using local analgesia in an office setting.

Similarly, most breast masses in children and adolescents are benign and may include normal but asymmetric breast bud development, fibroadenoma, fibrocyst, lymph node, or abscess. The most common breast mass identified in adolescence is a fibroadenoma, which accounts for 68 to 94 percent of all masses (Daniel, 1968; Goldstein, 1982). Fortunately, breast cancer in pediatric populations is rare, and cancer complicated less than 1 percent of breast masses identified in this group (Gutierrez, 2008; Neinstein, 1994). Primary breast cancer may develop more frequently in pediatric patients with a history of prior radiation, especially treatment directed to the chest wall. Additionally, metastatic disease is a consideration in those with cancer.

Treatment of breast masses includes observation, needle biopsy, and surgical excision. Observation may be appropriate for small asymptomatic lesions considered to be fibroadenomas. Masses that are symptomatic, large, or enlarging are preferably excised, and techniques mirror those in the adult (Chap. 12, p. 276). For any mass not surgically excised, clinical surveillance is recommended to ensure mass stability.

Mastitis is rare in the pediatric population. Its incidence displays a bimodal distribution that peaks in the neonatal period and in children older than 10 years. The etiology in these cases is unclear, but the association with breast enlargement during these two periods has been implicated. *Staphylococcus aureus* is the most common isolate, and abscess develops more commonly than in the adult (Faden, 2005; Montague, 2013; Stricker, 2006). In adolescents, infections may be associated with lactation and pregnancy, trauma from sexual foreplay, shaving periareolar hair, and nipple piercing (Templeman, 2000; Tweeten, 1998). Infections are treated with antibiotics and occasional drainage if an abscess has formed.

## VAGINAL BLEEDING

Neonates may present with vaginal bleeding during the first week of life due to the withdrawal of maternal hormones at birth. Bleeding typically resolves after a few days. Prepubertal bleeding in a child, however, merits careful evaluation (Table 14-2). Most instances of vaginal bleeding in these girls are due to local causes and can be elucidated with a simple history and physical examination. Occasionally, an examination under anesthesia with saline vaginoscopy is required for diagnosis, particularly if a foreign body is present in the upper vagina (Fig. 14-11).

## PRECOCIOUS PUBERTY

Early pubertal development may be seen in both sexes, but females are much more commonly affected, with a sex ratio

**TABLE 14-2.** Causes of Vaginal Bleeding in Children

of 23:1 (Bridges, 1994). For girls, precocious puberty has historically been defined as breast or pubic hair development in those younger than 8 years. However, Herman-Giddens and colleagues (1997) noted that girls in the United States overall are undergoing normal pubertal development at younger ages than previously reported. In addition, racial differences exist. Puberty begins earliest in black girls, followed by Hispanic and white girls. Accordingly, to limit the proportion of girls requiring unneeded assessment for precocious puberty, some have suggested lowering the threshold age for evaluation (Herman-Giddens, 1997; Kaplowitz, 1999).

Premature pubertal development may result from various causes. These have been categorized based on pathogenesis and include central precocious puberty, peripheral precocious puberty, heterosexual precocious puberty, and temporal variation of normal puberty. Most girls evaluated are found to have normal pubertal development that has merely begun prior to standard temporal milestones and does not stem from identifiable pathology. However, because many of the underlying etiologies of precocious puberty carry significant sequelae, girls with early pubertal development are fully evaluated when identified.

### Central Precocious Puberty (Gonadotropin Dependent)

Early activation of the hypothalamic-pituitary-ovarian axis leads to pulsatile GnRH secretion, increased gonadotropin

**FIGURE 14-11** A clump of retained toilet paper was the foreign body found in this prepubertal girl.

formation, and in turn, increased gonadal steroid levels. Often termed *true precocious puberty*, central precocious puberty is rare and affects 1 in 5000 to 10,000 individuals in the general population (Partsch, 2002). The most common cause of central precocious puberty is idiopathic, however, central nervous system lesions must be excluded (Table 14-3).

Symptoms of central precocious puberty are similar to those of normal puberty but at an earlier age. As outlined in Table 14-4, testing includes radiographic measurement of hand and wrist bone age. In affected girls, advanced skeletal maturation is seen. In addition, serum FSH, LH, and estradiol levels are elevated for chronologic age and typically lie in the pubertal range. Early in the process, however, FSH and LH levels may be elevated only in the evenings, and a leuprolide stimulation test can be helpful. During leuprolide stimulation, baseline FSH, LH, and estradiol levels are obtained. Leuprolide (Lupron) (20 µg/kg intravenous and not to exceed 500 µg) is given, and FSH plus LH levels are measured at 1, 2, and 3 hours. An estradiol level is measured at 24 hours. Central precocious puberty is confirmed by a rise in serum LH levels following infusion. In those with elevated gonadotropin levels, MR imaging of the central nervous system may identify a cerebral abnormality associated with central precocious puberty. Pelvic sonography is performed when the estradiol level is high and gonadotropin levels are suppressed to check for ovarian cysts.

TABLE 14-3. Common Etiologies of Precocious Puberty

<b>Central (Gnr H-dependent)</b>
Idiopathic <sup>a</sup>
CNS tumors
CNS anomaly
CNS infection
Head trauma
Ischemia
Iatrogenic: radiation, chemotherapy, surgical
<b>Peripheral (Gnr H-independent)</b>
Estrogen- or testosterone-producing tumors (adrenal or ovarian)
Gonadotropin- or hCG-producing tumors
Congenital adrenal hyperplasia
Exogenous androgen or estrogen exposure
McCune-Albright syndrome
Ovarian follicular cysts
Primary hypothyroidism
Aromatase excess syndrome
Glucocorticoid resistance

<sup>a</sup>The most common cause of precocious puberty is idiopathic.  
CNS = central nervous system; GnRH = gonadotropin-releasing hormone; hCG = human chorionic gonadotropin.

<sup>a</sup>Serum levels of the cited hormones.  
CNS = central nervous system; DHEAS = dehydroepian-drosterone sulfate; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

Treatment goals focus on preventing short adult height and limiting the psychologic effects of early pubertal development. Epiphyseal fusion is an estrogen-dependent process. Accordingly, girls with precocious puberty are at risk for early growth-plate closure and short stature in adulthood. Treatment consists of a GnRH agonist, which serves to downregulate pituitary gonadotropes and inhibit FSH and LH release. Estrogen levels drop, and often there is a marked regression of breast and uterine size. If therapy is instituted after menses have begun, menstrual periods will cease. Timing for the discontinuation of GnRH therapy and reinitiation of pubertal development is determined by the primary therapy goals: maximizing height, synchronizing puberty with peers, and allaying psychological distress. From a review of several studies, the mean age at treatment discontinuation was approximately 11 years (Carel, 2009).

■ **Peripheral Precocious Puberty (Gonadotropin Independent)**

Less commonly, elevated estrogen levels may originate from a peripheral source, such as an ovarian cyst. Termed peripheral precocious puberty, this category is characterized by lack of GnRH pulsatile release, low levels of pituitary gonadotropins, yet increased serum estrogen concentrations.

Although the originating source is variable, the most common cause is a granulosa cell tumor, accounting for more than 60 percent of cases (Emans, 2005). Other types of ovarian cysts, adrenal disorders, iatrogenic disorders, and primary hypothyroidism are additional causes (see Table 14-3). McCune-Albright syndrome is characterized by a “triad” of polyostotic fibrous dysplasia, irregular café-au-lait spots, and endocrinopathies. Precocious puberty is a frequent finding and results from estrogen production in the ovarian cysts that are common in these girls.

Testing of girls with peripheral precocious puberty finds estrogen levels that are characteristically elevated, whereas serum levels of LH and FSH are low. Bone age determination shows advanced aging, and GnRH stimulation shows no elevation in serum LH levels.

Treatment aims to eliminate estrogen. For those with exogenous exposure, halting the estrogen source, such as hormonal pills or creams, is sufficient. An estrogen-secreting ovarian or adrenal tumor will require surgical excision, and hypothyroidism is treated with thyroid hormone replacement.

## ■ Heterosexual Precocious Puberty

Androgen excess with signs of virilization is rare in childhood (Chap. 17, p. 389). Termed *heterosexual precocious puberty*, this condition is most commonly caused by increased androgen secretion in young females from the adrenal gland or ovary. Causes include androgen-secreting ovarian or adrenal tumors, congenital adrenal hyperplasia, Cushing syndrome, and exposure to exogenous androgens. Treatment is directed at correction of the underlying etiology.

## ■ Variations of Normal Puberty

Although standardized age guidelines accurately reflect the timing of pubertal development in most girls, others begin development early. Premature thelarche, premature adrenarche, and premature menarche describe the premature pubertal development of breast tissue, pubic hair, and menses, respectively. Each develops in isolation and without other evidence of pubertal development.

As described earlier (p. 327), *premature thelarche* is a diagnosis of exclusion, and evaluation for precocious puberty in these girls reveals bone ages consistent with chronologic age. Normal FSH and LH levels, normal or slightly elevated estradiol levels, normal pelvic sonographic examination, and normal growth are noted. Treatment consists of careful surveillance and reassurance that the remainder of pubertal development will progress at a normal age.

*Adrenarche* is the onset of dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEAS) production from the adrenal zona reticularis, which can be detected around age 6 years. The phenotypic result of adrenarche is axillary and pubic hair development, termed *pubarche*, which begins in girls at approximately age 8 years (Auchus, 2004). *Premature adrenarche* is defined therefore as the growth of pubic hair prior to age 8, but other signs of estrogenization or virilization are absent. Most girls will have an increased level of DHEAS, which suggests that the adrenal gland is maturing prematurely (Korth-Schultz, 1976). Some girls with premature adrenarche are found to develop polycystic ovarian syndrome in adolescence (Ibanez, 1993; Miller, 1996). Others have a partial deficiency of 21-hydroxylase. Therefore, girls with premature adrenarche are screened for precocious puberty. When isolated, premature adrenarche treatment includes reassurance and monitoring at 3- to 6-month intervals for other signs of puberty.

Uterine bleeding that occurs once for several days or monthly, without other signs of puberty, is termed *premature menarche*. The condition is rare, and other sources of bleeding are considered and excluded first.

**TABLE 14-5.** Causes of Delayed Puberty

### **Constitutional (physiologic delay)<sup>a</sup>**

Excessive exercise

Stress, depression

<sup>a</sup>The most common cause of delayed puberty.

GnRH = gonadotropin-releasing hormone; PCOS = polycystic ovarian syndrome.

## **DeLAYeD PUBerTY**

Puberty is considered delayed if no secondary sexual characteristics are noted by age 13, which is more than 2 standard deviations from the mean age, or if menses have not commenced by age 16. Delayed puberty affects 3 percent of adolescents. Causes include those in Table 14-5. With the exception of constitutional delay, these other abnormalities are discussed in greater detail in Chapters 16 and 18.

*Constitutional delay* is the most common cause, and adolescents lack both secondary sexual characteristics and pubertal growth spurt by age 13 years (Albanese, 1995; Malasano, 1997). The probable cause is a delay in reactivation of the GnRH pulse generator (Layman, 1994). Patients may be started on low-dose estrogen until puberty progresses, at which point estrogen may be discontinued. During low-dose estrogen treatment, it is not necessary to introduce progesterone withdrawal because in early puberty there is a similar long period of unopposed estrogen prior to ovulatory cycles.

## **SeXUALITY**

### ■ Gender Identity

In most cases, phenotypic gender directs rearing practices, and girls are “raised as girls” and boys are “raised as boys.”

Gender-appropriate clothes and behaviors are adopted by the child and reinforced by parental approval. Behaviors in conflict with gender are generally discouraged. However, young children will often explore various behaviors, both masculine and feminine, which make up normal experiences in the process of sex-role socialization (Mischel, 1970; Serbin, 1980).

In cases of ambiguous genitalia in the newborn, sexual assignment is more challenging. Initially, life-threatening disease such as congenital adrenal hyperplasia is excluded. As outlined in Chapter 18, gender assignment may be best delayed until test results identify genetic gender and the underlying problem.

The final gender assignment in such cases is termed the *sex of rearing* and reflects the pattern of gender behavior to be emphasized. The final determination for the sex of rearing is based not only on the individual's karyotype but also on the functional capacity of the external genitalia. For example, boys born with congenital absence of the penis, a rare disorder, are usually raised as females after bilateral orchiectomy and reconstruction of the scrotum to have the appearance of labia. If parental attitudes towards the assigned gender are consistent, most children assume the sex of rearing regardless of their genotype.

*Gender dysphoria* describes individuals who perceive themselves to be different from their assigned gender. In the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), this is a recognized psychiatric diagnosis but is not considered a psychiatric disorder (American Psychiatric Association, 2013). That said, the discordance may cause depression and anxiety. One New Zealand survey of 8166 adolescents showed a prevalence of 1.2 percent for this condition (Clark, 2014). This perception can present as early as age 2 to 3 years. At our institution, the Gender Education and Care Interdisciplinary Support (GENCIS) Clinic provides a multidisciplinary approach to treating the psychological, social, and medical needs of this population of children.

## ■ Adolescent Sexuality

Adolescent sexuality develops during a period of rapid change that provides opportunities for adolescents to experience both risk-taking and health-promoting behaviors. Data from a large survey of U.S. adolescents reveal that the percentage of those who become sexually active increases steadily after age 14 (Liu, 2015).

Adolescents view providers as an important resource for information and education regarding healthy sexual development. However, many parents and educators oppose sexuality education because of concerns that providing such information will encourage the onset of intercourse, termed *coitarche*, and will increase intercourse frequency. On the contrary, studies find that such education actually delays the onset and frequency of sexual activity, increases contraceptive use, and reduces the rate of unprotected intercourse (Kirby, 1999, 2001). One survey noted that 75 percent of adolescents attending grades 7 through 12 reported that they received classes in sexuality education (Hoff, 2000). A large percentage wanted more information on specific topics such as contraception, sexually transmitted diseases (STDs), condom use, and emotional issues.

Oral sex is now more commonplace among adolescents. The National Survey of Family Growth in 2005 reported that

one in four adolescents aged 15 to 19 years who had not had vaginal intercourse reported practicing oral sex with an opposite partner. Of those adolescents who practiced sexual intercourse, 83 percent of females and 88 percent of males stated they had engaged in oral sex (Mosher, 2005). Adolescents may see oral sex as an alternative way to maintain their “virginity,” prevent pregnancy, or avoid STDs, or they may perceive it as a step on the way to engaging in sexual intercourse with a dating partner.

Sexual activity and partner violence appear to have a frequent association in adolescent populations (Chap. 13, p. 311). For example, Kaestle and Halpern (2005) noted that violent victimization was more likely to occur in romantic relationships that included sexual intercourse (37 percent) compared with those that did not (19 percent). Abma and colleagues (2010) reported that among females with coitarche before age 20, 7 percent described their first intercourse as nonvoluntary.

## ■ Contraception

Despite wide availability of contraceptive options, nearly one half of pregnancies in the United States are unintended (Finer, 2014). Of adolescents, more than 20 percent do not use contraception at first intercourse, and there is a median delay of 22 months before seeking prescription methods after the sexual debut (Finer, 1998).

The most commonly used contraceptive by adolescents is the combination oral contraceptive (COC) pill. The intrauterine device and the etonogestrel implant are long-acting reversible contraceptives (LARC), and the American College of Obstetricians and Gynecologists (2014) now recommends the etonogestrel implant and the intrauterine device as first-line contraceptive options for adolescents. One study of 179 adolescents found an 85-percent continuation rate after 1 year with the levonorgestrel-releasing IUD (Paterson, 2009). Ideally, counseling begins prior to onset of sexual activity and includes discussion of emergency contraception. Many adolescents have misperceptions about contraception, including beliefs that it may cause infertility or birth defects. Such concerns may be important topics during contraceptive counseling.

Pelvic examination is not necessary when a contraceptive is prescribed if no other complaints are present. Moreover, guidelines from the American College of Obstetricians and Gynecologists (2012) note that cervical cancer screening does not usually begin until age 21 regardless of sexual activity. HIV-positive status is an exception, and full screening recommendations are described in Chapter 29 (p. 634). Sexually active adolescents are counseled and screened for gonorrhea and chlamydial infection (U.S. Preventive Services Task Force, 2014). For adolescents, the preferred method is collection of a urine sample for nucleic acid amplification testing (NAAT). Other STDs are screened as clinically indicated.

Information on HPV vaccination can also be offered. HPV vaccines, Cervarix, Gardasil 4, and Gardasil 9 are approved by the Food and Drug Administration for females aged 9 through 26 years and males ages 9 through 15. A series of three doses for girls, beginning with a first injection at age 11 or 12 years, is recommended (Kim, 2015). A second dose is administered 1 to 2 months later, and a third dose is given 6 months after the

initial one. These vaccines are discussed further in Chapter 29 (p. 630).

For these types of services, the Supreme Court has ruled that minors have the right to contraceptives (*Carry v. Population Services International*). Moreover, current law dictates that all states provide consent to adolescents for treatment of “medically emancipated” conditions such as contraception, STDs, pregnancy, substance abuse, and mental health. These are legally designated medical situations for which an adolescent may receive care without the permission or knowledge of a parent or legal guardian (Akinbami, 2003).

To smooth the transition to adult care, the American College of Obstetricians and Gynecologists (2015) has published guidelines, which include ages 18 to 26 years. In addition to contraception, providers ideally discuss and screen for sexual and mental health, sleep disorders, nutrition, safety, and substance abuse.

Reproductive endocrinology is the study of hormones and neuroendocrine factors that are produced by and/or affect reproductive tissues. These tissues include the hypothalamus, anterior pituitary gland, ovary, endometrium, and placenta.

A hormone is classically described as a cell product that is secreted into the peripheral circulation and that exerts its effects in distant target tissues (Fig. 15-1). This is termed *endocrine secretion*. Additional forms of cell-to-cell communication exist in reproductive physiology. *Paracrine* communication, common within the ovary, refers to chemical signaling between neighboring cells. *Autocrine* communication occurs when a cell releases substances that influence its own function. Production of a substance within a cell that affects that cell before secretion is termed an *intracrine* effect.

A neurotransmitter, in classic neural pathways, crosses a small extracellular space called a synaptic junction and binds to dendrites of a second neuron (Fig. 15-2). Alternatively, these factors are secreted into the vascular system and are transported to other tissues where they exert their effects in a process termed *neuroendocrine secretion* or *neuroendocrine signaling*. One example is gonadotropin-releasing hormone (GnRH) secretion into the portal vasculature with effects on the gonadotropes within the anterior pituitary gland.

Normal reproductive function requires precise quantitative and temporal regulation of the hypothalamic-pituitary-

ovarian axis (Fig. 15-3). Within the hypothalamus, specific centers or nuclei release GnRH in pulses. This is a decapeptide that binds to surface receptors on the gonadotrope subpopulation of the anterior pituitary gland. In response, gonadotropes secrete glycoprotein gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), into the peripheral circulation. Within the ovary, LH and FSH bind to the theca and granulosa cells to stimulate folliculogenesis and ovarian production of steroid hormones (estrogens, progesterone, and androgens), gonadal peptides (activin, inhibin, and follistatin), and growth factors. Among other functions, these ovarian-derived factors feed back to the hypothalamus and pituitary gland to inhibit or, at the midcycle surge, to augment GnRH and gonadotropin secretion. The ovarian steroids are also critical for preparing the endometrium for placental implantation if pregnancy ensues.

### HORMONE BIOSYNTHESIS AND MECHANISM OF ACTION

Hormones can be broadly classified as either steroids or peptides, each with their own mode of biosynthesis and mechanism of action. The receptors for these hormones can be divided into two groups: (1) those present on the cell surface, which in general interact with hormones that are water soluble, namely peptides, and (2) those that are primarily intracellular and interact with lipophilic hormones such as steroids. Hormones are normally present in serum and tissues in very low concentrations. Therefore, receptors must have both high affinity and high specificity for their ligand to produce the correct biologic response.

#### ■ Peptide Hormones: LH, FSH, and hCG

The gonadotropins LH and FSH are biosynthesized and secreted by the gonadotrope subpopulation of the anterior pituitary gland. These hormones play a critical role in stimulating ovarian steroidogenesis, follicular development, and ovulation. The closely related peptide human chorionic gonadotropin (hCG) is produced by placental trophoblast and is important for maintenance of pregnancy.

LH, FSH, and hCG are heterodimers consisting of a common glycoprotein  $\alpha$ -subunit linked to a unique  $\beta$ -subunit, which provides functional specificity. Although glycoprotein  $\alpha$ - and  $\beta$ -subunits can be found in their unassociated form in the circulation, these “free” subunits are not known to have biologic activity. Nevertheless, their measurement may be useful in screening tests for conditions such as pituitary adenomas and pregnancy.

**FIGURE 15-1** Different types of hormone communication. Endocrine: hormones travel through the circulation to reach their target cells. Paracrine: hormones diffuse through the extracellular space to reach their target cells, which are neighboring cells. Autocrine: hormones feed back on the cell of origin, without entering the circulation.

The LH and hCG  $\beta$ -subunits are encoded by two separate genes within a gene grouping called the LH/CG cluster. The amino acid sequence of the human LH and CG  $\beta$ -subunits demonstrates approximately 80-percent similarity. However, the hCG  $\beta$ -subunit contains an additional 24-amino-acid extension on the carboxy terminus. The presence of these additional amino acids has allowed the development of highly specific assays that can distinguish LH from hCG.

In pituitary thyrotropes, the shared glycoprotein  $\alpha$ -subunit also interacts with the thyroid-stimulating hormone  $\beta$ -subunit to form thyroid-stimulating hormone (TSH). The similarity between TSH and hCG can have clinical sequelae. For example, molar pregnancies frequently produce very high levels of hCG, which can bind to TSH receptors, resulting in hyperthyroidism (Walkington, 2011).

### Human Chorionic Gonadotropin

This glycosylated peptide hormone is produced by the placental syncytiotrophoblast. With this molecule, the degree and type of glycosylated moieties attached to the peptide frame is variable and may indicate pregnancy stage, placental function, or pathology (Fournier, 2015). One example is the hyperglycosylated

**FIGURE 15-2** Types of neurotransmitter secretion. **A.** Classic neurotransmitter release and binding. Transmission of an action potential down a neural axon leads to release of neurotransmitters, which travel across a synaptic cleft to reach their target cell. **B.** Neurohormonal secretion. An action potential leads to release of neurotransmitters. In this instance, neurotransmitters enter into and travel through the circulation to reach their target organ.

hCG that is found more commonly in gestational trophoblastic neoplasia.

hCG can be detected in serum as early as 7 to 9 days after the LH surge. In early pregnancy, hCG levels increase rapidly, doubling approximately every 2 days. Levels of this peptide hormone peak at approximately 100,000 mIU/mL during the first trimester of pregnancy. This is followed by a relatively sharp decline in the early second-trimester concentrations and then maintenance at lower levels throughout the remainder of pregnancy.

hCG binds to LH/CG receptors on corpus luteum cells and stimulates steroidogenesis in the ovary. To maintain endometrial integrity and uterine quiescence, hCG levels are critical. Namely, hCG supports corpus luteum steroid production during early pregnancy before the placenta attains adequate steroidogenic capability. The transition in production of estrogens and progesterone from the ovary to the placenta is often called the “luteal-placental shift.” In addition to effects on ovarian function, hCG exerts autocrine/paracrine effects in the placenta, promoting syncytiotrophoblast formation, trophoblast invasion, and angiogenesis.

As the placenta is the primary source for hCG production, measurement of plasma hCG levels has proved to be an effective screening tool for pregnancies with altered placental mass or function. Relatively elevated levels of hCG are observed in multifetal gestations and fetuses with Down syndrome. Lower hCG levels are observed in cases of poor placentation including ectopic pregnancy or spontaneous miscarriage. Serial hCG measurements can be very helpful to monitor these latter

**FIGURE 15-3** Positive and negative feedback loops seen with the hypothalamic-pituitary-ovarian axis. Pulsatile release of gonadotropin-releasing hormone (GnRH) leads to release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Effects of LH and FSH result in follicle maturation, ovulation, and production of the sex steroid hormones (estrogen, progesterone, and testosterone). Rising serum levels of these hormones exert negative feedback inhibition on GnRH and gonadotropin release. Sex-steroid hormones vary in their effects on the endometrium and myometrium as discussed in the text. Inhibin, produced in the ovary, has a negative effect on gonadotropin release.

conditions as the doubling time is relatively reliable. Markedly abnormal elevations in hCG levels are most often observed in the presence of gestational trophoblastic disease, discussed in Chapter 37 (p. 779).

Human CG is also secreted by nontrophoblastic neoplasias and can serve as a useful tumor marker. Ectopic (nonplacental) production of hCG, either the intact dimer or the  $\beta$ -subunit, is frequently associated with germ cell tumors and has been reported in various tumors arising from the mucosal epithelium of the cervix, bladder, lung, gastrointestinal tract, and nasopharynx. It has been postulated that hCG inhibits apoptosis in these tumors, thereby allowing rapid growth.

In addition to secretion by placental syncytiotrophoblast, hCG is produced by nonneoplastic cell types and presumably serves other functions (Cole, 2010). For example, cytotrophoblasts secrete a hyperglycosylated variant of hCG that may prove to be a sensitive marker of early pregnancy (Chuan, 2014). The pituitary gonadotropes also make small amounts of hCG. These concentrations rise in postmenopausal women and may be a rare cause of erroneously positive hCG testing in this age group (Cole, 2008).

## ■ Steroid Hormones

### Classification

Sex steroids are divided into three groups based on the number of carbon atoms that they contain. Each carbon in this structure is assigned a number identifier, and each ring is assigned a letter (Fig. 15-4). The 21-carbon series includes progestins, glucocorticoids, and mineralocorticoids. Androgens contain 19 carbons, whereas estrogens have 18.

Steroids are given scientific names according to a generally accepted convention in which functional groups below the plane of the molecule are preceded by the  $\alpha$  symbol and those above the plane of the molecule are indicated by a  $\beta$  symbol. A  $\Delta$  symbol indicates a double bond. Those steroids with a double bond between carbon atoms 5 and 6 are called  $\Delta^5$  steroids and include pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone. Those with a double bond between carbons 4 and 5 are termed  $\Delta^4$  steroids and include progesterone, 17-hydroxyprogesterone, androstenedione, testosterone, mineralocorticoids, and glucocorticoids.

### Steroidogenesis

Sex steroid hormones are synthesized in the gonads, adrenal gland, and placenta. Cholesterol is the primary building block. All steroid-producing tissues, except the placenta, are capable of synthesizing cholesterol from the two-carbon precursor, acetate. Steroid hormone production, which involves at least 17 enzymes, primarily occurs in the mitochondria and the abundant smooth endoplasmic reticulum found in steroidogenic cells (Mason, 2002). These enzymes are members

**FIGURE 15-4** The chemical structure of cholesterol, which is the common precursor in sex-steroid biosynthesis. All sex steroids contain the basic cyclopentanephentanrene molecule, which consists of three 6-carbon rings and one 5-carbon ring.

**TABLE 15-1.** Steroidogenic Enzymes

Enzyme	Cellular Location	Reactions
P450scc	Mitochondria	Cholesterol side chain cleavage
P450c11	Mitochondria	11-Hydroxylase 18-Hydroxylase 19-Methyloxidase
P450c17	ER	17-Hydroxylase 17,20-Lyase
P450c21	ER	21-Hydroxylase
P450arom	ER	Aromatase

ER= endoplasmic reticulum.

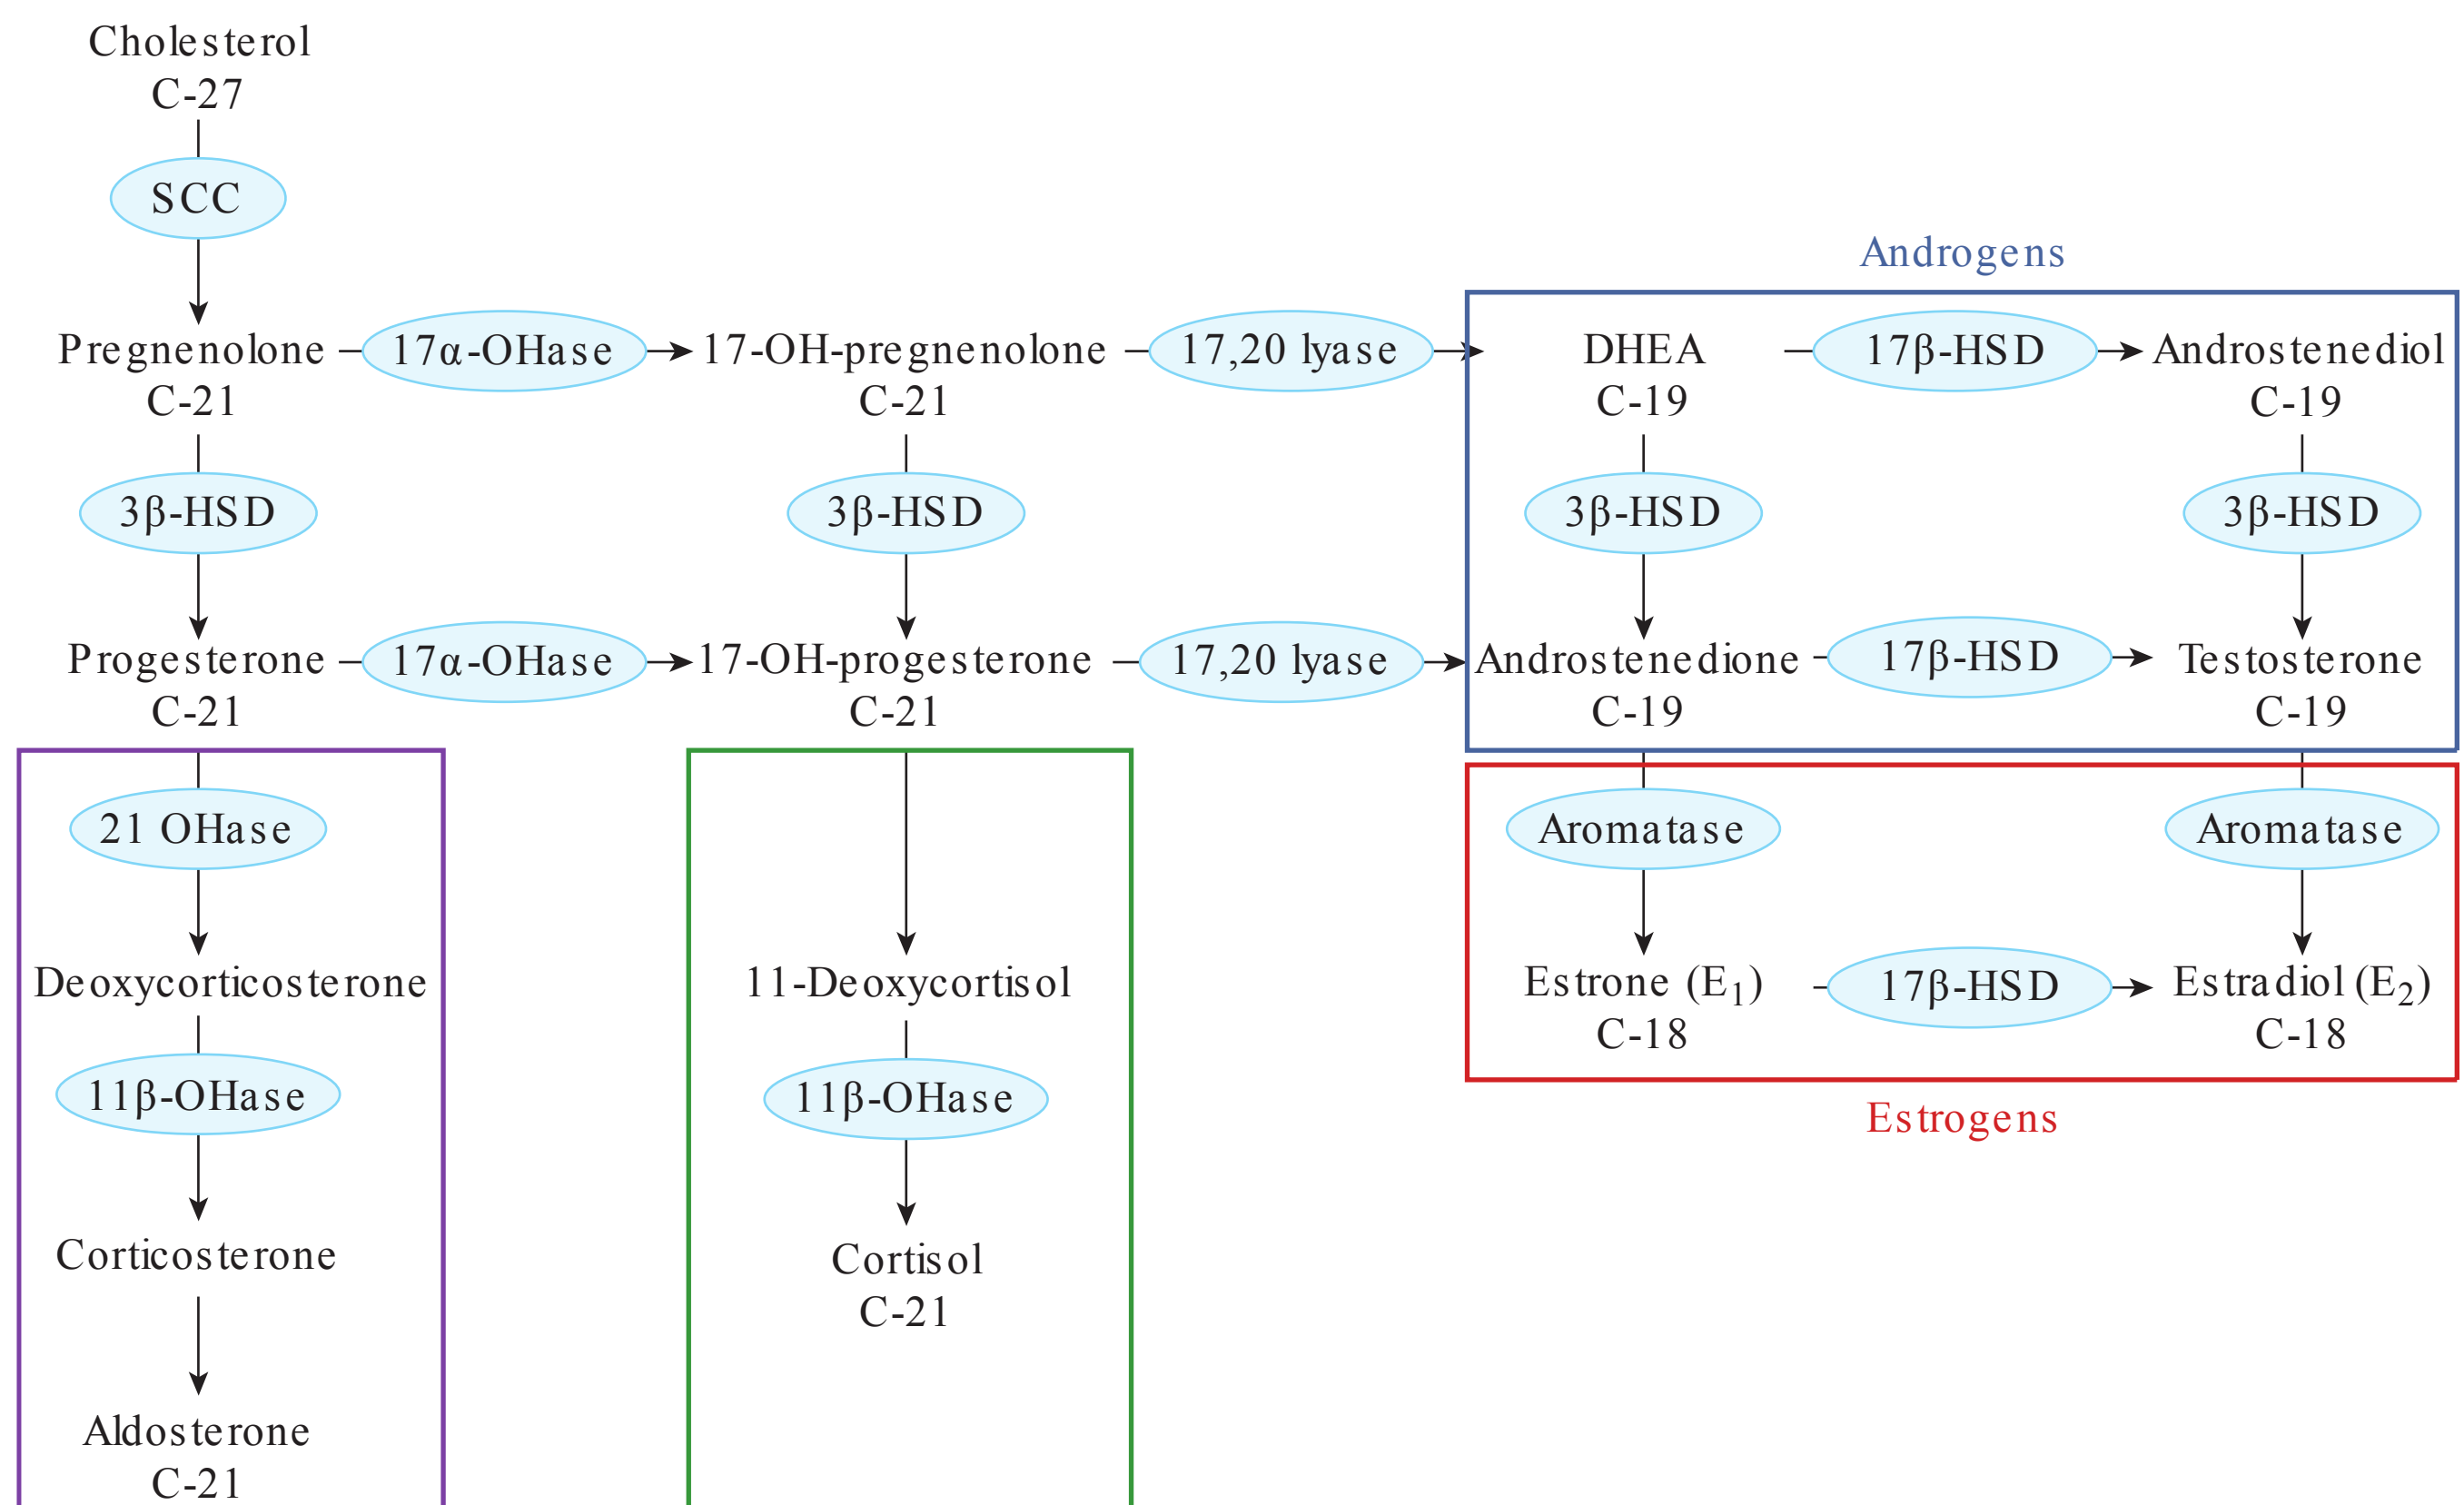

of the cytochrome P450 superfamily. As such, genes that encode these enzymes begin with *CYP*.

Steroidogenic enzymes catalyze four basic modifications of the steroid structure: (1) side-chain cleavage (desmolase reaction), (2) conversion of hydroxyl groups to ketones (dehydrogenase reactions), (3) addition of a hydroxyl group (hydroxylation reaction), and (4) removal or addition of hydrogen to create or reduce a double bond (Table 15-1). The steroid biosynthesis

pathway is shown in simplified form in Figure 15-5. The pathway is identical in all steroidogenic tissues, but the distribution of products synthesized by each tissue is determined by the presence of requisite enzymes. For example, the ovary is deficient in 21-hydroxylase and 11 $\beta$ -hydroxylase and thus is unable to produce corticosteroids. Of note, many steroidogenic enzymes exist as multiple isoforms, each with different precursor preferences and directional activities. As a result, specific steroids may be produced via multiple pathways in addition to the classic pathway shown in Figure 15-5 (Auchus, 2009).

Estrogens are synthesized by aromatization of C19 androgens by aromatase. The aromatase enzyme is a cytochrome P450 enzyme encoded by the gene *CYP19*. In addition to the ovary, aromatase is expressed in significant levels in adipose tissue, skin, and brain (Boon, 2010). Importantly, sufficient estrogen can be derived from peripheral aromatization to produce endometrial bleeding in postmenopausal women, especially those who are overweight or obese.

Circulating estrogens in the reproductive-aged female include estrone ( $E_1$ ), estradiol ( $E_2$ ), and estriol ( $E_3$ ). Estradiol is the primary estrogen produced by the ovary during reproductive years. Levels are derived both from direct synthesis in the granulosa cells of developing follicles and through conversion of the less potent estrone. Estrone, the primary estrogen during menopause, is secreted primarily by the ovary. Estriol, the

**FIGURE 15-5** Steps in the steroidogenesis pathway. Enzymes are found within the blue ovals. The C-18, C-19, or C-21 designation beneath the sex steroid reflects the number of carbon atoms it contains. Colored boxing groups these pathway products. 3 $\beta$ -HSD = 3 $\beta$ -hydroxysteroid dehydrogenase; 11 $\beta$ -OHase = 11 $\beta$ -hydroxylase; 17 $\alpha$ -OHase = 17 $\alpha$ -hydroxylase; 17 $\beta$ -HSD = 17 $\beta$ -hydroxysteroid dehydrogenase; 21OHase = 21-hydroxylase; DHEA = dehydroepiandrosterone; SCC = side-chain cleavage enzyme.

predominant estrogen during pregnancy, is primarily secreted from the placenta. However, both estrone and estriol can be converted from androstenedione in the periphery.

The ovary also produces androgens in response to LH stimulation of theca cell function. The primary products are the relatively weak androgens androstenedione and dehydroepiandrosterone (DHEA), although smaller amounts of testosterone are also secreted. Although the adrenal cortex primarily produces mineralocorticoids and glucocorticoids, it also contributes to approximately one half of the daily production of androstenedione and DHEA and essentially all of the sulfated form of DHEA (DHEAS). In women, 25 percent of circulating testosterone is secreted by the ovary, 25 percent is secreted by the adrenal gland, and the remaining 50 percent is produced by peripheral conversion of androstenedione to testosterone (Fig. 15-6) (Silva, 1987).

The adult adrenal gland is composed of three zones. Each of these zones expresses a different complement of steroidogenic enzymes and as a result synthesizes different products. The zona glomerulosa lacks 17 $\alpha$ -hydroxylase activity but contains large amounts of aldosterone synthase (P450aldo) and therefore produces mineralocorticoids. The zona fasciculata and zona reticularis, both of which express the 17 $\alpha$ -hydroxylase gene, synthesize glucocorticoids and androgens, respectively.

Within androgen synthesis, the 5 $\alpha$ -reductase enzyme converts testosterone to dihydrotestosterone (DHT), a more potent androgen. DHT promotes transformation of vellus hair to terminal hair. Thus, medications that antagonize 5 $\alpha$ -reductase are often effective in the treatment of hirsutism (Stout, 2010). This enzyme exists in two forms, each encoded by a separate gene. The type 1 enzyme is found in the skin, brain, liver, and kidneys. In contrast, the type 2 enzyme is predominantly expressed in male genitalia (Russell, 1994).

## Steroid Hormone Transport in the Circulation

Most steroids in the peripheral circulation are bound to carrier proteins. These proteins may be either specific proteins, such as sex hormone-binding globulin (SHBG), thyroid-binding globulin, or corticosteroid-binding globulin, or nonspecific proteins such as albumin. Only 1 to 2 percent of androgens and estrogens are unbound or free.

Only the unbound steroid fraction is believed to be biologically active, although albumin's low affinity for sex steroids likely allows steroids bound to this protein to exert some effect. The amount of free hormone is in equilibrium with the amount of bound. In other words, the amount of free, biologically active hormone is inversely related to the amount of bound hormone, and the amount of bound hormone is a direct reflection of the levels of carrier protein. As a result, small changes in carrier protein expression can produce substantial alterations in steroid effect.

SHBG circulates as a homodimer that binds a single steroid molecule. This binding protein is primarily synthesized in the liver, although it has also been detected in the brain, placenta, endometrium, and testes. SHBG levels are increased by hyperthyroidism, pregnancy, and estrogen administration. In contrast, androgens, progestins, growth hormone (GH), insulin, and corticoids decrease SHBG levels. An increase in weight, particularly central body fat, can significantly blunt SHBG expression. In turn, this decreases bound hormone levels and increases active hormone levels (Hammond, 2012).

Clinically, unbound hormone can be technically difficult to measure, and results should be interpreted with caution. Free testosterone levels are the most commonly ordered free steroid hormone tests, but the most accurate assays are performed by only a few commercial laboratories (Rosner, 2007).

**FIGURE 15-6** Contribution of the adrenal glands and ovaries to levels of androgens, dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEAS).

The more available *calculated* free levels are relatively inaccurate. Moreover, free testosterone measurement is rarely necessary for clinical diagnosis in the female and is unlikely to add more information than the total testosterone level. For example, measurement of testosterone levels in patients with presumed polycystic ovarian syndrome (PCOS) is important to exclude an androgen-producing tumor, which will produce markedly elevated total testosterone levels. In contrast, normal or high-normal levels of total testosterone are consistent with the diagnosis of PCOS. Because testosterone lowers SHBG levels, patients with normal total testosterone levels, but with clinical evidence of hyperandrogenism (hirsutism and/or acne), invariably have either increased free testosterone levels or increased sensitivity of the hair follicle and sebaceous glands.

Ultimately, steroids are metabolized mainly in the liver and to a lesser extent in the kidney and intestinal mucosa. Hydroxylation of estradiol results in production of estrone or catechol estrogens. These estrogens are then conjugated to glucuronides or sulfates to form water-soluble compounds for excretion in the urine. Accordingly, administration of certain pharmacologic steroid hormones may be contraindicated in those with active liver or renal disease.

## RECEPTOR STRUCTURE AND FUNCTION

Steroid hormones and peptide factors differ in their specific receptor-mediated actions, yet both eventually lead to DNA transcription and protein production in the target cell.

### ■ G-Protein Coupled Receptors

These are cell-membrane-associated receptors that bind peptide factors. These receptors consist of a hydrophilic extracellular domain, an intracellular domain, and a hydrophobic transmembrane domain that spans the cell membrane seven times. When bound to hormone, these receptors undergo a conformational change, activate intracellular signaling pathways, and, through a series of phosphorylation events, ultimately modulate transcription of multiple genes within the target cell.

The gonadotropin-releasing hormone receptor (GnRH-R) is a G-protein-coupled receptor that has been identified in the ovary, testes, hypothalamus, prostate, breast, and placenta (Yu, 2011). Although data are still preliminary, GnRH and its receptor may form an autocrine/paracrine regulatory network in reproductive tissues including the ovaries and placenta in addition to the classic neuroendocrine hypothalamic-pituitary system (Kim, 2007; Lee, 2010).

Both LH and hCG bind to the same G-protein-coupled receptor known as the LH/CG receptor. Relative to LH, hCG has a slightly higher affinity for the receptor and has a longer half-life. In contrast, FSH binds to a unique G-protein-coupled receptor located on the granulosa cell membrane.

Within the ovary, the LH/CG receptor is expressed on thecal cells, interstitial cells, and luteal cells. In the granulosa cells of preantral follicles, LH/CG receptor mRNA is nearly

undetectable. However, in the differentiated granulosa cells found during follicular maturation, high levels of this receptor are observed. In addition to the ovary, LH/CG and FSH receptors have also been identified in endometrium, myometrium, and placenta (Stilley, 2014; Ziecik, 2007). The function of the receptor in these extraovarian tissues is poorly understood.

### ■ Steroid Hormone Receptors

#### Classification and Structure

The nuclear receptor superfamily consists of three receptor groups: (1) those that bind steroidal ligands, (2) those that have affinity for nonsteroidal ligands such as thyroid hormone, and (3) orphan receptors. By definition, orphan nuclear receptors do not have an identified ligand. These are believed to be constitutively active, that is, they exhibit basal or intrinsic activity. Despite their structural similarities, estrogens, progestins, androgens, mineralocorticoids, and glucocorticoids all interact with unique members of the nuclear hormone receptor family.

Free steroids diffuse into cells and combine with specific receptors (Fig. 15-7A). Members of this receptor superfamily exhibit a modular structure of distinct domains (Fig. 15-8). Each region contributes distinct activities required for full receptor function. In general, nuclear receptors have two regions that are critical for gene activation, termed activation function 1 (AF1) and activation function 2 (AF2). AF1 is located in the A/B domain and is usually ligand independent. AF2 is in the ligand-binding domain (E) and is often hormone-dependent. The highly conserved DNA-binding region (C) inserts into the DNA helix. Subsequently, steroid receptors enhance or repress gene transcription through interactions with specific DNA sequences, called hormone response elements, in the promoter region of target genes (Klinge, 2001).

#### Estrogen, Progesterone, and Androgen Receptors

As a general rule, nuclear hormone receptors are localized to the cytoplasm. Following ligand binding, they then are translocated to the nucleus to exert their effects.

Two isoforms of estrogen receptors, ER $\alpha$  and ER $\beta$ , are encoded by separate genes (Kuiper, 1997). These receptors are differentially expressed in tissues and appear to serve distinct functions. For example, both ER $\alpha$  and ER $\beta$  are required for normal ovarian function. However, mice lacking ER $\alpha$  are anovulatory and accumulate cystic follicles, whereas ovaries missing ER $\beta$  are normal histologically despite impaired ovulation (Couse, 2000).

The progesterone receptor also exists in multiple isoforms. Encoded from a single gene, PRA and PRB are identical except for an additional 164 amino acids at the amino terminus (Conneely, 2002). Similar to estrogen receptors, the PR isoforms are not interchangeable. For example, PRA is required for normal ovarian and uterine functions but is expendable in the breast (Lydon, 1996). In contrast to the estrogen and progesterone receptor situation, only one form of the androgen receptor has been identified.

**FIGURE 15-7** Estrogen-receptor ligand-dependent and ligand-independent activation. **A.** Classically, the estrogen receptor can be activated by estrogen. Unbound hormone is free to bind with empty steroid receptors found either in the cytoplasm or, more commonly, in the cell's nucleus. Hormone-bound receptors then bind to specific DNA promoter sequences. This binding typically leads to DNA transcription and eventually to specific protein synthesis. **B.** The estrogen receptor can also be activated independently of estrogen. Growth factors can increase the activity of protein kinases that phosphorylate different sites on the receptor molecule. This unbound, yet activated, receptor will then exert transcriptional effects. **C.** Nonnuclear estrogen-signaling pathways can also produce effects. Cell-membrane estrogen receptors are located in invaginations called caveolae. Estrogen binding to these estrogen receptors is linked to the mitogen-activated protein kinase pathway and results in a rapid, nonnuclear effect. (Reproduced with permission from Gruber CJ, Tschugguel W, Schneeberger C, et al: Production and actions of estrogens. *N Engl J Med* 2002 Jan 31;346(5):340–352.)

#### ESTROGEN RECEPTOR

#### PROGESTERONE RECEPTOR

**FIGURE 15-8** Drawing depicts the concept of functional domains within estrogen and progesterone receptors and notes distinct sites for ligand and DNA binding. (Reproduced with permission from Yen SS, Jaffe RB, Barbieri RL: *Reproductive Endocrinology*, 4th ed. Philadelphia: Saunders; 1999.)

### Nongenomic Actions of Steroids

Recent studies have introduced the concept that a subset of steroids, including estrogens and progestins, may alter cell function via nongenomic effects, that is, independent of the classic nuclear hormone receptors (see Fig. 15-7C). These nongenomic effects occur rapidly and may be mediated via cell-surface receptors (Kowalik, 2013; Revelli, 1998). Pharmacologic agents under development specifically target these nongenomic effects to allow more precise therapy for steroid-sensitive disorders.

### Receptor Expression and Desensitization

Many influences alter cellular response to sex steroids and peptide factors. The number of receptors within a cell or on the cell membrane is critical to attain maximum hormonal response. Importantly, the number of receptors on a cell can be modified through gene transcription and receptor protein degradation.

Hormonally induced negative feedback of receptors is termed *homologous downregulation* or *desensitization*. Desensitization limits the duration of a hormonal response by decreasing the cell's sensitivity to a constant, prolonged level of hormone. Within the reproductive system, desensitization is best understood for the GnRH receptor and is used clinically to produce a hypoestrogenic state. Pharmacologic agonists of GnRH, such as leuprolide acetate (Lupron), initially stimulate

receptors on pituitary gonadotropes to cause a supraphysiologic release of both LH and FSH. Over a period of hours, agonists downregulate GnRH receptor sensitivity and number, thus preventing further GnRH stimulation. Correspondingly, decreased gonadotropin secretion leads to suppressed estrogen and progesterone levels 1 to 2 weeks after initial GnRH agonist administration.

IMMUNOASSAYS FOR PEPTIDE AND STEROID HORMONES

■ Immunoassays

These tests use antibodies to detect most polypeptide, steroid, and thyroid hormones. They are sensitive and easily automated. Hormone concentration is usually reported as international units per volume rather than mass per volume (Table 15-2). When interpreting immunoassays, several concepts must be

understood. These include reference standards, the “hook effect,” normal ranges, and supplementary hormone levels.

First, to minimize assay-to-assay variability, a reference material is needed to standardize assays. Reference standards serve as anchors that can provide comparability across time and methods. Such reference preparations are produced by the World Health Organization (WHO) and the National Institutes of Health (NIH). More than 20 assay standards are available to measure LH, FSH, prolactin (PRL), and hCG. Thus, knowing which reference standard is used by a specific assay is essential, as results may differ significantly. Clinically, this can become an issue in patients with possible ectopic pregnancies when serial  $\beta$ -hCG levels are obtained at different health care facilities.

Second, the “hook effect” can alter immunoassay result interpretation. With this effect, significantly elevated hormone levels saturate the assay’s targeting antibody and create a falsely low reading. Moreover, the amount of hormone present in a sample does not necessarily correlate with the biological

TABLE 15-2. Reference Ranges for Selected Reproductive Steroids in Adult Human Serum		
Steroid	Subjects	Reference Values
Androstenedione	Men	2.8–7.3 nmol/L
	Women	3.1–12.2 nmol/L
Testosterone	Men	6.9–34.7 nmol/L
	Women	0.7–2.8 nmol/L
Dihydrotestosterone	Men	1.0–3.10 nmol/L
	Women	0.07–.086 nmol/L
Dehydroepiandrosterone	Men/Women	5.5–24.3 nmol/L
Dehydroepiandrosterone sulfonate	Men/Women	2.5–10.4 $\mu$ mol/L
Progesterone	Men	< 0.3–1.3 nmol/L
	Women	
	Follicular	0.3–3.0 nmol/L
Estradiol	Luteal	19.0–45.0 nmol/L
	Men	< 37–210 pmol/L
	Women	
	Follicular	< 37–360 pmol/L
	Luteal	625–2830 pmol/L
Estrone	Midcycle	699–1250 pmol/L
	Postmenopausal	< 37–140 pmol/L
	Men	37–250 pmol/L
Estrone sulfonate	Women	
	Follicular	110–400 pmol/L
	Luteal	310–660 pmol/L
	Postmenopausal	22–230 pmol/L
Estrone sulfonate	Men	600–2500 pmol/L
	Women	
	Follicular	700–3600 pmol/L
	Luteal	1100–7300 pmol/L
Estrone sulfonate	Postmenopausal	130–1200 pmol/L

Reproduced with permission from Yen SS, Jaffe RB, Barbieri RL: Reproductive Endocrinology, 4th ed. Philadelphia: Saunders; 1999.

activity of that hormone. For example, PRL exists in multiple isoforms, many of which are immunologically detectable but not biologically active. Similarly, varying glycosylation patterns of gonadotropins at different times during the reproductive life span are believed to alter their biologic activity.

Another caveat is a result that lies in the “normal range.” For many hormones, a stated normal range is often broad. As such, the hormone level of an individual may double, but remain within the normal range even though the result is actually abnormal for that individual.

Last, the addition of other hormone levels may be necessary to define the significance of a result. In the context of the pituitary gland and its target endocrine glands, it may be adequate to measure the pituitary hormone alone. For example, high levels of circulating gonadotropins are almost invariably due to ovarian failure and loss of negative feedback. This is because pituitary overproduction of functional dimer is rare. Conversely, low gonadotropin levels can be attributed confidently to hypothalamic-pituitary dysfunction. Thus, the measurement of ovarian-derived products such as estrogen may be helpful to confirm the diagnosis but are not critical.

In other clinical scenarios, the measurement of both pituitary and target hormone levels may be indicated. For example, in many laboratories, an abnormal TSH value will lead to “reflex,” that is, automatic testing for thyroid hormone levels. Low levels of both a stimulating-hormone and target hormone indicate an abnormality in either hypothalamic or pituitary function. High levels of a target-gland hormone coupled with low levels of its stimulating pituitary hormone suggest autonomous secretion by the target organ such as occurs in the hyperthyroidism of Graves disease.

### ■ Stimulation Tests

These tests may be useful when hypofunction of an endocrine organ is suspected. These tests use an endogenous stimulating hormone to assess the reserve capacity of the tissue of interest. The trophic hormone used may be a hypothalamic releasing factor such as GnRH or thyrotropin-releasing hormone (TRH). Alternatively, a substitute pituitary hormone may be used, such as hCG as a substitute for LH or leuprolide acetate for GnRH. The ability of the target gland to respond is measured by an increase in the appropriate hormone’s plasma level. One example, the leuprolide stimulation test, may be used to evaluate abnormal pubertal development and is described in Chapter 14 (p. 328). Leuprolide substitutes for GnRH because clinical-grade GnRH is often unavailable (Rosenfield, 2013).

### ■ Suppression Tests

These tests may be performed when endocrine hyperfunction is suspected. For example, a dexamethasone suppression test may be given to a patient with suspected hypercortisolism (Cushing disease or syndrome). Described in full in Chapter 17 (p. 396), this test gauges the ability of dexamethasone to inhibit adrenocorticotrophic hormone (ACTH) secretion and thus cortisol production by the adrenal. The failure of glucocorticoid treatment to suppress cortisol production would be consistent with primary hyperadrenalism.

## THE HYPOTHALAMIC-PITUITARY AXIS

### ■ Anatomy

The hypothalamus consists of nuclei located at the base of the brain, just superior to the optic chiasm. Neurons within the hypothalamus form synaptic connections with other neurons throughout the central nervous system (CNS). A subset of the hypothalamic neurons within the arcuate, ventromedial, and paraventricular nuclei project to the median eminence. In the median eminence, a dense network of capillaries arises from the superior hypophyseal arteries. These capillaries drain into portal vessels that traverse the pituitary stalk and then form a capillary network within the anterior pituitary gland (adenohypophysis). The primary direction of this hypophyseal portal system is from hypothalamus to pituitary. However, retrograde flow also exists. This creates an ultrashort feedback loop between the pituitary gland and hypothalamic neurons. The hypothalamus is thus a critical locus for integration of information from the environment, nervous system, and other organ systems.

The anterior pituitary gland consists of endocrine cells and is derived from an invagination of Rathke pouch in the roof of the embryonic oral cavity. In contrast, the posterior pituitary gland (neurohypophysis) is neural tissue and consists of the axon terminals of magnocellular neurons arising in the supraoptic and paraventricular nuclei of the hypothalamus (Fig. 15-9).

**FIGURE 15-9** Sagittal section through the hypothalamus and pituitary gland with rostral structures to the left and caudal ones to the right. The hypothalamus is anatomically and functionally linked with the anterior pituitary by the portal system of blood supply. The posterior pituitary contains the axon terminals of neurons arising in the supraoptic (SO) nucleus and paraventricular nucleus (PVN) of the hypothalamus. AHA = anterior hypothalamic area; AN = arcuate nucleus; DMN = dorsomedial nucleus; PHN = posterior hypothalamic nucleus; POA = preoptic area; VMN = ventromedial nucleus. ## ■ Hypothalamic Neuroendocrinology

The list of known neurotransmitters continues to expand as does our understanding of their anatomic distribution, mode of regulation, and mechanism of action. Neurotransmitters can be classified as: (1) biogenic amines (dopamine, epinephrine, norepinephrine, serotonin, histamine), (2) neuropeptides, (3) acetylcholine, (4) excitatory amino neurotransmitters (glutamate, glycine, aspartic acid), (5) the inhibitory amino acid gamma-aminobutyric acid (GABA), (6) gaseous transmitters (nitric oxide, carbon monoxide), and (7) miscellaneous factors (cytokines, growth factors).

The most significant neurotransmitters in reproductive neuroendocrinology are the three monoamines: dopamine, norepinephrine, and serotonin. Clinically important neuropeptides within the reproductive axis include the endogenous opiates, kisspeptin, neuropeptide Y, galanin, and pituitary adenylate cyclase-activating peptide.

### Endogenous Opiates

Central opioidergic neurons are important mediators of hypothalamic-pituitary function. Depending on the precursor peptide from which they are derived, these neuropeptides can be categorized into three classes: endorphins, enkephalins, and dynorphins. Of these, endorphins (endogenous morphines) are cleavage products of the proopiomelanocortin *POMC* gene, which also yields ACTH and  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH) (Taylor, 1997). The endorphins serve a wide range of physiologic functions that include regulation of temperature, cardiovascular and respiratory systems, pain perception, mood, and reproduction.

Proopiomelanocortin is produced in highest concentration in the anterior pituitary gland but is also expressed in the brain, sympathetic nervous system, gonads, placenta, gastrointestinal tract, and lungs. The primary peptide synthesized from this pathway depends on the tissue source. For example, the predominant products in the brain are the opiates, whereas pituitary biosynthesis results principally in ACTH production.

Opioids in the brain play a central role in menstrual cyclicity by tonically suppressing the hypothalamic release of GnRH (Funabashi, 1994). Estrogen promotes endorphin secretion, and this is increased further with the addition of progesterone (Cetel, 1985). Thus, endorphin levels increase during the follicular phase, peak during the luteal phase, and drop markedly during menses. This pattern suggests that both opioid tone and progesterone decrease GnRH pulse frequency in the luteal phase, thus stimulating FSH secretion. For reasons that are not fully understood, opioid suppression of GnRH is relieved at the time of ovulation (King, 1984). In addition, functional hypothalamic amenorrhea due to eating disorders, intensive exercise, and stress is correlated with an increase in endogenous opiate concentrations (Chap. 16, p. 376).

### Other Hypothalamic Neuropeptides

Hypothalamic kisspeptin neurons play a critical role in sexual differentiation, puberty initiation, and adult reproductive function. These neurons are part of the KNDy neuronal system, named for the coexpression of kisspeptin with neurokinin B and dynorphin. This system likely provides an important link

between energy homeostasis and reproductive function. This link may stem in part from the action of the adipose-derived factor leptin, which regulates kisspeptin expression (Chehab, 2014).

Kisspeptin neurons send processes to GnRH neurons, allowing direct control of GnRH secretion. Interestingly, one group of kisspeptin neurons may mediate negative steroid feedback, whereas another is responsible for the positive feedback observed before ovulation (Lehman, 2010; Millar, 2014; Skorupskaite, 2014).

Other neurotransmitters, neuropeptide Y (NPY) and galanin, are expressed by neurons located throughout the hypothalamus and project to kisspeptin neurons, to GnRH neurons, and to other areas of the CNS that have roles in reproductive function. NPY and galanin secretion varies in response to changes in energy level as seen in anorexia and obesity. Both of these neuropeptides alter GnRH pulsatility and potentiate GnRH-induced gonadotrope secretion (Lawrence, 2011; Peters, 2009).

Pituitary adenylate cyclase-activating peptide (PACAP) is a hypothalamic peptide secreted into the pituitary portal system. It binds to receptors on anterior pituitary cells and stimulates hormone secretion including gonadotropin secretion, albeit more weakly than GnRH. Gonadotropes themselves also secrete PACAP, suggesting an autocrine/paracrine role for this hormone within the pituitary. PACAP modulates GnRH-receptor expression and, conversely, GnRH alters PACAP-receptor expression on the gonadotrope cell surface. Furthermore, pituitary PACAP gene expression is markedly increased by GnRH (Halvorson, 2014). Thus, these two important neuropeptides are functionally linked at the level of the anterior pituitary.

## ■ Anterior Pituitary Hormones

The anterior pituitary gland contains five hormone-producing cell types and their products. These include: (1) gonadotropes (which produce LH and FSH), (2) lactotropes (PRL), (3) somatotropes (GH), (4) thyrotropes (TSH), and (5) adrenocorticotropes (ACTH). Of these, gonadotropes comprise approximately 10 to 15 percent of all hormonally active cells in the anterior pituitary (Childs, 1983).

With the exception of PRL, which is under tonic inhibition, pituitary hormones are stimulated by hypothalamic neuroendocrine secretion. Both of the gonadotropins, LH and FSH, are regulated by a single releasing peptide, GnRH, which acts on the anterior pituitary's gonadotrope subpopulation. Most gonadotropes contain secretory granules that contain both LH and FSH, although a significant number of cells are monohormonal, that is, secrete only LH or only FSH.

Of the other pituitary-releasing hormones, corticotropin-releasing hormone stimulates biosynthesis and secretion of ACTH by the pituitary adrenocorticotropes. Thyrotropin-releasing hormone increases thyrotrope secretion of TSH, also known as thyrotropin. Various hypothalamic secretagogues regulate expression of somatotrope-derived growth hormone. Last, PRL expression is primarily under inhibitory regulation by dopamine. As a consequence of these regulatory mechanisms, damage to the pituitary stalk results in hypopituitarism for LH, FSH, GH, ACTH, and TSH, but an associated increase in PRL secretion.

## ■ Hypothalamic Releasing Peptides

These peptides have characteristics that are important for both their biologic function and clinical use. First, they are small peptides with short half-lives of a few minutes due to their rapid degradation. Second, hypothalamic releasing peptides are released in minute quantities and are highly diluted in the peripheral circulation. Therefore, biologically active concentrations of these factors are locally restricted to the anterior pituitary gland. Clinically, the extremely low concentrations of these hormones render them essentially undetectable in serum. Thus, levels of their corresponding pituitary factors are measured as surrogate markers.

### Gonadotropin-releasing Hormone

GnRH is a decapeptide with a half-life of less than 10 minutes. Amino acid modifications generate receptor antagonists or agonists with a prolonged half-life (Fig. 15-10) (Padula, 2005). Pulsatile GnRH input is required for activation and maintenance of GnRH receptors. This characteristic is exploited clinically by administering long-acting GnRH agonists to treat steroid-dependent conditions such as endometriosis, leiomyomas, precocious puberty, breast cancer, and prostate cancer. These agonists compete with endogenous pulsatile GnRH at the receptor, depressing gonadotropin secretion and thereby decreasing serum ovarian sex steroid levels.

Humans express two forms of GnRH termed GnRH I and GnRH II (Cheng, 2005). By convention, GnRH I is the classically described hypothalamic GnRH. The GnRH II peptide has been identified in peripheral tissues and differs in receptor activation (Neill, 2002). Further research is needed to determine the overlapping and divergent functions of these two forms.

**Migration of the Gonadotropin-releasing Hormone Neurons.** Many hypothalamic neurons arise within the CNS, but GnRH-containing neurons have a unique embryologic origin. Progenitor GnRH neurons originate in the medial olfactory placode and migrate along the vomeronasal nerve into the hypothalamus (Fig. 16-5, p. 376). A series of soluble factors regulate GnRH neuronal migration at specific locations along their migratory route. These factors include secreted signaling molecules such as GABA, adhesion molecules, and growth factors (Wierman, 2011). Failure of normal migration may

stem from various genetic defects in these signaling molecules and can lead to Kallmann syndrome, which is discussed in Chapter 16 (p. 375), and other forms of hypogonadotropic hypogonadism.

GnRH cell bodies are primarily located within the arcuate nucleus. From these neuronal cell bodies, GnRH is axonally transported along the tuberoinfundibular tract to the median eminence. GnRH is then secreted into the portal system that drains directly to the anterior pituitary gland and stimulates gonadotropin biosynthesis and secretion. The number of GnRH neurons in the adult is strikingly low, with only a few thousand cells dispersed within the arcuate nucleus.

The olfactory origin of GnRH neurons and nasal epithelial cells suggest a link between reproduction and olfactory signals. Compounds released by one individual that affect other members of the same species are known as *pheromones*. Pheromones obtained from the axillary secretions of women in the late follicular phase accelerate the LH surge and shorten menstrual cycles of women exposed to these chemicals. Secretions from women in the luteal phase have the opposite effects. Thus, pheromones may be one mechanism by which women who are together frequently often exhibit synchronous menstrual cycles (Stern, 1998).

A subset of GnRH neurons sends projections into other areas of the CNS, including the limbic system. These projections are not required for gonadotropin secretion, but they may play a role in modulation of reproductive behavior (Nakai, 1978; Silverman, 1987).

### Pulsatile Gonadotropin-releasing Hormone Secretion.

In elegant experiments, Knobil (1974) demonstrated that pulsatile delivery of GnRH to the pituitary gonadotropes is required to achieve sustained gonadotropin secretion. As shown in Figure 15-11, continuous infusion with GnRH rapidly decreases both LH and FSH secretion, an effect that is easily reversed with a return to pulsatile stimulation.

Compared with the luteal phase, follicular phase GnRH pulsatility is characterized by increased frequency and decreased amplitude. Higher pulse frequency preferentially stimulates LH, whereas lower frequency favors FSH secretion (Thompson, 2014). Therefore, changes in GnRH pulse frequency affect the absolute levels and the ratio of LH to FSH release.

**FIGURE 15-10** Schematic drawing shows the similar amino acid composition of the decapeptide gonadotropin-releasing hormone (GnRH) and of its agonist, leuprolide acetate (Lupron).

**FIGURE 15-11** Graph shows changes in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels with variation in gonadotropin-releasing hormone (GnRH) pulsatile release. (Adapted with permission from Knobil E: The neuroendocrine control of the menstrual cycle, *Recent Prog Horm Res* 1980;36:53–88.)

Pulsatile activity is currently believed to be an intrinsic property of GnRH neurons. Other hormones and neurotransmitters provide modulatory effects (Clayton, 1981; Yen, 1985). In animal models, estrogen increases GnRH pulse frequency and therefore leads to an increase in LH levels relative to FSH levels. In contrast, progesterone decreases GnRH pulsatility. The increase in progesterone during the luteal phase may explain the preferential stimulation of FSH observed toward the end of this phase. The rise in FSH is critical for the initiation of follicular recruitment.

## ■ Other Hypothalamic-Pituitary Axes

### Dopamine and Prolactin

In contrast to the other anterior pituitary hormones, PRL release is primarily regulated via inhibition, specifically by dopamine. These dopamine-containing fibers arise chiefly in the hypothalamic arcuate nucleus and project to the median eminence, where dopamine enters the portal vessels (Table 15-3). Prolactin-releasing factors, although less potent, include TRH, vasopressin, vasoactive intestinal peptide (VIP), endogenous opioids, and acetylcholine.

There are five forms of the dopamine receptor divided into two groups, D<sub>1</sub> and D<sub>2</sub>. Cells in the anterior pituitary gland

primarily express the D<sub>2</sub> subtypes. The medical treatment of prolactinomas has been improved in terms of both effectiveness and patient tolerance by the development of the D<sub>2</sub>-specific ligands. For example, the dopamine agonist cabergoline is a D<sub>2</sub>-specific ligand, whereas bromocriptine is nonspecific.

### Thyrotropin-releasing Hormone

As indicated by its name, thyrotropin-releasing hormone stimulates secretion of thyroid-stimulating hormone from the anterior pituitary gland's thyrotrope subpopulation. Of note, TRH is also a potent prolactin-releasing factor and results in a clinical link between hypothyroidism and secondary hyperprolactinemia (Messini, 2010).

TSH binds to specific receptors on the plasma cell membrane of thyroid gland cells. This stimulates thyroid hormone biosynthesis. Thyroid hormone exerts negative feedback on TRH- and TSH-releasing cells.

### Corticotropin-releasing Hormone

This is the primary hypothalamic factor that stimulates synthesis and secretion of ACTH. Corticotropin-releasing hormone (CRH) is distributed in multiple locations within the hypothalamus and other CNS areas. Release of CRH is stimulated by catecholaminergic input from other brain pathways and inhibited by endogenous opioids.

Corticotropin-releasing hormone binds to CRH receptors in the anterior pituitary to stimulate ACTH biosynthesis and secretion. In turn, ACTH stimulates glucocorticoid production by the adrenal's zona fasciculata and androgen production by its zona reticularis. CRH secretion is under negative-feedback regulation by circulating cortisol produced in the adrenal gland. In contrast, mineralocorticoid production by the zona glomerulosa is primarily regulated by the renin-angiotensin system. As a result, abnormalities in the CRH–ACTH pathway do not result in electrolyte disturbances.

Central CRH pathways are believed to mediate many stress responses (Kalantaridou, 2004). Clinically, in women with hypothalamic amenorrhea, CRH levels have been found to be elevated. Increased levels of CRH inhibit hypothalamic GnRH secretion by direct action and by augmenting central opioid concentrations (Fig. 16-6, p. 377). This functional pathway may explain the association between hypercortisolism and menstrual abnormalities.

### Growth Hormone–releasing Hormone

Growth hormone secretion by pituitary somatotropes is stimulated by hypothalamic growth hormone-releasing hormone (GHRH) and inhibited by somatostatin. GHRH is primarily secreted by the hypothalamus, but small quantities are released by placental and immune cells. In contrast, somatostatin is widely distributed in the CNS and in the placenta, pancreas, and gastrointestinal tract.

As with GnRH, GHRH depends on pulsatile secretion to exert a physiologic effect. Exercise, stress, sleep, and hypoglycemia stimulate GH release, whereas free fatty acids and other factors related to adiposity blunt GH release. Estrogen, testosterone, and thyroid hormone also play a role in increased GH secretion.

**TABLE 15-3.** Hypothalamic-Pituitary Products and Their End Organs

Hypothalamus	Pituitary	End Organ
GnRH	LH/FSH	Gonads
Dopamine	PRL	Breast
TRH	TSH	Thyroid
CRH	ACTH	Adrenal
GHRH	GH	Somatic

ACTH = adrenocorticotropin hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone–releasing hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; PRL = prolactin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

GH stimulates skeletal and muscle growth, regulates lipolysis, and promotes the cellular uptake of amino acids. T is hormone induces insulin resistance, and thus GH excess may be associated with new-onset diabetes mellitus. Most of the growth effects of GH are mediated via the insulin-like growth factors, IGF-I and IGF-II. T ese growth factors are produced in high quantities in the liver. Many of the target tissues in which they exert local effects also synthesize IGFs. Within the ovary, IGF-I and IGF-II stimulate granulosa cell proliferation and steroidogenesis during folliculogenesis (Silva, 2009). IGFs also suppress GH secretion through negative feedback mechanisms.

### ■ Posterior Pituitary Peptides

Neurons projecting to the posterior pituitary synthesize and secrete the nine-amino-acid cyclic peptides oxytocin and arginine vasopressin. Precursors for these peptides are produced in the neuronal cell body and transported down the axon in secretory granules. During transport, precursors are cleaved into mature peptides and a carrier protein—neurophysin (Verbalis, 1983). Activation of these neurons generates an axon potential that results in calcium influx and secretion of granule contents into the perivascular space. T ese secreted peptides then enter adjacent blood vessels for transport throughout the peripheral circulation.

Of these two peptides, oxytocin has significant roles in reproduction, specifically parturition and lactation (Kiss, 2005). T e role of oxytocin in labor initiation is disputed as serum oxytocin levels are constant until the expulsive portion of labor (Blanks, 2003). Nevertheless, an increase in myometrial and decidual oxytocin-receptor expression has been noted near term, primarily due to an increase in estrogen levels.

Once labor is initiated, oxytocin is the primary mediator of myometrial contractility. Cervical and vaginal stimulation results in an acute release of oxytocin from the posterior pituitary in a process known as the *Ferguson reflex*. Clinically, oxytocin's ability to induce uterine contractions is exploited to induce or augment labor.

Vaginal distention, such as occurs with coitus, also increases oxytocin release. Based on this observation, oxytocin may be responsible for the rhythmic uterine and tubal contractions that aid sperm delivery to the oocyte. Oxytocin may also play a role in orgasm and ejaculation.

During lactation, PRL is critical for milk production in breast alveoli. T e glandular cells of the alveoli are surrounded by a mesh of myoepithelial cells. Suckling triggers nerve impulses from mechanoreceptors in the nipple and areola that increase hypothalamic neuronal activity. Subsequent oxytocin release prompts the myoepithelial cells to contract and thereby express milk from the alveoli into the ducts and sinuses (Crowley, 1992). Other conditioned stimuli, such as the sight, sound, or smell of a baby or sexual arousal, will have similar effects.

Oxytocin expression has also been detected in the anterior pituitary, placenta, fallopian tubes, and gonads, with high expression in the corpus luteum (Williams, 1990). Its function in these tissues is unknown.

## MENSTRUAL CYCLE

T e “typical” menstrual cycle is  $28 \pm 7$  days with menstrual flow lasting  $4 \pm 2$  days and blood loss averaging 20 to 60 mL. By convention, the first day of vaginal bleeding is considered day 1 of the menstrual cycle. Menstrual cycle intervals vary among women and often for an individual woman at different times during her reproductive life. In a study of more than 2700 women, menstrual cycle intervals were found to be most irregular in the 2 years following menarche and the 3 years preceding menopause (Treloar, 1967). Specifically, a trend toward shorter intervals followed by interval lengthening is common during the menopausal transition. T e menstrual cycle is least variable between the ages of 20 and 40 years.

When viewed from a perspective of ovarian function, the menstrual cycle can be defined as a preovulatory follicular phase and postovulatory luteal phase (Fig. 15-12). Corresponding phases in the endometrium are termed the proliferative and secretory phases (Table 15-4). For most women, the luteal phase of the menstrual cycle is stable, lasting 13 to 14 days. T us, variations in normal cycle length generally result from variable duration of the follicular phase (Ferin, 1974).

### ■ The Ovary

#### Ovarian Morphology

T e adult human ovary is oval with a length of 2 to 5 cm, a width of 1.5 to 3 cm, and a thickness of 0.5 to 1.5 cm. During the reproductive years, the ovary weighs between 5 and 10 g. It is composed of three parts: an outer cortical region, which contains both the germinal epithelium and the follicles; a medullary region, which consists of connective tissue, myoid-like contractile cells, and interstitial cells; and a hilum, which contains blood vessels, lymphatics, and nerves that enter the ovary (Fig. 15-13).

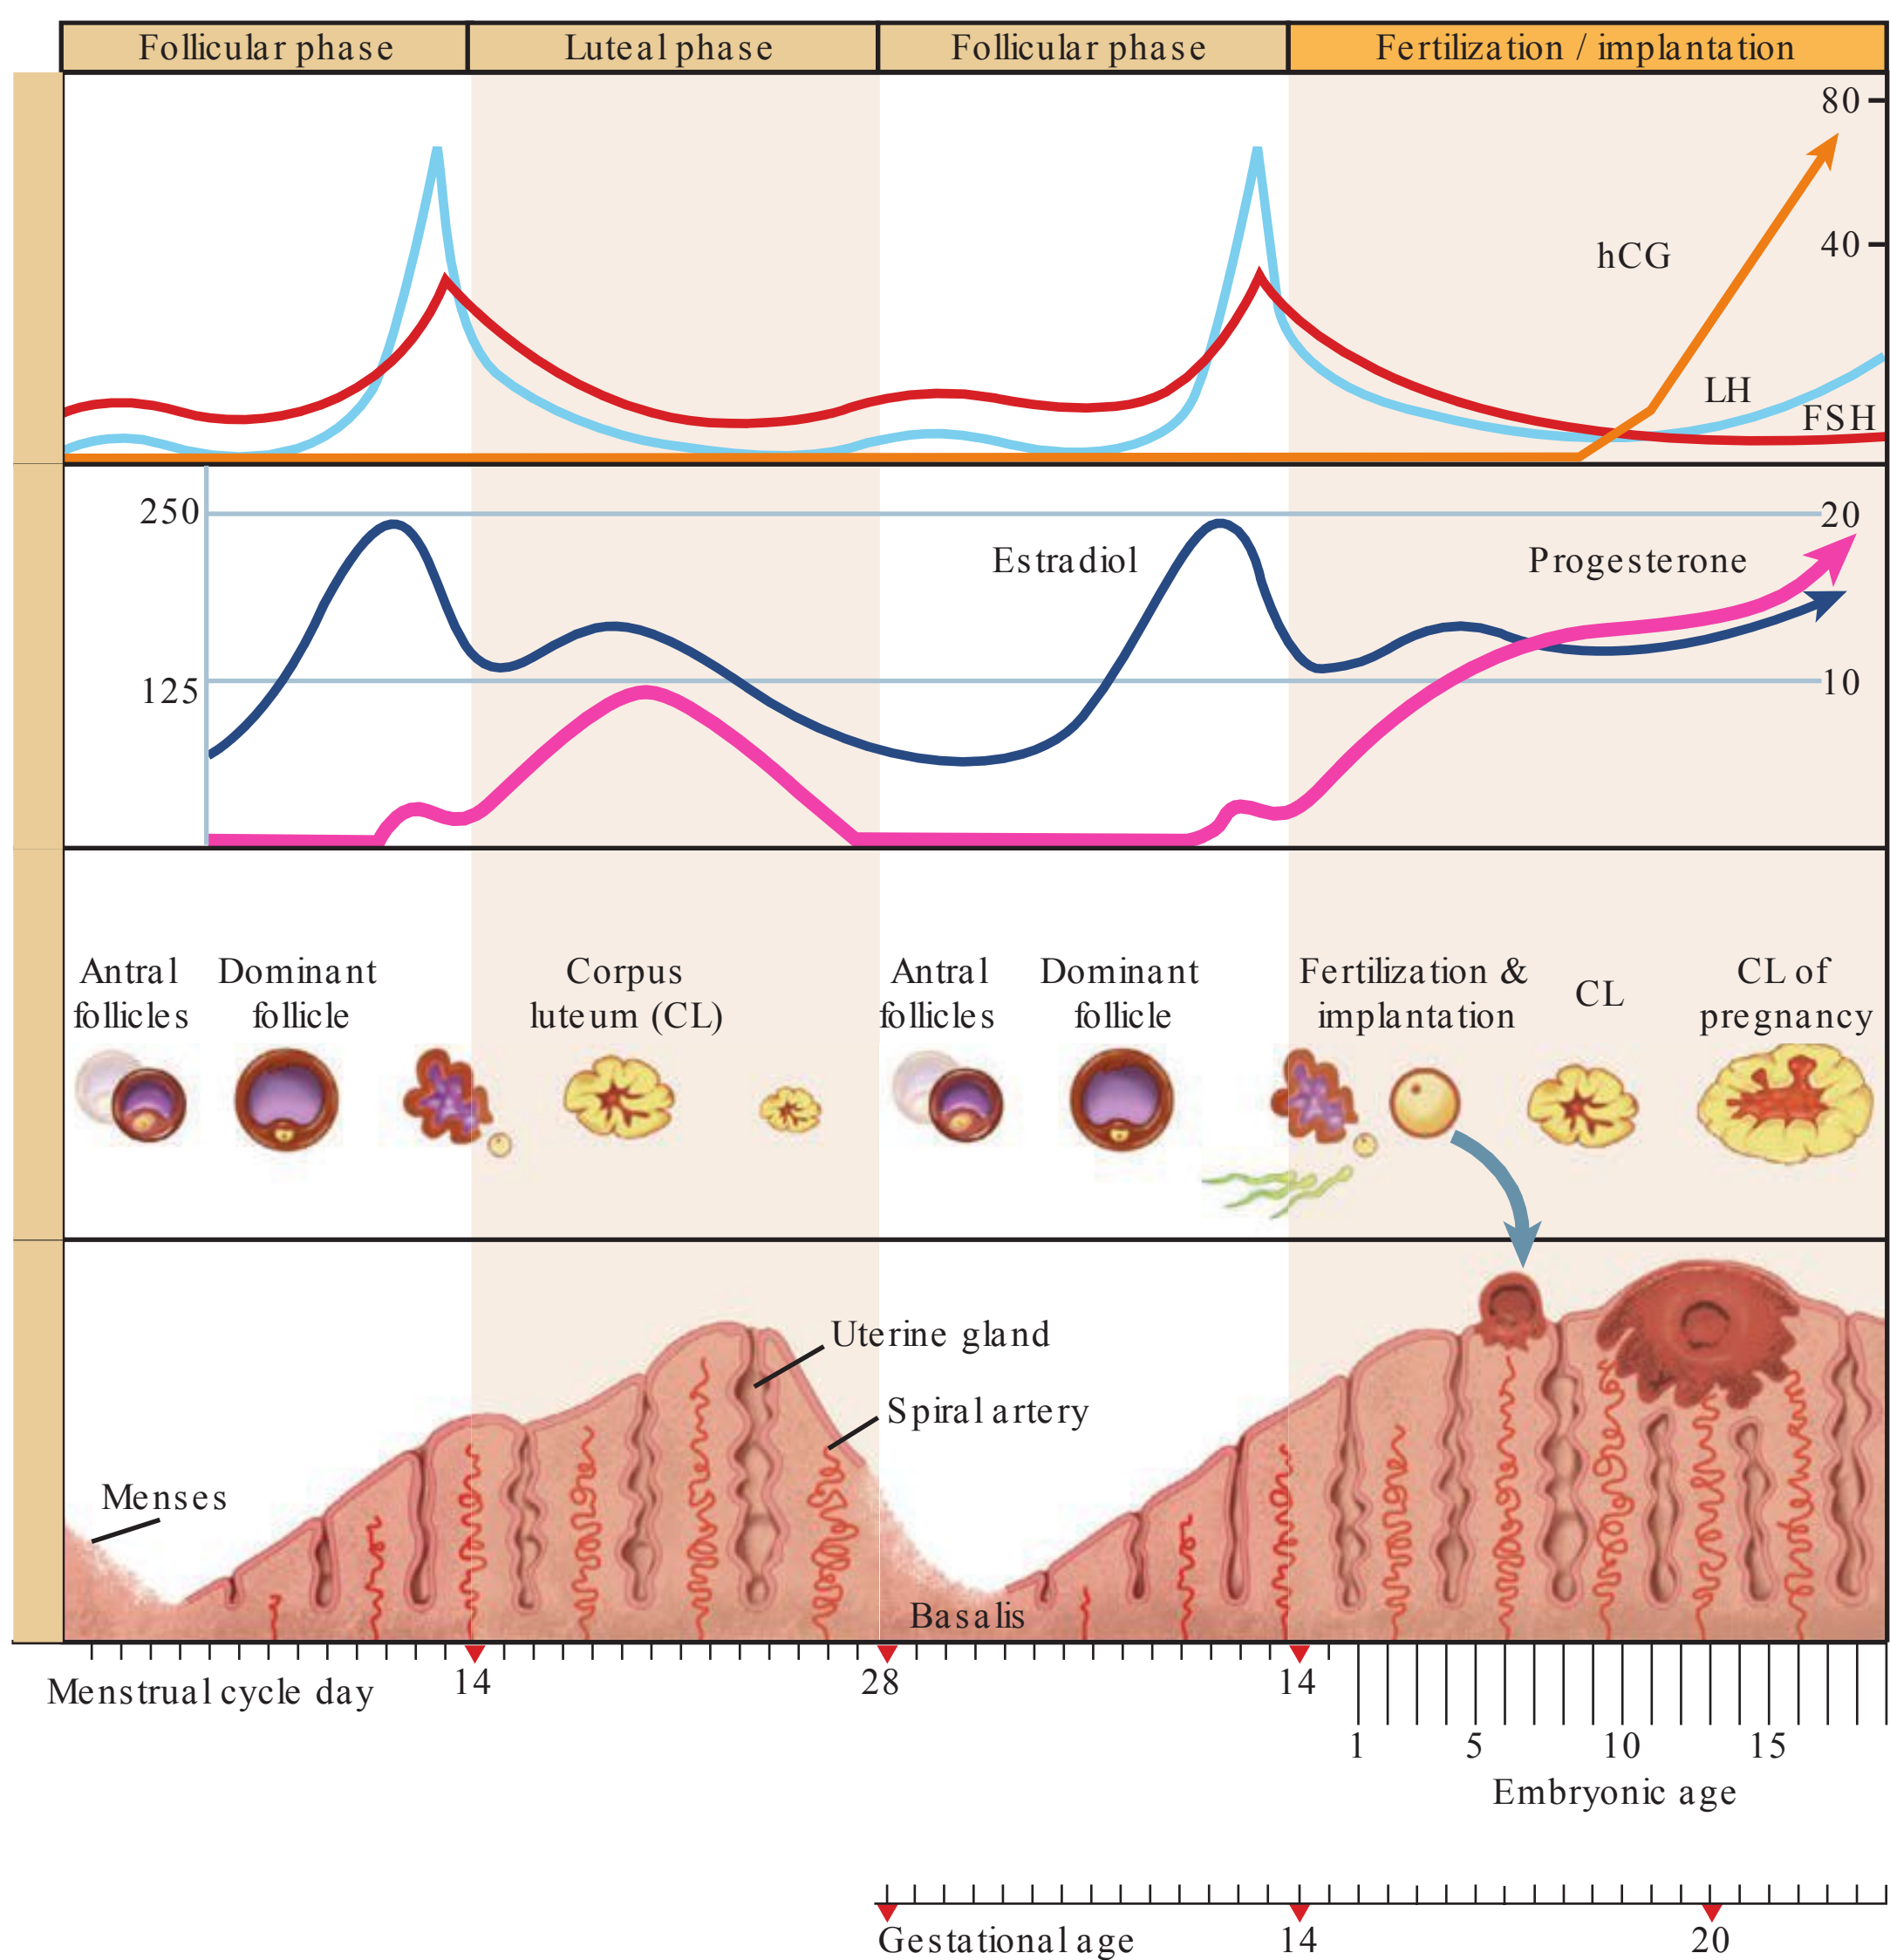

Ovaries have two interrelated functions: the generation of mature oocytes and the production of steroid and peptide hormones that create an environment in which fertilization and subsequent implantation in the endometrium can occur. Within each cycle, endocrine functions of the ovary correlate closely to the morphologic appearance and disappearance of follicles and corpus luteum.

#### Embryology of the Ovary

T e ovary develops from three major cellular sources: (1) primordial germ cells, which arise from the endoderm of the yolk sac and differentiate into the primary oogonia; (2) coelomic epithelial cells, which develop into granulosa cells; and (3) mesenchymal cells from the gonadal ridge, which become the ovarian stroma. Additional information regarding gonadal differentiation is found in Chapter 18 (p. 404).

Primordial germ cells can be seen in the yolk sac as early as the third week of gestation (Gosden, 2013). T ese cells begin their migration into the gonadal ridge during the sixth week of gestation and generate primary sex cords. T e ovary and testes are indistinguishable by histologic criteria until approximately 10 to 11 weeks of fetal life.

**FIGURE 15-12** Gonadotropin control of the ovarian and endometrial cycles. The ovarian-endometrial cycle has been structured as a 28-day cycle. The follicular phase (days 6 to 14) is characterized by rising levels of estrogen, thickening of the endometrium, and selection of the dominant “ovulatory” follicle. During the luteal phase (days 15 to 28), the corpus luteum produces estrogen and progesterone, which prepare the endometrium for implantation. If implantation occurs, the developing blastocysts will begin to produce human chorionic gonadotropin (hCG) and rescue the corpus luteum, thus maintaining progesterone production. FSH= follicle-stimulating hormone; LH= luteinizing hormone. (Reproduced with permission from Cunningham FG, Leveno KJ, Bloom SL, et al: Williams Obstetrics, 24th ed. New York: McGraw-Hill Education; 2014.)

After the primordial cells reach the gonad, they continue to multiply through successive mitotic divisions. Starting at 12 weeks’ gestation, a subset of oogonia will enter meiosis to become primary oocytes. Primary oocytes are surrounded by a single layer of flattened granulosa cells, creating a primordial follicle.

**Oocyte Loss with Aging**

All oogonia either develop into primary oocytes or become atretic. Classical teaching states that additional oocytes cannot be generated postnatally. This differs markedly from the male, in whom sperm are produced continuously throughout

TABLE 15-4. Menstrual Cycle Characteristics			
Cycle day	1–5	6–14	15–28
Ovarian phase	Early follicular	Follicular	Luteal
Endometrial phase	Menstrual	Proliferative	Secretory
Estrogen/progesterone	Low levels	Estrogen	Progesterone

**FIGURE 15-13** Ovarian anatomy and various sequential steps of follicular development.

adulthood. Exciting recent studies suggest that ovarian stem cells may be able to generate mature oocytes, providing hope for significant advances in female fertility preservation. Currently, these results remain preliminary and somewhat controversial (Notarianni, 2011; Virant-Klun, 2015).

The maximal number of oogonia is achieved at the 20th week of gestation, at which time 6 to 7 million oogonia are present in the ovary (Baker, 1963). Approximately 1 to 2 million oogonia are present at birth. Fewer than 400,000 are present at the initiation of puberty, of which fewer than 500 are destined to ovulate. Therefore, most germ cells are lost through atresia (Hsueh, 1996). Follicular atresia is thought not to be a passive, necrotic process, but rather a precisely controlled active process, namely apoptosis, which is under hormonal control. Apoptosis begins in utero and continues throughout reproductive life.

### Oocyte Maturation

As previously mentioned, primary oogonia enter meiosis in utero to become primary oocytes. These oocytes are arrested in development at prophase during the first meiotic division. Meiotic progression resumes each month in a cohort of follicles. Meiosis I is completed in the oocyte destined for ovulation in response to the LH surge. Meiosis II begins, and the process is arrested, this time in the second meiotic metaphase. Meiosis II is completed only if the ovum is fertilized (Fig. 15-14).

Normal oocyte development requires cytoplasmic modifications in addition to meiotic maturation. Changes in microtubules

and actin filaments enable rearrangement of cellular organelles to allow for successful polar body extrusion and fertilization (Coticchio, 2015). The cumulus cells modulate maturation both by cell-to-cell contact via gap junctions and by secretion of paracrine factors. Our growing understanding of these factors and processes is improving in vitro maturation protocols to aid fertility preservation and infertility treatments.

### Stromal Cells

Ovarian stroma contains interstitial cells, contractile cells, and connective tissue cells. These last cells provide structural support to the ovary. The group of interstitial cells that surround a developing follicle differentiates into theca cells. Under gonadotropin stimulation, these cells increase in size and develop lipid stores, characteristic of steroid-producing cells (Saxena, 1972).

Another group of interstitial cells in the ovarian hilum are known as hilus cells. These closely resemble testicular Leydig cells, and hyperplasia or neoplastic changes in hilar cells may result in excess testosterone secretion and virilization. The normal role of these cells is unknown, but their intimate association with blood vessels and neurons suggest that they may convey systemic signals to the remainder of the ovary.

### ■ Ovarian Hormone Production

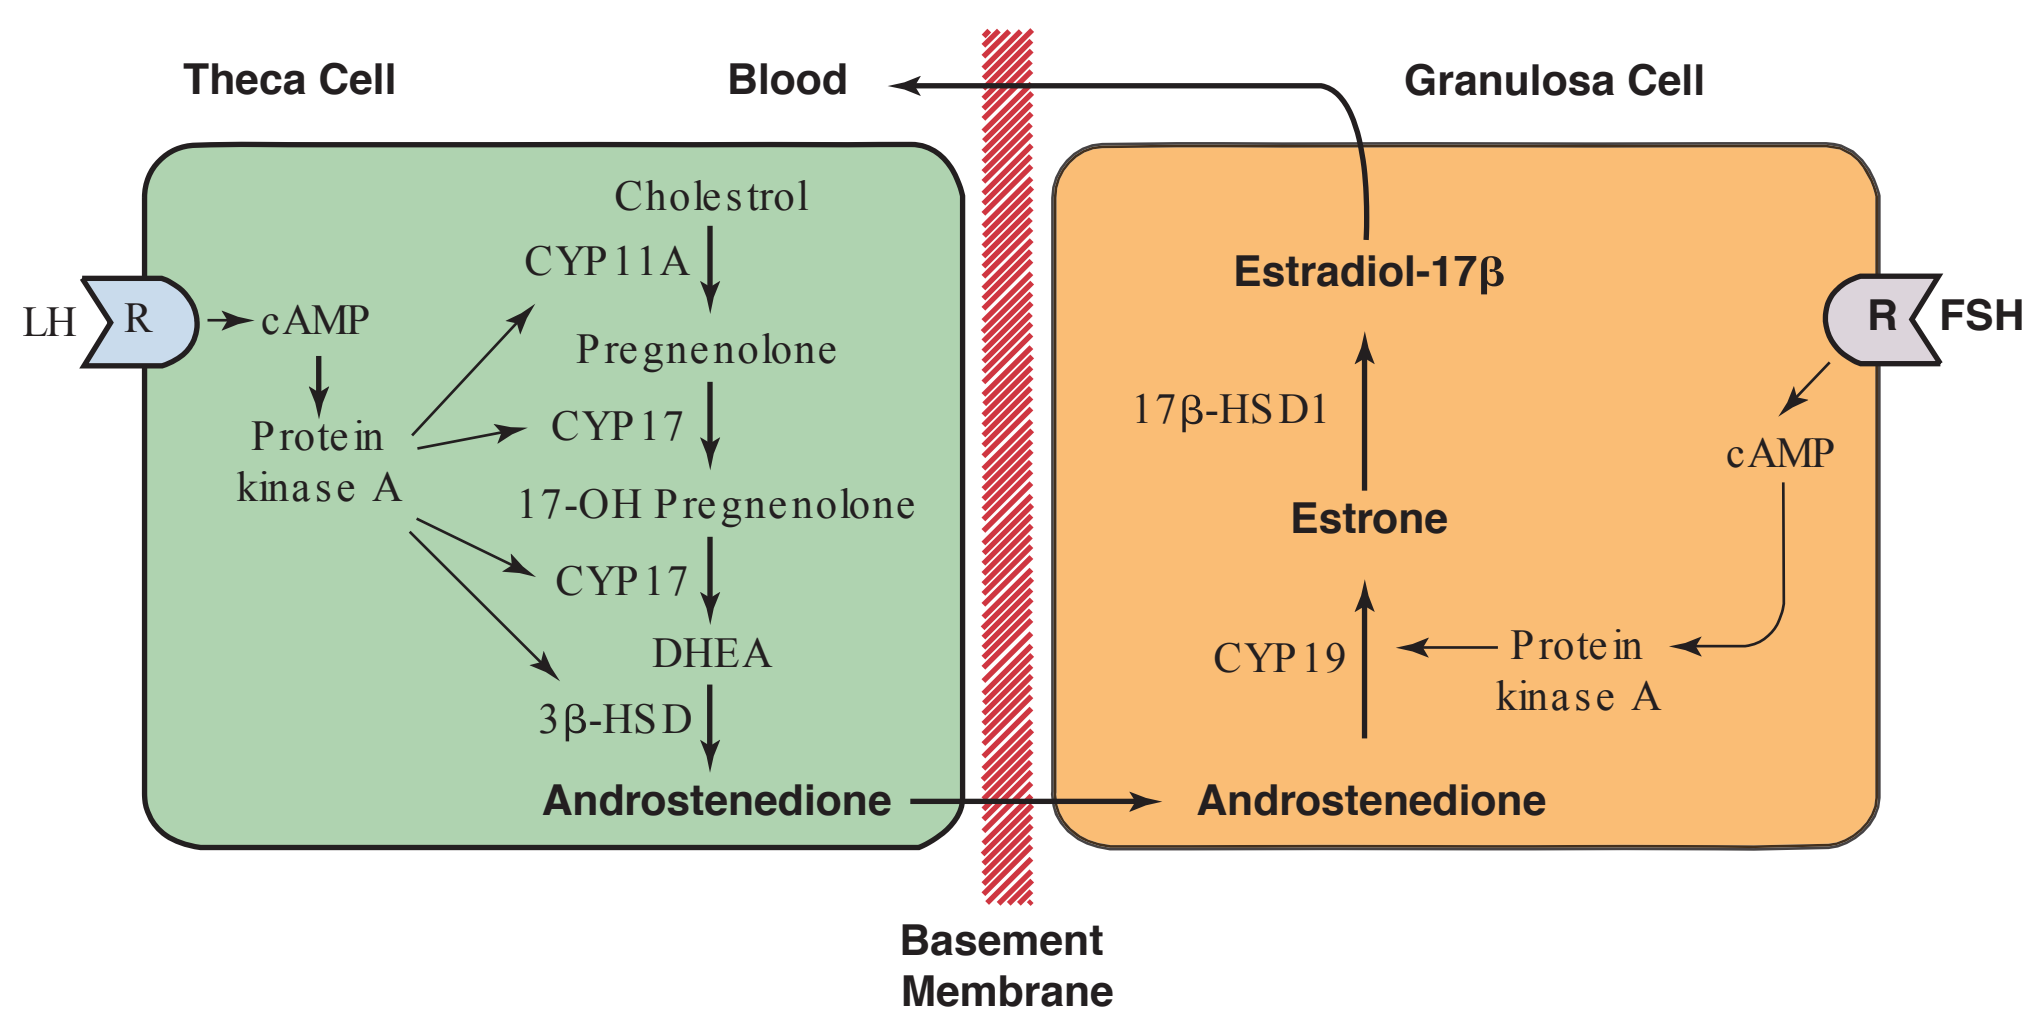

The normal functioning ovary synthesizes and secretes estrogens, androgens, and progesterone in a precisely controlled

**FIGURE 15-14** The steps of oocyte development and corresponding follicular maturation. In the fetal period, once the primordial germ cells arrive in the gonad, they differentiate into oogonia. Mitotic division of oogonia increases the population. Many oogonia further differentiate into primary oocytes, which begin meiosis. However, the process arrests after only prophase is completed. A primary oocyte with its surrounding epithelial cells is called a primordial follicle. In childhood, primary oocytes remain suspended in prophase. Beginning in puberty and extending through the reproductive years, several primordial follicles mature each month into primary follicles. A few of these continue development to secondary follicles. One or two secondary follicles progress to a tertiary or graafian follicle stage. At this stage, the first meiotic division completes to produce a haploid secondary oocyte and a polar body. During this process, cytoplasm is conserved by the secondary oocyte. Consequently, the polar body is disproportionately small. The secondary oocyte enters meiosis II, which then arrests in metaphase. One of the secondary oocytes is released at ovulation. If the oocyte is fertilized, completion of the second meiotic division follows. If fertilization fails to occur, then the oocyte degenerates before completion of the second meiotic division.

**FIGURE 15-15** Diagram illustrates the two-cell theory of ovarian follicular steroidogenesis. Theca cells contain large numbers of luteinizing hormone (LH) receptors. Binding of LH to these receptors leads to cyclic AMP activation and synthesis of androstenedione from cholesterol. Androstenedione diffuses across the basement membrane of theca cells to enter granulosa cells of the ovary. Here, under the activation of follicle-stimulating hormone (FSH), androstenedione is converted by the enzyme aromatase to estrone and estradiol. cAMP = cyclic adenosine monophosphate; DHEA = dehydroepiandrosterone; 3β-HSD = 3β-hydroxysteroid dehydrogenase; 17β-HSD1 = 17β-hydroxysteroid dehydrogenase; R = receptor. (Adapted with permission from Larsen PR, Kronenberg HM, Melmed S: *William's Textbook of Endocrinology*, 10th edition. Philadelphia: Elsevier/Saunders; 2003.)

pattern determined, in part, by the pituitary gonadotropins, FSH and LH. The most important secretory products of ovarian steroid biosynthesis are progesterone and estradiol. However, the ovary also secretes quantities of estrone, androstenedione, testosterone, and 17α-hydroxyprogesterone. Sex steroid hormones play an important role in the menstrual cycle by preparing the uterus for implantation of a fertilized ovum. If implantation does not occur, ovarian steroidogenesis declines, the endometrium degenerates, and menstruation ensues.

### Two-Cell Theory

Ovarian estrogen biosynthesis requires the combined action of two gonadotropins (LH and FSH) on two cell types (theca and granulosa cells). This concept is known as the two-cell theory of ovarian steroidogenesis (Fig. 15-15) (Peters, 1980). Until the late antral stage of follicular development, LH-receptor expression is limited to the thecal compartment, and FSH-receptor expression is limited to the granulosa cells.

Theca cells express all of the enzymes needed to produce androstenedione. This includes high levels of *CYP17* gene expression, whose enzyme product catalyzes 17-hydroxylation. This is the rate-limiting step in the conversion of progesterones to androgens (Sasano, 1989). This enzyme is absent in the granulosa cells, so they are incapable of producing the androgenic precursors needed to produce estrogens. Granulosa cells therefore rely on the theca cells. Namely, in response to LH stimulation, theca cells synthesize the androgens androstenedione and testosterone. These androgens are secreted into the extracellular fluid and diffuse across the basement membrane to the granulosa cells to provide precursors for estrogen production. In contrast to theca cells, granulosa cells have high levels of aromatase activity in response to FSH stimulation. Thus, these cells efficiently convert androgens to estrogens, primarily

the potent estrogen estradiol. In sum, ovarian steroidogenesis is dependent on the effects of LH and FSH acting independently on the theca cells and granulosa cells, respectively.

### Steroidogenesis across the Life Span

Circulating levels of the gonadotropins LH and FSH vary markedly at different ages of a woman's life. In utero, the fetal human ovary has the capacity to produce estrogens by 8 weeks' gestation. However, a minimal amount of steroid is actually synthesized during fetal development (Miller, 1988). During the second trimester, the plasma levels of gonadotropins rise to levels similar to those observed in menopause (Temeli, 1985). The fetal hypothalamic-pituitary axis continues to mature during this time, becoming more sensitive to the high circulating levels of estrogen and progesterone secreted by the placenta (Kaplan, 1976). Prior to birth and in response to these high steroid levels, fetal gonadotropins fall to low levels.

After delivery, gonadotropin levels in the neonate rise abruptly due to separation from the placenta and subsequent freedom from placental steroid inhibition (Winter, 1976). The elevated gonadotropin levels persist for the first few months of life and then decline to low levels in early childhood (Schmidt, 2000). There may be multiple etiologies for the low gonadotropin levels during this period of life. The hypothalamic-pituitary axis has increased sensitivity to negative feedback, even by the low circulating levels of gonadal steroids at this stage. There may be a direct CNS role in maintaining low gonadotropin levels. In support of this mechanism, low levels of LH and FSH are found even in children with gonadal dysgenesis who lack negative feedback by gonadal steroids.

With puberty, one early sign is a sleep-associated increase in LH secretion (Fig. 15-16). Over time, increased gonadotropin secretion is noted throughout the day. An increased FSH to LH

**FIGURE 15-16** Variations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) during different life stages in the female. (Modified with permission from Faiman C, Winter JS, Reyes FI: Patterns of gonadotrophins and gonadal steroids throughout life, Clin Obstet Gynaecol. 1976 Dec;3(3):467–483.)

ratio is typical in the premenarchal girl and postmenopausal woman. During the reproductive years, LH exceeds FSH levels, inverting this ratio. Increased gonadotropin levels stimulate ovarian estradiol production. The rise in estrogen levels prompts the growth spurt, maturation of the female internal and external genitalia, and development of a female habitus including pubertal breast enlargement, which is termed thelarche. Activation of the pituitary-adrenal axis results in an increase in adrenal androgen production and the associated pubertal development of axillary and pubic hair, termed adrenarche or pubarche. Increased gonadotropin levels ultimately lead to ovulation and subsequent menses. The first menstrual period defines menarche. This developmental process takes approximately 3 to 4 years and is discussed further in Chapter 14 (p. 319).

Following menopause, the postmenopausal ovary contains only a few follicles. As a result, plasma estrogen and inhibin levels decrease markedly after cessation of ovulatory cycles. Through loss of this negative feedback, LH and FSH levels are strikingly elevated. Elevated LH levels can stimulate production of C-19 steroids (mainly androstenedione) in ovarian stromal cells. This ovarian-derived androstenedione and adrenal androgens can be converted by peripheral tissues to estrone, the principal serum estrogen in the postmenopausal women. The major site for the conversion of androstenedione to estrone is adipose tissue. Peripheral conversion of circulating androstenedione to estrone is directly correlated to body weight. For a given body weight, conversion is higher in postmenopausal women than in premenopausal women. These low circulating estrogen levels are usually not adequate to protect against bone loss.

## ■ Gonadal Peptides and the Menstrual Cycle

Of the multiple gonadal peptides, three—*inhibin*, *activin*, and *folliculin*—modulate gonadotrope activity in addition to effects within the ovary (de Kretser, 2002). As suggested by their names, inhibin decreases and activin stimulates gonadotrope function. Folliculin suppresses FSH $\beta$  gene expression, most likely by binding to and thereby preventing the interaction of activin with its receptor (Xia, 2009).

Inhibin and activin are closely related peptides. Inhibin consists of an  $\alpha$ -subunit (unrelated to the LH and FSH glycoprotein  $\alpha$ -subunit) linked by a disulfide bridge to one of two highly homologous  $\beta$ -subunits to form inhibin A ( $\alpha\beta_A$ ) or inhibin B ( $\alpha\beta_B$ ). Activin is composed of homodimers ( $\beta_A\beta_A$ ,  $\beta_B\beta_B$ ) or heterodimers ( $\beta_A\beta_B$ ) of the same  $\beta$ -subunits as inhibin (Bilezikjian, 2012). In contrast, folliculin is structurally unrelated to either inhibin or activin.

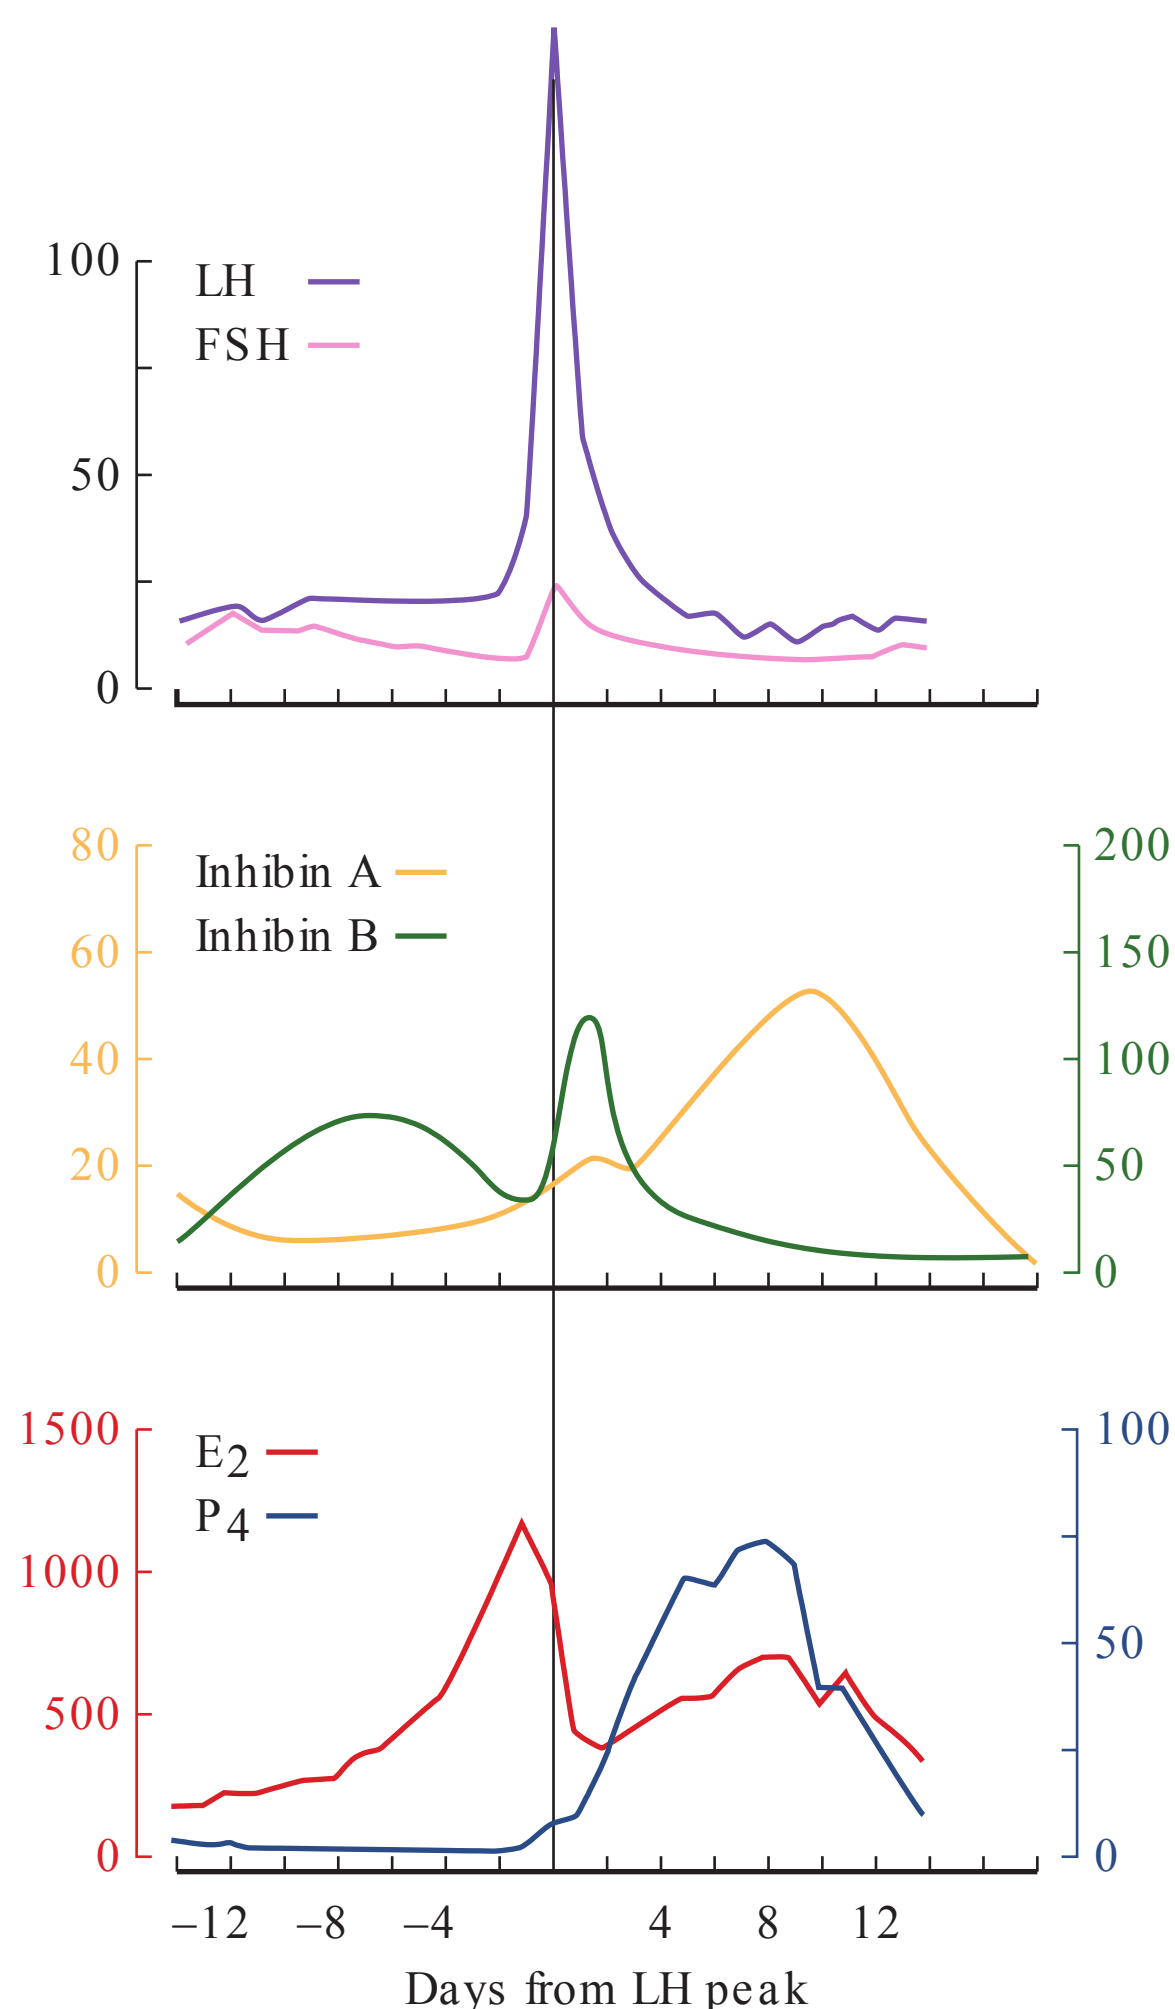

Although originally isolated from follicular fluid, these “gonadal” peptides are expressed in the pituitary, ovary, testes, and placenta and in the brain, adrenal, liver, kidney, and bone marrow to provide

diverse tissue-specific functions (Muttukrishna, 2004). Activin and folliculin most likely act as autocrine/paracrine factors in the tissues in which they are expressed, including the ovary.

In contrast, ovarian-derived inhibins circulate in significant concentrations and are believed to be critical for negative feedback of gonadotropin gene expression. Specifically, during the early follicular phase, FSH stimulates the secretion of inhibin B by the granulosa cells (Fig. 15-17) (Buckler, 1989). However, increasing levels of circulating inhibin B blunt later FSH secretion in the follicular phase. During the luteal phase, regulation of inhibin production comes under the control of LH and switches from inhibin B to inhibin A (McLachlan, 1989). Inhibin B levels peak with the LH surge, whereas inhibin A levels peak a few days later, in the midluteal phase. All inhibin levels decline with the loss of luteal function and remain low during the luteal-follicular transition and early follicular phase. The inverse relationship between circulating inhibin levels and FSH secretion is consistent with a negative-feedback role for inhibin in regulating FSH secretion.

Distinct from these three peptides, insulin-like growth factors also mediate ovarian function. Only IGF-II is involved in primordial follicle development, but both IGF-I and IGF-II stimulate growth of secondary follicles. Gonadotropins stimulate IGF-II production in theca cells, granulosa cells, and luteinized granulosa cells. Receptors for IGF are expressed on the theca and granulosa cells, supporting an autocrine/paracrine action in the follicle. FSH also mediates expression of IGF-binding proteins. This system, although complex, allows additional fine-tuning of intrafollicular activity (Silva, 2009).

**FIGURE 15-17** Graphs of gonadotropin, inhibin, and sex-steroid level changes during a normal menstrual cycle. The top graph displays peaking of luteinizing hormone (LH) (purple line) and follicle-stimulating hormone (FSH) (pink line) levels. The middle graph shows changing levels of inhibin A and inhibin B. Note that inhibin B levels (green line) peak temporally near the midcycle surge in the LH level, whereas maximal elevation of inhibin A (orange line) occurs several days following this peak. In the bottom graph, elevations in estradiol levels (red line) are noted prior to the surge in LH levels and in the midluteal phase. Progesterone levels (blue line) peak in the midluteal phase. E2 = estradiol; P4 = progesterone.

## ■ Follicular Development

### Follicle Stages

Development begins with primordial follicles that were generated during fetal life (see Fig. 15-14). These follicles consist of an oocyte arrested in the first meiotic division surrounded by a single layer of flattened granulosa cells. The follicles are separated from the stroma by a thin basement membrane. Preovulatory follicles are avascular. As such, they are critically dependent on diffusion and on the later development of gap junctions for obtaining nutrients and clearing metabolic waste. Diffusion also allows passage of steroid precursors from the theca to the granulosa cell layer.

In the primary follicle stage, the granulosa cells of developing follicles become cuboidal and increase in number to form

a pseudostratified layer. Intercellular gap junctions develop between adjacent granulosa cells and between granulosa cells and the developing oocyte (Albertini, 1974). These connections allow the passage of nutrients, ions, and regulatory factors between cells. Gap junctions also allow cells without gonadotropin receptors to receive signals from cells with receptor expression. As a result, hormone-mediated effects can be transmitted throughout the follicle.

During this stage, the oocyte begins to secrete products to form an acellular coat known as the zona pellucida. The human zona pellucida contains at least three proteins, named ZP1, ZP2, and ZP3. In current physiologic models, receptors on the acrosome head of the sperm recognize ZP3. This interaction releases acrosomal contents that permit penetration of the zona pellucida and ovum fertilization. Enzymes released from the acrosome induce alterations in ZP2 that result in hardening of the coat. This prevents fertilization of the oocyte by more than one sperm (Gupta, 2015).

Development of a secondary, or preantral, follicle includes final growth of the oocyte and a further increase in granulosa cell number. The stroma around the granulosa cell layer differentiates into the theca interna and the theca externa (Eppig, 1979).

Tertiary follicles, also called antral follicles, form from ongoing development in selected oocytes. In these, follicular fluid collects between the granulosa cells, ultimately producing a fluid-filled space known as the antrum. Granulosa cells in the antral follicle are histologically and functionally divided into two groups. The granulosa cells surrounding the oocyte form the cumulus oophorus, whereas the granulosa cells surrounding the antrum are known as mural granulosa cells. Antral fluid consists of a plasma filtrate and factors secreted by the granulosa cells. These locally produced factors, which include estrogen and growth factors, are present in substantially higher concentrations in follicular fluid than in the circulation and are likely critical for successful follicular maturation (Asimakopoulou, 2006; Silva, 2009). Further accumulation of antral fluid results in a rapid increase in follicular size and development of a preovulatory, or graafian, follicle (Hennet, 2012).

During this process, early stages of development (up to the secondary follicle) do not require gonadotropin stimulation and thus are said to be “gonadotropin-independent.” Final follicular maturation requires adequate amounts of circulating LH and FSH and is therefore said to be “gonadotropin-dependent” (Butt, 1970). Of note, data suggest that progression from gonadotropin-independent to dependent stages is not as discrete as previously believed.

### Concept of a Selection Window

Follicular development is a multistep process, which proceeds over at least 3 months and culminates in ovulation from a single follicle. Each month, a group of follicles known as a cohort begins a phase of semisynchronous growth. The size of this cohort appears to be proportional to the number of inactive primordial follicles within the ovaries and has been estimated at 3 to 11 follicles per ovary in young women (Hodgen, 1982; Pache, 1990). Importantly, the ovulatory follicle is recruited from a cohort that began development two to three cycles prior

to the ovulatory cycle. During this time, most follicles will die as they will not be at an appropriate stage of development during the selection window.

During the luteal-follicular transition, a small increase in FSH levels is responsible for selection of the single dominant follicle that will ultimately ovulate (Schipper, 1998). As previously described, theca cells produce androgens, which are converted to estrogens by the granulosa cells. Estrogen levels increase with increased follicular size, enhance the effects of FSH on granulosa cells, and create a feed-forward action on follicles that produce estrogens.

Intrafollicular levels of the insulin-like growth factors are believed to synergize with FSH to help select the dominant follicle (Son, 2011). Additional studies have also demonstrated elevated levels of vascular endothelial growth factor (VEGF) around the follicle that will be selected. This follicle would presumably be exposed to higher levels of circulating factors such as FSH (Ravindranath, 1992).

Granulosa cells also produce inhibin B, which passes from the follicle into the plasma and specifically inhibits the release of FSH, but not of LH, by the anterior pituitary. The combined production of estradiol and inhibin B by the dominant follicle results in the decline of follicular-phase FSH levels and may be responsible at least in part for the failure of the other follicles to reach preovulatory status during any one cycle.

### Estrogen-dominant Microenvironment

Ongoing follicular maturation requires the successful conversion from an “androgen-dominant” microenvironment to an “estrogen-dominant” one. At low concentrations, androgens stimulate aromatization and contribute to estrogen production. However, intrafollicular androgen levels will rise if aromatization in the granulosa cells lags behind androgen production by the thecal layer. At higher concentrations, androgens are converted to the more potent  $5\alpha$ -androgens, such as dihydrotestosterone. These androgens inhibit aromatase activity, cannot be aromatized to estrogens, and inhibit FSH induction of LH-receptor expression on the granulosa cells (Gervásio, 2014).

This model predicts that follicles that lack adequate FSH receptor and granulosa cell number will remain primarily androgenic and will therefore become atretic. An increased androgen-to-estrogen ratio is found in the follicular fluid of atretic follicles, and several studies have demonstrated that high estrogen levels prevent apoptosis.

IGF-I also has apoptosis-suppressing activity and is produced by granulosa cells. This action of IGF-I is suppressed by certain IGF-binding proteins that are present in the follicular fluid of atretic follicles. The action of FSH to prevent atresia may therefore result, in part, from its ability to stimulate IGF-I synthesis and suppress the synthesis of the IGF-binding proteins.

## ■ Menstrual Cycle Phases

### Follicular Phase

During the end of a previous cycle, estrogen, progesterone, and inhibin levels decrease abruptly with a corresponding increase

in circulating FSH levels (Hodgen, 1982). As just described, this increase in FSH level is responsible for recruitment of the cohort of follicles that contains the follicle destined for ovulation. Despite general belief, sonographic studies in women have demonstrated that ovulation does not alternate sides, but occurs randomly from either ovary (Baird, 1987).

In women with waning ovarian function, the FSH level at this time of the cycle is elevated relative to that of younger women, presumably due to a loss of ovarian inhibin production in the previous luteal phase. As a result, measurement of early follicular or cycle day 3 FSH and estradiol levels is frequently performed in infertility clinics. The accelerated increase in serum FSH levels results in more robust recruitment of follicles and may explain both the shortened follicular phase observed in these older reproductive-aged women and the increased incidence of spontaneous twinning.

During the midfollicular phase, follicles produce increased amounts of estrogen and inhibin, resulting in a decline in FSH levels through negative feedback. This drop in FSH levels is believed to contribute to selection of the follicle destined to ovulate, termed the dominant follicle. Based on this theory, nondominant follicles express decreased numbers of FSH receptors and therefore are unable to respond adequately to declining FSH levels.

During most of follicular development, granulosa cell responses to FSH stimulation include an increase in granulosa cell number, an increase in aromatase expression, and, in the presence of estradiol, expression of LH receptors on the granulosa cells. With the development of LH-receptor expression during the late follicular phase, granulosa cells begin to produce small amounts of progesterone. This progesterone decreases granulosa cell proliferation, thereby slowing follicular growth (Chaffkin, 1992).

### Ovulation

Toward the end of the follicular phase, estradiol levels increase dramatically. For reasons that are not completely understood but perhaps relate to changes at the kisspeptin neurons, the rapid estradiol level increase triggers a change from negative to positive feedback at both the hypothalamus and anterior pituitary gland to generate a surge in LH levels. Estradiol concentrations of 200 pg/mL for 50 hours are necessary to initiate this surge (Young, 1976). A small preovulatory increase in progesterone concentrations generates an FSH level surge, which occurs in tandem with the LH surge (McNatty, 1979). Progesterone may also augment the ability of estradiol to trigger the LH surge. These effects may explain the occasional induction of ovulation in anovulatory amenorrheic women when given progesterone to induce menses.

The LH surge acts rapidly on both the granulosa and theca cells of the preovulatory follicle to terminate the genes involved in follicular expression and turn on the genes necessary for ovulation and luteinization. In addition, the LH surge initiates the reentry of the oocyte into meiosis, expansion of the cumulus oophorus, synthesis of prostaglandins, and luteinization of granulosa cells. The mean duration of the LH surge is 48 hours, and ovulation occurs approximately 36 to 40 hours after the

onset of the LH surge (Hoff, 1983; Lemarchand-Beraud, 1982). Abrupt termination of the surge is postulated to follow acutely increased steroid and inhibin secretion by the corpus luteum. Alternatively, the secretion of a gonadotropin surge-inhibiting/attenuating factor (GnSIF/AF) by either the ovary or hypothalamus is also postulated. However, the identity of this factor remains unknown (Vega, 2015).

The granulosa cells surrounding the oocyte, unlike mural granulosa cells, do not express LH receptors or synthesize progesterone. These cumulus oophorus granulosa cells develop tight gap junctions between themselves and with the oocyte. The cumulus mass that accompanies the ovulating oocyte is believed to provide a rough surface and increased size to improve oocyte “pick-up” by the tubal fimbria.

It has recently been found that amphiregulin, epiregulin, and beta-cellulin, which are epidermal growth factor-like factors, can be substituted to elicit the morphologic and biochemical events triggered by LH (Hsieh, 2009). Thus, these growth factors are part of the downstream cascade that begins with LH binding to its receptor and ends with ovulation.

Based on sonographic surveillance, extrusion of the oocyte lasts only a few minutes (Fig. 15-18) (Knobil, 1994). The exact mechanism of this expulsion is poorly defined but is not due to an increase in follicular pressure (Espey, 1974). The presence of proteolytic enzymes in the follicle, including plasmin and collagenase, suggests that these enzymes are responsible for follicular wall thinning (Beers, 1975). The preovulatory gonadotropin surge stimulates expression of tissue plasminogen activator by the granulosa and theca cells. The surge also decreases expression of plasminogen inhibitor, resulting in a marked increase in plasminogen activity (Piquette, 1993).

Prostaglandins also reach a peak concentration in follicular fluid during the preovulatory gonadotropin surge (Lumsden, 1986). Prostaglandins may stimulate smooth muscle contraction in the ovary, thereby contributing to ovulation (Yoshimura, 1987). Women undergoing infertility treatment

are advised to avoid prostaglandin synthetase inhibitors in the preovulatory period to avoid luteinized unruptured follicle syndrome (LUFS) (Smith, 1996). Controversy exists as to whether LUFS should be considered pathologic or simply a sporadic event (Kerin, 1983).

### Luteal Phase

Following ovulation, the remaining follicular cells differentiate into the corpus luteum, literally *yellow body* (Corner, 1956). This process, which requires LH stimulation, includes both morphologic and functional changes known as luteinization. The granulosa and theca cells proliferate and undergo hypertrophy to form granulosa-lutein cells and smaller theca-lutein cells, respectively (Patton, 1991).

During corpus luteum formation, the basement membrane that separates granulosa cells from theca cells degenerates and allows vascularization of previously avascular granulosa cells. Capillary invasion begins 2 days after ovulation and reaches the center of the corpus luteum by the fourth day. This increase in perfusion provides these luteal cells with access to circulating low-density lipoprotein (LDL), which is used to provide precursor cholesterol for steroid biosynthesis. This marked increase in blood supply can have clinical implications, as pain from a hemorrhagic corpus luteum cyst is a relatively frequent presentation to emergency rooms.

Adequate steroidogenesis in the corpus luteum depends on serum LH levels, LH receptors on luteal cells, and a sufficient number of luteal cells. Thus, it is critical that LH receptor expression on granulosa cells was appropriately induced during the prior follicular phase. Furthermore, blunted serum LH concentrations have been correlated with a shortened luteal phase. Luteal function is also influenced by gonadotropin levels from the preceding follicular phase. A reduction in LH or FSH secretion is correlated with poor luteal function. Presumably, a lack of FSH leads to a decrease in the total number of granulosa cells. Furthermore, luteal cells in these suboptimal cycles will have a decreased number of FSH-induced LH receptors and thus will be less responsive to LH stimulation.

Based on the corpus luteum's steroidogenic products, the luteal phase is considered progesterone dominant, which contrasts with the estrogen dominance of the follicular phase. Increased vascularization, cellular hypertrophy, and an increased number of intracellular organelles transform the corpus luteum into the most active steroidogenic tissue in the body. Maximal levels of progesterone production are observed in the midluteal phase and have been estimated at an impressive 40 mg of progesterone per day. Ovulation can be safely assumed to have occurred if the progesterone level exceeds 3 ng/mL on cycle day 21.

Although progesterone is the most abundant ovarian steroid during the luteal phase, estradiol is also produced in significant quantities. Estradiol levels drop transiently immediately after the LH surge. This decline may explain the midcycle spotting noticed by some women. The reason for this decrease is not known, but it may result from a direct inhibition of granulosa cell growth by increasing progesterone levels (Hoff, 1983). The decline in estradiol levels is followed by a steady increase to reach a maximum during the midluteal phase.

**FIGURE 15-18** During laparoscopy, a stigma on the ovarian surface (arrow) prior to ovulation is seen. (Used with permission from Dr. David Rogers.)

The corpus luteum produces large quantities of inhibin A. This coincides with a decrease in circulating FSH levels in the luteal phase. If inhibin A levels decline at the end of the luteal phase, FSH levels rise once more to begin selection of a oocyte cohort for the next menstrual cycle.

If pregnancy does not occur, the corpus luteum regresses through a process called luteolysis. The mechanism for luteolysis is poorly understood, but luteal regression is presumed to be tightly regulated as luteal cycle length varies minimally among women. Following luteolysis, the blood supply to the corpus luteum diminishes, progesterone and estrogen secretion drop precipitously, and the luteal cells undergo apoptosis and become fibrotic. This creates the *corpus albicans* (white body).

If pregnancy occurs, hCG produced by the early gestation “rescues” the corpus luteum from atresia by binding to and activating the LH receptor on luteal cells. hCG stimulation of corpus luteum steroidogenesis maintains endometrial stability until placental steroid production is adequate to assume this function late in the first trimester. For this reason, surgical removal of the corpus luteum during pregnancy should be followed by progesterone replacement as outlined in Chapter 9 (p. 223) until approximately 10 weeks’ gestation.

## ENDOMETRIUM

### ■ Histology across the Menstrual Cycle

The endometrium consists of two layers: the *basalis layer*, which lies against the myometrium, and the *functionalis layer*, which is apposed to the uterine lumen. The basalis layer, which does not change significantly across the menstrual cycle, serves as the reserve for endometrium regeneration following menstrual sloughing. The functionalis layer is further subdivided into the more superficial *stratum compactum*, a thin layer of gland necks and dense stroma, and the underlying *stratum spongiosum* containing glands and large amounts of loosely organized stroma and interstitial tissue.

After menstruation, the endometrium is 1 to 2 mm thick. Under the influence of estrogen, the glandular and stromal cells of the functionalis layer proliferate rapidly following menses (Fig. 15-19). This period of rapid growth, the *proliferative phase*, corresponds to the ovary’s follicular phase. As this phase progresses, glands become more tortuous and cells lining the glandular lumen undergo pseudostratification. The stroma remains compact. Endometrial thickness approximates 12 mm at the time of the LH surge and does not increase significantly thereafter.

Following ovulation, the endometrium transforms into a secretory tissue. The period during and after this transformation is defined as the *secretory phase* of the endometrium and correlates to the ovary’s *luteal phase*. Glycogen-rich subnuclear vacuoles appear in cells lining the glands. Under further stimulation by progesterone, these vacuoles move from the glandular cells’ base toward their lumen and expel their contents. This secretory process peaks on approximately postovulatory day 6, coinciding with the day of implantation. Throughout

the luteal phase, glands become increasingly tortuous, and the stroma becomes more edematous. In addition, spiral arteries that feed the endometrium increase their number and coiling.

If a blastocyst does not implant and the corpus luteum is not maintained by placental hCG, progesterone levels drop and endometrial glands begin to collapse. Polymorphonuclear leukocytes and monocytes from nearby vessels infiltrate the endometrium. The spiral arteries constrict, leading to local ischemia, and lysosomes release proteolytic enzymes that accelerate tissue destruction. Prostaglandins, particularly prostaglandin  $F_{2\alpha}$ , are present in the endometrium and likely contribute to arteriolar vasospasm. Prostaglandin  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ) also induces myometrial contractions, which may aid in expelling the endometrial tissue.

The entire endometrial functionalis layer is thought to exfoliate with menstruation, leaving only the basalis layer to provide cells for endometrial regeneration. However, in studies, the amount of tissue shed from different levels of the endometrium varies widely. Following menstruation, reepithelialization of the desquamated endometrium is initiated within 2 to 3 days after the onset of menses and completed within 48 hours.

### ■ Regulation of Endometrial Function

#### Tissue Degradation and Hemorrhage

Within the endometrium, numerous proteins maintain a delicate balance between tissue integrity and the localized destruction required for menstrual sloughing or for trophoblast invasion during implantation. Cytokines, growth factors, and steroid hormones are believed to regulate the genes encoding these tissue proteins (Critchley, 2001). Of these proteins, tissue factor, a membrane-associated protein, activates the coagulation cascade upon contact with blood. In addition, urokinase and tissue plasminogen activator (TPA) increase the conversion of plasminogen to plasmin to activate tissue breakdown. TPA activity is blocked by plasminogen activator inhibitor 1, which is present in endometrial stroma (Lockwood, 1993; Schatz, 1995). Another key mediator group, matrix metalloproteinases (MMPs), is an enzyme family with overlapping substrate specificities for collagens and other extracellular matrix components. The composition of MMPs varies within different endometrial tissues and during the menstrual cycle. Endogenous MMP inhibitors are increased premenstrually and limit MMP degradative activity.

#### Vasoconstriction and Myometrial Contractility

Effective menstruation depends on appropriately timed endometrial vasoconstriction and myometrial contraction. Vasoconstriction produces ischemia, endometrial damage, and subsequent menstrual sloughing. Within the endometrium, epithelial and stromal cells secrete endothelin-1, a potent vasoconstrictor. Enkephalinase, an endothelin-degrading enzyme, is expressed at its highest levels in the midsecretory endometrium (Head, 1993). However, in the late luteal phase, the drop in serum progesterone leads to a loss of enkephalinase expression. This permits increased endothelin activity promoting a physiologic environment amenable to vasoconstriction.

**FIGURE 15-19** Endometrial changes during the menstrual cycle. **A.** Proliferative phase: straight to slightly coiled, tubular glands are lined by pseudostratified columnar epithelium with scattered mitoses. **B.** Early secretory phase: coiled glands with a slightly widened diameter are lined by simple columnar epithelium with clear subnuclear vacuoles. Stroma is variably edematous in the secretory phase. **C.** Late secretory phase: serrated, dilated glands with intraluminal secretion are lined by short columnar cells. **D.** Menstrual phase: fragmented endometrium with condensed stroma and glands with secretory vacuoles are seen in a background of blood. **E.** Atrophic endometrium: thin endometrium of the postmenopausal period has straight tubular glands lined by mitotically inactive, cuboidal epithelium. Stroma is dense and mitotically inactive. **F.** Gestational endometrium: hypersecretory glandular pattern featuring closely apposed glands with papillary infoldings and variable cytoplasmic vacuolization. The hypersecretory gland in the center shows the benign Arias-Stella reaction, with nuclear atypia characterized by variable nuclear enlargement, nuclear membrane irregularities, slight chromatin coarseness, nuclear vacuolization, and intranuclear pseudoinclusions. (Used with permission from Dr. Kelley Carrick.)

In concert with endometrial sloughing, myometrial contractions control blood loss by compressing endometrial vasculature and expelling menstrual discharge. A fall in serum progesterone decreases an enzyme that degrades prostaglandins. This increases  $\text{PGF}_{2\alpha}$  activity in the myometrium and triggers myometrial contractions (Casey, 1980).

### Estrogens and Progestins

The expression of estrogen and progesterone receptors in the endometrium is highly regulated across the menstrual cycle. This provides an additional mechanism for controlling steroid effects on endometrial development and function. Estrogen receptors are expressed in the nuclei of epithelial, stromal, and myometrial cells, and concentrations peak during the proliferative phase. However, during the luteal phase, rising progesterone levels decrease estrogen receptor expression. Endometrial progesterone receptors peak at midcycle in response to rising estrogen levels. By midluteal phase, progesterone receptor expression in the glandular epithelium is nearly absent, although expression remains strong in the stromal compartment (Lessey, 1988).

The proliferation and differentiation of the uterine epithelium is under the control of estradiol, progesterone, and various growth factors. The importance of estrogens for endometrial development is demonstrated by the predominance of endometrial hyperplasia seen in women receiving unopposed estrogen therapy. Estrogen interacts directly with estrogen receptors but can also indirectly induce various growth factors that include IGF-I, transforming growth factor  $\alpha$ , and epidermal growth factor (Beato, 1989; Dickson, 1987). The effects of progesterone on endometrial growth vary among endometrial layers. Progesterone is critical for the conversion of the functionalis layer from a proliferative to a secretory pattern. Within the basalis layer, progesterone appears to promote cellular proliferation.

### Growth Factors and Cell Adhesion Molecules

Numerous growth factors and associated receptors act in the endometrium. Each factor has its own pattern of expression, making it difficult to determine which factor is most critical for endometrial function (Ohlsson, 1989; Sharkey, 1995).

In addition to growth factors, cell adhesion molecules play an important role in endometrial function. These molecules fall into four classes: integrins, cadherins, selectins, and members of the immunoglobulin superfamily. Each has been implicated in endometrial regeneration and embryo implantation, discussed next.

### Implantation Window

The embryo enters the uterine cavity 2 to 3 days after fertilization with implantation beginning approximately 4 days later. Studies have demonstrated that normal implantation and embryonic development require synchronous development of the endometrium and the embryo (Pope, 1988). The human blastocyst may have less stringent requirements for implantation than other species as ectopic implantation occurs relatively frequently.

Uterine receptivity can be defined as the temporal window of endometrial maturation during which trophoblast

attaches to endometrial epithelial cells with subsequent invasion into endometrial stroma. The window of implantation in the human is relatively broad, extending from day 20 through day 24 of the menstrual cycle. Precise determination of this temporal window is critical since only those factors expressed during this time act as direct functional mediators of uterine receptivity.

Endometrial receptivity is associated with loss of surface microvilli and ciliated cells and with development of cellular protrusions, called *pinopods*, on the apical surface of the endometrium. Pinopods are considered an important morphologic marker of periimplantation endometrium. Pinopod formation is known to be highly progesterone dependent (Yoshinaga, 1989).

Various factors are believed to be necessary for uterine receptivity, including cell adhesion molecules, immunoglobulins, and cytokines. Integrins have been a particularly well-studied factor in this regard (Casals, 2010). However, to date, no single integrin molecule has been determined to be the critical marker of the implantation window.

The term *luteal phase defect* describes dyssynchrony between endometrial development and menstrual cycle phase that leads to subsequent implantation failure and early pregnancy loss (Noyes, 1950; Olive, 1991). This term currently is of limited utility in clinical practice due to our inability to accurately diagnose or treat the disorder.

Following implantation, the endometrium undergoes essential remodeling by invading trophoblast. In addition, the maternal endocrine environment changes extensively because of altered maternal physiology and contributions by the placenta and fetus. A more detailed discussion of these changes can be found in *Williams Obstetrics*, 24th edition (Cunningham, 2014).

## ABNORMALITIES IN THE HYPOTHALAMIC-PITUITARY AXIS

Knowledge of normal hypothalamic-pituitary axis function, described in the preceding sections, is essential to understand reproductive endocrine pathology. Classically, abnormalities in this axis result in low gonadotropin and resultant low sex steroid levels. Termed *hypogonadotropic hypogonadism*, this can be developmental or acquired. Developmental lesions due to inherited genetic defects include Kallmann syndrome and idiopathic hypogonadotropic hypogonadism. Acquired abnormalities include functional disorders (eating disorders, excessive exercise, stress) and hypothalamic-pituitary lesions due to tumor, infiltrative diseases, infarction, surgery, or radiation therapy. Information regarding hypothalamic disorders and other causes of hypogonadotropic hypogonadism can be found in Chapter 16 (p. 375). Hyperprolactinemia and pituitary adenomas are discussed here.

### ■ Hyperprolactinemia

#### Etiology

Elevated circulating PRL levels can be caused by various physiologic activities including pregnancy, sleep, eating, and coitus.

Increased PRL levels may also be observed following chest wall stimulation such as occurs with suckling, breast examination, chest wall surgery, herpes zoster infection, or nipple piercing (Table 12-2, p. 281). PRL secretion is primarily regulated through tonic inhibition by dopamine released by the hypothalamus. PRL secretion is increased by serotonin, norepinephrine, opioids, estrogen, and TRH. Therefore, medications that block dopamine-receptor action (phenothiazines) or deplete catecholamine levels (monoamine oxidase inhibitors) may increase PRL levels (Table 12-2). Moreover, hyperprolactinemia may be caused by tumor, radiation, or infiltrative diseases such as sarcoid and tuberculosis. These can damage the pituitary stalk and thereby prevent dopamine-mediated inhibition of PRL secretion.

Primary hypothyroidism is also associated with mild elevations in serum PRL levels. Specifically, low circulating thyroid hormone levels produce a reflex increase in hypothalamic TRH levels due to loss of feedback inhibition. TRH can bind directly to anterior pituitary lactotrotes and stimulate PRL production. As a rule, thyroid function tests should be performed when confirming a diagnosis of hyperprolactinemia, as a patient may require thyroid replacement rather than further evaluation for pituitary adenoma (Hekimsoy, 2010).

Prolactin-secreting adenomas, also termed prolactinomas, are the most common pituitary adenoma and the most common adenomas to be diagnosed by gynecologists. Affected women typically present with microadenomas and signs of PRL excess such as galactorrhea and amenorrhea.

### Diagnosis

Hyperprolactinemia is, by definition, present in any patient with an elevated serum PRL level. Optimally, PRL levels are drawn in the morning, that is, at the time of the PRL nadir. Prior to testing, breast examination is avoided to prevent false-positive results. If a mildly elevated PRL level is found, sampling is repeated because PRL levels vary throughout the day. Moreover, many factors including the stress of venipuncture may produce false elevations.

Normal PRL levels are typically < 20 ng/mL in nonpregnant women, although the upper limit of normal varies by assay.

Importantly, PRL levels rise nearly 10-fold during pregnancy and make detection of a prolactinoma difficult at this time. Occasionally, the reported PRL value will be falsely low due to a “hook effect” present in the assay (Frieze, 2002). As explained on page 341, very high levels of endogenous hormone oversaturate the test antibodies and thereby prevent required binding between a patient’s PRL and the assay PRL. This problem is overcome with dilution of a patient’s sample. Importantly, a mismatch between the adenoma size noted on magnetic resonance (MR) imaging and the degree of PRL level elevation should alert a clinician to either the possibility of an incorrect assay result or the likelihood that the macroadenoma is actually not primarily PRL secreting. Macroadenomas of any cell type may damage the pituitary stalk and prevent transfer of hypothalamic dopamine to the lactotrotes.

Conversely, a patient may rarely have an elevated PRL level on assay despite a lack of clinical features of hyperprolactinemia. The hyperprolactinemia in these patients is thought to be secondary to alternate forms of PRL, including the so-called big or macroprolactin, which contains multimers of native PRL. Macroprolactin is not physiologically active but may be detected by PRL assays (Fahie-Wilson, 2005).

For all patients with confirmed hyperprolactinemia, MR imaging is advisable. Some advocate limiting imaging to women with a PRL level > 100 ng/mL, as lower levels are most likely due to small microadenomas (Fig. 15-20). Although this is undoubtedly a safe approach in most women, mildly elevated PRL levels also may be due to pituitary stalk compression by a nonprolactin-secreting macroadenoma or a craniopharyngioma, diagnoses with severe potential consequences.

The availability of sensitive neuroimaging techniques now affords earlier diagnosis and intervention. In the past, pituitary adenomas were identified using a coned-down view of the sella turcica during standard head radiography. Although computed tomography (CT) scanning provides useful information on tumor size, bony artifacts may limit interpretation. Therefore, MR imaging, using both T1- and T2-weighted images, has become the preferred radiologic approach due to its high sensitivity and excellent spatial resolution (Ruscalleda, 2005). Frequently,

**FIGURE 15-20** Magnetic resonance image of a pituitary microadenoma. **A.** Coronal image. **B.** Sagittal image.

MR imaging is performed with and without gadolinium infusion for maximum definition of tumor size and extension.

Associated Amenorrhea

The primary mechanism linking hyperprolactinemia and amenorrhea is believed to be a reflex increase in central dopamine levels. Stimulation of the dopaminergic receptors on the GnRH neurons alters GnRH pulsatility, thereby disrupting folliculogenesis. As dopamine receptors have also been identified in the ovaries, detrimental effects on folliculogenesis may also play a role. Additional mechanisms undoubtedly exist in view of the complexity of the interactions among the various hormones, peptides, and neurotransmitters that influence hypothalamic function.

■ Pituitary Adenomas

Classification

Pituitary adenomas are the most common cause of acquired pituitary dysfunction and comprise approximately 15 percent of all intracranial tumors (Melmed, 2015; Pekic, 2015). Clinically, symptoms of galactorrhea, menstrual disturbances, or infertility may lead to its diagnosis. Most tumors are benign, and only an estimated 0.1 percent of adenomas develop into frank carcinoma with metastasis (Kaltsas, 2005). Nevertheless, pituitary adenomas may cause striking abnormalities in both endocrine and nervous system function (Table 15-5).

Pituitary adenomas were historically classified as eosinophilic, basophilic, or chromophobic according to their hematoxylin and eosin staining characteristics. Tumors are now

classified by their hormonal expression pattern as determined by immunohistochemistry (Fig. 15-21). Adenomas are further grouped by size into microadenomas (< 10 mm in diameter) and macroadenomas (> 10 mm in diameter).

The most common adenomas secrete PRL alone. However, adenomas may secrete any of the pituitary hormones either singly (monohormonal adenoma) or in combination (multihormonal adenoma). In the past, a subset of tumors was considered nonsecreting. However, with more sensitive assays, most have been determined to secrete the common  $\alpha$ -subunit or the gonadotropin  $\beta$ -subunits and therefore are gonadotrope-derived. Rarely, both  $\alpha$ - and  $\beta$ -subunits are secreted as functional dimeric hormone.

Symptoms

Pituitary adenomas may cause symptoms via excess hormone secretion and lead to clinical conditions such as hyperprolactinemia, acromegaly, or Cushing disease. Alternatively, adenomas may result in hormone deficiency due to damage of other pituitary cell types or the pituitary stalk by an expanding adenoma or following treatment of the primary lesion.

As might be predicted, pituitary microadenomas are typically diagnosed during evaluation of an endocrinopathy. Macroadenomas frequently present with patient symptoms from invasion of surrounding structures. The anterior pituitary gland neighbors both the optic chiasm and cavernous sinuses. Disruption of the optic chiasm by suprasellar growth of the pituitary mass may create bitemporal hemianopsia, in which the outer portion of the right and left visual fields is lost. The cavernous sinuses are a paired collection of thin-walled veins

TABLE 15-5. Clinical Features of Pituitary Adenomas

Adenoma Cell Origin (Hormone)	Clinical Syndrome	Testing <sup>a</sup>	Typical Results	Treatment
Lactotrope (PRL)	Galactorrhea; hypogonadism	PRL	Elevated	Dopamine agonist; surgical excision
Gonadotrope (LH, FSH, free subunits)	Silent or hypogonadism; rarely gonadotrope excess	Free $\alpha$ -, FSH $\beta$ -, and LH $\beta$ -subunits	Elevated	Surgical excision
Somatotrope (GH)	Acromegaly or gigantism; menstrual irregularity	IGF-I; 100-g glucose suppression test	Elevated; no GH suppression	Surgical excision; somatostatin analogues
Corticotrope (ACTH)	Cushing syndrome; menstrual irregularity	ACTH; 24-hour urinary free cortisol; dexamethasone suppression	Elevated ACTH and cortisol; no suppression	Surgical excision; ketoconazole to blunt adrenal steroidogenesis
Thyrotrope (TSH)	Thyrotoxicosis; menstrual irregularity	TSH, T <sub>3</sub> , and T <sub>4</sub>	All elevated	Surgical excision; PTU or methimazole; $\beta$ -blockers for tachycardia

<sup>a</sup>All tests are serum measurements except for urinary free cortisol. ACTH = adrenocorticotropin hormone; CRH = corticotropin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GnRH = gonadotropin-releasing hormone; IGF = insulin-like growth factor; LH = luteinizing hormone; PRL = prolactin; PTU = propylthiouracil; SHBG = sex hormone-binding globulin; TSH = thyroid-stimulating hormone; T<sub>3</sub> = triiodothyronine; T<sub>4</sub> = thyroxine.

**FIGURE 15-21** Photomicrographs from the anterior pituitary gland. **A.** Normal anterior pituitary gland. Secretory cells of the various types are arranged in small clusters between sinusoidal capillaries. **B.** Pituitary adenoma. In contrast to normal anterior pituitary gland, adenomas are composed of highly monomorphic cells. Note the absence of small clusters and sinusoids. **C.** Prolactin-secreting adenoma. Immunohistochemistry demonstrates expression of prolactin by many of the neoplastic cells. The dotlike pattern is characteristic of many prolactin-producing adenomas. (Used with permission from Dr. Jack Raisanen.)

located on either side of the sella turcica. Pituitary tumor compression can lead to cavernous sinus syndrome. The constellation of symptoms includes headache, visual disturbances, and cranial nerve palsies, specifically of cranial nerves III, IV, and VI.

Any pituitary mass or infiltrate can lead to reproductive dysfunction that may include delayed puberty, anovulation, oligomenorrhea, and infertility. The exact mechanisms linking adenomas to menstrual dysfunction are not well understood for many adenoma subtypes. Macroadenomas likely affect reproductive function either by compressing the pituitary stalk, which results in hyperprolactinemia, or less commonly, by directly compressing gonadotropes.

Spontaneous hemorrhage into a pituitary adenoma, termed *pituitary apoplexy*, is a rare life-threatening medical emergency. Signs and symptoms include acute visual changes, severe headache, neck stiffness, hypotension, loss of consciousness, and coma. These symptoms result from: (1) leakage of blood and necrotic material into the subarachnoid space, (2) acute hypopituitarism, and (3) a rapidly expanding hemorrhagic intrasellar mass that compresses the optic chiasm, cranial nerves, or hypothalamus and internal carotid arteries. Apoplexy may lead to severe hypoglycemia, hypotension, CNS hemorrhage, and death. Nevertheless, with rapid diagnosis and management, the outcome of patients with pituitary apoplexy is excellent (Singh, 2015). Glucocorticoid replacement is a mainstay of treatment. Surgical decompression is frequently but not invariably required.

### Pregnancy and Pituitary Adenomas

The pituitary gland enlarges during pregnancy, primarily due to hypertrophy and hyperplasia of the lactotropes in response to elevated serum estrogen levels. Although the tumor can enlarge during pregnancy, the risk of clinically significant growth is small.

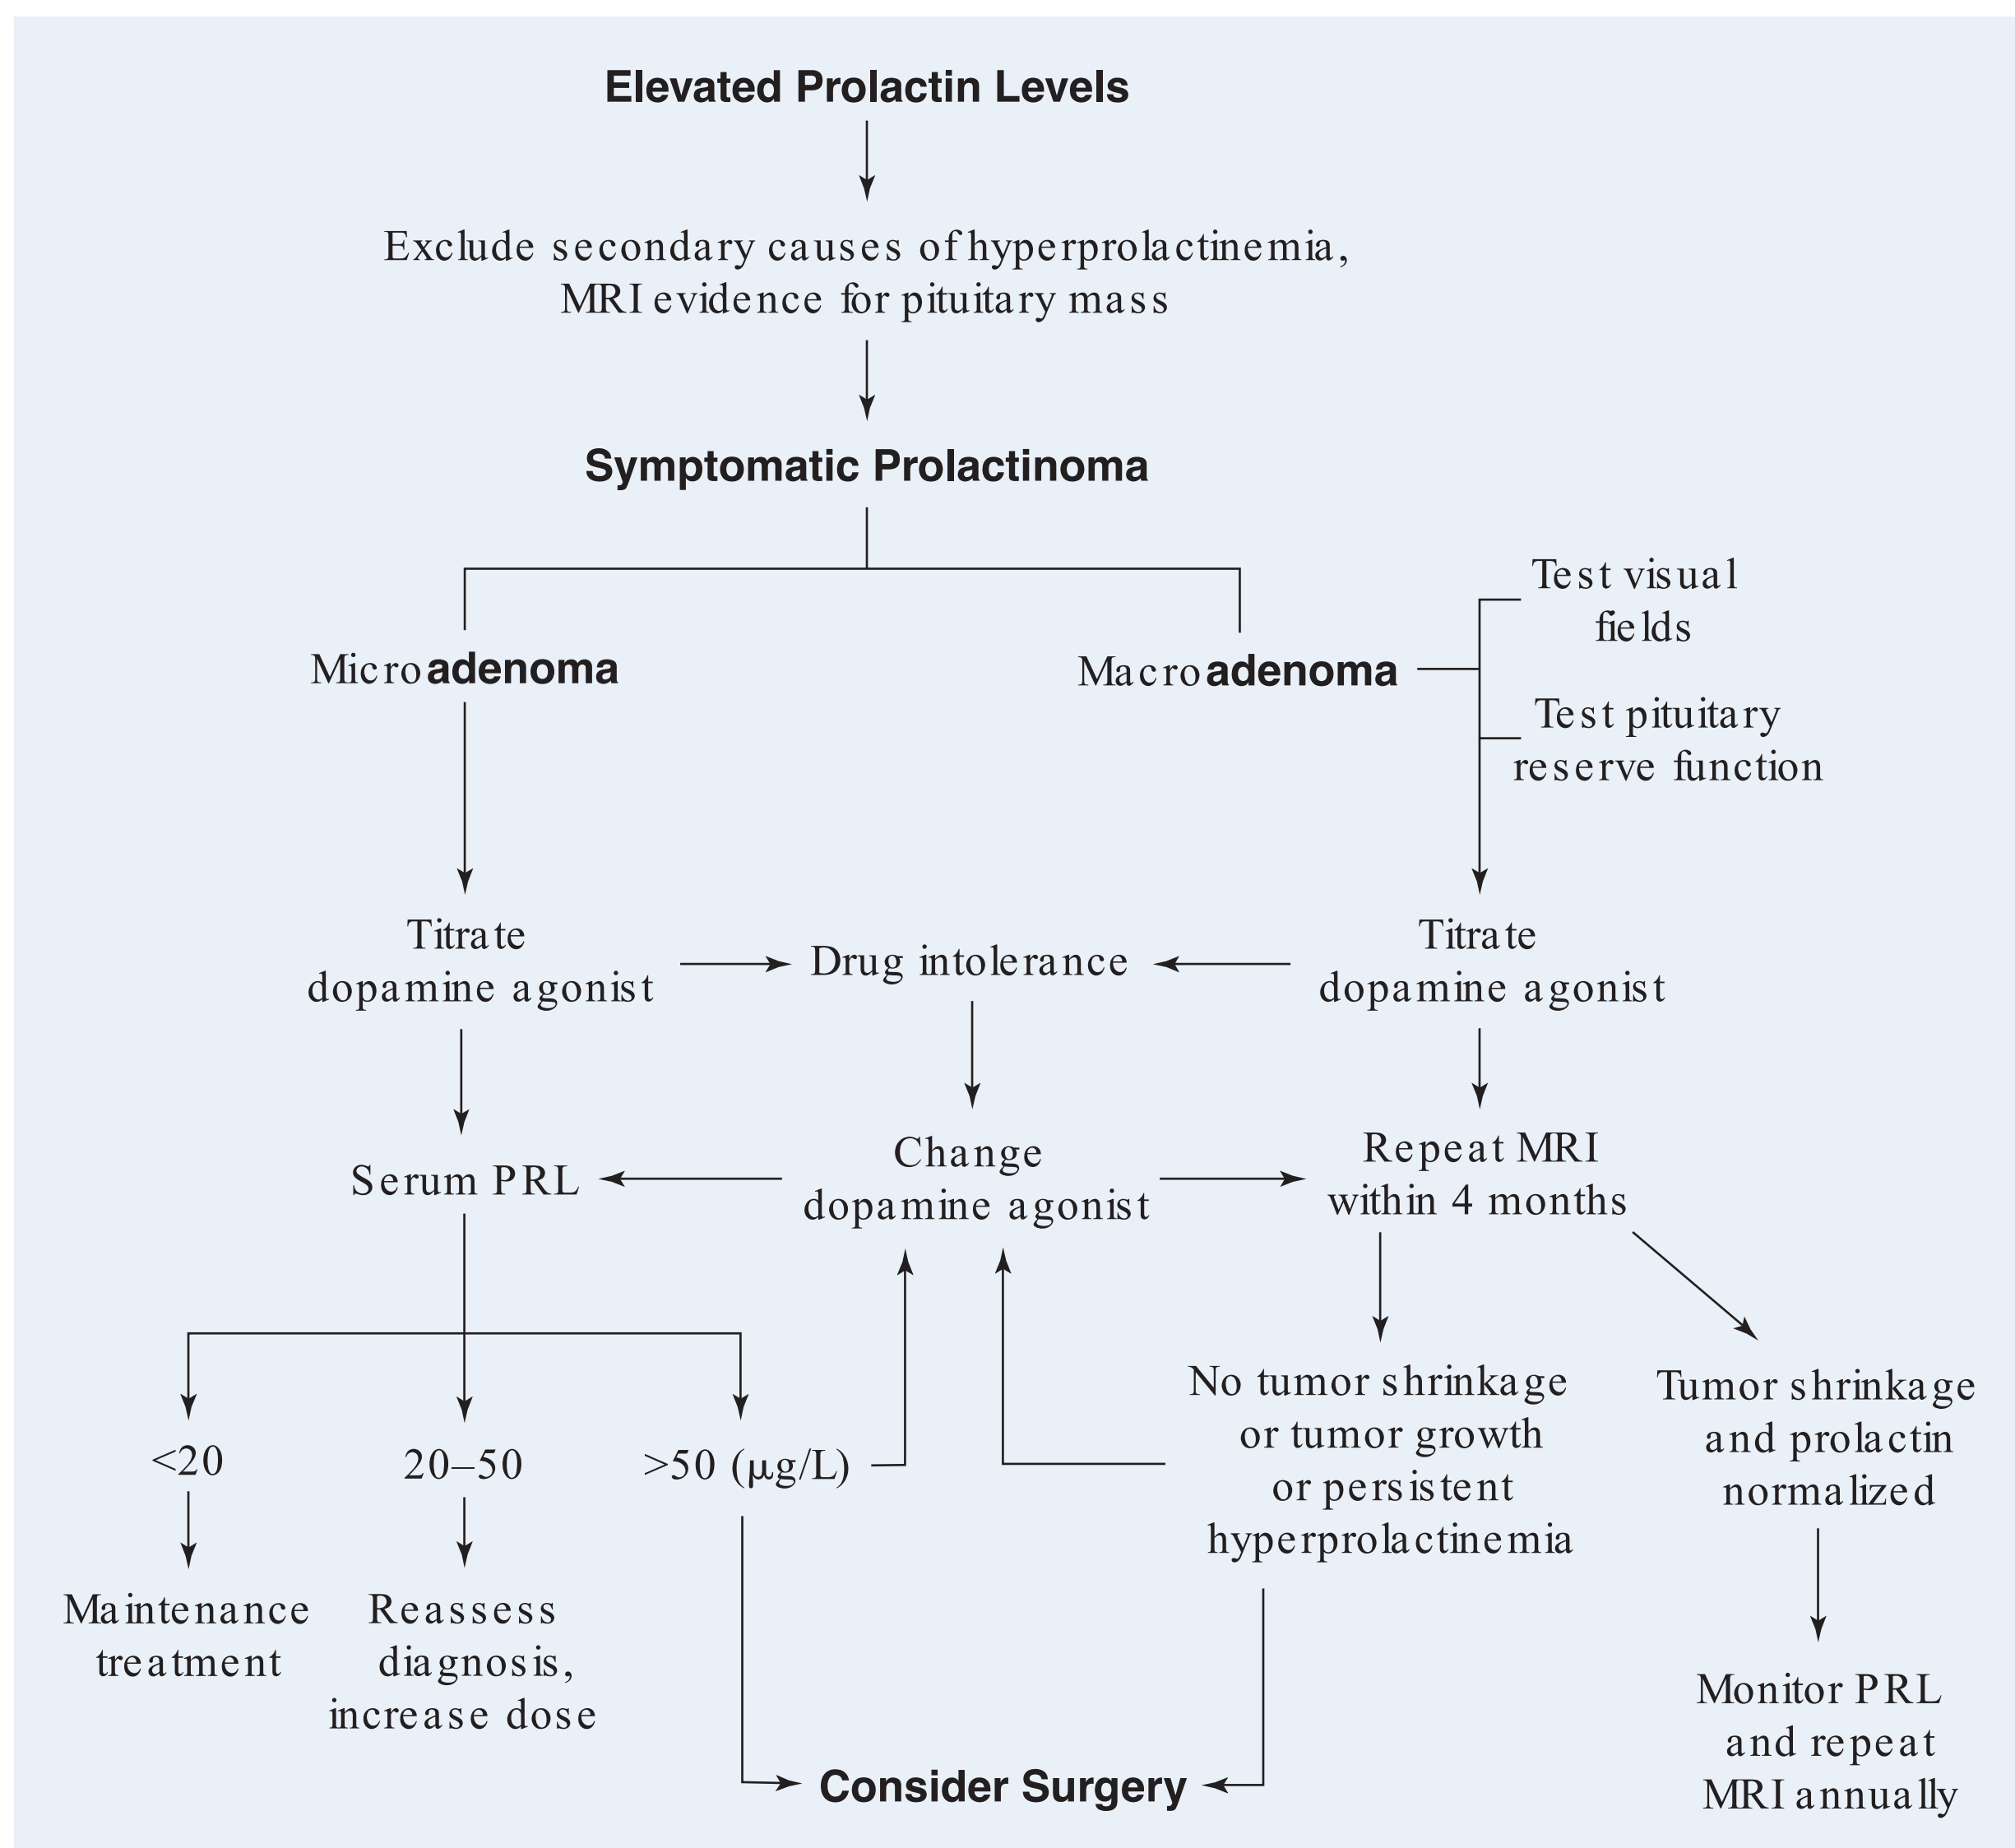

Tumor growth causing significant symptoms has been reported in approximately 2 percent of patients with microadenomas and 21 percent of those with macroadenomas without prior surgical or radiation treatment (Molitch, 2015). However, because significant expansion may lead to headaches or compression of the optic chiasm and blindness, visual field testing is considered in every trimester for women with macroadenomas. Although dopamine agonist therapy has been associated with an increased risk of spontaneous abortions, preterm deliveries, and congenital malformation, the data overall suggest that treatment is safe for most patients. Nevertheless, most experts advise that dopamine agonist therapy be discontinued during pregnancy when possible.

### ■ Treatment of Hyperprolactinemia and Pituitary Adenomas

Most pituitary tumors grow slowly, and many cease growth after attainment of a certain size. Thus, asymptomatic patients with a microprolactinoma may be managed conservatively with serial MR imaging and serum PRL levels every 1 to 2 years as the risk of progression to a macroadenoma is < 10 percent (Schlechte, 1989). These women should be followed for even mild changes in menstrual cyclicity as they are at risk for developing hypoestrogenism.

When tumors of any size are associated with amenorrhea or galactorrhea, therapy is considered (Fig. 15-22). Neurosurgical evaluation is mandatory when visual field defects or severe headaches are present. In general, first-line treatment is medical for both micro- and macroadenomas. Specifically, women should receive a dopamine agonist such as the nonspecific dopamine-receptor agonist bromocriptine (Parlodel) or the dopamine-receptor type 2 agonist cabergoline (Dostinex). Of note, the patient with hyperprolactinemia and normal imaging

**FIGURE 15-22** Algorithm describing the evaluation and treatment of pituitary adenomas. MRI = magnetic resonance imaging; PRL = prolactin. (Reproduced with permission from Kasper DL, Braunwald E, Fauci AS, et al (eds): *Harrison's Principles of Internal Medicine*, 17th ed. New York: McGraw-Hill; 2008.)

likely has an undetectable microadenoma and should be treated if symptomatic. The incidence of this occurring is decreasing with the advent of highly sensitive MR imaging.

Dopamine agonists decrease PRL secretion and shrink tumor size. However, bromocriptine treatment is associated with several common side effects, including headache, postural hypotension, blurry vision, drowsiness, and leg cramps. Most of these are attributable to activation of type 1 dopamine receptors. Due to its receptor specificity, cabergoline treatment is generally better tolerated than bromocriptine. Cabergoline also has a longer half-life, allowing once- or twice-weekly dosing compared with the multiple daily doses that may be required for bromocriptine. Typical initial cabergoline dosages are 0.25 mg orally twice weekly. Cabergoline has been found to be more effective than bromocriptine in normalizing PRL levels (dos Santos Nunes, 2011). Nevertheless, cabergoline can be prohibitively expensive. Most patients can tolerate bromocriptine if started at a low dose—½ tab or 0.125 mg—each night to minimize associated nausea and dizziness. This dose can be

slowly increased to three times daily as tolerated. Reliable measurement of posttreatment serum PRL levels can usually be obtained 1 month following a steady medication dose.

Neurosurgery is required for refractory tumors or those causing acutely worsening symptoms. The pituitary is approached through a transsphenoidal route whenever possible (Fig. 15-23). Complications of surgery, although rare, include intraoperative hemorrhage, a cerebrospinal fluid leak (rhinorrhea), diabetes insipidus, damage to other pituitary cell types, and meningitis (Miller, 2014).

Radiation therapy may be used for patients with surgically nonresectable, persistent, or aggressive tumors. The radiation dose necessary to stop tumor growth is lower than the dose necessary to achieve normalization of hormonal hypersecretion. More precise stereotactic radiosurgical approaches such as the gamma knife have improved radiation-beam focus, which significantly decreases local tissue damage and improves patient tolerance. Risks include optic nerve damage and delayed development of hypopituitarism (Pashtan, 2014).

**FIGURE 15-23** Magnetic resonance image of a pituitary before and after surgical resection of a macroadenoma. **A.** Preoperative coronal image reveals tumor measuring greater than 10 mm. **B.** Postoperative coronal image of the same patient following tumor excision.

### DISORDERS OF PEPTIDE AND STEROID HORMONES IN REPRODUCTION

Clinical disorders may result from mutations in genes affecting hormone biosynthesis or the receptors that transduce the response. Both mechanisms have been described for pituitary peptide and steroid hormones.

First, numerous mutations have been identified in the genes that encode the LH/CG and FSH receptors. Most of the identified mutations are inactivating. These produce gonadotropin resistance of variable severity that ranges from primary amenorrhea to oligoamenorrhea and infertility (Latronico, 2013). Activating receptor mutations appear to be rare. However, a constitutively active LH/CG mutant receptor does cause a familial gonadotropin-independent precocious puberty that is limited to males (Ulloa-Aguirre, 2014). Although uncommon, mutations in the genes encoding the gonadotropin hormones themselves result in varying degrees of hypogonadism (Basciani, 2012; Kottler, 2010).

Second, gene mutation can lead to decreased function in steroid receptors. The best known of the latter is androgen insensitivity syndrome (AIS). With AIS, inactivating mutations in the androgen receptor impair the ability to respond to androgens. As a result, these 46,XY individuals have female external genitalia and scant to absent pubic and axillary hair. However, their testes do produce anti-müllerian hormone, their müllerian ducts fail to develop, and thus a blind-ending vaginal pouch without uterus or fallopian tubes results. Breasts develop in response to estrogens derived from aromatization of circulating testicular steroids (Tadokoro-Cucaro, 2014). Phenotypes of AIS are further described in Chapter 18 (p. 412).

Last, mutations in the enzymes necessary for steroidogenesis create broad clinical effects. Phenotypes depend on the location and severity of the resulting enzymatic deficiency within the

steroidogenic pathway (Miller, 2011). The most common is congenital adrenal hyperplasia (CAH), typically due to a 21-hydroxylase deficiency. With severe enzymatic deficiency, affected patients have life-threatening salt wasting and female-to-male disorder of sexual differentiation (46,XX DSD). A less severe mutation may lead to “simple virilizing CAH” in which increased androgen levels are the primary hormonal abnormality (Auchus, 2015). The mildest abnormalities present as “nonclassic,” “late-onset,” or “adult-onset” CAH. In these patients, activation of the adrenal axis at puberty increases steroidogenesis and unmasks a mild 21-hydroxylase deficiency. Excess androgen provides negative feedback to GnRH receptors in the hypothalamus. These patients often present with hirsutism, acne, and anovulation. Thus, late-onset CAH may mimic PCOS (McCann-Crosby, 2014). Additional information regarding the CAH spectrum is found in Chapter 18 (p. 413).

### ESTROGENS AND PROGESTINS IN CLINICAL PRACTICE

In gynecology, estrogen and/or progestins are used for contraception and the treatment of abnormal uterine bleeding, endometriosis, leiomyomas, PCOS, and menopausal symptoms. Specific uses are found in respective chapters on these topics. Of the various estrogen and progesterone preparations, each differs in its biologic efficacy, and clinicians should understand the reasons behind some of these differences.

#### ■ Estrogens

Classic estrogens are C-18 steroid compounds containing a phenolic ring (Fig. 15-24). This group contains the natural estrogens—estradiol, estrone, estriol—and their derivatives

**FIGURE 15-24** Chemical structures of important sex steroids and selective estrogen-receptor modulators.

as well as conjugated equine estrogens (CEE). The predominant synthetic C-18 estrogen is ethinyl estradiol, the estrogen present in combination oral contraceptives. Synthetic nonsteroidal estrogens include diethylstilbestrol (DES) and selective estrogen-receptor modulators such as tamoxifen and clomiphene citrate. Despite their variation from the classic steroid ring shape, these nonsteroidal estrogens are still able to bind to the estrogen receptor.

Of the natural estrogens,  $17\beta$ -estradiol is the most potent followed by estrone and then estriol. In comparing some pharmacologically used estrogens, ethinyl estradiol, a derivative of  $17\beta$ -estradiol, has been estimated to be approximately 100 to 1000 times more potent on a per weight basis than either micronized estradiol or CEE in terms of increasing SHBG levels, which is one marker of estrogen potency (Kuhl, 2005; Mashchak, 1982).

### ■ Progestogens

Although there is no formal rule, progestogens include natural progesterone and synthetic progestogens called progestins.

Only progesterone can maintain human pregnancy. Progestins can be classified as derivatives of either 19-norprogesterone or 19-nortestosterone (Kuhl, 2005). Of the 19-norprogesterones, the most commonly used are medroxyprogesterone acetate and megestrol acetate.

Most progestins used in contraceptives are derived from 19-nortestosterone. These are commonly described as first generation (norethindrone), second generation (levonorgestrel, norgestrel), or third generation (desogestrel, norgestimate). As described in Chapter 5 (p. 118), each generation has been designed to have progressively less androgenic effect. The fourth-generation progestin, drospirenone, is unique in that it is derived from spironolactone. Although it has no androgenic activity, drospirenone has an affinity for the mineralocorticoid receptor approximately five times that of aldosterone. This explains its diuretic action.

### ■ Selective Steroid-receptor Modulators

As indicated by their names, these synthetic compounds bind to their target receptors and exert tissue-specific effects,

**TABLE 15-6.** Agonist or Antagonist Effects of Estradiol and Selected SERMs

Drug	Breast	Bone	Lipids	Endometrium

SERM= selective estrogen-receptor modulator.  
Data from Archer, 2015; Miller, 2008; Ylikorkala, 2003.

acting as agonists in some tissues and antagonists in others (Table 15-6). The best known of these are the selective estrogen-receptor modulators (SERMs) (Haskell, 2003). The variable activity among the SERMs can be attributed to differences at the molecular level. Each SERM binds to an estrogen receptor to generate a unique molecular conformation that affects the interaction of the complex with transcriptional cofactors and gene promoter regions. The response is also modified by the relative expression of ER $\alpha$  and ER $\beta$  receptors in the target tissue. The hormonal milieu may also be important in determining the agonist–antagonist profile of a specific SERM. For example, a SERM may act as an estrogen agonist in a low-estrogen state, such as menopause, but as a competitive antagonist in a patient with high circulating levels of the potent estrogen estradiol.

Development of new SERMs with specific agonist/antagonist profiles is an active area of current research. The SERM ospemifene (Osphena) may have favorable characteristics for long-term relief of genitourinary syndrome of menopause (Archer, 2015). Another SERM, bazedoxifene, is combined with CEE and marketed as Duavee. This coupled approach yields a drug group categorized as tissue-selective estrogen complexes (TSECs). The goal of TSECs is to craft agents with estrogen agonist/antagonist profiles that optimize clinical efficacy and safety.

More recently, selective progesterone-receptor modulators (SPRMs) have been developed to improve emergency contraception efficacy and expand treatment options for disorders includ-

ing leiomyomas and endometriosis (Chwalisz, 2005). Selective androgen-receptor modulators (SARMs) are also under investigation for the treatment of osteopenia and decreased libido in women. Ideally, these will avoid the virilizing effects of testosterone treatment (Negro-Vilar, 1999).

As indicated by the preceding discussion, the agonist–antagonist effect of a steroid hormone is inextricably related to the clinical tissue of interest. Although this concept is most frequently discussed in terms of selective steroid modulators, in fact all steroid hormones within a class exert differences in their pattern of action across tissues. As a result, when a steroid is chosen for treatment, each clinical end point should be considered individually.

■ **Steroid Hormone Potency**

The efficacy of estrogen and progesterone treatments is altered by numerous factors such as: (1) receptor binding affinity, (2) formulation, (3) administration route, (4) metabolism, and (5) affinity for binding globulins. First, even small chemical modifications can substantially alter the biologic effects of steroid preparations. For example, the progestins in clinical use all exert progestogenic effects but may also act as weak androgens, antiandrogens, glucocorticoids, or antimineralocorticoids. These differences are likely explained by variations in binding affinity for each of these steroid receptors (Table 15-7).

Second, estrogens and progestins can be administered as oral, transdermal, vaginal, or intramuscular preparations,

**TABLE 15-7.** Relative Binding Affinities of Steroid Receptors and Serum Binding Globulins to Progestogens

among others. The choice of carrier molecule affects hormone bioavailability. For example, although crystalline progesterone is poorly absorbed via the intestine, dispersion of the progesterone into small particles (micronization) markedly increases surface area and uptake.

First, oral medications pass through the intestine and the liver prior to systemic dissemination. As these tissues are sites for steroid metabolism, oral medications and their levels may be significantly altered prior to reaching their target organs. As an example, the bioavailability of orally administered micronized progesterone is less than 10 percent and compares poorly with the estimated 50- to 70-percent bioavailability for norethindrone and 100 percent for levonorgestrel. This difference is due to a high level of “first pass” metabolism of micronized progesterone but not these modified progestins (Stanczyk, 2002). As another example, the half-life of ethinyl estradiol is greatly extended relative to that of unconjugated estradiol by the presence of the ethinyl group, which impairs metabolism.

Absorption and metabolism rates may differ between individuals due to inherited or acquired differences in liver, intestinal, and renal function (Kuhl, 2005). Local metabolism will also lower steroid efficacy and can include conversion between steroids (for example, androgens to estrogens by aromatase) or within a steroid type (for example, estradiol to the weaker estrone). Diet, alcohol consumption, cigarette smoking, exercise, and stress have all been postulated to alter steroid metabolism. Thyroid disease also affects drug metabolism rates. Medications that increase hepatic enzyme activity may increase estrogen metabolism. Best understood is the ability of some antiepileptic drugs to decrease estrogen-containing contraceptive efficacy (O’Brien, 2010).

Last, steroid potency depends on affinity for the various carrier proteins produced by the liver. Only unbound hormone and to a much lesser extent, the amount bound to albumin or cortisol-binding globulin (CBG) is functionally active. Steroid bound to SHBG is considered inactive. Ethinyl estradiol is bound nearly exclusively to albumin, and this increases its bioavailability (Barnes, 2007). As shown in Table 15-7, significant differences in carrier binding are also observed for progestogens (Wiegratz, 2004).

Importantly, hormonal status affects expression of carrier proteins. Specifically, estrogens and thyroid hormone stimulate

SHBG while androgens blunt serum SHBG levels. To add further complexity, it is now believed that target cells can secrete SHBG, which then acts locally as a membrane receptor to stimulate cyclic adenosine monophosphate (cAMP) intracellular signaling pathways (Rosner, 2010).

■ Steroid Bioassays

A limited number of studies have used bioassays to evaluate the efficacy of estrogens in women using clinical, endocrinologic, and metabolic parameters (Table 15-8) (Kuhl, 2005). As seen in animal studies, different preparations vary markedly in their potency. Of note, estrogens also demonstrate differences in terms of their tissue specificity. For example, 17β-estradiol and CEE suppress pituitary FSH to a similar extent, whereas CEE is a more potent stimulator of liver SHBG production.
