Even before the Human Genome Project began, earlier research had sketched a rough picture of the organization of the genomes of many organisms. For instance, the karyotyping of many species had revealed their chromosome numbers and banding patterns (see Figure 13.3). And some genes had already been located on a particular region of a chromosome by fluorescence *in situ* hybridization (FISH), a method in which fluorescently labeled probes are allowed to hybridize to an immobilized array of whole chromosomes (see Figure 15.1). Cytogenetic maps based on this type of information provided the starting point for more detailed mapping.

With these cytogenetic maps of the chromosomes in hand, the initial stage in sequencing the human genome was to construct a **linkage map** (a type of genetic map; see Chapter 15) of several thousand genetic markers spaced throughout the chromosomes (**Figure 21.2** stage 1). The order of the markers and the relative distances between them on such a map are based on recombination frequencies (see Figure 15.11). The markers can be genes or any other identifiable sequences in the DNA, such as RFLPs or the short tandem repeats (STRs) discussed in Chapter 20. By 1992, researchers had compiled a human linkage map with some 5,000 markers. Such a map enabled them to locate other markers, including genes, by testing for genetic linkage to the known markers. It was also valuable as a framework for organizing more detailed maps of particular regions.

The next stage was the physical mapping of the human genome. In a **physical map**, the distances between markers are expressed by some physical measure, usually the number

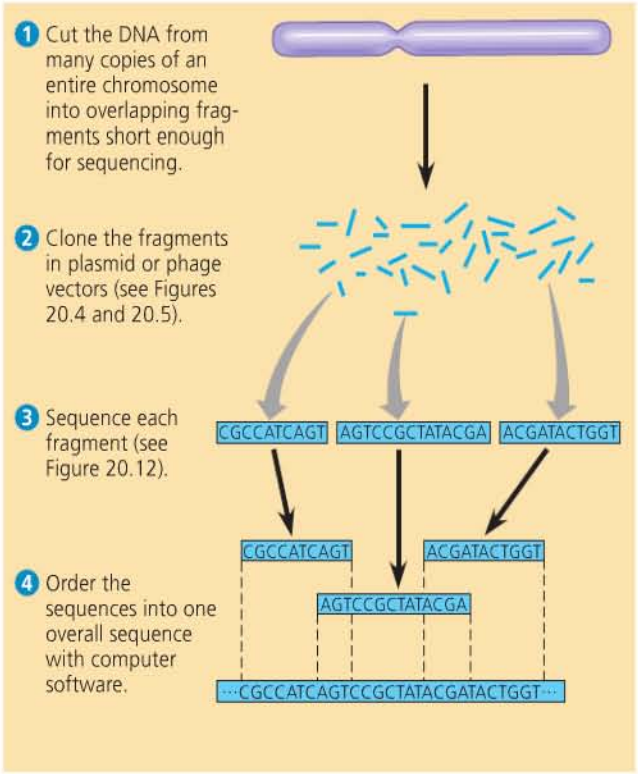
▲ **Figure 21.2 Three-stage approach to sequencing an entire genome.** Starting with a cytogenetic map of each chromosome, researchers with the Human Genome Project proceeded through three stages to reach the ultimate goal, the virtually complete nucleotide sequence of every chromosome.

of base pairs along the DNA. For whole-genome mapping, a physical map is made by cutting the DNA of each chromosome into a number of restriction fragments and then determining the original order of the fragments in the chromosomal DNA. The key is to make fragments that overlap and then use probes or automated nucleotide sequencing of the ends to find the overlaps (Figure 21.2, stage 2). In this way, fragments can be assigned to a sequential order that corresponds to their order in a chromosome.

Supplies of the DNA fragments used for physical mapping are prepared by DNA cloning. In working with large genomes, researchers carry out several rounds of DNA cutting, cloning, and physical mapping. The first cloning vector is often a yeast artificial chromosome (YAC), which can carry inserted fragments a million base pairs long, or a bacterial artificial chromosome (BAC), which typically carries inserts of 100,000 to 300,000 base pairs. After such long fragments are put in order,

each fragment is cut into smaller pieces, which are cloned in plasmids or phages, ordered in turn, and finally sequenced.

The ultimate goal in mapping a genome is to determine the complete nucleotide sequence of each chromosome (Figure 21.2, stage 3). For the human genome, this was accomplished by sequencing machines, using the dideoxy chain-termination method described in Figure 20.12. Even with automation, the sequencing of all 3.2 billion base pairs in a haploid set of human chromosomes presented a formidable challenge. In fact, a major thrust of the Human Genome Project was the development of technology for faster sequencing. Improvements over the years chipped away at each time-consuming step, enabling the rate of sequencing to accelerate impressively: Whereas a productive lab could typically sequence 1,000 base pairs a day in the 1980s, by the year 2000 each research center working on the Human Genome Project was sequencing 1,000 base pairs *per second*, 24 hours a day, seven days a week. Methods like this that can analyze biological materials very rapidly and produce enormous volumes of data are said to be "high-throughput." Sequencing machines are an example of high-throughput devices.



In practice, the three stages shown in Figure 21.2 overlap in a way that our simplified version does not portray, but they accurately represent the overarching strategy employed in the Human Genome Project. During the project, an alternative strategy for genome sequencing emerged that has been widely adopted due to its extreme efficiency.

Whole-Genome Shotgun Approach to Genome Sequencing

In 1992, emboldened by advances in sequencing and computer technology, molecular biologist J. Craig Venter devised an alternative approach to the sequencing of whole genomes. Called the *whole-genome shotgun approach*, it essentially skips the linkage mapping and physical mapping stages and starts directly with the sequencing of random DNA fragments. Powerful computer programs then assemble the resulting very large number of overlapping short sequences into a single continuous sequence **(Figure 21.3)**.

Despite the skepticism of many scientists, the value of Venter's approach became clear in 1995 when he and colleagues reported the first complete genome sequence of an organism, the bacterium *Haemophilus influenzae*. In 1998, he set up a company, Celera Genomics, and declared his intention to sequence the entire human genome. Five years later, Celera Genomics and the public consortium jointly announced that sequencing of the human genome was largely complete, two years before the original target date of the Human Genome Project.

Representatives of the public consortium point out that Celera's accomplishment relied heavily on the consortium's maps and sequence data and that the infrastructure established by their approach was a tremendous aid to Celera's efforts. Venter, on the other hand, argues for the efficiency and economy of Celera's methods, and indeed, the public consortium has made some use of them as well. Clearly, both approaches are valuable and have contributed to the rapid completion of genome sequencing for quite a few species.

▲ **Figure 21.3 Whole-genome shotgun approach to sequencing.** In this approach, developed by Craig Venter and colleagues at the company he founded, Celera Genomics, random DNA fragments are sequenced and then ordered relative to each other. Compare this approach with the hierarchical, three-stage approach shown in Figure 21.2.

? *The fragments in stage 2 of this figure are depicted as scattered, whereas those in stage 2 of Figure 21.2 are drawn in a much more orderly fashion. How do these depictions reflect the two approaches?*

Today, the whole-genome shotgun approach is widely used. Typically, the fragments are cloned into three different vectors, each of which takes a defined size of insert. The known distance between the ends of the inserted DNA is one more piece of information the computer can use to assemble the sequences properly. A recent study comparing the two approaches has shown that whole-genome shotgun sequencing can miss some duplicated sequences, thus underestimating the size of the genome and missing some genes in those regions. The hybrid approach that ended up being used for the human genome, with the more rapid shotgun sequencing being augmented by some mapping of clones, may in fact prove to be most useful in the long run.

As of 2007, there were still some small sections of the human genome that had not been sequenced. Because of the presence of repetitive DNA and for other poorly understood

reasons, certain parts of the chromosomes of multicellular organisms resist detailed sequencing by the usual methods.

At first glance, genome sequences of humans and other organisms are simply dry lists of nucleotide bases—millions of A's, T's, C's, and G's in mind-numbing succession. Crucial to making sense of this massive amount of data have been new analytical approaches, which we discuss next.

CONCEPT CHECK 21.1

1. What is the major difference between a linkage map and a physical map of a chromosome?
2. In general, how does the approach to genome mapping used in the Human Genome Project differ from the whole-genome shotgun approach?
3. **WHAT IF?** Imagine you decide to sequence the genome of a field mouse, a species closely related to the lab mouse whose genome has already been sequenced. Why might having the lab mouse sequence available lead you to use the whole-genome shotgun approach instead of the three-stage approach?

For suggested answers, see Appendix A.

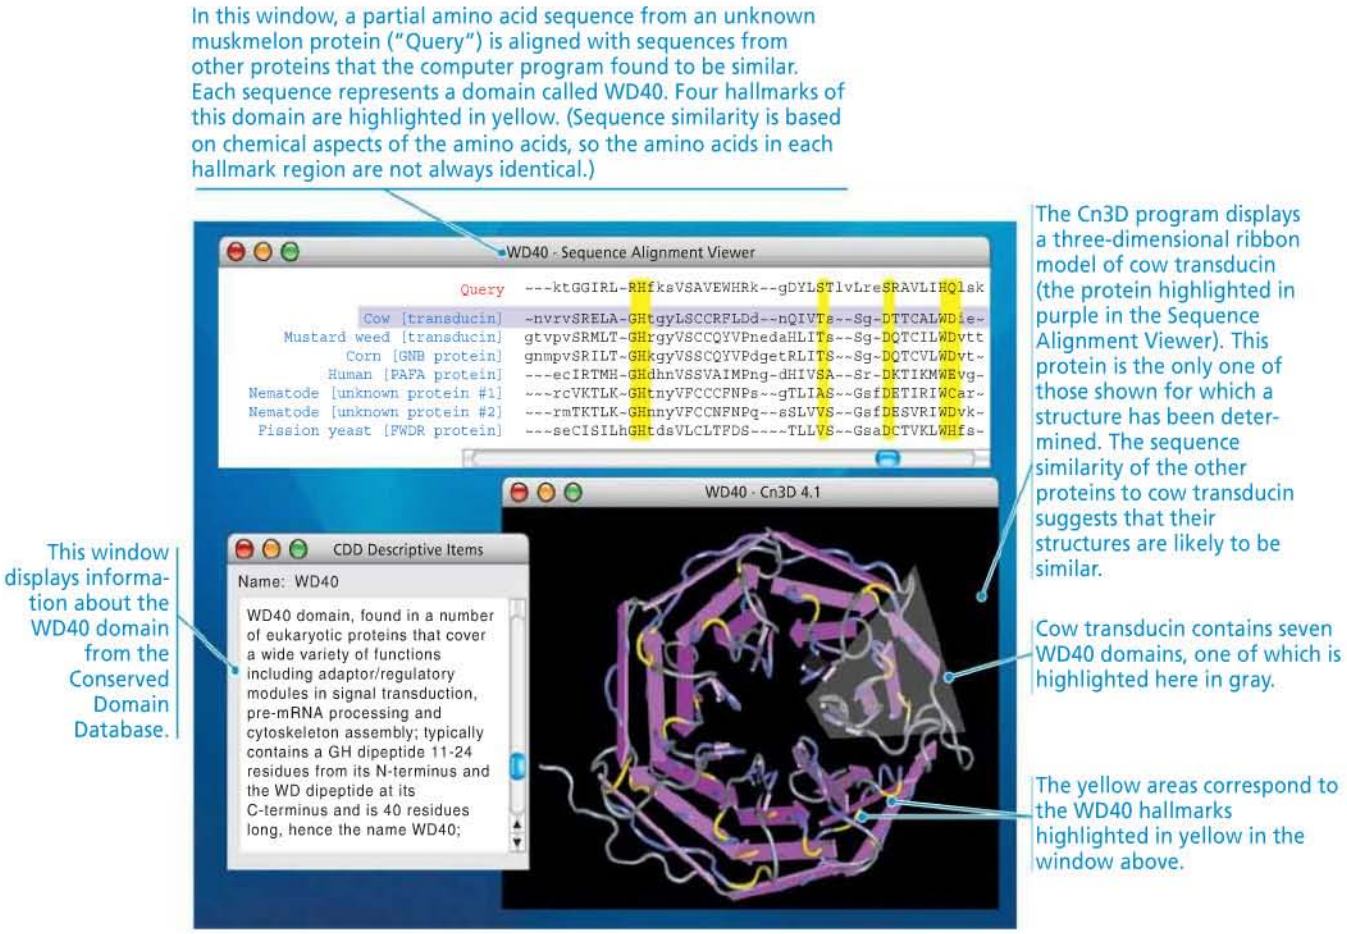
CONCEPT 21.2
Scientists use bioinformatics to analyze genomes and their functions

Each of the 20 or so sequencing centers around the world working on the Human Genome Project churned out voluminous amounts of DNA sequence day after day. As the data began to accumulate, the need to coordinate efforts to keep track of all the sequences became clear. Thanks to the foresight of scientists and government officials involved in the Human Genome Project, its goals included the establishment of banks of data, or databases, and the refining of analytical software. These databases and software programs would then be centralized and made readily accessible on the Internet. Accomplishing this aim has accelerated progress in DNA sequence analysis by making bioinformatics resources available to researchers worldwide and by speeding up the dissemination of information.

Centralized Resources for Analyzing Genome Sequences

Government-funded agencies carried out their mandate to establish databases and provide software with which scientists could analyze the sequence data. For example, in the United States, a joint endeavor between the National Library of Medicine and the National Institutes of Health (NIH) created the National Center for Biotechnology Information (NCBI), which maintains a website (www.ncbi.nlm.nih.gov) with extensive bioinformatics resources. On this site are links to databases, software, and a wealth of information about genomics and related topics. Similar websites have also been established by the European Molecular Biology Laboratory and the DNA Data Bank of Japan, two genome centers with which the NCBI collaborates. These large, comprehensive websites are complemented by others maintained by individual or small groups of laboratories. Smaller websites often provide databases and software designed for a narrower purpose, such as studying genetic and genomic changes in one particular type of cancer.

The NCBI database of sequences is called Genbank. As of August 2007, it included the sequences of 76 million fragments of genomic DNA, totaling 80 billion base pairs! Genbank is constantly updated, and the amount of data it contains is estimated to double approximately every 18 months. Any sequence in the database can be retrieved and analyzed using software from the NCBI website or elsewhere.



One software program available on the NCBI website, called BLAST, allows the visitor to compare a DNA sequence with every sequence in Genbank, base by base, to look for similar regions. Another program allows comparison of predicted protein sequences. Yet a third can search any protein sequence for common stretches of amino acids (domains) for which a function is known or suspected, and it can show a three-dimensional model of the domain alongside other relevant information (**Figure 21.4**, on the next page). There is even a software program that can compare a collection of sequences, either nucleic acids or polypeptides, and diagram them in the form of an evolutionary tree based on the sequence relationships. (You'll learn more about such diagrams in Chapter 26.)

The NCBI website also maintains a database that includes all three-dimensional protein structures that have been determined. (To review how protein structures are analyzed, see Figure 5.25.) These structures can be rotated by the viewer to see all sides of the protein. Let's say a researcher has an amino acid sequence for all or part of an unknown protein, and it is similar to an amino acid sequence for which the structure has been worked out. In this event, the possible structure of the unknown protein can be predicted by one software program and compared with all other known protein structures using another program. This information can aid the researcher in determining the function of the unknown protein.

There is a vast array of resources available for researchers anywhere in the world to use. Let us now consider the types of questions scientists can address using these resources.

Identifying Protein-Coding Genes Within DNA Sequences

Using available DNA sequences, geneticists can study genes directly, without having to infer genotype from phenotype, as in classical genetics. But this approach poses a new challenge:

▲ **Figure 21.4 Bioinformatics tools available on the Internet.** A website maintained by the National Center for Biotechnology Information allows scientists and the public to access DNA and protein sequences and other stored data. The site includes a link to a protein structure database (Conserved Domain Database, CDD) that can find and describe similar domains in related proteins, as well as software (Cn3D, "see in 3D") that displays three-dimensional models of domains for which the structure has been determined. Some results are shown from a search for regions of proteins similar to an amino acid sequence in a muskmelon protein.

determining the phenotype from the genotype. Given a long DNA sequence from a database such as Genbank, how can we recognize as-yet unknown protein-coding genes and determine their function?

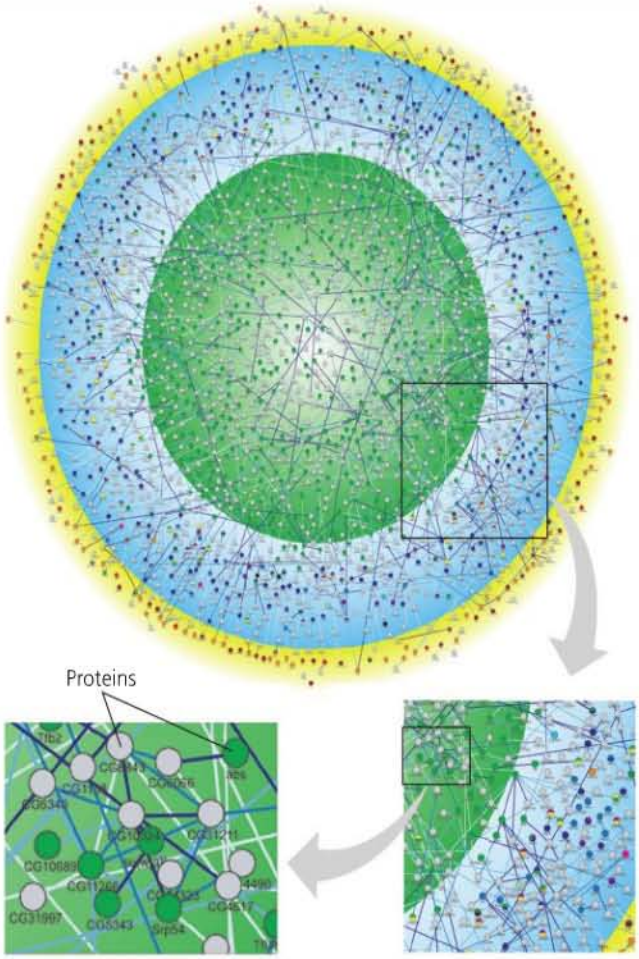
The usual approach is to use software to scan these stored sequences for transcriptional and translational start and stop signals, for RNA-splicing sites, and for other telltale signs of protein-coding genes. The software also looks for certain short sequences that correspond to sequences present in known mRNAs. Thousands of such sequences, called *expressed sequence tags*, or *ESTs*, have been collected from cDNA sequences and are cataloged in computer databases. This type of analysis identifies sequences that may be previously unknown protein-coding genes.

The identities of about half of the human genes were known before the Human Genome Project began. But what about the others, the previously unknown genes revealed by analysis of DNA sequences? Clues about their identities come from comparing the sequences of gene candidates with those of known genes from other organisms, using the software described previously. Due to redundancy in the genetic code, the DNA sequence itself may vary more than the protein sequence does. Thus, scientists interested in proteins often compare the predicted amino acid sequence of the protein to that of other proteins.

Sometimes a newly identified sequence will match, at least partially, the sequence of a gene or protein whose function is well known. For example, part of a new gene may match a known gene that encodes an important signaling pathway protein such as a protein kinase (see Chapter 11), suggesting that the new gene does, too. Alternatively, the new gene sequence may be similar to a previously encountered sequence whose function is still unknown. Another possibility is that the sequence is entirely unlike anything ever seen before. This was true for about a third of the genes of *E. coli* when its genome was sequenced. In the last case, protein function is usually deduced through a combination of biochemical and functional studies. The biochemical approach aims to determine the three-dimensional structure of the protein as well as other attributes, such as potential binding sites for

other molecules. Functional studies usually involve blocking or disabling the gene to see what effect that has on the phenotype. RNAi, described in Chapter 20, is an example of an experimental technique used to block gene function.

Understanding Genes and Their Products at the Systems Level



The impressive computational power provided by the tools of bioinformatics allows the study of whole sets of genes and their interactions, as well as the comparison of genomes from different species. Genomics is a rich source of new insights into fundamental questions about genome organization, regulation of gene expression, growth and development, and evolution.

The success in sequencing genomes and studying entire sets of genes has encouraged scientists to attempt similar systematic study of the full protein sets (*proteomes*) encoded by genomes, an approach called **proteomics**. Proteins, not the genes that encode them, actually carry out most of the activities of the cell. Therefore, we must study when and where proteins are produced in an organism, as well as how they interact in networks, if we are to understand the functioning of cells and organisms.

How Systems Are Studied: An Example

Genomics and proteomics are enabling biologists to approach the study of life from an increasingly global perspective. Using the tools we have described, biologists have begun to compile catalogs of genes and proteins—listings of all the "parts" that contribute to the operation of cells, tissues, and organisms. With such catalogs in hand, researchers have shifted their attention from the individual parts to their functional integration in biological systems. As you may recall, in Chapter 1 we discussed this systems biology approach, which aims to model the dynamic behavior of whole biological systems.

One basic application of the systems biology approach is to define gene circuits and protein interaction networks. To map the protein interaction network in *Drosophila* that was mentioned in Chapter 1, for instance, researchers started with over 10,000 predicted RNA transcripts. They then used molecular techniques to test interactions between the whole or partial protein products of these transcripts. Using statistical tests to select the interactions for which the data were strongest, they ended up with approximately 4,700 proteins that appeared to participate in more than 4,000 interactions. A subset of these interactions is displayed graphically in **Figure 21.5**; the details are more easily seen in the two successive blowups in the figure. To process the vast number of protein-protein interactions generated by this experiment and integrate them into the graphic model required powerful computers, mathematical tools, and newly developed software. Thus, the systems biology approach has really been made possible by advances in bioinformatics.

▲ **Figure 21.5 The systems biology approach to protein interactions.** This global protein interaction map shows a subset of the most statistically likely interactions (lines) among about 2,300 proteins (small circles) in *Drosophila*. The three background colors in the map correspond to the general location of each protein: Green is the nucleus, blue the cytoplasm, and yellow the plasma membrane. The proteins are also color-coded according to their specific subcellular localization; for example, green circles represent nuclear proteins.

Application of Systems Biology to Medicine

The Cancer Genome Atlas is another example of systems biology in which a large group of interacting genes and gene products are analyzed together. This project, under the joint leadership of the National Cancer Institute and the NIH, aims to understand how changes in biological systems lead to cancer. In a three-year pilot project running from 2007 to 2010, three types of cancer—lung cancer, ovarian cancer, and glioblastoma of the brain—are being analyzed by comparing gene sequences and patterns of gene expression in cancer cells with those of normal cells. A set of approximately 2,000 genes from the cancer cells will be sequenced at several different times during the progression of the disease to monitor changes due to mutations and rearrangements. If this approach proves fruitful, it will be extended to other types of cancer.

◀ **Figure 21.6 A human gene microarray chip.** Tiny dots of DNA arranged in a grid on this silicon wafer represent almost all of the genes in the human genome. Using this chip, researchers can analyze expression patterns for all human genes at the same time, minimizing the amount of reagents used and ensuring uniform conditions for all the genes.

Systems biology has tremendous potential in human medicine that is just starting to be explored. Silicon and glass "chips" have already been developed that hold a microarray of most of the known human genes **(Figure 21.6)**. Such chips are being used to analyze gene expression patterns in patients suffering from various cancers and other diseases, with the eventual aim of tailoring their treatment to their unique genetic makeup and the specifics of their cancers. This approach has already had modest success in characterizing subsets of several cancers.

Ultimately, every person may carry with their medical records a catalog of their DNA sequence, a sort of genetic bar code, with regions highlighted that predispose them to specific diseases. The potential application for disease prevention and treatment is substantial.

Systems biology is a highly efficient way to study emergent properties at the molecular level. Recall from Chapter 1 that according to the concept of emergent properties, novel properties arise at each successive level of biological complexity as a result of the arrangement of building blocks at the underlying level. The more we are able to learn about the arrangement and interactions of the components of genetic systems, the deeper will be our understanding of organisms. The remaining sections of this chapter will survey what we've learned from genomic studies thus far.

CONCEPT CHECK 21.2

1. What role does the Internet play in current genomics and proteomics research?
2. Explain the advantage of the systems biology approach to studying cancer versus the approach of studying a single gene at a time.
3. **WHAT IF?** Let's say you used the classic genetic approach to study a certain inherited trait in *Drosophila*—that is, you mutated flies and selected those with a phenotype of interest to you. Assuming you could use molecular biological tools to obtain the region of DNA that is mutated, how would you analyze it further to determine how it is involved in the trait of interest?

For suggested answers, see Appendix A.

CONCEPT 21.3

Genomes vary in size, number of genes, and gene density

By early 2008, the sequencing of over 700 genomes had been completed and that of more than 2,700 genomes was in progress. In the completely sequenced group, about 600 are genomes of bacteria, and 50 are archaeal genomes. Among the 65 eukaryotic species in the group are vertebrates, invertebrates, protists, fungi, and plants. The accumulated genome sequences contain a wealth of information that we are just beginning to mine. What have we learned so far by comparing the genomes that have now been sequenced? In this section, we will examine the characteristics of genome size, number of genes, and gene density. Because these characteristics are so broad, we will focus on general trends, for which there are often exceptions.

Genome Size

Comparing the three domains (Bacteria, Archaea, and Eukarya), we find a general difference in genome size between prokaryotes and eukaryotes **(Table 21.1)**. While there are some exceptions, most bacterial genomes have between 1 and 6 million base pairs (Mb); the genome of *E. coli*, for instance, has 4.6 Mb. Genomes of archaea are, for the most part, within the size range of bacterial genomes. (Keep in mind, however, that many fewer archaeal genomes have been completely sequenced, so this picture may change.) Eukaryotic genomes tend to be larger: The genome of the single-celled yeast *Saccharomyces cerevisiae* (a fungus) has about 13 Mb, while most animals and plants, which are multicellular, have genomes of at least 100 Mb. There are 180 Mb in the fruit fly genome, while humans have 3,200 Mb, about 500 to 3,000 times as many as a typical bacterium.

Aside from this general difference between prokaryotes and eukaryotes, a comparison of genome sizes among eukaryotes fails to reveal any systematic relationship between genome size and the organism's phenotype. For instance, the genome of *Fritillaria assyriaca*, a flowering plant in the lily family, contains 120 billion base pairs (120,000 Mb), about 40 times the size of the human genome. Even more striking, there is a single-celled amoeba, *Amoeba dubia*, whose genome has 670,000 Mb. (This genome has not yet been sequenced.) On a finer scale, comparing two insect species, the cricket (*Anabrus simplex*) genome turns out to have 11 times as many base pairs as the *Drosophila melanogaster* genome. There is a wide range of genome sizes within the groups of protists, insects, amphibians, and plants and less of a range within mammals and reptiles.

Number of Genes

A similar difference holds true for the number of genes: Bacteria and archaea, in general, have fewer genes than eukaryotes.

Free-living bacteria and archaea have from 1,500 to 7,500 genes, while the number of genes in eukaryotes ranges from about 5,000 for unicellular fungi to at least 40,000 for some multicellular eukaryotes (see Table 21.1).

Within the eukaryotes, the number of genes in a species is often lower than expected from simply considering the size of its genome. Looking at Table 21.1, you can see that the genome of the nematode *C. elegans* is 100 Mb in size and contains roughly 20,000 genes. The *Drosophila* genome, in comparison, is almost twice as big (180 Mb) but has about two-thirds the number of genes—only 13,700 genes.

Considering an example closer to home, we noted that the human genome contains 3,200 Mb, well over ten times the size of either the *Drosophila* or *C. elegans* genome. At the outset of the Human Genome Project, biologists expected somewhere between 50,000 and 100,000 genes to be identified in the completed sequence, based on the number of known human proteins. As the project progressed, the estimate was revised downward several times, and, as of 2007, the most reliable count places the number at 20,488. This relatively low number, similar to the number of genes in the nematode *C. elegans*, has surprised biologists, who had clearly expected many more human genes.

What genetic attributes allow humans (and other vertebrates) to get by with no more genes than nematodes? An important factor is that vertebrate genomes "get more bang for the buck" from their coding sequences because of extensive alternative splicing of RNA transcripts. Recall that this process generates more than one functional protein from a single gene (see Figure 18.11). For instance, nearly all human genes contain multiple exons, and an estimated 75% of these multi-exon genes are spliced in at least two different ways. If we assume that each alternatively spliced human gene on average specifies three different polypeptides, then the total number of different human polypeptides would be about 75,000. Additional polypeptide diversity could result from post-translational modifications such as cleavage or addition of carbohydrate groups in different cell types or at different developmental stages.

Gene Density and Noncoding DNA

In addition to genome size and number of genes, we can compare gene density in different species—in other words, how many genes there are in a given length of DNA. When we compare the genomes of bacteria, archaea, and eukaryotes, we see that eukaryotes generally have larger genomes but fewer genes in a given number of base pairs. Humans have hundreds or thousands of times as many base pairs in their genome as most bacteria, as we already noted, but they have only 5 to 15 times as many genes; thus, gene density is lower in humans (see Table 21.1). Even unicellular eukaryotes, such as yeasts, have fewer genes per million base pairs than bacteria and archaea. Among the genomes that have been sequenced completely thus far, humans and other mammals have the lowest gene density.

In all bacterial genomes studied so far, most of the DNA consists of genes for protein, tRNA, or rRNA; the small amount of other DNA consists mainly of nontranscribed regulatory sequences, such as promoters. The sequence of nucleotides along a bacterial protein-coding gene proceeds from start to finish without interruption by noncoding sequences (introns). In eukaryotic genomes, by contrast, most of the DNA neither encodes protein nor is transcribed into known functional RNA molecules (such as tRNAs), and the DNA includes more complex regulatory sequences. In fact, humans have 10,000 times as much noncoding DNA as bacteria. Some of this DNA in multicellular eukaryotes is present as introns within genes. Indeed, introns account for most of the difference in average length between human genes (27,000 base pairs) and bacterial genes (1,000 base pairs).

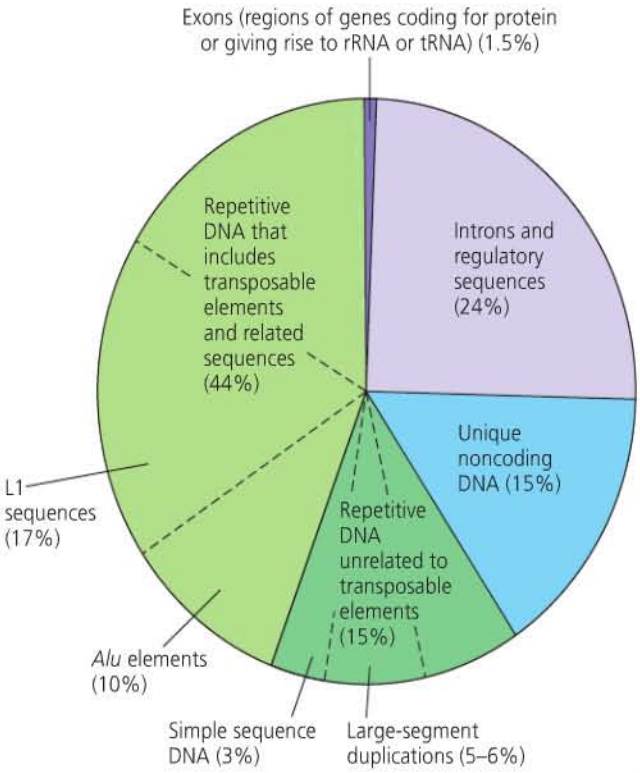
Table 21.1 Genome Sizes and Estimated Numbers of Genes*

Organism	Haploid Genome Size (Mb)	Number of Genes	Genes per Mb
Bacteria			
Haemophilus influenzae	1.8	1,700	940
Escherichia coli	4.6	4,400	950
Archaea			
Archaeoglobus fulgidus	2.2	2,500	1,130
Methanosarcina barkeri	4.8	3,600	750
Eukaryotes			
Saccharomyces cerevisiae (yeast, a fungus)	13	6,200	480
Caenorhabditis elegans (nematode)	100	20,000	200
Arabidopsis thaliana (mustard family plant)	118	25,500	215
Drosophila melanogaster (fruit fly)	180	13,700	76
Oryza sativa (rice)	390	40,000	140
Danio rerio (zebrafish)	1,700	23,000	13
Mus musculus (house mouse)	2,600	22,000	11
Homo sapiens (human)	3,200	20,500	7
Fritillaria assyriaca (lily family plant)	120,000	ND	ND

*Some values given here are likely to be revised as genome analysis continues. Mb = million base pairs. ND = not determined.

In addition to introns, multicellular eukaryotes have a vast amount of noncoding DNA between genes. In the next section, we will describe the composition and arrangement of these great stretches of DNA in the human genome.

CONCEPT CHECK 21.3



1. According to the best current estimate, the human genome contains about 20,500 genes. However, there is evidence that human cells produce more than 20,500 different polypeptides. What processes might explain this discrepancy?
2. The number of sequenced genomes is constantly being updated. Use the website www.genomesonline.org to find the current number of completed genomes within each domain as well as the number of genomes whose sequencing is in progress. (*Hint:* Click on "GOLD Tables," and then click on "Published Complete Genomes" for extra information.)
3. **WHAT IF?** What evolutionary processes might account for prokaryotes having smaller genomes than eukaryotes?

For suggested answers, see Appendix A.

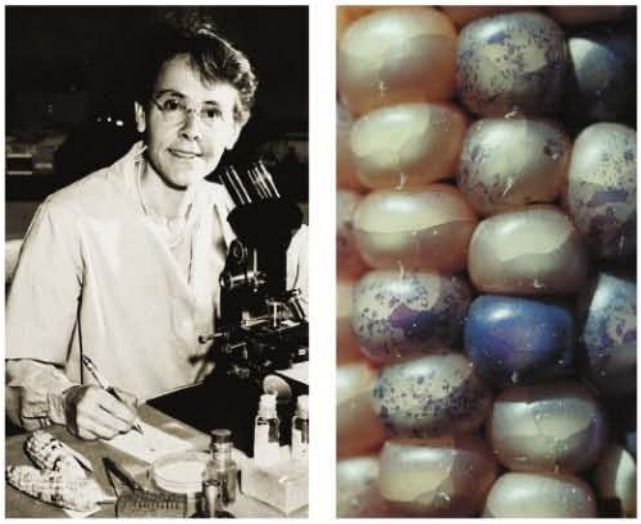
CONCEPT 21.4
Multicellular eukaryotes have much noncoding DNA and many multigene families

We have spent most of this chapter, and indeed this unit, focusing on genes that code for proteins. Yet the coding regions of these genes and the genes for RNA products such as rRNA, tRNA, and microRNA (miRNA) make up only a small portion of the genomes of most multicellular eukaryotes. The bulk of most eukaryotic genomes consists of DNA sequences that neither code for proteins nor are transcribed to produce known RNAs; this noncoding DNA was often described in the past as "junk DNA." However, much evidence is accumulating that this DNA plays important roles in the cell, an idea supported by its persistence in diverse genomes over many hundreds of generations. For example, comparison of the genomes of humans, rats, and mice has revealed the presence of almost 500 regions of noncoding DNA that are identical in sequence in all three species. This is a higher level of sequence conservation than is seen for protein-coding regions in these species, strongly suggesting that the noncoding regions have important functions. In this section, we examine how genes and noncoding DNA sequences are organized within genomes of multicellular eukaryotes, using the human genome as our main example. Genome organization tells us much about how genomes have evolved and continue to evolve, the next subject we'll consider.

Once the sequencing of the human genome was completed, it became clear that only a tiny part—1.5%—codes for proteins or is transcribed into rRNAs or tRNAs. **Figure 21.7** shows what is known about the makeup of the remaining 98.5%. Gene-related regulatory sequences and introns account for 24% of the human genome; the rest, located between functional genes, includes some unique noncoding DNA, such as gene fragments and **pseudogenes**, former genes that have accumulated mutations over a long time and have become nonfunctional. Most intergenic DNA, however, is **repetitive DNA**, which consists of sequences that are present in multiple copies in the genome. Somewhat surprisingly, about three-fourths of this repetitive DNA (44% of the entire human genome) is made up of units called transposable elements and sequences related to them.

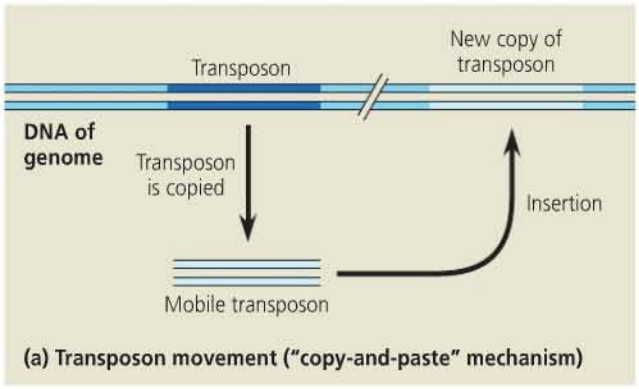
▲ **Figure 21.7 Types of DNA sequences in the human genome.** The gene sequences that code for proteins or are transcribed into rRNA or tRNA molecules make up only about 1.5% of the human genome (dark purple in the pie chart), while introns and regulatory sequences associated with genes (light purple) make up about a quarter. The vast majority of the human genome does not code for proteins or give rise to known RNAs, and much of it is repetitive DNA (dark and light green). Because repetitive DNA is the most difficult to sequence and analyze, classification of some portions is tentative, and the percentages given here may shift slightly as genome analysis proceeds. The genes that are transcribed into miRNAs, which were recently discovered, are found among unique noncoding DNA sequences and within introns; thus, they are included in two segments of this chart.

Transposable Elements and Related Sequences

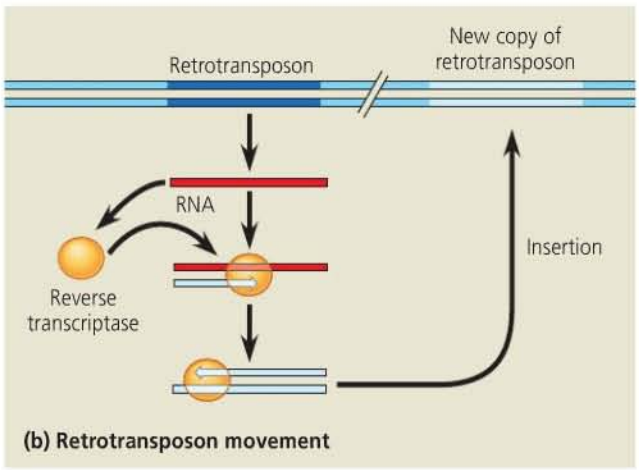


Both prokaryotes and eukaryotes have stretches of DNA that can move from one location to another within the genome. These stretches are known as *transposable genetic elements*, or simply **transposable elements**. During the process called *transposition*, a transposable element moves from one site in a cell's DNA to a different target site by a type of recombination process. Transposable elements are sometimes called "jumping genes," but the phrase is misleading because they never completely detach from the cell's DNA. (The original and new DNA sites are brought together by DNA bending.)

The first evidence for wandering DNA segments came from American geneticist Barbara McClintock's breeding experiments with Indian corn (maize) in the 1940s and 1950s **(Figure 21.8)**. As she tracked corn plants through multiple generations, McClintock identified changes in the color of corn kernels that made sense only if she postulated the existence of genetic elements capable of moving from other locations in the genome into the genes for kernel color, disrupting the genes so that the kernel color was changed. McClintock's discovery was met with great skepticism and virtually discounted at the time. Her careful work and insightful ideas were finally validated many years later when transposable elements were found in bacteria and microbial geneticists learned more about the molecular basis of transposition.



Movement of Transposons and Retrotransposons



Eukaryotic transposable elements are of two types. The first type are **transposons**, which move within a genome by means of a DNA intermediate. Transposons can move by a "cut-and-paste" mechanism, which removes the element from the original site, or by a "copy-and-paste" mechanism, which leaves a copy behind **(Figure 21.9a)**.

Most transposable elements in eukaryotic genomes are of the second type, **retrotransposons**, which move by means of an RNA intermediate that is a transcript of the retrotransposon DNA. Retrotransposons always leave a copy at the original site during transposition, since they are initially transcribed into an RNA intermediate **(Figure 21.9b)**. To insert at another site, the RNA intermediate is first converted back to DNA by reverse transcriptase, an enzyme encoded in the retrotransposon itself. Thus, reverse transcriptase can be present in cells not infected with retroviruses. (In fact, retroviruses, which were discussed in Chapter 19, may have evolved from retrotransposons.) A cellular enzyme catalyzes insertion of the reverse-transcribed DNA at a new site.

▲ **Figure 21.8 The effect of transposable elements on corn kernel color.** Barbara McClintock first proposed the idea of mobile genetic elements after observing variegations in corn kernel color. Although her idea was met with skepticism when she proposed it in the 1940s, it was later fully validated. She received the Nobel Prize in 1983, at the age of 81, for her pioneering research.

▲ **Figure 21.9 Movement of eukaryotic transposable elements. (a)** Movement of transposons by either the cut-and-paste mechanism or the copy-and-paste mechanism (shown here) involves a double-stranded DNA intermediate that is inserted into the genome. **(b)** Movement of retrotransposons begins with formation of a single-stranded RNA intermediate. The remaining steps are essentially identical to part of the retrovirus reproductive cycle (see Figure 19.8). In the movement of transposons by the copy-and-paste mechanism and in the movement of retrotransposons, the DNA sequence remains in the original site as well as appearing in a new site.

? *How would part (a) differ if it showed the cut-and-paste mechanism?*

Sequences Related to Transposable Elements

Multiple copies of transposable elements and sequences related to them are scattered throughout eukaryotic genomes. A single unit is usually hundreds to thousands of base pairs long, and the dispersed "copies" are similar but usually not identical to each other. Some of these are transposable elements that can move; the enzymes required for this movement may be encoded by any transposable element, including the one that is moving. Others are related sequences that have lost the ability to move altogether. Transposable elements and related sequences make up 25–50% of most mammalian genomes (see Figure 21.7) and even higher percentages in amphibians and many plants.

In humans and other primates, a large portion of transposable element–related DNA consists of a family of similar sequences called *Alu elements*. These sequences alone account for approximately 10% of the human genome. *Alu* elements are about 300 nucleotides long, much shorter than most functional transposable elements, and they do not code for any protein. However, many *Alu* elements are transcribed into RNA; its cellular function, if any, is currently unknown.

An even larger percentage (17%) of the human genome is made up of a type of retrotransposon called *LINE-1*, or *L1*. These sequences are much longer than *Alu* elements—about 6,500 base pairs—and have a low rate of transposition. What might account for this low rate? Recent research has uncovered the presence of sequences within L1 that block progress of RNA polymerase, which is necessary for transposition. An accompanying genomic analysis found L1 sequences within the introns of nearly 80% of the human genes that were analyzed, suggesting that L1 may help regulate gene expression. Other researchers have proposed that L1 retrotransposons may have differential effects on gene expression in developing neurons, contributing to the great diversity of neuronal cell types (see Chapter 48).

Although many transposable elements encode proteins, these proteins do not carry out normal cellular functions. Therefore, transposable elements are often included in the "noncoding" DNA category, along with other repetitive sequences.

Other Repetitive DNA, Including Simple Sequence DNA

Repetitive DNA that is not related to transposable elements probably arises due to mistakes during DNA replication or recombination. Such DNA accounts for about 15% of the human genome (see Figure 21.7). About a third of this (5–6% of the human genome) consists of duplications of long stretches of DNA, with each unit ranging from 10,000 to 300,000 base pairs. The large segments seem to have been copied from one chromosomal location to another site on the same or a different chromosome.

In contrast to scattered copies of long sequences, **simple sequence DNA** contains many copies of tandemly repeated short sequences, as in the following example (showing one DNA strand only):

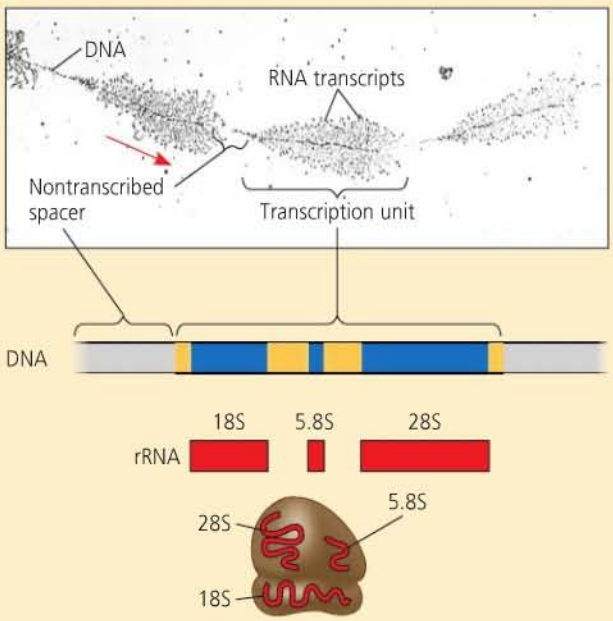
. . . GTTACGTTACGTTACGTTACGTTACGTTAC . . .

In this case, the repeated unit (GTTAC) consists of five nucleotides. Repeated units may contain as many as 500 nucleotides, but often contain fewer than 15 nucleotides, as seen for this example. When the unit contains 2 to 5 nucleotides, the series of repeats is called a **short tandem repeat**, or **STR**; we discussed the use of STR analysis in preparing genetic profiles in Chapter 20. The number of copies of the repeated unit can vary from site to site within a given genome. There could be as many as several hundred thousand repetitions of the GTTAC unit at one site, but only half that number at another. The repeat number can also vary from person to person, producing the variation represented in the genetic profiles that result from STR analysis. Altogether, simple sequence DNA makes up 3% of the human genome.

The nucleotide composition of simple sequence DNA is often different enough from the rest of the cell's DNA to have an intrinsically different density. If genomic DNA is cut into pieces and centrifuged at high speed, segments of different density migrate to different positions in the centrifuge tube. Repetitive DNA isolated in this way was originally called *satellite DNA* because it appeared as a "satellite" band in the centrifuge tube, separate from the rest of the DNA. Now the term is often used interchangeably with simple sequence DNA.

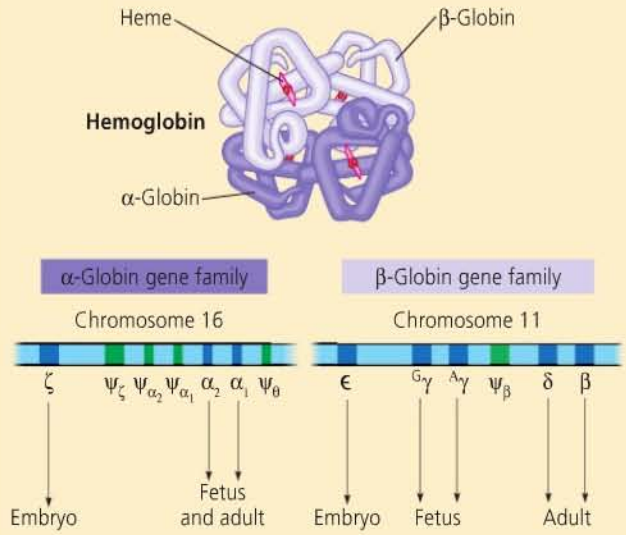
Much of a genome's simple sequence DNA is located at chromosomal telomeres and centromeres, suggesting that this DNA plays a structural role for chromosomes. The DNA at centromeres is essential for the separation of chromatids in cell division (see Chapter 12). Centromeric DNA, along with simple sequence DNA located elsewhere, may also help organize the chromatin within the interphase nucleus. The simple sequence DNA located at telomeres, at the tips of chromosomes, prevents genes from being lost as the DNA shortens with each round of replication (see Chapter 16). Telomeric DNA also binds proteins that protect the ends of a chromosome from degradation and from joining to other chromosomes.

Genes and Multigene Families



We finish our discussion of the various types of DNA sequences in eukaryotic genomes with a closer look at genes. Recall that DNA sequences that code for proteins or give rise to tRNA or rRNA compose a mere 1.5% of the human genome (see Figure 21.7). If we include introns and regulatory sequences associated with genes, the total amount of gene-related DNA—coding and noncoding—constitutes about 25%

of the human genome. Put another way, only about 6% (1.5% out of 25%) of the length of the average gene is represented in the final gene product.



Like the genes of bacteria, many eukaryotic genes are present as unique sequences, with only one copy per haploid set of chromosomes. But in the human genome and the genomes of many other animals and plants, such solitary genes make up less than half of the total transcribed DNA. The rest occurs in **multigene families**, collections of two or more identical or very similar genes.

In multigene families that consist of *identical* DNA sequences, those sequences are usually clustered tandemly and, with the notable exception of the genes for histone proteins, have RNAs as their final products. An example is the family of identical DNA sequences that are the genes for the three largest rRNA molecules **(Figure 21.10a)**. These rRNA molecules are transcribed from a single transcription unit that is repeated tandemly hundreds to thousands of times in one or several clusters in the genome of a multicellular eukaryote. The many copies of this rRNA transcription unit help cells to quickly make the millions of ribosomes needed for active protein synthesis. The primary transcript is cleaved to yield the three rRNA molecules. These are then combined with proteins and one other kind of rRNA (5S rRNA) to form ribosomal subunits.

The classic examples of multigene families of *nonidentical* genes are two related families of genes that encode globins, a group of proteins that include the α and β polypeptide subunits of hemoglobin. One family, located on chromosome 16 in humans, encodes various forms of α-globin; the other, on chromosome 11, encodes forms of β-globin **(Figure 21.10b)**. The different forms of each globin subunit are expressed at different times in development, allowing hemoglobin to function effectively in the changing environment of the developing animal. In humans, for example, the embryonic and fetal forms of hemoglobin have a higher affinity for oxygen than the adult forms, ensuring the efficient transfer of oxygen from mother to fetus. Also found in the globin gene family clusters are several pseudogenes.

(a) Part of the ribosomal RNA gene family. Three of the hundreds of copies of rRNA transcription units in a salamander genome are shown at the top (TEM). Each "feather" corresponds to a single transcription unit being transcribed by about 100 molecules of RNA polymerase (the dark dots along the DNA), moving left to right. The growing RNA transcripts extend out from the DNA. In the diagram below the TEM, one transcription unit is shown. It includes the genes for three types of rRNA (blue), adjacent to regions that are transcribed but later removed (yellow). A single transcript is made and then processed to yield one molecule of each of the three rRNAs, which are crucial components of the ribosome. A fourth rRNA (5S rRNA) is also found in the ribosome, but the gene encoding it is not part of this transcription unit.

(b) The human α-globin and β-globin gene families. Hemoglobin is composed of two α-globin and two β-globin polypeptide subunits. The genes (dark blue) encoding α- and β-globins are found in two families, organized as shown here. The noncoding DNA separating the functional genes within each family cluster includes pseudogenes (green), nonfunctional versions of the functional genes. Genes and pseudogenes are named with Greek letters.

▲ **Figure 21.10 Gene families.**

? *In (a), how could you determine the direction of transcription if it wasn't indicated by the red arrow?*

The arrangement of the genes in gene families has given biologists insight into the evolution of genomes. We will consider some of the processes that have shaped the genomes of different species over evolutionary time in the next section.

CONCEPT CHECK 21.4

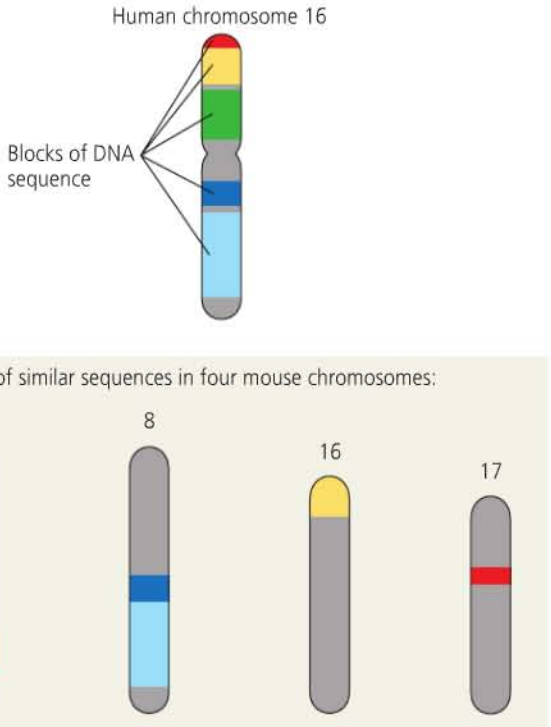
1. Discuss the characteristics of mammalian genomes that make them larger than prokaryotic genomes.
2. How are introns, transposable elements, and simple sequence DNA distributed differently in the genome?
3. Discuss the differences in the organization of the rRNA gene family and the globin gene families. For each, explain how the existence of a family of genes benefits the organism.
4. **WHAT IF?** Imagine you have found a DNA sequence similar to that of a known gene, but with quite a few nucleotide differences. How would you determine whether the "gene" you found is functional?

For suggested answers, see Appendix A.

CONCEPT 21.5

Duplication, rearrangement, and mutation of DNA contribute to genome evolution

The basis of change at the genomic level is mutation, which underlies much of genome evolution. It seems likely that the earliest forms of life had a minimal number of genes—those necessary for survival and reproduction. If this were indeed the case, one aspect of evolution must have been an increase in the size of the genome, with the extra genetic material providing the raw material for gene diversification. In this section, we will first describe how extra copies of all or part of a genome can arise and then consider subsequent processes that can lead to the evolution of proteins (or RNA products) with slightly different or entirely new functions.



Duplication of Entire Chromosome Sets

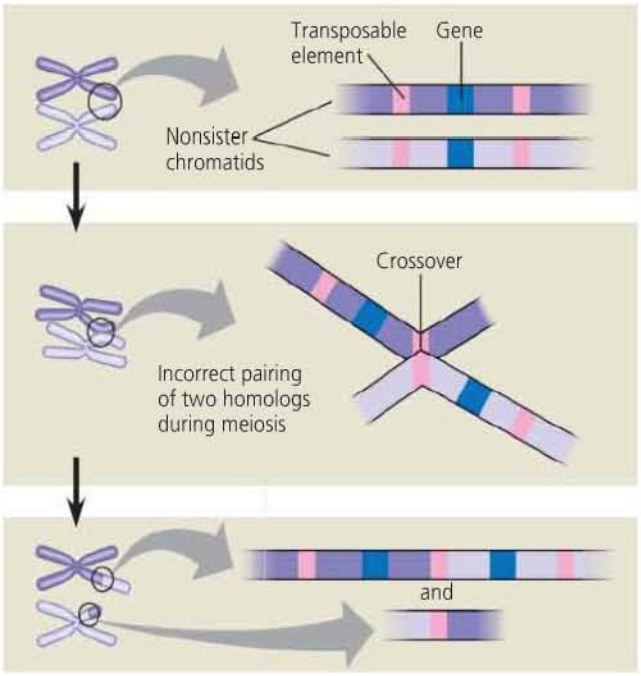
An accident in meiosis can result in one or more extra sets of chromosomes, a condition known as polyploidy. Although such accidents would most often be lethal, in rare cases they could facilitate the evolution of genes. In a polyploid organism, one set of genes can provide essential functions for the organism. The genes in the one or more extra sets can diverge by accumulating mutations; these variations may persist if the organism carrying them survives and reproduces. In this way, genes with novel functions can evolve. As long as one copy of an essential gene is expressed, the divergence of another copy can lead to its encoded protein acting in a novel way, thereby changing the organism's phenotype. The outcome of this accumulation of mutations may be the branching off of a new species, as happens often in plants (see Chapter 24). Polyploid animals also exist, but they are rare.

Alterations of Chromosome Structure

Scientists have long known that sometime in the last 6 million years, when the ancestors of humans and chimpanzees diverged as species, the fusion of two ancestral chromosomes in the human line led to different haploid numbers for humans ($n = 23$) and chimpanzees ($n = 24$). With the recent explosion in genomic sequence information, we can now compare the chromosomal organization of many different species on a much finer scale. This information allows us to make inferences about the evolutionary processes that shape chromosomes and may drive speciation.

In one study, for example, researchers compared the DNA sequence of each human chromosome with the whole genome sequence of the mouse. **Figure 21.11** shows the results of this comparison for human chromosome 16: Large blocks of genes on this chromosome are found on four mouse chromosomes, indicating that the genes in each block stayed together during the evolution of the mouse and human lineages. Performing the same comparative analysis between chromosomes of humans

▲ **Figure 21.11 Similar blocks of sequences on human and mouse chromosomes.** DNA sequences very similar to large blocks of human chromosome 16 are found on mouse chromosomes 7, 8, 16, and 17. This suggests that the DNA sequence in each block has stayed together in the mouse and human lineages since the time they diverged from a common ancestor.



and six other mammalian species allowed the researchers to reconstruct the evolutionary history of chromosomal rearrangements in these eight species. They found many duplications and inversions of large portions of chromosomes, the result of mistakes during meiotic recombination in which the DNA broke and was rejoined incorrectly. The rate of these events seems to have accelerated about 100 million years ago, around the time large dinosaurs became extinct and the number of mammalian species increased rapidly. The apparent coincidence is interesting because chromosomal rearrangements are thought to contribute to the generation of new species. Although two individuals with different arrangements could still mate and produce offspring, the offspring would have two nonequivalent sets of chromosomes, making meiosis inefficient or even impossible. Thus, chromosomal rearrangements would lead to two populations that could not successfully mate with each other, a step on the way to their becoming two separate species. (You'll learn more about this in Chapter 24.)

Somewhat unexpectedly, the same study also unearthed a pattern with medical relevance. Analysis of the chromosomal breakage points associated with the rearrangements showed that they were not randomly distributed, but that specific sites were used over and over again. A number of these recombination "hot spots" correspond to locations of chromosomal rearrangements within the human genome that are associated with congenital diseases. Researchers are, of course, looking at the other sites as well for their possible association with as yet unidentified diseases.

Duplication and Divergence of Gene-Sized Regions of DNA

Errors during meiosis can also lead to the duplication of chromosomal regions that are smaller than the ones we've just discussed, including segments the length of individual genes. Unequal crossing over during prophase I of meiosis, for instance, can result in one chromosome with a deletion and another with a duplication of a particular gene. As illustrated in **Figure 21.12**, transposable elements in the genome can provide sites where nonsister chromatids can cross over, even when their homologous sequences are not correctly aligned.

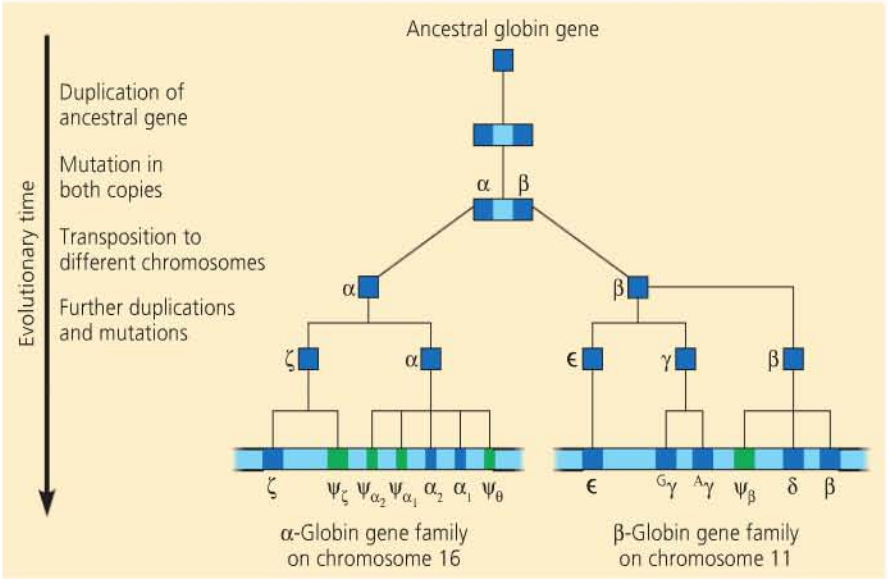
Also, slippage can occur during DNA replication, such that the template shifts with respect to the new complementary strand, and a part of the template strand is either skipped by the replication machinery or used twice as a template. As a result, a segment of DNA is deleted or duplicated. It is easy to imagine how such errors could occur in regions of repeats like the simple sequence DNA described previously. The variable number of repeated units of simple sequence DNA at a given site, used for STR analysis, is probably due to errors like these. Evidence that unequal crossing over and template slippage during DNA replication lead to duplication of genes is found in the existence of multigene families.

▲ **Figure 21.12 Gene duplication due to unequal crossing over.** One mechanism by which a gene (or other DNA segment) can be duplicated is recombination during meiosis between copies of a transposable element flanking the gene. Such recombination between misaligned nonsister chromatids of homologous chromosomes produces one chromatid with two copies of the gene and one chromatid with no copy.

Evolution of Genes with Related Functions: The Human Globin Genes

Duplication events can lead to the evolution of genes with related functions, such as those of the α-globin and β-globin gene families (see Figure 21.10b). A comparison of gene sequences within a multigene family can suggest the order in which the genes arose. This approach to re-creating the evolutionary history of the globin genes indicates that they all evolved from one common ancestral globin gene that underwent duplication and divergence into the α-globin and β-globin ancestral genes about 450–500 million years ago (**Figure 21.13**, on the next page). Each of these genes was later duplicated several times, and the copies then diverged from each other in sequence, yielding the current family members. In fact, the common ancestral globin gene also gave rise to the oxygen-binding muscle protein myoglobin and to the plant protein leghemoglobin. The latter two proteins function as monomers, and their genes are included in a "globin superfamily."

After the duplication events, the differences between the genes in the globin families undoubtedly arose from mutations that accumulated in the gene copies over many generations. The current model is that the necessary function provided by an α-globin protein, for example, was fulfilled by one gene, while other copies of the α-globin gene accumulated random mutations. Many mutations may have had an adverse effect on



the organism and others may have had no effect, but a few mutations must have altered the function of the protein product in a way that was advantageous to the organism at a particular life stage without substantially changing the protein's oxygen-carrying function. Presumably, natural selection acted on these altered genes, maintaining them in the population.

The similarity in the amino acid sequences of the various α-globin and β-globin polypeptides supports this model of gene duplication and mutation **(Table 21.2)**. The amino acid sequences of the β-globins, for instance, are much more similar to each other than to the α-globin sequences. The existence of several pseudogenes among the functional globin genes provides additional evidence for this model (see Figure 21.10b): Random mutations in these "genes" over evolutionary time have destroyed their function.

Evolution of Genes with Novel Functions

In the evolution of the globin gene families, gene duplication and subsequent divergence produced family members whose protein products performed similar functions (oxygen transport). Alternatively, one copy of a duplicated gene can undergo alterations that lead to a completely new function for the protein product. The genes for lysozyme and α-lactalbumin are good examples.

Lysozyme is an enzyme that helps protect animals against bacterial infection by hydrolyzing bacterial cell walls; α-lactalbumin is a nonenzymatic protein that plays a role in milk production in mammals. The two proteins are quite similar in their amino acid sequences and three-dimensional structures. Both genes are found in mammals, whereas only the lysozyme gene is present in birds. These findings suggest that at some time after the lineages leading to mammals and birds had separated, the lysozyme gene underwent a duplication event in the mammalian lineage but not in the avian lineage. Subsequently, one copy of the duplicated lysozyme gene evolved into a gene encoding α-lactalbumin, a protein with a completely different function.

▲ **Figure 21.13 A model for the evolution of the human α-globin and β-globin gene families from a single ancestral globin gene.**

? *The green elements are pseudogenes. Explain how they could have arisen after gene duplication.*

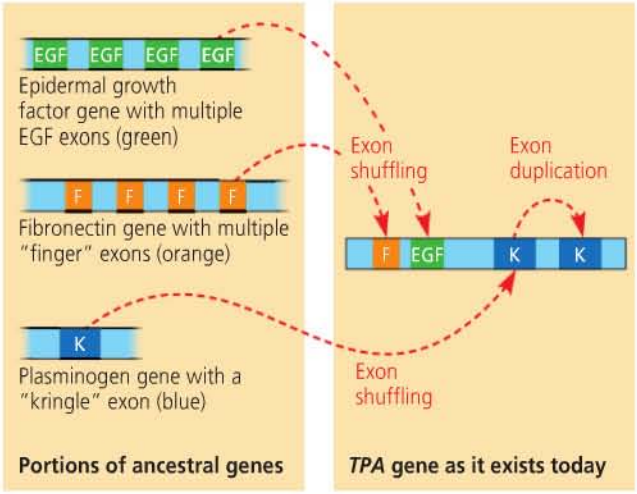


Table 21.2 Percentage of Similarity in Amino Acid Sequence Between Human Globin Proteins

		α-Globins		β-Globins		
		α	ζ	β	γ	ϵ
α-Globins	α	—	58	42	39	37
	ζ	58	—	34	38	37
β-Globins	β	42	34	—	73	75
	γ	39	38	73	—	80
	ϵ	37	37	75	80	—

Rearrangements of Parts of Genes: Exon Duplication and Exon Shuffling

Rearrangement of existing DNA sequences within genes has also contributed to genome evolution. The presence of introns in most genes of multicellular eukaryotes may have promoted the evolution of new and potentially useful proteins by facilitating the duplication or repositioning of exons in the genome. Recall from Chapter 17 that an exon often codes for a domain, a distinct structural or functional region of a protein.

We've already seen that unequal crossing over during meiosis can lead to duplication of a gene on one chromosome and its loss from the homologous chromosome (see Figure 21.12). By a similar process, a particular exon within a gene could be duplicated on one chromosome and deleted from the other. The gene with the duplicated exon would code for a protein containing a second copy of the encoded domain. This change in the protein's structure could augment its function by increasing its stability, enhancing

▲ **Figure 21.14 Evolution of a new gene by exon shuffling.** Exon shuffling could have moved exons from ancestral forms of the genes for epidermal growth factor, fibronectin, and plasminogen (left) into the evolving gene for tissue plasminogen activator, TPA (right). The order in which these events might have occurred is unknown. Duplication of the "kringle" exon from the plasminogen gene after its movement could account for the two copies of this exon in the *TPA* gene. Each type of exon encodes a particular domain in the TPA protein.

? *How could the presence of transposable elements in introns have facilitated the exon shuffling shown here?*

its ability to bind a particular ligand, or altering some other property. Quite a few protein-coding genes have multiple copies of related exons, which presumably arose by duplication and then diverged. The gene encoding the extracellular matrix protein collagen is a good example. Collagen is a structural protein with a highly repetitive amino acid sequence, which is reflected in the repetitive pattern of exons in the collagen gene.

Alternatively, we can imagine the occasional mixing and matching of different exons either within a gene or between two nonallelic genes owing to errors in meiotic recombination. This process, termed *exon shuffling*, could lead to new proteins with novel combinations of functions. As an example, let's consider the gene for tissue plasminogen activator (TPA). The TPA protein is an extracellular protein that helps control blood clotting. It has four domains of three types, each encoded by an exon; one exon is present in two copies. Because each type of exon is also found in other proteins, the gene for TPA is thought to have arisen by several instances of exon shuffling and duplication **(Figure 21.14)**.

How Transposable Elements Contribute to Genome Evolution

The persistence of transposable elements as a large fraction of some eukaryotic genomes is consistent with the idea that they play an important role in shaping a genome over evolutionary time. These elements can contribute to the evolution of the genome in several ways. They can promote recombination, disrupt cellular genes or control elements, and carry entire genes or individual exons to new locations.

Transposable elements of similar sequence scattered throughout the genome facilitate recombination between different chromosomes by providing homologous regions for crossing over. Most such alterations are probably detrimental, causing chromosomal translocations and other changes in the genome that may be lethal to the organism. But over the course of evolutionary time, an occasional recombination event of this sort may be advantageous to the organism.

The movement of a transposable element can also have direct consequences. For instance, if a transposable element "jumps" into the middle of a protein-coding sequence, it will prevent the production of a normal transcript of the gene. If a transposable element inserts within a regulatory sequence, the transposition may lead to increased or decreased production of one or more proteins. Transposition caused both types of effects on the genes coding for pigment-synthesizing enzymes in McClintock's corn kernels. Again, while such changes may usually be harmful, in the long run some may prove beneficial by providing a survival advantage.

During transposition, a transposable element may carry along a gene or group of genes to a new position in the genome. This mechanism probably accounts for the location of the α-globin and β-globin gene families on different human chromosomes, as well as the dispersion of the genes of certain other gene families. By a similar tag-along process, an exon from one gene may be inserted into another gene in a mechanism similar to that of exon shuffling during recombination. For example, an exon may be inserted by transposition into the intron of a protein-coding gene. If the inserted exon is retained in the RNA transcript during RNA splicing, the protein that is synthesized will have an additional domain, which may confer a new function on the protein.

A recent study reveals yet another way that transposable elements can bring about new coding sequences. This work shows that an *Alu* element may hop into an intron in a way that creates a weak alternative splice site in the RNA transcript. During processing of the transcript, the regular splice sites are used more often, so that the original protein is made. On occasion, however, splicing occurs at the new weak site, with the result that some of the *Alu* element ends up in the mRNA, coding for a new portion of the protein. In this way, alternative genetic combinations may be "tried out" while the function of the original gene product is retained.

Clearly, all the processes discussed in this section most often produce either harmful effects, which may be lethal, or no effect at all. In a few cases, however, small beneficial changes may occur. Over many generations, the resulting genetic diversity provides valuable raw material for natural selection. Diversification of genes and their products is an important factor in the evolution of new species. Thus, the accumulation of changes in the genome of each species provides a record of

its evolutionary history. To read this record, we must be able to identify genomic changes. Comparing the genomes of different species allows us to do that and has increased our understanding of how genomes evolve. You will learn more about these topics in the final section.

CONCEPT CHECK 21.5

1. Describe three examples of errors in cellular processes that lead to DNA duplications.
2. Explain how multiple exons might have arisen in the ancestral EGF and fibronectin genes shown in Figure 21.14 (left).
3. What are three ways that transposable elements are thought to contribute to genome evolution?
4. **WHAT IF?** In 2005, Icelandic scientists reported finding a large chromosomal inversion present in 20% of northern Europeans, and they noted that Icelandic women with this inversion had significantly more children than women without it. What would you expect to happen to the frequency of this inversion in the Icelandic population in future generations?

For suggested answers, see Appendix A.

CONCEPT 21.6

Comparing genome sequences provides clues to evolution and development

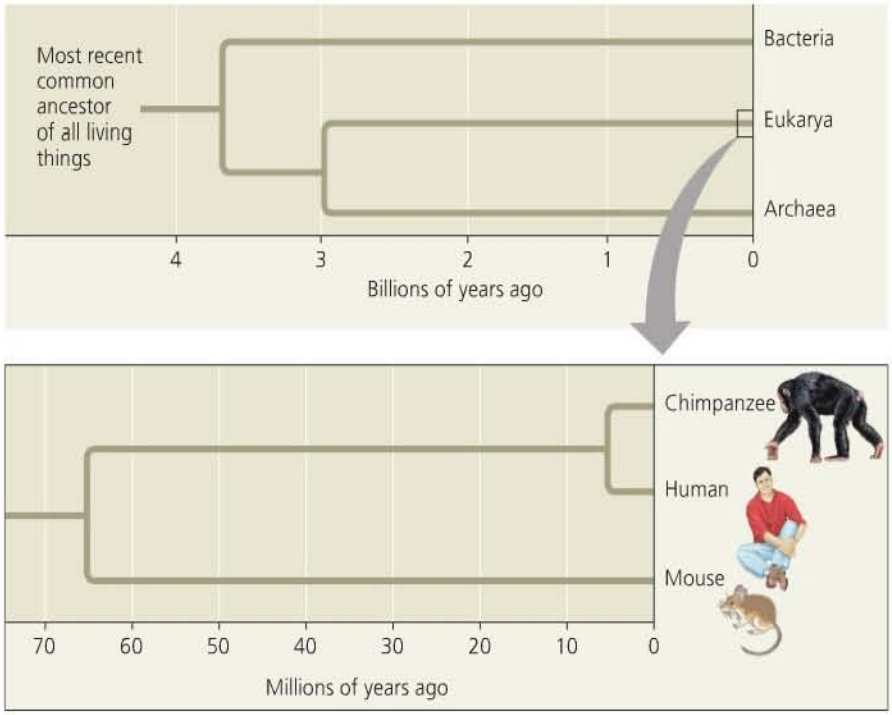
One researcher has likened the current state of biology to the Age of Exploration in the 15th century after major improvements in navigation and the building of faster ships. In the last 20 years, we have seen rapid advances in genome sequencing and data collection, new techniques for assessing gene activity across the whole genome, and refined approaches for understanding how genes and their products work together in complex systems. We are truly poised on the brink of a new world.

Comparisons of genome sequences from different species reveal much about the evolutionary history of life, from very ancient to more recent. Similarly, comparative studies of the genetic programs that direct embryonic development in different species are beginning to clarify the mechanisms that generated the great diversity of life-forms present today. In this final section of the chapter, we will discuss what has been learned from these two approaches.

Comparing Genomes

The more similar in sequence the genes and genomes of two species are, the more closely related those species are in their evolutionary history. Comparing genomes of closely related species sheds light on more recent evolutionary events, whereas comparing genomes of very distantly related species helps us understand ancient evolutionary history. In either case, learning about characteristics that are shared or divergent between groups enhances our picture of the evolution of life-forms and biological processes. As you learned in Chapter 1, the evolutionary relationships between species can be represented by a diagram in the form of a tree (often turned sideways), where each branch point marks the divergence of two lineages. **Figure 21.15** shows the evolutionary relationships of some groups and species we will be discussing. We will consider comparisons between distantly related species first.

Comparing Distantly Related Species



Analyzing which genes have remained similar—that is, are *highly conserved*—in distantly related species can help clarify evolutionary relationships among species that diverged from each other long ago. Indeed, comparisons of the complete genome sequences of bacteria, archaea, and eukaryotes indicate that these three groups diverged between 2 and 4 billion years ago and strongly support the theory that they are the fundamental domains of life (see Figure 21.15).

In addition to their value in evolutionary biology, comparative genomic studies confirm the relevance of research on model organisms to our understanding of biology in general and human biology in particular. Genes that evolved a very long time ago can still be surprisingly similar in disparate species. As a case in point, several genes in yeast are so similar to certain human disease genes that researchers have deduced the functions of the disease genes by studying their yeast counterparts. This striking similarity underscores the common origin of these two distantly related species.

Comparing Closely Related Species

The genomes of two closely related species are likely to be organized similarly because of their relatively recent divergence. As we mentioned earlier, this allows the fully sequenced genome of one species to be used as a scaffold for assembling the genomic sequences of a closely related species, accelerating mapping of the second genome. For instance, using the human genome sequence as a guide, researchers were able to quickly sequence the mouse genome.

The recent divergence of two closely related species also underlies the small number of gene differences that are found when their genomes are compared. The particular genetic differences can therefore be more easily correlated with phenotypic differences between the two species. An exciting application of this type of analysis is seen as researchers compare the human genome with the genomes of the chimpanzee, mouse, rat, and other mammals. Identifying the genes shared by all of these species but not by nonmammals should give clues about what it

▲ **Figure 21.15 Evolutionary relationships of the three domains of life.** This tree diagram shows the ancient divergence of bacteria, archaea, and eukaryotes. A portion of the eukaryote lineage is expanded in the inset to show the more recent divergence of three mammalian species discussed in this chapter.

takes to make a mammal, while finding the genes shared by chimpanzees and humans but not by rodents should tell us something about primates. And, of course, comparing the human genome with that of the chimpanzee should help us answer the tantalizing question we asked at the beginning of the chapter: What genomic information makes a human or a chimpanzee?

An analysis of the overall composition of the human and chimpanzee genomes, which are thought to have diverged only about 6 million years ago (see Figure 21.15), reveals some general differences. Considering single base substitutions, the two genomes differ by only 1.2%. When researchers looked at longer stretches of DNA, however, they were surprised to find a further 2.7% difference due to insertions or deletions of larger regions in the genome of one or the other species; many of the insertions were duplications or other repetitive DNA. In fact, a third of the human duplications are not present in the chimpanzee genome, and some of these duplications contain regions associated with human diseases. There are more *Alu* elements in the human genome than in that of the chimpanzee, and the latter contains many copies of a retroviral provirus not present in humans. All of these observations provide clues to the forces that might have swept the two genomes along different paths, but we don't have a complete picture yet. We also don't know how these differences might account for the distinct characteristics of each species.

To discover the basis for the phenotypic differences between the two species, biologists are studying specific genes and types of genes that differ between humans and chimpanzees and comparing them with their counterparts in other mammals. This approach has revealed a number of genes that are apparently changing (evolving) faster in the human than in either the chimpanzee or the mouse. Among them are genes involved in defense against malaria and tuberculosis and at least one gene that regulates brain size. When genes are classified by function, the genes that seem to be evolving the fastest are those that code for transcription factors. This is exciting news because transcription factors regulate gene expression and thus play a key role in orchestrating the overall genetic program.

One transcription factor whose gene shows evidence of rapid change in the human lineage is called FOXP2. Several lines of evidence suggest that the *FOXP2* gene functions in vocalization in vertebrates. For one thing, mutations in this gene can produce severe speech and language impairment in humans. Moreover, the *FOXP2* gene is expressed in the brains of zebra finches and canaries at the time when these songbirds are learning their songs. But perhaps the strongest evidence comes from a "knock-out" experiment in which Joseph Buxbaum and colleagues disrupted the *FOXP2* gene in mice and analyzed the resulting phenotype (**Figure 21.16**, on the next page). The homozygous mutant mice had malformed brains and failed to emit normal ultrasonic vocalizations, and mice with one faulty copy of the gene also showed significant problems with vocalization. These results support the idea that the *FOXP2* gene product turns on genes involved in vocalization.

Expanding on this notion, researchers are exploring the question of whether differences between the human and chimpanzee FOXP2 proteins could account for the ability of humans, but not chimpanzees, to communicate by speech. There are only two amino acid differences between the human and chimpanzee FOXP2 proteins, and the effect of these differences on the function of the human protein is an intriguing question, whose answer is not yet known.

The *FOXP2* story is an excellent example of how different approaches complement each other in uncovering biological phenomena of widespread importance. The experiment described in Figure 21.16 uses mice as a model for humans because it would be unethical (as well as impractical) to carry out such an experiment in humans. Mice and humans diverged about 65.5 million years ago (see Figure 21.15) and share about 85% of their genes. This genetic similarity can be exploited in

▼ Figure 21.16 Inquiry

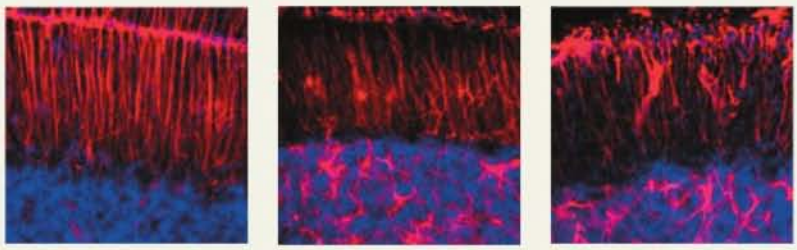
What is the function of a gene (*FOXP2*) that is rapidly evolving in the human lineage?

EXPERIMENT Several lines of evidence support a role for the *FOXP2* gene in the development of speech and language in humans and of vocalization in other vertebrates. In 2005, Joseph Buxbaum and collaborators at the Mount Sinai School of Medicine and several other institutions set out to test the function of *FOXP2*. They used the mouse, a model organism in which genes can be easily knocked out, as a representative vertebrate that vocalizes. Mice produce ultrasonic squeaks, referred to as whistles, to communicate stress. The researchers applied genetic engineering techniques to produce mice in which one or both copies of *FOXP2* were disrupted.

Wild type: two normal copies of *FOXP2*

Heterozygote: one copy of *FOXP2* disrupted

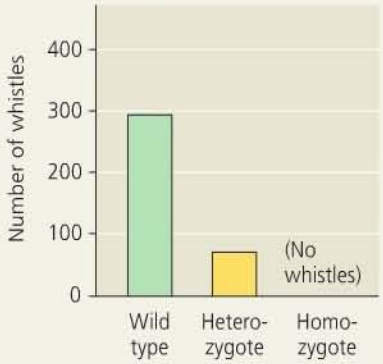
Homozygote: both copies of *FOXP2* disrupted



They then compared the phenotypes of these mice. Two of the characters they examined are included here: brain anatomy and vocalization.

Experiment 1: Researchers cut thin sections of brain and stained them with reagents, allowing visualization of brain anatomy in a UV fluorescence microscope.

Experiment 2: Researchers separated each newborn pup from its mother and recorded the number of ultrasonic whistles produced by the pup.



RESULTS

Experiment 1: Disruption of both copies of *FOXP2* led to brain abnormalities in which the cells were disorganized. Phenotypic effects on the brain of heterozygotes, with one disrupted copy, were less severe.

Wild type | Heterozygote | Homozygote

Experiment 2: Disruption of both copies of *FOXP2* led to an absence of ultrasonic vocalization in response to stress. The effect on vocalization in the heterozygote was also extreme.

CONCLUSION *FOXP2* plays a significant role in the development of functional communication systems in mice. The results augment evidence from studies of birds and humans, supporting the hypothesis that *FOXP2* may act similarly in diverse organisms.

SOURCE W. Shu et al., Altered ultrasonic vocalization in mice with a disruption in the *Foxp2* gene, *Proceedings of the National Academy of Sciences* 102:9643–9648 (2005).

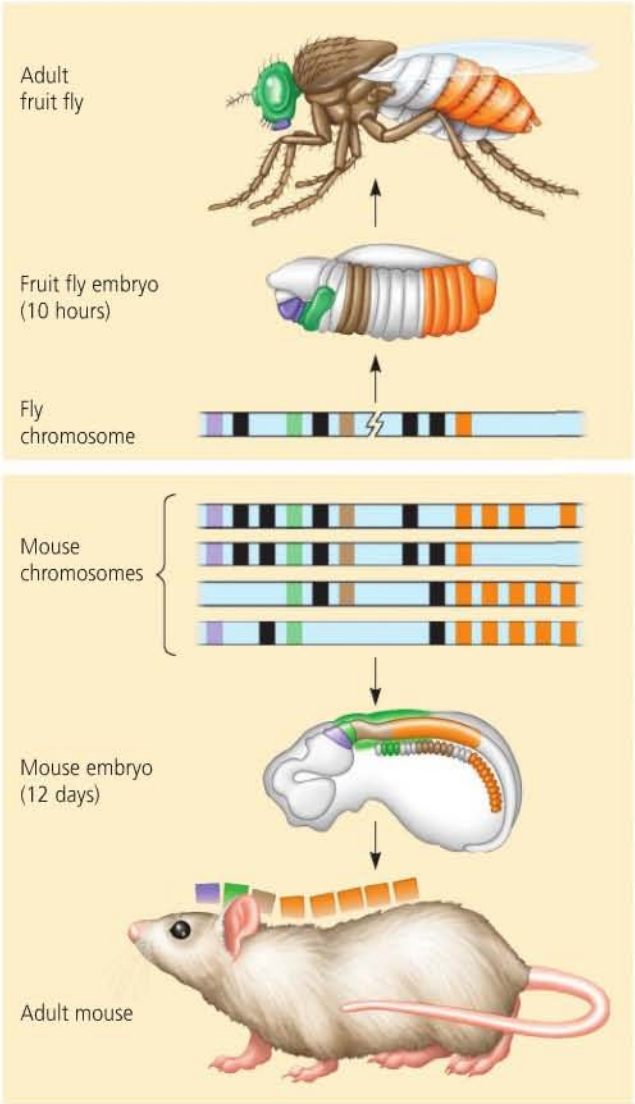
WHAT IF? Since the results support a role for mouse *FOXP2* in vocalization, you might wonder whether the human FOXP2 protein is a key regulator of speech. If you were given the amino acid sequences of wild-type and mutant human FOXP2 proteins and the wild-type chimpanzee FOXP2 protein, how would you investigate this question? What further clues could you obtain by comparing these sequences to that of the mouse FOXP2 protein?

studying other human genetic disorders. If researchers know the organ or tissue that is affected by a particular genetic disorder, they can look for genes that are expressed in these locations in experiments using mice. This approach has revealed several human genes of interest, including one that may contribute to Down syndrome.

Further research efforts are under way to extend genomic studies to many more microbial species, additional primates, and neglected species from diverse branches of the tree of life. These studies will advance our understanding of all aspects of biology, including health and ecology as well as evolution.

Comparing Genomes Within a Species

Another exciting prospect that stems from our ability to analyze genomes is increasing our understanding of the spectrum of genetic variation in humans. Because the history of the human species is so short—probably about 200,000 years—the amount of DNA variation among humans is small compared to that of many other species. Much of our diversity seems to be in the form of single nucleotide polymorphisms (SNPs, described in Chapter 20), usually detected by DNA sequencing. In the human genome, SNPs occur on average about once in 100 to 300 base pairs.



Scientists have already identified the location of several million SNP sites in the human genome and continue to find more. In the course of this search, they have also found other variations—including inversions, deletions, and duplications—that occur without apparent ill effect on the individual carrying them. These variations, as well as SNPs, will be useful genetic markers for studying human evolution, the differences between human populations, and the migratory routes of human populations throughout history. Such polymorphisms in human DNA will also be valuable markers for identifying genes that cause diseases or affect our health in more subtle ways. As well as informing us about evolution, analysis of the differences in individual genomes is likely to change the practice of medicine later in the 21st century.

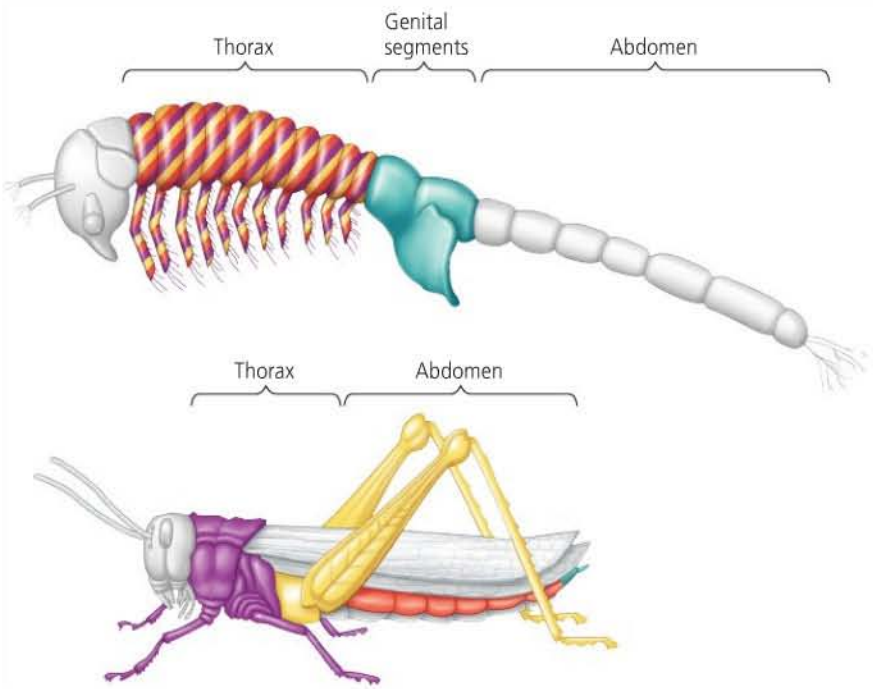
Comparing Developmental Processes

Biologists in the field of evolutionary developmental biology, or **evo-devo** as it is often called, compare developmental processes of different multicellular organisms. Their aim is to understand how these processes have evolved and how changes in them can modify existing organismal features or lead to new ones. With the advent of molecular techniques and the recent flood of genomic information, we are beginning to realize that the genomes of related species with strikingly different forms may have only minor differences in gene sequence or regulation. Discovering the molecular basis underlying these differences in turn helps us understand the origin of the myriad diverse forms that cohabit this planet, thus informing our study of evolution.

Widespread Conservation of Developmental Genes Among Animals

In Chapter 18, you learned about the homeotic genes in *Drosophila*, which specify the identity of body segments in the fruit fly (see Figure 18.18). Molecular analysis of the homeotic genes in *Drosophila* has shown that they all include a 180-nucleotide sequence called a **homeobox**, which specifies a 60-amino-acid *homeodomain* in the encoded proteins. An identical or very similar nucleotide sequence has been discovered in the homeotic genes of many invertebrates and vertebrates. The sequences are so similar between humans and fruit flies, in fact, that one researcher has whimsically referred to flies as "little people with wings." The resemblance even extends to the organization of these genes: The vertebrate genes homologous to the homeotic genes of fruit flies have kept the same chromosomal arrangement **(Figure 21.17)**. Homeobox-containing sequences have also been found in regulatory genes of much more distantly related eukaryotes, including plants and yeasts. From these similarities, we can deduce that the homeobox DNA sequence evolved very early in the history of

▲ **Figure 21.17 Conservation of homeotic genes in a fruit fly and a mouse.** Homeotic genes that control the form of anterior and posterior structures of the body occur in the same linear sequence on chromosomes in *Drosophila* and mice. Each colored band on the chromosomes shown here represents a homeotic gene. In fruit flies, all homeotic genes are found on one chromosome. The mouse and other mammals have the same or similar sets of genes on four chromosomes. The color code indicates the parts of the embryos in which these genes are expressed and the adult body regions that result. All of these genes are essentially identical in flies and mice, except for those represented by black bands, which are less similar in the two animals.



life and was sufficiently valuable to organisms to have been conserved in animals and plants virtually unchanged for hundreds of millions of years.

Homeotic genes in animals were named *Hox* genes, short for *h*omeob*ox*-containing genes, because homeotic genes were the first genes found to have this sequence. Other homeobox-containing genes were later found that do not act as homeotic genes; that is, they do not directly control the identity of body parts. However, most of these genes, in animals at least, are associated with development, suggesting their ancient and fundamental importance in that process. In *Drosophila*, for example, homeoboxes are present not only in the homeotic genes but also in the egg-polarity gene *bicoid* (see Chapter 18), in several of the segmentation genes, and in a master regulatory gene for eye development.

Researchers have discovered that the homeobox-encoded homeodomain is the part of a protein that binds to DNA when the protein functions as a transcriptional regulator. However, the shape of the homeodomain allows it to bind to any DNA segment; by itself it cannot select a specific sequence. Rather, other domains in a homeodomain-containing protein, ones that are more variable, determine which genes the protein regulates. Interaction of these latter domains with still other transcription factors helps a homeodomain-containing protein recognize specific enhancers in the DNA. Proteins with homeodomains probably regulate development by coordinating the transcription of batteries of developmental genes, switching them on or off. In embryos of *Drosophila* and other animal species, different combinations of homeobox genes are active in different parts of the embryo. This selective expression of regulatory genes, varying over time and space, is central to pattern formation.

Developmental biologists have found that in addition to homeotic genes, many other genes involved in development are highly conserved from species to species. These include numerous genes encoding components of signaling pathways. The extraordinary similarity among particular developmental genes in different animal species raises a question: How can the same genes be involved in the development of animals whose forms are so very different from each other?

Current studies are suggesting answers to this question. In some cases, small changes in regulatory sequences of particular genes cause changes in gene expression patterns that can lead to major changes in body form. For example, the differing patterns of expression of the *Hox* genes along the body axis in insects and crustaceans can explain the variation in number of leg-bearing segments among these segmented animals **(Figure 21.18)**. Also, recent research suggests that the same *Hox* gene product may have subtly dissimilar effects in different species, turning on new genes or turning on the same genes at higher or lower levels. In other cases, similar genes direct distinct developmental processes in different organisms, resulting in diverse body shapes. Several *Hox* genes, for instance, are expressed in the embryonic and larval stages of the sea urchin, a nonsegmented animal that has a body plan quite different from those of insects and mice. Sea urchin adults make the pincushion-shaped shells you may have seen on the beach. They are among the organisms long used in classical embryological studies (see Chapter 47).

▲ **Figure 21.18 Effect of differences in *Hox* gene expression during development in crustaceans and insects.** Changes in the expression patterns of four *Hox* genes have occurred over evolutionary time. These changes account in part for the different body plans of the brine shrimp *Artemia*, a crustacean (top), and the grasshopper, an insect. Shown here are regions of the adult body color-coded for expression of the *Hox* genes that determine formation of particular body parts during embryonic development. Each color represents a specific *Hox* gene.

Comparison of Animal and Plant Development

The last common ancestor of animals and plants was probably a single-celled eukaryote that lived hundreds of millions of years ago, so the processes of development must have evolved independently in the two multicellular lineages of organisms. Plants evolved with rigid cell walls, which rule out the morphogenetic movements of cells and tissues that are so important in animals. Instead, morphogenesis in plants relies primarily on differing planes of cell division and on selective cell enlargement. (You will learn about these processes in

Chapter 35.) But despite the differences between animals and plants, there are similarities in the molecular mechanisms of development, which are legacies of their shared unicellular origin.

In both animals and plants, development relies on a cascade of transcriptional regulators turning on or turning off genes in a finely tuned series. For example, work on a small flowering plant in the mustard family, *Arabidopsis thaliana*, has shown that establishing the radial pattern of flower parts, like setting up the head-to-tail axis in *Drosophila*, involves a cascade of transcription factors. The genes that direct these processes, however, differ considerably in animals and plants. While quite a few of the master regulatory switches in *Drosophila* are homeobox-containing *Hox* genes, those in *Arabidopsis* belong to a completely different family of genes, called the *Mads-box* genes. And although homeobox-containing genes can be found in plants and *Mads-box* genes in animals, in neither case do they perform the same major roles in development that they do in the other group. Thus, molecular evidence supports the supposition that developmental programs evolved separately in animals and plants.

In this final chapter of the genetics unit, you have learned how studying genomic composition and comparing the genomes of different species can disclose much about how genomes evolve. Further, comparing developmental programs, we can see that the unity of life is reflected in the similarity of molecular and cellular mechanisms used to establish body pattern, although the genes directing development may differ among organisms. The similarities between genomes reflect the common ancestry of life on Earth. But the differences are also crucial, for they have created the huge diversity of organisms that have evolved. In the remainder of the book, we expand our perspective beyond the level of molecules, cells, and genes to explore this diversity on the organismal level.

CONCEPT CHECK 21.6

1. Would you expect the genome of the macaque (a monkey) to be more similar to the mouse genome or the human genome? Why?
2. The DNA sequences called homeoboxes, which help homeotic genes in animals direct development, are common to flies and mice. Given this similarity, explain why these animals are so different.
3. **WHAT IF?** There are three times as many *Alu* elements in the human genome as in the chimpanzee genome. How do you think these extra *Alu* elements arose in the human genome? Propose a role they might have played in the divergence of these two species.

For suggested answers, see Appendix A.

Activity The Human Genome Project: Genes on Human Chromosome 17

SUMMARY OF KEY CONCEPTS

CONCEPT 21.1

New approaches have accelerated the pace of genome sequencing (pp. 427–429)

- **Three-Stage Approach to Genome Sequencing** In linkage mapping, the order of genes and other inherited markers in the genome and the relative distances between them can be determined from recombination frequencies. Next, physical mapping uses overlaps between DNA fragments to order the fragments and determine the distance in base pairs between markers. Finally, the ordered fragments are sequenced, providing the finished genome sequence.
- **Whole-Genome Shotgun Approach to Genome Sequencing** The whole genome is cut into many small, overlapping fragments that are sequenced; computer software then assembles the complete sequence. Correct assembly is made easier when mapping information is also available.

CONCEPT 21.2

Scientists use bioinformatics to analyze genomes and their functions (pp. 429–432)

- **Centralized Resources for Analyzing Genome Sequences** Websites on the Internet provide centralized access to genome sequence databases, analytical tools, and genome-related information.
- **Identifying Protein-Coding Genes Within DNA Sequences** Computer analysis of genome sequences helps researchers identify sequences likely to encode proteins. Comparison of the sequences of "new" genes with those of known genes in other species may help identify functions of new genes. For a gene of unknown function, experimental inactivation of the gene and observation of the resulting phenotypic effects can provide clues to its function.
- **Understanding Genes and Their Products at the Systems Level** Using the computer-based tools of bioinformatics, scientists can compare genomes and study sets of genes and proteins as whole systems (genomics and proteomics). Studies include large-scale analyses of protein interactions.

CONCEPT 21.3

Genomes vary in size, number of genes, and gene density (pp. 432–434)

	Bacteria	Archaea	Eukarya
Genome size	Most are 1–6 Mb		Most are 10–4,000 Mb, but a few are much larger
Number of genes	1,500–7,500		5,000–40,000
Gene density	Higher than in eukaryotes		Lower than in prokaryotes (Within eukaryotes, lower density is correlated with larger genomes.)
Introns	None in protein-coding genes	Present in some genes	Unicellular eukaryotes: present, but prevalent only in some species Multicellular eukaryotes: present in most genes
Other noncoding DNA	Very little		Can be large amounts; generally more repetitive noncoding DNA in multicellular eukaryotes

CONCEPT 21.4

Multicellular eukaryotes have much noncoding DNA and many multigene families (pp. 434–438)

- Only 1.5% of the human genome codes for proteins or gives rise to rRNAs or tRNAs; the rest is noncoding DNA, including repetitive DNA.
- **Transposable Elements and Related Sequences** The most abundant type of repetitive DNA in multicellular eukaryotes consists of transposable elements and related sequences. Two types of transposable elements occur in eukaryotes: transposons, which move via a DNA intermediate, and retrotransposons, which are more prevalent and move via an RNA intermediate. Each element may be hundreds or thousands of base pairs long, and similar but usually not identical copies are dispersed throughout the genome.
- **Other Repetitive DNA, Including Simple Sequence DNA** Short noncoding sequences that are tandemly repeated thousands of times (simple sequence DNA, which includes STRs) are especially prominent in centromeres and telomeres, where they probably play structural roles in the chromosome.
- **Genes and Multigene Families** Though many eukaryotic genes are present in one copy per haploid chromosome set, others (most, in some species) are members of a family of related genes. The transcription unit corresponding to the three largest rRNAs is tandemly repeated hundreds to thousands of times at one or several chromosomal sites, enabling the cell to quickly make the rRNA for millions of ribosomes. The multiple, slightly different genes in the two globin gene families encode polypeptides used at different developmental stages of an animal.

CONCEPT 21.5

Duplication, rearrangement, and mutation of DNA contribute to genome evolution (pp. 438–442)

- **Duplication of Entire Chromosome Sets** Accidents in cell division can lead to extra copies of all or part of a genome, which may then diverge if one set accumulates sequence changes.
- **Alterations of Chromosome Structure** The chromosomal organization of genomes can be compared among species, providing information about evolutionary relationships. Within a given species, rearrangements of chromosomes are thought to contribute to the emergence of new species.
- **Duplication and Divergence of Gene-Sized Regions of DNA** The genes encoding the various globin proteins evolved from one common ancestral globin gene, which duplicated and diverged into α-globin and β-globin ancestral genes. Subsequent duplication and random mutation gave rise to the present globin genes, all of which code for oxygen-binding proteins. The copies of some duplicated genes have diverged so much that the functions of their encoded proteins are now substantially different.
- **Rearrangements of Parts of Genes: Exon Duplication and Exon Shuffling** Rearrangement of exons within and between genes during evolution has led to genes containing multiple copies of similar exons and/or several different exons derived from other genes.
- **How Transposable Elements Contribute to Genome Evolution** Movement of transposable elements or recombination between copies of the same element occasionally generates new sequence combinations that are beneficial to the organism. Such mechanisms can alter the functions of genes or their patterns of expression and regulation.

Biology Labs On-Line HemoglobinLab

CONCEPT 21.6

Comparing genome sequences provides clues to evolution and development (pp. 442–447)

- **Comparing Genomes** Comparative studies of genomes from widely divergent and closely related species provides valuable information about ancient and more recent evolutionary history, respectively. Human and chimpanzee sequences show about 4% difference, mostly due to insertions, deletions, and duplications in one lineage. Along with nucleotide variations in specific genes (such as *FOXP2*, a gene affecting speech), these differences may account for the distinct characteristics of the two species. Single nucleotide polymorphisms among individuals in a species can also yield information about the history of that species.
- **Comparing Developmental Processes** Homeotic genes and some other genes associated with animal development contain a homeobox region, whose sequence is identical or similar in diverse species. Related sequences are present in the genes of plants and yeasts. Other developmental genes also are highly conserved among animal species, but they may play different roles in the development of different species. During embryonic development in both plants and animals, a cascade of transcription regulators turns genes on or off in a carefully regulated sequence. However, the genes that direct analogous developmental processes differ considerably in sequence in plants and animals as a result of their remote ancestry.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Bioinformatics includes all of the following *except*
   a. using computer programs to align DNA sequences.
   b. analyzing protein interactions in a species.
   c. using molecular biology to combine DNA from two different sources in a test tube.
   d. development of computer-based tools for genome analysis.
   e. use of mathematical tools to make sense of biological systems.

2. Which of the following has the largest genome and the fewest genes per million base pairs?
   a. *Haemophilus influenzae* (bacterium)
   b. *Saccharomyces cerevisiae* (yeast)
   c. *Arabidopsis thaliana* (plant)
   d. *Drosophila melanogaster* (fruit fly)
   e. *Homo sapiens* (human)

3. One of the characteristics of retrotransposons is that
   a. they code for an enzyme that synthesizes DNA using an RNA template.
   b. they are found only in animal cells.
   c. they generally move by a cut-and-paste mechanism.
   d. they contribute a significant portion of the genetic variability seen within a population of gametes.
   e. their amplification is dependent on a retrovirus.

4. Multigene families are
   a. groups of enhancers that control transcription.
   b. usually clustered at the telomeres.
   c. equivalent to the operons of prokaryotes.
   d. sets of genes that are coordinately controlled.
   e. sets of identical or similar genes that have evolved by gene duplication.

5. Two eukaryotic proteins have one domain in common but are otherwise very different. Which of the following processes is most likely to have contributed to this similarity?
   a. gene duplication
   b. RNA splicing
   c. exon shuffling
   d. histone modification
   e. random point mutations

6. Homeotic genes
   a. encode transcription factors that control the expression of genes responsible for specific anatomical structures.
   b. are found only in *Drosophila* and other arthropods.
   c. are the only genes that contain the homeobox domain.
   d. encode proteins that form anatomical structures in the fly.
   e. are responsible for patterning during plant development.

7. **DRAW IT** At the top of the next column are the amino acid sequences (using the single-letter code; see Figure 5.17) of four short segments of the FOXP2 protein from six species: chimpanzee, orangutan, gorilla, rhesus macaque, mouse, and human. These segments contain all of the amino acid differences between the FOXP2 proteins of these species.

   1. ATETI...PKSSD...TSSTT...NARRD
   2. ATETI...PKSSE...TSSTT...NARRD
   3. ATETI...PKSSD...TSSTT...NARRD
   4. ATETI...PKSSD...TSSNT...SARRD
   5. ATETI...PKSSD...TSSTT...NARRD
   6. VTETI...PKSSD...TSSTT...NARRD

   Use a highlighter to color any amino acid that varies among the species. (Color that amino acid in all sequences.) Then answer the following questions.
   a. The chimpanzee, gorilla, and rhesus macaque (C, G, R) sequences are identical. Which lines correspond to those sequences?
   b. The human sequence differs from that of the C, G, R species at two amino acids. Which line corresponds to the human sequence? Underline the two differences.
   c. The orangutan sequence differs from the C, G, R sequence at one amino acid (having valine instead of alanine) and from the human sequence at three amino acids. Which line corresponds to the orangutan sequence?
   d. How many amino acid differences are there between the mouse and the C, G, R species? Circle the amino acid(s) that differ(s) in the mouse. How many amino acid differences are there between the mouse and the human? Draw a square around the amino acid(s) that differ(s) in the mouse.
   e. Primates and rodents diverged between 60 and 100 million years ago, and chimpanzees and humans diverged about 6 million years ago. Knowing that, what can you conclude by comparing the amino acid differences between the mouse and the C, G, R species with the differences between the human and the C, G, R species?

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

8. Genes important in the embryonic development of animals, such as homeobox-containing genes, have been relatively well conserved during evolution; that is, they are more similar among different species than are many other genes. Why is this?

SCIENTIFIC INQUIRY

9. The scientists mapping the SNPs in the human genome noticed that groups of SNPs tended to be inherited together, in blocks known as haplotypes, ranging in length from 5,000 to 200,000 base pairs. There are as few as four or five commonly occurring combinations of SNPs per haplotype. Propose an explanation for this observation, integrating what you've learned throughout this chapter and this unit.

UNIT 4

Mechanisms of Evolution

AN INTERVIEW WITH

Scott V. Edwards

Birds—and the birds of Australia in particular—might seem a surprising focus for a scientist who grew up in New York City, but they are the main subjects of Scott Edwards's research on evolution. A graduate of Harvard College, with a Ph.D. from the University of California, Berkeley, and postdoctoral work at the University of Florida, Dr. Edwards was at the University of Washington until he returned to Harvard in 2003 as Professor of Organismic and Evolutionary Biology. Jane Reece and Michael Cain interviewed Dr. Edwards at Harvard's Museum of Comparative Zoology, where he is Curator of Ornithology and the head of an active research group.

How big is the bird collection here?

Since the Museum of Comparative Zoology was founded in 1859, its collection of bird specimens has grown to 350,000 specimens, the largest university collection in the world. Each specimen is tagged with data about the location where it was obtained, the date, often the bird's sex and weight, and other pertinent information. The collection provides a remarkable record of how bird species have changed over the years, as environments have changed. Using the oldest specimens here, we can now compare the sizes, shapes, and genes of birds from populations separated by more than a century. What's exciting now is that all the information is being digitized, so that we can easily look at large amounts of data from multiple museums.

Were you interested in birds as a child?

When I was about six years old, we moved from an urban neighborhood to Riverdale, in the northwest corner of the Bronx. There were actually trees there, and we were close to the Hudson River. A few years later, a neighbor took me bird watching—and the rest is history. I'll never forget how impressed I was with my first Northern flicker; it was just remarkable to me that this bizarrely colored woodpecker lived right in my backyard.

Later, as an undergraduate biology major, I really needed a break after taking organic chemistry, and I was able to take a year off. I volunteered at the Smithsonian for several months and then at national parks in Hawaii and California. It was that first exposure to fieldwork that showed me what biologists do. And when I came back to college, I was much more focused and motivated. I think it should be mandatory for biology majors to work in the field or in a lab for a few months, because that's how you find out what science is all about.

How did you get interested in evolution?

I was impressed with the precision that molecular tools seemed to bring to the study of evolution. I realize now that things are not as precise as I thought, but the DNA code is still a remarkable yardstick for comparing different species on the same scale. I actually didn't like biochemistry or molecular biology until I could connect them with evolution. But coming back from my year off, I worked in a lab that helped me make the connection. The world is very diverse biologically—there are millions of species—and the fact that these species can be compared at the DNA level was a revelation to me.

What led you to study Australian birds?

After entering grad school, I volunteered for a research project on birds of paradise in New Guinea; these are flamboyant songbirds that live in the rain forest. I was hunting around for a project of my own. Several ornithologists directed me to a group of songbirds called babblers, which mostly live in Australia. These birds are fascinating: They live in family groups, using large, domed nests with a hole on the side. Eight or nine of them will clamber into one of these nests. It was very interesting to see the organization of their family groups in the wild and also to study the birds on the DNA level. Were they all related to each other, or not? How different were different families in a single locality? So I ended up doing my dissertation on babblers, comparing individuals within a family, families within a region, and populations in different parts of the continent.

As a postdoc in Florida, you studied the evolution of genes involved in disease resistance in birds. What were these genes?

They're called MHC genes, for Major Histocompatibility Complex. These genes are important components of the immune systems of all vertebrates. In humans, they are the genes you try to match when looking for a compatible donor for an organ transplant. The MHC genes encode proteins that bind to fragments of pathogens and other foreign cells that have been phagocytized. The MHC proteins then move to the cell surface and present the fragments to the rest of the immune system, saying, "Hey, I found something foreign." The MHC is fascinating from an evolutionary standpoint, because pathogens and parasites seem to be major drivers of evolutionary change. They're constantly playing cat and mouse with the host. In the pathogens, more efficient ways of infecting the host keep evolving, while evolving defenses keep pace in their hosts. So MHC genes are under strong selection by pathogens, and we can see signs of that selection when we look at the DNA sequences. In mammals, these genes are wildly diverse compared to typical "housekeeping" genes. I was curious to see if they were as diverse in birds as they are in mammals.

How did so much variation evolve in MHC genes?

There are a couple of different hypotheses. One comes from the idea that the primary drivers of MHC diversity are pathogens. It says that if you are heterozygous—if you have two different alleles for each of these MHC genes—you have a better surveillance system for dealing with the pathogenic world. You're going to be able to recognize at least twice as many pathogens compared to a homozygous individual. When you have a situation where heterozygotes are more fit because they can combat disease, it results in a lot of diversity. The other hypothesis focuses on mating preferences, though it's not inconsistent with the

pathogen hypothesis. If it's true that being heterozygous is advantageous, then it would make sense for females to choose mates whose MHC alleles are different from theirs. Scientists in the lab where I was a postdoc documented this in lab mice. We're interested in documenting it in birds, as well. Birds are good organisms for this kind of study because many bird populations are being monitored in great detail. For these populations, researchers know who has mated with whom, and they have blood samples from offspring. So we can look at many different pairings and see if the members of each pair are significantly more different in MHC genes than, say, random pairs in the human population. We have an ongoing project on MHC genes and parasitism in red-winged blackbirds.

Does this research have relevance to avian flu and other bird diseases that threaten humans?

It certainly relates to the important question of whether all individuals of a species are equally susceptible to such a disease. For avian flu and West Nile virus, this is being studied now in chicken and songbird populations. We know that many different species of birds are carrying the highly pathogenic type of flu virus, so a logical next step is to compare different individual birds, both susceptible and resistant, to see if they differ in their MHC genes. One of my postdocs is addressing this kind of question for a bacterial pathogen of the house finch.

What is some other research you're doing?

We want to understand how the MHC evolved in the transition from early reptiles to birds, which are in the reptilian family tree. We've made genomic libraries of DNA from five different species: an emu (an Australian bird that resembles an ostrich), an alligator, a turtle, a tuatara (an ancient reptile that lives in New Zealand), and a garter snake. They make a great system for doing comparative genomics. In addition to looking at MHC genes, which seem to be under strong selection, we also look at neutral markers, which aren't under selection, to track species through space and time.

I go to Australia pretty regularly. Australia is a good natural laboratory for my work because the geography and the geographic ranges of birds are very consistent across different species. We're interested in using genetic tools to understand the times of speciation in different groups of birds. When did an eastern species diverge from the western species? And are those times the same across different species? We're comparing the evolution and geography of different species.

What is a species?

You'd think that a concept like species would be very well hammered out and agreed upon by scientists, but it's actually one of the more contentious areas of biology! I tend to be a traditionalist in this matter; I regard species as reproductively isolated groups of related individuals, as Ernst Mayr defined them in 1942. That is, individuals of one species don't breed with those of other species. The isolation can come about by many different mechanisms. For example, it can result from divergence after a population has colonized a new area. New species arise when gene flow (transfer) between different populations mostly ceases.

Can evolutionary trees give insights into mechanisms of evolution?

One way to use evolutionary trees to look at mechanisms is to focus on the tempo of evolution and the shape of the tree. Do we see a rapid burst of speciation, of many rapid branchings toward the tips, for example? Or do we see very long branches that are unbroken by speciation events? We try to link the branching patterns in these trees to environmental events in the past. In Australia, we're looking at related species in the east and west of the continent, and if we know how long ago these species separated, we may be able to link their separation to specific events, such as intrusions of the sea near a coast or desert formation in inland areas. There are records of such environmental changes going back several hundred thousand years in Australia.

Do you have evidence that speciation can be driven by sexual selection?

In sexual selection, individuals with certain inherited traits—bright plumage, for instance—are more likely than others to obtain mates. We have a lot of indirect evidence that sexual selection can play a role in the formation of new species. When DNA evidence shows that two species that look very different are actually extremely closely related, we can reasonably conclude that the species evolved recently and that some sort of selection was involved. We find this situation in Australian birds of paradise, where different species may have different plumage, different calls, and different behaviors, while being very similar in the neutral components of their genomes. So clearly some sort of selection, probably sexual selection, has driven the phenotypes apart. Birds of paradise, which are fantastically diverse in phenotype, have diverged into different species in the blink of an eye.

Is it true that all the world's songbirds got their start in Australia?

Many lines of evidence suggest that Australia and nearby New Guinea may have been the cradle of songbird evolution. And more broadly, Gondwana may have been the origin of many groups of birds. Gondwana was an ancient supercontinent that included most of the landmasses that are now in the Southern Hemisphere. Some of the oldest fossil songbirds have been found in Australia. The evidence suggests that many new groups of songbirds arose in Australia around 55–65 million years ago. They then spread around the globe. Also, our North American crows and jays trace their roots back to Australia. It's interesting that taxonomists in the early 20th century thought that Australian bird species were all just twigs of evolutionary trees rooted in the Northern Hemisphere. But really, it's the opposite.

. . . we can now compare the sizes, shapes, and genes of birds from populations separated by more than a century.

KEY CONCEPTS

22.1 The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species

22.2 Descent with modification by natural selection explains the adaptations of organisms and the unity and diversity of life

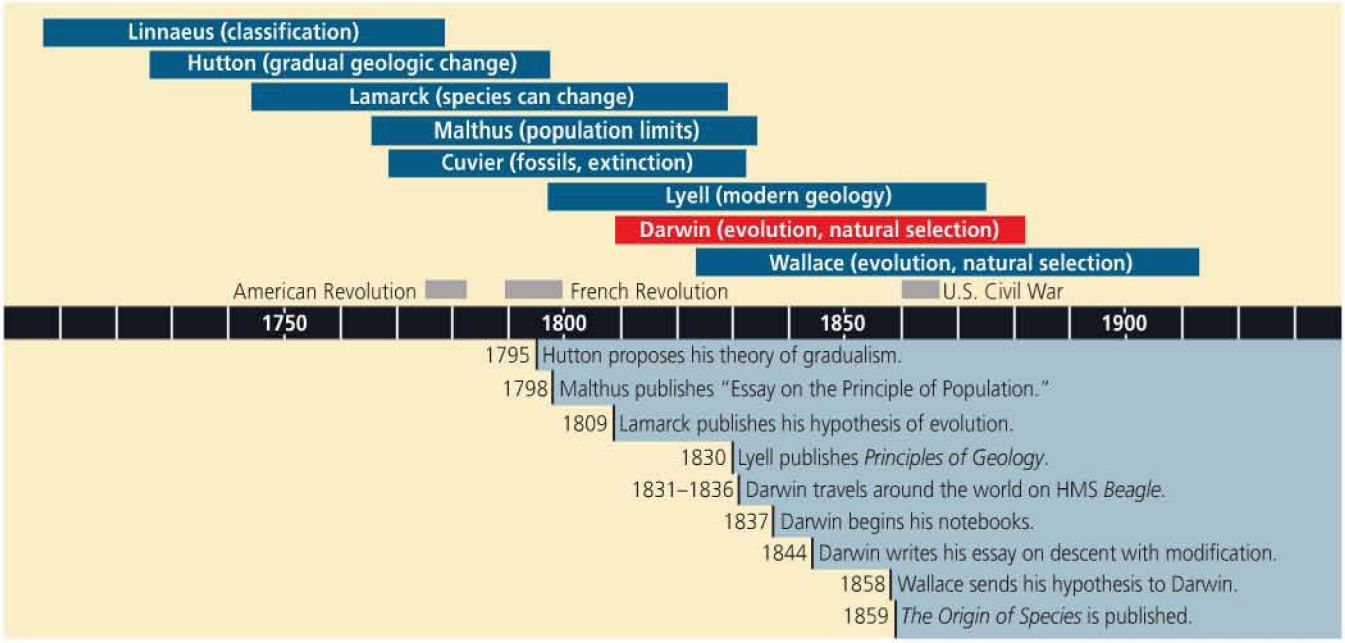
22.3 Evolution is supported by an overwhelming amount of scientific evidence

OVERVIEW

Endless Forms Most Beautiful

The *Onymacris unguicularis* beetle lives in the coastal Namib desert of southwestern Africa, a land where fog is common, but virtually no rain falls. To obtain the water it needs to survive, the beetle relies on a peculiar "headstanding" behavior **(Figure 22.1)**. Tilting head-downward, the beetle faces into the winds that blow fog across the dunes. Droplets of moisture from the fog collect on the beetle's body and run down into its mouth.

This headstander beetle shares many features with the more than 350,000 other beetle species on Earth, including six pairs of legs, a hard outer surface, and two pairs of wings. But how did there come to be so many variations on the basic beetle theme? The headstander beetle and its many close relatives illustrate three key observations about life: the striking ways in which organisms are suited for life in their environments; the many shared characteristics (unity) of life; and the rich diversity of life. A century and a half ago, Charles Darwin was inspired to develop a scientific explanation for these three broad observations. When he published his hypothesis in *The Origin of Species*, Darwin ushered in a scientific revolution—the era of evolutionary biology.



For now, we will define **evolution** as *descent with modification*, a phrase Darwin used in proposing that Earth's many species are descendants of ancestral species that were different from the present-day species. Evolution can also be defined more narrowly as a change in the genetic composition of a population from generation to generation, as we'll explore in Chapter 23. Whether it is defined broadly or narrowly, we can view evolution in two related but different ways: as a pattern and as a process. The *pattern* of evolutionary change is revealed by data from a range of scientific disciplines, including biology, geology, physics, and chemistry. These data are facts—they are observations about the natural world. The *process* of evolution consists of the mechanisms that produce the observed pattern of change. These mechanisms represent natural causes of the natural phenomena we observe. Indeed, the power of evolution as a unifying theory is its ability to explain and connect a vast array of observations about the living world.

As with all general theories in science, we continue to test our theory of evolution by examining whether it can account for new observations and experimental results. In this and the following chapters, we'll examine how ongoing discoveries shape our current understanding of the pattern and process of evolution. To set the stage, we'll first retrace Darwin's quest to explain the adaptations, unity, and diversity of life's "endless forms most beautiful."

CONCEPT 22.1

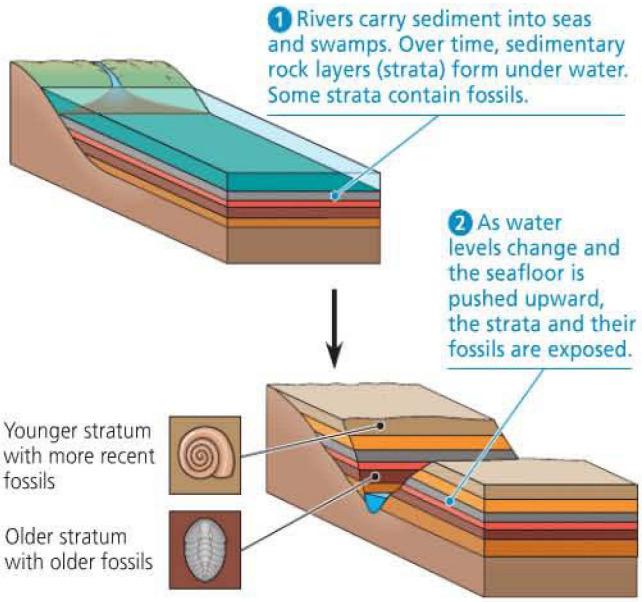
The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species

What impelled Darwin to challenge the prevailing views of his time about Earth and its life? His revolutionary proposal actually had its roots in the work of many other individuals **(Figure 22.2)**.

▲ **Figure 22.2 The historical context of Darwin's life and ideas.** The dark blue bars represent the lives of some individuals whose ideas contributed to Darwin's thinking about evolution.

Scala Naturae and Classification of Species

Long before Darwin was born, several Greek philosophers suggested that life might have changed gradually over time. But one philosopher who greatly influenced early Western science, Aristotle (384–322 B.C.), viewed species as fixed (unchanging). Through his observations of nature, Aristotle recognized certain "affinities" among organisms. He concluded that life-forms could be arranged on a ladder, or scale, of increasing complexity, later called the *scala naturae* ("scale of nature"). Each form of life, perfect and permanent, had its allotted rung on this ladder.



These ideas coincided with the Old Testament account of creation, which holds that species were individually designed by God and therefore perfect. In the 1700s, many scientists interpreted the often remarkable match of organisms to their environment as evidence that the Creator had designed each species for a particular purpose.

One such scientist was Carolus Linnaeus (1707–1778), a Swedish physician and botanist who sought to classify life's diversity, in his words, "for the greater glory of God." Linnaeus developed the two-part, or binomial, system of naming species (such as *Homo sapiens* for humans) that is still used today. In contrast to the linear hierarchy of the *scala naturae*, Linnaeus adopted a nested classification system, grouping similar species into increasingly general categories. For example, similar species are grouped in the same genus, similar genera (plural of genus) are grouped in the same family, and so on (see Figure 1.14).

Linnaeus did not ascribe the resemblances among species to evolutionary kinship, but rather to the pattern of their creation. However, a century later his classification system would play a role in Darwin's argument for evolution.

Ideas About Change over Time

Darwin drew many of his ideas from the work of scientists studying **fossils**, the remains or traces of organisms from the past. Most fossils are found in sedimentary rocks formed from the sand and mud that settle to the bottom of seas, lakes, and swamps **(Figure 22.3)**. New layers of sediment cover older ones and compress them into superimposed layers of rock

▲ **Figure 22.3 Formation of sedimentary strata with fossils.**

called **strata** (singular, *stratum*). The fossils in a particular stratum provide a glimpse of some of the organisms that populated Earth at the time that layer formed. Later, erosion may carve through upper (younger) strata, revealing deeper (older) strata that had been buried.

Paleontology, the study of fossils, was largely developed by French scientist Georges Cuvier (1769–1832). In examining strata near Paris, Cuvier noted that the older the stratum, the more dissimilar its fossils were to current life-forms. He also observed that from one layer to the next, some new species appeared while others disappeared. He inferred that extinctions must have been a common occurrence in the history of life. Yet Cuvier staunchly opposed the idea of evolution. To explain his observations, he advocated **catastrophism**, the principle that events in the past occurred suddenly and were caused by mechanisms different from those operating in the present. Cuvier speculated that each boundary between strata represented a catastrophe, such as a flood, that had destroyed many of the species living at that time. He proposed that these periodic catastrophes were usually confined to local regions, which were later repopulated by species immigrating from other areas.

In contrast, other scientists suggested that profound change could take place through the cumulative effect of slow but continuous processes. In 1795, Scottish geologist James Hutton (1726–1797) proposed that Earth's geologic features could be explained by gradual mechanisms still operating. For example, he suggested that valleys were often formed by rivers wearing through rocks and that rocks containing marine fossils were formed when sediments that had eroded from the land were carried by rivers to the sea, where they buried dead marine organisms. The leading geologist of Darwin's time, Charles Lyell (1797–1875), incorporated Hutton's thinking into his principle of **uniformitarianism**, which stated that mechanisms of change are constant over time. Lyell proposed that the same geologic processes are operating today as in the past, and at the same rate.

Hutton and Lyell's ideas strongly influenced Darwin's thinking. Darwin agreed that if geologic change results from slow, continuous actions rather than from sudden events, then Earth must be much older than the widely accepted age of a few thousand years. It would, for example, take a very long time for a river to carve a canyon by erosion. He later reasoned that perhaps similarly slow and subtle processes could produce substantial biological change. Darwin was not the first to apply the idea of gradual change to biological evolution, however.

Lamarck's Hypothesis of Evolution

During the 18th century, several naturalists (including Darwin's grandfather, Erasmus Darwin) suggested that life evolves as environments change. But only one of Charles Darwin's predecessors proposed a mechanism for *how* life changes over time: French biologist Jean-Baptiste de Lamarck (1744–1829). Alas, Lamarck is primarily remembered today *not* for his visionary recognition that evolutionary change explains patterns in fossils and the match of organisms to their environments, but for the incorrect mechanism he proposed to explain how evolution occurs.

Lamarck published his hypothesis in 1809, the year Darwin was born. By comparing living species with fossil forms, Lamarck had found what appeared to be several lines of descent, each a chronological series of older to younger fossils leading to a living species. He explained his findings using two principles. The first was *use and disuse*, the idea that parts of the body that are used extensively become larger and stronger, while those that are not used deteriorate. As an example, he cited a giraffe stretching its neck to reach leaves on high branches. The second principle, *inheritance of acquired characteristics*, stated that an organism could pass these modifications to its offspring. Lamarck reasoned that the long, muscular neck of the living giraffe had evolved over many generations as giraffes stretched their necks ever higher.

Lamarck also thought that evolution happens because organisms have an innate drive to become more complex. Darwin rejected this idea, but he, too, thought that variation was introduced into the evolutionary process in part through inheritance of acquired characteristics. Today, however, our understanding of genetics refutes this mechanism: There is no evidence that acquired characteristics can be inherited in the way proposed by Lamarck **(Figure 22.4)**.

Lamarck was vilified in his own time, especially by Cuvier, who denied that species ever evolve. In retrospect, however, Lamarck deserves credit for recognizing that the match of organisms to their environments can be explained by gradual evolutionary change and for proposing a testable mechanism for this change.

▲ **Figure 22.4 Acquired traits cannot be inherited.** This bonsai tree was trained " to grow as a dwarf by pruning and shaping. However, seeds from this tree would produce offspring of normal size.

CONCEPT CHECK 22.1

1. How did Hutton's and Lyell's ideas influence Darwin's thinking about evolution?
2. **WHAT IF?** In Chapter 1, you read that scientific hypotheses must be testable and falsifiable. If you apply these criteria, are Cuvier's explanation of the fossil record and Lamarck's hypothesis of evolution scientific? Explain your answer in each case.

For suggested answers, see Appendix A.

CONCEPT 22.2

Descent with modification by natural selection explains the adaptations of organisms and the unity and diversity of life

As the 19th century dawned, it was generally believed that species had remained unchanged since their creation. A few clouds of doubt about the permanence of species were beginning to gather, but no one could have forecast the thundering storm just beyond the horizon. How did Charles Darwin become the lightning rod for a revolutionary view of life?

Darwin's Research

Charles Darwin (1809–1882) was born in Shrewsbury in western England. Even as a boy, he had a consuming interest in nature. When he was not reading nature books, he was fishing, hunting, and collecting insects. Darwin's father, a physician, could see no future for his son as a naturalist and sent him to medical school in Edinburgh. But Charles found medicine boring and surgery before the days of anesthesia horrifying. He quit medical school and enrolled at Cambridge University, intending to become a clergyman. (At that time in England, many scholars of science belonged to the clergy.)

At Cambridge, Darwin became the protégé of the Reverend John Henslow, a botany professor. Soon after Darwin graduated, Henslow recommended him to Captain Robert FitzRoy, who was preparing the survey ship HMS *Beagle* for a long voyage around the world. Darwin would pay his own way and serve as a conversation partner to the young captain. FitzRoy accepted Darwin because of his education and because they were of the same social class and about the same age.

The Voyage of the Beagle

Darwin embarked from England on the *Beagle* in December 1831. The primary mission of the voyage was to chart poorly known stretches of the South American coastline **(Figure 22.5)**. While the ship's crew surveyed the coast, Darwin spent most of his time on shore, observing and collecting thousands of South American plants and animals. He noted the characteristics of plants and animals that made them well suited to such diverse environments as the humid jungles of Brazil, the expansive grasslands of Argentina, and the towering peaks of the Andes.

Darwin observed that the plants and animals in temperate regions of South America more closely resembled species living in the South American tropics than species living in

▲ **Figure 22.5 The voyage of HMS *Beagle*.**

temperate regions of Europe. Furthermore, the fossils he found, though clearly different from living species, were distinctly South American in their resemblance to the living organisms of that continent.

Darwin also spent much time thinking about geology during the voyage. Despite bouts of seasickness, he read Lyell's *Principles of Geology* while aboard the *Beagle*. He experienced geologic change firsthand when a violent earthquake rocked the coast of Chile, and he observed afterward that rocks along the coast had been thrust upward by several feet. Finding fossils of ocean organisms high in the Andes, Darwin inferred that the rocks containing the fossils must have been raised there by a series of many similar earthquakes. These observations reinforced what he had learned from Lyell: The physical evidence did not support the traditional view of a static Earth only a few thousand years old.

Darwin's interest in the geographic distribution of species was further stimulated by the *Beagle*'s stop at the Galápagos, a group of volcanic islands located near the equator about 900 km (540 miles) west of South America. Darwin was fascinated by the unusual organisms he found there. The birds he collected on the Galápagos included several kinds of mockingbirds that, although similar, seemed to be different species. Some were unique to individual islands, while others lived on two or more adjacent islands. Furthermore, although the animals on the Galápagos resembled species living on the South American mainland, most of the Galápagos species were not known from anywhere else in the world. Darwin hypothesized that the Galápagos had been colonized by organisms that had strayed from South America and then diversified, giving rise to new species on the various islands.

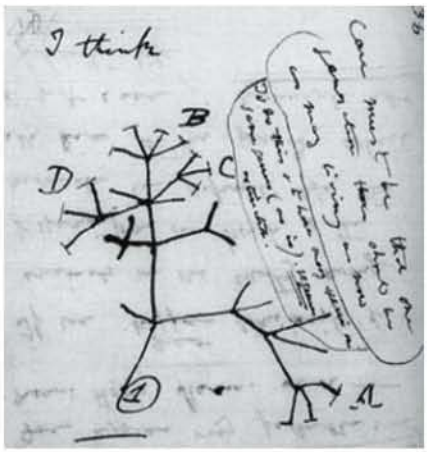
Darwin's Focus on Adaptation

During the voyage of the *Beagle*, Darwin observed many examples of **adaptations**, characteristics of organisms that enhance their survival and reproduction in specific environments. Later, as he reassessed his observations, he began to perceive adaptation to the environment and the origin of new species as closely related processes. Could a new species arise from an ancestral form by the gradual accumulation of adaptations to a different environment? From studies made years after Darwin's voyage, biologists have concluded that this is indeed what happened to the diverse group of Galápagos finches we discussed in Chapter 1 (see Figure 1.22). The finches' various beaks and behaviors are adapted to the specific foods available on their home islands **(Figure 22.6)**. Darwin realized that explaining such adaptations was essential to understanding evolution. As we'll explore further, his explanation of how adaptations arise centered on **natural selection**, a process in which individuals with certain inherited traits leave more offspring than individuals with other traits.

By the early 1840s, Darwin had worked out the major features of his hypothesis. He set these ideas on paper in 1844, when he wrote a long essay on descent with modification and its underlying mechanism, natural selection. Yet he was still reluctant to publish his ideas, apparently because he anticipated the uproar they would cause. Even as he procrastinated, Darwin continued to compile evidence in support of his hypothesis. By the mid-1850s, he had described his ideas to Lyell and a few others. Lyell, who was not yet convinced of evolution, nevertheless urged Darwin to publish on the subject before someone else came to the same conclusions and published first.

In June 1858, Lyell's prediction came true. Darwin received a manuscript from Alfred Russel Wallace (1823–1913), a British naturalist working in the East Indies who had developed a hypothesis of natural selection similar to Darwin's. Wallace asked Darwin to evaluate his paper and forward it to Lyell if it merited publication. Darwin complied, writing to Lyell: "Your words have come true with a vengeance. . . . I never saw a more striking coincidence . . . so all my originality, whatever it may amount to, will be smashed." Lyell and a colleague then presented Wallace's paper, along with extracts from Darwin's unpublished 1844 essay, to the Linnean Society of London on July 1, 1858. Darwin quickly finished his book, titled *On the Origin of Species by Means of Natural Selection* (commonly referred to as *The Origin of Species*), and published it the next year. Although Wallace had

(a) Cactus-eater. The long, sharp beak of the cactus ground finch (*Geospiza scandens*) helps it tear and eat cactus flowers and pulp.



(b) Insect-eater. The green warbler finch (*Certhidea olivacea*) uses its narrow, pointed beak to grasp insects.

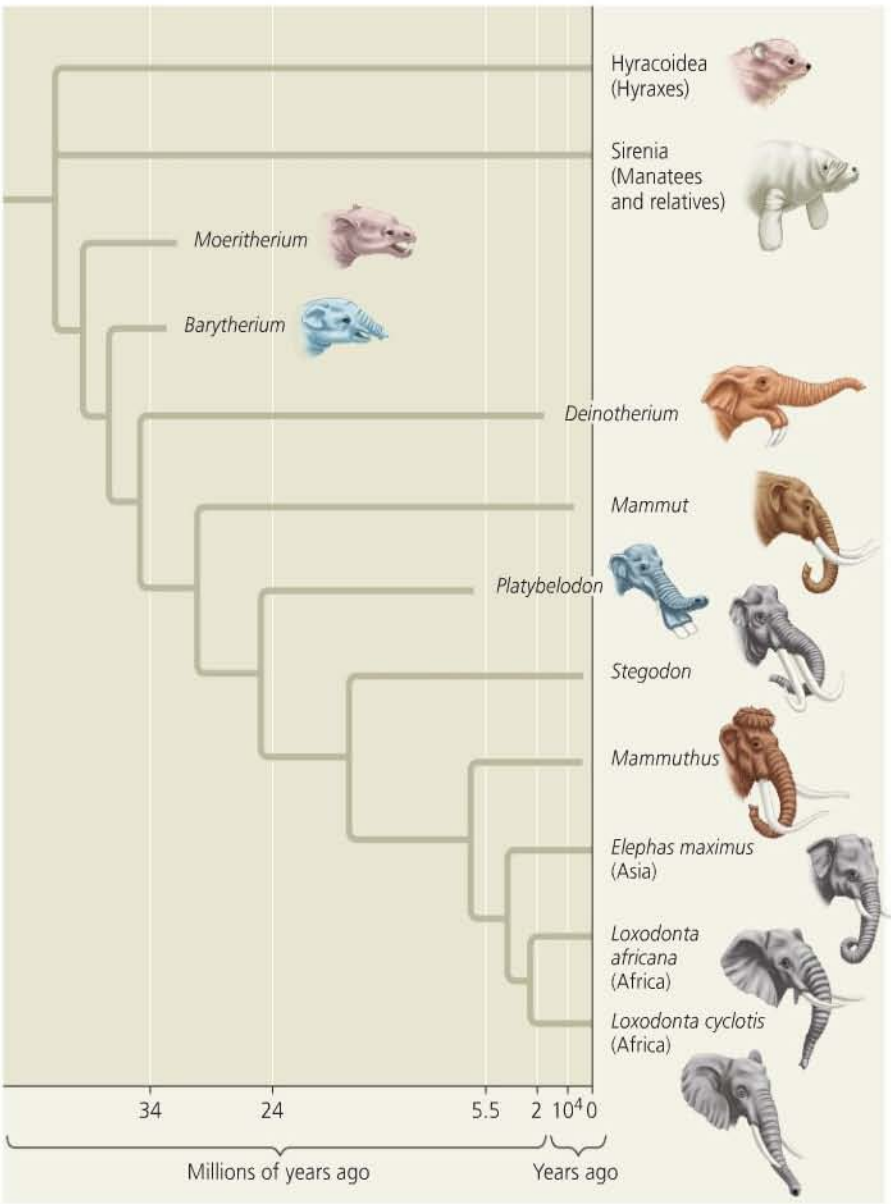
(c) Seed-eater. The large ground finch (*Geospiza magnirostris*) has a large beak adapted for cracking seeds that fall from plants to the ground.

▲ **Figure 22.6 Beak variation in Galápagos finches.** The Galápagos Islands are home to more than a dozen species of closely related finches, some found only on a single island. The most striking differences among them are their beaks, which are adapted for specific diets.

submitted his ideas for publication first, he admired Darwin and thought that Darwin had developed the idea of natural selection so extensively that he should be known as its main architect.

Within a decade, Darwin's book and its proponents had convinced most biologists that life's diversity is the product of evolution. Darwin succeeded where previous evolutionists had failed, mainly because he had presented a plausible scientific mechanism with immaculate logic and an avalanche of evidence.

▶ **Figure 22.7 "I think. . ."** In this 1837 sketch, Darwin envisioned the branching pattern of evolution.



The Origin of Species

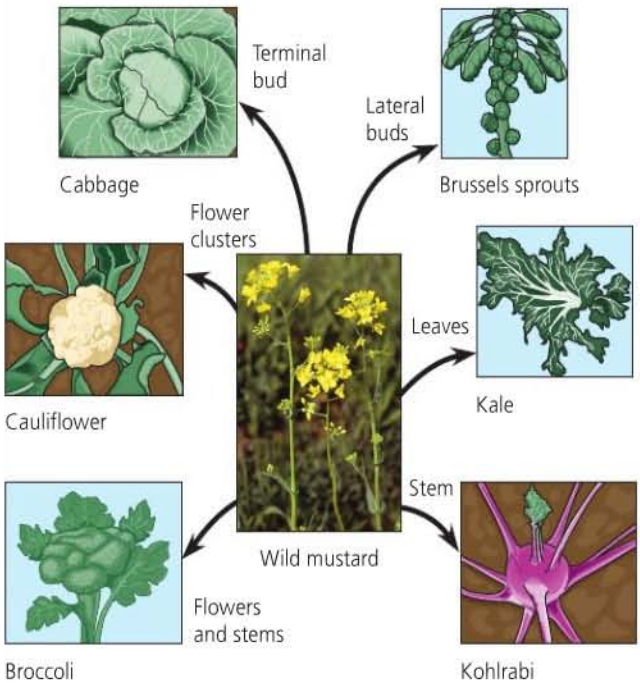
In his book, Darwin developed two main ideas: that descent with modification explains life's unity and diversity and that natural selection brings about the match between organisms and their environment.

Descent with Modification

In the first edition of *The Origin of Species*, Darwin never used the word *evolution* (although the final word of the book is "evolved"). Rather, he discussed *descent with modification*, a phrase that summarized his view of life. Darwin perceived unity in life, which he attributed to the descent of all organisms from an ancestor that lived in the remote past. He also thought that as the descendants of that ancestral organism lived in various habitats over millions of years, they had accumulated diverse modifications, or adaptations, that fit them to specific ways of life. Darwin reasoned that over long periods of time, descent with modification eventually led to the rich diversity of life we see today.

Darwin viewed the history of life as a tree, with multiple branchings from a common trunk out to the tips of the youngest twigs **(Figure 22.7)**. The tips of the twigs represent the diversity of organisms living in the present. Each fork of the tree represents an ancestor of all the lines of evolution that subsequently branch from that point. As shown in the tree diagram in **Figure 22.8**, closely related species, such as the Asian elephant and African elephants, are very similar because they shared the same line of descent until a relatively recent split from

▲ **Figure 22.8 Descent with modification.** This evolutionary tree of elephants and their relatives is based mainly on fossils—their anatomy, order of appearance in strata, and geographic distribution. Note that most branches of descent ended in extinction. (Time line not to scale.)



? *Based on the tree shown here, approximately when did the most recent ancestor shared by* Mammuthus *(woolly mammoths), Asian elephants, and African elephants live?*

their common ancestor. Note that seven lineages related to elephants have become extinct over the past 30 million years. As a result, there are no living species that fill the gap between the elephants and their nearest relatives today, the manatees and hyraxes. In fact, many branches of evolution, even some major ones, are dead ends: Scientists estimate that over 99% of all species that have ever lived are now extinct.

In his efforts at classification, Linnaeus had realized that some organisms resemble each other more closely than others, but he had not linked these resemblances to evolution. Nonetheless, because he had recognized that the great diversity of organisms could be organized into "groups subordinate to groups" (Darwin's phrase), Linnaeus's system meshed well with Darwin's hypothesis. To Darwin, the Linnaean hierarchy reflected the branching history of the tree of life, with organisms at the various levels related through descent from common ancestors.

Artificial Selection, Natural Selection, and Adaptation

Darwin proposed a mechanism, natural selection, to explain the observable patterns of evolution. He crafted his argument carefully, to persuade even the most skeptical readers. First he discussed familiar examples of selective breeding of domesticated plants and animals. Humans have modified other species over many generations by selecting and breeding individuals that possess desired traits—a process called **artificial selection** (Figure 22.9).

▲ **Figure 22.9 Artificial selection.** These different vegetables have all been selected from one species of wild mustard. By selecting variations in different parts of the plant, breeders have obtained these divergent results.

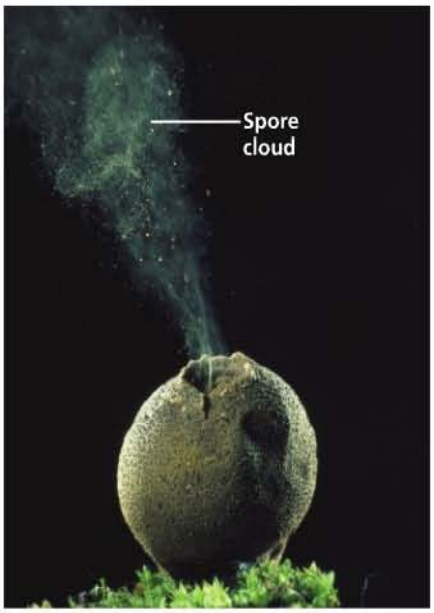
▲ **Figure 22.10 Variation in a population.** To the extent that the variation in color and banding patterns in this snail population is heritable, it can be acted on by natural selection.

As a result of artificial selection, crop plants and animals bred as livestock or pets often bear little resemblance to their wild ancestors.

Darwin then described four observations of nature from which he drew two inferences:

Observation #1: Members of a population often vary greatly in their traits (Figure 22.10).

Observation #2: Traits are inherited from parents to offspring.



Observation #3: All species are capable of producing more offspring than their environment can support (Figure 22.11).

Observation #4: Owing to lack of food or other resources, many of these offspring do not survive.

Inference #1: Individuals whose inherited traits give them a higher probability of surviving and reproducing in a given environment tend to leave more offspring than other individuals.

Inference #2: This unequal ability of individuals to survive and reproduce will lead to the accumulation of favorable traits in the population over generations.

Darwin perceived an important connection between natural selection and the capacity of organisms to "overreproduce." He began to make this connection after reading an essay by economist Thomas Malthus, who contended that much of human suffering—disease, famine, and war—was the inescapable consequence of the human population's potential to increase faster than food supplies and other resources. Darwin realized that the capacity to overreproduce was characteristic of all species. Of the many eggs laid, young born, and seeds spread, only a tiny fraction complete their development and leave offspring of their own. The rest are eaten, starved, diseased, un-

▲ **Figure 22.11 Overproduction of offspring.** A single puffball fungus can produce billions of offspring. If all of these offspring and their descendants survived to maturity, they would carpet the surrounding land surface.

(a) A flower mantid in Malaysia

(b) A stick mantid in Africa

▲ **Figure 22.12 Camouflage as an example of evolutionary adaptation.** Related species of the insects called mantids have diverse shapes and colors that evolved in different environments.

mated, or unable to tolerate physical conditions of the environment such as salinity or temperature.

An organism's traits can influence not only its own performance, but also how well its offspring cope with environmental challenges. For example, an organism might have a heritable trait that gives its offspring an advantage in escaping predators, obtaining food, or tolerating physical conditions. When such advantages increase the number of offspring that survive and reproduce, the traits that are favored will likely appear at a greater frequency in the next generation. Thus, over time, natural selection imposed by factors such as predators, lack of food, or adverse physical conditions can increase the proportion of favorable traits in a population.

How rapidly do such changes occur? Darwin reasoned that if artificial selection can bring about dramatic change in a relatively short period of time, then natural selection should be capable of substantial modification of species over many hundreds of generations. Even if the advantages of some heritable traits over others are slight, the advantageous variations will gradually accumulate in the population, and less favorable variations will diminish. Over time, this process will increase the frequency of individuals with favorable adaptations and hence refine the match between organisms and their environment.

Natural Selection: A Summary

Let's now recap the main ideas of natural selection:

- Natural selection is a process in which individuals that have certain heritable characteristics survive and reproduce at a higher rate than other individuals.
- Over time, natural selection can increase the match between organisms and their environment **(Figure 22.12)**.
- If an environment changes, or if individuals move to a new environment, natural selection may result in adaptation to these new conditions, sometimes giving rise to new species in the process.

One subtle but important point is that although natural selection occurs through interactions between individual organisms and their environment, *individuals do not evolve.* Rather, it is the population that evolves over time.

A second key point is that natural selection can amplify or diminish *only heritable traits*—traits that are passed from organisms to their offspring. Though an organism may become modified during its lifetime, and these acquired characteristics may even help the organism in its environment, there is little evidence that such acquired characteristics can be inherited by offspring.

Third, remember that environmental factors vary from place to place and over time. A trait that is favorable in one place or time may be useless—or even detrimental—in other places or times. Natural selection is always operating, but which traits are favored depends on the environmental context.

Next, we'll survey the wide range of observations that support a Darwinian view of evolution by natural selection.

CONCEPT CHECK 22.2

1. How does the concept of descent with modification explain both the unity and diversity of life?
2. Describe how overreproduction and heritable variation relate to evolution by natural selection.
3. **WHAT IF?** If you discovered a fossil of an extinct mammal that lived high in the Andes, would you predict that it would more closely resemble present-day mammals from South American jungles or present-day mammals that live high in African mountains? Explain.

For suggested answers, see Appendix A.

CONCEPT 22.3

Evolution is supported by an overwhelming amount of scientific evidence

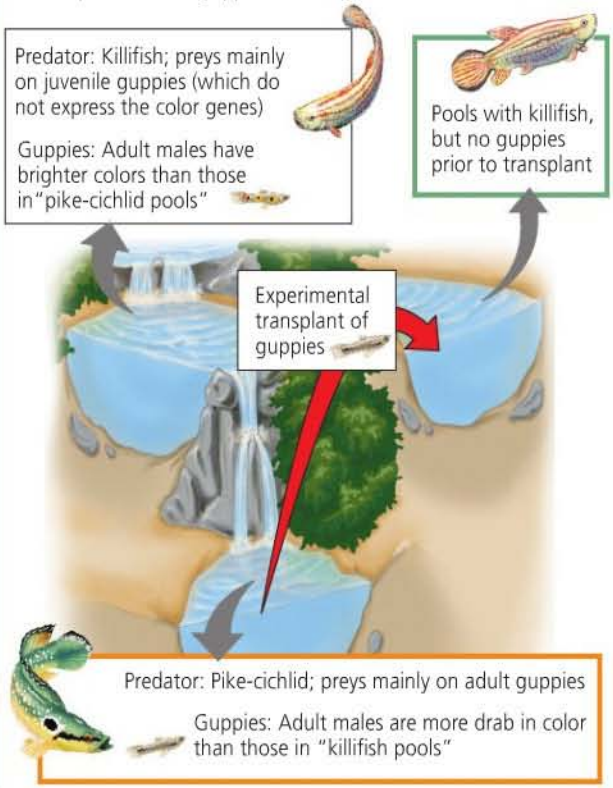
In *The Origin of Species*, Darwin marshaled a broad range of evidence to support the concept of descent with modification. Still—as he readily acknowledged—there were instances in which key evidence was lacking. For example, Darwin referred to the origin of flowering plants as an "abominable mystery," and he lamented the lack of fossils showing how earlier groups of organisms gave rise to new groups.

In the 150 years since, new discoveries have filled many of the gaps that Darwin identified. The origin of flowering plants, for example, is better understood (see Chapter 29), and many fossils have been discovered that signify the origin of new groups of organisms (see Chapter 25). In this section, we'll consider four types of data that document the pattern of evolution and illuminate the processes by which it occurs: direct observations of evolution, the fossil record, homology, and biogeography.

Direct Observations of Evolutionary Change

Biologists have documented evolutionary change in thousands of scientific studies. We'll examine many such studies throughout this unit, but let's look here at two examples.

Predation and Coloration in Guppies: Scientific Inquiry



Predators (organisms that feed on other species, called prey) are a potent force in shaping the adaptations of their food source. The predator is most likely to feed on prey individuals that are least able to avoid detection, escape, or defend themselves. As a result, such prey individuals are less likely to reproduce and pass their traits to their offspring than are individuals whose traits help them evade predators.

For many years, John Endler, of the University of California, Santa Barbara, has studied the impact of predators on guppies (*Poecilia reticulata*), small freshwater fish that you may know as aquarium pets. He observed that among wild

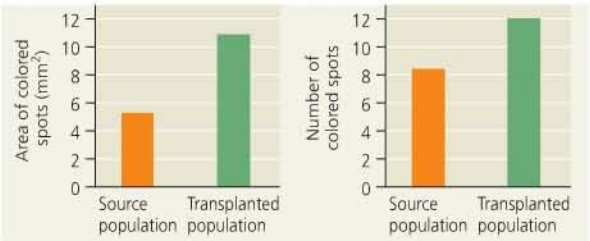


Figure 22.13 Inquiry

Can predation result in natural selection for color patterns in guppies?

EXPERIMENT John Endler, of the University of California, Santa Barbara, studied wild guppies in the Aripo River system on the Caribbean island of Trinidad. He transplanted 200 guppies from pools containing pike-cichlids, intense guppy predators, to pools containing killifish, less active predators of guppies. He tracked the number of bright-colored spots and the total area of those spots on male guppies in each generation.

RESULTS After 22 months (15 generations), the number and total area of colored spots on male guppies in the transplanted population had increased compared to those of males in the source population.

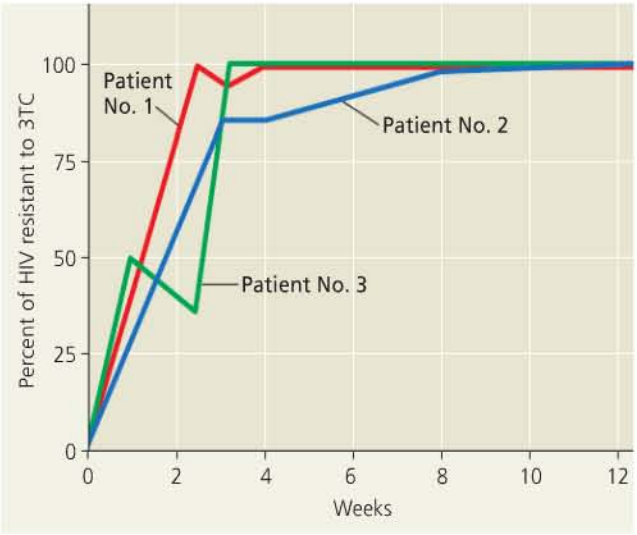
CONCLUSION Endler concluded that the change in predator resulted in different variations (brighter color patterns) being favored in the transplanted population. Over a relatively short time, an observable evolutionary change occurred in this population.

SOURCE J. A. Endler, Natural selection on color patterns in *Poecilia reticulata*, *Evolution* 34:76–91 (1980).

WHAT IF? What would happen if, after 22 months, guppies from the transplanted population were returned to the source pool?

guppy populations in Trinidad, the male guppies' color patterns are so variable that no two males look alike. These highly variable colors are controlled by a number of genes that, in the wild, are only expressed in adult males. Female guppies are attracted to males with bright colors, choosing them as mates more often than they choose males with drab coloring. But the bright colors that attract females might also make the males more conspicuous to predators. Thus, if a guppy population contained both brightly colored and drab males, we might predict that predators would tend to eat more of the brightly colored fish.

Endler wondered how the trade-off between attracting mates and attracting predators affects coloration in male guppies. In the field, he observed that the color patterns of male guppies appeared to correspond to the intensity of predation. In pools that had few predator species, male guppies tended to be brightly colored, whereas in pools that had many predators, males were less brightly colored. Based on these observations, Endler hypothesized that intense predation caused natural selection in male guppies, favoring the trait of drab coloration. He tested this hypothesis by transferring brightly colored guppies to a pool with many predators. As he predicted, over time the transplanted guppy population became less brightly colored.



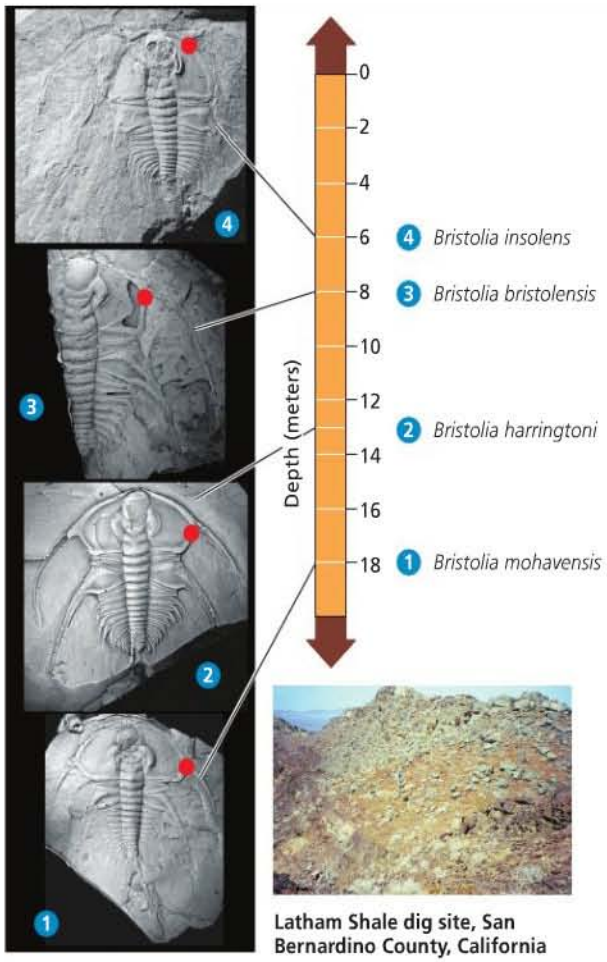
One guppy predator, the killifish, preys on juvenile guppies that have not yet displayed their adult coloration. Endler predicted that if guppies with drab colors were transferred to a pool with only killifish, eventually the descendants of these guppies would be more brightly colored (because females prefer males with bright colors). **Figure 22.13**, on the facing page, describes this experiment. Indeed, in their new environment, the guppy population rapidly came to feature brighter colors, demonstrating that selection can cause rapid evolution in wild populations.

The Evolution of Drug-Resistant HIV

An example of ongoing natural selection that affects our own lives dramatically is the evolution of drug-resistant pathogens (disease-causing organisms and viruses). This is a particular problem with bacteria and viruses that reproduce rapidly, because individuals that are resistant to a particular drug can increase in number very quickly.

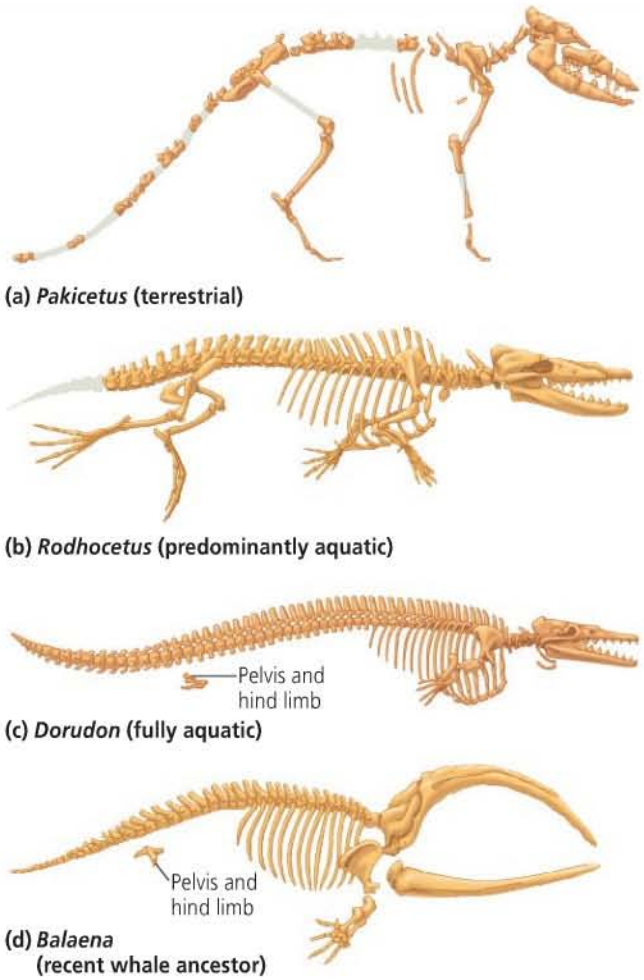
Consider the example of HIV (human immunodeficiency virus), the virus that causes AIDS (see Chapters 19 and 43). Researchers have developed numerous drugs to combat this pathogen, but using these medications selects for viruses resistant to the drugs. A few drug-resistant viruses may be present by chance at the beginning of treatment. Those that survive the early doses reproduce, passing on the alleles that enable them to resist the drug. In this way, the frequency of resistant viruses increases rapidly in the population.

Figure 22.14 illustrates the evolution of HIV resistance to the drug 3TC. Scientists designed 3TC to interfere with reverse transcriptase. HIV uses this enzyme to make a DNA version of its RNA genome, which is then inserted into the DNA of the human host cell (see Figure 19.8). Because the 3TC molecule is similar in shape to the cytosine-bearing (C-bearing) nucleotide of DNA, HIV's reverse transcriptase picks up a 3TC molecule instead of a C-bearing nucleotide and inserts the 3TC into a growing DNA chain. This error terminates further elongation of the DNA and thus blocks reproduction of HIV.



▲ **Figure 22.14 Evolution of drug resistance in HIV.** Rare resistant viruses multiplied quickly when each of these patients was treated with the anti-HIV drug 3TC. Within just a few weeks, 3TC-resistant organisms made up 100% of the virus population in each case.

The 3TC-resistant varieties of HIV have versions of reverse transcriptase that are able to discriminate between the drug and the normal C-bearing nucleotide. These viruses have no advantage in the absence of 3TC; in fact, they replicate more slowly than viruses that carry the typical version of reverse transcriptase. But once 3TC is added to their environment, it becomes a powerful selecting force, favoring the survival of resistant viruses (see Figure 22.14).



Both the guppy example and the HIV example highlight two key points about natural selection. First, natural selection is a process of editing rather than a creative mechanism. A drug does not *create* resistant pathogens; it *selects for* resistant individuals that were already present in the population. Second, natural selection depends on time and place. It favors those characteristics in a genetically variable population that provide advantage in the current, local environment. What is beneficial in one situation may be useless or even harmful in another. In the guppy example, individuals that have drab colors are at an advantage in pools with fierce predators but at a disadvantage in pools without them.

The Fossil Record

A second type of evidence for evolution comes from fossils. The fossil record shows that past organisms differed from present-day organisms and that many species have become

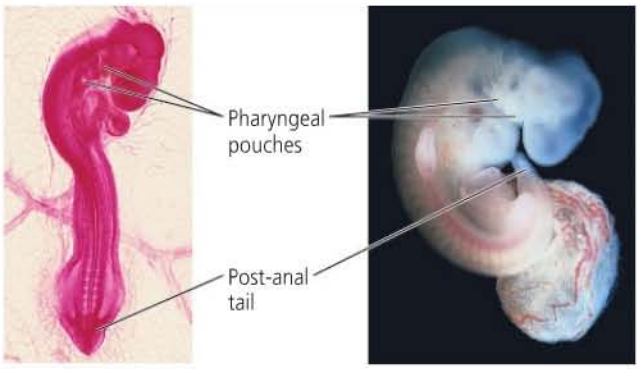
▲ **Figure 22.15 Fossil evidence of evolution in a group of trilobites.** These fossils are just a few in a series discovered in the Latham Shale bed, which was deposited between 513 and 512 million years ago. The sequence shows change over time in the location and angle of the spines of the head shield (the area marked by red dots).

▲ **Figure 22.16 The transition to life in the sea.** The hypothesis that whales and other cetaceans evolved from terrestrial organisms predicts that cetacean ancestors were four-legged. Indeed, paleontologists have unearthed fossils of extinct cetaceans that had hind limbs, including the four species whose skeletons are depicted here (not drawn to scale). Additional fossils show that *Pakicetus* and *Rodhocetus* had a type of ankle bone that is otherwise unique to a group of land mammals that includes pigs, hippos, cows, camels, and deer. This similarity strongly suggests that cetaceans are most closely related to this group of land mammals.

extinct. Fossils also show the evolutionary changes that have occurred over time in various groups of organisms **(Figure 22.15)**.

Over longer time scales, fossils document the origins of major new groups of organisms. An example is the fossil record of early cetaceans, the mammalian order that includes whales, dolphins, and porpoises. The earliest cetaceans lived 50–60 million years ago. The fossil record indicates that prior to that time, most mammals were terrestrial. Although scientists had long realized that whales and other cetaceans must have originated from land mammals, few fossils had been found that revealed how cetacean limb structure had changed over time, leading eventually to the loss of hind limbs and the development of flippers. In the past few decades, however, a series of remarkable fossils have been discovered in Pakistan, Egypt, and North America that document the transition from life on land to life in the sea. Each organism shown in **Figure 22.16** differs from present-day mammals, including present-day whales, and is now extinct. Collectively, these and other early fossils document the formation of new species and the origin of a major new group of mammals, the cetaceans.

In addition to providing evidence of how life on Earth has changed over time—the pattern of evolution—the fossil record also can be used to test evolutionary hypotheses arising from other kinds of evidence. For example, based on anatomical data, scientists think that early land vertebrates evolved from a group of fishes and that early amphibians evolved from descendants of early land vertebrates. If these relationships are correct, we would predict that the earliest fossils of fishes should be older than the earliest fossils of land vertebrates. Similarly, we would predict that the earliest fossil land vertebrates should be older than the earliest fossil amphibians. These predictions can be tested using radioactive dating techniques (see Chapter 25) to determine the age of fossils. To date, all of these predictions have been upheld, which suggests that our understanding of the evolutionary relationships on which the predictions were based is correct.

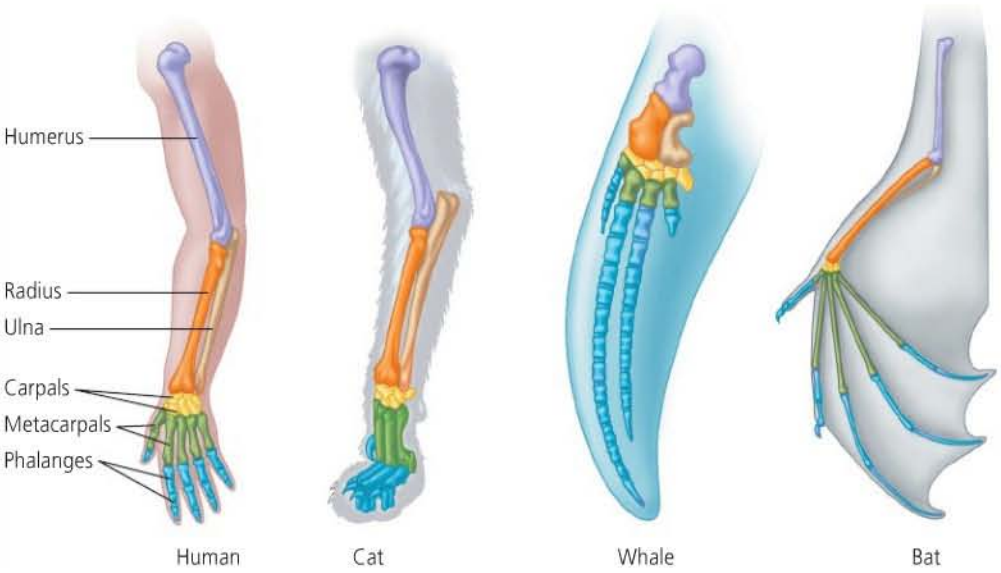


Homology

A third type of evidence for evolution comes from analyzing similarities among different organisms. As we've discussed, evolution is a process of descent with modification: Characteristics present in an ancestral organism are altered (by natural selection) in its descendants over time as they face different environmental conditions. As a result, related species can have characteristics with an underlying similarity even though they may have very different functions. Such similarity resulting from common ancestry is known as **homology**.

Anatomical and Molecular Homologies

The view of evolution as a remodeling process leads to the prediction that closely related species should share similar features—and they do. Of course, closely related species share the features used to determine their relationship, but they also share many other features. Some of these shared features make little sense except in the context of evolution. For example, the forelimbs of all mammals, including humans, cats, whales, and bats, show the same arrangement of bones from the shoulder to the tips of the digits, even though these appendages have very different functions: lifting, walking, swimming, and flying **(Figure 22.17)**. Such striking anatomical resemblances would be highly unlikely if these structures had arisen anew in each species. Rather, the underlying skeletons of the arms, forelegs, flippers, and wings of different mammals are **homologous structures** that represent variations on a structural theme that was present in their common ancestor.



Comparing early stages of development in different animal species reveals additional anatomical homologies not visible in adult organisms. For example, at some point in their development, all vertebrate embryos have a tail located posterior to (behind) the anus, as well as structures called pharyngeal (throat) pouches **(Figure 22.18)**. These homologous throat pouches ultimately develop into structures with very different functions, such as gills in fishes and parts of the ears and throat in humans and other mammals.

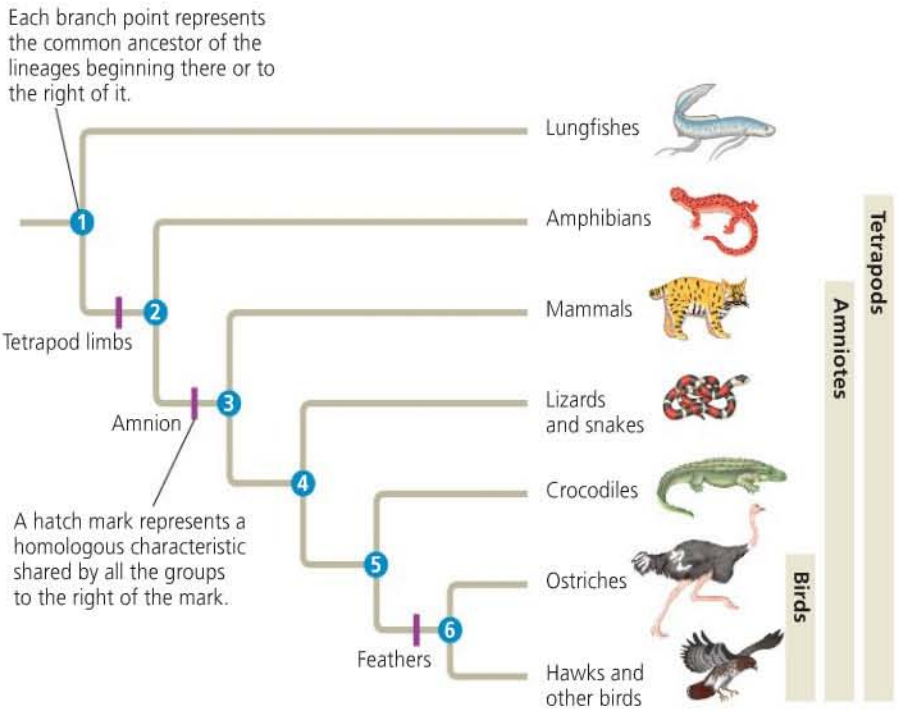
▲ **Figure 22.18 Anatomical similarities in vertebrate embryos.** At some stage in their embryonic development, all vertebrates have a tail located posterior to the anus (referred to as a post-anal tail), as well as pharyngeal (throat) pouches. Descent from a common ancestor can explain such similarities.

Some of the most intriguing homologies concern "leftover" structures of marginal, if any, importance to the organism. These **vestigial structures** are remnants of features that served important functions in the organism's ancestors. For instance, the skeletons of some snakes retain vestiges of the pelvis and leg bones of walking ancestors. Another example is the decreased size and loss of function in cetaceans' hind limbs as these organisms faced the challenges of life in water (see Figure 22.16). We would not expect to see these vestigial structures if snakes and whales had origins separate from other vertebrate animals.

Biologists also observe similarities among organisms at the molecular level. All forms of life use the same genetic language of DNA and RNA, and the genetic code is essentially universal (see Chapter 17). Thus, it is likely that all species descended from common ancestors that used this code. But molecular homologies go beyond a shared code. For example, organisms as dissimilar as humans and bacteria share genes inherited from a very distant common ancestor. Like the forelimbs of humans and whales, these genes have often acquired different functions.

▲ **Figure 22.17 Mammalian forelimbs: homologous structures.** Even though they have become adapted for different functions, the forelimbs of all mammals are constructed from the same basic skeletal elements: one large bone (purple), attached to two smaller bones (orange and tan), attached to several small bones (gold), attached to several metacarpals (green), attached to approximately five digits, or phalanges (blue).

Homologies and "Tree Thinking"



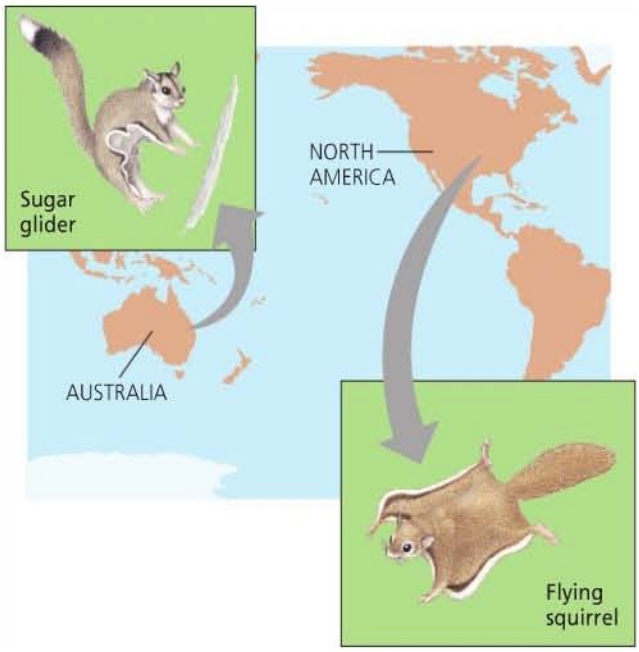
Some homologous characteristics, such as the genetic code, are shared by all species because they date to the deep ancestral past. In contrast, homologous characteristics that evolved more recently are shared only within smaller groups of organisms. Consider an example in the tetrapods (from the Greek *tetra*, four, and *pod*, foot), the vertebrate group that consists of amphibians, mammals, and reptiles (including birds—see Figure 22.19). All tetrapods possess the same basic limb bone structure illustrated in Figure 22.17, but the ancestors of tetrapods do not. Thus, homologous characteristics form a nested pattern: All life shares the deepest layer, and each successive smaller group adds their own homologies to those they share with larger groups. This nested pattern is exactly what we would expect to result from descent with modification from a common ancestor.

Biologists often represent the pattern of descent from common ancestors and the resulting homologies with an **evolutionary tree**, a diagram that reflects evolutionary relationships among groups of organisms. We will explore in detail how evolutionary trees are constructed in Chapter 26, but for now, let's consider how we can interpret and use such trees.

Figure 22.19 is an evolutionary tree of tetrapods and their closest living relatives, the lungfishes. In this diagram, each branch point represents the common ancestor of all species that descended from it. For example, lungfishes and all tetrapods descended from ancestor 1, whereas mammals, lizards and snakes, crocodiles, and birds all descended from ancestor 3. As expected, the three homologies shown on the tree—tetrapod limbs, the amnion (a protective embryonic membrane), and feathers—form a nested pattern. Tetrapod limbs were present in common ancestor 2 and hence are found in all of the descendants of that ancestor (the tetrapods). The amnion was present only in ancestor 3 and hence is shared only by some tetrapods (mammals and reptiles). Feathers were present only in common ancestor 6 and hence are found only in birds.

To explore "tree thinking" further, note that in Figure 22.19, mammals are positioned closer to amphibians than to birds. As a result, you might conclude that mammals are more closely related to amphibians than they are to birds. However, mammals are actually more closely related to birds than to amphibians because mammals and birds share a more recent common ancestor (ancestor 3) than do mammals and amphibians (ancestor 2).

Evolutionary trees are hypotheses that summarize our current understanding of patterns of descent. Our confidence in these relationships, as with any hypothesis, depends on the strength of the supporting data. In the case of Figure 22.19, the tree is supported by a variety of independent data sets, including both anatomical and DNA sequence data. As a result, biologists feel confident that it accurately reflects actual evolutionary history. As you will read in Chapter 26, scientists can use such well-supported evolutionary trees to make specific and sometimes surprising predictions about the biology of organisms.



▲ **Figure 22.19 Tree thinking: information provided in an evolutionary tree.** This evolutionary tree for tetrapods and their closest living relatives, the lungfishes, is based on anatomical and DNA sequence data. The purple bars indicate the origin of three important homologies, each of which evolved only once. Birds are nested within and evolved from reptiles; hence, the group of organisms called "reptiles" technically includes birds.

? *Are crocodiles more closely related to lizards or birds? Explain your answer.*

Convergent Evolution

Although organisms that are closely related share characteristics because of common descent, distantly related organisms can resemble one another for a different reason: **convergent evolution**, the independent evolution of similar features in different lineages. Consider marsupial mammals, many of which live in Australia. Marsupials are distinct from another group of mammals—the eutherians—that live elsewhere on Earth. (Eutherians complete their embryonic development in the uterus, whereas marsupials are born as embryos and complete their development in an external pouch.) Some Australian

▲ **Figure 22.20 Convergent evolution.** The sugar glider is a marsupial mammal that evolved in isolation on the island continent of Australia. Although sugar gliders superficially resemble the eutherian flying squirrels of North America, the ability to glide through the air evolved independently in these two distantly related groups of mammals.

marsupials have eutherian look-alikes with similar adaptations. For instance, a forest-dwelling Australian marsupial called the sugar glider is superficially very similar to flying squirrels, gliding eutherians that live in North American forests **(Figure 22.20)**. But the sugar glider has many other characteristics that make it a marsupial, much more closely related to kangaroos and other Australian marsupials than to flying squirrels or other eutherians. Once again, our understanding of evolution can explain these observations. Although they evolved independently from different ancestors, these two mammals have adapted to similar environments in similar ways. In such examples in which species share features because of convergent evolution, the resemblance is said to be **analogous**, not homologous.

Biogeography

A fourth type of evidence for evolution comes from **biogeography**, the geographic distribution of species. The geographic distribution of organisms is influenced by many factors, including **continental drift**, the slow movement of Earth's continents over time. About 250 million years ago, these movements united all of Earth's landmasses into a single large continent, called **Pangaea** (see Figure 25.13). Roughly 200 million years ago, Pangaea began to break apart; by 20 million years ago, the continents we know today were within a few hundred kilometers of their present locations.

We can use our understanding of evolution and continental drift to predict where fossils of different groups of organisms might be found. For example, as you will read in Chapter 25, evolutionary biologists have constructed evolutionary trees for horses based on anatomical data. Based on these trees and on the ages of fossils of horse ancestors, researchers estimate that present-day horse species originated 5 million years ago in North America. At that time, North and South America were close to their present locations, but they were not yet connected to one another, making it difficult for horses to travel between them. Thus, we would predict that the oldest horse fossils should be found only on the continent on which horses originated—North America. This prediction and others like it for different groups of organisms have been upheld, providing more evidence for evolution.

We can also use our understanding of evolution to explain biogeographic data. For example, islands generally have many species of plants and animals that are **endemic**, which means they are found nowhere else in the world. Yet, as Darwin described in *The Origin of Species*, most island species are closely related to species from the nearest mainland or a neighboring island. He explained this observation by suggesting that islands are colonized by species from the nearest mainland. These colonists eventually give rise to new species as they adapt to their new environments. Such a process also explains why two islands with similar environments in different parts of the world are populated not by closely related species but rather by species that resemble those of the nearest mainland, where the environment is often quite different.

What Is Theoretical About Darwin's View of Life?

Some people dismiss Darwin's ideas as "just a theory." However, as we have seen, the pattern of evolution—the observation that life has evolved over time—has been documented directly and is supported by a great deal of evidence. In addition, Darwin's explanation of the process of evolution—that natural selection is the primary cause of the observed pattern of evolutionary change—makes sense of massive amounts of data. The effects of natural selection also can be observed and tested in nature.

What, then, is theoretical about evolution? Keep in mind that the scientific meaning of the term *theory* is very different from its meaning in everyday use. The colloquial use of the word *theory* comes close to what scientists mean by a hypothesis. In science, a theory is more comprehensive than a hypothesis. A theory, such as Darwin's theory of evolution by natural selection, accounts for many observations and explains and integrates a great variety of phenomena. Such a unifying theory does not become widely accepted unless its predictions stand up to thorough and continual testing by experiment and additional observation (see Chapter 1). As the next three chapters demonstrate, this has certainly been the case with the theory of evolution by natural selection.

The skepticism of scientists as they continue to test theories prevents these ideas from becoming dogma. For

example, although Darwin thought that evolution was a very slow process, we now know that this isn't always true. New species can form in relatively short periods of time (a few thousand years or less; see Chapter 24). Furthermore, as we'll explore throughout this unit, evolutionary biologists now recognize that natural selection is not the only mechanism responsible for evolution. Indeed, the study of evolution today is livelier than ever as scientists find more ways to test the predictions of Darwin's theory.

Although Darwin's theory attributes the diversity of life to natural processes, the diverse products of evolution nevertheless remain elegant and inspiring. As Darwin wrote in the final sentence of *The Origin of Species*, "There is grandeur in this view of life . . . [in which] endless forms most beautiful and most wonderful have been, and are being, evolved."

CONCEPT CHECK 22.3

1. Explain how the following statement is inaccurate: "Anti-HIV drugs have created drug resistance in the virus."
2. How does evolution account for (a) the similar mammalian forelimbs with different functions shown in Figure 22.17 and (b) the similar lifestyle of the two distantly related mammals shown in Figure 22.20?
3. **WHAT IF?** The fossil record shows that dinosaurs originated 200–250 million years ago. Would you expect the geographic distribution of early dinosaur fossils to be broad (on many continents) or narrow (on one or a few continents only)? Explain.

For suggested answers, see Appendix A.

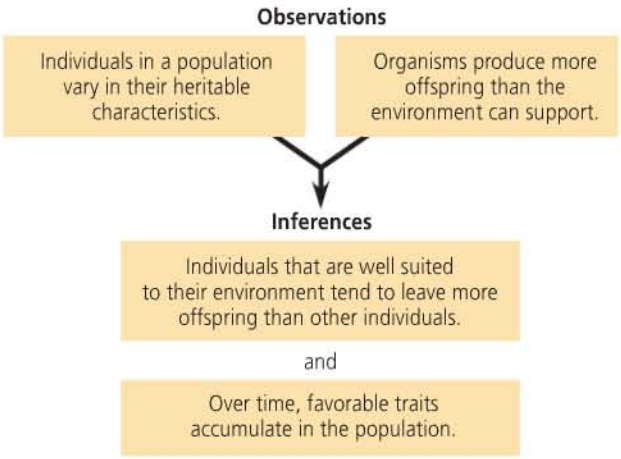
SUMMARY OF KEY CONCEPTS

CONCEPT 22.1



The Darwinian revolution challenged traditional views of a young Earth inhabited by unchanging species (pp. 452–455)

- ***Scala Naturae* and Classification of Species** Darwin's proposal that life's diversity has arisen from ancestral species through natural selection was a radical departure from the prevailing views of Western culture.
- **Ideas About Change over Time** In contrast to the principle that events in the past occurred suddenly by mechanisms not operating today, geologists Hutton and Lyell perceived that changes in Earth's surface can result from slow, continuous actions still operating at the present time.
- **Lamarck's Hypothesis of Evolution** Lamarck hypothesized that species evolve, but the mechanisms he proposed are not supported by evidence.

CONCEPT 22.2

Descent with modification by natural selection explains the adaptations of organisms and the unity and diversity of life (pp. 455–460)

- **Darwin's Research** Darwin's experiences during the voyage of the *Beagle* gave rise to his idea that new species originate from ancestral forms through the accumulation of adaptations. He refined his theory for more than 20 years and finally published it in 1859 after learning that Wallace had come to the same idea.
- ***The Origin of Species*** Darwin's book proposed that evolution occurs by natural selection:

MEDIA

MP3 Tutor Natural Selection
Activity Darwin and the Galápagos Islands
Activity The Voyage of the *Beagle*: Darwin's Trip Around the World

CONCEPT 22.3

Evolution is supported by an overwhelming amount of scientific evidence (pp. 460–466)

- **Direct Observations of Evolutionary Change** Researchers have directly observed natural selection leading to adaptive evolution in many studies, including research on wild guppy populations and on pathogens such as HIV.
- **The Fossil Record** Fossils show that past organisms differed from living organisms, that many species have become extinct, and that species have evolved over long periods of time.

- **Homology** Organisms share characteristics because of common descent (homology) or because natural selection affects independently evolving species in similar environments in similar ways (convergent evolution).
- **Biogeography** The geographic distribution of organisms is consistent with evolutionary theory.
- **What Is Theoretical About Darwin's View of Life?** The theory of evolution by natural selection integrates diverse areas of study and stimulates many new questions.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which of the following is *not* an observation or inference on which natural selection is based?
   a. There is heritable variation among individuals.
   b. Poorly adapted individuals never produce offspring.
   c. Species produce more offspring than the environment can support.
   d. Individuals whose characteristics are best suited to the environment generally leave more offspring than those whose characteristics are less suited.
   e. Only a fraction of the offspring produced by an individual may survive.

2. The upper forelimbs of humans and bats have fairly similar skeletal structures, whereas the corresponding bones in whales have very different shapes and proportions. However, genetic data suggest that all three kinds of organisms diverged from a common ancestor at about the same time. Which of the following is the most likely explanation for these data?
   a. Humans and bats evolved by natural selection, and whales evolved by Lamarckian mechanisms.
   b. Forelimb evolution was adaptive in people and bats, but not in whales.
   c. Natural selection in an aquatic environment resulted in significant changes to whale forelimb anatomy.
   d. Genes mutate faster in whales than in humans or bats.
   e. Whales are not properly classified as mammals.

3. Which of the following observations helped Darwin shape his concept of descent with modification?
   a. Species diversity declines farther from the equator.
   b. Fewer species live on islands than on the nearest continents.
   c. Birds can be found on islands located farther from the mainland than the birds' maximum nonstop flight distance.
   d. South American temperate plants are more similar to the tropical plants of South America than to the temperate plants of Europe.
   e. Earthquakes reshape life by causing mass extinctions.

4. Within a few weeks of treatment with the drug 3TC, a patient's HIV population consists entirely of 3TC-resistant viruses. How can this result best be explained?
   a. HIV can change its surface proteins and resist vaccines.
   b. The patient must have become reinfected with 3TC-resistant viruses.
   c. HIV began making drug-resistant versions of reverse transcriptase in response to the drug.
   d. A few drug-resistant viruses were present at the start of treatment, and natural selection increased their frequency.
   e. The drug caused the HIV RNA to change.

5. DNA sequences in many human genes are very similar to the sequences of corresponding genes in chimpanzees. The most likely explanation for this result is that
   a. humans and chimpanzees share a relatively recent common ancestor.
   b. humans evolved from chimpanzees.
   c. chimpanzees evolved from humans.
   d. convergent evolution led to the DNA similarities.
   e. humans and chimpanzees are not closely related.

6. Which of the following pairs of structures is *least* likely to represent homology?
   a. the wings of a bat and the arms of a human
   b. the hemoglobin of a baboon and that of a gorilla
   c. the mitochondria of a plant and those of an animal
   d. the wings of a bird and those of an insect
   e. the brain of a cat and that of a dog

23 The Evolution of Populations

▲ **Figure 23.1 Is this finch evolving by natural selection?**

KEY CONCEPTS

23.1 Mutation and sexual reproduction produce the genetic variation that makes evolution possible

23.2 The Hardy-Weinberg equation can be used to test whether a population is evolving

23.3 Natural selection, genetic drift, and gene flow can alter allele frequencies in a population

23.4 Natural selection is the only mechanism that consistently causes adaptive evolution

OVERVIEW

The Smallest Unit of Evolution

One common misconception about evolution is that individual organisms evolve. It is true that natural selection *acts* on individuals: Each organism's combination of traits affects its survival and reproductive success compared to other individuals. But the evolutionary impact of natural selection is only apparent in the changes in a *population* of organisms over time.

Consider the medium ground finch (*Geospiza fortis*), a seed-eating bird that inhabits the Galápagos Islands **(Figure 23.1)**. In 1977, the *G. fortis* population on the island of Daphne Major was decimated by a long period of drought: Of some 1,200 birds, only 180 survived. Researchers Peter and Rosemary Grant observed that the surviving finches tended to have larger, deeper beaks than others in the population. The Grants also observed that during the drought, small, soft seeds were in short supply. The finches mostly fed on large, hard seeds that were more plentiful. The birds with larger, deeper beaks were able to crack these larger seeds, increasing their rate of survival compared to finches with smaller beaks. As a result, the average beak size in the next generation of *G. fortis* was greater than it had been in the pre-drought population. The finch population had evolved by natural selection. However, the *individual* finches did not evolve. Each bird had a beak of a particular size, which did not grow larger during the drought. Rather, the proportion of large beaks in the population increased over generations: The population evolved, not its individual members.

Focusing on evolutionary change in populations, we can define evolution on its smallest scale, called **microevolution**, as change in allele frequencies in a population over generations. As we will see in this chapter, natural selection is not the only cause of microevolution. In fact, there are three main mechanisms that can cause allele frequency change: natural selection, genetic drift (chance events that alter allele frequencies), and gene flow (the transfer of alleles between populations). Each of these mechanisms has distinctive effects on the genetic composition of populations. However, only natural selection consistently improves the match between organisms and their environment, thus bringing about the type of change we refer to as adaptive evolution. Before we examine natural selection and adaptation more closely, let's revisit how the variations that are the raw material for evolutionary change arise.

CONCEPT 23.1

Mutation and sexual reproduction produce the genetic variation that makes evolution possible

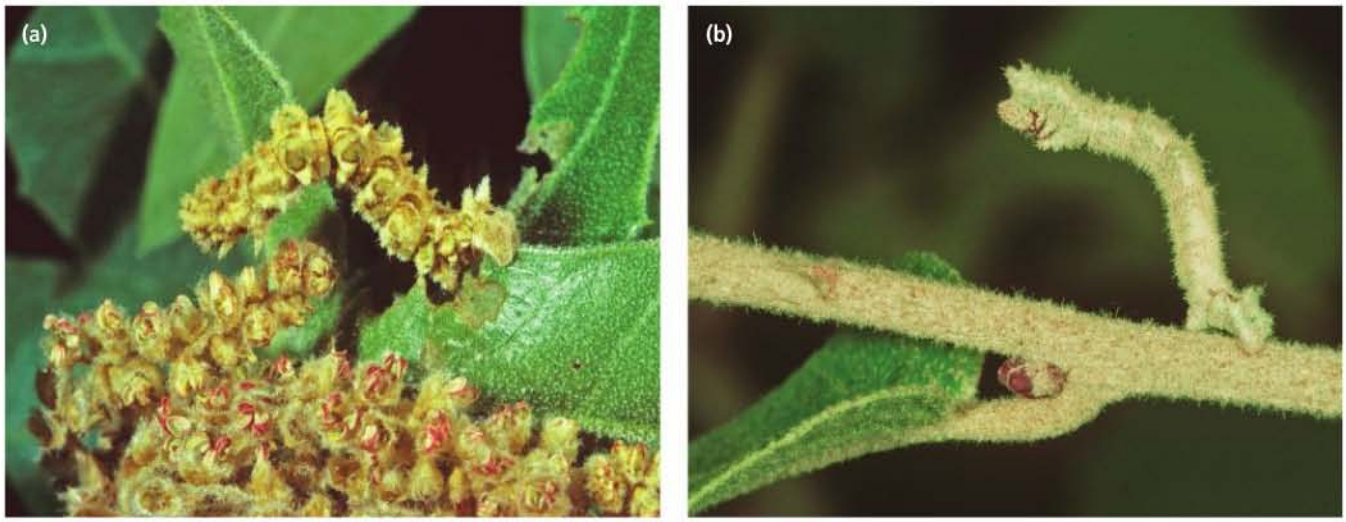
In *The Origin of Species*, Darwin provided abundant evidence that life on Earth has evolved over time, and he proposed natural selection as the primary mechanism for that change. Darwin also emphasized the importance of heritable differences among individuals. He knew that natural selection could not cause evolutionary change unless individuals differed in their inherited characteristics. But Darwin could not explain precisely how organisms pass heritable traits to their offspring.

Just a few years after Darwin published *The Origin of Species*, Gregor Mendel wrote a groundbreaking paper on inheritance in pea plants (see Chapter 14). In that paper, Mendel proposed a particulate model of inheritance, which stated that organisms transmit discrete heritable units (now called genes) to their offspring. Although Darwin never learned about genes, Mendel's paper set the stage for understanding the genetic differences on which evolution is based. Here we'll examine such genetic differences along with two processes that produce them, mutation and sexual reproduction.

Genetic Variation

You probably have no trouble recognizing your friends in a crowd. Each person has a unique genotype, reflected in individual phenotypic variations such as facial features, height, and voice. Indeed, individual variation occurs in all species. In addition to the differences that we can see or hear, species have extensive genetic variation that can only be observed at the molecular level. For example, you cannot identify a person's blood group (A, B, AB, or O) from his or her appearance, but this and many other such inherited characters vary among individuals.

As you read in earlier chapters, however, some phenotypic variation is not heritable (**Figure 23.2** shows a striking example in a caterpillar of the southwestern United States). Phenotype is the product of an inherited genotype and many environmental influences. In a human example, bodybuilders alter their phenotypes dramatically but do not pass their huge muscles on to the next generation. Only the genetic part of variation can have evolutionary consequences.



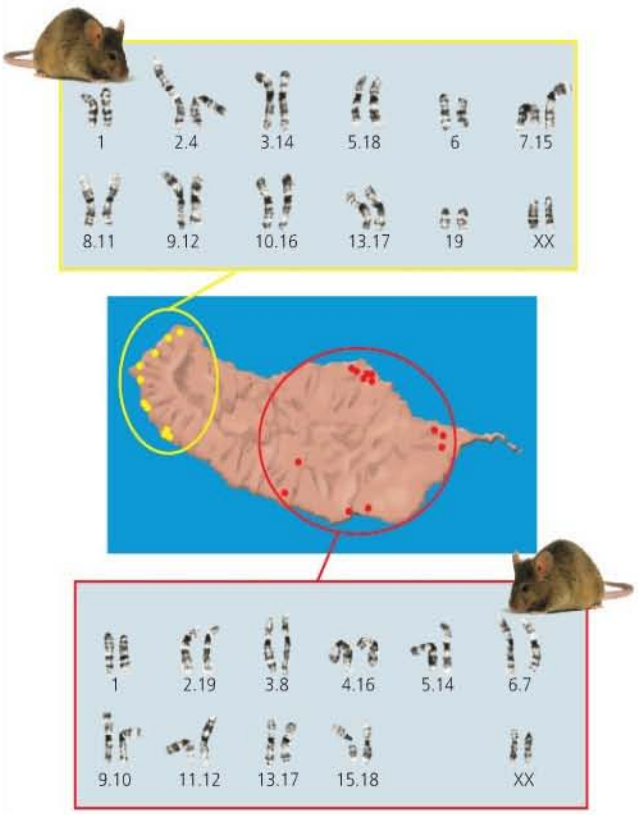
Variation Within a Population

Characters that vary within a population may be discrete or quantitative. *Discrete characters*, such as the purple or white flower colors of Mendel's pea plants (see Figure 14.3), can be classified on an either-or basis (each plant has flowers that are either purple or white). Many discrete characters are determined by a single gene locus with different alleles that produce distinct phenotypes. However, most heritable variation involves *quantitative characters*, which vary along a continuum within a population. Heritable quantitative variation usually results from the influence of two or more genes on a single phenotypic character.

Whether considering discrete or quantitative characters, biologists can measure genetic variation in a population at both the whole-gene level (gene variability) and the molecular level of DNA (nucleotide variability). Gene variability can be quantified as the **average heterozygosity**, the average percent of loci that are heterozygous. (Recall that a heterozygous individual has two different alleles for a given locus, whereas a homozygous individual has two identical alleles for that locus.) As an example, consider the fruit fly *Drosophila melanogaster*, which has about 13,700 genes in its genome. On average, a fruit fly is heterozygous for about 1,920 of its loci (14%) and homozygous for all the rest. We can therefore say that a *D. melanogaster* population has an average heterozygosity of 14%.

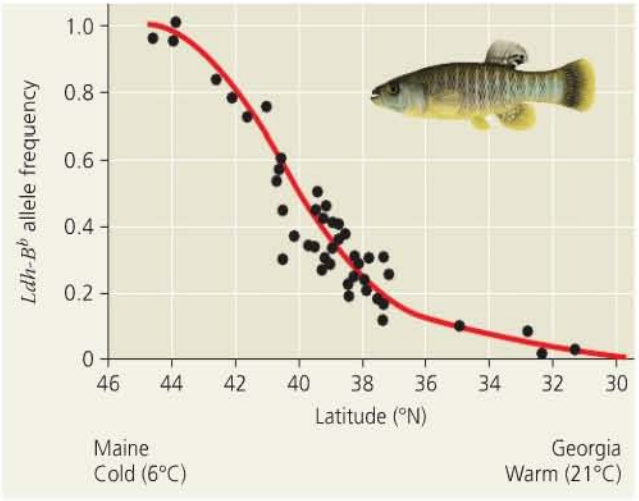
Average heterozygosity is often estimated by surveying the protein products of genes using gel electrophoresis (see Figure 20.9). While useful, this approach cannot detect silent mutations that alter the DNA sequence of a gene but not the amino acid sequence of the protein (see Figure 17.23). To include silent mutations in their estimates of average heterozygosity, researchers must use other approaches, such as PCR-based methods and restriction fragment analyses (see Figures 20.8 and 20.10).

Nucleotide variability is measured by comparing the DNA sequences of two individuals in a population and then



▲ **Figure 23.2 Nonheritable variation.** These caterpillars of the moth *Nemoria arizonaria* owe their different appearances to chemicals in their diets, not to their genotypes. Caterpillars raised on a diet of oak flowers resembled the flowers **(a)**, whereas their siblings raised on oak leaves resembled oak twigs **(b)**.

averaging the data from many such comparisons. The genome of *D. melanogaster* has about 180 million nucleotides, and the sequences of any two fruit flies differ on average by approximately 1.8 million (1%) of their nucleotides. Thus, the nucleotide variability of *D. melanogaster* populations is about 1%.



As in this fruit fly example, gene variability (that is, average heterozygosity) tends to be greater than nucleotide variability. Why is this true? Remember that a gene can consist of thousands of nucleotides. A difference at only one of these nucleotides can be sufficient to make two alleles of that gene different and thereby increase gene variability.

Variation Between Populations

In addition to variation observed within a population, species also exhibit **geographic variation**, differences in the genetic composition of separate populations. **Figure 23.3** illustrates geographic variation in populations of house mice (*Mus musculus*) separated by mountains on the Atlantic island of Madeira. Inadvertently introduced by Portuguese settlers in the 15th century, several populations of mice have evolved in isolation from one another. Researchers have observed differences in the karyotypes (chromosome sets) of these isolated populations. In some of the populations, a

▲ **Figure 23.3 Geographic variation in isolated mouse populations on Madeira.** The number pairs represent fused chromosomes. For example, "2.4" indicates fusion of chromosome 2 and chromosome 4. Mice in the areas indicated by the yellow dots have the set of fused chromosomes in the yellow box; mice in the red-dot locales have the set of fusions in the red box.

▲ **Figure 23.4 A cline determined by temperature.** In mummichog fish, the frequency of the $Ldh\text{-}B^b$ allele for the enzyme lactate dehydrogenase-B (which functions in metabolism) decreases in fish sampled from Maine to Georgia. The $Ldh\text{-}B^b$ allele codes for a form of the enzyme that is a better catalyst in cold water than are other versions of the enzyme. Individuals with the $Ldh\text{-}B^b$ allele can swim faster in cold water than can individuals with other alleles.

number of the original chromosomes have become fused. However, the patterns of fused chromosomes differ from one population to another. Because these chromosome-level changes leave genes intact, their phenotypic effects on the mice seem to be neutral. Thus, the variation between these populations appears to have resulted from chance events (drift) rather than natural selection.

Other examples of geographic variation occur as a **cline**, a graded change in a character along a geographic axis. Some clines are produced by a gradation in an environmental variable, as illustrated by the impact of temperature on the frequency of a cold-adaptive allele in mummichog fish (*Fundulus heteroclitus*). Clines such as the one depicted in **Figure 23.4** probably result from natural selection—otherwise there would be no reason to expect a close association between the environmental variable and the frequency of the allele. But selection can only operate if multiple alleles exist for a given locus. Such variation in alleles is the product of mutation, as we will discuss next.

Mutation

The ultimate source of new alleles is **mutation**, a change in the nucleotide sequence of an organism's DNA. A mutation is like a shot in the dark—we cannot predict accurately which segments of DNA will be altered or in what way. In multicellular organisms, only mutations in cell lines that produce gametes can be passed to offspring. In plants and fungi, this is not as limiting as it may sound, since many different cell lines can produce gametes (see Figures 29.13, 30.6, and 31.17). But in animals, most mutations occur in somatic cells and are lost when the individual dies.

Point Mutations

A change of as little as one base in a gene—a "point mutation"—can have a significant impact on phenotype, as in sickle-cell disease (see Figure 17.22). Organisms reflect thousands of generations of past selection, and hence their phenotypes generally provide a close match to their environment. As a result, it's unlikely that a new mutation that alters a phenotype will improve it. In fact, most such mutations are at least slightly harmful. But much of the DNA in eukaryotic genomes does not code for protein products, and point mutations in these noncoding regions are often harmless. Also, because of the redundancy in the genetic code, even a point mutation in a gene that encodes a protein will have no effect on the protein's function if the amino acid composition is not changed. Moreover, even if there is a change in an amino acid, this may not affect the protein's shape and function. However—as we will see—on rare occasions, a mutant allele may actually make its bearer better suited to the environment, enhancing reproductive success.

Mutations That Alter Gene Number or Sequence

Chromosomal changes that delete, disrupt, or rearrange many loci at once are almost certain to be harmful. However, when such large-scale mutations leave genes intact, their effects on organisms may be neutral (see Figure 23.3). In rare cases, chromosomal rearrangements may even be beneficial. For example, the translocation of part of one chromosome to a different chromosome could link DNA segments in a way that results in a positive effect.

An important source of variation begins when genes are duplicated due to errors in meiosis (such as unequal crossing over), slippage during DNA replication, or the activities of transposable elements (see Chapters 15 and 21). Duplications of large chromosome segments, like other chromosomal aberrations, are often harmful, but the duplication of smaller pieces of DNA may not be. Gene duplications that do not have severe effects can persist over generations, allowing mutations to accumulate. The result is an expanded genome with new loci that may take on new functions.

Such beneficial increases in gene number appear to have played a major role in evolution. For example, the remote ancestors of mammals carried a single gene for detecting odors that has been duplicated many times. As a result, humans today have about 1,000 olfactory receptor genes, and mice have 1,300. It is likely that such dramatic increases in the number of olfactory genes helped early mammals by enabling them to detect faint odors and to distinguish among many different smells. More recently, about 60% of human olfactory receptor genes have been inactivated by mutations, whereas mice have lost only 20% of theirs. This dramatic difference demonstrates that a versatile sense of smell is more important to mice than it is to us!

Mutation Rates

Mutation rates tend to be low in plants and animals, averaging about one mutation in every 100,000 genes per generation, and they are often even lower in prokaryotes. But prokaryotes typically have short generation spans, so mutations can quickly generate genetic variation in populations of these organisms. The same is true of viruses. For instance, HIV has a generation span of about two days. It also has an RNA genome, which has a much higher mutation rate than a typical DNA genome because of the lack of RNA repair mechanisms in host cells (see Chapter 19). For this reason, it is unlikely that a single-drug treatment would ever be effective against HIV; mutant forms of the virus that are resistant to a particular drug would no doubt proliferate in relatively short order. The most effective AIDS treatments to date have been drug "cocktails" that combine several medications. It is less likely that multiple mutations conferring resistance to *all* the drugs will occur in a short time period.

Sexual Reproduction

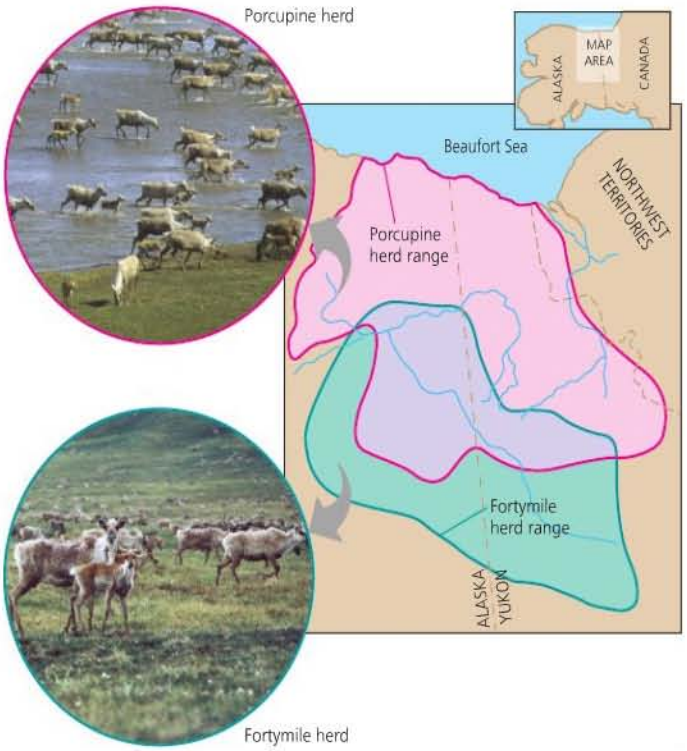
In organisms that reproduce sexually, most of the genetic variation in a population results from the unique combination of alleles that each individual receives. Of course, at the nucleotide level, all the differences among these alleles have originated from past mutations. But it is the mechanism of sexual reproduction that shuffles existing alleles and deals them at random to determine individual genotypes.

As described in Chapter 13, three mechanisms contribute to this shuffling: crossing over, independent assortment of chromosomes, and fertilization. During meiosis, homologous chromosomes, one inherited from each parent, trade some of their alleles by crossing over. These homologous chromosomes and the alleles they carry are then distributed at random into gametes. Then, because myriad possible mating combinations exist in a population, fertilization brings together gametes of individuals that are likely to have different genetic backgrounds. The combined effects of these three mechanisms ensure that sexual reproduction rearranges existing alleles into fresh combinations each generation, providing much of the genetic variation that makes evolution possible.

CONCEPT CHECK 23.1

1. (a) Explain why genetic variation within a population is a prerequisite for evolution. (b) What factors can produce genetic variation among populations?
2. Of all the mutations that occur in a population, why do only a small fraction become widespread among the population's members?
3. **WHAT IF?** If a population stopped reproducing sexually (but still reproduced asexually), how would its genetic variation be affected over time? Explain.

For suggested answers, see Appendix A.



CONCEPT **23.2**

The Hardy-Weinberg equation can be used to test whether a population is evolving

As we've seen, the individuals in a population must differ genetically for evolution to occur. But the presence of genetic variation does not guarantee that a population will evolve. For that to happen, one of the factors that cause evolution must be at work. In this section, we'll explore how to test whether evolution is occurring in a population. The first step in this process is to clarify what we mean by a population.

Gene Pools and Allele Frequencies

A **population** is a group of individuals of the same species that live in the same area and interbreed, producing fertile offspring. Different populations of a single species may be isolated geographically from one another, thus exchanging genetic material only rarely. Such isolation is common for species that live on widely separated islands or in different lakes. But not all populations are isolated, nor must populations have sharp boundaries **(Figure 23.5)**. Still, members of a population typically breed with one another and thus on average are more closely related to each other than to members of other populations.

▲ **Figure 23.5 One species, two populations.** These two caribou populations in the Yukon are not totally isolated; they sometimes share the same area. Nonetheless, members of either population are more likely to breed with members of their own population than with members of the other population.

We can characterize a population's genetic makeup by describing its **gene pool**, which consists of all the alleles for all the loci in all individuals of the population. If only one allele exists for a particular locus in a population, that allele is said to be *fixed* in the gene pool, and all individuals are homozygous for that allele. But if there are two or more alleles for a particular locus in a population, individuals may be either homozygous or heterozygous.

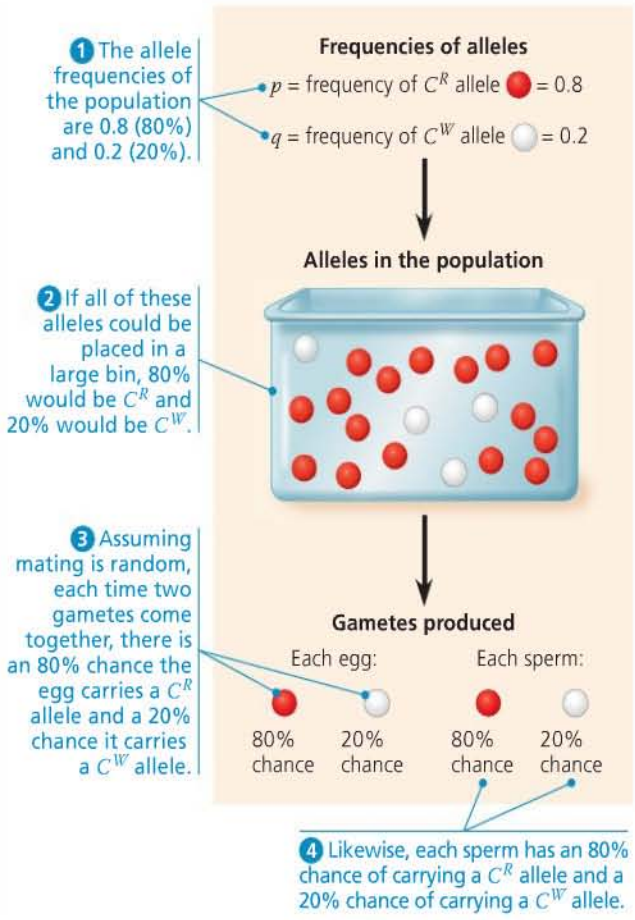
Each allele has a frequency (proportion) in the population. For example, imagine a population of 500 wildflower plants with two alleles, C^R and C^W, for a certain locus that codes for flower pigment. These alleles show incomplete dominance (see Chapter 14); thus, each genotype has a distinct phenotype. Plants homozygous for the C^R allele (C^RC^R) produce red pigment and have red flowers; plants homozygous for the C^W allele (C^WC^W) produce no red pigment and have white flowers; and heterozygotes (C^RC^W) produce some red pigment and have pink flowers. In our population, suppose there are 320 plants with red flowers, 160 with pink flowers, and 20 with white flowers. Because these are diploid organisms, there are a total of 1,000 copies of genes for flower color in the population of 500 individuals. The C^R allele accounts for 800 of these genes ($320 \times 2 = 640$ for C^RC^R plants, plus $160 \times 1 = 160$ for C^RC^W plants).

When studying a locus with two alleles, the convention is to use p to represent the frequency of one allele and q to represent the frequency of the other allele. Thus, p, the frequency of the C^R allele in the gene pool of this population, is $800/1{,}000 = 0.8 = 80\%$. And because there are only two alleles for this gene, the frequency of the C^W allele, represented by q, must be $200/1{,}000 = 0.2 = 20\%$. For loci that have more than two alleles, the sum of all allele frequencies must still equal 1 (100%).

Next we'll see how allele and genotype frequencies can be used to test whether evolution is occurring in a population.

The Hardy-Weinberg Principle

One way to assess whether natural selection or other factors are causing evolution at a particular locus is to determine what the genetic makeup of a population would be if it were *not* evolving at that locus. We can then compare that scenario with data from a real population. If there are no differences, we can conclude that the real population is not evolving. If there are differences, we can conclude that the real population is evolving—and then we can try to figure out why.



Hardy-Weinberg Equilibrium

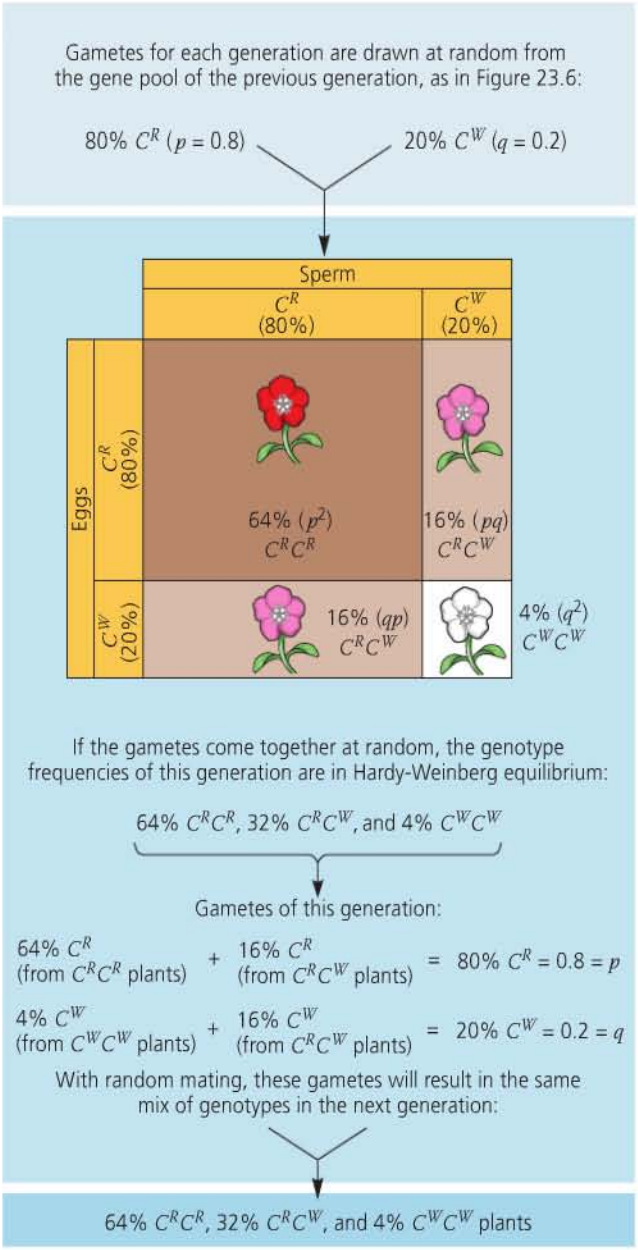
The gene pool of a population that is not evolving can be described by the **Hardy-Weinberg principle**, named for the British mathematician and German physician, respectively, who independently derived it in 1908. This principle states that the frequencies of alleles and genotypes in a

population will remain constant from generation to generation, provided that only Mendelian segregation and recombination of alleles are at work. Such a gene pool is said to be in **Hardy-Weinberg equilibrium**.

To understand and use the Hardy-Weinberg principle, it is helpful to think about alleles and genetic crosses in a new way. Previously, we used Punnett squares to determine the genotypes of offspring in a genetic cross (see Figure 14.5). We can take a similar approach here, but instead of considering the possible allele combinations from one genetic cross, our focus now is on the combination of alleles in *all* of the genetic crosses in a population.

Imagine that alleles for a given locus from all of the individuals in a population could be mixed together in a large bin **(Figure 23.6)**. We can think of this bin as holding the population's gene pool for that locus. "Reproduction" occurs by selecting alleles at random from the bin; somewhat similar events occur in nature when fish release sperm and eggs into the water or when pollen (containing plant sperm) is blown about by the wind. By viewing reproduction as a random selection of alleles from the bin (the gene pool), we are in effect assuming that mating occurs at random—that is, that all male-female matings are equally likely.

▲ **Figure 23.6 Selecting alleles at random from a gene pool.**



Let's apply our bin analogy to the hypothetical wildflower population discussed earlier. In that population, the frequency of the allele for red flowers (C^R) is $p = 0.8$, and the frequency of the allele for white flowers (C^W) is $q = 0.2$. Thus, a bin holding all 1,000 flower-color alleles of the 500 wildflowers contains 800 C^R alleles and 200 C^W alleles. Assuming that gametes are formed by selecting alleles at random from the bin, the probability that an egg or sperm contains a C^R or C^W allele is equal to the frequency of these alleles in the bin. Thus, as shown in Figure 23.6, each egg has an 80% chance of containing a C^R allele and a 20% chance of containing a C^W allele; the same is true for each sperm.

Using the rule of multiplication (see Chapter 14), we can now calculate the frequencies of the three possible genotypes, assuming random unions of sperm and eggs. The probability that two C^R alleles will come together is $p \times p = p^2 = 0.8 \times 0.8 = 0.64$. Thus, about 64% of the plants in the next generation will have the genotype C^RC^R. The frequency of C^WC^W individuals is expected to be about $q \times q = q^2 = 0.2 \times 0.2 = 0.04$, or 4%. C^RC^W heterozygotes can arise in two different ways. If the sperm provides the C^R allele and the egg provides the C^W allele, the resulting heterozygotes will be $p \times q = 0.8 \times 0.2 = 16\%$ of the total. If the sperm provides the C^W allele and the egg the C^R allele, the heterozygous offspring will make up $q \times p = 0.2 \times 0.8 = 16\%$. The frequency of heterozygotes is thus the sum of these possibilities: $pq + qp = 0.16 + 0.16 = 0.32$, or 32%.

As shown in **Figure 23.7** on the next page, the genotype frequencies in the next generation must add up to 1 (100%). Thus, the equation for Hardy-Weinberg equilibrium states that at a locus with two alleles, the three genotypes will appear in the following proportions:

$$\underset{\substack{\text{Expected frequency of genotype } C^RC^R}}{p^2} + \underset{\substack{\text{Expected frequency of genotype } C^RC^W}}{2pq} + \underset{\substack{\text{Expected frequency of genotype } C^WC^W}}{q^2} = 1$$

Note that for a locus with two alleles, only three genotypes are possible (in this case, C^RC^R, C^RC^W, and C^WC^W). As a result, the sum of the frequencies of the three genotypes must equal 1 (100%) in *any* population—regardless of whether the population is in Hardy-Weinberg equilibrium. A population is in Hardy-Weinberg equilibrium only if the genotype frequencies are such that the actual frequency of one homozygote is p^2, the actual frequency of the other homozygote is q^2, and the actual frequency of heterozygotes is $2pq$. Finally, as suggested by Figure 23.7, if a population such as our wildflowers is in Hardy-Weinberg equilibrium and its members continue to mate randomly generation after generation, allele and genotype frequencies will remain constant. The system operates somewhat like a deck of cards: No matter how many times the deck is reshuffled to deal out new hands, the deck

▲ **Figure 23.7 The Hardy-Weinberg principle.** In our wildflower population, the gene pool remains constant from one generation to the next. Mendelian processes alone do not alter frequencies of alleles or genotypes.

? *If the frequency of the C^R allele is 60%, predict the frequencies of the C^RC^R, C^RC^W, and C^WC^W genotypes.*

itself remains the same. Aces do not grow more numerous than jacks. And the repeated shuffling of a population's gene pool over the generations cannot, in itself, change the frequency of one allele relative to another.

Conditions for Hardy-Weinberg Equilibrium

The Hardy-Weinberg principle describes a hypothetical population that is not evolving. But in real populations, the allele and genotype frequencies often *do* change over time. Such changes can occur when at least one of the following five conditions of Hardy-Weinberg equilibrium is not met:

1. **No mutations.** By altering alleles or (in large-scale changes) deleting or duplicating entire genes, mutations modify the gene pool.
2. **Random mating.** If individuals mate preferentially within a subset of the population, such as their close relatives (inbreeding), random mixing of gametes does not occur, and genotype frequencies change.
3. **No natural selection.** Differences in the survival and reproductive success of individuals carrying different genotypes can alter allele frequencies.
4. **Extremely large population size.** The smaller the population, the more likely it is that allele frequencies will fluctuate by chance from one generation to the next (genetic drift).
5. **No gene flow.** By moving alleles into or out of populations, gene flow can alter allele frequencies.

Departure from any of these conditions usually results in evolutionary change, which, as we've already described, is common in natural populations. But it is also common for natural populations to be in Hardy-Weinberg equilibrium for specific genes. This apparent contradiction occurs because a population can be evolving at some loci, yet simultaneously be in Hardy-Weinberg equilibrium at other loci. In addition, some populations evolve so slowly that the changes in their allele and genotype frequencies are difficult to distinguish from those predicted for a nonevolving population.

Applying the Hardy-Weinberg Principle

The Hardy-Weinberg equation is often used to test whether evolution is occurring in a population (you'll encounter an example in Concept Check 23.2, question 3). The equation also has medical applications, such as estimating the percentage of a population carrying the allele for an inherited disease. For example, phenylketonuria (PKU), a metabolic disorder that results from homozygosity for a recessive allele, occurs in about one out of every 10,000 babies born in the United States. Left untreated, PKU results in mental retardation and other problems. (Newborns are now tested for PKU, and symptoms can be lessened with a phenylalanine-free diet. For this reason, products that contain phenylalanine—diet colas, for example—carry warning labels.)

To apply the Hardy-Weinberg equation, we must assume that new PKU mutations are not being introduced into the population (condition 1), and that people neither choose their mates on the basis of whether or not they carry this gene nor generally mate with close relatives (condition 2). We must also neglect any effects of differential survival and reproductive success among PKU genotypes (condition 3) and assume that there are no effects of genetic drift (condition 4) or of gene flow from other populations into the United States (condition 5). These assumptions are rea-

sonable: The mutation rate for the PKU gene is low, inbreeding is not common in the United States, selection occurs only against the rare homozygotes (and then only if dietary restrictions are not followed), the United States' population is very large, and populations outside the country have PKU allele frequencies similar to those seen in the United States. If all these assumptions hold, then the frequency of individuals in the population born with PKU will correspond to q^2 in the Hardy-Weinberg equation (q^2 = frequency of homozygotes). Because the allele is recessive, we must estimate the number of heterozygotes rather than counting them directly as we did with the pink flowers. Since we know there is one PKU occurrence per 10,000 births (q^2 = 0.0001), the frequency of the recessive allele for PKU is

$$q = \sqrt{0.0001} = 0.01$$

and the frequency of the dominant allele is

$$p = 1 - q = 1 - 0.01 = 0.99$$

The frequency of carriers, heterozygous people who do not have PKU but may pass the PKU allele to offspring, is

$$2pq = 2 \times 0.99 \times 0.01 = 0.0198$$

(approximately 2% of the U.S. population)

Remember, the assumption of Hardy-Weinberg equilibrium yields an approximation; the real number of carriers may differ. Still, our calculations suggest that harmful recessive alleles at this and other loci can be concealed in a population because they are carried by healthy heterozygotes.

CONCEPT CHECK 23.2

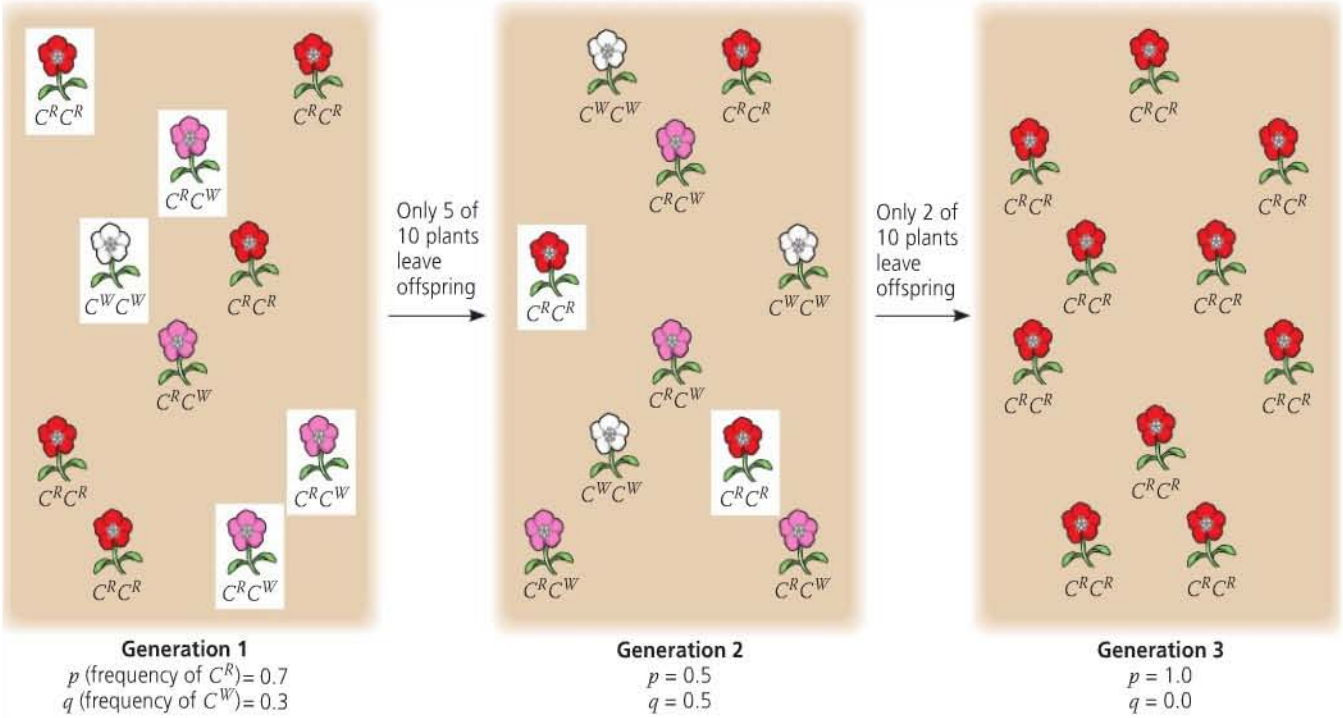
1. Suppose a population of organisms with 500 loci is fixed at half of these loci and has two alleles at each of the other loci. How many different alleles are found in its entire gene pool? Explain.
2. If p is the frequency of allele A, which parts of the Hardy-Weinberg equation correspond to the frequency of individuals that have at least one A allele?
3. **WHAT IF?** For a locus with two alleles (A and a) in a population at risk from an infectious neurodegenerative disease, 16 people had genotype AA, 92 had genotype Aa, and 12 had genotype aa. Use the Hardy-Weinberg equation to determine whether this population appears to be evolving.

For suggested answers, see Appendix A.

CONCEPT 23.3
Natural selection, genetic drift, and gene flow can alter allele frequencies in a population

Note again the five conditions required for a population to be in Hardy-Weinberg equilibrium. A deviation from any of these conditions is a potential cause of evolution. New mutations (violation of condition 1) can alter allele frequencies, but because mutations are rare, the change from one generation to the next is likely to be very small. Nevertheless, as we'll see, mutation ultimately can have a large effect on allele frequencies when it produces new alleles that strongly influence fitness in a positive or negative way. Nonrandom mating (violation of condition 2) can affect the frequencies of homozygous and heterozygous genotypes but by itself usually has no effect on allele frequencies in the gene pool. The three mechanisms that alter allele frequencies directly and cause most evolutionary change are natural selection, genetic drift, and gene flow (violations of conditions 3–5).

Natural Selection



As you read in Chapter 22, Darwin's concept of natural selection is based on differential success in survival and reproduction: Individuals in a population exhibit variations in their heritable traits, and those with traits that are better suited to their environment tend to produce more offspring than those with traits that are less well suited.

We now know that selection results in alleles being passed to the next generation in proportions different from their proportions in the present generation. For example, the fruit fly *Drosophila melanogaster* has an allele that confers resistance to several insecticides, including DDT. This allele has a frequency of 0% in laboratory strains of *D. melanogaster* established from flies collected in the wild in the early 1930s, prior to DDT usage. However, in strains established from flies collected after 1960 (following 20 or more years of DDT usage), the allele frequency is 37%. We can infer that this allele either arose by mutation between 1930 and 1960 or that this allele was present in the population in 1930, but was very rare. In any case, the observed increase in the frequency of this allele most likely occurred because DDT is a powerful poison that is a strong selective force in exposed fly populations.

As the *D. melanogaster* example shows, an allele that confers insecticide resistance will increase in frequency in a population exposed to that insecticide. Such changes are not coincidental. Instead, by consistently favoring some alleles over others, natural selection can cause *adaptive evolution* (evolution that results in a better match between organisms and their environment). We'll explore this process in more detail a little later in this chapter.

Genetic Drift

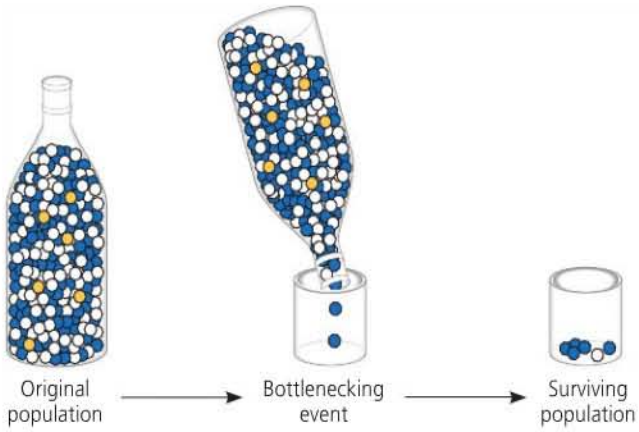
If you flip a coin 1,000 times, a result of 700 heads and 300 tails might make you suspicious about that coin. But if you flip a coin 10 times, an outcome of 7 heads and 3 tails would not be surprising. The smaller the number of coin flips, the more likely it is that chance alone will cause a deviation from the predicted result—in this case, the prediction is an equal number of heads and tails. Chance events can also cause allele frequencies

▲ **Figure 23.8 Genetic drift.** This small wildflower population has a stable size of ten plants. Suppose that by chance only five plants (those in white boxes) of generation 1 produce fertile offspring. This could occur, for example, if only those plants happened to grow in a location that provided enough nutrients to support the production of offspring. Again by chance, only two plants of generation 2 leave fertile offspring. As a result, by chance alone, the frequency of the C^W allele first increases in generation 2, then falls to zero in generation 3.

to fluctuate unpredictably from one generation to the next, especially in small populations—a process called **genetic drift**.

Figure 23.8 models how genetic drift might affect a small population of our wildflowers. In this example, an allele is lost from the gene pool, but it is purely a matter of chance that the C^W allele is lost, not the C^R allele. Such unpredictable changes in allele frequencies can be caused by chance events associated with survival and reproduction. Perhaps a large animal such as a moose stepped on the three C^WC^W individuals in generation 2, killing them and increasing the chance that only the C^R allele would be passed to the next generation. Allele frequencies can also be affected by chance events that occur during fertilization. For example, suppose two individuals of genotype C^RC^W had a small number of offspring. By chance alone, every egg and sperm pair that generated offspring could happen to have carried the C^R allele, not the C^W allele.

Certain circumstances can result in genetic drift having a significant impact on a population. Two examples are the founder effect and the bottleneck effect.



The Founder Effect

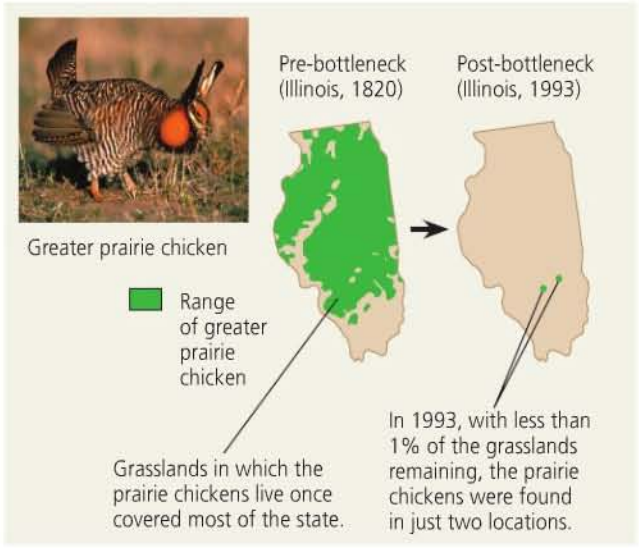
When a few individuals become isolated from a larger population, this smaller group may establish a new population whose gene pool differs from the source population; this is called the **founder effect**. The founder effect might occur, for example, when a few members of a population are blown by a storm to a new island. Genetic drift—in which chance events alter allele frequencies—occurs in such a case because the storm indiscriminately transports some individuals (and their alleles), but not others, from the source population.

The founder effect probably accounts for the relatively high frequency of certain inherited disorders among isolated human populations. For example, in 1814, 15 British colonists founded a settlement on Tristan da Cunha, a group of small islands in the Atlantic Ocean midway between Africa and South America. Apparently, one of the colonists carried a recessive allele for retinitis pigmentosa, a progressive form of blindness that afflicts homozygous individuals. Of the founding colonists' 240 descendants on the island in the late 1960s, 4 had retinitis pigmentosa. The frequency of the allele that causes this disease is ten times higher on Tristan da Cunha than in the populations from which the founders came.

The Bottleneck Effect

A sudden change in the environment, such as a fire or flood, may drastically reduce the size of a population. A severe drop in population size can cause the **bottleneck effect**, so named because the population has passed through a restrictive "bottleneck" in size **(Figure 23.9)**. By chance alone, certain alleles may be overrepresented among the survivors, others may be underrepresented, and some may be absent altogether. Ongoing genetic drift is likely to have substantial effects on the gene pool

▲ **Figure 23.9 The bottleneck effect.** Shaking just a few marbles through the narrow neck of a bottle is analogous to a drastic reduction in the size of a population. By chance, blue marbles are overrepresented in the surviving population and gold marbles are absent.



until the population becomes large enough that chance events have less effect. But even if a population that has passed through a bottleneck ultimately recovers in size, it may have low levels of genetic variation for a long period of time—a legacy of the genetic drift that occurred when the population was small.

One reason it is important to understand the bottleneck effect is that human actions sometimes create severe bottlenecks for other species. The following example illustrates the impact of genetic drift on an endangered population.

Case Study: *Impact of Genetic Drift on the Greater Prairie Chicken*

Millions of greater prairie chickens (*Tympanuchus cupido*) once lived on the prairies of Illinois. As these prairies were converted to farmland and other uses during the 19th and 20th centuries, the number of greater prairie chickens plummeted **(Figure 23.10a)**. By 1993, only two Illinois populations remained, which together harbored fewer than 50 birds. The few surviving birds had low levels of genetic variation, and less than 50% of their eggs hatched, compared to much higher hatching rates of the larger populations in Kansas, Nebraska, and Minnesota **(Figure 23.10b)**.

These data suggest that genetic drift during the bottleneck may have led to a loss of genetic variation and an increase in the frequency of harmful alleles. To investigate this hypothesis, Juan Bouzat, of Bowling Green State University, Ohio, and his colleagues extracted DNA from 15 museum specimens of Illinois greater prairie chickens. Of the 15 birds, 10 had been collected in the 1930s, when there were 25,000 greater prairie chickens in Illinois, and 5 had been collected in the 1960s, when there were 1,000 greater prairie chickens in Illinois. By studying the DNA of these specimens, the researchers were able to obtain a minimum, baseline estimate of how much genetic variation was present in the Illinois population *before* the population shrank to extremely low numbers.

(a) The Illinois population of greater prairie chickens dropped from millions of birds in the 1800s to fewer than 50 birds in 1993.

Location	Population size	Number of alleles per locus	Percentage of eggs hatched
Illinois			
1930–1960s	1,000–25,000	5.2	93
1993	<50	3.7	<50
Kansas, 1998 (no bottleneck)	750,000	5.8	99
Nebraska, 1998 (no bottleneck)	75,000–200,000	5.8	96
Minnesota, 1998 (no bottleneck)	4,000	5.3	85

(b) As a consequence of the drastic reduction in the size of the Illinois population, genetic drift resulted in a drop in the number of alleles per locus (averaged across six loci studied) and a decrease in the percentage of eggs that hatched.

▲ **Figure 23.10 Bottleneck effect and reduction of genetic variation.**

The researchers surveyed six loci and found that the 1993 Illinois greater prairie chicken population had lost nine alleles present in the museum specimens. The 1993 population also had fewer alleles per locus than the pre-bottleneck Illinois or the current Kansas, Nebraska, and Minnesota populations (see Figure 23.10b). Thus, as predicted, drift had reduced the genetic variation of the small 1993 population. Drift may also have increased the frequency of harmful alleles, leading to the low egg-hatching rate. To counteract possible negative effects of genetic drift, the researchers added a total of 271 birds from neighboring states to the Illinois population over four years.

This strategy succeeded. New alleles entered the population, and the egg-hatching rate improved to over 90%. Overall, studies on the Illinois greater prairie chicken illustrate the powerful effects of genetic drift in small populations and provide hope that in at least some populations, these effects can be reversed.

Effects of Genetic Drift: A Summary

The examples we've described highlight four key points:

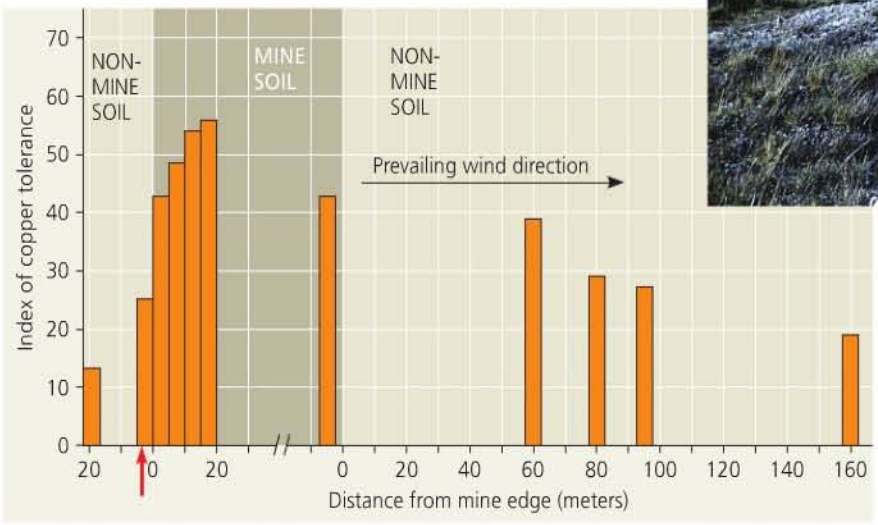
1. **Genetic drift is significant in small populations.** Chance events can cause an allele to be disproportionately over- or underrepresented in the next generation. Although chance events occur in populations of all sizes, they alter allele frequencies substantially only in small populations.
2. **Genetic drift can cause allele frequencies to change at random.** Because of genetic drift, an allele may increase in frequency one year, then decrease the next; the change from one year to the next is not predictable. Thus, unlike natural selection, which in a given environment consistently favors some alleles over others, genetic drift causes allele frequencies to change at random over time.
3. **Genetic drift can lead to a loss of genetic variation within populations.** By causing allele frequencies to fluctuate randomly over time, genetic drift can eliminate alleles from a population (see Figures 23.8 and 23.10). Because evolution depends on genetic variation, such losses can influence how effectively a population can adapt to a change in the environment.
4. **Genetic drift can cause harmful alleles to become fixed.** Alleles that are neither harmful nor beneficial can be lost or become fixed entirely by chance through genetic drift. In very small populations, genetic drift can also cause alleles that are slightly harmful to become fixed. When this occurs, the population's survival can be threatened (as for the Illinois greater prairie chicken).

Gene Flow

Natural selection and genetic drift are not the only phenomena affecting allele frequencies. Allele frequencies can also change by **gene flow**, the transfer of alleles into or out of a population due to the movement of fertile individuals or their gametes. For example, suppose that near our original hypothetical wildflower population there is another population consisting primarily of white-flowered individuals (C^WC^W). Insects carrying pollen from these plants may fly to and pollinate plants in our original population. The introduced C^W alleles would modify our original population's allele frequencies in the next generation.

Because alleles are exchanged among populations, gene flow tends to reduce the genetic differences between populations. If it is extensive enough, gene flow can result in neighboring populations combining into a single population with a common gene pool. For example, humans today move much more freely about the world than in the past. As a result, mating is more common between members of populations that previously were quite isolated **(Figure 23.11)**. The result is that gene flow has become an increasingly important agent of evolutionary change in human populations.

▲ **Figure 23.11 Gene flow and human evolution.** The migration of people throughout the world has increased gene flow between populations that once were isolated from one another. The computer-generated image on this magazine cover illustrates how gene flow can homogenize the gene pools of such populations, thereby reducing geographic variation in appearance.



When neighboring populations live in different environments, alleles transferred by gene flow may prevent a population from fully adapting to its environment. Consider the example of bent grass (*Agrostis tenuis*) populations growing next to copper mines. These mine soils have high concentrations of copper, causing toxic effects in nontolerant plants. If alleles for copper tolerance are present in the bent grass population, these favorable alleles rapidly spread in the population. However, on nearby soils not contaminated with copper, copper-tolerant plants reproduce poorly compared to nontolerant ones. Thus we might expect that the percentage of plants that are copper tolerant would be close to 100% on mine soils and close to 0% on nearby (uncontaminated) soils. But bent grass is wind pollinated, and the wind can blow pollen from one population to another, moving alleles in the process. Thus, copper-tolerance alleles are transferred to non-mine soils; likewise, alleles associated with copper nontolerance are transferred to mine soils **(Figure 23.12)**.

Sometimes beneficial alleles are transferred very widely. For example, gene flow has resulted in the worldwide spread of several insecticide-resistance alleles in the mosquito *Culex pipiens*, a vector of West Nile virus and malaria. Each of these alleles has a unique genetic signature that allowed researchers

▼ **Figure 23.12 Gene flow and selection.** The bent grass in the foreground of the photo is growing on the tailings of an abandoned mine and is more copper tolerant than the bent grass in the pasture beyond the fence. The graph shows the degree of copper tolerance at various locations. These data suggest that ongoing gene flow prevents each population from adapting fully to its local conditions.

WHAT IF? *If prevailing winds blew the opposite way, how would copper tolerance change at the location marked by the red arrow?*

to document that it arose by mutation in one or a few geographic locations. In their population of origin, these alleles increased because they provided insecticide resistance. These alleles were then transferred to new populations, where again, their frequencies increased as a result of natural selection.

To sum up, gene flow, like mutation, can introduce new alleles into a population. But because it can occur at a higher rate than mutation, gene flow is more likely than mutation to alter allele frequencies directly. And once gene flow or mutation introduces a new allele to a population, natural selection may then cause the new allele to increase in frequency (as in the insecticide-resistance alleles in mosquitoes) or decrease in frequency (as in the copper-tolerance alleles in bent grass in non-mine soil).

CONCEPT CHECK 23.3

1. In what sense is natural selection more "predictable" than genetic drift?
2. Distinguish genetic drift from gene flow in terms of (a) how they occur and (b) their implications for future genetic variation in a population.
3. **WHAT IF?** Suppose two plant populations exchange pollen and seeds. In one population, individuals of genotype *AA* are most common (9,000 *AA*, 900 *Aa*, 100 *aa*), while the opposite is true in the other population (100 *AA*, 900 *Aa*, 9,000 *aa*). If neither allele has a selective advantage, what will happen over time to the allele and genotype frequencies of these populations?

For suggested answers, see Appendix A.

CONCEPT 23.4
Natural selection is the only mechanism that consistently causes adaptive evolution

Evolution by natural selection is a blend of chance and "sorting"—chance in the creation of new genetic variations (originally by mutation) and sorting as natural selection favors some alleles over others. Because of this sorting effect, only natural selection consistently increases the frequencies of alleles that provide reproductive advantage and thus leads to adaptive evolution.

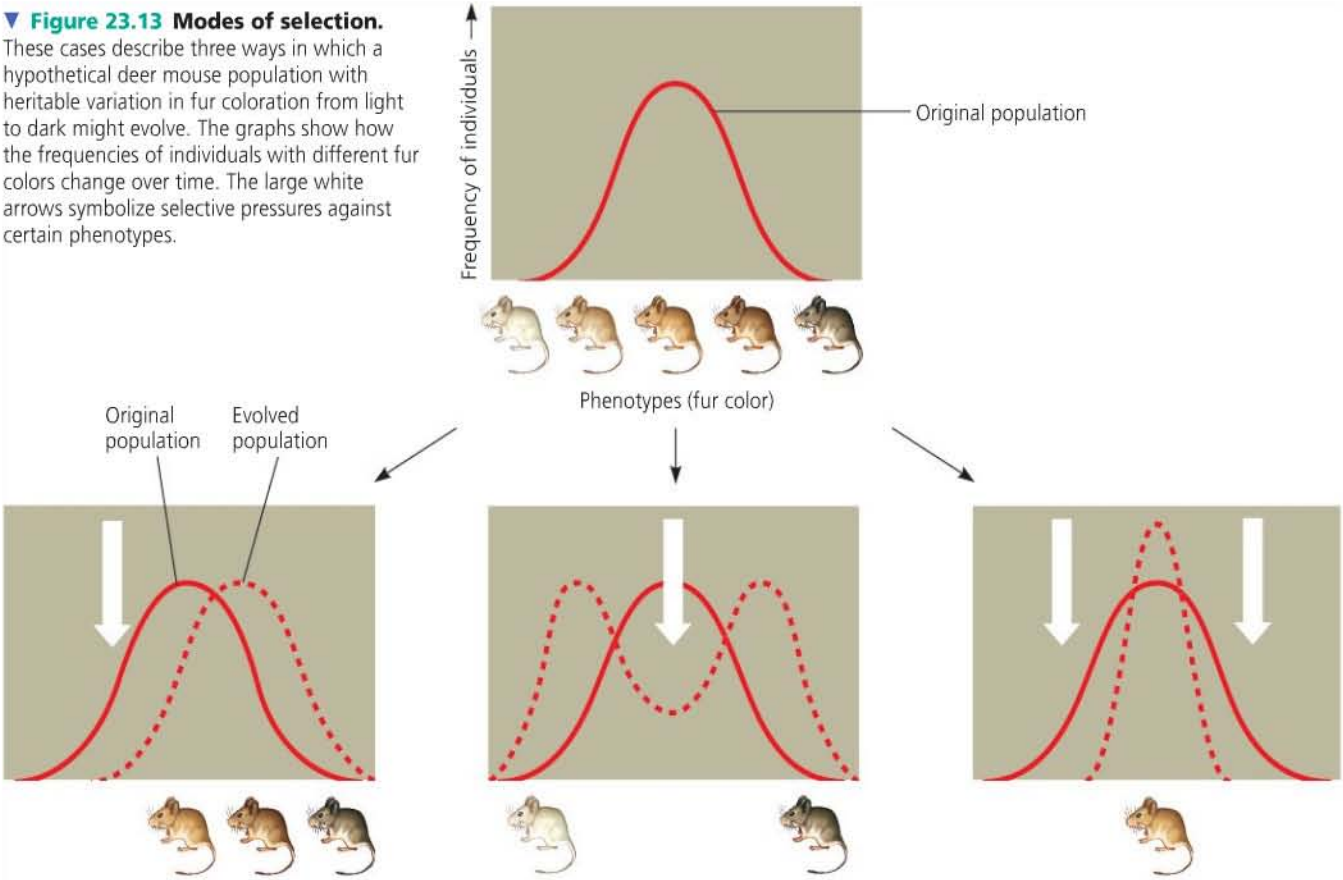
A Closer Look at Natural Selection

In examining how natural selection brings about adaptive evolution, we'll begin with the concept of relative fitness and the different ways that an organism's phenotype is subject to natural selection.

Relative Fitness

The phrases "struggle for existence" and "survival of the fittest" are commonly used to describe natural selection, yet these expressions are misleading if taken to mean direct competitive contests among individuals. There *are* animal species in which individuals, usually the males, lock horns or otherwise do combat to determine mating privilege. But reproductive success is generally more subtle and depends on many factors besides

outright battle. For example, a barnacle that is more efficient at collecting food than its neighbors may have greater stores of energy and hence be able to produce a larger number of eggs. A moth may have more offspring than other moths in the same population because its body colors more effectively conceal it from predators, improving its chance of surviving long enough to produce more offspring. These examples illustrate how adaptive advantage can lead to greater **relative fitness**: the contribution an individual makes to the gene pool of the next generation, *relative to* the contributions of other individuals.



Although we often refer to the relative fitness of a genotype, remember that the entity that is subjected to natural selection is the whole organism, not the underlying genotype. Thus, selection acts more directly on the phenotype than on the genotype; it acts on the genotype indirectly, via how the genotype affects the phenotype. Furthermore, the relative fitness conferred by a particular allele depends on the entire genetic and environmental context in which it is expressed. For example, an allele that is slightly disadvantageous might increase in frequency by "hitchhiking," that is, as a result of being located close to an allele at another locus that is strongly favored by natural selection (see Chapter 15 to review how distance between genes affects their inheritance).

Directional, Disruptive, and Stabilizing Selection

Natural selection can alter the frequency distribution of heritable traits in three ways, depending on which phenotypes in a population are favored. These three modes of selection are called directional selection, disruptive selection, and stabilizing selection.

Directional selection occurs when conditions favor individuals exhibiting one extreme of a phenotypic range, thereby shifting the frequency curve for the phenotypic character in one direction or the other **(Figure 23.13a)**. Directional selection is common when a population's environment changes or when members of a population migrate to a new (and different) habitat. For instance, fossil evidence indicates that the average size of black bears in Europe increased during each frigid glacial period, only to decrease again during warmer interglacial periods. Larger bears, with a smaller surface-to-

▼ Figure 23.13 Modes of selection. These cases describe three ways in which a hypothetical deer mouse population with heritable variation in fur coloration from light to dark might evolve. The graphs show how the frequencies of individuals with different fur colors change over time. The large white arrows symbolize selective pressures against certain phenotypes.

(a) Directional selection shifts the overall makeup of the population by favoring variants that are at one extreme of the distribution. In this case, darker mice are favored because they live among dark rocks, and a darker fur color conceals them from predators.

(b) Disruptive selection favors variants at both ends of the distribution. These mice have colonized a patchy habitat made up of light and dark rocks, with the result that mice of an intermediate color are at a disadvantage.

(c) Stabilizing selection removes extreme variants from the population and preserves intermediate types. If the environment consists of rocks of an intermediate color, both light and dark mice will be selected against.

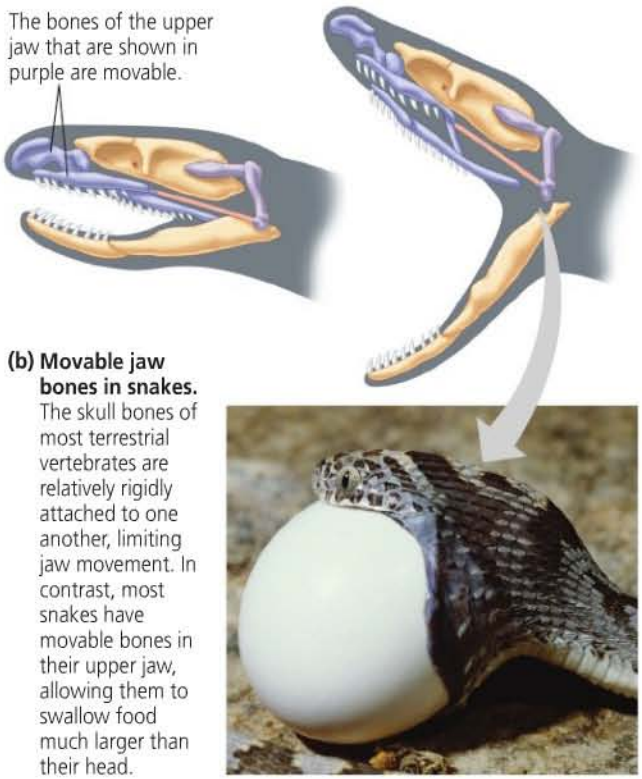
volume ratio, are better at conserving body heat and surviving periods of extreme cold.

Disruptive selection (Figure 23.13b) occurs when conditions favor individuals at both extremes of a phenotypic range over individuals with intermediate phenotypes. One example is a population of black-bellied seedcracker finches in Cameroon whose members display two distinctly different beak sizes. Small-billed birds feed mainly on soft seeds, whereas large-billed birds specialize in cracking hard seeds. It appears that birds with intermediate-sized bills are relatively inefficient at cracking both types of seeds and thus have lower relative fitness.

Stabilizing selection (Figure 23.13c) acts against both extreme phenotypes and favors intermediate variants. This mode of selection reduces variation and tends to maintain the status quo for a particular phenotypic character. For example, the birth weights of most human babies lie in the range of 3–4 kg (6.6–8.8 pounds); babies who are either much smaller or much larger suffer higher rates of mortality.

Regardless of the mode of selection, however, the basic mechanism remains the same. Selection favors individuals whose heritable phenotypic traits provide higher reproductive success than do the traits of other individuals.

The Key Role of Natural Selection in Adaptive Evolution



The adaptations of organisms include many striking examples. Consider the ability of cuttlefish to rapidly change color, enabling them to blend into different backgrounds (Figure 23.14a). Another example is the remarkable jaws of snakes (Figure 23.14b), which enable them to swallow prey much larger than their own head (a feat analogous to a person swallowing a whole watermelon). Other adaptations, such as a version of an enzyme that shows improved function in cold environments (see Figure 23.4), may be less visually dramatic but just as important for survival and reproduction.

Such adaptations can arise gradually over time as natural selection increases the frequencies of alleles that enhance survival and reproduction. As the proportion of individuals that have favorable traits increases, the match between a species and its environment improves; that is, adaptive evolution occurs. However, as we saw in Chapter 22, the physical and biological components of an organism's environment may change over time. As a result, what constitutes a "good match" between an organism and its environment can be a moving target, making adaptive evolution a continuous, dynamic process.

And what about the two other important mechanisms of evolutionary change in populations, genetic drift and gene flow? Both can, in fact, increase the frequencies of alleles that improve the match between organisms and their environment—but neither does so consistently. Genetic drift can cause the frequency of a slightly beneficial allele to increase, but it also can cause the frequency of such an allele to decrease. Similarly, gene flow may introduce alleles that are advantageous or ones that are disadvantageous. Natural selection is the only evolutionary mechanism that consistently leads to adaptive evolution.

(a) Color-changing ability in cuttlefish. In a split second, this cuttlefish can blend against its background, enabling it to hide from predators and surprise its prey.

(b) Movable jaw bones in snakes. The skull bones of most terrestrial vertebrates are relatively rigidly attached to one another, limiting jaw movement. In contrast, most snakes have movable bones in their upper jaw, allowing them to swallow food much larger than their head.

▲ **Figure 23.14 Examples of adaptations.**

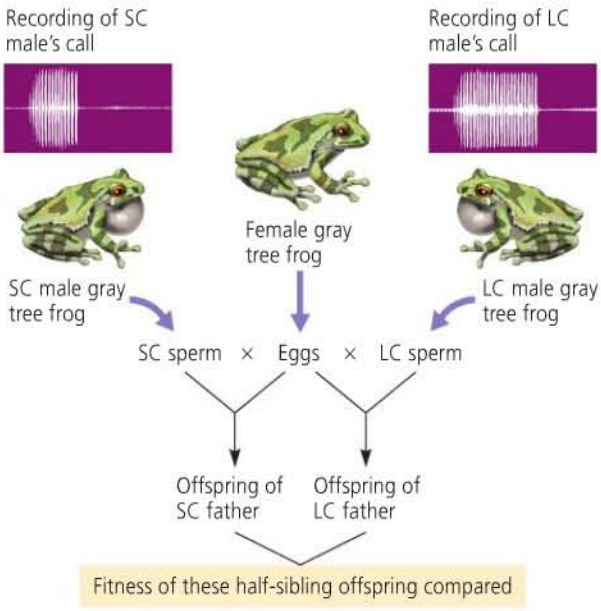
Sexual Selection

Charles Darwin was the first to explore the implications of **sexual selection**, a form of natural selection in which individuals with certain inherited characteristics are more likely than other individuals to obtain mates. Sexual selection can result in **sexual dimorphism**, marked differences between the two sexes in secondary sexual characteristics,

▲ **Figure 23.15 Sexual dimorphism and sexual selection.** Peacocks and peahens show extreme sexual dimorphism. There is intrasexual selection between competing males, followed by intersexual selection when the females choose among the showiest males.

which are not directly associated with reproduction or survival (**Figure 23.15**). These distinctions include differences in size, color, ornamentation, and behavior.

How does sexual selection operate? There are several ways. In **intrasexual selection**, meaning selection within the same sex, individuals of one sex compete directly for mates of the opposite sex. In many species, intrasexual selection occurs among males. For example, a single male may patrol a group of females and prevent other males from mating with them. The patrolling male may defend his status by defeating smaller, weaker, or less fierce males in combat. More often, this male is the psychological victor in ritualized displays that discourage would-be competitors but do not risk injury that would reduce his own fitness (see Figure 51.22). But intrasexual selection has also been observed among females in some species, including ring-tailed lemurs.



In **intersexual selection**, also called *mate choice*, individuals of one sex (usually the females) are choosy in selecting their mates from the other sex. In many cases, the female's choice depends on the showiness of the male's appearance or behavior (see Figure 23.15). What intrigued Darwin about mate choice is that male showiness may not seem adaptive in any other way and may in fact pose some risk. For example, bright plumage may make male birds more visible to predators. But if such characteristics help a male gain a mate, and if this benefit outweighs the risk from predation, then both the bright plumage and the female preference for it will be reinforced because they enhance overall reproductive success.

How do female preferences for certain male characteristics evolve in the first place? One hypothesis is that females prefer male traits that are correlated with "good genes." If the trait preferred by females is indicative of a male's overall genetic quality, both the male trait and female preference for it should increase in frequency. **Figure 23.16** describes one experiment testing this hypothesis in gray tree frogs (*Hyla versicolor*).

▼ Figure 23.16 Inquiry

Do females select mates based on traits indicative of "good genes"?

EXPERIMENT Female gray tree frogs prefer to mate with males that give long mating calls. Allison Welch and colleagues, at the University of Missouri, tested whether the genetic makeup of long-calling (LC) males is superior to that of short-calling (SC) males. The researchers fertilized half the eggs of each female with sperm from an LC male and fertilized the remaining eggs with sperm from an SC male. The resulting half-sibling offspring were raised in a common environment and tracked for two years.

RESULTS

Fitness Measure	1995	1996
Larval growth	NSD	LC better
Larval survival	LC better	NSD
Time to metamorphosis	LC better (shorter)	LC better (shorter)

NSD = no significant difference; LC better = offspring of LC males superior to offspring of SC males.

CONCLUSION Because offspring fathered by an LC male had higher fitness than their half-siblings fathered by an SC male, the team concluded that the duration of a male's mating call is indicative of the male's overall genetic quality. This result supports the hypothesis that female mate choice can be based on a trait that indicates whether the male has "good genes."

SOURCE A.M. Welch et al., Call duration as an indicator of genetic quality in male gray tree frogs, *Science* 280:1928–1930 (1998).

InquiryinAction Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers*.

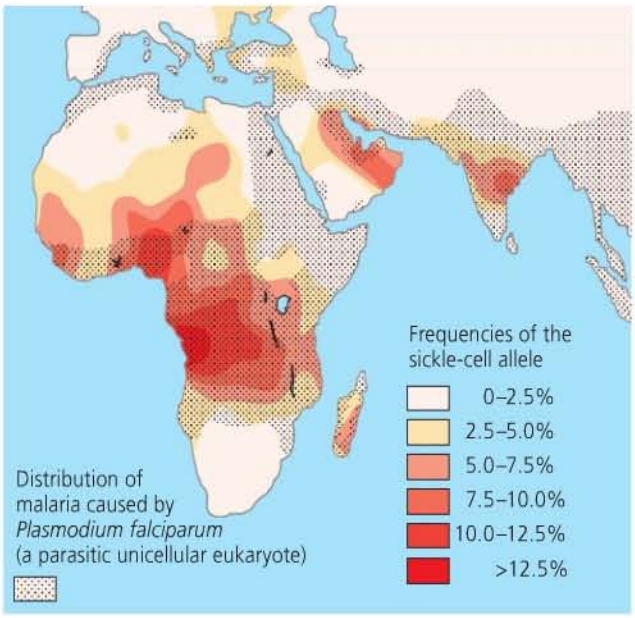
WHAT IF? Why did the researchers split each female frog's eggs into two batches for fertilization by different males? Why didn't they mate each female with a single male frog?

Other researchers have shown that in several bird species, the traits preferred by females are related to overall male health. Here, too, female preference appears to be based on traits that reflect "good genes," in this case alleles indicative of a robust immune system.

The Preservation of Genetic Variation

What prevents natural selection from reducing genetic variation by culling all unfavorable genotypes? The tendency for directional and stabilizing selection to reduce variation is countered by mechanisms that preserve or restore it.

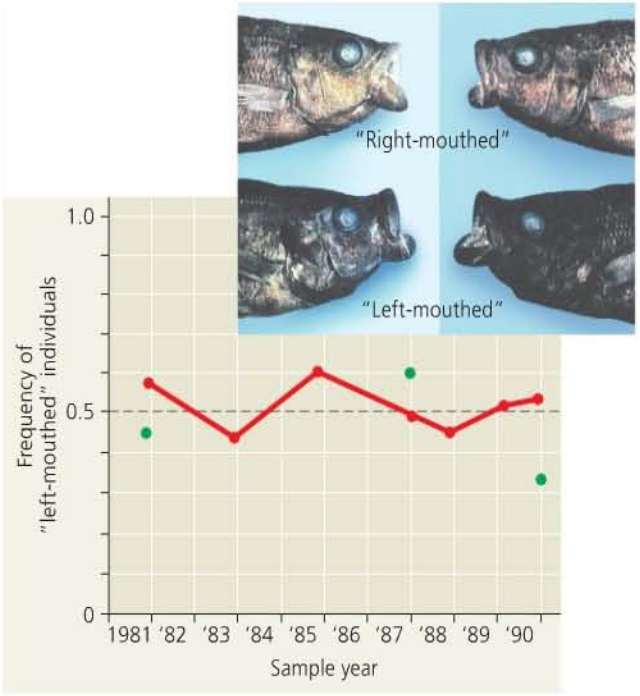
Diploidy



Because most eukaryotes are diploid, a considerable amount of genetic variation is hidden from selection in the form of recessive alleles. Recessive alleles that are less favorable than their dominant counterparts, or even harmful in the current environment, can persist by propagation in heterozygous individuals. This latent variation is exposed to natural selection only when both parents carry the same recessive allele and two copies end up in the same zygote. This happens only rarely if the frequency of the recessive allele is very low. Heterozygote protection maintains a huge pool of alleles that might not be favored under present conditions, but which could bring new benefits if the environment changes.

Balancing Selection

Selection itself may preserve variation at some loci. **Balancing selection** occurs when natural selection maintains two or more forms in a population. This type of selection includes heterozygote advantage and frequency-dependent selection.



Heterozygote Advantage If individuals who are heterozygous at a particular locus have greater fitness than do both kinds of homozygotes, they exhibit **heterozygote advantage**. In such a case, natural selection tends to maintain two or more alleles at that locus. Note that heterozygote advantage is defined in terms of *genotype*, not phenotype. Thus, whether heterozygote advantage represents stabilizing or directional selection depends on the relationship between the genotype and the phenotype. For example, if the phenotype of a heterozygote is intermediate to the phenotypes of both homozygotes, heterozygote advantage is a form of stabilizing selection.

There are relatively few well-documented examples of heterozygote advantage. One such example occurs at the locus in humans that codes for the β polypeptide subunit of hemoglobin, the oxygen-carrying protein of red blood cells. In homozygous individuals, a certain recessive allele at that locus causes sickle-cell disease. The red blood cells of people with sickle-cell disease become distorted in shape (see Figure 5.22), which can lead to serious complications, including damage to the kidney, heart, and brain. However, heterozygotes are protected against the most severe effects of malaria (although they are not resistant to malarial infection). This protection is important in tropical regions where malaria is a major killer. In such regions, selection favors heterozygotes over homozygous dominant individuals, who are more susceptible to malaria, and also over homozygous recessive individuals, who develop sickle-cell disease. The frequency of the sickle-cell allele in Africa is generally highest in areas where the malaria parasite is most common **(Figure 23.17)**. In some populations, it accounts for 20% of the hemoglobin alleles in the gene pool, a very high frequency for such a harmful allele.

▲ **Figure 23.17 Mapping malaria and the sickle-cell allele.** The sickle-cell allele is most common in Africa, but it is not the only case of heterozygote advantage providing protection against malaria. Alleles at other loci are favored by heterozygote advantage in populations near the Mediterranean Sea and in southeast Asia, where malaria is also widespread.

Frequency-Dependent Selection In **frequency-dependent selection**, the fitness of a phenotype declines if it becomes too common in the population. Consider the scale-eating fish (*Perissodus microlepis*) of Lake Tanganyika in Africa. These fish attack other fish from behind, darting in to remove a few scales from the flank of their prey. Of interest here is a peculiar feature of the scale-eating fish: Some are "left-mouthed" and some are "right-mouthed." Simple Mendelian inheritance determines these phenotypes, with the right-mouthed allele being dominant to the left-mouthed allele. Because their mouth twists to the left, left-mouthed fish always attack their prey's right flank. (To see why, twist your lower jaw and lips to the left and imagine trying to take a bite from the left side of a fish, approaching it from behind.) Similarly, right-mouthed fish always attack from the left. Prey species guard against attack from whatever phenotype of scale-eating fish is most common in the lake. Thus, from year to

▲ **Figure 23.18 Frequency-dependent selection in scale-eating fish (*Perissodus microlepis*).** Michio Hori, of Kyoto University, Japan, noted that the frequency of left-mouthed individuals rises and falls in a regular manner. At each of three time periods when the phenotypes of breeding adults were assessed, adults that reproduced (represented by green dots) had the opposite phenotype of that which was most common in the population. Thus, it appeared that right-mouthed individuals were favored by selection when left-mouthed individuals were more common, and vice versa.

? *What did the researchers measure to determine which phenotype was favored by selection? Are any assumptions implied by this choice? Explain.*

year, selection favors whichever mouth phenotype is least common. As a result, the frequency of left- and right-mouthed fish oscillates over time, and balancing selection (due to frequency dependence) keeps the frequency of each phenotype close to 50% **(Figure 23.18)**.

Neutral Variation

Much of the DNA variation in populations probably has little or no impact on reproductive success, and thus natural selection does not affect this DNA. In humans, many of the nucleotide differences in noncoding sequences appear to confer no selective advantage or disadvantage and therefore are considered **neutral variation**. Mutations that cause changes in proteins also can be neutral. Data from *Drosophila* suggest that roughly half of the amino-acid-changing mutations that arise and subsequently become fixed have little or no selective effect because they have little effect on protein function and reproductive fitness (see Figure 17.23). Over time, the frequencies of alleles that are not affected by natural selection may increase or decrease as a result of genetic drift.

Why Natural Selection Cannot Fashion Perfect Organisms

Though natural selection leads to adaptation, there are several reasons why nature abounds with examples of organisms that are less than ideally "engineered" for their lifestyles.

1. **Selection can act only on existing variations.** Natural selection favors only the fittest phenotypes among those currently in the population, which may not be the ideal traits. New advantageous alleles do not arise on demand.
2. **Evolution is limited by historical constraints.** Each species has a legacy of descent with modification from ancestral forms. Evolution does not scrap the ancestral anatomy and build each new complex structure from scratch; rather, evolution co-opts existing structures and adapts them to new situations. We could imagine that if a terrestrial animal were to adapt to an environment in which flight would be advantageous, it might be best just to grow an extra pair of limbs that would serve as wings. However, evolution does not work in this way—it operates on the traits an organism already has. Thus, in birds and bats, an existing pair of limbs took on new functions for flight as these organisms evolved from walking ancestors.
3. **Adaptations are often compromises.** Each organism must do many different things. A seal spends part of its time on rocks; it could probably walk better if it had legs instead of flippers, but then it would not swim nearly as well. We humans owe much of our versatility and athleticism to our prehensile hands and flexible limbs, but these also make us prone to sprains, torn ligaments, and dislocations: Structural reinforcement has been compromised for agility. **Figure 23.19** depicts another example of evolutionary compromise.
4. **Chance, natural selection, and the environment interact.** Chance events can affect the subsequent evolutionary history of populations. For instance, when a storm blows insects or birds hundreds of kilometers over an ocean to an island, the wind does not necessarily transport those individuals that are best suited to the new environment. Thus, not all alleles present in the founding population's gene pool are better suited to the new environment than the alleles that are "left behind." In addition, the environment at a particular location may change unpredictably from year to year, again limiting the extent to which adaptive evolution results in a close match between the organism and current environmental conditions.

With these four constraints, evolution cannot craft perfect organisms. Natural selection operates on a "better than" basis. We can, in fact, see evidence for evolution in the many imperfections of the organisms it produces.

▲ **Figure 23.19 Evolutionary compromise.** The loud call that enables a Túngara frog to attract mates also attracts more unsavory characters in the neighborhood—in this case, a bat about to seize a meal.

CONCEPT CHECK 23.4

1. What is the relative fitness of a sterile mule? Explain your answer.
2. Explain why natural selection is the only evolutionary mechanism that consistently leads to adaptive evolution.
3. **WHAT IF?** Consider a population in which heterozygotes at a certain locus have an extreme phenotype (such as being much larger than homozygotes) that also confers a selective advantage. Does such a situation represent directional, disruptive, or stabilizing selection? Explain.

For suggested answers, see Appendix A.

Chapter 23 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 23.1

Mutation and sexual reproduction produce the genetic variation that makes evolution possible (pp. 468–471)

- **Genetic Variation** Genetic variation includes variation among individuals within a population in discrete and quantitative characters, as well as geographic variation between populations.
- **Mutation** New alleles ultimately originate by mutation. Most mutations are harmful or have no effect, but a few may be beneficial.
- **Sexual Reproduction** In sexually reproducing organisms, most of the genetic differences among individuals result from crossing over, the independent assortment of chromosomes, and fertilization.

MEDIA

Activity Genetic Variation from Sexual Reproduction

CONCEPT 23.2

The Hardy-Weinberg equation can be used to test whether a population is evolving (pp. 472–475)

- **Gene Pools and Allele Frequencies** A population, a localized group of organisms belonging to one species, is united by its gene pool, the aggregate of all the alleles in the population.
- **The Hardy-Weinberg Principle** The Hardy-Weinberg principle states that the allele and genotype frequencies of a population will remain constant if the population is large, mating is random, mutation is negligible, there is no gene flow, and there is no natural selection. For such a population, if p and q represent the frequencies of the only two possible alleles at a particular locus, then p^2 is the frequency of one kind of homozygote, q^2 is the frequency of the other kind of homozygote, and $2pq$ is the frequency of the heterozygous genotype.

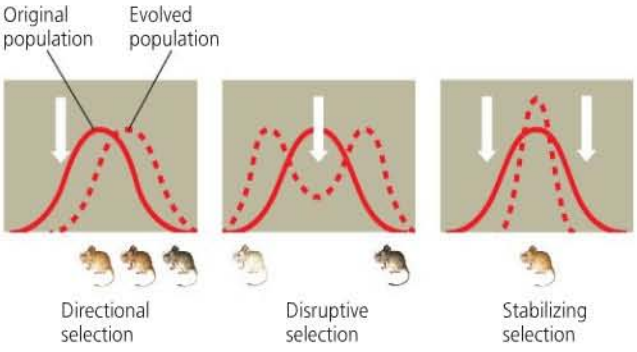
MEDIA

Investigation How Can the Frequencies of Alleles Be Calculated?

CONCEPT 23.3

Natural selection, genetic drift, and gene flow can alter allele frequencies in a population (pp. 475–479)

- **Natural Selection** Differential success in reproduction results in certain alleles being passed to the next generation in greater proportions than others.
- **Genetic Drift** Chance fluctuations in allele frequencies from generation to generation tend to reduce genetic variation.
- **Gene Flow** Genetic exchange between populations tends to reduce differences between populations over time.



MEDIA

Activity Causes of Evolutionary Change
Biology Labs On-Line PopulationGeneticsLab

CONCEPT 23.4

Natural selection is the only mechanism that consistently causes adaptive evolution (pp. 479–485)

- **A Closer Look at Natural Selection** One organism has greater fitness than another if it leaves more fertile descendants. The modes of natural selection differ in how selection acts on phenotype (arrows indicate selective pressure).

- **The Key Role of Natural Selection in Adaptive Evolution** Natural selection increases the frequencies of alleles that enhance survival and reproduction, thus improving the match between organisms and their environment.
- **Sexual Selection** Sexual selection leads to the evolution of secondary sex characteristics, which can give individuals advantages in mating.
- **The Preservation of Genetic Variation** Diploidy maintains a reservoir of concealed recessive variation in heterozygotes. Genetic variation also can be maintained by balancing selection.
- **Why Natural Selection Cannot Fashion Perfect Organisms** Natural selection can act only on available variation; structures result from modified ancestral anatomy; adaptations are often compromises; and chance, natural selection, and the environment interact.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. A fruit fly population has a gene with two alleles, *A1* and *A2*. Tests show that 70% of the gametes produced in the population contain the *A1* allele. If the population is in Hardy-Weinberg equilibrium, what proportion of the flies carry both *A1* and *A2*?
   a. 0.7 b. 0.49 c. 0.21 d. 0.42 e. 0.09

2. There are 40 individuals in population 1, all of which have genotype *A1A1*, and there are 25 individuals in population 2, all of genotype *A2A2*. Assume that these populations are located far from one another and that their environmental conditions are very similar. Based on the information given here, the observed genetic variation is mostly likely an example of
   a. genetic drift.
   b. gene flow.
   c. disruptive selection.
   d. discrete variation.
   e. directional selection.

3. Natural selection changes allele frequencies because some _____ survive and reproduce more successfully than others.
   a. alleles c. gene pools e. individuals
   b. loci d. species

4. No two people are genetically identical, except for identical twins. The chief cause of genetic variation among human individuals is
   a. new mutations that occurred in the preceding generation.
   b. the reshuffling of alleles in sexual reproduction.
   c. genetic drift due to the small size of the population.
   d. geographic variation within the population.
   e. environmental effects.

5. Sparrows with average-sized wings survive severe storms better than those with longer or shorter wings, illustrating
   a. the bottleneck effect.
   b. stabilizing selection.
   c. frequency-dependent selection.
   d. neutral variation.
   e. disruptive selection.

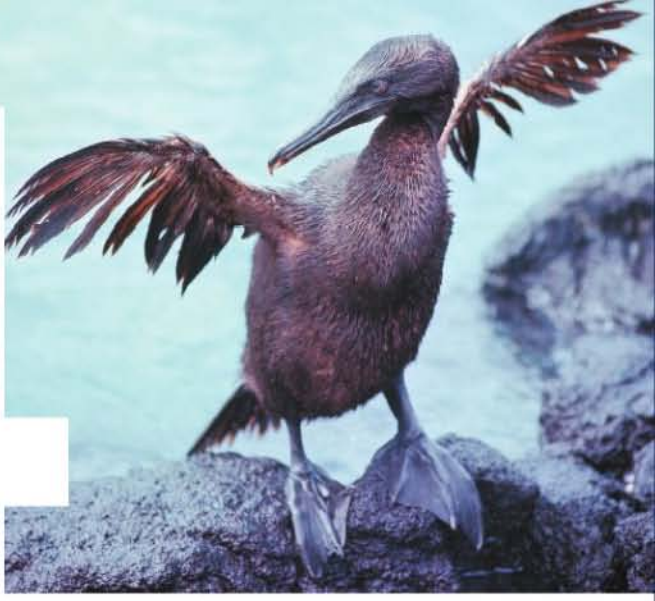
EVOLUTION CONNECTION

6. How is the process of evolution revealed by the imperfections of living organisms?

SCIENTIFIC INQUIRY

7. **DRAW IT** Richard Koehn, of the State University of New York, Stony Brook, and Thomas Hilbish, of the University of South Carolina, studied genetic variation in the marine mussel *Mytilus edulis* around Long Island, New York. They measured the frequency of a particular allele (lap^{94}) for an enzyme involved in regulating the mussel's internal salt-water balance. The researchers presented their data as a series of pie charts linked to sampling sites within Long Island Sound, where the salinity is highly variable, and along the coast of the open ocean, where salinity is constant:



Create a data table for the 11 sampling sites by estimating the frequency of lap^{94} from the pie charts. (*Hint*: Think of each pie chart as a clock face to help you estimate the proportion of the shaded area.) Then graph the frequencies for sites 1–8 to show how the frequency of this allele changes with increasing salinity in Long Island Sound (from southwest to northeast). How do the data from sites 9–11 compare with the data from the sites within the Sound?

Construct a hypothesis that explains the patterns you observe in the data and that accounts for the following observations: (1) the lap^{94} allele helps mussels maintain osmotic balance in water with a high salt concentration but is costly to use in less salty water; and (2) mussels produce larvae that can disperse long distances before they settle on rocks and grow into adults.

SCIENCE, TECHNOLOGY, AND SOCIETY

8. To what extent are humans who live in a technological society exempt from natural selection? Justify your answer.

24 The Origin of Species

▲ **Figure 24.1 How did this flightless bird come to live on the isolated Galápagos Islands?**

KEY CONCEPTS

24.1 The biological species concept emphasizes reproductive isolation

24.2 Speciation can take place with or without geographic separation

24.3 Hybrid zones provide opportunities to study factors that cause reproductive isolation

24.4 Speciation can occur rapidly or slowly and can result from changes in few or many genes

OVERVIEW

That "Mystery of Mysteries"

Darwin came to the Galápagos Islands eager to explore landforms newly emerged from the sea. He noted that these volcanic islands, despite their geologic youth, were teeming with plants and animals found nowhere else in the world **(Figure 24.1)**. Later he realized that these species, like the islands, were relatively new. He wrote in his diary: "Both in space and time, we seem to be brought somewhat near to that great fact—that mystery of mysteries—the first appearance of new beings on this Earth."

The "mystery of mysteries" that captivated Darwin is **speciation**, the process by which one species splits into two or more species. Speciation fascinated Darwin (and many biologists since) because it is responsible for the tremendous diversity of life, repeatedly yielding new species that differ from existing ones. Speciation explains not only differences between species, but also similarities between them (the unity of life). When one species splits, the species that result share many characteristics because they are descended from this common ancestral species. For example, DNA similarities indicate that the flightless cormorant (*Phalacrocorax harrisi*) in Figure 24.1 is closely related to flying cormorant species found on the west coast of the Americas. This suggests that the flightless cormorant may have originated from an ancestral cormorant species that migrated from the mainland to the Galápagos.

Speciation also forms a conceptual bridge between **microevolution**, changes over time in allele frequencies in a population, and **macroevolution**, the broad pattern of evolution over long time spans. An example of macroevolutionary change is the origin of new groups of organisms, such as mammals or flowering plants, through a series of speciation events. We examined microevolutionary mechanisms (mutation, natural selection, genetic drift, and gene flow) in Chapter 23, and we'll turn to macroevolution in Chapter 25. In this chapter, we will explore the "bridge"—the mechanisms by which new species originate from existing ones. First, however, we need to establish what we actually mean when we talk about "species."

CONCEPT 24.1

The biological species concept emphasizes reproductive isolation

The word *species* is Latin for "kind" or "appearance." In daily life, we commonly distinguish between various "kinds" of organisms—dogs and cats, for instance—from differences in their appearance. But are organisms truly divided into the discrete units we call species, or is this classification an arbitrary attempt to impose order on the natural world? To answer this question, biologists compare not only the morphology (body form) of different groups of organisms but also less obvious differences in physiology, biochemistry, and DNA sequences. The results generally confirm that morphologically distinct species are indeed discrete groups, with many differences in addition to morphological ones.

The Biological Species Concept

The primary definition of species used in this textbook is referred to as the **biological species concept**. According to this concept, as described in 1942 by biologist Ernst Mayr, a **species** is a group of populations whose members have the potential to interbreed in nature and produce viable, fertile offspring—but do not produce viable, fertile offspring with members of other such groups **(Figure 24.2)**. Thus, the members of a biological species are united by being reproductively compatible, at least potentially. All human beings, for example, belong to the same species. A businesswoman in Manhattan may be unlikely to meet a dairy farmer in Mongolia, but if the two should happen to meet and mate, they could have viable babies that develop into fertile adults. In contrast, humans and chimpanzees remain distinct biological species even where they share territory, because many factors keep them from interbreeding and producing fertile offspring.

(a) Similarity between different species. The eastern meadowlark (*Sturnella magna*, left) and the western meadowlark (*Sturnella neglecta*, right) have similar body shapes and colorations. Nevertheless, they are distinct biological species because their songs and other behaviors are different enough to prevent interbreeding should they meet in the wild.

(b) Diversity within a species. As diverse as we may be in appearance, all humans belong to a single biological species (*Homo sapiens*), defined by our capacity to interbreed.

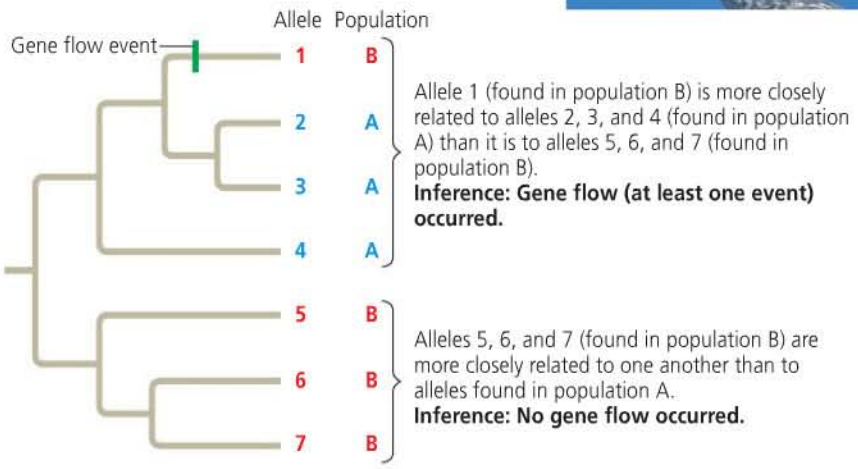
▲ Figure 24.2 The biological species concept is based on the potential to interbreed rather than on physical similarity.

What holds the gene pool of a species together, causing its members to resemble each other more than they resemble other species? To answer this question, we need to reconsider an evolutionary mechanism discussed in Chapter 23: *gene flow*, the transfer of alleles between populations. Members of a species often resemble each other because their populations are connected by gene flow. As you might expect, populations located near one another exchange alleles relatively often. But what about populations separated by long distances? Evolutionary biologist Scott Edwards, interviewed on pages 450–451, examined this question for the grey-crowned babbler, *Pomatostomus temporalis* **(Figure 24.3)**. His results showed that a low level of gene flow occurred between even widely separated populations. Similar results have been found for other animal species, as well as for various fungi and plants. Such results illustrate that gene flow has the potential to hold the gene pool of a species together, so long as it is not outweighed by effects of selection or drift (either of which can result in populations diverging). As we'll explore in the next section, gene flow also plays a key role in the formation of new species.

Reproductive Isolation

Because biological species are defined in terms of reproductive compatibility, the formation of a new species hinges on **reproductive isolation**—the existence of biological factors (barriers) that impede members of two species from producing viable, fertile offspring. Such barriers block gene flow between the species and limit the formation of **hybrids**, offspring that result from an interspecific mating. Although a single barrier may not prevent all gene flow, a combination of several barriers can effectively isolate a species' gene pool.

Clearly, a fly cannot mate with a frog or a fern, but the reproductive barriers between more closely related species are not so obvious. These barriers can be classified according to whether they contribute to reproductive isolation before or after fertilization. **Prezygotic barriers** ("before the zygote") block fertilization from occurring. Such barriers typically act in one of three ways: by impeding members of different species from attempting to mate, by preventing an attempted mating from being completed successfully, or by hindering fertilization if mating is completed successfully. If a sperm cell from one species overcomes prezygotic barriers and fertilizes an ovum from another species, a variety of **postzygotic barriers** ("after the zygote") may contribute to reproductive isolation



▼ Figure 24.3 Inquiry

Does gene flow occur between widely separated populations?

EXPERIMENT In many species, individuals disperse only short distances from their parent population. Can gene flow unify the gene pool of a species with widespread populations? Scott Edwards, then at the University of California, Berkeley, studied gene flow in a bird thought to disperse only short distances, the grey-crowned babbler (*Pomatostomus temporalis*). Edwards sequenced a segment of DNA from birds in 12 widely separated populations (named populations A–L) located throughout Australia and Papua New Guinea. He used these data to construct *gene trees*, evolutionary trees showing patterns of relatedness among the alleles at the locus he studied. If a gene tree showed that some birds in one population had an allele that shared a recent common ancestor with alleles found in a different population, Edwards reasoned that gene flow must have occurred between those populations (see the example tree at right). In this way, Edwards analyzed allele relatedness for various combinations of the 12 study populations.

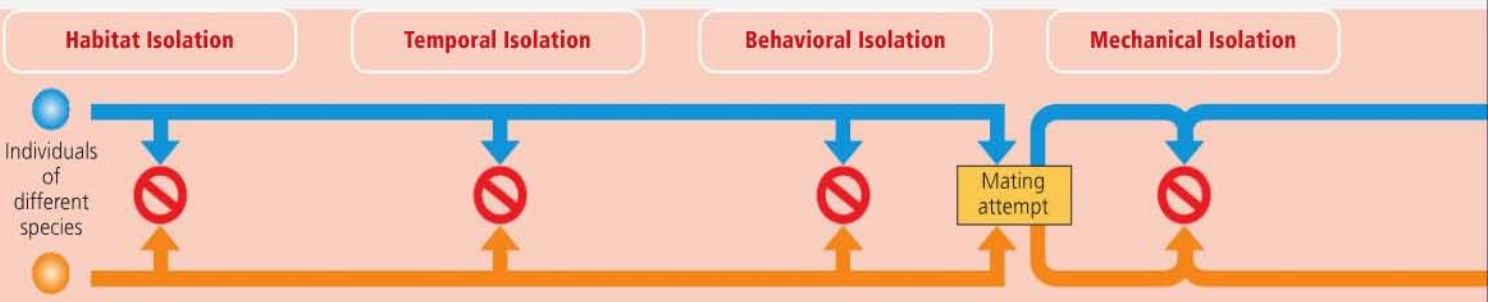
▼ Example of a gene tree for population pair A-B

RESULTS Among the 12 study populations, Edwards inferred that gene flow occurred in 7 population pairs.

Pair of populations with detected gene flow	Estimated minimum number of gene flow events to account for genetic patterns	Distance between populations (km)
A-B	5	340
K-L	3	720
A-C	2–3	1,390
B-C	2	1,190
F-G	2	760
G-I	2	1,110
C-E	1–2	1,310

CONCLUSION Because gene flow was detected between populations separated by over 1,000 km, Edwards concluded that gene flow can potentially hold the grey-crowned babbler gene pool together even though individuals were thought to disperse only short distances. The long-distance movement of alleles could result from a series of shorter movements by individual birds, or from chance events such as a storm that transports birds to a distant location.

SOURCE S. V. Edwards, Long-distance gene flow in a cooperative breeder detected in genealogies of mitochondrial DNA sequences, *Proceedings of the Royal Society of London, Series B, Biological Sciences* 252:177–185 (1993).



WHAT IF? Do the data indicate that the gene flow event shown on the tree occurred as the transfer of an allele from population A to population B, or the reverse? Explain.

after the hybrid zygote is formed. For example, developmental errors may reduce survival among hybrid embryos. Or problems after birth may cause hybrids to be infertile or may decrease their chance of surviving long enough to reproduce. **Figure 24.4**, on the next two pages, describes prezygotic and postzygotic barriers in more detail.

▼ Figure 24.4

Exploring Reproductive Barriers

Prezygotic barriers impede mating or hinder fertilization if mating does occur

Habitat Isolation

Two species that occupy different habitats within the same area may encounter each other rarely, if at all, even though they are not isolated by obvious physical barriers, such as mountain ranges.

Example: Two species of garter snakes in the genus *Thamnophis* occur in the same geographic areas, but one lives mainly in water (a) while the other is primarily terrestrial (b).

Temporal Isolation

Species that breed during different times of the day, different seasons, or different years cannot mix their gametes.

Example: In North America, the geographic ranges of the eastern spotted skunk (*Spilogale putorius*) (c) and the western spotted skunk (*Spilogale gracilis*) (d) overlap, but *S. putorius* mates in late winter and *S. gracilis* mates in late summer.

Behavioral Isolation

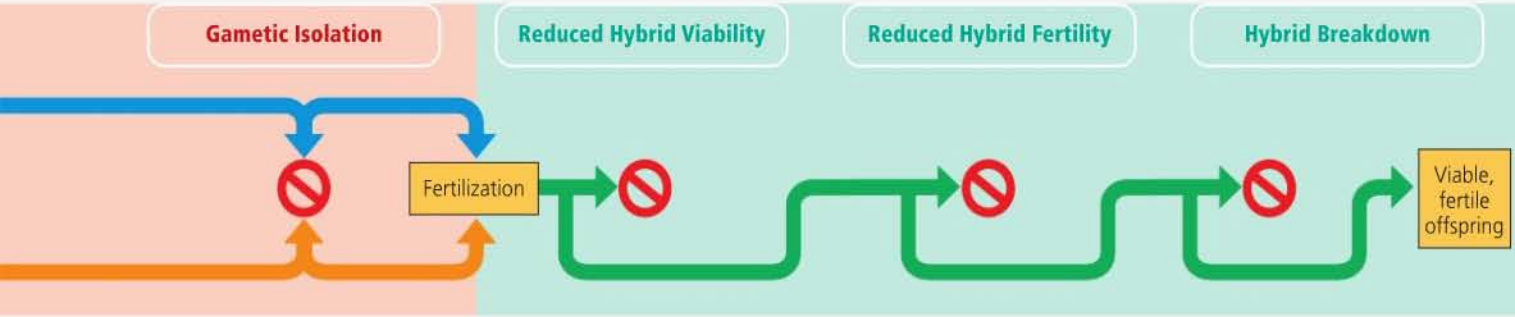
Courtship rituals that attract mates and other behaviors unique to a species are effective reproductive barriers, even between closely related species. Such behavioral rituals enable *mate recognition*—a way to identify potential mates of the same species.

Example: Blue-footed boobies, inhabitants of the Galápagos, mate only after a courtship display unique to their species. Part of the "script" calls for the male to high-step (e), a behavior that calls the female's attention to his bright blue feet.

Mechanical Isolation

Mating is attempted, but morphological differences prevent its successful completion.

Example: The shells of two species of snails in the genus *Bradybaena* spiral in different directions: Moving inward to the center, one spirals in a counter-clockwise direction (f, left), the other in a clockwise direction (f, right). As a result, the snails' genital openings (indicated by arrows) are not aligned, and mating cannot be completed.



Postzygotic barriers prevent a hybrid zygote from developing into a viable, fertile adult

Sperm of one species may not be able to fertilize the eggs of another species. For instance, sperm may not be able to survive in the reproductive tract of females of the other species, or biochemical mechanisms may prevent the sperm from penetrating the membrane surrounding the other species' eggs.

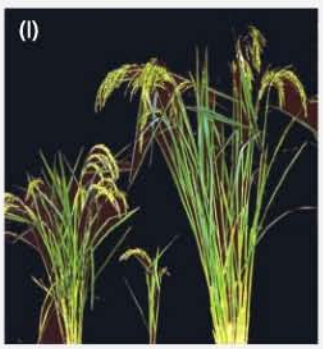
Example: Gametic isolation separates certain closely related species of aquatic animals, such as sea urchins (g). Sea urchins release their sperm and eggs into the surrounding water, where they fuse and form zygotes. Gametes of different species, such as the red and purple urchins shown here, are unable to fuse because proteins on the surfaces of the eggs and sperm cannot bind to each other.

The genes of different parent species may interact in ways that impair the hybrid's development or survival in its environment.

Example: Some salamander subspecies of the genus *Ensatina* live in the same regions and habitats, where they may occasionally hybridize. But most of the hybrids do not complete development, and those that do are frail (h).

Even if hybrids are vigorous, they may be sterile. If the chromosomes of the two parent species differ in number or structure, meiosis in the hybrids may fail to produce normal gametes. Since the infertile hybrids cannot produce offspring when they mate with either parent species, genes cannot flow freely between the species.

Example: The hybrid offspring of a donkey (i) and a horse (j) is a mule (k), which is robust but sterile.



Some first-generation hybrids are viable and fertile, but when they mate with one another or with either parent species, offspring of the next generation are feeble or sterile.

Example: Strains of cultivated rice have accumulated different mutant recessive alleles at two loci in the course of their divergence from a common ancestor. Hybrids between them are vigorous and fertile (l, left and right), but plants in the next generation that carry too many of these recessive alleles are small and sterile (l, center). Although these rice strains are not yet considered different species, they have begun to be separated by postzygotic barriers.

Limitations of the Biological Species Concept

One strength of the biological species concept is that it directs our attention to how speciation occurs: by the evolution of reproductive isolation. However, the number of species to which this concept can be usefully applied is limited. There is, for example, no way to evaluate the reproductive isolation of fossils. The biological species concept also does not apply to organisms that reproduce asexually all or most of the time, such as prokaryotes. (Many prokaryotes do transfer genes among themselves, as we will discuss in Chapter 27, but this is not part of their reproductive process.) Furthermore, in the biological species concept, species are designated by the *absence* of gene flow. There are, however, many pairs of species that are morphologically and ecologically distinct, and yet gene flow occurs between them. As we'll see, natural selection can cause such species to remain distinct despite gene flow. This observation has led some researchers to argue that the biological species concept overemphasizes gene flow and downplays the role of natural selection. Because of the limitations to the biological species concept, alternative species concepts are useful in certain situations.

Other Definitions of Species

While the biological species concept emphasizes the *separateness* of species from one another due to reproductive barriers, several other definitions emphasize the *unity within* a species. For example, the **morphological species concept** characterizes a species by body shape and other structural features. The morphological species concept has several advantages. It can be applied to asexual and sexual organisms, and it can be useful even without information on the extent of gene flow. In practice, this is how scientists distinguish most species. One disadvantage, however, is that this definition relies on subjective criteria; researchers may disagree on which structural features distinguish a species.

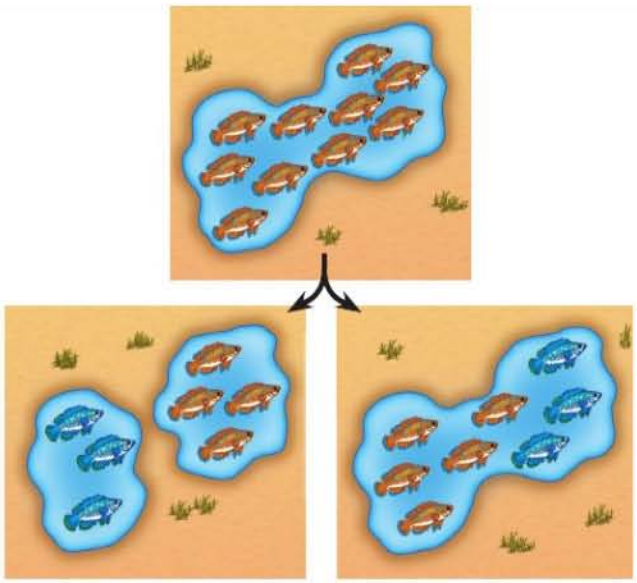
The **ecological species concept** views a species in terms of its ecological niche, the sum of how members of the species interact with the nonliving and living parts of their environment (see Chapter 54). For example, two species of amphibians might be similar in appearance but differ in the foods they eat or in their ability to tolerate dry conditions. Unlike the biological species concept, the ecological species concept can accommodate asexual as well as sexual species; it also emphasizes the role of disruptive natural selection as organisms adapt to different environmental conditions.

The **phylogenetic species concept** defines a species as the smallest group of individuals that share a common ancestor, forming one branch on the tree of life. Biologists trace the phylogenetic history of a species by comparing its characteristics, such as morphology or molecular sequences, with those of other organisms. Such analyses can distinguish groups of individuals that are sufficiently different to be considered separate species. Of course, the difficulty with this species concept is determining the degree of difference required to indicate separate species.

In addition to those discussed here, more than 20 other species definitions have been proposed. The usefulness of each definition depends on the situation and the research questions being asked. For our purposes of studying how species originate, the biological species concept, with its focus on reproductive barriers, is particularly helpful.

CONCEPT CHECK 24.1

1. (a) Which species concept(s) could you apply to both asexual and sexual species? (b) Which would be most useful for identifying species in the field? Explain.
2. **WHAT IF?** Suppose you are studying two bird species that live in a forest and are not known to interbreed. One species feeds and mates in the treetops and the other on the ground. But in captivity, the birds can interbreed and produce viable, fertile offspring. What type of reproductive barrier most likely keeps these species separate in nature? Explain.



For suggested answers, see Appendix A.

CONCEPT 24.2
Speciation can take place with or without geographic separation

Now that we have a clearer sense of what constitutes a unique species, let's return to our discussion of the process by which such species arise from existing species. Speciation can occur in two main ways, depending on how gene flow is interrupted between populations of the existing species **(Figure 24.5)**.

Allopatric ("Other Country") Speciation

In **allopatric speciation** (from the Greek *allos,* other, and *patra,* homeland), gene flow is interrupted when a population is divided into geographically isolated subpopulations. For example, the water level in a lake may subside, resulting in two or more smaller lakes that are now home to separated populations (see Figure 24.5a). Or a river may change course and divide a population of animals that cannot cross it. Allopatric speciation can also occur without geologic remodeling, such as when individuals colonize a remote area and their descendants become geographically isolated from the parent population. The flightless cormorant shown in Figure 24.1 likely originated in this way from an ancestral flying species that migrated to the Galápagos Islands.

(a) Allopatric speciation. A population forms a new species while geographically isolated from its parent population.

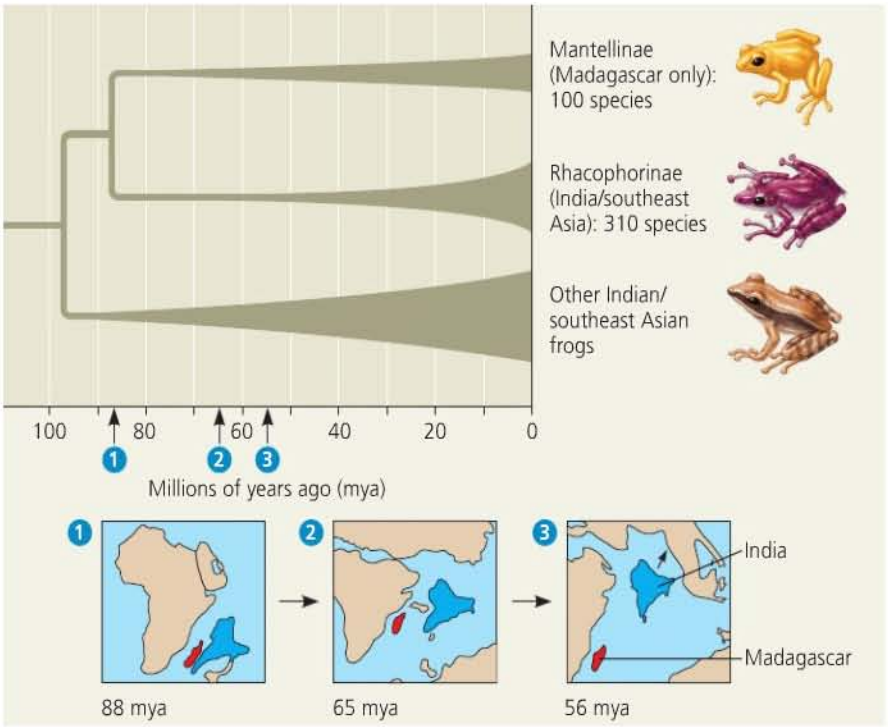
(b) Sympatric speciation. A small population becomes a new species without geographic separation.

▲ **Figure 24.5 Two main modes of speciation.**

The Process of Allopatric Speciation

How formidable must a geographic barrier be to promote allopatric speciation? The answer depends on the ability of the organisms to move about. Birds, mountain lions, and coyotes can cross rivers and canyons. Nor do such barriers hinder the windblown pollen of pine trees or the seeds of many flowering plants. In contrast, small rodents may find a wide river or a deep canyon a formidable barrier **(Figure 24.6)**.

Once geographic separation has occurred, the separated gene pools may diverge through the mechanisms described in Chapter 23. Different mutations arise, natural selection acts on the separated organisms, and genetic drift alters allele frequencies. Reproductive isolation may then arise as a by-product of selection or drift having caused the populations to diverge genetically. For example, in the monkey flower *Mimulus guttatus*, selection has favored the evolution of copper tolerance in populations living near copper mines. Soil copper concentrations in these areas can reach levels that are lethal to nontolerant individuals. When members of copper-tolerant *M. guttatus* populations interbreed with individuals from other populations, the offspring survive poorly. Genetic analyses have shown that the gene for copper tolerance or an allele genetically linked to the copper-tolerance gene is responsible for the poor survival of the hybrid offspring. Thus, selection for copper tolerance appears to have had an important but coincidental side effect: partial reproductive isolation between *M. guttatus* populations.

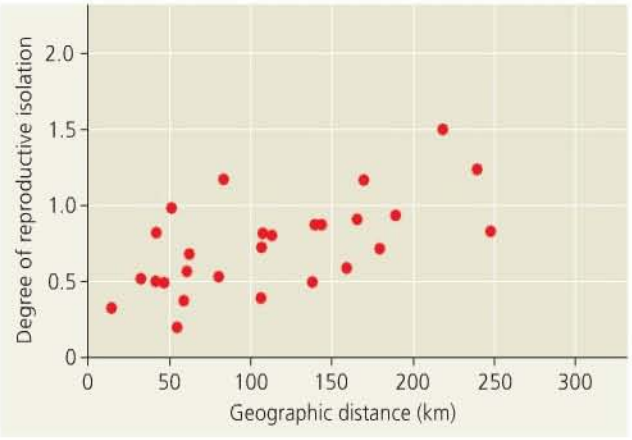


The gene pools of highly isolated populations (such as those on remote islands) experience very little gene flow and hence are particularly likely to undergo allopatric speciation. For example, in less than 2 million years, the few animals and plants from the South and North American mainlands that colonized the Galápagos Islands gave rise to all the new species now found there.

Evidence of Allopatric Speciation

Many studies provide evidence that speciation can occur in allopatric populations. For example, biogeographic and genetic data together suggest that two present-day groups of frog species, the subfamilies Mantellinae and Rhacophorinae, began to diverge about 88 million years ago, when what is now the island of Madagascar started to separate from the Indian landmass. It appears that these two frog groups shared a common ancestor that lived on the Madagascar-India landmass

▲ **Figure 24.6 Allopatric speciation of antelope squirrels on opposite rims of the Grand Canyon.** Harris's antelope squirrel (*Ammospermophilus harrisi*) inhabits the canyon's south rim (left). Just a few kilometers away on the north rim (right) lives the closely related white-tailed antelope squirrel (*Ammospermophilus leucurus*). In contrast, birds and other organisms that can disperse easily across the canyon have not diverged into different species on the two rims.



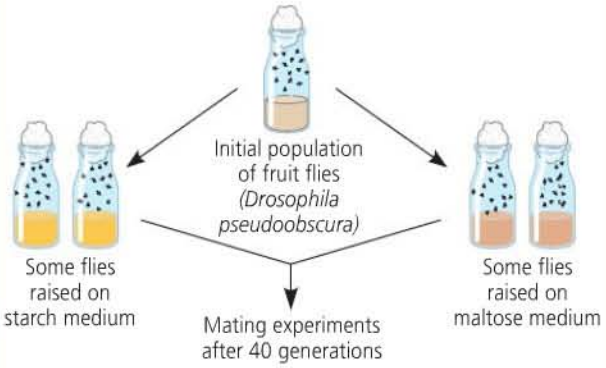
▶ **Figure 24.7 Allopatric speciation in frogs.** The frog subfamilies Mantellinae and Rhacophorinae diverged when present-day Madagascar separated from India. The maps show the movement of Madagascar (red) and India (blue) over time.

before it began to break apart **(Figure 24.7)**. Following the breakup, allopatric speciation occurred within the separated populations of this common ancestor. The result was the formation of many new species in each location.

The importance of allopatric speciation is also suggested by the fact that regions that are highly subdivided by geographic barriers typically have more species than do regions with fewer barriers. For example, an unusually large number of bird species are found in the mountainous regions of New Guinea, and many unique plants and animals are found on the geographically isolated Hawaiian Islands (we'll return to the origin of Hawaiian species in Chapter 25).

Laboratory and field tests also provide evidence that reproductive isolation between two populations generally increases as the distance between them increases. In one such study of dusky salamanders (*Desmognathus ochrophaeus*), biologists brought individuals from different populations into the laboratory and tested their ability to produce viable, fertile offspring **(Figure 24.8)**. The researchers observed little reproductive isolation in salamanders from neighboring populations. In contrast, salamanders from widely separated populations often failed to reproduce. One possible explanation for these results is that long-distance gene flow is not occurring between the dusky salamander populations (unlike the grey-crowned babblers studied by Scott Edwards). Alternatively, long-distance gene flow between the salamander populations may be outweighed by the effects of natural selection or genetic drift, either of which can cause the populations to diverge. In other studies, researchers have tested whether intrinsic reproductive barriers develop when populations are isolated experimentally and subjected to different environmental conditions. In such cases, too, the results provide strong support for allopatric speciation (**Figure 24.9**, on the facing page).

We need to emphasize here that although geographic isolation prevents interbreeding between allopatric populations, separation itself is not a biological barrier to reproduction. Biological reproductive barriers such as those described in Figure 24.4 are intrinsic to the organisms themselves. Hence, these barriers can prevent interbreeding when members of different populations come into contact with one another.



▲ **Figure 24.8 Variation in reproductive isolation with distance between populations of dusky salamanders.** The degree of reproductive isolation is represented here by an index ranging from 0 (no isolation) to 2 (complete isolation).

▼ Figure 24.9 Inquiry

Can divergence of allopatric populations lead to reproductive isolation?

EXPERIMENT Diane Dodd, then at Yale University, divided a fruit fly population, raising some flies on a starch medium and others on a maltose medium. After one year (about 40 generations), natural selection resulted in divergent evolution: Populations raised on starch digested starch more efficiently, while those raised on maltose digested maltose more efficiently. Dodd then put flies from the same or different populations in mating cages and measured mating frequencies.

RESULTS When flies from "starch populations" were mixed with flies from "maltose populations," the flies tended to mate with like partners. But in the control group shown here, flies from different populations adapted to starch were about as likely to mate with each other as with flies from their own population; similar results were obtained for control groups adapted to maltose.

Mating frequencies in experimental group

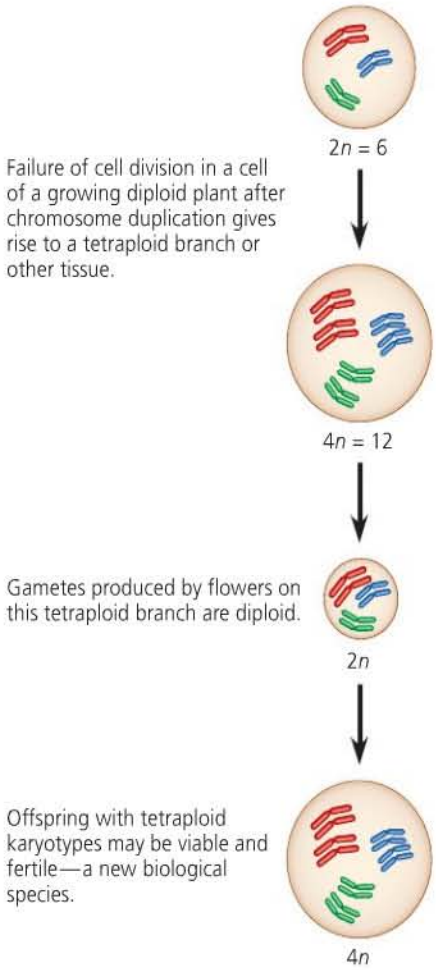
Male \ Female	Starch	Maltose
Starch	22	9
Maltose	8	20

Mating frequencies in control group

Male \ Female	Starch population 1	Starch population 2
Starch population 1	18	15
Starch population 2	12	15

CONCLUSION In the experimental group, the strong preference of "starch flies" and "maltose flies" to mate with like-adapted flies indicates that a reproductive barrier was forming between the divergent populations of flies. Although the barrier was not absolute (some mating between starch flies and maltose flies did occur), after 40 generations it appeared to be under way, the result of differing selective pressures as these allopatric populations adapted to different environments.

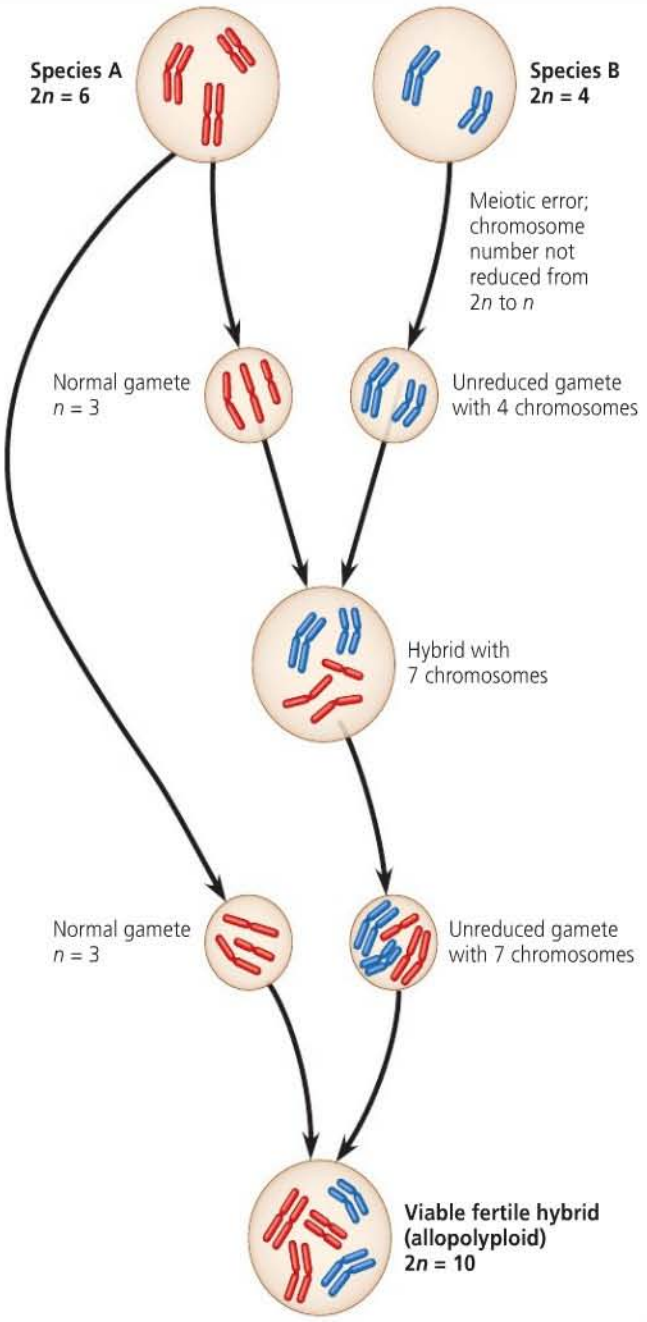
SOURCE D. M. B. Dodd, Reproductive isolation as a consequence of adaptive divergence in *Drosophila pseudoobscura*, *Evolution* 43:1308–1311 (1989).



WHAT IF? How would the results have changed if in each generation a few flies from the starch population had been placed in the maltose population and vice versa? Explain your prediction.

Sympatric ("Same Country") Speciation

In **sympatric speciation** (from the Greek *syn*, together), speciation occurs in populations that live in the same geographic area. How can reproductive barriers form between sympatric populations while their members remain in contact with each other? Although such contact (and the ongoing gene flow that results) makes sympatric speciation less common than allopatric speciation, sympatric speciation can occur if gene flow is reduced by such factors as polyploidy, habitat differentiation, and sexual selection. (Note that these factors can also promote allopatric speciation.)



Polyploidy

A species may originate from an accident during cell division that results in extra sets of chromosomes, a condition called **polyploidy**. There are two distinct forms of polyploidy. An **autopolyploid** (from the Greek *autos*, self) is an individual that has more than two chromosome sets that are all derived from a single species. For example, a failure of cell division could double a cell's chromosome number from the diploid number ($2n$) to a tetraploid number ($4n$) **(Figure 24.10)**. This mutation

▲ **Figure 24.10 Sympatric speciation by autopolyploidy in plants.**

causes the tetraploid to be reproductively isolated from diploid plants of the original population, because the triploid ($3n$) offspring of such unions have reduced fertility. However, the tetraploid plants can produce fertile tetraploid offspring by self-pollinating or by mating with other tetraploids. Thus, in just one generation, autopolyploidy can generate reproductive isolation without any geographic separation.

▲ **Figure 24.11 One mechanism for allopolyploid speciation in plants.** Most hybrids are sterile because their chromosomes are not homologous and cannot pair during meiosis. However, such a hybrid may be able to reproduce asexually. This diagram traces one mechanism that can produce fertile hybrids (allopolyploids) as new species. The new species has a diploid chromosome number equal to the sum of the diploid chromosome numbers of the two parent species.

A second form of polyploidy can occur when two different species interbreed and produce hybrid offspring. Most hybrids are sterile because the set of chromosomes from one species cannot pair during meiosis with the set of chromosomes from the other species. However, an infertile hybrid may be able to propagate itself asexually (as many plants can do). In subsequent generations, various mechanisms can change a sterile hybrid into a fertile polyploid called an **allopolyploid** (Figure 24.11). The allopolyploids are fertile when mating with each other but cannot interbreed with either parent species; thus, they represent a new biological species.

Polyploid speciation occasionally occurs in animals; for example, the gray tree frog *Hyla versicolor* (see Figure 23.16) is thought to have originated in this way. However, polyploidy is far more common in plants. Botanists estimate that more than 80% of the plant species alive today are descended from ancestors that formed by polyploid speciation. One documented example involves two new species of goatsbeard plants (genus *Tragopogon)* that originated in the Pacific Northwest in the mid-1900s. *Tragopogon* first arrived in the region when humans introduced three European species in the early 1900s. These species, *T. dubius*, *T. pratensis*, and *T. porrifolius*, are now common weeds in abandoned parking lots and other urban sites. In the 1950s, botanists identified two new *Tragopogon* species in regions of Idaho and Washington, where all three European species are also found. One new species, *T. miscellus*, is a tetraploid hybrid of *T. dubius* and *T. pratensis*; the other new species, *T. mirus*, is also an allopolyploid, but its ancestors are *T. dubius* and *T. porrifolius.* Although the *T. mirus* population grows mainly by reproduction of its own members, additional episodes of hybridization between the parent species continue to add new members to the *T. mirus* population—just one example of an ongoing speciation process that can be observed.

Many important agricultural crops—such as oats, cotton, potatoes, tobacco, and wheat—are polyploids. The wheat used for bread, *Triticum aestivum*, is an allohexaploid (six sets of chromosomes, two sets from each of three different species). The first of the polyploidy events that eventually led to modern wheat probably occurred about 8,000 years ago in the Middle East as a spontaneous hybrid of an early cultivated wheat species and a wild grass. Today, plant geneticists generate new polyploids in the laboratory by using chemicals that induce meiotic and mitotic errors. By harnessing the evolutionary process, researchers can produce new hybrid species with desired qualities, such as a hybrid that combines the high yield of wheat with the hardiness of rye.

Habitat Differentiation

Sympatric speciation can also occur when genetic factors enable a subpopulation to exploit a habitat or resource not used by the

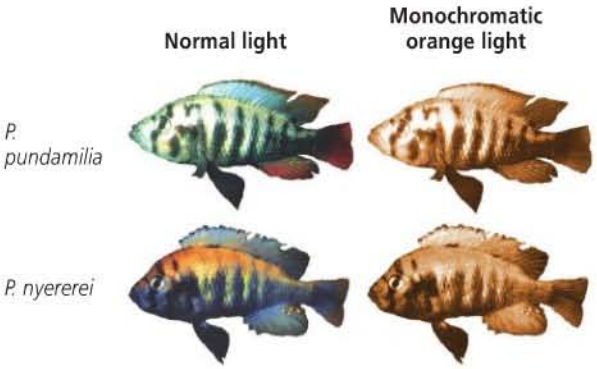
parent population. Such is the case with the North American apple maggot fly (*Rhagoletis pomonella*). The fly's original habitat was the native hawthorn tree, but about 200 years ago, some populations colonized apple trees that had been introduced by European settlers. As apples mature more quickly than hawthorn fruit, natural selection has favored apple-feeding flies with rapid development. These apple-feeding populations now show temporal isolation from the hawthorn-feeding *R. pomonella*, providing a prezygotic restriction to gene flow between the two populations. Researchers also have identified alleles that benefit the flies that use one host plant but harm the flies that use the other host plant. As a result, natural selection operating on these alleles provides a postzygotic barrier to reproduction, further limiting gene flow. Altogether, although the two populations are still classified as subspecies rather than separate species, sympatric speciation appears to be well under way.

Sexual Selection

There is evidence that sympatric speciation can also be driven by sexual selection. Clues to how this can occur have been found in cichlid fish from one of Earth's hot spots of animal speciation, East Africa's Lake Victoria. This lake was once home to as many as 600 species of cichlids. Genetic data indicate that these species originated within the last 100,000 years from a small number of colonist species that arrived from rivers and lakes located elsewhere. How did so many species—more than double the number of freshwater fish species known in all of Europe—originate within a single lake?

One hypothesis is that subgroups of the original cichlid populations adapted to different food sources and that the resulting genetic divergence contributed to speciation in Lake Victoria. But sexual selection, in which (typically) females select males based on their appearance (see Chapter 23), may also have been a factor. Researchers have studied two closely related sympatric species of cichlids that differ mainly in the coloration of breeding males: Breeding *Pundamilia pundamilia* males have a blue-tinged back, whereas breeding *Pundamilia nyererei* males have a red-tinged back **(Figure 24.12)**. Their results suggest that mate choice based on male breeding coloration is the main reproductive barrier that normally keeps the gene pools of these two species separate.

Allopatric and Sympatric Speciation: *A Review*



Now let's recap the two main modes by which new species form. In allopatric speciation, a new species forms in geographic isolation from its parent population. Geographic isolation severely restricts gene flow. As a result, other reproductive barriers from the ancestral species may arise as a by-product of genetic changes that occur within the isolated population. Many different processes can produce such genetic changes, including natural selection under different environmental conditions, genetic drift, and sexual selection. Once formed, intrinsic reproductive barriers that arise in allopatric populations can prevent interbreeding with the parent population even if the populations come back into contact.

Sympatric speciation, in contrast, requires the emergence of a reproductive barrier that isolates a subset of a population from the remainder of the population in the same area. Though rarer than allopatric speciation, sympatric speciation can occur when gene flow to and from the isolated subpopulation is blocked. This can occur as a result of polyploidy, a condition in which an organism has extra sets of chromosomes. Sympatric speciation also can occur when a subset of

▼ Figure 24.12 Inquiry

Does sexual selection in cichlids result in reproductive isolation?

EXPERIMENT Ole Seehausen and Jacques van Alphen, then at the University of Leiden, placed males and females of *Pundamilia pundamilia* and *P. nyererei* together in two aquarium tanks, one with natural light and one with a monochromatic orange lamp. Under normal light, the two species are noticeably different in male breeding coloration; under monochromatic orange light, the two species are very similar in color. The researchers then observed the mate choices of the females in each tank.

RESULTS Under normal light, females of each species strongly preferred males of their own species. But under orange light, females of each species responded indiscriminately to males of both species. The resulting hybrids were viable and fertile.

CONCLUSION Seehausen and van Alphen concluded that mate choice by females based on male breeding coloration is the main reproductive barrier that normally keeps the gene pools of these two species separate. Since the species can still interbreed when this prezygotic behavioral barrier is breached in the laboratory, the genetic divergence between the species is likely to be small. This suggests that speciation in nature has occurred relatively recently.

SOURCE O. Seehausen and J. J. M. van Alphen, The effect of male coloration on female mate choice in closely related Lake Victoria cichlids (*Haplochromis nyererei* complex), *Behavioral Ecology and Sociobiology* 42:1–8 (1998).

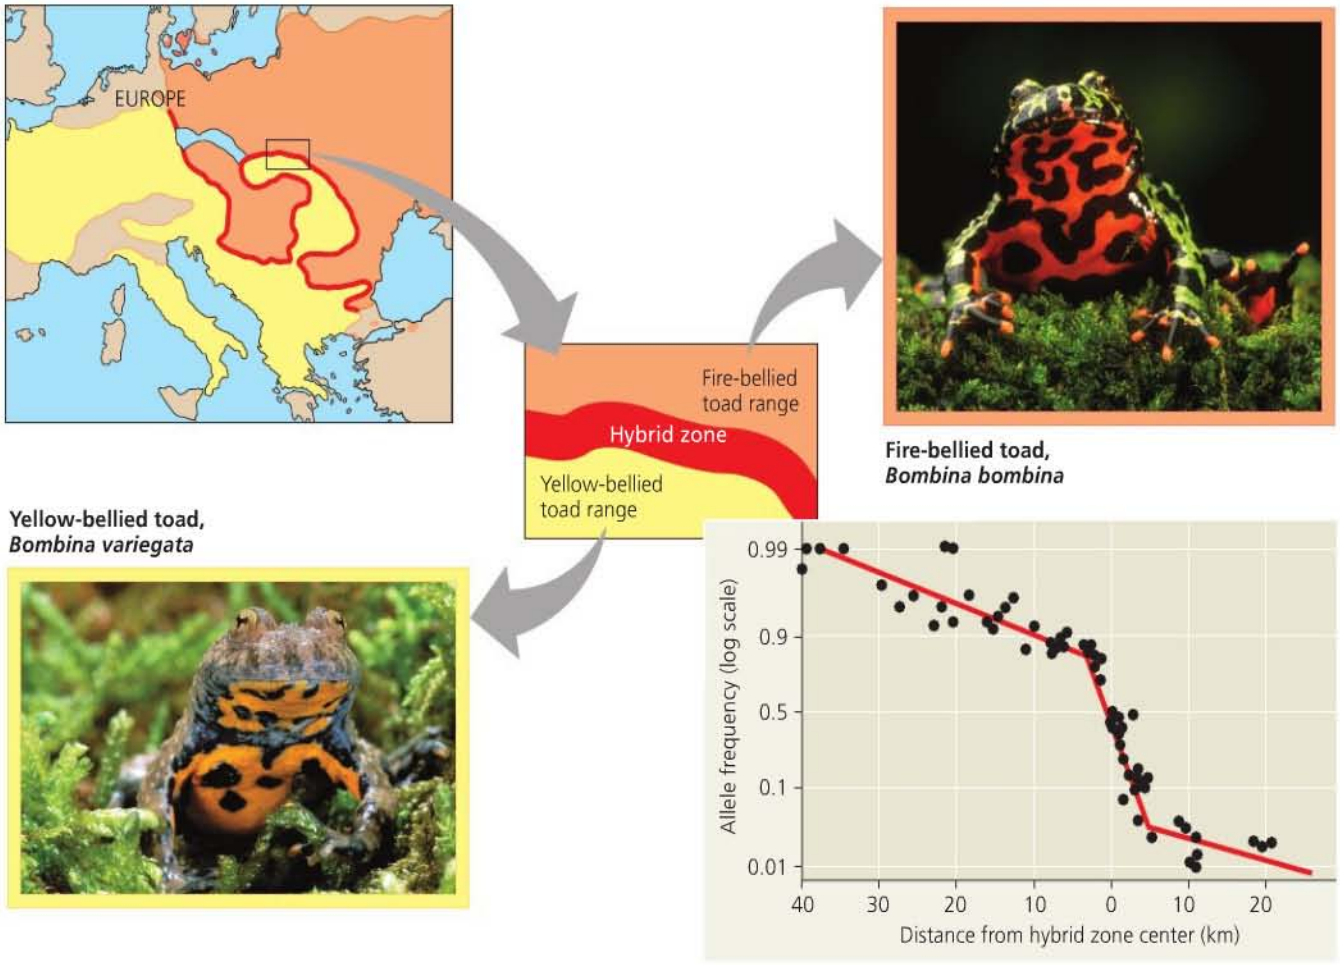
WHAT IF? If changing the light to orange had not affected the mating behavior of the cichlids, how would the researchers' conclusion in this study have changed?

a population becomes reproductively isolated because of natural selection that results from a switch to a habitat or food source not used by the parent population. Finally, sympatric speciation can result from sexual selection. Having reviewed the geographic context in which new species form, we'll next explore in more detail what can happen when allopatric populations come back into contact.

CONCEPT CHECK 24.2

1. Summarize key differences between allopatric and sympatric speciation. Which type of speciation is more common, and why?
2. Describe two mechanisms that can decrease gene flow in sympatric populations, thereby making sympatric speciation more likely to occur.
3. **WHAT IF?** Is allopatric speciation more likely to occur on an island close to a mainland or on a more isolated island of the same size? Explain your prediction.

For suggested answers, see Appendix A.



CONCEPT 24.3

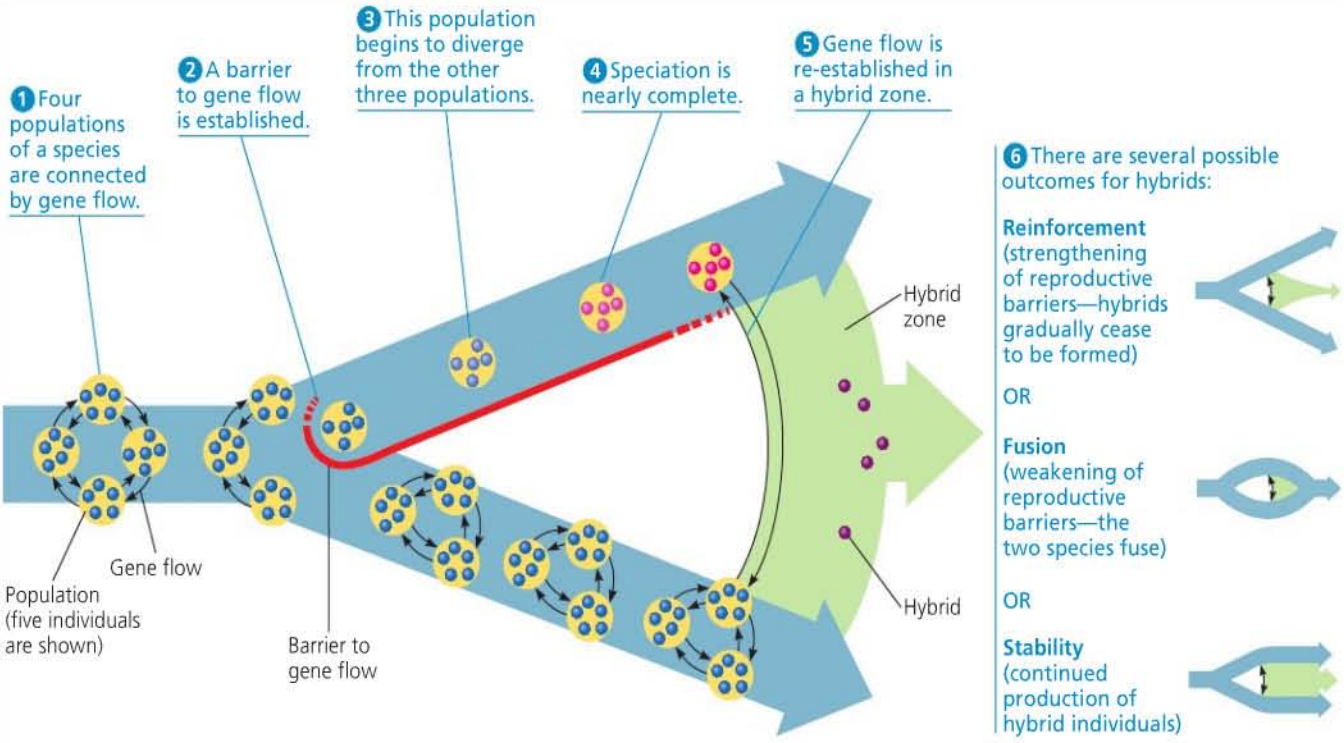
Hybrid zones provide opportunities to study factors that cause reproductive isolation

What happens if allopatric populations come back into contact with one another? One possible outcome is the formation of a **hybrid zone**, a region in which members of different species meet and mate, producing at least some offspring of mixed ancestry. In this section, we'll explore hybrid zones and what they reveal about factors that cause the evolution of reproductive isolation.

Patterns Within Hybrid Zones

Hybrid zones exhibit a variety of structures. Some hybrid zones form as narrow bands, such as the one depicted in **Figure 24.13** for two species of toads in the genus *Bombina*, the yellow-bellied toad (*B. variegata*) and the fire-bellied toad (*B. bombina*). This

▲ **Figure 24.13 A narrow hybrid zone for *B. variegata* and *B. bombina* in Europe.** The graph shows the pattern of allele frequency changes across the width of the zone near Krakow, Poland.



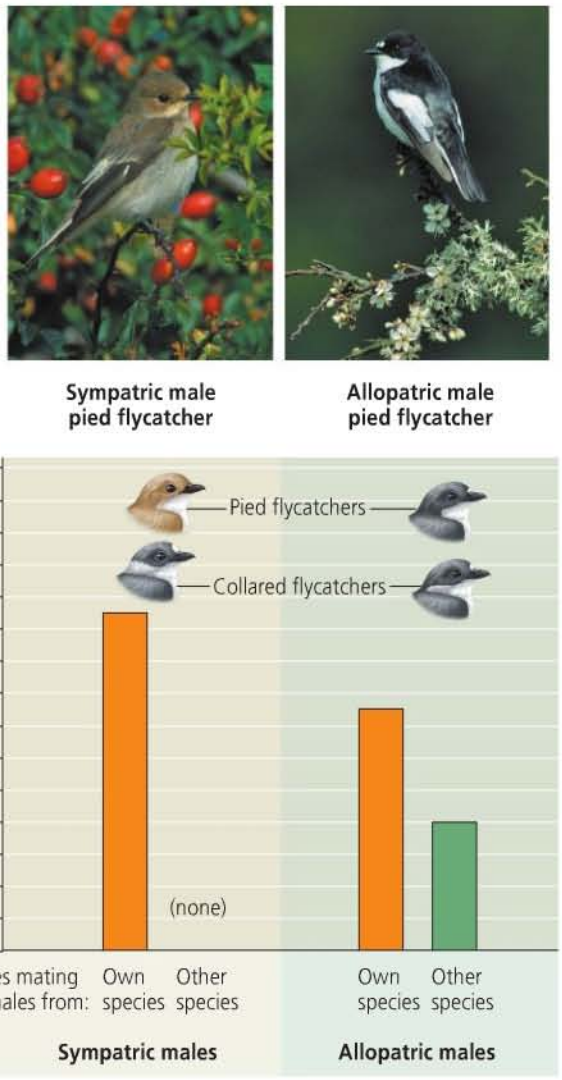
hybrid zone, represented by the thick red line on the map, extends for 4,000 km but is less than 10 km wide in most places. Across a given "slice" of the hybrid zone, the frequency of alleles specific to yellow-bellied toads typically decreases from close to 100% at the edge where only yellow-bellied toads are found, to 50% in the central portion of the zone, to 0% at the edge where only fire-bellied toads are found.

What causes such a pattern of allele frequencies across a hybrid zone? We can infer that there is an obstacle to gene flow—otherwise alleles from one parent species would also be found in the gene pool of the other parent species. Are geographic barriers reducing gene flow? Not in this case, since the toads move freely throughout the zone. A more important factor is that hybrid toads have increased rates of embryonic mortality and a variety of morphological abnormalities, including ribs that are fused to the spine and malformed tadpole mouthparts. Because the hybrids have poor survival and reproduction, they produce few viable offspring with members of the parent species. As a result, hybrids rarely serve as a stepping-stone from which alleles are passed from one species to the other.

Other hybrid zones have more complicated spatial patterns. Consider the hybrid zone between the ground crickets *Allonemobius fasciatus* and *Allonemobius socius*, both found in the Appalachian Mountains in the eastern United States. The environment has a powerful impact on the fitness of the parent species. *A. fasciatus* is more successful than *A. socius* in colder portions of the zone, and the reverse is true in warm locations. Thus *A. fasciatus* predominates in cooler sites (high elevation or north-facing locations), and *A. socius* predominates in warmer sites (low elevation or south-facing locations). The topography of this region is complex, with many hills and valleys, so there are many areas where patches of the two species are closely interspersed. As a result, populations of the two parent species come into contact, and hybrids are formed. Unlike the situation in the *Bombina* hybrid zone, where hybrid individuals are consistently less fit than individuals of either parent species, the fitness of *Allonemobius* hybrids varies from year to year and sometimes exceeds that of both parent species. As we'll see, the differences in the fitness of the *Bombina* and *Allonemobius* hybrids lead to different predictions regarding how reproductive barriers for these species change over time.

Hybrid Zones over Time

Studying a hybrid zone is like observing a natural experiment on speciation. Will the result be the rapid formation of a new species, as occurred by polyploidy in the goatsbeard plants of the Pacific Northwest? If not, there are three possible outcomes for the hybrid zone over time **(Figure 24.14)**. Reproductive barriers between species may be strengthened over time (limiting the formation of hybrids) or weakened over time (causing the two species to fuse into a single species). Or hybrids may continue to be produced, creating a long-term, stable hybrid zone. Let's examine what the field evidence suggests about these three possibilities.



▲ **Figure 24.14 Formation of a hybrid zone and possible outcomes for hybrids over time.** The thick colored arrows represent the passage of time.

WHAT IF? *What might happen if gene flow were re-established at step 3 in this process?*

Reinforcement: Strengthening Reproductive Barriers

When hybrids are less fit than members of their parent species, as in the *Bombina* example, we might expect natural selection to strengthen prezygotic barriers to reproduction, thus reducing the formation of unfit hybrids. Because this process involves *reinforcing* reproductive barriers, it is called **reinforcement**. If reinforcement is occurring, we would predict that barriers to reproduction between species should be stronger for sympatric species than for allopatric species.

As an example, let's consider the evidence for reinforcement in two closely related species of European flycatcher, the pied flycatcher and the collared flycatcher. In allopatric populations of these birds, males of the two species closely resemble one another. But in sympatric populations, the males of the two species look very different: Male pied flycatchers are a dull brown, whereas male collared flycatchers have enlarged patches of white. Female pied and collared flycatchers do not select males of the other species when given a choice between males from sympatric populations, but they frequently do make mistakes when selecting between males from allopatric populations **(Figure 24.15)**. Thus, barriers to reproduction appear to be stronger in birds from sympatric populations than in birds from allopatric populations, as predicted by the reinforcement hypothesis. Similar results have been observed in a number of organisms, including fishes, insects, plants, and other birds. But interestingly, reinforcement does *not* appear to be at work in the case of the *Bombina* toads, as we'll discuss shortly.

▲ **Figure 24.15 Reinforcement of barriers to reproduction in closely related species of European flycatchers.**

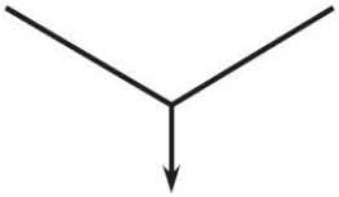
Fusion: Weakening Reproductive Barriers

Next let's consider the case in which two species contact one another in a hybrid zone, but the barriers to reproduction are not strong. So much gene flow may occur that reproductive barriers weaken further and the gene pools of the two species become increasingly alike. In effect, the speciation process reverses, eventually causing the two hybridizing species to fuse into a single species.

Such a situation may be occurring among some of the Lake Victoria cichlids we discussed earlier. Many pairs of ecologically similar cichlid species are reproductively isolated by female mate choice—the females of one species prefer to mate with males of one color, while females of the other species prefer to mate with males of a different color (see Figure 24.12).

In the past 30 years, about 200 of the former 600 species of Lake Victoria cichlids have vanished. Some of these species were driven to extinction by an introduced predator, the Nile perch. But many species not eaten by Nile perch also have disappeared. Researchers think that murky waters caused by pollution may have reduced the ability of females to use color to distinguish males of their own species from males of closely related species. If further evidence supports this hypothesis, it would seem that pollution in Lake Victoria has produced a cascade of related effects. First, by decreasing the ability of females to distinguish males of their own species, pollution has increased the frequency of mating between members of species that had been isolated reproductively from one another. Second, as a result of these matings, many hybrids have been produced, leading to fusion of the parent species' gene pools and a loss of species **(Figure 24.16)**. Third, future speciation events in Lake Victoria cichlids are now less likely because female mate choice based on male breeding color, which can promote speciation in these fish, is hindered.

Stability: Continued Formation of Hybrid Individuals



Many hybrid zones are stable in the sense that hybrids continue to be produced—a result you might not expect. For example, recall that hybrids are at a strong disadvantage in the *Bombina* hybrid zone. As a result, the offspring of individuals that prefer to mate with members of their own species should survive or

Pundamilia nyererei

Pundamilia pundamilia

Pundamilia "turbid water,"
hybrid offspring from a location with turbid water

▲ **Figure 24.16 The breakdown of reproductive barriers.** Increasingly cloudy water in Lake Victoria over the past 30 years may have weakened reproductive barriers between *P. nyererei* and *P. pundamilia*. In areas of cloudy water, the two species have hybridized extensively, causing their gene pools to fuse.

reproduce better than the unfit hybrid offspring of individuals that mate indiscriminately with members of the other species. This suggests that reinforcement should occur, strengthening reproductive barriers and thereby limiting the production of hybrid toads. But in more than 20 years of study, no evidence for reinforcement has been found, and hybrids continue to be produced. What could explain this surprising finding? One possibility relates to the narrowness of the *Bombina* hybrid zone. Perhaps extensive gene flow from outside the zone leads to the continued production of hybrids and overwhelms selection for increased reproductive isolation inside the hybrid zone. If the hybrid zone were wider, this would be less likely to occur, since the center of the zone would receive little gene flow from distant populations outside the hybrid zone.

In the *Allonemobius* hybrid zone, hybrids sometimes have higher fitness than the parent species. Thus, we might predict that many hybrids would be formed, at least in some years. As these hybrids mated with each other and with members of both parent species, the gene pools of the parent species could fuse, reversing the speciation process. However, although hybrids do continue to be formed, more than 20 years of data indicate that they are uncommon and that gene flow between the parent species is not extensive. Why aren't hybrids more common? Throughout much of the hybrid zone, the two parent species meet at locations where one or both of them are near the limit of the environmental conditions that they can tolerate. As a result, even a slight change in the local environment can cause one or the other of the parent species to disappear from that location. In a 14-year study, researchers observed several such local extinctions. Thus, because locations where hybrids are formed may appear and disappear rapidly, hybrids remain uncommon, and fusion of the *A. fasciatus* and *A. socius* gene pools may be prevented by insufficient time for the reproductive barriers to break down.

In short, sometimes the outcomes in hybrid zones match our predictions (European flycatchers and cichlid fishes), and sometimes they don't (*Bombina* and *Allonemobius*). But whether our predictions are upheld or not, events in hybrid zones can shed light on how barriers to reproduction between closely related species change over time. In the next section, we'll examine how interactions between hybridizing species can also provide a glimpse into the speed and genetic control of speciation.

CONCEPT CHECK 24.3

1. What are hybrid zones, and why can they be viewed as "natural laboratories" in which to study speciation?
2. **WHAT IF?** Consider two species that diverged while geographically separated but resumed contact before reproductive isolation was complete. Predict what would happen over time if the two species mated indiscriminately and (a) hybrid offspring survived and reproduced more poorly than offspring from intraspecific matings or (b) hybrid offspring survived and reproduced as well as offspring from intraspecific matings.

For suggested answers, see Appendix A.

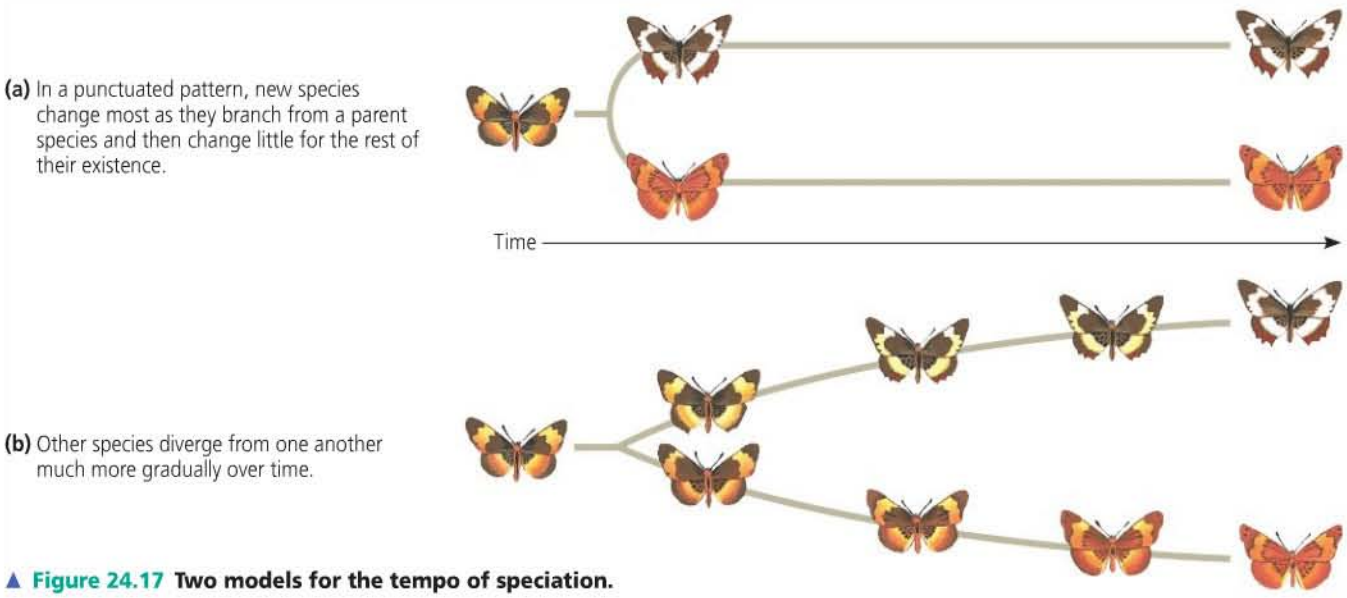
CONCEPT 24.4
Speciation can occur rapidly or slowly and can result from changes in few or many genes

Darwin faced many unanswered questions when he began to ponder that "mystery of mysteries," speciation. As you read in Chapter 22, he found answers to some of those questions when he realized that evolution by natural selection helped to explain both the diversity of life and the adaptations of organisms. But biologists since Darwin have continued to ask fundamental questions about speciation, such as, How long does it take new species to form? and, How many genes change when one species splits into two? Answers to these questions are also beginning to emerge.

The Time Course of Speciation

We can gather information about how long it takes new species to form from broad patterns in the fossil record and from studies that use morphological data (including fossils) or molecular data to assess the time interval between speciation events in particular groups of organisms.

Patterns in the Fossil Record



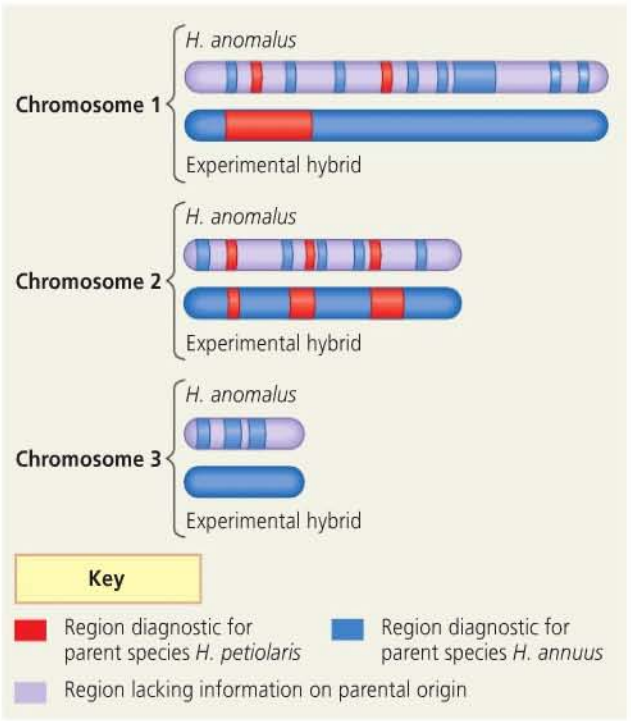
The fossil record includes many episodes in which new species appear suddenly in a geologic stratum, persist essentially unchanged through several strata, and then disappear. Paleontologists Niles Eldredge, of the American Museum of Natural History, and Stephen Jay Gould (1941–2002), of Harvard University, coined the term **punctuated equilibria** to describe these periods of apparent stasis punctuated by sudden change **(Figure 24.17a)**. Other species do not show a punctuated pattern; instead, they change more gradually over long periods of time **(Figure 24.17b)**.

What do punctuated and gradual patterns tell us about how long it takes new species to form? Suppose that a species survived for 5 million years, but most of the morphological changes that caused it to be designated a new species occurred during the first 50,000 years of its existence—just 1% of its total lifetime. Time periods this short (in geologic terms) often cannot be distinguished in fossil strata, in part because the rate of sediment accumulation is too slow to separate layers this close in time. Thus, based on its fossils, the species would seem to have appeared suddenly and then lingered with little or no change before becoming extinct. Even though such a species may have originated more slowly than its fossils suggest (in this case taking 50,000 years), a punctuated pattern indicates that speciation occurred relatively rapidly. For species whose fossils change much more gradually, we also cannot tell exactly when a new biological species forms, since information about reproductive isolation does not fossilize. However, it is likely that speciation in such groups occurred relatively slowly, perhaps taking millions of years.

Speciation Rates

The punctuated pattern suggests that once the process begins, speciation can be completed relatively rapidly—a suggestion confirmed by a growing number of studies.

For example, research conducted by Loren Rieseberg, then at Indiana University, and colleagues suggests that rapid speciation produced the wild sunflower *Helianthus anomalus*. This species is thought to have originated by the hybridization of two other sunflower species, *H. annuus* and *H. petiolaris*. The hybrid species *H. anomalus* is ecologically distinct and reproductively isolated from both parent species **(Figure 24.18)**. Unlike allopolyploid speciation, in which there is a change in chromosome number after hybridization, in these sunflowers the two parent species and the hybrid all have the same number of chromosomes ($2n = 34$). How then did speciation occur? In laboratory experiments designed to answer this question, only 5% of the F_1 hybrids were fertile. However, after just four more generations in which hybrids mated among themselves and also mated with the parent species, the fertility rose to more than 90%. To explain this finding, Rieseberg and colleagues hypothesized that experimental hybrids whose chromosomes contained blocks of DNA from the parent species that were not compatible with one another failed to reproduce and thus were eliminated by selection. As a result, the chromosomes of the experimental hybrids rapidly became similar in composition to the chromosomes of *H. anomalus* individuals from natural populations (see Figure 24.18).



▲ **Figure 24.17 Two models for the tempo of speciation.**

The sunflower example, along with the apple maggot fly, Lake Victoria cichlid, and fruit fly examples discussed earlier, suggests that new species can form rapidly once divergence begins. But what is the total length of time between speciation events? This interval consists of the time that elapses before populations of a newly formed species start to diverge from one another plus the time it takes for speciation to be complete once divergence begins. It turns out that the total time between speciation events varies considerably. For example, in a survey of data from 84 groups of plants and animals, the interval between speciation events ranged from 4,000 years (in cichlids of Lake Nabugabo, Uganda) to 40 million years (in some beetles). Overall, the time between speciation events averaged 6.5 million years and rarely took less than 500,000 years.

(a) The wild sunflower *Helianthus anomalus* lives in dry sand dune environments. *H. anomalus* originated via the hybridization of two other sunflowers, *H. annuus* and *H. petiolaris*, which live in nearby but moister environments.

(b) The genetic composition of three chromosomes in *H. anomalus* and in experimental hybrids. After a five-generation experiment, the chromosomes in the experimental hybrids were similar to the chromosomes of naturally occurring *H. anomalus*.

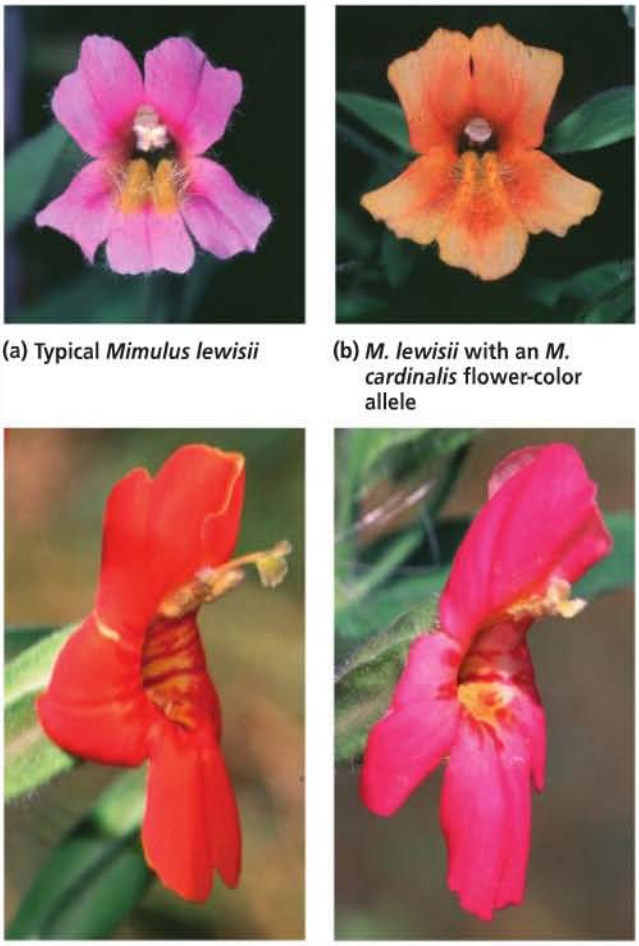
▲ **Figure 24.18 Rapid speciation in a sunflower hybrid zone.**

What can we learn from such data? First, the data suggest that on average, millions of years may pass before a newly formed species will itself give rise to another new species. As we'll see in Chapter 25, this result has implications for how long it takes Earth's life to recover from mass extinction events. Second, the extreme variability in the time it takes new species to form indicates that organisms do not have a "speciation clock" ticking inside them, causing them to produce new species at regular time intervals. Instead, speciation begins only after gene flow between populations is interrupted, perhaps by an unpredictable event such as a storm that transports a few individuals to an isolated area. Furthermore, once gene flow has been interrupted, the populations must diverge genetically to such an extent that they become reproductively isolated—all before another event causes gene flow to resume, reversing the speciation process (see Figure 24.16).

Studying the Genetics of Speciation

Studies of ongoing speciation (as in hybrid zones) can reveal traits that cause reproductive isolation. By identifying the genes that control those traits, scientists can explore a fundamental question of evolutionary biology: How many genes change when a new species forms?

In a few cases, the evolution of reproductive isolation is due to a change in a single gene. For example, in Japanese snails of the genus *Euhadra*, alleles of a single gene can induce a mechanical barrier to reproduction. This gene controls the direction in which the shells spiral **(Figure 24.19)**. When their shells spiral in different directions, the snails' genitals are oriented in a manner that prevents mating (Figure 24.4f shows a similar example).



A major barrier to reproduction between two closely related species of monkey flower, *Mimulus lewisii* and *M. cardinalis*,

▲ **Figure 24.19 Single-gene speciation.** A mutation in one gene causes the shell of the Japanese land snail (*Euhadra*) to spiral in the opposite direction from others. Snails with opposite spirals cannot mate, resulting in reproductive isolation.

also appears to be influenced by a relatively small number of genes. These two species are isolated both by prezygotic barriers (pollinator choice and partial gametic isolation) and by postzygotic barriers (interspecific crosses produce fewer offspring than intraspecific crosses, and F_1 hybrids have reduced fertility and survival). Of these barriers, pollinator choice accounts for most of the isolation: In a hybrid zone between *M. lewisii* and *M. cardinalis*, nearly 98% of pollinator visits were restricted to one species or the other.

The two monkey flower species are visited by different pollinators: Bumblebees prefer the pink-flowered *M. lewisii* and hummingbirds prefer the red-flowered *M. cardinalis*. Douglas Schemske, of Michigan State University, and colleagues have shown that pollinator choice is affected by at least two loci in the monkey flowers, one of which, the "yellow upper," or *yup*, locus, influences flower color **(Figure 24.20)**. By producing F_1 hybrids and then performing repeated backcrosses to each parent species, Schemske and colleagues succeeded in transferring the *M. lewisii* allele at this locus into *M. cardinalis*, and vice versa. In a field experiment, *M. lewisii* plants with the *M. cardinalis yup* allele received 68-fold more visits from hummingbirds than did wild-type *M. lewisii*. Similarly, *M. cardinalis* plants with the *M. lewisii yup* allele received 74-fold more visits from bumblebees than did wild-type *M. cardinalis*. Thus, a mutation at a single locus can influence pollinator preference and hence contribute to reproductive isolation in monkey flowers.

(a) Typical *Mimulus lewisii*

(b) *M. lewisii* with an *M. cardinalis* flower-color allele

(c) Typical *Mimulus cardinalis*

(d) *M. cardinalis* with an *M. lewisii* flower-color allele

▲ **Figure 24.20 A locus that influences pollinator choice.** Pollinator preferences provide a strong barrier to reproduction between *Mimulus lewisii* and *M. cardinalis*. After transferring the *M. lewisii* allele for a flower-color locus into *M. cardinalis* and vice versa, researchers observed a shift in some pollinators' preferences.

WHAT IF? *If* M. cardinalis *individuals that had the* M. lewisii yup *allele were planted in an area that housed both monkey flower species, how might the production of hybrid offspring be affected?*

In other organisms, the speciation process is influenced by larger numbers of genes and gene interactions. For example, hybrid sterility between two subspecies of *Drosophila pseudoobscura* results from gene interactions among at least four loci, and postzygotic isolation in the sunflower hybrid zone discussed earlier is influenced by at least 26 chromosomal segments (and an unknown number of genes). Overall, studies conducted to date suggest that few or many genes can influence the evolution of reproductive isolation and hence the emergence of a new species—a new addition to the great diversity of life.

From Speciation to Macroevolution

As you've seen in this chapter's examples, speciation may begin with differences as seemingly small as the color on a cichlid's back. However, as speciation occurs again and again, such differences can accumulate and become more pronounced, eventually leading to the formation of new groups of organisms that differ greatly from their ancestors (as in the origin of whales from land-dwelling mammals; see Figure 22.16). Furthermore, as one group of organisms increases in size by producing many new species, another group of organisms may shrink, losing species to extinction. The cumulative effects of many such speciation and extinction events have helped to shape the sweeping evolutionary changes that are documented in the fossil record. In the next chapter, we turn to such large-scale evolutionary changes as we begin our study of macroevolution.

CONCEPT CHECK 24.4

1. Speciation can occur rapidly between diverging populations, yet the length of time between speciation events is often more than a million years. Explain this apparent contradiction.
2. **WHAT IF?** Summarize experimental evidence that the *yup* locus acts as a prezygotic barrier to reproduction in two species of monkey flowers. Do these results demonstrate that the *yup* locus alone controls barriers to reproduction between these closely related monkey flower species? Explain your answer.

For suggested answers, see Appendix A.

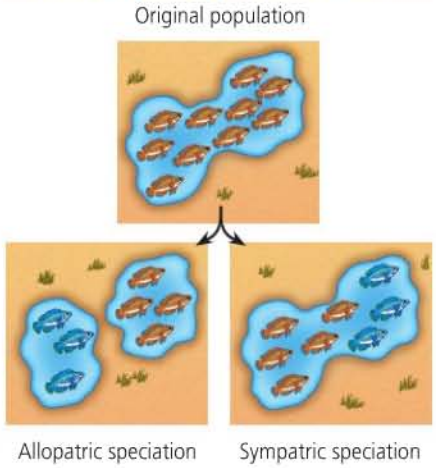
SUMMARY OF KEY CONCEPTS

CONCEPT 24.1

The biological species concept emphasizes reproductive isolation (pp. 487–492)

- **The Biological Species Concept** A biological species is a group of populations whose individuals have the potential to interbreed and produce viable, fertile offspring with each other but not with members of other species. The biological species concept emphasizes reproductive isolation through prezygotic and postzygotic barriers that separate gene pools.
- **Other Definitions of Species** Although helpful in thinking about how speciation occurs, the biological species concept has limitations. For instance, it cannot be applied to organisms known only as fossils or to organisms that reproduce only asexually. Thus, scientists use other species concepts, such as the morphological species concept, in certain circumstances.



MEDIA

Activity Overview of Macroevolution

CONCEPT 24.2

Speciation can take place with or without geographic separation (pp. 492–498)

- **Allopatric ("Other Country") Speciation** Evidence indicates that allopatric speciation can occur when two populations of one species become geographically separated from each other. One or both populations may undergo evolutionary change during the period of separation, resulting in the establishment of prezygotic or postzygotic barriers to reproduction.
- **Sympatric ("Same Country") Speciation** A new species can originate while remaining in a geographically overlapping area with the parent species. Plant species (and, more rarely, animals) have evolved sympatrically through polyploidy. Sympatric speciation can also result from habitat shifts and sexual selection.
- **Allopatric and Sympatric Speciation: *A Review***

MEDIA

MP3 Tutor Speciation

CONCEPT 24.3

Hybrid zones provide opportunities to study factors that cause reproductive isolation (pp. 498–501)

- **Patterns Within Hybrid Zones** Many groups of organisms form hybrid zones in which members of different species meet and mate, producing at least some offspring of mixed ancestry.
- **Hybrid Zones over Time** In many hybrid zones, a limited number of hybrid offspring continue to be produced over time. In others, reinforcement strengthens prezygotic barriers to reproduction, thus decreasing the formation of unfit hybrids. In still other hybrid zones, barriers to reproduction may weaken over time, resulting in the fusion of the species' gene pools (reversing the speciation process).

CONCEPT 24.4

Speciation can occur rapidly or slowly and can result from changes in few or many genes (pp. 501–504)

- **The Time Course of Speciation** New species can form rapidly once divergence begins—but it can take millions of years for that to happen. The time interval between speciation events varies considerably, from a few thousand years to tens of millions of years.
- **Studying the Genetics of Speciation** New developments in genetics have enabled researchers to identify specific genes involved in some cases of speciation. Results show that speciation can be driven by few or many genes.
- **From Speciation to Macroevolution** Due to repeated events, small differences between organisms can accumulate, leading to the formation of new groups of organisms.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. The *largest* unit within which gene flow can readily occur is a
   a. population.
   b. species.
   c. genus.
   d. hybrid.
   e. phylum.

2. Bird guides once listed the myrtle warbler and Audubon's warbler as distinct species. Recently, these birds have been classified as eastern and western forms of a single species, the yellow-rumped warbler. Which of the following pieces of evidence, if true, would be cause for this reclassification?
   a. The two forms interbreed often in nature, and their offspring have good survival and reproduction.
   b. The two forms live in similar habitats.
   c. The two forms have many genes in common.
   d. The two forms have similar food requirements.
   e. The two forms are very similar in coloration.

3. Males of different species of the fruit fly *Drosophila* that live in the same parts of the Hawaiian Islands have different elaborate courtship rituals that involve fighting other males and stylized movements that attract females. What type of reproductive isolation does this represent?
   a. habitat isolation
   b. temporal isolation
   c. behavioral isolation
   d. gametic isolation
   e. postzygotic barriers

4. Which of the following factors would *not* contribute to allopatric speciation?
   a. A population becomes geographically isolated from the parent population.
   b. The separated population is small, and genetic drift occurs.
   c. The isolated population is exposed to different selection pressures than the ancestral population.
   d. Different mutations begin to distinguish the gene pools of the separated populations.
   e. Gene flow between the two populations is extensive.

5. Plant species A has a diploid number of 12. Plant species B has a diploid number of 16. A new species, C, arises as an allopolyploid from A and B. The diploid number for species C would probably be
   a. 12. b. 14. c. 16.
   d. 28. e. 56.

6. According to the punctuated equilibria model,
   a. natural selection is unimportant as a mechanism of evolution.
   b. given enough time, most existing species will branch gradually into new species.
   c. most new species accumulate their unique features relatively rapidly as they come into existence, then change little for the rest of their duration as a species.
   d. most evolution occurs in sympatric populations.
   e. speciation is usually due to a single mutation.

EVOLUTION CONNECTION

7. What is the biological basis for assigning all human populations to a single species? Can you think of a scenario by which a second human species could originate in the future?

SCIENTIFIC INQUIRY

8. **DRAW IT** In this chapter, you read that bread wheat (*Triticum aestivum*) is an allohexaploid, containing two sets of chromosomes from each of three different parent species. Genetic analysis suggests that the three species pictured below each contributed chromosome sets to *T. aestivum*. (The capital letters here represent sets of chromosomes rather than individual genes.) Evidence also indicates that the first polyploidy event was a spontaneous hybridization of the early cultivated wheat species *T. monococcum* and a wild grass species. Based on this information, draw a diagram of one possible chain of events that could have produced the allohexaploid *T. aestivum*.

SCIENCE, TECHNOLOGY, AND SOCIETY

9. In the United States, the rare red wolf (*Canis lupus*) has been known to hybridize with coyotes (*Canis latrans*), which are much more numerous. Although red wolves and coyotes differ in terms of morphology, DNA, and behavior, genetic evidence suggests that living red wolf individuals are actually hybrids. Red wolves are designated as an endangered species and hence receive legal protection under the Endangered Species Act. Some people think that their endangered status should be withdrawn because the remaining red wolves are hybrids, not members of a "pure" species. Do you agree? Why or why not?

25 The History of Life on Earth

25.2 The fossil record documents the history of life

25.3 Key events in life's history include the origins of single-celled and multicelled organisms and the colonization of land

25.4 The rise and fall of dominant groups reflect continental drift, mass extinctions, and adaptive radiations

25.5 Major changes in body form can result from changes in the sequences and regulation of developmental genes

25.6 Evolution is not goal oriented

OVERVIEW

Lost Worlds

Visitors to Antarctica today encounter one of Earth's harshest, most barren environments. In this land of extreme cold where there is almost no liquid water, life is sparse and small—the largest fully terrestrial animal is a fly 5 mm long. But even as early antarctic explorers struggled to survive, some of them made an astonishing discovery: fossil evidence that life once thrived where it now barely exists. Fossils reveal that 500 million years ago, the ocean waters surrounding Antarctica were warm and teeming with tropical invertebrates. Later, the continent was covered in forests for hundreds of millions of years. At various times, a wide range of animals stalked through these forests, including 3-meter-tall predatory "terror birds" and giant dinosaurs such as the voracious *Cryolophosaurus* (Figure 25.1), a 7-meter-long relative of *Tyrannosaurus rex*.

Fossils discovered in other parts of the world tell a similar, if not quite as surprising, story: Past organisms were very different from those now alive. The sweeping changes in life on Earth revealed by fossils illustrate **macroevolution**, the pattern of evolution over large time scales. Specific examples of macroevolutionary change include the origin of key biochemical processes such as photosynthesis, the emergence of the first terrestrial vertebrates, and the long-term impact of a mass extinction on the diversity of life.

▲ ***Cryolophosaurus* skull**

Taken together, such changes provide a grand view of the evolutionary history of life on Earth. We'll examine that history in this chapter, beginning with hypotheses regarding the origin of life. The origin of life is the most speculative topic of the entire unit, for no fossil evidence of that seminal episode exists. We will then turn to the fossil record and what it tells us about major events in the history of life, paying particular attention to factors that have helped to shape the rise and fall of different groups of organisms over time.

CONCEPT 25.1

Conditions on early Earth made the origin of life possible

The earliest evidence of life on Earth comes from fossils of microorganisms that are about 3.5 billion years old. But when and how did the first living cells appear? Observations and experiments in chemistry, geology, and physics have led scientists to propose one scenario that we'll examine here. They hypothesize that chemical and physical processes on early Earth, aided by the emerging force of

natural selection, could have produced very simple cells through a sequence of four main stages:

1. The abiotic (nonliving) synthesis of small organic molecules, such as amino acids and nucleotides
2. The joining of these small molecules into macromolecules, including proteins and nucleic acids
3. The packaging of these molecules into "protobionts," droplets with membranes that maintained an internal chemistry different from that of their surroundings
4. The origin of self-replicating molecules that eventually made inheritance possible

Though speculative, this scenario leads to predictions that can be tested in the laboratory. In this section, we will examine some of the evidence for each stage.

Synthesis of Organic Compounds on Early Earth

There is scientific evidence that Earth and the other planets of the solar system formed about 4.6 billion years ago, condensing from a vast cloud of dust and rocks that surrounded the young sun. For the first few hundred million years, life probably could not have originated or survived on Earth because the planet was still being bombarded by huge chunks of rock and ice left over from the formation of the solar system. The collisions generated enough heat to vaporize the available water and prevent seas from forming. This phase likely ended about 3.9 billion years ago.

As the bombardment of early Earth slowed, conditions on the planet were extremely different from those of today. The first atmosphere was probably thick with water vapor, along with various compounds released by volcanic eruptions, including nitrogen and its oxides, carbon dioxide, methane, ammonia, hydrogen, and hydrogen sulfide. As Earth cooled, the water vapor condensed into oceans, and much of the hydrogen quickly escaped into space.

In the 1920s, Russian chemist A. I. Oparin and British scientist J. B. S. Haldane independently hypothesized that Earth's early atmosphere was a reducing (electron-adding) environment, in which organic compounds could have formed from simple molecules. The energy for this organic synthesis could have come from lightning and intense UV radiation. Haldane suggested that the early oceans were a solution of organic molecules, a "primitive soup" from which life arose.

In 1953, Stanley Miller and Harold Urey, of the University of Chicago, tested the Oparin-Haldane hypothesis by creating laboratory conditions comparable to those that scientists at the time thought existed on early Earth (see Figure 4.2). Their apparatus yielded a variety of amino acids found in organisms today, along with other organic compounds. Many laboratories have since repeated the experiment using different recipes for the atmosphere. Some of these variations also produced organic compounds.

However, it is unclear whether the atmosphere of young Earth contained enough methane and ammonia to be reducing. Growing evidence suggests that the early atmosphere was made up primarily of nitrogen and carbon dioxide and was neither reducing nor oxidizing (electron removing). Some recent Miller-Urey-type experiments using such atmospheres have produced organic molecules. In any case, it is likely that small "pockets" of the early atmosphere—perhaps near volcanic openings—were reducing. Perhaps instead of forming in the atmosphere, the first organic compounds formed near submerged volcanoes and deep-sea vents, where hot water and minerals gush into the ocean from Earth's interior **(Figure 25.2)**. These regions are also rich in inorganic sulfur and iron compounds, which are important in ATP synthesis by present-day organisms.

Miller-Urey-type experiments demonstrate that the abiotic synthesis of organic molecules is possible. Support for this idea also comes from analyses of the chemical composition of meteorites. Among the meteorites that land on Earth are carbonaceous chondrites, rocks that are 1–2% carbon compounds by mass. Fragments of a fallen 4.5-billion-year-old chondrite found in Australia in 1969 contain more than 80 amino acids, some in large amounts. Remarkably, the proportions of these amino acids are similar to those produced in the Miller-Urey experiment. The chondrite amino acids cannot

▲ **Figure 25.2 A window to early life?** An instrument on the research submarine *Alvin* samples the water around a hydrothermal vent in the Sea of Cortés. More than 1.5 km below the surface, the vent releases hydrogen sulfide and iron sulfide, which react and produce pyrite (fool's gold) and hydrogen gas. Prokaryotes that live near the vent use the hydrogen as an energy source. Such environments are among the most extreme in which life exists today, and some researchers favor the hypothesis that life may have begun in similar regions of early Earth.

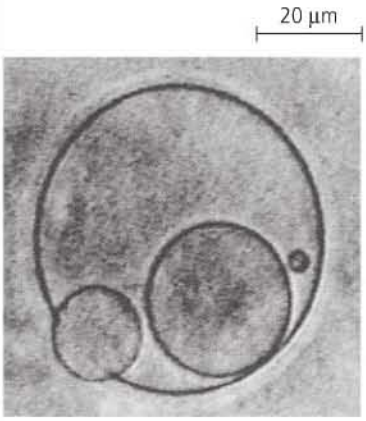
be contaminants from Earth because they consist of an equal mix of D and L isomers (see Chapter 4). Organisms make and use only L isomers, with a few rare exceptions.

Abiotic Synthesis of Macromolecules

The presence of small organic molecules, such as amino acids, is not sufficient for the emergence of life as we know it. Every cell has a vast assortment of macromolecules, including enzymes and other proteins and the nucleic acids that are essential for self-replication. Could such macromolecules have formed on early Earth? By dripping solutions of amino acids onto hot sand, clay, or rock, researchers have been able to produce amino acid polymers. The polymers formed spontaneously, without the help of enzymes or ribosomes. But unlike proteins, these polymers are a complex mix of linked and cross-linked amino acids. Nevertheless, it is possible that such polymers may have acted as weak catalysts for a variety of reactions on early Earth.

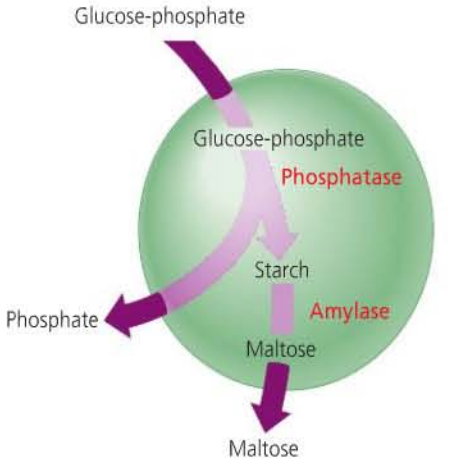
Protobionts

Two key properties of life are accurate replication and metabolism. Neither property can exist without the other. DNA molecules carry genetic information, including the instructions needed to replicate themselves accurately. But the replication of DNA requires elaborate enzymatic machinery, along with a copious supply of nucleotide building blocks that must be provided by the cell's metabolism (see Chapter 16). While Miller-Urey-type experiments have yielded some of the nitrogenous bases of DNA and RNA, they have not produced anything like nucleotides. If building blocks of nucleic acids were not part of the early organic soup, self-replicating molecules and a metabolism-like source of the building blocks must have appeared together. How did that happen?



The necessary conditions may have been met by **protobionts**, collections of abiotically produced molecules surrounded by a membrane-like structure. Protobionts may exhibit some properties of life, including simple reproduction and metabolism, as well as the maintenance of an internal chemical environment different from that of their surroundings.

Laboratory experiments demonstrate that protobionts could have formed spontaneously from abiotically produced organic compounds. For example, certain small membrane-bounded droplets called liposomes can form when lipids or other organic molecules are added to water. The hydrophobic molecules in the mixture organize into a bilayer at the surface of the droplet, much like the lipid bilayer of a plasma membrane. Liposomes can "reproduce" (Figure 25.3a), and because their bilayer is selectively permeable, liposomes undergo osmotic swelling or shrinking when placed in solutions of different solute concentrations. Some of these liposomes can perform simple metabolic reactions, another important step toward the origin of life (Figure 25.3b).



Self-Replicating RNA and the Dawn of Natural Selection

The first genetic material was most likely RNA, not DNA. Thomas Cech, of the University of Colorado, and Sidney Altman, of Yale University, found that RNA, which plays a central role in protein synthesis, can also carry out a number of enzyme-like catalytic functions. Cech called these RNA catalysts **ribozymes**. Some ribozymes can make complementary copies of short pieces of RNA, provided that they are supplied with nucleotide building blocks.

Natural selection on the molecular level has produced ribozymes capable of self-replication in the laboratory. How does this occur? Unlike double-stranded DNA, which takes the form of a uniform helix, single-stranded RNA molecules assume a variety of specific three-dimensional shapes mandated by their nucleotide sequences. In a particular environment, RNA molecules with certain base sequences are more stable and replicate faster and with fewer errors than other sequences. The RNA molecule whose sequence is best suited to the surrounding environment and has the greatest ability to replicate itself will leave the most descendant molecules. Its descendants will not be a single RNA "species" but instead will be a family of sequences that differ slightly because of copying

(a) Simple reproduction. This liposome is "giving birth" to smaller liposomes (LM).

(b) Simple metabolism. If enzymes—in this case, phosphatase and amylase—are included in the solution from which the droplets self-assemble, some liposomes can carry out simple metabolic reactions and export the products.

▲ **Figure 25.3 Laboratory versions of liposome protobionts.**

errors. Occasionally, a copying error will result in a molecule that folds into a shape that is even more stable or more adept at self-replication than the ancestral sequence. Similar selection events may have occurred on early Earth. Thus, the molecular biology of today may have been preceded by an "RNA world," in which small RNA molecules that carried genetic information were able to replicate and to store information about the protobionts that carried them.

A protobiont with self-replicating, catalytic RNA would differ from its many neighbors that did not carry RNA or that carried RNA without such capabilities. If that protobiont could grow, split, and pass its RNA molecules to its daughters, the daughters would have some of the properties of their parent. Although the first such protobionts must have carried only limited amounts of genetic information, specifying only a few properties, their inherited characteristics could have been acted on by natural selection. The most successful of the early protobionts would have increased in number because they could exploit their resources effectively and pass their abilities on to subsequent generations. The emergence of such protobionts may seem unlikely, but remember that there could have been trillions of protobionts in bodies of water on early Earth. Even those with only a limited capacity for inheritance would have had a huge advantage over the rest.

Once RNA sequences that carried genetic information appeared in protobionts, many further changes would have been possible. For example, RNA could have provided the template on which DNA nucleotides were assembled. Double-stranded DNA is a much more stable repository for genetic information than the more fragile single-stranded RNA. DNA also can be replicated more accurately. Accurate replication was a necessity as genomes grew larger through gene duplication and other processes and as more properties of the protobionts became coded in genetic information. After DNA appeared, perhaps RNA molecules began to take on their present-day roles as intermediates in the translation of genetic programs, and the RNA world gave way to a "DNA world." The stage was now set for a blossoming of diverse life-forms—a change we see documented in the fossil record.

CONCEPT CHECK 25.1

1. What hypothesis did Miller and Urey test in their famous experiment?
2. How would the appearance of protobionts have represented a key step in the origin of life?
3. **WHAT IF?** If scientists built a protobiont with self-replicating RNA and metabolism under conditions similar to those on early Earth, would this prove that life began as in the experiment? Explain.

For suggested answers, see Appendix A.

CONCEPT 25.2

The fossil record documents the history of life

Starting with the earliest traces of life, the fossil record opens a window into the world of long ago and provides glimpses of the evolution of life over billions of years. In this section, we'll explore what the fossil record reveals about the major changes in the history of life—what those changes have been and how they may have occurred.

The Fossil Record

Recall from Chapter 22 that sedimentary rocks are the richest source of fossils. As a result, the fossil record is based primarily on the sequence in which fossils have accumulated in sedimentary rock layers called *strata* (see Figure 22.3). Useful information is also provided by other types of fossils, such as insects preserved in amber (fossilized tree sap) and mammals frozen in ice.

The fossil record shows that there have been great changes in the kinds of organisms that dominated life on Earth at different points in time **(Figure 25.4)**. Many past organisms were unlike today's organisms, and many organisms that once were common are now extinct. As we'll see later, fossils also document how new groups of organisms arose from previously existing ones.

As substantial and significant as the fossil record is, keep in mind that it is an incomplete chronicle of evolutionary change. Many of Earth's organisms probably did not die in the right place at the right time to be preserved as fossils. Of those fossils that were formed, many were destroyed by later geologic processes, and only a fraction of the others have been discovered. As a result, the known fossil record is biased in favor of species that existed for a long time, were abundant and widespread in certain kinds of environments, and had hard shells, skeletons, or other parts that facilitated their fossilization. Even with its limitations, however, the fossil record is a remarkably detailed account of biological change over the vast scale of geologic time. Furthermore, as shown by the recently unearthed fossils of whale ancestors with hind limbs (see Figure 22.16), gaps in the fossil record continue to be filled by new discoveries.

How Rocks and Fossils Are Dated

Fossils are valuable data for reconstructing the history of life, but only if we can determine where they fit in that unfolding story. While the order of fossils in rock strata tells us the sequence in which the fossils were laid down—their relative ages—it does not tell us their actual (absolute) ages. Examining the relative positions of fossils in strata is like peeling off layers of wallpaper in an old house. You can determine the

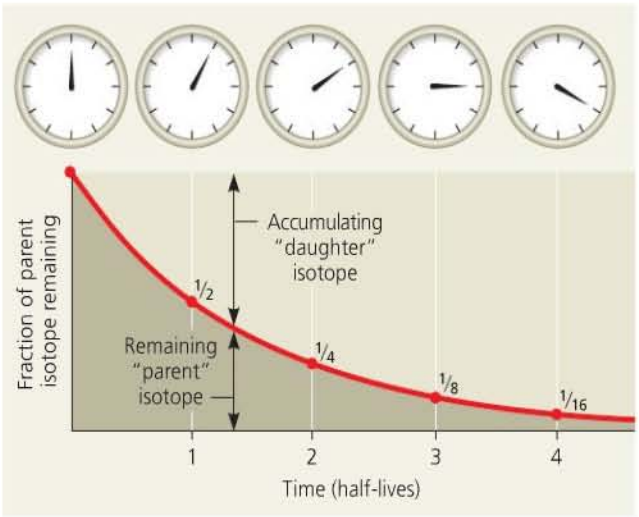
sequence in which the layers were applied, but not the year each layer was added.



How can we determine the absolute age of a fossil? (Note that "absolute" dating does not mean errorless dating, but only that an age is given in years rather than relative terms such as *before* and *after*.) One of the most common techniques is **radiometric dating**, which is based on the decay of radioactive isotopes (see Chapter 2). A radioactive "parent" isotope decays to a "daughter" isotope at a constant rate. The rate of decay is expressed by the **half-life**, the time required for 50% of the parent isotope to decay **(Figure 25.5)**. Each variety of radioactive isotope has a characteristic half-life, which is not affected by temperature, pressure, or other such environmental variables. For example, carbon-14 decays relatively quickly; it has a half-life of 5,730 years. Uranium-238 decays slowly; its half-life is 4.5 billion years.

Fossils contain isotopes of elements that accumulated in the organisms when they were alive. For example, the carbon in a living organism includes the most common carbon isotope, carbon-12, as well as a radioactive isotope, carbon-14. When the organism dies, it stops accumulating carbon, and the amount of carbon-12 in its tissues does not change over time. However, the carbon-14 that it contains at the time of death slowly decays and becomes another element, nitrogen-14. Thus, by measuring the ratio of carbon-14 to carbon-12 in a fossil, we can determine the fossil's age. This method works for fossils up to about 75,000 years old; fossils older than that contain too little carbon-14 to be detected with current techniques. Radioactive isotopes with longer half-lives are used to date older fossils.

Determining the age of old fossils in sedimentary rocks can be challenging. One reason is that organisms do not use radioisotopes that have long half-lives, such as uranium-238, to build their bones or shells. Moreover, the sedimentary rocks themselves tend to be composed of sediments of differing ages. Hence, we usually cannot date old fossils directly. However, geologists can apply an indirect method to infer the absolute age of fossils that are sandwiched between two layers of volcanic rocks. For example, researchers might measure the amount in each rock layer of the radioactive isotope potassium-40, which has a half-life of 1.3 billion years. If the two surrounding rock layers were determined to be 525 million and 535 million years old, the fossils likely represent organisms that lived about 530 million years ago.

The magnetism of rocks can also provide dating information. During the formation of volcanic and sedimentary rocks, iron particles in the rock align themselves with Earth's magnetic field. When the rock hardens, the particles' orientation is frozen in time. Measurements of the magnetism of various rock layers indicate that Earth's north and south magnetic poles have reversed repeatedly in the past. Because these magnetic reversals affect the entire planet at once, reversals in one location can be matched with corresponding patterns elsewhere. This approach allows rocks to be dated when other methods are not available. It also can be used to corroborate ages estimated in other ways.

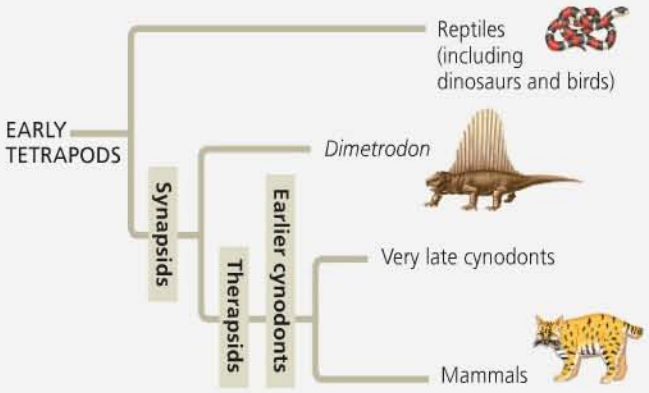
Now that we've seen how fossils can be dated, let's turn to an example of what we can learn from them.

▲ **Figure 25.5 Radiometric dating.** In this diagram, each division of the clock face represents a half-life.

DRAW IT *Relabel the x-axis (time) of this graph to illustrate the radioactive decay of uranium-238 (half-life = 4.5 billion years).*

The Origin of New Groups of Organisms

Some fossils provide a detailed look at the origin of new groups of organisms. Such fossils are central to our understanding of evolution; they illustrate how new features of organisms arise and how long it takes for such changes to occur. We'll examine one such case here, the origin of mammals.

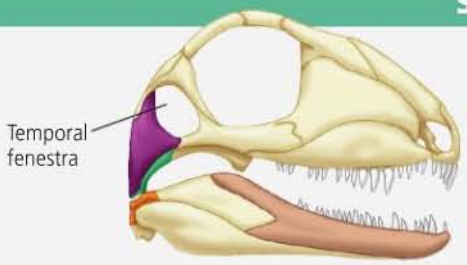


Along with amphibians and reptiles, mammals belong to the group of animals called *tetrapods* (from the Greek *tetra*, four, and *pod*, foot), named for having four limbs. Mammals have a number of unique anatomical features that fossilize readily, allowing scientists to trace their origin. For example, the lower jaw is composed of one bone (the dentary) in mammals but several bones in other tetrapods. In addition, the lower and upper jaws hinge between a different set of bones in mammals than in other tetrapods. As we'll explore in Chapter 34, mammals also have a unique set of three bones that transmit sound in the middle ear (the hammer, anvil, and stirrup), whereas other tetrapods have only one such bone (the stirrup). Finally, the teeth of mammals are differentiated into incisors (for tearing), canines (for piercing), and the multi-pointed premolars and molars (for grinding). In contrast, the teeth of other tetrapods usually consist of a row of undifferentiated, single-pointed teeth.

As detailed in **Figure 25.6**, the fossil record shows that the unique features of mammalian jaws and teeth evolved as a series of gradual modifications. As you study Figure 25.6, bear in

▼ Figure 25.6

Exploring The Origin of Mammals

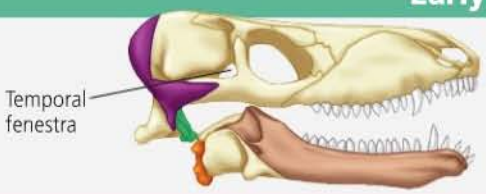


Over the course of 120 million years, mammals originated gradually from a group of tetrapods called synapsids. Shown here are a few of the many fossil organisms whose morphological features represent intermediate steps between living mammals and their synapsid ancestors. The evolutionary context of the origin of mammals is shown in the tree diagram at right.

Key

- Articular
- Quadrate
- Dentary
- Squamosal

Synapsid (300 mya)



Synapsids had multiple bones in the lower jaw and single-pointed teeth. The jaw hinge was formed by the articular and quadrate bones. Synapsids also had an opening called the temporal fenestra behind the eye socket. Powerful cheek muscles for closing the jaws probably passed through the temporal fenestra. Over time, this opening enlarged and moved in front of the hinge between the lower and upper jaws, thereby increasing the power and precision with which the jaws could be closed (much as moving a doorknob away from the hinge makes a door easier to close).

Therapsid (280 mya)

Later, a group of synapsids called therapsids appeared. Therapsids had large dentary bones, long faces, and the first signs of specialized teeth, large canines.

Early cynodont (260 mya)

In early cynodont therapsids, the dentary was the largest bone in the lower jaw, the temporal fenestra was large and positioned forward of the jaw hinge, and teeth with several cusps first appeared (not visible in the diagram). As in earlier synapsids, the jaw had an articular-quadrate hinge.

Later cynodont (220 mya)

Later cynodonts had teeth with complex cusp patterns and their lower and upper jaws hinged in two locations: They retained the original articular-quadrate hinge and formed a new, second hinge between the dentary and squamosal bones.

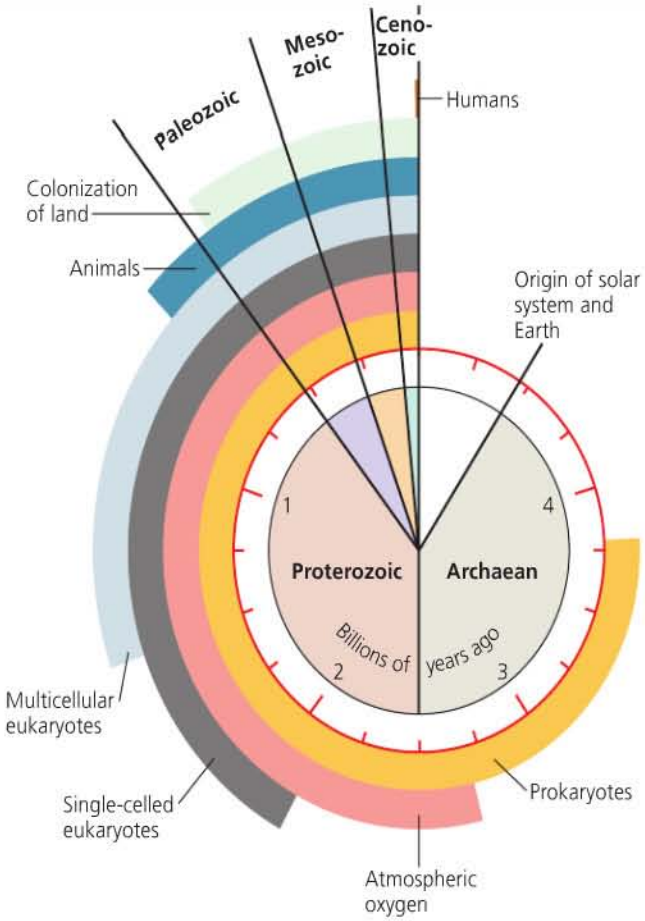
Very late cynodont (195 mya)

In the common ancestor of this very late cynodont and mammals, the original articular-quadrate hinge was lost, leaving the dentary-squamosal hinge as the only hinge between the lower and upper jaws (as in living mammals). The articular and quadrate bones migrated into the ear region (not shown), where they functioned in transmitting sound. In the mammal lineage, these two bones later evolved into the familiar hammer and anvil (see Figure 34.31).

mind that it includes just a few examples of the fossil skulls that document the origin of mammals. If all the known fossils in the sequence were arranged by shape and placed side by side, their features would blend smoothly from one group to the next, reflecting how the features of a new group, the mammals, gradually arose in a previously existing group, the cynodonts.

CONCEPT CHECK 25.2

1. Your measurements indicate that a fossilized skull you unearthed has a carbon-14/carbon-12 ratio about ⅛ that of the skulls of present-day animals. What is the approximate age of the fossilized skull?
2. Describe an example from the fossil record that shows how life has changed over time.
3. **WHAT IF?** Suppose researchers discover a fossil of an organism that lived 300 million years ago, but had mammalian teeth and a mammalian jaw hinge. What inferences might you draw from this fossil about the origin of mammals and the evolution of novel skeletal structures? Explain.



For suggested answers, see Appendix A.

CONCEPT 25.3

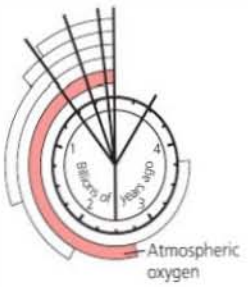
Key events in life's history include the origins of single-celled and multicelled organisms and the colonization of land

The study of fossils has helped geologists to establish a **geologic record** of Earth's history, which is divided into three eons (**Table 25.1**, on the facing page). The first two eons—the Archaean and the Proterozoic—together lasted approximately 4 billion years. The Phanerozoic eon, roughly the last half billion years, encompasses most of the time that animals have existed on Earth. It is divided into three eras: the Paleozoic, Mesozoic, and Cenozoic. Each era represents a distinct age in the history of Earth and its life. For example, the Mesozoic era is sometimes called the "age of reptiles" because of its abundance of reptilian fossils, including those of dinosaurs. The boundaries between the eras correspond to major extinction events seen in the fossil record, when many forms of life disappeared and were replaced by forms that evolved from the survivors.

As we've seen, the fossil record provides a sweeping overview of the history of life over geologic time. Here we will focus on a few major events in that history, returning to study the details in Unit Five. **Figure 25.7** uses the analogy of a clock to place these events in the context of the geologic record. This clock will reappear at various points in this section as a quick visual reminder of when the events we are discussing took place.

▲ **Figure 25.7 Clock analogy for some key events in Earth's history.** The clock ticks down from the origin of Earth 4.6 billion years ago to the present.

The First Single-Celled Organisms



The earliest evidence of life, dating from 3.5 billion years ago, comes from fossilized stromatolites (see Figure 25.4). **Stromatolites** are layered rocks that form when certain prokaryotes bind thin films of sediment together. Present-day stromatolites are found in a few warm, shallow, salty bays. If microbial communities complex enough to form stromatolites existed 3.5 billion years ago, it is a reasonable hypothesis that single-celled organisms originated much earlier, perhaps as early as 3.9 billion years ago.

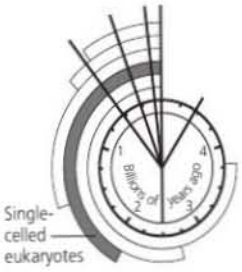
Early prokaryotes were Earth's sole inhabitants from at least 3.5 billion years ago to about 2.1 billion years ago. As we will see, these prokaryotes transformed life on our planet.

Table 25.1 The Geologic Record

Relative Duration of Eons	Era	Period	Epoch	Age (Millions of Years Ago)	Some Important Events in the History of Life
Phanerozoic	Cenozoic	Neogene	Holocene	0.01	Historical time
			Pleistocene	1.8	Ice ages; humans appear
			Pliocene	5.3	Origin of genus *Homo*
			Miocene	23	Continued radiation of mammals and angiosperms; apelike ancestors of humans appear
		Paleogene	Oligocene	33.9	Origins of many primate groups, including apes
			Eocene	55.8	Angiosperm dominance increases; continued radiation of most present-day mammalian orders
			Paleocene	65.5	Major radiation of mammals, birds, and pollinating insects
Proterozoic	Mesozoic	Cretaceous		145.5	Flowering plants (angiosperms) appear and diversify; many groups of organisms, including most dinosaurs, become extinct at end of period
		Jurassic		199.6	Gymnosperms continue as dominant plants; dinosaurs abundant and diverse
		Triassic		251	Cone-bearing plants (gymnosperms) dominate landscape; dinosaurs evolve and radiate; origin of mammals
	Paleozoic	Permian		299	Radiation of reptiles; origin of most present-day groups of insects; extinction of many marine and terrestrial organisms at end of period
		Carboniferous		359.2	Extensive forests of vascular plants form; first seed plants appear; origin of reptiles; amphibians dominant
		Devonian		416	Diversification of bony fishes; first tetrapods and insects appear
		Silurian		443.7	Diversification of early vascular plants
		Ordovician		488.3	Marine algae abundant; colonization of land by diverse fungi, plants, and animals
Archaean		Cambrian		542	Sudden increase in diversity of many animal phyla (Cambrian explosion)
		Ediacaran		635	Diverse algae and soft-bodied invertebrate animals appear
				2,100	Oldest fossils of eukaryotic cells appear
				2,500	
				2,700	Concentration of atmospheric oxygen begins to increase
				3,500	Oldest fossils of cells (prokaryotes) appear
				3,800	Oldest known rocks on Earth's surface
				Approx. 4,600	Origin of Earth

Photosynthesis and the Oxygen Revolution

Most atmospheric oxygen gas (O_2) is of biological origin, produced during the water-splitting step of photosynthesis. When oxygenic photosynthesis first evolved, the free O_2 it produced probably dissolved in the surrounding water until it reached a high enough concentration to react with dissolved iron. This would have caused the iron to precipitate as iron oxide, which accumulated as sediments. These sediments were compressed into banded iron formations, red layers of rock containing iron oxide that are a source of iron ore today **(Figure 25.8)**. Once all of the dissolved iron had precipitated, additional O_2 dissolved in the water until the seas and lakes became saturated with O_2. After this occurred, the O_2 finally began to "gas out" of the water and enter the atmosphere. This change left its mark in the rusting of iron-rich terrestrial rocks, a process that began about 2.7 billion years ago. This chronology implies that bacteria similar to today's cyanobacteria (oxygen-releasing, photosynthetic bacteria) originated well before 2.7 billion years ago.

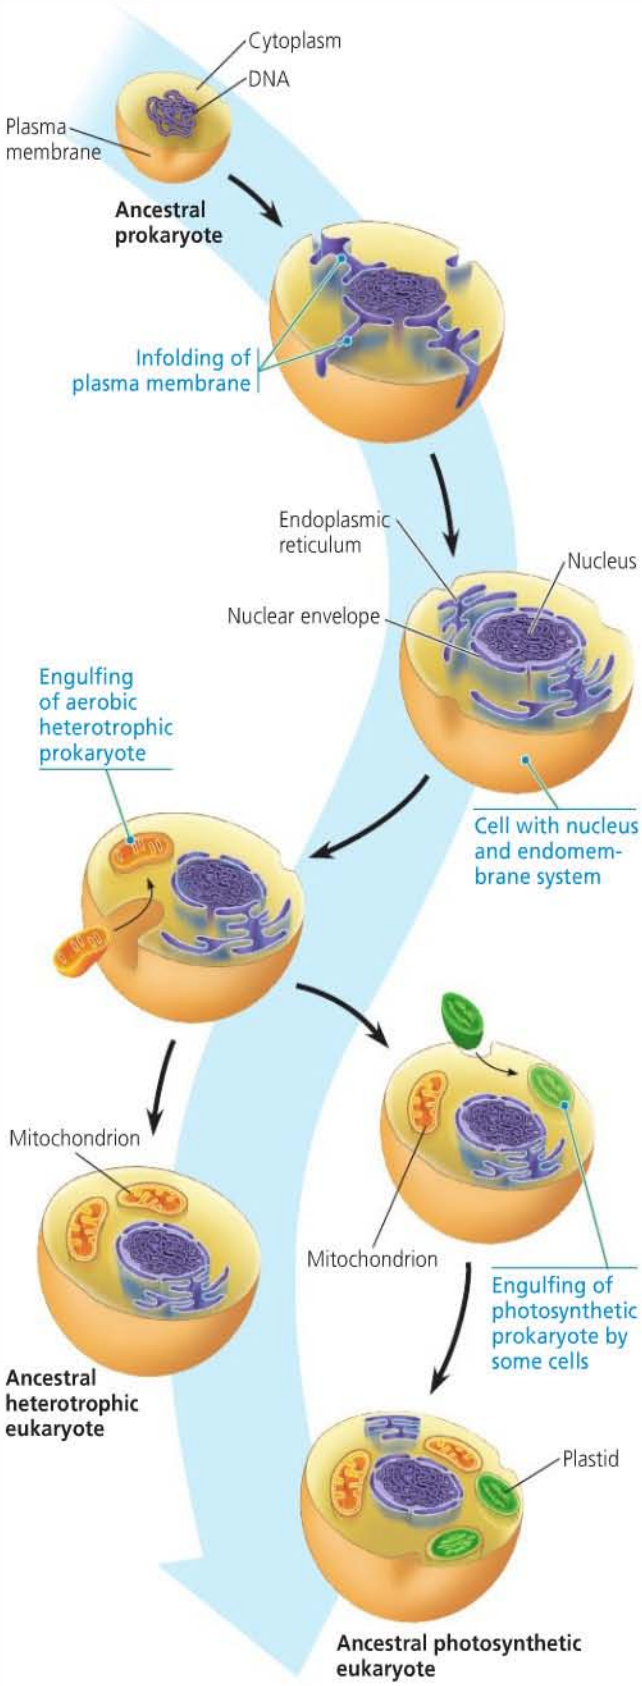


The amount of atmospheric O_2 increased gradually from about 2.7 to 2.2 billion years ago, but then shot up relatively rapidly to more than 10% of its present level. This "oxygen revolution" had an enormous impact on life. In certain of its chemical forms, oxygen attacks chemical bonds and can inhibit enzymes and damage cells. As a result the rising concentration of atmospheric O_2 probably doomed many prokaryotic groups. Some species survived in habitats that remained anaerobic, where we find their descendants living today (see Chapter 27). Among other survivors, diverse adaptations to the changing atmosphere evolved, including cellular respiration, which uses O_2 in the process of harvesting the energy stored in organic molecules.

▲ **Figure 25.8 Banded iron formations: evidence of oxygenic photosynthesis.** The reddish streaks in this sedimentary rock are bands of iron oxide.

As mentioned previously, the early, gradual rise in atmospheric O_2 levels was probably brought about by ancient cyanobacteria. A few hundred million years later, the rise in O_2 accelerated. What caused this acceleration? One hypothesis is that this rise followed the evolution of eukaryotic cells containing chloroplasts, as we will discuss in the next section.

The First Eukaryotes

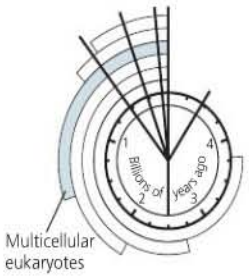


The oldest widely accepted fossils of eukaryotic organisms are about 2.1 billion years old. Recall that eukaryotic cells have more complex organization than prokaryotic cells: Eukaryotic cells have a nuclear envelope, mitochondria, endoplasmic reticulum, and other internal structures that prokaryotes lack. Also, unlike prokaryotic cells, eukaryotic cells have a cytoskeleton, a feature that enables eukaryotic cells to change their shape and thereby surround and engulf other cells.

How did these eukaryotic features evolve from prokaryotic cells? A range of evidence supports a model called **endosymbiosis**, which posits that mitochondria and plastids (a general term for chloroplasts and related organelles) were formerly small prokaryotes that began living within larger cells. The term *endosymbiont* refers to a cell that lives within another cell, called the *host cell.* The prokaryotic ancestors of mitochondria and plastids probably gained entry to the host cell as undigested prey or internal parasites. Though such a process may seem unlikely, scientists have directly observed cases in which endosymbionts that began as prey or parasites came to have a mutually beneficial relationship with the host in as little as five years.

By whatever means the relationships began, we can hypothesize how the symbiosis could have become mutually beneficial. A heterotrophic host could use nutrients released from photosynthetic endosymbionts. And in a world that was becoming increasingly aerobic, a host that was itself an anaerobe would have benefited from endosymbionts that turned the oxygen to advantage. Over time, the host and endosymbionts would have become a single organism, its parts inseparable. Although all eukaryotes have mitochondria or remnants of these organelles, they do not all have plastids. Thus, the model of **serial endosymbiosis** supposes that mitochondria evolved before plastids through a sequence of endosymbiotic events **(Figure 25.9)**.

A great deal of evidence supports the endosymbiotic origin of mitochondria and plastids. The inner membranes of both organelles have enzymes and transport systems that are homologous to those found in the plasma membranes of living prokaryotes. Mitochondria and plastids replicate by a splitting process that is similar to that of certain prokaryotes. In addition, each of these organelles contains a single, circular DNA



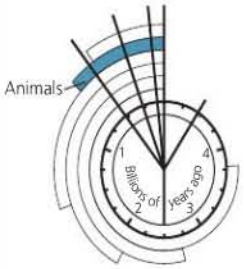
▲ **Figure 25.9 A model of the origin of eukaryotes through serial endosymbiosis.** The proposed ancestors of mitochondria were aerobic, heterotrophic prokaryotes (meaning they used oxygen to metabolize organic molecules obtained from other organisms). The proposed ancestors of plastids were photosynthetic prokaryotes. Note that the arrows represent change over evolutionary time.

molecule that, like the chromosomes of bacteria, is not associated with histones or large amounts of other proteins. As might be expected of organelles descended from free-living organisms, mitochondria and plastids also have the cellular machinery (including ribosomes) needed to transcribe and translate their DNA into proteins. Finally, in terms of size, nucleotide sequence, and sensitivity to certain antibiotics, the ribosomes of mitochondria and plastids are more similar to prokaryotic ribosomes than they are to the cytoplasmic ribosomes of eukaryotic cells.

The Origin of Multicellularity

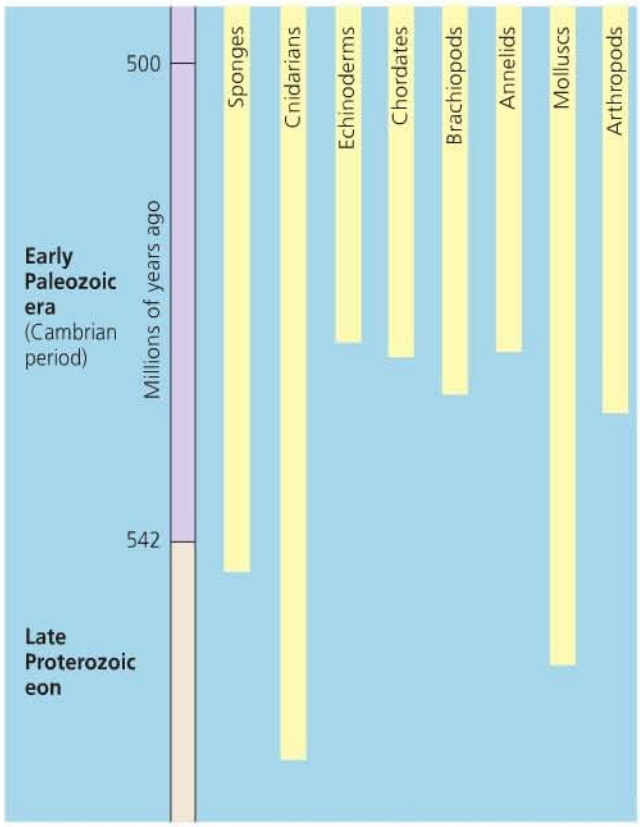
An orchestra can play a greater variety of musical compositions than a violin soloist can; the increased complexity of the orchestra makes more variations possible. Likewise, the appearance of structurally complex eukaryotic cells sparked the evolution of greater morphological diversity than was possible for the simpler prokaryotic cells. After the first eukaryotes appeared, a great range of unicellular forms evolved, giving rise to the diversity of single-celled eukaryotes that continue to flourish today. Another wave of diversification also occurred: Some single-celled eukaryotes gave rise to multicellular forms, whose descendants include a variety of algae, plants, fungi, and animals.

The Earliest Multicellular Eukaryotes



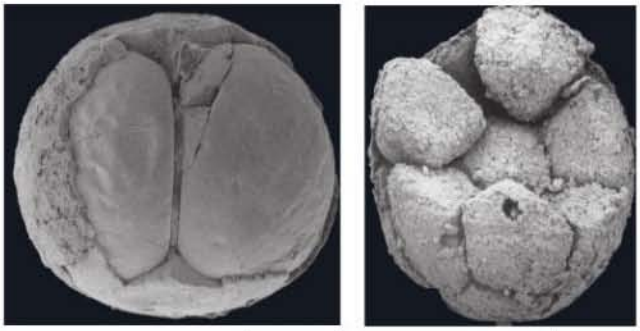
Based on comparisons of DNA sequences, researchers have suggested that the common ancestor of multicellular eukaryotes lived 1.5 billion years ago. This result is in rough agreement with the fossil record; the oldest known fossils of multicellular eukaryotes are of relatively small algae that lived about 1.2 billion years ago. Larger and more diverse multicellular eukaryotes do not appear in the fossil record until about 565 million years ago (see Figure 25.4). These fossils, referred to as the Ediacaran biota, were of soft-bodied organisms—some over 1 m long—that lived from 565 to 535 million years ago.

Why were multicellular eukaryotes limited in size and diversity until the late Proterozoic? Geologic evidence indicates that a series of severe ice ages occurred from 750 to 580 million years ago. At various times during this period, glaciers covered all of the planet's landmasses, and the seas were largely iced over. The "snowball Earth" hypothesis suggests that most life would have been confined to areas near deep-sea vents and hot springs or to equatorial regions of the ocean that lacked ice cover. The fossil record of the first major diversification of multicellular eukaryotes (beginning about 565 million years ago) corresponds roughly to the time when snowball Earth thawed. As that diversification came to a close about 30 million years



later, the stage was set for another, even more spectacular burst of evolutionary change.

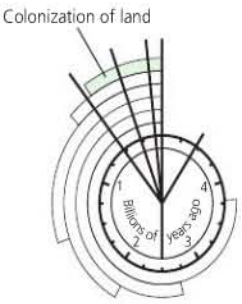
The Cambrian Explosion



Many phyla of living animals appear suddenly in fossils formed early in the Cambrian period (535–525 million years ago), a phenomenon referred to as the **Cambrian explosion**. Fossils of at least three living animal phyla—Cnidaria (sea anemones and their relatives), Porifera (sponges), and Mollusca (molluscs)—appear in even older rocks dating from the late Proterozoic **(Figure 25.10)**.

Prior to the Cambrian explosion, all large animals were soft-bodied. The fossils of large pre-Cambrian animals reveal little evidence of predation. Instead, these animals appear to have been herbivores (feeding on algae), filter feeders, or scavengers, not hunters. The Cambrian explosion changed all of that. In a relatively short period of time (10 million years), predators over 1 m in length emerged that had claws and other features for capturing prey; simultaneously, new defensive adaptations, such as sharp spines and heavy body armor, appeared in their prey (see Figure 25.4). The safe, slow-moving

▲ **Figure 25.10 Appearance of selected animal phyla.** The yellow bars indicate earliest appearances of these phyla in the fossil record, although they could have originated earlier.



▲ **Figure 25.11 Proterozoic fossils that may be animal embryos (SEM).**

world that characterized larger forms of life before the Cambrian explosion was gone forever.

Although the Cambrian explosion had an enormous impact on life on Earth, it is possible that many animal phyla originated long before that time. Some DNA analyses suggest that most animal phyla originated and began to diverge from one another as early as 700 million to 1 billion years ago. Even if these estimates are not correct, recent fossil discoveries in China suggest that animals similar to members of living animal phyla were present tens of millions of years before the Cambrian explosion. The discoveries include 575-million-year-old fossils of beautifully preserved specimens interpreted by some scientists as animal embryos and by others as members of extinct groups closely related to animals **(Figure 25.11)**. Overall, as noted by Cambridge University paleontologist Simon Conway Morris, "the Cambrian explosion had a long fuse"—at least 40 million years long, based on the Chinese fossils. The fuse may have been hundreds of millions of years long if some animal phyla originated as far back as some DNA-based estimates suggest.

The Colonization of Land

The colonization of land was another milestone in the history of life. There is fossil evidence that cyanobacteria and other photosynthetic prokaryotes coated damp terrestrial surfaces well over a billion years ago. However, larger forms of life, such as fungi, plants, and animals, did not begin to colonize land until about 500 million years ago. This gradual evolutionary venture out of aquatic environments was associated with adaptations that made it possible to reproduce on land and that helped prevent dehydration. For example, many land plants today have a vascular system for transporting materials internally and a waterproof coating of wax on their leaves that slows the loss of water to the air. Early signs of these adaptations were present 420 million years ago, at which time there were

small plants (about 10 cm high) that had a vascular system but lacked true roots or leaves. About 50 million years later, plants had diversified greatly and included reeds and treelike plants with true roots and leaves.

Plants colonized land in the company of fungi. Even today, the roots of most plants are associated with fungi that aid in the absorption of water and minerals from the soil (see Chapter 31). These root fungi, in turn, obtain their organic nutrients from the plants. Such mutually beneficial associations of plants and fungi are evident in some of the oldest fossilized roots, dating this relationship back to the early spread of life onto land.

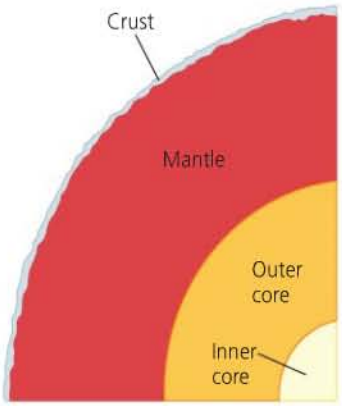
Although many animal groups are now represented in terrestrial environments, the most widespread and diverse land animals are arthropods (particularly insects and spiders) and tetrapods. The earliest tetrapods found in the fossil record lived about 365 million years ago and appear to have evolved from a group of lobe-finned fishes (see Chapter 34). Tetrapods include humans, although we are late arrivals on the scene. The human lineage diverged from other primates around 6–7 million years ago, and our species originated only about 195,000 years ago. If the clock of Earth's history were rescaled to represent an hour, humans appeared less than 0.2 second ago.

CONCEPT CHECK 25.3

1. The first appearance of free oxygen in the atmosphere likely triggered a massive wave of extinctions among the prokaryotes of the time. Why?
2. What evidence supports the hypothesis that mitochondria preceded plastids in the evolution of eukaryotic cells?
3. **WHAT IF?** What would a fossil record of life today look like?

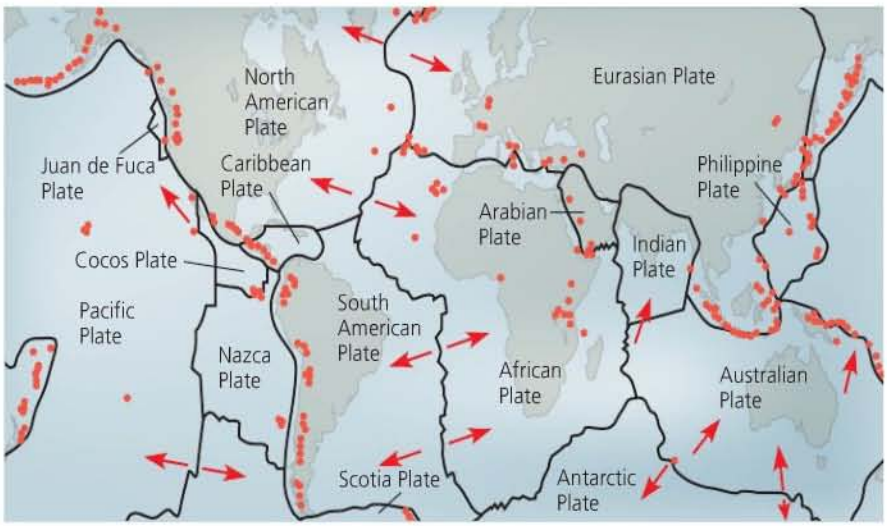
For suggested answers, see Appendix A.

CONCEPT 25.4
The rise and fall of dominant groups reflect continental drift, mass extinctions, and adaptive radiations



From its beginnings, life on Earth has seen the rise and fall of groups of organisms. Anaerobic prokaryotes originated, flourished, and then declined as the oxygen content of the atmosphere rose. Billions of years later, the first tetrapods emerged from the sea, giving rise to amphibians that went on to dominate life on land for 100 million years—until other tetrapods (including dinosaurs and later, mammals) replaced them as the dominant terrestrial vertebrates. These and other major changes in life on Earth have been influenced by large-scale processes such as continental drift, mass extinctions, and adaptive radiations.

Continental Drift



If photographs of Earth were taken from space every 10,000 years and spliced together to make a movie, it would show something many of us find hard to imagine: The seemingly "rock solid" continents we live on move over time. Since the origin of multicellular eukaryotes roughly 1.5 billion years ago, there have been three occasions (1.1 billion, 600 million, and 250 million years ago) in which all of the landmasses of Earth came together to form a supercontinent, then later broke apart. Each time they yielded a different configuration of continents. Looking into the future, geologists estimate that the continents will come together again and form a new supercontinent roughly 250 million years from now.

The continents are part of great plates of Earth's crust that essentially float on the hot, underlying portion of the mantle **(Figure 25.12a)**. These plates move over time in a process

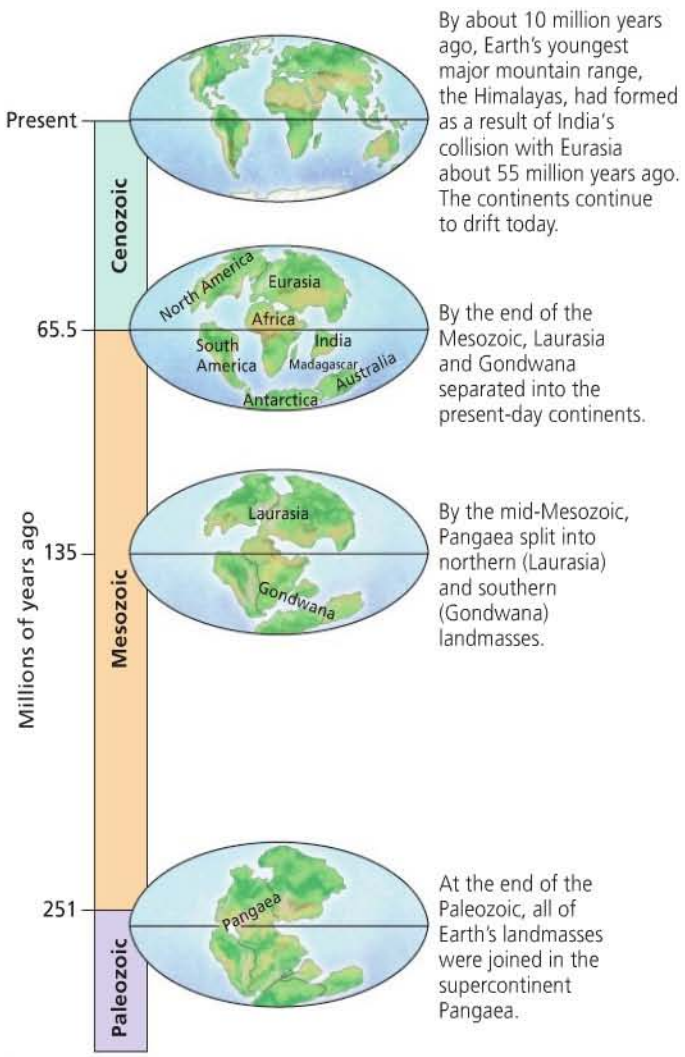
▼ **Figure 25.12 Earth and its continental plates.**

(a) Cutaway view of Earth. The thickness of the crust is exaggerated here.

(b) Major continental plates. The arrows indicate direction of movement. The reddish-orange dots represent zones of violent tectonic activity.

called **continental drift**. Geologists can measure the rate at which the continental plates are moving today—usually only a few centimeters per year. They can also infer the past locations of the continents using the magnetic signal recorded in rocks at the time of their formation. This method works because as a continent shifts its position over time, the direction of magnetic north recorded in its newly formed rocks also changes.

Earth's major continental plates are shown in **Figure 25.12b**. Many important geologic processes, including the formation of mountains and islands, occur at plate boundaries. In some cases, two plates are moving away from one another, as are the North American and Eurasian plates, which are currently drifting apart at a rate of about 2 cm per year. In other cases, two plates are sliding past one another, forming regions where earthquakes are common. California's infamous San Andreas Fault is part of a border where two plates slide past each other. In still other cases, two plates are colliding. Typically, oceanic plates (those found on the bottom of the ocean) are more dense than terrestrial plates. As a result, when an oceanic plate collides with a terrestrial plate, the oceanic plate usually sinks below the terrestrial plate. When two oceanic plates or two terrestrial plates collide with one another, violent upheavals occur and mountains form along the plate boundaries. One spectacular example of this occurred 55 million years ago, when the Indian plate crashed into the Eurasian plate, starting the formation of the Himalayan mountains.



Consequences of Continental Drift

Plate movements rearrange geography slowly, but their cumulative effects are dramatic. In addition to reshaping the physical features of our planet, continental drift also has a major impact on life on Earth.

One reason for its great impact on life is that continental drift alters the habitats in which organisms live. Consider the changes shown in **Figure 25.13**. About 250 million years ago, plate movements brought all the previously separated landmasses together into a supercontinent named **Pangaea**, meaning "all land." Ocean basins became deeper, which lowered sea level and drained shallow coastal seas. At that time, as now, most marine species inhabited shallow waters, and the formation of Pangaea destroyed a considerable amount of that habitat. The interior of the vast continent was cold and dry, probably an even more severe environment than that of central Asia today. Overall, the formation of Pangaea had a tremendous impact on the physical environment and climate, which drove some species to extinction and provided new opportunities for groups of organisms that survived the crisis.

Another effect of continental drift is the climate change that results when a continent shifts northward or southward. The southern tip of Labrador, Canada, for example, once was located near the equator but has moved 40° to the north over the last 200 million years. To appreciate the impact of such a shift, compare the climate of Wilmington, Delaware (about 40° north latitude), to that of Belem, Brazil (located near the equator). In the winter, temperatures in Wilmington have fallen as low as −26°C (−15°F), while temperatures in Belem have never dropped below 18°C (64°F). When faced with such changes in climate, organisms adapt, move to a new location, or become extinct (this last outcome occurred for most organisms stranded on Antarctica, such as *Cryolophosaurus*, depicted in Figure 25.1). The shifting positions of the continents are also thought to have rerouted the world's ocean currents, causing the global climate to become colder and contributing to the formation of polar ice caps over the past 15 million years.

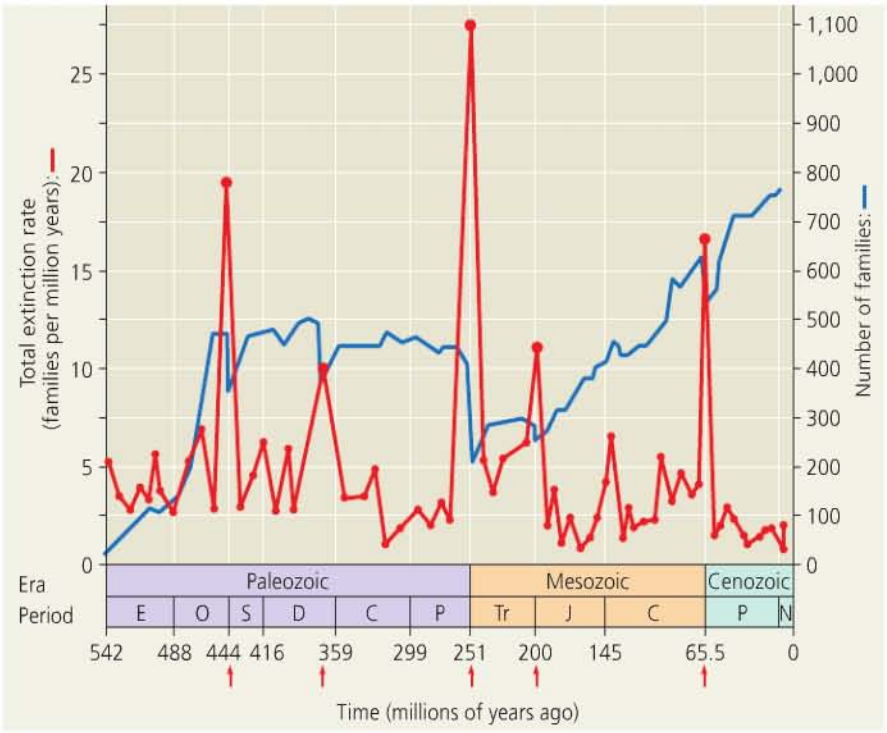
Continental drift also promotes allopatric speciation on a grand scale. When supercontinents break apart, regions that once were connected become geographically isolated. As the continents drifted apart over the last 200 million years, each became a separate evolutionary arena, with lineages of plants and animals that diverged from those on other continents (see Figure 24.6 for one example).

▲ **Figure 25.13 The history of continental drift during the Phanerozoic eon.**

Finally, continental drift can help explain puzzles about the geographic distribution of extinct organisms, such as why fossils of the same species of Permian freshwater reptiles have been discovered in both Brazil and the West African nation of Ghana. These two parts of the world, now separated by 3,000 km of ocean, were joined together when these reptiles were living. Continental drift also explains much about the current distributions of organisms, such as why Australian fauna and flora contrast so sharply with those of the rest of the world. Marsupial mammals fill ecological roles in Australia analogous to those filled by eutherians (placental mammals) on other continents (see Figure 22.20). Marsupials probably originated in what is now Asia and North America and reached Australia via South America and Antarctica while the continents were still joined. The subsequent breakup of the southern continents set Australia "afloat" like a great ark of marsupials. In Australia, marsupials diversified, and the few early eutherians that lived there became extinct; on other continents, most marsupials became extinct, and the eutherians diversified.

Mass Extinctions

The fossil record shows that the overwhelming majority of species that ever lived are now extinct. A species may become extinct for many reasons. Its habitat may have been destroyed, or its environment may have changed in a manner unfavorable to the species. For example, if ocean temperatures fall by even a few degrees, species that are otherwise well adapted may perish. Even if physical factors in the environment remain stable, biological factors may change—the origin of one species can spell doom for another.



Although extinction occurs on a regular basis, at certain times disruptive global environmental changes have caused the rate of extinction to increase dramatically. When this occurs, a **mass extinction** results, in which large numbers of species become extinct throughout Earth.

The "Big Five" Mass Extinction Events

Five mass extinctions are documented in the fossil record over the past 500 million years **(Figure 25.14)**. These events are particularly well documented for the decimation of hard-bodied animals that lived in shallow seas, the organisms for which the fossil record is most complete. In each mass extinction, 50% or more of Earth's marine species became extinct.

Two mass extinctions—the Permian and the Cretaceous—have received the most attention. The Permian mass extinction, which defines the boundary between the Paleozoic and Mesozoic eras (251 million years ago), claimed about 96% of marine animal species and drastically altered life in the ocean. Terrestrial life was also affected. For example, 8 out of 27 known orders of insects were wiped out. This mass extinction occurred in less than 5 million years, possibly in a few thousands of years—an instant in the context of geologic time.

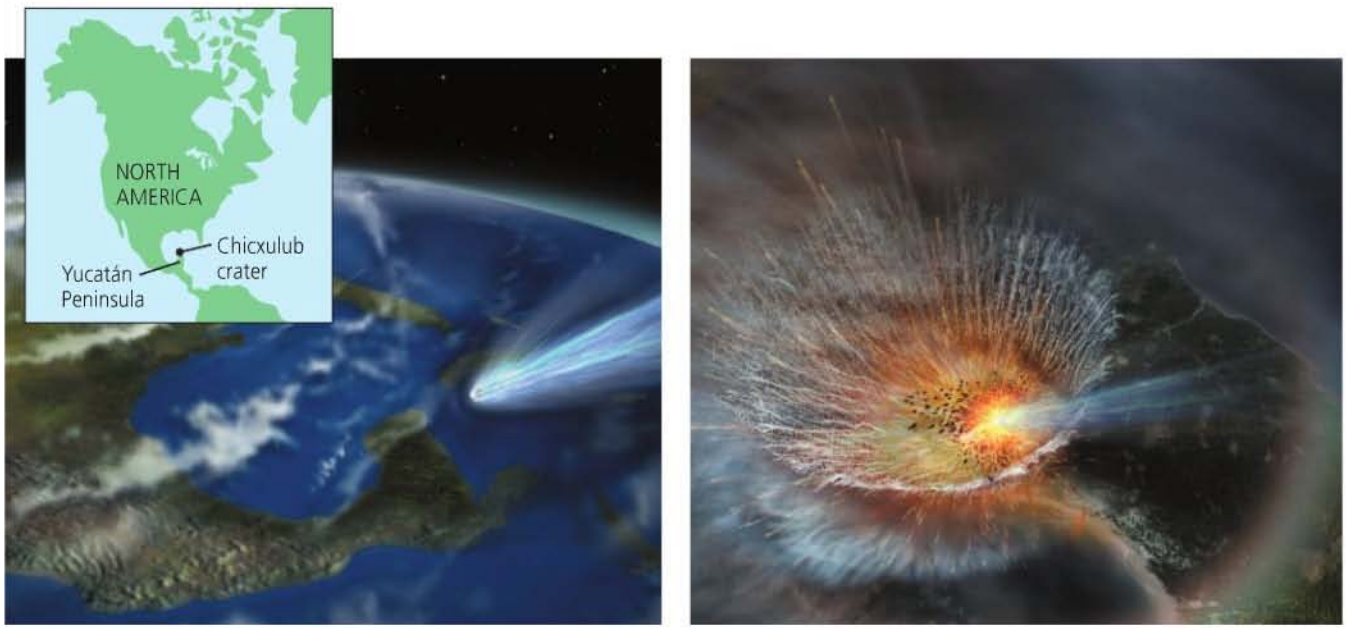
The Permian mass extinction occurred at the time of enormous volcanic eruptions in what is now Siberia. This period was the most extreme episode of volcanism to have occurred during the past half billion years. Geologic data indicate that an area of 1.6 million km^2 (roughly half the size of western Europe) was covered with a layer of lava hundreds to thousands of meters thick. Besides spewing enormous amounts of lava and ash, the eruptions may have produced enough carbon

◀ **Figure 25.14 Mass extinction and the diversity of life.** The five generally recognized mass extinction events, indicated by red arrows, represent peaks in the extinction rate of marine animal families (red line and left vertical axis). These mass extinctions interrupted the overall increase in the number of marine animal families over time (blue line and right vertical axis).

dioxide to warm the global climate by an estimated 6°C. Reduced temperature differences between the equator and the poles would have slowed the mixing of ocean water, which in turn would have reduced the amount of oxygen available to marine organisms. This oxygen deficit may have been a major cause of the Permian extinction of marine life.

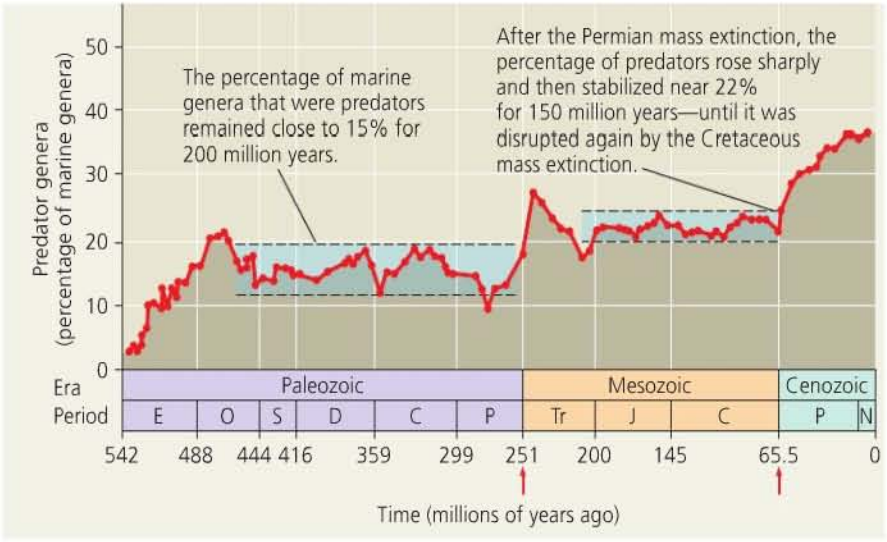
The Cretaceous mass extinction occurred about 65.5 million years ago and marks the boundary between the Mesozoic and Cenozoic eras. This event extinguished more than half of all marine species and eliminated many families of terrestrial plants and animals, including most of the dinosaurs. One clue to a possible cause of the Cretaceous mass extinction is a thin layer of clay enriched in iridium that separates sediments from the Mesozoic and Cenozoic eras. Iridium is an element that is very rare on Earth but common in many of the meteorites and other extraterrestrial objects that occasionally fall to Earth. Walter Alvarez and the late Luis Alvarez, of the University of California, Berkeley, and their colleagues proposed that this clay is fallout from a huge cloud of debris that billowed into the atmosphere when an asteroid or large comet collided with Earth. This cloud would have blocked sunlight and severely disturbed the global climate for several months.

Is there evidence of such an asteroid or comet? Research has focused on the Chicxulub crater, a 65-million-year-old scar beneath sediments off the Yucatán coast of Mexico **(Figure 25.15)**. About 180 km in diameter, the crater is the right size to have been caused by an object with a diameter of 10 km. Critical evaluation of this and other hypotheses for mass extinctions continues.



Is a Sixth Mass Extinction Under Way?

As we will explore in Chapter 56, human actions, such as habitat destruction, are modifying the global environment to such an extent that many species are threatened with extinction. More than a thousand species have become extinct in the last 400 years. Scientists estimate that this rate is 100 to 1,000 times the typical background rate seen in the fossil record. Is a sixth mass extinction now in progress?



This question is difficult to answer, in part because it is hard to document the total number of extinctions occurring today. Tropical rain forests, for example, harbor many undiscovered species. As a result, destroying tropical forest may drive species to extinction before we even learn of their existence. Such uncertainties make it hard to assess the full extent of the current extinction crisis. Even so, it is clear that losses to date have not reached those of the "big five" mass extinctions, in which large percentages of Earth's species became extinct. This does not in any way discount the seriousness of today's situation. Monitoring programs show that many species are declining at an alarming rate. Such data suggest that unless dramatic actions are taken, a sixth (human-caused) mass extinction is likely to occur within the next few centuries or millennia.

Consequences of Mass Extinctions

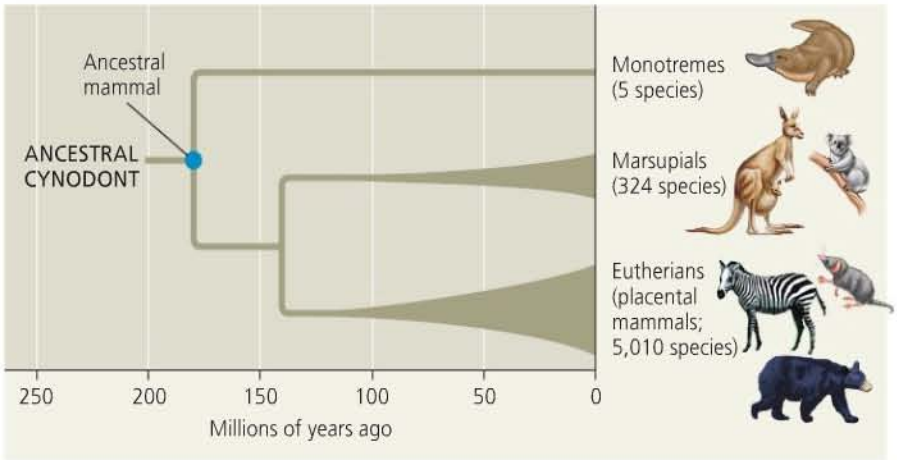
By removing large numbers of species, a mass extinction can reduce a thriving and complex ecological community to a pale shadow of its former self. In addition, when an evolutionary lineage disappears, it cannot reappear. This changes the course of evolution forever. Consider what would have happened if the early primates living 66 million years ago had died out in the

▲ **Figure 25.15 Trauma for Earth and its Cretaceous life.** The 65-million-year-old Chicxulub impact crater is located in the Caribbean Sea near the Yucatán Peninsula of Mexico. The horseshoe shape of the crater and the pattern of debris in sedimentary rocks indicate that an asteroid or comet struck at a low angle from the southeast. This artist's interpretation represents the impact and its immediate effect—a cloud of hot vapor and debris that could have killed many of the plants and animals in North America within hours.

▲ **Figure 25.16 Mass extinctions and ecology.** The Permian and Cretaceous mass extinctions (indicated by red arrows) altered the ecology of the oceans by increasing the percentage of marine genera that were predators.

Cretaceous mass extinction. Humans would not exist, and life on Earth would differ greatly from how we know it.

The fossil record shows that it typically takes 5–10 million years for the diversity of life to recover to previous levels after a mass extinction. In some cases, it has taken much longer than that: It took about 100 million years for the number of marine families to recover after the Permian mass extinction (see Figure 25.14). These data have sobering implications. If current trends continue and a sixth mass extinction occurs, it will take millions of years for life on Earth to recover.



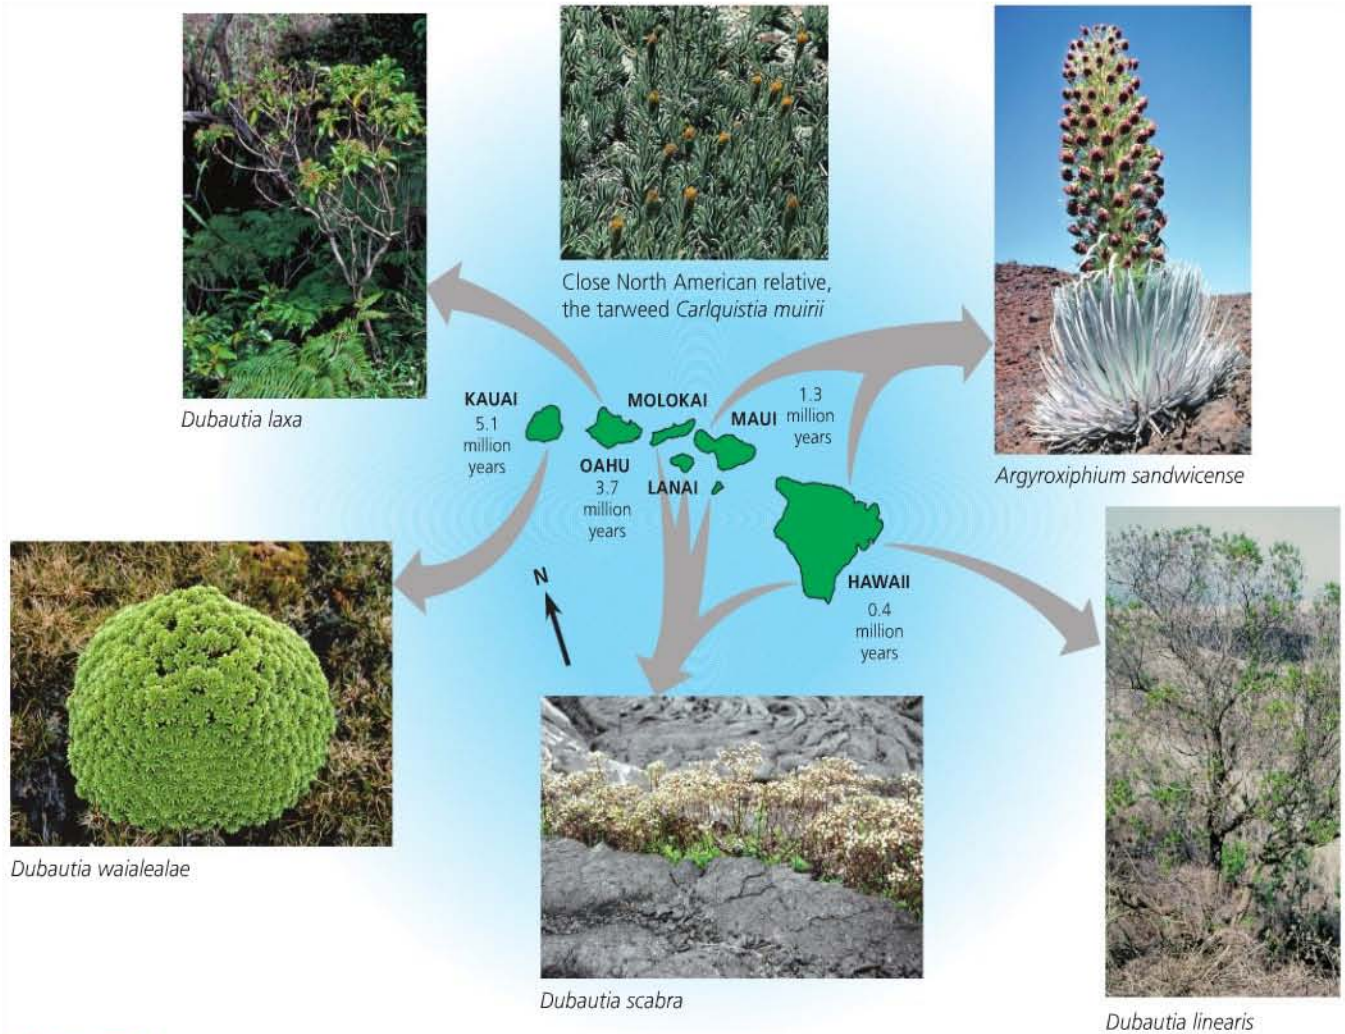
Mass extinctions can also alter ecological communities by changing the types of organisms found in them. For example, after the Permian and Cretaceous mass extinctions, the percentage of marine organisms that were predators increased substantially **(Figure 25.16)**. A rise in the number of predator species can increase both the pressures faced by prey and the competition among predators for food. In addition, mass extinctions can remove lineages with highly advantageous features. For example, in the late Triassic a group of gastropods (snails and their relatives) arose that could drill through the shells of bivalves (such as clams) and feed on the animals inside. Although shell drilling provided access to a new and abundant source of food, this newly formed group was wiped out during the mass extinction at the end of the Triassic (about 200 million years ago). Another 120 million years passed before another group of gastropods (the oyster drills) exhibited the ability to drill through shells. As their predecessors might have done if they had not originated shortly before the Triassic mass extinction, oyster drills have since diversified into many new species. Finally, by eliminating so many of Earth's species, mass extinctions can pave the way for adaptive radiations, in which new groups of organisms rise to prominence.

Adaptive Radiations

The fossil record indicates that the diversity of life has increased over the past 250 million years (see Figure 25.14). This increase has been fueled by **adaptive radiations**, periods of evolutionary change in which groups of organisms form many new species whose adaptations allow them to fill different ecological roles, or niches, in their communities. Large-scale adaptive radiations occurred after each of the big five mass extinctions, when survivors became adapted to the many vacant ecological niches. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations, such as seeds or armored body coverings, or that colonized regions in which they faced little competition from other species.

Worldwide Adaptive Radiations

Fossil evidence indicates that mammals underwent a dramatic adaptive radiation after the extinction of terrestrial dinosaurs 65.5 million years ago **(Figure 25.17)**. Although mammals originated about 180 million years ago, the mammal fossils older than 65.5 million years are mostly small and not morphologically diverse. Many species appear to have been nocturnal based on their large eye sockets, similar to those in living nocturnal mammals. A few early mammals were intermediate in



▲ **Figure 25.17 Adaptive radiation of mammals.**

size, such as *Repenomamus giganticus*, a 1-meter-long predator that lived 130 million years ago—but none approached the size of many dinosaurs. Early mammals may have been restricted in size and diversity because they were eaten or outcompeted by the larger and more diverse dinosaurs. With the disappearance of the dinosaurs (except for birds, which are considered members of the same group; see Chapter 34), mammals expanded greatly in both diversity and size, filling the ecological roles once occupied by terrestrial dinosaurs.

The history of life has also been greatly altered by radiations in which groups of organisms increased in diversity as they came to play entirely new ecological roles in their communities. Examples include the rise of photosynthetic prokaryotes, the evolution of large predators in the Cambrian explosion, and the radiations following the colonization of land by plants, insects, and tetrapods. Each of these last three radiations was associated with major evolutionary innovations that facilitated life on land. The radiation of land plants, for example, was associated with key adaptations, such as stems that support plants against gravity and a waxy coat that protects leaves from water loss. Finally, organisms that arise in an adaptive radiation can serve as a new source of food for still other organisms. In fact, the diversification of land plants stimulated a series of adaptive radiations in insects that ate or pollinated plants, helping to make insects the most diverse group of animals on Earth today.

Regional Adaptive Radiations

Striking adaptive radiations have also occurred over more limited geographic areas. Such radiations can be initiated when a few organisms make their way to a new, often distant location in which they face relatively little competition from other organisms. The Hawaiian archipelago is one of the world's great showcases of this type of adaptive radiation **(Figure 25.18)**. Located about 3,500 km from the nearest continent, the volcanic islands are progressively older as one follows the chain toward

▲ **Figure 25.18 Adaptive radiation on the Hawaiian Islands.** Molecular analysis indicates that these remarkably varied Hawaiian plants, known collectively as the "silversword alliance," are all descended from an ancestral tarweed that arrived on the islands about 5 million years ago from North America. Members of the silversword alliance have since spread into different habitats and formed new species with strikingly different adaptations.

the northwest; the youngest island, Hawaii, is less than a million years old and still has active volcanoes. Each island was born "naked" and was gradually populated by stray organisms that rode the ocean currents and winds either from far-distant land areas or from older islands of the archipelago itself. The physical diversity of each island, including immense variation in elevation and rainfall, provides many opportunities for evolutionary divergence by natural selection. Multiple invasions followed by speciation events have ignited an explosion of adaptive radiation in Hawaii. Most of the thousands of species that inhabit the islands are found nowhere else on Earth.

CONCEPT CHECK 25.4

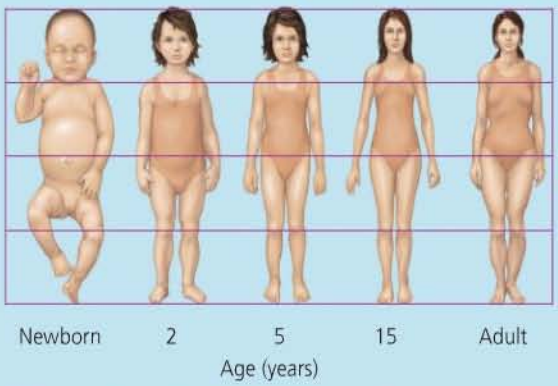
1. Explain consequences of continental drift for life on Earth.
2. What factors promote adaptive radiations?
3. **WHAT IF?** If a mass extinction were caused by a single, catastrophic event (such as an asteroid impact), what pattern would you expect regarding the dates when formerly common species lost in the extinction are last observed in the fossil record?

For suggested answers, see Appendix A.

CONCEPT 25.5

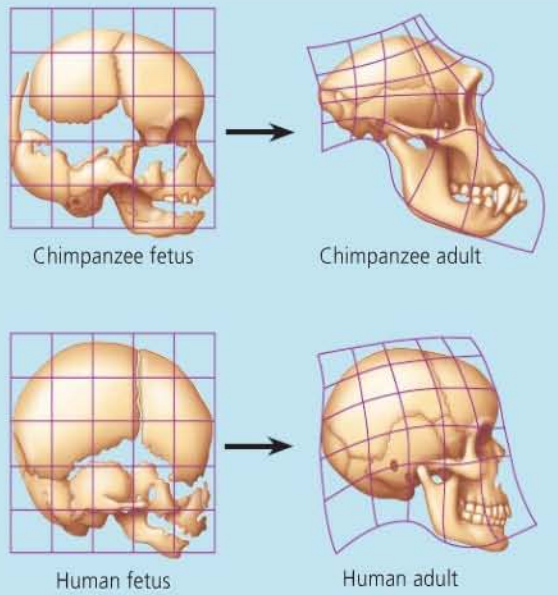
Major changes in body form can result from changes in the sequences and regulation of developmental genes

The fossil record tells us what the great changes in the history of life have been and when they occurred. Moreover, an understanding of continental drift, mass extinction, and adaptive radiation provides a picture of how those changes came about. But we can also seek to understand the intrinsic biological mechanisms that underlie changes seen in the fossil record. For this, we turn to genetic mechanisms of change, paying particular attention to genes that influence development.



Evolutionary Effects of Developmental Genes

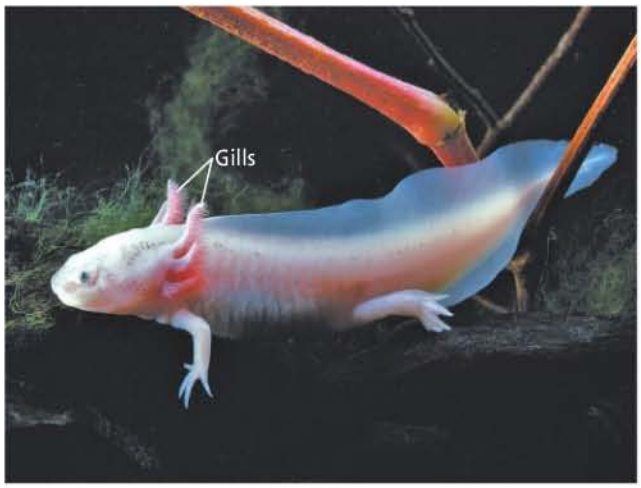
As you read in Chapter 21, "evo-devo"—research at the interface between evolutionary biology and developmental biology—is illuminating how slight genetic divergences can produce major morphological differences between species. Genes that control development influence the rate, timing, and spatial pattern of change in an organism's form as it develops from a zygote into an adult.



Changes in Rate and Timing

Many striking evolutionary transformations are the result of **heterochrony** (from the Greek *hetero,* different, and *chronos,* time), an evolutionary change in the rate or timing of developmental events. For example, an organism's shape depends in part on the relative growth rates of different body parts during development. **Figure 25.19a** tracks how changes in such growth rates alter human body proportions during development. Even slight changes in relative rates of growth can change the adult form substantially, as seen in the contrasting shapes of human and chimpanzee skulls **(Figure 25.19b)**.

Heterochrony can also alter the timing of reproductive development relative to the development of nonreproductive organs. If reproductive-organ development accelerates compared to other organs, the sexually mature stage of a species may retain

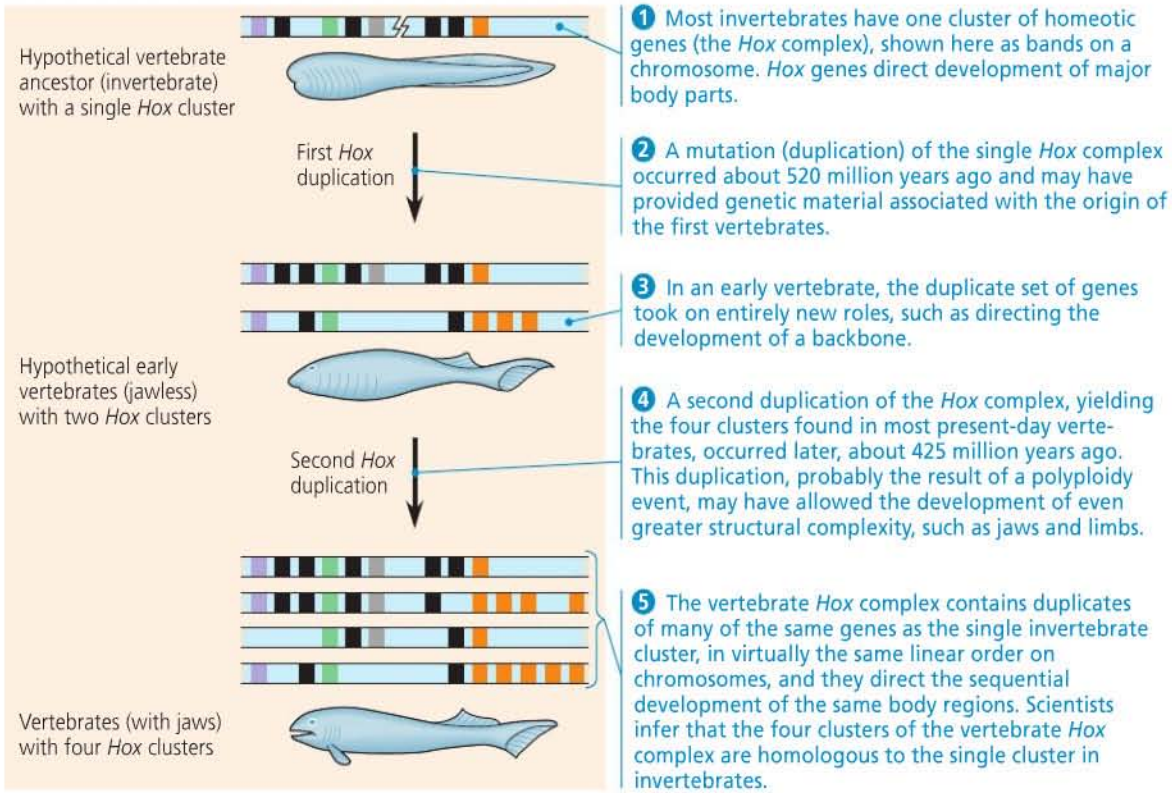


(a) Differential growth rates in a human. The arms and legs lengthen more during growth than the head and trunk, as can be seen in this conceptualization of an individual at different ages all rescaled to the same height.

(b) Comparison of chimpanzee and human skull growth. The fetal skulls of chimpanzees and humans are similar in shape. However, growth in the jaw is accelerated in chimpanzees relative to humans, producing the characteristic elongated skull and sloping forehead of an adult chimpanzee.

▲ **Figure 25.19 Relative growth rates of body parts.**

body features that were juvenile structures in an ancestral species—a condition called **paedomorphosis** (from the Greek *paedos*, of a child, and *morphosis*, formation). For example, most salamander species have aquatic larvae that undergo metamorphosis in becoming adults. But some species grow to adult size and become sexually mature while retaining gills and other larval features **(Figure 25.20)**. Such an evolutionary alteration of developmental timing can produce animals that appear very different from their ancestors, even though the overall genetic change may be small. Indeed, recent evidence indicates that a change at a single locus was probably sufficient to bring about paedomorphosis in the axolotl salamander, although other genes may have contributed as well.



▲ **Figure 25.20 Paedomorphosis.** The adults of some species retain features that were juvenile in ancestors. This salamander is an axolotl, an aquatic species that grows to full size, becomes sexually mature, and reproduces while retaining certain larval (tadpole) characteristics, including gills.

Changes in Spatial Pattern

Substantial evolutionary changes can also result from alterations in genes that control the placement and spatial organization of body parts. For example, master regulatory genes called **homeotic genes** (described in Chapters 18 and 21) determine such basic features as where a pair of wings and a pair of legs will develop on a bird or how a plant's flower parts are arranged.

The products of one class of homeotic genes, the *Hox* genes, provide positional information in an animal embryo. This information prompts cells to develop into structures appropriate for a particular location. Changes in *Hox* genes or in how they are expressed can have a profound impact on morphology. For example, among crustaceans, a change in the location where two *Hox* genes (*Ubx* and *Scr*) are expressed correlates with the conversion of a swimming appendage to a feeding appendage.

The evolution of vertebrates from invertebrate animals was an even larger evolutionary change, and it, too, may have been influenced by alterations in *Hox* genes and the genes that regulate them. Two duplications of *Hox* genes have occurred in the vertebrate lineage, and all vertebrate genomes tested to date have both of these duplications. As outlined in **Figure 25.21**,

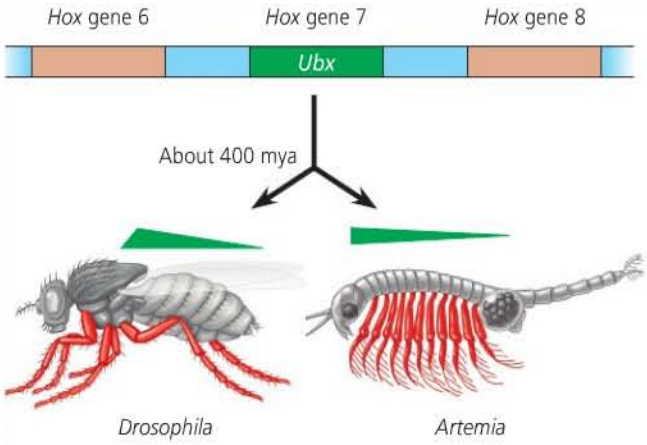
▲ **Figure 25.21 *Hox* mutations and the origin of vertebrates.**

these duplications may have been instrumental in the origin of novel characteristics in the vertebrates. This hypothesis remains controversial, however, in part because in addition to the *Hox* genes, many other genes (perhaps the entire genome) were duplicated in the vertebrate ancestor. Thus, the origin of novel characteristics cannot be ascribed solely to new *Hox* genes.

The Evolution of Development

The 565-million-year-old fossils of Ediacaran animals suggest that a set of genes sufficient to produce complex animals existed at least 30 million years *before* the Cambrian explosion. If developmental genes have existed for so long, how can we explain the astonishing increases in diversity seen during and since the Cambrian explosion?

Adaptive evolution by natural selection provides one answer to this question. As we've seen throughout this unit, by sorting among differences in the sequence of protein-encoding genes, selection can improve adaptations rapidly. In addition, new genes (created by gene duplication events) may have taken on a wide range of new metabolic and structural functions. Thus, adaptive evolution of new and existing genes may have played a key role in shaping the great diversity of life.



Examples in the previous section suggest that developmental genes may play a critical role. For the remainder of this section, we'll focus on how new morphological forms arise by changing the nucleotide sequences or regulation of developmental genes.

Changes in Genes

New developmental genes arising after gene duplication events very likely facilitated the origin of new morphological forms. But as we discussed regarding the possible role of new *Hox* genes in the origin of vertebrates, it can be difficult to establish causal links between genetic and morphological changes that occurred in the past.

This difficulty was sidestepped in a recent study of developmental changes associated with the divergence of six-legged insects from crustacean-like ancestors that had more than six legs. In insects, such as *Drosophila*, the *Ubx* gene is expressed in the abdomen, while in crustaceans, such as *Artemia*, it is expressed in the main trunk of the body **(Figure 25.22)**. When expressed, the *Ubx* gene suppresses leg formation in insects but not in crustaceans. To examine the workings of this gene, researchers cloned the *Ubx* gene from *Drosophila* and *Artemia*. Next, they genetically engineered fruit fly embryos to express either the *Drosophila Ubx* gene or the *Artemia Ubx* gene throughout their bodies. The *Drosophila* gene suppressed 100% of the limbs in the embryos, as expected, whereas the *Artemia* gene suppressed only 15%.

The researchers then sought to uncover key steps involved in the evolutionary transition from a crustacean *Ubx* gene to an insect *Ubx* gene. Their approach was to identify mutations that would cause the *Artemia Ubx* gene to suppress leg formation, thus making the crustacean gene act more like an insect *Ubx* gene. To do this, they constructed a series of "hybrid" *Ubx* genes, each of which contained known segments of the *Drosophila Ubx* gene and known segments of the *Artemia Ubx* gene. By inserting these hybrid genes into fruit fly embryos (one hybrid gene per embryo) and observing their effects on leg development, the researchers were able to pinpoint the exact amino acid changes responsible for the suppression of additional limbs in insects. In so doing, this study provided experimental evidence linking a particular change in the sequence of a developmental gene to a major evolutionary change—the origin of the six-legged insect body plan.

▲ **Figure 25.22 Origin of the insect body plan.** Expression of the *Hox* gene *Ubx* suppresses the formation of legs in fruit flies (*Drosophila*) but not in brine shrimp (*Artemia*), thus helping to build the insect body plan. Fruit fly and brine shrimp *Hox* genes have evolved independently for 400 million years.

Changes in Gene Regulation

A change in the nucleotide sequence of a gene may affect its function wherever the gene is expressed. In contrast, changes in the regulation of gene expression can be limited to a single cell type (see Chapter 18). Thus, a change in the regulation of a developmental gene may have fewer harmful side effects than a change to the sequence of the gene. This line of reasoning has prompted researchers to suggest that changes in the form of organisms often may be caused by mutations that affect the regulation of developmental genes—not their sequence.

This idea is supported by studies in a variety of species, including three-spine stickleback fish. These fish live in the open ocean and in shallow, coastal waters. In western Canada, they also live in lakes formed when the coastline receded in the past 12,000 years. David Kingsley, of Stanford University, and colleagues have identified a key developmental gene, *Pitx1*, that influences whether the fish have a set of large spines on their ventral (lower) surface, in addition to the three dorsal spines that give them their name. Marine populations have the ventral spines, which help to deter some predators. However, the spines are reduced or absent in lake populations. The loss of ventral spines may have been

driven by natural selection because the lakes harbor large invertebrate predators, such as dragonfly larvae, which may at times capture juvenile sticklebacks by grasping onto the spines.

Was the reduction of spines due to changes in the *Pitx1* gene or due to changes in how the gene is expressed **(Figure 25.23)**? The researchers' results indicate that the regulation of gene expression has changed, not the DNA sequence of the gene. Furthermore, lake sticklebacks do express the *Pitx1* gene in tissues not related to the production of spines (for example, the mouth), illustrating how morphological change can be caused by altering the expression of a developmental gene in some parts of the body but not others.

▼ Figure 25.23 Inquiry

What causes the loss of spines in lake stickleback fish?

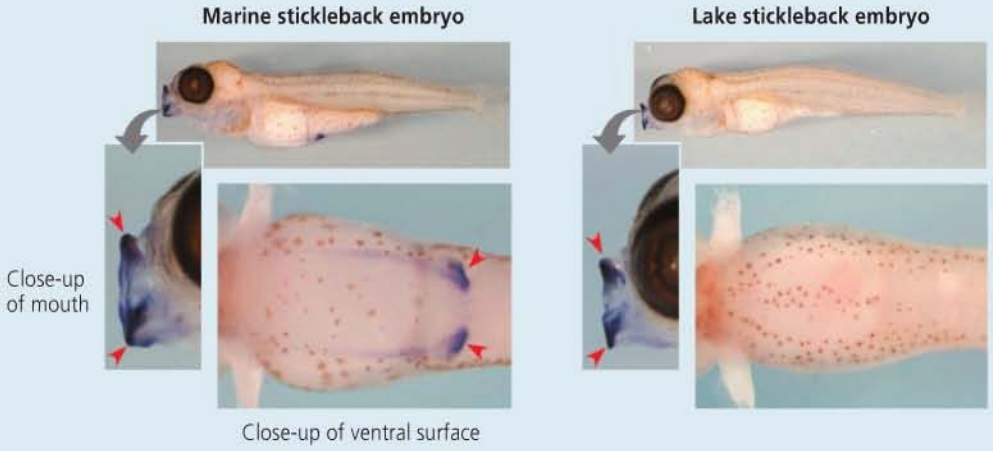
EXPERIMENT Marine populations of the three-spine stickleback fish (*Gasterosteus aculeatus*) have a set of protective spines on their lower (ventral) surface; these spines are lost or reduced in lake populations of this fish. Working at Stanford University, Michael Shapiro, David Kingsley, and colleagues tested two hypotheses about the cause of this morphological change.

Hypothesis A: A change in the DNA sequence of a key developmental gene, *Pitx1*, caused the loss of spines in lake populations. To test this idea, the team used DNA sequencing to compare the coding sequence of the *Pitx1* gene between marine and lake stickleback populations.

Hypothesis B: A change in the regulation of the expression of *Pitx1* caused the loss of spines. To test this idea, the researchers monitored where in the developing embryo the *Pitx1* gene is expressed. They conducted whole-body *in situ* hybridization experiments (see Chapter 20) using *Pitx1* DNA as a probe to detect *Pitx1* mRNA in the fish.

RESULTS

Test of Hypothesis A: Are there differences in the coding sequence of the *Pitx1* gene in marine and lake sticklebacks?



Result: No →

The 283 amino acids of the *Pitx1* protein are identical in marine and lake stickleback populations.

Test of Hypothesis B: Are there any differences in the regulation of expression of *Pitx1*?

Result: Yes →

Red arrows indicate regions of *Pitx1* gene expression in the photographs below. *Pitx1* is expressed in the ventral spine and mouth regions of developing marine sticklebacks but only in the mouth region of developing lake sticklebacks.

CONCLUSION The loss or reduction of ventral spines in lake populations of three-spine stickleback fish results from a change in the regulation of *Pitx1* gene expression, not from a change in the gene's sequence.

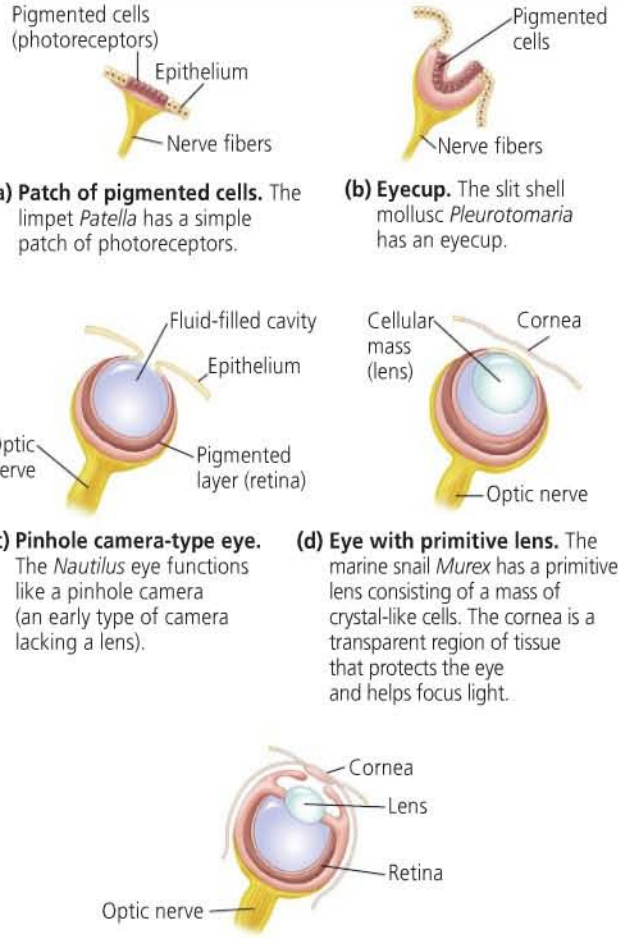
SOURCE M. D. Shapiro et al., Genetic and developmental basis of evolutionary pelvic reduction in three-spine sticklebacks, *Nature* 428:717–723 (2004).

WHAT IF? Describe the set of results that would have led researchers to the conclusion that a change in the coding sequence of the *Pitx1* gene was more important than a change in regulation of gene expression.

CONCEPT CHECK 25.5

1. How can heterochrony cause the evolution of different body forms?
2. Why is it likely that *Hox* genes have played a major role in the evolution of novel morphological forms?
3. **WHAT IF?** Given that changes in morphology are often caused by changes in gene regulation, predict whether noncoding DNA is likely to be affected by natural selection. (Noncoding DNA includes the sequences called control elements that regulate gene expression by binding to transcription factors.)

For suggested answers, see Appendix A.



CONCEPT 25.6 Evolution is not goal oriented

What does our study of macroevolution tell us about how evolution works? To paraphrase the Nobel Prize-winning geneticist François Jacob, evolution is like tinkering—a process in which new forms arise by the slight modification of existing forms. Even large changes, like the ones that produced the first mammals or the six-legged body plan of insects, can result from the gradual modification of existing structures or the slight modification of existing developmental genes.

Evolutionary Novelties

François Jacob's view of evolution harkens back to Darwin's concept of descent with modification. As new species form, novel and complex structures can arise as gradual modifications of ancestral structures. In many cases, complex structures have evolved in increments from simpler versions that performed the same basic function. For example, consider the human eye, an intricate organ constructed from numerous parts that work together in forming an image and transmitting it to the brain. How could the human eye have evolved in gradual increments? Some argue that if the eye needs all of its components to function, a partial eye could not have been of use to our ancestors.

The flaw in this argument, as Darwin himself noted, lies in the assumption that only complicated eyes are useful. In fact, many animals depend on eyes that are far less complex than our own **(Figure 25.24)**. The simplest eyes that we know of are patches of light-sensitive photoreceptor cells. These simple eyes appear to have had a single evolutionary origin and are now found in a variety of animals, including small molluscs called limpets. Such eyes have no equipment for focusing images, but they do enable the animal to distinguish light from dark. Limpets cling more tightly to their rock when a shadow falls on them—a behavioral adaptation that reduces the risk of being eaten. Because limpets have had a long evolutionary history, we can conclude that their "simple" eyes are quite adequate to support their survival and reproduction.

(a) Patch of pigmented cells. The limpet *Patella* has a simple patch of photoreceptors.

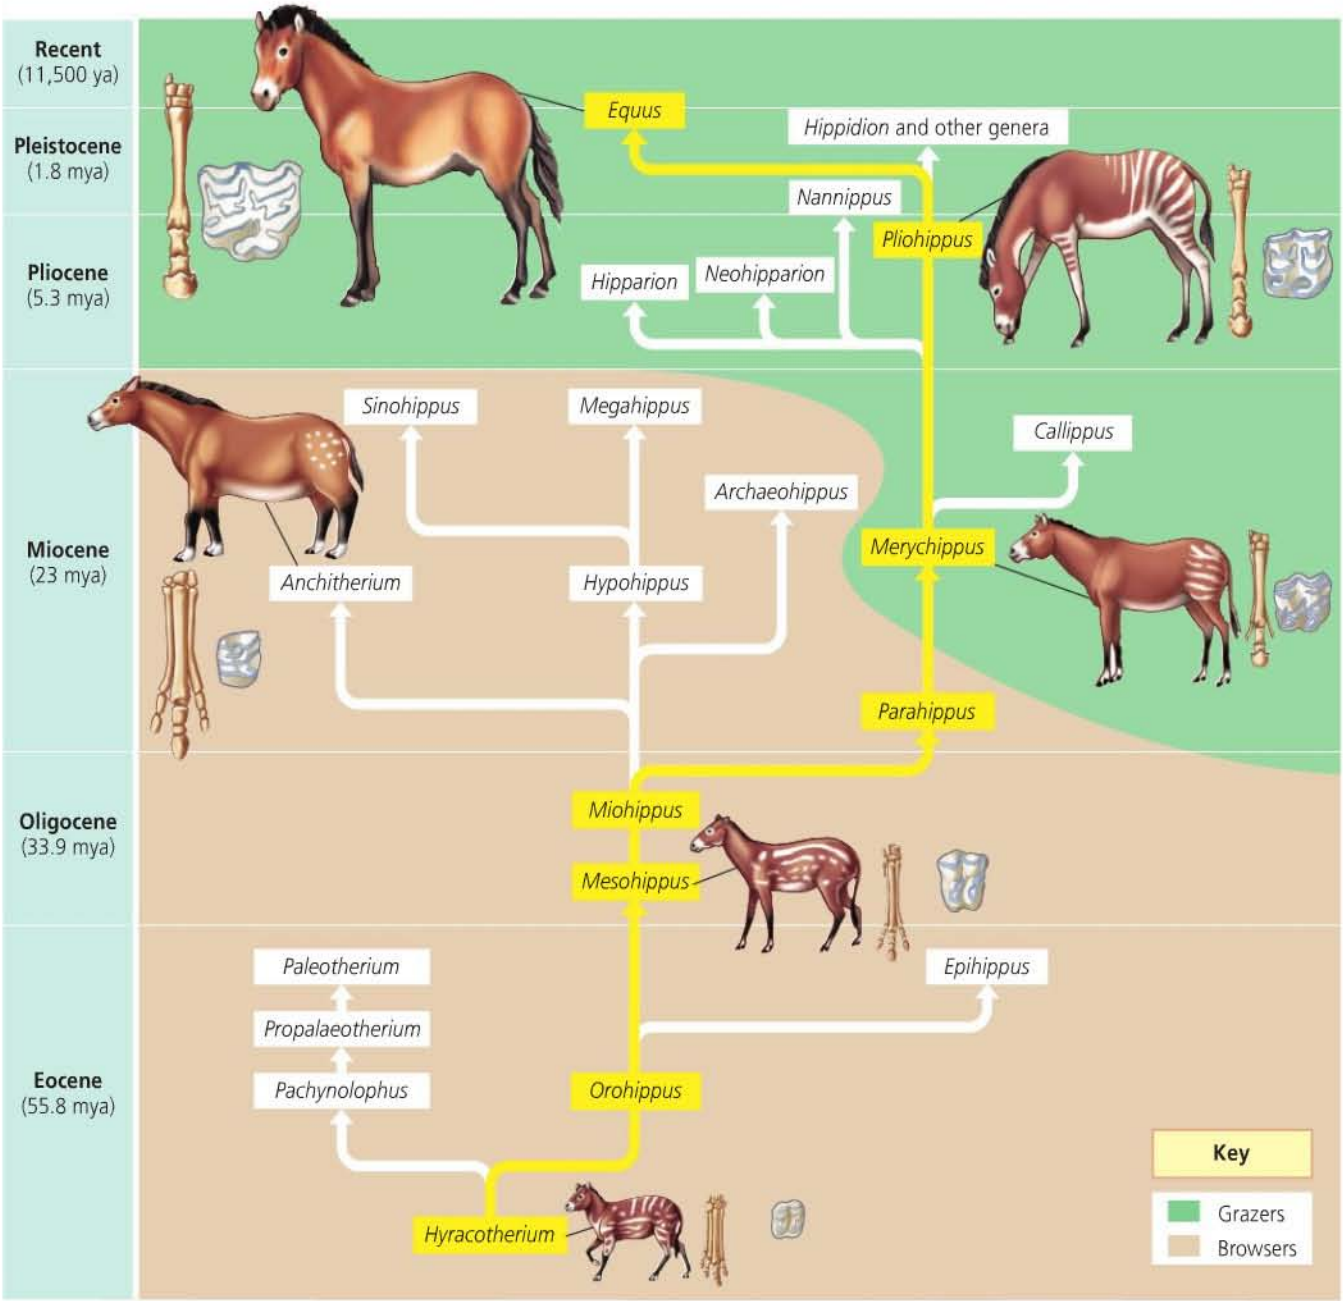
(b) Eyecup. The slit shell mollusc *Pleurotomaria* has an eyecup.

(c) Pinhole camera-type eye. The *Nautilus* eye functions like a pinhole camera (an early type of camera lacking a lens).

(d) Eye with primitive lens. The marine snail *Murex* has a primitive lens consisting of a mass of crystal-like cells. The cornea is a transparent region of tissue that protects the eye and helps focus light.

(e) Complex camera-type eye. The squid *Loligo* has a complex eye whose features (cornea, lens, and retina), though similar to those of vertebrate eyes, evolved independently.

▲ **Figure 25.24 A range of eye complexity among molluscs.**



In the animal kingdom, complex eyes have evolved independently from such basic structures many times. Some molluscs, such as squids and octopuses, have eyes as complex as those of humans and other vertebrates (see Figure 25.24). Although complex mollusc eyes evolved independently of vertebrate eyes, both evolved from a simple cluster of photoreceptor cells present in a common ancestor. In each case, the evolution of the complex eye took place through a series of incremental modifications that benefited the eyes' owners at every stage. Evidence for these evolutionary paths comes from phylogenetic analysis of the genes that act as "master regulators" of eye development and are shared by all animals with eyes.

Throughout their evolutionary history, eyes retained their basic function of vision. But evolutionary novelties can also arise when structures that originally played one role gradually acquire a different one. For example, as cynodonts gave rise to early mammals, bones that formerly comprised the jaw hinge (the articular and quadrate; see Figure 25.6) were incorporated into the ear region of mammals, where they eventually took on a new function: the transmission of sound (see Chapter 34).

Structures that evolve in one context but become co-opted for another function are sometimes called *exaptations* to distinguish them from the adaptive origin of the original structure. Note that the concept of exaptation does not imply that a structure somehow evolves in anticipation of future use. Natural selection cannot predict the future; it can only improve a structure in the context of its *current* utility. Novel features, such as the new jaw hinge and ear bones of early mammals, can arise gradually via a series of intermediate stages, each of which has some function in the organism's current context.

Evolutionary Trends

What else can we learn from patterns of macroevolution? Consider evolutionary "trends" observed in the fossil record. For instance, some evolutionary lineages exhibit a trend toward larger or smaller body size. An example is the evolution of the present-day horse (genus *Equus*), a descendant of the 55-million-year-old *Hyracotherium* (**Figure 25.25**). About the size of a large dog, *Hyracotherium* had four toes on its front feet, three toes on its hind feet, and teeth adapted for browsing on bushes and trees. In

▲ **Figure 25.25 The branched evolution of horses.** Using yellow to trace the sequence of fossil horses that are intermediate in form between the present-day horse (*Equus*) and its Eocene ancestor *Hyracotherium* creates the illusion of a progressive trend toward larger size, reduced number of toes, and teeth modified for grazing. In fact, *Equus* is the only surviving twig of an evolutionary bush with many divergent trends.

comparison, present-day horses are larger, have only one toe on each foot, and possess teeth modified for grazing on grasses.

Extracting a single evolutionary progression from the fossil record can be misleading, however; it is like describing a bush as growing toward a single point by tracing only the branches that lead to that twig. For example, by selecting certain species from the available fossils, it is possible to arrange a succession of animals intermediate between *Hyracotherium* and living horses that shows a trend toward large, single-toed species (follow the lineage highlighted in yellow in Figure 25.25). However, if we consider *all* fossil horses known today, this apparent trend vanishes. The genus *Equus* did not evolve in a straight line; it is the only surviving twig of an evolutionary tree that is so branched that it is more like a bush. *Equus* actually descended through a series of speciation episodes that included several adaptive radiations, not all of which led to large, one-toed, grazing horses. For instance, notice in Figure 25.25 that only those lineages derived from *Parahippus* include grazers; other lineages derived from *Miohippus,* all of which are now extinct, remained multi-toed browsers for 35 million years.

Branching evolution *can* result in a real evolutionary trend even if some species counter the trend. One model of long-term trends proposed by Steven Stanley, of Johns Hopkins University, views species as analogous to individuals: Speciation is their birth, extinction is their death, and new species that diverge from them are their offspring. In this model, Stanley suggests that just as individual organisms undergo natural selection, species undergo *species selection*. The species that endure the longest and generate the most new offspring species determine the direction of major evolutionary trends. The species selection model suggests that "differential speciation success" plays a role in macroevolution similar to the role of differential reproductive success in microevolution. Evolutionary trends can also result directly from natural selection. For example, when horse ancestors invaded the grasslands that spread during the mid-Cenozoic, there was strong selection for grazers that could escape predators by running faster. This trend would not have occurred without open grasslands.

Whatever its cause, an evolutionary trend does not imply that there is some intrinsic drive toward a particular phenotype. Evolution is the result of the interactions between organisms and their current environments; if environmental conditions change, an evolutionary trend may cease or even reverse itself. The cumulative effect of these ongoing interactions between organisms and their environments is enormous: It is through them that the staggering diversity of life—Darwin's "endless forms most beautiful"—has arisen.

CONCEPT CHECK 25.6

1. How can the Darwinian concept of descent with modification explain the evolution of such complex structures as the vertebrate eye?
2. **WHAT IF?** The myxoma virus is highly lethal to European rabbits (*Oryctolagus cuniculus*). In a naive rabbit population (one with no previous exposure to the virus), the virus kills up to 99.8% of infected rabbits. The virus is transmitted between living rabbits by mosquitoes. Describe an evolutionary trend (in either the rabbits or the virus) that might occur after a naive rabbit population first encounters the virus.

For suggested answers, see Appendix A.

Chapter 25 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 25.1

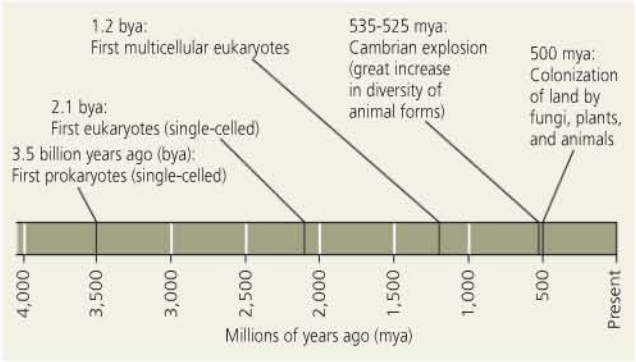
Conditions on early Earth made the origin of life possible (pp. 507–510)

- **Synthesis of Organic Compounds on Early Earth** Earth formed about 4.6 billion years ago. Laboratory experiments simulating a reducing atmosphere have produced organic molecules from inorganic precursors. Amino acids have also been found in meteorites.
- **Abiotic Synthesis of Macromolecules** Amino acids polymerize when added to hot sand, clay, or rock.
- **Protobionts** Organic compounds can spontaneously assemble in the laboratory into protobionts, membrane-bounded droplets that have some of the properties of cells.
- **Self-Replicating RNA and the Dawn of Natural Selection** The first genetic material may have been short pieces of RNA capable of guiding polypeptide synthesis and self-replication. Early protobionts containing such RNA would have been more effective at using resources and would have increased in number through natural selection.

MEDIA

Investigation How Did Life Begin on Early Earth?

CONCEPT 25.2



The fossil record documents the history of life (pp. 510–514)

- **The Fossil Record** The fossil record, based largely on fossils found in sedimentary rocks, documents the rise and fall of different groups of organisms over time.
- **How Rocks and Fossils Are Dated** Sedimentary strata reveal the relative ages of fossils. The absolute ages of fossils can be estimated by radiometric dating and other methods.

▶ **The Origin of New Groups of Organisms** The fossil record shows how new groups of organisms can arise via the gradual modification of preexisting organisms.

CONCEPT 25.3

Key events in life's history include the origins of single-celled and multicelled organisms and the colonization of land (pp. 514–519)

MEDIA

Activity A Scrolling Geologic Record
Activity The History of Life

CONCEPT 25.4

The rise and fall of dominant groups reflect continental drift, mass extinctions, and adaptive radiations (pp. 519–525)

▶ **Continental Drift** Continental plates move gradually over time, altering the physical geography and climate of Earth; these changes lead to extinctions in some groups of organisms and bursts of speciation in others.

▶ **Mass Extinctions** Evolutionary history has been punctuated by five mass extinctions that radically altered the history of life. Some of these extinctions may have been caused by changes in continent positions, volcanic activity, or impacts from meteorites or comets.

▶ **Adaptive Radiations** Large increases in the diversity of life have resulted from adaptive radiations that followed mass extinctions. Adaptive radiations have also occurred in groups of organisms that possessed major evolutionary innovations or that colonized new regions in which there was little competition from other organisms.

CONCEPT 25.5

Major changes in body form can result from changes in the sequences and regulation of developmental genes (pp. 525–529)

▶ **Evolutionary Effects of Developmental Genes** Developmental genes affect morphological differences between species by influencing the rate, timing, and spatial patterns of change in an organism's form as it develops into an adult.

▶ **The Evolution of Development** The evolution of new morphological forms can be caused by changes in the nucleotide sequences or regulation of developmental genes.

CONCEPT 25.6

Evolution is not goal oriented (pp. 529–531)

▶ **Evolutionary Novelties** Novel and complex biological structures can evolve through a series of incremental modifications, each of which benefits the organism that possesses it.

▶ **Evolutionary Trends** Evolutionary trends can be caused by factors such as natural selection in a changing environment or species selection. Like all aspects of evolution, evolutionary trends result from interactions between organisms and their current environments.

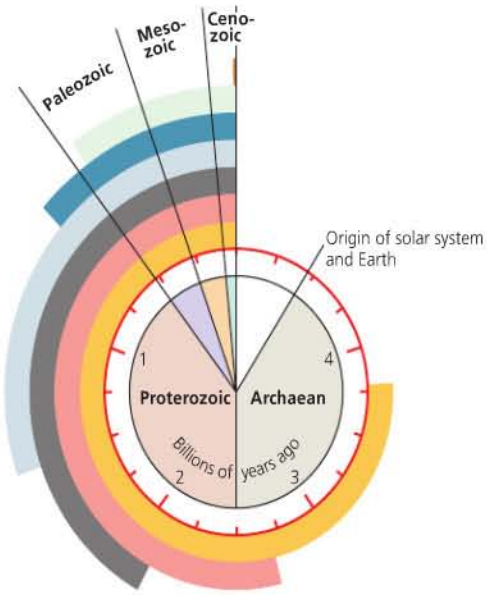
TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Fossilized stromatolites
   a. all date from 2.7 billion years ago.
   b. formed around deep-sea vents.
   c. resemble structures formed by bacterial communities that are found today in some warm, shallow, salty bays.
   d. provide evidence that plants moved onto land in the company of fungi around 500 million years ago.
   e. contain the first undisputed fossils of eukaryotes and date from 2.1 billion years ago.

2. The oxygen revolution changed Earth's environment dramatically. Which of the following adaptations took advantage of the presence of free oxygen in the oceans and atmosphere?
   a. the evolution of cellular respiration, which used oxygen to help harvest energy from organic molecules
   b. the persistence of some animal groups in anaerobic habitats
   c. the evolution of photosynthetic pigments that protected early algae from the corrosive effects of oxygen
   d. the evolution of chloroplasts after early protists incorporated photosynthetic cyanobacteria
   e. the evolution of multicellular eukaryotic colonies from communities of prokaryotes

3. Select the factor most likely to have caused the animals and plants of India to differ greatly from species in nearby southeast Asia.
   a. The species have become separated by convergent evolution.
   b. The climates of the two regions are similar.
   c. India is in the process of separating from the rest of Asia.
   d. Life in India was wiped out by ancient volcanic eruptions.
   e. India was a separate continent until 55 million years ago.



4. Adaptive radiations can be a direct consequence of four of the following five factors. Select the exception.
   a. vacant ecological niches
   b. genetic drift
   c. colonization of an isolated region that contains suitable habitat and few competitor species
   d. evolutionary innovation
   e. an adaptive radiation in a group of organisms (such as plants) that another group uses as food

5. A genetic change that caused a certain *Hox* gene to be expressed along the tip of a vertebrate limb bud instead of farther back helped make possible the evolution of the tetrapod limb. This type of change is illustrative of
   a. the influence of environment on development.
   b. paedomorphosis.
   c. a change in a developmental gene or in its regulation that altered the spatial organization of body parts.
   d. heterochrony.
   e. gene duplication.

6. Which of the following steps has *not* yet been accomplished by scientists studying the origin of life?
   a. synthesis of small RNA polymers by ribozymes
   b. abiotic synthesis of polypeptides
   c. formation of molecular aggregates with selectively permeable membranes
   d. formation of protobionts that use DNA to direct the polymerization of amino acids
   e. abiotic synthesis of organic molecules

7. A swim bladder is a gas-filled sac that helps fish maintain buoyancy. The evolution of the swim bladder from lungs of an ancestral fish is an example of
   a. an evolutionary trend.
   b. exaptation.
   c. changes in *Hox* gene expression.
   d. paedomorphosis.
   e. adaptive radiation.

8. **DRAW IT** Use the unlabeled clock diagram below to test your memory of the sequence of key events in the history of life described in this chapter by labeling the colored bars. As a visual aid to help you study, add labels that represent other significant events, including the Cambrian explosion, origin of mammals, and Permian and Cretaceous mass extinctions.

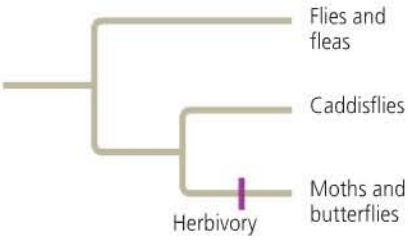
MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.



EVOLUTION CONNECTION

9. Describe how gene flow, genetic drift, and natural selection all can influence macroevolution.

SCIENTIFIC INQUIRY

10. Herbivory (plant-eating) has evolved repeatedly in insects, typically from meat-eating or detritus-feeding ancestors (detritus is dead organic matter). Moths and butterflies, for example, eat plants, whereas their "sister group" (the insect group to which they are most closely related), the caddisflies, feed on animals, fungi, or detritus. As illustrated in the phylogenetic tree below, the combined moth/butterfly and caddisfly group shares a common ancestor with flies and fleas. Like caddisflies, flies and fleas are thought to have evolved from ancestors that did not eat plants.

    There are 140,000 species of moths and butterflies and 7,000 species of caddisflies. State a hypothesis about the impact of herbivory on adaptive radiations in insects. How could this hypothesis be tested?

SCIENCE, TECHNOLOGY, AND SOCIETY

11. Experts estimate that human activities cause the extinction of hundreds of species every year. In contrast, the natural rate of extinction is thought to average only a few species per year. If we continue to alter the global environment, especially by destroying tropical rain forests and altering Earth's climate, the likely result will be a wave of extinctions that could rival those at the end of the Cretaceous period. Considering that life has endured five mass extinctions, should we be concerned that we may cause a sixth mass extinction? How would such an extinction differ from previous extinctions? What might be some of the consequences for the surviving species, including ourselves?

Biology Inquiry: A Workbook of Investigative Cases Life on Earth has gone through repeated cycles of mass extinction and diversification. Explore the latter with the case "Unveiling the Carboniferous."

UNIT 5

The Evolutionary History of Biological Diversity

AN INTERVIEW WITH

Sean B. Carroll

Passionately committed to sharing the revelations of evo-devo with students and the public, Sean Carroll is a popular speaker and the author of several acclaimed trade books—as well as a leading researcher on the genetics and evolution of animal development. He completed his formal education in record time, earning a B.A. in Biology at Washington University and a Ph.D. in Immunology at Tufts University School of Medicine in less than six years. Dr. Carroll is now an investigator at the Howard Hughes Medical Institute and a professor of molecular biology and genetics at the University of Wisconsin, Madison. He is a member of the National Academy of Sciences.

How did you get interested in evolutionary biology?

As a kid, I really enjoyed flipping over logs and seeing what was underneath. I was fascinated by reptiles, snakes in particular, and also liked to catch frogs and salamanders. That attraction to wildlife has always nurtured my interest in biology. At Washington University, students like myself could get exposed to almost anything in biology. I would go to seminars on subjects ranging from wolf ecology to the molecular biology of viruses. There I started to learn something about the big questions that were being asked in various disciplines at the time. I was smitten with immunology because of the big questions still open in that field and because of its practical side—vaccines and the treatment of infectious diseases.

But while working on my Ph.D. in immunology, I started reading a lot on my own—Stephen Jay Gould, for example—and going to science talks all over the Boston area. I would just hop on the subway and go to talks at any of three or four different universities. The unanswered questions in evolutionary biology drew me in that direction. At the time, the debate over punctuated equilibrium was fresh, and this new idea was changing interpretations of the fossil record and raising questions about the rate of morphological change. All this prompted a simple question in my mind: How can we have this debate when we don't know anything about how form is made? And how can we start to get a grip on that?

At around that time, I came across some of the early papers on the developmental genetics of fruit flies, which described fascinating body-pattern mutants—homeotic mutants [see Figure 18.18]. I got it in my head that homeotic genes were the ones that people would have to study to understand the evolution of form. Despite advice to the contrary, I committed myself to studying these kinds of genes in fruit flies.

Let's talk about your book *Endless Forms Most Beautiful: The New Science of Evo Devo and the Making of the Animal Kingdom*. What does the title mean?

The first part of the title is borrowed from the last sentence of Charles Darwin's *Origin of Species*: "from so simple a beginning endless forms most beautiful . . . have been and are being evolved." The "most beautiful" part is important to me because I think that part of our attraction to nature is aesthetic. The book tries to explain what the new science of the last 20 years—advances in developmental genetics and the evolutionary study of development—has revealed about the generation of the physical diversity of the animal kingdom.

There is an intimate connection between development and evolution. Development is the process that gives rise to form, and so the evolution of form comes about through the evolution of development. Understanding how development happens in the first place is the starting point. Then we want to understand how changes in development can evolve. Only a small percentage of our genes are devoted to building body form, maybe a couple of thousand in us and six or seven hundred in a fruit fly. But when those genes are disrupted by mutation, the effects can be pretty catastrophic.

The book looks at the central ideas in evolutionary developmental biology—*evo-devo*, for short. A few of the key discoveries in this area were stunning, completely unanticipated. So the book traces those discoveries and discusses how they force us to look at the evolution of diversity very differently from how previous generations of evolutionary biologists did. The biggest discovery of evo-devo has been that the genes that build the bodies and body parts of fruit flies are shared with us and with virtually every other creature in the animal kingdom. That shows us a deep connection shared by all animals, no matter how different the bodies are. Gene for gene, we are essentially the same as a mouse, a rat, or a dog, and especially a chimpanzee. And the genes involved in building our eyes and our hearts and our bones have been around for 500 million years. So much like astronomy did four centuries ago, evo-devo is contributing to the realization that humans are not the center of everything. The human species is a member of the animal kingdom and not really above or very distinct from the other members.

What are you doing research on now?

We're working on the question of *how* the differences between animal species arise. There has been an idea around biology for a long time that to get new things you need new genes—for new structures, for new capabilities, or for whole new types of animals. But it doesn't look like that at all. Instead, it looks like new things arise because very old genes learn new tricks. We are focusing on understanding the mechanisms of these changes. This involves the question of how a gene involved in setting up the basic body plan and building body parts can change its roles without the whole machine falling apart. How do you change the car while the engine is running? It turns out that body-building genes have very sophisticated and extensive sets of regulatory instructions—control elements in the DNA nearby or embedded within the genes. An individual gene might act in a dozen places in the body in the course of develop-

ment, but its action in a particular body part at a particular moment in development is controlled independently from its action in other places. We are trying to understand how these regulatory instructions are used, because we think that these are the hot spots of evolution. It is becoming more clear how and why these regulatory elements are the keys to understanding how so much diversity can be generated with a limited set of body-building genes.

The rules for the evolution of body form and physiology are different: In the evolution of physiological processes—for example, respiration, olfaction, or immunity—the evolution of new protein-coding genes has been more important. For example, the multiple types of globins that act at different stages of our life arose as genes were duplicated and the copies then diverged.

Are you using fruit flies currently?

Yes. To get at some of the *general* rules about the evolution of form, we often studied animals that are distant relatives; we might compare a snake with a bird. But if you really want to trace the specific genetic steps involved in the evolution of form, you need to have greater resolving power. The strategy we have taken is to study closely related species, which share a very recent common ancestor. If you take two such "sister" species, you can actually identify the genetic changes that cause the differences in the appearance and behavior of these animals. Fruit flies provide a great opportunity to do that, because *Drosophila melanogaster*, the familiar lab fruit fly, has hundreds of relatives out there in the wild, different species with all sorts of differences in body appearance. For instance, there are *Drosophila* species where the male has large black spots on the tips of the wings that are used in a courtship display. Now, genes that influence mating are among the most important targets of natural selection, because whether the male passes his genes on depends on whether the female is induced to mate. We can compare these flies with flies of sister species that do not have these spots and do not use the same mating ritual. Because the relationship is close, we can pinpoint very specifically the bits of regulatory DNA that have changed. So we are looking at the smoking guns of evolution.

What can one learn about animal phylogeny from DNA sequences versus fossils and morphology?

It's useful to have both—independent but intersecting lines of evidence. There are things you cannot see in fossils that you can learn about by studying DNA, and there is a lot that the molecules cannot tell you about the history of life. You can't look at DNA and know that the dinosaurs existed. Fossils tell you what animals roamed the earth, what structures existed, and even how the structures evolved, if the fossil record is rich enough. When you have extant species, the molecular record is good for figuring out other things. For example, if you want to know whether annelids are more closely related to molluscs or to arthropods—an issue that for a hundred-plus years was argued on the basis of appearance—the molecules now weigh in on the problem. Sometimes the results from molecules are consistent with long-held notions, and sometimes they throw the old notions for a loop.

What does evo-devo tell us about the Cambrian explosion?

Evo-devo tells us that the body-building genes we've been talking about must have been in place in the very early ancestors of most animals, in the ancestors of the animals seen in fossils from the geologic period we call the Cambrian. We can infer that the earliest bilateral animals—"bilaterians," which have left and right sides—had a pretty sophisticated genetic toolkit, and that those animals must have lived prior to the Cambrian. The Cambrian coming-out party may not have been so much a matter of new genes as an ecologically driven explosion of diversity. My personal view is that all the key genes and circuits were probably in place cryptically in small creatures before the Cambrian. So evo-devo is a great window to understanding the mechanism of diversification, but there's a huge ecological story, too.

Going back before the Cambrian, when did the first animals arise, and what did they look like?

The first animals probably appeared about 600 million years ago, give or take a week. I tend to believe that a lot of the early evolution of animals is cryptic because the earliest animals were tiny, soft-bodied organisms and didn't leave a good fossil record. These first animals would have been, by today's standards, dull-looking spongelike things. The first bilaterians probably looked like worms. Also, because there are significant differences between sponges and cnidarians and cnidarians and bilaterians, I think there were all sorts of intermediate phyla that we don't know anything about. Maybe some tremendous breakthrough in finding and analyzing microfossils will lead to discovery of some of the missing phyla.

Why should people who are not going to be evolutionary biologists learn about the evolution of biological diversity?

I think the study of evolution and diversity is as fundamental as studying the history of human civilizations. That's just the last 10,000 years! But our history as animals goes back some 600 million years and as organisms several billion years. In addition, there are important practical reasons. We humans are managing the natural resources on the planet. If we don't understand the basic principles of evolutionary biology, we cannot conduct those activities intelligently for the long term. To take one example, what's the effect of trawling for ocean fish with a 7-cm mesh net? Organisms that are smaller than 7 cm escape and flourish, and ones that are larger than 7 cm are removed. How does that influence the harvest ten years later? We have to understand the fundamental role that selection plays in the real world and that we are a major agent of selection. We can foresee some of the consequences of our activities from the first principles of evolutionary biology.

Evo-devo tells us that the body-building genes . . . must have been in place in the very early ancestors of most animals . . .

26 Phylogeny and the Tree of Life

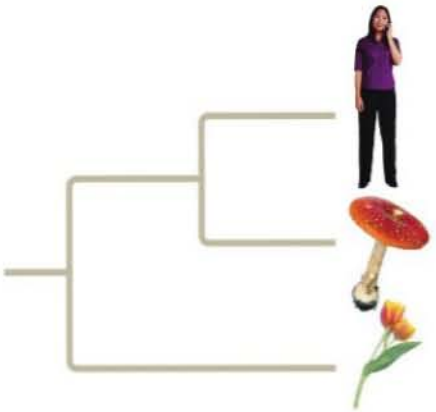
▲ **Figure 26.1 What is this organism?**

KEY CONCEPTS

26.1 Phylogenies show evolutionary relationships
26.2 Phylogenies are inferred from morphological and molecular data
26.3 Shared characters are used to construct phylogenetic trees
26.4 An organism's evolutionary history is documented in its genome
26.5 Molecular clocks help track evolutionary time
26.6 New information continues to revise our understanding of the tree of life

OVERVIEW

Investigating the Tree of Life



Look closely at the organism in **Figure 26.1**. Although it resembles a snake, this animal is actually an Australian legless lizard known as the common scaly-foot (*Pygopus lepidopodus*). Why isn't the scaly-foot considered a snake? More generally, how do biologists distinguish and categorize the millions of species on Earth?

An understanding of evolutionary relationships suggests one way to address these questions: We can decide in which "container" to place a species by comparing its traits to those of potential close relatives. For example, the scaly-foot does not have a fused eyelid, a highly mobile jaw, or a short tail posterior to the anus, three traits of snakes. These and other characteristics suggest that despite a superficial resemblance, the scaly-foot is not a snake. Furthermore, a survey of the lizards reveals that the scaly-foot is not alone; the legless condition has evolved repeatedly in lizards. Most legless lizards are burrowers or live in grasslands, and like snakes, these species lost their legs over generations as they adapted to their environments.

Snakes and lizards are part of the continuum of life extending from the earliest organisms to the great variety of species alive today. In this unit, we will survey this diversity and describe hypotheses regarding how it evolved. As we do so, our emphasis will shift from the *process* of evolution (the evolutionary mechanisms described in Unit Four) to its *pattern* (observations of evolution's products over time).

To set the stage for our survey of life's diversity, in this chapter we consider how biologists trace **phylogeny**, the evolutionary history of a species or group of species. A phylogeny of lizards and snakes, for example, indicates that both the scaly-foot and snakes evolved from lizards with legs—but they evolved from different lineages of legged lizards. Thus, it appears that their legless conditions evolved independently.

To construct a phylogeny such as that of lizards and snakes, biologists utilize **systematics**, a discipline focused on classifying organisms and determining their evolutionary relationships. Systematists use data ranging from fossils to molecules and genes to infer evolutionary relationships **(Figure 26.2)**. This information is enabling biologists to construct a comprehensive tree of life, which will continue to be refined as additional data are collected.

▲ **Figure 26.2 An unexpected family tree.** What are the evolutionary relationships between a human, a mushroom, and a tulip? A phylogeny based on DNA data reveals that—despite appearances—animals (including humans) and fungi (including mushrooms) are more closely related to each other than either is to plants.

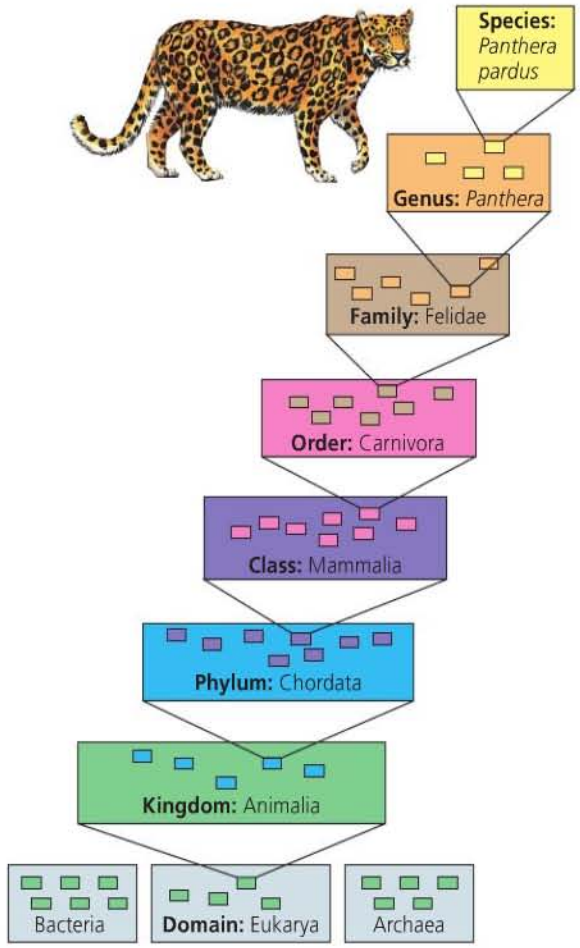
CONCEPT **26.1**

Phylogenies show evolutionary relationships

As we discussed in Chapter 22, organisms share homologous characteristics because of common ancestry. As a result, we can learn a great deal about a species if we know its evolutionary history. For example, an organism is likely to share many of its genes, metabolic pathways, and structural proteins with its close relatives. We'll consider practical applications of such information at the close of this section, but first we'll examine how organisms are named and classified, the scientific discipline of **taxonomy**. We'll also look at how we can interpret and use diagrams that represent evolutionary history.

Binomial Nomenclature

Common names for organisms—such as monkey, finch, and lilac—convey meaning in casual usage, but they can also cause confusion. Each of these names, for example, refers to more than one species. Moreover, some common names do not accurately reflect the kind of organism they signify. Consider these three "fishes": jellyfish (a cnidarian), crayfish (a small lobsterlike crustacean), and silverfish (an insect). And of course, different languages have different words for various organisms.



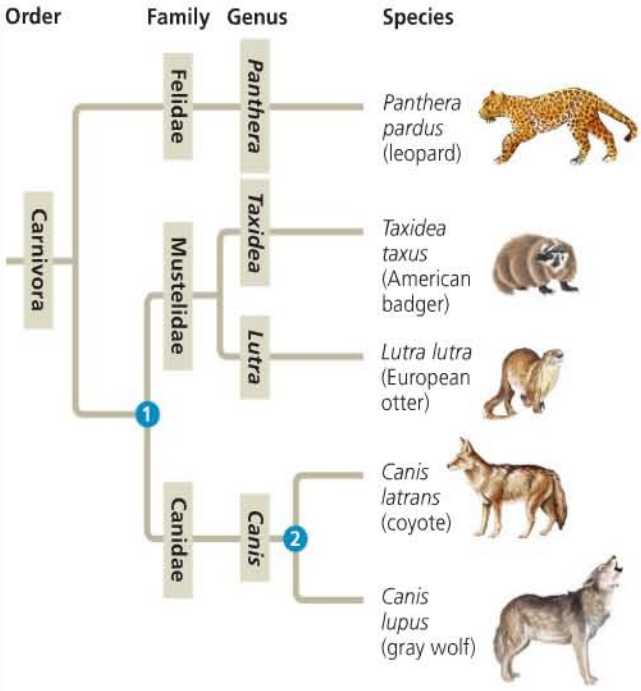
To avoid ambiguity when communicating about their research, biologists refer to organisms by Latin scientific names. The two-part format of the scientific name, commonly called a **binomial**, was instituted in the 18th century by Carolus Linnaeus (see Chapter 22). The first part of a binomial is the name of the **genus** (plural, *genera*) to which the species belongs. The second part, called the specific epithet, is unique for each species within the genus. An example of a binomial is *Panthera pardus*, the scientific name for the large cat commonly called the leopard. Notice that the first letter of the genus is capitalized and the entire binomial is italicized. (Newly created scientific names are also "latinized": You can name an insect you discover after a friend, but you must add a Latin ending.) Many of the more than 11,000 binomials assigned by Linnaeus are still used today, including the optimistic name he gave our own species—*Homo sapiens*, meaning "wise man."

Hierarchical Classification

In addition to naming species, Linnaeus also grouped them into a hierarchy of increasingly inclusive categories. The first grouping is built into the binomial: Species that appear to be closely related are grouped into the same genus. For example, the leopard (*Panthera pardus*) belongs to a genus that also includes the African lion (*Panthera leo*), the tiger (*Panthera tigris*), and the jaguar (*Panthera onca*). Beyond genera, taxonomists employ progressively more comprehensive categories of classification. The taxonomic system named after Linnaeus, the Linnaean system, places related genera in the same **family**, families into **orders**, orders into **classes**, classes into **phyla** (singular, *phylum*), phyla into **kingdoms**, and, more recently, kingdoms into **domains** (Figure 26.3). The resulting biological classification of a particular organism is somewhat like a postal address identifying a person in a particular apartment, in a building with many apartments, on a street with many apartment buildings, in a city with many streets, and so on.

The named taxonomic unit at any level of the hierarchy is called a **taxon** (plural, *taxa*). In the leopard example, *Panthera* is a taxon at the genus level, and Mammalia is a taxon at the class level that includes all the many orders of mammals. Note that in the Linnaean system, taxa broader than the genus are not italicized, though they are capitalized.

Classifying species seems to come naturally to humans—it is a way to structure our view of the world. We lump together various species of trees to which we give the common name of pines and distinguish them from other trees that we call firs. Taxonomists have decided that pines and firs are different enough to be placed in separate genera, yet similar enough to be grouped into the same family, the Pineaceae. As with pines and firs,

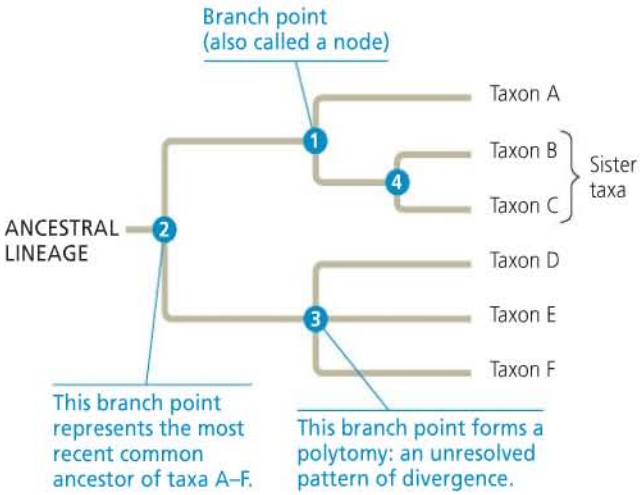


▲ **Figure 26.3 Hierarchical classification.** At each level of the Linnaean classification system, species are placed into groups belonging to more comprehensive groups.

higher levels of classification are usually defined by particular morphological characters chosen by taxonomists, rather than by measurements applicable to all organisms. For this reason, the larger categories often are not comparable between lineages; that is, an order of snails does not exhibit the same degree of morphological or genetic diversity as an order of mammals. Furthermore, as we'll see, the placement of species into orders, classes, and so on, does not necessarily reflect evolutionary history.

Linking Classification and Phylogeny

The evolutionary history of a group of organisms can be represented in a branching diagram called a **phylogenetic tree**. The branching pattern in some cases matches the hierarchical classification of groups nested within more inclusive groups **(Figure 26.4)**. In other situations, however, certain similarities among organisms may lead taxonomists to place a species within a group of organisms (for example, a genus or family) other than the group to which it is most closely related. If systematists conclude that such a mistake has occurred, the organism may be reclassified (that is, placed in a different genus or family) to accurately reflect its evolutionary history. In addition, the categories in the Linnaean classification system may provide little information about phylogeny: We may distinguish 17 families of lizards, but that tells us nothing about their evolutionary relationships to one another.



▲ **Figure 26.4 The connection between classification and phylogeny.** Hierarchical classification is reflected in the progressively finer branching of phylogenetic trees. This tree traces possible evolutionary relationships between some of the taxa within order Carnivora, itself a branch of class Mammalia. The branch point 1 represents the most recent common ancestor of all members of the weasel (Mustelidae) and dog (Canidae) families. The branch point 2 represents the most recent common ancestor of coyotes and gray wolves.

In fact, such difficulties in aligning Linnaean classification with phylogeny have led some systematists to propose that classification be based entirely on evolutionary relationships. A recent example of this approach is the **PhyloCode**, which only names groups that include a common ancestor and all of its descendants. While PhyloCode would change the way taxa are defined and recognized, the taxonomic names of most species would remain the same. But species would no longer necessarily have "ranks" attached to them, such as family, order, or class. Also, some commonly recognized groups would become part of other groups previously of the same rank. For example, because birds evolved from a group of reptiles, Aves (the Linnaean class to which birds are assigned) would be considered a subgroup of Reptilia (also a class in the Linnaean system). Although PhyloCode is controversial and still being developed, many systematists are adopting the phylogenetic approach on which it is based.

Whether groups are named according to PhyloCode or to Linnaean classification, a phylogenetic tree represents a hypothesis about evolutionary relationships. These relationships often are depicted as a series of dichotomies, or two-way **branch points (Figure 26.5)**. Each branch point represents the divergence of two evolutionary lineages from a common ancestor. For example, in Figure 26.5, branch point 1 represents the common ancestor of taxa A, B, and C. The position of branch point 4 to the right of branch point 1 indicates that taxa B and C diverged after their shared lineage split from that of taxon A. Note that tree branches can be rotated around a branch point without changing their evolutionary relationships.

In Figure 26.5, taxa B and C are **sister taxa**, groups of organisms that share an immediate common ancestor (branch point 4) and hence are each other's closest relatives. Note also that this tree, like most of the phylogenetic trees in this book, is **rooted**, which means that a branch point within the

▲ **Figure 26.5 How to read a phylogenetic tree.**
DRAW IT *Redraw this tree, rotating the branches around branch points 2 and 4. Does your new version tell a different story about the evolutionary relationships between the taxa? Explain.*

tree (typically, the one farthest to the left) represents the last common ancestor of all taxa in the tree. Finally, the lineage leading to taxa D–F includes a **polytomy**, a branch point from which more than two descendant groups emerge. A polytomy indicates that evolutionary relationships among the descendant taxa are not yet clear.

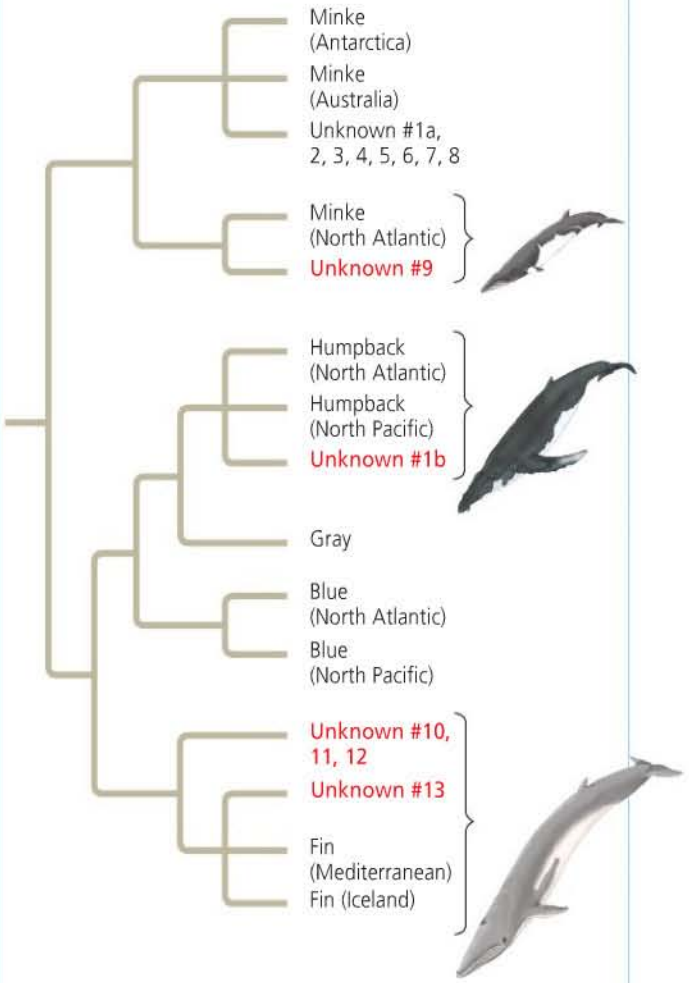
What We Can and Cannot Learn from Phylogenetic Trees

Let's pause to summarize two key points about phylogenetic trees and what they signify. First, the sequence of branching in a tree does not necessarily indicate the actual (absolute) ages of the particular species. For example, the tree in Figure 26.4 does *not* indicate that the wolf evolved more recently than the European otter; rather, the tree shows only that the most recent common ancestor of the wolf and European otter (branch point 1) lived before the most recent common ancestor of the wolf and coyote (branch point 2). To indicate when wolves and European otters evolved, the tree would need to include additional divergences in each evolutionary lineage, as well as the dates when those splits occurred. More generally, unless given specific information about what the branch lengths in a phylogenetic tree mean—for example, that they are proportional to time or genetic change—we should interpret the diagram solely in terms of patterns of descent. No assumptions should be made about when particular species evolved or how much genetic change occurred in each evolutionary lineage.

Second, we cannot assume that a taxon on a phylogenetic tree evolved from the taxon next to it. Figure 26.4 does not indicate that wolves evolved from coyotes or vice versa. We can infer only that the lineage leading to wolves and the lineage leading to coyotes both evolved from the common ancestor 2.

Applying Phylogenies

Why do biologists care about studying phylogenies? One reason is that a species' phylogeny provides an enormous amount of information. Consider maize (corn), the second most important source of food worldwide (after wheat). From a phylogeny of maize based on DNA data, researchers identified two species of wild grasses that may be the closest living relatives to maize. These two close relatives may prove useful as "reservoirs" of beneficial genes that can be transferred to cultivated maize by plant breeding or genetic engineering. The phylogenetic analysis of maize also led to the identification of the gene responsible for maize's unique fruiting body, the cob.



Phylogenetic trees have played a key role in a wide range of other applications. One example is an investigation into whether food sold as "whale meat" in Japan was illegally harvested from whale species protected under international law **(Figure 26.6)**. Although it is legal to harvest some whales for food, such as Minke whales that are caught in the Southern Hemisphere, this phylogeny indicated that meat from

▼ Figure 26.6 Inquiry

What is the species identity of food being sold as whale meat?

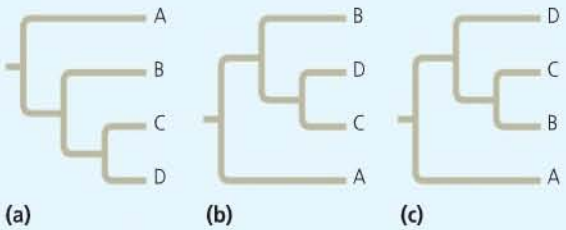
EXPERIMENT C. S. Baker, at the University of Auckland, New Zealand, and S. R. Palumbi, then at the University of Hawaii, purchased 13 samples of "whale meat" from several Japanese fish markets. They sequenced a region with the mitochondrial DNA from each sample and compared their results with the comparable DNA sequence from known whale species. To infer the species identity of their samples, Baker and Palumbi constructed a *gene tree*, a phylogenetic tree that shows patterns of relatedness among DNA sequences rather than among taxa.

RESULTS Baker and Palumbi's analysis yielded the following gene tree:

CONCLUSION This analysis indicated that DNA sequences of six of the unknown samples (in red) were most closely related to DNA sequences of whales that are not legal to harvest.

SOURCE C. S. Baker and S. R. Palumbi, Which whales are hunted? A molecular genetic approach to monitoring whaling, *Science* 265:1538–1539 (1994).

WHAT IF? What are some potential sources of error in this study? How might the chances of reaching an erroneous conclusion be reduced?



humpback, fin, and Minke whales caught in the Northern Hemisphere was being sold illegally in fish markets.

Another newsworthy application of phylogeny relates to bioterrorism. In fall 2001, several politicians and journalists were sent envelopes containing anthrax bacteria. Researchers used phylogenetic trees based on DNA data to identify the strain of the bacterium used in the 2001 attacks—information that may eventually help trace the source of the attacks.

How do researchers construct trees like those we've considered here? In the next section, we'll begin to answer that question by examining the data used to estimate phylogenies.

CONCEPT CHECK 26.1

1. Which levels of the classification in Figure 26.3 do humans share with leopards?
2. What does the phylogenetic tree in Figure 26.4 indicate about the evolutionary relationships of the leopard, badger, and wolf?
3. Which of the trees shown below depicts a different evolutionary history for taxa A–D than the other two trees? Explain.

4. **WHAT IF?** If new evidence were uncovered indicating that taxon E in Figure 26.5 is the sister taxon of a group that consists of taxa D and F, how would this change the phylogeny? Redraw the tree to accommodate this new finding.

For suggested answers, see Appendix A.

CONCEPT 26.2
Phylogenies are inferred from morphological and molecular data

To infer phylogeny, systematists must gather as much information as possible about the morphology, genes, and biochemistry of the relevant organisms. It is important to focus on features that result from common ancestry, because only these features reflect evolutionary relationships.

Morphological and Molecular Homologies

Recall that similarities due to shared ancestry are called homologies. For example, the similarity in the number and arrangement of bones in the forelimbs of mammals is due to their descent from a common ancestor with the same bone structure; this is an example of a morphological homology (see Figure 22.17). In the same way, genes or other DNA sequences are homologous if they are descended from sequences carried by a common ancestor.

In general, organisms that share very similar morphologies or similar DNA sequences are likely to be more closely related than organisms with vastly different structures or sequences. In some cases, however, the morphological divergence between related species can be great and their genetic divergence small (or vice versa). Consider the Hawaiian silversword plants discussed in Chapter 25. These species vary dramatically in appearance throughout the islands. Some are tall, twiggy trees, and others are dense, ground-hugging shrubs (see Figure 25.18). But despite these striking phenotypic differences, the silverswords' genes are very similar. Based on these small molecular divergences, scientists estimate that the silversword group began to diverge 5 million years ago, which is also about the time when the oldest of the current islands formed. We'll discuss how scientists use molecular data to make such estimates later in this chapter.

Sorting Homology from Analogy

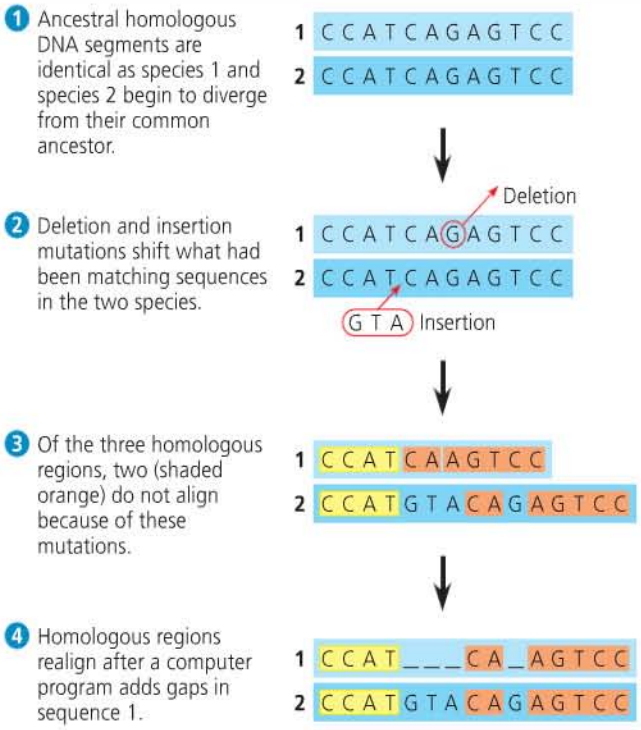
A potential red herring in constructing a phylogeny is similarity due to convergent evolution—called **analogy**—rather than to shared ancestry (homology). As you read in Chapter 22, convergent evolution occurs when similar environmental pressures and natural selection produce similar (analogous) adaptations in organisms from different evolutionary lineages. For example, the two mole-like animals illustrated in **Figure 26.7** are very similar in their external appearance. However, their internal anatomy, physiology, and reproductive systems are very dissimilar. Australian "moles" are marsupials; their young complete

▲ **Figure 26.7 Convergent evolution of analogous burrowing characteristics.** An elongated body, enlarged front paws, small eyes, and a pad of thickened skin that protects a tapered nose all evolved independently in the marsupial Australian "mole" (top) and a eutherian North American mole (bottom).

their embryonic development in a pouch on the outside of the mother's body. North American moles, in contrast, are eutherians; their young complete their embryonic development in the uterus within the mother's body. Indeed, genetic comparisons and the fossil record provide evidence that the common ancestor of these moles lived 140 million years ago, about the time the marsupial and eutherian mammals diverged. This ancestor and most of its descendants were not mole-like, but analogous characteristics evolved independently in these two mole lineages as they became adapted to similar lifestyles.

Distinguishing between homology and analogy is critical in reconstructing phylogenies. To see why, consider bats and birds, both of which have adaptations that enable flight. This superficial resemblance might imply that bats are more closely related to birds than they are to cats, which cannot fly. But a closer examination reveals that a bat's wing is far more similar to the forelimbs of cats and other mammals than to a bird's wing. Bats and birds descended from a common tetrapod ancestor that lived about 320 million years ago. This common ancestor could not fly. Thus, although the underlying skeletal systems of bats and birds are homologous, their *wings* are not. Flight is enabled in different ways—stretched membranes in the bat wing versus feathers in the bird wing. Fossil evidence also documents that bat wings and bird wings arose independently from the forelimbs of different tetrapod ancestors. Thus, with respect to flight, a bat's wing is *analogous*, not homologous, to a bird's wing. Analogous structures that arose independently are also called **homoplasies** (from the Greek for "to mold in the same way").

Besides corroborative similarities and fossil evidence, another clue to distinguishing between homology and analogy is the complexity of the characters being compared. The more points of resemblance that two complex structures have, the more likely it is that they evolved from a common ancestor. For instance, the skulls of an adult human and an adult chimpanzee both consist of many bones fused together. The compositions of the skulls match almost perfectly, bone for bone. It is highly improbable that such complex structures, matching in so many details, have separate origins. More likely, the genes involved in the development of both skulls were inherited from a common ancestor. The same argument applies to comparisons at the gene level. Genes are sequences of thousands of nucleotides, each of which represents an inherited character in the form of one of the four DNA bases: A (adenine), G (guanine), C (cytosine), or T (thymine). If genes in two organisms share many portions of their nucleotide sequences, it is highly likely that the genes are homologous.



Evaluating Molecular Homologies

Molecular comparisons of nucleic acids often pose technical challenges for researchers. The first step after sequencing the molecules is to align comparable sequences from the species being studied. If the species are very closely related, the sequences probably differ at only one or a few sites. In contrast, comparable nucleic acid sequences in distantly related species usually have different bases at many sites and may have different lengths. This is because insertions and deletions accumulate over long periods of time (see Chapter 23).

Suppose, for example, that particular noncoding DNA sequences in a particular gene in two species are very similar, except that the first base of the sequence has been deleted in one of the species. The effect is that the remaining sequence shifts back one notch. A comparison of the two sequences that does not take this deletion into account would overlook what in fact is a very good match. To address such problems, systematists have developed computer programs that estimate the best way to align comparable DNA segments of differing lengths **(Figure 26.8)**.

Such molecular comparisons reveal that a large number of base substitutions and other differences have accumulated between the comparable genes of the Australian mole and a North American mole. The many differences indicate that their lineages have diverged greatly since their common ancestor; thus, we say that the living species are not closely related. In contrast, the high degree of gene sequence similarity among the silverswords supports the hypothesis that they are all very closely related, in spite of their considerable morphological differences.

Just as with morphological characters, it is necessary to distinguish homology from analogy in evaluating molecular

▲ **Figure 26.8 Aligning segments of DNA.** Systematists use computer software to find and align similar sequences along DNA segments from two species. (In this example, no bases have changed in these sequences since divergence, and so the comparable sequences are still identical once the length is adjusted.)

ACGGATAGTCCACTAGGCACTA

TCACCGACAGGTCTTTGACTAG

▲ **Figure 26.9 A molecular homoplasy.** These two DNA sequences from organisms that are not closely related coincidentally share 25% of their bases. Statistical tools have been developed to determine whether DNA sequences that share more than 25% of their bases do so because they are homologous.

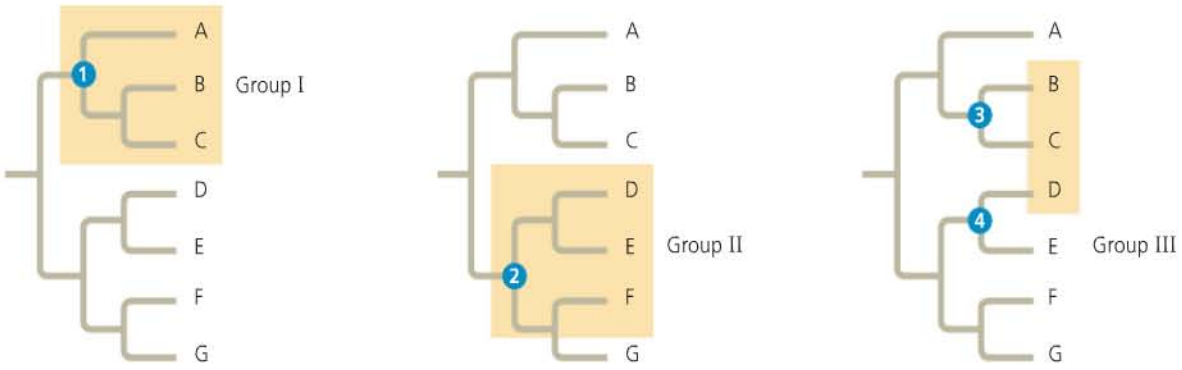
? *Why might you expect organisms that are not closely related to nevertheless share roughly 25% of their bases?*

similarities for evolutionary studies. Two sequences that resemble each other at many points along their length most likely are homologous (see Figure 26.8). But in organisms that do not appear to be closely related, the bases that their otherwise very different sequences happen to share may simply be coincidental matches, called molecular homoplasies **(Figure 26.9)**. Scientists have developed statistical tools that can help distinguish "distant" homologies from such coincidental matches in extremely divergent sequences.

Scientists have so far sequenced more than 100 billion bases' worth of nucleic acid data from thousands of species. This enormous collection of data has fed a boom in the study of phylogeny. The new data have supported earlier hypotheses regarding many evolutionary relationships, such as that between the Australian and North American moles, and have clarified other relationships, such as those between the various silverswords. In the rest of this chapter and unit, you will see many examples of the tremendous impact of **molecular systematics**, the discipline that uses DNA and other molecular data to determine evolutionary relationships.

CONCEPT CHECK 26.2

1. Decide whether each of the following pairs of structures more likely represents analogy or homology, and explain your reasoning: (a) a porcupine's quills and a cactus's spines; (b) a cat's paw and a human's hand; (c) an owl's wing and a hornet's wing.
2. **WHAT IF?** Suppose that species 1 and species 2 have similar appearances but very divergent gene sequences and that species 2 and species 3 have very different appearances but similar gene sequences. Which pair of species is more likely to be closely related: 1 and 2, or 2 and 3? Explain.



For suggested answers, see Appendix A.

CONCEPT 26.3
Shared characters are used to construct phylogenetic trees

In reconstructing phylogenies, the first step is to distinguish homologous features from analogous features (since only the former reflect evolutionary history). Once that task is accomplished, biologists must choose a method of inferring phylogeny from these homologous characters. In this section, we'll examine a widely used set of methods known as cladistics.

Cladistics

In the approach to systematics called **cladistics**, common ancestry is the primary criterion used to classify organisms. Using this methodology, biologists place species into groups called **clades**, each of which includes an ancestral species and all of its descendants **(Figure 26.10a)**. Clades, like taxonomic

(a) Monophyletic group (clade). Group I, consisting of three species (A, B, C) and their common ancestor 1, is a clade, also called a monophyletic group. A monophyletic group consists of an ancestral species and *all* of its descendants.

(b) Paraphyletic group. Group II is paraphyletic, meaning that it consists of an ancestral species 2 and some of its descendants (species D, E, F) but not all of them (missing species G).

(c) Polyphyletic group. Group III is polyphyletic, meaning that its members have different ancestors. In this case, species B and C share common ancestor 3, but species C has a different ancestor: 4.

▲ **Figure 26.10 Monophyletic, paraphyletic, and polyphyletic groups.**

ranks, are nested within larger clades. For example, the cat group represents a clade within a larger clade that also includes the dog group. However, a taxon is equivalent to a clade only if it is **monophyletic** (from the Greek meaning "single tribe"), signifying that it consists of an ancestral species and all its descendants (see Figure 26.10a). Contrast this with a **paraphyletic** ("beside the tribe") group, which consists of an ancestral species and some, but not all, of its descendants **(Figure 26.10b)**, or a **polyphyletic** ("many tribes") group, which includes taxa with different ancestors **(Figure 26.10c)**. Next we'll discuss how clades are identified: using shared derived characters.

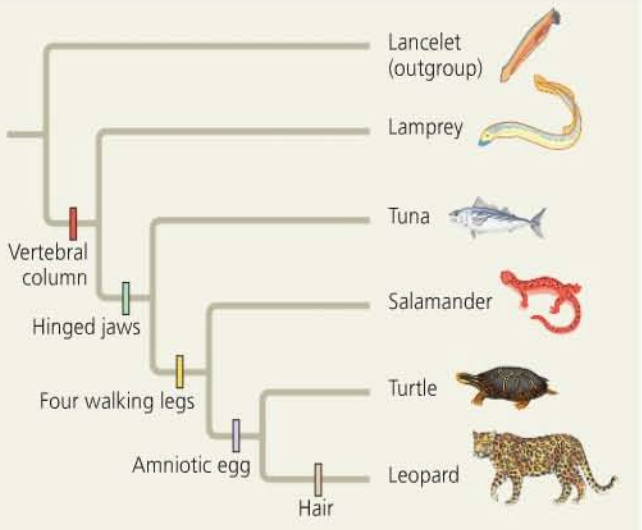
Shared Ancestral and Shared Derived Characters

As a result of descent with modification, organisms both share characteristics with their ancestors and differ from them (see Chapter 22). For example, all mammals have backbones, but the presence of a backbone does not distinguish mammals from other vertebrates because *all* vertebrates have backbones. The backbone predates the branching of the mammalian clade from other vertebrates. Thus, we say that for mammals, the backbone is a **shared ancestral character**, a character that originated in an ancestor of the taxon. In contrast, hair is a character shared by all mammals but *not* found in their ancestors. Thus, in mammals, hair is considered a **shared derived character**, an evolutionary novelty unique to a particular clade.

Note that a backbone can also qualify as a shared derived character, but only at a deeper branch point that distinguishes all vertebrates from other animals. Among vertebrates, a backbone is considered a shared ancestral character because it was present in the ancestor common to all vertebrates.

Inferring Phylogenies Using Derived Characters

Shared derived characters are unique to particular clades. Because all features of organisms arose at some point in the history of life, it should be possible to determine the clade in which each shared derived character first appeared and to use that information to infer evolutionary relationships.



To see how this analysis is done, consider the set of characters shown in **Figure 26.11a** for each of five vertebrates—a leopard, turtle, salamander, tuna, and lamprey (a jawless aquatic vertebrate). As a basis of comparison, we need to select an outgroup. An **outgroup** is a species or group of species from an evolutionary lineage that is known to have diverged before the lineage that includes the species we are studying (the **ingroup**). A suitable outgroup can be determined based on evidence from morphology, paleontology, embryonic development, and gene sequences. An appropriate outgroup for our example is the lancelet, a small animal that lives in mudflats and (like vertebrates) is a member of the Chordata. Unlike the vertebrates, however, the lancelet does not have a backbone.

By comparing members of the ingroup to each other and to the outgroup, we can determine which characters were derived at the various branch points of vertebrate evolution. For example, *all* of the vertebrates in the ingroup have backbones: This character was present in the ancestral vertebrate, but not in the outgroup. Now note that hinged jaws are a character absent in lampreys but present in other members of the ingroup; this character helps us to identify an early branch point in the vertebrate clade. Proceeding in this way, we can translate the data in our table of characters into a phylogenetic tree **(Figure 26.11b)**.

TAXA

CHARACTERS	Lancelet (outgroup)	Lamprey	Tuna	Salamander	Turtle	Leopard
Vertebral column (backbone)	0	1	1	1	1	1
Hinged jaws	0	0	1	1	1	1
Four walking legs	0	0	0	1	1	1
Amniotic (shelled) egg	0	0	0	0	1	1
Hair	0	0	0	0	0	1

(a) Character table. A 0 indicates that a character is absent; a 1 indicates that a character is present.

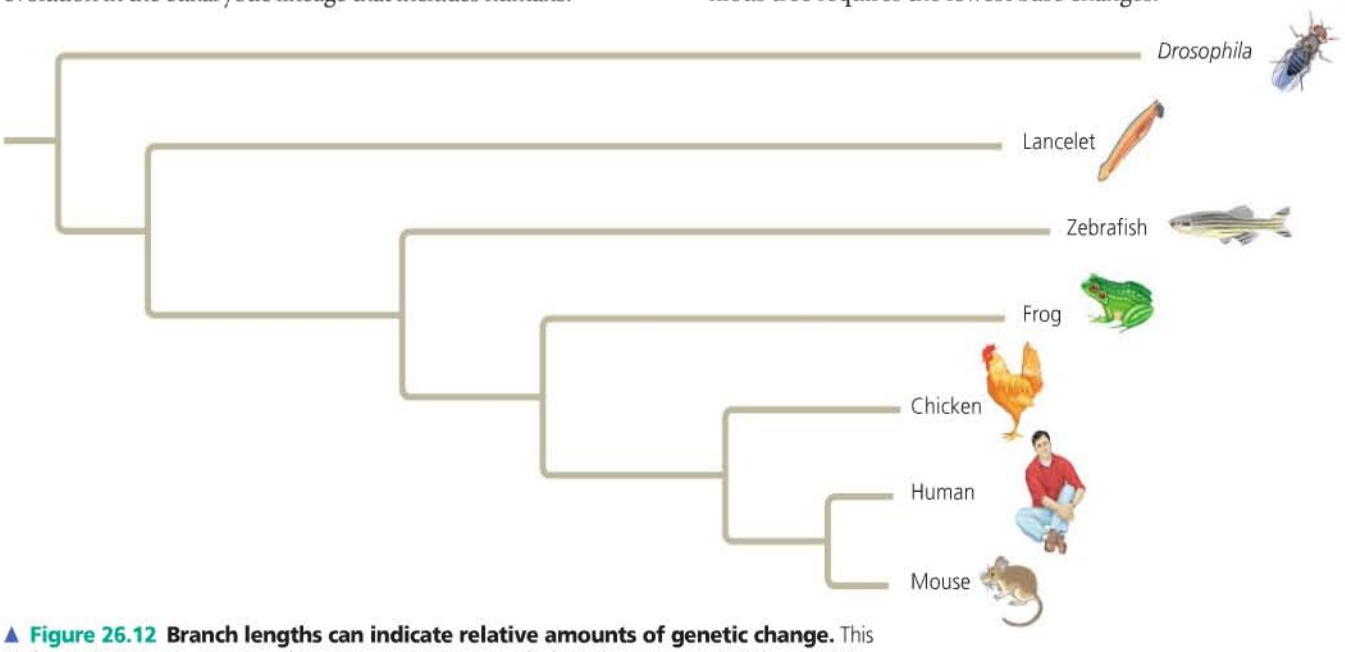
(b) Phylogenetic tree. Analyzing the distribution of these derived characters can provide insight into vertebrate phylogeny.

▲ **Figure 26.11 Constructing a phylogenetic tree.**

Phylogenetic Trees with Proportional Branch Lengths

In the phylogenetic trees we have presented so far, the lengths of the tree's branches do not indicate the degree of evolutionary change in each lineage. Furthermore, the chronology represented by the branching pattern of the tree is relative (earlier versus later) rather than absolute (how many millions of years ago). But in some tree diagrams, branch lengths are proportional to amount of evolutionary change or to the times at which particular events occurred.

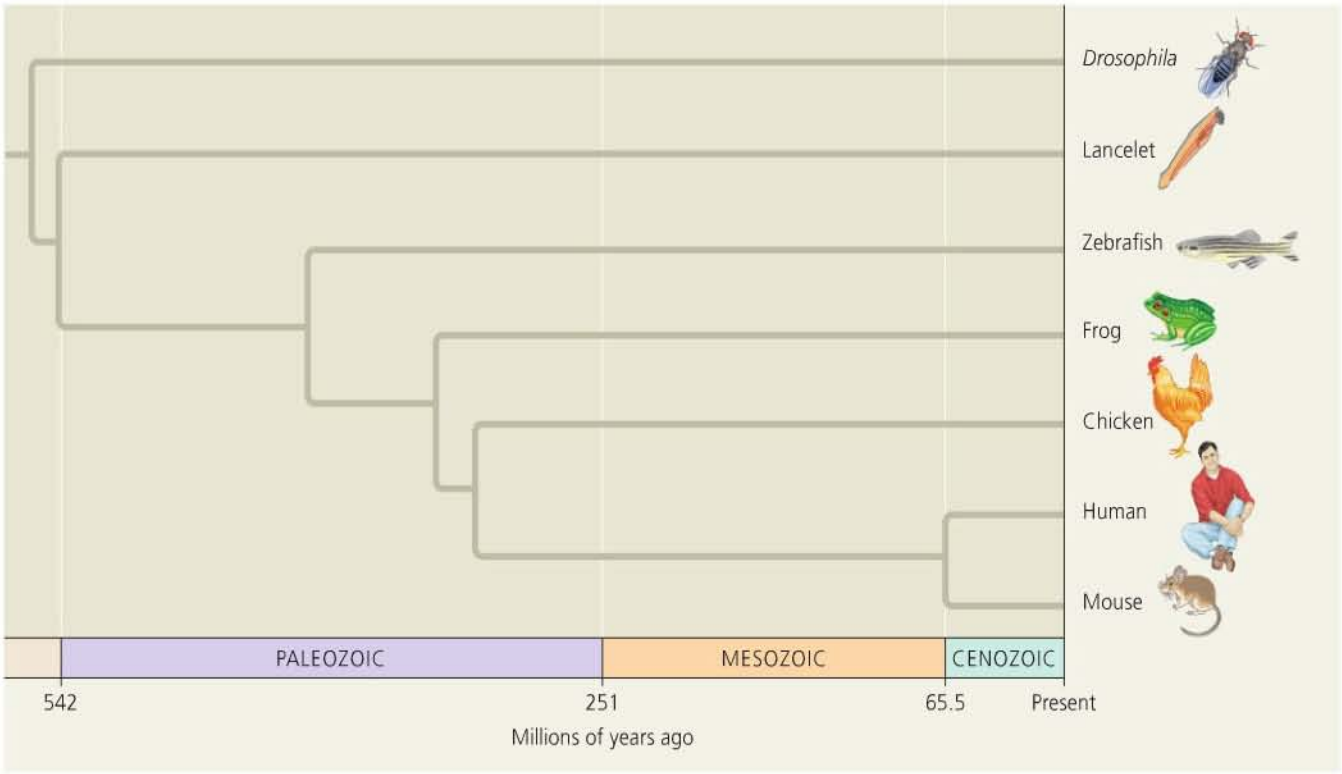
For example, the branch length of a phylogenetic tree can reflect the number of changes that have taken place in a particular DNA sequence in that lineage **(Figure 26.12)**. Note that in Figure 26.12, the *total length* of the horizontal lines from the base of the tree to the mouse is less than that of the line leading to the outgroup species, the fruit fly *Drosophila*. This implies that in the time since the mouse and fly diverged from a common ancestor, more genetic changes have occurred in the *Drosophila* lineage than in the mouse lineage.



Even though the branches of a phylogenetic tree may have different lengths, among organisms alive today, all the different lineages that descend from a common ancestor have survived for the same number of years. To take an extreme example, humans and bacteria had a common ancestor that lived over 3 billion years ago. Fossils and genetic evidence indicate that this ancestor was a single-celled prokaryote. Even though bacteria have apparently changed little in their structure since that common ancestor, there have nonetheless been 3 billion years of evolution in the bacterial lineage, just as there have been 3 billion years of evolution in the eukaryotic lineage that includes humans.

These equal spans of chronological time can be represented in a phylogenetic tree whose branch lengths are proportional to time **(Figure 26.13)**. Such a tree draws on fossil data to place branch points in the context of geologic time. Additionally, it is possible to combine these two types of trees by labeling branch points with information about rates of genetic change or dates of divergence.

Maximum Parsimony and Maximum Likelihood

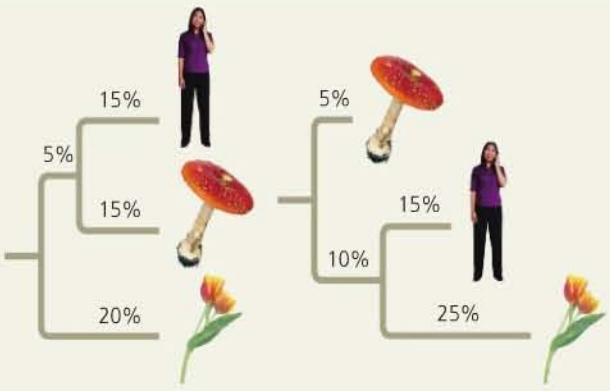


As the growing database of DNA sequences enables us to study more species, the difficulty of building the phylogenetic tree that best describes their evolutionary history also grows. What if you are analyzing data for 50 species? There are 3×10^{76} different ways to arrange 50 species into a tree! And which tree in this huge forest reflects the true phylogeny? Systematists can never be sure of finding the most accurate tree in such a large data set, but they can narrow the possibilities by applying the principles of maximum parsimony and maximum likelihood.

According to the principle of **maximum parsimony**, we should first investigate the simplest explanation that is consistent with the facts. (The parsimony principle is also called "Occam's razor" after William of Occam, a 14th-century English philosopher who advocated this minimalist problem-solving approach of "shaving away" unnecessary complications.) In the case of trees based on morphology, the most parsimonious tree requires the fewest evolutionary events, as measured by the origin of shared derived morphological characters. For phylogenies based on DNA, the most parsimonious tree requires the fewest base changes.

▲ **Figure 26.12 Branch lengths can indicate relative amounts of genetic change.** This phylogenetic tree was constructed by comparing sequences of a homologous gene that plays a role in development. The *Drosophila* gene was used as an outgroup. The branch lengths are proportional to the amount of genetic change in each lineage. Thus, the varying branch lengths indicate that the gene has evolved at slightly different rates in the different lineages.

? *In which vertebrate lineage has the studied gene evolved most rapidly? Explain.*



▲ **Figure 26.13 Branch lengths can indicate time.** The relationships shown in this tree are based on the same molecular data as the tree in Figure 26.12. Branch lengths were then drawn to fit the dates of the different branch points based on fossil evidence. As a result, branch lengths are proportional to time. Each evolutionary lineage has the same total length from the base of the tree to the branch tip, indicating that all the lineages have diverged from the common ancestor for equal amounts of time.

The principle of **maximum likelihood** states that given certain rules about how DNA changes over time, a tree can be found that reflects the most likely sequence of evolutionary events. Maximum-likelihood methods are complex, but as a simple example, let us return to the phylogenetic relationships between a human, a mushroom, and a tulip. **Figure 26.14** shows two possible, equally parsimonious trees for this trio. Tree 1 is more likely if we assume that DNA changes have occurred at equal rates along all the branches of the tree from the common ancestor. Tree 2 requires assuming that the rates of evolution slowed greatly in the mushroom lineage and sped up greatly in the tulip lineage. Thus, assuming that equal rates are more common than unequal rates, tree 1 is more likely. We will soon see that many genes do evolve at approximately equal rates in different lineages. But note that if we find new evidence

	Human	Mushroom	Tulip
Human	0	30%	40%
Mushroom		0	40%
Tulip			0

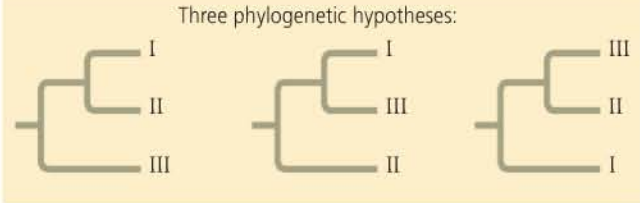
(a) Percentage differences between sequences

(b) Comparison of possible trees

▶ **Figure 26.14 Trees with different likelihoods.** Based on percentage differences between genes carried by a human, a mushroom, and a tulip (a), we can construct two possible phylogenetic trees with the same total branch length (b). The sum of the percentages from a point of divergence in a tree equals the percentage differences as listed in (a). For example, in tree 1, the human–tulip divergence is 15% + 5% + 20% = 40%. In tree 2, this divergence also equals 40% (15% + 25%). Assuming that the genes have evolved at the same rate in the different branches, tree 1 is more likely than tree 2.

▼ Figure 26.15 Research Method

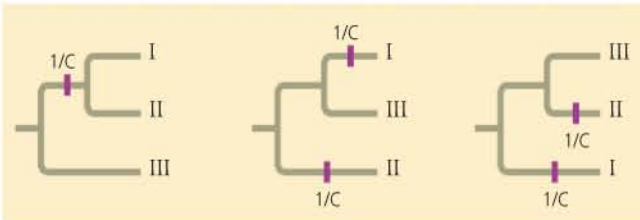
Applying Parsimony to a Problem in Molecular Systematics



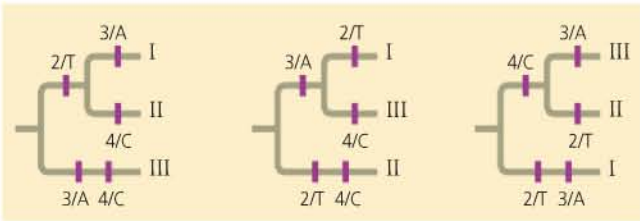
APPLICATION In considering possible phylogenies for a group of species, systematists compare molecular data for the species. An efficient way to begin is by identifying the most parsimonious hypothesis—the one that requires the fewest evolutionary events (molecular changes) to have occurred.

TECHNIQUE Follow the numbered steps as we apply the principle of parsimony to a hypothetical phylogenetic problem involving three closely related bird species.

Species I Species II Species III

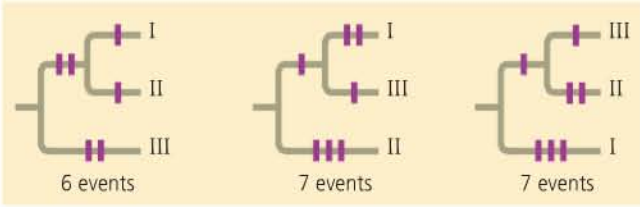


1. First, draw the three possible phylogenies for the species. (Although only 3 trees are possible when ordering 3 species, the number of possible trees increases rapidly with the number of species: There are 15 trees for 4 species and 34,459,425 trees for 10 species.)



2. Tabulate the molecular data for the species. In this simplified example, the data represent a DNA sequence consisting of just four nucleotide bases. Data from several outgroup species (not shown) were used to infer the ancestral DNA sequence.

	Site 1	2	3	4
Species I	C	T	A	T
Species II	C	T	T	C
Species III	A	G	A	C
Ancestral sequence	A	G	T	T



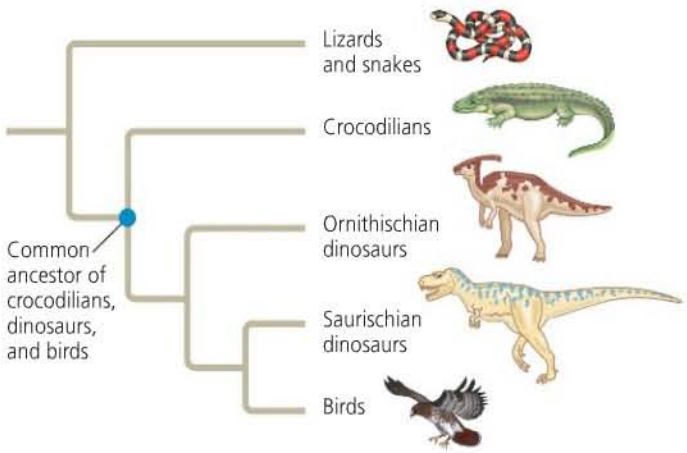
3. Now focus on site 1 in the DNA sequence. In the tree on the left, a single base-change event, represented by the purple hatchmark on the branch leading to species I and II (and labeled 1/C, indicating a change at site 1 to nucleotide C), is sufficient to account for the site 1 data. In the other two trees, two base-change events are necessary.

4. Continuing the comparison of bases at sites 2, 3, and 4 reveals that each of the three trees requires a total of five additional base-change events (purple hatchmarks).

RESULTS To identify the most parsimonious tree, we total all of the base-change events noted in steps 3 and 4. We conclude that the first tree is the most parsimonious of the three possible phylogenies.

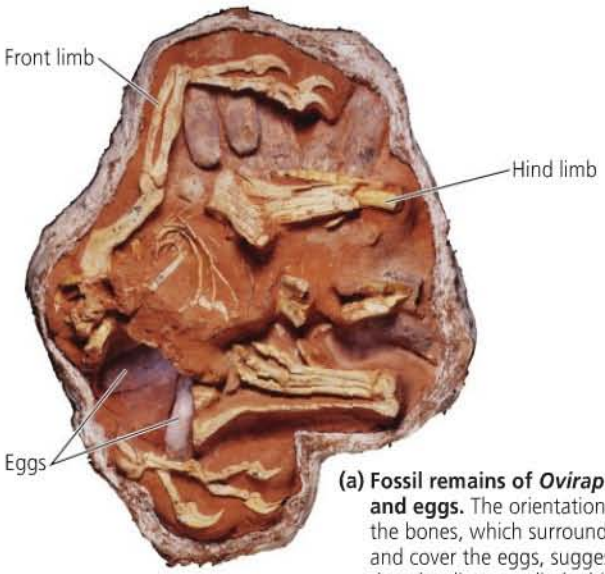
of unequal rates, tree 2 might be more likely! The likelihood of a tree depends on the assumptions on which it is based.

Many computer programs have been developed to search for trees that are parsimonious and likely. When a large amount of accurate data is available, the methods used in these programs usually yield similar trees. As an example of one method, **Figure 26.15**, on the facing page, walks you through the process of identifying the most parsimonious molecular tree for a three-species problem. Computer programs based on parsimony estimate phylogenies in a similar way: They exhaustively examine all possible trees and select the tree or trees that require fewest evolutionary changes.



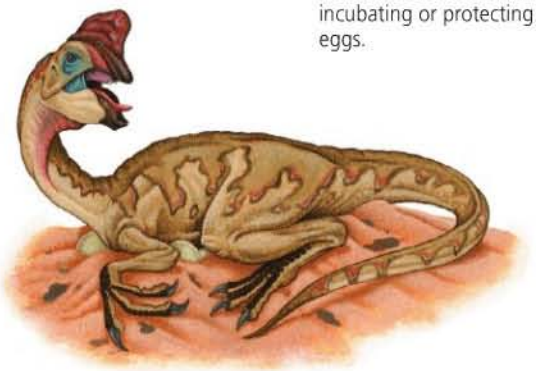
Phylogenetic Trees as Hypotheses

This is a good place to reiterate that any phylogenetic tree represents a hypothesis about how the various organisms in the tree are related to one another. The best hypothesis is the one that best fits all the available data. A phylogenetic hypothesis may be modified when new evidence compels systematists to revise their trees. Indeed, while many older phylogenetic hypotheses have been supported, others have been changed or rejected based on new morphological and molecular data.



Thinking of phylogenies as hypotheses also allows us to use them in a powerful way: We can make and test predictions based on the assumption that a phylogeny—our hypothesis—is correct. For example, in an approach known as **phylogenetic bracketing**, we can predict (by parsimony) that features shared by two groups of closely related organisms are present in their common ancestor and all of its descendants, unless independent data indicate otherwise. (Note that here the term *prediction* includes past events, not only future evolutionary change.)

This approach has been used to make novel predictions about dinosaurs. For example, there is evidence that birds descended from the theropods, a group of bipedal dinosaurs within the Saurischian clade. As seen in **Figure 26.16**, the closest living relatives of birds are crocodiles. Birds and crocodiles share numerous features: They have four-chambered hearts, they "sing" to defend territories and attract mates (although a crocodile "song" is more like a bellow), and they build nests. Both birds and crocodiles also care for their eggs by *brooding*, a behavior in which a parent warms the eggs with its body. Birds brood by sitting on their eggs, whereas crocodiles cover their eggs with their neck. Reasoning that any feature shared by birds and crocodiles is likely to have been present in their common ancestor (denoted by the blue dot in Figure 26.16) and *all* of its descendants, biologists predicted that dinosaurs had four-chambered hearts, sang, built nests, and exhibited brooding.



Internal organs, such as the heart, rarely fossilize, and it is, of course, difficult to test whether dinosaurs sang to defend territories and attract mates. However, fossilized dinosaur eggs and nests have provided evidence supporting the prediction of brooding in dinosaurs. First, a fossil embryo of an *Oviraptor* dinosaur was found, still inside its egg. This egg was identical to those found in another fossil, one that showed an *Oviraptor* adult crouching over a group of eggs in a posture similar to that in brooding birds today **(Figure 26.17)**. Researchers suggested

▲ **Figure 26.16 A phylogenetic tree of birds and their close relatives.**

(a) Fossil remains of *Oviraptor* and eggs. The orientation of the bones, which surround and cover the eggs, suggests that the dinosaur died while incubating or protecting its eggs.

(b) Artist's reconstruction of the dinosaur's posture based on the fossil findings.

▲ **Figure 26.17 Fossils support a phylogenetic prediction: Dinosaurs built nests and brooded their eggs.**

that the *Oviraptor* dinosaur preserved in this second fossil died while incubating or protecting its eggs. The broader conclusion that emerged from this work—that dinosaurs built nests and exhibited brooding—has since been supported by additional fossil discoveries that show that other species of dinosaurs built nests and sat on their eggs. Finally, by supporting predictions based on the phylogenetic hypothesis shown in Figure 26.16, fossil discoveries of nests and brooding in dinosaurs provide independent data that suggest the hypothesis is correct.

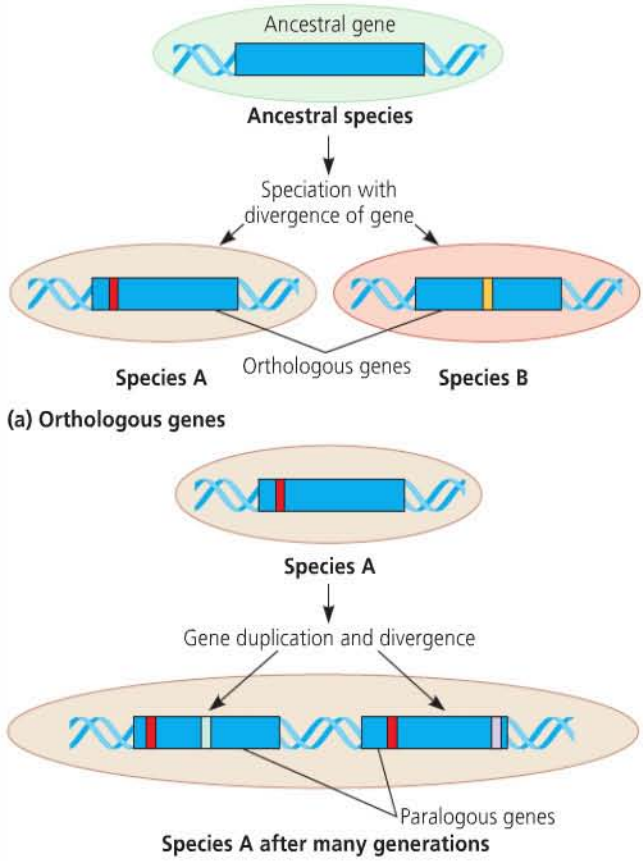
CONCEPT CHECK 26.3

1. To distinguish a particular clade of mammals within the larger clade that corresponds to class Mammalia, would hair be a useful character? Why or why not?
2. Why might the most parsimonious tree not necessarily be the most accurate in representing evolutionary relationships for a particular group of species?
3. **WHAT IF?** Draw a phylogenetic tree that includes the relationships from both Figure 25.6 and Figure 26.16. Traditionally, all the taxa shown besides birds and mammals were classified as reptiles. Using a cladistic approach, critique that classification.

For suggested answers, see Appendix A.

CONCEPT 26.4
An organism's evolutionary history is documented in its genome

You have seen throughout this chapter that molecular systematics—using comparisons of nucleic acids or other molecules to deduce relatedness—is a valuable tool for tracing evolutionary history. The molecular approach helps us to understand phylogenetic relationships that cannot be determined by nonmolecular methods such as comparative anatomy. For example, molecular systematics helps us uncover evolutionary relationships between groups that have little common ground for morphological comparison, such as animals and fungi. And molecular methods allow us to reconstruct phylogenies among groups of present-day prokaryotes and other microorganisms for which we have no fossil record at all. Molecular biology has helped to extend systematics to evolutionary relationships far above and below the species level, ranging from the major branches of the tree of life to its finest twigs. Still, the findings are often inconclusive, as in cases where several taxa diverged at nearly the same time in the distant past. The differences may be apparent, but not the order of their appearance.



Different genes evolve at different rates, even in the same evolutionary lineage. As a result, molecular trees can represent short or long periods of time, depending on what genes are used. For example, the DNA that codes for ribosomal RNA (rRNA) changes relatively slowly, and so comparisons of DNA sequences in these genes are useful for investigating relationships between taxa that diverged hundreds of millions of years ago. Studies of rRNA sequences indicate, for example, that fungi are more closely related to animals than to green plants (see Figure 26.2). In contrast, mitochondrial DNA (mtDNA) evolves relatively rapidly and can be used to explore recent evolutionary events. One research team has traced the relationships among Native American groups through their mtDNA sequences. The molecular findings corroborate other evidence that the Pima of Arizona, the Maya of Mexico, and the Yanomami of Venezuela are closely related, probably descending from the first of three waves of immigrants that crossed the Bering land bridge from Asia to the Americas about 13,000 years ago.

Gene Duplications and Gene Families

What does molecular systematics reveal about the evolutionary history of genome change? Consider gene duplication, which plays a particularly important role in evolution because it increases the number of genes in the genome, providing more opportunities for further evolutionary changes. Molecular techniques now allow us to trace the phylogenies of gene duplications and the influence of these duplications on genome evolution. These molecular phylogenies must account for repeated duplications that have resulted in *gene families,* groups of related genes within an organism's genome (see Figure 21.10). Like homologous genes in different species, these duplicated genes have a common ancestor. We distinguish these types of homologous genes by different names: orthologous genes and paralogous genes.

The term **orthologous genes** (from the Greek *orthos,* straight) refers to homologous genes that are found in different species because of speciation **(Figure 26.18a)**. The cytochrome *c* genes (which code for an electron transport chain protein) in humans and dogs are orthologous. **Paralogous genes** (from the Greek *para,* beside) result from gene duplication, so they are found in more than one copy in the same genome **(Figure 26.18b)**. In Chapter 23, you encountered the example of olfactory receptor genes, which have undergone many gene duplications in vertebrates. Humans and mice both have huge families of more than 1,000 of these paralogous genes.

It is possible to describe most of the genes that make up genomes as representing one of these two types of homology. Note that orthologous genes can only diverge after speciation has taken place, with the result that the genes are found in separate gene pools. For example, although the cytochrome *c* genes in humans and dogs serve a similar function, the

▲ **Figure 26.18 How two types of homologous genes originate.** The colored bands mark regions of the genes where differences in base sequences have accumulated.

gene's sequence in humans has diverged from that in dogs in the time since these species last shared a common ancestor. Paralogous genes, on the other hand, can diverge within a species because they are present in more than one copy in the genome. The paralogous genes that make up the olfactory receptor gene family in humans have diverged from each other during our long evolutionary history. They now specify proteins that confer sensitivity to a wide variety of odors, ranging from various foods to sex pheromones.

Genome Evolution

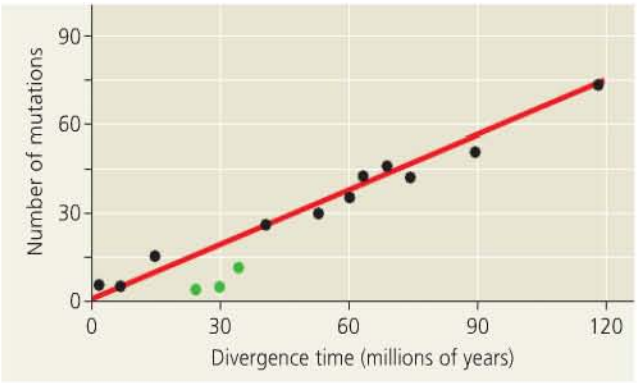
Now that we can compare the entire genomes of different organisms, including our own, two remarkable facts have emerged. First, orthologous genes are widespread and can extend over huge evolutionary distances. Ninety-nine percent of the genes of humans and mice are detectably orthologous, and 50% of our genes are orthologous with those of yeast. This remarkable commonality demonstrates that all living organisms share many biochemical and developmental pathways.

Second, the number of genes seems not to have increased through duplication at the same rate as perceived phenotypic complexity. Humans have only about four times as many genes as yeast, a single-celled eukaryote, even though—unlike yeast cells—we have a large, complex brain and a body that contains more than 200 different types of tissues. Evidence is emerging that many human genes are more versatile than those of yeast in that the proteins they encode carry out a wider variety of tasks in various body tissues. Before us lies a huge and exciting scientific challenge: unraveling the mechanisms that enable this genomic versatility.

CONCEPT CHECK 26.4

1. Explain how comparisons between the proteins of two species can yield data about their evolutionary relationship.
2. **WHAT IF?** Suppose gene A is orthologous in species 1 and species 2, and gene B is paralogous to gene A in species 1. Suggest a sequence of two evolutionary events that could result in the following: Gene A differs considerably between species, yet gene A and gene B show little sequence divergence from each other.

For suggested answers, see Appendix A.



CONCEPT 26.5 Molecular clocks help track evolutionary time

One of the long-term goals of evolutionary biology is to understand the relationships among all organisms, including those for which there is no fossil record. When we extend molecular phylogenies beyond the fossil record, however, we must rely on an important assumption about how change occurs at the molecular level.

Molecular Clocks

We stated earlier that researchers have estimated that the common ancestor of Hawaiian silverswords lived about 5 million years ago. How did they make this estimate? They relied on the concept of a **molecular clock**, a yardstick for measuring the absolute time of evolutionary change based on the observation that some genes and other regions of genomes appear to evolve at constant rates. The assumption underlying the molecular clock is that the number of nucleotide substitutions in orthologous genes is proportional to the time that has elapsed since the species branched from their common ancestor (divergence time). In the case of paralogous genes, the number of substitutions is proportional to the time since the genes became duplicated.

We can calibrate the molecular clock of a gene that has a reliable average rate of evolution by graphing the number of genetic differences—for example, nucleotide, codon, or amino acid differences—against the dates of evolutionary branch

▲ **Figure 26.19 A molecular clock for mammals.** The number of accumulated mutations in seven proteins increased over time in a consistent manner for most mammal species. The three green data points represent primate species, whose proteins appear to have evolved more slowly than those of other mammals. The divergence time for each data point was based on fossil evidence.

? *Use the clock to estimate the divergence time for a mammal with a total of 30 mutations in the seven proteins.*

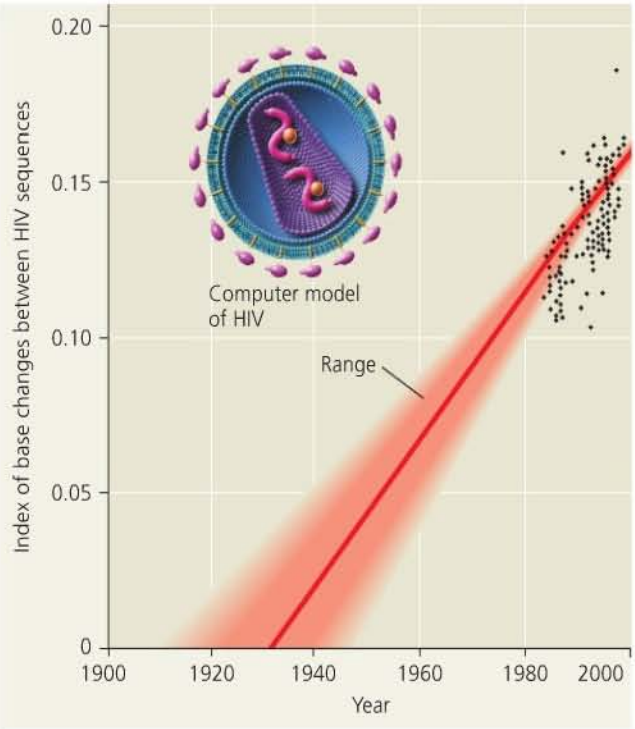
points that are known from the fossil record **(Figure 26.19)**. Such graphs can then be used to estimate the dates of evolutionary episodes that cannot be discerned from the fossil record, such as the origin of the silverswords discussed earlier.

Of course, no gene marks time with complete precision. In fact, some portions of the genome appear to have evolved in irregular fits and starts that are not at all clocklike. And even those genes that seem to have reliable molecular clocks are accurate only in the statistical sense of showing a fairly smooth *average* rate of change. Over time, there may still be chance deviations above and below that average rate. Furthermore, the same gene may evolve at different rates in different groups of organisms, making it necessary to calibrate and use molecular clocks with care. Finally, even among genes that are clocklike, the rate of the clock may vary greatly from one gene to another; some genes evolve a million times faster than others.

Neutral Theory

The regularity of change that enables us to use some genes as molecular clocks raises the possibility that many of the changes in these sequences result from genetic drift (see Chapter 23) and that the changes are mostly neutral—neither adaptive nor detrimental. In the 1960s, Jack King and Thomas Jukes, at the University of California, Berkeley, and Motoo Kimura, at the Japanese National Institute of Genetics, published papers supporting this **neutral theory**—that much evolutionary change in genes and proteins has no effect on fitness and therefore is not influenced by Darwinian selection. Kimura pointed out that many new mutations are harmful and are removed quickly. But if most of the rest are neutral and have little or no effect on fitness, then the rate of molecular change should indeed be regular like a clock. Differences in the clock rate for different genes are a function of how important a gene is. If the exact sequence of amino acids that a gene specifies is essential to survival, most of the mutational changes will be harmful and only a few will be neutral. As a result, such genes change only slowly. But if the exact sequence of amino acids is less critical, fewer of the new mutations will be harmful and more will be neutral. Such genes change more quickly.

Difficulties with Molecular Clocks



In fact, molecular clocks do not run as smoothly as neutral theory predicts. Many irregularities are likely to be the result of natural selection in which certain DNA changes are favored over others. Consequently, some scientists question the utility of molecular clocks for timing evolution. Their skepticism is part of a broader debate about the extent to which neutral genetic variation can account for some kinds of DNA diversity. Indeed, evidence suggests that almost half the amino acid differences in proteins of two *Drosophila* species, *D. simulans* and *D. yakuba*, are not neutral but have resulted from directional natural selection. But because the direction of natural selection may change repeatedly over long periods of time (and hence may average out), some genes experiencing selection can nevertheless serve as approximate markers of elapsed time.

Another question arises when researchers attempt to extend molecular clocks beyond the time span documented by the fossil record. Although some fossils are more than 3 billion years old, these are very rare. An abundant fossil record extends back only about 550 million years, but molecular clocks have been used to date evolutionary divergences that occurred a billion or more years ago. These estimates assume that the clocks have been constant for all that time. Such estimates are highly uncertain.

In some cases, problems may be avoided by calibrating molecular clocks with many genes rather than just one or a few genes (as is often done). By using many genes, fluctuations in evolutionary rate due to natural selection or other factors that vary over time may average out. For example, one group of researchers constructed molecular clocks of vertebrate evolution from published sequence data for 658 nuclear genes. Despite the broad period of time covered (nearly 600 million years) and the fact that natural selection probably affected some of these genes, their estimates of divergence times agreed closely with fossil-based estimates.

Applying a Molecular Clock: The Origin of HIV

Researchers at Los Alamos National Laboratory in New Mexico used a molecular clock to date the origin of HIV infection in humans. Phylogenetic analysis shows that HIV, the virus that causes AIDS, is descended from viruses that infect chimpanzees and other primates. (The viruses do not cause any AIDS-like diseases in nonhuman hosts.) When did HIV jump to humans? There is no simple answer, because the virus has

▲ **Figure 26.20 Dating the origin of HIV-1 M with a molecular clock.** The numerous data points in the upper right-hand corner of this graph are based on DNA sequences for a specific HIV gene in blood samples collected from patients at different known times. If we project the relatively constant rate at which changes occurred in this gene in the 1980s and 1990s back in time, we intersect the *x*-axis of the graph in the 1930s.

spread to humans more than once. The multiple origins of HIV are reflected in the variety of strains (genetic types) of the virus. HIV's genetic material is made of RNA, and like other RNA viruses, it evolves quickly.

The most widespread strain in humans is HIV-1 M. To pinpoint the earliest HIV-1 M infection, the researchers compared samples of the virus from various times during the epidemic, including one sample from 1959. A comparison of gene sequences showed that the virus has evolved in a clocklike fashion since 1959 **(Figure 26.20)**. By extrapolating from their molecular clock, the researchers concluded that the HIV-1 M strain first spread to humans during the 1930s.

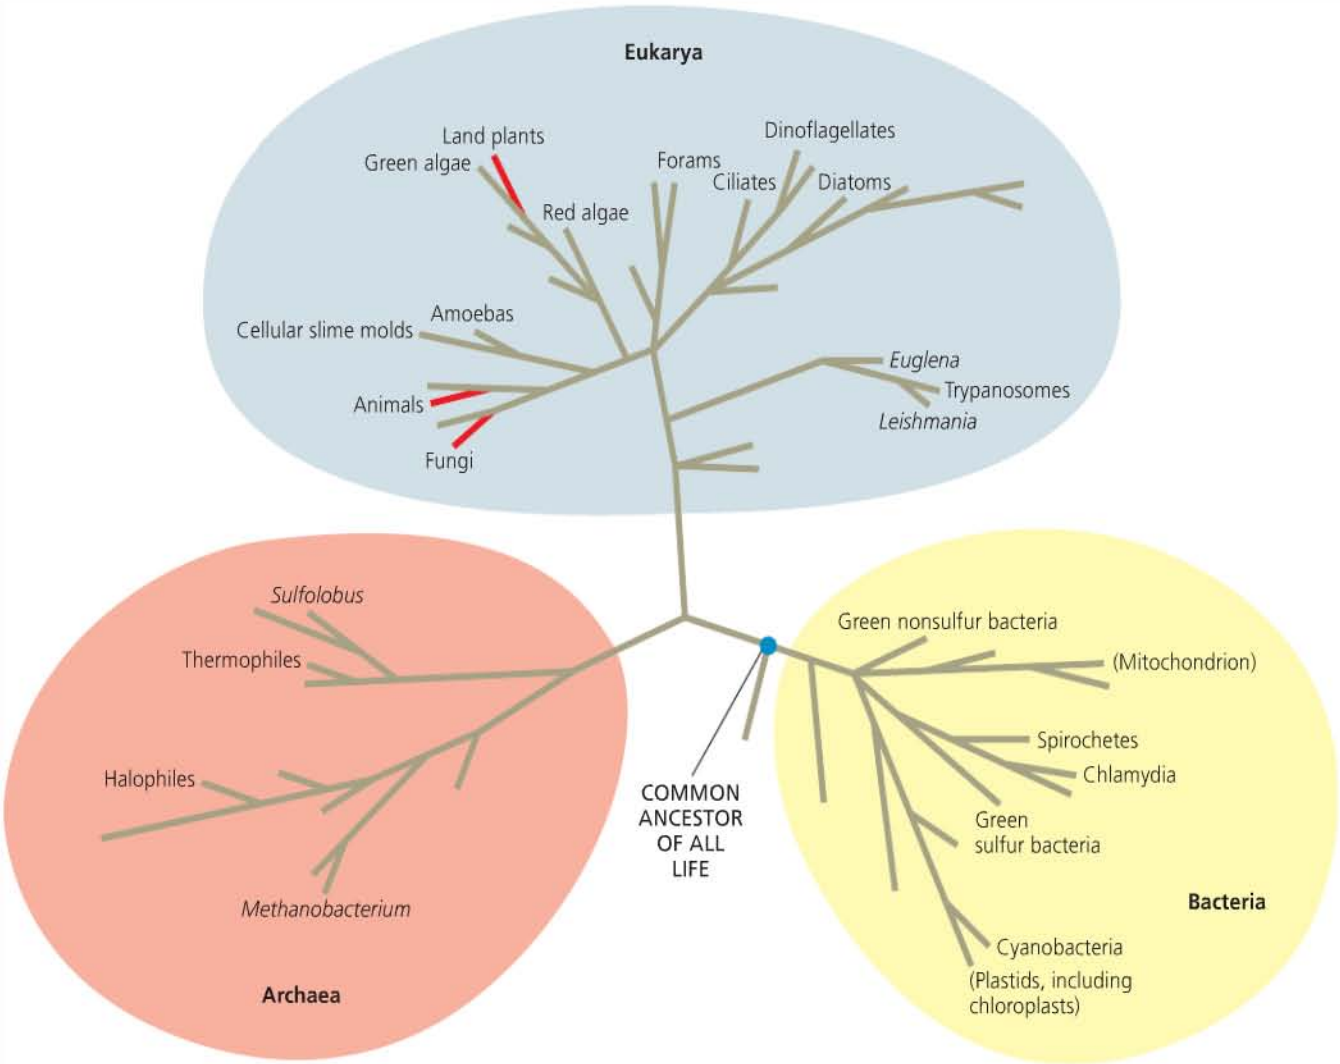
CONCEPT CHECK 26.5

1. What is a molecular clock? What assumption underlies the use of a molecular clock?
2. Explain how numerous base changes could occur in DNA, yet have no effect on an organism's fitness.
3. **WHAT IF?** Suppose a molecular clock dates the divergence of two taxa at 80 million years ago, but new fossil evidence shows that the taxa diverged at least 120 million years ago. Explain how this could happen.

For suggested answers, see Appendix A.

CONCEPT 26.6
New information continues to revise our understanding of the tree of life

The discovery that the scaly-foot in Figure 26.1 evolved from a different lineage of legless lizards than did snakes is one example of how systematics is used to reconstruct the evolutionary relationships of life's diverse forms. In recent decades, we have gained insight into even the very deepest branches of the tree of life through molecular systematics.



From Two Kingdoms to Three Domains

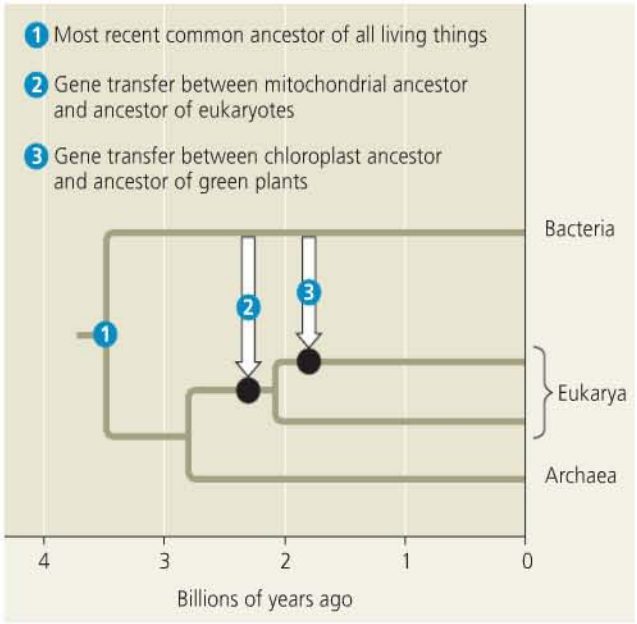
Early taxonomists classified all known species into two kingdoms: plants and animals. Even with the discovery of the diverse microbial world, the two-kingdom system persisted: Noting that bacteria had a rigid cell wall, taxonomists placed them in the plant kingdom. Eukaryotic unicellular organisms with chloroplasts were also considered plants. Fungi, too, were classified as plants, partly because most fungi, like most plants, are unable to move about, and despite the fact that fungi are not photosynthetic and have little in common structurally with plants. In the two-kingdom system, unicellular organisms that move and ingest food—protozoans—were classified as animals. Microorganisms such as *Euglena* that move and are photosynthetic were claimed by both botanists and zoologists and showed up in both kingdoms.

Taxonomic schemes with more than two kingdoms did not gain broad acceptance until the late 1960s, when many biologists recognized five kingdoms: Monera (prokaryotes), Protista (a diverse kingdom consisting mostly of unicellular organisms), Plantae, Fungi, and Animalia. This system highlighted the two fundamentally different types of cells, prokaryotic and eukaryotic, and set the prokaryotes apart from all eukaryotes by placing them in their own kingdom, Monera.

However, shortly after the widespread adoption of the five-kingdom approach, phylogenies based on genetic data began to reveal a fundamental problem with this system: Some prokaryotes differed as much from each other as they did from eukaryotes. Such difficulties have led biologists to adopt a three-domain system. The three domains—Bacteria, Archaea, and Eukarya—are a taxonomic level higher than the kingdom level. The validity of these domains has now been confirmed by many studies, including an analysis of nearly 100 of the many hundreds of completely sequenced genomes.

The domain Bacteria contains most of the currently known prokaryotes, including the bacteria closely related to chloroplasts and mitochondria. The second domain, Archaea, consists of a diverse group of prokaryotic organisms that inhabit a wide variety of environments. Some archaea can use hydrogen as an energy source, and others were the chief source of the

▲ **Figure 26.21 The three domains of life.** Based on rRNA gene sequences, all of life can be grouped into three domains. Branch lengths are proportional to the amount of genetic change in each lineage. (To simplify the figure, only some branches are labeled.) In this diagram, the lineages within Eukarya that are dominated by multicellular organisms (plants, fungi, and animals) are shown in red. All other lineages consist solely or primarily of single-celled organisms.

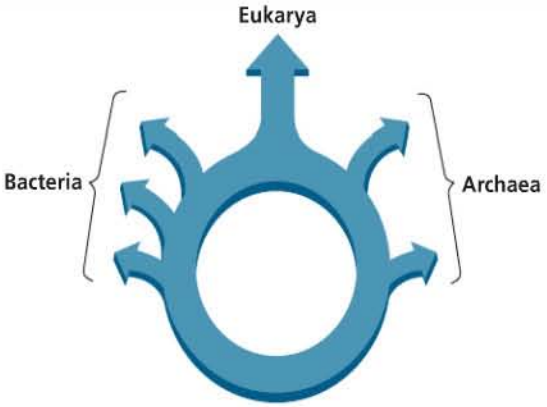


? *Based on this diagram, which domain was the first to diverge? Which is the sister domain to Eukarya?*

natural gas deposits that are found throughout Earth's crust. As you will read in Chapter 27, bacteria differ from archaea in many structural, biochemical, and physiological characteristics. The third domain, Eukarya, consists of all the organisms that have cells containing true nuclei. This domain includes many groups of single-celled organisms (see Chapter 28) as well as multicellular plants (Chapters 29 and 30), fungi (Chapter 31), and animals (Chapters 32–34). **Figure 26.21** represents one possible phylogenetic tree for the three domains and the many lineages they encompass.

The three-domain system highlights the fact that much of the history of life has been about single-celled organisms. The two prokaryotic domains consist entirely of single-celled organisms, and even in Eukarya, only the branches shown in red (plants, fungi, and animals) are dominated by multicellular organisms. Of the five kingdoms previously recognized by taxonomists, most biologists continue to recognize Plantae, Fungi, and Animalia, but not Monera and Protista. The kingdom Monera is obsolete because it would have members in two different domains. As you'll read in Chapter 28, the kingdom Protista has also crumbled because it is polyphyletic—it includes members that are more closely related to plants, fungi, or animals than to other protists.

A Simple Tree of All Life



The evolutionary relationships shown in Figure 26.21 can be summarized in a simpler tree **(Figure 26.22)**. In this tree, the first major split in the history of life occurred when the bacteria diverged from other organisms. If this tree is correct, eukaryotes and archaea are more closely related to each other than either is to bacteria.

▲ **Figure 26.22 The role of horizontal gene transfer in the history of life.** This tree shows two major episodes of horizontal gene transfer, the dates of which are uncertain. It is known that many more such events occurred.

This reconstruction of the tree of life is based largely on sequence comparisons of rRNA genes, which code for the RNA parts of ribosomes. Because ribosomes are fundamental to the workings of the cell, rRNA genes have evolved so slowly that homologies between distantly related organisms can still be detected—making these genes very useful for determining evolutionary relationships among deep branches in the history of life. However, other genes reveal a different set of relationships. For example, researchers have found that many of the genes that influence metabolism in yeast (a single-celled eukaryote) are more similar to genes in the domain Bacteria than they are to genes in the domain Archaea—a finding that suggests that the eukaryotes may share a more recent common ancestor with bacteria than with archaea.

Comparisons of complete genomes from the three domains show that there have been substantial movements of genes between organisms in the different domains (see Figure 26.22). These took place through **horizontal gene transfer**, a process in which genes are transferred from one genome to another through mechanisms such as exchange of transposable elements and plasmids, viral infection (see Chapter 19), and perhaps fusions of organisms. Some biologists hypothesize that the first eukaryote may have arisen through a fusion between an ancestral bacterium and an ancestral archaean. Because phylogenetic trees are based on the assumption that genes are passed vertically from one generation to the next, the occurrence of such horizontal transfer events helps to explain why universal trees built using different genes can give inconsistent results.

▲ **Figure 26.23 A ring of life.** In this hypothesis, the earliest organisms form a "ring of life" through horizontal gene transfer. Three great domains (Bacteria, Eukarya, and Archaea) eventually emerged from the ring and gave rise to the tremendous diversity of life we observe today.

Is the Tree of Life Really a Ring?

Some scientists have argued that horizontal gene transfers were so common that the early history of life should be represented as a tangled network of connected branches—not a simple, dichotomously branching tree like that in Figure 26.22. Others have suggested that relationships among early organisms are best represented by a ring, not a tree **(Figure 26.23)**. In an analysis based on hundreds of genes, these researchers hypothesized that eukaryotes arose as an endosymbiosis between an early bacterium and an early archaean. If correct, eukaryotes are simultaneously most closely related to bacteria *and* archaea—an evolutionary relationship that cannot be depicted in a tree of life, but can be depicted in a *ring* of life.

Although scientists continue to debate whether early steps in the history of life are best represented as a tree, a ring, or a tangled web, in recent decades there have been many exciting discoveries about evolutionary events that occurred later in time. We'll explore such discoveries in the rest of this unit's chapters, beginning with Earth's earliest inhabitants, the prokaryotes.

CONCEPT CHECK 26.6

1. Why is the kingdom Monera no longer considered a valid taxon?
2. Explain why phylogenies based on different genes can yield different branching patterns for the universal tree of life.
3. **WHAT IF?** Draw the three possible dichotomously branching trees showing evolutionary relationships for the domains Bacteria, Archaea, and Eukarya. Two of these trees have been supported by genetic data. Is it likely that the third tree might also receive such support? Explain your answer.

For suggested answers, see Appendix A.

Chapter 26 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 26.1

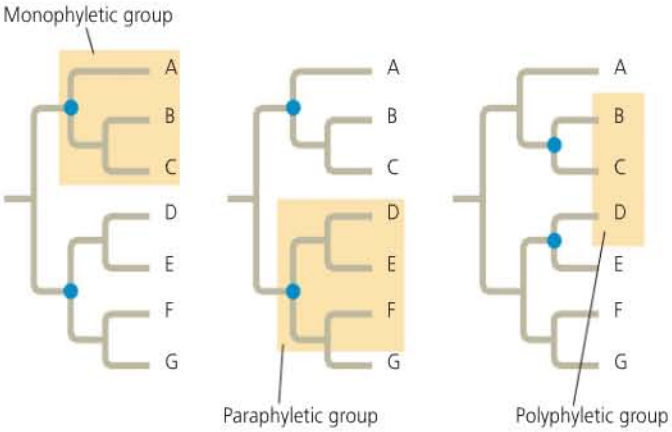
Phylogenies show evolutionary relationships (pp. 537–540)

- **Binomial Nomenclature** Linnaeus's system gives organisms two-part names: a genus plus a specific epithet.
- **Hierarchical Classification** Linnaeus introduced a formal system for grouping species in increasingly broad categories: related genera are placed in the same family, families into orders, orders into classes, classes into phyla, phyla into kingdoms, and (more recently) kingdoms into domains.
- **Linking Classification and Phylogeny** Systematists depict evolutionary relationships as branching phylogenetic trees. Some systematists propose that classification be based entirely on evolutionary relationships.

- **What We Can and Cannot Learn from Phylogenetic Trees** Unless branch lengths are proportional to time or genetic change, a phylogenetic tree indicates only patterns of descent.
- **Applying Phylogenies** Much information can be learned about a species from its evolutionary history; hence, phylogenies are useful in a wide range of applications.

MEDIA
Activity Classification Schemes

CONCEPT 26.2



Phylogenies are inferred from morphological and molecular data (pp. 540–542)

- **Morphological and Molecular Homologies** Organisms that share very similar morphologies or DNA sequences are likely to be more closely related than organisms with very different structures and genetic sequences.
- **Sorting Homology from Analogy** Homology (similarity due to shared ancestry) must be sorted from analogy (similarity due to convergent evolution).
- **Evaluating Molecular Homologies** Computer programs are used to align comparable nucleic acid sequences and to distinguish molecular homologies from coincidental matches between taxa that diverged long ago.

CONCEPT 26.3

Shared characters are used to construct phylogenetic trees (pp. 542–548)

- **Cladistics** A clade is a monophyletic grouping that includes an ancestral species and all of its descendants. Clades can be distinguished by their shared derived characters.

- **Phylogenetic Trees with Proportional Branch Lengths** Branch lengths can be drawn proportional to the amount of evolutionary change or time.
- **Maximum Parsimony and Maximum Likelihood** Among phylogenies, the most parsimonious tree is the one that requires the fewest evolutionary changes. The most likely tree is the one based on the most likely pattern of changes.
- **Phylogenetic Trees as Hypotheses** Well-supported phylogenetic hypotheses are consistent with a wide range of data.

MEDIA
Investigation How Is Phylogeny Determined by Comparing Proteins?

CONCEPT 26.4

An organism's evolutionary history is documented in its genome (pp. 548–549)

- **Gene Duplications and Gene Families** Orthologous genes are homologous genes found in different species because of speciation. Paralogous genes arise through duplication within a genome and can diverge within a clade, often adding new functions.
- **Genome Evolution** Distantly related species often have orthologous genes. The small variation in gene number in organisms of varying complexity suggests that genes are versatile and may have multiple functions.

CONCEPT 26.5

Molecular clocks help track evolutionary time (pp. 549–551)

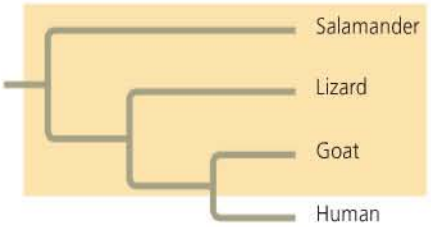
- **Molecular Clocks** The base sequences of some regions of DNA change at a rate consistent enough to allow dating of episodes in past evolution. Other genes change in a less predictable way.
- **Applying a Molecular Clock: The Origin of HIV** A molecular clock analysis suggests that the most common strain of HIV jumped from primates to humans in the 1930s.

CONCEPT 26.6

New information continues to revise our understanding of the tree of life (pp. 551–553)

- **From Two Kingdoms to Three Domains** Past classification systems have given way to the current view of the tree of life, which consists of three great domains: Bacteria, Archaea, and Eukarya.
- **A Simple Tree of All Life** Phylogenies based on rRNA genes suggest that eukaryotes are most closely related to archaea, while data from other genes suggest a closer relationship to bacteria.
- **Is the Tree of Life Really a Ring?** Genetic analyses suggest that the earliest organisms may have formed a "ring of life" in which eukaryotes are equally closely related to bacteria and to archaea.

TESTING YOUR KNOWLEDGE



SELF-QUIZ

1. In Figure 26.4, which similarly inclusive taxon descended from the same common ancestor as Canidae?
   a. Felidae
   b. Mustelidae
   c. Carnivora
   d. *Canis*
   e. *Lutra*

2. Three living species X, Y, and Z share a common ancestor T, as do extinct species U and V. A grouping that includes species T, X, Y, and Z makes up
   a. a valid taxon.
   b. a monophyletic clade.
   c. an ingroup, with species U as the outgroup.
   d. a paraphyletic group.
   e. a polyphyletic group.

3. In a comparison of birds and mammals, having four appendages is
   a. a shared ancestral character.
   b. a shared derived character.
   c. a character useful for distinguishing birds from mammals.
   d. an example of analogy rather than homology.
   e. a character useful for sorting bird species.

4. Based on this tree, which statement is *not* correct?

   a. The lineage leading to salamanders was the first to diverge from the other lineages.
   b. Salamanders are a sister group to the group containing lizards, goats, and humans.
   c. Salamanders are as closely related to goats as to humans.
   d. Lizards are more closely related to salamanders than to humans.
   e. The group highlighted by shading is paraphyletic.

5. If you were using cladistics to build a phylogenetic tree of cats, which of the following would be the best outgroup?
   a. lion
   b. domestic cat
   c. wolf
   d. leopard
   e. tiger

6. The relative lengths of the amphibian and mouse branches in the phylogeny in Figure 26.12 indicate that
   a. amphibians evolved before mice.
   b. mice evolved before amphibians.
   c. the genes of amphibians and mice have only coincidental homoplasies.
   d. the homologous gene has evolved more slowly in mice.
   e. the homologous gene has evolved more rapidly in mice.

7. To apply parsimony to constructing a phylogenetic tree,
   a. choose the tree that assumes all evolutionary changes are equally probable.
   b. choose the tree in which the branch points are based on as many shared derived characters as possible.
   c. base phylogenetic trees only on the fossil record, as this provides the simplest explanation for evolution.
   d. choose the tree that represents the fewest evolutionary changes, either in DNA sequences or morphology.
   e. choose the tree with the fewest branch points.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

8. Darwin suggested looking at a species' close relatives to learn what its ancestors may have been like. How does his suggestion anticipate recent methods, such as phylogenetic bracketing and the use of outgroups in cladistic analysis?

Biological Inquiry: A Workbook of Investigative Cases Explore the use of outgroups and other aspects of cladistic analysis in "Tree Thinking."

SCIENTIFIC INQUIRY

9. **DRAW IT** (a) Draw a phylogenetic tree based on the first five characters in the table below. Place hatch marks on the tree to indicate the origin(s) of each of the six characters. (b) Assume that tuna and dolphins are sister species and redraw the phylogenetic tree accordingly, keeping other evolutionary relationships the same as in the first tree. Place hatch marks on the tree to indicate the origin(s) of each of the six characters. (c) How many evolutionary changes are required in each tree? Which tree is most parsimonious?

Character	SPECIES						
	Lancelet (outgroup)	*Lamprey*	*Tuna*	*Salamander*	*Turtle*	*Leopard*	*Dolphin*
Backbone	0	1	1	1	1	1	1
Hinged jaw	0	0	1	1	1	1	1
Four limbs	0	0	0	1	1	1	1*
Amniotic egg	0	0	0	0	1	1	1
Milk	0	0	0	0	0	1	1
Dorsal fin	0	0	1	0	0	0	1

*Although adult dolphins have only two obvious limbs (their flippers), as embryos they have two hind-limb buds, for a total of four limbs.

27 Bacteria and Archaea

▲ **Figure 27.1 Why is this lakebed red?**

KEY CONCEPTS

27.1 Structural and functional adaptations contribute to prokaryotic success

27.2 Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes

27.3 Diverse nutritional and metabolic adaptations have evolved in prokaryotes

27.4 Molecular systematics is illuminating prokaryotic phylogeny

27.5 Prokaryotes play crucial roles in the biosphere

27.6 Prokaryotes have both harmful and beneficial impacts on humans

OVERVIEW

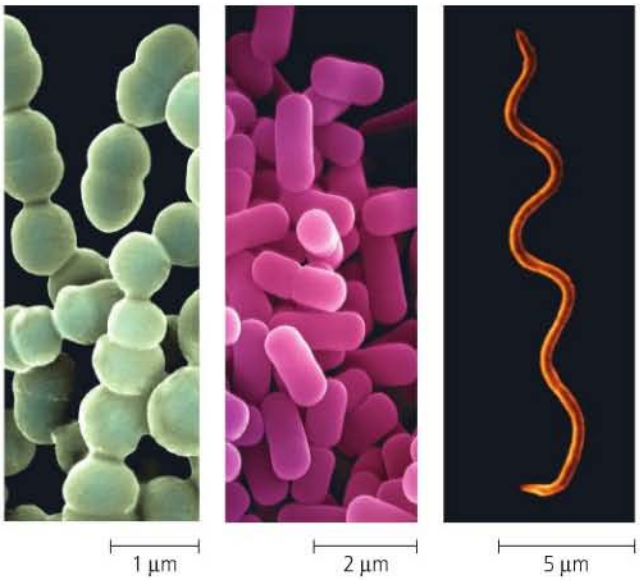
Masters of Adaptation

After a heavy summer rain, California's Owens Lake can contain waters so hot and salty that they would burn and dehydrate your skin on contact. The salt concentration can reach 32%, more than nine times that of seawater. Yet despite these harsh conditions, the briny lakebed's reddish color, shown in **Figure 27.1**, is caused by organisms, not by minerals or other nonliving sources. What organisms can live in such an inhospitable environment, and how do they do it?

The pink color of Owens Lake comes from trillions of cells of *Halobacterium*, a single-celled prokaryote in domain Archaea that is one of the few kinds of organisms living in the lake. This archaean has a red membrane pigment, bacteriorhodopsin, that uses light energy to drive ATP synthesis. *Halobacterium* is among the most salt-tolerant organisms on Earth—it thrives in salinities that dehydrate and kill other cells. This archaean compensates for osmotic water loss by pumping potassium ions (K^+) or other ions into the cell until the ionic concentration inside the cell matches the concentration outside.

Like *Halobacterium*, many other prokaryotes are master adapters. Examples include *Deinococcus radiodurans*, which can survive 3 million rads of radiation (3,000 times the dose fatal to humans), and *Picrophilus oshimae*, which can grow at a pH of 0.03 (acidic enough to dissolve metal). Other prokaryotes live in environments that are too cold or too hot for most other organisms, and some have even been found living in rocks 3.2 km (2 miles) below Earth's surface.

Prokaryotic species are also very well adapted to more "normal" habitats—the lands and waters in which most other species are found. Their ability to adapt to a broad range of habitats helps to explain why prokaryotes are the most abundant organisms on Earth: Their collective biological mass (biomass) is at least ten times that of all eukaryotes, and the number of prokaryotes in a handful of fertile soil is greater than the number of people who have ever lived. In this chapter, we'll examine the adaptations, diversity, ecological impact, and importance to humans of these small but amazing organisms that comprise two of the three domains of life.



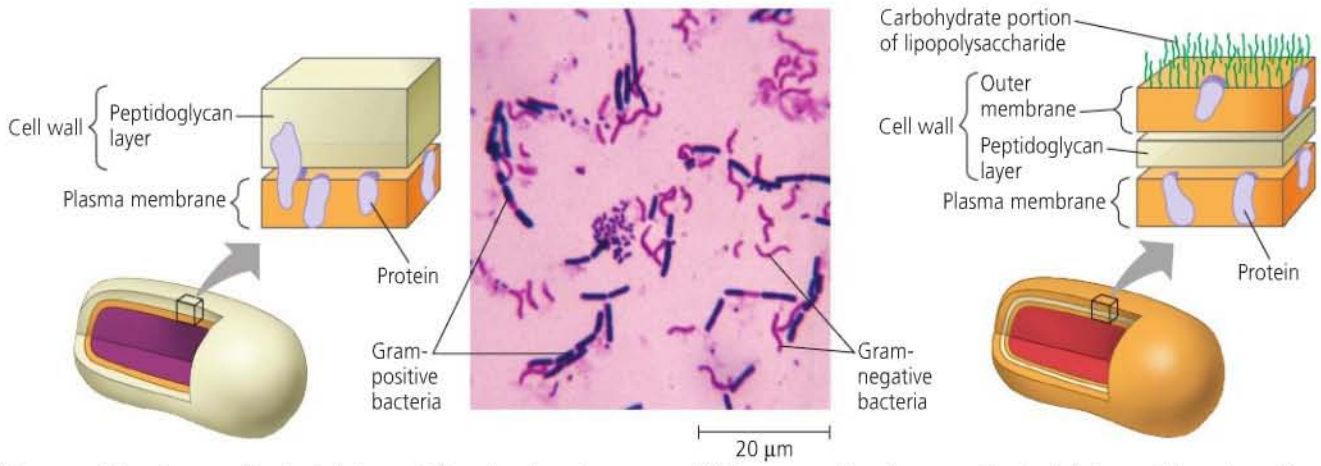
CONCEPT 27.1

Structural and functional adaptations contribute to prokaryotic success

As we discussed in Chapter 25, the first organisms to inhabit Earth are thought to have been prokaryotes. Throughout their long evolutionary history, prokaryotic populations have been (and continue to be) subjected to natural selection under many different environmental conditions. This process ultimately has resulted in the great diversity of adaptations found among prokaryotes today.

In this and the following sections, we'll survey the biology of prokaryotes. Most prokaryotes are unicellular, although some species aggregate temporarily or permanently in colonies.

Prokaryotic cells typically have diameters in the range of 0.5–5 μm, much smaller than the 10–100 μm diameter of many eukaryotic cells. (One notable exception is the giant prokaryote *Thiomargarita namibiensis*, which is about 750 μm in diameter—just visible to the unaided eye.) Prokaryotic cells have a variety of shapes, the three most common of which are spheres (cocci), rods (bacilli), and spirals **(Figure 27.2)**. Finally, although they are unicellular and small, prokaryotes are well organized, achieving all of an organism's life functions within a single cell.

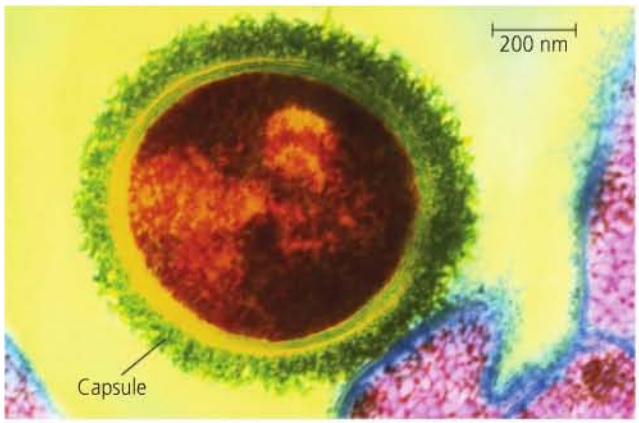


▲ **Figure 27.2 The most common shapes of prokaryotes.** **(a)** Cocci (singular, *coccus*) are spherical prokaryotes. They occur singly, in pairs (diplococci), in chains of many cells (streptococci, shown here), and in clusters resembling bunches of grapes (staphylococci). **(b)** Bacilli (singular, *bacillus*) are rod-shaped prokaryotes. They are usually solitary, but in some forms the rods are arranged in chains (streptobacilli). **(c)** Spiral prokaryotes include spirilla, which range from comma-like shapes to long coils, and spirochetes (shown here), which are corkscrew-shaped (colorized SEMs).

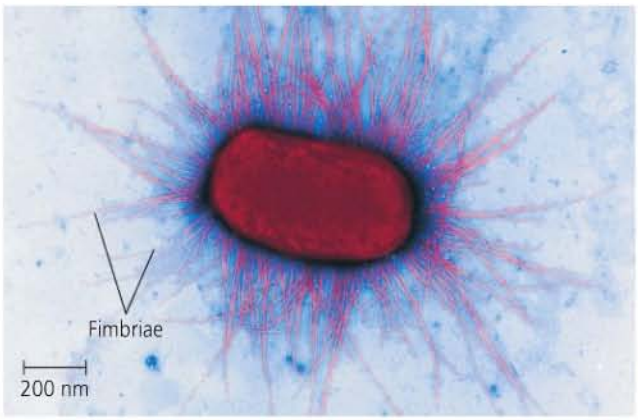
Cell-Surface Structures

A key feature of nearly all prokaryotic cells is the cell wall, which maintains cell shape, provides physical protection, and prevents the cell from bursting in a hypotonic environment (see Chapter 7). In a hypertonic environment, most prokaryotes lose water and shrink away from their wall (plasmolyze), like other walled cells. Severe water loss inhibits cell reproduction. Salt thus can be used to preserve foods because it causes prokaryotes to lose water.

The cell walls of prokaryotes differ in molecular composition and construction from those of eukaryotes. As you read in Chapter 5, eukaryotic cell walls are usually made of cellulose or chitin. In contrast, most bacterial cell walls contain **peptidoglycan**, a network of modified-sugar polymers cross-linked by short polypeptides. This molecular fabric encloses the entire bacterium and anchors other molecules that extend from its surface. Archaeal cell walls contain a variety of polysaccharides and proteins but lack peptidoglycan.



Using a technique called the **Gram stain**, developed by the nineteenth-century Danish physician Hans Christian Gram, scientists can classify many bacterial species into two groups based on differences in cell wall composition. **Gram-positive** bacteria have simpler walls with a relatively large amount of peptidoglycan **(Figure 27.3a)**. **Gram-negative** bacteria have less peptidoglycan and are structurally more complex, with an outer membrane that contains lipopolysaccharides (carbohydrates bonded to lipids) **(Figure 27.3b)**.



(a) Gram-positive. Gram-positive bacteria have a thick cell wall made of peptidoglycan that traps the crystal violet in the cytoplasm. The alcohol rinse does not remove the crystal violet, which masks the added red safranin dye.

(b) Gram-negative. Gram-negative bacteria have a thinner layer of peptidoglycan, and it is located in a layer between the plasma membrane and an outer membrane. The crystal violet is easily rinsed from the cytoplasm, and the cell appears pink or red.

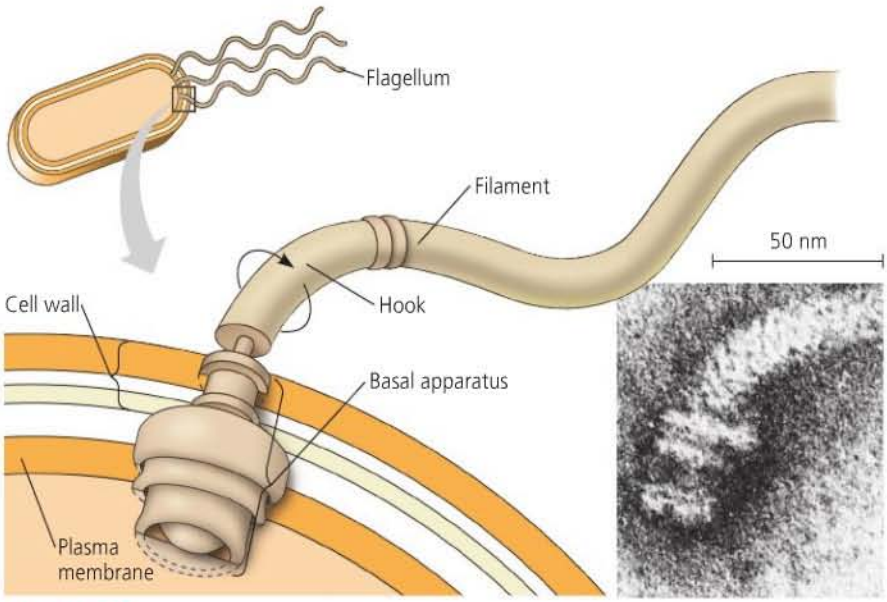
▲ **Figure 27.3 Gram staining.** Samples are first stained with crystal violet dye and iodine, then rinsed in alcohol, and finally stained with a red dye such as safranin. The structure of a bacterium's cell wall determines the staining response (LM).

▲ **Figure 27.4 Capsule.** The polysaccharide capsule around this *Streptococcus* bacterium enables the prokaryote to attach to cells in the respiratory tract—in this colorized TEM, a tonsil cell.

▲ **Figure 27.5 Fimbriae.** These numerous appendages enable some prokaryotes to attach to surfaces or to other prokaryotes (colorized TEM).

Gram staining is a valuable tool in medicine for quickly determining if a patient's infection is due to gram-negative or to gram-positive bacteria. This information has treatment implications. The lipid portions of the lipopolysaccharides in the walls of many gram-negative bacteria are toxic, causing fever or shock. Furthermore, the outer membrane of a gram-negative bacterium helps protect it from the body's defenses. Gram-negative bacteria also tend to be more resistant than gram-positive species to antibiotics because the outer membrane impedes entry of the drugs. However, certain gram-positive species (for example, *Mycobacterium tuberculosis*, which causes tuberculosis) have virulent strains that are resistant to one or more antibiotics.

The effectiveness of certain antibiotics, such as penicillin, derives from their inhibition of the peptidoglycan cross-linking. The resulting cell wall may not be functional, particularly in gram-positive bacteria. Such drugs destroy many species of pathogenic bacteria without adversely affecting human cells, which do not contain peptidoglycan.



The cell wall of many prokaryotes is covered by a **capsule**, a sticky layer of polysaccharide or protein **(Figure 27.4)**. The capsule enables prokaryotes to adhere to their substrate or to other individuals in a colony. Some capsules protect against dehydration, and some shield pathogenic prokaryotes from attacks by their host's immune system.

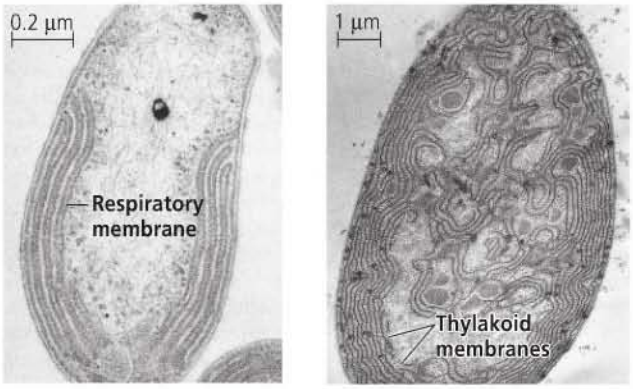
Some prokaryotes stick to their substrate or to one another by means of hairlike protein appendages called **fimbriae** (singular, *fimbria*) **(Figure 27.5)**; thus, fimbriae are also known as *attachment pili*. The bacterium that causes gonorrhea, *Neisseria gonorrhoeae*, uses fimbriae to fasten itself to the mucous membranes of its host. Fimbriae are usually shorter and more numerous than **sex pili** (singular, *sex pilus*), appendages that pull two cells together prior to DNA transfer from one cell to the other.

Motility

About half of all prokaryotes are capable of directional movement. Some species can move at velocities exceeding 50 μm/sec—up to 50 times their body length per second. For perspective, consider that a person 1.7 m tall moving that fast would be running 306 km (190 miles) per hour!

Of the various structures that enable prokaryotes to move, the most common are flagella **(Figure 27.6)**. Flagella (singular, *flagellum*) may be scattered over the entire surface of the cell or concentrated at one or both ends. Prokaryotic flagella are one-tenth the width of eukaryotic flagella and are not covered by an

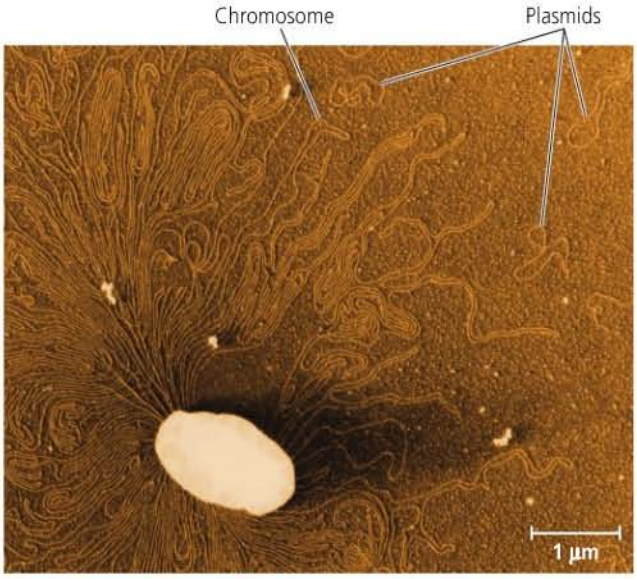
▲ **Figure 27.6 Prokaryotic flagellum.** The motor of the prokaryotic flagellum is the basal apparatus, a system of rings embedded in the cell wall and plasma membrane (TEM). ATP-driven pumps transport protons out of the cell, and the diffusion of protons back into the cell directly powers the basal apparatus, which turns a curved hook. The hook is attached to a filament composed of chains of flagellin, a globular protein. (This diagram shows flagellar structures characteristic of gram-negative bacteria.)



extension of the plasma membrane (see Figures 6.24 and 6.25 to review eukaryotic flagella). The flagella of prokaryotes are also very different from those of eukaryotes in their molecular composition and their mechanism of propulsion.

In a relatively uniform environment, flagellated prokaryotes may move randomly. In a heterogeneous environment, however, many prokaryotes exhibit **taxis**, movement toward or away from a stimulus (from the Greek *taxis,* to arrange). For example, prokaryotes that exhibit *chemotaxis* change their movement pattern in response to chemicals. They may move *toward* nutrients or oxygen (positive chemotaxis) or *away from* a toxic substance (negative chemotaxis). Consider movement patterns in *Escherichia coli*, the well-studied bacterial species that has been called the "lab rat of molecular biology." In 2003, scientists at Princeton University and the Institut Curie in Paris demonstrated that solitary *E. coli* cells exhibit positive chemotaxis toward other members of their species, enabling the formation of colonies.

Internal and Genomic Organization



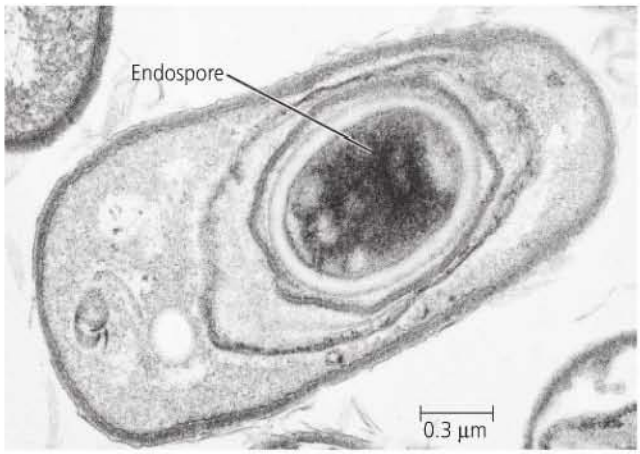
The cells of prokaryotes are simpler than those of eukaryotes, in both their internal structure and their genomic organization (see Figure 6.6). Prokaryotic cells lack the complex compartmentalization found in eukaryotic cells. However, some prokaryotic cells do have specialized membranes that perform metabolic functions **(Figure 27.7)**. These membranes are usually infoldings of the plasma membrane.

The genome of a prokaryote is structurally different from a eukaryotic genome and in most cases has considerably less DNA. In the majority of prokaryotes, the genome consists of a circular chromosome whose structure includes fewer proteins than found in the linear chromosomes of eukaryotes **(Figure 27.8)**. Also unlike eukaryotes, prokaryotes lack a membrane-bounded nucleus; their chromosome is located in the **nucleoid**, a region of cytoplasm that appears lighter than the surrounding cytoplasm

(a) Aerobic prokaryote (b) Photosynthetic prokaryote

▲ **Figure 27.7 Specialized membranes of prokaryotes.** **(a)** Infoldings of the plasma membrane, reminiscent of the cristae of mitochondria, function in cellular respiration in some aerobic prokaryotes (TEM). **(b)** Photosynthetic prokaryotes called cyanobacteria have thylakoid membranes, much like those in chloroplasts (TEM).

▲ **Figure 27.8 A prokaryotic chromosome and plasmids.** The thin, tangled loops surrounding this ruptured *E. coli* cell are parts of the cell's large, circular chromosome (colorized TEM). Three of the cell's plasmids, the much smaller rings of DNA, are also shown.



in electron micrographs. In addition to its single chromosome, a typical prokaryotic cell may also have much smaller rings of separately replicating DNA called **plasmids** (see Figure 27.8), most carrying only a few genes.

As explained in Chapters 16 and 17, DNA replication, transcription, and translation are fundamentally similar processes in prokaryotes and eukaryotes, although there are some differences. For example, prokaryotic ribosomes are slightly smaller than eukaryotic ribosomes and differ in their protein and RNA content. These differences allow certain antibiotics, such as erythromycin and tetracycline, to bind to ribosomes and block protein synthesis in prokaryotes but not in eukaryotes. As a result, we can use these antibiotics to kill bacteria without harming ourselves.

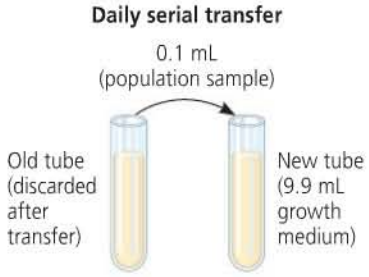
Reproduction and Adaptation

Prokaryotes are highly successful in part because of their potential to reproduce quickly in a favorable environment. By binary fission (see Figure 12.11), a single prokaryotic cell divides into 2 cells, which then divide into 4, 8, 16, and so on. Under optimal conditions, many prokaryotes can divide every 1–3 hours; some species can produce a new generation in only 20 minutes. If reproduction continued unchecked at this rate, a single prokaryotic cell could give rise to a colony outweighing Earth in only three days!

In reality, of course, prokaryotic reproduction is limited. The cells eventually exhaust their nutrient supply, poison themselves with metabolic wastes, face competition from other microorganisms, or are consumed by other organisms. Thus, *E. coli*, which can divide as often as every 20 minutes under ideal conditions, more typically divides once every 12 to 24 hours in a

▲ **Figure 27.9 An endospore.** *Bacillus anthracis*, the bacterium that causes the disease anthrax, produces endospores (TEM). An endospore's thick, protective coat helps it survive in the soil for years.

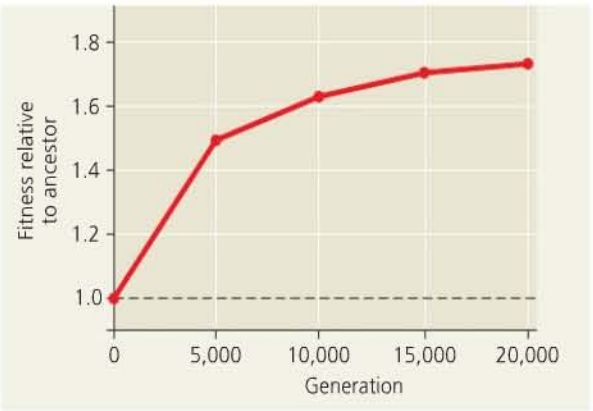
human intestine. But whether cell division occurs every 20 minutes or every few days, reproduction in prokaryotes draws attention to three key features of their biology: *They are small, they reproduce by binary fission, and they have short generation times.* As a result, prokaryotic populations can consist of many trillions of individuals—far more than populations of multicellular eukaryotes, such as plants and animals.



The ability of some prokaryotes to withstand harsh conditions also contributes to their success. Some, like *Halobacterium*, have biochemical adaptations; others have structural adaptations. Certain bacteria, for example, develop resistant cells called **endospores** when an essential nutrient is lacking **(Figure 27.9)**. The original cell produces a copy of its chromosome and surrounds it with a tough wall, forming the endospore. Water is removed from the endospore, and its metabolism halts. The rest of the original cell then disintegrates, leaving the endospore behind. Most endospores are so durable that they can survive in boiling water; killing them requires heating lab equipment to 121°C under high pressure. In less hostile environments, endospores can remain dormant but viable for centuries, able to rehydrate and resume metabolism when their environment improves.

Finally, in part because of their short generation times, prokaryotic populations can evolve substantially in short periods of time. For example, in a remarkable study that spanned 20,000 generations (roughly eight years) of evolution, Vaughn Cooper and Richard Lenski, of Michigan State University, documented adaptive evolution in bacterial populations **(Figure 27.10)**. The ability of prokaryotes to adapt rapidly to new conditions highlights the fact that although the structure of their cells is simpler than that of eukaryotic cells, prokaryotes are not "primitive" or "inferior" in an evolutionary sense. They are, in fact, highly evolved: For over 3.5 billion years, prokaryotic populations have responded successfully to many different types of environmental challenges. As we will see, one reason for this is that their populations harbor high levels of genetic diversity on which selection can act.

▼ Figure 27.10 Inquiry



Can prokaryotes evolve rapidly in response to environmental change?

EXPERIMENT Vaughn Cooper and Richard Lenski, of Michigan State University, tested the ability of *E. coli* populations to adapt to a new environment. They established 12 populations, each founded by a single cell from an asexual strain of *E. coli*, and followed these populations for 20,000 generations (3,000 days). To maintain a continual supply of resources, each day the researchers performed a *serial transfer*: They transferred 0.1 mL of each population to a new tube containing 9.9 mL of fresh growth medium. The growth medium used throughout the experiment represented a challenging environment that contained only low levels of glucose and other resources needed for growth.

Samples were periodically removed from the 12 populations and grown in competition with the common ancestor in the experimental (low-glucose) environment.

RESULTS The fitness of the experimental populations, as measured by the rate at which each population grew, increased rapidly for the first 5,000 generations (two years) and more slowly for the next 15,000 generations. The graph below shows the averages for the 12 populations.

CONCLUSION Asexual populations of *E. coli* continued to accumulate beneficial mutations for 20,000 generations, allowing rapid evolution of improved performance in their new environment.

SOURCE V. S. Cooper and R. E. Lenski, The population genetics of ecological specialization in evolving *Escherichia coli* populations, *Nature* 407:736–739 (2000).

WHAT IF? Suggest possible functions of the genes whose sequence or expression was altered as the experimental populations evolved in the low-glucose environment.

CONCEPT CHECK 27.1

1. Identify and explain at least two adaptations that enable prokaryotes to survive in environments too harsh for other organisms.
2. Contrast the cellular and genomic organization of prokaryotes and eukaryotes.
3. **WHAT IF?** Researchers discover bacterial endospores in silt at the bottom of a lake that has been contaminated with an industrial pollutant for 50 years. This silt was deposited in annual layers; thus, the age of an endospore can be estimated from the layer in which it is found. Predict how 40- and 150-year-old endospores each would grow if placed in flasks containing growth medium along with the pollutant.

For suggested answers, see Appendix A.

CONCEPT 27.2

Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes

As we discussed in Unit Four, genetic variation is a prerequisite for natural selection to occur in a population. The fact that prokaryotes exhibit such a range of adaptations suggests that their populations must have considerable genetic variation—and they do. For example, a ribosomal RNA gene differs more between two strains of *E. coli* than it does between a human and a platypus. In this section, we'll examine three factors that give rise to high levels of genetic diversity in prokaryotes: rapid reproduction, mutation, and genetic recombination.

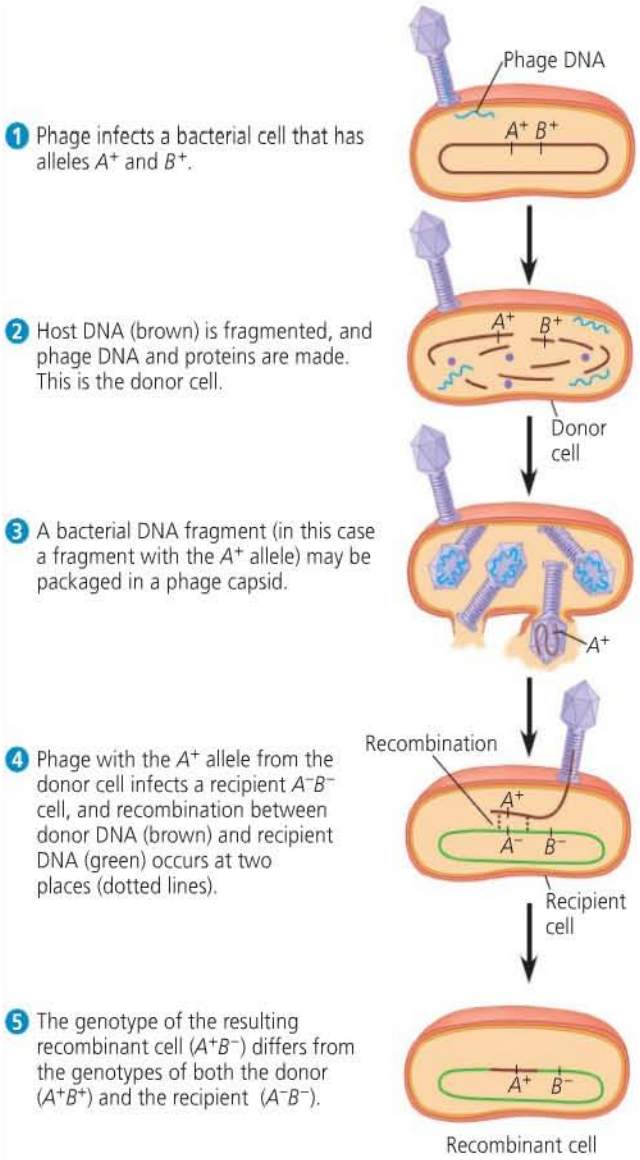
Rapid Reproduction and Mutation

In sexually reproducing species, the generation of a novel allele by a new mutation is rare at any particular gene. Instead, most of the genetic variation in sexual populations results from the way existing alleles are arranged in new combinations during meiosis and fertilization (see Chapter 13). Prokaryotes do not reproduce sexually, so at first glance their extensive genetic variation may seem puzzling. A closer look, however, reveals that prokaryotic populations may have large amounts of genetic variation as a result of rapid reproduction and mutation.

Consider a prokaryote reproducing by binary fission. After repeated rounds of division, most of the offspring cells are genetically identical to the original parent cell. However, owing to insertions, deletions, and base-pair substitutions in their DNA, some of the offspring cells may differ genetically. The probability of a spontaneous mutation occurring in a given *E. coli* gene averages only about one in 10 million (1×10^{-7}) per cell division. But among the 2×10^{10} new *E. coli* cells that arise each day in a person's intestine, there will be approximately $(2 \times 10^{10}) \times (1 \times 10^{-7}) = 2{,}000$ bacteria that have a mutation in that gene. The total number of mutations when all 4,300 *E. coli* genes are considered is about $4{,}300 \times 2{,}000 = 9$ million per day per human host.

The important point is that new mutations, though individually rare, can greatly increase genetic diversity in species like *E. coli* that have short generation times and large population sizes. This diversity, in turn, can lead to rapid evolution: Individuals that are genetically better equipped for their local environment tend to survive and reproduce more prolifically than less fit individuals.

Genetic Recombination



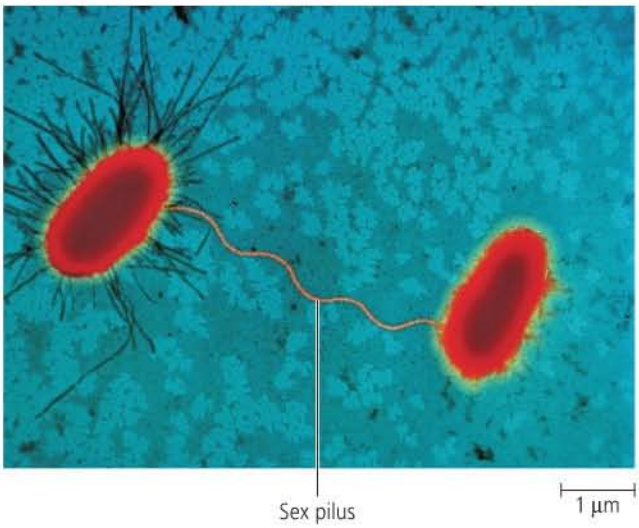
Although new mutations are a major source of variation in prokaryotic populations, additional diversity arises from genetic recombination, the combining of DNA from two sources. In eukaryotes, the sexual processes of meiosis and fertilization combine DNA from two individuals in a single zygote. But meiosis and fertilization do not occur in prokaryotes. Instead, three other processes—transformation, transduction, and conjugation—can bring together prokaryotic DNA from different individuals.

Transformation and Transduction

In **transformation**, the genotype and possibly phenotype of a prokaryotic cell are altered by the uptake of foreign DNA from its surroundings. For example, bacteria from a harmless strain of *Streptococcus pneumoniae* can be transformed to pneumonia-causing cells if they are placed into a medium containing dead, broken-open cells of the pathogenic strain (see Figure 16.2). This transformation occurs when a live nonpathogenic cell takes up a piece of DNA carrying the allele for pathogenicity. The foreign allele is then incorporated into the cell's chromosome, replacing the existing nonpathogenic allele—an exchange of homologous DNA segments. The cell is now a recombinant: Its chromosome contains DNA derived from two different cells.

For many years after transformation was discovered in laboratory cultures, most biologists thought the process to be too rare and haphazard to play an important role in natural bacterial populations. But researchers have since learned that many bacteria have cell-surface proteins that recognize DNA from closely related species and transport it into the cell. Once inside the cell, the foreign DNA can be incorporated into the genome by homologous DNA exchange.

In **transduction**, bacteriophages (also called phages, the viruses that infect bacteria) carry bacterial genes from one host cell to another; transduction is a type of horizontal gene transfer (see Chapter 26). For most phages, transduction results from accidents that occur during the phage reproductive



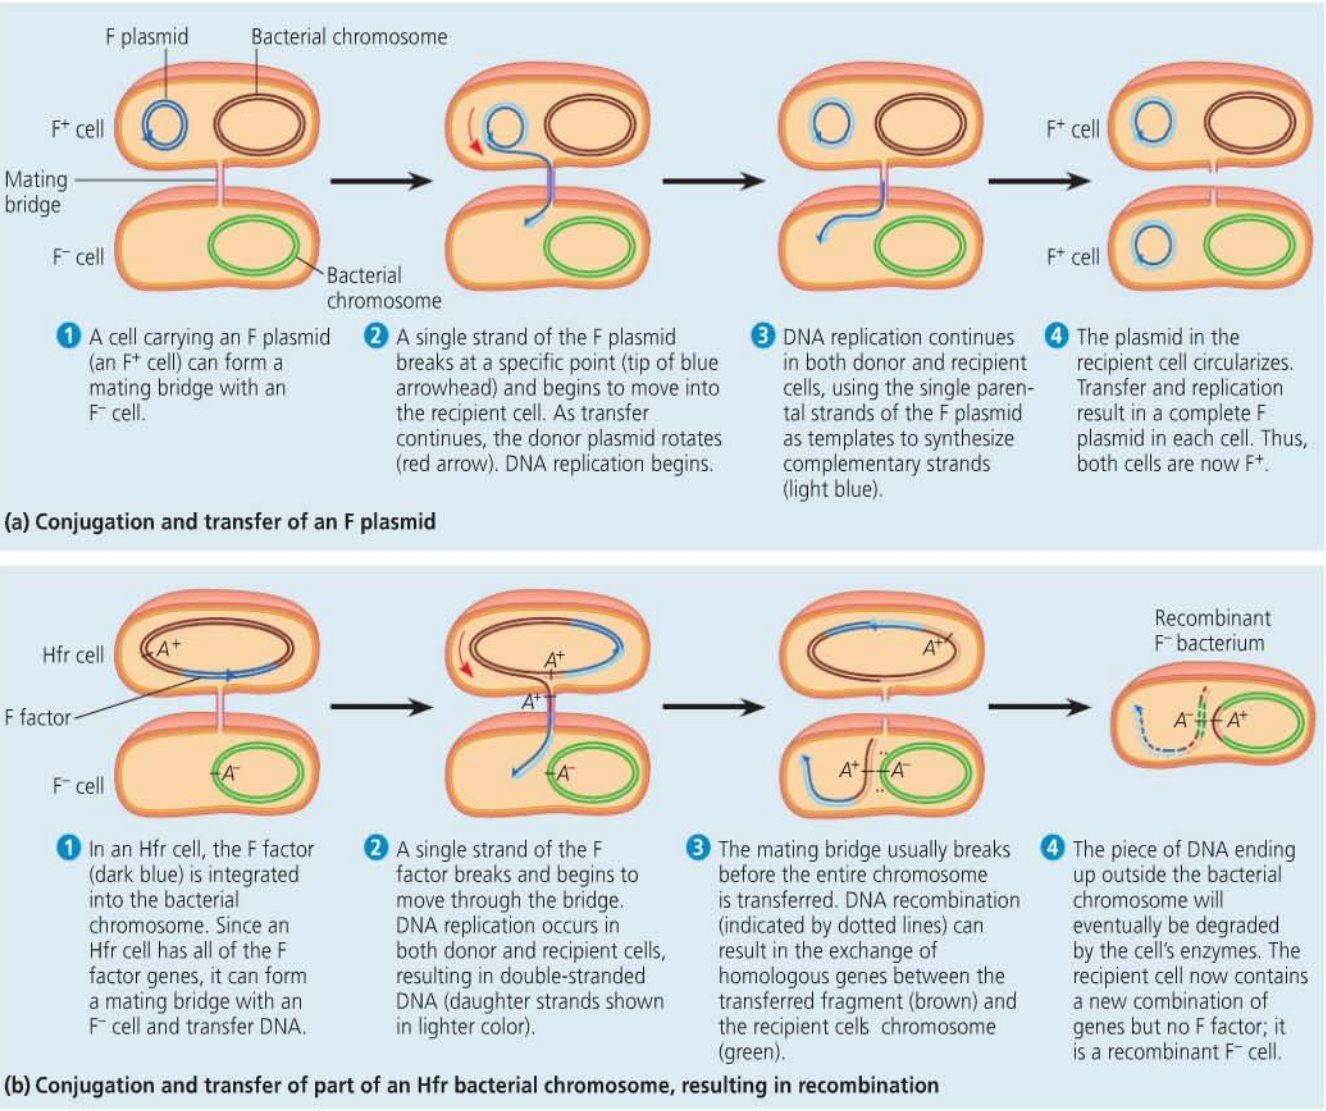
▲ **Figure 27.11 Transduction.** Phages occasionally carry random pieces of the host chromosome containing bacterial genes from one cell (the donor) to another (the recipient). Recombination may cause the transferred DNA to be incorporated into the genome of the recipient.

cycle **(Figure 27.11)**. A virus that carries bacterial DNA may not be able to reproduce because it lacks its own genetic material. However, the virus may be able to attach to another bacterium (a recipient) and inject the piece of bacterial DNA acquired from the first cell (the donor). Some of this DNA may subsequently replace the homologous region of the recipient cell's chromosome by DNA recombination. In such a case, the recipient cell's chromosome becomes a combination of DNA derived from two cells; genetic recombination has occurred.

Conjugation and Plasmids

In a process called **conjugation**, genetic material is transferred between two bacterial cells (of the same or different

▲ **Figure 27.12 Bacterial conjugation.** The *E. coli* donor cell (left) extends a sex pilus that attaches to a recipient cell. The two cells will be drawn close together, allowing a mating bridge to form between them (not shown). Through this bridge, the donor will transfer DNA to the recipient (colorized TEM).



WHAT IF? *In a rapidly changing environment, which population would likely be more successful, one that included individuals capable of conjugation or one that did not? Explain.*

species) that are temporarily joined. The DNA transfer is one-way: One cell donates the DNA, and the other receives it. The donor uses sex pili to attach to the recipient **(Figure 27.12)**. After contacting a recipient cell, each sex pilus retracts, pulling the two cells together, much like a grappling hook. A temporary "mating bridge" then forms between the two cells, providing an avenue for DNA transfer.

In most cases, the ability to form sex pili and donate DNA during conjugation results from the presence of a particular piece of DNA called the **F factor** (F for *f*ertility). The F factor consists of about 25 genes, most required for the production of sex pili. The F factor can exist either as a plasmid or as a segment of DNA within the bacterial chromosome.

The F Factor as a Plasmid The F factor in its plasmid form is called the **F plasmid**. Cells containing the F plasmid, designated F^+ cells, function as DNA donors during conjugation. Cells lacking the F factor, designated F^-, function as DNA recipients during conjugation. The F^+ condition is transferable in the sense that an F^+ cell converts an F^- cell to F^+ if a copy of the entire F^+ plasmid is transferred **(Figure 27.13a)**.

The F Factor in the Chromosome Chromosomal genes can be transferred during conjugation when the donor cell's F factor is integrated into the chromosome. A cell with the F factor built into its chromosome is called an *Hfr cell* (for *h*igh *f*requency of *r*ecombination). Like an F^+ cell, an Hfr cell functions as a donor during conjugation with an F^- cell **(Figure 27.13b)**. When chromosomal DNA from an Hfr cell enters an F^- cell, homologous regions of the Hfr and F^- chromosomes may align, allowing

▲ **Figure 27.13 Conjugation and recombination in *E. coli*.** The DNA replication that accompanies transfer of an F plasmid or part of an Hfr bacterial chromosome is called *rolling circle replication*. This is sometimes referred to as the "toilet paper model" because of the way the single strand rolls off the donor cell DNA and moves into the recipient cell.

segments of their DNA to be exchanged. This results in the production of a recombinant bacterium that has genes derived from two different cells—a new genetic variant on which evolution can act. Though these processes of horizontal gene transfer have so far been studied almost exclusively in bacteria, it is assumed that they are similarly important in archaea.

R Plasmids and Antibiotic Resistance During the 1950s in Japan, physicians started noticing that some hospital patients with bacterial dysentery, which produces severe diarrhea, did not respond to antibiotics that had generally been effective in the past. Apparently, resistance to these antibiotics had evolved in certain strains of *Shigella*, the bacterium that causes the disease.

Eventually, researchers began to identify the specific genes that confer antibiotic resistance in *Shigella* and other pathogenic bacteria. Sometimes, mutation in a chromosomal gene of the pathogen can confer resistance. For example, a mutation in one gene may make it less likely that the pathogen will transport a particular antibiotic into the cell. Mutation in a different gene may alter the intracellular target protein for an antibiotic molecule, reducing its inhibitory effect. In other cases, bacteria have "resistance genes," which code for enzymes that specifically destroy or otherwise hinder the effectiveness of certain antibiotics, such as tetracycline or ampicillin. Such resistance genes are carried by plasmids known as **R plasmids** (R for *r*esistance).

Exposing a bacterial population to a specific antibiotic, whether in a laboratory culture or within a host organism, will kill antibiotic-sensitive bacteria but not those that happen to have R plasmids with genes that counter the antibiotic. The theory of natural selection predicts that under these circumstances, the fraction of the bacterial population carrying genes for antibiotic resistance will increase, and that is exactly what

happens. The medical consequences are also predictable: Resistant strains of pathogens are becoming more common, making the treatment of certain bacterial infections more difficult. The problem is compounded by the fact that many R plasmids, like F plasmids, have genes that encode sex pili and enable plasmid transfer from one bacterial cell to another by conjugation. Making the problem still worse, some R plasmids carry as many as ten genes for resistance to that many antibiotics.

CONCEPT CHECK 27.2

1. What features of prokaryotes make it likely that considerable genetic variation will be added to their populations in each generation?
2. Distinguish between the three mechanisms of transferring DNA from one bacterial cell to another.
3. **WHAT IF?** If a nonpathogenic bacterium were to acquire resistance to antibiotics, could this strain pose a health risk to people? Explain. In general, how does genetic recombination among bacteria affect the spread of resistance genes?

For suggested answers, see Appendix A.

CONCEPT 27.3

Diverse nutritional and metabolic adaptations have evolved in prokaryotes

The mechanisms discussed in the previous section—rapid reproduction, mutation, and genetic recombination—underlie the extensive genetic variation found in prokaryotic populations. This variation is reflected in the nutritional adaptations found in prokaryotes. Like all organisms, prokaryotes can be categorized by their nutrition—how they obtain energy and the carbon used in building the organic molecules that make up cells. Nutritional diversity is greater among prokaryotes than among eukaryotes: Every type of nutrition observed in eukaryotes is represented among prokaryotes, along with some nutritional modes unique to prokaryotes.

Organisms that obtain energy from light are called *phototrophs*, and those that obtain energy from chemicals are called *chemotrophs*. Organisms that need only an inorganic compound such as CO_2 as a carbon source are called *autotrophs*. In contrast, *heterotrophs* require at least one organic nutrient—such as glucose—to make other organic compounds. Combining these possibilities for energy sources and carbon sources results in four major modes of nutrition, described here and summarized in **Table 27.1**.

1. **Photoautotrophs** are photosynthetic organisms that capture light energy and use it to drive the synthesis of organic compounds from CO_2 or other inorganic carbon compounds, such as bicarbonate (HCO_3^-). Cyanobacteria and many other groups of prokaryotes are photoautotrophs, as are plants and algae.
2. **Chemoautotrophs** also need only an inorganic compound such as CO_2 as a carbon source. However, instead of using light as an energy source, they oxidize inorganic substances, such as hydrogen sulfide (H_2S), ammonia (NH_3), or ferrous ions (Fe^{2+}). This mode of nutrition is unique to certain prokaryotes.
3. **Photoheterotrophs** harness energy from light but must obtain carbon in organic form. This mode is unique to certain marine and halophilic (salt-loving) prokaryotes.
4. **Chemoheterotrophs** must consume organic molecules to obtain both energy and carbon. This nutritional mode is widespread among prokaryotes. Fungi, animals, most protists, and even some parasitic plants are also chemoheterotrophs.

The Role of Oxygen in Metabolism

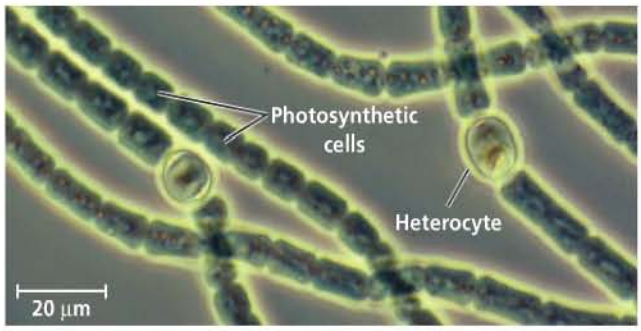
Prokaryotic metabolism also varies with respect to oxygen. **Obligate aerobes** use O_2 for cellular respiration (see Chapter 9) and cannot grow without it. **Obligate anaerobes**, on the other hand, are poisoned by O_2. Some obligate anaerobes live exclusively by fermentation; others extract chemical energy by **anaerobic respiration**, in which substances other than O_2, such as nitrate ions (NO_3^-) or sulfate ions (SO_4^{2-}), accept electrons at the "downhill" end of electron transport chains. **Facultative anaerobes** use O_2 if it is present but can also carry out anaerobic respiration or fermentation in an anaerobic environment.

Table 27.1 Major Nutritional Modes

Mode of Nutrition	Energy Source	Carbon Source	Types of Organisms
Autotroph			
Photoautotroph	Light	CO_2	Photosynthetic prokaryotes (for example, cyanobacteria); plants; certain protists (for example, algae)
Chemoautotroph	Inorganic chemicals	CO_2	Certain prokaryotes (for example, *Sulfolobus*)
Heterotroph			
Photoheterotroph	Light	Organic compounds	Certain prokaryotes (for example, *Rhodobacter, Chloroflexus*)
Chemoheterotroph	Organic compounds	Organic compounds	Many prokaryotes (for example, *Clostridium*) and protists; fungi; animals; some plants

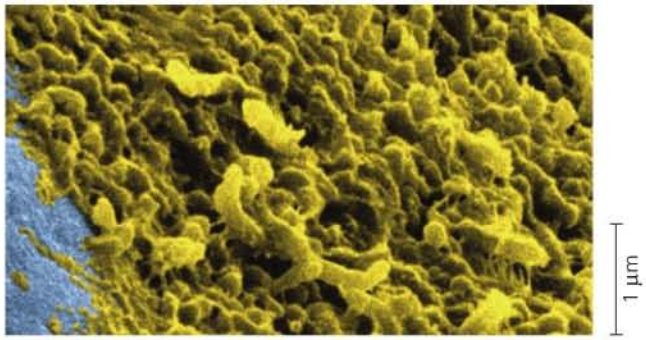
Nitrogen Metabolism

Nitrogen is essential for the production of amino acids and nucleic acids in all organisms. Whereas eukaryotes can obtain nitrogen from only a limited group of nitrogen compounds, prokaryotes can metabolize nitrogen in a wide variety of forms. For example, some cyanobacteria and some methanogens (a group of archaea) convert atmospheric nitrogen (N_2) to ammonia (NH_3), a process called **nitrogen fixation**. The cells can then incorporate this "fixed" nitrogen into amino acids and other organic molecules. In terms of their nutrition, nitrogen-fixing cyanobacteria are some of the most self-sufficient organisms, since they need only light, CO_2, N_2, water, and some minerals to grow.



Nitrogen fixation by prokaryotes has a large impact on other organisms. For example, nitrogen-fixing prokaryotes can increase the nitrogen available to plants, which cannot use atmospheric nitrogen but can use the nitrogen compounds that the prokaryotes produce from ammonia. Chapter 55 discusses this and other essential roles that prokaryotes play in the nitrogen cycles of ecosystems.

Metabolic Cooperation



Cooperation between prokaryotes allows them to use environmental resources they could not use as individual cells. In some cases, this cooperation takes place between specialized cells of a colony. For instance, the cyanobacterium *Anabaena* has genes that encode proteins for photosynthesis and for nitrogen fixation, but a single cell cannot carry out both processes at the same time. The reason is that photosynthesis produces O_2, which inactivates the enzymes involved in nitrogen fixation. Instead of living as isolated cells, *Anabaena* forms filamentous colonies **(Figure 27.14)**. Most cells in a filament carry out only photosynthesis, while a few specialized cells called **heterocytes** (formerly called *heterocysts*) carry out only nitrogen fixation. Each heterocyte is surrounded by a thickened cell wall that restricts entry of O_2 produced by neighboring photosynthetic cells. Intercellular connections allow heterocytes to transport fixed nitrogen to neighboring cells and to receive carbohydrates.

Metabolic cooperation between different prokaryotic species often occurs in surface-coating colonies known as **biofilms (Figure 27.15)**. Cells in a biofilm secrete signaling molecules that recruit nearby cells, causing the colonies to grow. The cells also produce proteins that stick the cells to the substrate and to one another. Channels in the biofilm allow nutrients to reach cells in the interior and wastes to be expelled. Biofilms damage industrial and medical equipment, contaminate products, and contribute to tooth decay and more serious health problems, altogether costing billions of dollars annually.

In another example of cooperation between prokaryotes, sulfate-consuming bacteria coexist with methane-consuming archaea in ball-shaped aggregates on the ocean floor. The bacteria appear to use the archaea's waste products, such as organic compounds and hydrogen. In turn, the bacteria produce compounds that facilitate methane consumption by the archaea. This partnership has global ramifications: Each year, these archaea consume an estimated 300 billion kilograms of methane, a major contributor to the greenhouse effect (see Chapter 55).

▲ **Figure 27.14 Metabolic cooperation in a colonial prokaryote.** In the filamentous cyanobacterium *Anabaena*, cells called heterocytes fix nitrogen, while the other cells carry out photosynthesis (LM). *Anabaena* is found in many freshwater lakes.

▲ **Figure 27.15 A biofilm.** The yellow mass in this colorized SEM is dental plaque, a biofilm consisting of numerous bacterial species that forms on tooth surfaces.

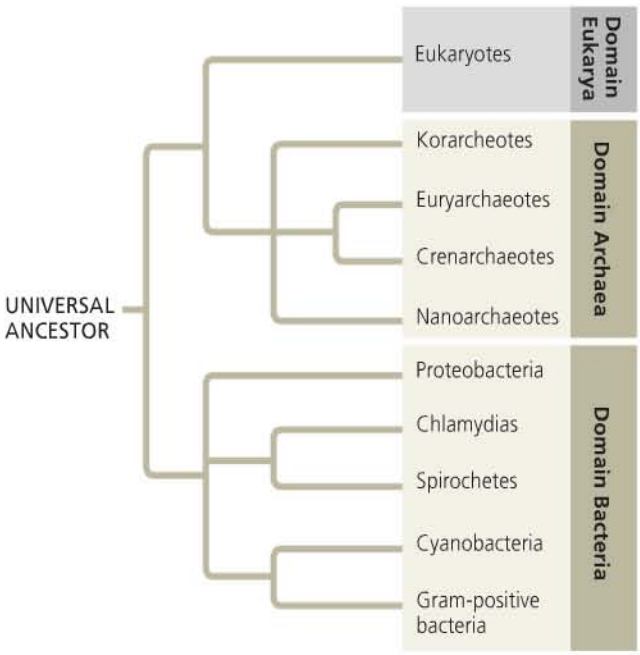
CONCEPT CHECK 27.3

1. Distinguish between the four major modes of nutrition, noting which are unique to prokaryotes.
2. A bacterium requires only the amino acid methionine as an organic nutrient and lives in lightless caves. What mode of nutrition does it employ? Explain.
3. **WHAT IF?** Describe what you might eat for a typical meal if humans, like cyanobacteria, could fix nitrogen.

For suggested answers, see Appendix A.

CONCEPT 27.4
Molecular systematics is illuminating prokaryotic phylogeny

Until the late 20th century, systematists based prokaryotic taxonomy on phenotypic criteria such as shape, motility, nutritional mode, and response to Gram staining. These criteria are still



valuable in certain contexts, such as the rapid identification of pathogenic bacteria cultured from a patient's blood. But when it comes to prokaryotic phylogeny, comparing these characteristics does not reveal a clear evolutionary history. Applying molecular systematics to the investigation of prokaryotic phylogeny, however, has led to some dramatic conclusions.

Lessons from Molecular Systematics

As discussed in Chapter 26, microbiologists began comparing the sequences of prokaryotic genes in the 1970s. Using small-subunit ribosomal RNA as a marker for evolutionary relationships, Carl Woese and his colleagues concluded that many prokaryotes once classified as bacteria are actually more closely related to eukaryotes and belong in a domain of their own: Archaea. Microbiologists have since analyzed larger amounts of genetic data—in some cases, entire genomes—and have concluded that a few traditional taxonomic groups, such as cyanobacteria, do appear to be monophyletic. However, other groups, such as gram-negative bacteria, are scattered throughout several lineages. **Figure 27.16** shows one phylogenetic hypothesis for some of the major taxa of prokaryotes based on molecular systematics.

One lesson from studying prokaryotic phylogeny is that the genetic diversity of prokaryotes is immense. When researchers began to sequence the genes of prokaryotes, they could investigate only those species that could be cultured in the laboratory—a small fraction of all prokaryotic species. In the 1980s, Norman Pace, of the University of Colorado, pioneered the use of the polymerase chain reaction (PCR; see Chapter 20) to analyze the genes of prokaryotes collected directly from their environment (such as from soil or water samples). Such "genetic prospecting" is now widely used, and each year it adds new branches to the tree of life. (Some researchers suggest that certain branches represent entire new kingdoms.) While only about 6,300 prokaryotic species have been assigned scientific names, a single handful of soil could contain 10,000 prokaryotic species, according to some estimates. You can see why taking full stock of this diversity will require many years of research.

Another important lesson from molecular systematics is the apparent significance of horizontal gene transfer in the evolution of prokaryotes. Over hundreds of millions of years, prokaryotes have acquired genes from even distantly related species, and they continue to do so today. As a result, significant portions of the genomes of many prokaryotes are actually mosaics of genes imported from other species. As we saw in Chapter 26, horizontal gene transfer obscures the location of the root of the tree of life. Still, it is clear that very early in the history of life, the prokaryotes diverged into two main lineages, the archaea and the bacteria (see Figure 27.16).

▲ **Figure 27.16 A simplified phylogeny of prokaryotes.** This phylogenetic tree based on molecular data highlights the relationships between the major prokaryotic groups discussed in this chapter. Within Archaea, the placement of the korarcheotes and nanoarcheotes remains unclear.

Archaea

Archaea share certain traits with bacteria and others with eukaryotes **(Table 27.2)**. However, archaea also have many unique characteristics, as we would expect in a taxon that has followed a separate evolutionary path for so long.

The first prokaryotes assigned to domain Archaea live in environments so extreme that few other organisms can survive there. Such organisms are called **extremophiles**, meaning "lovers" of extreme conditions (from the Greek *philos,* lover), and include extreme halophiles and extreme thermophiles.

Extreme halophiles (from the Greek *halo,* salt) live in highly saline environments, such as the Great Salt Lake, the Dead Sea, and Owens Lake (see Figure 27.1). Some species merely tolerate salinity, while others require an environment that is several times saltier than seawater (which has a salinity of 3.5%). For example, the proteins and cell wall of *Halobacterium* have unusual features that improve function in extremely salty environments but render these organisms incapable of survival if the salinity drops below 9%.

Extreme thermophiles (from the Greek *thermos,* hot) thrive in very hot environments **(Figure 27.17)**. For example, archaea in the genus *Sulfolobus* live in sulfur-rich volcanic springs as hot as 90°C. At temperatures this high, the cells of most organisms die because their DNA does not stay together in a double helix, and many of their proteins denature. *Sulfolobus* and other extreme thermophiles avoid this fate because their DNA and proteins have adaptations that make them stable at high temperatures. One extreme thermophile that lives near deep-sea hydrothermal vents in the Pacific Ocean, *Geogemma barossii*, is informally

Table 27.2 A Comparison of the Three Domains of Life

CHARACTER	DOMAIN		
	Bacteria	Archaea	Eukarya
Nuclear envelope	Absent	Absent	Present

Peptidoglycan in cell wall	Present	Absent	Absent
Membrane lipids	Unbranched hydrocarbons	Some branched hydrocarbons	Unbranched hydrocarbons
RNA polymerase	One kind	Several kinds	Several kinds
Initiator amino acid for protein synthesis	Formyl-methionine	Methionine	Methionine
Introns in genes	Very rare	Present in some genes	Present
Response to the antibiotics streptomycin and chloramphenicol	Growth inhibited	Growth not inhibited	Growth not inhibited
Histones associated with DNA	Absent	Present in some species	Present
Circular chromosome	Present	Present	Absent
Growth at temperatures > 100°C	No	Some species	No

known as "strain 121," since it can double its cell numbers even at 121°C. Another extreme thermophile, *Pyrococcus furiosus*, is used in biotechnology as a source of DNA polymerase for the PCR technique (see Chapter 20).

Other archaea live in more moderate environments. Some of these are included among the **methanogens**, a group of archaea named for the unique way they obtain energy: They use CO_2 to oxidize H_2, releasing methane as a waste product. Among the strictest of anaerobes, methanogens are poisoned by O_2. Although some methanogens live in extreme environments, such as under kilometers of ice in Greenland, others live in swamps and marshes where other microorganisms have consumed all the O_2. The "marsh gas" found in such environments is the methane produced by these archaea. Other species of methanogens inhabit the anaerobic environment within the guts of cattle, termites, and other herbivores, playing an essential role in the nutrition of these animals. Methanogens also have an important application as decomposers in sewage treatment facilities.

Many extreme halophiles and all known methanogens are archaea in the clade Euryarchaeota (from the Greek *eurys*, broad, a reference to the habitat range of these prokaryotes).

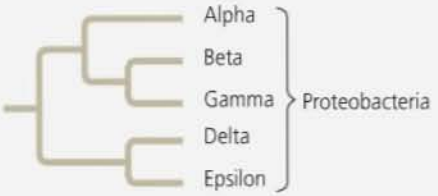
▲ **Figure 27.17 Extreme thermophiles.** Orange and yellow colonies of thermophilic prokaryotes grow in the hot water of a Nevada geyser.

? *How might the enzymes of thermophiles differ from those in other organisms?*

The euryarchaeotes also include some extreme thermophiles, though most thermophilic species belong to a second clade, Crenarchaeota (*cren* means "spring," such as a hydrothermal spring). Recently, genetic prospecting has revealed many species of euryarchaeotes and crenarchaeotes that are not extremophiles. These archaea exist in habitats ranging from farm soils to lake sediments to the surface waters of the open ocean.

New findings continue to update the picture of archaeal phylogeny. In 1996, researchers sampling a hot spring in Yellowstone National Park discovered archaea that do not appear to belong to either Euryarchaeota or Crenarchaeota. They placed these archaea in a new clade, Korarchaeota (from the Greek *koron*, young man). In 2002, researchers exploring hydrothermal vents off the coast of Iceland discovered archaeal cells only 0.4 μm in diameter attached to a much larger crenarchaeote. The genome of the smaller archaean is one of the smallest known of any organism, containing only 500,000 base pairs. Genetic analysis indicates that this prokaryote belongs to a fourth archaeal clade, called Nanoarchaeota (from the Greek *nanos*, dwarf). Within a year after this clade was named, three other DNA sequences from nanoarchaeote species were isolated: one from Yellowstone's hot springs, one from hot springs in Siberia, and one from a hydrothermal vent in the Pacific. As prospecting continues, it seems likely that the tree in Figure 27.16 will undergo further changes.

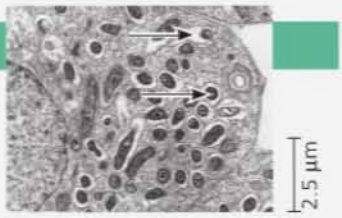
Bacteria



Examine **Figure 27.18**, on the following two pages, for a closer look at several major groups of bacteria. Bacteria include the vast majority of prokaryotes that most people are aware of, from the pathogenic species that cause strep throat and tuberculosis to

▼ Figure 27.18

Exploring Major Groups of Bacteria



PROTEOBACTERIA

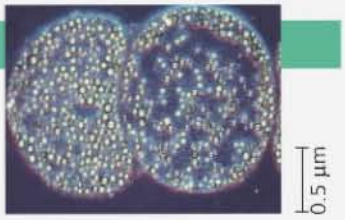
This large and diverse clade of gram-negative bacteria includes photoautotrophs, chemoautotrophs, and heterotrophs. Some proteobacteria are anaerobic, while others are aerobic. Molecular systematists currently recognize five subgroups of proteobacteria; the phylogenetic tree at right shows their relationships based on molecular data.

Subgroup: Alpha Proteobacteria

Many of the species in this subgroup are closely associated with eukaryotic hosts. For example, *Rhizobium* species live in nodules within the roots of legumes (plants of the pea/bean family), where the bacteria convert atmospheric N_2 to compounds the host plant can use to make proteins. Species in the genus *Agrobacterium* produce tumors in plants; genetic engineers use these bacteria to carry foreign DNA into the genomes of crop plants (see Figure 20.25). As explained in Chapter 25, scientists hypothesize that mitochondria evolved from aerobic alpha proteobacteria through endosymbiosis.

Rhizobium (arrows) inside a root cell of a legume (TEM)

Subgroup: Beta Proteobacteria

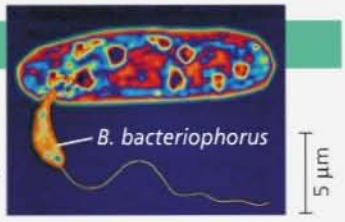


This nutritionally diverse subgroup includes *Nitrosomonas*, a genus of soil bacteria that play an important role in nitrogen recycling by oxidizing ammonium (NH_4^+), producing nitrite (NO_2^-) as a waste product.

Nitrosomonas (colorized TEM)

Subgroup: Gamma Proteobacteria

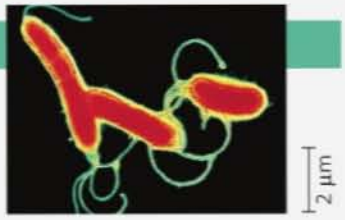
This subgroup's autotrophic members include sulfur bacteria such as *Thiomargarita namibiensis*, which obtain energy by oxidizing H_2S, producing sulfur as a waste product (the small globules in the photograph at right). Some heterotrophic gamma proteobacteria are pathogens; for example, *Legionella* causes Legionnaires' disease, *Salmonella* is responsible for some cases of food poisoning, and *Vibrio cholerae* causes cholera. *Escherichia coli*, a common resident of the intestines of humans and other mammals, normally is not pathogenic.



Thiomargarita namibiensis containing sulfur wastes (LM)

Subgroup: Delta Proteobacteria

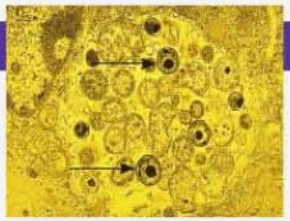
This subgroup includes the slime-secreting myxobacteria (left). When the soil dries out or food is scarce, the cells congregate into a fruiting body that releases resistant "myxospores." These cells found new colonies in favorable environments. Bdellovibrios (right) are delta proteobacteria that attack other bacteria, charging at up to 100 µm/sec (comparable to a human running 600 km/hr) and boring into their prey by spinning at 100 revolutions/sec.



Fruiting bodies of *Chondromyces crocatus*, a myxobacterium (SEM)

Bdellovibrio bacteriophorus attacking a larger bacterium (colorized TEM)

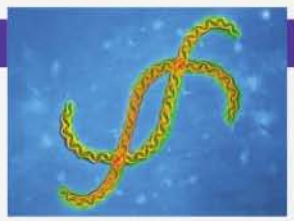
Subgroup: Epsilon Proteobacteria



Most species in this subgroup are pathogenic to humans or other animals. Epsilon proteobacteria include *Campylobacter*, which causes blood poisoning and intestinal inflammation, and *Helicobacter pylori*, which causes stomach ulcers.

Helicobacter pylori (colorized TEM)

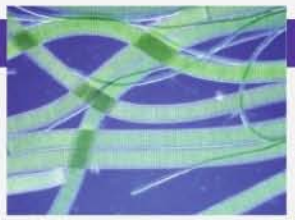
CHLAMYDIAS



These parasites can survive only within animal cells, depending on their hosts for resources as basic as ATP. The gram-negative walls of chlamydias are unusual in that they lack peptidoglycan. One species, *Chlamydia trachomatis*, is the most common cause of blindness in the world and also causes nongonococcal urethritis, the most common sexually transmitted disease in the United States.

Chlamydia (arrows) inside an animal cell (colorized TEM)

SPIROCHETES

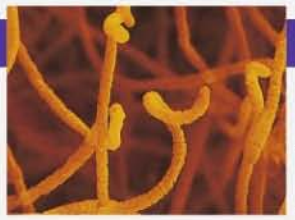


These helical heterotrophs spiral through their environment by means of rotating, internal, flagellum-like filaments. Many spirochetes are free-living, but others are notorious pathogenic parasites: *Treponema pallidum* causes syphilis, and *Borrelia burgdorferi* causes Lyme disease (see Figure 27.21).

Leptospira, a spirochete (colorized TEM)

CYANOBACTERIA

These photoautotrophs are the only prokaryotes with plantlike, oxygen-generating photosynthesis. (In fact, chloroplasts likely evolved from an endosymbiotic cyanobacterium; see Chapter 25.) Both solitary and colonial cyanobacteria are abundant wherever there is water, providing an enormous amount of food for freshwater and marine ecosystems. Some filamentous colonies have cells specialized for nitrogen fixation, the process that incorporates atmospheric N_2 into inorganic compounds that can be used in the synthesis of amino acids and other organic molecules (see Figure 27.14).



Two species of *Oscillatoria*, filamentous cyanobacteria (LM)

GRAM-POSITIVE BACTERIA

Gram-positive bacteria rival the proteobacteria in diversity. Species in one subgroup, the actinomycetes (from the Greek *mykes*, fungus, for which these bacteria were once mistaken), form colonies containing branched chains of cells. Two species of actinomycetes cause tuberculosis and leprosy. However, most actinomycetes are free-living species that help decompose the organic matter in soil; their secretions are partly responsible for the "earthy" odor of rich soil. Soil-dwelling species in the genus *Streptomyces* (top) are cultured by pharmaceutical companies as a source of many antibiotics, including streptomycin.

In addition to the colonial actinomycetes, gram-positive bacteria include many solitary species, such as *Bacillus anthracis* (see Figure 27.9), which causes anthrax, and *Clostridium botulinum*, which causes botulism. The various species of *Staphylococcus* and *Streptococcus* are also gram-positive bacteria.

Mycoplasmas (bottom) are the only bacteria known to lack cell walls. They are also the tiniest of all known cells, with diameters as small as 0.1 µm, only about five times as large as a ribosome. Mycoplasmas have remarkably small genomes—*Mycoplasma genitalium* has only 517 genes, for example. Many mycoplasmas are free-living soil bacteria, but others are pathogens.

Streptomyces, the source of many antibiotics (colorized SEM)

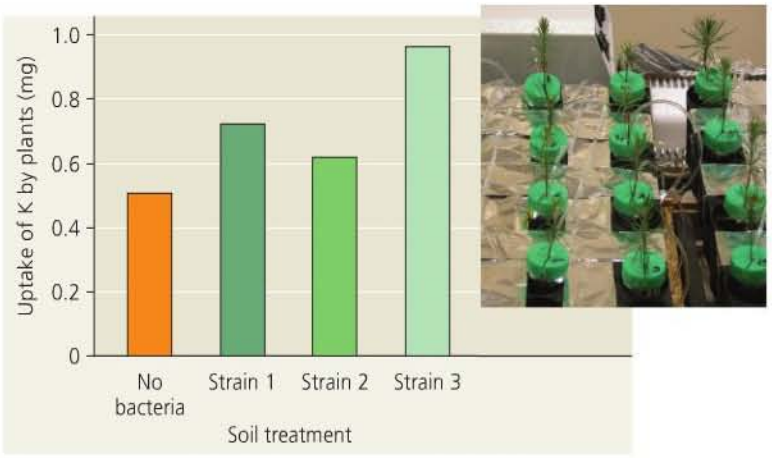
Hundreds of mycoplasmas covering a human fibroblast cell (colorized SEM)

the beneficial species used to make Swiss cheese and yogurt. Every major mode of nutrition and metabolism is represented among bacteria, and even a small taxonomic group of bacteria may contain species exhibiting many different nutritional modes. As we'll see, the diverse nutritional and metabolic capabilities of bacteria—and archaea—are behind the great impact of these tiny organisms on Earth and its life.

CONCEPT CHECK 27.4

1. Explain how molecular systematics has contributed to our understanding of prokaryotic phylogeny.
2. How has genetic prospecting contributed to our understanding of prokaryotic diversity and phylogeny?
3. **WHAT IF?** What would the discovery of a bacterial species that is a methanogen imply about the evolution of that metabolic pathway?

For suggested answers, see Appendix A.



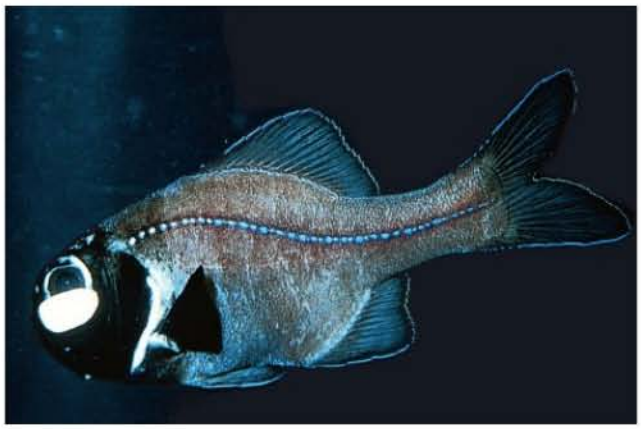
CONCEPT 27.5
Prokaryotes play crucial roles in the biosphere

If humans were to disappear from the planet tomorrow, life on Earth would change for many species, but few would be driven to extinction. In contrast, prokaryotes are so important to the biosphere that if they were to disappear, the prospects of survival for many other species would be dim.

Chemical Recycling

The atoms that make up the organic molecules in all living things were at one time part of inorganic substances in the soil, air, and water. Sooner or later, those atoms will return there. Ecosystems depend on the continual recycling of chemical elements between the living and nonliving components of the environment, and prokaryotes play a major role in this process. For example, chemoheterotrophic prokaryotes function as **decomposers**, breaking down corpses, dead vegetation, and waste products, and thereby unlocking supplies of carbon, nitrogen, and other elements. Without the actions of prokaryotes and other decomposers such as fungi, all life would cease. (See Chapter 55 for a detailed discussion of chemical cycles.)

Prokaryotes also convert inorganic compounds to forms that can be taken up by other organisms. Autotrophic prokaryotes, for example, use CO_2 to make organic compounds, which are then passed up through food chains. Cyanobacteria produce atmospheric O_2, and a variety of prokaryotes fix atmospheric nitrogen (N_2) into forms that other organisms can use to make the building blocks of proteins and nucleic acids. Under some conditions, prokaryotes can increase the availability of nutrients that plants require for growth, such as nitrogen, phosphorus, and potassium **(Figure 27.19)**. Prokaryotes can also *decrease* the availability of



▲ **Figure 27.19 Impact of bacteria on soil nutrient availability.** Pine seedlings grown in soils to which one of three strains of the bacterium *Burkholderia glathei* had been added absorbed more potassium (K) than did seedlings grown in soil without any bacteria. Other results (not shown) demonstrated that strain 3 increased the amount of K released from mineral crystals to the soil.

WHAT IF? *Estimate the average uptake of K for seedlings in soils with bacteria. What would you expect this average to be if bacteria had no effect on nutrient availability?*

key plant nutrients; this occurs when prokaryotes "immobilize" nutrients by using them to synthesize molecules that remain within their cells. Thus, prokaryotes can have complex effects on soil nutrient concentrations. In marine environments, a 2005 study found that an archaean from the clade Crenarchaeota can perform nitrification, a key step in the nitrogen cycle (see Figure 55.14). Crenarchaeotes dominate the oceans by numbers, comprising an estimated 10^{28} cells. The sheer abundance of these organisms suggests that they may have a large impact on the global nitrogen cycle; scientists are investigating this question.

Ecological Interactions

Prokaryotes play a central role in many ecological interactions. Consider **symbiosis** (from a Greek word meaning "living together"), an ecological relationship in which two species live in close contact with one another. Prokaryotes are small, and they often form symbiotic associations with much larger organisms. In general, the larger organism in a symbiotic relationship is known as the **host**, and the smaller is known as the **symbiont**. There are many cases in which a prokaryote and its host participate in **mutualism**, an ecological interaction between two species in which both benefit **(Figure 27.20)**. In other cases, the interaction takes the form of **commensalism**, an ecological relationship in which one species benefits while the other is not harmed or helped in any significant way. For example, more than 150 bacterial species live on the surface of your body, covering portions of your skin with up to 10 million cells per square centimeter. Some of these species are commensalists: You provide them with food, such as the oils that exude from your pores, and a place to live, while they do not harm or benefit you. Finally, some prokaryotes engage in **parasitism**, an ecological relationship in which a **parasite** eats the cell contents, tissues, or body

▲ **Figure 27.20 Mutualism: bacterial "headlights."** The glowing oval below the eye of the flashlight fish (*Photoblepharon palpebratus*) is an organ harboring bioluminescent bacteria. The fish uses the light to attract prey and to signal potential mates. The bacteria receive nutrients from the fish.

fluids of its host; as a group, parasites harm but usually do not kill their host, at least not immediately (unlike a predator). Parasites that cause disease are known as **pathogens**, many of which are prokaryotic. (We'll discuss mutualism, commensalism, and parasitism in greater detail in Chapter 54.)

The well-being of many eukaryotes—yourself included—depends on mutualistic prokaryotes. Human intestines are home to an estimated 500 to 1,000 species of bacteria; their cells outnumber all human cells in the body by as much as ten times. Different species live in different portions of the intestines, and they vary in their ability to process different foods. Many of these species are mutualists, digesting food that our own intestines cannot break down. In 2003, scientists at Washington University in St. Louis published the first complete genome of one of these gut mutualists, *Bacteroides thetaiotaomicron.* The genome includes a large array of genes involved in synthesizing carbohydrates, vitamins, and other nutrients needed by humans. Signals from the bacterium activate human genes that build the network of intestinal blood vessels necessary to absorb nutrient molecules. Other signals induce human cells to produce antimicrobial compounds to which *B. thetaiotaomicron* is not susceptible. This action may reduce the population sizes of other, competing species, thus potentially benefiting both *B. thetaiotaomicron* and its human host.

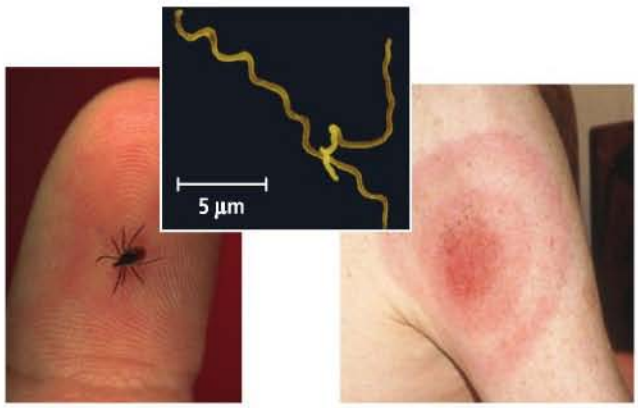
CONCEPT CHECK 27.5

1. Explain how individual prokaryotes, though small, can be considered giants in their collective impact on Earth and its life.
2. Explain how the relationship between humans and *B. thetaiotaomicron* is an example of mutualism.
3. **WHAT IF?** If you suddenly and dramatically changed your diet, how might this affect the diversity of prokaryotic species that live in your intestine?

For suggested answers, see Appendix A.

CONCEPT 27.6

Prokaryotes have both harmful and beneficial impacts on humans



Though the best-known prokaryotes tend to be the bacteria that cause illness in humans, these pathogens represent only a small fraction of prokaryotic species. Many other prokaryotes have positive interactions with humans, and some play essential roles in agriculture and industry.

Pathogenic Bacteria

All the pathogenic prokaryotes known to date are bacteria, and they deserve their negative reputation. Bacteria cause about half of all human diseases. Roughly 2 million people a year die of the lung disease tuberculosis, caused by *Mycobacterium tuberculosis*. And another 2 million people die each year from diarrheal diseases caused by various bacteria.

Some bacterial diseases are transmitted by other species, such as fleas or ticks. In the United States, the most widespread pest-carried disease is Lyme disease, which infects 15,000 to 20,000 people each year **(Figure 27.21)**. Caused by a bacterium carried by ticks that live on deer and field mice, Lyme disease can produce debilitating arthritis, heart disease, and nervous disorders if untreated.

Pathogenic prokaryotes usually cause illness by producing poisons, which are classified as exotoxins or endotoxins. **Exotoxins** are proteins secreted by certain bacteria and other organisms. Cholera, a dangerous diarrheal disease, is caused by an exotoxin secreted by the proteobacterium *Vibrio cholerae.* The exotoxin stimulates intestinal cells to release chloride ions into the gut, and water follows by osmosis. In another example, the potentially fatal disease botulism is caused by botulinum toxin, an exotoxin secreted by the gram-positive bacterium *Clostridium botulinum* as it ferments various foods, including improperly canned meat, seafood, and vegetables. Like other exotoxins, the botulinum toxin can produce disease

▲ **Figure 27.21 Lyme disease.** Ticks in the genus *Ixodes* spread the disease by transmitting the spirochete *Borrelia burgdorferi* (colorized SEM). A rash may develop at the site of the tick's bite; the rash may be large and ring-shaped (as shown) or much less distinctive.

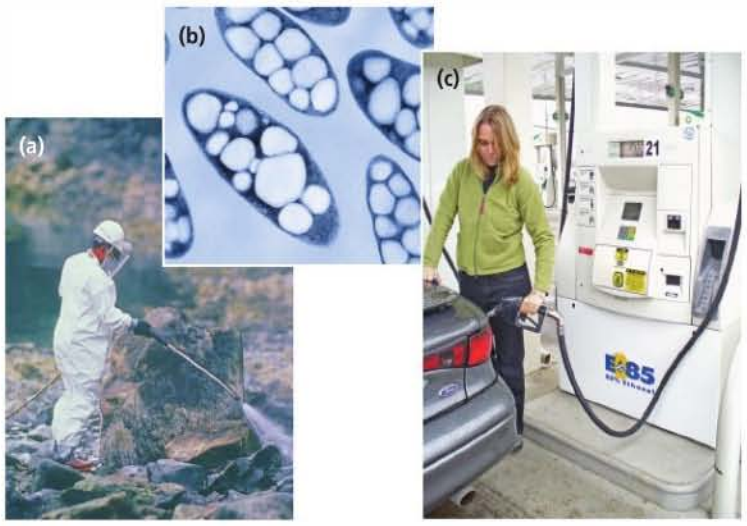
even if the bacteria that manufacture it are not present. In one such case, eight people contracted botulism after eating salted fish that did not contain any *C. botulinum* bacteria, but did contain the botulinum toxin. Even though the bacterium was no longer present, at some point in the fish preparation process, the bacterium had been able to grow and secrete the toxin.

Endotoxins are lipopolysaccharide components of the outer membrane of gram-negative bacteria. In contrast to exotoxins, endotoxins are released only when the bacteria die and their cell walls break down. Examples of endotoxin-producing bacteria include species in the genus *Salmonella*, which are not normally present in healthy animals. *Salmonella typhi* causes typhoid fever, and several other *Salmonella* species, some of which are frequently found in poultry, cause food poisoning.

Since the 19th century, improved sanitation systems in the industrialized world have greatly reduced the threat of pathogenic bacteria. Antibiotics have saved a great many lives and reduced the incidence of disease. However, resistance to antibiotics is currently evolving in many bacterial strains. As you read earlier, the rapid reproduction of bacteria enables genes conferring resistance to multiply quickly throughout bacterial populations as a result of natural selection, and these genes can spread to other species by horizontal gene transfer.

Horizontal gene transfer can also spread genes associated with virulence, turning normally harmless bacteria into lethal pathogens. *E. coli*, for instance, is ordinarily a harmless symbiont in the human intestines, but pathogenic strains that cause bloody diarrhea have emerged. One of the most dangerous strains, called O157:H7, is a global threat; in the United States alone, there are 75,000 cases of O157:H7 infection per year, often from contaminated beef or produce. In 2001, scientists sequenced the genome of O157:H7 and compared it with the genome of a harmless strain of *E. coli* called K-12. They discovered that 1,387 out of the 5,416 genes in O157:H7 have no counterpart in K-12. Many of these 1,387 genes are found in chromosomal regions that include DNA sequences related to bacteriophage DNA. This result suggests that at least some of the 1,387 genes were incorporated into the genome of 0157:H7 through bacteriophage-mediated horizontal gene transfer (see Figure 27.11). Some of the genes found only in 0157:H7 are associated with virulence, including genes that code for adhesive fimbriae that enable O157:H7 to attach itself to the intestinal wall and extract nutrients.

Pathogenic bacteria pose a potential threat as weapons of bioterrorism. For example, endospores of *Bacillus anthracis* sent through the mail caused 18 people—5 of whom died—to develop inhalation anthrax (see also Chapter 26). Such scenarios have stimulated intense research on pathogenic prokaryotic species in the hope of developing new vaccines and antibiotics.



Prokaryotes in Research and Technology

On a positive note, we reap many benefits from the metabolic capabilities of both bacteria and archaea. For example, humans have long used bacteria to convert milk into cheese and yogurt. In recent years, our greater understanding of prokaryotes has led to an explosion of new applications in biotechnology; two examples are the use of *E. coli* in gene cloning and of *Agrobacterium tumefaciens* in producing transgenic plants such as Golden Rice (see Chapter 20).

Prokaryotes are the principal agents in **bioremediation**, the use of organisms to remove pollutants from soil, air, or water. For example, anaerobic bacteria and archaea decompose the organic matter in sewage, converting it to material that can be used as landfill or fertilizer after chemical sterilization. Other bioremediation applications include cleaning up oil spills **(Figure 27.22a)** and precipitating radioactive material (such as uranium) out of groundwater.

Bacteria may soon figure prominently in a major industry: plastics. Globally, each year about 350 billion pounds of plastic are produced from petroleum and used to make toys, storage containers, soft drink bottles, and many other items. These products degrade slowly, creating environmental problems. Bacteria can now be used to make natural plastics **(Figure 27.22b)**. For example, some bacteria synthesize a type of polyester known as PHA (polyhydroxyalkanoate), which they use to store chemical energy. When these bacteria are fed sugars derived from corn, the PHA they produce can be extracted, formed into pellets, and used to make durable, biodegradable plastics.

Through genetic engineering, humans can now modify bacteria to produce vitamins, antibiotics, hormones, and other products (see Chapter 20). Researchers are seeking to reduce fossil fuel use by engineering bacteria that can produce ethanol from various forms of biomass, including agricultural waste, switchgrass, fast-growing woody plants such as willows, and corn **(Figure 27.22c)**. One radical idea for modifying bacteria

▲ **Figure 27.22 Some applications of prokaryotes. (a)** Spraying fertilizers on an oil-soaked area stimulates growth of native bacteria that metabolize the oil, speeding the natural breakdown process up to fivefold. **(b)** These bacteria synthesize and store the polyester PHA. The PHA can be extracted and used to make biodegradable plastic products. **(c)** Current research seeks to develop bacteria that produce ethanol (E-85) fuel efficiently from renewable plant products.

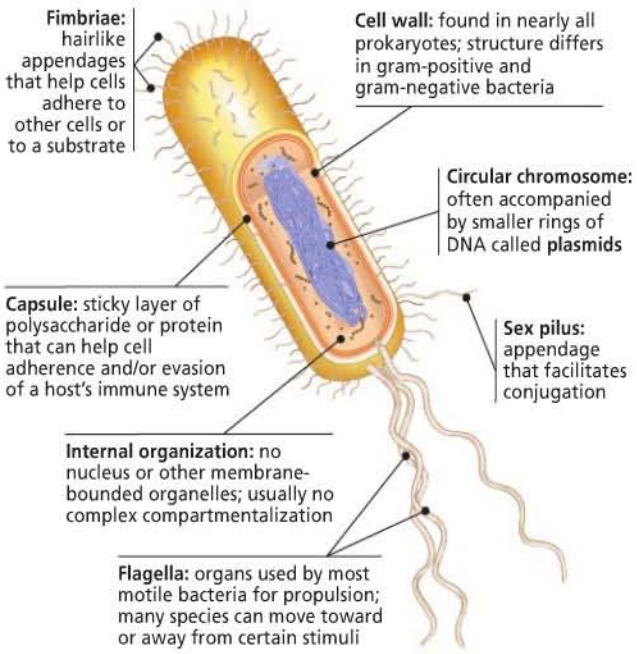
comes from Craig Venter, head of The Institute for Genomic Research (TIGR). Venter and his colleagues are attempting to build "synthetic chromosomes" for bacteria—in effect, producing new species from scratch. They hope to "design" bacteria that can perform specific tasks, such as producing large amounts of hydrogen to reduce dependence on fossil fuels. Some scientists, however, question whether this approach may have unanticipated harmful effects.

The usefulness of prokaryotes largely derives from their diverse forms of nutrition and metabolism. All this metabolic versatility evolved prior to the appearance of the structural novelties that heralded the evolution of eukaryotic organisms, to which we devote the remainder of this unit.

CONCEPT CHECK 27.6

1. Identify at least two ways that prokaryotes have affected you positively today.
2. A pathogenic bacterium's toxin causes symptoms that increase the bacterium's chance of spreading from host to host. Does this information indicate whether the poison is an exotoxin or endotoxin? Explain.
3. **WHAT IF?** In addition to horizontal gene transfer, propose another hypothesis that could account for *E. coli* strain O157:H7 having genes not found in strain K-12. How could your hypothesis be tested?

For suggested answers, see Appendix A.



Chapter 27 Review

MEDIA Go to the Study Area at **www.masteringbio.com** for BioFlix 3-D Animations, MP3 Tutors, Videos, Practice Tests, an eBook, and more.

SUMMARY OF KEY CONCEPTS

CONCEPT 27.1

Structural and functional adaptations contribute to prokaryotic success (pp. 556–561)

- **Reproduction and Adaptation** Prokaryotes can reproduce quickly by binary fission. Some form endospores, which can remain viable in harsh conditions for centuries. Prokaryotic populations can evolve in short periods of time in response to changing environmental conditions.

MEDIA

Activity Prokaryotic Cell Structure and Function

CONCEPT 27.2

Rapid reproduction, mutation, and genetic recombination promote genetic diversity in prokaryotes (pp. 561–564)

- **Rapid Reproduction and Mutation** Because prokaryotes can often proliferate rapidly, mutations can quickly increase a population's genetic variation, enabling adaptive evolution.
- **Genetic Recombination** Genetic diversity in prokaryotes also can arise by recombination of the DNA from two different cells (in bacteria, via transformation, transduction, or conjugation). By transferring advantageous alleles, such as those for antibiotic resistance, genetic recombination can promote adaptive evolution in prokaryotic populations.

MEDIA

Investigation What Are the Patterns of Antibiotic Resistance?

CONCEPT 27.3

Diverse nutritional and metabolic adaptations have evolved in prokaryotes (pp. 564–565)

- Examples of all four modes of nutrition—photoautotrophy, chemoautotrophy, photoheterotrophy, and chemoheterotrophy—are found among prokaryotes.
- **The Role of Oxygen in Metabolism** Obligate aerobes require O_2, obligate anaerobes are poisoned by O_2, and facultative anaerobes can survive with or without O_2.
- **Nitrogen Metabolism** Prokaryotes can metabolize a wide variety of nitrogenous compounds. Some can convert atmospheric nitrogen to ammonia in a process called nitrogen fixation.
- **Metabolic Cooperation** Many prokaryotes depend on the metabolic activities of other prokaryotes. In *Anabaena*, photosynthetic cells and nitrogen-fixing cells exchange metabolic products. Some prokaryotes form surface-coating biofilms, typically including different species.

MEDIA

Investigation What Are the Modes of Nutrition in Prokaryotes?

CONCEPT 27.4

Molecular systematics is illuminating prokaryotic phylogeny (pp. 565–570)

- **Lessons from Molecular Systematics** Molecular systematics is leading to a phylogenetic classification of prokaryotes, allowing systematists to identify major new clades.
- **Archaea** Archaea share certain traits with bacteria and other traits with eukaryotes. Some archaea, such as extreme thermophiles and extreme halophiles, live in extreme environments. Other archaea, including most methanogens and species in soils, lakes, and oceans, live in moderate environments.
- **Bacteria** Diverse nutritional types are scattered among the major groups of bacteria. The two largest groups are the proteobacteria and the gram-positive bacteria.

MEDIA

Activity Classification of Prokaryotes

CONCEPT 27.5

Prokaryotes play crucial roles in the biosphere (pp. 570–571)

- **Chemical Recycling** Decomposition by heterotrophic prokaryotes and the synthetic activities of autotrophic and nitrogen-fixing prokaryotes contribute to the recycling of elements in ecosystems.
- **Ecological Interactions** Many prokaryotes have a symbiotic relationship with a host; the relationships between prokaryotes and their hosts range from mutualism to commensalism to parasitism.

CONCEPT 27.6

Prokaryotes have both harmful and beneficial impacts on humans (pp. 571–573)

- **Pathogenic Bacteria** Pathogenic bacteria typically cause disease by releasing exotoxins or endotoxins and are potential weapons of bioterrorism. Horizontal gene transfer can spread genes associated with virulence to harmless strains.
- **Prokaryotes in Research and Technology** Experiments involving bacteria such as *E. coli* and *A. tumefaciens* have led to important advances in DNA technology. Prokaryotes can be used in bioremediation, production of biodegradable plastics, and the synthesis of vitamins, antibiotics, and other products.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Genetic variation in bacterial populations cannot result from
   a. transduction.
   b. transformation.
   c. conjugation.
   d. mutation.
   e. meiosis.

2. Photoautotrophs use
   a. light as an energy source and CO_2 as a carbon source.
   b. light as an energy source and methane as a carbon source.
   c. N_2 as an energy source and CO_2 as a carbon source.
   d. CO_2 as both an energy source and a carbon source.
   e. H_2S as an energy source and CO_2 as a carbon source.

3. Which of the following statements is *not* true?
   a. Archaea and bacteria have different membrane lipids.
   b. Both archaea and bacteria generally lack membrane-enclosed organelles.
   c. The cell walls of archaea lack peptidoglycan.
   d. Only bacteria have histones associated with DNA.
   e. Only some archaea use CO_2 to oxidize H_2, releasing methane.

4. Which of the following features of prokaryotic biology involves metabolic cooperation among cells?
   a. binary fission
   b. endospore formation
   c. endotoxin release
   d. biofilms
   e. photoautotrophy

5. Which prokaryotic group is mismatched with its members?
   a. Proteobacteria—diverse gram-negative bacteria
   b. Gram-positive bacteria—symbionts in legume root nodules
   c. Spirochetes—helical heterotrophs
   d. Chlamydias—intracellular parasites
   e. Cyanobacteria—solitary and colonial photoautotrophs

6. Plantlike photosynthesis that releases O_2 occurs in
   a. cyanobacteria.
   b. chlamydias.
   c. archaea.
   d. actinomycetes.
   e. chemoautotrophic bacteria.

For Self-Quiz answers, see Appendix A.

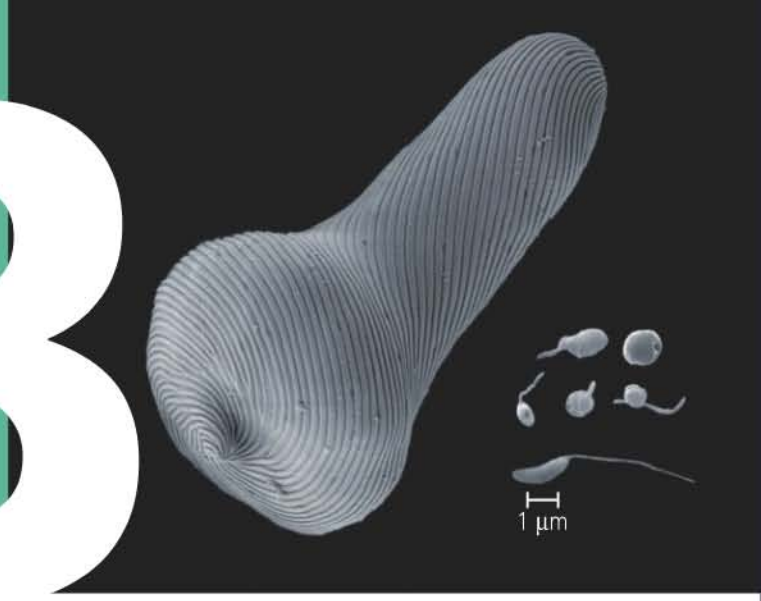
MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

7. Health officials worldwide are concerned about antibiotic resistance in bacteria that cause disease. In patients infected with nonresistant strains of the bacterium that causes tuberculosis, antibiotics can relieve symptoms in a few weeks. However, it takes much longer to halt the infection, and patients may discontinue treatment while bacteria are still present. How can bacteria quickly cause symptoms again if they are not wiped out? How might this result in the evolution of drug-resistant pathogens?

SCIENTIFIC INQUIRY

8. **DRAW IT** The nitrogen-fixing bacterium *Rhizobium* infects the roots of some plant species, forming a mutualism in which the bacterium provides the plant with nitrogen, and the plant provides the bacterium with carbohydrates. Scientists measured how well one such plant species (*Acacia irrorata*) grew when its roots were infected by six different *Rhizobium* strains.



(a) Graph the data. (b) Interpret your graph.

Rhizobium strain	Plant mass (g) after 12 weeks of growth
1	0.91
2	0.06
3	1.56
4	1.72
5	0.14
6	1.03

Source: J. J. Burdon, et al., Variation in the effectiveness of symbiotic associations between native rhizobia and temperate Australian *Acacia*: within species interactions, *Journal of Applied Ecology*, 36:398-408 (1999).

Note: In the absence of *Rhizobium*, after 12 weeks of growth, *Acacia* plants have a mass of about 0.1 g.

28 Protists

▲ **Figure 28.1 Which of these organisms are prokaryotes and which are eukaryotes?**

KEY CONCEPTS

28.1 Most eukaryotes are single-celled organisms
28.2 Excavates include protists with modified mitochondria and protists with unique flagella
28.3 Chromalveolates may have originated by secondary endosymbiosis
28.4 Rhizarians are a diverse group of protists defined by DNA similarities
28.5 Red algae and green algae are the closest relatives of land plants
28.6 Unikonts include protists that are closely related to fungi and animals
28.7 Protists play key roles in ecological relationships

OVERVIEW

Living Small

Knowing that most prokaryotes are extremely small organisms, you might assume that **Figure 28.1** depicts six prokaryotes and one much larger eukaryote. But in fact, only the organism immediately above the scale bar is a prokaryote. The others are recently discovered members of diverse, mostly unicellular groups of eukaryotes informally known as **protists**. Very small eukaryotes have intrigued scientists for more than 300 years, ever since the Dutch microscopist Antoni van Leeuwenhoek first laid eyes on them. As he discovered, viewing a drop of pond water under a light microscope can reveal a fascinating world of unicellular protists and prokaryotes. Some protists propel themselves with whipping flagella, while others creep along by means of blob-like appendages. Some are shaped like tiny trumpets; others resemble miniature jewelry. Recalling his observations, van Leeuwenhoek wrote, "No more pleasant sight has met my eye than this, of so many thousands of living creatures in one small drop of water."

Until recently, biologists thought that 300 years of observation had uncovered a representative sample of living protist species. But in the last decade, genetic prospecting has turned up a treasure trove of previously unknown protists within the world of microscopic life. As shown in Figure 28.1, many of these newly discovered species have cells just 0.5–2 µm in diameter—as small as many prokaryotes.

The surprising discovery of many species of minuscule protists followed close on the heels of recent findings regarding protist phylogeny. All protists were once classified in a single kingdom, Protista, but advances in eukaryotic systematics have caused the kingdom to crumble. It has become clear that Protista is in fact polyphyletic (see Figure 26.10): Some protists are more closely related to plants, fungi, or animals than they are to other protists. As a result, the kingdom Protista has been abandoned, and various lineages of protists are now recognized as kingdoms in their own right. Most biologists still use the term *protist*, but only as a convenient way to refer to eukaryotes that are neither plants, animals, nor fungi.

In this chapter, you will become acquainted with some of the most significant groups of protists. You will learn about their structural and biochemical adaptations as well as their enormous impact on ecosystems, agriculture, industry, and human health.

CONCEPT 28.1

Most eukaryotes are single-celled organisms

Protists, along with plants, animals, and fungi, are classified as eukaryotes; they are in domain Eukarya, one of the three domains of life. Unlike the cells of prokaryotes, eukaryotic cells have a nucleus and other membrane-bounded organelles, such

as mitochondria and the Golgi apparatus. Such organelles provide specific locations in which particular functions are accomplished, making the structure and organization of eukaryotic cells more complex than that of prokaryotic cells.

We'll survey the diversity of eukaryotes throughout the rest of this unit, beginning in this chapter with the protists. As you explore this material, bear in mind that the organisms in most eukaryotic lineages are protists, and most protists are unicellular. Thus, life differs greatly from what we commonly think it is like. The large, multicellular organisms that we know best (plants, animals, and fungi) are the tips of just a few branches on the great tree of life (see Figure 26.21).

Structural and Functional Diversity in Protists

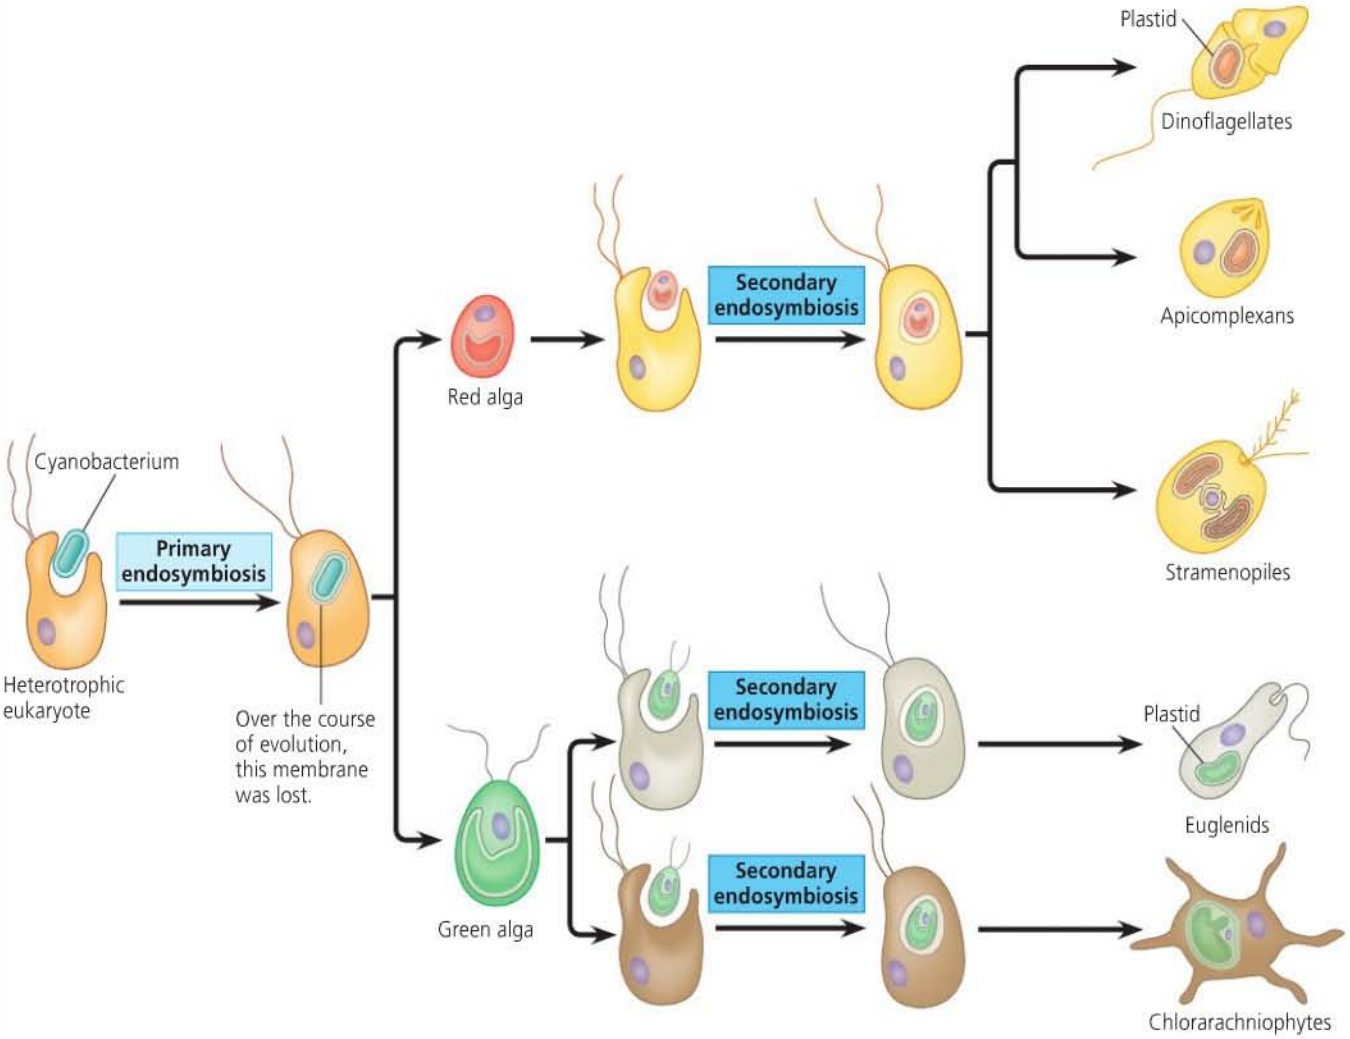
Given the paraphyletic nature of the group once called Protista, it isn't surprising that few general characteristics of protists can be cited without exceptions. In fact, protists exhibit more structural and functional diversity than any other group of eukaryotes.

Most protists are unicellular, although there are some colonial and multicellular species. Single-celled protists are justifiably considered the simplest eukaryotes, but at the cellular level, many protists are very complex—the most elaborate of all cells. In multicellular organisms, essential biological functions are carried out by organs. Unicellular protists carry out the same essential functions, but they do so using subcellular organelles, not multicellular organs. The organelles that protists use are mostly those discussed in Chapter 6, including the nucleus, endoplasmic reticulum, Golgi apparatus, and lysosomes. Certain protists also rely on organelles not found in most other eukaryotic cells, such as contractile vacuoles that pump excess water from the protistan cell (see Figure 7.14).

Protists are more nutritionally diverse than other eukaryote groups. Some protists are photoautotrophs and contain chloroplasts. Some are heterotrophs, absorbing organic molecules or ingesting larger food particles. Still others, called **mixotrophs**, combine photosynthesis *and* heterotrophic nutrition. Photoautotrophy, heterotrophy, and mixotrophy have all arisen independently in many protist lineages.

Reproduction and life cycles also are highly varied among protists. Some protists are exclusively asexual; others can also reproduce sexually or at least employ the sexual processes of meiosis and fertilization. All three basic types of sexual life cycles (see Figure 13.6) are represented among protists, along with some variations that do not quite fit any of these types. We will examine the life cycles of several protist groups later in this chapter.

Endosymbiosis in Eukaryotic Evolution



What gave rise to the enormous diversity of protists that exist today? There is abundant evidence that much of protist diversity has its origins in endosymbiosis, the process in which certain unicellular organisms engulf other cells, which become endosymbionts and ultimately organelles in the host cell. For example, as we discussed in Chapter 25, structural, biochemical, and DNA sequence data indicate that the first eukaryotes acquired mitochondria by engulfing an aerobic prokaryote (specifically, an alpha proteobacterium). The early origin of mitochondria is supported by the fact that all eukaryotes studied so far either have mitochondria or show signs that their ancestors had them.

Much evidence also indicates that later in eukaryotic history, one lineage of heterotrophic eukaryotes acquired an additional endosymbiont—a photosynthetic cyanobacterium—that then evolved into plastids. In the model illustrated in **Figure 28.2**, this plastid-bearing lineage eventually gave rise to red algae and green algae. These hypotheses are supported by the observation that the DNA of plastid genes in red algae and green algae closely resembles the DNA of cyanobacteria. In addition, plastids in red algae and green algae are surrounded by two membranes, which correspond to the inner and outer membranes of the gram-negative cyanobacterial endosymbionts.

On several occasions during eukaryotic evolution, red algae and green algae underwent **secondary endosymbiosis**: They were ingested in the food vacuole of heterotrophic eukaryotes and became endosymbionts themselves. For example, protists known as chlorarachniophytes likely evolved when a heterotrophic eukaryote engulfed a green alga. Biologists infer that this process occurred relatively recently in evolutionary time because the engulfed green alga still carries out photosynthesis with its plastids and contains a tiny vestigial nucleus of its own, called a *nucleomorph*. Consistent with the hypothesis that chlorarachniophytes evolved from a eukaryote that engulfed another eukaryote, their plastids are surrounded by *four* membranes. The two inner membranes originated as the inner and outer membranes of the ancient cyanobacterium. The third membrane is derived from the engulfed alga's plasma membrane, and the outermost membrane is derived from the heterotrophic eukaryote's food vacuole. In other protists, plastids acquired by secondary endosymbiosis are surrounded by three membranes, indicating that one of the original four membranes was lost during the course of evolution.

Five Supergroups of Eukaryotes

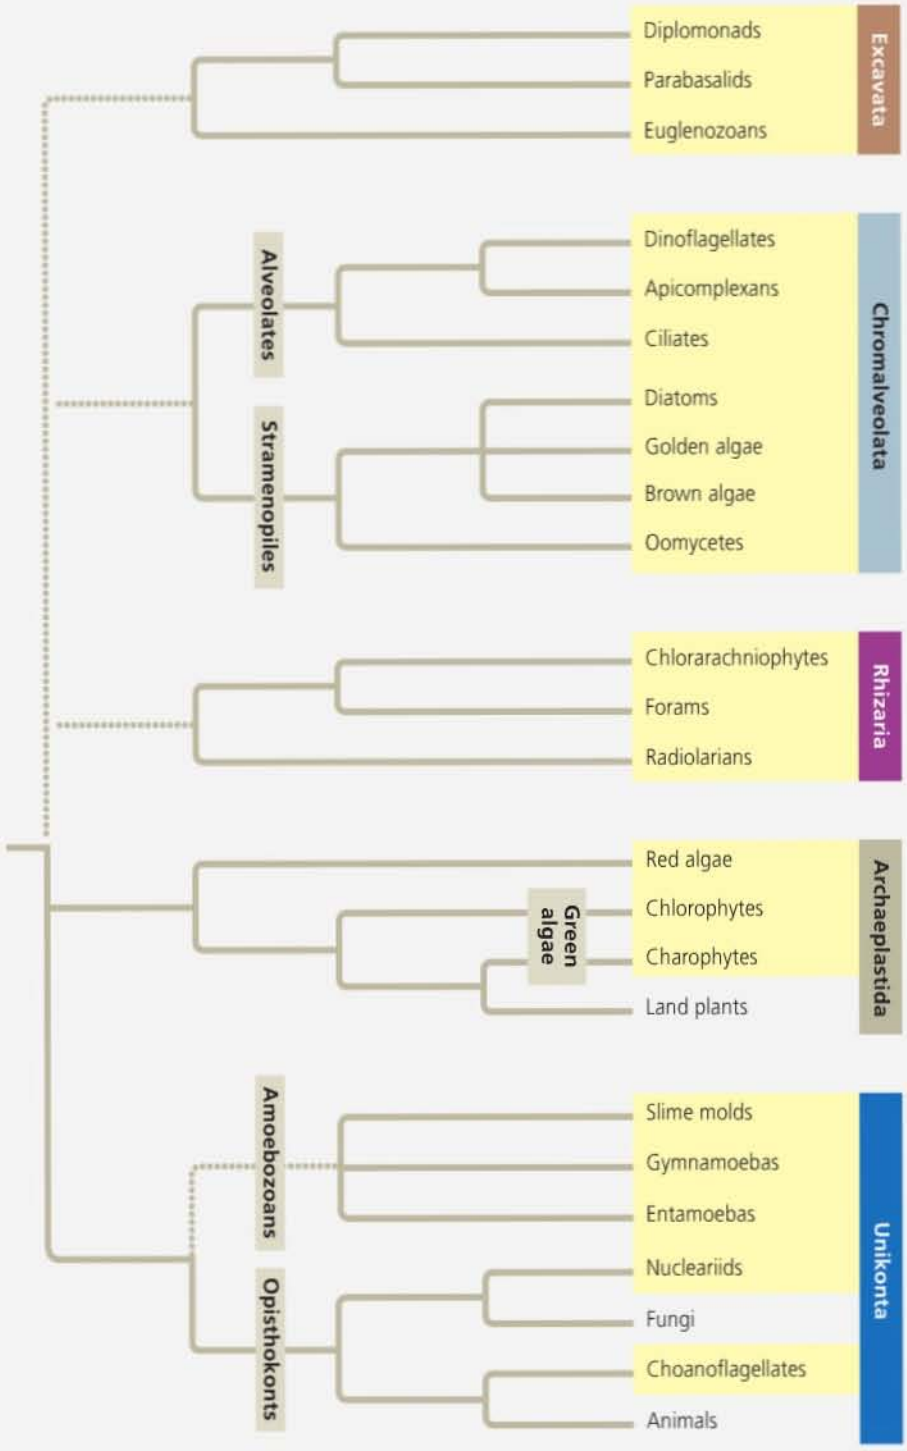
Our understanding of the evolutionary history of protists has been in a state of flux in recent years. Not only has kingdom Protista been abandoned, but a variety of other hypotheses have been discarded as well. For example, in the early 1990s, many biologists thought that the oldest lineage of living eukaryotes were the *amitochondriate protists*, a group lacking conventional mitochondria and having fewer membrane-bounded organelles than other protist groups. But recent structural and DNA data have undermined this hypothesis. Many of the so-called amitochondriate protists have been shown to have mitochondria—though reduced ones—and some of these organisms are now classified in entirely differ-

▲ **Figure 28.2 Diversity of plastids produced by secondary endosymbiosis.** Studies of plastid-bearing eukaryotes suggest that all plastids evolved from a gram-negative cyanobacterium that was engulfed by an ancestral heterotrophic eukaryote (primary endosymbiosis). That ancestor then diversified into red algae and green algae, some of which were subsequently engulfed by other eukaryotes (secondary endosymbiosis).

ent groups. For example, microsporidians, once considered amitochondriate protists, are now classified as fungi.

The ongoing changes in our understanding of the phylogeny of protists pose challenges to students and instructors alike. Hypotheses about these relationships are a hotbed of scientific activity, changing rapidly as new data cause previous ideas to be modified or discarded. In this chapter, our discussion is organized around one current hypothesis: the five supergroups of eukaryotes shown in **Figure 28.3**, on the next two pages. Because the root of the eukaryotic tree is not known, all five supergroups are shown as diverging simultaneously from a common ancestor—something that we know is not correct, but we do not know which organisms were the first to diverge from the others. In addition, bear in mind that while some of the groups in Figure 28.3 are well supported by morphological and DNA data, others are more controversial. As you read this chapter, it may be helpful to focus less on the specific names of groups of organisms and more on why the organisms are important and how ongoing research is designed to elucidate their evolutionary relationships.

CONCEPT CHECK 28.1



1. Cite at least four examples of structural and functional diversity among protists.
2. Summarize the role of endosymbiosis in eukaryotic evolution.
3. **WHAT IF?** After studying Figure 28.3, on the next two pages, draw a simplified version of the phylogenetic tree that shows only the five supergroups of eukaryotes. Now sketch how the tree would look if the unikonts were the first group of eukaryotes to diverge from other eukaryotes.

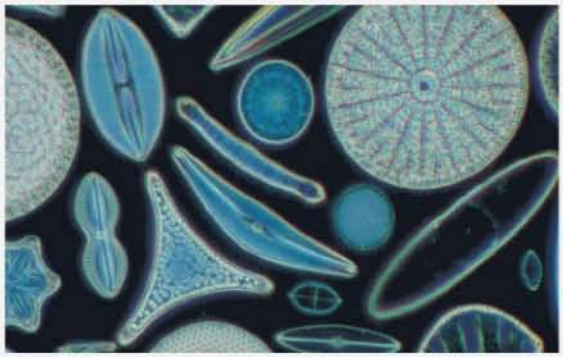
For suggested answers, see Appendix A.

▼ Figure 28.3

Exploring Protistan Diversity

In the phylogenetic hypothesis represented in the tree below, the eukaryote groups at the branch tips are related in larger "supergroups," labeled vertically at the far right of the tree. The kingdoms Plantae (land plants), Fungi, and Animalia (animals) have survived from the five-kingdom system of classification. Groups that were formerly classified in the kingdom Protista are highlighted in yellow. Dotted lines indicate evolutionary relationships that are uncertain or under active debate.

Excavata

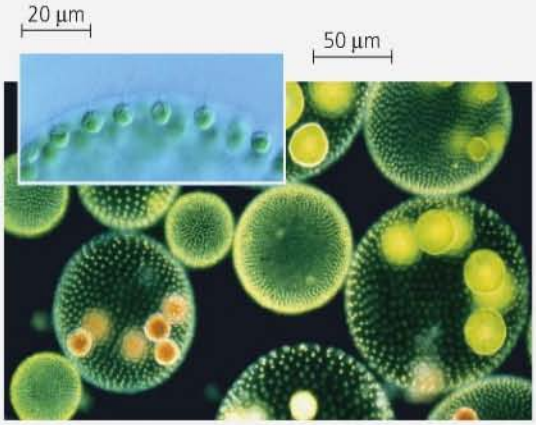


Some members of this supergroup have an "excavated" groove on one side of the cell body. Two major clades (the parabasalids and diplomonads) have modified mitochondria; others (the euglenozoans) have flagella that differ in structure from those of other organisms. Excavates include parasites such as *Giardia*, as well as many predatory and photosynthetic species.

▲ ***Giardia intestinalis*, a diplomonad parasite.** This diplomonad (colorized SEM) can infect people when they drink water contaminated with feces containing the cysts of the parasite. Drinking such water—even from a seemingly pristine stream—can cause severe diarrhea. Boiling the water kills the parasite.

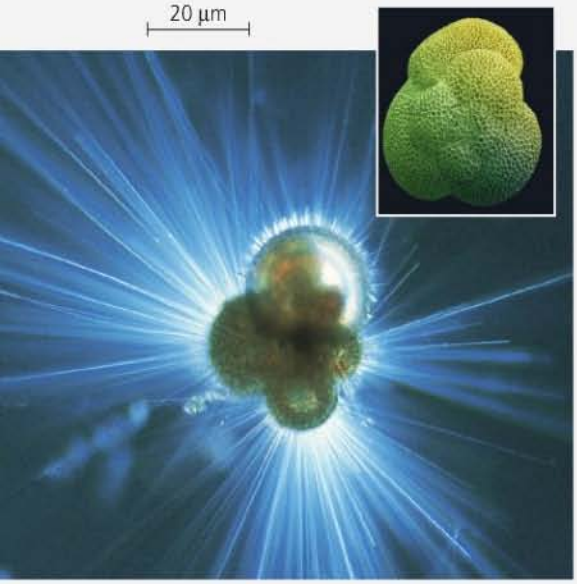
Chromalveolata

This group may have originated by an ancient secondary endosymbiosis event. Chromalveolates include some of the most important photosynthetic organisms on Earth, such as the diatoms shown here. The group also includes the brown algae that form underwater kelp "forests," as well as important pathogens, such as *Plasmodium*, which causes malaria, and *Phytophthora*, which caused the devastating potato famine in 19th-century Ireland.



▶ **Diatom diversity.** These beautiful single-celled protists are important photosynthetic organisms in aquatic communities (LM).

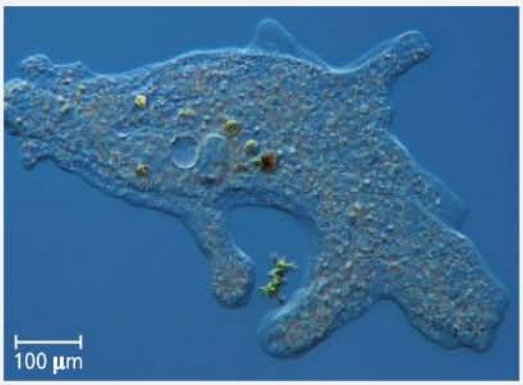
Archaeplastida



This group of eukaryotes includes red algae and green algae, along with land plants (kingdom Plantae, discussed in Chapters 29 and 30). Red algae and green algae include unicellular species, colonial species (such as the green alga *Volvox*), and multicellular species. Many of the large algae known informally as "seaweeds" are multicellular red or green algae. Protists in Archaeplastida include key photosynthetic species that form the base of the food web in some aquatic communities.

▼ ***Volvox*, a colonial freshwater green alga.** The colony is a hollow ball whose wall is composed of hundreds of biflagellated cells (see inset LM) embedded in a gelatinous matrix. The cells are usually connected by cytoplasmic strands; if isolated, these cells cannot reproduce. The large colonies seen here will eventually release the small "daughter" colonies within them (LM).

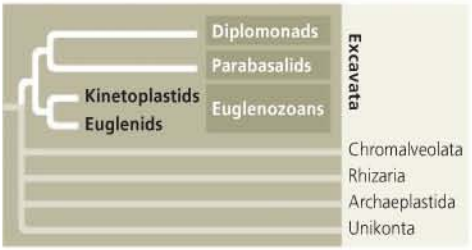
Rhizaria



This group consists of species of amoebas, most of which have pseudopodia that are threadlike in shape. Pseudopodia are extensions that can bulge from any portion of the cell; they are used in movement and in the capture of prey.

▲ ***Globigerina*, a foram in the supergroup Rhizaria.** Threadlike pseudopodia extend through pores in the shell, or test (LM). The inset SEM shows a foram test, which contains calcium carbonate that makes it hard.

Unikonta



This group of eukaryotes includes amoebas that have lobe- or tube-shaped pseudopodia, as well as animals, fungi, and protists that are closely related to animals or fungi. According to one current hypothesis, the unikonts may have been the first group of eukaryotes to diverge from other eukaryotes (see Figure 28.23); however, this hypothesis has yet to be widely accepted.

◀ **A unikont amoeba.** This amoeba (*Amoeba proteus*) is using its pseudopodia to engulf a small green alga.

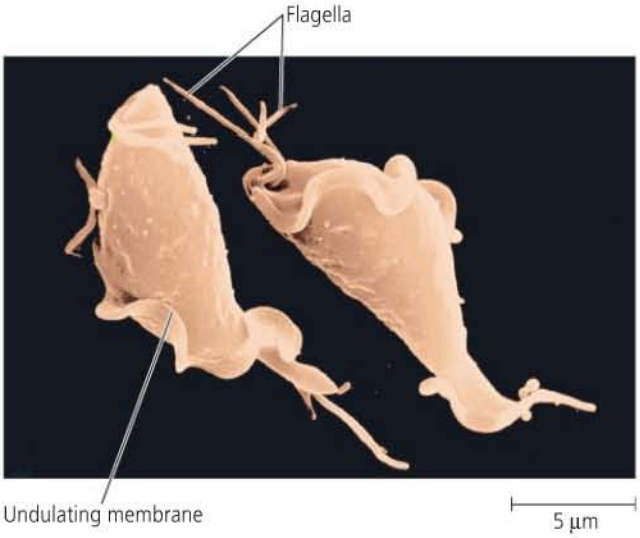
CONCEPT **28.2**

Excavates include protists with modified mitochondria and protists with unique flagella

Now that we have examined some of the broad patterns in eukaryotic evolution, we will look more closely at the five main groups of protists shown in Figure 28.3.

We begin this tour with **Excavata** (the excavates), a recently proposed clade that has emerged from morphological studies of the cytoskeleton. Some members of this diverse group also have an "excavated" feeding groove on one side of the cell body.

The excavates include the diplomonads, the parabasalids, and the euglenozoans. Molecular data indicate that each of these three groups is monophyletic, but the data have neither confirmed nor strongly refuted the monophyly of the excavate supergroup. Although unique cytoskeletal features are shared by many excavates, we cannot yet tell whether that is because the excavates are monophyletic or because the common ancestor of eukaryotes had those features. Overall, support for the excavate clade is relatively weak, making it one of the more controversial of the five supergroups.



Diplomonads and Parabasalids

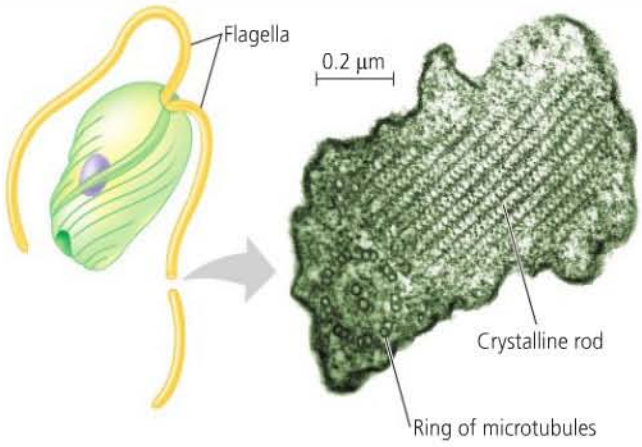
The protists in these two groups lack plastids and have modified mitochondria (until recently, they were thought to lack mitochondria altogether). Most diplomonads and parabasalids are found in anaerobic environments.

Diplomonads have modified mitochondria called *mitosomes*. These organelles lack functional electron transport chains and hence cannot use oxygen to help extract energy from carbohydrates and other organic molecules. Instead, diplomonads get the energy they need from anaerobic biochemical pathways, such as glycolysis (see Chapter 9).

Structurally, diplomonads have two equal-sized nuclei and multiple flagella. Recall that eukaryotic flagella are extensions of the cytoplasm, consisting of bundles of microtubules covered by the cell's plasma membrane (see Figure 6.24). They are quite different from prokaryotic flagella, which are filaments composed of the globular protein flagellin attached to the cell surface (see Figure 27.6).

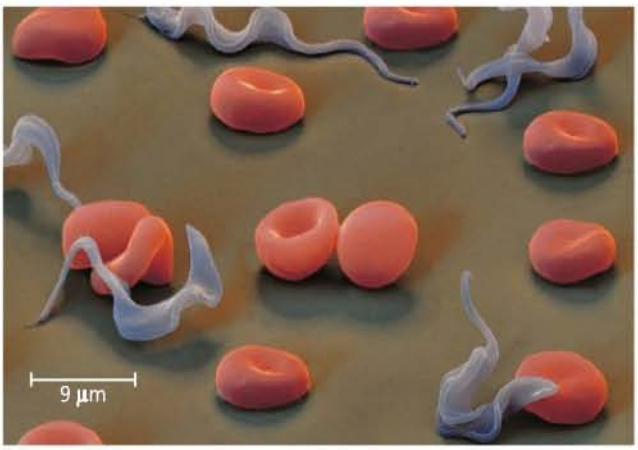
Many diplomonads are parasites. An infamous example is *Giardia intestinalis* (also known as *Giardia lamblia*; see Figure 28.3), which inhabits the intestines of mammals.

▲ **Figure 28.4 The parabasalid *Trichomonas vaginalis*** (colorized SEM).



Parabasalids also have reduced mitochondria; called *hydrogenosomes*, these organelles generate some energy anaerobically, releasing hydrogen gas as a by-product. The best-known parabasalid is *Trichomonas vaginalis*, a sexually transmitted parasite that infects some 5 million people each year. *T. vaginalis* travels along the mucus-coated lining of the human reproductive and urinary tracts by moving its flagella and by undulating part of its plasma membrane **(Figure 28.4)**. In females, if the vagina's normal acidity is disturbed, *T. vaginalis* can outcompete beneficial microorganisms there and infect the vagina. *Trichomonas* infections also can occur in the urethra of males, though often without symptoms. Studies suggest that *T. vaginalis* acquired a particular gene by horizontal gene transfer from bacterial parasites in the vagina. The gene allows *T. vaginalis* to feed on the vaginal lining, aiding the infection process.

Euglenozoans



Protists called **euglenozoans** belong to a diverse clade that includes predatory heterotrophs, photosynthetic autotrophs, and parasites. The main morphological feature that distinguishes protists in this clade is the presence of a spiral or crystalline rod of unknown function inside their flagella **(Figure 28.5)**. The two best-studied groups of euglenozoans are the kinetoplastids and the euglenids.

Kinetoplastids

Protists called **kinetoplastids** have a single, large mitochondrion that contains an organized mass of DNA called a *kinetoplast*. These protists include species that feed on prokaryotes in freshwater, marine, and moist terrestrial ecosystems, as well as species that parasitize animals, plants, and other protists. For example, kinetoplastids in the genus *Trypanosoma* cause sleeping sickness in humans, a neurological disease that is invariably fatal if it is not treated. The trypanosomes infect

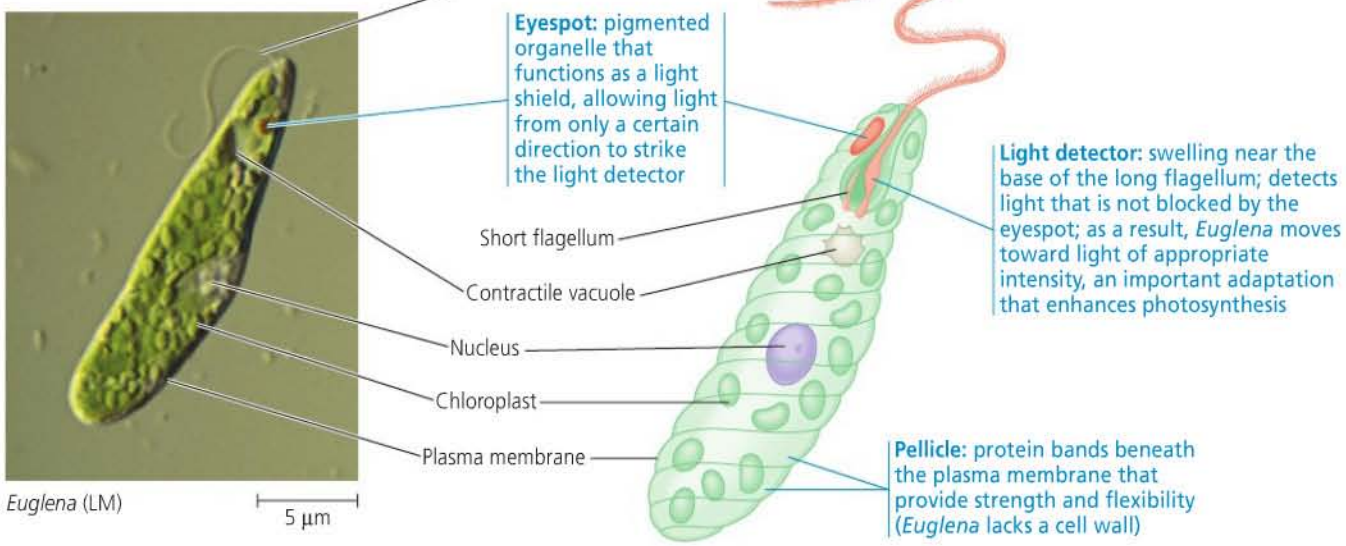
▲ **Figure 28.5 Euglenozoan flagellum.** Most euglenozoans have a crystalline rod inside one of their flagella (the TEM is a flagellum shown in cross section). The rod lies alongside the 9 + 2 ring of microtubules found in all eukaryotic flagella (compare with Figure 6.24).

▲ **Figure 28.6 *Trypanosoma*, the kinetoplastid that causes sleeping sickness.** The purple, ribbon-shaped cells among these red blood cells are the trypanosomes (colorized SEM).

humans via the bite of a vector (carrier) organism, the African tsetse fly **(Figure 28.6)**. Trypanosomes also cause Chagas' disease, which is transmitted by bloodsucking insects and can lead to congestive heart failure.

Trypanosomes evade immune responses with an effective "bait-and-switch" defense. The surface of a trypanosome is coated with millions of copies of a single protein. However, before the host's immune system can recognize the protein and mount an attack, new generations of the parasite switch to another surface protein with a different molecular structure. Frequent changes in the surface protein prevent the host from developing immunity (see Figure 43.25). About a third of *Trypanosoma*'s genome is dedicated to producing these surface proteins.

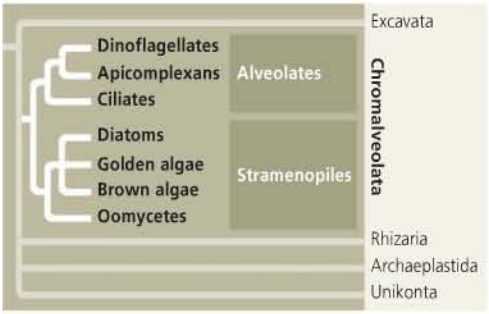
Euglenids



A **euglenid** has a pocket at one end of the cell from which one or two flagella emerge **(Figure 28.7)**. Many species of the euglenid *Euglena* are mixotrophs: In sunlight they are autotrophic, but when sunlight is unavailable, they can become heterotrophic, absorbing organic nutrients from their environment. Many other euglenids engulf prey by phagocytosis.

CONCEPT CHECK 28.2

1. Why do some biologists describe the mitochondria of diplomonads and parabasalids as "highly reduced"?
2. **WHAT IF?** DNA sequence data for a diplomonad, a euglenid, a plant, and an unidentified protist suggest that the unidentified species is most closely related to the diplomonad. Further studies reveal that the unknown species has fully functional mitochondria. Based on these data, at what point on the phylogenetic tree in Figure 28.3 did the mystery protist's lineage probably diverge from other eukaryote lineages? Explain.



For suggested answers, see Appendix A.

▼ **Figure 28.7 *Euglena*, a euglenid commonly found in pond water.**

CONCEPT **28.3**

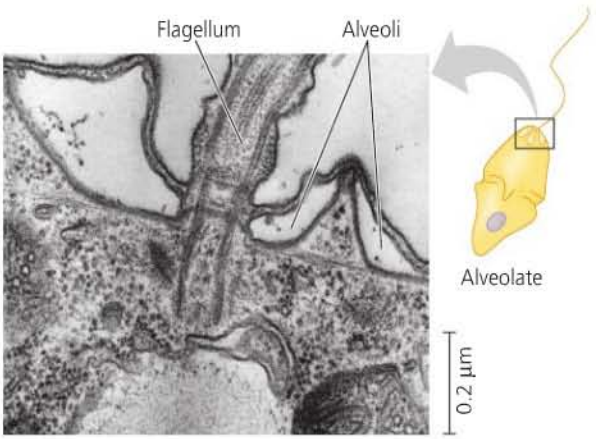
Chromalveolates may have originated by secondary endosymbiosis

The supergroup **Chromalveolata** (the chromalveolates), a large, extremely diverse clade of protists, has recently been proposed based on two lines of evidence. First, some (though not all) DNA sequence data suggest that the chromalveolates form a monophyletic group. Second, some data support the hypothesis that the chromalveolates originated more than a billion years ago, when a common ancestor of the group engulfed a single-celled, photosynthetic red alga. Because red algae are thought to have originated by primary endosymbiosis (see Figure 28.2), such an origin for the chromalveolates is referred to as secondary endosymbiosis.

How strong is the evidence that the chromalveolates originated by secondary endosymbiosis? Many species in the clade have plastids whose structure and DNA indicate that they are of red algal origin. Others have reduced plastids that seem to be derived from a red algal endosymbiont. Still other species lack plastids altogether—yet some of these species have plastid genes in their nuclear DNA. Such data have led researchers to suggest that the common ancestor of the chromalveolates had plastids of red algal origin, but that later, some evolutionary lineages within the group lost the plastids. Others question this idea, noting that the entire genome has been sequenced for several chromalveolates that lack plastids, yet no evidence of plastid genes has been found. Overall, the endosymbiotic origin of the chromalveolates is an interesting current hypothesis—but, like any scientific hypothesis, new data may show it to be incorrect.

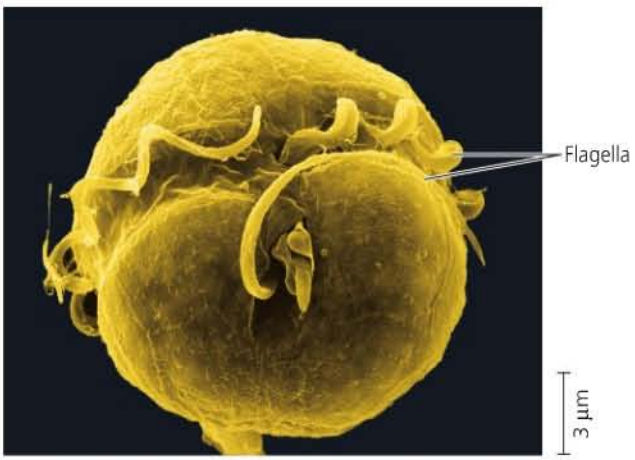
The chromalveolates are perhaps the most controversial of the five supergroups we describe in this chapter. Even so, for many scientists, this supergroup represents the best current hypothesis for the phylogeny of the two large protist clades to which we now turn: the alveolates and the stramenopiles.

Alveolates



The **alveolates** are a group of protists whose monophyly is well supported by molecular systematics. Structurally, species in this group have membrane-bounded sacs (alveoli) just under the plasma membrane (**Figure 28.8**). The function of the alveoli is unknown; researchers hypothesize that they may help stabilize the cell surface or regulate the cell's water and ion content.

The alveolates include three subgroups: a group of flagellates (the dinoflagellates), a group of parasites (the apicomplexans), and a group of protists that move using cilia (the ciliates).



Dinoflagellates

The **dinoflagellates** are characterized by cells that are reinforced by cellulose plates. Two flagella located in perpendicular grooves in this "armor" make dinoflagellates (from the Greek *dinos*, whirling) spin as they move through the water (**Figure 28.9**). Dinoflagellates are abundant components of both marine and freshwater plankton, communities of microorganisms that live near the water's surface. These dinoflagellates include some of the most important photosynthetic species. However, many photosynthetic dinoflagellates are mixotrophic, and roughly half of all dinoflagellates are purely heterotrophic.

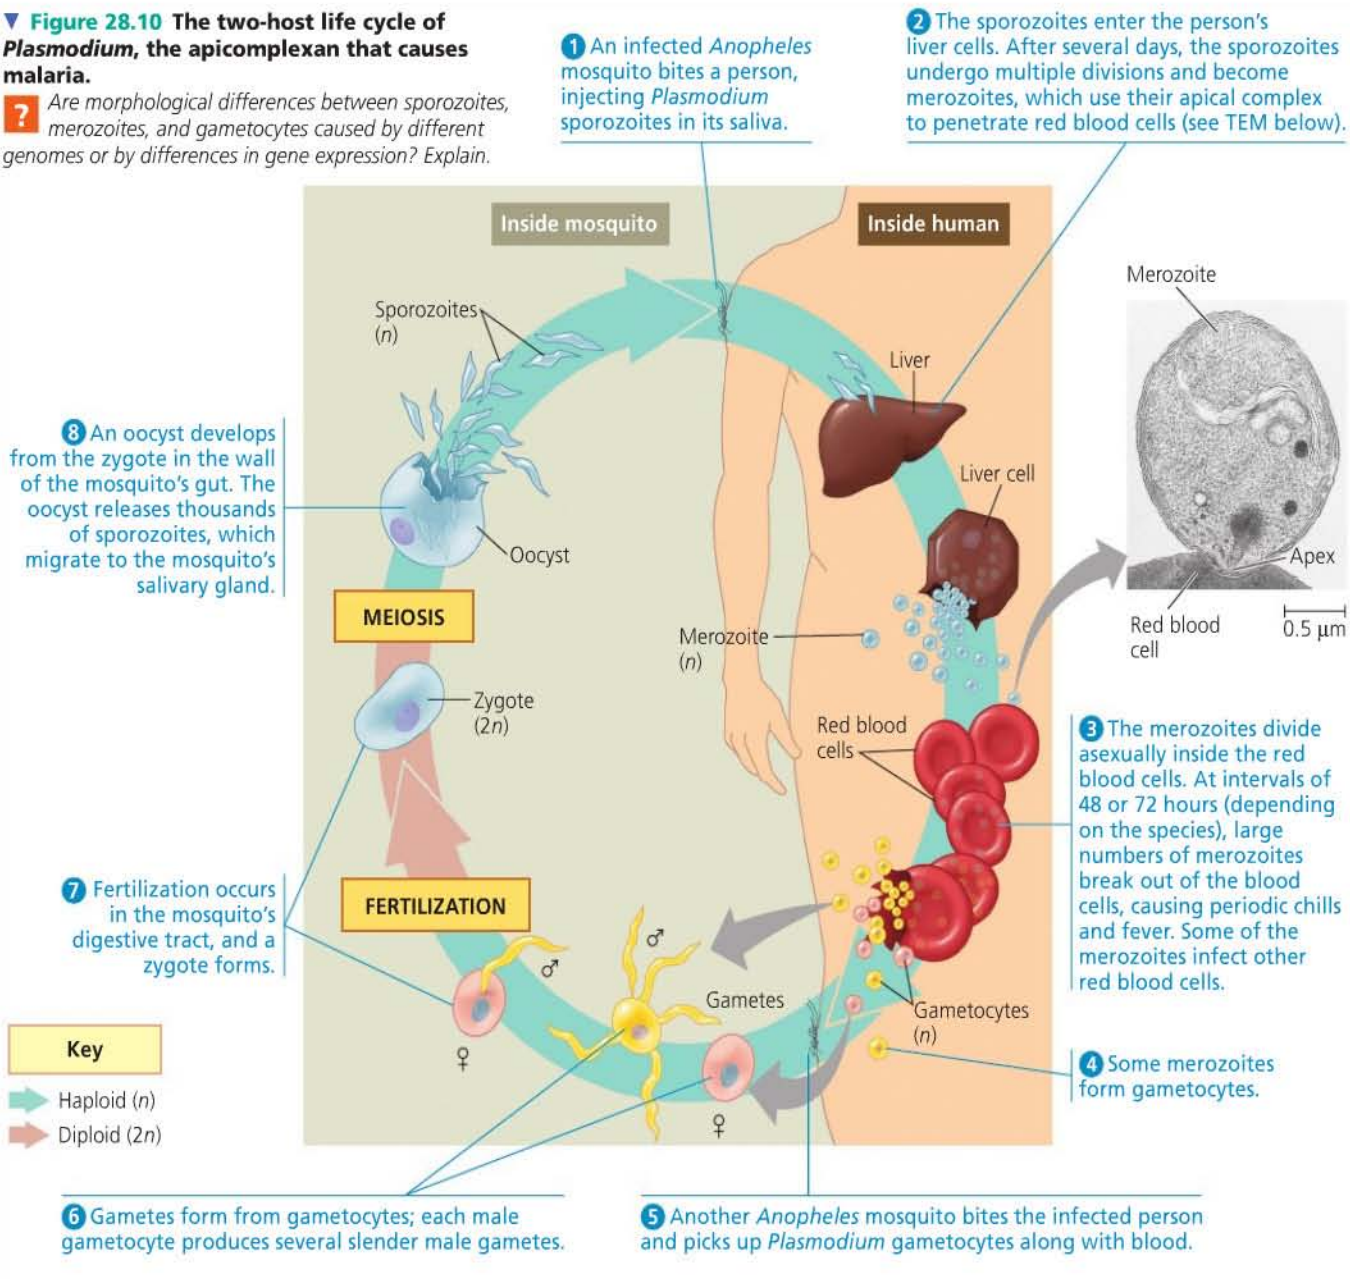
Dinoflagellate blooms—episodes of explosive population growth—sometimes cause a phenomenon called "red tide" in

▲ **Figure 28.8 Alveoli.** These sacs under the plasma membrane are a characteristic that distinguishes alveolates from other eukaryotes (TEM).

▲ **Figure 28.9 *Pfiesteria shumwayae*, a dinoflagellate.** Beating of the spiral flagellum, which lies in a groove that encircles the cell, makes this alveolate spin (colorized SEM).

coastal waters. The blooms appear brownish red or pink because of the presence of carotenoids, the most common pigments in dinoflagellate plastids. Toxins produced by certain dinoflagellates (such as *Karenia brevis,* which inhabits the Gulf of Mexico) have caused massive kills of invertebrates and fishes. Humans who eat molluscs that have accumulated the toxins are affected as well, sometimes fatally.

Apicomplexans



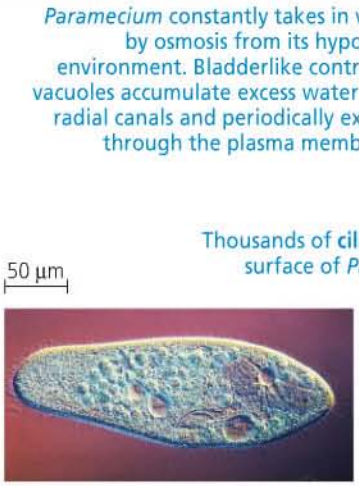
Nearly all **apicomplexans** are parasites of animals, and some cause serious human diseases. The parasites spread through their host as tiny infectious cells called *sporozoites*. Apicomplexans are so named because one end (the *apex*) of the sporozoite cell contains a *complex* of organelles specialized for penetrating host cells and tissues. Although apicomplexans are not photosynthetic, recent data show that they retain a modified plastid (apicoplast), most likely of red algal origin.

Most apicomplexans have intricate life cycles with both sexual and asexual stages. Those life cycles often require two or more host species for completion. For example, *Plasmodium*, the parasite that causes malaria, lives in both mosquitoes and humans **(Figure 28.10)**.

Historically, malaria has rivaled tuberculosis as the leading cause of human death by infectious disease. The incidence of malaria was greatly diminished in the 1960s by insecticides that reduced carrier populations of *Anopheles* mosquitoes and by drugs that killed *Plasmodium* in humans. But the emergence of resistant varieties of both *Anopheles* and *Plasmodium* has led to a resurgence of malaria. About 300 million people in the tropics are now infected, and 2 million die each year.

▼ Figure 28.10 The two-host life cycle of *Plasmodium*, the apicomplexan that causes malaria.

? *Are morphological differences between sporozoites, merozoites, and gametocytes caused by different genomes or by differences in gene expression? Explain.*



The search for malarial vaccines has been hampered by the fact that *Plasmodium* lives mainly inside cells, hidden from the host's immune system. And, like trypanosomes, *Plasmodium* continually changes its surface proteins. The urgent need for treatments inspired an ambitious effort to sequence *Plasmodium*'s genome. Researchers have now tracked the expression of most of the parasite's genes at numerous points in its life cycle. This research could help identify vaccine targets. Antibiotics that target the apicoplast are also in development. This approach may be effective because the apicoplast, being derived by secondary endosymbiosis from a prokaryote, has metabolic pathways different from those in people.

Ciliates

Ciliates are a large, varied group of protists named for their use of cilia to move and feed **(Figure 28.11a)**. The cilia may

▼ **Figure 28.11 Structure and function in the ciliate *Paramecium caudatum*.**

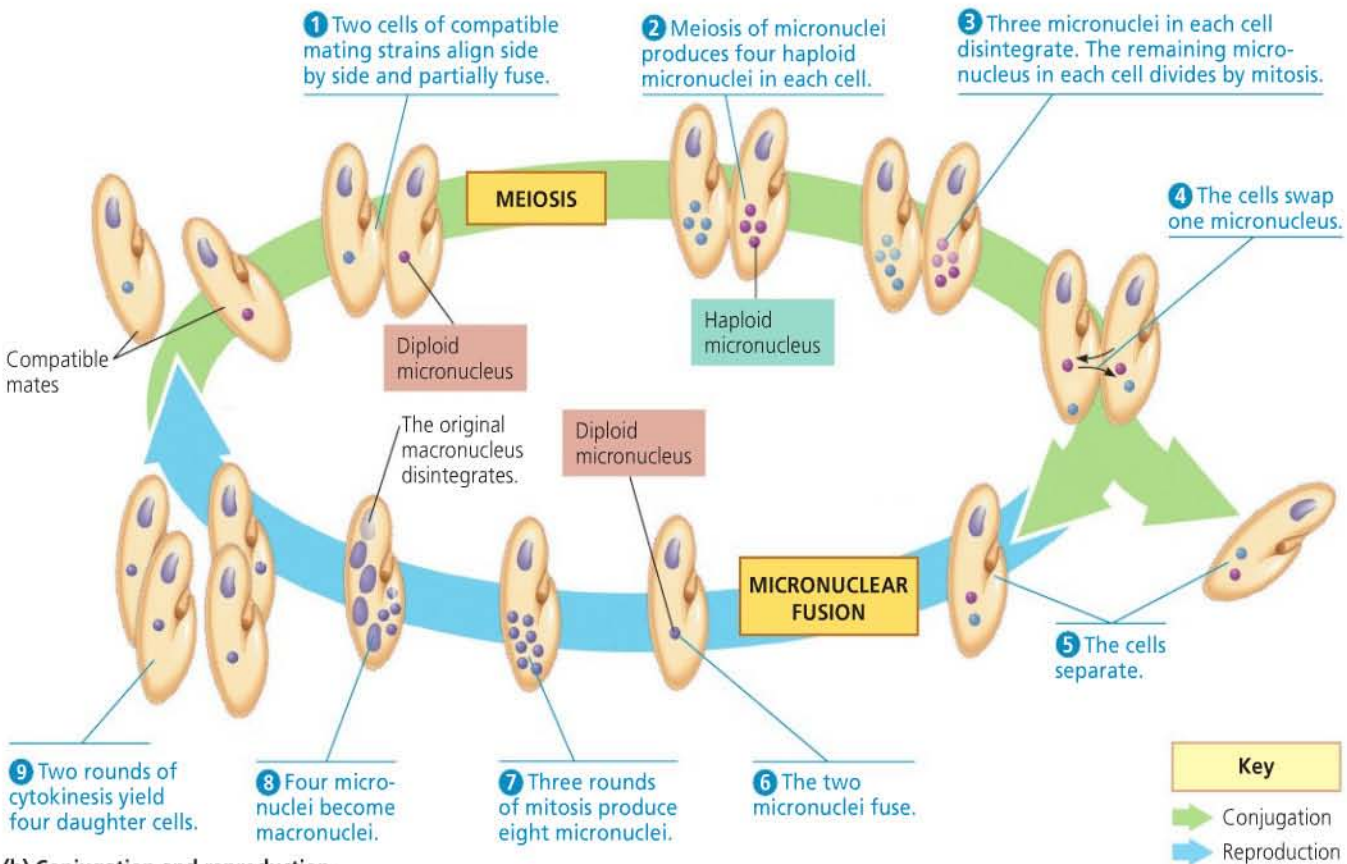
Paramecium constantly takes in water by osmosis from its hypotonic environment. Bladderlike contractile vacuoles accumulate excess water from radial canals and periodically expel it through the plasma membrane.

Contractile vacuole

Cilia along a funnel-shaped oral groove move food (mainly bacteria) into the cell mouth, where the food is engulfed into food vacuoles by phagocytosis.

Oral groove

Cell mouth



Thousands of **cilia** cover the surface of *Paramecium*.

Micronucleus

Macronucleus

Food vacuoles fuse with lysosomes (not shown). As the food is digested, the vacuoles follow a looping path through the cell. Wastes are released when the vacuoles fuse with a specialized region of the plasma membrane that functions as an anal pore.

(a) Feeding, waste removal, and water balance.

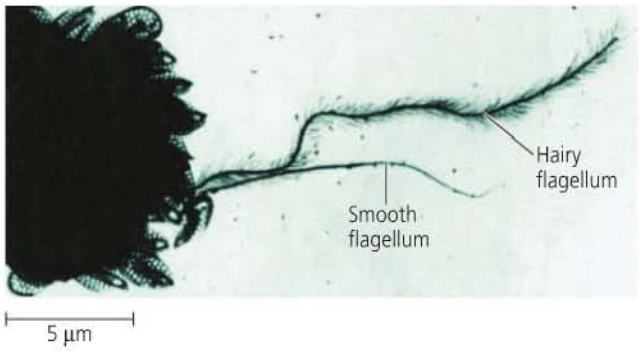
(b) Conjugation and reproduction.

completely cover the cell surface or may be clustered in a few rows or tufts. In certain species, rows of tightly packed cilia function collectively in locomotion. Other ciliates scurry about on leg-like structures constructed from many cilia bonded together.

A distinctive feature of ciliates is the presence of two types of nuclei: tiny micronuclei and large macronuclei. A cell has one or more nuclei of each type. Genetic variation results from conjugation, a sexual process in which two individuals exchange haploid micronuclei **(Figure 28.11b)**. Ciliates generally reproduce asexually by binary fission, during which the existing macronucleus disintegrates and a new one is formed from the cell's micronuclei. Each macronucleus typically contains multiple copies of the ciliate's genome. Genes in the macronucleus control the everyday functions of the cell, such as feeding, waste removal, and maintaining water balance (see Figure 28.11a).

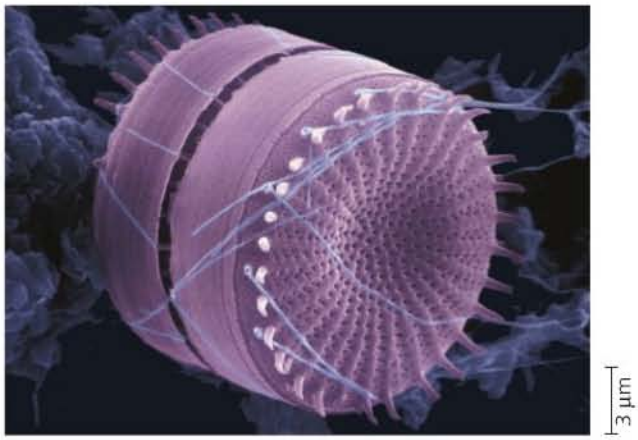
Stramenopiles

The **stramenopiles** are a group of marine algae that include some of the most important photosynthetic organisms on the planet, as well as several clades of heterotrophs. Their name (from the Latin *stramen*, straw, and *pilos*, hair) refers to their characteristic flagellum, which has numerous fine, hairlike projections. In most stramenopiles, this "hairy" flagellum is paired with a shorter "smooth" (nonhairy) flagellum **(Figure 28.12)**.



Diatoms

Diatoms are unicellular algae that have a unique glass-like wall made of hydrated silica (silicon dioxide) embedded in an organic matrix. The wall consists of two parts that overlap like a shoe box and its lid **(Figure 28.13)**. These walls provide effective protection from the crushing jaws of predators: In 2003, researchers in Germany found that live diatoms can withstand pressures as great as 1.4 million kg/m^2, equal to the pressure under each leg of a table supporting an elephant! Much of the diatoms' strength comes from the delicate lacework of holes and grooves in their walls; if the walls were smooth, it would take 60% less force to crush them.



Most of the year, diatoms reproduce asexually by mitosis; each daughter cell receives half of the parental cell wall and generates a new half that fits inside it. Some species form cysts as resistant stages. Sexual reproduction occurs but is not common in diatoms.

With an estimated 100,000 living species, diatoms are a highly diverse group of protists (see Figure 28.3). They are a major component of plankton both in the ocean and in lakes: One bucket of water scooped from the surface of the sea may contain millions of these microscopic algae.

Like golden algae and brown algae, diatoms store energy in the form of a glucose polymer called laminarin. Some diatoms also store energy in oil molecules.

▲ **Figure 28.12 Stramenopile flagella.** Most stramenopiles, such as *Synura petersenii*, have two flagella: one covered with fine, stiff hairs and a shorter one that is smooth.

▲ **Figure 28.13 A freshwater diatom** (colorized SEM).

Massive accumulations of fossilized diatom walls are major constituents of the sediments known as diatomaceous earth, which is mined for its quality as a filtering medium and for many other uses. Diatoms also have an interesting application in the field of nanotechnology—the fashioning of microscopic devices. In building their shells, diatoms perform an intricate, three-dimensional self-assembly of microscopic components. Nanoengineers are studying this process as a model for the manufacture of miniature motors and medicine delivery systems.

Diatom populations may increase rapidly (bloom) when ample nutrients are available. Although typically eaten by a variety of protists and invertebrates, during a bloom many diatoms escape this fate. When diatoms that are not eaten die, their bodies sink to the ocean floor. This sinking process is part of a *biological carbon pump* that begins during photosynthesis when diatoms incorporate carbon into their bodies from carbon dioxide in the air. Diatoms that sink to the ocean floor are not very likely to be broken down by bacteria and other decomposers. Hence, the carbon in their bodies is not returned to the air in the form of carbon dioxide respired by decomposers; instead it is "pumped" to the ocean bottom. With an eye toward reducing global warming by lowering atmospheric carbon dioxide levels, some scientists advocate promoting diatom blooms by

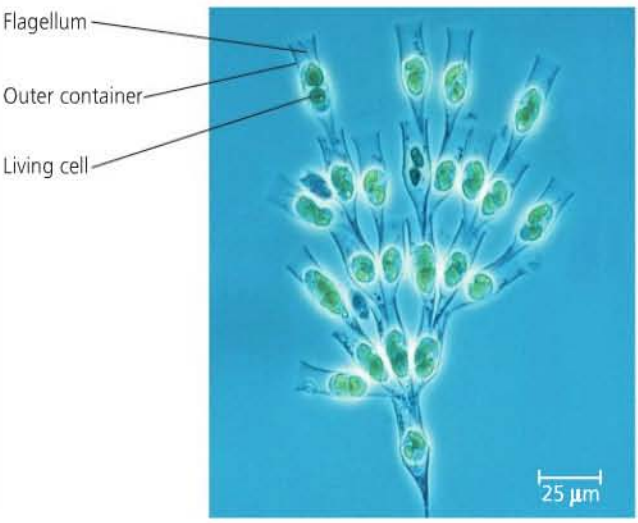
fertilizing the ocean with nutrients such as iron. Other scientists question the wisdom of this strategy, noting that it is difficult to predict the effects of such large-scale manipulations of ecological communities.

Golden Algae

The characteristic color of **golden algae** results from their yellow and brown carotenoids. The cells of golden algae are typically biflagellated, with both flagella attached near one end of the cell.

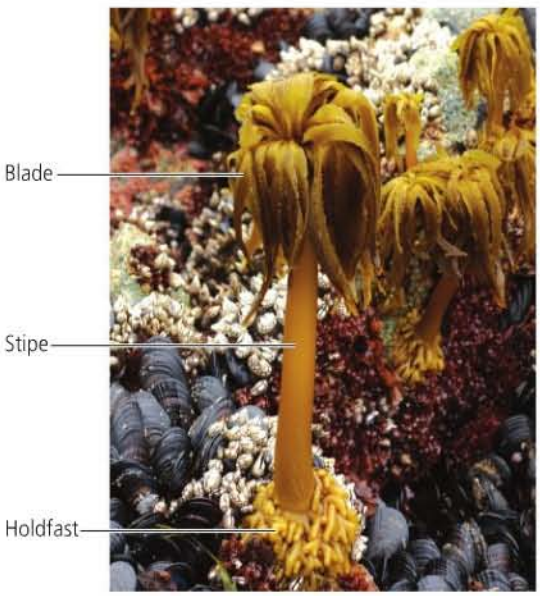
Many golden algae are components of freshwater and marine plankton. While all golden algae are photosynthetic, some species are mixotrophic. These mixotrophs can absorb dissolved organic compounds or ingest food particles, including living cells (eukaryotes and prokaryotes), by phagocytosis. Most species are unicellular, but some, such as those in the freshwater genus *Dinobryon*, are colonial **(Figure 28.14)**. If environmental conditions deteriorate, many species form protective cysts that can survive for decades.

Brown Algae



The largest and most complex algae are **brown algae**. All are multicellular, and most are marine. Brown algae are especially common along temperate coasts, where the water is cool. They owe their characteristic brown or olive color to the carotenoids in their plastids.

Many of the species commonly called "seaweeds" are brown algae. (Some large, multicellular species of red and green algae are also referred to as seaweeds. We will examine them later in this chapter.) Brown algae include species that have the most complex multicellular anatomy of all algae; some even have specialized tissues and organs that resemble those in plants. But morphological and DNA evidence indicates that the similarities evolved independently in the algal and plant lineages and are thus analogous, not homologous.

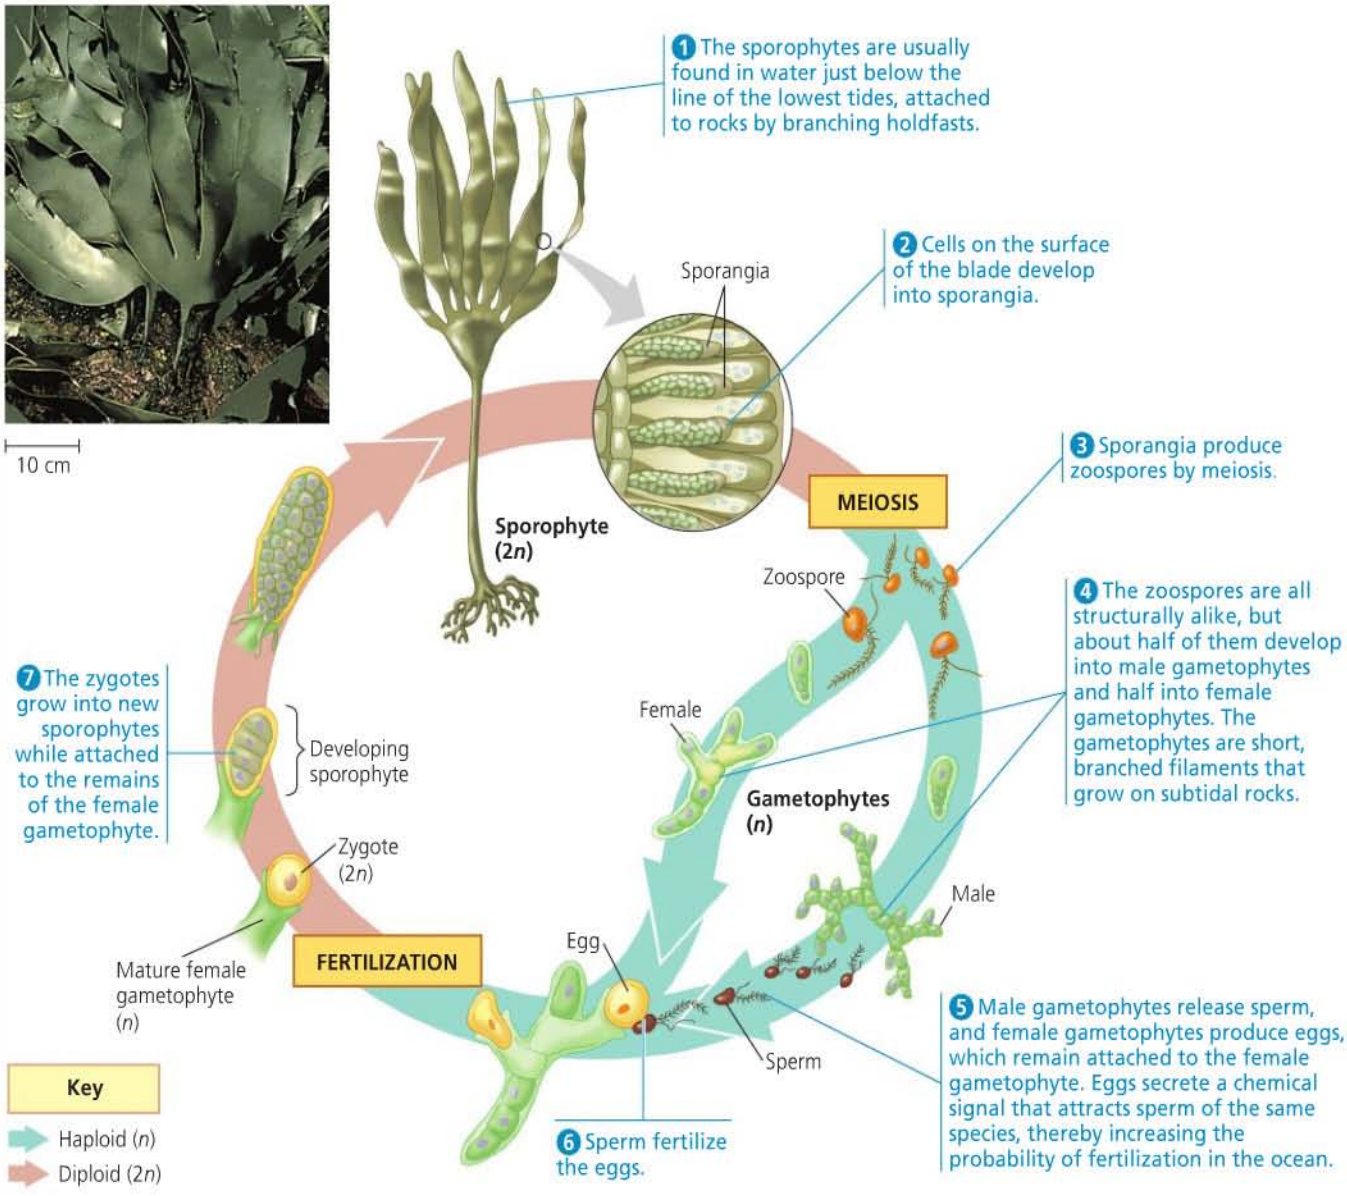


The term **thallus** (plural, *thalli*; from the Greek *thallos*, sprout) refers to an algal body that is plantlike. Unlike the body of a plant, however, a thallus lacks true roots, stems, and leaves. A typical thallus consists of a rootlike **holdfast**, which anchors the alga, and a stemlike **stipe**, which supports leaflike **blades (Figure 28.15)**. The blades provide most of the alga's photosynthetic surface. Some brown algae are equipped with gas-filled, bubble-shaped floats, which help keep the blades up near the water surface. Beyond the intertidal zone in deeper waters live giant seaweeds known as kelps. The stipes of these brown algae may be as long as 60 m—more than half the length of a football field.

Brown algae that inhabit the intertidal zone must cope with water churned by waves and wind, along with low tides that expose the algae to the drying atmosphere and intense rays of the sun. Unique adaptations enable these seaweeds to survive. For example, their cell walls are composed of cellulose and gel-forming polysaccharides that help cushion the thalli from waves and reduce drying when the algae are exposed.

Brown algae are important commodities for humans. Some species are eaten, including *Laminaria* (Japanese "kombu"), which is used in soups. In addition, the gel-forming substance in the cell walls of brown algae, called algin, is used to thicken many processed foods, including pudding, ice cream, and salad dressing.

▲ **Figure 28.14** ***Dinobryon*, a colonial golden alga found in fresh water** (LM).



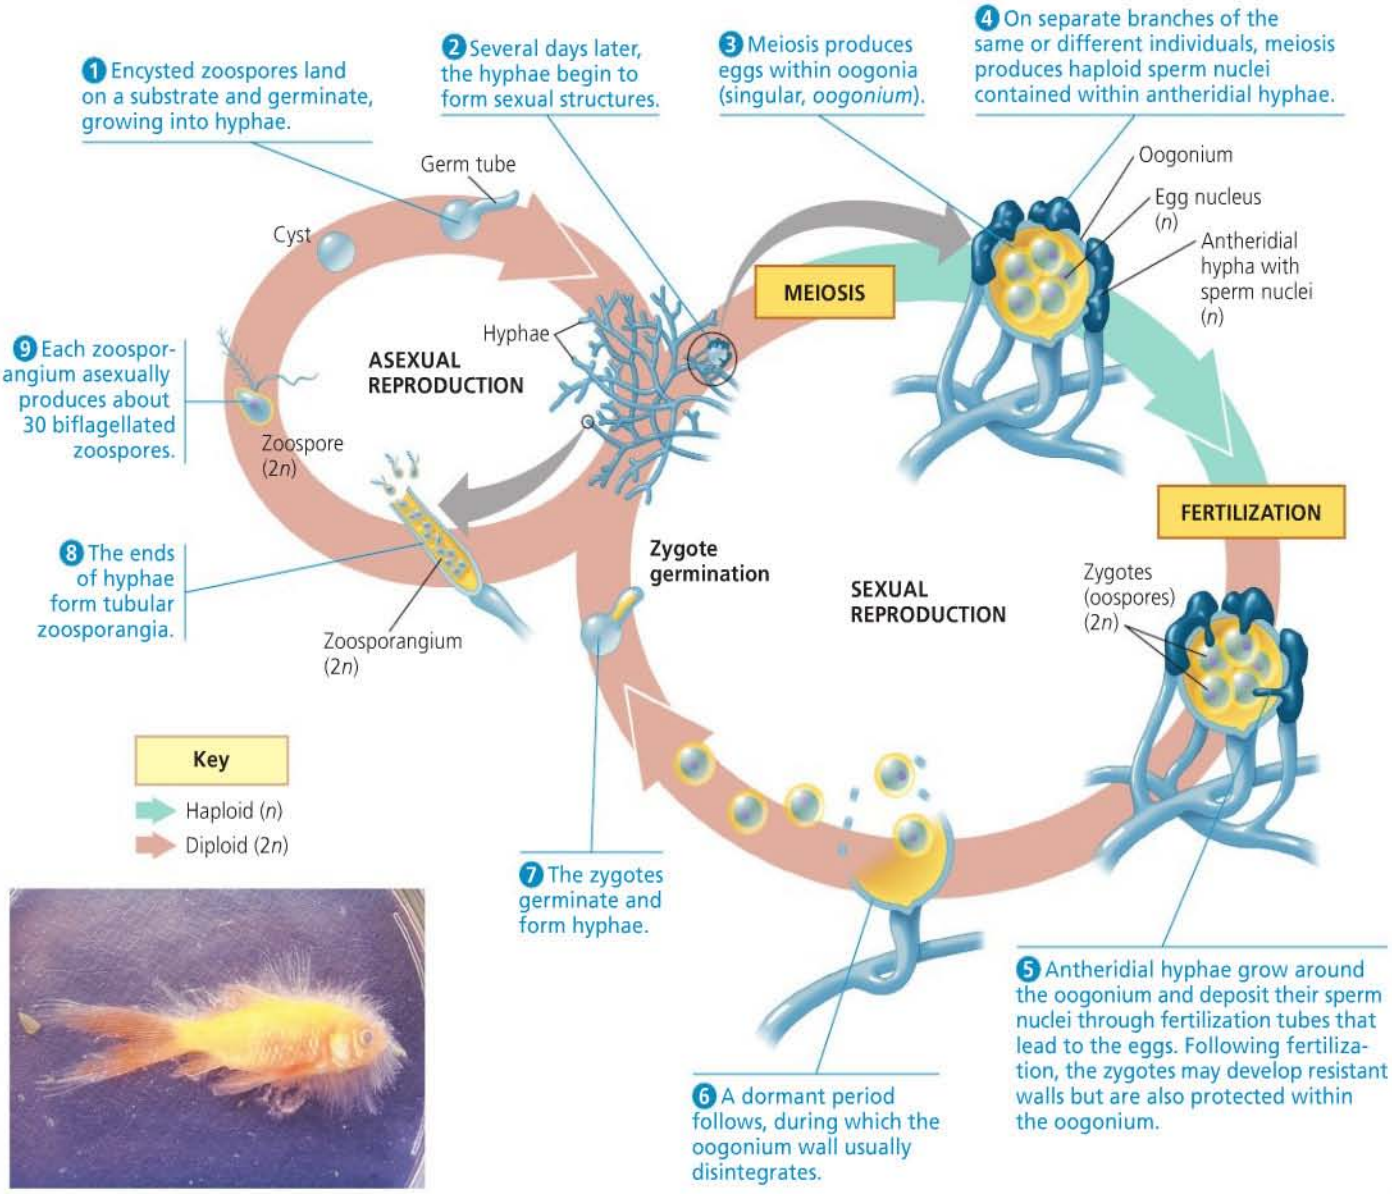
▲ **Figure 28.15 Seaweeds: adapted to life at the ocean's margins.** The sea palm (*Postelsia*) lives on rocks along the coast of the northwestern United States and western Canada. The thallus of this brown alga is well adapted to maintaining a firm foothold despite the crashing surf.

Alternation of Generations

A variety of life cycles have evolved among the multicellular algae. The most complex life cycles include an **alternation of generations**, the alternation of multicellular haploid and diploid forms. Although haploid and diploid conditions alternate in *all* sexual life cycles—human gametes, for example, are haploid—the term *alternation of generations* applies only to life cycles in which both haploid and diploid stages are multicellular. As you will read in Chapter 29, alternation of generations also evolved in plants.

The complex life cycle of the brown alga *Laminaria* provides an example of alternation of generations **(Figure 28.16)**. The diploid individual is called the sporophyte because it produces spores. The spores are haploid and move by means of flagella; the flagellated spores are called *zoospores*. The zoospores develop into haploid male and female gametophytes, which produce gametes. The union of two gametes (fertilization, or syngamy) results in a diploid zygote, which matures and gives rise to a new sporophyte.

In *Laminaria*, the two generations are **heteromorphic**, meaning that the sporophytes and gametophytes are structurally different. Other algal life cycles have an alternation of **isomorphic** generations, in which the sporophytes and gametophytes look similar to each other, although they differ in chromosome number.



▲ **Figure 28.16 The life cycle of the brown alga *Laminaria*: an example of alternation of generations.**

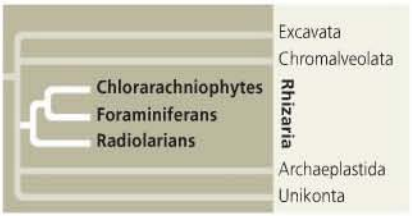
Oomycetes (Water Molds and Their Relatives)

Oomycetes include the water molds, the white rusts, and the downy mildews. Based on their morphology, these organisms were previously classified as fungi (in fact, *oomycete* means "egg fungus"). For example, many oomycetes have multinucleate filaments (hyphae) that resemble fungal hyphae **(Figure 28.17)**. However, there are many differences between oomycetes and fungi. Among the differences, oomycetes typically have cell walls made of cellulose, whereas the walls of fungi consist mainly of another polysaccharide, chitin. Data from molecular systematics have confirmed that oomycetes are not closely related to fungi. Their superficial similarity is a case of convergent evolution. In both oomycetes and fungi, the high surface-to-volume ratio of filamentous structures enhances the uptake of nutrients from the environment.

Although oomycetes descended from plastid-bearing ancestors, they no longer have plastids and do not perform photosynthesis. Instead, they typically acquire nutrients as decomposers or parasites. Most water molds are decomposers that grow as cottony masses on dead algae and animals, mainly in freshwater habitats (see Figure 28.17). White rusts and downy mildews generally live on land as plant parasites.

The ecological impact of oomycetes can be significant. For example, the oomycete *Phytophthora infestans* causes potato late blight, which turns the stalk and stem of potato plants to black slime. Late blight contributed to the devastating Irish famine of the 19th century, in which a million people died and at least that many were forced to leave Ireland. The disease remains a major problem today, causing crop losses of typically 15% in North America and as high as 70% in some parts of Russia where farmers cannot afford pesticides.

▲ **Figure 28.17 The life cycle of a water mold.** Water molds help decompose dead insects, fishes, and other animals in fresh water. (Note the hyphal mass growing on the goldfish in the inset.)



To understand this pathogen better, molecular biologists have isolated DNA from a specimen of *P. infestans* preserved from the Irish potato blight of the 1840s. Genetic studies show that in recent decades, the oomycete has acquired genes that make it more aggressive and more resistant to pesticides. Scientists are looking within the genomes of both *Phytophthora* and potatoes to identify new weapons against the disease. In 2003, for example, a team of researchers engineered domestic potatoes that were resistant to late blight by transferring genes from a blight-resistant strain of wild potato.

CONCEPT CHECK 28.3

1. Summarize the evidence for and against the hypothesis that the species currently classified as chromalveolates are members of a single clade.
2. Looking back to Chapter 13, which of the three life cycles in Figure 13.6 exhibits alternation of generations? How does it differ from the other two?
3. **WHAT IF?** Would you expect the plastid DNA of photosynthetic dinoflagellates, diatoms, and golden algae to be more similar to the nuclear DNA of plants (domain Eukarya) or to the chromosomal DNA of cyanobacteria (domain Bacteria)? Explain.

For suggested answers, see Appendix A.

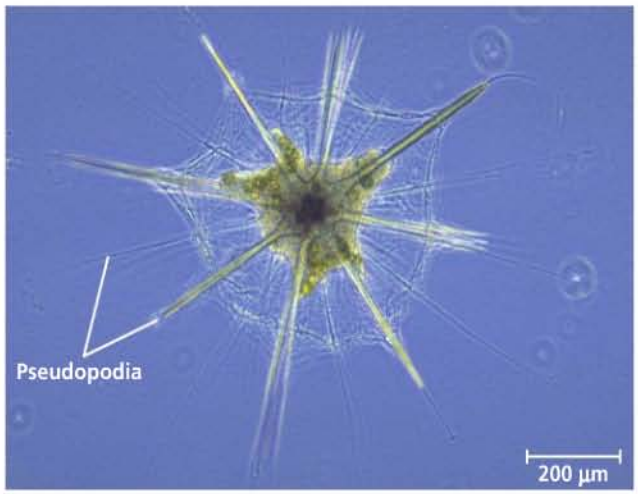
CONCEPT 28.4
Rhizarians are a diverse group of protists defined by DNA similarities

The clade **Rhizaria** has recently been proposed based on results from molecular systematics. Although its members vary greatly in morphology, DNA evidence suggests that rhizarians are a monophyletic group.

Many species in Rhizaria are among the organisms referred to as amoebas. **Amoebas** were formerly defined as protists that move and feed by means of **pseudopodia**, extensions that may bulge from almost anywhere on the cell surface. An amoeba moves by extending a pseudopodium and anchoring the tip; more cytoplasm then streams into the pseudopodium. However, based on molecular systematics, it is now clear that amoebas do not constitute a monophyletic group but are dispersed across many distantly related eukaryotic taxa. Most of those that belong to the clade Rhizaria are distinguished morphologically from other amoebas by having threadlike pseudopodia.

Rhizarians include chlorarachniophytes (mentioned earlier in the discussion of secondary endosymbiosis), and two larger groups we'll examine here: forams and radiolarians.

Forams



The protists called **foraminiferans** (from the Latin *foramen*, little hole, and *ferre*, to bear), or **forams**, are named for their porous shells, called **tests** (see Figure 28.3). Foram tests consist of a single piece of organic material hardened with calcium carbonate. The pseudopodia that extend through the pores function in swimming, test formation, and feeding. Many forams also derive nourishment from the photosynthesis of symbiotic algae that live within the tests.

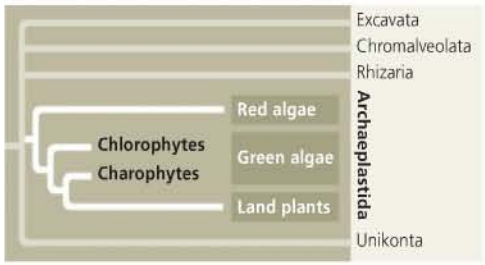
Forams are found in both the ocean and fresh water. Most species live in sand or attach themselves to rocks or algae, but some are abundant in plankton. The largest forams, though single-celled, grow to a diameter of several centimeters.

Ninety percent of all identified species of forams are known from fossils. Along with the calcium-containing remains of other protists, the fossilized tests of forams are part of marine sediments, including sedimentary rocks that are now land formations. Foram fossils are excellent markers for correlating the ages of sedimentary rocks in different parts of the world.

Radiolarians

The protists called **radiolarians** have delicate, intricately symmetrical internal skeletons that are generally made of silica. The pseudopodia of these mostly marine protists radiate from the central body **(Figure 28.18)** and are reinforced by bundles of microtubules. The microtubules are covered by a

▲ **Figure 28.18 A radiolarian.** Numerous threadlike pseudopodia radiate from the central body of this radiolarian, which is found in the Red Sea (LM).



thin layer of cytoplasm, which engulfs smaller microorganisms that become attached to the pseudopodia. Cytoplasmic streaming then carries the captured prey into the main part of the cell. After radiolarians die, their skeletons settle to the seafloor, where they have accumulated as an ooze that is hundreds of meters thick in some locations.

CONCEPT CHECK 28.4

1. Explain why forams have such a well-preserved fossil record.
2. **WHAT IF?** DNA evidence suggests that a newly discovered amoeba is in the clade Rhizaria—yet its morphology is more similar to amoebas in other eukaryotic groups. Suggest an explanation that could account for these conflicting observations.

For suggested answers, see Appendix A.

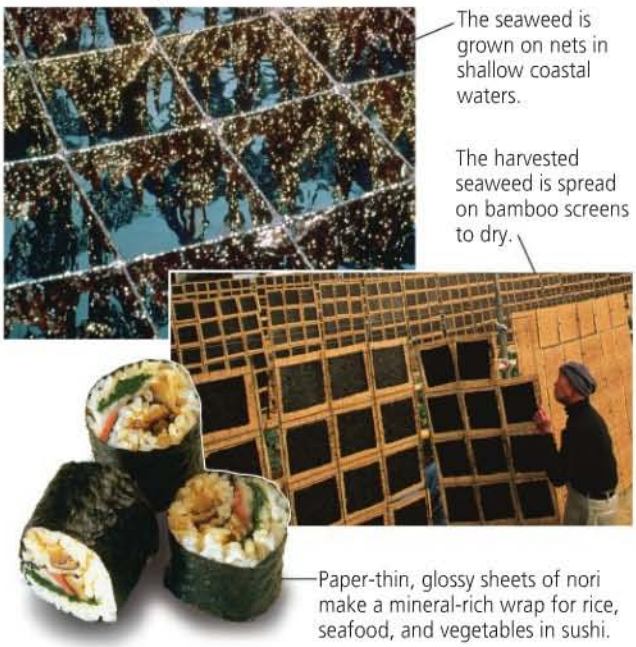
CONCEPT 28.5
Red algae and green algae are the closest relatives of land plants

As we described in Chapter 25, molecular systematics and studies of cell structure support the following scenario: More than a billion years ago, a heterotrophic protist acquired a cyanobacterial endosymbiont, and the photosynthetic descendants of this ancient protist evolved into red algae and green algae. At least 475 million years ago, the lineage that produced green algae gave rise to land plants. Together, red algae, green algae, and land plants make up the fourth eukaryotic supergroup, which is called **Archaeplastida**. Archaeplastida is a monophyletic group that descended from the ancient protist that engulfed a cyanobacterium. We will examine land plants in Chapters 29 and 30; here we will look at the diversity of their closest algal relatives, red algae and green algae.

Red Algae

Many of the 6,000 known species of **red algae** (rhodophytes, from the Greek *rhodos*, red) are reddish, owing to a photosynthetic accessory pigment called phycoerythrin, which masks the green of chlorophyll **(Figure 28.19)**. However, species adapted to more shallow water have less phycoerythrin. As a result, red algal species may be greenish red in very shallow water, bright red at moderate depths, and almost black in deep water. Some species lack pigmentation altogether and function heterotrophically as parasites on other red algae.

Red algae are the most abundant large algae in the warm coastal waters of tropical oceans. Their accessory pigments allow them to absorb blue and green light, which penetrate relatively far into the water. A species of red alga has been discovered living



▶ ***Bonnemaisonia hamifera*.** This red alga has a filamentous form.

◀ **Dulse (*Palmaria palmata*).** This edible species has a "leafy" form.

▼ **Nori.** The red alga *Porphyra* is the source of a traditional Japanese food.

▲ **Figure 28.19 Red algae.**

near the Bahamas at a depth of more than 260 m. There are also a small number of freshwater and terrestrial species.

Most red algae are multicellular. Although none are as big as the giant brown kelps, the largest multicellular red algae are included in the informal designation "seaweeds." You may have eaten one of these multicellular red algae, *Porphyra* (Japanese "nori"), as crispy sheets or as a wrap for sushi (see Figure 28.19). The thalli of many red algae are filamentous, often branched and interwoven in lacy patterns. The base of the thallus is usually differentiated as a simple holdfast.

Red algae have especially diverse life cycles, and alternation of generations is common. But unlike other algae, they have no flagellated stages in their life cycle and depend on water currents to bring gametes together for fertilization.

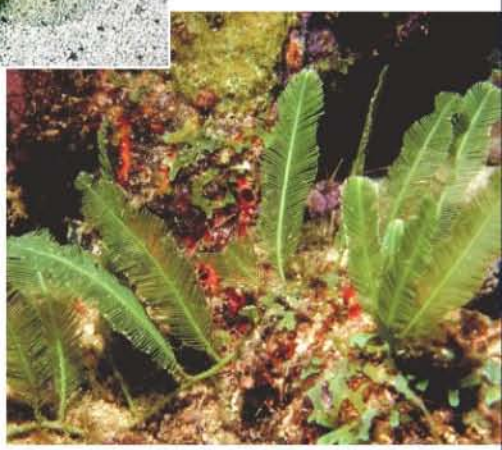
Green Algae

The grass-green chloroplasts of **green algae** have an ultrastructure and pigment composition much like the chloroplasts of land plants. Molecular systematics and cellular morphology leave little doubt that green algae and land plants are closely related. In fact, some systematists now advocate including green algae in an expanded "plant" kingdom, Viridiplantae (from the Latin *viridis*, green). Phylogenetically, this change makes sense, since otherwise the green algae are a paraphyletic group.

Green algae are divided into two main groups, chlorophytes (from the Greek *chloros*, green) and charophytes. More than 7,000 species of chlorophytes have been identified. Most live in fresh water, but there are also many marine and some terrestrial species. The simplest chlorophytes are unicellular organisms such as *Chlamydomonas*, which resemble the gametes and zoospores of more complex chlorophytes. Various species of unicellular chlorophytes exist as plankton or inhabit damp soil. Some live symbiotically within other eukaryotes, contributing part of their photosynthetic output to the food supply of their hosts. Some chlorophytes have even adapted to one of the last habitats you might expect to find them: snow. For example, *Chlamydomonas nivalis* can form dense algal blooms on high-altitude glaciers and snowfields, where its reddish pigments produce an effect known as "watermelon snow" **(Figure 28.20)**. These chlorophytes carry out photosynthesis despite subfreezing temperatures and intense visible and ultraviolet radiation. They are protected by the snow itself, which acts as a shield, and by radiation-blocking compounds in their cytoplasm. Other chlorophytes contain similar protective compounds in their cell wall or in a durable coat that surrounds the zygote.

Larger size and greater complexity evolved in chlorophytes by three different mechanisms:

1. The formation of colonies of individual cells, as seen in *Volvox* (see Figure 28.3) and in filamentous forms that contribute to the stringy masses known as pond scum
2. The formation of true multicellular bodies by cell division and differentiation, as seen in the seaweed *Ulva* **(Figure 28.21a)**
3. The repeated division of nuclei with no cytoplasmic division, as seen in the multinucleate filaments of *Caulerpa* **(Figure 28.21b)**



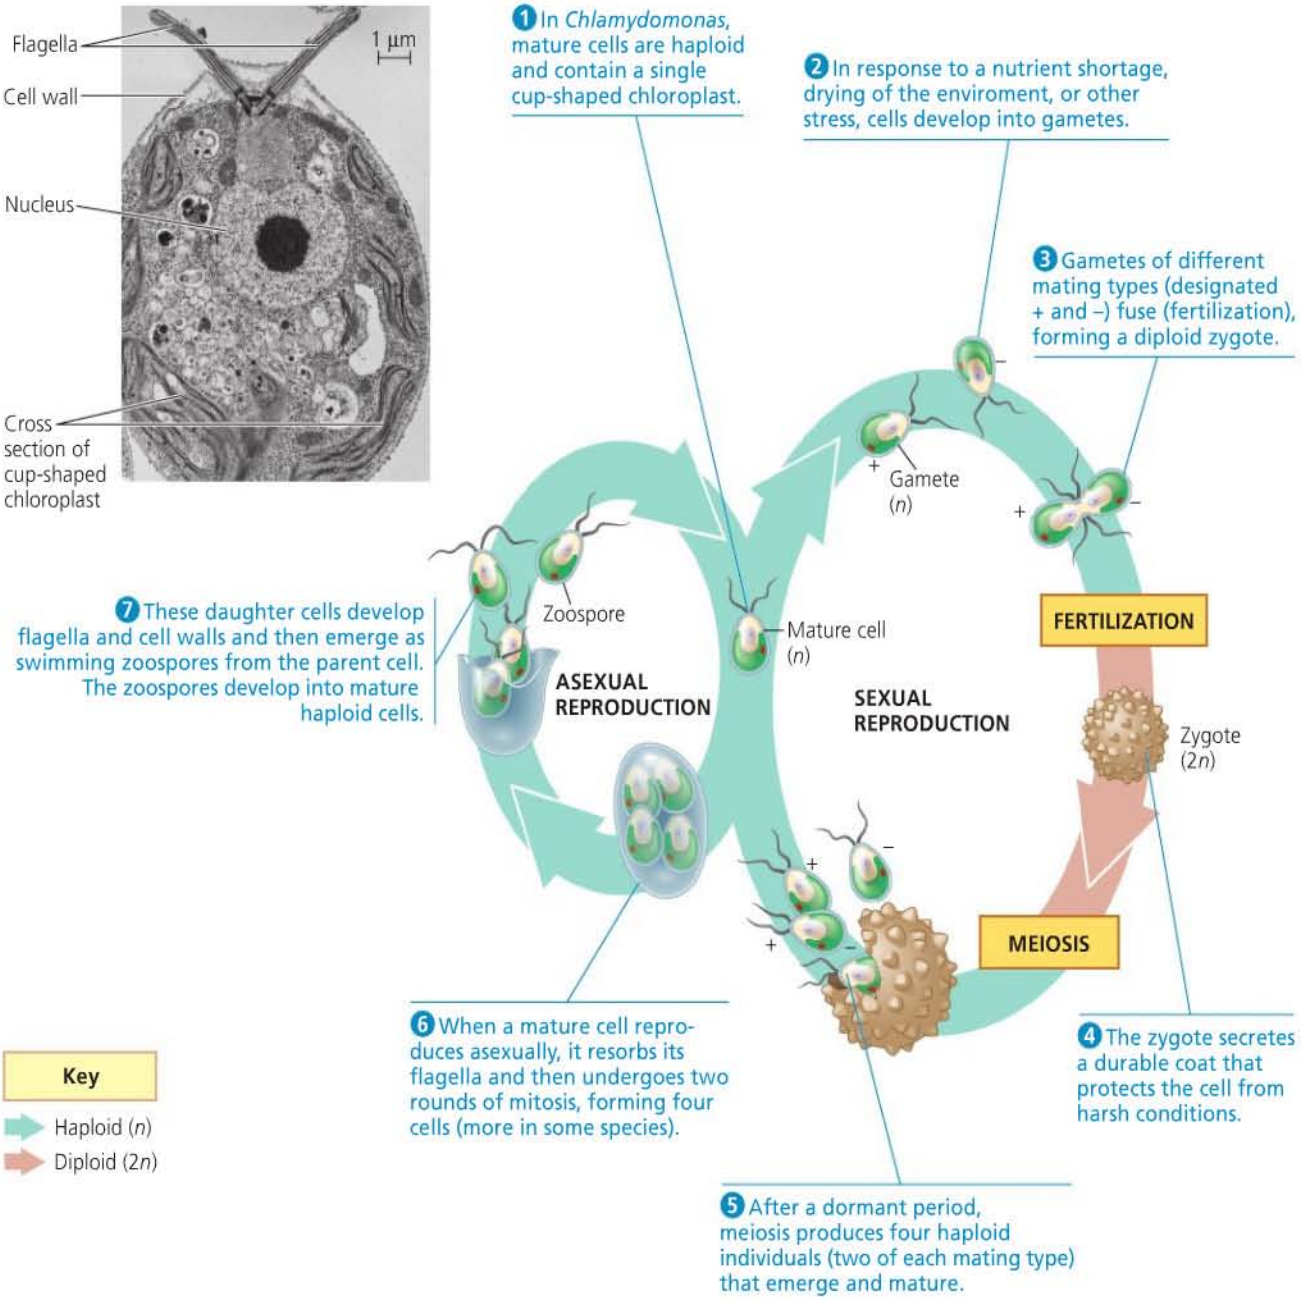
◀ **Figure 28.20 Watermelon snow.** Carotenoid pigments in some snow-dwelling chlorophytes, such as *Chlamydomonas nivalis*, turn the snow red.

2 cm

(a) *Ulva*, or sea lettuce. This edible seaweed has a multicellular thallus differentiated into leaflike blades. Its rootlike holdfast anchors the alga against turbulent waves and tides.

(b) *Caulerpa*, an intertidal chlorophyte. The branched filaments lack cross-walls and thus are multinucleate. In effect, the thallus is one huge "supercell."

▲ **Figure 28.21 Multicellular chlorophytes.**



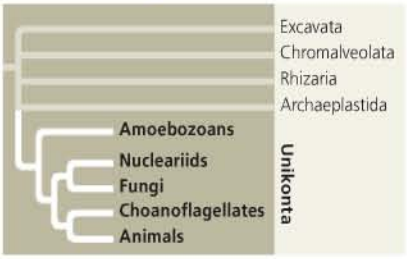
Most chlorophytes have complex life cycles, with both sexual and asexual reproductive stages. Nearly all species of chlorophytes reproduce sexually by means of biflagellated gametes that have cup-shaped chloroplasts **(Figure 28.22)**. Alternation of generations has evolved in the life cycles of chlorophytes, including *Ulva*, in which the alternate generations are isomorphic.

The other main group of green algae, the charophytes, are the algae most closely related to land plants. For that reason, we will discuss them along with plants in Chapter 29.

CONCEPT CHECK 28.5

1. Identify two ways in which red algae differ from brown algae.
2. Why is it accurate to say that *Ulva* has true multicellularity but *Caulerpa* does not?
3. **WHAT IF?** Suggest a possible reason why species in the green algal lineage were more likely to colonize land than species in the red algal lineage.

For suggested answers, see Appendix A.



▲ **Figure 28.22 The life cycle of *Chlamydomonas*, a unicellular chlorophyte.**

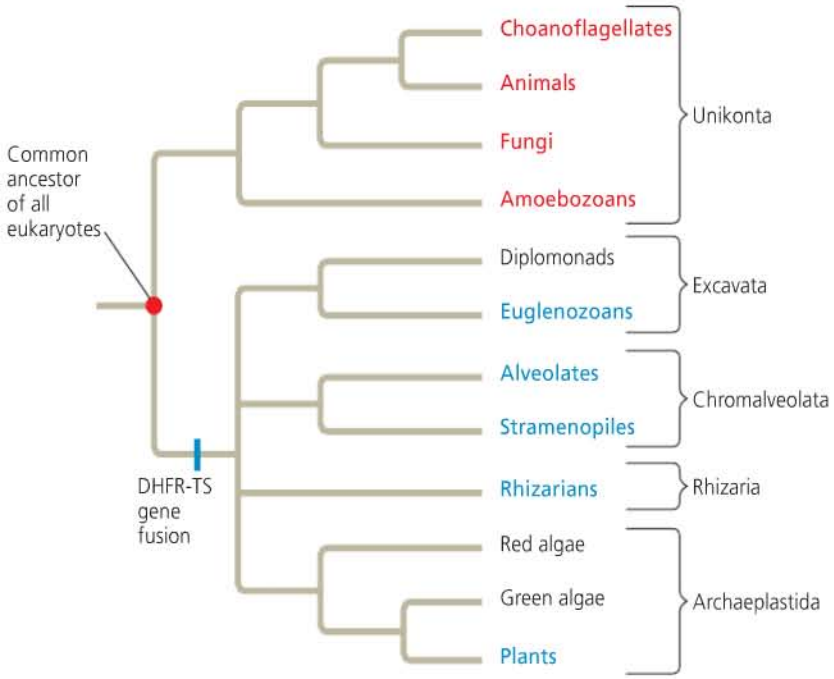
DRAW IT *Circle the stage(s) in the diagram in which clones are formed, producing additional new daughter cells that are genetically identical to the parent cell(s).*

CONCEPT **28.6**

Unikonts include protists that are closely related to fungi and animals

Unikonta is a recently proposed, extremely diverse supergroup of eukaryotes that includes animals, fungi, and some protists. There are two major clades of unikonts, the amoebozoans and the opisthokonts (animals, fungi, and closely related protist groups). Each of these two major clades is strongly supported by molecular systematics. The close relationship between amoebozoans and opisthokonts is more controversial. Support for this close relationship is provided by comparisons of myosin proteins and by several studies based on hundreds of genes, but not by other studies based on single genes.

Another controversy involving the unikonts concerns the root of the eukaryotic tree. Recall that the root of a phylogenetic tree anchors the tree in time: Branch points close to the root are the oldest. At present, the root of the eukaryotic tree is uncertain; thus, we do not know which group of eukaryotes was the first to diverge from other eukaryotes. Some hypotheses, such as the amitochondriate hypothesis described earlier, have been abandoned, but researchers have yet to agree on an alternative. If the root of the eukaryotic tree were known, scientists could infer characteristics of the common ancestor of all eukaryotes—information that would help to resolve some of the current debates about the five supergroups of eukaryotes.



In efforts to root the eukaryotic tree, phylogenies based on different sets of genes have provided conflicting results. In a 2002 paper, Alexandra Stechmann and Thomas Cavalier-Smith, of Oxford University, described a different approach, results from which supported a radical new hypothesis about the root of the eukaryotic tree **(Figure 28.23)**. According to their hypothesis, the unikonts were the first eukaryotes to diverge from other eukaryotes. This hypothesis proposes that animals

▼ Figure 28.23 Inquiry

What is the root of the eukaryotic tree?

EXPERIMENT Responding to the difficulty in determining the root of the eukaryotic phylogenetic tree, Alexandra Stechmann and Thomas Cavalier-Smith, of Oxford University, proposed a new approach. They studied two genes, one for the enzyme dihydrofolate reductase (DHFR), the other for the enzyme thymidylate synthase (TS). Their approach took advantage of a rare evolutionary event: In some organisms, the DHFR and TS genes have fused, leading to the production of a single protein with both enzyme activities. Stechmann and Cavalier-Smith amplified (using PCR; see Figure 20.8) and sequenced DHFR and TS genes in nine species (one choanoflagellate; two amoebozoans; one euglenozoan; two chromalveolates; and three rhizarians). They combined their data with previously published data for species of bacteria, animals, plants, and fungi.

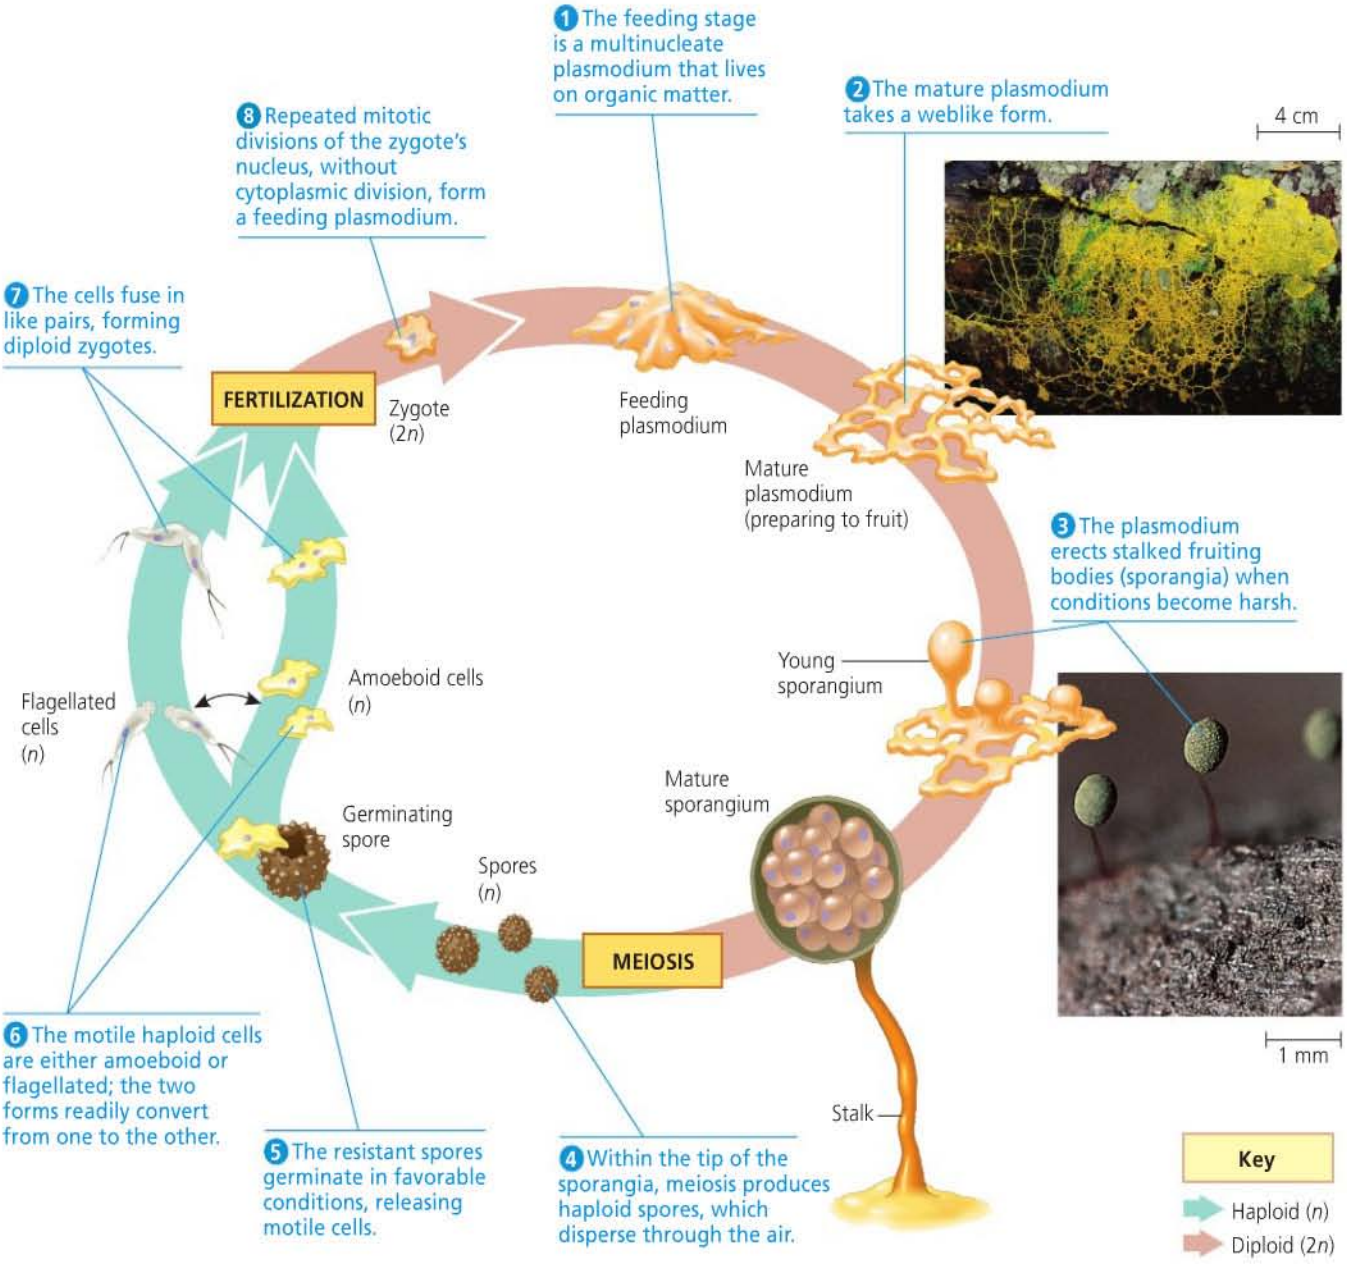
RESULTS The bacteria studied all have separate DHFR and TS genes, suggesting that this is the ancestral condition (red dot on the tree below). Other taxa with separate genes are denoted by red type. Fused genes are a derived character, found in certain members (blue type) of the supergroups Excavata, Chromalveolata, Rhizaria, and Archaeplastida:

CONCLUSION These results place the root of the tree between the unikonts and all other eukaryotes, suggesting that the unikonts may have been the first group of eukaryotes to diverge. Because this conclusion is based on only one trait—the fusion of the DHFR and TS genes—more data are needed to evaluate its validity.

SOURCE A. Stechmann and T. Cavalier-Smith, Rooting the eukaryote tree by using a derived gene fusion, *Science* 297:89–91 (2002).

WHAT IF? Stechmann and Cavalier-Smith wrote that their conclusions are "valid only if the genes fused just once and were never secondarily split." Why is this assumption critical to their approach?

and fungi belong to an early-diverging group of eukaryotes, while protists that lack typical mitochondria (such as the diplomonads and parabasalids) diverged much later in the history of life. The Stechmann and Cavalier-Smith hypothesis remains controversial and will require more supporting evidence to be widely accepted.



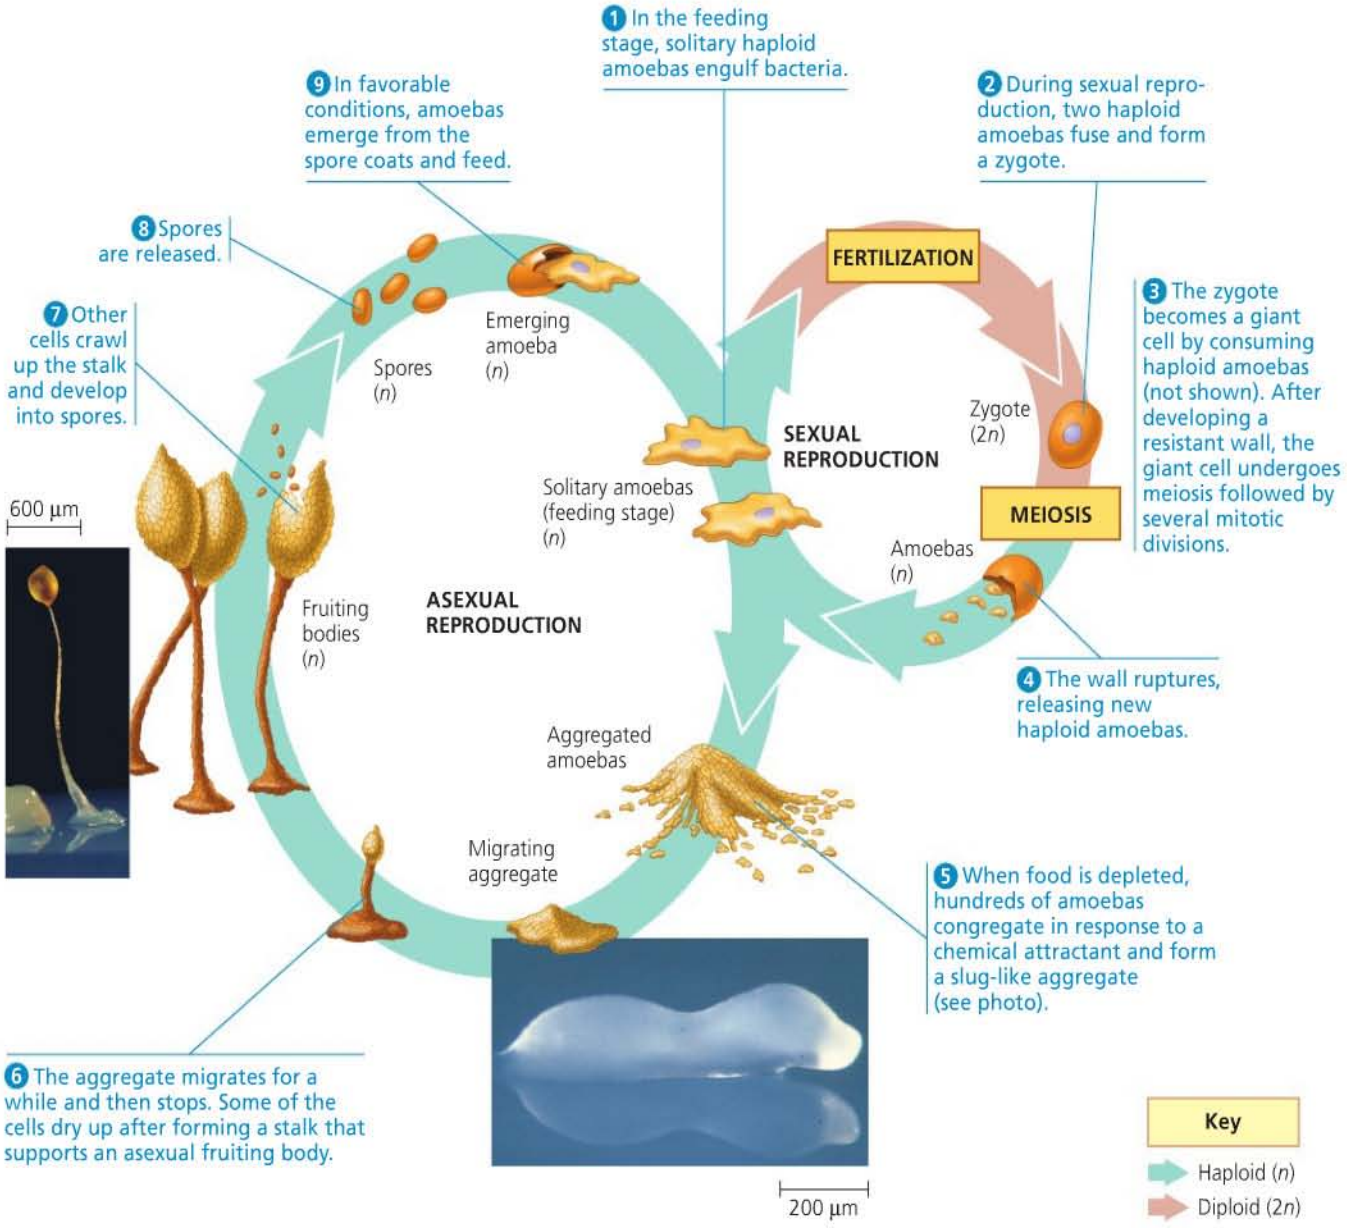
Amoebozoans

As already mentioned, **amoebozoans** form a clade that is well supported by molecular data. This clade includes many species of amoebas that have lobe- or tube-shaped, rather than thread-like, pseudopodia. Amoebozoans include slime molds, gymnamoebas, and entamoebas.

Slime Molds

Slime molds, or mycetozoans (from the Latin meaning "fungus animals"), were once thought to be fungi because, like fungi, they produce fruiting bodies that aid in spore dispersal. However, the resemblance between slime molds and fungi appears to be another example of evolutionary convergence. Molecular systematics places slime molds in Amoebozoa and suggests that they descended from unicellular ancestors. Slime molds have diverged into two main branches, plasmodial slime molds and cellular slime molds, distinguished in part by their unique life cycles.

Plasmodial Slime Molds Many **plasmodial slime molds** are brightly colored, often yellow or orange **(Figure 28.24)**.



▲ **Figure 28.24 The life cycle of a plasmodial slime mold.** In most plasmodial slime molds, the diploid condition is the predominant part of the life cycle.

At one stage in their life cycle, they form a mass called a **plasmodium**, which may grow to a diameter of many centimeters. (Don't confuse a slime mold's plasmodium with the genus *Plasmodium*, which includes the parasitic apicomplexan that causes malaria.) Despite its size, the plasmodium is not multicellular; it is a single mass of cytoplasm that is undivided by plasma membranes and that contains many diploid nuclei. This "supercell" is the product of mitotic nuclear divisions that are not followed by cytokinesis.

Within the plasmodium, cytoplasm streams first one way, then the other, in pulsing flows that are beautiful to watch through a microscope. This cytoplasmic streaming apparently helps distribute nutrients and oxygen. The plasmodium extends pseudopodia through moist soil, leaf mulch, or rotting logs, engulfing food particles by phagocytosis as it grows. If the habitat begins to dry up or there is no food left, the plasmodium stops growing and differentiates into fruiting bodies, which function in sexual reproduction.

Cellular Slime Molds The life cycle of the protists called **cellular slime molds** can prompt us to question what it means to be an individual organism. The feeding stage of these organisms consists of solitary cells that function individually, but when food is depleted, the cells form an aggregate that functions as a unit **(Figure 28.25)**. Although this mass of cells superficially resembles a plasmodial slime mold, the cells remain separated by their individual plasma membranes. Cellular slime molds also differ from plasmodial slime molds in

▲ **Figure 28.25 The life cycle of *Dictyostelium*, a cellular slime mold.** Cellular slime molds differ from plasmodial slime molds in being haploid organisms (only the zygote is diploid).

being haploid organisms (only the zygote is diploid) and in having fruiting bodies that function in asexual rather than sexual reproduction.

Dictyostelium discoideum, a cellular slime mold commonly found on forest floors, has become a model organism for studying the evolution of multicellularity. One line of research has focused on the slime mold's fruiting body stage. During this stage, the cells that form the stalk die as they dry out, while the spore cells at the top survive and have the potential to reproduce. Scientists have found that mutations to a single gene can turn individual *Dictyostelium* cells into "cheaters" that never become part of the stalk. Because these mutants gain a strong reproductive advantage over noncheaters, why don't all *Dictyostelium* cells cheat?

In 2003, scientists at Rice University and the University of Turin, Italy, discovered an answer to this question. Cheating mutants lack a protein on their cell surface, and noncheating cells can recognize this difference. Noncheaters preferentially aggregate with other noncheaters, thus depriving cheaters of the opportunity to exploit them. Such a recognition system may have been important in the evolution of multicellular eukaryotes such as animals and plants.

Gymnamoebas

Gymnamoebas constitute a large and varied group of amoebozoans. These unicellular protists are ubiquitous in soil as well as freshwater and marine environments. Most are heterotrophs that actively seek and consume bacteria and other protists (see Figure 28.3). Some gymnamoebas also feed on detritus (nonliving organic matter).

Entamoebas

Whereas most amoebozoans are free-living, those that belong to the genus *Entamoeba* are parasites. They infect all classes of vertebrates as well as some invertebrates. Humans are host to at least six species of *Entamoeba*, but only one, *E. histolytica*, is known to be pathogenic. *E. histolytica* causes amebic dysentery and is spread via contaminated drinking water, food, or eating utensils. Responsible for up to 100,000 deaths worldwide every year, the disease is the third-leading cause of death due to eukaryotic parasites, after malaria (see Figure 28.10) and schistosomiasis (see Figure 33.11).

Opisthokonts

Opisthokonts are an extremely diverse group of eukaryotes that includes animals, fungi, and several groups of protists. We will discuss the evolutionary history of fungi and animals in Chapters 31–34. Of the opisthokont protists, we will discuss the nucleariids in Chapter 31 because they are more closely related to fungi than they are to other protists. Similarly, we will discuss choanoflagellates in Chapter 32, since they are more closely related to animals than they are to other protists. The nucleariids and choanoflagellates illustrate why scientists have abandoned the former kingdom Protista: A monophyletic group that included these single-celled eukaryotes would also have to include the multicellular animals and fungi that are closely related to them.

CONCEPT CHECK 28.6

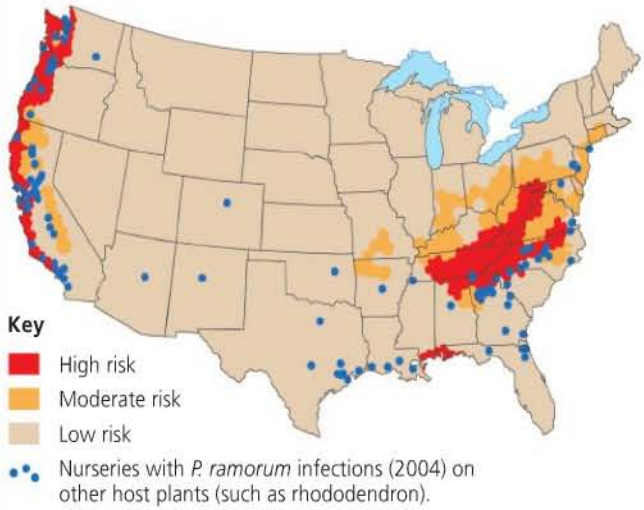
1. Contrast the pseudopodia of amoebozoans and forams.
2. In what sense is "fungus animal" a fitting description of a slime mold? In what sense is it not a fitting description?
3. **WHAT IF?** If further evidence indicates that the root of the eukaryotic tree is as shown in Figure 28.23, would this evidence support, contradict, or have no bearing on the hypothesis that Excavata is monophyletic?

For suggested answers, see Appendix A.

CONCEPT 28.7
Protists play key roles in ecological relationships

Most protists are aquatic, and they are found almost anywhere there is water, including moist terrestrial habitats such as damp soil and leaf litter. In oceans, ponds, and lakes, many protists are bottom-dwellers that attach to rocks and other substrates or creep through the sand and silt. Other protists are important constituents of plankton. We'll focus here on two key roles that protists play in the varied habitats in which they live: that of symbiont and that of producer.

Symbiotic Protists

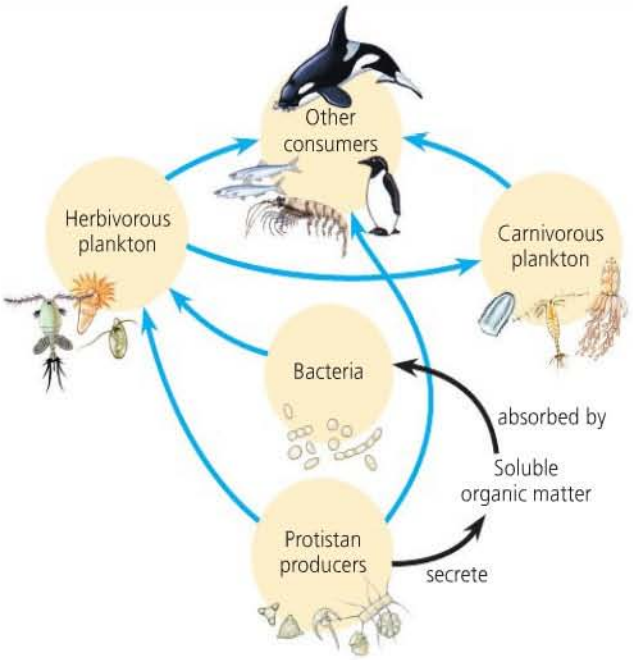


Many protists form symbiotic associations with other species. For example, photosynthetic dinoflagellates provide nourishment to their symbiotic partners, the coral polyps that build coral reefs. Coral reefs are highly diverse ecological communities. That diversity ultimately depends on corals—and on the mutualistic protist symbionts that provide corals with an essential source of energy. Corals support reef diversity by providing food to some species and habitat to many others.

Another example is termites, which cause over $3.5 billion in damage annually to wood homes in the United States. Unaided, the termites cannot digest wood. It is only the large populations of wood-digesting protists inhabiting these termites' gut that enable them to break down wood **(Figure 28.26)**.

Symbiotic protists also include parasites that have compromised the economies of entire countries. Consider the malaria-causing protist *Plasmodium*: Income levels in countries hard hit by malaria are 33% lower than in similar countries free of the disease. Protists can have similar devastating effects in natural communities. Massive fish kills have been attributed to *Pfiesteria*

◀ **Figure 28.26 A protist symbiont.** This organism is a hypermastigote, a member of a group of parabasalids that live in the gut of termites and certain cockroaches and enable the hosts to digest wood (SEM).



▲ **Figure 28.27 Risk map for sudden oak death in the contiguous United States.** Sudden oak death (SOD) is caused by the parasitic oomycete *Phytophthora ramorum*. Since 1995, this disease has spread in the wild, killing more than 1 million trees in coastal California and southern Oregon.

shumwayae, a dinoflagellate parasite (see Figure 28.9) that attaches to its victims and eats their skin. Among species that parasitize plants, the oomycete protist *Phytophthora ramorum* has emerged as a major new forest pathogen. This species causes sudden oak death (SOD), a disease that affects oaks and other trees **(Figure 28.27)**.

Photosynthetic Protists

Many protists are important **producers**, organisms that use energy from light (or inorganic chemicals) to convert carbon dioxide to organic compounds. Producers form the base of ecological food webs. In aquatic communities, the main producers are photosynthetic protists and prokaryotes. All other organisms in the community depend on them for food, either directly (by eating them) or indirectly (for example, by eating an organism that ate a producer) **(Figure 28.28)**. Scientists estimate that up to one-quarter

▲ **Figure 28.28 Protists are key producers in aquatic communities.** This simplified food web illustrates how organisms in an aquatic community depend directly or indirectly on photosynthetic protists for food. Blue arrows lead from food sources to the organisms that eat them.

of the world's photosynthesis is performed by diatoms, dinoflagellates, multicellular algae, and other protists.

Because producers form the foundation of food webs, factors that affect producers can dramatically affect their entire community. In aquatic environments, photosynthetic protists are often held in check by low concentrations of nitrogen, phosphorus, or iron. Various human actions can increase the concentrations of these elements in aquatic communities. For example, when fertilizer is applied to a field, some of the fertilizer may be washed by rainfall into a river that drains into a lake or ocean. When people add nutrients to aquatic communities in this or other ways, the abundance of photosynthetic protists can increase spectacularly. Such increases can alter the abundance of other species in the community, as we'll see in Chapter 55. Similar effects can occur on land, but there the base of food webs is occupied not by protists but by land plants, which we will discuss in Chapters 29 and 30.

CONCEPT CHECK 28.7

1. Justify the claim that photosynthetic protists are among the most important organisms in the biosphere.
2. Discuss the range of symbiotic associations that include protists.
3. **WHAT IF?** High water temperatures and pollution can cause corals to expel their dinoflagellate symbionts. Predict how such "coral bleaching" would affect corals and other species in the community.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

CONCEPT 28.1

Most eukaryotes are single-celled organisms (pp. 575–579)

- **Structural and Functional Diversity in Protists** Protists are more diverse than all other eukaryotes and are no longer classified in a single kingdom. Most are unicellular. Protists include photoautotrophs, heterotrophs, and mixotrophs. Some species are exclusively asexual; others can reproduce sexually.
- **Endosymbiosis in Eukaryotic Evolution** Mitochondria and plastids are thought to be descendants of bacteria that were engulfed by other cells and became endosymbionts. The plastid-bearing lineage eventually evolved into red algae and green algae. Other protist groups evolved from secondary endosymbiosis events in which red algae or green algae were themselves engulfed.
- **Five Supergroups of Eukaryotes** In one hypothesis, eukaryotes are grouped into five monophyletic clades: Excavata, Chromalveolata, Rhizaria, Archaeplastida, and Unikonta.

MEDIA

Activity Tentative Phylogeny of Eukaryotes

Key Concept/Eukaryote Supergroup	Major Clades	Key Morphological Characteristics	Specific Examples
Concept 28.2 **Excavates include protists with modified mitochondria and protists with unique flagella (pp. 580–581)**	**Diplomonads and parabasalids**	Modified mitochondria	*Giardia*, *Trichomonas*
	Euglenozoans Kinetoplastids Euglenids	Spiral or crystalline rod inside flagella	*Trypanosoma*, *Euglena*
Concept 28.3 **Chromalveolates may have originated by secondary endosymbiosis (pp. 582–589)**	**Alveolates** Dinoflagellates Apicomplexans Ciliates	Membrane-bounded sacs (alveoli) beneath plasma membrane	*Pfiesteria*, *Plasmodium*, *Paramecium*
	Stramenopiles Diatoms Golden algae Brown algae Oomycetes	Hairy and smooth flagella	*Phytophthora*, *Laminaria*
Concept 28.4 **Rhizarians are a diverse group of protists defined by DNA similarities (pp. 589–590)**	**Forams**	Amoebas with threadlike pseudopodia and a porous shell	*Globigerina*
	Radiolarians	Amoebas with threadlike pseudopodia radiating from central body	
Concept 28.5 **Red algae and green algae are the closest relatives of land plants (pp. 590–592—Archaeplastida)**	**Red algae**	Phycoerythrin (accessory pigment)	*Porphyra*
	Green algae	Plant-type chloroplasts	*Chlamydomonas*, *Ulva*
	Land plants	(See Chapters 29 and 30.)	Mosses, ferns, conifers, flowering plants
Concept 28.6 **Unikonts include protists that are closely related to fungi and animals (pp. 593–596)**	**Amoebozoans** Slime molds Gymnamoebas Entamoebas	Amoebas with lobe-shaped pseudopodia	*Amoeba*, *Entamoeba*, *Dictyostelium*
	Opisthokonts	(Highly variable; see Chapters 31–34.)	Nucleariids, choanoflagellates, animals, fungi

CONCEPT 28.7

Protists play key roles in ecological relationships (pp. 596–597)

- **Symbiotic Protists** Protists form a wide range of mutualistic and parasitic relationships that affect their symbiotic partners and many other members of the community.
- **Photosynthetic Protists** Photosynthetic protists are among the most important producers in aquatic communities. Because they are at the base of the food web, factors that affect photosynthetic protists affect many other species in the community.

Investigation What Kinds of Protists Do Various Habitats Support?

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Plastids that are surrounded by more than two membranes are evidence of
   a. evolution from mitochondria.
   b. fusion of plastids.
   c. origin of the plastids from archaea.
   d. secondary endosymbiosis.
   e. budding of the plastids from the nuclear envelope.

2. Biologists suspect that endosymbiosis gave rise to mitochondria before plastids partly because
   a. the products of photosynthesis could not be metabolized without mitochondrial enzymes.
   b. all eukaryotes have mitochondria (or their remnants), whereas many eukaryotes do not have plastids.
   c. mitochondrial DNA is less similar to prokaryotic DNA than is plastid DNA.
   d. without mitochondrial CO_2 production, photosynthesis could not occur.
   e. mitochondrial proteins are synthesized on cytosolic ribosomes, whereas plastids utilize their own ribosomes.

3. Which group is *incorrectly* paired with its description?
   a. rhizarians—morphologically diverse group defined by DNA similarities
   b. diatoms—important producers in aquatic communities
   c. red algae—acquired plastids by secondary endosymbiosis
   d. apicomplexans—parasites with intricate life cycles
   e. diplomonads—protists with modified mitochondria

4. Based on the phylogenetic tree in Figure 28.3, which of the following statements is correct?
   a. The most recent common ancestor of Excavata is older than that of Chromalveolata.
   b. The most recent common ancestor of Chromalveolata is older than that of Rhizaria.
   c. The most recent common ancestor of red algae and land plants is older than that of nucleariids and fungi.
   d. The most basal (first to diverge) eukaryotic supergroup cannot be determined.
   e. Excavata is the most basal eukaryotic supergroup.

5. Which protists are in the same eukaryotic supergroup as land plants?
   a. green algae
   b. dinoflagellates
   c. red algae
   d. brown algae
   e. both a and c

6. In life cycles with an alternation of generations, multicellular haploid forms alternate with
   a. unicellular haploid forms.
   b. unicellular diploid forms.
   c. multicellular haploid forms.
   d. multicellular diploid forms.
   e. multicellular polyploid forms.

EVOLUTION CONNECTION

7. **DRAW IT** Medical researchers seek to develop drugs that can kill or restrict the growth of human pathogens yet have few harmful effects on patients. These drugs often work by disrupting the metabolism of the pathogen or by targeting its structural features.

   Draw and label a phylogenetic tree that includes an ancestral prokaryote and the following groups of organisms: Excavata, Chromalveolata, Rhizaria, Archaeplastida, and, within Unikonta, amoebozoans, animals, choanoflagellates, fungi, and nucleariids. Based on this tree, hypothesize whether it would be most difficult to develop drugs to combat human pathogens that are prokaryotes, protists, animals, or fungi. (You do not need to consider the evolution of drug resistance by the pathogen.)

SCIENTIFIC INQUIRY

8. Applying the "If . . . then" logic of science (see Chapter 1), what are a few of the predictions that arise from the hypothesis that plants evolved from green algae? Put another way, how could you test this hypothesis?

SCIENCE, TECHNOLOGY, AND SOCIETY

9. The ability of the pathogen *Plasmodium* to evade the human immune system is one reason developing a malaria vaccine is so difficult. Another reason is that less money is spent on malaria research than on research into diseases that affect far fewer people, such as cystic fibrosis. What are possible reasons for this imbalance in research effort?

29 Plant Diversity I: How Plants Colonized Land

KEY CONCEPTS

29.1 Land plants evolved from green algae

29.2 Mosses and other nonvascular plants have life cycles dominated by gametophytes

29.3 Ferns and other seedless vascular plants were the first plants to grow tall

OVERVIEW

The Greening of Earth

Looking at a lush landscape, such as the forest scene in **Figure 29.1** it is difficult to imagine the terrestrial environment without any plants or other organisms. Yet for more than 3 billion years of Earth's history, the land surface was largely lifeless. Geochemical evidence suggests that thin coatings of cyanobacteria existed on land about 1.2 billion years ago. But it was only within the last 500 million years that small plants as well as fungi and animals joined them ashore. Finally, by about 370 million years ago, some plants appeared that could grow much taller, leading to the formation of the first forests (though with a very different set of species than those in Figure 29.1).

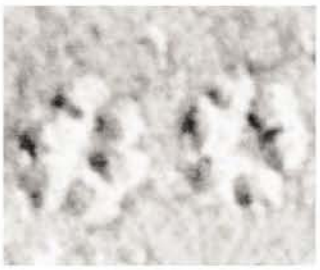
Since colonizing land, plants have diversified widely; today, there are more than 290,000 known plant species. Plants inhabit all but the harshest environments—some mountaintops, a few desert areas, and the polar regions. A few plant species, such as sea grasses, returned to aquatic habitats during their evolution, but most present-day plants live in terrestrial environments. Therefore, in this chapter we will refer to all plants as *land* plants, even those that are now aquatic, to distinguish them from algae, which are photosynthetic protists.

The presence of land plants has enabled other life-forms—including animals—to survive on land. Plant roots have created habitats for other organisms by stabilizing landscapes. Plants also supply oxygen and are the ultimate provider of most of the food eaten by terrestrial animals.

This chapter traces the first 100 million years of plant evolution, including the emergence of seedless plants such as mosses and ferns. Chapter 30 examines the later evolution of seed plants.

CONCEPT 29.1

Land plants evolved from green algae



As you read in Chapter 28, researchers have identified green algae called charophytes as the closest relatives of land plants. What is the evidence for this relationship, and what does it suggest about the algal ancestors of land plants?

Morphological and Molecular Evidence

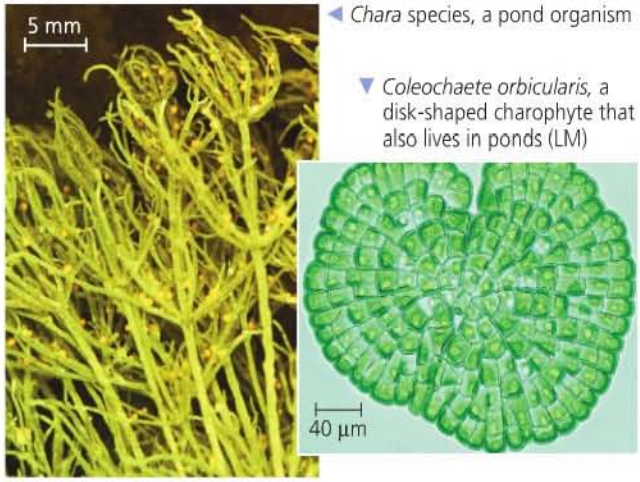
Many key characteristics of land plants also appear in a variety of protists, primarily algae. For example, plants are multicellular, eukaryotic, photosynthetic autotrophs, as are brown, red, and certain green algae (see Chapter 28). Plants have cell walls made of cellulose, and so do green algae, dinoflagellates, and brown algae. And chloroplasts with chlorophylls *a* and *b* are present in green algae, euglenids, and a few dinoflagellates, as well as in plants.

However, the charophytes are the only algae that share the following four distinctive traits with land plants, strongly suggesting that they are the closest relatives of plants:

- **Rosette-shaped cellulose-synthesizing complexes.** The cells of both land plants and charophytes have circular, petal-shaped arrays of proteins in the plasma membrane **(Figure 29.2)**. These protein arrays synthesize the cellulose microfibrils of the cell wall. In contrast, noncharophyte algae have linear arrays of proteins that synthesize cellulose.
- **Peroxisome enzymes.** The peroxisomes (see Figure 6.19) of both land plants and charophytes contain enzymes that help minimize the loss of organic products as a result of

▶ **Figure 29.2 Rosette cellulose-synthesizing complexes.** These rings of proteins embedded in the plasma membrane are found only in land plants and charophyte algae (SEM).

photorespiration (see Chapter 10). The peroxisomes of other algae lack these enzymes.



- **Structure of flagellated sperm.** In species of land plants that have flagellated sperm, the structure of the sperm closely resembles that of charophyte sperm.
- **Formation of a phragmoplast.** Particular details of cell division occur only in land plants and certain charophytes, including the genera *Chara* and *Coleochaete*. For example, in these organisms a group of microtubules known as the **phragmoplast** forms between the daughter nuclei of a dividing cell. A cell plate then develops in the middle of the phragmoplast, across the midline of the dividing cell (see Figure 12.10). The cell plate, in turn, gives rise to a new cross wall that separates the daughter cells.

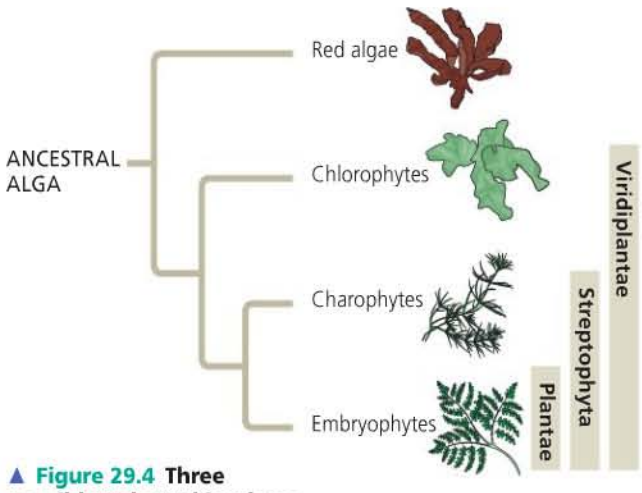
Genetic evidence also supports the conclusion drawn from these four morphological and biochemical traits. Analyses of nuclear and chloroplast genes from a wide range of plants and algae indicate that charophytes—particularly *Chara* and *Coleochaete*—are the closest living relatives of land plants **(Figure 29.3)**. Note that this does not mean that plants are descended from these living algae; however, present-day charophytes may tell us something about what the algal ancestors of plants were like.

Adaptations Enabling the Move to Land

Many species of charophyte algae inhabit shallow waters around the edges of ponds and lakes, where they are subject to occasional drying. In such environments, natural selection favors individual algae that can survive periods when they are not submerged in water. In charophytes, a layer of a durable polymer called **sporopollenin** prevents exposed zygotes from drying out. A similar chemical adaptation is found in the tough sporopollenin walls that encase the spores of plants.

The accumulation of such traits by at least one population of charophyte ancestors probably enabled their descendants—the first land plants—to live permanently above the waterline. These evolutionary novelties opened a new frontier: a terrestrial habitat that offered enormous benefits. The bright sunlight was unfiltered by water and plankton; the atmosphere offered more plentiful carbon dioxide than did water; the soil was rich in mineral nutrients; and initially there were relatively few herbivores and pathogens. But these benefits were accompanied by challenges: a relative scarcity of water and a lack of structural support against gravity. (To appreciate why such support is important, picture how the soft body of a jellyfish sags when it is taken out of water.) Land plants diversified as adaptations evolved that enabled plants to thrive despite these challenges.

◀ *Chara* species, a pond organism



▼ *Coleochaete orbicularis*, a disk-shaped charophyte that also lives in ponds (LM)

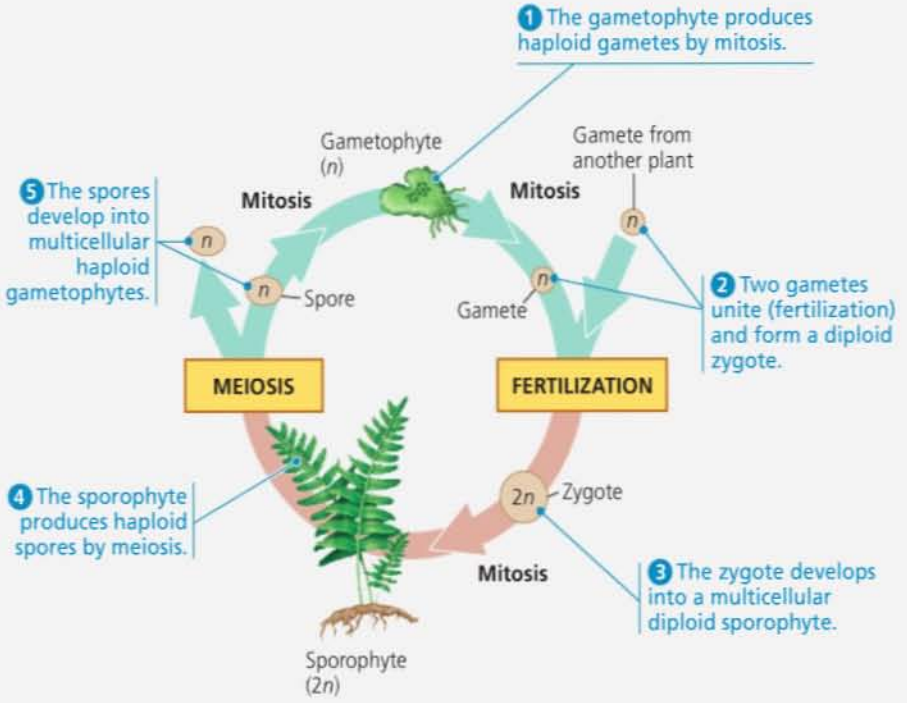
▲ **Figure 29.3 Examples of charophytes, the closest algal relatives of land plants.**

Today, what adaptations are unique to plants? The answer to this question depends on where you draw the boundary dividing land plants from algae **(Figure 29.4)**. Many biologists equate the kingdom Plantae with embryophytes (plants with embryos). Others propose that the boundaries of the plant kingdom should be expanded to include some or all of the green algae (kingdoms Streptophyta and Viridiplantae). Since the debate is ongoing, this text retains the embryophyte definition of the plant kingdom and uses Plantae as the formal name for the taxon. In this context, let's now identify the derived traits that separate land plants from their closest algal relatives.

Derived Traits of Plants

Many of the adaptations that appear to have emerged after land plants diverged from their algal relatives facilitated survival and reproduction on dry land. **Figure 29.5**, on the next two pages, depicts four key traits that appear in nearly all land plants but not in the charophyte algae. These four traits of land plants

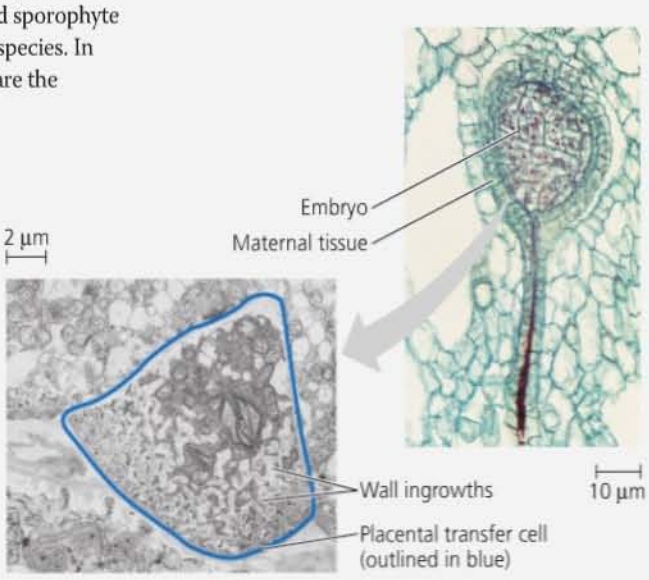
▲ **Figure 29.4 Three possible "plant" kingdoms.**



▼ Figure 29.5

Exploring Derived Traits of Land Plants

Alternation of Generations and Multicellular, Dependent Embryos

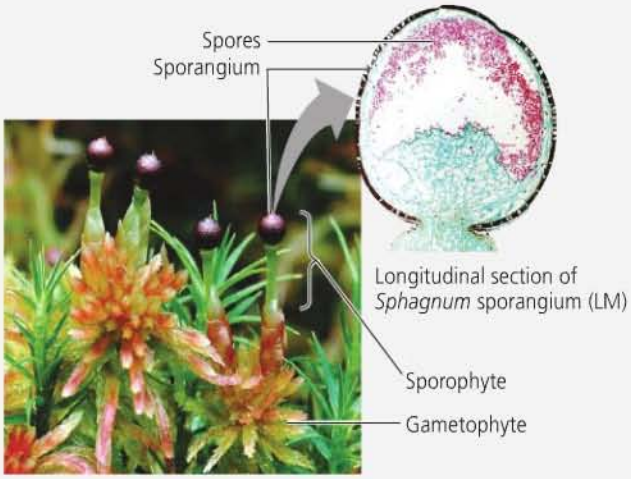


The life cycles of all land plants alternate between two generations of multicellular organisms: gametophytes and sporophytes. As shown in the diagram, each generation gives rise to the other, a process called **alternation of generations**. This type of reproductive cycle evolved in various groups of algae but does not occur in the charophytes, the algae most closely related to land plants.

Take care not to confuse the alternation of generations in plants with the haploid and diploid stages in the life cycles of other sexually reproducing organisms (see Figure 13.6). In humans, for example, meiosis produces haploid gametes that unite, forming diploid zygotes that divide and become multicellular. The haploid stage is represented only by single-celled gametes. In contrast, alternation of generations is distinguished by the fact that the life cycle includes both multicellular haploid organisms and multicellular diploid organisms. The names of the two multicellular generations of the plant life cycle refer to the reproductive cells they produce. The haploid **gametophyte** ("gamete-producing plant") is named for its production by mitosis of haploid gametes—eggs and sperm—that fuse during fertilization, forming diploid zygotes. Mitotic division of the zygote produces a multicellular diploid **sporophyte** ("spore-producing plant"). Meiosis in a mature sporophyte produces haploid **spores**, reproductive cells that can develop into a new haploid organism without fusing with another cell. Mitotic division of the spore cell produces a new multicellular gametophyte, and the cycle begins again. In many seedless plants, such as the fern in the diagram, the gametophyte and sporophyte look like different types of plants, even though they are forms of the same species. In seed plants, the gametophytes are microscopic; the familiar plants we see are the sporophytes.

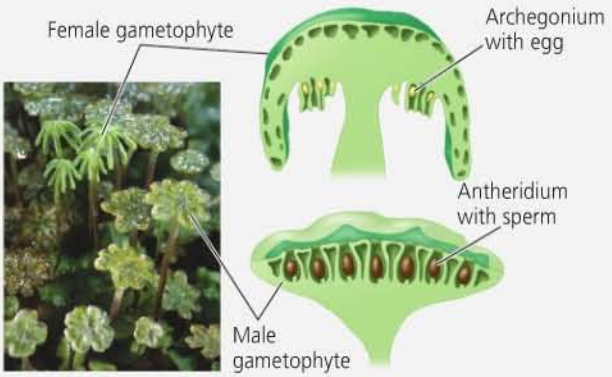
Alternation of generations: five generalized steps

As part of a life cycle with alternation of generations, multicellular plant embryos develop from zygotes that are retained within tissues of the female parent (a gametophyte). The parental tissues provide the developing embryo with nutrients, such as sugars and amino acids. The embryo has specialized **placental transfer cells**, sometimes present in the adjacent maternal tissue as well, which enhance the transfer of nutrients from parent to embryo through elaborate ingrowths of the wall surface (plasma membrane and cell wall). This interface is analogous to the nutrient-transferring embryo-mother interface of eutherian (placental) mammals. The multicellular, dependent embryo of land plants is such a significant derived trait that land plants are also known as **embryophytes**.



Embryo (LM) and placental transfer cell (TEM) of *Marchantia* (a liverwort)

Walled Spores Produced in Sporangia

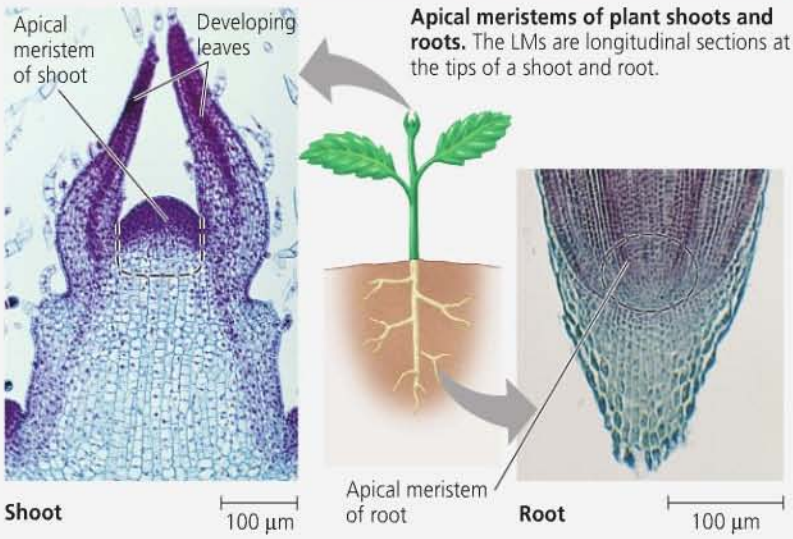


Plant spores are haploid reproductive cells that can grow into multicellular haploid gametophytes by mitosis. The polymer sporopollenin makes the walls of plant spores tough and resistant to harsh environments. This chemical adaptation enables spores to be dispersed through dry air without harm.

The sporophyte has multicellular organs called **sporangia** (singular, *sporangium*) that produce the spores. Within a sporangium, diploid cells called **sporocytes**, or spore mother cells, undergo meiosis and generate the haploid spores. The outer tissues of the sporangium protect the developing spores until they are released into the air. Multicellular sporangia that produce spores with sporopollenin-enriched walls are key terrestrial adaptations of land plants. Although charophytes also produce spores, these algae lack multicellular sporangia, and their flagellated, water-dispersed spores lack sporopollenin.

Sporophytes and sporangia of *Sphagnum* (a moss)

Multicellular Gametangia



Archegonia and antheridia of *Marchantia* (a liverwort)

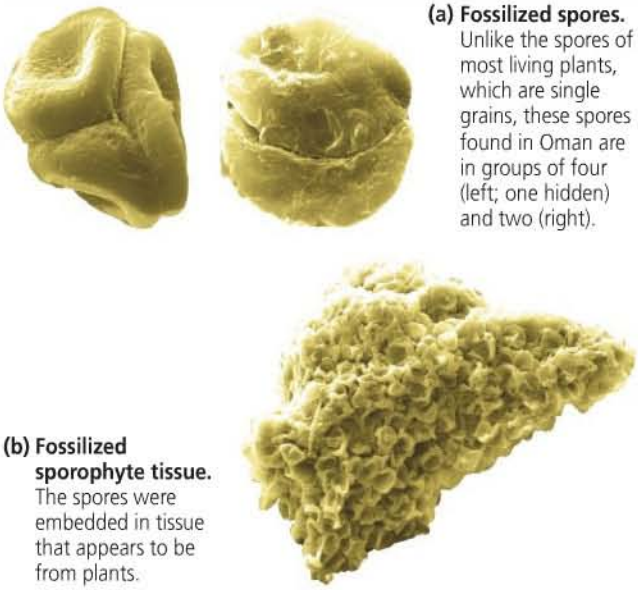
Another feature distinguishing early land plants from their algal ancestors was the production of gametes within multicellular organs called **gametangia**. The female gametangia are called **archegonia** (singular, *archegonium*). Each archegonium is a pear-shaped organ that produces a single nonmotile egg retained within the bulbous part of the organ (the top for the species shown here). Male gametangia, called **antheridia** (singular, *antheridium*), produce sperm and release them into the environment. In many groups of present-day plants, the sperm have flagella and swim to the eggs through water droplets or a film of water. Each egg is fertilized within an archegonium, where the zygote develops into an embryo. As you will see in Chapter 30, the gametophytes of seed plants are so reduced in size that the archegonia and antheridia have been lost in some lineages.

Apical Meristems

In terrestrial habitats, a photosynthetic organism finds essential resources in two very different places. Light and CO_2 are mainly available above ground; water and mineral nutrients are found mainly in the soil. Though plants cannot move from place to place, their roots and shoots can elongate, increasing exposure to environmental resources. This growth in length is sustained throughout the plant's life by the activity of **apical meristems**, localized regions of cell division at the tips of shoots and roots. Cells produced by apical meristems differentiate into the outer epidermis, which protects the body, and various types of internal tissues. Shoot apical meristems also generate leaves in most plants. Thus, the complex bodies of plants have specialized below- and aboveground organs.

Apical meristems of plant shoots and roots. The LMs are longitudinal sections at the tips of a shoot and root.

are alternation of generations (along with an associated trait—multicellular, dependent embryos); walled spores produced in sporangia; multicellular gametangia; and apical meristems. We can infer that these traits were absent in the ancestor common to land plants and charophytes but instead evolved as derived traits of land plants. Note that some of these traits are not unique to plants, having evolved independently in other lineages. And not every land plant exhibits all four of these traits; certain lineages of plants have lost some traits over time.



In addition to the four traits shown in Figure 29.5, other derived traits that relate to terrestrial life have evolved in many plant species. For example, the epidermis in many species has a covering, the **cuticle**, which consists of polyester and wax polymers. Permanently exposed to the air, land plants run a far greater risk of desiccation (drying out) than their algal ancestors. The cuticle acts as waterproofing, helping prevent excessive water loss from the above-ground plant organs, while also providing some protection from microbial attack.

Early land plants lacked true roots and leaves. Without roots, how did these plants absorb nutrients from the soil? Fossils dating from 420 million years ago reveal an adaptation that may have aided early plants in nutrient uptake: They formed symbiotic associations with fungi similar in structure to beneficial associations observed today between plants and fungi. We'll describe these associations, called *mycorrhizae,* and their benefits to both plants and fungi in more detail in Chapter 31. For now, the main point is that mycorrhizal fungi form extensive networks of filaments through the soil, enabling them to absorb nutrients more effectively than a plant can on its own. The fungi transfer nutrients to their symbiotic plant partner—a benefit that may have helped plants without roots to colonize land.

Finally, many land plants produce molecules called *secondary compounds*, so named because they are products of secondary metabolic pathways—side branches off the primary metabolic pathways that produce the lipids, carbohydrates, amino acids, and other compounds common to all organisms. Secondary compounds include alkaloids, terpenes, tannins, and phenolics such as flavonoids. Various alkaloids, terpenes, and tannins have a bitter taste, strong odor, or toxic effect that helps defend against herbivores and parasites. Flavonoids absorb harmful UV radiation, and some other phenolics deter attack by pathogens. Humans also benefit from secondary compounds, many of which are used in spices, medicines, and other products.

The Origin and Diversification of Plants

Paleobotanists seeking the evolutionary origin of plants have long debated what constitutes the oldest fossil evidence of land plants. In the 1970s, researchers found fossil spores dating to the Ordovician period, up to 475 million years old. Although the fossil spores resemble those of living plants, they also have some striking differences. For example, spores of present-day plants are typically dispersed as single grains, but the fossil spores are fused together in groups of two or four. This difference raises the possibility that the fossil spores were not produced by plants, but by some extinct algal relative. Furthermore, the oldest known fragments of plant body tissues are 50 million years younger than the puzzling spores.

(a) Fossilized spores. Unlike the spores of most living plants, which are single grains, these spores found in Oman are in groups of four (left; one hidden) and two (right).

(b) Fossilized sporophyte tissue. The spores were embedded in tissue that appears to be from plants.

▲ **Figure 29.6 Ancient plant spores and tissue** (colorized SEMs).

In 2003, scientists from Britain and the Middle Eastern country of Oman shed some light on this mystery when they extracted spores from 475-million-year-old rocks from Oman **(Figure 29.6a)**. Unlike previously discovered spores of this age, these were embedded in plant cuticle material that is similar to spore-bearing tissue in living plants **(Figure 29.6b)**. After uncovering other small fragments of tissue that clearly belonged to plants, the scientists concluded that the spores from Oman represent fossil plants rather than algae.

Whatever the precise age of the first land plants, those ancestral species gave rise to the vast diversity of living plants. **Table 29.1** summarizes the ten extant phyla in the taxonomic scheme used in this text. (Extant lineages are those that have surviving members, not only extinct ones.) As you read the rest of this section, look at Table 29.1 together with **Figure 29.7**, which reflects a view of plant phylogeny based on plant morphology, biochemistry, and genetics.

One way to distinguish plants is by whether or not they have an extensive system of **vascular tissue**, cells joined into tubes that transport water and nutrients throughout the plant body. Most plants have a complex vascular tissue system and are therefore called **vascular plants**. Plants that do not have an extensive transport system—liverworts, hornworts, and mosses—are described as "nonvascular" plants, even though

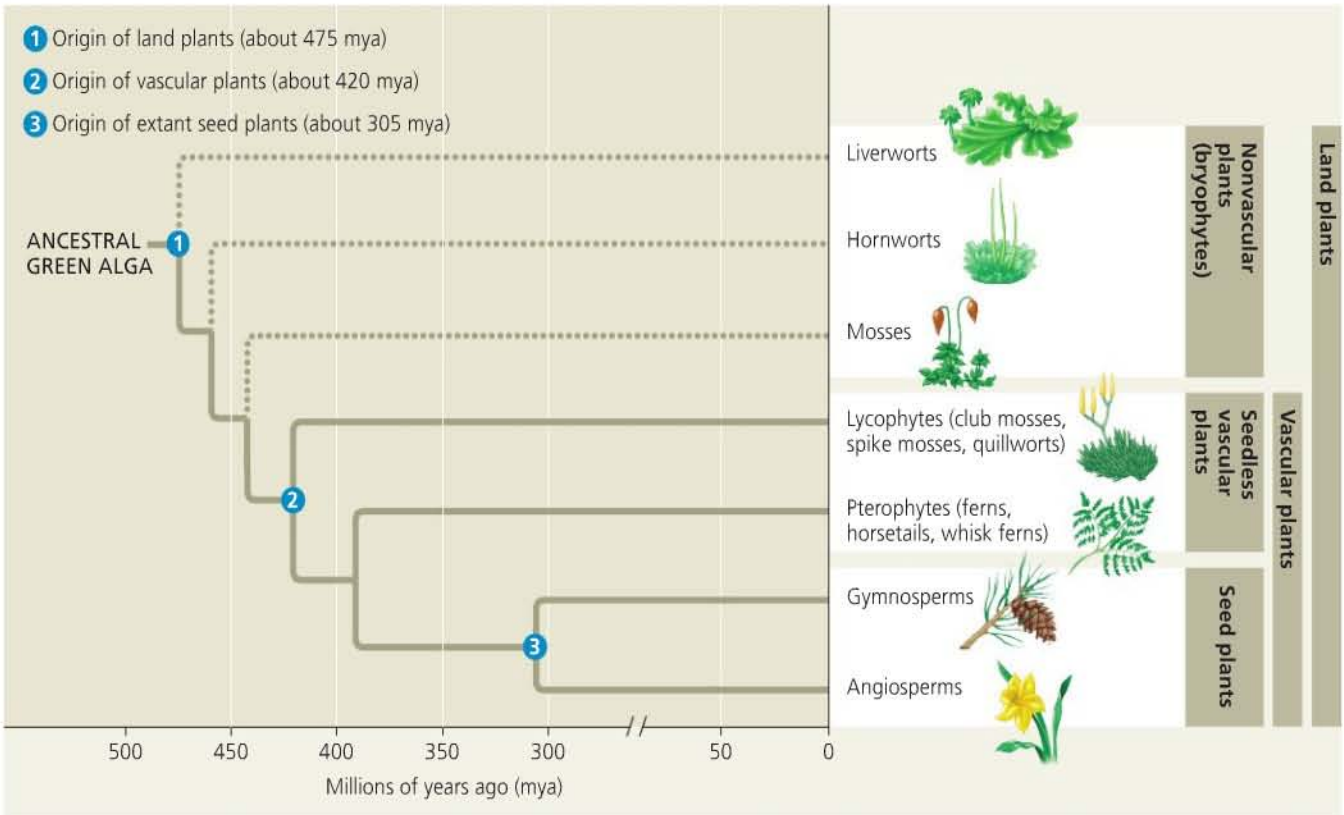


Table 29.1 Ten Phyla of Extant Plants

	Common Name	Estimated Number of Species
Nonvascular Plants (Bryophytes)		
Phylum Hepatophyta	Liverworts	9,000
Phylum Anthocerophyta	Hornworts	100
Phylum Bryophyta	Mosses	15,000
Vascular Plants		
Seedless Vascular Plants		
Phylum Lycophyta	Lycophytes	1,200
Phylum Pterophyta	Pterophytes	12,000
Seed Plants		
Gymnosperms		
Phylum Ginkgophyta	Ginkgo	1
Phylum Cycadophyta	Cycads	130
Phylum Gnetophyta	Gnetophytes	75
Phylum Coniferophyta	Conifers	600
Angiosperms		
Phylum Anthophyta	Flowering plants	250,000

some mosses do have simple vascular tissue. Nonvascular plants are often informally called **bryophytes** (from the Greek *bryon*, moss, and *phyton*, plant).

Although the term *bryophyte* is commonly used to refer to all nonvascular plants, debate continues over the relationships of liverworts, hornworts, and mosses to each other and to vascular plants. Whereas some molecular studies have concluded that bryophytes do not form a monophyletic group (a clade; see Figure 26.10), several recent analyses of amino acid sequences in chloroplasts assert that bryophytes do form a clade. Whether or not bryophytes are monophyletic, they share some derived traits with vascular plants, such as multicellular embryos and apical meristems, while lacking many innovations of vascular plants, such as roots and true leaves.

Vascular plants, which form a clade that comprises about 93% of all plant species, can be categorized further into smaller clades. Two of these clades are the **lycophytes** (club mosses and their relatives) and the **pterophytes** (ferns and their relatives). The plants in each of these clades lack seeds, which is why collectively the two clades are often informally called **seedless vascular plants**. However, notice in Figure 29.7 that seedless vascular plants are paraphyletic, not monophyletic. Groups such as the seedless vascular plants are sometimes referred to as a **grade**, a collection of organisms that share a common level of biological organization or adaptation.

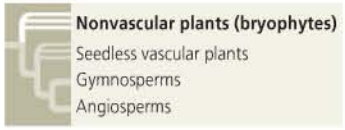
▲ **Figure 29.7 Highlights of plant evolution.** Several hypotheses about relationships between plant groups are actively under debate, including one proposing that bryophytes are a monophyletic group. The dotted lines indicate groups whose evolutionary relationships are unclear.

DRAW IT *Redraw this phylogeny assuming that bryophytes are a monophyletic group in which liverworts diverged first.*

Although grades can be informative by grouping organisms according to key biological features (such as lack of seeds), they can be misleading in other ways. Pterophytes, for example, share a more recent common ancestor with seed plants than with lycophytes. As a result, we would expect pterophytes and seed plants to share key traits not found in lycophytes—and they do, as you'll read.

A third clade of vascular plants consists of seed plants, which represent the vast majority of living plant species. A **seed** is an embryo packaged with a supply of nutrients inside a protective coat. Seed plants can be divided into two groups, gymnosperms and angiosperms, based on the absence or presence of enclosed chambers in which seeds mature. **Gymnosperms** (from the Greek *gymnos*, naked, and *sperm*, seed) are grouped together as "naked seed" plants because their seeds are not enclosed in chambers. Living gymnosperm species, the most familiar of which are the conifers, probably form a clade. **Angiosperms** (from the Greek *angion*, container) are a huge clade consisting of all flowering plants. Angiosperm seeds develop inside chambers called ovaries, which originate within flowers and mature into fruits. Nearly 90% of living plant species are angiosperms.

Note that the phylogeny depicted in Figure 29.7 focuses only on the relationships between extant plant lineages. Paleobotanists have also discovered fossils belonging to extinct plant lineages. Many of these fossils reveal intermediate steps in the emergence of the distinctive plant groups found on Earth today.



CONCEPT CHECK 29.1

1. Why do researchers identify charophytes rather than another group as the closest relatives of land plants?
2. Identify three derived traits that distinguish plants from charophytes *and* facilitate life on land. Explain.
3. **WHAT IF?** What would the human life cycle be like if we had alternation of generations? Assume that the multicellular diploid stage is similar in form to an adult human.

For suggested answers, see Appendix A.

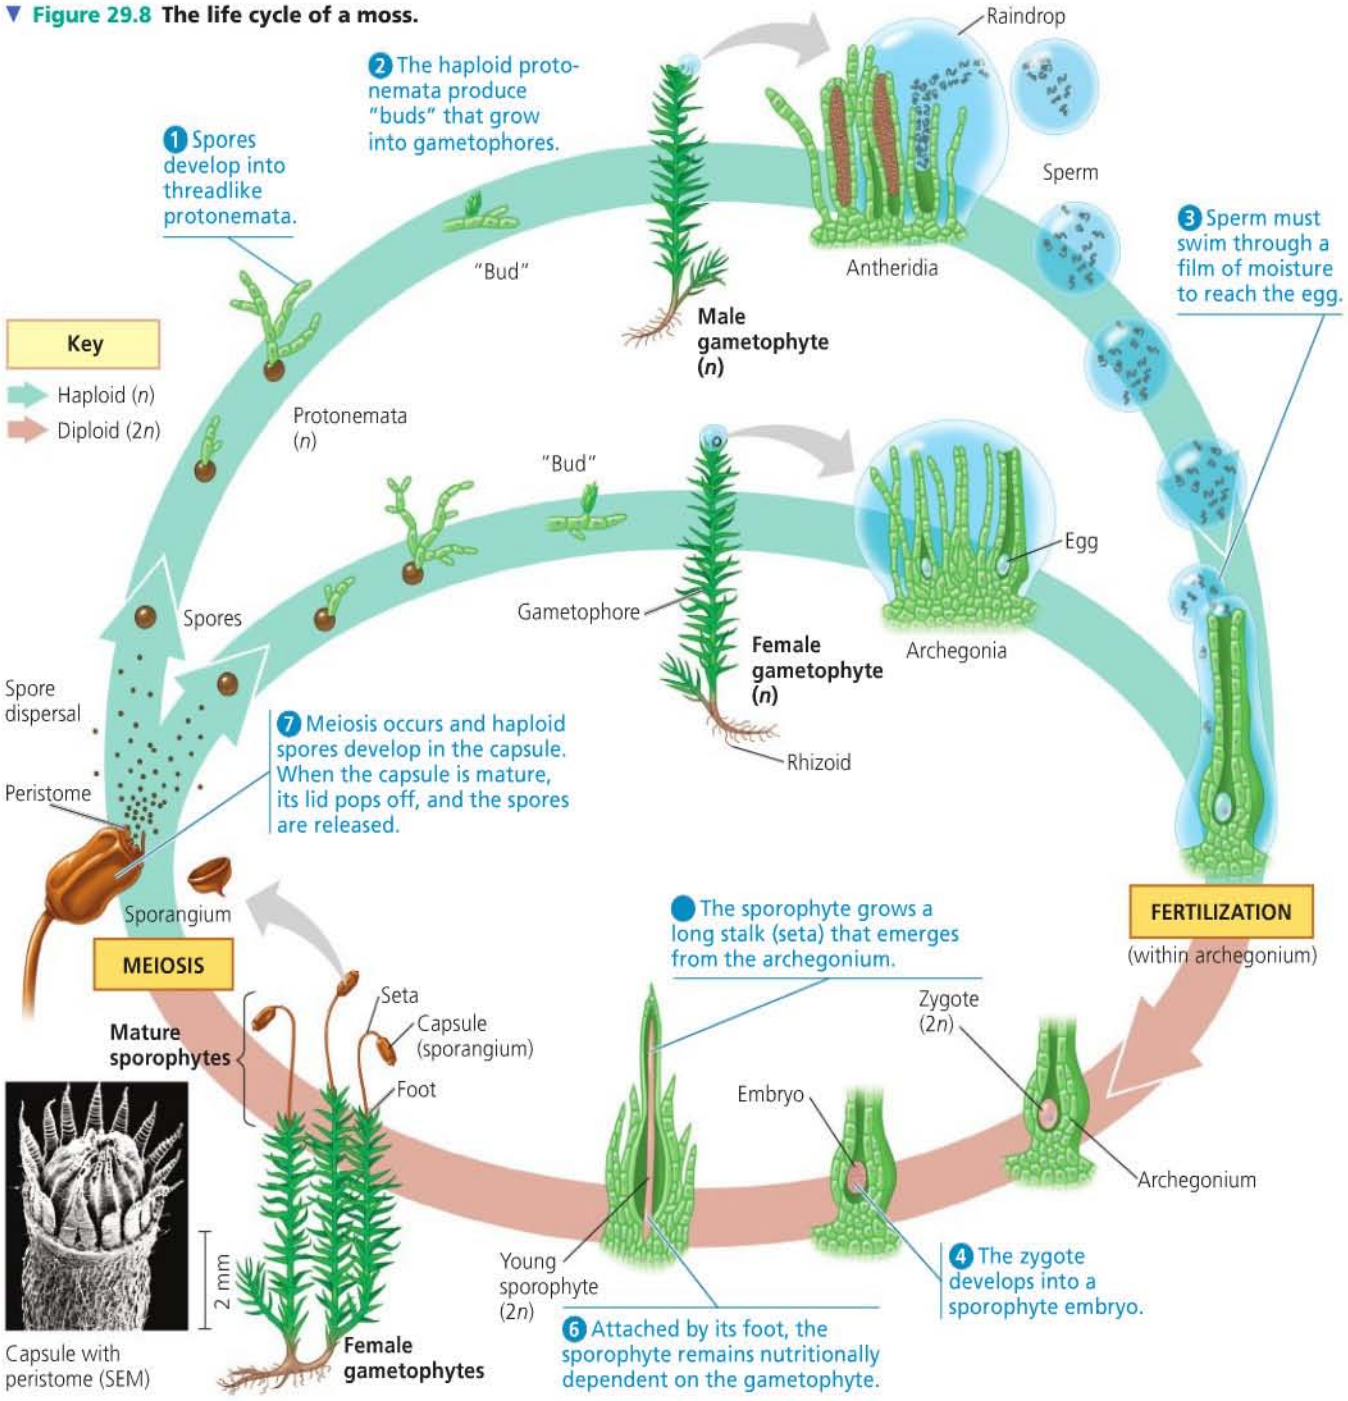
CONCEPT 29.2

Mosses and other nonvascular plants have life cycles dominated by gametophytes

The nonvascular plants (bryophytes) are represented today by three phyla of small herbaceous (nonwoody) plants: **liverworts** (phylum Hepatophyta), **hornworts** (phylum Anthocerophyta), and **mosses** (phylum Bryophyta). Liverworts and hornworts are named for their shapes, plus the suffix *wort* (from the Anglo-Saxon for "herb"). Mosses are familiar to many people, although some plants commonly called "mosses" are not really mosses at all. These include Irish moss (a red seaweed), reindeer moss (a lichen), club mosses (seedless vascular plants), and Spanish mosses (lichens in some regions and flowering plants in others).

Note that the terms *Bryophyta* and *bryophyte* are not synonymous. Bryophyta is the formal taxonomic name for the phylum that consists solely of mosses. As mentioned earlier, the term *bryophyte* is used informally to refer to *all* nonvascular plants—liverworts, hornworts, and mosses. Systematists continue to debate the sequence in which the three phyla of bryophytes evolved.

Liverworts, hornworts, and mosses acquired many unique adaptations over the long course of their evolution. Nevertheless, living bryophytes likely reflect some traits of the earliest plants. The oldest known fossils of plant fragments, for example, include tissues very similar to those inside liverworts. Researchers hope to discover more parts of these ancient plants to see if this resemblance is reflected more broadly.



Bryophyte Gametophytes

Unlike vascular plants, in all three bryophyte phyla the gametophytes are the dominant stage of the life cycle: They are larger and longer-living than the sporophytes, as shown in the moss life cycle in **Figure 29.8**. Sporophytes are typically present only part of the time.

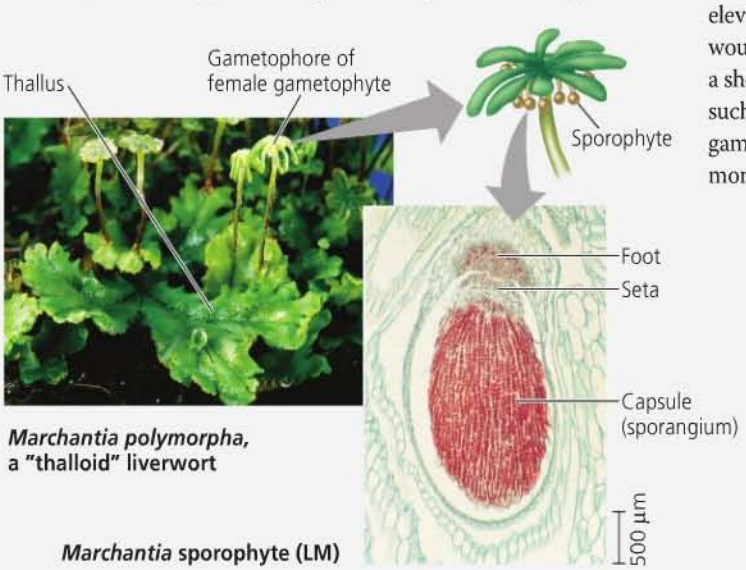
When bryophyte spores are dispersed to a favorable habitat, such as moist soil or tree bark, they may germinate and grow into gametophytes. Germinating moss spores, for example, characteristically produce a mass of green, branched, one-cell-thick filaments known as a **protonema** (plural, *protonemata*; from the Greek *proto*, first, and *nema*, threads). A protonema has a large surface area that enhances absorption of water and minerals. In favorable conditions, a protonema produces one or more "buds." (Note that when referring to nonvascular plants, we typically use quotation marks for structures similar to the buds, stems, and leaves of vascular plants because the definitions of these terms are based on vascular plant organs.) Each of these bud-like growths has an apical meristem that generates a gamete-producing structure known as a **gametophore** ("gamete bearer"). Together, a protonema and one or more gametophores make up the body of a moss gametophyte.

Bryophyte gametophytes generally form ground-hugging carpets, partly because their body parts are too thin to support a tall plant. A second constraint on the height of many bryophytes is the absence of vascular tissue, which would enable long-distance transport of water and nutrients. The thin structure of bryophyte organs makes it possible to distribute materials without specialized vascular tissue. Some mosses, however, such as the genus *Polytrichum*, have conducting tissues in the center of their "stems." A few of these mosses can grow as tall as 2 m as a result.

▼ **Figure 29.8 The life cycle of a moss.**

Phylogenetic analyses suggest that in these and some other bryophytes, conducting tissues similar to those of vascular plants arose independently by convergent evolution.

The gametophytes are anchored by delicate **rhizoids**, which are long, tubular single cells (in liverworts and hornworts) or filaments of cells (in mosses). Unlike roots, which are characteristic of vascular plants, rhizoids are not composed of tissues. Bryophyte rhizoids also lack specialized conducting cells and do not play a primary role in water and mineral absorption.



Mature gametophytes form gametangia that produce gametes and are covered by protective tissue. A gametophyte may have multiple gametangia. Eggs are produced singly in pear-shaped archegonia, whereas each antheridium produces many sperm. Some bryophyte gametophytes are bisexual, but in mosses the archegonia and antheridia are typically carried on separate female and male gametophytes. Flagellated sperm swim through a film of water toward eggs, entering the archegonia in response to chemical attractants. Eggs are not released but instead remain within the bases of archegonia. After fertilization, embryos are retained within the archegonia. Layers of placental transfer cells help transport nutrients to the embryos as they develop into sporophytes.

▼ Figure 29.9

Exploring Bryophyte Diversity

Liverworts (Phylum Hepatophyta)

This phylum's common and scientific names (from the Latin *hepaticus*, liver) refer to the liver-shaped gametophytes of its members, such as *Marchantia*, shown below. In medieval times, their shape was thought to be a sign that the plants could help treat liver diseases. Some liverworts, including *Marchantia*, are described as "thalloid" because of the flattened shape of their gametophytes. (Recall from Chapter 28 that the body of a multicellular alga is called a thallus.) *Marchantia* gametangia are elevated on gametophores that look like miniature trees. You would need a magnifying glass to see the sporophytes, which have a short seta (stalk) with an oval or round capsule. Other liverworts, such as *Plagiochila*, below, are called "leafy" because their stemlike gametophytes have many leaflike appendages. There are many more species of leafy liverworts than thalloid liverworts.

***Marchantia polymorpha*, a "thalloid" liverwort**

***Marchantia* sporophyte (LM)**

***Plagiochila deltoidea*, a "leafy" liverwort**

Hornworts (Phylum Anthocerophyta)

This phylum's common and scientific names (from the Greek *keras*, horn) refer to the long, tapered shape of the sporophyte. A typical sporophyte can grow to about 5 cm high. Unlike a liverwort or moss sporophyte, a hornwort sporophyte lacks a seta and consists only of a sporangium. The sporangium releases mature spores by splitting open, starting at the tip of the horn. The gametophytes, which are usually 1–2 cm in diameter, grow mostly horizontally and often have multiple sporophytes attached. Hornworts are frequently among the first species to colonize open areas with moist soils; a symbiotic relationship with nitrogen-fixing cyanobacteria contributes to their ability to do this (nitrogen is often in short supply in such areas).

An *Anthoceros* hornwort species

Mosses (Phylum Bryophyta)

Moss gametophytes, which range in height from less than 1 mm to up to 2 m, are less than 15 cm in most species. The familiar carpet of moss you observe consists mainly of gametophytes. The blades of their "leaves" are usually only one cell thick, but more complex "leaves" that have ridges coated with cuticle can be found on the common hairy-cap moss (*Polytrichum*, below) and its close relatives. Moss sporophytes are typically elongated and visible to the naked eye, with heights ranging up to about 20 cm. Though green and photosynthetic when young, they turn tan or brownish red when ready to release spores.

***Polytrichum commune*, hairy-cap moss**

Bryophyte sperm require a film of water to reach the eggs. Given this requirement, it is not surprising that many bryophyte species are found in moist habitats. The fact that sperm must swim through water to reach the egg also means that in species with separate male and female gametophytes (most mosses), sexual reproduction is likely to be more successful when individuals are located close to one another. Many bryophyte species can increase the number of individuals in a local area through various methods of asexual reproduction. For example, some mosses reproduce asexually by forming *brood bodies*, small plantlets that detach from the parent plant and grow into a new, genetically identical copy of their parent.

Bryophyte Sporophytes

Although bryophyte sporophytes are usually green and photosynthetic when young, they cannot live independently. They remain attached to their parental gametophytes, from which they absorb sugars, amino acids, minerals, and water.

Bryophytes have the smallest sporophytes of all extant plant groups, consistent with the hypothesis that larger sporophytes evolved only later, in the vascular plants. A typical bryophyte sporophyte consists of a foot, a seta, and a sporangium. Embedded in the archegonium, the **foot** absorbs nutrients from the gametophyte. The **seta** (plural, *setae*), or stalk, conducts these materials to the sporangium, also called a **capsule**, which uses them to produce spores by meiosis. One capsule can generate up to 50 million spores.

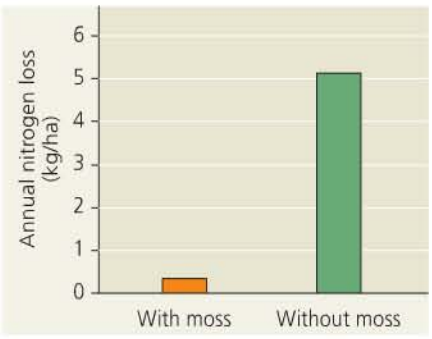
In most mosses, the seta becomes elongated, enhancing spore dispersal by elevating the capsule. Typically, the upper part of the capsule features a ring of interlocking, tooth-like structures known as the **peristome** (see Figure 29.8). These "teeth" open under dry conditions and close again when it is moist. This allows spores to be discharged gradually, via periodic gusts of wind that can carry them long distances.

Hornwort and moss sporophytes are larger and more complex than those of liverworts. Both hornwort and moss sporophytes also have specialized pores called **stomata** (singular, *stoma*), which are also found in all vascular plants. These pores support photosynthesis by allowing the exchange of CO_2 and O_2 between the outside air and the sporophyte interior (see Figure 10.3). Stomata are also the main avenues by which water evaporates from the sporophyte. In hot, dry conditions, the stomata close, minimizing water loss.

The fact that stomata are present in mosses and hornworts but absent in liverworts suggests three possible hypotheses for their evolution. If liverworts are the deepest-branching lineage of land plants, as in Figure 29.7, then stomata may have evolved once in the ancestor of hornworts, mosses, and vascular plants. If hornworts or mosses are the deepest-branching lineage, or if bryophytes are monophyletic, stomata may have evolved once and then been lost in the liverwort lineage. Finally, if hornworts are the deepest-branching lineage and mosses are the closest relatives of vascular plants, it is also possible that hornworts acquired stomata independently of mosses and vascular plants. This question is important to understanding plant evolution because stomata play a crucial role in the success of vascular plants, as you will learn in Chapter 36.

Figure 29.9, on the facing page, shows some examples of gametophytes and sporophytes in the bryophyte phyla.

The Ecological and Economic Importance of Mosses



Wind dispersal of their lightweight spores has distributed mosses throughout the world. These plants are particularly common and diverse in moist forests and wetlands. Some mosses colonize bare, sandy soil, where researchers have found they help retain nitrogen in the soil **(Figure 29.10)**. Other

▼ Figure 29.10 Inquiry

Can bryophytes reduce the rate at which key nutrients are lost from soils?

EXPERIMENT Soils in terrestrial ecosystems are often low in nitrogen, a nutrient that is required for normal plant growth. Richard Bowden, of Allegheny College, measured annual inputs (gains) and outputs (losses) of nitrogen in a sandy-soil ecosystem dominated by the moss *Polytrichum*. Nitrogen inputs to the ecosystem were measured from rainfall (dissolved ions such as nitrate, NO_3^-), biological N_2 fixation, and wind deposition. Nitrogen losses were measured in leached water (dissolved ions, such as NO_3^-) and gaseous emissions (such as NO_2 emitted by some bacteria). Bowden measured nitrogen losses for soils with *Polytrichum* and for soils where the moss had been removed two months before the experiment began.

RESULTS A total of 10.5 kg of nitrogen per hectare (kg/ha) entered the ecosystem each year. Little nitrogen was lost by gaseous emissions (0.10 kg/ha per year). The results of comparing nitrogen losses by leaching are shown below.

CONCLUSION The moss *Polytrichum* greatly reduced the loss of nitrogen by leaching in this ecosystem. Each year, the moss ecosystem retained over 95% of the 10.5 kg/ha of total nitrogen inputs (only 0.1 kg/ha and 0.3 kg/ha were lost to gaseous emissions and leaching, respectively).

SOURCE R. D. Bowden, Inputs, outputs, and accumulation of nitrogen in an early successional moss (*Polytrichum*) ecosystem, *Ecological Monographs* 61:207–223 (1991).

WHAT IF? How might the presence of *Polytrichum* affect plant species that typically colonize the sandy soils *after* the moss?

mosses inhabit such extreme environments as mountaintops, tundra, and deserts. Many mosses are able to live in very cold or dry habitats because they can survive the loss of most of their body water, then rehydrate when moisture is available. Few vascular plants can survive the same degree of desiccation.

One wetland moss genus, *Sphagnum*, or "peat moss," is especially widespread, forming extensive deposits of partially decayed organic material known as **peat** (Figure 29.11a). Boggy regions dominated by this moss are called peatlands. *Sphagnum* does not decay readily, in part because of phenolic compounds embedded in its cell walls. The low temperature, pH, and oxygen level of peatlands also inhibit decay of moss—and other organisms. As a result, some peatlands have preserved corpses for thousands of years (Figure 29.11b).

Peat has long been a fuel source in Europe and Asia, and it is still harvested for fuel today, notably in Ireland and Canada. In addition, peat moss is useful as a soil conditioner and for packing plant roots during shipment because it has large dead cells that can absorb roughly 20 times the moss's weight in water. Worldwide, an estimated 400 billion tons of organic carbon are stored in peat. These carbon reservoirs help stabilize atmospheric CO_2 concentrations (see Chapter 55). Current overharvesting of *Sphagnum* may reduce its beneficial ecological effects and contribute to global warming by releasing stored CO_2.

(a) Peat being harvested from a peatland

(b) "Tollund Man," a bog mummy dating from 405–100 B.C.E. The acidic, oxygen-poor conditions produced by *Sphagnum* can preserve human or other animal bodies for thousands of years.

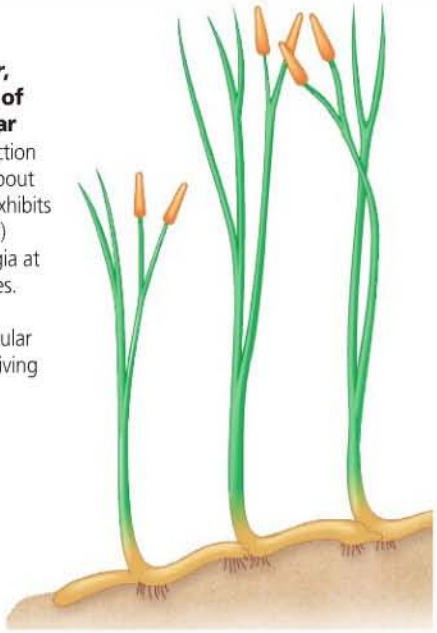
CONCEPT CHECK 29.2

1. How do bryophytes differ from other plants?
2. Give three examples of how structure fits function in bryophytes.
3. **WHAT IF?** For each hypothesis of stomatal evolution, label each gain and loss of stomata on the phylogenetic tree in Figure 29.7 (or a modified version).

For suggested answers, see Appendix A.

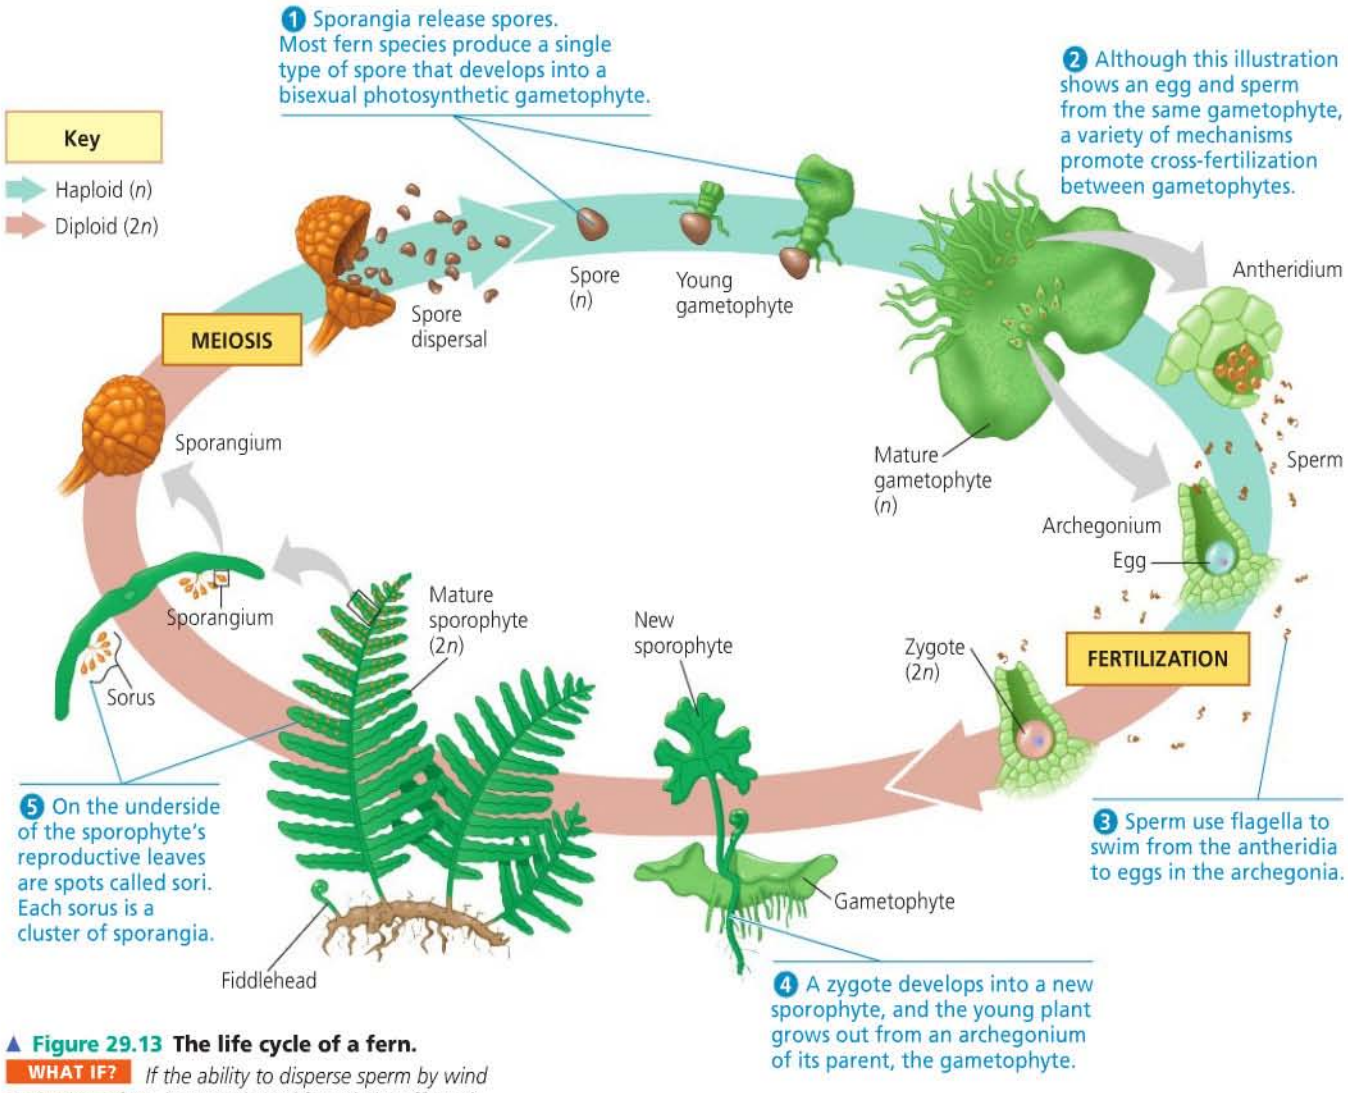


CONCEPT 29.3
Ferns and other seedless vascular plants were the first plants to grow tall

During the first 100 million years of plant evolution, bryophytes or bryophyte-like plants were the prevalent vegetation. But it is vascular plants that dominate most landscapes today. Fossils and living seedless vascular plants can provide insights into plant evolution during the Devonian and Carboniferous periods, when vascular plants began to diversify but most groups of seed plants had not yet evolved. Fossils show that lycophytes, ferns, and other seedless vascular plants had well-developed vascular systems by the Devonian. As we'll see, this evolutionary innovation set the stage for vascular plants to grow taller than their bryophyte counterparts. As in nonvascular plants, however, the sperm of ferns and all other seedless vascular plants are flagellated and must swim through a film of water to reach eggs. In part because of these swimming sperm, seedless vascular plants today are most common in damp environments.

Origins and Traits of Vascular Plants

Fossils of the forerunners of present-day vascular plants date back about 420 million years. Unlike the nonvascular plants, these species had branched sporophytes that were not dependent on gametophytes for nutrition (Figure 29.12). Although these ancestors of vascular plants grew no taller than about 50 cm, their branching made possible more complex bodies with multiple sporangia. As their bodies became



▶ **Figure 29.12 Sporophytes of *Aglaophyton major*, an ancient relative of present-day vascular plants.** This reconstruction from fossils dating to about 420 million years ago exhibits dichotomous (Y-shaped) branching with sporangia at the ends of the branches. Sporophyte branching characterizes living vascular plants but is lacking in living nonvascular plants (bryophytes).

increasingly complex, competition for space and sunlight probably increased. As we'll see, that competition may have stimulated still more evolution in vascular plants.

The ancestors of vascular plants already had some derived traits of today's vascular plants, but they lacked roots and some other adaptations that evolved later. This section describes the main traits that characterize living vascular plants: life cycles with dominant sporophytes, transport in vascular tissues called xylem and phloem, and well-developed roots and leaves, including spore-bearing leaves called sporophylls.

Life Cycles with Dominant Sporophytes

Fossils suggest that the ancestors of vascular plants had gametophytes and sporophytes that were about equal in size. Among living vascular plants, however, the sporophyte (diploid) generation is the larger and more complex plant in the alternation of generations **(Figure 29.13)**. In ferns, for example, the familiar leafy plants are the sporophytes. You

▲ **Figure 29.13 The life cycle of a fern.**

WHAT IF? *If the ability to disperse sperm by wind evolved in a fern, how might its life cycle be affected?*

would have to get down on your hands and knees and search the ground carefully to find fern gametophytes, which are tiny structures that often grow on or just below the soil surface. Until you have a chance to do that, you can study the sporophyte-dominant life cycle of seedless vascular plants in Figure 29.13, which uses a fern as an example. Then, for review, compare this life cycle with Figure 29.8, which represents a gametophyte-dominated life cycle typical of mosses and other nonvascular plants. In Chapter 30, you will see that gametophytes became even more reduced during the evolution of seed plants.

Transport in Xylem and Phloem

Vascular plants have two types of vascular tissue: xylem and phloem. **Xylem** conducts most of the water and minerals. The xylem of most vascular plants includes **tracheids**, tube-shaped cells that carry water and minerals up from roots (see Figure 35.10). (Tracheids have been lost in some highly specialized species, such as *Wolffia*, a tiny aquatic angiosperm.) Because nonvascular plants lack tracheids, vascular plants are sometimes referred to as tracheophytes. The water-conducting cells in vascular plants are *lignified;* that is, their cell walls are strengthened by the phenolic polymer **lignin**. The tissue called **phloem** has cells arranged into tubes that distribute sugars, amino acids, and other organic products (see Figure 35.10).

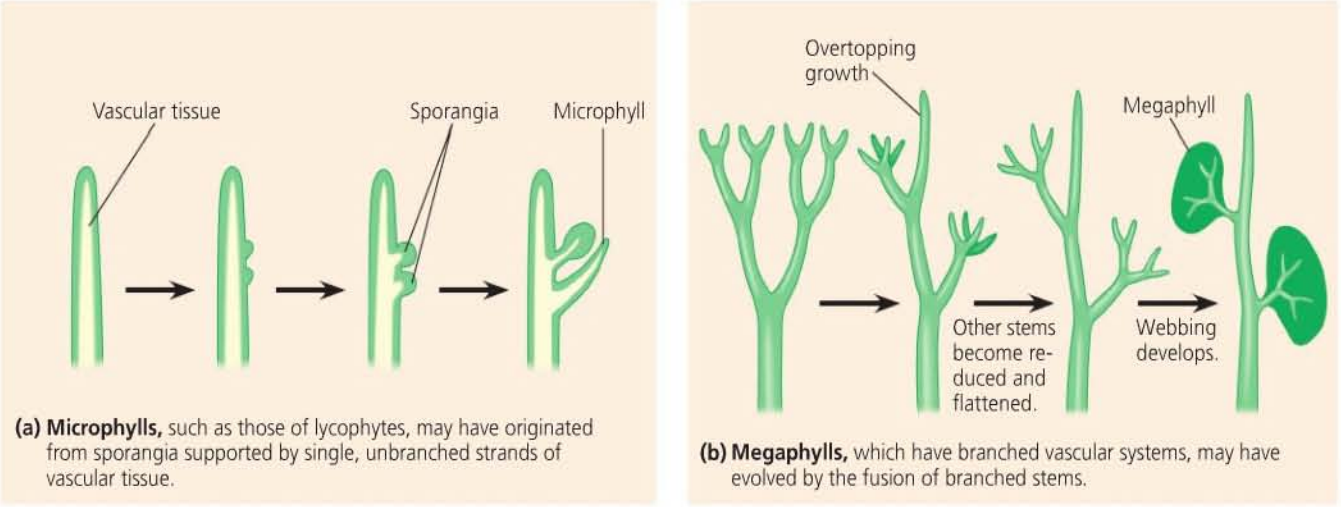
Lignified vascular tissue permitted vascular plants to grow tall. Their stems became strong enough to provide support against gravity, and they could transport water and mineral nutrients high above the ground. The ability to grow tall was a major evolutionary innovation: Tall plants could shade other plants, reducing their access to the sunlight needed for photosynthesis. This gave vascular plants a competitive edge over nonvascular plants, which rarely grow above 20 cm in height. Competition for light among vascular plants also increased, and taller growth forms were favored by natural selection—such as the treelike plants that formed the first forests about 370 million years ago.

Evolution of Roots

Lignified vascular tissue also provides benefits below ground. Instead of the rhizoids seen in bryophytes, roots evolved in almost all vascular plants. **Roots** are organs that absorb water and nutrients from the soil. Roots also anchor vascular plants, hence allowing the shoot system to grow taller.

Root tissues of living plants closely resemble stem tissues of early vascular plants preserved in fossils. This suggests that roots may have evolved from the lowest belowground portions of stems in ancient vascular plants. It is unclear whether roots evolved only once in the common ancestor of all vascular plants or independently in different lineages. Although the roots of living members of these lineages of vascular plants share many similarities, fossil evidence hints at convergent evolution. The oldest lycophyte fossils, for example, already displayed simple roots 400 million years ago, when the ancestors of ferns and seed plants still had none. Studying genes that control root development in different vascular plant species may help resolve this question.

Evolution of Leaves



Leaves increase the surface area of the plant body and serve as the primary photosynthetic organ of vascular plants. In terms of size and complexity, leaves can be classified as either microphylls or megaphylls. All of the lycophytes (the oldest lineage of present-day vascular plants)—and only the lycophytes—have **microphylls**, small, usually spine-shaped leaves supported by a single strand of vascular tissue. Almost all other vascular plants have **megaphylls**, leaves with a highly branched vascular system; a few species have reduced leaves that appear to have evolved from megaphylls. So named because they are typically larger than microphylls, megaphylls support greater photosynthetic productivity than microphylls as a result of the greater surface area served by their network of veins. Microphylls first appear in the fossil record 410 million years ago, but megaphylls do not emerge until about 370 million years ago, near the end of the Devonian period.

According to one model of leaf evolution, microphylls originated from sporangia located on the side of the stem **(Figure 29.14a)**. Megaphylls, by contrast, may have evolved from a series of branches lying close together on a stem. As one of these branches came to grow above, or *overtop*, the others, the lower branches became flattened and developed webbing that joined them to one another. These joined branches thus became a leaf attached to the branch that overtopped them **(Figure 29.14b)**. To better understand the origin of leaves, scientists are exploring genetic control of leaf development.

Sporophylls and Spore Variations

One milestone in the evolution of plants was the emergence of **sporophylls**, modified leaves that bear sporangia. Sporophylls vary greatly in structure. For example, fern sporophylls produce clusters of sporangia known as **sori** (singular, *sorus*), usually on the undersides of the sporophylls (see Figure 29.13). In many lycophytes and in most gymnosperms, groups of sporophylls form cone-like structures called **strobili** (from the Greek *strobilos*, cone). In Chapter 30, you will see how sporophylls form gymnosperm strobili and parts of angiosperm flowers.

Most seedless vascular plant species are **homosporous**: they have one type of sporangium that produces one type of spore, which typically develops into a bisexual gametophyte, as in most ferns. In contrast, a **heterosporous** species has two types of sporangia and produces two kinds of spores: Megasporangia on megasporophylls produce **megaspores**, which develop into female gametophytes; microsporangia on

(a) Microphylls, such as those of lycophytes, may have originated from sporangia supported by single, unbranched strands of vascular tissue.

(b) Megaphylls, which have branched vascular systems, may have evolved by the fusion of branched stems.

▲ **Figure 29.14 Hypotheses for the evolution of leaves.**

microsporophylls produce **microspores**, which develop into male gametophytes. All seed plants and a few seedless vascular plants are heterosporous. The following diagram compares the two conditions:

Homosporous spore production

Sporangium on sporophyll → Single type of spore → Typically a bisexual gametophyte → Eggs, Sperm

Heterosporous spore production

Megasporangium on megasporophyll → Megaspore → Female gametophyte → Eggs

Microsporangium on microsporophyll → Microspore → Male gametophyte → Sperm

Classification of Seedless Vascular Plants

As we noted earlier, biologists recognize two clades of living seedless vascular plants: the lycophytes (phylum Lycophyta) and the pterophytes (phylum Pterophyta). The Lycophytes include the club mosses, the spike mosses, and the quillworts. The pterophytes include the ferns, the horsetails, and the whisk ferns and their relatives. Because they differ greatly in appearance, the ferns, horsetails, and whisk ferns have long been considered separate phyla: phylum Pterophyta (ferns), phylum Sphenophyta (horsetails), and phylum Psilophyta (whisk ferns and a related genus). However, recent molecular comparisons provide convincing evidence that all three groups form a clade. Accordingly, many systematists now classify them together as the phylum Pterophyta, as we do in this chapter. Others refer to these groups as three separate phyla within a clade.

Figure 29.15, on the next page, describes the two main groups of seedless vascular plants.

Phylum Lycophyta: Club Mosses, Spike Mosses, and Quillworts

Present-day species of lycophytes—the most ancient group of vascular plants—are relicts of a far more impressive past. By the Carboniferous period (359 to 299 million years ago), there were two evolutionary lineages of lycophytes: one consisting of small herbaceous plants and another consisting of giant woody treelike plants with diameters of more than 2 m and heights of more than 40 m. The giant "tree lycophytes" thrived for millions of years in moist swamps, but they became extinct when Earth's climate became drier at the end of the Carboniferous period. The small lycophytes survived, represented today by about 1,200 species. Though some are commonly called club mosses and spike mosses, they are not true mosses (which, as discussed earlier, are nonvascular plants).

Phylum Pterophyta: Ferns, Horsetails, and Whisk Ferns and Relatives

Ferns radiated extensively from their Devonian origins and grew alongside tree lycophytes and horsetails in the great Carboniferous swamp forests. Today, ferns are by far the most widespread seedless vascular plants, numbering more than 12,000 species. Though most diverse in the tropics, many ferns thrive in temperate forests, and some species are even adapted to arid habitats.

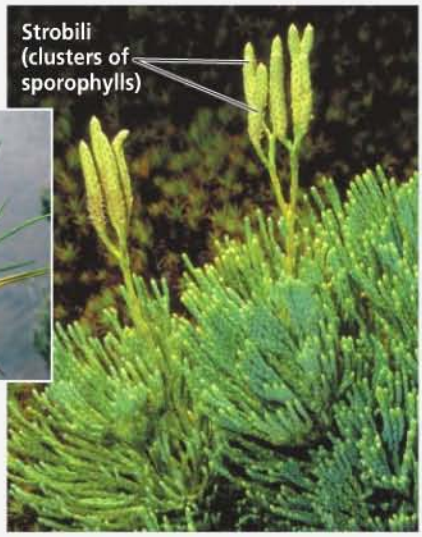
As mentioned earlier, ferns and other pterophytes are more closely related to seed plants than to lycophytes. As a result, pterophytes and seed plants share traits that are not

▼ Figure 29.15

Exploring Seedless Vascular Plant Diversity

Lycophytes (Phylum Lycophyta)

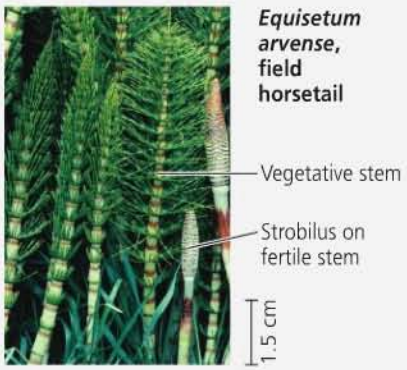
Many lycophytes grow on tropical trees as epiphytes, plants that use other plants as a substrate but are not parasites. Other species grow on temperate forest floors. In some species, the tiny gametophytes live above ground and are photosynthetic. Others live below ground, nurtured by symbiotic fungi.



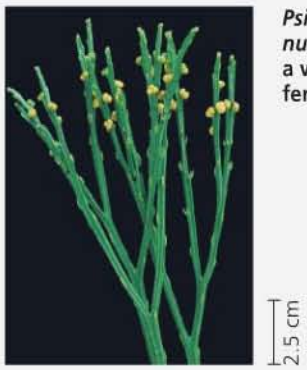
Sporophytes have upright stems with many small leaves, as well as ground-hugging stems that produce dichotomously branching roots. Spike mosses are usually relatively small and often grow horizontally. In many club mosses and spike mosses, sporophylls are clustered into club-shaped cones (strobili). Quillworts, named for their leaf shape, form a single genus that lives in marshy areas. Club mosses are all homosporous, whereas spike mosses and quillworts are all heterosporous. Spores of club mosses are released in clouds and are so rich in oil that magicians and photographers once ignited them to create smoke or flashes of light.

***Selaginella apoda*, a spike moss**

***Isoetes gunnii*, a quillwort**



***Diphasiastrum tristachyum*, a club moss**



Pterophytes (Phylum Pterophyta)

***Athyrium filix-femina*, lady fern**

***Equisetum arvense*, field horsetail**

***Psilotum nudum*, a whisk fern**

Ferns

Unlike the lycophytes, ferns have megaphylls (see Figure 29.14b). The sporophytes typically have horizontal stems that give rise to large leaves called fronds, often divided into leaflets. A frond grows as its coiled tip, the fiddlehead, unfurls.

Almost all species are homosporous. The gametophyte in some species shrivels and dies after the young sporophyte detaches itself. In most species, sporophytes have stalked sporangia with springlike devices that catapult spores several meters. Airborne spores can be carried far from their origin. Some species produce more than a trillion spores in a plant's lifetime.

Horsetails

The group's name refers to the brushy appearance of the stems, which have a gritty texture that made them historically useful as "scouring rushes" for pots and pans. Some species have separate fertile (cone-bearing) and vegetative stems. Horsetails are homosporous, with cones releasing spores that typically give rise to bisexual gametophytes.

Horsetails are also called arthrophytes ("jointed plants") because their stems have joints. Rings of small leaves or branches emerge from each joint, but the stem is the main photosynthetic organ. Large air canals carry oxygen to the roots, which often grow in waterlogged soil.

Whisk Ferns and Relatives

Like primitive vascular plant fossils, the sporophytes of whisk ferns (genus *Psilotum*) have dichotomously branching stems but no roots. Stems have scalelike outgrowths that lack vascular tissue and may have evolved as very reduced leaves. Each yellow knob on a stem consists of three fused sporangia. Species of the genus *Tmesipteris*, closely related to whisk ferns and found only in the South Pacific, also lack roots but have small, leaflike outgrowths in their stems, giving them a vine-like appearance. Both genera are homosporous, with spores giving rise to bisexual gametophytes that grow underground and are only about a centimeter long.

found in lycophytes, including overtopping growth (see Figure 29.14b), megaphyll leaves, and roots that can branch at various points along the length of an existing root (in lycophytes, by contrast, roots branch only at the growing tip of the root by forming a Y-shaped structure).

Horsetails were very diverse during the Carboniferous period, some growing as tall as 15 m. Today however, only about 15 species survive as a single, widely distributed genus, *Equisetum*, found in marshy places and along streams.

Psilotum (whisk ferns) and the closely related genus, *Tmesipteris*, form a clade consisting mainly of tropical epiphytes. Plants in these two genera, the only vascular plants lacking true roots, are called "living fossils" because of their striking resemblance to fossils of ancient relatives of living vascular plants (see Figures 29.12 and 29.15). However, much evidence, including analyses of DNA sequences and sperm structure, indicates that the genera *Psilotum* and *Tmesipteris* are closely related to ferns. This hypothesis suggests that their ancestor's true roots were lost during evolution. Today, plants in these two genera absorb water and nutrients through numerous absorptive rhizoids.

▲ **Figure 29.16 Artist's conception of a Carboniferous forest based on fossil evidence.** Most of the large plants with straight trunks are tree lycophytes. The shorter, spiky plant near the middle of the scene is a horsetail. Animals, including giant dragonflies like the one in the foreground, also thrived in the "coal forests" of the Carboniferous.

The Significance of Seedless Vascular Plants

The ancestors of living lycophytes, horsetails, and ferns, along with their extinct seedless vascular relatives, grew to great heights during the late Devonian and early Carboniferous, forming the first forests **(Figure 29.16)**. How did their dramatic growth affect Earth and its other life? With the evolution of vascular tissue, roots, and leaves, these plants accelerated their rate of photosynthesis, dramatically increasing the removal of CO_2 from the atmosphere. Scientists estimate that CO_2 levels dropped by as much as a factor of five during the Carboniferous, causing global cooling that resulted in widespread glacier formation. Ancient CO_2 levels can be estimated in several ways. These include counting the number of stomata in fossil leaves (data from living species show that this number increases as CO_2 levels drop) and measuring carbon isotope levels in fossils of plankton. Different methods yield comparable results, suggesting that reconstructions of past climates are accurate.

The seedless vascular plants that formed the first forests eventually became coal. In the stagnant waters of Carboniferous swamps, dead plants did not completely decay. This organic material turned to thick layers of peat, later covered by the sea. Marine sediments piled on top, and over millions of years, heat and pressure converted the peat to coal. In fact, Carboniferous coal deposits are the most extensive ever formed. Coal was crucial to the Industrial Revolution, and people worldwide still burn 6 billion tons a year. It is ironic that coal, formed from plants that contributed to a global cooling, now contributes to global warming by returning carbon to the atmosphere (see Chapter 55).

Growing along with the seedless plants in Carboniferous swamps were primitive seed plants. Though seed plants were not dominant at that time, they rose to prominence after the swamps began to dry up at the end of the Carboniferous period. The next chapter traces the origin and diversification of seed plants, continuing our story of adaptation to life on land.

CONCEPT CHECK 29.3

1. List the key derived traits that are found in pterophytes and seed plants, but not in lycophytes.
2. How do the main similarities and differences between seedless vascular plants and nonvascular plants influence function in these plants?
3. **WHAT IF?** If (contrary to current evidence) lycophytes and pterophytes formed a clade, what could you conclude about how members of this clade gained (or lost) traits shared by pterophytes and seed plants?

For suggested answers, see Appendix A.

Chapter 29 Review

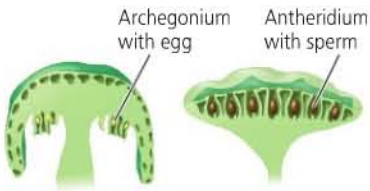
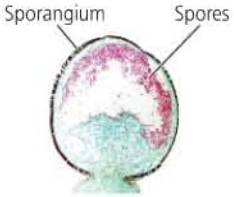
SUMMARY OF KEY CONCEPTS

CONCEPT 29.1

Land plants evolved from green algae (pp. 600–606)



- **Morphological and Molecular Evidence** Traits shared by plants and charophytes include rosette cellulose-synthesizing complexes, peroxisome enzymes, similarities in flagellated sperm structure, and formation of phragmoplasts during cell division. Similarities in nuclear and chloroplast genes also suggest that charophytes are the closest living relatives of land plants.
- **Adaptations Enabling the Move to Land** Sporopollenin and other traits allow charophytes to tolerate occasional drying along the edges of ponds and lakes. Such traits may have enabled the algal ancestors of plants to survive in terrestrial conditions, opening the way to the colonization of dry land. Although some biologists treat the plant kingdom as including some or all green algae, this textbook uses the embryophyte definition of kingdom Plantae.
- **Derived Traits of Plants** Derived traits that distinguish the clade of land plants from charophytes, their closest algal relatives, include the four shown here:



1 Alternation of generations

2 Apical meristems

3 Multicellular gametangia

4 Walled spores in sporangia

- **The Origin and Diversification of Plants** Fossil evidence indicates that plants were on land at least 475 million years ago. Subsequently, plants diverged into several major groups, including nonvascular plants (bryophytes); seedless vascular plants, such as lycophytes and ferns; and the two groups of seed plants, gymnosperms and angiosperms.

MEDIA

Activity Terrestrial Adaptations of Plants
Activity Highlights of Plant Phylogeny

CONCEPT 29.2

Mosses and other nonvascular plants have life cycles dominated by gametophytes (pp. 606–610)

- The three phyla of bryophytes—liverworts, hornworts, and mosses—may not form a clade.
- **Bryophyte Gametophytes** Gametophytes are the dominant generation and are typically most visible, such as those that make up a carpet of moss. Rhizoids anchor gametophytes to the substrate on which they grow. The flagellated sperm produced by antheridia require a film of water to travel to the eggs in the archegonia.
- **Bryophyte Sporophytes** Sporophytes grow out of archegonia and are attached to and dependent on the haploid gametophytes for nourishment. Smaller and simpler than vascular plant sporophytes, they typically consist of a foot, seta (stalk), and sporangium.
- **The Ecological and Economic Importance of Mosses** Peat moss (*Sphagnum*) covers large regions known as peatlands and has many practical uses, including as a fuel.

MEDIA

Activity Moss Life Cycle

CONCEPT 29.3

Ferns and other seedless vascular plants were the first plants to grow tall (pp. 610–615)

- **Origins and Traits of Vascular Plants** Fossils of the forerunners of today's vascular plants date back about 420 million years and show that these small plants had independent, branching sporophytes. However, these ancestral species lacked other derived traits of living vascular plants, such as a life cycle with dominant sporophytes; lignified vascular tissue; well-developed roots and leaves; and sporophylls.
- **Classification of Seedless Vascular Plants** Seedless vascular plants include phylum Lycophyta (club mosses, spike mosses, and quillworts) and phylum Pterophyta (ferns, horsetails, and whisk ferns and relatives). Ancient lycophytes included both small herbaceous plants and large treelike plants. Present-day lycophytes are small herbaceous plants.
- **The Significance of Seedless Vascular Plants** Seedless vascular plants dominated the earliest forests. Their growth may have helped produce the major global cooling that characterized the end of the Carboniferous period. The decaying remnants of the first forests eventually became coal.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which of the following is *not* evidence that charophytes are the closest algal relatives of plants?
   a. similar sperm structure
   b. similarities in chloroplast shape
   c. similarities in cell wall formation during cell division
   d. genetic similarities in chloroplasts
   e. similarities in proteins that synthesize cellulose

2. Which of the following characteristics of plants is absent in their closest relatives, the charophyte algae?
   a. chlorophyll *b*
   b. cellulose in cell walls
   c. formation of a cell plate during cytokinesis
   d. sexual reproduction
   e. alternation of multicellular generations

3. Which of the following is *not* shared by all phyla of vascular plants?
   a. the development of seeds
   b. alternation of generations
   c. dominance of the diploid generation
   d. xylem and phloem
   e. the addition of lignin to cell walls

4. In plants, which of the following are produced by meiosis?
   a. haploid sporophytes
   b. haploid gametes
   c. diploid gametes
   d. haploid spores
   e. diploid spores

5. Microphylls are found in which of the following groups of plants?
   a. mosses
   b. liverworts
   c. lycophytes
   d. ferns
   e. hornworts

6. Which of the following is a land plant that produces flagellated sperm and has a sporophyte-dominated life cycle?
   a. moss
   b. fern
   c. liverwort
   d. charophyte
   e. hornwort

7. Suppose an efficient conducting system evolved in a moss that could transport water and other materials as high as a tall tree. Which of the following statements about "trees" of such a species would *not* be true?
   a. Fertilization would probably be more difficult.
   b. Spore dispersal distances might increase but probably would not decrease.
   c. Females could produce only one archegonium.
   d. Unless its body parts were strengthened, such a "tree" might flop over.
   e. Individuals could compete more effectively for access to light.

8. Identify each of the following structures as haploid or diploid:
   a. sporophyte
   b. spore
   c. gametophyte
   d. zygote
   e. sperm

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

9. **DRAW IT** Draw a phylogenetic tree that represents our current understanding of evolutionary relationships between a moss, a lycophyte, a fern, and a gymnosperm. Use a charophyte alga as the outgroup. (See Chapter 26 to review phylogenetic trees.) Label each branch point of the phylogeny with at least one derived character unique to the clade descended from the common ancestor represented by the branch point.

SCIENTIFIC INQUIRY

10. In April 1986, an accident at a nuclear power plant in Chernobyl, Ukraine, scattered radioactive fallout for hundreds of kilometers. In assessing the biological effects of the radiation, researchers found mosses to be especially valuable as organisms for monitoring the damage. Radiation damages organisms by causing mutations. Explain why the genetic effects of radiation can be observed sooner in bryophytes than in plants from other groups.

    Now imagine that you are conducting tests shortly after a nuclear accident. Using potted moss plants as your experimental organisms, design an experiment to test the hypothesis that the frequency of mutations decreases with the organism's distance from the source of radiation.

SCIENCE, TECHNOLOGY, AND SOCIETY

11. Nonvascular plants (bryophytes) and seedless vascular plants are common, and several of them have important economic and ecological uses. Nevertheless, very few are important agriculturally. Why? What attributes do they lack that make a plant useful in agriculture? What attributes limit their agricultural utility?

30 Plant Diversity II: The Evolution of Seed Plants

▲ **Figure 30.1 What human reproductive organ is functionally similar to this seed?**

KEY CONCEPTS

30.1 Seeds and pollen grains are key adaptations for life on land

30.2 Gymnosperms bear "naked" seeds, typically on cones

30.3 The reproductive adaptations of angiosperms include flowers and fruits

30.4 Human welfare depends greatly on seed plants

OVERVIEW

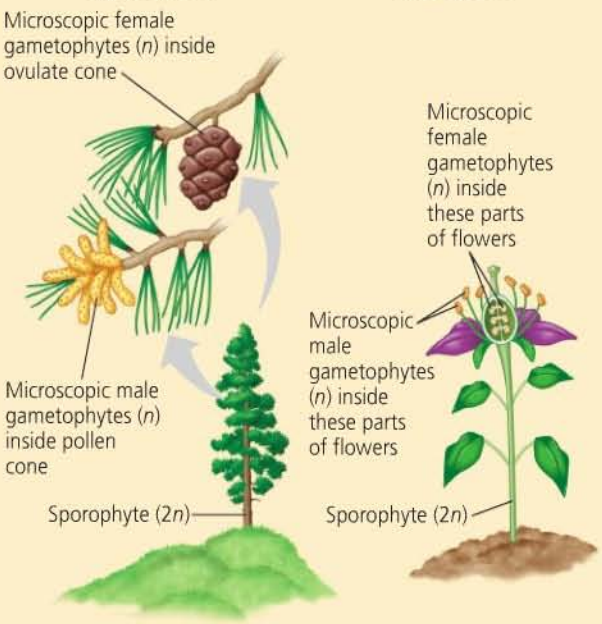
Transforming the World

Continuing the saga of how plants have transformed Earth, this chapter follows the emergence and diversification of seed plants. Fossils and comparative studies of living plants offer clues about the origin of seed plants some 360 million years ago. As this new group of plants became established, they dramatically altered the course of plant evolution. We'll begin our exploration of how this occurred by looking at the innovation for which seed plants are named: seeds **(Figure 30.1)**.

A **seed** consists of an embryo and its food supply, surrounded by a protective coat. When mature, seeds are dispersed from their parent by wind or other means. Because it nourishes and protects the embryo—yet can move away from the mother plant—a seed is analogous to a detachable and mobile version of a pregnant woman's womb. As we'll see, seeds are a key adaptation that helped seed plants to become the dominant producers on land and to make up the vast majority of plant biodiversity today.

Seed plants have also had an enormous impact on human society. Starting about 13,000 years ago, humans began to cultivate wheat, figs, maize (commonly called corn in the United States), bananas, and other wild seed plants. This practice emerged independently in various parts of the world, including the Near East, East Asia, Africa, and the Americas. One piece of evidence, the well-preserved squash seed in Figure 30.1, was found in a cave in Mexico and dates from between 8,000 and 10,000 years ago. This seed differs from wild squash seeds, suggesting that squash was being domesticated by that time. The domestication of seed plants, particularly angiosperms, produced the most important cultural change in human history, transforming most human societies from roving bands of hunter-gatherers to permanent settlements anchored by agriculture.

In this chapter, we will first examine the general characteristics of seed plants. Then we will look at the distinguishing features and evolution of gymnosperms and angiosperms.



CONCEPT **30.1**

Seeds and pollen grains are key adaptations for life on land

We begin with an overview of terrestrial adaptations that seed plants added to those already present in nonvascular plants (bryophytes) and seedless vascular plants (see Chapter 29). In addition to seeds, the following are common to all seed plants: reduced gametophytes, heterospory, ovules, and pollen. As you'll read, these adaptations provided new ways for seed plants to cope with terrestrial conditions such as drought and exposure to the ultraviolet (UV) radiation in sunlight. Novel adaptations also freed seed plants from requiring water for fertilization, enabling reproduction to occur under a broader range of conditions than in seedless plants.

Advantages of Reduced Gametophytes

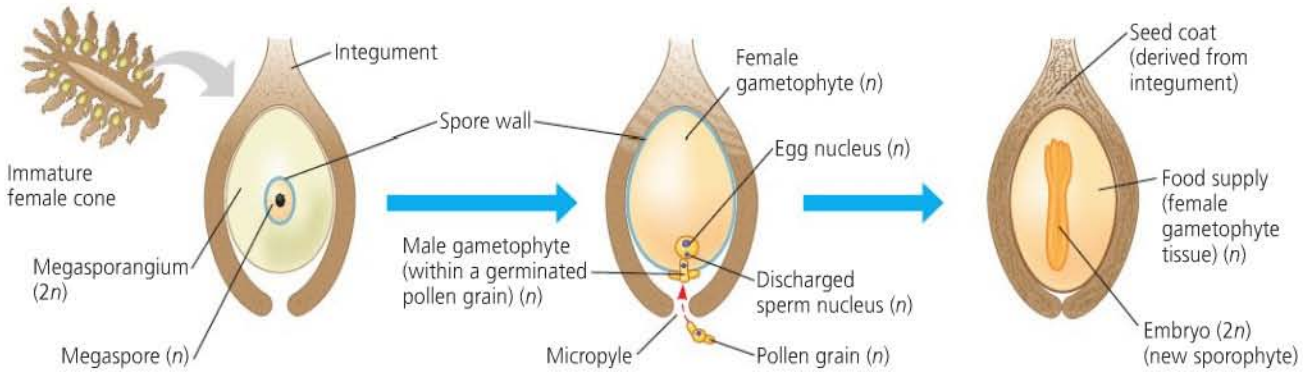
Mosses and other bryophytes have life cycles dominated by gametophytes, whereas ferns and other seedless vascular plants have sporophyte-dominated life cycles. The evolutionary trend

	PLANT GROUP		
	Mosses and other nonvascular plants	**Ferns and other seedless vascular plants**	**Seed plants (gymnosperms and angiosperms)**
Gametophyte	Dominant	Reduced, independent (photosynthetic and free-living)	Reduced (usually microscopic), dependent on surrounding sporophyte tissue for nutrition
Sporophyte	Reduced, dependent on gametophyte for nutrition	Dominant	Dominant
Example			**Gymnosperm** **Angiosperm** 

▲ **Figure 30.2 Gametophyte-sporophyte relationships in different plant groups.**

of gametophyte reduction continued further in the vascular plant lineage that led to seed plants. While the gametophytes of seedless vascular plants are visible to the naked eye, the gametophytes of seed plants are mostly microscopic.

This miniaturization allowed for an important evolutionary innovation in seed plants: Their tiny gametophytes can develop from spores retained within the sporangia of the parental sporophyte. This arrangement protects the delicate female (egg-containing) gametophytes from environmental stresses. The moist reproductive tissues of the sporophyte shield the gametophytes from UV radiation and protect against drying out. This relationship also enables the dependent gametophytes to obtain nutrients from the sporophyte. In contrast, the free-living gametophytes of seedless plants must fend for themselves. **Figure 30.2** contrasts the gametophyte-sporophyte relationships in nonvascular plants, seedless vascular plants, and seed plants.



Heterospory: The Rule Among Seed Plants

You read in Chapter 29 that nearly all seedless plants are homosporous—they produce one kind of spore, which usually gives rise to a bisexual gametophyte. The closest relatives of seed plants are all homosporous, suggesting that seed plants had homosporous ancestors. At some point, seed plants or their ancestors became heterosporous: Megasporangia produce megaspores that give rise to female gametophytes, and microsporangia produce microspores that give rise to male gametophytes. Each megasporangium has a single functional megaspore, whereas each microsporangium contains vast numbers of microspores.

As we noted previously, the miniaturization of seed plant gametophytes likely contributed to the great success of this clade. Next we will look at the development of the female gametophyte within an ovule and the development of the male gametophyte in a pollen grain. Then we will follow the transformation of a fertilized ovule into a seed.

Ovules and Production of Eggs

Although a few species of seedless plants are heterosporous, seed plants are unique in retaining the megasporangium and megaspore within the parent sporophyte. A layer of sporophyte tissue called **integument** envelops and protects the megasporangium.

(a) Unfertilized ovule. In this longitudinal section through the ovule of a pine (a gymnosperm), a fleshy megasporangium is surrounded by a protective layer of tissue called an integument. (Angiosperms have two integuments.)

(b) Fertilized ovule. A megaspore develops into a multicellular female gametophyte. The micropyle, the only opening through the integument, allows entry of a pollen grain. The pollen grain contains a male gametophyte, which develops a pollen tube that discharges sperm, thereby fertilizing the egg.

(c) Gymnosperm seed. Fertilization initiates the transformation of the ovule into a seed, which consists of a sporophyte embryo, a food supply, and a protective seed coat derived from the integument.

▲ **Figure 30.3 From ovule to seed in a gymnosperm.**

? *A gymnosperm seed contains cells from how many different plant generations? Identify the cells and whether each is haploid or diploid.*

Gymnosperm megasporangia are surrounded by one integument, whereas those in angiosperms usually have two integuments. The whole structure—megasporangium, megaspore, and their integument(s)—is called an **ovule** (Figure 30.3a). Inside each ovule (from the Latin *ovulum,* little egg), a female gametophyte develops from a megaspore and produces one or more eggs.

Pollen and Production of Sperm

A microspore develops into a **pollen grain** that consists of a male gametophyte enclosed within the pollen wall. The tough pollen wall, which contains the polymer sporopollenin, protects a pollen grain as it is transported from the parent plant by wind, for example, or by hitchhiking on the body of an animal. The transfer of pollen to the part of a seed plant that contains the ovules is called **pollination**. If a pollen grain germinates (begins growing), it gives rise to a pollen tube that discharges sperm into the female gametophyte within the ovule, as shown in Figure 30.3b.

Recall that in nonvascular plants and seedless vascular plants such as ferns, free-living gametophytes release flagellated sperm that must swim through a film of water to reach eggs. The distance for this sperm transport rarely exceeds a few centimeters. By contrast, in seed plants a sperm-producing male gametophyte inside a pollen grain can be carried long distances by wind or by animals, eliminating the dependence on water for sperm transport. The sperm of seed plants also do not require motility because sperm are carried directly to the eggs by pollen tubes. Living gymnosperms provide evidence of the evolutionary transition to nonmotile sperm. The sperm of some gymnosperm species (such as ginkgos and cycads, depicted a little later in Figure 30.5) retain the ancient flagellated condition, but flagella have been lost in the sperm of most gymnosperms and all angiosperms.

The Evolutionary Advantage of Seeds

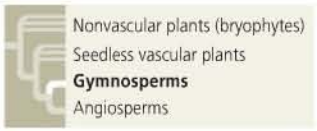
If a sperm fertilizes an egg of a seed plant, the zygote grows into a sporophyte embryo. As shown in Figure 30.3c, the whole ovule develops into a seed: the embryo, along with a food supply, packaged within a protective coat derived from the integument(s).

Until the advent of seeds, the spore was the only protective stage in any plant life cycle. Moss spores, for example, may survive even if the local environment becomes too cold, too hot, or too dry for the mosses themselves to live. Their tiny size enables the moss spores to be dispersed in a dormant state to a new area, where they can germinate and give rise to new moss gametophytes if and when conditions are favorable enough for them to break dormancy. Spores were the main way that mosses and other seedless plants spread over Earth for the first 100 million years of plant life on land.

Although mosses and other seedless plants continue to be very successful today, seeds represent a major evolutionary innovation that contributed to the opening of new ways of life for seed plants. What advantages do seeds provide over spores? Spores are usually single-celled, whereas seeds have a multicellular layer of tissue, the seed coat, that provides extra protection to the embryo. Unlike spores, seeds also have a supply of stored food. This enables a seed to remain dormant for days, months, or even years after being released from the parent plant. (Most spores have much shorter lifetimes.) Under favorable conditions, the seed can then germinate, with its stored food providing critical support for growth as the sporophyte embryo emerges as a

seedling. Some seeds land close to their parent sporophyte plant; others are transported long distances (up to hundreds of kilometers) by wind or animals.

CONCEPT CHECK 30.1



1. Contrast sperm delivery in seedless vascular plants with sperm delivery in seed plants.
2. What additional features of seed plants, not present in seedless plants, have contributed to the enormous success of seed plants on land?
3. **WHAT IF?** If seed plants were homosporous, what aspects of their reproduction would change? Explain.

For suggested answers, see Appendix A.

◀ Figure 30.4 A progymnosperm. *Archaeopteris*, which lived 380 million years ago, produced wood and was heterosporous, but it did not produce seeds. Growing up to 20 m tall, it had fernlike leaves.

CONCEPT 30.2
Gymnosperms bear "naked" seeds, typically on cones

Recall from Chapter 29 that gymnosperms are plants that have "naked" seeds that are not enclosed in ovaries. Their seeds are exposed on modified leaves (sporophylls) that usually form cones (strobili). (In contrast, angiosperm seeds are enclosed in fruits, which are mature ovaries.) We turn now to the origin of gymnosperms and other early seed plants.

Gymnosperm Evolution

Fossil evidence reveals that by late in the Devonian period (about 380 million years ago), some plants had begun to acquire adaptations characteristic of seed plants. For example, *Archaeopteris* was a heterosporous tree that had a woody stem **(Figure 30.4)**. It did not, however, bear seeds. Such transitional species of seedless vascular plants are sometimes called **progymnosperms**.

The first seed-bearing plants to appear in the fossil record date from around 360 million years ago, more than 200 million years before the first angiosperm fossils. These early seed plants became extinct, as did several later lineages. Although the relationships between extinct and surviving lineages of seed plants remain uncertain, morphological and molecular evidence places the surviving lineages of seed plants into two monophyletic sister clades: the gymnosperms and the angiosperms (see Figure 29.7).

The earliest fossils of gymnosperms are about 305 million years old. These early gymnosperms lived in Carboniferous ecosystems still dominated by lycophytes, horsetails, ferns, and other seedless vascular plants. As the Carboniferous period gave way to the Permian, markedly drier climatic conditions favored the spread of gymnosperms. The flora and fauna changed dramatically, as many groups of organisms disappeared and others became prominent (see Chapter 25). Though most pronounced in the seas, the changeover also affected terrestrial life. For example, in the animal kingdom, amphibians decreased in diversity and were replaced by reptiles, which were especially well adapted to the arid conditions. Similarly, the lycophytes, horsetails, and ferns that dominated the Carboniferous swamps were largely replaced by gymnosperms, which were more suited to the drier climate. Gymnosperms have the key terrestrial adaptations found in all seed plants, such as seeds and pollen. In addition, some gymnosperms were particularly well suited to arid conditions because of the thick cuticles and relatively small surface areas of their needle-shaped leaves.

Geologists consider the end of the Permian period, about 251 million years ago, to be the boundary between the Paleozoic ("old life") and Mesozoic ("middle life") eras. Life changed profoundly as gymnosperms dominated terrestrial ecosystems throughout the Mesozoic, serving as the food supply for giant herbivorous dinosaurs. The Mesozoic era ended with mass extinctions of most of the dinosaurs and many other animal groups, and the planet gradually cooled. Although angiosperms now dominate most terrestrial ecosystems, many gymnosperms remain an important part of Earth's flora. For example, vast regions in northern latitudes are covered by forests of cone-bearing gymnosperms called **conifers**, which include spruce, pine, fir, and redwood (see Figure 52.21).

Of the ten plant phyla in the taxonomic scheme adopted by this textbook (see Table 29.1), four are gymnosperms: Cycadophyta, Ginkgophyta, Gnetophyta, and Coniferophyta. The relationships of these four phyla to each other are uncertain. **Figure 30.5**, on the next two pages, surveys the diversity of extant gymnosperms.

▼ Figure 30.5

Exploring Gymnosperm Diversity

Phylum Cycadophyta

Cycads are the next largest group of gymnosperms after the conifers. They have large cones and palmlike leaves (true palm species are angiosperms). Only about 130 species survive today, but cycads thrived during the Mesozoic era, known as the age of cycads as well as the age of dinosaurs.

Cycas revoluta

Phylum Ginkgophyta

Ginkgo biloba is the only surviving species of this phylum. Also known as the maidenhair tree, it has deciduous fanlike leaves that turn gold in autumn. It is a popular ornamental tree in cities because it tolerates air pollution well. Landscapers often plant only pollen-producing trees because the fleshy seeds smell rancid as they decay.

Phylum Gnetophyta

Plants in the phylum Gnetophyta, called gnetophytes, consist of three genera: *Gnetum*, *Ephedra*, and *Welwitschia*. Some species are tropical, whereas others live in deserts. Although very different in appearance, the genera are grouped together based on molecular data.

Welwitschia. This genus consists of one species, *Welwitschia mirabilis*, a plant that lives only in the deserts of southwestern Africa. Its straplike leaves are among the largest leaves known.

Ovulate cones

Gnetum. This genus includes about 35 species of tropical trees, shrubs, and vines, mainly native to Africa and Asia. Their leaves look similar to those of flowering plants, and their seeds look somewhat like fruits.

Ephedra. This genus includes about 40 species that inhabit arid regions worldwide. These desert shrubs, commonly called "Mormon tea," produce the compound ephedrine, which is used medicinally as a decongestant.

Phylum Coniferophyta

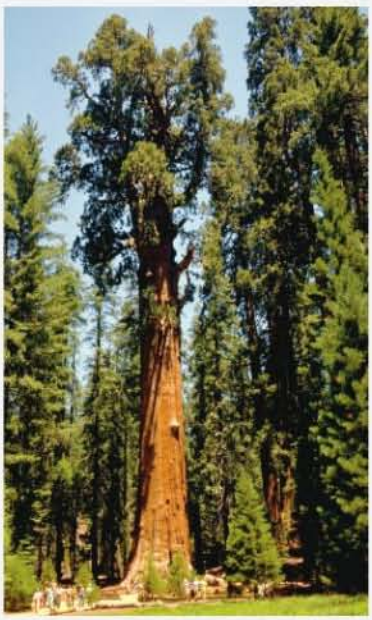
Phylum Coniferophyta is by far the largest of the gymnosperm phyla, consisting of about 600 species of conifers (from the Latin *conus*, cone, and *ferre*, to carry). Many are large trees, such as cypresses and redwoods. A few conifer species dominate vast forested regions of the Northern Hemisphere, where the growing season is relatively short because of latitude or altitude.

Most conifers are evergreens; they retain their leaves throughout the year. Even during winter, a limited amount of photosynthesis occurs on sunny days. When spring comes, conifers already have fully developed leaves that can take advantage of the sunnier, warmer days. Some conifers, such as the dawn redwood, tamarack, and larch, are deciduous trees that lose leaves each autumn.

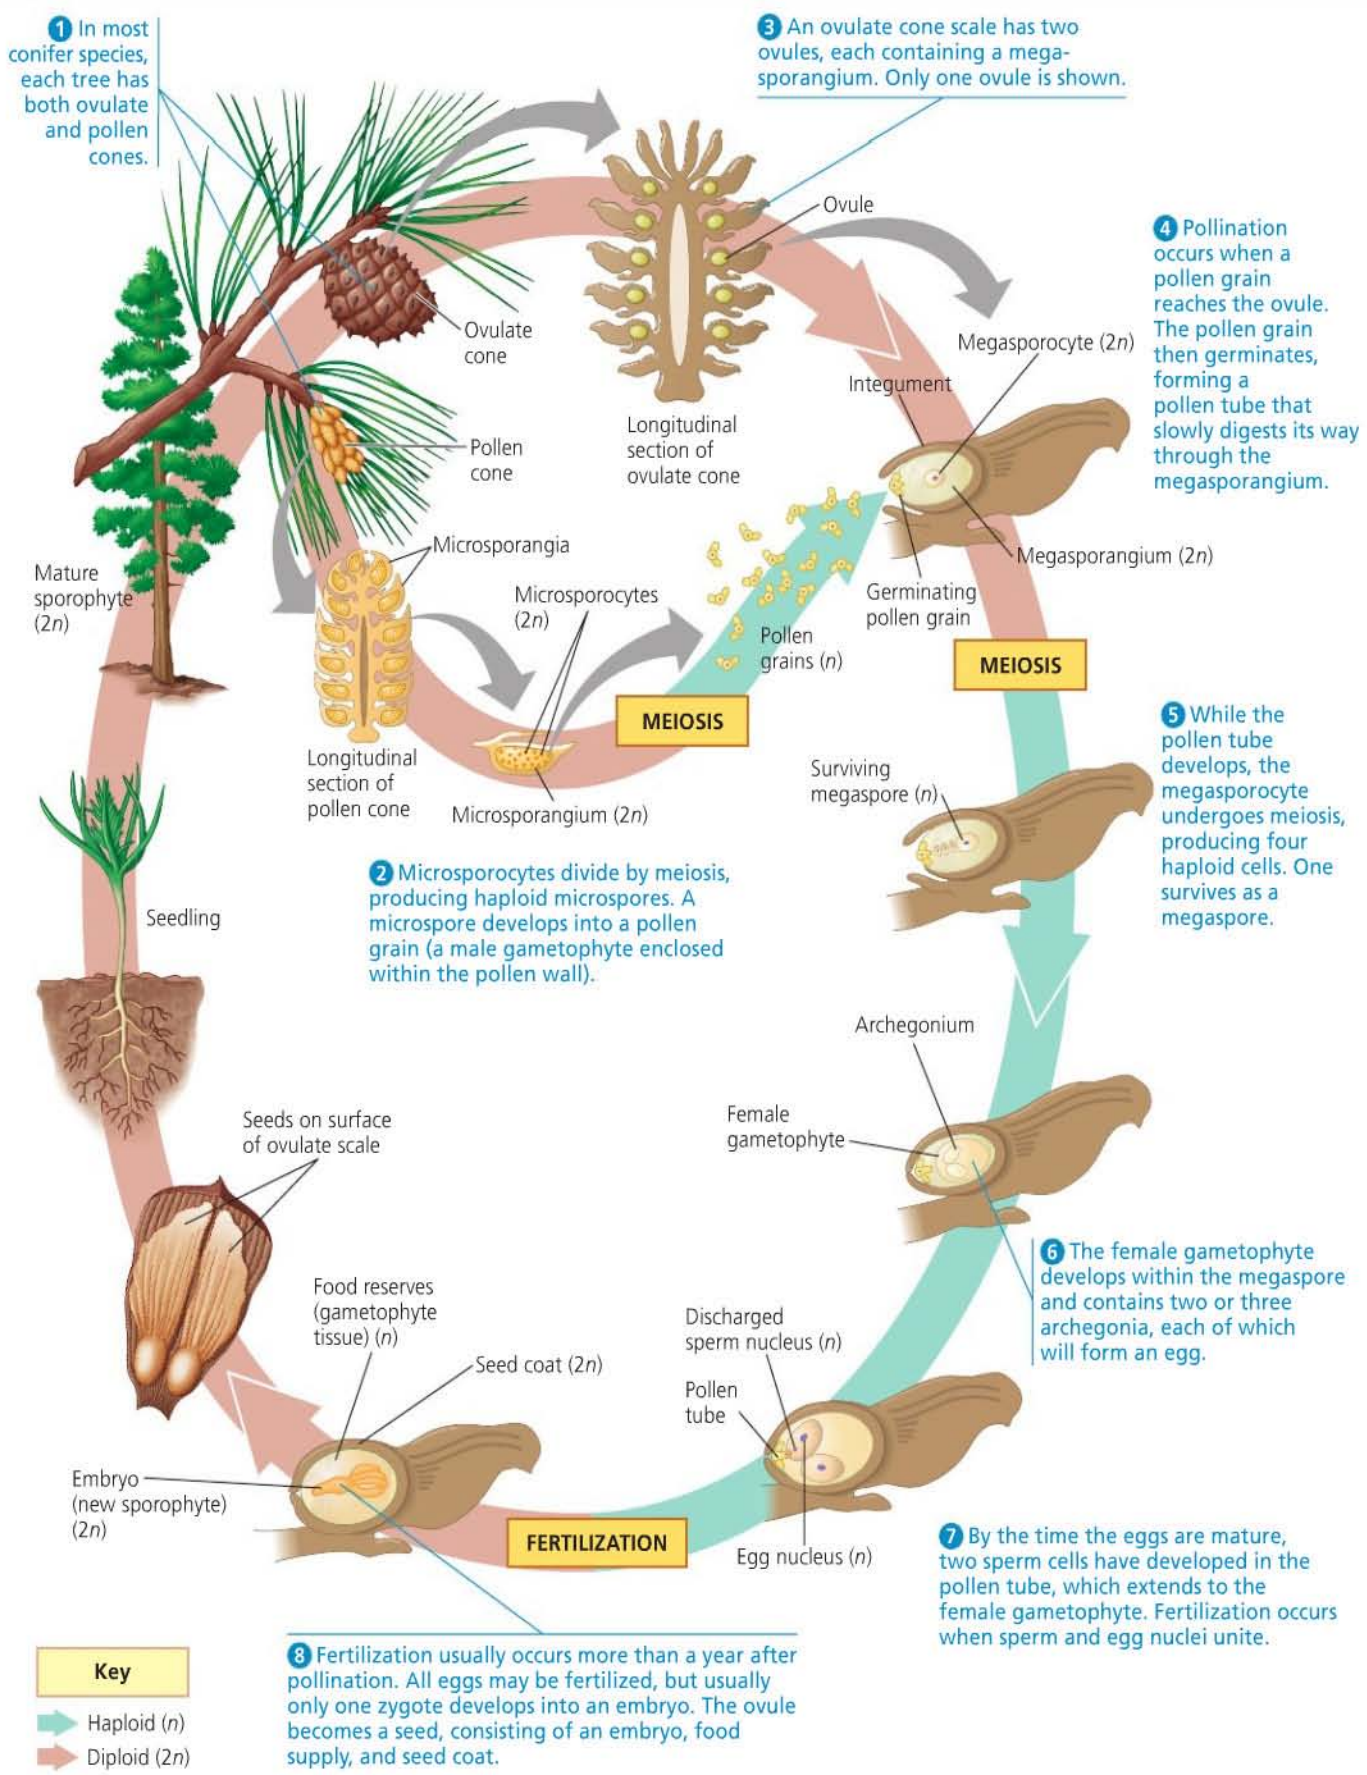
Douglas fir. This evergreen tree (*Pseudotsuga menziesii*) provides more timber than any other North American tree species. Some uses include house framing, plywood, pulpwood for paper, railroad ties, and boxes and crates.

Common juniper. The "berries" of the common juniper (*Juniperus communis*) are actually ovule-producing cones consisting of fleshy sporophylls.

Wollemi pine. A survivor of a conifer group once known only from fossils, living Wollemi pines (*Wollemia nobilis*) were discovered in 1994 in a national park only 150 km from Sydney, Australia. The species consists of just 40 known individuals in two small groves. The inset photo compares the leaves of this "living fossil" with actual fossils.



European larch. The needle-like leaves of this deciduous conifer (*Larix decidua*) turn yellow before they are shed in autumn. Native to the mountains of central Europe, including Switzerland's Matterhorn, depicted here, this species is extremely cold-tolerant, able to survive winter temperatures that plunge to –50°C.



Bristlecone pine. This species (*Pinus longaeva*), which is found in the White Mountains of California, includes some of the oldest living organisms, reaching ages of more than 4,600 years. One tree (not shown here) is called Methuselah because it may be the world's oldest living tree. To protect the tree, scientists keep its location a secret.

Sequoia. This giant sequoia (*Sequoiadendron giganteum*) in California's Sequoia National Park weighs about 2,500 metric tons, equivalent to about 24 blue whales (the largest animals) or 40,000 people. The giant sequoia is one of the largest living organisms and also among the most ancient, with some individuals estimated to be between 1,800 and 2,700 years old. Their cousins, the coast redwoods (*Sequoia sempervirens*), grow to heights of more than 110 m (taller than the Statue of Liberty) and are found only in a narrow coastal strip of northern California and southern Oregon.

▲ **Figure 30.6 The life cycle of a pine.**

The Life Cycle of a Pine: *A Closer Look*

As you read earlier, seed plant evolution has included three key reproductive adaptations: the increasing dominance of the sporophyte; the advent of the seed as a resistant, dispersible stage in the life cycle; and the appearance of pollen as an airborne agent that brings gametes together. **Figure 30.6**, on the facing page, shows how these adaptations come into play during the life cycle of a pine, a familiar conifer.

The pine tree is the sporophyte; its sporangia are located on scalelike structures packed densely in cones. Like all seed plants, conifers are heterosporous. In conifers, the two types of spores are produced by separate cones: small pollen cones and large ovulate cones. In most pine species, each tree has both types of cones. In pollen cones, microsporocytes (microspore mother cells) undergo meiosis, producing haploid microspores. Each microspore develops into a pollen grain containing a male gametophyte. In pines and other conifers, the yellow pollen is released in large amounts and carried by the wind, dusting everything in its path. Meanwhile, in ovulate cones, megasporocytes (megaspore mother cells) undergo meiosis and produce haploid megaspores inside the ovule. Surviving megaspores develop into female gametophytes, which are retained within the sporangia.

From the time young pollen and ovulate cones appear on the tree, it takes nearly three years for the male and female gametophytes to be produced and brought together and for mature seeds to form from the fertilized ovules. The scales of each ovulate cone then separate, and the seeds are dispersed by the wind. A seed that lands in a suitable environment then germinates, its embryo emerging as a pine seedling.

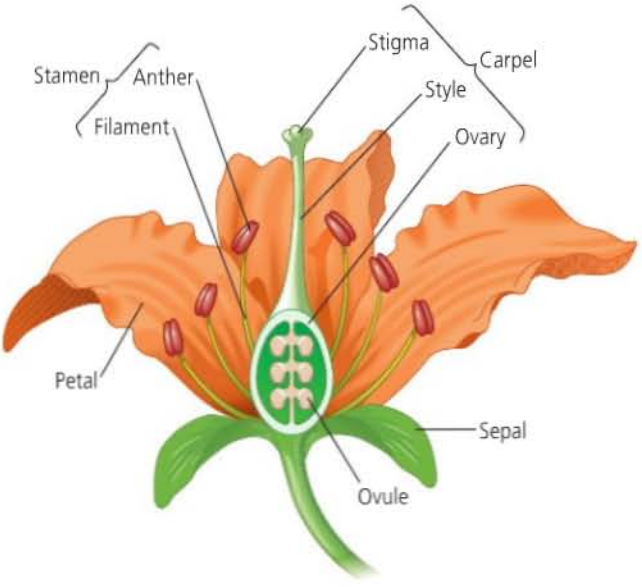
CONCEPT CHECK 30.2

1. Use examples from Figure 30.5 to describe how various gymnosperms are similar yet distinctive.
2. Explain how the pine life cycle (see Figure 30.6) reflects basic characteristics of seed plants.
3. **WHAT IF?** Does the hypothesis that gymnosperms and angiosperms are sister clades imply that these two lineages originated at the same time? Explain.

For suggested answers, see Appendix A.

CONCEPT 30.3
The reproductive adaptations of angiosperms include flowers and fruits

Commonly known as flowering plants, angiosperms are seed plants that produce the reproductive structures called flowers and fruits. The name *angiosperm* (from the Greek *angion*, container) refers to seeds contained in fruits, the mature ovaries. Today, angiosperms are the most diverse and widespread of all plants, with more than 250,000 species (about 90% of all plant species).



Characteristics of Angiosperms

All angiosperms are classified in a single phylum, Anthophyta (from the Greek *anthos*, flower). Before considering the evolution of angiosperms, we will examine their key adaptations—flowers and fruits—and their roles in the angiosperm life cycle.

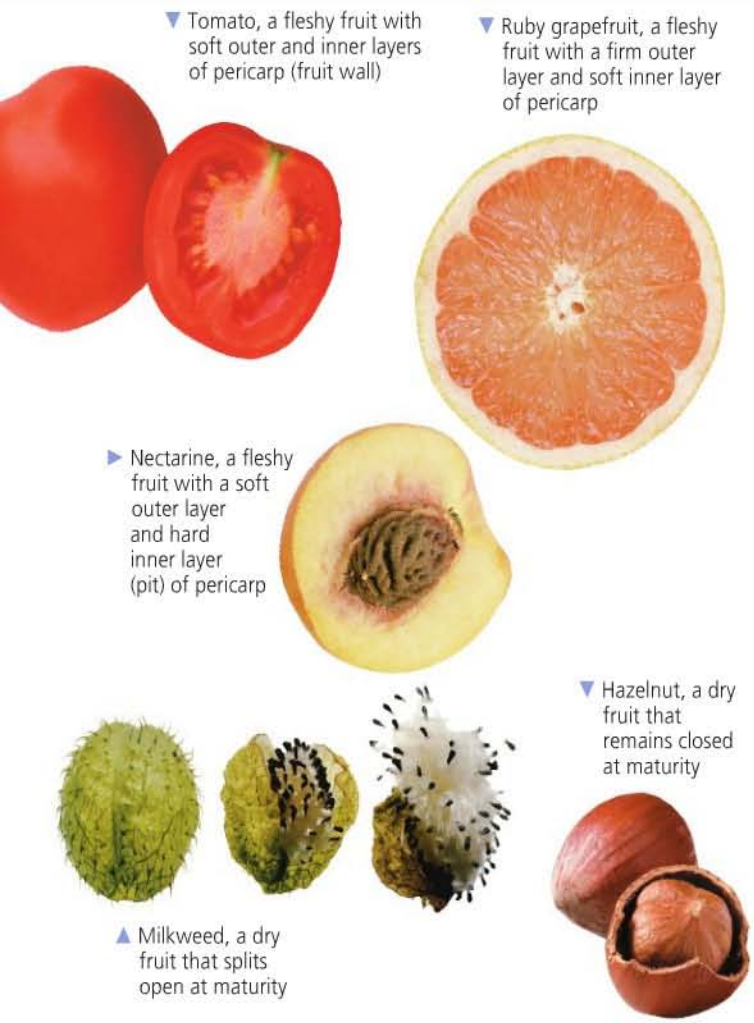
Flowers

The **flower** is an angiosperm structure specialized for sexual reproduction. In many angiosperm species, insects or other animals transfer pollen from one flower to the sex organs on another flower, which makes pollination more directed than the wind-dependent pollination of most gymnosperms. However, some angiosperms *are* wind-pollinated, particularly those species that occur in dense populations, such as grasses and tree species in temperate forests.

A flower is a specialized shoot that can have up to four rings of modified leaves (sporophylls) called floral organs: sepals, petals, stamens, and carpels **(Figure 30.7)**. Starting at the base of the flower are the **sepals**, which are usually green and enclose the flower before it opens (think of a rosebud). Interior to the sepals are the **petals**, which are brightly colored in most flowers and aid in attracting pollinators. Flowers that are wind-pollinated, however, generally lack brightly colored parts. In all angiosperms, the sepals and petals are sterile floral organs, meaning that they are not directly involved in reproduction. Within the petals are two whorls of fertile floral organs that produce spores, the stamens and carpels. **Stamens** produce

▲ **Figure 30.7 The structure of an idealized flower.**

microspores that develop into pollen grains containing male gametophytes. A stamen consists of a stalk called the **filament** and a terminal sac, the **anther**, where pollen is produced. **Carpels** make megaspores and their products, female gametophytes. Some flowers, such as pea blossoms, have a single carpel, while others, such as the magnolia on the cover of this book, have several separate carpels. At the tip of the carpel is a sticky **stigma** that receives pollen. A **style** leads from the stigma to the **ovary** at the base of the carpel; the ovary contains one or more ovules. If fertilized, an ovule develops into a seed.



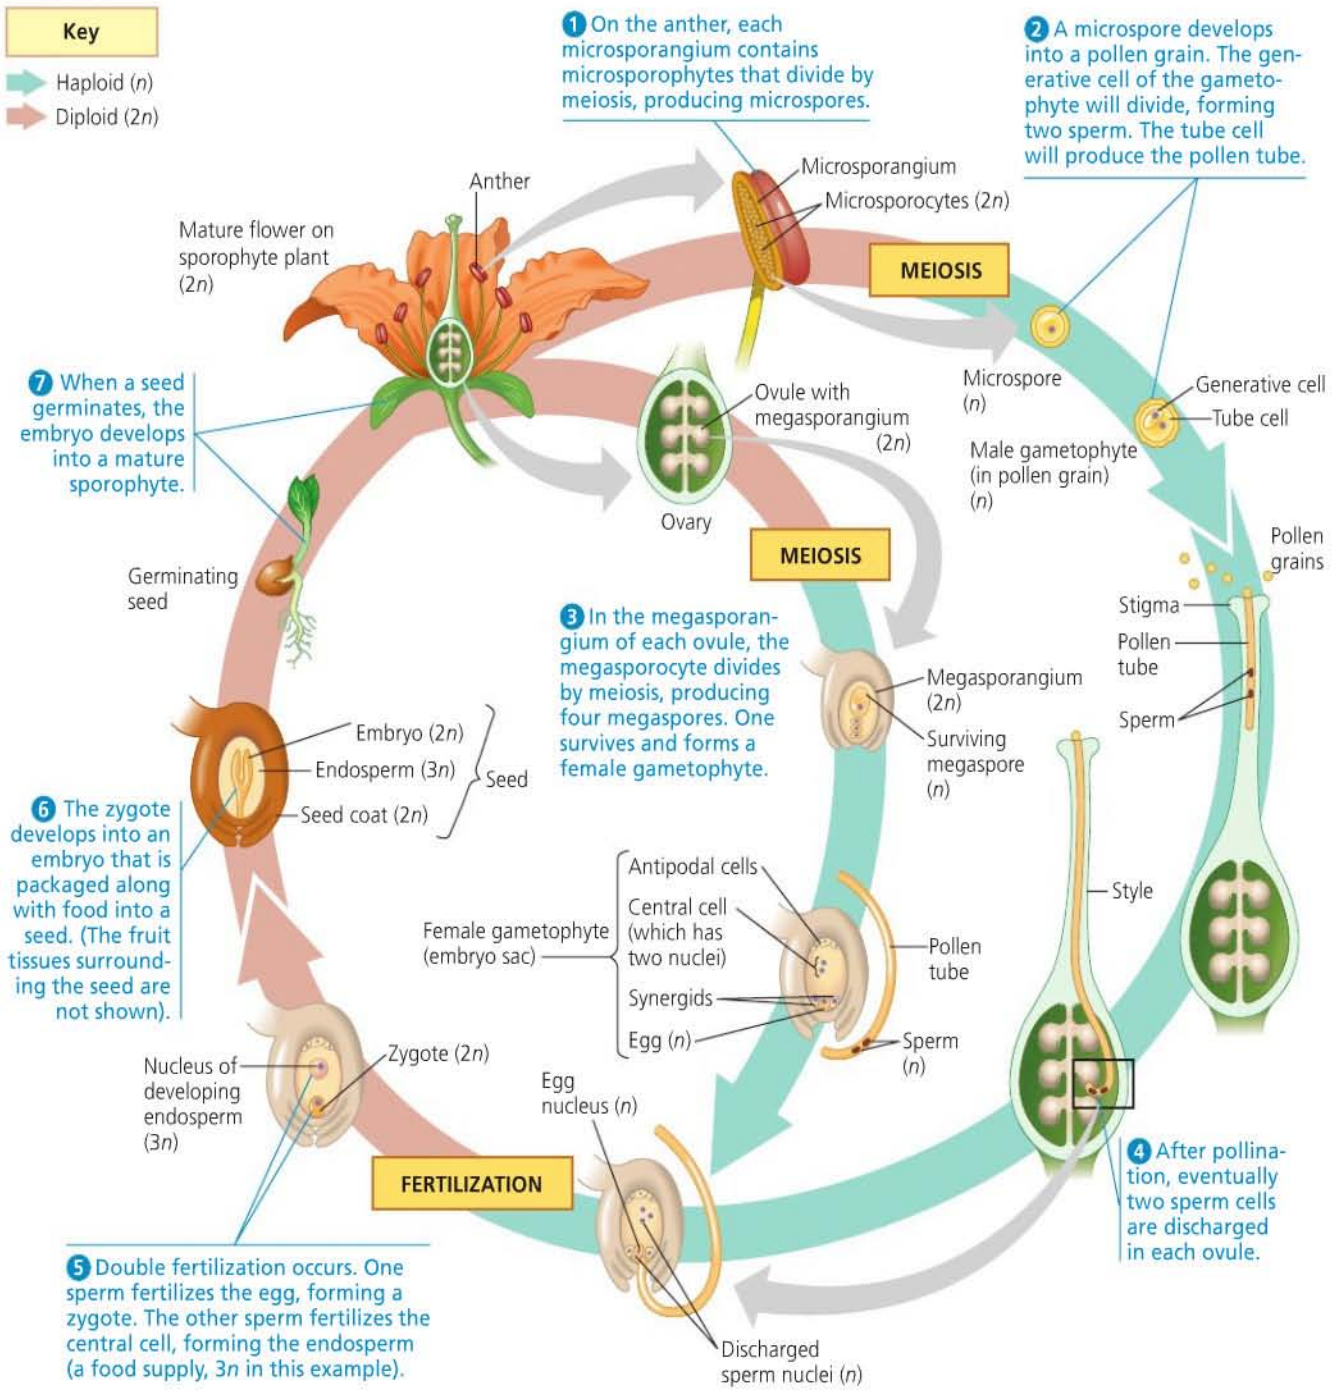
Fruits

A **fruit** typically consists of a mature ovary, although it can include other flower parts as well. As seeds develop from ovules after fertilization, the wall of the ovary thickens. A pea pod is an example of a fruit, with seeds (mature ovules, the peas) encased in the ripened ovary (the pod).

Fruits protect dormant seeds and aid in their dispersal. Mature fruits can be either fleshy or dry **(Figure 30.8)**. Oranges, plums, and grapes are examples of fleshy fruits, in which the wall of the ovary becomes soft during ripening. Dry fruits include beans, nuts, and grains. The dry, wind-dispersed fruits of grasses, harvested while on the plant, are major staple foods for humans. The cereal grains of wheat, rice, maize, and other grasses, though easily mistaken for seeds, are each actually a fruit with a dry outer covering (the former wall of the ovary) that adheres to the seed coat of the seed within.

Various adaptations of fruits help to disperse seeds **(Figure 30.9)**. The seeds of some flowering plants, such as dandelions and maples, are contained within fruits that function like parachutes or propellers, adaptations that enhance dispersal by wind. Some fruits, such as coconuts, are adapted to dispersal by water (see Figure 38.11). And many angiosperms rely on animals to carry seeds. Some of these plants have fruits modified as burrs that cling to animal fur (or the clothes of humans). Other angiosperms produce edible fruits, which are usually nutritious, sweet tasting, and vividly colored, advertising their ripeness. When an animal eats the fruit, it digests the fruit's fleshy part, but the tough seeds usually pass unharmed through the animal's digestive tract. Animals may deposit the seeds, along with a supply of natural fertilizer, many kilometers from where the fruit was eaten.

▼ Figure 30.8 Some variations in fruit structure.



▼ Figure 30.9 Fruit adaptations that enhance seed dispersal.

The Angiosperm Life Cycle

You can follow a typical angiosperm life cycle in **Figure 30.10**. The flower of the sporophyte produces microspores that form male gametophytes and megaspores that form female gametophytes. The male gametophytes are in the pollen grains, which develop within microsporangia in the anthers. Each male gametophyte has two haploid cells: a *generative cell* that divides, forming two sperm, and a *tube cell* that produces a pollen tube. Each ovule, which develops in an ovary, contains a female gametophyte, also known as an **embryo sac**. The embryo sac consists of only a few cells, one of which is the egg. (We will discuss gametophyte development in more detail in Chapter 38.)

After its release from the anther, the pollen is carried to the sticky stigma at the tip of a carpel. Although some flowers self-pollinate, most have mechanisms that ensure **cross-pollination**, which in angiosperms is the transfer of pollen from an anther

▲ **Figure 30.10 The life cycle of an angiosperm.**

of a flower on one plant to the stigma of a flower on another plant of the same species. Cross-pollination enhances genetic variability. In some cases, stamens and carpels of a single flower may mature at different times, or they may be so arranged that self-pollination is unlikely.

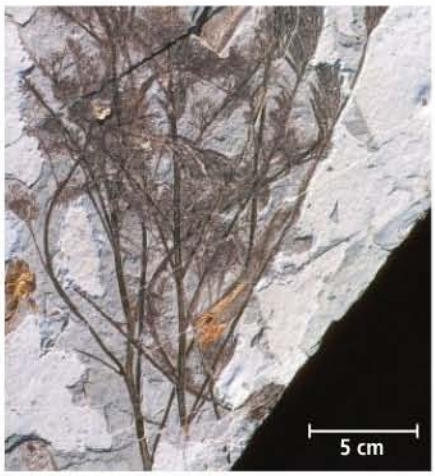
The pollen grain germinates after it adheres to the stigma of a carpel. The pollen grain's male gametophyte extends a pollen tube that grows down within the style of the carpel. After reaching the ovary, the pollen tube penetrates through the **micropyle**, a pore in the integuments of the ovule, and discharges two sperm cells into the female gametophyte (embryo sac). One sperm fertilizes the egg, forming a diploid zygote. The other sperm fuses with the two nuclei in the large central cell of the female gametophyte, producing a triploid cell. This type of **double fertilization**, in which one fertilization event produces a zygote and the other produces a triploid cell, is unique to angiosperms.

After double fertilization, the ovule matures into a seed. The zygote develops into a sporophyte embryo with a rudimentary root and one or two seed leaves called **cotyledons**. The fertilized nucleus of the central cell of the female gametophyte divides repeatedly and develops into **endosperm**, tissue rich in starch and other food reserves that nourish the developing embryo.

What is the function of double fertilization in angiosperms? One hypothesis is that double fertilization synchronizes the development of food storage in the seed with the development of the embryo. If a particular flower is not pollinated or sperm cells are not discharged into the embryo sac, fertilization does not occur, and neither endosperm nor embryo forms. So perhaps double fertilization is an adaptation that prevents flowering plants from squandering nutrients on infertile ovules.

Another type of double fertilization occurs in some gymnosperm species belonging to the phylum Gnetophyta. However, double fertilization in these species gives rise to two embryos rather than to an embryo and endosperm.

As you read earlier, the seed consists of the embryo, endosperm, and a seed coat derived from the integuments. An ovary develops into a fruit as its ovules become seeds. After being dispersed, a seed may germinate if environmental conditions are favorable. The coat ruptures and the embryo emerges as a seedling, using food stored in the endosperm and cotyledons.



Angiosperm Evolution

Clarifying the origin and early evolution of angiosperms—what Charles Darwin once called an "abominable mystery"—poses fascinating challenges to evolutionary biologists. Angiosperms originated at least 140 million years ago, and during the late Mesozoic, the major branches of the clade diverged from their common ancestor. By the mid-Cretaceous period (100 million years ago), angiosperms began to dominate many terrestrial ecosystems. Landscapes changed dramatically as conifers, cycads, and other gymnosperms gave way to flowering plants in many parts of the world.

The flowers and fruits of angiosperms distinguish them markedly from living gymnosperms, which makes the origins of angiosperms puzzling. To understand how the angiosperm body plan emerged, scientists are studying fossils, refining angiosperm phylogeny, and elucidating developmental patterns that underlie flowers and other angiosperm innovations. As we'll see, much progress has been made toward solving Darwin's mystery—but we still do not fully understand how angiosperms originated from earlier seed plants.

Fossil Angiosperms

In the late 1990s, scientists in China discovered several intriguing fossils of 125-million-year-old angiosperms. These fossils, now named *Archaefructus liaoningensis* and *Archaefructus sinensis* **(Figure 30.11)**, display both derived and ancestral traits. *Archaefructus sinensis,* for example, has anthers and also has seeds inside closed carpels but lacks petals and sepals. In 2002, scientists completed a phylogenetic comparison of *A. sinensis* with 173 living plants. (*Archaefructus liaoningensis* was not included because its fossils are not as well preserved.) The researchers concluded that *Archaefructus* ". . . may belong to the earliest-diverging group of angiosperms known."

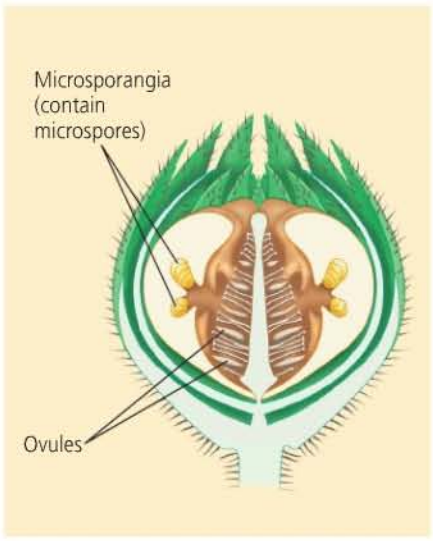
(a) *Archaefructus sinensis*, a 125-million-year-old fossil. This species may represent the sister group to all other angiosperms.

(b) Artist's reconstruction of *Archaefructus sinensis*

▲ **Figure 30.11 A primitive flowering plant?**

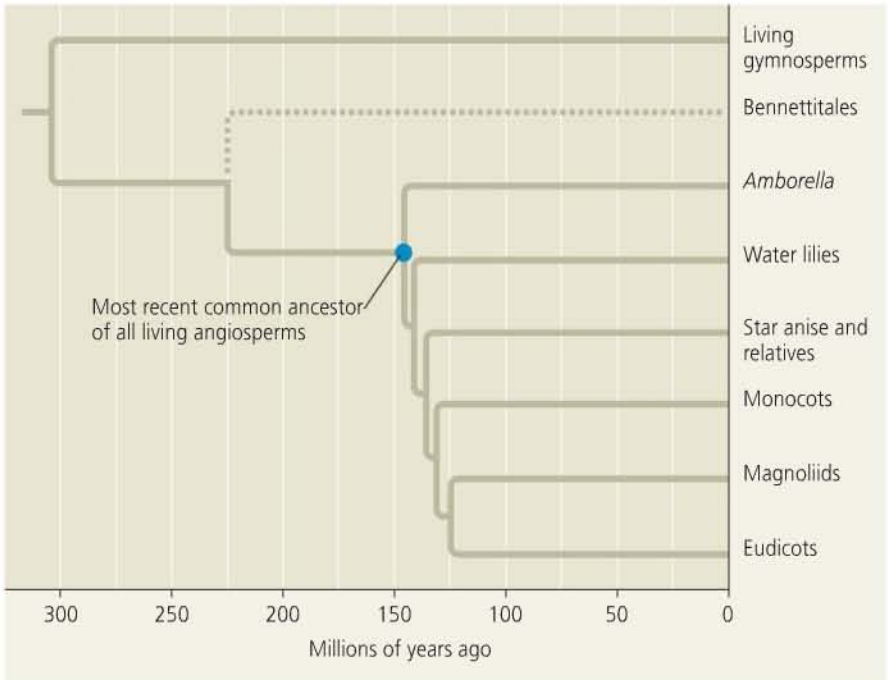
If *Archaefructus* was indeed a very early angiosperm, that would suggest that the ancestors of flowering plants were herbaceous rather than woody. *Archaefructus* was discovered along with fish fossils and has bulbous structures that might be aquatic adaptations, implying that angiosperms may have originated as aquatic plants. The discoverers of *Archaefructus* have suggested that fast-growing herbaceous plants could have returned to water and thrived there, escaping competition with other seed plants and then later taking over the land.

More recently, however, some paleobotantists have disputed this interpretation. They cite examples of angiosperms from later-diverging lineages that became aquatic, and in which simpler flowers evolved that resemble the "primitive" flowers of *Archaefructus*. Such debates, typical whenever a seemingly transitional fossil is discovered, may be resolved when more fossils and other types of evidence emerge.



Angiosperm Phylogeny

To shed light on the body plan of early angiosperms, scientists have long sought to identify which seed plants, including fossil species, are most closely related to angiosperms. Molecular and morphological evidence suggests that living gymnosperms are a monophyletic group whose earliest lineages diverged from the ancestors of angiosperms about 305 million years ago. Note that this does not necessarily imply that angiosperms originated 305 million years ago—but that the most recent common ancestor of gymnosperms and angiosperms lived at that time. Angiosperms may, in fact, be most closely related to extinct seed plants such as the group called Bennettitales, which had flowerlike structures that may have been pollinated by insects **(Figure 30.12a)**. Systematists hope to resolve this issue through phylogenetic studies that combine data from fossil and living species of a wide range of seed plants.



Making sense of the origin of angiosperms also depends on working out the order in which angiosperm clades diverged from one another. Here, dramatic progress has been made in recent years. Molecular and morphological evidence suggests that *Amborella* and water lilies are living representatives of two of the most ancient angiosperm lineages **(Figure 30.12b)**. This information has already proved useful as researchers seek to interpret new findings about plant development.

Developmental Patterns in Angiosperms

Additional clues about the origin of flowering plants are emerging from studies of plant development. For example, a 2006 study demonstrated that in *Amborella*, eggs form from precursor cells that differ from the egg precursor cells of most other living angiosperms. Intriguingly, the way in which eggs form in *Amborella* has similarities to how eggs form in gymnosperms—a possible link to the ancient common ancestor of gymnosperms and angiosperms. Other studies suggest that in a variety of early angiosperms (as well as in *Amborella*), the outer of the two protective integuments appears to be a modified leaf that originates

(a) A possible ancestor of the angiosperms? This reconstruction shows a cross section through the flowerlike structures found in the Bennettitales, an extinct group of seed plants hypothesized to be more closely related to angiosperms than to gymnosperms.

(b) Angiosperm phylogeny. This tree represents one current hypothesis of angiosperm evolutionary relationships, based on morphological and molecular evidence. Angiosperms originated at least 140 million years ago. The dotted line indicates the uncertain position of the Bennettitales, a possible sister group to the angiosperms.

▲ **Figure 30.12 Angiosperm evolutionary history.**

? *Would the branching order of the phylogeny in (b) necessarily have to be redrawn if a 150-million-year-old fossil monocot were discovered? Explain.*

separately from the inner integument. Because gymnosperms have only one integument, scientists are curious exactly how the second integument originated in angiosperms. Finally, in work that holds great promise for deepening our understanding of the origin of flowering plants, researchers are currently studying how genes that control flower development in angiosperms are expressed in a range of gymnosperm and angiosperm species (see Chapter 38).

Angiosperm Diversity

From their humble beginnings in the Mesozoic, angiosperms have diversified into more than 250,000 living species. Until the late 1990s, most systematists divided flowering plants into two groups, based partly on the number of cotyledons, or seed leaves, in the embryo. Species with one cotyledon were called **monocots**, and those with two were called **dicots**. Other features, such as flower and leaf structure, were also used to define the two groups. For example, monocots typically have parallel leaf veins (think of a grass blade), while the veins of most dicots have a netlike pattern (think of an oak leaf). Some examples of monocots are orchids, palms, and grain crops such as maize, wheat, and rice. Some examples of dicots are roses, peas, sunflowers, and maples.

Recent DNA studies, however, indicate that the monocot-dicot distinction does not completely reflect evolutionary relationships. Current research supports the hypothesis that monocots form a clade but reveals that the species traditionally called dicots are polyphyletic. The vast majority of species once categorized as dicots form a large clade, now known as **eudicots** ("true" dicots). The rest of the former dicots are now grouped into several small lineages. Three of these lineages are informally called **basal angiosperms** because they appear to include the flowering plants belonging to the oldest lineages. A fourth lineage, called the **magnoliids**, evolved later. **Figure 30.13** provides an overview of angiosperm diversity.

Evolutionary Links Between Angiosperms and Animals

Ever since they colonized land, animals have influenced the evolution of terrestrial plants, and vice versa. For example, herbivores can reduce a plant's reproductive success by eating its roots, leaves, or seeds. As a result, if a novel and effective defense against herbivores originates in a group of plants, those plants may be favored by natural selection—as will any herbivores that can overcome this new defense.

▼ **Figure 30.13**

Exploring Angiosperm Diversity

Basal Angiosperms

Surviving basal angiosperms are currently thought to consist of three lineages comprising only about 100 species. The oldest lineage seems to be represented by a single species, *Amborella trichopoda*. The other surviving lineages diverged later: a clade that includes water lilies and a clade consisting of the star anise and its relatives.

Water lily (*Nymphaea "Rene Gerard"*). Water lilies are living members of a clade that may be predated only by the *Amborella* lineage.

Star anise (*Illicium floridanum*). This species represents a third surviving lineage of basal angiosperms.

Amborella trichopoda. This small shrub, found only on the South Pacific island of New Caledonia, may be the sole survivor of a branch at the base of the angiosperm tree. *Amborella* lacks vessels, which are present in angiosperms in later-diverging lineages. Consisting of xylem cells arranged in continuous tubes, vessels transport water more efficiently than tracheids. Their absence in *Amborella* indicates they evolved after the lineage that gave rise to *Amborella* diverged.

Magnoliids

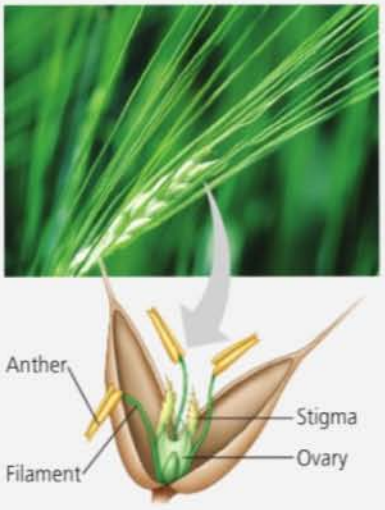
Magnoliids consist of about 8,000 species, most notably magnolias, laurels, and black pepper plants. They include both woody and herbaceous species. Although they share some traits with basal angiosperms, such as a typically spiral rather than whorled arrangement of floral organs, magnoliids are more closely related to eudicots and monocots.

Southern magnolia (*Magnolia grandiflora*). This member of the magnolia family is a woody magnoliid. This variety of southern magnolia, called "Goliath," has flowers that measure up to about a foot across.

Monocots

More than one-quarter of angiosperm species are monocots—about 70,000 species. These examples represent some of the largest families.

Orchid (*Lemboglossum rossii*)



Pygmy date palm (*Phoenix roebelenii*)

Lily (*Lilium "Enchantment"*)

Barley (*Hordeum vulgare*), a grass

Eudicots

More than two-thirds of angiosperm species are eudicots—roughly 170,000 species. Below is a sampling of eudicot floral diversity.

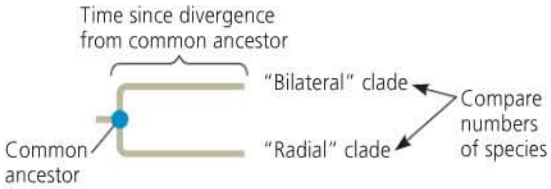
Monocot Characteristics		Eudicot Characteristics
 One cotyledon	**Embryos**	 Two cotyledons
 Veins usually parallel	**Leaf venation**	 Veins usually netlike
 Vascular tissue scattered	**Stems**	 Vascular tissue usually arranged in ring
 Root system usually fibrous (no main root)	**Roots**	 Taproot (main root) usually present
 Pollen grain with one opening	**Pollen**	 Pollen grain with three openings
 Floral organs usually in multiples of three	**Flowers**	 Floral organs usually in multiples of four or five

California poppy (*Eschscholzia californica*)

Pyrenean oak (*Quercus pyrenaica*)

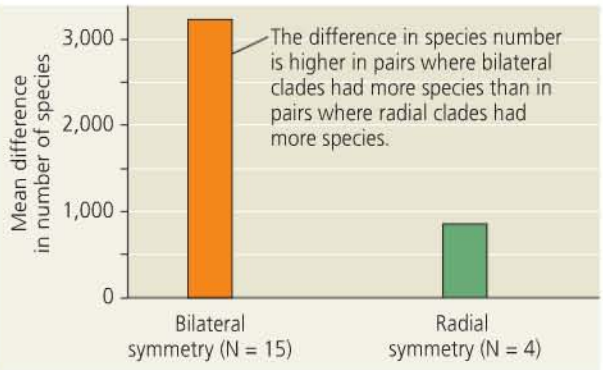
Dog rose (*Rosa canina*), a wild rose

Snow pea (*Pisum sativum*), a legume



Zucchini (*Cucurbita pepo*) flowers

Figure 30.14 Inquiry



Can flower shape influence speciation rate?

EXPERIMENT The shapes of bilaterally symmetrical flowers can force pollinators seeking nectar to enter the flower from certain directions only. This facilitates the placement of pollen on particular parts of the pollinator's body, which in turn can increase how effectively pollen is transferred between flowers of the same species. Such specificity in plant-pollinator relationships tends to decrease gene flow between diverging plant populations and hence could lead to increased rates of plant speciation. Risa Sargent, then at the University of British Columbia, tested this hypothesis by determining whether angiosperm families with bilaterally symmetrical flowers contain more species than do closely related families with radially symmetrical flowers. She took this approach:

1. Identify as many cases as possible in which a clade of one or more families with bilaterally symmetrical flowers is sister to a clade whose members have radially symmetrical flowers. By definition, such sister clades share an immediate common ancestor and hence had the same amount of time to form new species.
2. Determine the number of species in each pair of sister clades. The hypothesis would be supported if bilaterally symmetrical clades consistently have more species than their radially symmetrical sister clades.

RESULTS Sargent identified 19 pairs of sister clades that differed in flower shape. In 15 of these pairs, clades with bilateral symmetry had more species than did clades with radial symmetry.

CONCLUSION Sargent's results supported the hypothesis that flower shape affects the rate at which new species form, with bilateral symmetry promoting increased rates of speciation.

SOURCE R. D. Sargent, Floral symmetry affects speciation rates in angiosperms, *Proceedings of the Royal Society B: Biological Sciences* 271:603–608 (2004).

Inquiry in Action Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers*.

WHAT IF? Does this study show that flower shape is *correlated with* the rate at which new species form, or that flower shape is *responsible for* this rate? Explain.

Plant-pollinator and other mutually beneficial interactions can have similar effects. Consider the evolutionary impact of how flower petals are arranged. Flower petals can be symmetrical in one direction only (bilateral symmetry, as in the pea blossom in Figure 30.13), or they can be symmetrical in all directions (radial symmetry, as in the dog rose in Figure 30.13). On a flower with bilateral symmetry, an insect pollinator may be able to obtain nectar only when it approaches the flower from a certain direction. Such constraints can make it more likely that as an insect moves from flower to flower, pollen is placed on a part of the insect's body that will come into contact with the stigma of a flower of the same species.

Because of this specificity of pollen transfer, gene flow may be reduced more easily in diverging populations with bilateral symmetry than in populations with radial symmetry. As a result, researchers have hypothesized that speciation should occur more rapidly in flowers with bilateral symmetry than in flowers with radial symmetry **(Figure 30.14)**. Working at the University of British Columbia, Risa Sargent tested this hypothesis and found that clades with bilaterally symmetrical flowers do indeed have more species than do closely related clades with radially symmetrical flowers. Overall, such effects of plant-pollinator interactions are thought to have contributed to the increasing dominance of flowering plants in the Cretaceous period, helping to make angiosperms of central importance in ecological communities and human societies.

CONCEPT CHECK 30.3

1. It has been said that an oak is an acorn's way of making more acorns. Write an explanation that includes these terms: sporophyte, gametophyte, ovule, seed, ovary, and fruit.
2. Compare and contrast a pine cone and a flower in terms of structure and function.
3. **WHAT IF?** If researchers discovered a 135-million-year-old fossil angiosperm that had woody tissues as well as sepals and petals, how would their findings affect current interpretations of *Archaefructus sinensis* fossils?

For suggested answers, see Appendix A.

CONCEPT 30.4
Human welfare depends greatly on seed plants

Throughout this unit, we are highlighting the ways in which humans depend on various organisms. In forests and on farms, seed plants are key sources of food, fuel, wood products, and medicine. Our reliance on them makes the preservation of plant diversity critical.

Products from Seed Plants

Most of our food comes from angiosperms. Just six crops—wheat, rice, maize, potatoes, cassava, and sweet potatoes—yield 80% of all the calories consumed by humans. We also depend on angiosperms to feed livestock: It takes 5–7 kg of grain to produce 1 kg of grain-fed beef.

Today's crops are the products of a relatively recent burst of genetic change, resulting from artificial selection after humans began domesticating plants approximately 13,000 years ago. To appreciate the scale of the transformation, note how the number and size of seeds in domesticated plants is greater than those of their wild relatives, as in the case of maize and teosinte (see Figure 38.16). At the genetic level, scientists can glean information about domestication by comparing the genes of crops with those of wild relatives. With maize, dramatic changes, such as increased cob size and loss of the hard coating around teosinte kernels, may have been initiated by as few as five mutations.

How did wild plants change so dramatically in such a relatively short time? For thousands of years, farmers have selected the seeds of plants with desirable traits (large fruits, for example) to plant for the next year's crops. Humans may also have selected the traits of some plants indirectly, as in the case of wild almonds. Almonds contain a bitter compound called amygdalin that repels birds and other animals. Amygdalin breaks down into cyanide, so eating a large number of wild almonds can be fatal. But mutations can reduce the level of amygdalin, making almonds sweet rather than bitter. Wild birds eat almonds from trees with such mutations. According to one hypothesis, humans may have observed birds eating the almonds and then eaten the almonds themselves—ultimately using such seeds to grow trees that produced sweeter, less dangerous almonds.

In addition to staple crops, flowering plants provide other edible products. Two of the world's most popular beverages come from tea leaves and coffee beans, and you can thank the tropical cacao tree for cocoa and chocolate. Spices are derived from various plant parts, such as flowers (cloves, saffron), fruits and seeds (vanilla, black pepper, mustard, cumin), leaves (basil, mint, sage), and even bark (cinnamon).

Many seed plants, both gymnosperms and angiosperms, are sources of wood, which is absent in all living seedless plants. Wood consists of an accumulation of tough-walled xylem cells (see Chapter 35). Wood is the primary source of fuel for much of the world, and wood pulp, typically derived from conifers such as fir and pine, is used to make paper. Worldwide, wood also remains the most widely used construction material.

For centuries, humans have also depended on seed plants for medicines. Many cultures have a long tradition of using herbal remedies, and scientific research has identified the relevant secondary compounds in many of these plants, leading to the synthesis of medicines. Willow leaves and bark, for instance, have been used since ancient times in pain-relieving remedies, including prescriptions by the Greek physician Hippocrates. In the 1800s, scientists traced the willow's medicinal property to the chemical salicin. A synthesized derivative, acetylsalicylic acid, is what we call aspirin. Although modern chemistry facilitates laboratory synthesis, plants remain an important direct source of medicinal compounds. In the United States, for example, about 25% of prescription drugs contain one or more active ingredients extracted or derived from plants, typically from seed plants. Other ingredients were first discovered in seed plants and then synthesized artificially. **Table 30.1** lists some medicinal uses of secondary compounds of seed plants.

Table 30.1 A Sampling of Medicines Derived from Seed Plants

Compound	Source	Example of Use
Atropine	Belladonna plant	Pupil dilator in eye exams
Digitalin	Foxglove	Heart medication
Menthol	Eucalyptus tree	Ingredient in cough medicines
Morphine	Opium poppy	Pain reliever
Quinine	Cinchona tree (see below)	Malaria preventive
Taxol	Pacific yew	Ovarian cancer drug
Tubocurarine	Curare tree	Muscle relaxant during surgery
Vinblastine	Periwinkle	Leukemia drug

Cinchona bark, source of quinine

Threats to Plant Diversity

Although plants may be a renewable resource, plant diversity is not. The exploding human population and its demand for space and resources are extinguishing plant species at an extremely rapid rate. The problem is especially severe in the tropics, where more than half the human population lives and where population growth is fastest. Thirty-five million acres of tropical rain forest, an area nearly the size of Iowa, are cleared each year, a rate that would completely eliminate Earth's tropical forests within 100 to 150 years. The most common cause of this destruction is slash-and-burn clearing of forests for agricultural use (see Chapter 56). As forests disappear, so do thousands of plant species. Of course, once a species becomes extinct, it can never return.

The loss of plant species is often accompanied by the loss of insects and other rain forest animals. Researchers estimate that habitat destruction in rain forests and other ecosystems is pushing hundreds of species toward extinction each year. If current rates of loss in the tropics and elsewhere continue, scientists estimate that within the next 100 to 200 years, 50% or more of Earth's species will become extinct. Such losses would constitute a global mass extinction, rivaling the Permian and Cretaceous mass extinctions and forever changing the evolutionary history of land plants (and many other organisms).

Many people have ethical concerns about contributing to the extinction of living forms. In addition, there are practical reasons to be concerned about the loss of plant diversity. So far, we have explored the potential uses of only a tiny fraction of the more than 290,000 known plant species. For example, almost all our food is based on the cultivation of only about two dozen species of seed plants. And fewer than 5,000 plant species have been studied as potential sources of medicines. The tropical rain forest may be a medicine chest of healing plants that could be extinct before we even know they exist. If we begin to view rain forests and other ecosystems as living treasures that can regenerate only slowly, we may learn to harvest their products at sustainable rates. What else can we do to preserve plant diversity? Few questions are as important, as we'll explore more fully in Unit Eight (Ecology).

CONCEPT CHECK 30.4

1. Explain why plant diversity may be considered a nonrenewable resource.
2. **WHAT IF?** How could phylogenies be used to improve the efficiency with which researchers search for novel medicines derived from seed plants?

For suggested answers, see Appendix A.

Chapter 30 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 30.1

Seeds and pollen grains are key adaptations for life on land (pp. 618–621)

Five Derived Traits of Seed Plants

Reduced gametophytes	Microscopic male and female gametophytes (*n*) are nourished and protected by the sporophyte (2*n*) 
Heterospory	Microspore (gives rise to a male gametophyte) Megaspore (gives rise to a female gametophyte) 
Ovules	Ovule (gymnosperm) 
Pollen	Pollen grains make water unnecessary for fertilization 
Seeds	Seeds: survive better than unprotected spores, can be transported long distances 

CONCEPT 30.2

Gymnosperms bear "naked" seeds, typically on cones (pp. 621–625)

- **Gymnosperm Evolution** Gymnosperms appear early in the plant fossil record and dominated Mesozoic terrestrial ecosystems. Living seed plants can be divided into two monophyletic groups: gymnosperms and angiosperms. Extant gymnosperms include cycads, *Ginkgo biloba*, gnetophytes, and conifers.
- **The Life Cycle of a Pine: *A Closer Look*** Dominance of the sporophyte generation, the development of seeds from fertilized ovules, and the role of pollen in transferring sperm to ovules are key features of a typical gymnosperm life cycle.

MEDIA
Activity Pine Life Cycle

CONCEPT 30.3

The reproductive adaptations of angiosperms include flowers and fruits (pp. 625–632)

- **Characteristics of Angiosperms** Flowers generally consist of four whorls of modified leaves: sepals, petals, stamens (which produce pollen), and carpels (which produce ovules). Ovaries ripen into fruits, which often carry seeds by wind, water, or animals to new locations.
- **Angiosperm Evolution** An adaptive radiation of angiosperms occurred during the Cretaceous period. Fossils, phylogenetic analyses, and developmental studies offer insights into the origin of flowers.
- **Angiosperm Diversity** Several groups of basal angiosperms have been identified. Other major clades of angiosperms include monocots, magnoliids, and eudicots.
- **Evolutionary Links Between Angiosperms and Animals** Pollination and other interactions between angiosperms and

animals may have led to increased species diversity in both of these groups.

MEDIA

Activity Angiosperm Life Cycle
Investigation How Are Trees Identified by Their Leaves?

CONCEPT 30.4

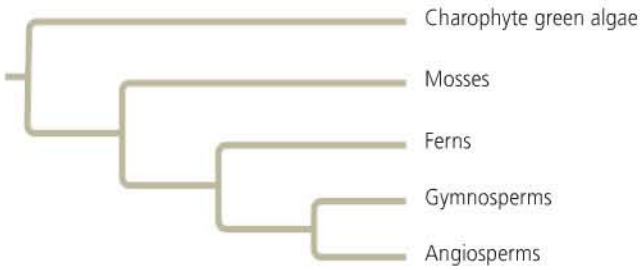
Human welfare depends greatly on seed plants (pp. 632–634)

- **Products from Seed Plants** Humans depend on seed plants for food, wood, and many medicines.
- **Threats to Plant Diversity** Destruction of habitat threatens the extinction of many plant species and the animal species they support.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Where in an angiosperm would you find a megasporangium?
   a. in the style of a flower
   b. inside the tip of a pollen tube
   c. enclosed in the stigma of a flower
   d. within an ovule contained within an ovary of a flower
   e. packed into pollen sacs within the anthers found on a stamen



2. A fruit is most commonly
   a. a mature ovary.
   b. a thickened style.
   c. an enlarged ovule.
   d. a modified root.
   e. a mature female gametophyte.

3. With respect to angiosperms, which of the following is *incorrectly* paired with its chromosome count?
   a. egg—n
   b. megaspore—$2n$
   c. microspore—n
   d. zygote—$2n$
   e. sperm—n

4. Which of the following is *not* a characteristic that distinguishes gymnosperms and angiosperms from other plants?
   a. alternation of generations
   b. ovules
   c. integuments
   d. pollen
   e. dependent gametophytes

5. Gymnosperms and angiosperms have the following in common *except*
   a. seeds.
   b. pollen.
   c. vascular tissue.
   d. ovaries.
   e. ovules.

6. **DRAW IT** Use the letters a–d to label where on the phylogenetic tree each of the following derived characters appeared.
   a. flowers
   b. embryos
   c. seeds
   d. vascular tissue

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

7. The history of life has been punctuated by several mass extinctions. For example, the impact of a meteorite may have wiped out most of the dinosaurs and many forms of marine life at the end of the Cretaceous period (see Chapter 25). Fossils indicate that plants were less severely affected by this and other mass extinctions. What adaptations may have enabled plants to withstand these disasters better than animals?

SCIENTIFIC INQUIRY

8. **DRAW IT** As will be described in detail in Chapter 38, the female gametophyte of angiosperms typically has seven cells, one of which, the central cell, is diploid. After double fertilization, the central cell develops into endosperm, which is triploid. Because all monocots, magnoliids, and eudicots have female gametophytes with seven cells and triploid endosperm, scientists assumed that this was the ancestral state for angiosperms. Consider, however, the following recent discoveries:
   - Our understanding of angiosperm phylogeny has changed to that shown in Figure 30.12b.
   - *Amborella* has eight-celled female gametophytes and triploid endosperm.
   - Water lilies and star anise have four-celled female gametophytes and diploid endosperm.

   (a) Draw a phylogeny of the angiosperms (see Figure 30.12b), incorporating the data given above about the number of cells in female gametophytes and the ploidy of the endosperm. Assume that all of the star anise relatives have four-celled female gametophytes and diploid endosperm.
   (b) What does your labeled phylogeny suggest about the evolution of the female gametophyte and endosperm in angiosperms?

31 Fungi

▲ **Figure 31.1 Can you spot the largest organism in this forest?**

KEY CONCEPTS

31.1 Fungi are heterotrophs that feed by absorption
31.2 Fungi produce spores through sexual or asexual life cycles
31.3 The ancestor of fungi was an aquatic, single-celled, flagellated protist
31.4 Fungi have radiated into a diverse set of lineages
31.5 Fungi play key roles in nutrient cycling, ecological interactions, and human welfare

OVERVIEW

Mighty Mushrooms

Hiking through the Malheur National Forest in eastern Oregon, you might notice a few clusters of honey mushrooms (*Armillaria ostoyae*) scattered here and there beneath the towering trees (**Figure 31.1**). Though the trees appear to dwarf the mushrooms, as strange as it sounds, the reverse is actually true. All these mushrooms are just the aboveground portion of a single enormous fungus. Its subterranean network of filaments spreads through 965 hectares of the forest—more than the area of 1,800 football fields. Based on its current growth rate, scientists estimate that this fungus, which weighs hundreds of tons, has been growing for more than 1,900 years.

The inconspicuous honey mushrooms on the forest floor are a fitting symbol of the neglected grandeur of the kingdom Fungi. Most of us are barely aware of these eukaryotes beyond the occasional brush with athlete's foot or spoiled food. Yet fungi are a huge and important component of the biosphere. Their diversity is staggering: While about 100,000 species have been described, it is estimated that there are actually as many as 1.5 million species of fungi. Some fungi are exclusively single-celled, but most have complex multicellular bodies, which in many cases include the structures we know as mushrooms. This diversity has enabled fungi to colonize just about every imaginable terrestrial habitat; airborne spores have even been found 160 km above ground.

Fungi are not only diverse and widespread, but they are also essential for the well-being of most terrestrial ecosystems. They break down organic material and recycle nutrients, allowing other organisms to assimilate essential chemical elements. Humans benefit from fungi's services to agriculture and forestry as well as their essential role in making products ranging from bread to antibiotics. But it is also true that some fungi cause diseases in plants and animals.

In this chapter, we will investigate the structure and evolutionary history of fungi, survey the members of kingdom Fungi, and discuss their ecological and commercial significance.

CONCEPT 31.1

Fungi are heterotrophs that feed by absorption

Despite their vast diversity, fungi share some key traits, most importantly the way they derive nutrition. In addition, many fungi grow by forming multicellular filaments, a body structure that plays an important role in how they obtain food.

Nutrition and Ecology

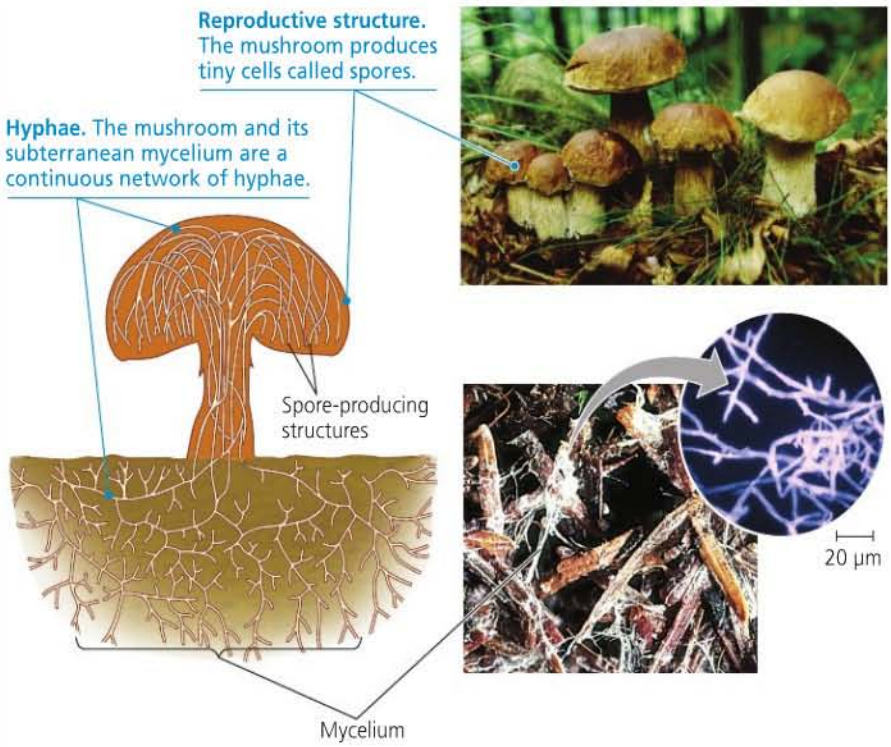
Like animals, fungi are heterotrophs—they cannot make their own food as plants and algae can. But unlike animals, fungi do not ingest (eat) their food. Instead, a fungus absorbs nutrients from the environment outside of its body. Many fungi accomplish this task by secreting powerful hydrolytic enzymes into their surroundings. These enzymes break down complex molecules to smaller organic compounds that the fungi can absorb into their bodies and use. Other fungi use enzymes to penetrate the walls of plant cells, enabling the fungi to absorb nutrients from the plant cell.

Collectively, the different enzymes found in various fungal species can digest compounds from a wide range of sources,

living or dead. As a result, fungi take on many roles in ecological communities, with different species living as decomposers, parasites, or mutualists. Decomposer fungi break down and absorb nutrients from nonliving organic material, such as fallen logs, animal corpses, and the wastes of living organisms. Parasitic fungi absorb nutrients from the cells of living hosts. Some parasitic fungi are pathogenic, including species that infect human lungs and other species that are responsible for about 80% of plant diseases. Mutualistic fungi also absorb nutrients from a host organism, but they reciprocate with actions that benefit the host. For example, mutualistic fungi that live inside certain termite species use their enzymes to break down wood, as do mutualistic protists in other termite species (see Figure 28.26).

The versatile enzymes that enable fungi to digest a wide range of food sources are not the only reason for their ecological success. Another important factor is how their body structure increases the efficiency of nutrient absorption.

Body Structure

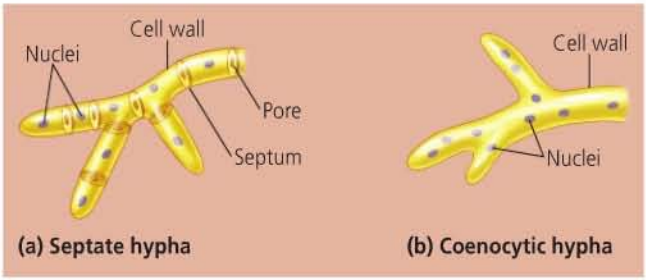


The most common fungal body structures are multicellular filaments and single cells (**yeasts**). Many species can grow as both filaments and yeasts, but even more grow only as filaments; relatively few species grow only as yeasts. Yeasts often inhabit moist environments, including plant sap and animal tissues, where there is a ready supply of soluble nutrients, such as sugars and amino acids. We'll discuss yeasts and their particular importance to humans later; here, we'll focus on the morphology of multicellular fungi.

Fungal Morphology

The morphology of multicellular fungi enhances their ability to grow into and absorb nutrients from their surroundings **(Figure 31.2)**. The bodies of these fungi typically form a network of tiny filaments, which are called **hyphae** (singular, *hypha*). Hyphae consist of tubular cell walls surrounding the plasma membrane and cytoplasm of the cells. Unlike plant cell walls, which contain cellulose, fungal cell walls are strengthened by **chitin**. This strong but flexible nitrogen-containing polysaccharide is also found in the external skeletons of insects and other arthropods.

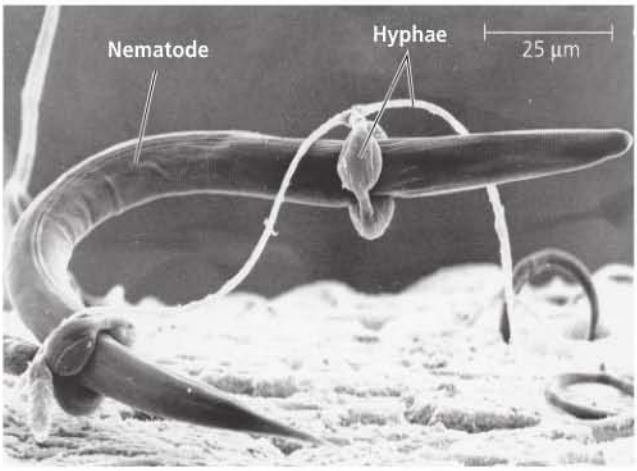
Fungal hyphae form an interwoven mass called a **mycelium** (plural, *mycelia*) that infiltrates the material on which the fungus feeds. A mycelium's structure maximizes its surface area-to-volume ratio, making feeding more efficient. Just 1 cm^3 of rich soil may contain as much as 1 km of hyphae with a total surface area of 300 cm^2 in contact with the soil. A fungal mycelium grows rapidly, as proteins and other materials synthesized by the fungus are channeled through cytoplasmic streaming to the tips of the extending hyphae. The fungus concentrates its energy and resources on adding hyphal length and thus overall absorptive surface area, rather than on increasing hyphal girth. Fungi are not motile in the typical sense of the word—they cannot run, swim, or fly in search of food or mates. However, as they grow, fungi can move into new places, swiftly extending the tips of their hyphae into previously unoccupied territory.



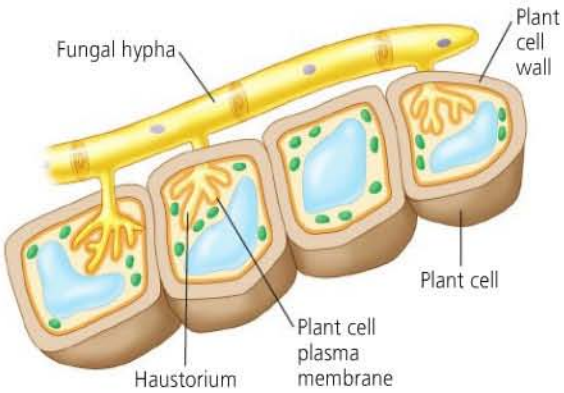
In most fungi, the hyphae are divided into cells by crosswalls, or **septa** (singular, *septum*) **(Figure 31.3a)**. Septa generally have pores large enough to allow ribosomes, mitochondria, and even nuclei to flow from cell to cell. Some fungi lack septa **(Figure 31.3b)**. Known as **coenocytic fungi**, these organisms

▲ **Figure 31.2 Structure of a multicellular fungus.** The top photograph shows the sexual structures, in this case called mushrooms, of the penny bun fungus (*Boletus edulis*). The bottom photograph shows a mycelium growing on fallen conifer needles. The inset LM shows hyphae.

? *Although the mushrooms in the top photograph appear to be different individuals, could their DNA be identical? Explain.*



▶ **Figure 31.3 Two forms of hyphae.**



consist of a continuous cytoplasmic mass having hundreds or thousands of nuclei. The coenocytic condition results from the repeated division of nuclei without cytokinesis. This description may remind you of the plasmodial slime molds you read about in Chapter 28, which also consist of cytoplasmic masses containing many nuclei. This similarity is one reason that slime molds were once classified as fungi; molecular data have since shown that slime molds and fungi belong to distinct clades.

Specialized Hyphae in Mycorrhizal Fungi

Some fungi have specialized hyphae that allow them to feed on living animals **(Figure 31.4a)**. Other fungal species have specialized hyphae called **haustoria**, which the fungi use to extract nutrients from—or exchange nutrients with—their hosts **(Figure 31.4b)**. Mutually beneficial relationships between such fungi and plant roots are called **mycorrhizae** (the term means "fungus roots").

(a) Hyphae adapted for trapping and killing prey. In *Arthrobotrys*, a soil fungus, portions of the hyphae are modified as hoops that can constrict around a nematode (roundworm) in less than a second. The fungus then penetrates its prey with hyphae and digests the prey's inner tissues (SEM).

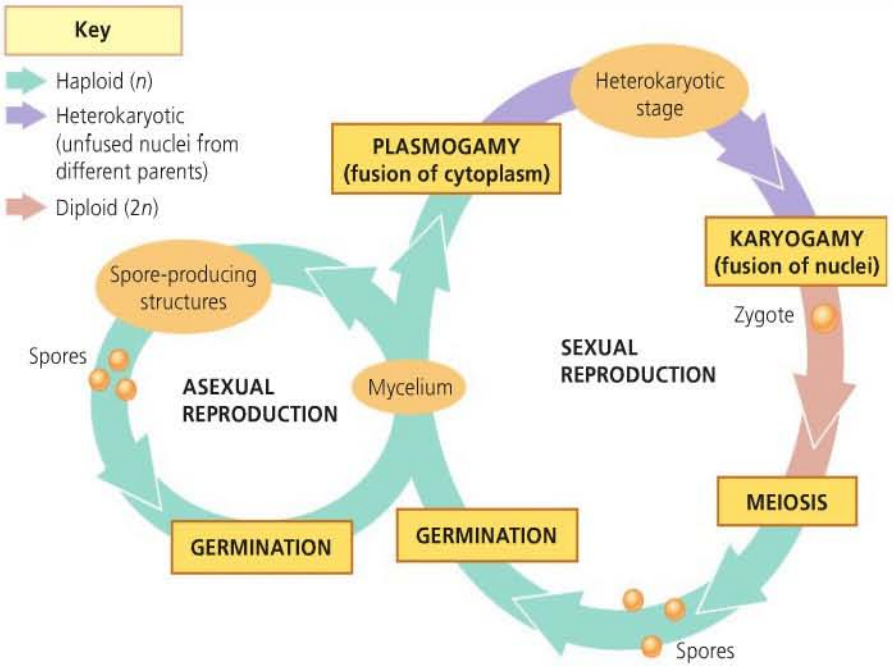
(b) Haustoria. Some mutualistic and parasitic fungi grow specialized hyphae called haustoria that can extract nutrients from living plant cells. Haustoria remain separated from a plant cell's cytoplasm by the plasma membrane of the plant cell (orange).

▲ **Figure 31.4 Specialized hyphae.**

Mycorrhizal fungi (fungi that form mycorrhizae) can improve delivery of phosphate ions and other minerals to plants because the vast mycelial networks of the fungi are more efficient than the plants' roots at acquiring these minerals from the soil. In exchange, the plants supply the fungi with organic nutrients such as carbohydrates. There are several types of mycorrhizal fungi. **Ectomycorrhizal fungi** (from the Greek *ektos*, out) form sheaths of hyphae over the surface of a root and also grow into the extracellular spaces of the root cortex (see Figure 37.12a). **Arbuscular mycorrhizal fungi** (from the Latin *arbor*, tree) extend their branching hyphae through the root cell wall and into tubes formed by invagination (pushing inward) of the root cell membrane (see Figure 37.12b).

Mycorrhizae are enormously important in natural ecosystems and agriculture. Almost all vascular plants have mycorrhizae and rely on their fungal partners for essential nutrients. Many studies have demonstrated the significance of mycorrhizae by comparing the growth of plants with and without them (see Figure 37.13). Foresters commonly inoculate pine seedlings with mycorrhizal fungi to promote growth. In the absence of human intervention, mycorrhizal fungi colonize soils by spore dispersal, a key component of how fungi reproduce and spread to new areas, as we discuss next.

CONCEPT CHECK 31.1



1. Compare and contrast the nutritional mode of a fungus with your own nutritional mode.
2. **WHAT IF?** Suppose a certain fungus is a mutualist that lives within its insect host, yet its ancestors were parasites that grew in and on the insect's body. What derived traits might you find in this mutualistic fungus?

For suggested answers, see Appendix A.

CONCEPT 31.2
Fungi produce spores through sexual or asexual life cycles

Most fungi propagate themselves by producing vast numbers of spores, either sexually or asexually. For example, puffballs, the reproductive structures of certain fungal species, may release trillions of spores in cloud-like bursts (see Figure 31.18). Spores can be carried long distances by wind or water. If they land in a moist place where there is food, they germinate, producing new mycelia. To appreciate how effective spores are at dispersing, leave a slice of melon exposed to the air. Even without a visible source of spores nearby, within a week or so, you will likely observe fuzzy mycelia growing from the microscopic spores constantly falling onto the melon.

Figure 31.5 generalizes the many different life cycles that can produce fungal spores. In this section, we will survey general

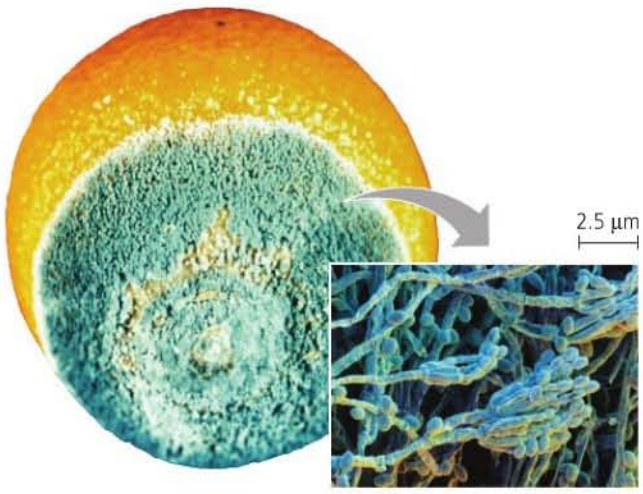
▲ **Figure 31.5 Generalized life cycle of fungi.** Many—but not all—fungi reproduce both sexually and asexually. Some reproduce only sexually, others only asexually.

aspects of the sexual and asexual life cycles of fungi. Later, we'll examine more closely the life cycles of specific fungi.

Sexual Reproduction

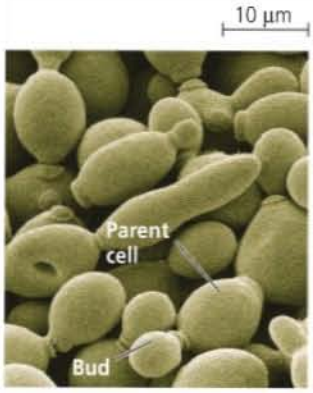
The nuclei of fungal hyphae and the spores of most fungal species are haploid, although many fungi have transient diploid stages that form during sexual life cycles. Generally, sexual reproduction begins when hyphae from two mycelia release sexual signaling molecules called **pheromones**. If the mycelia are of different mating types, the pheromones from each partner bind to receptors on the other, and the hyphae extend toward the source of the pheromones. When the hyphae meet, they fuse. In species with such a "compatibility test," this process contributes to genetic variation by preventing hyphae from fusing with other hyphae from the same mycelium or another genetically identical mycelium.

The union of the cytoplasms of two parent mycelia is known as **plasmogamy**. In most fungi, the haploid nuclei contributed by each parent do not fuse right away. Instead, parts of the fused mycelium contain coexisting, genetically different nuclei. Such a mycelium is said to be a **heterokaryon** (meaning "different nuclei"). In some species, the different nuclei may even exchange chromosomes and genes in a process similar to crossing over (see Chapter 13). In other species, the haploid nuclei pair off two to a cell, one from each parent. Such a mycelium is **dikaryotic** (meaning "two nuclei"). As a dikaryotic mycelium grows, the two nuclei in each cell divide in tandem without fusing. Because these cells retain two separate haploid nuclei, they differ from diploid cells, which have pairs of homologous chromosomes within a single nucleus.



Hours, days, or (in some fungi) even centuries may pass between plasmogamy and the next stage in the sexual cycle, **karyogamy**. During karyogamy, the haploid nuclei contributed by the two parents fuse, producing diploid cells. Zygotes and other transient structures form during karyogamy, the only diploid stage in most fungi. Meiosis then restores the haploid condition, leading to the formation of spores that enable fungi to disperse.

The sexual processes of karyogamy and meiosis generate extensive genetic variation, a prerequisite for natural selection. (See Chapters 13 and 23 to review how sex can increase genetic diversity in a population.) The heterokaryotic condition also offers some of the advantages of diploidy, in that one haploid genome may compensate for harmful mutations in the other.



Asexual Reproduction

In addition to sexual reproduction, many fungi can reproduce asexually. Some 20,000 fungal species are only known to reproduce asexually. As with sexual reproduction, the processes of asexual reproduction vary widely among fungi.

Many fungi reproduce asexually by growing as filamentous fungi that produce (haploid) spores by mitosis; such species are known informally as **molds** if they form visible mycelia. Depending on your housekeeping habits, you may have observed molds in your kitchen, forming furry carpets on fruit, bread, and other foods **(Figure 31.6)**. Molds typically

▲ **Figure 31.6 *Penicillium*, a mold commonly encountered as a decomposer of food.** The bead-like clusters in the colorized SEM are conidia, structures involved in asexual reproduction.

▲ **Figure 31.7 The yeast *Saccharomyces cerevisiae* in several stages of budding** (SEM).

grow rapidly and produce many spores asexually—enabling the fungi to colonize new sources of food. Many species that produce such spores can also reproduce sexually if they happen to contact a member of their species of a different mating type.

Other fungi reproduce asexually by growing as single-celled yeasts. Instead of producing spores, asexual reproduction in yeasts occurs by ordinary cell division or by the pinching of small "bud cells" off a parent cell (**Figure 31.7**). As already mentioned, some fungi that grow as yeasts can also grow as filamentous mycelia, depending on the availability of nutrients.

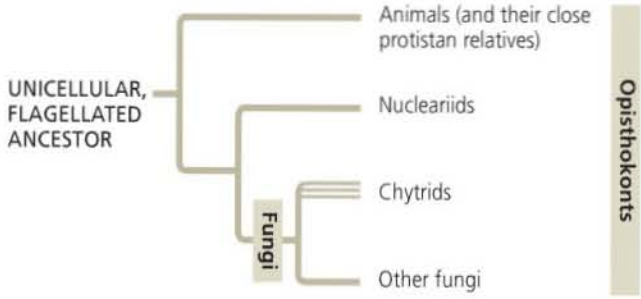
Many yeasts and filamentous fungi have no known sexual stage. Mycologists (biologists who study fungi) have traditionally called such fungi **deuteromycetes** (from the Greek *deutero*, second, and *mycete*, fungus). Whenever a sexual stage is discovered for a so-called deuteromycete, the species is reclassified in a particular phylum, depending on the type of sexual structures it forms. In addition to searching for little-known sexual stages of such unassigned fungi, mycologists can now use genetic techniques to determine the taxonomic status of a fungus.

CONCEPT CHECK 31.2

1. In terms of haploidy versus diploidy, how do the life cycles of humans and fungi differ?
2. **WHAT IF?** Suppose that you sample the DNA of two mushrooms on opposite sides of your yard and find that they are identical. Propose two hypotheses that could reasonably account for this result.

For suggested answers, see Appendix A.

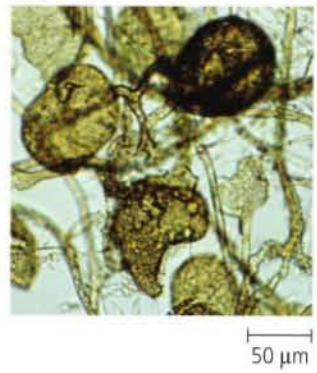
CONCEPT 31.3
The ancestor of fungi was an aquatic, single-celled, flagellated protist



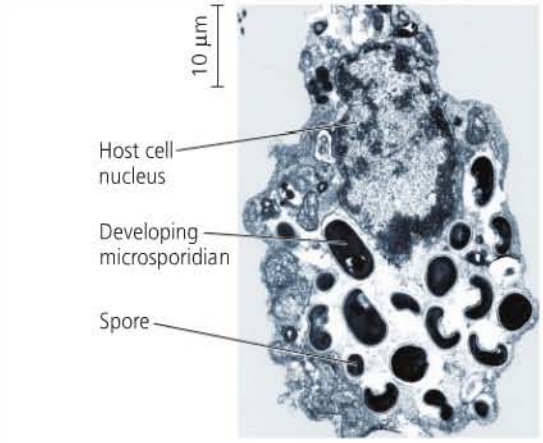
Data from both paleontology and molecular systematics offer insights into the early evolution of fungi. As a result, systematists now recognize that the kingdoms Fungi and Animalia are more closely related to each other than either is to plants or most other eukaryotes.

The Origin of Fungi

Phylogenetic systematics suggests that fungi evolved from a flagellated ancestor. While the majority of fungi lack flagella, some of the earliest-diverging lineages of fungi (the chytrids, discussed later in this chapter) do have flagella. Moreover, most of the protists that share a close common ancestor with animals and fungi also have flagella. DNA sequence data also indicate that these three groups of eukaryotes—the fungi, the animals, and their protistan relatives—form a clade (**Figure 31.8**). As discussed in Chapter 28, members of this clade are called **opisthokonts**, a name that refers to the posterior (*opistho-*) location of the flagellum in these organisms.



DNA sequence data also indicate that fungi are more closely related to several groups of single-celled protists than they are to other opisthokonts, suggesting that the ancestor of fungi was unicellular. One such group of unicellular protists, the **nucleariids**, consists of amoebas that feed on algae and bacteria. Furthermore, DNA evidence indicates that animals are more closely related to a *different* group of protists (the choanoflagellates) than they are to either fungi or nucleariids. Together, these results suggest that multicellularity must have evolved in animals and fungi independently, from different single-celled ancestors.



Based on molecular clock analysis (see Chapter 26), scientists have estimated that the ancestors of animals and fungi diverged into separate lineages about one billion years ago. However, the oldest undisputed fossils of fungi are only about 460 million years old (**Figure 31.9**). One possible explanation

▲ **Figure 31.8 Fungi and their close relatives.** Molecular evidence indicates that the nucleariids, a group of single-celled protists, are the closest living relatives of fungi. The three parallel lines leading to the chytrids indicate that this group may be paraphyletic.

▶ **Figure 31.9 Fossil fungal hyphae and spores from the Ordovician period (about 460 million years ago)** (LM).

▲ **Figure 31.10 A eukaryotic cell infected by microsporidia.** A large vacuole inside this host eukaryotic cell contains spores and developing forms of the parasite *Encephalitozoon intestinalis* (TEM).

for this discrepancy is that the microscopic ancestors of today's terrestrial fungi fossilized poorly.

Are Microsporidia Closely Related to Fungi?

In addition to animals and protists such as the nucleariids, another group of organisms, the microsporidia, may be closely related to fungi. Microsporidia are unicellular parasites of animals and protists **(Figure 31.10)**. They are often used to control insect pests. While microsporidia do not normally cause illness in humans, they do pose a risk to people with AIDS and other immune-compromised conditions.

In many ways, microsporidia are unlike most other eukaryotes. They do not have conventional mitochondria, for example. As a result, microsporidia have been something of a taxonomic mystery, thought by some researchers to be an ancient, deep-branching lineage of eukaryotes. In recent years, however, researchers have discovered that microsporidia actually have tiny organelles derived from mitochondria. Meanwhile, some molecular comparisons indicate that microsporidia are closely related to fungi, suggesting they are highly derived parasites. Other molecular evidence—including a 2006 analysis of DNA sequence data from six genes in nearly 200 fungal species—indicates that microsporidia may, in fact, be an early-diverging lineage of fungi. Additional genetic data from species belonging to early-diverging lineages of fungi are needed to resolve whether microsporidia are fungi or are a closely related but distinct group of organisms.

The Move to Land

Much of the fungal diversity we observe today may have originated during an adaptive radiation that began when multicellular plants and animals colonized land. For example, fossils of the earliest known vascular plants from the late Silurian period (420 million years ago) contain evidence of mycorrhizal relationships between plants and fungi. Plants probably existed in this beneficial relationship with fungi from the earliest periods of colonization of land.

CONCEPT CHECK 31.3

1. Why are fungi classified as opisthokonts despite the fact that most fungi lack flagella?
2. Explain the evolutionary significance of the presence of mycorrhizae in the earliest vascular plants.
3. **WHAT IF?** If fungi had colonized land before plants, where might the fungi have lived? What might they have eaten?

For suggested answers, see Appendix A.

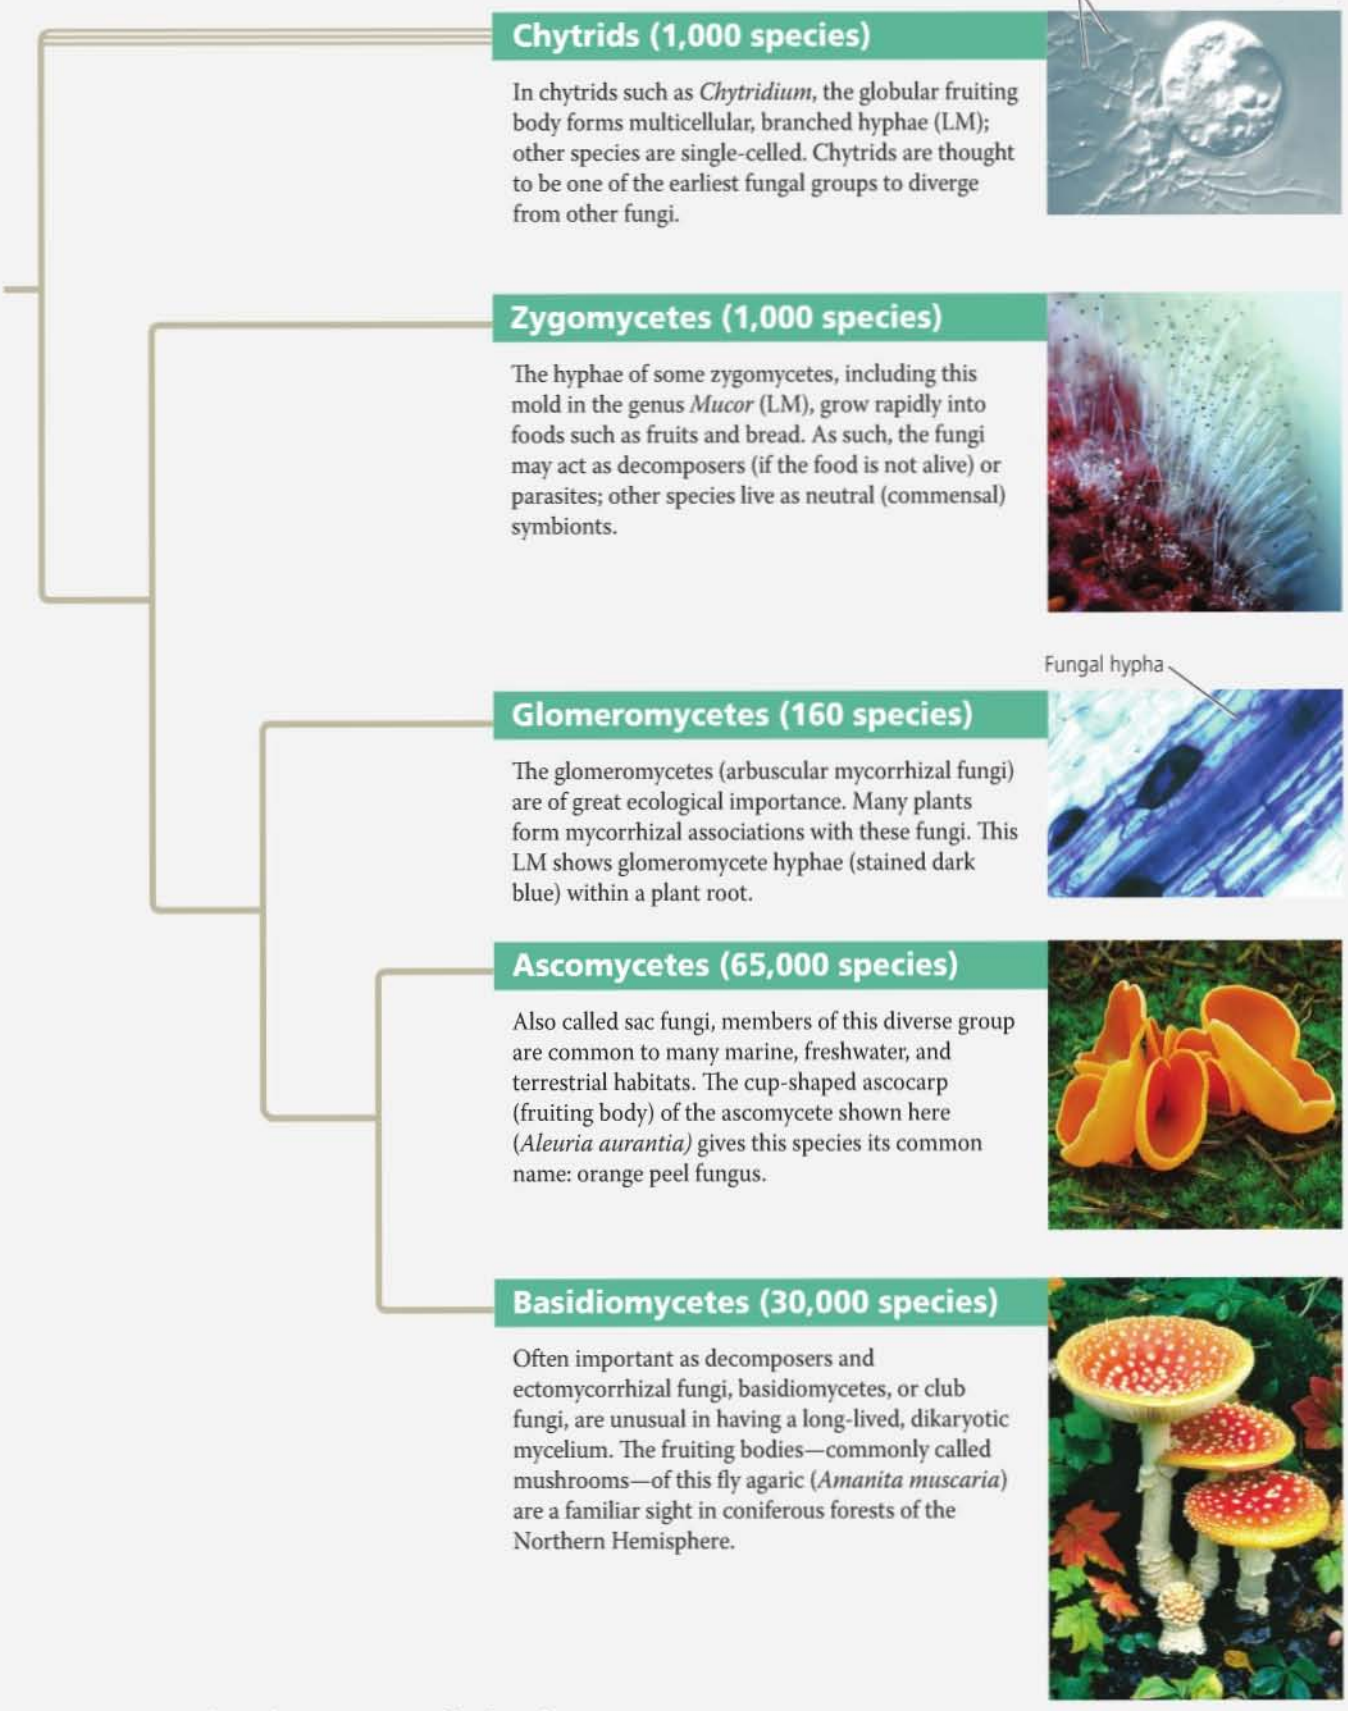
CONCEPT 31.4
Fungi have radiated into a diverse set of lineages

The phylogeny of fungi is currently the subject of much research. In the past decade, molecular analyses have helped clarify the evolutionary relationships between fungal groups, although there are still areas of uncertainty. **Figure 31.11**, on the next page, presents a simplified version of one current hypothesis. In this section, we will survey each of the major fungal groups identified in this phylogenetic tree.

Chytrids

Fungi classified in the phylum Chytridiomycota, called **chytrids**, are ubiquitous in lakes and soil. Some of the approximately 1,000 chytrid species are decomposers, while others are parasites of protists, other fungi, plants, or animals. Still other chytrids are important mutualists. For example, anaerobic chytrids that live in the digestive tracts of sheep and cattle help to break down plant matter, thereby contributing significantly to the animals' growth.

Molecular evidence supports the hypothesis that chytrids diverged early in fungal evolution. Like other fungi, chytrids have cell walls made of chitin, and they also share certain key enzymes and metabolic pathways with other fungal groups. Some chytrids form colonies with hyphae, while others exist as single spherical cells. But chytrids are unique among fungi in having flagellated spores, called **zoospores (Figure 31.12)**.

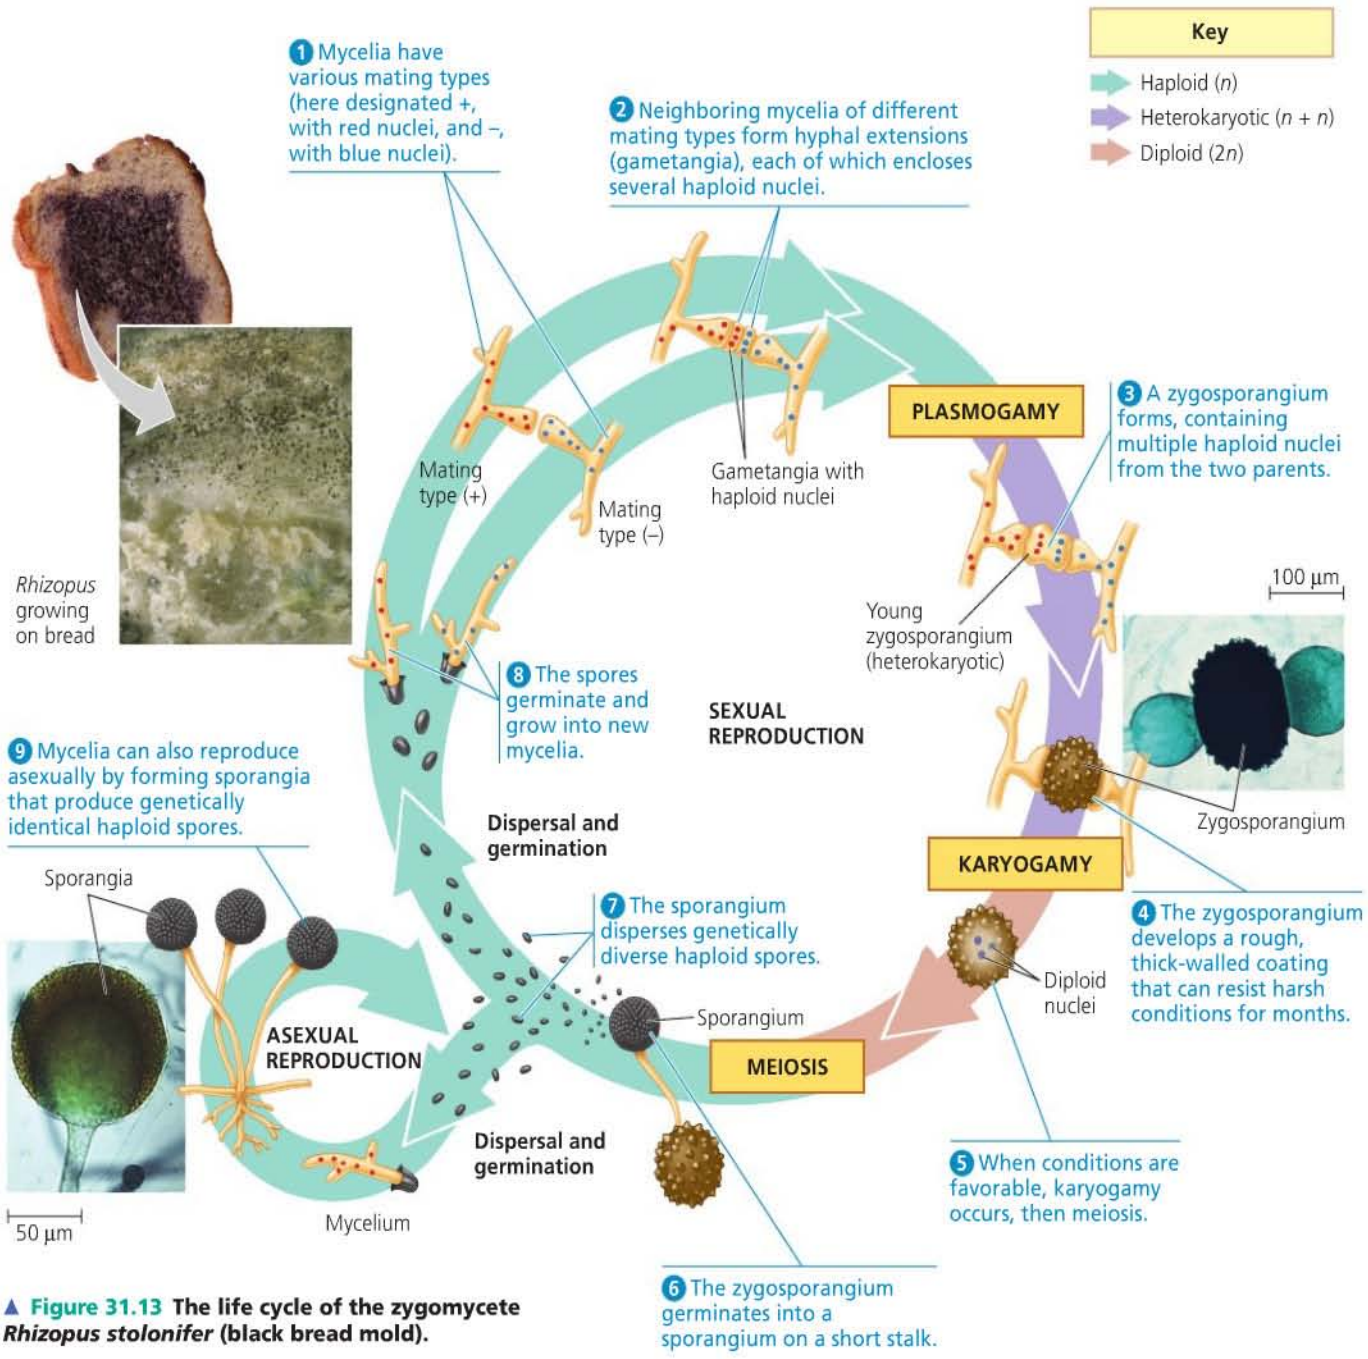


◀ **Figure 31.12 Flagellated chytrid zoospore** (TEM).

▼ Figure 31.11

Exploring Fungal Diversity

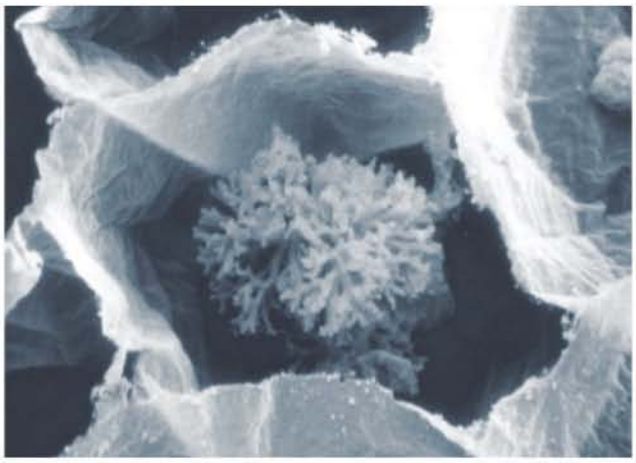
Most mycologists currently recognize five phyla of fungi, although at least the chytrids are probably paraphyletic (as indicated by the parallel lines).



Until recently, systematists thought that fungi lost flagella only once in their history, after chytrids had diverged from other lineages. However, molecular data indicate that chytrids are a paraphyletic group: Some "chytrids" are actually more closely related to another fungal group, the zygomycetes, than they are to other chytrids. These data also suggest that flagella have been lost several times during the evolution of fungi.

Zygomycetes

There are approximately 1,000 known species of **zygomycetes** (fungi in the phylum Zygomycota). This diverse phylum includes the fast-growing molds responsible for causing foods such as bread, peaches, strawberries, and sweet potatoes to rot during storage. Other zygomycetes live as parasites or as commensal (neutral) symbionts of animals.



The life cycle of *Rhizopus stolonifer* (black bread mold) is fairly typical of zygomycetes **(Figure 31.13)**. Its hyphae spread out over the food surface, penetrate it, and absorb nutrients. The hyphae are coenocytic, with septa found only where reproductive cells are formed. In the asexual phase, bulbous black sporangia develop at the tips of upright hyphae. Within each sporangium, hundreds of haploid spores develop and are dispersed through the air. Spores that happen to land on moist food germinate, growing into new mycelia. Some zygomycetes,

▲ **Figure 31.13 The life cycle of the zygomycete *Rhizopus stolonifer* (black bread mold).**

▲ **Figure 31.14** ***Pilobolus*** **aiming its sporangia.** The spore-bearing hyphae of this zygomycete, which decomposes animal dung, bend toward light, where grass is likely to grow. The fungus then launches its sporangia in a jet of water as far as 2 m. Grazing animals ingest the fungi with the grass and then scatter the spores in feces.

▲ **Figure 31.15** **Arbuscular mycorrhizae.** Glomeromycetes form arbuscular mycorrhizae with plant roots, supplying minerals and other nutrients to the roots. This SEM depicts the branched hyphae—an arbuscule—of *Glomus mosseae* bulging into a root cell by pushing in the membrane (the root has been treated to remove the cytoplasm).

such as *Pilobolus*, can actually "aim" and then shoot their sporangia toward bright light **(Figure 31.14)**.

If environmental conditions deteriorate—for instance, if the mold consumes all its food—*Rhizopus* may reproduce sexually. The parents in a sexual union are mycelia of different mating types that possess different chemical markers, although they may appear identical. Plasmogamy produces a sturdy structure called a **zygosporangium**, in which karyogamy and then meiosis occur. Note that while a zygosporangium represents the zygote ($2n$) stage in the life cycle, it is not a zygote in the usual sense (that is, a cell with one diploid nucleus). Rather, a zygosporangium is a multinucleate structure, first heterokaryotic with many haploid nuclei from the two parents, then with many diploid nuclei after karyogamy.

Zygosporangia are resistant to freezing and drying and are metabolically inactive. When conditions improve, a zygosporangium undergoes meiosis, germinates into a sporangium, and releases genetically diverse haploid spores that may colonize a new substrate.

Glomeromycetes

The **glomeromycetes**, fungi assigned to the phylum Glomeromycota, were formerly thought to be zygomycetes. But recent molecular studies, including a phylogenetic analysis of DNA sequence data from six genes in hundreds of fungal species, indicate that glomeromycetes form a separate clade (monophyletic group). In spite of their small numbers—only 160 species have been identified to date—the glomeromycetes are an ecologically significant group. Nearly all glomeromycetes form arbuscular mycorrhizae **(Figure 31.15)**. The tips of the hyphae that push into plant root cells branch into tiny treelike structures known as arbuscules. About 90% of all plant species have such mutualistic partnerships with glomeromycetes.

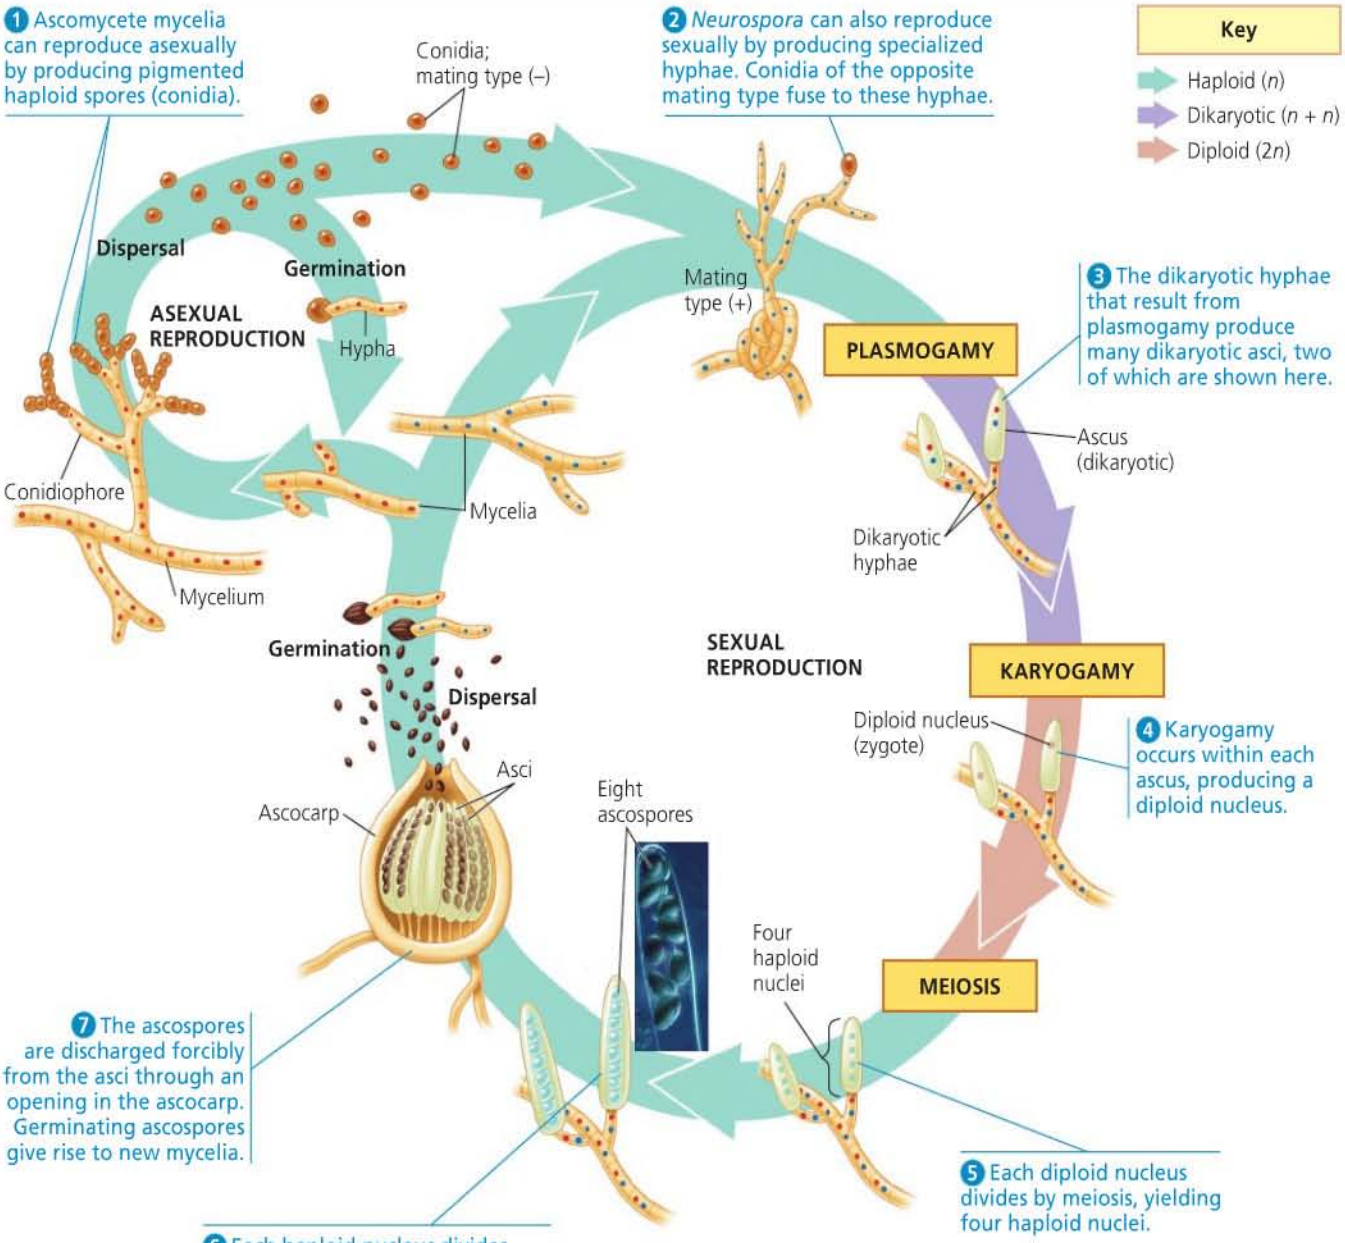
Ascomycetes

Mycologists have described 65,000 species of **ascomycetes** (fungi in the phylum Ascomycota) from a wide variety of marine, freshwater, and terrestrial habitats. The defining feature of ascomycetes is the production of sexual spores in saclike **asci** (singular, *ascus*); thus, they are commonly called **sac fungi**. Unlike zygomycetes, most ascomycetes bear their sexual stages in

▼ The edible ascocarp of *Morchella esculenta*, the tasty morel, is often found under trees in orchards.

▼ *Tuber melanosporum* is a truffle species that forms ectomycorrhizae with trees. The ascocarp grows underground and emits a strong odor. These ascocarps have been dug up and the middle one sliced open.

▲ **Figure 31.16** **Ascomycetes (sac fungi).**



? *Ascomycetes vary greatly in morphology (see also Figure 31.11). How could you confirm that a fungus is an ascomycete?*

fruiting bodies, or **ascocarps**, which range in size from microscopic to macroscopic (**Figure 31.16**, on the facing page). The spore-forming asci are found in the ascocarps.

Ascomycetes vary in size and complexity from unicellular yeasts to elaborate cup fungi and morels (see Figure 31.16). They include some of the most devastating plant pathogens, which we will discuss later. However, many ascomycetes are important decomposers, particularly of plant material. More than 40% of all ascomycete species live with green algae or cyanobacteria in beneficial symbiotic associations called lichens. Some ascomycetes form mycorrhizae with plants. Many others live between mesophyll cells in leaves; some of these species release toxic compounds that help protect the plant from insects.

Although the life cycles of various ascomycete groups differ in the details of their reproductive structures and processes, we'll illustrate some common elements using the bread mold *Neurospora crassa* **(Figure 31.17)**. Ascomycetes reproduce asexually by producing enormous numbers of asexual spores called **conidia** (singular, *conidium*). Conidia are not formed inside sporangia, as are the asexual spores of most zygomycetes. Rather, they are produced externally at the tips of specialized hyphae called conidiophores, often in clusters or long chains, from which they may be dispersed by the wind.

Conidia may also be involved in sexual reproduction, fusing with hyphae from a mycelium of a different mating type, as occurs in *Neurospora*. Fusion of two different mating types is

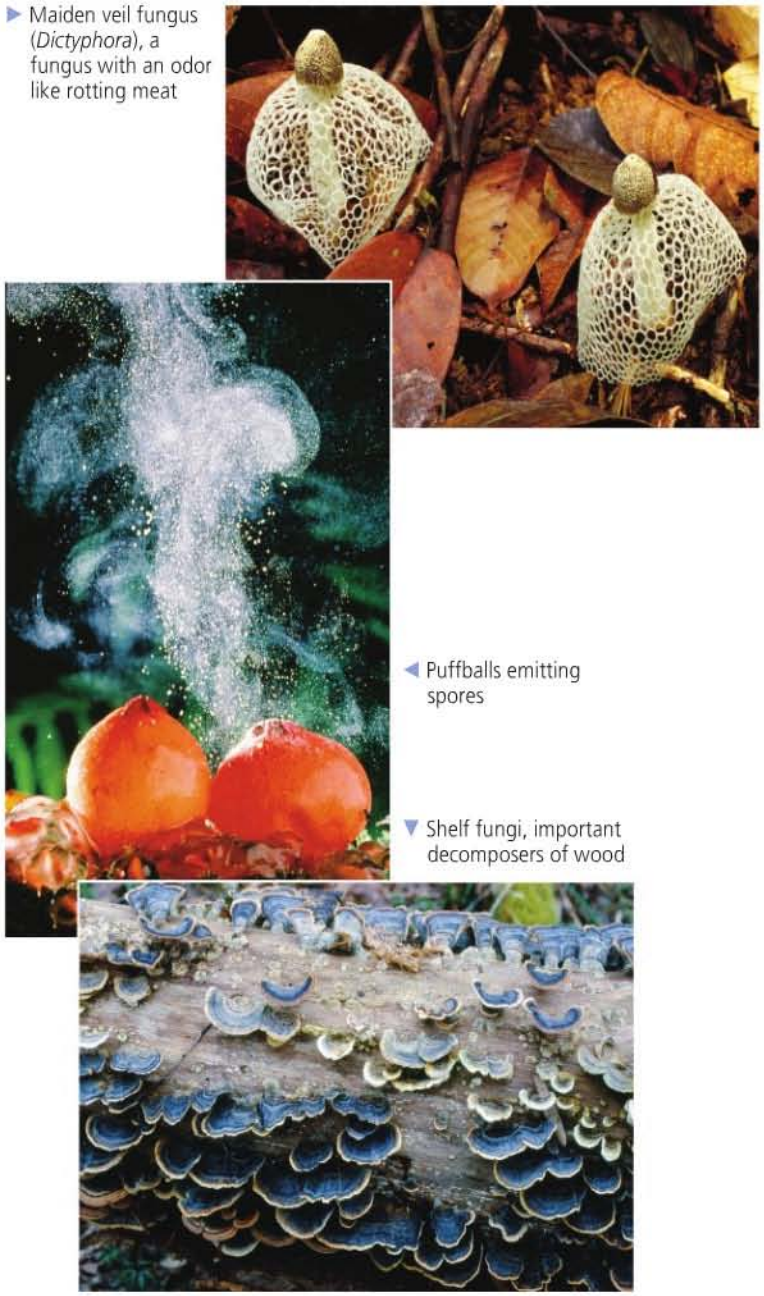
▲ **Figure 31.17 The life cycle of *Neurospora crassa*, an ascomycete.** *Neurospora* is a bread mold and research organism that also grows in the wild on burned vegetation.

followed by plasmogamy, resulting in the formation of dikaryotic cells, each with two haploid nuclei representing the two parents. The cells at the tips of these dikaryotic hyphae develop into many asci. Within each ascus, karyogamy combines the two parental genomes, and then meiosis forms four genetically different nuclei. This is usually followed by a mitotic division, forming eight ascospores. The ascospores develop in and are eventually discharged from the ascocarp.

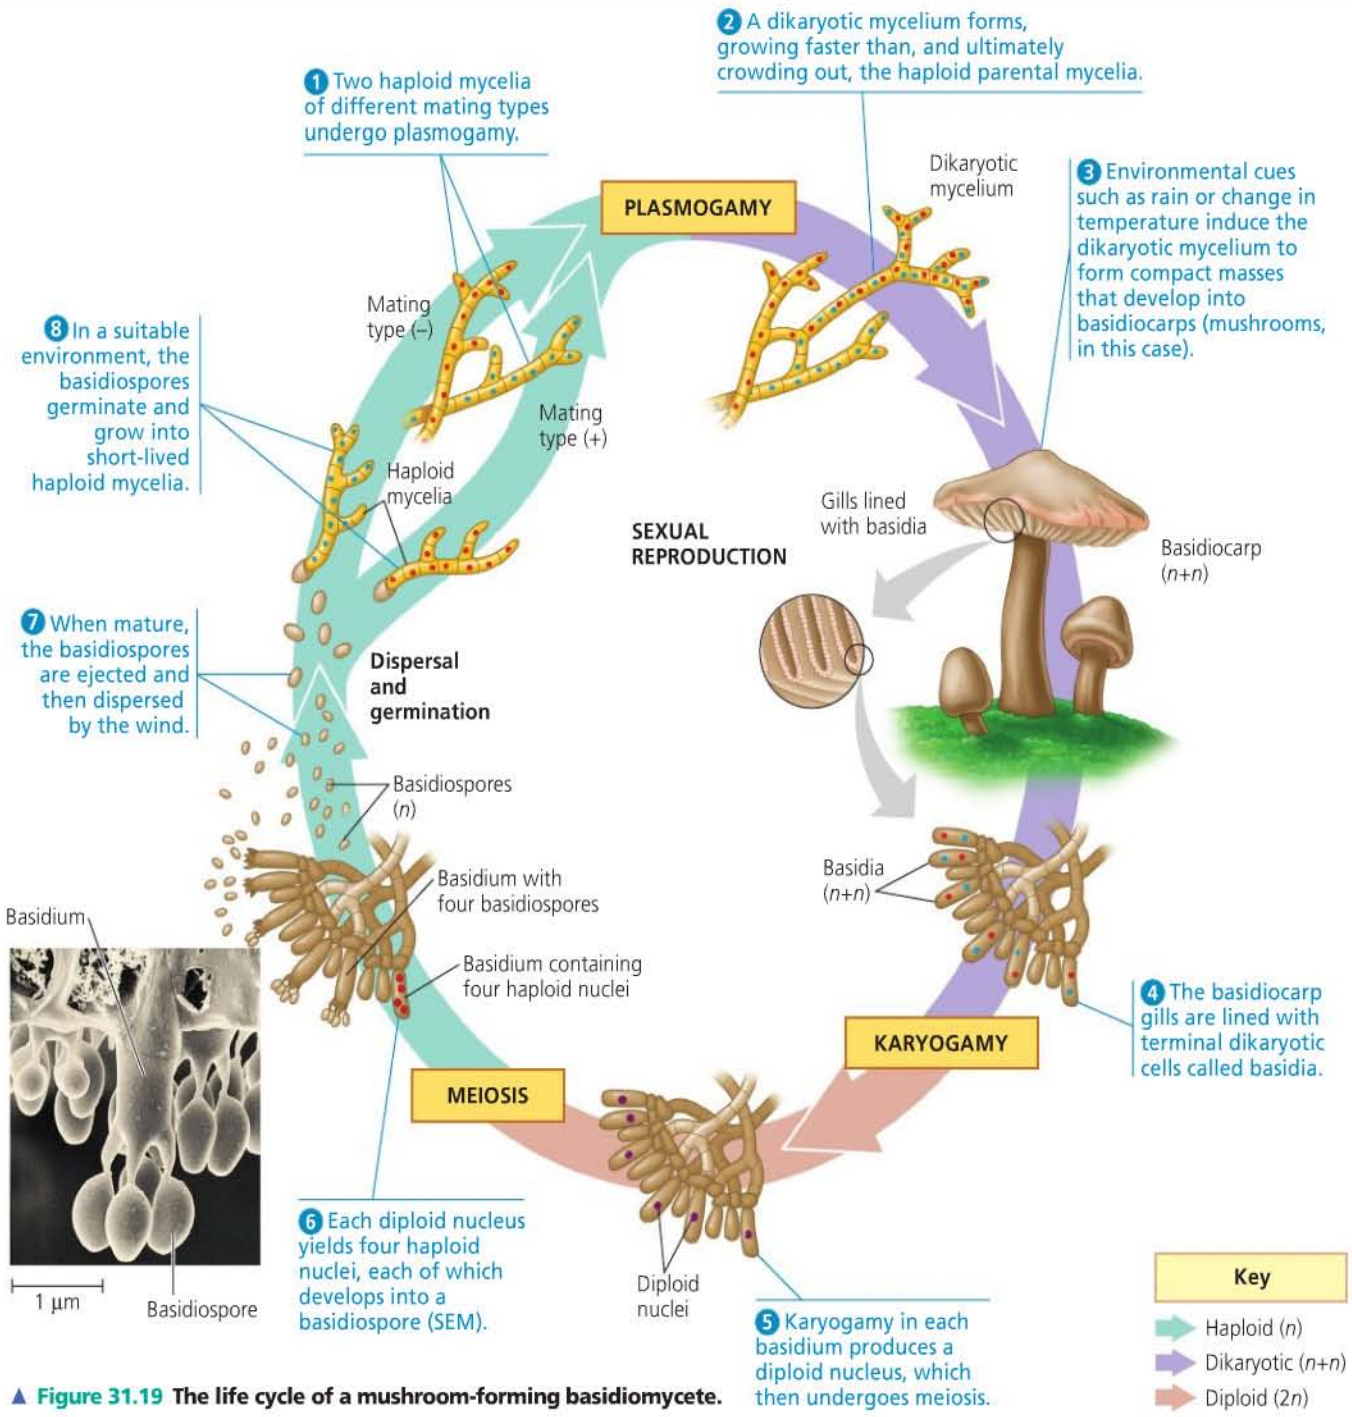
In contrast to the life cycle of zygomycetes, the extended dikaryotic stage of ascomycetes (and also basidiomycetes) provides increased opportunity for genetic recombination. In *Neurospora*, for example, many dikaryotic cells can develop into asci, recombining genomes and resulting in a multitude of genetically different offspring from one mating event (see Figure 31.17).

Neurospora has a significant history in biological research. As we discussed in Chapter 17, biologists in the 1930s used *Neurospora* in research that led to the one gene–one enzyme hypothesis. Today, this ascomycete continues to serve as a model research organism; in 2003, its entire genome was published. With 10,000 genes, the genome of this tiny fungus is about three-fourths the size of the *Drosophila* genome and half the size of the human genome. The *Neurospora* genome is relatively compact, having few of the stretches of noncoding DNA that occupy much space in the genomes of humans and many other eukaryotes. In fact, there is evidence that *Neurospora* has a genomic defense system that prevents noncoding DNA such as transposons from accumulating.

Basidiomycetes



Approximately 30,000 species, including mushrooms, puffballs, and shelf fungi, are called **basidiomycetes** and are classified in the phylum Basidiomycota **(Figure 31.18)**. The phylum also includes mutualists that form mycorrhizae and two groups of destructive plant parasites: rusts and smuts. The name of the phylum derives from the **basidium** (Latin for "little pedestal"), a cell in which karyogamy occurs, followed immediately by meiosis. The club-like shape of the basidium also gives rise to the common name **club fungus**.



Basidiomycetes are important decomposers of wood and other plant material. Of all the fungi, certain basidiomycetes are the best at decomposing the complex polymer lignin, an abundant component of wood. Many shelf fungi break down the wood of weak or damaged trees and continue to decompose the wood after the tree dies.

The life cycle of a basidiomycete usually includes a long-lived dikaryotic mycelium **(Figure 31.19)**. As in ascomycetes, this extended dikaryotic stage provides opportunities for many genetic recombination events, in effect multiplying the result of a single mating. Periodically, in response to environmental stimuli, the mycelium reproduces sexually by producing elaborate fruiting bodies called **basidiocarps**. The common white mushrooms in the supermarket are familiar examples of a basidiocarp.

By concentrating growth in the hyphae of mushrooms, a basidiomycete mycelium can quickly erect its fruiting structures in just a few hours; a mushroom pops up as it absorbs water and as cytoplasm streams in from the dikaryotic mycelium. By this process, a ring of mushrooms, popularly called a "fairy ring," may appear literally overnight **(Figure 31.20)**. The mycelium below the fairy ring expands outward at a rate of about 30 cm per year, decomposing organic matter in the soil as it grows. Some giant fairy rings are produced by mycelia that are centuries old.

▲ **Figure 31.18 Basidiomycetes (club fungi).**

▲ **Figure 31.19 The life cycle of a mushroom-forming basidiomycete.**

▲ **Figure 31.20 A fairy ring.** According to legend, these mushrooms spring up where fairies have danced in a ring on a moonlit night. (The text provides a biological explanation of how fairy rings form.)

The numerous basidia in a basidiocarp are the sources of sexual spores called basidiospores. After a mushroom forms, its cap supports and protects a large surface area of dikaryotic basidia on gills. During karyogamy, the two nuclei in each basidium fuse, producing a diploid nucleus (see Figure 31.19). This nucleus then undergoes meiosis, yielding four haploid nuclei. The basidium then grows four appendages, and one haploid nucleus enters each appendage and develops into a basidiospore. Large numbers of basidiospores are produced: The gills of a common white mushroom have a surface area of about 200 cm^2 and may release a billion basidiospores, which drop from the bottom of the cap and are blown away.

CONCEPT CHECK 31.4

1. What feature of chytrids supports the hypothesis that they represent an early-diverging fungal lineage?
2. Give different examples of how form fits function in zygomycetes, glomeromycetes, ascomycetes, and basidiomycetes.
3. **WHAT IF?** Suppose that mutation of an ascomycete changed its life cycle so that plasmogamy, karyogamy, and meiosis occurred in quick succession. How might this affect the ascospores and ascocarp?

For suggested answers, see Appendix A.

CONCEPT 31.5

Fungi play key roles in nutrient cycling, ecological interactions, and human welfare

In our survey of fungal classification, we've touched on some of the ways fungi influence other organisms, including ourselves. We will now look more closely at these impacts, focusing on how fungi act as decomposers, mutualists, and pathogens.

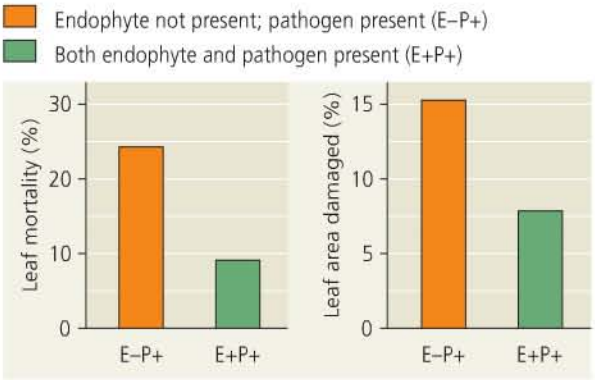
Fungi as Decomposers

Fungi are well adapted as decomposers of organic material, including the cellulose and lignin of plant cell walls. In fact, almost any carbon-containing substrate—even jet fuel and house paint—can be consumed by at least some fungi. As you might expect, researchers are developing ways to use a variety of fungal species in bioremediation projects. In addition, fungi and bacteria are primarily responsible for keeping ecosystems stocked with the inorganic nutrients essential for plant growth. Without these decomposers, carbon, nitrogen, and other elements would remain tied up in organic matter. Plants and the animals that eat them could not exist because elements taken from the soil would not be returned (see Chapter 55). Without decomposers, life as we know it would cease.

Fungi as Mutualists

Fungi may form mutualistic relationships with plants, algae, cyanobacteria, and animals. All of these relationships have profound ecological effects.

Fungus-Plant Mutualisms



We've already considered the enormous importance of the mutualistic associations that most vascular plants form with mycorrhizal fungi. In addition, all plant species studied to date appear to harbor symbiotic **endophytes**, fungi that live inside leaves or other plant parts without causing harm. Most endophytes identified to date are ascomycetes. Endophytes have been shown to benefit certain grasses and other nonwoody plants by making toxins that deter herbivores or by increasing host plant tolerance of heat, drought, or heavy metals. Seeking to discover how endophytes affect a woody plant, researchers tested whether leaf endophytes benefited seedlings of the cacao tree, *Theobroma cacao* **(Figure 31.21)**. Their findings show that the endophytes of woody flowering plants can play an important role in defending against pathogens.

▼ Figure 31.21 Inquiry

Do endophytes benefit a woody plant?

EXPERIMENT Endophytes are symbiotic fungi found within the bodies of all plants examined to date. A. Elizabeth Arnold at the University of Arizona, Tucson, and colleagues tested whether endophytes benefit the cacao tree (*Theobroma cacao*). This tree, whose name means "food of the gods" in Greek, is the source of the beans used to make chocolate, and it is cultivated throughout the tropics. Endophytes were added to the leaves of some cacao seedlings, but not others. (In cacao, endophytes colonize leaves after the seedling germinates.) The seedlings were then inoculated with a virulent pathogen, the protist *Phytophthora* (see Chapter 28).

RESULTS Fewer leaves were killed by the pathogen in seedlings with endophytes than in seedlings without endophytes. Among leaves that survived, pathogens damaged less of the leaf surface area in seedlings with endophytes than in seedlings without endophytes.

CONCLUSION The presence of endophytes appears to benefit cacao trees by reducing the leaf mortality and damage caused by *Phytophthora*.

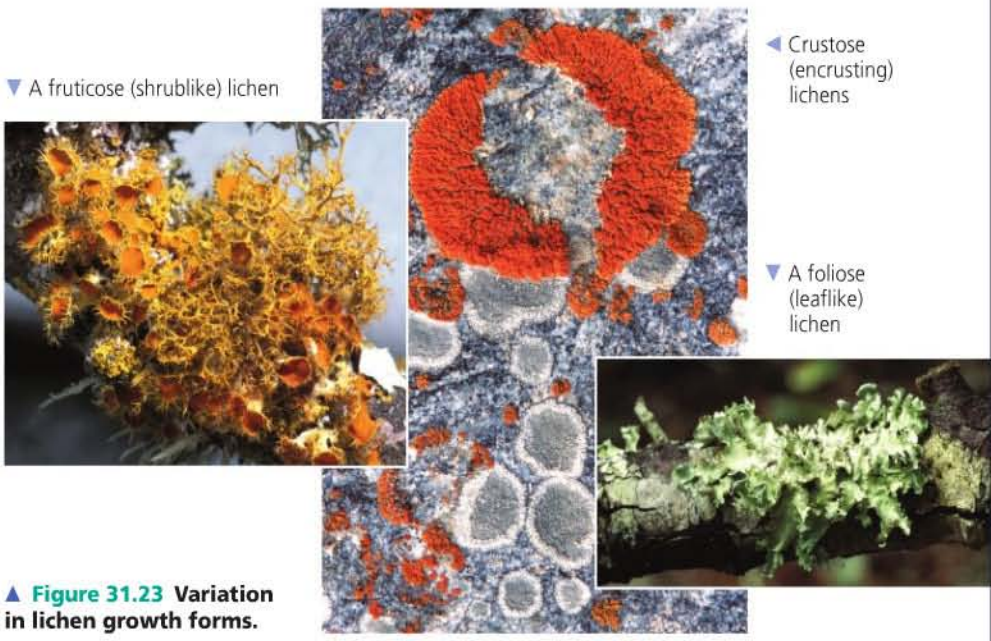
SOURCE A. E. Arnold et al., Fungal endophytes limit pathogen damage in a tropical tree, *Proceedings of the National Academy of Sciences* 100:15649–15654 (2003).

WHAT IF? Arnold and colleagues also performed control treatments. Suggest two controls they might have used, and explain how each would be helpful in interpreting the results described here.

Fungus-Animal Symbioses

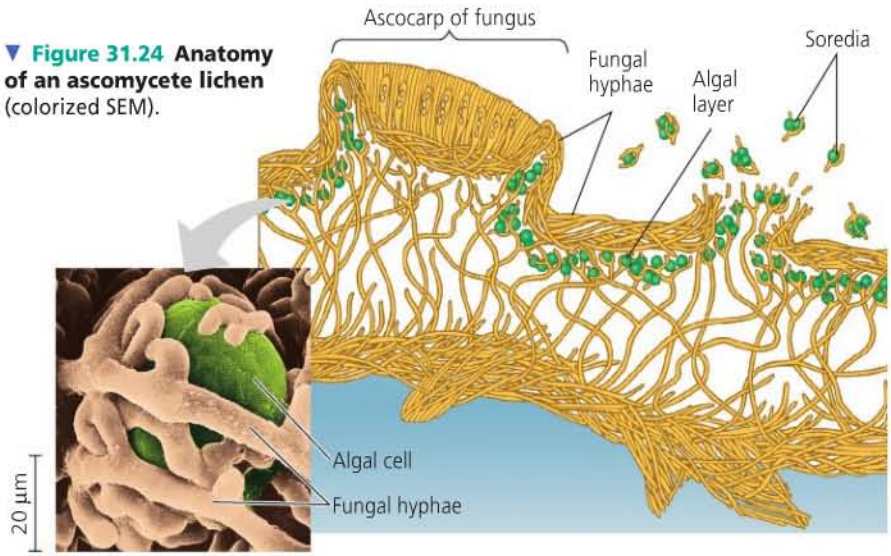
As mentioned earlier, some fungi share their digestive services with animals, helping break down plant material in the guts of cattle and other grazing mammals. Many species of ants take advantage of the digestive power of fungi by raising them in

▲ **Figure 31.22 Fungus-gardening insects.** These leaf-cutting ants depend on fungi to convert plant material to a form the insects can digest. The fungi, in turn, depend on the nutrients from the leaves the ants feed them.



"farms." Leaf-cutter ants, for example, scour tropical forests in search of leaves, which they cannot digest on their own but carry back to their nests and feed to the fungi **(Figure 31.22)**. As the fungi grow, their hyphae develop specialized swollen tips that are rich in proteins and carbohydrates. The ants feed primarily on these nutrient-rich tips. In effect, the fungi break down plant leaves into substances the insects can digest, and they also detoxify plant defensive compounds that would otherwise kill or harm the ants. In some tropical forests, the fungi have helped these insects become the major consumers of leaves.

The evolution of such farmer ants and that of their fungal "crops" have been tightly linked for over 50 million years. The fungi have become so dependent on their caretakers that in many cases they can no longer survive without the ants, and vice versa.



Lichens

A **lichen** is a symbiotic association between a photosynthetic microorganism and a fungus in which millions of photosynthetic cells are held in a mass of fungal hyphae. Lichens grow on the surfaces of rocks, rotting logs, trees, and roofs in various forms **(Figure 31.23)**. The photosynthetic partners are unicellular or filamentous green algae or cyanobacteria. The fungal component is most often an ascomycete, but one glomeromycete and several basidiomycete lichens are known. The fungus usually gives a lichen its overall shape and structure, and tissues formed by hyphae account for most of the lichen's mass. The algae or cyanobacteria generally occupy an inner layer below the lichen surface **(Figure 31.24)**. The merger of fungus and alga or cyanobacterium is so complete that lichens are actually given scientific names as though they were single organisms. More than 13,500 species have been described, accounting for nearly one out of seven of all known fungi.

In most lichens that have been studied, each partner provides something the other could not obtain on its own. The algae provide carbon compounds; the cyanobacteria also fix nitrogen (see Chapter 27) and provide organic nitrogen. The fungi provide their photosynthetic partners with a suitable environment for growth. The physical arrangement of hyphae allows for gas

▲ **Figure 31.23 Variation in lichen growth forms.**

▼ **Figure 31.24 Anatomy of an ascomycete lichen** (colorized SEM).

exchange, protects the photosynthetic partner, and retains water and minerals, most of which are absorbed either from airborne dust or from rain. The fungi also secrete acids, which aid in the uptake of minerals. Fungal pigments help shade the algae or cyanobacteria from intense sunlight. Some fungal compounds are toxic and prevent most lichens from being eaten by animals.

The fungi of many lichens reproduce sexually by forming ascocarps or basidiocarps. Lichen algae reproduce independently of the fungus by asexual cell division. As might be expected of "dual organisms," asexual reproduction as a symbiotic unit also occurs commonly, either by fragmentation of the parental lichen or by the formation of **soredia**, small clusters of hyphae with embedded algae (see Figure 31.24).

Lichens are important pioneers on newly cleared rock and soil surfaces, such as burned forests and volcanic flows. They break down the surface by physically penetrating and chemically attacking it, and they trap windblown soil. Nitrogen-fixing lichens also add organic nitrogen to some ecosystems. These processes make it possible for a succession of plants to grow (see Chapter 54).

As tough as lichens are, many do not stand up very well to air pollution. Their passive mode of mineral uptake from rain and moist air makes them particularly sensitive to sulfur dioxide and other airborne poisons. The death of sensitive lichens in an area can be an early warning that air quality is deteriorating.

Fungi as Pathogens

About 30% of the 100,000 known species of fungi make a living as parasites or pathogens, mostly of plants **(Figure 31.25)**. For example, *Cryphonectria parasitica*, the ascomycete fungus that causes chestnut blight, dramatically changed the landscape of the northeastern United States. Accidentally introduced on trees imported from Asia in the early 1900s, spores of the fungus enter cracks in the bark of American chestnut trees and produce hyphae, killing the tree. American chestnuts once were common in many forests in eastern North America, but now they typically persist only as sprouts from the stumps of former trees. Another ascomycete, *Fusarium circinatum*, causes pine pitch canker, a disease that threatens pines throughout the world. Fungi are also serious pests of food crops. Between 10% and 50% of the world's fruit harvest is lost each year to fungal attack. Grain crops also suffer major losses each year from fungi such as the basidiomycete *Puccinia graminis*, which causes black stem rust on wheat.

Some of the fungi that attack food crops are toxic to humans. For example, certain species of the ascomycete mold *Aspergillus* contaminate improperly stored grain and peanuts by secreting carcinogenic compounds called aflatoxins. Another example is the ascomycete *Claviceps purpurea*, which grows on rye plants, forming purple structures called ergots. If diseased rye is inadvertently milled into flour and then consumed, poisons from the ergots can cause ergotism, a condition characterized by gangrene, nervous spasms, burning sensations, hallucinations, and temporary insanity. An epidemic of ergotism around 944 C.E. killed more than 40,000 people in France. One compound that has been isolated from ergots is lysergic acid, the raw material from which the hallucinogen LSD is made.

(a) Corn smut on corn (b) Tar spot fungus on maple leaves (c) Ergots on rye

▲ **Figure 31.25 Examples of fungal diseases of plants.**

Animals are much less susceptible to parasitic fungi than are plants. Only about 50 fungal species are known to parasitize animals, but these few species do considerable damage. The general term for such a fungal infection is **mycosis**.

Skin mycoses include the disease ringworm, so named because it appears as circular red areas on the skin. The ascomycetes that cause ringworm can infect almost any skin surface. Most commonly, they grow on the feet, causing the intense itching and blisters known as athlete's foot. Though highly contagious, athlete's foot and other ringworm infections can be treated with fungicidal lotions and powders.

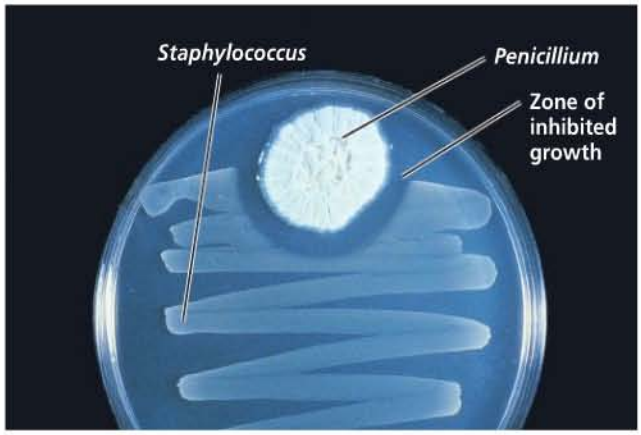
Systemic mycoses, by contrast, spread through the body and usually cause very serious illnesses. They are typically caused by inhaled spores. For example, coccidioidomycosis is a systemic mycosis that produces tuberculosis-like symptoms in the lungs. Each year, hundreds of cases in North America require treatment with antifungal drugs, without which the disease would be fatal.

Some mycoses are opportunistic, occurring only when a change in the body's microorganisms, chemical environment, or immune system allows fungi to grow unchecked. *Candida albicans*, for example, is one of the normal inhabitants of moist epithelia, such as the vaginal lining. Under certain circumstances, *Candida* can grow too rapidly and become pathogenic, leading to so-called "yeast infections." Many other opportunistic mycoses in humans have become more common in recent decades, due in part to AIDS, which compromises the immune system.

Over the past few years, the alleged dangers of indoor molds (including the ascomycete *Stachybotrys chartarum*) have been the subject of sensationalistic news reports. Indoor molds thrive in damp buildings and have been implicated in some studies as the cause of a wide variety of diseases. As a result, entire "sick buildings" have been abandoned. Yet there is no well-substantiated evidence linking the presence of indoor molds to these diseases. Many other factors—including bacteria and human-made chemicals—may explain some of the symptoms attributed to indoor molds.

Practical Uses of Fungi

The dangers posed by fungi should not overshadow the immense benefits we derive from these remarkable eukaryotes. We depend on their ecological services as decomposers and recyclers of organic matter. Without mycorrhizae, our agriculture would be far less productive.



Mushrooms are not the only fungi of interest for human consumption. The distinctive flavors of certain kinds of cheeses, including Roquefort and other blue cheeses, come from the fungi used to ripen them. The soft drink industry uses a species of *Aspergillus* to produce citric acid for colas. Morels and truffles, the edible fruiting bodies of various ascomycetes, are highly prized for their complex flavors (see Figure 31.16). These fungi can sell for several hundred dollars a pound. Truffles release strong odors that attract mammals and insects, which feed on them and disperse their spores. In some cases, the odors mimic the pheromones (sex attractants) of certain mammals. For example, several European truffles mimic the pheromones released by male pigs, which explains why *female* pigs have historically been used to help find these delicacies.

Humans have used yeasts to produce alcoholic beverages and raise bread for thousands of years. Under what are typically anaerobic conditions, yeasts ferment sugars to alcohol and CO_2, which leavens dough. Only relatively recently have the yeasts involved been separated into pure cultures for more controlled use. The yeast *Saccharomyces cerevisiae* is the most important of all cultured fungi (see Figure 31.7). It is available as many strains of baker's yeast and brewer's yeast.

Many fungi have great medical value as well. For example, a compound extracted from ergots is used to reduce high blood pressure and to stop maternal bleeding after childbirth. Some fungi produce antibiotics that are essential in treating bacterial infections. In fact, the first antibiotic discovered was penicillin, made by the ascomycete mold *Penicillium* **(Figure 31.26)**. Other examples of pharmaceuticals derived from fungi include cholesterol-lowering drugs and cyclosporine, a drug used to suppress the immune system after organ transplants.

Fungi also figure prominently in research in molecular biology and biotechnology. Researchers use the yeast *Saccharomyces* to study the molecular genetics of eukaryotes because its cells are easy to culture and manipulate. Scientists are gaining insight into the genes involved in human diseases such as Parkinson's disease and Huntington's disease by examining the interactions of homologous genes in *Saccharomyces*.

Genetically modified fungi hold much promise. Although bacteria such as *Escherichia coli* can produce some useful proteins, they cannot synthesize glycoproteins because they lack enzymes that can attach carbohydrates to proteins. Fungi, on the other hand, do produce such enzymes. In 2003, scientists succeeded in engineering a strain of *S. cerevisiae* that produces human glycoproteins, including insulin-like growth factor. Such

▲ **Figure 31.26 Fungal production of an antibiotic.** The mold *Penicillium* produces an antibiotic that inhibits the growth of *Staphylococcus* bacteria, resulting in the clear area between the mold and the bacteria.

fungus-produced glycoproteins could treat people with medical conditions that prevent them from producing these compounds. Meanwhile, other researchers are sequencing the genome of the wood-digesting basidiomycete *Phanerochaete chrysosporium*, one of many "white rot" fungi. They hope to decipher the metabolic pathways by which white rot breaks down wood, with the goal of harnessing these pathways to produce paper pulp.

Having now completed our survey of the kingdom Fungi, we will turn in the remaining chapters of this unit to the closely related kingdom Animalia, to which we humans belong.

CONCEPT CHECK 31.5

1. What are some of the benefits that lichen algae can derive from their relationship with fungi?
2. What characteristics of pathogenic fungi result in their being efficiently transmitted?
3. **WHAT IF?** How might life on Earth differ from what we know today if no mutualistic relationships between fungi and other organisms had ever evolved?

For suggested answers, see Appendix A.

Chapter 31 Review

MEDIA Go to the Study Area at **www.masteringbio.com** for BioFlix 3-D Animations, MP3 Tutors, Videos, Practice Tests, an eBook, and more.

SUMMARY OF KEY CONCEPTS

CONCEPT 31.1

Fungi are heterotrophs that feed by absorption (pp. 636–638)

- **Nutrition and Ecology** All fungi are heterotrophs (including decomposers and symbionts) that acquire nutrients by absorption. Many fungi secrete enzymes that break down complex molecules in food to smaller molecules that can be absorbed.
- **Body Structure** Most fungi grow as multicellular filaments; relatively few species grow exclusively as single-celled yeasts. In their multicellular form, fungi consist of mycelia, networks of branched hyphae adapted for absorption. Mycorrhizal fungi have specialized hyphae that enable them to form a mutually beneficial relationship with plants.

MEDIA
Activity Fungal Reproduction and Nutrition

CONCEPT 31.2

Fungi produce spores through sexual or asexual life cycles (pp. 638–640)

- **Sexual Reproduction** The sexual cycle involves cytoplasmic fusion (plasmogamy) and nuclear fusion (karyogamy), with an intervening heterokaryotic stage in which cells have haploid nuclei from two parents. The diploid phase resulting from karyogamy is short-lived and undergoes meiosis, producing haploid spores.
- **Asexual Reproduction** Many fungi can reproduce asexually as filamentous fungi or yeasts. DNA sequence data now allow mycologists to classify all fungi, even those lacking a known sexual morphology.

CONCEPT 31.3

The ancestor of fungi was an aquatic, single-celled, flagellated protist (pp. 640–641)

- **The Origin of Fungi** Molecular evidence supports the hypothesis that fungi and animals diverged from a common ancestor that was unicellular and had a flagellum.
- **Are Microsporidia Closely Related to Fungi?** Unicellular parasites called microsporidia may be protists that are closely related to fungi, or they may be an early-diverging fungal lineage.
- **The Move to Land** Fungi were among the earliest colonizers of land, probably as symbionts with early land plants.

CONCEPT 31.4

Fungi have radiated into a diverse set of lineages (pp. 641–648)

Fungal Phylum	Distinguishing Features of Morphology and Life Cycles	
Chytridiomycota (chytrids)	Flagellated spores	
Zygomycota (zygote fungi)	Resistant zygosporangium as sexual stage	
Glomeromycota (arbuscular mycorrhizal fungi)	Form arbuscular mycorrhizae with plants	
Ascomycota (sac fungi)	Sexual spores (ascospores) borne internally in sacs called asci; ascomycetes also produce vast numbers of asexual spores (conidia)	
Basidiomycota (club fungi)	Elaborate fruiting body (basidiocarp) containing many basidia that produce sexual spores (basidiospores)	

MEDIA
Activity Fungal Life Cycles

CONCEPT 31.5

Fungi play key roles in nutrient cycling, ecological interactions, and human welfare (pp. 648–652)

- **Fungi as Decomposers** Fungi perform essential recycling of chemical elements between the living and nonliving world.
- **Fungi as Mutualists** Some endophytes help protect plants from herbivores and pathogens, while other fungi help certain animals digest plant tissue. Lichens are highly integrated symbiotic associations of fungi and algae or cyanobacteria.
- **Fungi as Pathogens** About 30% of all known fungal species are parasites, mostly of plants. Some fungi also cause human diseases.
- **Practical Uses of Fungi** Humans eat many fungi and use others to make cheeses, alcoholic beverages, and bread. Antibiotics produced by fungi treat bacterial infections. Genetic research on fungi is leading to applications in biotechnology.

Investigation How Does the Fungus *Pilobolus* Succeed as a Decomposer?

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. *All* fungi share which of the following characteristics?
   a. symbiotic
   b. heterotrophic
   c. flagellated
   d. pathogenic
   e. act as decomposers

2. Which feature seen in chytrids supports the hypothesis that they diverged earliest in fungal evolution?
   a. the absence of chitin within the cell wall
   b. coenocytic hyphae
   c. flagellated spores
   d. formation of resistant zygosporangia
   e. parasitic lifestyle

3. Which of the following cells or structures are associated with *asexual* reproduction in fungi?
   a. ascospores
   b. basidiospores
   c. zygosporangia
   d. conidiophores
   e. ascocarps

4. The adaptive advantage associated with the filamentous nature of fungal mycelia is primarily related to
   a. the ability to form haustoria and parasitize other organisms.
   b. avoiding sexual reproduction until the environment changes.
   c. the potential to inhabit almost all terrestrial habitats.
   d. the increased probability of contact between different mating types.
   e. an extensive surface area well suited for invasive growth and absorptive nutrition.

5. The photosynthetic symbiont of a lichen is often
   a. a moss.
   b. a green alga.
   c. a brown alga.
   d. an ascomycete.
   e. a small vascular plant.

6. Among the organisms listed here, which are thought to be the closest relatives of fungi?
   a. animals
   b. vascular plants
   c. mosses
   d. brown algae
   e. slime molds

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

7. The fungus-alga symbiosis that makes up lichens is thought to have evolved multiple times independently in different fungal groups. However, lichens fall into three well-defined growth forms (see Figure 31.23). What research could you perform to test the following hypotheses?
   Hypothesis 1: Crustose, foliose, and fruticose lichens each represent a monophyletic group.
   Hypothesis 2: Each lichen growth form represents convergent evolution by taxonomically diverse fungi.

SCIENTIFIC INQUIRY

8. **DRAW IT** The grass *Dichanthelium languinosum* lives in hot soils and houses fungi of the genus *Curvularia*. Regina Redman, of Montana State University, and colleagues performed field experiments to test the impact of *Curvularia* on the heat tolerance of this grass. They grew plants without (E−) and with (E+) *Curvularia* endophytes in soils of different temperatures and measured plant mass and the number of new shoots the plants produced. Draw a bar graph of the results for plant mass versus temperature and interpret it.

Soil Temp.	*Curvularia* Presence	Plant Mass (g)	Number of New Shoots
30°C	E−	16.2	32
	E+	22.8	60
35°C	E−	21.7	43
	E+	28.4	60
40°C	E−	8.8	10
	E+	22.2	37
45°C	E−	0	0
	E+	15.1	24

SCIENCE, TECHNOLOGY, AND SOCIETY

9. As you read in the chapter, the ascomycete fungus that causes chestnut blight and has killed an estimated 4 billion chestnut trees in North America was accidentally imported from Asia. More recently, the fungus *Discula destructiva*, introduced to eastern North America in the 1980s, has killed more than 80% of the eastern dogwood trees in some locations. Why are plants particularly vulnerable to fungi imported from other regions? What kinds of human activities might contribute to the spread of plant diseases? Do you think introductions of fungal plant pathogens are more or less likely to occur in the future? Why?

32 An Introduction to Animal Diversity

▲ **Figure 32.1** **Which of these organisms are animals?**

KEY CONCEPTS

32.1 Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers

32.2 The history of animals spans more than half a billion years

32.3 Animals can be characterized by "body plans"

32.4 New views of animal phylogeny are emerging from molecular data

OVERVIEW

Welcome to Your Kingdom

Reading the last few chapters, you may have felt like a tourist among some unfamiliar organisms, such as slime molds, whisk ferns, and sac fungi. You probably are more at home with the topic introduced in this chapter—the animal kingdom, which of course includes yourself. But animal diversity extends far beyond humans and the dogs, cats, birds, and other animals we humans regularly encounter. For example, the diverse organisms in **Figure 32.1** are all animals, including those that appear to resemble lacy branches, thick stems, and curly leaves. To date biologists have identified 1.3 million extant (living) species of animals. Estimates of the actual number of animal species run far higher. This vast diversity encompasses a spectacular range of morphological variation, from corals to cockroaches to crocodiles.

In this chapter, we embark on a tour of the animal kingdom that will continue in the next two chapters. We will consider the characteristics that all animals share, as well as those that distinguish various taxonomic groups. This information is central to understanding animal phylogeny, a topic that is currently a lively arena of biological research and debate, as you will read.

CONCEPT 32.1

Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers

Constructing a good definition of an animal is not straightforward, as there are exceptions to nearly every criterion for distinguishing animals from other life-forms. However, several characteristics of animals, when taken together, sufficiently define the group for our discussion.

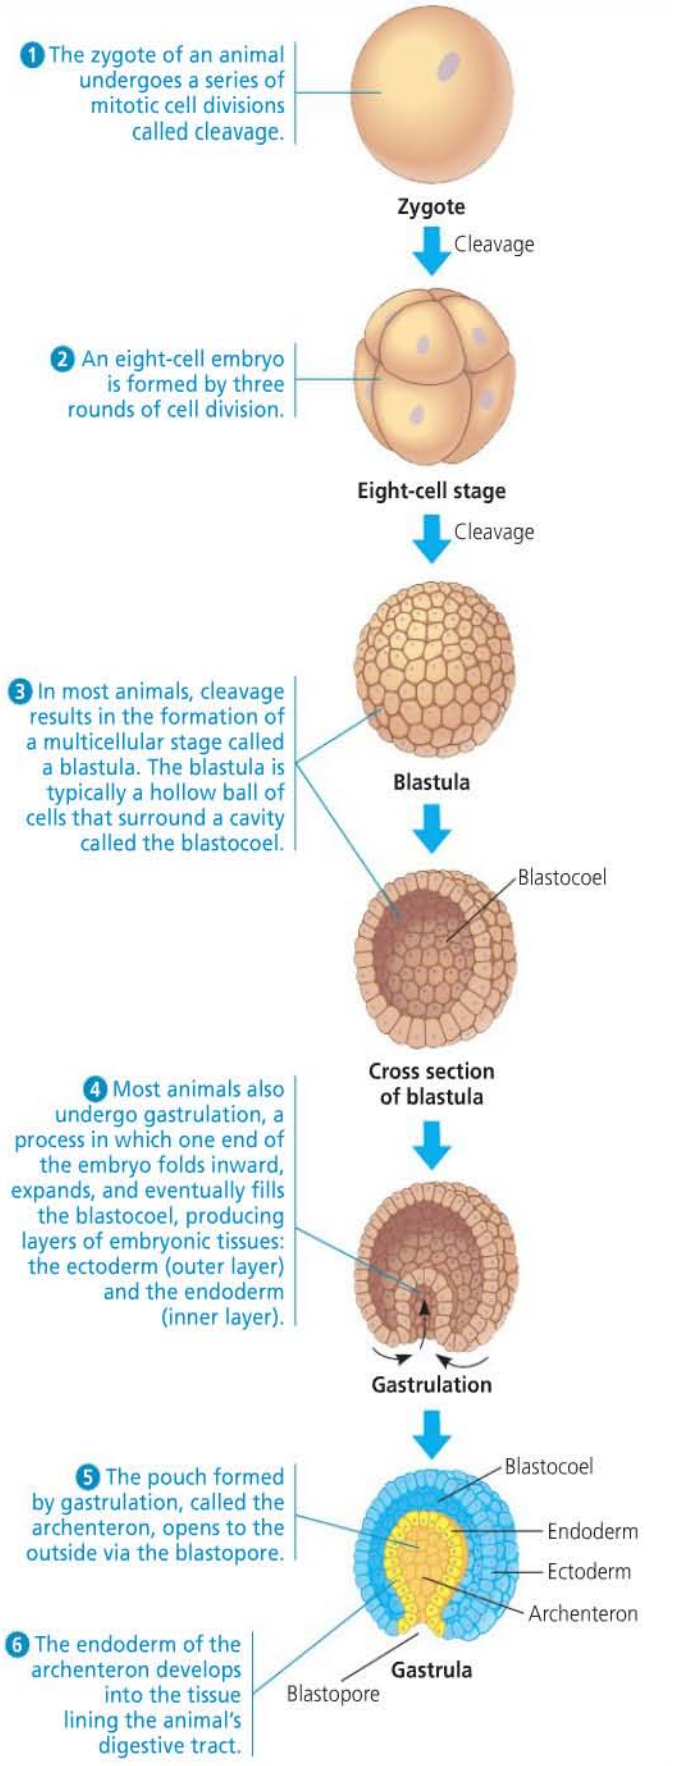
Nutritional Mode

Animals differ from both plants and fungi in their mode of nutrition. Plants are autotrophic eukaryotes capable of generating organic molecules through photosynthesis. Fungi are heterotrophs that grow on or near their food and that feed by absorption (often after they have released enzymes that digest the food outside their bodies). Unlike plants, animals cannot construct all of their own organic molecules and so, in most cases, they ingest them—either by eating other living organisms or by eating nonliving organic material. But unlike fungi, most animals do not feed by absorption; instead, animals ingest their food and then use enzymes to digest it within their bodies.

Cell Structure and Specialization

Animals are eukaryotes, and like plants and most fungi (but unlike most protists), animals are multicellular. In contrast to plants and fungi, however, animals lack the structural support of cell walls. Instead, animal cells are held together by structural proteins, the most abundant being collagen (see Figure 6.30), which is found only in animals.

Many animals have two types of specialized cells not seen in other multicellular organisms: muscle cells and nerve cells. In most animals, these cells are organized into muscle tissue and nervous tissue, respectively, and are responsible for moving the body and conducting nerve impulses. The ability to move and conduct nerve impulses underlies many of the adaptations that differentiate animals from plants and fungi, making muscle and nerve cells central to what it means to be an animal.



Reproduction and Development

Most animals reproduce sexually, and the diploid stage usually dominates the life cycle. In most species, a small, flagellated sperm fertilizes a larger, nonmotile egg, forming a diploid zygote. The zygote then undergoes **cleavage**, a succession of mitotic cell divisions without cell growth between division cycles. During the development of most animals, cleavage leads to the formation of a multicellular stage called a **blastula**, which in many animals takes the form of a hollow ball **(Figure 32.2)**. Following the blastula stage is the process of **gastrulation**, during which layers of embryonic tissues that will develop into adult body parts are produced. The resulting developmental stage is called a **gastrula**.

Some animals, including humans, develop directly into adults through transient stages of maturation, but the life cycles of many animals also include at least one larval stage. A **larva** is a sexually immature form of an animal that is morphologically distinct from the adult, usually eats different food, and may even have a different habitat than the adult, as in the case of the aquatic larva of a mosquito or a dragonfly. Animal larvae eventually undergo **metamorphosis**, a developmental transformation that turns the animal into a juvenile, which resembles an adult but is not yet sexually mature.

Although adult animals vary widely in morphology, the underlying genetic network that controls animal development is similar across a broad range of taxa. All eukaryotes have genes that regulate the expression of other genes, and many of these regulatory genes contain common sets of DNA sequences called *homeoboxes* (see Chapter 21). Animals share a unique homeobox-containing family of genes, known as *Hox* genes. *Hox* genes play important roles in the development of animal embryos, controlling the expression of dozens or even hundreds of other genes that influence animal morphology (see Chapter 25).

Sponges, which are among the simplest extant animals, have *Hox* genes that regulate formation of water channels in the body wall, a key feature of sponge morphology (see Chapter 33). In the ancestors of more complex animals, the *Hox* gene family underwent further duplications, yielding a more versatile "toolkit" for regulating development. In vertebrates, insects, and most other animals, *Hox* genes regulate patterning of the anterior-posterior (front-to-back) axis, as well as other aspects of development. The same conserved genetic network governs the development of both a fly and a human, despite their obvious differences and hundreds of millions of years of divergent evolution.

▲ **Figure 32.2 Early embryonic development in animals.**

CONCEPT CHECK 32.1

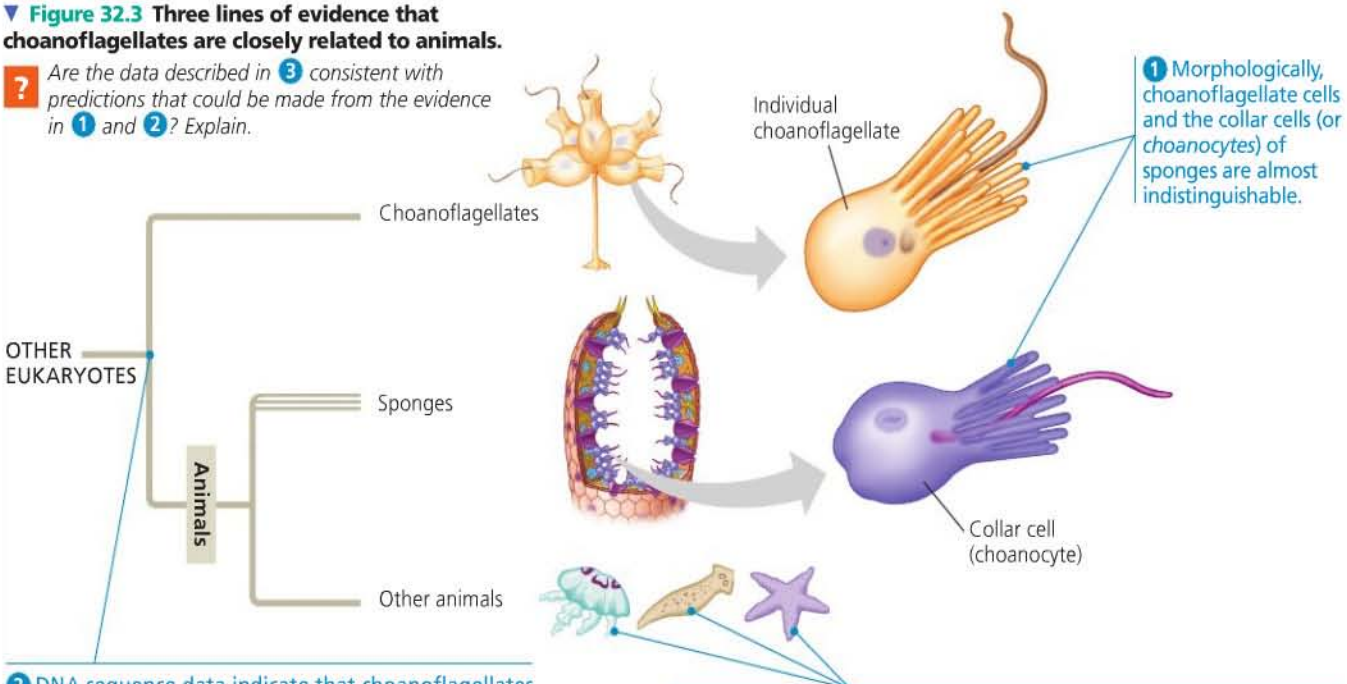
1. Summarize the main steps of animal development. What family of control genes plays a major role?
2. **WHAT IF?** What animal characteristics would be needed by an imaginary plant that could chase, capture, and digest its prey—yet could also extract nutrients from soil and conduct photosynthesis?

For suggested answers, see Appendix A.

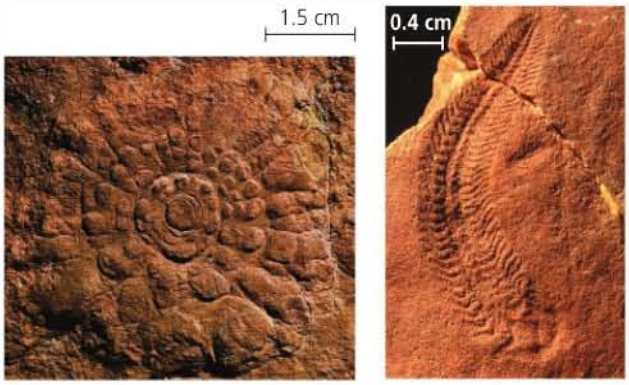
CONCEPT 32.2
The history of animals spans more than half a billion years

The animal kingdom includes not only the great diversity of living species, but also the even greater diversity of extinct ones. (Some paleontologists have estimated that 99% of all animal species are extinct.) Various studies suggest that this great diversity has its origins in evolutionary changes that occurred during the last billion years. For example, some estimates based on molecular clocks suggest that the ancestors of animals diverged from the ancestors of fungi about a billion years ago. Similar studies suggest that the common ancestor of living animals may have lived sometime between 675 and 875 million years ago.

To learn what this common ancestor may have been like, scientists have sought to identify protist groups that are closely related to animals. As shown in **Figure 32.3**, a combination of morphological and molecular evidence indicates that choanoflagellates are among the closest living relatives of animals. Based on such results, researchers hypothesize that the common ancestor of living animals may have been a stationary suspension feeder, similar to present-day choanoflagellates. In this section, we will survey the fossil evidence for how animals evolved from their distant common ancestor over four geologic eras (see Table 25.1 to review the geologic time scale.)



Neoproterozoic Era (1 Billion–542 Million Years Ago)



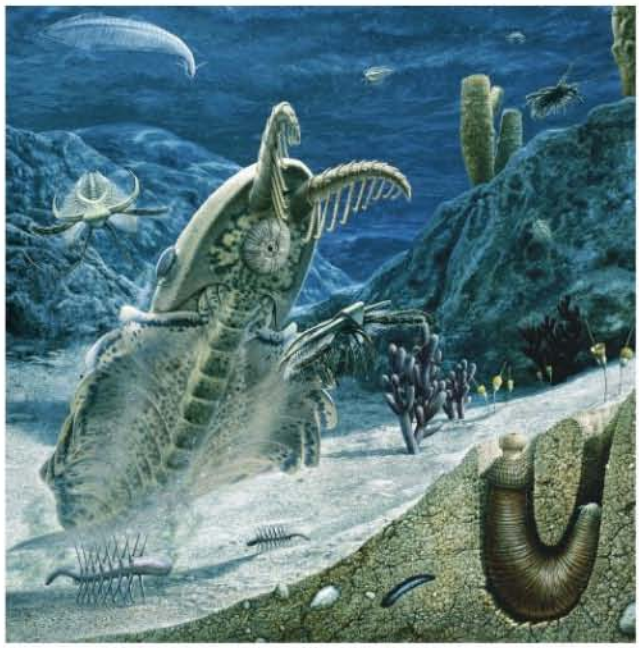
Despite the molecular data indicating an earlier origin of animals, the first generally accepted macroscopic fossils of animals range in age from 565 to 550 million years old. These fossils are members of an early group of multicellular eukaryotes, known collectively as the **Ediacaran biota**. These soft-bodied organisms were named for the Ediacara Hills of Australia, where they were first discovered **(Figure 32.4)**. Similar fossils have since been found on other continents. Some are sponges, while others may be related to living cnidarians. Still others of these fossil organisms have proved difficult to classify, as they do not seem to be closely related to any living animal or plant groups.

In addition to these macroscopic fossils, Neoproterozoic rocks have also yielded what may be microscopic signs of early animals. As you read in Chapter 25, 575-million-year-old microfossils discovered in China appear to exhibit the basic structural organization of present-day animal embryos. However, debate continues about whether the fossil embryos are animals

▼ Figure 32.3 Three lines of evidence that choanoflagellates are closely related to animals.

? *Are the data described in 3 consistent with predictions that could be made from the evidence in 1 and 2? Explain.*

(a) *Mawsonites spriggi* (b) *Spriggina floundersi*



▲ **Figure 32.4 Ediacaran fossils.** Fossils dating from 565–550 million years ago include animals **(a)** with simple, radial forms and **(b)** with many body segments.

or are members of extinct groups that are closely related to animals (but are not actually animals). Though older fossils of animals may be discovered in the future, the fossil record as it is known today strongly suggests that the end of the Neoproterozoic era was a time of increasing animal diversity.

Paleozoic Era (542–251 Million Years Ago)

Animal diversification appears to have accelerated dramatically from 535 to 525 million years ago, during the Cambrian period of the Paleozoic era—a phenomenon often referred to as the **Cambrian explosion** (see Chapter 25). In strata formed before the Cambrian explosion, only a few animal phyla can be recognized. But in strata that are 535 to 525 million years old, paleontologists have found the oldest fossils of about half of all extant animal phyla, including the first arthropods, chordates, and echinoderms. Many of these distinctive fossils—which include the first animals with hard mineralized skeletons—look quite different from most living animals **(Figure 32.5)**. But for the most part, paleontologists have established that these Cambrian fossils are members of extant animal phyla—or at least are close relatives.

What caused the Cambrian explosion? There are several current hypotheses. Some evidence suggests that new predator-prey relationships that emerged in the Cambrian period generated diversity through natural selection. Predators acquired novel adaptations, such as forms of locomotion that helped them catch prey, while prey species acquired new defenses, such as protective shells. Another hypothesis focuses on a rise in atmospheric oxygen that preceded the Cambrian explosion. Greater oxygen availability would have provided opportunities for animals with higher metabolic rates and larger body sizes to thrive. A third hypothesis proposes that the evolution of the *Hox* gene complex provided the developmental flexibility that resulted in variations in morphology. These hypotheses are not mutually exclusive, however; predator-prey relationships, atmospheric changes, and developmental flexibility may each have played a role.

▲ **Figure 32.5 A Cambrian seascape.** This artist's reconstruction depicts a diverse array of organisms found in fossils from the Burgess Shale site in British Columbia, Canada. The animals include *Pikaia* (swimming eel-like chordate), *Hallucigenia* (animal with toothpick-like spikes), *Anomalocaris* (large animal with anterior grasping limbs and a circular mouth), and *Marella* (arthropod swimming at left).

The Cambrian period was followed by the Ordovician, Silurian, and Devonian periods, when animal diversity continued to increase, although punctuated by episodes of mass extinctions (see Figure 25.14). Vertebrates (fishes) emerged as the top predators of the marine food web. By 460 million years ago, groups that diversified during the Cambrian period were making an impact on land. Arthropods began to adapt to terrestrial habitats, as indicated by the appearance of millipedes and centipedes. Fern galls—enlarged cavities that resident insects stimulate fern plants to form, providing protection for the insects—date back at least 302 million years, suggesting that insects and plants were influencing each other's evolution by that time.

Vertebrates made the transition to land around 360 million years ago and diversified into numerous terrestrial groups. Two of these survive today: the amphibians (such as frogs and salamanders) and the amniotes (reptiles and mammals). We will explore these groups, known collectively as the tetrapods, in more detail in Chapter 34.

Mesozoic Era (251–65.5 Million Years Ago)

No fundamentally new animal groups emerged during the Mesozoic era. But the animal phyla that had evolved during the Paleozoic now began to spread into new ecological habitats. In the oceans, the first coral reefs formed, providing other animals with new marine habitats. Some reptiles returned to the water and succeeded as large aquatic predators. On land, descent with modification in some tetrapods led to the origin of wings and other flight equipment in pterosaurs and birds. Large and

small dinosaurs emerged, both as predators and herbivores. At the same time, the first mammals—tiny nocturnal insect-eaters—appeared on the scene. In addition, as you read in Chapter 30, flowering plants (angiosperms) and insects both underwent dramatic diversifications during the late Mesozoic.

Cenozoic Era (65.5 Million Years Ago to the Present)

Mass extinctions of both terrestrial and marine animals ushered in a new era, the Cenozoic. Among the groups of species that disappeared were the large, nonflying dinosaurs and the marine reptiles. The fossil record of the early Cenozoic documents the rise of large mammalian herbivores and predators as mammals began to exploit the vacated ecological niches. The global climate gradually cooled throughout the Cenozoic, triggering significant shifts in many animal lineages. Among primates, for example, some species in Africa adapted to the open woodlands and savannas that replaced the former dense forests. The ancestors of our own species were among those grassland apes.

CONCEPT CHECK 32.2

1. Put the following milestones in animal evolution in chronological order from oldest to most recent: (a) origin of mammals, (b) earliest evidence of terrestrial arthropods, (c) Ediacaran fauna, (d) extinction of large, nonflying dinosaurs.
2. **WHAT IF?** Suppose the most recent common ancestor of fungi and animals lived 1 billion years ago. If the first fungi lived 990 million years ago, would animals also have been alive at that time? Explain.

For suggested answers, see Appendix A.

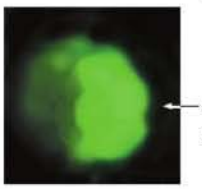
CONCEPT 32.3 Animals can be characterized by "body plans"

Although animal species vary tremendously in morphology, their great diversity in form can be categorized into a relatively small number of major "body plans." A **body plan** is a set of morphological and developmental traits, integrated into a functional whole—the living animal. (Note that the term *plan* here is not meant to imply that animal forms are the result of conscious planning or invention.)

Like all features of organisms, animal body plans have evolved over time. Some of the evolutionary changes appear to have occurred early in the history of animal life. For example, recent research suggests that a key step in the molecular control of gastrulation has remained unchanged for more than 500 million years **(Figure 32.6)**. This early evolutionary innovation was of fundamental importance: Gastrulation explains why most

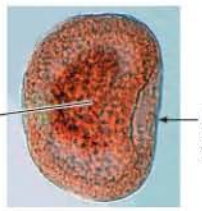
▼ Figure 32.6 Inquiry

Did β-catenin play an ancient role in the molecular control of gastrulation?



EXPERIMENT In most animals, gastrulation leads to the formation of three layers of embryonic cells. In several species, the protein β-catenin marks the site of gastrulation and activates the transcription of genes necessary for gastrulation. Athula Wikramanayake and Mark Martindale, of the University of Hawaii, and colleagues tested whether β-catenin also helps to control gastrulation in the sea anemone *Nematostella vectensis*. This species is in the phylum Cnidaria, a group that predates the origin of animals whose embryos form three layers of cells.

RESULTS



1. In early stages of development, β-catenin (here labeled with green fluorescent protein) is found throughout the *N. vectensis* embryo.

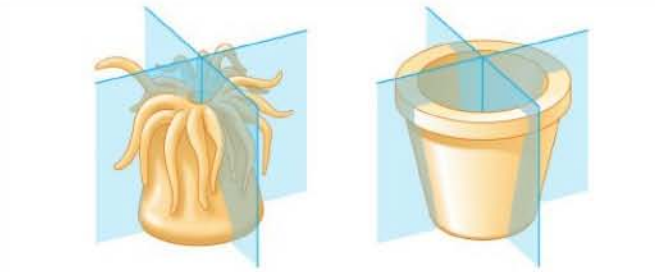
2. By the 32-cell stage, β-catenin is concentrated on the side of the embryo where gastrulation will occur.

3. In the early gastrula stage, β-catenin activity (here stained a darker red) occurs in the inner layer of cells.

4. In embryos in which β-catenin activity is blocked (by a protein that binds to β-catenin), gastrulation does not occur.

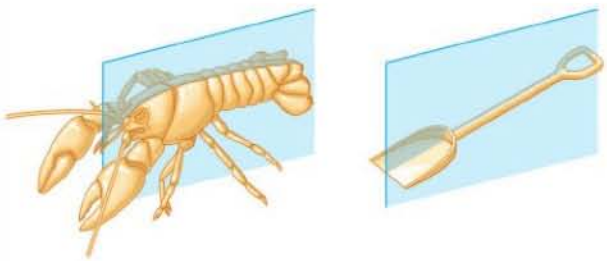
CONCLUSION In *N. vectensis*, β-catenin helps to determine the site of gastrulation and is required for gastrulation to occur. The fossil record indicates that cnidarians diverged more than 500 million years ago from other species in which β-catenin is known to influence gastrulation, suggesting that β-catenin played an ancient role in the molecular control of gastrulation.

SOURCE A. H. Wikramanayake et al., An ancient role for nuclear β-catenin in the evolution of axial polarity and germ layer segregation, *Nature* 426:446–450 (2003).



WHAT IF? β-catenin binds to DNA, thereby stimulating the transcription of genes necessary for gastrulation. Based on this information, suggest a different experiment that could be used to confirm the results in step 4. What would be the purpose of performing such an experiment?

animals are not a hollow ball of cells. But other aspects of animal body plans may have changed many times as various animal lineages evolved and diversified. As you explore the major features of animal body plans, bear in mind that similar body forms may have evolved independently in two different lineages. Consider, for example, the group of invertebrate animals called gastropods (class Gastropoda). This group includes many species that lack shells and are referred to as slugs, along with many shelled species, such as snails. All slugs have a similar body plan and hence belong to the same *grade* (a group whose members share key biological features). However, phylogenetic studies show that several gastropod lineages independently lost their shells and became slugs. As illustrated by this example, a grade is not necessarily equivalent to a *clade* (a group that includes an ancestral species and all of its descendants).



Symmetry

One very basic way that animals can be categorized is by the type of symmetry of their bodies—or the absence of symmetry. Most sponges, for example, lack symmetry altogether. Among the animals that do have symmetrical bodies, symmetry can take different forms. Some animals exhibit **radial symmetry**, the form found in a flowerpot **(Figure 32.7a)**. Sea anemones, for example, have a top side (where the mouth is located) and a bottom side. But they have no front and back ends and no left and right sides.

The two-sided symmetry seen in a shovel is an example of **bilateral symmetry (Figure 32.7b)**. A bilateral animal has two axes of orientation: front to back and top to bottom.

(a) Radial symmetry. A radial animal, such as a sea anemone (phylum Cnidaria), does not have a left side and a right side. Any imaginary slice through the central axis divides the animal into mirror images.

(b) Bilateral symmetry. A bilateral animal, such as a lobster (phylum Arthropoda), has a left side and a right side. Only one imaginary cut divides the animal into mirror-image halves.

▲ **Figure 32.7 Body symmetry.** The flowerpot and shovel are included to help you remember the radial-bilateral distinction.

Thus, such animals have a **dorsal** (top) side and a **ventral** (bottom) side, as well as a left side and a right side and an **anterior** (front) end with a mouth and a **posterior** (back) end. Many animals with a bilaterally symmetrical body plan (such as arthropods and mammals) have sensory equipment concentrated at their anterior end, including a central nervous system ("brain") in the head—an evolutionary trend called **cephalization** (from the Greek *kephale*, head).

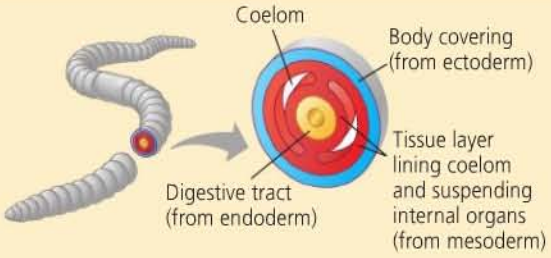
The symmetry of an animal generally fits its lifestyle. Many radial animals are sessile (living attached to a substrate) or planktonic (drifting or weakly swimming, such as jellyfish, more accurately called jellies). Their symmetry equips them to meet the environment equally well from all sides. In contrast, bilateral animals typically move actively from place to place. Most bilateral animals have a central nervous system that enables them to coordinate the complex movements involved in crawling, burrowing, flying, or swimming. Fossil evidence indicates that these two fundamentally different kinds of symmetry have been present for at least 550 million years.

Tissues

Animal body plans also vary according to the organization of the animal's tissues. True tissues are collections of specialized cells isolated from other tissues by membranous layers. Sponges and a few other groups lack true tissues. In all other animals, the embryo becomes layered through the process of gastrulation (see Figure 32.2). As development progresses, these concentric layers, called *germ layers*, form the various tissues and organs of the body. **Ectoderm**, the germ layer covering the surface of the embryo, gives rise to the outer covering of the animal and, in some phyla, to the central nervous system. **Endoderm**, the innermost germ layer, lines the developing digestive tube, or **archenteron**, and gives rise to the lining of the digestive tract (or cavity) and organs such as the liver and lungs of vertebrates.

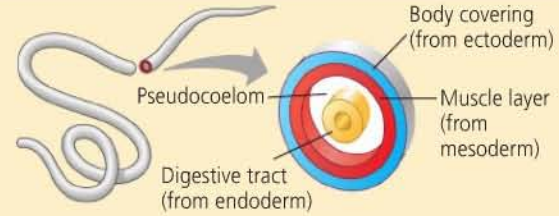
Animals that have only these two germ layers are said to be **diploblastic**. Diploblasts include the animals called cnidarians (jellies and corals, for example) as well as the comb jellies (see Chapter 33). All bilaterally symmetrical animals have a third germ layer, called the **mesoderm**, between the ectoderm and endoderm. Thus, animals with bilateral symmetry are also said to be **triploblastic** (having three germ layers). In triploblasts, the mesoderm forms the muscles and most other organs between the digestive tract and the outer covering of the animal. Triploblasts include a broad range of animals, from flatworms to arthropods to vertebrates. (Although some diploblasts actually do have a third germ layer, it is not nearly as well developed as the mesoderm of animals considered to be triploblastic.)

Body Cavities



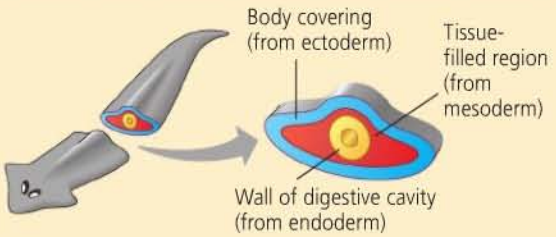
Most triploblastic animals possess a **body cavity**, a fluid- or air-filled space separating the digestive tract from the outer body wall. This body cavity is also known as a **coelom** (from the Greek

koilos, hollow). A so-called "true" coelom forms from tissue derived from mesoderm. The inner and outer layers of tissue that surround the cavity connect dorsally and ventrally and form structures that suspend the internal organs. Animals that possess a true coelom are known as **coelomates** (Figure 32.8a).



Some triploblastic animals have a body cavity that is formed from mesoderm and endoderm (Figure 32.8b). Such a cavity is called a "pseudocoelom" (from the Greek *pseudo*, false), and animals that have one are **pseudocoelomates**. Despite its name, however, a pseudocoelom is not false; it is a fully functional body cavity. Finally, some triplobastic animals lack a body cavity altogether (Figure 32.8c). They are known collectively as **acoelomates** (from the Greek *a*, without).

A body cavity has many functions. Its fluid cushions the suspended organs, helping to prevent internal injury. In soft-bodied coelomates, such as earthworms, the coelom contains noncompressible fluid that acts like a skeleton against which muscles can work. The cavity also enables the internal organs to grow and move independently of the outer body wall. If it were not for your coelom, for example, every beat of your heart or ripple of your intestine would warp your body's surface.



Current phylogenetic research suggests that true coeloms and pseudocoeloms have been gained or lost multiple times in the course of animal evolution. Thus, the terms *coelomates* and *pseudocoelomates* refer to grades, not clades.

(a) Coelomate. Coelomates such as earthworms have a true coelom, a body cavity completely lined by tissue derived from mesoderm.

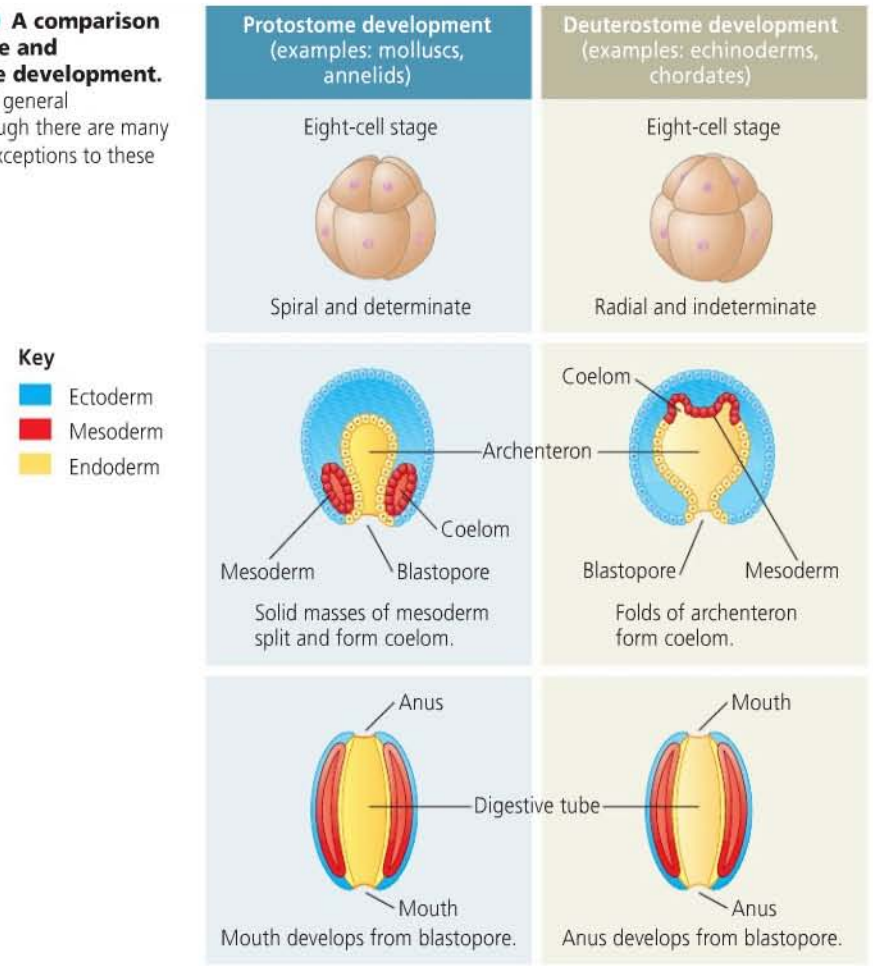
(b) Pseudocoelomate. Pseudocoelomates such as roundworms have a body cavity lined in part by tissue derived from mesoderm, but also by tissue derived from endoderm.

(c) Acoelomate. Acoelomates such as planarians lack a body cavity between the digestive cavity and outer body wall.

▲ **Figure 32.8 Body cavities of triploblastic animals.** The various organ systems of a triploblastic animal develop from the three germ layers that form in the embryo. Blue represents tissue derived from ectoderm, red from mesoderm, and yellow from endoderm.

Protostome and Deuterostome Development

Based on certain aspects of early development, many animals can be categorized as having one of two developmental modes: **protostome development** or **deuterostome development**. These modes can generally be distinguished by differences in cleavage, coelom formation, and fate of the blastopore.



Cleavage

A pattern in many animals with protostome development is **spiral cleavage**, in which the planes of cell division are diagonal to the vertical axis of the embryo; as seen in the eight-cell stage, smaller cells lie in the grooves between larger, underlying cells (Figure 32.9a, left). Furthermore, the so-called **determinate cleavage** of some animals with protostome development rigidly casts ("determines") the developmental fate of each embryonic cell very early. A cell isolated at the four-cell stage from a snail, for example, after repeated divisions will form an inviable embryo that lacks many parts.

In contrast to the spiral cleavage pattern, deuterostome development is predominantly characterized by **radial cleavage**. The cleavage planes are either parallel or perpendicular to the vertical axis of the embryo; as seen in the eight-cell stage, the tiers of cells are aligned, one directly above the other (see Figure 32.9a, right). Most animals with deuterostome development also have **indeterminate cleavage**, meaning that each cell produced by early cleavage divisions retains the capacity to develop into a complete embryo. For example, if the cells of a sea urchin embryo are isolated at the four-cell stage, each will form a complete larva. It is the indeterminate cleavage of the human zygote that makes identical twins possible. This characteristic also explains the developmental versatility of embryonic stem cells that may provide new ways to overcome a variety of diseases (see Chapter 20).

Coelom Formation

Another difference between protostome and deuterostome development is apparent later in the process. During gastrulation, an embryo's developing digestive tube initially forms as a blind pouch, the archenteron, which becomes the gut (Figure 32.9b). As the archenteron forms in protostome development, initially solid masses of mesoderm split and form the coelom. In contrast, in deuterostome development, the mesoderm buds from the wall of the archenteron, and its cavity becomes the coelom.

▶ **Figure 32.9 A comparison of protostome and deuterostome development.** These are useful general distinctions, though there are many variations and exceptions to these patterns.

(a) Cleavage. In general, protostome development begins with spiral, determinate cleavage. Deuterostome development is characterized by radial, indeterminate cleavage.

(b) Coelom formation. Coelom formation begins in the gastrula stage. In protostome development, the coelom forms from splits in the mesoderm. In deuterostome development, the coelom forms from mesodermal outpocketings of the archenteron.

(c) Fate of the blastopore. In protostome development, the mouth forms from the blastopore. In deuterostome development, the mouth forms from a secondary opening.

Fate of the Blastopore

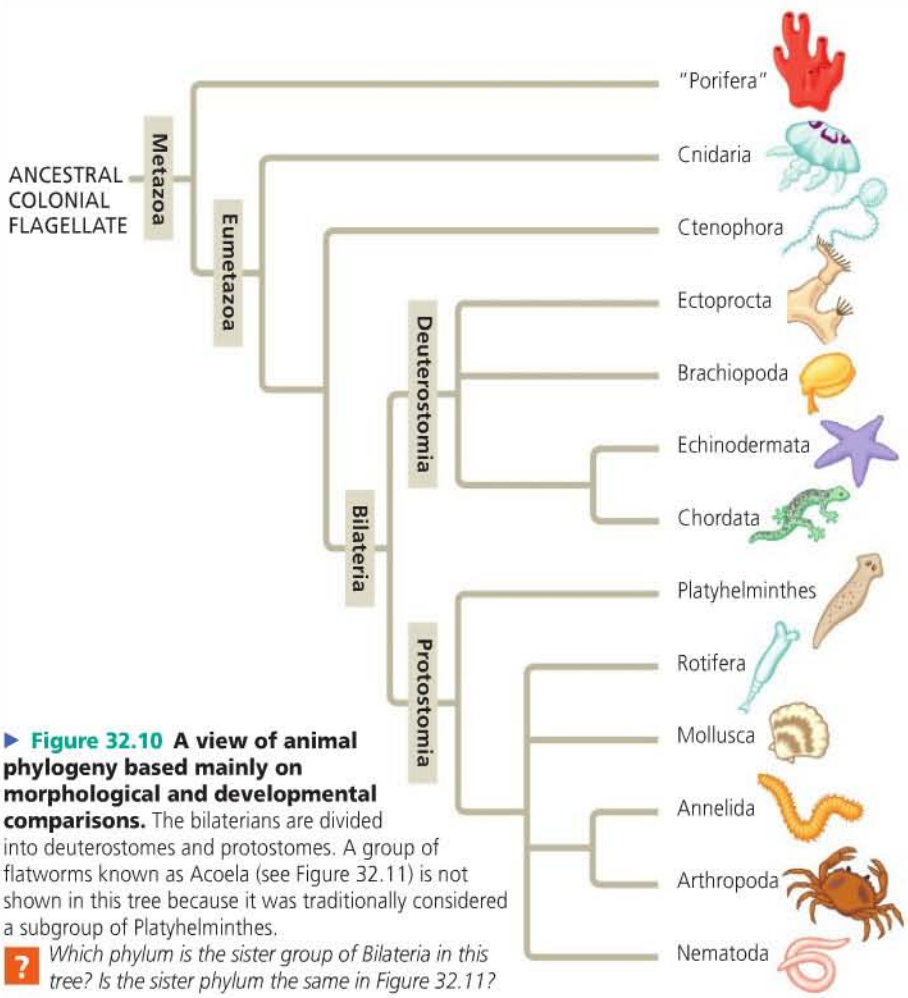
Protostome and deuterostome development often differ in the fate of the **blastopore**, the indentation that during gastrulation leads to the formation of the archenteron **(Figure 32.9c)**. After the archenteron develops, in most animals a second opening forms at the opposite end of the gastrula. Ultimately, the blastopore and this second opening become the two openings of the digestive tube (the mouth and the anus). In protostome development, the mouth generally develops from the first opening, the blastopore, and it is for this characteristic that the term *protostome* derives (from the Greek *protos*, first, and *stoma*, mouth). In deuterostome (from the Greek *deuteros*, second) development, the mouth is derived from the secondary opening, and the blastopore usually forms the anus.

CONCEPT CHECK 32.3

1. Distinguish the terms *grade* and *clade*.
2. Compare three aspects of the early development of a snail (a mollusc) and a human (a chordate).
3. **WHAT IF?** Evaluate this claim: Ignoring the details of their specific anatomy, worms, humans, and almost all other triploblasts are basically shaped like a doughnut.

For suggested answers, see Appendix A.

CONCEPT 32.4
New views of animal phylogeny are emerging from molecular data



Zoologists currently recognize about three dozen animal phyla. But the relationships between these phyla continue to be debated. Although it might be frustrating that the phylogenies in textbooks cannot be memorized as set-in-stone truths, the uncertainty inherent in these diagrams is a healthy reminder that science is an ongoing, dynamic process of inquiry.

Researchers have long based their hypotheses about animal phylogeny on morphological data. In the late 1980s, biologists also began to study the molecular systematics of animals. Additional clues about animal phylogeny have come from new studies of lesser-known phyla, along with fossil analyses that can help clarify which traits are ancestral in various animal groups and which are derived.

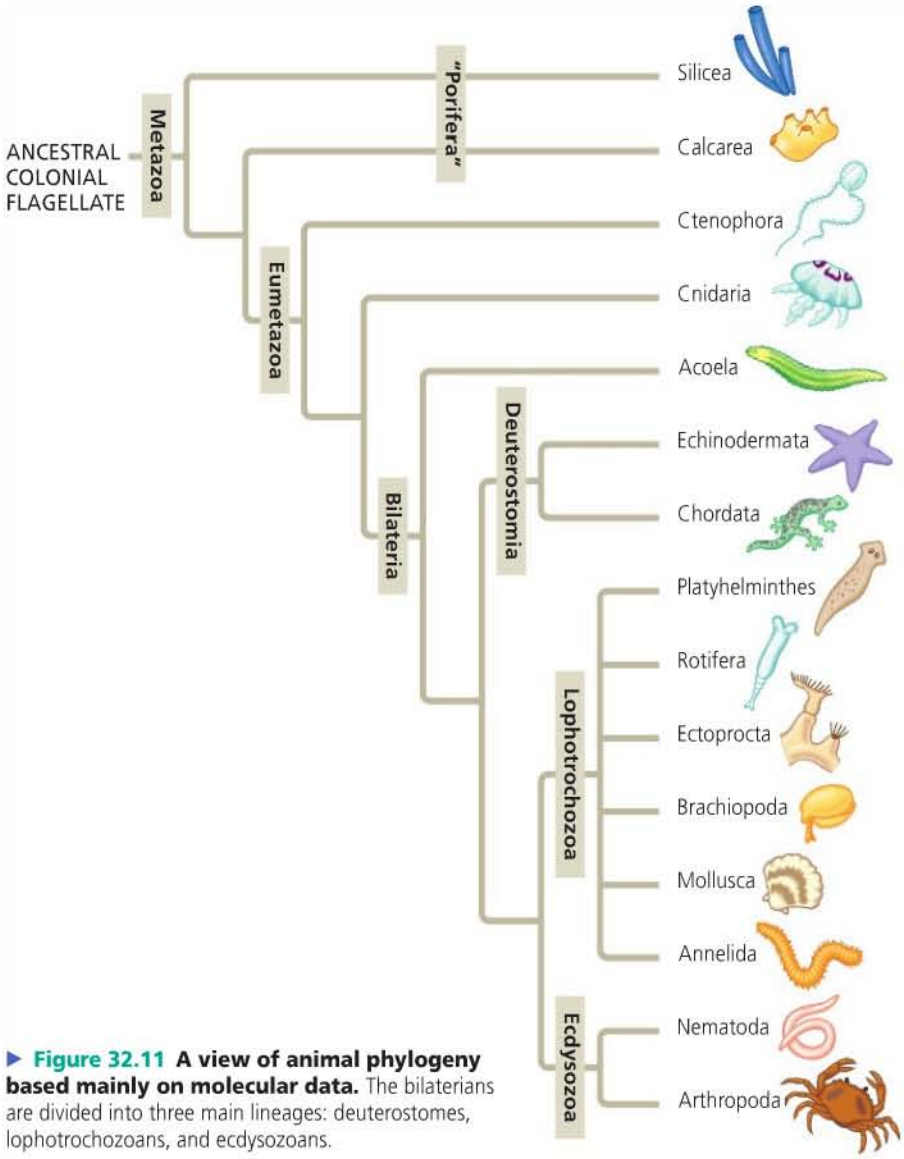
As you read in Chapter 26, phylogenetic systematists seek to classify organisms based on common descent. Their goal is to place organisms into groups that correspond to clades, each of which includes an ancestral species and all of its

descendants. Based on cladistic methods, a phylogenetic tree takes shape as a hierarchy of clades nested within larger clades—the finer branches and the thicker branches of the tree, respectively. Clades are inferred from shared derived characters that are unique to members of the clade and their common ancestor. For example, a clade might be inferred from key anatomical and embryological similarities that researchers conclude are homologous. In recent years, molecular data such as DNA sequences have provided another source of information for inferring common ancestry and defining clades. But whether the data used are "traditional" morphological characters or "new" molecular sequences or a combination of both, the overall goal is the same—to reconstruct the evolutionary history of life.

To get a sense of the debates that occur in animal systematics, we'll compare a traditional view of animal phylogeny, based primarily on morphological data **(Figure 32.10)**, with a view based mainly on molecular data **(Figure 32.11)**.

▶ **Figure 32.10 A view of animal phylogeny based mainly on morphological and developmental comparisons.** The bilaterians are divided into deuterostomes and protostomes. A group of flatworms known as Acoela (see Figure 32.11) is not shown in this tree because it was traditionally considered a subgroup of Platyhelminthes.

? *Which phylum is the sister group of Bilateria in this tree? Is the sister phylum the same in Figure 32.11?*



Points of Agreement

The morphological and molecular trees agree on a number of major features of animal phylogeny. After reading each point, see how the statement is reflected in the phylogenetic trees in Figures 32.10 and 32.11.

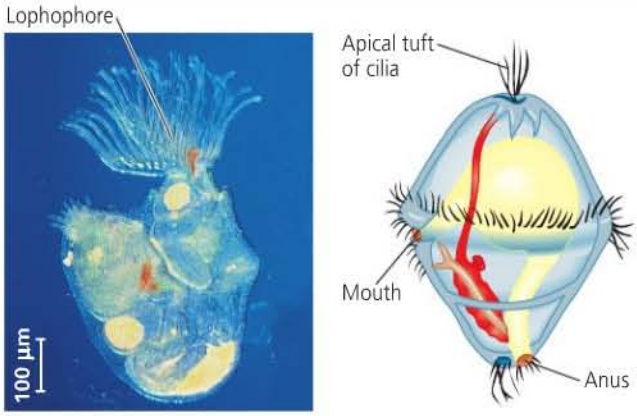
1. **All animals share a common ancestor.** Both trees indicate that the animal kingdom is monophyletic, representing a clade called Metazoa. In other words, if we could trace all extant and extinct animal lineages back to their origin, they would converge on a common ancestor.
2. **Sponges are basal animals.** Among the extant taxa, sponges (formerly, the phylum Porifera) branch from the base of both animal trees. Some molecular analyses suggest that sponges are paraphyletic, falling into at least the two phyla shown in Figure 32.11.
3. **Eumetazoa is a clade of animals with true tissues.** All animals except for sponges and a few other groups belong to a clade of **eumetazoans** ("true animals"). True tissues evolved in the common ancestor of living eumetazoans. Basal members of the eumetazoan clade include the phyla Ctenophora (comb jellies) and Cnidaria. These basal eumetazoans are diploblastic and generally feature radial symmetry.
4. **Most animal phyla belong to the clade Bilateria.** Bilateral symmetry and the presence of three germ layers are shared derived characters that help to define the clade Bilateria. This clade contains the majority of animal phyla, and its members are known as **bilaterians**. The Cambrian explosion was primarily a rapid diversification of the bilaterians.
5. **Chordates and some other phyla belong to the clade Deuterostomia.** The term *deuterostome* refers not only to a mode of animal development, but also to the members of a clade that includes vertebrates and other chordates. (Note, however, that the traditional and molecular views of animal phylogeny disagree as to which other phyla are also deuterostomes.)

Progress in Resolving Bilaterian Relationships

While evolutionary relationships inferred from traditional morphological data and molecular data are similar in many respects, there also are some differences. For example, the morphology-based tree in Figure 32.10 divides the bilaterians into two clades: deuterostomes and protostomes. This view assumes that these two modes of development reflect a

▶ **Figure 32.11 A view of animal phylogeny based mainly on molecular data.** The bilaterians are divided into three main lineages: deuterostomes, lophotrochozoans, and ecdysozoans.

phylogenetic pattern. Within the protostomes, Figure 32.10 indicates that arthropods (which include insects and crustaceans) are grouped with annelids. Both groups have segmented bodies (think of the tail of a lobster, which is an arthropod, and an earthworm, which is an annelid).



A different view has emerged from molecular phylogenies based on ribosomal genes, *Hox* genes, and dozens of other protein-coding nuclear genes, as well as mitochondrial genes. Collectively, these studies indicate that there are three major clades of bilaterally symmetrical animals: Deuterostomia, Lophotrochozoa, and Ecdysozoa (see Figure 32.11). In contrast to the traditional morphological view, the molecular phylogeny holds that the arthropods and annelids are not closely related to one another. Note also that Figure 32.11 includes a group of acoelomate flatworms (Acoela) not shown in Figure 32.10. Traditionally, acoel flatworms were classified with other flatworms in the phylum Platyhelminthes. However, recent research indicates that acoel flatworms are basal bilaterians, not members of the phylum Platyhelminthes. Acoela's basal position suggests that the bilaterians may have descended from a common ancestor that resembled living acoel flatworms—that is, from an ancestor that had a simple nervous system, a saclike gut, and no excretory system.

As seen in Figure 32.11, the molecular phylogeny assigns the animal phyla that are not in Deuterostomia to two taxa rather than one: the **ecdysozoans** and the **lophotrochozoans**. The clade name Ecdysozoa refers to a characteristic shared by nematodes, arthropods, and some of the other ecdysozoan phyla that are not included in our survey. These animals secrete external skeletons (exoskeletons); the stiff covering of a cicada or cricket is an example. As the animal grows, it molts, squirming out of its old exoskeleton and secreting a larger one. The process of shedding the old exoskeleton is called *ecdysis* **(Figure 32.12)**. Though named for this characteristic, the clade was proposed based mainly on molecular data that support the common ancestry of its members. Furthermore, some taxa excluded from this clade by their molecular data, such as certain species of leeches, do in fact molt.

The name Lophotrochozoa refers to two different features observed in some animals belonging to this clade. Some lophotrochozoans, such as brachiopods, develop a structure called a **lophophore** (from the Greek *lophos*, crest, and *pherein*, to carry), a crown of ciliated tentacles that function in

◀ **Figure 32.12 Ecdysis.** This molting cicada is in the process of emerging from its old exoskeleton. The animal will now secrete a new, larger exoskeleton.

(b) Structure of a trochophore larva

▲ **Figure 32.13 Morphological characteristics found among lophotrochozoans.**

feeding (Figure 32.13a). Individuals in other phyla, including molluscs and annelids, go through a distinctive developmental stage called the **trochophore larva** (Figure 32.13b)—hence the name lophotrochozoan.

Future Directions in Animal Systematics

Like any area of scientific inquiry, animal systematics is a work in progress. At present, most (but not all) systematists think that the tree shown in Figure 32.11 is more strongly supported than is the tree shown in Figure 32.10. Of course, as new information emerges, our understanding of the evolutionary relationships shown in these trees may change. Researchers continue to conduct large-scale analyses of multiple genes across a wide sample of animal phyla. A better understanding of the relationships between these phyla will give scientists a clearer picture of how the diversity of animal body plans arose. In Chapters 33 and 34, we will take a closer look at the diverse phyla of extant animals and their evolutionary history.

CONCEPT CHECK 32.4

1. Describe the evidence that cnidarians share a more recent common ancestor with other animals than with sponges.
2. How do the phylogenetic hypotheses presented in Figures 32.10 and 32.11 differ in structuring the major branches within the clade Bilateria?
3. **WHAT IF?** If Figure 32.11 accurately reflects phylogeny, could both of the following be correct? (a) A newly discovered arthropod fossil is 560 million years old. (b) The most recent common ancestor of Deuterostomia lived 535 million years ago. Explain.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

CONCEPT 32.1

Animals are multicellular, heterotrophic eukaryotes with tissues that develop from embryonic layers (pp. 654–656)

- **Nutritional Mode** Animals are heterotrophs that ingest their food.
- **Cell Structure and Specialization** Animals are multicellular eukaryotes. Their cells lack cell walls; instead, they are held together by structural proteins such as collagen. Nervous tissue and muscle tissue are unique to animals.
- **Reproduction and Development** In most animals, gastrulation follows the formation of the blastula and leads to the formation of embryonic tissue layers. All animals, and only animals, have *Hox* genes that regulate the development of body form. Although *Hox* genes have been highly conserved, they can produce a wide diversity of animal morphology.

CONCEPT 32.2

The history of animals spans more than half a billion years (pp. 656–658)

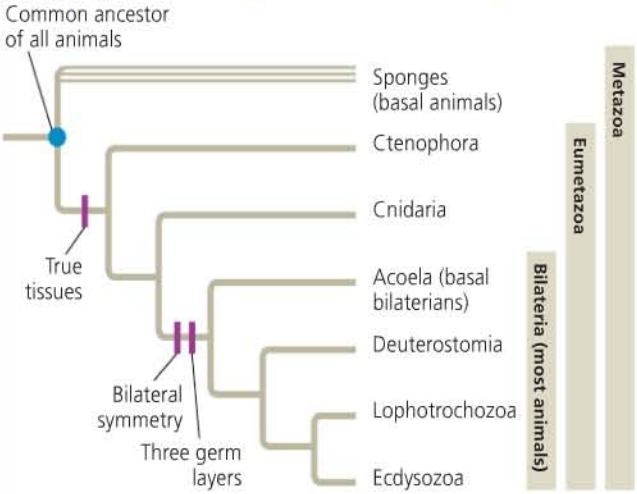
- **Neoproterozoic Era (1 Billion–542 Million Years Ago)** Early animal fossils include the Ediacaran fauna.
- **Paleozoic Era (542–251 Million Years Ago)** The Cambrian explosion marks the earliest fossil appearance of many major groups of living animals.
- **Mesozoic Era (251–65.5 Million Years Ago)** Dinosaurs were the dominant land vertebrates. Coral reefs emerged, providing marine habitats for other organisms.
- **Cenozoic Era (65.5 Million Years Ago to the Present)** Mammalian orders diversified during the Cenozoic.

CONCEPT 32.3

Animals can be characterized by "body plans" (pp. 658–661)

- **Symmetry** Animals may lack symmetry or may have radial or bilateral symmetry. Bilaterally symmetrical animals have dorsal and ventral sides, as well as anterior and posterior ends.
- **Tissues** Eumetazoan embryos may be diploblastic (having two germ layers) or triploblastic (having three germ layers).

▶ **Body Cavities** In triploblastic animals, a body cavity may be present or absent. A body cavity can be a pseudocoelom (derived from both mesoderm and endoderm) or a true coelom (derived only from mesoderm).



▶ **Protostome and Deuterostome Development** These two modes of development often differ in patterns of cleavage, coelom formation, and fate of the blastopore.

CONCEPT 32.4

New views of animal phylogeny are emerging from molecular data (pp. 661–664)

▶ **Points of Agreement**

▶ **Progress in Resolving Bilaterian Relationships**

▶ **Future Directions in Animal Systematics** Phylogenetic studies based on larger databases may provide further insights into animal evolutionary history.

Investigation How Do Molecular Data Fit Traditional Phylogenies?

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Among the characteristics unique to animals is
   a. gastrulation.
   b. multicellularity.
   c. sexual reproduction.
   d. flagellated sperm.
   e. heterotrophic nutrition.

2. The distinction between sponges and other animal phyla is based mainly on the absence versus the presence of
   a. a body cavity.
   b. a complete digestive tract.
   c. a circulatory system.
   d. true tissues.
   e. mesoderm.

3. Which of these is a point of conflict between the phylogenetic analyses presented in Figures 32.10 and 32.11?
   a. the monophyly of the animal kingdom
   b. the relationship of taxa of segmented animals to taxa of nonsegmented animals
   c. that sponges are basal animals
   d. that chordates are deuterostomes
   e. the monophyly of the bilaterians

4. Acoelomates are characterized by
   a. the absence of a brain.
   b. the absence of mesoderm.
   c. deuterostome development.
   d. a coelom that is not completely lined with mesoderm.
   e. a solid body without a cavity surrounding internal organs.

5. Which of the following was probably the *least* important factor in bringing about the Cambrian explosion?
   a. the emergence of predator-prey relationships among animals
   b. the accumulation of diverse adaptations, such as shells and different modes of locomotion
   c. the movement of animals onto land
   d. the evolution of *Hox* genes that controlled development
   e. the accumulation of sufficient atmospheric oxygen to support the more active metabolism of mobile animals

6. What is the main basis for placing the arthropods and nematodes in Ecdysozoa in one hypothesis of animal phylogeny?
   a. Animals in both groups are segmented.
   b. Animals in both groups undergo ecdysis.
   c. They both have radial, determinate cleavage, and their embryonic development is similar.
   d. Fossils reveal a common ancestor of the two phyla.
   e. Analysis of genes shows that their sequences are quite similar, and these sequences differ from those of the lophotrochozoans and deuterostomes.

For Self-Quiz answers, see Appendix A.

EVOLUTION CONNECTION

7. Some scientists suggest that the phrase "Cambrian fizzle" might be more appropriate than "Cambrian explosion" to describe the diversification of animals during that geologic period. Other scientists have compared observing an explosion of animal diversity in Cambrian strata to monitoring Earth from a satellite and noticing the emergence of cities only when they are large enough to be visible from that distance. What do these views imply about the evolutionary history of animals during that time?

SCIENTIFIC INQUIRY

8. **DRAW IT** Redraw the eumetazoan portion of Figure 32.11. Using the information in the table below, label each branch that leads to a phylum with S, R, or I, depending on the cleavage pattern of its members. What is the ancestral cleavage pattern? How many times have cleavage patterns changed over the course of evolution? Explain.

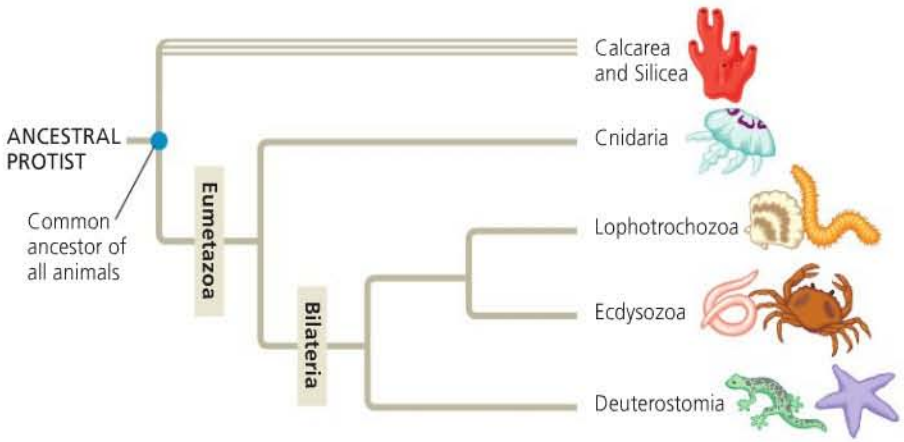
Cleavage Pattern	Phyla
Spiral (S)	Mollusca, Platyhelminthes, Annelida
Idiosyncratic (I)	Acoela, Arthropoda
Radial (R)	All eumetazoan phyla not listed above

33 Invertebrates

▲ **Figure 33.1 What function do the red whorls of this organism have?**

KEY CONCEPTS

33.1 Sponges are basal animals that lack true tissues
33.2 Cnidarians are an ancient phylum of eumetazoans
33.3 Lophotrochozoans, a clade identified by molecular data, have the widest range of animal body forms
33.4 Ecdysozoans are the most species-rich animal group
33.5 Echinoderms and chordates are deuterostomes



OVERVIEW

Life Without a Backbone

At first glance, you might mistake the organism shown in **Figure 33.1** for some type of seaweed. But this colorful inhabitant of coral reefs is actually an animal, not an alga. Specifically, it is a species of segmented worm known as a Christmas tree worm (*Spirobranchus giganteus*). The two tree-shaped whorls are tentacles, which the worm uses for gas exchange and for filtering small food particles from the surrounding water. The tentacles emerge from a tube of calcium carbonate secreted by the worm that protects and supports its soft body. Light-sensitive structures on the tentacles can detect the shadow cast by a predator, triggering the worm to contract muscles that rapidly withdraw the tentacles into the tube.

Christmas tree worms are **invertebrates**—animals that lack a backbone. Invertebrates account for 95% of known animal species. They occupy almost every habitat on Earth, from the scalding water released by deep-sea hydrothermal vents to the rocky, frozen ground of Antarctica. Adaptation to these varied environments has produced an immense diversity of forms, ranging from a species consisting simply of a flat bilayer of cells to other species with silk-spinning glands, pivoting spines, dozens of jointed legs, or tentacles covered with suction cups, just to list a few.

In this chapter, we'll take a tour of the invertebrate world, using the phylogenetic tree in **Figure 33.2** as a guide. **Figure 33.3** on the next three pages, surveys 23 invertebrate phyla. As representatives of invertebrate diversity, many of those phyla are explored in more detail in the rest of this chapter.

▶ **Figure 33.2 Review of animal phylogeny.** Except for sponges (basal animals in phyla Calcarea and Silicea) and a few other groups, all animals have tissues and are in the clade Eumetazoa. Most animals are in the diverse clade Bilateria.

▼ Figure 33.3

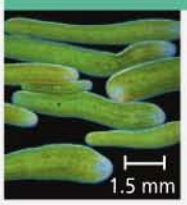
Exploring Invertebrate Diversity

Kingdom Animalia encompasses 1.3 million known species, and estimates of total species range far higher. Of the 23 phyla surveyed here, those illustrated with smaller-sized "preview" photographs are discussed more fully in this chapter or another.

Calcarea and Silicea (5,500 species)

A sponge

Animals in these phyla are informally called "sponges." Sponges are sessile animals that lack true tissues. They live as suspension feeders, trapping particles that pass through the internal channels of their bodies (see Concept 33.1).



Cnidaria (10,000 species)

Cnidarians include corals, jellies, and hydras. These animals have a diplobastic, radially symmetrical body plan that includes a gastrovascular cavity with a single opening that serves as both mouth and anus (see Concept 33.2).

A jelly

Acoela (400 species)

Acoel flatworms (LM)

Acoel flatworms have a simple nervous system and a saclike gut, and thus had been placed in phylum Platyhelminthes. Molecular analyses, however, indicate Acoela is a separate lineage that diverged before the three main bilaterian clades (see Concept 32.4).

Placozoa (1 species)

The single known species in this phylum, *Trichoplax adhaerens*, does not even look like an animal. It consists of a few thousand cells arranged in a double-layered plate. *Trichoplax* can reproduce by dividing into two individuals or by budding off many multicellular individuals.

A placozoan (LM)

Ctenophora (100 species)

A ctenophore, or comb jelly

Ctenophores (comb jellies) are diploblastic and radially symmetrical like cnidarians, suggesting that both phyla diverged from other animals very early. Comb jellies make up much of the ocean's plankton. They have many distinctive traits, including eight "combs" of cilia that propel the animals through the water. When a small animal contacts the tentacles of some comb jellies, specialized cells burst open, covering the prey with sticky threads.

LOPHOTROCHOZOANS

Platyhelminthes (20,000 species)

A marine flatworm

Flatworms (including tapeworms, planarians, and flukes) have bilateral symmetry and a central nervous system that processes information from sensory structures. They have no body cavity or organs for circulation (see Concept 33.3).

Rotifera (1,800 species)

Despite their microscopic size, rotifers have specialized organ systems, including an alimentary canal (digestive tract). They feed on microorganisms suspended in water (see Concept 33.3).

A rotifer (LM)

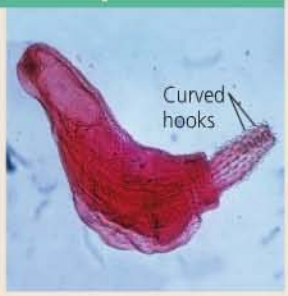
Ectoprocta (4,500 species)

Ectoprocts (also known as bryozoans) live as sessile colonies and are covered by a tough exoskeleton (see Concept 33.3).

Ectoprocts

Brachiopoda (335 species)

A brachiopod

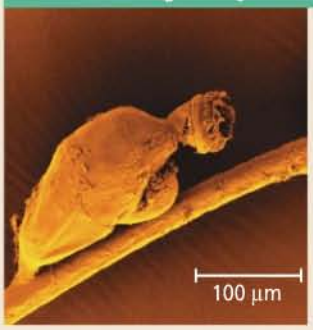


Brachiopods, or lamp shells, may be easily mistaken for clams or other molluscs. However, most brachiopods have a unique stalk that anchors them to their substrate (see Concept 33.3).

Continued on next page

▼ Figure 33.3 (continued)

Exploring Invertebrate Diversity



Acanthocephala (1,100 species)

An acanthocephalan (LM)

Acanthocephalans (from the Greek *acanthias*, prickly, and *cephalo*, head) are called spiny-headed worms because of the curved hooks on the proboscis at the anterior end of their body. All species are parasites. Some acanthocephalans manipulate their intermediate hosts (generally arthropods) in ways that increase their chances of reaching their final hosts (generally vertebrates). For example, acanthocephalans that infect New Zealand mud crabs force their hosts to move to more visible areas on the beach, where the crabs are more likely to be eaten by birds, the worms' final hosts.

Cycliophora (1 species)

A cycliophoran (colorized SEM)

The only known species of cycliophoran, *Symbion pandora*, was discovered in 1995 on the mouthparts of a lobster. This tiny, vase-shaped creature has a unique body plan and a particularly bizarre life cycle. Males impregnate females that are still developing in their mothers' bodies. The fertilized females then escape, settle elsewhere on the lobster, and release their offspring. The offspring apparently leave that lobster and search for another one to which they attach.

Nemertea (900 species)

A ribbon worm

Proboscis worms, or ribbon worms, swim through water or burrow in sand, extending a unique proboscis to capture prey. Like flatworms, they lack a true coelom. However, unlike flatworms, nemerteans have an alimentary canal and a closed circulatory system in which the blood is contained in vessels and hence is distinct from fluid in the body cavity.

Mollusca (93,000 species)

An octopus

Molluscs (including snails, clams, squids, and octopuses) have a soft body that in many species is protected by a hard shell (see Concept 33.3).

Annelida (16,500 species)

A marine annelid

Annelids, or segmented worms, are distinguished from other worms by their body segmentation. Earthworms are the most familiar annelids, but the phylum also includes marine and freshwater species (see Concept 33.3).

ECDYSOZOA

Loricifera (10 species)

A loriciferan (LM)

Loriciferans (from the Latin *lorica*, corset, and *ferre*, to bear) are tiny animals that inhabit the deep-sea bottom. A loriciferan can telescope its head, neck, and thorax in and out of the lorica, a pocket formed by six plates surrounding the abdomen. Though the natural history of loriciferans is mostly a mystery, at least some species likely eat bacteria.

Priapula (16 species)

A priapulan

Priapulans are worms with a large, rounded proboscis at the anterior end. (They are named after Priapos, the Greek god of fertility, who was symbolized by a giant penis.) Ranging from 0.5 mm to 20 cm in length, most species burrow through seafloor sediments. Fossil evidence suggests that priapulans were among the major predators during the Cambrian period.

Tardigrada (800 species)

Tardigrades (colorized SEM)

Tardigrades (from the Latin *tardus*, slow, and *gradus*, step) are sometimes called water bears for their rounded shape, stubby appendages, and lumbering, bearlike gait. Most tardigrades are less than 0.5 mm in length. Some live in oceans or fresh water, while others live on plants or animals. As many as 2 million tardigrades can be found on a square meter of moss. Harsh conditions may cause tardigrades to enter a state of dormancy; while dormant, they can survive temperatures as low as −272°C, close to absolute zero!

Onychophora (110 species)

Onychophorans, also called velvet worms, originated during the Cambrian explosion (see Chapter 32). Originally, they thrived in the ocean, but at some point they succeeded in colonizing land. Today they live only in humid forests. Onychophorans have fleshy antennae and several dozen pairs of saclike legs.

An onychophoran

Nematoda (25,000 species)

A roundworm

Roundworms are enormously abundant and diverse in the soil and in aquatic habitats; many species parasitize plants and animals. The most distinctive feature of roundworms is a tough cuticle that coats the body (see Concept 33.4).

Arthropoda (1,000,000 species)

The vast majority of known animal species, including insects, crustaceans, and arachnids, are arthropods. All arthropods have a segmented exoskeleton and jointed appendages (see Concept 33.4).

A scorpion (an arachnid)

DEUTEROSTOMIA

Hemichordata (85 species)

An acorn worm

Like echinoderms and chordates, hemichordates are members of the deuterostome clade (see Chapter 32). Hemichordates share some traits with other chordates, such as gill slits and a dorsal nerve cord. The largest group of hemichordates are the enteropneusts, or acorn worms. Acorn worms are marine and generally live buried in mud or under rocks; they may grow to more than 2 m in length.

Echinodermata (7,000 species)

A sea urchin

Echinoderms, such as sand dollars, sea stars, and sea urchins, are aquatic animals in the deuterostome clade that are bilaterally symmetrical as larvae but not as adults. They move and feed by using a network of internal canals to pump water to different parts of their body (see Concept 33.5).

Chordata (52,000 species)

More than 90% of all known chordate species have backbones (and thus are vertebrates). However, the phylum Chordata also includes three groups of invertebrates: lancelets, tunicates, and hagfishes. See Chapter 34 for a full discussion of this phylum.

A tunicate

CONCEPT **33.1**

Sponges are basal animals that lack true tissues

Animals in the phyla Calcarea and Silicea are known informally as "sponges." (Previously, all sponges were placed in a single phylum, Porifera, now thought to be paraphyletic based on molecular data.) Among the simplest of animals, sponges are sedentary and were mistaken for plants by the ancient Greeks. They range in size from a few millimeters to a few meters and live in both fresh and marine waters. Sponges are **suspension feeders**: They capture food particles suspended in the water that passes through their body, which in some species resembles a sac perforated with pores. Water is drawn through the pores into a central cavity, the **spongocoel**, and then flows out of the sponge through a larger opening called the **osculum** (Figure 33.4). More complex sponges have folded body walls, and many contain branched water canals and several oscula.

Sponges are basal animals; that is, they represent a lineage that originates near the root of the phylogenetic tree of animals. Unlike nearly all other animals, sponges lack true tissues, groups of similar cells that act as a functional unit and are isolated from other tissues by membranous layers. However, the sponge body does contain several different cell types. For example, lining the interior of the spongocoel are flagellated **choanocytes**, or collar cells (named for the membranous collar around the base of the flagellum). The similarity between choanocytes and the cells of choanoflagellates supports molecular evidence suggesting that animals evolved from a choanoflagellate-like ancestor (see Figure 32.3).

The body of a sponge consists of two layers of cells separated by a gelatinous region called the **mesohyl**. Wandering through the mesohyl are cells called **amoebocytes**, named for their use of pseudopodia. Amoebocytes have many functions. They take up food from the water and from choanocytes, digest it, and carry nutrients to other cells. They also manufacture tough skeletal fibers within the mesohyl. In some groups of sponges, these fibers are sharp spicules made from calcium carbonate or silica. Other sponges produce more flexible fibers composed of a protein called spongin; you may have seen these pliant skeletons being sold as fluffy brown bath sponges.

Most sponges are **hermaphrodites**, meaning that each individual functions as both male and female in sexual reproduction by producing sperm *and* eggs. Almost all sponges exhibit sequential hermaphroditism, functioning first as one sex and then as the other.

Azure vase sponge (*Callyspongia plicifera*)

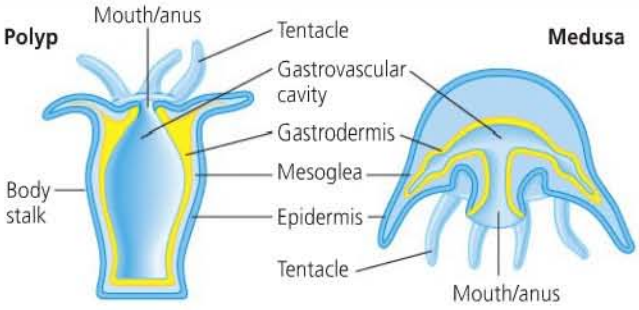
▲ **Figure 33.4 Anatomy of a sponge.**

Sponge gametes arise from choanocytes or amoebocytes. Eggs reside in the mesohyl, but sperm are carried out of the sponge by the water current. Cross-fertilization results from some of the sperm being drawn into neighboring individuals. Fertilization occurs in the mesohyl, where the zygotes develop into flagellated, swimming larvae that disperse from the parent sponge. After settling on a suitable substrate, a larva develops into a sessile adult.

Sponges produce a variety of antibiotics and other defensive compounds. Researchers are now isolating these compounds, which hold promise for fighting human diseases. For example, a compound called cribrostatin isolated from marine sponges can kill penicillin-resistant strains of the bacterium *Streptococcus*. Other sponge-derived compounds are being tested as possible anticancer agents.

CONCEPT CHECK 33.1

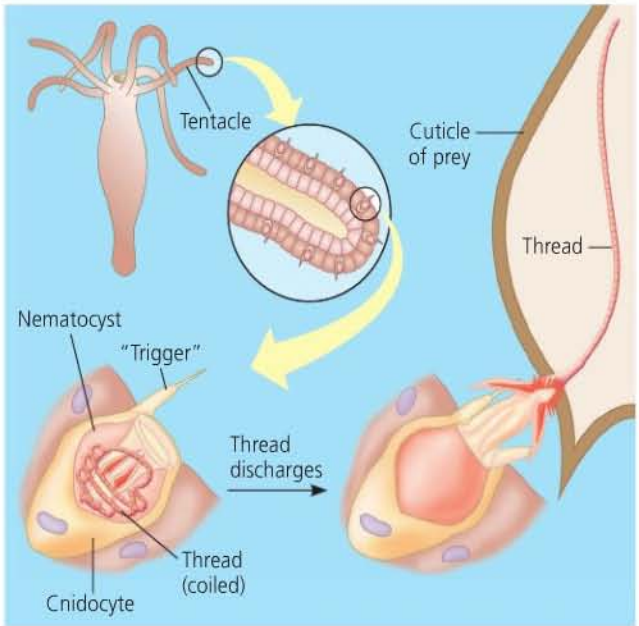
1. Describe how sponges feed.
2. **WHAT IF?** Some molecular evidence suggests that the sister group of animals is not the choanoflagellates, but rather a group of parasitic protists, Mesomycetozoa. Given that these parasites lack collar cells, can this hypothesis be correct? Explain.



For suggested answers, see Appendix A.

CONCEPT 33.2
Cnidarians are an ancient phylum of eumetazoans

All animals except sponges and a few other groups belong to the clade Eumetazoa, animals with true tissues (see Chapter 32). One of the oldest lineages in this clade is the phylum Cnidaria. Cnidarians have diversified into a wide range of sessile and motile forms, including hydras, corals, and jellies (commonly called "jellyfish"). Yet most cnidarians still exhibit the relatively simple, diploblastic, radial body plan that existed some 570 million years ago.



The basic body plan of a cnidarian is a sac with a central digestive compartment, the **gastrovascular cavity**. A single opening to this cavity functions as both mouth and anus. There are two variations on this body plan: the sessile polyp and the motile medusa **(Figure 33.5)**. **Polyps** are cylindrical forms that adhere to the substrate by the aboral end of their body (the end opposite the mouth) and extend their tentacles, waiting for prey. Examples of the polyp form include hydras and sea anemones. A **medusa** is a flattened, mouth-down version of the polyp. It moves freely in the water by a combination of passive drifting and contractions of its bell-shaped body. Medusae include free-swimming jellies. The tentacles of a jelly dangle

▲ **Figure 33.5 Polyp and medusa forms of cnidarians.** The body wall of a cnidarian has two layers of cells: an outer layer of epidermis (from ectoderm) and an inner layer of gastrodermis (from endoderm). Digestion begins in the gastrovascular cavity and is completed inside food vacuoles in the gastrodermal cells. Flagella on the gastrodermal cells keep the contents of the gastrovascular cavity agitated and help distribute nutrients. Sandwiched between the epidermis and gastrodermis is a gelatinous layer, the mesoglea.

from the oral surface, which points downward. Some cnidarians exist only as polyps or only as medusae; others have both a polyp stage and a medusa stage in their life cycle.

Cnidarians are carnivores that often use tentacles arranged in a ring around their mouth to capture prey and push the food into their gastrovascular cavity, where digestion begins. Any undigested remains are expelled through the mouth/anus. The tentacles are armed with batteries of **cnidocytes**, cells unique to cnidarians that function in defense and prey capture **(Figure 33.6)**. Cnidocytes contain cnidae (from the Greek *cnide*, nettle), capsule-like organelles that are capable of exploding outward and that give phylum Cnidaria its name. Specialized cnidae called **nematocysts** contain a stinging thread

▲ **Figure 33.6 A cnidocyte of a hydra.** This type of cnidocyte contains a stinging capsule, the nematocyst, which contains a coiled thread. When a "trigger" is stimulated by touch or by certain chemicals, the thread shoots out, puncturing and injecting poison into prey.

that can penetrate the body wall of the cnidarian's prey. Other kinds of cnidae have long threads that stick to or entangle small prey that bump into the cnidarian's tentacles.

Contractile tissues and nerves occur in their simplest forms in cnidarians. Cells of the epidermis (outer layer) and gastrodermis (inner layer) have bundles of microfilaments arranged into contractile fibers (see Chapter 6). The gastrovascular cavity acts as a hydrostatic skeleton against which the contractile cells can work. When a cnidarian closes its mouth, the volume of the cavity is fixed, and contraction of selected cells causes the animal to change shape. Movements are coordinated by a nerve net. Cnidarians have no brain, and the noncentralized nerve net is associated with sensory structures that are distributed radially around the body. Thus, the animal can detect and respond to stimuli from all directions.

As summarized in **Table 33.1**, the phylum Cnidaria is divided into four major classes: Hydrozoa, Scyphozoa, Cubozoa, and Anthozoa **(Figure 33.7)**.

Table 33.1 Classes of Phylum Cnidaria

Class and Examples	Main Characteristics
Hydrozoa (Portuguese man-of-wars, hydras, *Obelia*, some corals; see Figures 33.7a and 33.8)	Most marine, a few freshwater; both polyp and medusa stages in most species; polyp stage often colonial
Scyphozoa (jellies, sea nettles; see Figure 33.7b)	All marine; polyp stage absent or reduced; free-swimming; medusae up to 2 m in diameter
Cubozoa (box jellies, sea wasps; see Figure 33.7c)	All marine; box-shaped medusae; complex eyes; potent venom
Anthozoa (sea anemones, most corals, sea fans; see Figure 33.7d)	All marine; medusa stage completely absent; most sessile; many colonial

Hydrozoans

Most hydrozoans alternate between polyp and medusa forms, as in the life cycle of *Obelia* **(Figure 33.8)**. The polyp stage, a colony of interconnected polyps in the case of *Obelia*, is more conspicuous than the medusa. Hydras, among the few cnidarians found in fresh water, are unusual hydrozoans in that they exist only in polyp form. When environmental conditions are favorable, a hydra reproduces asexually by budding, forming outgrowths that pinch off from the parent and live independently (see Figure 13.2). When conditions deteriorate, hydras can reproduce sexually, forming resistant zygotes that remain dormant until conditions improve.

Scyphozoans

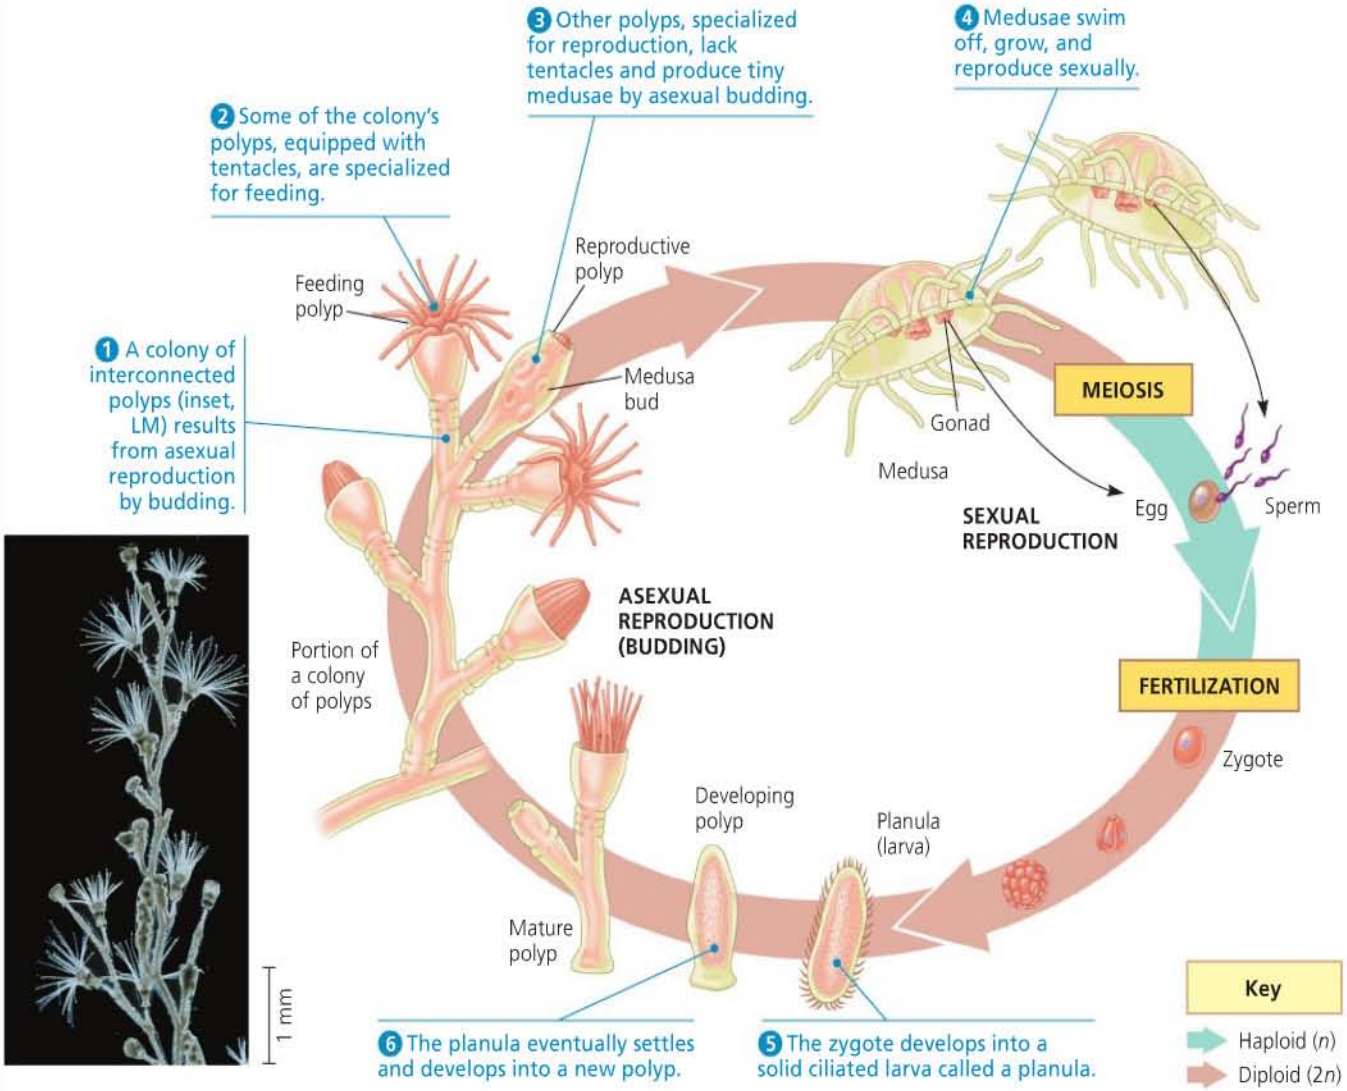
The medusa generally is the predominant stage in the life cycle of the class Scyphozoa. The medusae of most species live among the plankton as jellies. Most coastal scyphozoans go through a stage as small polyps during their life cycle, whereas those that live in the open ocean generally lack the polyp stage altogether.

Cubozoans

As their name (which means "cube animals") suggests, cubozoans have a box-shaped medusa stage. Cubozoans can be distinguished from scyphozoans in other significant ways, such as having complex eyes embedded in the fringe of their medusae. They are comparatively strong swimmers and as a result are less likely to be stranded on shore. Cubozoans, which generally live in tropical oceans, are often equipped with highly toxic cnidocytes. The sea wasp (*Chironex fleckeri*), a cubozoan that lives off the coast of northern Australia, is one of the deadliest organisms: Its sting causes intense pain and can lead to respiratory failure, cardiac arrest, and death within minutes. The poison of sea wasps isn't universally fatal, however; sea turtles have defenses against it, allowing them to eat the cubozoan in great quantities.

(a) These colonial polyps are members of class Hydrozoa.

(b) Many jellies (class Scyphozoa) are bioluminescent. Food captured by nematocyst-bearing tentacles is transferred to specialized oral arms (that lack nematocysts) for transport to the mouth.



(c) The sea wasp (*Chironex fleckeri*) is a member of class Cubozoa. Its poison, which can subdue fish and other large prey, is more potent than cobra venom.

(d) Sea anemones and other members of class Anthozoa exist only as polyps.

▲ **Figure 33.7 Cnidarians.**

▲ **Figure 33.8 The life cycle of the hydrozoan *Obelia*.** The polyp stage is asexual, and the medusa stage is sexual; these two stages alternate, one producing the other. Do not confuse this with the alternation of generations that occurs in plants and some algae: In *Obelia*, both the polyp and the medusa are diploid organisms. Typical of animals, only the single-celled gametes are haploid. By contrast, plants have a multicellular haploid generation and a multicellular diploid generation.

WHAT IF? *Suppose that* Obelia *medusae and gametes were haploid, but all other stages were diploid. What aspects of its actual life cycle would have to change for this to occur?*

Anthozoans

Sea anemones (see Figure 33.7d) and corals belong to the class Anthozoa (meaning "flower animals"). These cnidarians occur only as polyps. Corals live as solitary or colonial forms, and many species secrete a hard external skeleton of calcium carbonate. Each polyp generation builds on the skeletal remains of earlier generations, constructing "rocks" with shapes characteristic of their species. It is these skeletons that we usually think of as coral.

Coral reefs are to tropical seas what rain forests are to tropical land areas: They provide habitat for a wealth of other species. Unfortunately, like rain forests, coral reefs are being destroyed at an alarming rate by human activity. Pollution and overfishing are major threats, and global warming (see Chapter 55) may also be contributing to their demise by raising seawater temperatures above the narrow range in which corals thrive.

CONCEPT CHECK 33.2

1. Compare and contrast the polyp and medusa forms of cnidarians.
2. Describe the structure and function of the stinging cells for which cnidarians are named.
3. **WHAT IF?** If the common ancestor of cnidarians were an open-ocean jelly, what might you infer about evolutionary trends in the relative importance of the polyp and medusa stages?

For suggested answers, see Appendix A.

CONCEPT **33.3**

Lophotrochozoans, a clade identified by molecular data, have the widest range of animal body forms

The vast majority of animal species belong to the clade Bilateria, whose members exhibit bilateral symmetry and triploblastic development (see Chapter 32). Most bilaterians are also coelomates. While the sequence of bilaterian evolution is a subject of active investigation, most researchers think that the most recent common ancestor of living bilaterians probably existed in the late Proterozoic eon (about 575 million years ago). Most major groups of bilaterians first appeared in the fossil record during the Cambrian explosion.

As you read in Chapter 32, molecular evidence suggests that there are three major clades of bilaterally symmetrical animals: Lophotrochozoa, Ecdysozoa, and Deuterostomia. This section will focus on the first of these clades, the lophotrochozoans. Concepts 33.4 and 33.5 will explore the other two clades.

Although the clade Lophotrochozoa was identified by molecular data, its name comes from features found in some of its members. Some lophotrochozoans develop a structure called a *lophophore*, a crown of ciliated tentacles that functions in feeding, while others go through a distinctive stage called the *trochophore larva* (see Figure 32.13). Other members of the group have neither of these features. Few other unique morphological features are widely shared within the group—in fact, the lophotrochozoans are the most diverse bilaterian clade in terms of body plan. This diversity in form is reflected in the number of phyla classified in the group: Lophotrochozoa includes about 18 phyla, more than twice the number in any other clade of bilaterians.

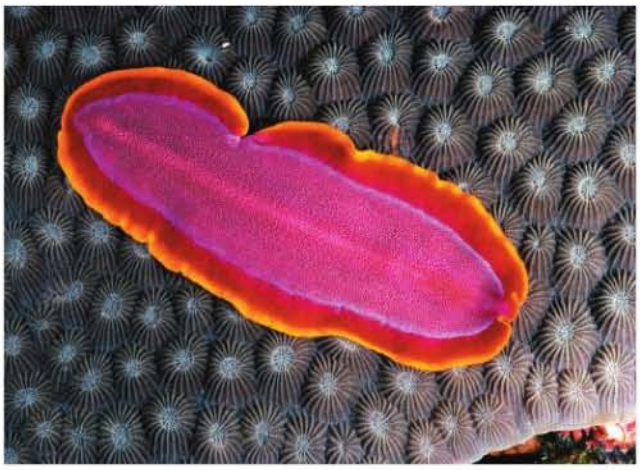
We'll now introduce six lophotrochozoan phyla: the flatworms, rotifers, ectoprocts, brachiopods, molluscs, and annelids.

Flatworms

Flatworms (phylum Platyhelminthes) live in marine, freshwater, and damp terrestrial habitats. In addition to free-living forms, flatworms include many parasitic species, such as flukes and tapeworms. Flatworms are so named because they have thin bodies that are flattened dorsoventrally (between the dorsal and ventral surfaces); *platyhelminth* means "flat worm." (Note that *worm* is not a formal taxonomic name but a general term for animals with long, thin bodies.) The smallest flatworms are nearly microscopic free-living species, while some tapeworms are more than 20 m long.

Although flatworms undergo triploblastic development, they are acoelomates (animals that lack a body cavity). Their flat shape places all their cells close to water in the surrounding environment or in their gut. Because of this proximity to water, gas exchange and the elimination of nitrogenous waste (ammonia) can occur by diffusion across the body surface. Flatworms have no organs specialized for gas exchange, and their relatively simple excretory apparatus functions mainly to maintain osmotic balance with their surroundings. This apparatus consists of **protonephridia**, networks of tubules with ciliated structures called *flame bulbs* that pull fluid through branched ducts opening to the outside (see Figure 44.11). Most flatworms have a gastrovascular cavity with only one opening. Though flatworms lack a circulatory system, the fine branches of the gastrovascular cavity distribute food directly to the animal's cells.

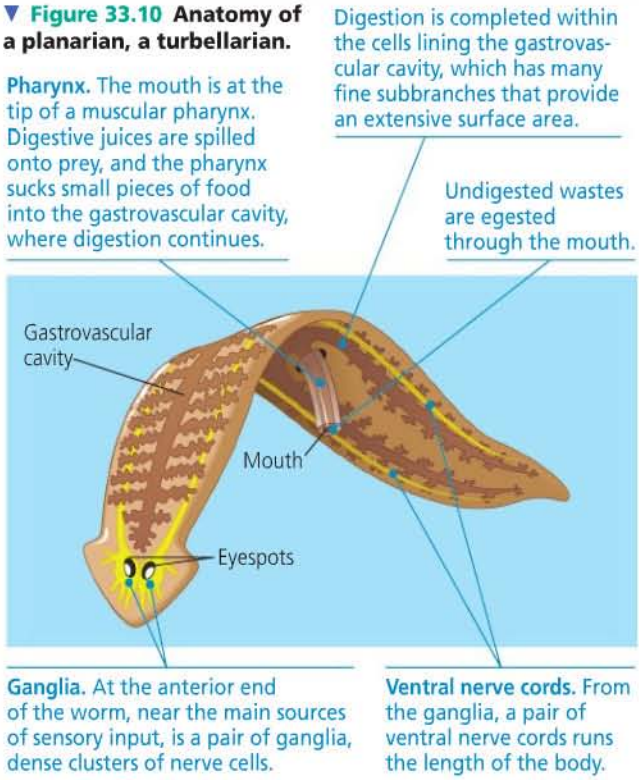
Table 33.2 Classes of Phylum Platyhelminthes



Class and Examples	Main Characteristics
Turbellaria (mostly free-living flatworms, such as *Dugesia*; see Figures 33.9 and 33.10)	Most marine, some freshwater, a few terrestrial; predators and scavengers; body surface ciliated
Monogenea (monogeneans)	Marine and freshwater parasites; most infect external surfaces of fishes; life history simple; ciliated larva starts infection on host
Trematoda (trematodes, also called flukes; see Figure 33.11)	Parasites, mostly of vertebrates; two suckers attach to host; most life cycles include intermediate and final hosts
Cestoda (tapeworms; see Figure 33.12)	Parasites of vertebrates; scolex attaches to host; proglottids produce eggs and break off after fertilization; no head or digestive system; life cycle with one or more intermediate hosts

Flatworms are divided into four classes **(Table 33.2)**: Turbellaria (mostly free-living flatworms), Monogenea (monogeneans), Trematoda (trematodes, or flukes), and Cestoda (tapeworms).

Turbellarians

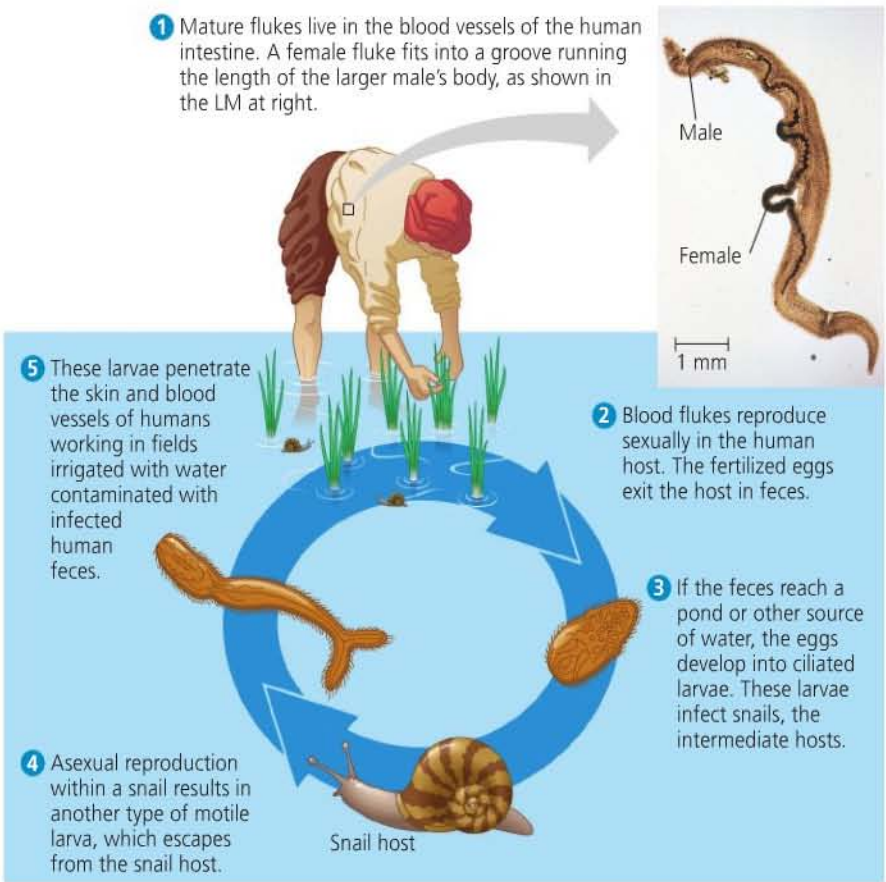


Turbellarians are nearly all free-living and mostly marine **(Figure 33.9)**. The best-known freshwater turbellarians are members of the genus *Dugesia*, commonly called **planarians**. Abundant in unpolluted ponds and streams, planarians prey on smaller animals or feed on dead animals. They move by using cilia on their ventral surface, gliding along a film of mucus they secrete. Some other turbellarians also use their muscles to swim through water with an undulating motion.

A planarian's head is equipped with a pair of light-sensitive eyespots and lateral flaps that function mainly to detect specific chemicals. The planarian nervous system is more complex and centralized than the nerve nets of cnidarians **(Figure 33.10)**. Experiments have shown that planarians can learn to modify their responses to stimuli.

▲ **Figure 33.9 A marine flatworm (class Turbellaria).**

▼ **Figure 33.10 Anatomy of a planarian, a turbellarian.**



Some planarians can reproduce asexually through fission. The parent constricts roughly in the middle of its body, separating into a head end and a tail end; each end then regenerates the missing parts. Sexual reproduction also occurs. Planarians are hermaphrodites, and copulating mates typically cross-fertilize each other.

Monogeneans and Trematodes

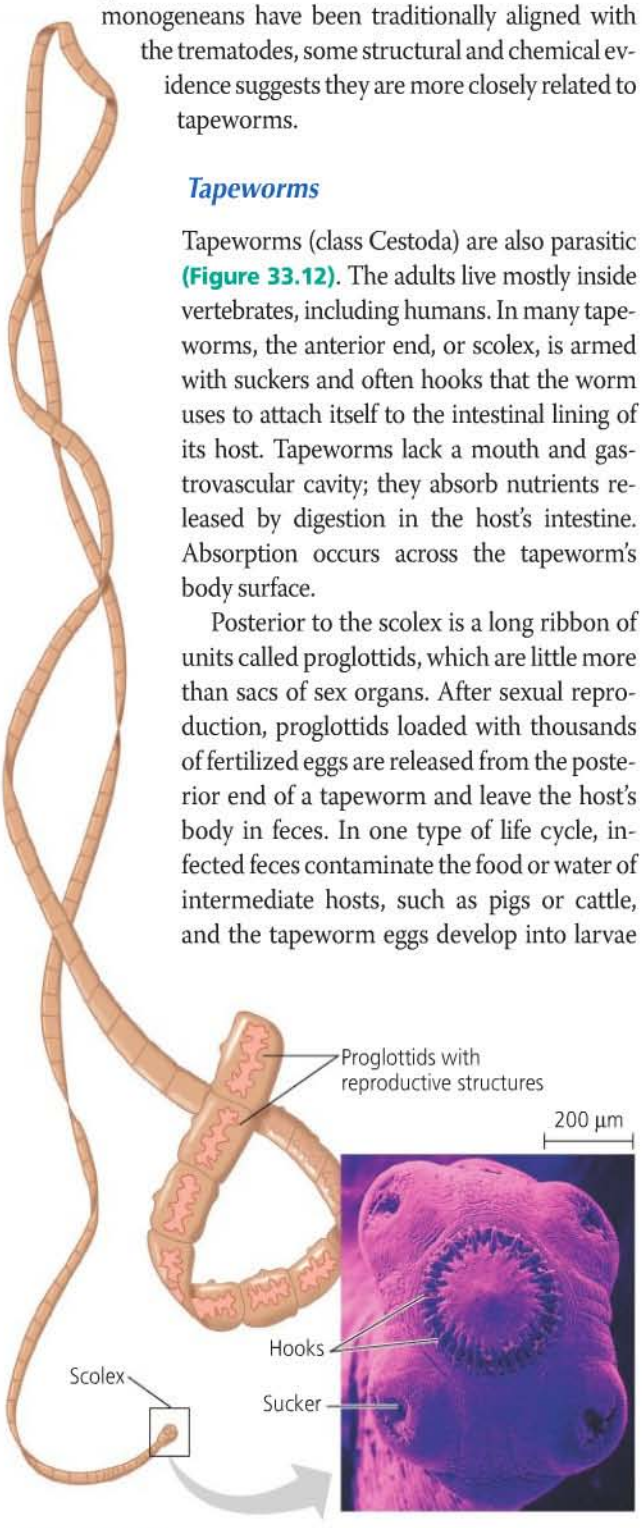
Monogeneans and trematodes live as parasites in or on other animals. Many have suckers that attach to the internal organs or outer surfaces of the host animal. A tough covering helps protect the parasites within their hosts. Reproductive organs occupy nearly the entire interior of these worms.

As a group, trematodes parasitize a wide range of hosts, and most species have complex life cycles with alternating sexual and asexual stages. Many trematodes require an intermediate host in which larvae develop before infecting the final host (usually a vertebrate), where the adult worms live. For example, trematodes that parasitize humans spend part of their lives in snail hosts **(Figure 33.11)**. Around the world, some 200 million people are infected with blood flukes (*Schistosoma*) and suffer from schistosomiasis, a disease whose symptoms include pain, anemia, and dysentery.

Living within different hosts puts demands on trematodes that free-living animals don't face. A blood fluke, for instance, must evade the immune systems of both snails and humans. By mimicking the surface proteins of its hosts, the blood fluke creates a partial immunological camou-

▲ **Figure 33.11 The life cycle of a blood fluke (*Schistosoma mansoni*), a trematode.**

WHAT IF? *Snails eat algae, whose growth is stimulated by nutrients found in fertilizer. How would the contamination of irrigation water with fertilizer likely affect the occurrence of schistosomiasis? Explain.*



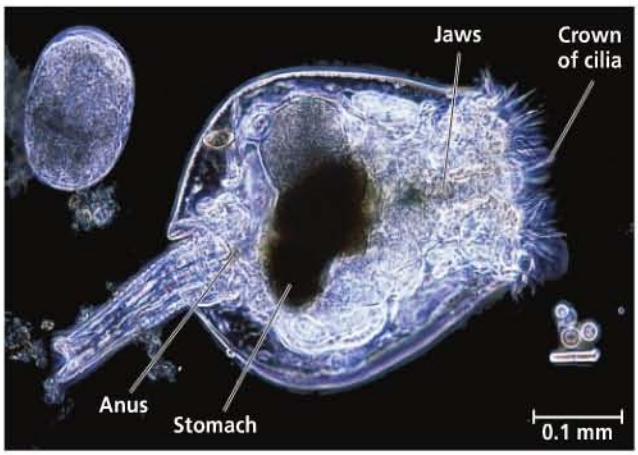
flage for itself. It also releases molecules that manipulate the hosts' immune systems into tolerating the parasite's existence. These defenses are so effective that individual blood flukes can survive in humans for more than 40 years.

Most monogeneans, however, are external parasites of fish. The monogenean life cycle is relatively simple; a ciliated, free-swimming larva initiates the infection of a host fish. Although monogeneans have been traditionally aligned with the trematodes, some structural and chemical evidence suggests they are more closely related to tapeworms.

Tapeworms

Tapeworms (class Cestoda) are also parasitic **(Figure 33.12)**. The adults live mostly inside vertebrates, including humans. In many tapeworms, the anterior end, or scolex, is armed with suckers and often hooks that the worm uses to attach itself to the intestinal lining of its host. Tapeworms lack a mouth and gastrovascular cavity; they absorb nutrients released by digestion in the host's intestine. Absorption occurs across the tapeworm's body surface.

Posterior to the scolex is a long ribbon of units called proglottids, which are little more than sacs of sex organs. After sexual reproduction, proglottids loaded with thousands of fertilized eggs are released from the posterior end of a tapeworm and leave the host's body in feces. In one type of life cycle, infected feces contaminate the food or water of intermediate hosts, such as pigs or cattle, and the tapeworm eggs develop into larvae that encyst in muscles of these animals. A human acquires the larvae by eating undercooked meat contaminated with cysts, and the worms develop into mature adults within the human. Large tapeworms can block the intestines and rob enough nutrients from the human host to cause nutritional deficiencies. Doctors use an orally administered drug, niclosamide, to kill the adult worms.



▲ **Figure 33.12 Anatomy of a tapeworm.** The inset shows a close-up of the scolex (colorized SEM).

Rotifers

Rotifers (phylum Rotifera) are tiny animals that inhabit freshwater, marine, and damp soil habitats. Ranging in size from about 50 µm to 2 mm, rotifers are smaller than many protists but nevertheless are multicellular and have specialized organ systems **(Figure 33.13)**. In contrast to cnidarians and flatworms, which have a gastrovascular cavity, rotifers have an **alimentary canal**, a digestive tube with a separate mouth and anus. Internal organs lie within the pseudocoelom, a body cavity that is not completely lined by mesoderm (see Figure 32.8b). Fluid in the pseudocoelom serves as a hydrostatic skeleton (see Chapter 50). Movement of a rotifer's body distributes the fluid throughout the body, circulating nutrients.

The word *rotifer*, derived from Latin, means "wheel-bearer," a reference to the crown of cilia that draws a vortex of water into the mouth. Posterior to the mouth, a region of the digestive tract called the pharynx bears jaws called trophi that grind up food, mostly microorganisms suspended in the water.

Rotifers exhibit some unusual forms of reproduction. Some species consist only of females that produce more females from unfertilized eggs, a type of reproduction called **parthenogenesis**. Other species produce two types of eggs that develop by parthenogenesis. One type forms females while the other type (produced when conditions deteriorate) develops into simplified males that cannot even feed themselves. These males survive only long enough to fertilize eggs, which form resistant

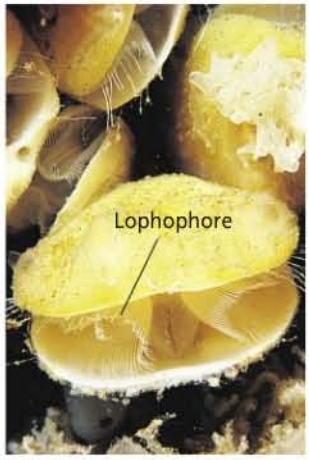
▲ **Figure 33.13 A rotifer.** These pseudocoelomates, smaller than many protists, are generally more anatomically complex than flatworms (LM).

zygotes that can survive when a pond dries up. When conditions are favorable, the zygotes break dormancy and develop into a new female generation that reproduces by parthenogenesis until conditions become unfavorable again.

It is puzzling that so many rotifer species survive without males. The vast majority of animals and plants reproduce sexually at least some of the time, and sexual reproduction has certain advantages over asexual reproduction. For example, species that reproduce asexually tend to accumulate harmful mutations in their genomes faster than sexually reproducing species. As a result, asexual species should experience higher rates of extinction and lower rates of speciation.

Seeking to understand this unusual group, Nobel Prize-winning biologist Matthew Meselson, of Harvard University, has been studying a class of asexual rotifers named Bdelloidea. Some 360 species of bdelloid rotifers are known, and all of them reproduce by parthenogenesis without any males. Paleontologists have discovered bdelloid rotifers preserved in 35-million-year-old amber, and the morphology of these fossils resembles only the female form, with no evidence of males. By comparing the DNA of bdelloids with that of their closest sexually reproducing rotifer relatives, Meselson and his colleagues concluded that bdelloids have likely been asexual for much longer than 35 million years. How these animals manage to flout the general rule against long-lived asexuality remains a puzzle.

Lophophorates: Ectoprocts and Brachiopods



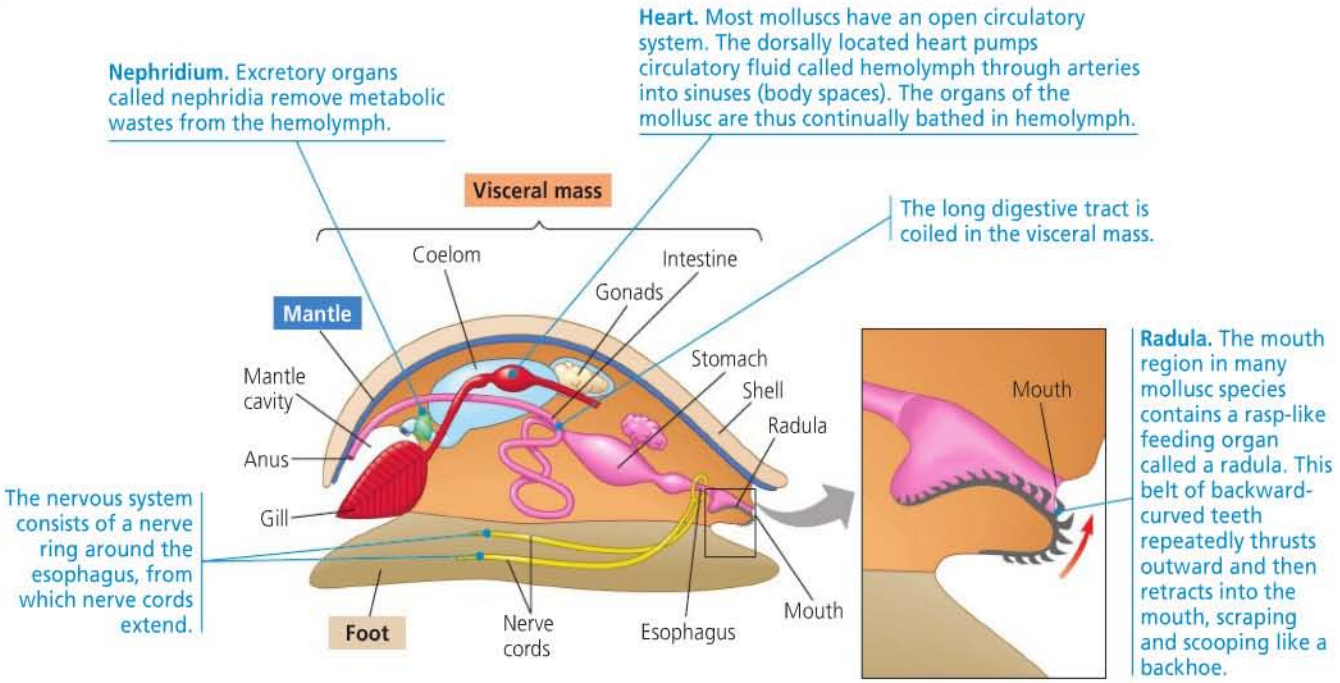
Bilaterians in the phyla Ectoprocta and Brachiopoda are among those known as lophophorates. These animals have a *lophophore*, a crown of ciliated tentacles that surround the mouth (see Figure 32.13a). As the cilia draw water toward the mouth, these tentacles trap suspended food particles. Other similarities, such as a U-shaped alimentary canal and the absence of a distinct head, reflect these organisms' sessile existence. In contrast to flatworms, which lack a body cavity, and rotifers, which have a pseudocoelom, lophophorates have a true coelom that is completely lined by mesoderm (see Figure 32.8a).

Ectoprocts (from the Greek *ecto*, outside, and *procta*, anus) are colonial animals that superficially resemble clumps of moss. (In fact, their common name, bryozoans, means "moss animals.") In most species, the colony is encased in a hard **exoskeleton** (external skeleton) studded with pores through which the lophophores extend **(Figure 33.14a)**. Most ectoproct species live in the sea, where they are among the most widespread and numerous sessile animals. Several species are important reef builders. Ectoprocts also live in lakes and rivers. Colonies of the freshwater ectoproct *Pectinatella magnifica* grow on submerged sticks or rocks and can grow into a gelatinous, ball-shaped mass more than 10 cm across.

Brachiopods, or lamp shells, superficially resemble clams and other hinge-shelled molluscs, but the two halves of the brachiopod shell are dorsal and ventral rather than lateral, as in clams **(Figure 33.14b)**. All brachiopods are marine. Most live attached to the seafloor by a stalk, opening their shell slightly to allow water to flow through the lophophore. The living brachiopods are remnants of a much richer past that included 30,000 species in the Paleozoic and Mesozoic eras. Some living brachiopods, such as those in the genus *Lingula*, are nearly identical to fossils of species that lived 400 million years ago.

(a) Ectoprocts, such as this sea mat (*Membranipora membranacea*), are colonial lophophorates.

(b) Brachiopods have a hinged shell. The two parts of the shell are dorsal and ventral.



▲ **Figure 33.14 Lophophorates.**

Molluscs

Snails and slugs, oysters and clams, and octopuses and squids are all molluscs (phylum Mollusca). Most molluscs are marine, though some inhabit fresh water, and some snails and slugs live on land. Molluscs are soft-bodied animals (from the Latin *molluscus*, soft), but most secrete a hard protective shell made of calcium carbonate. Slugs, squids, and octopuses have a reduced internal shell or have lost their shell completely during their evolution.

Despite their apparent differences, all molluscs have a similar body plan (**Figure 33.15**, on the next page). Molluscs are coelomates, and their bodies have three main parts: a muscular **foot**, usually used for movement; a **visceral mass** containing most of the internal organs; and a **mantle**, a fold of tissue that drapes over the visceral mass and secretes a shell (if one is present). In many molluscs, the mantle extends beyond the visceral mass, producing a water-filled chamber, the **mantle cavity**, which houses the gills, anus, and excretory pores. Many molluscs feed by using a straplike rasping organ called a **radula** to scrape up food.

Most molluscs have separate sexes, and their gonads (ovaries or testes) are located in the visceral mass. Many snails, however, are hermaphrodites. The life cycle of many marine molluscs includes a ciliated larval stage, the trochophore (see Figure 32.13b),

▲ **Figure 33.15 The basic body plan of a mollusc.**

Table 33.3 Major Classes of Phylum Mollusca

Class and Examples	Main Characteristics
Polyplacophora (chitons; see Figure 33.16)	Marine; shell with eight plates; foot used for locomotion; radula; no head
Gastropoda (snails, slugs; see Figures 33.17 and 33.18)	Marine, freshwater, or terrestrial; head present; a symmetrical body, usually with a coiled shell; shell reduced or absent; foot for locomotion; radula
Bivalvia (clams, mussels, scallops, oysters; see Figures 33.19 and 33.20)	Marine and freshwater; flattened shell with two valves; head reduced; paired gills; no radula; most are suspension feeders; mantle forms siphons
Cephalopoda (squids, octopuses, cuttlefishes, chambered nautiluses; see Figure 33.21)	Marine; head surrounded by grasping tentacles, usually with suckers; shell external, internal, or absent; mouth with or without radula; locomotion by jet propulsion using siphon formed from foot

which is also characteristic of marine annelids (segmented worms) and some other lophotrochozoans.

The basic body plan of molluscs has evolved in various ways in the phylum's eight classes. We'll examine four of those classes here **(Table 33.3)**: Polyplacophora (chitons), Gastropoda (snails and slugs), Bivalvia (clams, oysters, and other bivalves), and Cephalopoda (squids, octopuses, cuttlefishes, and chambered nautiluses).

▲ **Figure 33.16 A chiton.** Note the eight-plate shell characteristic of molluscs in the class Polyplacophora.

Chitons

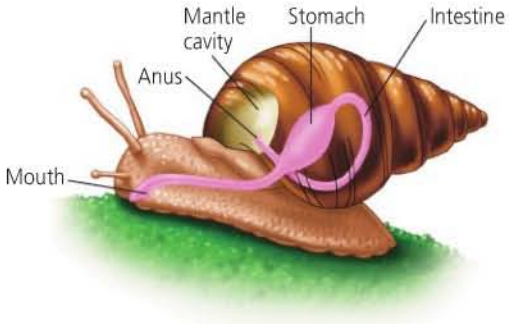
Chitons have an oval-shaped body and a shell divided into eight dorsal plates **(Figure 33.16)**. The chiton's body itself, however, is unsegmented. You can find these marine animals clinging to rocks along the shore during low tide. If you try to dislodge a chiton by hand, you will be surprised at how well its foot, acting as a suction cup, grips the rock. A chiton can also use its foot to creep slowly over the rock surface. Chitons use their radula to scrape algae off the rock surface.

Gastropods

About three-quarters of all living species of molluscs are gastropods **(Figure 33.17)**. Most gastropods are marine, but there are also many freshwater species. Some gastropods have adapted to life on land, including garden snails and slugs.

A distinctive characteristic of class Gastropoda is a developmental process known as **torsion**. As a gastropod embryo develops, its visceral mass rotates up to 180°, causing the animal's anus and mantle cavity to wind up above its head **(Figure 33.18)**. After torsion, some organs that were bilateral may be reduced in size, while others may be lost on one side of the body. Torsion should not be confused with the formation of a coiled shell, which is an independent developmental process.

Most gastropods have a single, spiraled shell into which the animal can retreat when threatened. The shell is often conical but is somewhat flattened in abalones and limpets. Many gastropods have a distinct head with eyes at the tips of tentacles. Gastropods move literally at a snail's pace by a rippling motion of their foot or by means of cilia, often leaving a trail of slime in their wake. Most gastropods use their radula to graze on algae or plants. Several groups, however, are predators, and their radula has become modified for boring holes in the shells of other molluscs or for tearing apart prey. In the cone snails, the teeth of the radula act as poison darts that are used to subdue prey.



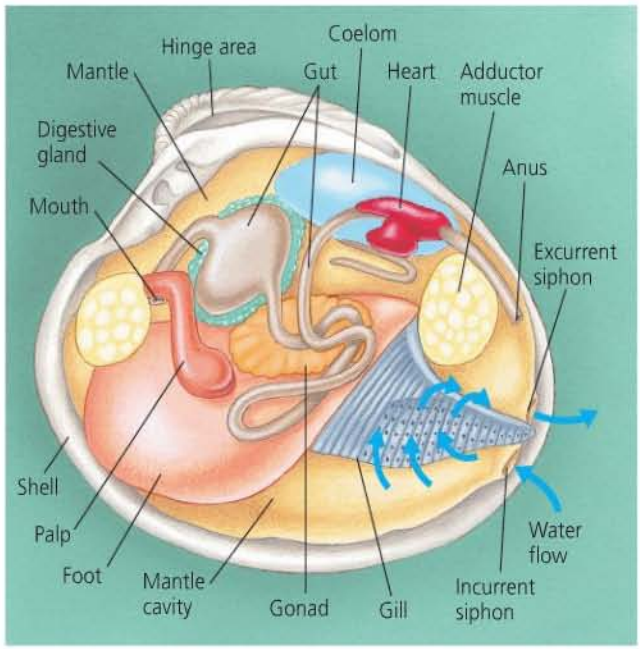
Terrestrial snails lack the gills typical of most aquatic gastropods. Instead, the lining of their mantle cavity functions as a lung, exchanging respiratory gases with the air.

(a) A land snail

(b) **A sea slug.** Nudibranchs, or sea slugs, lost their shell during their evolution.

▲ **Figure 33.17 Gastropods.**

▲ **Figure 33.18 The results of torsion in a gastropod.** Because of torsion (twisting of the visceral mass) during embryonic development, the digestive tract is coiled and the anus is near the anterior end of the animal.



Bivalves

The molluscs of class Bivalvia include many species of clams, oysters, mussels, and scallops. Bivalves have a shell divided into two halves **(Figure 33.19)**. The halves are hinged at the mid-dorsal line, and powerful adductor muscles draw them tightly together to protect the animal's soft body. Bivalves have no distinct head, and the radula has been lost. Some bivalves have eyes and sensory tentacles along the outer edge of their mantle.

The mantle cavity of a bivalve contains gills that are used for gas exchange as well as feeding in most species **(Figure 33.20)**. Most bivalves are suspension feeders. They trap fine food particles in mucus that coats their gills, and cilia then convey those particles to the mouth. Water enters the mantle cavity through an incurrent siphon, passes over the gills, and then exits the mantle cavity through an excurrent siphon.

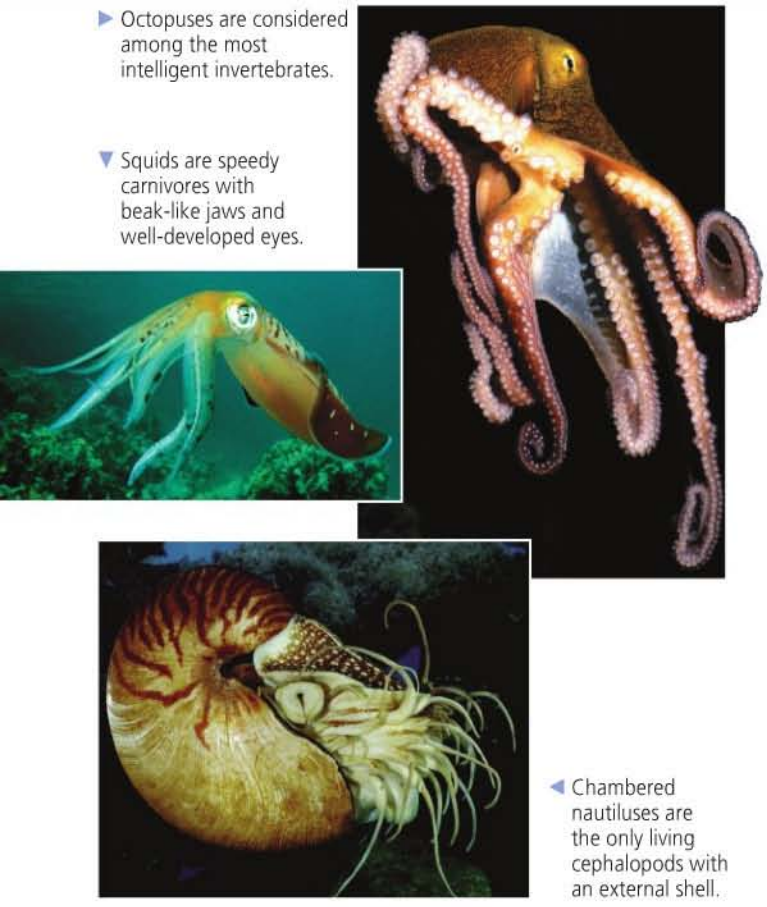
▲ **Figure 33.19 A bivalve.** This scallop has many eyes (dark blue spots) peering out from each half of its hinged shell.

▲ **Figure 33.20 Anatomy of a clam.** Food particles suspended in water that enters through the incurrent siphon are collected by the gills and passed via cilia to the mouth.

Most bivalves lead sedentary lives, a characteristic suited to suspension feeding. Sessile mussels secrete strong threads that tether them to rocks, docks, boats, and the shells of other animals. However, clams can pull themselves into the sand or mud, using their muscular foot for an anchor, and scallops can skitter along the seafloor by flapping their shells, rather like the mechanical false teeth sold in novelty shops.

Cephalopods

Cephalopods are active predators **(Figure 32.21)**. They use their tentacles to grasp prey, which they then bite with beak-like jaws and immobilize with a poison found in their saliva. The foot of a cephalopod has become modified into a muscular excurrent siphon and part of the tentacles. Squids dart about by drawing water into their mantle cavity and then firing a jet of water through the excurrent siphon; they steer by pointing the siphon in different directions. Octopuses use a similar mechanism to escape predators.



A mantle covers the visceral mass of cephalopods, but the shell is reduced and internal (in squids and cuttlefishes) or missing altogether (in many octopuses). One small group of shelled cephalopods, the chambered nautiluses, survives today.

Cephalopods are the only molluscs with a closed circulatory system. They also have well-developed sense organs and a complex brain. The ability to learn and behave in a complex manner is probably more critical to fast-moving predators than to sedentary animals such as clams.

The ancestors of octopuses and squids were probably shelled molluscs that took up a predatory lifestyle; the shell was lost in later evolution. Shelled cephalopods called **ammonites**, some of them as large as truck tires, were the dominant invertebrate predators of the seas for hundreds of millions of years until their disappearance during the mass extinction at the end of the Cretaceous period, 65.5 million years ago (see Chapter 25).

Most species of squid are less than 75 cm long, but some are considerably larger. The giant squid (*Architeuthis dux*) was for a long time the largest squid known, with a mantle up to 2.25 m long and a total length of 18 m. In 2003, however, a specimen of the rare species *Mesonychoteuthis hamiltoni* was caught near Antarctica; its mantle was 2.5 m long. Some biologists think that this specimen was a juvenile and estimate that adults of its species could be twice as large! Unlike *A. dux*, which has large suckers and small teeth on its tentacles, *M. hamiltoni* has two rows of sharp hooks at the ends of its tentacles that can deliver deadly lacerations.

It is likely that *A. dux* and *M. hamiltoni* spend most of their time in the deep ocean, where they may feed on large fishes. Remains of both giant squid species have been found in the stomachs of sperm whales, which are probably their only natural predator. In 2005, scientists reported the first observations of *A. dux* in the wild, photographed while attacking baited hooks at a depth of 900 m. *M. hamiltoni* has yet to be observed in nature. Overall, these marine giants remain among the great mysteries of invertebrate life.

▶ Octopuses are considered among the most intelligent invertebrates.

▼ Squids are speedy carnivores with beak-like jaws and well-developed eyes.

◀ Chambered nautiluses are the only living cephalopods with an external shell.

▲ **Figure 33.21 Cephalopods.**

Annelids

Annelida means "little rings," referring to the annelid body's resemblance to a series of fused rings. Annelids are segmented

Table 33.4 Classes of Phylum Annelida

Class and Examples	Main Characteristics
Oligochaeta (freshwater, marine, and terrestrial segmented worms; see Figure 33.22)	Reduced head; no parapodia, but chaetae present
Polychaeta (mostly marine segmented worms; see Figure 33.23)	Many have a well-developed head; each segment usually has parapodia with many chaetae; free-living
Hirudinea (leeches; see Figure 33.24)	Body usually flattened, with reduced coelom and segmentation; chaetae usually absent; suckers at anterior and posterior ends; parasites, predators, and scavengers

worms that live in the sea, in most freshwater habitats, and in damp soil. Annelids are coelomates, and they range in length from less than 1 mm to more than 3 m, the length of a giant Australian earthworm.

The phylum Annelida can be divided into three classes (**Table 33.4**, on the facing page): Oligochaeta (the earthworms and their relatives), Polychaeta (the polychaetes), and Hirudinea (the leeches).

Oligochaetes

Oligochaetes (from the Greek *oligos*, few, and *chaitē*, long hair) are named for their relatively sparse chaetae, or bristles made of chitin. This class of segmented worms includes the earthworms and a variety of aquatic species. **Figure 33.22** provides a guided tour of the anatomy of an earthworm, which is representative of annelids. Earthworms eat their way through the soil, extracting

Each segment is surrounded by longitudinal muscle, which in turn is surrounded by circular muscle. Earthworms coordinate the contraction of these two sets of muscles to move (see Figure 50.33). These muscles work against the noncompressible coelomic fluid, which acts as a hydrostatic skeleton.

Coelom. The coelom of the earthworm is partitioned by septa.

Metanephridium. Each segment of the worm contains a pair of excretory tubes, called metanephridia, with ciliated funnel-shaped openings called nephrostomes. The metanephridia remove wastes from the blood and coelomic fluid through exterior pores.

Many of the internal structures are repeated within each segment of the earthworm.

Epidermis
Cuticle
Circular muscle
Septum (partition between segments)
Longitudinal muscle
Dorsal vessel
Intestine
Anus

Chaetae. Each segment has four pairs of chaetae, bristles that provide traction for burrowing.

Tiny blood vessels are abundant in the earthworm's skin, which functions as its respiratory organ. The blood contains oxygen-carrying hemoglobin.

Giant Australian earthworm

Fused nerve cords
Ventral vessel
Nephrostome
Clitellum
Esophagus
Pharynx
Crop
Metanephridium
Intestine
Gizzard
Mouth
Subpharyngeal ganglion

Cerebral ganglia. The earthworm nervous system features a brain-like pair of cerebral ganglia above and in front of the pharynx. A ring of nerves around the pharynx connects to a subpharyngeal ganglion, from which a fused pair of nerve cords runs posteriorly.

The circulatory system, a network of vessels, is closed. The dorsal and ventral vessels are linked by segmental pairs of vessels. The dorsal vessel and five pairs of vessels that circle the esophagus are muscular and pump blood through the circulatory system.

Ventral nerve cords with segmental ganglia. The nerve cords penetrate the septa and run the length of the animal, as do the digestive tract and longitudinal blood vessels.

▲ **Figure 33.22 Anatomy of an earthworm, an oligochaete.**

nutrients as the soil passes through the alimentary canal. Undigested material, mixed with mucus secreted into the canal, is eliminated as fecal castings through the anus. Farmers value earthworms because the animals till and aerate the earth, and their castings improve the texture of the soil. (Charles Darwin estimated that a single acre of British farmland contains about 50,000 earthworms, producing 18 tons of castings per year.)

Earthworms are hermaphrodites, but they cross-fertilize. Two earthworms mate by aligning themselves in opposite directions in such a way that they exchange sperm (see Figure 46.1), and then they separate. The received sperm are stored temporarily while an organ called the clitellum secretes a cocoon of mucus. The cocoon slides along the worm, picking up the eggs and then the stored sperm. The cocoon then slips off the worm's head and remains in the soil while the embryos develop. Some earthworms can also reproduce asexually by fragmentation followed by regeneration.

Polychaetes

Each segment of a polychaete has a pair of paddle-like or ridge-like structures called parapodia ("near feet") that function in locomotion **(Figure 33.23)**. Each parapodium has numerous chaetae, so polychaetes usually have many more chaetae per segment than do oligochaetes. In many polychaetes, the parapodia are richly supplied with blood vessels and also function as gills.

Polychaetes make up a large and diverse class, most of whose members are marine. A few species drift and swim among the plankton, many crawl on or burrow in the seafloor, and many others live in tubes. Some tube-dwellers, such as the fan worms, build their tubes by mixing mucus with bits of sand and broken shells. Others, such as Christmas tree worms (see Figure 33.1), construct tubes using only their own secretions.

Leeches

The majority of leeches inhabit fresh water, but there are also marine species as well as terrestrial leeches found in moist vegetation. Leeches range in length from about 1 to 30 cm.

▶ **Figure 33.23 A polychaete.** *Hesiolyra bergi* lives on the seafloor around deep-sea hydrothermal vents.

▶ **Figure 33.24 A leech.** A nurse applied this medicinal leech (*Hirudo medicinalis*) to a patient's sore thumb to drain blood from a hematoma (an abnormal accumulation of blood around an internal injury).

Many are predators that feed on other invertebrates, but some are parasites that suck blood by attaching temporarily to other animals, including humans **(Figure 33.24)**. Some parasitic species use bladelike jaws to slit the skin of their host, whereas others secrete enzymes that digest a hole through the skin. The host is usually oblivious to this attack because the leech secretes an anesthetic. After making the incision, the leech secretes another chemical, hirudin, which keeps the blood of the host from coagulating near the incision. The parasite then sucks as much blood as it can hold, often more than ten times its own weight. After this gorging, a leech can last for months without another meal.

Until this century, leeches were frequently used for bloodletting. Today they are used to drain blood that accumulates in tissues following certain injuries or surgeries. Researchers have also investigated the potential use of hirudin to dissolve unwanted blood clots that form during surgery or as a result of heart disease. Several recombinant forms of hirudin have been developed, two of which were recently approved for clinical use.

As a group, Lophotrochozoa encompasses a remarkable range of body plans, as illustrated by members of such phyla as Rotifera, Ectoprocta, Mollusca, and Annelida. Next we'll explore the diversity of Ecdysozoa, a dominant presence on Earth in terms of sheer number of species.

CONCEPT CHECK 33.3

1. Explain how tapeworms can survive without a coelom, a mouth, a digestive system, or an excretory system.
2. How does the modification of the molluscan foot in gastropods and cephalopods relate to their respective lifestyles?
3. Annelid anatomy can be described as "a tube within a tube." Explain.
4. **WHAT IF?** Relatively few free-living lophotrochozoans live *on* land, above the surface of the soil. Focusing on gravity, hypothesize why this is so.

For suggested answers, see Appendix A.

CONCEPT **33.4**

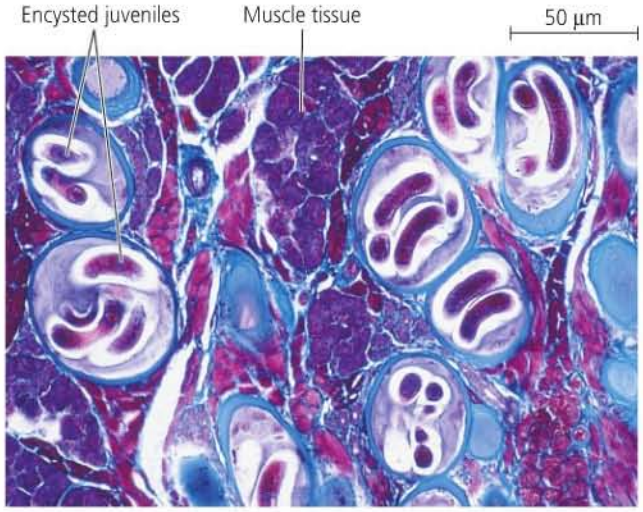
Ecdysozoans are the most species-rich animal group

Although defined primarily by molecular evidence, the clade Ecdysozoa includes animals that shed a tough external coat (**cuticle**) as they grow; in fact, the group derives its name from this process, which is called **molting**, or ecdysis. Ecdysozoa consists of about eight animal phyla and contains more known species than all other protist, fungus, plant, and animal groups combined. Here we'll focus on the two largest ecdysozoan phyla, the nematodes and arthropods, which are among the most successful and abundant of all animal groups.

Nematodes

Some of the most ubiquitous animals, nematodes (phylum Nematoda), or roundworms, are found in most aquatic habitats, in the soil, in the moist tissues of plants, and in the body fluids and tissues of animals. In contrast to annelids, nematodes do not have segmented bodies. The cylindrical bodies of nematodes range from less than 1 mm to more than a meter in length, often tapering to a fine tip at the posterior end and to a more blunt tip at the anterior end **(Figure 33.25)**. A nematode's body is covered by a tough cuticle; as the worm grows, it periodically sheds its old cuticle and secretes a new, larger one. Nematodes have an alimentary canal, though they lack a circulatory system. Nutrients are transported throughout the body via fluid in the pseudocoelom. The body wall muscles are all longitudinal, and their contraction produces a thrashing motion.

Nematodes usually reproduce sexually, by internal fertilization. In most species, the sexes are separate and females are larger than males. A female may deposit 100,000 or more fertilized eggs (zygotes) per day. The zygotes of most species are resistant cells that can survive harsh conditions.



▲ **Figure 33.25 A free-living nematode** (colorized SEM).

Multitudes of nematodes live in moist soil and in decomposing organic matter on the bottoms of lakes and oceans. While 25,000 species are known, perhaps 20 times that number actually exist. It has been said that if nothing but nematodes remained on Earth, they would still preserve the outline of the planet and many of its features. These free-living worms play an important role in decomposition and nutrient cycling, but little is known about most species. One species of soil nematode, *Caenorhabditis elegans*, however, is very well studied and has become a model research organism in biology (see Chapter 21). Ongoing studies on *C. elegans* are revealing some of the mechanisms involved in aging in humans, among other findings.

Phylum Nematoda includes many significant agricultural pests that attack the roots of plants. Other species of nematodes parasitize animals. Humans are hosts to at least 50 nematode species, including various pinworms and hookworms. One notorious nematode is *Trichinella spiralis*, the worm that causes trichinosis **(Figure 33.26)**. Humans acquire this nematode by eating raw or undercooked pork or other meat (including wild game such as bear or walrus) that has juvenile worms encysted in the muscle tissue. Within the human intestines, the juveniles develop into sexually mature adults. Females burrow into the intestinal muscles and produce more juveniles, which bore through the body or travel in lymphatic vessels to other organs, including skeletal muscles, where they encyst.

Parasitic nematodes have an extraordinary molecular toolkit that enables them to redirect some of the cellular functions of their hosts and thus evade their immune systems. Plant-parasitic nematodes inject molecules that induce the development of root cells, which then supply nutrients to the parasites. *Trichinella* controls the expression of specific muscle-cell genes that code for proteins that make the cell elastic enough to house the nematode. Additionally, the infected muscle cell releases signals that attract blood vessels, which

▲ **Figure 33.26 Juveniles of the parasitic nematode *Trichinella spiralis* encysted in human muscle tissue** (LM).

then supply the nematode with nutrients. These extraordinary parasites have been dubbed "animals that act like viruses."

Arthropods

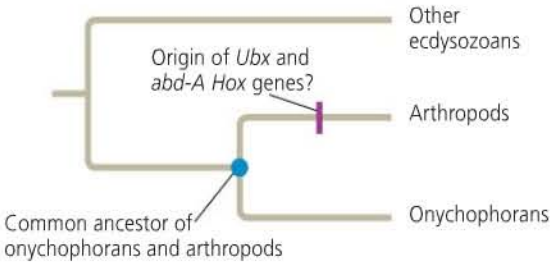
Zoologists estimate that there are about a billion billion (10^{18}) arthropods living on Earth. More than 1 million arthropod species have been described, most of which are insects. In fact, two out of every three known species are arthropods, and members of the phylum Arthropoda can be found in nearly all habitats of the biosphere. By the criteria of species diversity, distribution, and sheer numbers, arthropods must be regarded as the most successful of all animal phyla.

Arthropod Origins

Biologists hypothesize that the diversity and success of **arthropods** is related to their body plan—their segmented bodies, hard exoskeleton, and jointed appendages (*arthropod* means "jointed feet"). The earliest fossils with this body plan are from the Cambrian explosion (535–525 million years ago), indicating that the arthropods are at least that old.

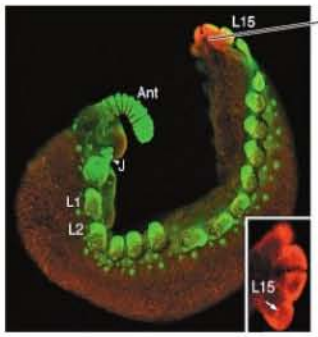
Along with arthropods, the fossil record of the Cambrian explosion contains many species of *lobopods*, an extinct group from which arthropods may have evolved. Lobopods such as *Hallucigenia* (see Figure 25.4) had segmented bodies, but most of their body segments were identical to one another. Early arthropods, such as the trilobites, also showed little variation from segment to segment **(Figure 33.27)**. As arthropods continued to evolve, the segments tended to fuse and become fewer, and the appendages became specialized for a variety of functions. These evolutionary changes resulted not only in great diversification but also in an efficient body plan that permits the division of labor among different body regions.

What genetic changes led to the increasing complexity of the arthropod body plan? Arthropods today have two unusual *Hox* genes, both of which influence segmentation. To test whether these genes could have driven the evolution of increased body segment diversity in arthropods, Sean Carroll (see pages 534–535) and colleagues studied *Hox* genes in onychophorans, close relatives of arthropods **(Figure 33.28)**.



▶ **Figure 33.27 A trilobite fossil.** Trilobites were common denizens of the shallow seas throughout the Paleozoic era but disappeared with the great Permian extinctions about 250 million years ago. Paleontologists have described about 4,000 trilobite species.

▼ Figure 33.28 Inquiry



Did the arthropod body plan result from new *Hox* genes?

EXPERIMENT How did the highly successful arthropod body plan arise? One hypothesis suggests that it resulted from the origin (by a gene duplication event) of two unusual *Hox* genes found in arthropods: *Ultrabithorax* (*Ubx*) and *abdominal-A* (*abd-A*). To test this hypothesis, Sean Carroll, of the University of Wisconsin, Madison, and colleagues turned to the onychophorans, a group of invertebrates closely related to arthropods. Unlike many living arthropods, onychophorans have a body plan in which most body segments are identical to one another. Thus, Carroll and colleagues reasoned that if the origin of the *Ubx* and *abd-A Hox* genes drove the evolution of body segment diversity in arthropods, these genes probably arose on the arthropod branch of the evolutionary tree:

As the hypothesis depicted above suggests, *Ubx* and *abd-A* would not have been present in the common ancestor of arthropods and onychophorans, and hence, onychophorans should not have these genes. To find out whether this was the case, Carroll and colleagues examined the *Hox* genes of the onychophoran *Acanthokara kaputensis*.

RESULTS The onychophoran *A. kaputensis* has all arthropod *Hox* genes, including *Ubx* and *abd-A*.

Red indicates the body regions of this onychophoran embryo in which *Ubx* or *abd-A* genes were expressed. (The inset shows this area enlarged.)

Ant = antenna
J = jaws
L1–L15 = body segments

CONCLUSION Since *A. kaputensis*, an onychophoran, has the arthropod *Hox* genes, the evolution of increased body segment diversity in arthropods must not have been related to the origin of new *Hox* genes.

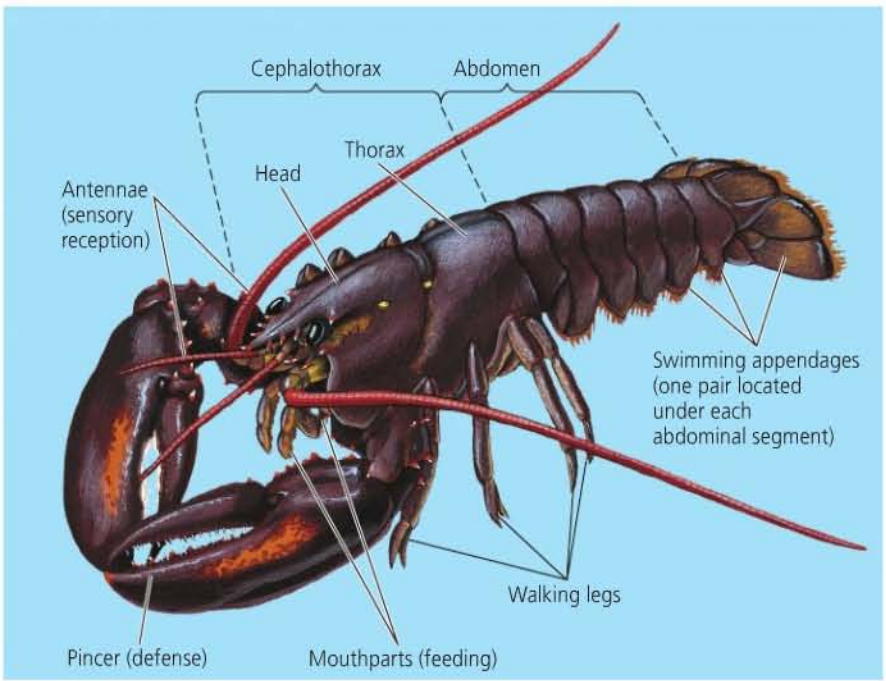
SOURCE J. K. Grenier, S. Carroll et al., Evolution of the entire arthropod *Hox* gene set predated the origin and radiation of the onychophoran/arthropod clade, *Current Biology* 7:547–553 (1997).

WHAT IF? If Carroll and colleagues had found that *A. kaputensis* did *not* have the *Ubx* and *abd-A Hox* genes, how would their conclusion have been affected? Explain.

Their results indicate that arthropod body plan diversity did *not* arise from the acquisition of new *Hox* genes. Instead, the evolution of body segment diversity in arthropods may have been driven by changes in the sequence or regulation of existing *Hox* genes. (See Chapter 25 for a discussion of how changes in form can result from changes in the sequence or regulation of developmental genes such as *Hox* genes.)

General Characteristics of Arthropods

Over the course of evolution, the appendages of some arthropods have become modified, specializing in functions such as walking, feeding, sensory reception, reproduction, and defense. **Figure 33.29** illustrates the diverse appendages and other arthropod characteristics of a lobster.



The body of an arthropod is completely covered by the cuticle, an exoskeleton constructed from layers of protein and the polysaccharide chitin. The cuticle can be thick and hard over some parts of the body and paper-thin and flexible over others, such as the joints. The rigid exoskeleton protects the animal and provides points of attachment for the muscles that move the appendages. But it also means that an arthropod cannot grow without occasionally shedding its exoskeleton and producing a larger one. This molting process is energetically expensive. A molting or recently molted arthropod is also vulnerable to predation and other dangers until its new, soft exoskeleton hardens.

When the arthropod exoskeleton first evolved in the sea, its main functions were probably protection and anchorage for muscles, but it later additionally enabled certain arthropods to live on land. The exoskeleton's relative impermeability to water helped prevent desiccation, and its strength solved the problem of support when arthropods left the buoyancy of water. Arthropods began to diversify on land following the colonization of land by plants in the early Paleozoic. Evidence includes a 428-million-year-old fossil of a millipede found in 2004 by an amateur fossil hunter in Scotland. Fossilized tracks of other terrestrial arthropods date from about 450 million years ago.

Arthropods have well-developed sensory organs, including eyes, olfactory (smell) receptors, and antennae that function in both touch and smell. Most sensory organs are concentrated at the anterior end of the animal.

Like many molluscs, arthropods have an **open circulatory system**, in which fluid called *hemolymph* is propelled by a heart through short arteries and then into spaces called sinuses surrounding the tissues and organs. (The term *blood* is generally reserved for fluid in a closed circulatory system.) Hemolymph reenters the arthropod heart through pores that are usually equipped with valves. The hemolymph-filled body sinuses are collectively called the *hemocoel*, which is not part of the coelom. Although arthropods are coelomates, in most species the coelom that forms in the embryo becomes much reduced as development progresses, and the hemocoel becomes the main body cavity in adults. Despite their similarity, the open circulatory systems of molluscs and arthropods probably arose independently.

A variety of specialized gas-exchange organs have evolved in arthropods. These organs allow the diffusion of respiratory gases in spite of the exoskeleton. Most aquatic species have gills with thin, feathery extensions that place an extensive surface area in contact with the surrounding water. Terrestrial arthropods generally have internal surfaces specialized for gas exchange. Most insects, for instance, have tracheal systems, branched air ducts leading into the interior from pores in the cuticle.

◀ **Figure 33.29 External anatomy of an arthropod.** Many of the distinctive features of arthropods are apparent in this dorsal view of a lobster, along with some uniquely crustacean characteristics. The body is segmented, but this characteristic is obvious only in the abdomen. The appendages (including antennae, pincers, mouthparts, walking legs, and swimming appendages) are jointed. The head bears a pair of compound (multilens) eyes, each situated on a movable stalk. The whole body, including appendages, is covered by an exoskeleton.

Table 33.5 Subphyla of Phylum Arthropoda

Subphylum and Examples	Main Characteristics
Cheliceriformes (horseshoe crabs, spiders, scorpions, ticks, mites; see Figures 33.30–33.32)	Body having one or two main parts; six pairs of appendages (chelicerae, pedipalps, and four pairs of walking legs); mostly terrestrial or marine
Myriapoda (millipedes and centipedes; see Figures 33.33 and 33.34)	Distinct head bearing antennae and chewing mouthparts; terrestrial; millipedes are herbivorous and have two pairs of walking legs per trunk segment; centipedes are carnivorous and have one pair of walking legs per trunk segment and poison claws on first body segment
Hexapoda (insects, springtails; see Figures 33.35–33.37)	Body divided into head, thorax, and abdomen; antennae present; mouthparts modified for chewing, sucking, or lapping; three pairs of legs and usually two pairs of wings; mostly terrestrial
Crustacea (crabs, lobsters, crayfishes, shrimps; see Figures 33.29 and 33.38)	Body of two or three parts; antennae present; chewing mouthparts; three or more pairs of legs; mostly marine and freshwater

Morphological and molecular evidence suggests that living arthropods consist of four major lineages that diverged early in the evolution of the phylum **(Table 33.5)**: **cheliceriforms** (sea spiders, horseshoe crabs, scorpions, ticks, mites, and spiders); **myriapods** (centipedes and millipedes); **hexapods** (insects and their wingless, six-legged relatives); and **crustaceans** (crabs, lobsters, shrimps, barnacles, and many others).

Cheliceriforms

Cheliceriforms (subphylum Cheliceriformes; from the Greek *cheilos*, lips, and *cheir*, arm) are named for clawlike feeding appendages called **chelicerae**, which serve as pincers or fangs. Cheliceriforms have an anterior cephalothorax and a posterior abdomen. They lack antennae, and most have simple eyes (eyes with a single lens).

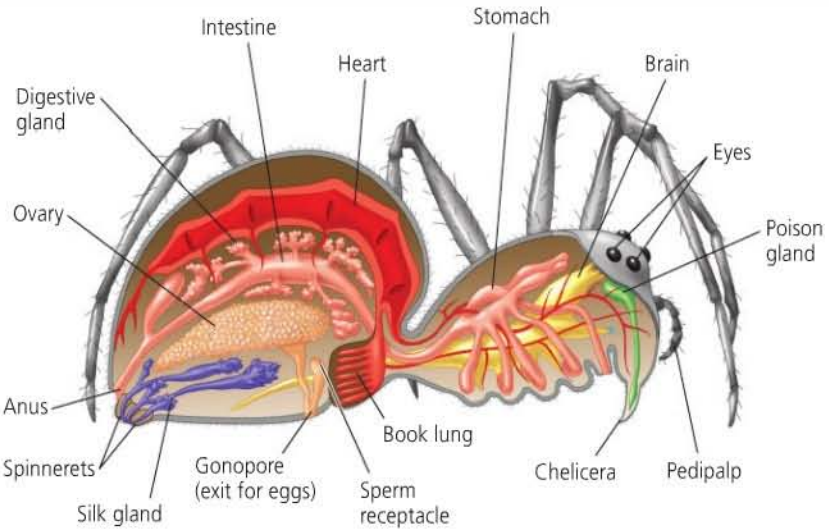
The earliest cheliceriforms were **eurypterids**, or water scorpions. These marine and freshwater predators grew up to 3 m long; it is thought that some species could have walked on land, much as land crabs do today. Most of the marine cheliceriforms, including all of the eurypterids, are extinct. Among the marine cheliceriforms that survive today are the sea spiders (pycnogonids) and horseshoe crabs **(Figure 33.30)**.

The bulk of modern cheliceriforms are **arachnids**, a group that includes scorpions, spiders, ticks, and mites **(Figure 33.31)**. Ticks

▲ **Figure 33.30 Horseshoe crabs (*Limulus polyphemus*).** Common on the Atlantic and Gulf coasts of the United States, these "living fossils" have changed little in hundreds of millions of years. They are surviving members of a rich diversity of cheliceriforms that once filled the seas.

▲ Scorpions have pedipalps that are pincers specialized for defense and the capture of food. The tip of the tail bears a poisonous stinger.

▲ Dust mites are ubiquitous scavengers in human dwellings but are harmless except to those people who are allergic to them (colorized SEM).



◀ Web-building spiders are generally most active during the daytime.

▲ **Figure 33.31 Arachnids.**

and many mites are among a large group of parasitic arthropods. Nearly all ticks are bloodsucking parasites that live on the body surfaces of reptiles or mammals. Parasitic mites live on or in a wide variety of vertebrates, invertebrates, and plants.

Arachnids have a cephalothorax that has six pairs of appendages: the chelicerae; a pair of appendages called *pedipalps* that function in sensing, feeding, or reproduction; and four pairs of walking legs **(Figure 33.32)**. Spiders use their fanglike chelicerae, which are equipped with poison glands, to attack prey. As the chelicerae pierce the prey, the spider secretes digestive juices onto the prey's torn tissues. The food softens, and the spider sucks up the liquid meal.

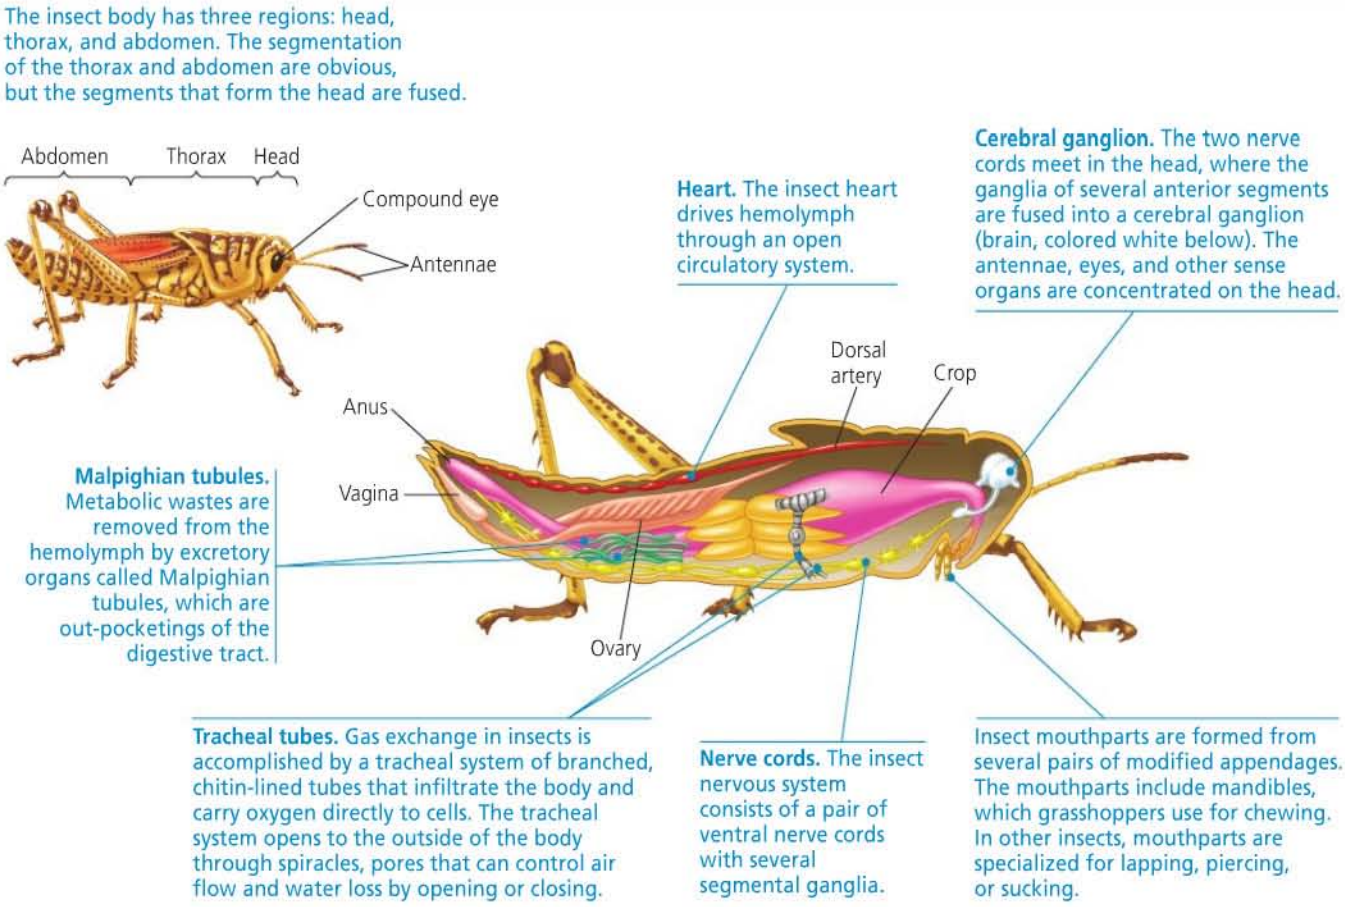
▲ **Figure 33.32 Anatomy of a spider.**

In most spiders, gas exchange is carried out by **book lungs**, stacked platelike structures contained in an internal chamber (see Figure 33.32). The extensive surface area of these respiratory organs is a structural adaptation that enhances the exchange of O_2 and CO_2 between the hemolymph and air.

A unique adaptation of many spiders is the ability to catch insects by constructing webs of silk, a liquid protein produced by specialized abdominal glands. The silk is spun by organs called spinnerets into fibers that then solidify. Each spider engineers a web characteristic of its species and builds it perfectly on the first try. This complex behavior is apparently inherited. Various spiders also use silk in other ways: as droplines for rapid escape, as a cover for eggs, and even as "gift wrap" for food that males offer females during courtship. Many small spiders also extrude silk into the air and let themselves be transported by wind, a behavior known as "ballooning."

▲ **Figure 33.33 A millipede.**

Myriapods



Millipedes and centipedes belong to the subphylum Myriapoda, the myriapods. All living myriapods are terrestrial. The myriapod head has a pair of antennae and three pairs of appendages modified as mouthparts, including the jaw-like **mandibles**.

Millipedes (class Diplopoda) have a large number of legs, though fewer than the thousand their name implies **(Figure 33.33)**. Each trunk segment is formed from two fused segments and bears two pairs of legs. Millipedes eat decaying leaves and other plant matter. They may have been among the earliest animals on land, living on mosses and primitive vascular plants.

Unlike millipedes, centipedes (class Chilopoda) are carnivores. Each segment of a centipede's trunk region has one pair of legs **(Figure 33.34)**. Centipedes have poison claws on their foremost trunk segment that paralyze prey and aid in defense.

▲ **Figure 33.34 A centipede.**

▲ **Figure 33.35 Anatomy of a grasshopper, an insect.**

Insects

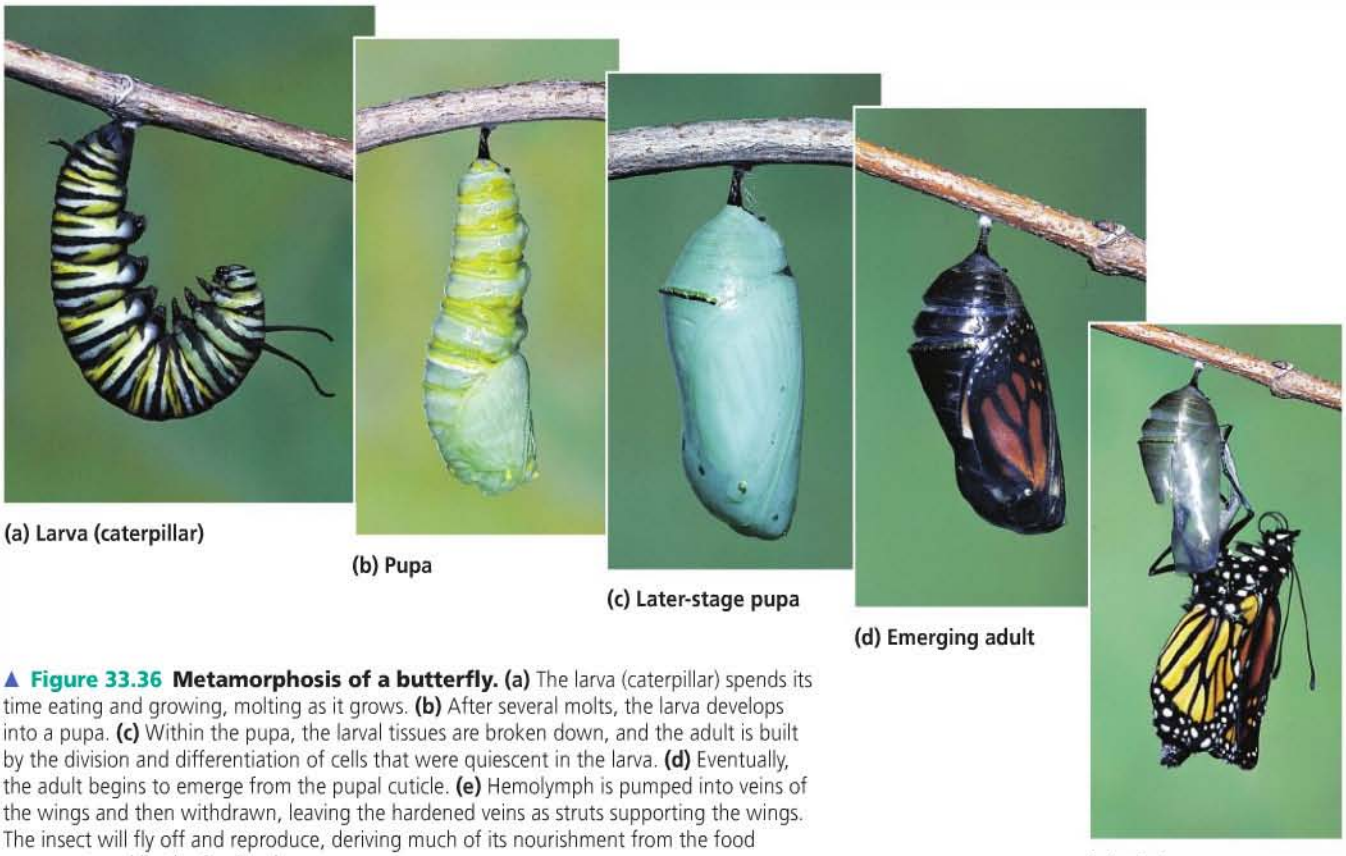
Insects and their relatives (subphylum Hexapoda) are more species-rich than all other forms of life combined. They live in almost every terrestrial habitat and in fresh water, and flying insects fill the air. Insects are rare, though not absent, in marine habitats, where crustaceans are the dominant arthropods. The internal anatomy of an insect includes several complex organ systems, which are highlighted in **Figure 33.35**.

The oldest insect fossils date from the Devonian period, which began about 416 million years ago. However, when flight evolved during the Carboniferous and Permian periods, it spurred an explosion in insect diversity. A fossil record of diverse insect mouthparts indicates that specialized feeding on gymnosperms and other Carboniferous plants also contributed to early adaptive radiations of insects. Later, a major increase in insect diversity appears to have been stimulated by the evolutionary expansion of flowering plants during the mid-Cretaceous period (about 90 million years ago). Although insect and plant diversity decreased during the Cretaceous mass extinction, both groups rebounded over the next 65 million years. Studies indicate that rebounds of particular insect groups often were associated with radiations of the flowering plants on which they fed.

Flight is obviously one key to the great success of insects. An animal that can fly can escape many predators, find food and mates, and disperse to new habitats much faster than an animal that must crawl about on the ground. Many insects have one or two pairs of wings that emerge from the dorsal side of the thorax. Because the wings are extensions of the cuticle and not true appendages, insects can fly without sacrificing any walking legs. By contrast, the flying vertebrates—birds and bats—have one of their two pairs of walking legs modified into wings, making some of these species clumsy on the ground.

Insect wings may have first evolved as extensions of the cuticle that helped the insect body absorb heat, only later becoming organs for flight. Other hypotheses suggest that wings allowed terrestrial insects to glide from vegetation to the ground or that they served as gills in aquatic insects. Still another hypothesis is that insect wings functioned for swimming before they functioned for flight.

Morphological and molecular data indicate that wings evolved only once in insects. Dragonflies, which have two similar pairs of wings, were among the first insects to fly. Several insect orders that evolved later than dragonflies have modified flight equipment. The wings of bees and wasps, for instance, are hooked together and move as a single pair. Butterfly wings



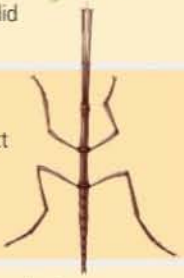
operate in a similar fashion because the anterior pair overlaps the posterior wings. In beetles, the posterior wings function in flight, while the anterior ones are modified as covers that protect the flight wings when the beetle is walking on the ground or burrowing.

Many insects undergo metamorphosis during their development. In the **incomplete metamorphosis** of grasshoppers and some other insect groups, the young (called nymphs) resemble adults but are smaller, have different body proportions, and lack wings. The nymph undergoes a series of molts, each time looking more like an adult. With the final molt, the insect reaches full size, acquires wings, and becomes sexually mature. Insects with **complete metamorphosis** have larval stages specialized for eating and growing that are known by such names as caterpillar, maggot, or grub. The larval stage looks entirely different from the adult stage, which is specialized for dispersal and reproduction. Metamorphosis from the larval stage to the adult occurs during a pupal stage **(Figure 33.36)**.

Reproduction in insects is usually sexual, with separate male and female individuals. Adults come together and recognize each other as members of the same species by advertising with bright colors (as in butterflies), sound (as in crickets), or odors (as in moths). Fertilization is generally internal. In most species, sperm are deposited directly into the female's vagina at the time of copulation, though in some species the male deposits a sperm packet outside the female, and the female picks it up. An internal structure in the female called the spermatheca stores the sperm, usually enough to fertilize more than one batch of eggs. Many insects mate only once in a lifetime. After mating, a female often lays her eggs on an appropriate food source where the next generation can begin eating as soon as it hatches.

Insects are classified in more than 30 orders, 15 of which are presented in **Figure 33.37**, on the next two pages.

Animals as numerous, diverse, and widespread as insects are bound to affect the lives of most other terrestrial organisms, including humans. We depend on bees, flies, and many other insects to pollinate our crops and orchards. On the other hand, insects are carriers for many diseases, including African sleeping sickness (spread by tsetse flies that carry the protist *Trypanosoma*; see Figure 28.6) and malaria (spread by mosquitoes that carry the protist *Plasmodium*; see Figure 28.10). Furthermore, insects compete with humans for food. In parts of Africa, for instance, insects claim about 75% of the crops. In the United States, billions of dollars are spent each year on pesticides, spraying crops with massive doses of some of the deadliest poisons ever invented. Try as they may, not even humans have challenged the preeminence of insects and their arthropod kin. As Cornell University entomologist Thomas Eisner puts it: "Bugs are not going to inherit the Earth. They own it now. So we might as well make peace with the landlord."



▲ **Figure 33.36 Metamorphosis of a butterfly. (a)** The larva (caterpillar) spends its time eating and growing, molting as it grows. **(b)** After several molts, the larva develops into a pupa. **(c)** Within the pupa, the larval tissues are broken down, and the adult is built by the division and differentiation of cells that were quiescent in the larva. **(d)** Eventually, the adult begins to emerge from the pupal cuticle. **(e)** Hemolymph is pumped into veins of the wings and then withdrawn, leaving the hardened veins as struts supporting the wings. The insect will fly off and reproduce, deriving much of its nourishment from the food reserves stored by the feeding larva.

▼ Figure 33.37

Exploring Insect Diversity

Order	Approximate Number of Species	Main Characteristics	Examples
Blattodea	4,000	Cockroaches have a dorsoventrally flattened body, with legs modified for rapid running. Forewings, when present, are leathery, whereas hind wings are fanlike. Fewer than 40 cockroach species live in houses; the rest exploit habitats ranging from tropical forest floors to caves and deserts.	German cockroach 
Coleoptera	350,000	Beetles comprise the most species-rich order of insects. They have two pairs of wings, one of which is thick and stiff, the other membranous. They have an armored exoskeleton and mouthparts adapted for biting and chewing. Beetles undergo complete metamorphosis.	Japanese beetle 
Dermaptera	1,200	Earwigs are generally nocturnal scavengers. Some species are wingless, while others have two pairs of wings, one of which is thick and leathery, the other membranous. Earwigs have biting mouthparts and large posterior pincers. They undergo incomplete metamorphosis.	 Earwig
Diptera	151,000	Dipterans have one pair of wings; the second pair has become modified into balancing organs called halteres. Their mouthparts are adapted for sucking, piercing, or lapping. Dipterans undergo complete metamorphosis. Flies and mosquitoes are among the best-known dipterans, which live as scavengers, predators, and parasites.	Horsefly 
Hemiptera	85,000	Hemipterans are so-called "true bugs," including bed bugs, assassin bugs, and chinch bugs. (Insects in other orders are sometimes erroneously called bugs.) Hemipterans have two pairs of wings, one pair partly leathery, the other membranous. They have piercing or sucking mouthparts and undergo incomplete metamorphosis.	Leaf-footed bug 
Hymenoptera	125,000	Ants, bees, and wasps are generally highly social insects. They have two pairs of membranous wings, a mobile head, and chewing or sucking mouthparts. The females of many species have a posterior stinging organ. Hymenopterans undergo complete metamorphosis.	 Cicada-killer wasp
Isoptera	2,000	Termites are widespread social insects that produce enormous colonies. It has been estimated that there are 700 kg of termites for every person on Earth! Some termites have two pairs of membranous wings, while others are wingless. They feed on wood with the aid of microbial symbionts carried in specialized chambers in their hindgut.690	 Termite

Order	Approximate Number of Species	Main Characteristics	Examples
Lepidoptera	120,000	Butterflies and moths are among the best-known insects. They have two pairs of wings covered with tiny scales. To feed, they uncoil a long proboscis. Most feed on nectar, but some species feed on other substances, including animal blood or tears.	 Swallowtail butterfly
Odonata	5,000	Dragonflies and damselflies have two pairs of large, membranous wings. They have an elongated abdomen, large, compound eyes, and chewing mouthparts. They undergo incomplete metamorphosis and are active predators.	 Dragonfly
Orthoptera	13,000	Grasshoppers, crickets, and their relatives are mostly herbivorous. They have large hind legs adapted for jumping, two pairs of wings (one leathery, one membranous), and biting or chewing mouthparts. Males commonly make courtship sounds by rubbing together body parts, such as a ridge on their hind legs. Orthopterans undergo incomplete metamorphosis.	 Katydid
Phasmatodea	2,600	Stick insects and leaf insects are exquisite mimics of plants. The eggs of some species even mimic seeds of the plants on which the insects live. Their body is cylindrical or flattened dorsoventrally. They lack forewings but have fanlike hind wings. Their mouthparts are adapted for biting or chewing.	 Stick insect
Phthiraptera	2,400	Commonly called sucking lice, these insects spend their entire life as an ectoparasite feeding on the hair or feathers of a single host. Their legs, equipped with clawlike tarsi, are adapted for clinging to their hosts. They lack wings and have reduced eyes. Sucking lice undergo incomplete metamorphosis.	 Human body louse
Siphonaptera	2,400	Fleas are bloodsucking ectoparasites on birds and mammals. Their body is wingless and laterally compressed. Their legs are modified for clinging to their hosts and for long-distance jumping. They undergo complete metamorphosis.	 Flea
Thysanura	450	Silverfish are small, wingless insects with a flattened body and reduced eyes. They live in leaf litter or under bark. They can also infest buildings, where they can become pests.	 Silverfish
Trichoptera	7,100	The larvae of caddisflies live in streams, where they make houses from sand grains, wood fragments, or other material held together by silk. Adults have two pairs of hairy wings and chewing or lapping mouthparts. They undergo complete metamorphosis.	 Caddisfly

Crustaceans

While arachnids and insects thrive on land, crustaceans, for the most part, have remained in marine and freshwater environments. Crustaceans (subphylum Crustacea) typically have highly specialized appendages. Lobsters and crayfishes, for instance, have a toolkit of 19 pairs of appendages (see Figure 33.29). The anteriormost appendages are antennae; crustaceans are the only arthropods with two pairs. Three or more pairs of appendages are modified as mouthparts, including the hard mandibles. Walking legs are present on the thorax, and, unlike insects, crustaceans also have appendages on their abdomen. A lost appendage can be regenerated at next molt.

Small crustaceans exchange gases across thin areas of the cuticle; larger species have gills. Nitrogenous wastes also diffuse through thin areas of the cuticle, but a pair of glands regulates the salt balance of the hemolymph.

Sexes are separate in most crustaceans. In the case of lobsters and crayfish, the male uses a specialized pair of abdominal appendages to transfer sperm to the reproductive pore of the female during copulation. Most aquatic crustaceans go through one or more swimming larval stages.

One of the largest groups of crustaceans (numbering about 10,000 species) is the **isopods**, which include terrestrial, freshwater, and marine species. Some isopod species are abundant in habitats at the bottom of the deep ocean. Among the terrestrial isopods are the pill bugs, or wood lice, common on the undersides of moist logs and leaves.

Lobsters, crayfishes, crabs, and shrimps are all relatively large crustaceans called **decapods** (Figure 33.38a). The cuticle of decapods is hardened by calcium carbonate; the portion that covers the dorsal side of the cephalothorax forms a shield called the carapace. Most decapod species are marine. Crayfishes, however, live in fresh water, and some tropical crabs live on land.

Many small crustaceans are important members of marine and freshwater plankton communities. Planktonic crustaceans include many species of **copepods**, which are among the most numerous of all animals, as well as the shrimplike krill, which grow to about 5 cm long (Figure 33.38b). A major food source for baleen whales (including blue whales, humpbacks, and right whales), krill are now being harvested in great numbers by humans for food and agricultural fertilizer. The larvae of many larger-bodied crustaceans are also planktonic.

Barnacles are a group of mostly sessile crustaceans whose cuticle is hardened into a shell containing calcium carbonate (Figure 33.38c). Most barnacles anchor themselves to rocks, boat hulls, pilings, and other submerged surfaces. Their natural adhesive is as strong as synthetic glues. To feed, these barnacles extend appendages from their shell to strain food from the water. Barnacles were not recognized as crustaceans until the 1800s, when naturalists discovered that barnacle larvae resemble the larvae of other crustaceans. The remarkable mix of unique traits and crustacean homologies found in barnacles was a major inspiration to Charles Darwin as he developed his theory of evolution.

(a) Ghost crabs live on sandy ocean beaches worldwide. Primarily nocturnal, they take shelter in burrows during the day.

(b) Planktonic crustaceans known as krill are consumed in vast quantities by some whales.

(c) The jointed appendages projecting from the shells of these barnacles capture organisms and organic particles suspended in the water.

▲ **Figure 33.38 Crustaceans.**

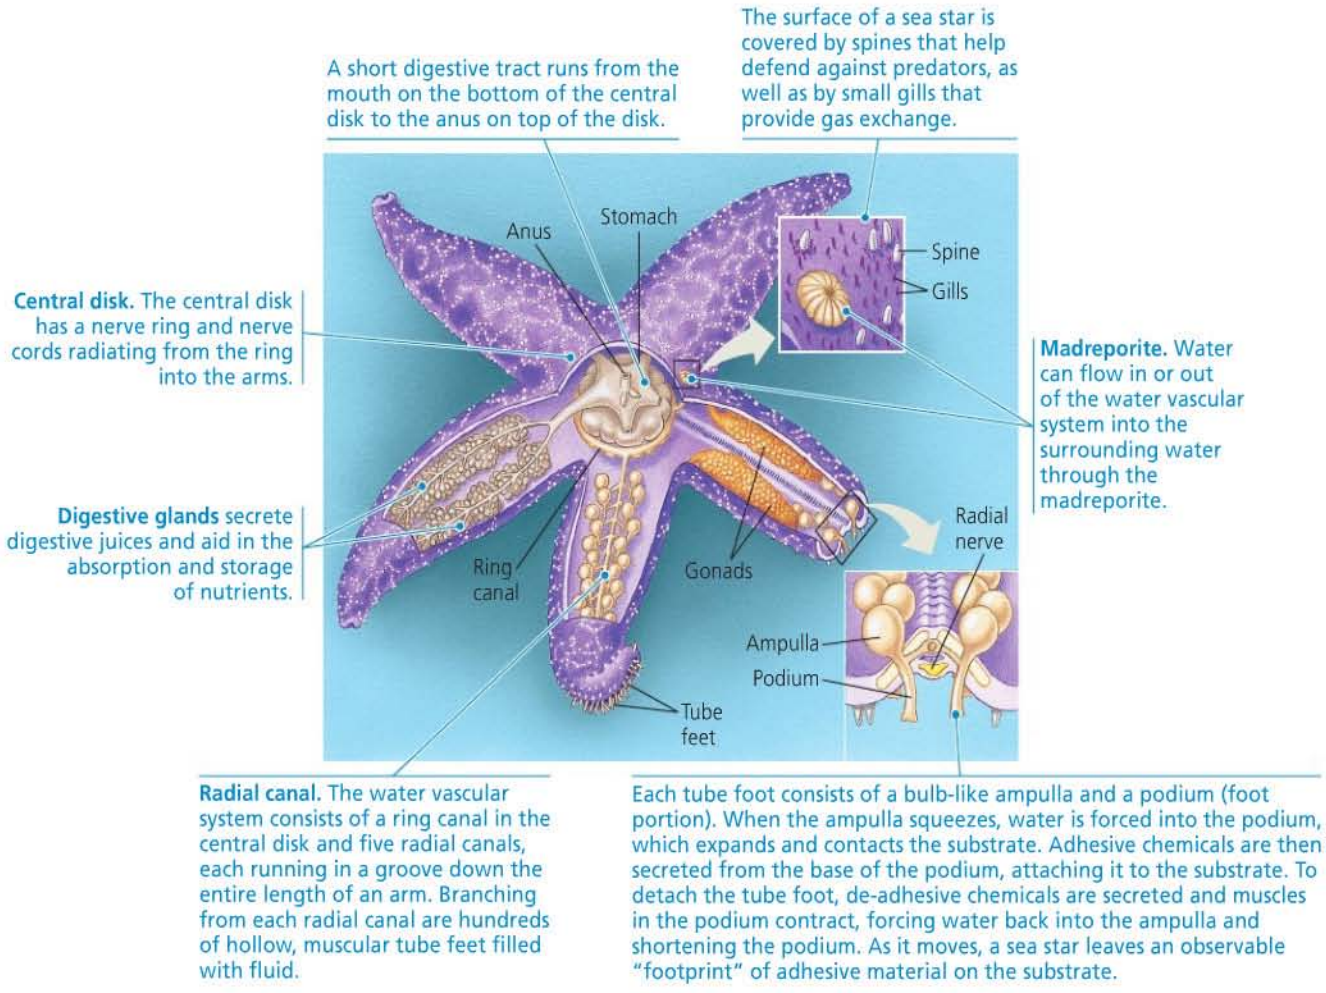
CONCEPT CHECK 33.4

1. How do nematode and annelid body plans differ?
2. In contrast to our jaws, which move up and down, the mouthparts of arthropods move side to side. Explain this feature of arthropods in terms of the origin of their mouthparts.
3. Describe two adaptations that have enabled insects to thrive on land.
4. **WHAT IF?** Traditionally, annelids and arthropods were thought to be closely related because both groups show body segmentation. Yet molecular data indicate that annelids belong to one clade (Lophotrochozoa) and arthropods to another (Ecdysozoa). Could traditional and molecular hypotheses be tested by studying the expression of *Hox* genes that control body segmentation? Explain.

For suggested answers, see Appendix A.

CONCEPT **33.5**

Echinoderms and chordates are deuterostomes



Sea stars, sea urchins, and other echinoderms (phylum Echinodermata) may seem to have little in common with phylum Chordata, which includes the vertebrates—animals that have a backbone. In fact, however, echinoderms and chordates share features characteristic of a deuterostome mode of development, such as radial cleavage and formation of the mouth at the end of the embryo opposite the blastopore (see Figure 32.9). Molecular systematics has reinforced Deuterostomia as a clade of bilaterian animals. But molecular evidence also indicates that some animal phyla with members that have deuterostome developmental features, including ectoprocts and brachiopods, are not in the deuterostome clade (see Chapter 32). Hence, despite its name, the clade Deuterostomia is defined primarily by DNA similarities—not developmental similarities.

Echinoderms

Sea stars and most other **echinoderms** (from the Greek *echin*, spiny, and *derma*, skin) are slow-moving or sessile marine animals. A thin epidermis covers an endoskeleton of hard calcareous plates. Most echinoderms are prickly from skeletal bumps and spines. Unique to echinoderms is the **water vascular system**, a network of hydraulic canals branching into extensions called **tube feet** that function in locomotion, feeding, and gas exchange **(Figure 33.39)**. Sexual reproduction of echinoderms usually involves separate male and female individuals that release their gametes into the water.

The internal and external parts of most adult echinoderms radiate from the center, often as five spokes. However, echinoderm larvae have bilateral symmetry. Furthermore, the symmetry of adult echinoderms is not truly radial. For example, the opening (madreporite) of a sea star's water vascular system is not central but shifted to one side.

▲ **Figure 33.39 Anatomy of a sea star, an echinoderm.**

Table 33.6 Classes of Phylum Echinodermata

Class and Examples	Main Characteristics
Asteroidea (sea stars; see Figure 33.39 and Figure 33.40a)	Star-shaped body with multiple arms; mouth directed to substrate
Ophiuroidea (brittle stars; see Figure 33.40b)	Distinct central disk; long, flexible arms; incomplete digestive system
Echinoidea (sea urchins, sand dollars; see Figure 33.40c)	Roughly spherical or disk-shaped; no arms; five rows of tube feet, enabling slow movement; mouth ringed by complex, jaw-like structure
Crinoidea (sea lilies, feather stars; see Figure 33.40d)	Feathered arms surrounding upward-pointing mouth; suspension feeders
Holothuroidea (sea cucumbers; see Figure 33.40e)	Cucumber-shaped body; five rows of tube feet; tube feet around the mouth are modified as feeding tentacles; reduced skeleton; no spines
Concentricycloidea (sea daisies; see Figure 33.40f)	Armless, disk-shaped body ringed with small spines; incomplete digestive system; live on submerged wood

Living echinoderms are divided into six classes **(Table 33.6; Figure 33.40)**: Asteroidea (sea stars), Ophiuroidea (brittle stars), Echinoidea (sea urchins and sand dollars), Crinoidea (sea lilies and feather stars), Holothuroidea (sea cucumbers), and Concentricycloidea (sea daisies).

Sea Stars

Sea stars have multiple arms radiating from a central disk, the undersurfaces of which bear tube feet. By a combination of muscular and chemical actions, the tube feet can attach to or detach from a substrate. The sea star adheres firmly to rocks or creeps along slowly as its tube feet extend, grip, release, extend, and grip again. Although the base of a sea star tube foot has a flattened disk that resembles a suction cup, the gripping action results from adhesive chemicals, not suction (see Figure 33.39). Sea stars also use their tube feet to grasp prey, such as clams and oysters. The arms of the sea star embrace the closed bivalve, clinging tightly with the tube feet. The sea star then turns part of its stomach inside out, everting it through its mouth and into the narrow opening between the halves of the bivalve's shell. The digestive system of the sea star secretes juices that begin digesting the soft body of the mollusc within its own shell.

Sea stars and some other echinoderms have considerable powers of regeneration. Sea stars can regrow lost arms, and members of one genus can even regrow an entire body from a single arm if part of the central disk remains attached.

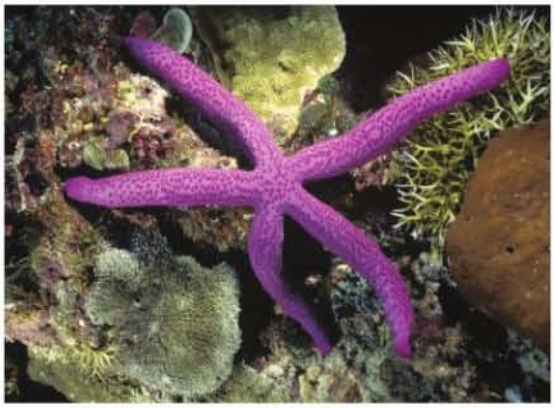
Brittle Stars

Brittle stars have a distinct central disk and long, flexible arms. They move primarily by lashing their arms in serpentine movements. The base of a brittle star tube foot lacks the flattened disk found in sea stars but does secrete adhesive chemicals. Hence, like sea stars and other echinoderms, brittle stars can use their tube feet to grip substrates. Some species are suspension feeders; others are predators or scavengers.

Sea Urchins and Sand Dollars

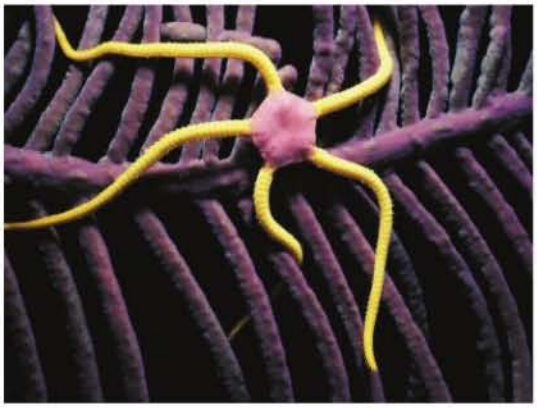
Sea urchins and sand dollars have no arms, but they do have five rows of tube feet that function in slow movement. Sea urchins also have muscles that pivot their long spines, which aid in locomotion as well as protection. The mouth of a sea urchin is ringed by highly complex, jaw-like structures that are well adapted to eating seaweed. Sea urchins are roughly spherical, whereas sand dollars are flat disks.

Sea Lilies and Feather Stars



Sea lilies live attached to the substrate by a stalk; feather stars crawl about by using their long, flexible arms. Both use their arms in suspension feeding. The arms encircle the mouth, which is directed upward, away from the substrate. Crinoidea is an ancient class whose evolution has been very conservative; fossilized sea lilies some 500 million years old are extremely similar to present-day members of the class.

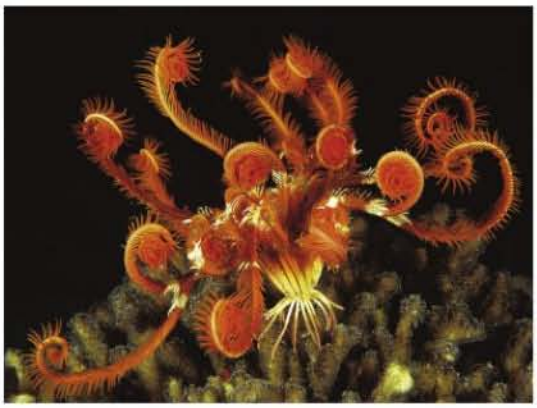
Sea Cucumbers



On casual inspection, sea cucumbers do not look much like other echinoderms. They lack spines, and their endoskeleton is much reduced. They are also elongated in their oral-aboral axis, giving them the shape for which they are named and further disguising their relationship to sea stars and sea urchins. Closer examination, however, reveals that sea cucumbers have five rows of tube feet. Some of the tube feet around the mouth are developed as feeding tentacles.

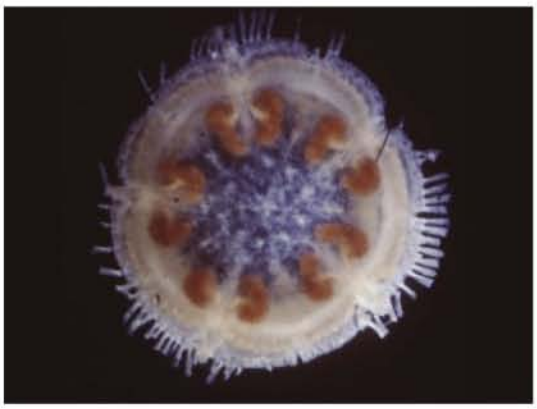
Sea Daisies

Sea daisies were discovered in 1986, and only three species are known (one near New Zealand, a second in the Bahamas, and a third in the North Pacific). All live on submerged wood. A sea daisy's body is armless and is typically disk-shaped; it has a five-sided organization and measures less than a centimeter in diameter. The edge of the body is ringed with small spines. Sea daisies absorb nutrients through the membrane surrounding their body. The relationship of sea daisies to other echinoderms remains unclear; some systematists consider sea daisies the sister group of sea stars.



(a) A sea star (class Asteroidea)

(b) A brittle star (class Ophiuroidea)



(c) A sea urchin (class Echinoidea)

(d) A feather star (class Crinoidea)

(e) A sea cucumber (class Holothuroidea)

(f) A sea daisy (class Concentricycloidea)

▲ **Figure 33.40** **Echinoderms.**

Chordates

Phylum Chordata consists of two subphyla of invertebrates as well as the hagfishes and the vertebrates. Chordates are bilaterally symmetrical coelomates with segmented bodies. The close relationship between echinoderms and chordates does not mean that one phylum evolved from the other. In fact, echinoderms and chordates have evolved independently of one another for at least 500 million years. We will trace the phylogeny of chordates in Chapter 34, focusing on the history of vertebrates.

CONCEPT CHECK 33.5

1. Describe how sea star tube feet attach to substrates.
2. Are characteristics shared by a sea star and a sea daisy homologous or analogous? Explain.
3. **WHAT IF?** The insect *Drosophila melanogaster* and the nematode *Caenorhabditis elegans* are prominent model organisms. Are these species the most appropriate invertebrates for making inferences about humans and other vertebrates in Deuterostomia? Explain.

For suggested answers, see Appendix A.

SUMMARY OF KEY CONCEPTS

The table below summarizes the groups of animals surveyed in this chapter.

Selected Animal Phyla

Key Concept	Phylum		Description
Concept 33.1 **Sponges are basal animals that lack true tissues** **(pp. 670–671)**	Calcarea, Silicea (sponges)		Lack true tissues; have choanocytes (collar cells—flagellated cells that ingest bacteria and tiny food particles)
Concept 33.2 **Cnidarians are an ancient phylum of eumetazoans** **(pp. 671–673)**	Cnidaria (hydras, jellies, sea anemones, corals)		Unique stinging structures (nematocysts) housed in specialized cells (cnidocytes); diploblastic; radially symmetrical; gastrovascular cavity (digestive compartment with a single opening)
Concept 33.3 **Lophotrochozoans, a clade identified by molecular data, have the widest range of animal body forms** **(pp. 674–682)**	Platyhelminthes (flatworms)		Dorsoventrally flattened, unsegmented acoelomates; gastrovascular cavity or no digestive tract
	Rotifera (rotifers)		Pseudocoelomates with alimentary canal (digestive tube with mouth and anus); jaws (trophi) in pharynx; head with ciliated crown
	Lophophorates: Ectoprocta, Brachiopoda		Coelomates with lophophores (feeding structures bearing ciliated tentacles)
	Mollusca (clams, snails, squids)		Coelomates with three main body parts (muscular foot, visceral mass, mantle); coelom reduced; most have hard shell made of calcium carbonate
	Annelida (segmented worms)		Coelomates with segmented body wall and internal organs (except digestive tract, which is unsegmented)
Concept 33.4 **Ecdysozoans are the most species-rich animal group** **(pp. 683–692)** **MEDIA** Investigation How Are Insect Species Identified?	Nematoda (roundworms)		Cylindrical, unsegmented pseudocoelomates with tapered ends; no circulatory system; undergo ecdysis
	Arthropoda (crustaceans, insects, spiders)		Coelomates with segmented body, jointed appendages, and exoskeleton made of protein and chitin
Concept 33.5 **Echinoderms and chordates are deuterostomes** **(pp. 693–695)** **MEDIA** Activity Characteristics of Invertebrates	Echinodermata (sea stars, sea urchins)		Coelomates with bilaterally symmetrical larvae and five-part body organization as adults; unique water vascular system; endoskeleton
	Chordata (lancelets, tunicates, vertebrates)		Coelomates with notochord; dorsal, hollow nerve cord; pharyngeal slits; post-anal tail (see Chapter 34)

Metazoa; Eumetazoa; Bilateria; Lophotrochozoa; Ecdysozoa; Deuterostomia

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which two main clades branch from the most recent common ancestor of the eumetazoans?
   a. Calcarea and Silicea
   b. Lophotrochozoa and Ecdysozoa
   c. Cnidaria and Bilateria
   d. Rotifera and Deuterostomia
   e. Deuterostomia and Bilateria

2. A land snail, a clam, and an octopus all share
   a. a mantle.
   b. a radula.
   c. gills.
   d. embryonic torsion.
   e. distinct cephalization.

3. Which phylum is characterized by animals that have a segmented body?
   a. Cnidaria
   b. Platyhelminthes
   c. Silicea
   d. Arthropoda
   e. Mollusca

4. Which of the following characteristics is probably *most* responsible for the great diversification of insects on land?
   a. segmentation
   b. antennae
   c. eyes
   d. bilateral symmetry
   e. exoskeleton

5. The water vascular system of echinoderms
   a. functions as a circulatory system that distributes nutrients to body cells.
   b. functions in locomotion, feeding, and gas exchange.
   c. is bilateral in organization, even though the adult animal is not bilaterally symmetrical.
   d. moves water through the animal's body during suspension feeding.
   e. is analogous to the gastrovascular cavity of flatworms.

6. Which of the following combinations of phylum and description is *incorrect?*
   a. Echinodermata—bilateral symmetry as a larva, coelom present
   b. Nematoda—roundworms, pseudocoelomate
   c. Cnidaria—radial symmetry, polyp and medusa body forms
   d. Platyhelminthes—flatworms, gastrovascular cavity, acoelomate
   e. Calcarea—gastrovascular cavity, coelom present

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

7. **DRAW IT** Draw a phylogenetic tree of Bilateria that includes the ten phyla of bilaterians discussed in detail in this chapter. Label each branch that leads to a phylum with a C, P, or A, depending on whether members of the phylum are coelomates (C), pseudocoelomates (P), or acoelomates (A). Use your labeled tree to answer the following questions:
   (a) For each of the three major clades of bilaterians, what (if anything) can be inferred about whether the common ancestor of the clade had a true coelom?
   (b) To what extent has the presence of a true coelom in animals changed over the course of evolution?

SCIENTIFIC INQUIRY

8. A marine biologist has dredged up an unknown animal from the seafloor. Describe some of the characteristics she should look at to determine the phylum to which the animal should be assigned.

SCIENCE, TECHNOLOGY, AND SOCIETY

9. Construction of a dam and irrigation canals in an African country has enabled farmers to increase the amount of food they can grow. In the past, crops were planted only after spring floods; the fields were too dry the rest of the year. Now fields can be watered year-round. But improved crop yields have had an unexpected cost—a tremendous increase in the incidence of schistosomiasis. Imagine that your Peace Corps assignment is to help local health officials control the disease. Reviewing the blood fluke life cycle in Figure 33.11, why do you think the irrigation project increased the incidence of schistosomiasis? It is difficult and expensive to control this disease with drugs. Suggest three other methods that could be tried to prevent people from becoming infected.

34 Vertebrates

▲ **Figure 34.1 Are humans among the descendants of this ancient organism?**

KEY CONCEPTS

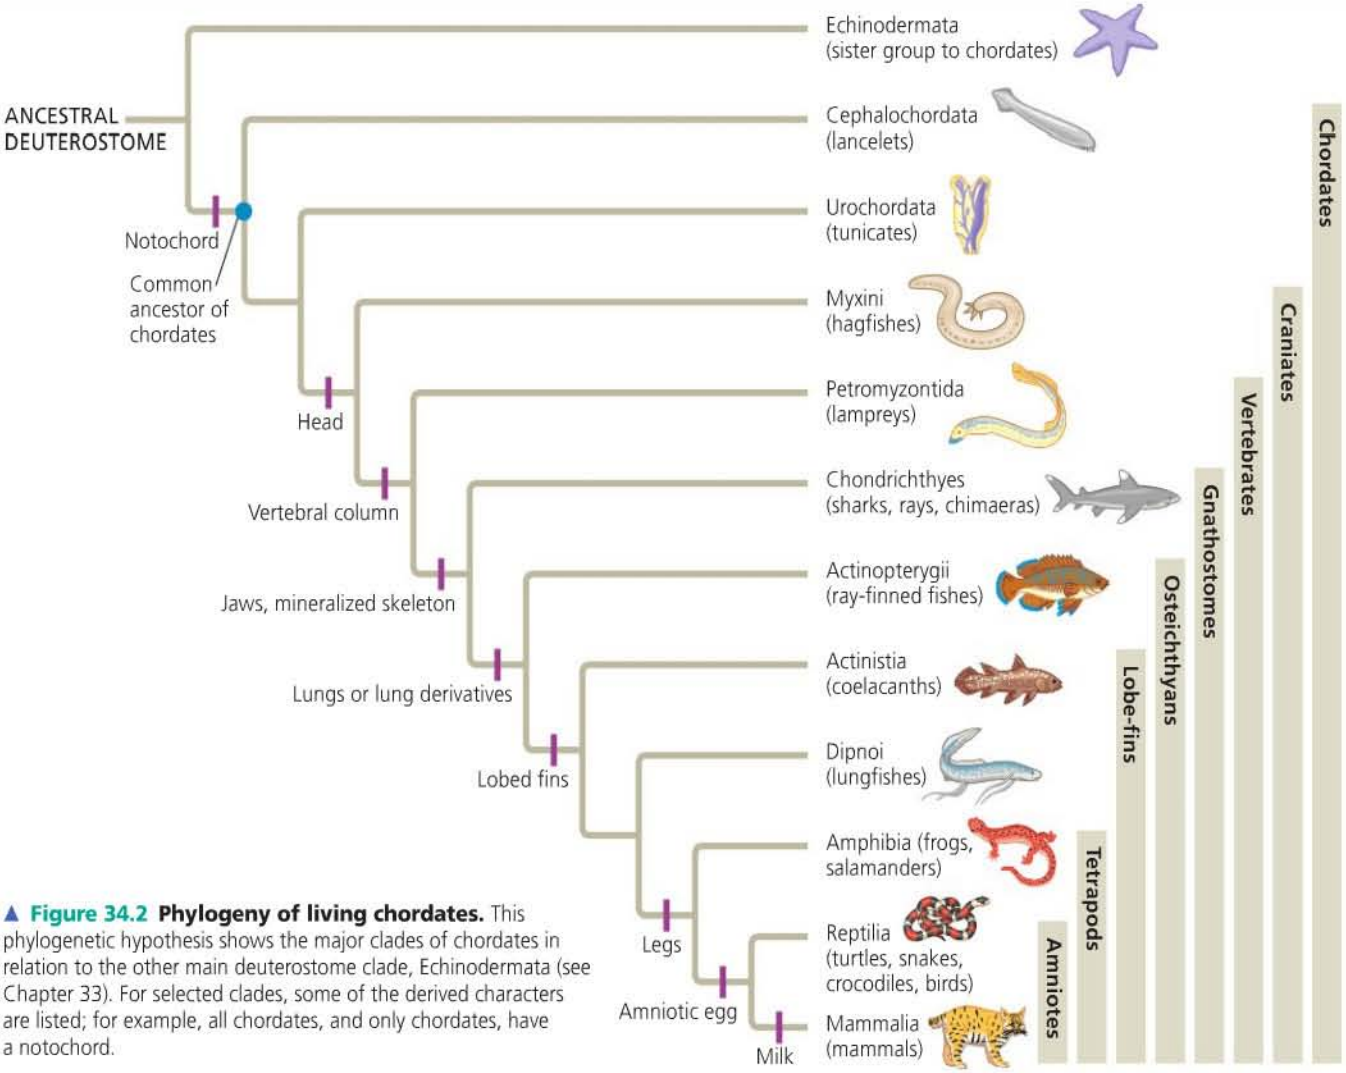
34.1 Chordates have a notochord and a dorsal, hollow nerve cord
34.2 Craniates are chordates that have a head
34.3 Vertebrates are craniates that have a backbone
34.4 Gnathostomes are vertebrates that have jaws
34.5 Tetrapods are gnathostomes that have limbs
34.6 Amniotes are tetrapods that have a terrestrially adapted egg
34.7 Mammals are amniotes that have hair and produce milk
34.8 Humans are mammals that have a large brain and bipedal locomotion

OVERVIEW

Half a Billion Years of Backbones

Early in the Cambrian period, some 530 million years ago, an immense variety of animals inhabited Earth's oceans. Predators used sharp claws and mandibles to skewer their prey. Many animals had protective spikes or armor as well as modified mouthparts that enabled their bearers to filter food from the water. Worms slithered in the bottom muck, feeding on organic matter. Amidst this bustle, it would have been easy to overlook certain slender, 3-cm-long creatures gliding through the water **(Figure 34.1)**: *Myllokunmingia fengjiaoa*. Although lacking armor and appendages, these animals would leave behind a remarkable legacy. They gave rise to one of the most successful groups of animals ever to swim, walk, slither, or fly: the **vertebrates**, which derive their name from vertebrae, the series of bones that make up the vertebral column, or backbone.

For nearly 200 million years, vertebrates were restricted to the oceans, but about 360 million years ago, the evolution of limbs in one lineage of vertebrates set the stage for these vertebrates to colonize land. There they diversified into amphibians, reptiles (including birds), and mammals.



There are approximately 52,000 species of vertebrates, a relatively small number compared to, say, the 1 million insect species on Earth. But what vertebrates lack in species diversity they make up for in *disparity*, showing a wide range of differences in characteristics such as body mass. Vertebrates include the heaviest animals ever to walk on land, plant-eating dinosaurs as massive as 40,000 kg (more than 13 pickup trucks). They also include the biggest animal ever to exist on Earth, the blue whale, which can exceed a mass of 100,000 kg. On the other end of the spectrum, a fish discovered in 2004 is just 8.4 mm long and has a mass roughly 100 billion times smaller than that of a blue whale.

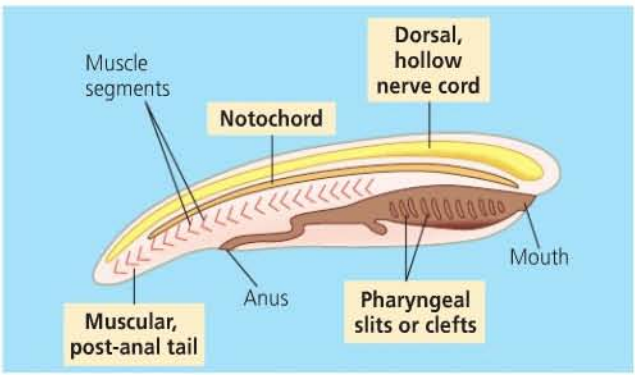
In this chapter, you will learn about current hypotheses regarding the origins of vertebrates from invertebrate ancestors. We will track the evolution of the vertebrate body plan, from a notochord to a head to a mineralized skeleton. We'll also explore the major groups of vertebrates (both living and extinct), as well as the evolutionary history of our own species.

CONCEPT 34.1

Chordates have a notochord and a dorsal, hollow nerve cord

Vertebrates are members of the phylum Chordata, the chordates. **Chordates** are bilaterian (bilaterally symmetrical) animals, and within Bilateria, they belong to the clade of animals known as Deuterostomia (see Chapter 32). The best-known deuterostomes, aside from vertebrates, are the echinoderms, the group that includes sea stars and sea urchins. However, as shown in **Figure 34.2**, two groups of invertebrate deuterostomes, the cephalochordates and the urochordates, are more closely related

▲ **Figure 34.2 Phylogeny of living chordates.** This phylogenetic hypothesis shows the major clades of chordates in relation to the other main deuterostome clade, Echinodermata (see Chapter 33). For selected clades, some of the derived characters are listed; for example, all chordates, and only chordates, have a notochord.



to vertebrates than to other invertebrates. Along with the hagfishes and the vertebrates, they make up the chordates.

Derived Characters of Chordates

All chordates share a set of derived characters, though many species possess some of these traits only during embryonic development. **Figure 34.3** illustrates four key characters of chordates: a notochord; a dorsal, hollow nerve cord; pharyngeal slits or clefts; and a muscular, post-anal tail.

Notochord

Chordates are named for a skeletal structure, the notochord, present in all chordate embryos as well as in some adult chordates. The **notochord** is a longitudinal, flexible rod located between the digestive tube and the nerve cord. It is composed of large, fluid-filled cells encased in fairly stiff, fibrous tissue. The notochord provides skeletal support throughout most of the length of a chordate, and in larvae or adults that retain it, it also provides a firm but flexible structure against which

▲ **Figure 34.3 Chordate characteristics.** All chordates possess the four highlighted structural trademarks at some point during their development.

muscles can work during swimming. In most vertebrates, a more complex, jointed skeleton develops around the ancestral notochord, and the adult retains only remnants of the embryonic notochord. In humans, the notochord is reduced to gelatinous disks sandwiched between the vertebrae.

Dorsal, Hollow Nerve Cord

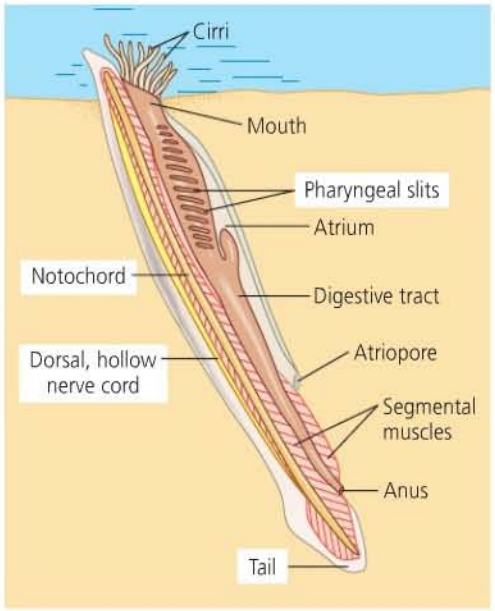
The nerve cord of a chordate embryo develops from a plate of ectoderm that rolls into a tube located dorsal to the notochord. The resulting dorsal, hollow nerve cord is unique to chordates. Other animal phyla have solid nerve cords, and in most cases they are ventrally located. The nerve cord of a chordate embryo develops into the central nervous system: the brain and spinal cord.

Pharyngeal Slits or Clefts

The digestive tube of chordates extends from the mouth to the anus. The region just posterior to the mouth is the pharynx. In all chordate embryos, a series of pouches separated by grooves forms along the sides of the pharynx. In most chordates, these grooves (known as **pharyngeal clefts**) develop into slits that open to the outside of the body. These **pharyngeal slits** allow water entering the mouth to exit the body without passing through the entire digestive tract. Pharyngeal slits function as suspension-feeding devices in many invertebrate chordates. In vertebrates (with the exception of vertebrates with limbs, the tetrapods), these slits and the structures that support them have been modified for gas exchange and are known as gill slits. In tetrapods, the pharyngeal clefts do not develop into slits. Instead, they play an important role in the development of parts of the ear and other structures in the head and neck.

Muscular, Post-Anal Tail

Chordates have a tail that extends posterior to the anus, although in many species it is greatly reduced during embryonic development. In contrast, most nonchordates have a digestive tract that extends nearly the whole length of the body. The chordate tail contains skeletal elements and muscles, and it helps propel many aquatic species in the water.



Lancelets

The animals called **lancelets** (Cephalochordata) get their name from their bladelike shape **(Figure 34.4)**. As larvae, lancelets develop a notochord, a dorsal, hollow nerve cord, numerous pharyngeal slits, and a post-anal tail. The larvae feed on plankton in the water column, alternating between upward swimming and passive sinking. As the larvae sink, they trap plankton and other suspended particles in their pharynx.

Adult lancelets can reach 5 cm in length. They retain key chordate traits, closely resembling the idealized chordate shown in Figure 34.3. Following metamorphosis, an adult lancelet swims down to the seafloor and wriggles backward into the sand, leaving only its anterior end exposed. Cilia draw seawater into the lancelet's mouth. A net of mucus secreted across the pharyngeal slits removes tiny food particles as the water passes through the slits, and the trapped food enters the intestine. The pharynx and pharyngeal slits play a minor role in gas exchange, which occurs mainly across the external body surface.

A lancelet frequently leaves its burrow to swim to a new location. Though feeble swimmers, these invertebrate chordates display, in a simple form, the swimming mechanism of fishes. Coordinated contraction of muscles arranged like rows of chevrons (<<<<) along the sides of the notochord flexes the notochord, producing side-to-side undulations that thrust the

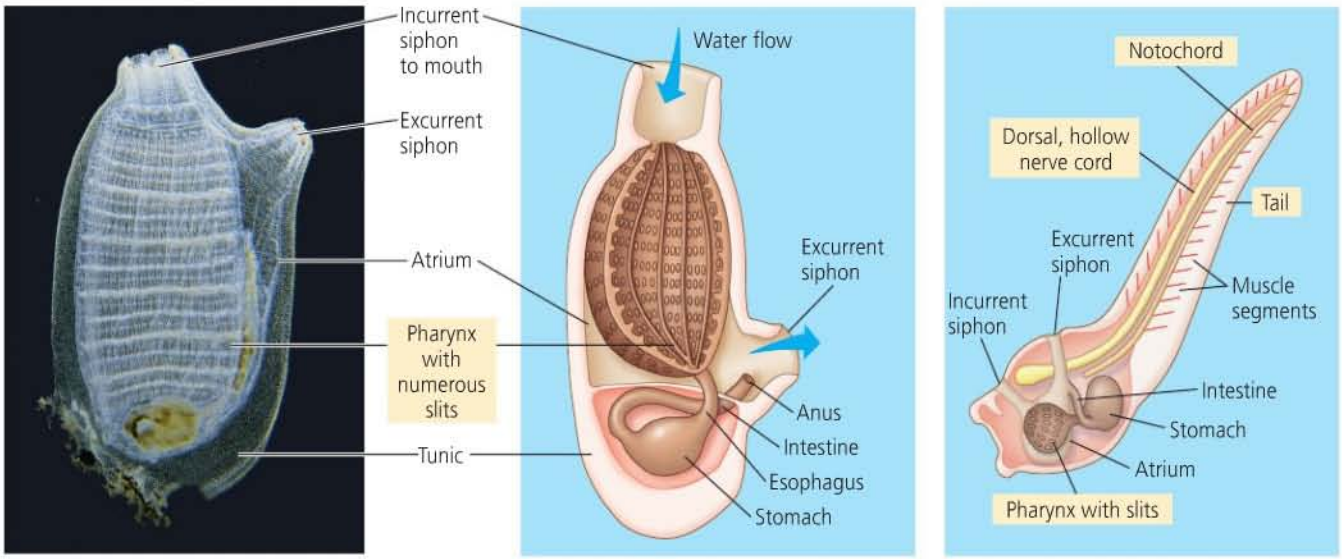
▶ **Figure 34.4 The lancelet *Branchiostoma*, a cephalochordate.** This small invertebrate displays all four main chordate characters. Water enters the mouth and passes through the pharyngeal slits into the atrium, a chamber that vents to the outside via the atriopore; large particles are blocked from entering the mouth by tentacle-like projections called cirri. Smaller food particles that enter are trapped by mucus and are swept by cilia into the digestive tract. The serially arranged segmental muscles produce the lancelet's undulatory (wavelike) swimming movements.

body forward. This serial arrangement of muscles is evidence of the lancelet's segmentation. The muscle segments develop from blocks of mesoderm called *somites*, which are found along each side of the notochord in all chordate embryos.

Globally, lancelets are rare, but in a few regions (including Tampa Bay, along the Florida coast) they occasionally reach densities in excess of 5,000 individuals per square meter.

Tunicates

Contrary to what was formerly thought, recent molecular studies suggest that the **tunicates** (Urochordata) are more closely related to other chordates than are lancelets. The chordate characters of tunicates are most apparent during their larval stage, which may be as brief as a few minutes. In many species, the larva uses its tail muscles and notochord to swim through water in search of a suitable substrate on which it can settle, guided by cues it receives from light- and gravity-sensitive cells.



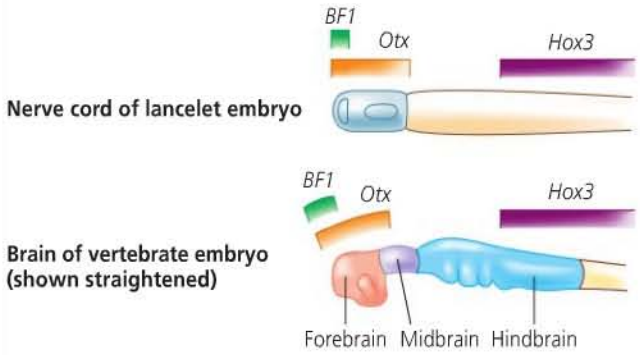
Once a tunicate has settled on a substrate, it undergoes a radical metamorphosis in which many of its chordate characters disappear. Its tail and notochord are resorbed; its nervous system degenerates; and its remaining organs rotate 90°. As an adult, a tunicate draws in water through an incurrent siphon; the water then passes through the pharyngeal slits into a chamber called the atrium and exits through an excurrent siphon **(Figure 34.5)**. Food particles are filtered from the water by a mucous net and transported by cilia to the esophagus. The anus empties into the excurrent siphon. Some tunicate species shoot a jet of water through their excurrent siphon when attacked, earning them the informal name of "sea squirts."

The degenerate adult stage of tunicates appears to have evolved only after the tunicate lineage branched off from other chordates. Even the tunicate larva appears to be highly derived, rather than a faithful reproduction of the body plan of early chordates. For example, tunicates have 9 *Hox* genes, whereas all other chordates studied to date—including the early-diverging lancelets—share a set of 13 *Hox* genes. The apparent loss of 4 *Hox* genes during their evolution indicates that tunicates have an unusual developmental program with different genetic controls than other chordates.

Early Chordate Evolution

Although lancelets and tunicates are relatively obscure animals, they occupy key positions in the history of life. Possessing many—but not all—of the derived characters shared by vertebrates, they can provide clues about the evolutionary origin of vertebrates.

As you have read, lancelets display a number of chordate characters as adults, and their lineage branches from the base of the chordate phylogenetic tree. These findings suggest that the ancestral chordate may have looked something like a lancelet—that is, it had an anterior end with a mouth; a notochord; a dorsal, hollow nerved cord; pharyngeal slits; and a post-anal tail. As for tunicates, their genome has been completely sequenced and can be used to identify genes likely to have been present in early chordates. Researchers taking this approach have suggested that ancestral chordates had genes



(a) An adult tunicate, or sea squirt, is a sessile animal (photo is approximately life-sized).

(b) In the adult, prominent pharyngeal slits function in suspension feeding, but other chordate characters are not obvious.

(c) A tunicate larva is a free-swimming but nonfeeding "tadpole" in which all four chief characters of chordates are evident.

▲ **Figure 34.5 A tunicate, a urochordate.**

▲ **Figure 34.6 Expression of developmental genes in lancelets and vertebrates.** *Hox* genes (including *BF1*, *Otx*, and *Hox3*) control the development of major regions of the vertebrate brain. These genes are expressed in the same anterior-to-posterior order in lancelets and vertebrates.

associated with vertebrate organs such as the heart and thyroid gland. These genes are found in tunicates and vertebrates but are absent from nonchordate invertebrates. In contrast, tunicates lack many genes that in vertebrates are associated with the long-range transmission of nerve impulses. This result suggests that such genes arose in an early vertebrate and are unique to the vertebrate evolutionary lineage.

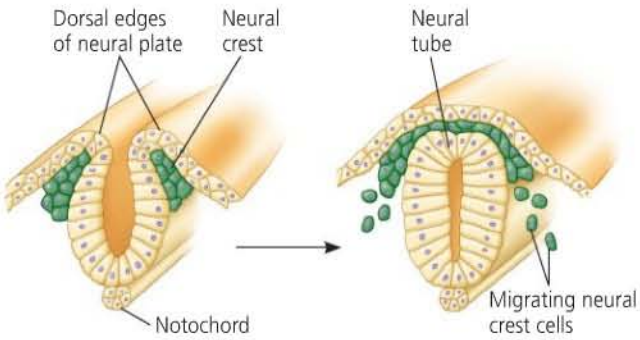
Finally, research on lancelets has revealed important clues about the evolution of the chordate brain. Rather than a full-fledged brain, lancelets have only a slightly swollen tip on the anterior end of their dorsal nerve cord. But the same *Hox* genes that organize major regions of the forebrain, midbrain, and hindbrain of vertebrates express themselves in a corresponding pattern in this small cluster of cells in the lancelet's nerve cord **(Figure 34.6)**. This suggests that the vertebrate brain is an elaboration of an ancestral structure similar to the lancelet's simple nerve cord tip.

CONCEPT CHECK 34.1

1. How do pharyngeal slits function during feeding in lancelets and tunicates?
2. You are a chordate, yet you lack most of the main derived characters of chordates. Explain.
3. **WHAT IF?** Suppose lancelets lacked a gene found in tunicates and vertebrates. Would this imply that the chordates' most recent common ancestor also lacked this gene? Explain.

For suggested answers, see Appendix A.

CONCEPT 34.2
Craniates are chordates that have a head



After the evolution of the basic chordate body plan, that seen in lancelets and tunicates, the next major transition in chordate evolution was the appearance of a head. Chordates with a head are known as **craniates** (from the word *cranium*, skull). The origin of a head—consisting of a brain at the anterior end of the dorsal nerve cord, eyes and other sensory organs, and a skull—enabled chordates to coordinate more complex movement and feeding behaviors. (Note that heads evolved independently in other animal lineages as well, as described in Chapter 33.)

Derived Characters of Craniates

Living craniates share a set of derived characters that distinguish them from other chordates. On a genetic level, they possess two clusters of *Hox* genes (lancelets and tunicates have only one). Other important families of genes that produce signaling molecules and transcription factors are also duplicated in craniates. This additional genetic complexity may have made it possible for craniates to develop more complex morphologies than those of tunicates and lancelets.

One feature unique to craniates is the **neural crest**, a collection of cells that appears near the dorsal margins of the closing neural tube in an embryo **(Figure 34.7)**. Neural crest cells disperse throughout the body, where they give rise to a variety of structures, including teeth, some of the bones and cartilage of the skull, the inner layer of skin (dermis) of the facial region, several types of neurons, and the sensory capsules in which eyes and other sense organs develop.

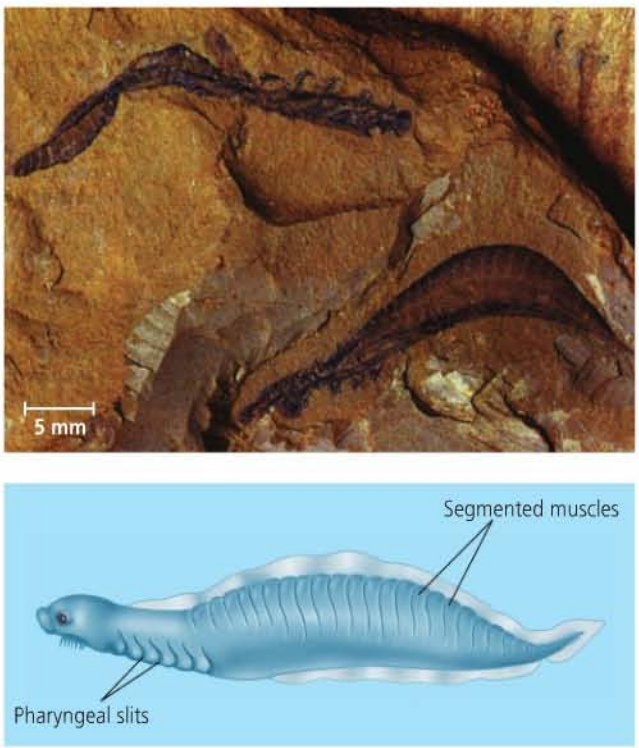
In aquatic craniates, the pharyngeal clefts evolved into gill slits. Unlike the pharyngeal slits of lancelets, which are used primarily for suspension feeding, gill slits are associated with muscles and nerves that allow water to be pumped through

(a) The neural crest consists of bilateral bands of cells near the margins of the embryonic folds that form the neural tube.

(b) Neural crest cells migrate to distant sites in the embryo.

(c) The migrating neural crest cells give rise to some of the anatomical structures unique to vertebrates, including some of the bones and cartilage of the skull.

▲ **Figure 34.7 The neural crest, embryonic source of many unique craniate characters.**



the slits. This pumping can assist in sucking in food, and it facilitates gas exchange. (In terrestrial craniates, the pharyngeal clefts develop into other structures, as we'll explain later.)

Craniates, which are more active than tunicates and lancelets, also have a higher metabolic rate and a much more extensive muscular system. Muscles lining their digestive tract aid digestion by moving food through the tract. Craniates also have a heart with at least two chambers, red blood cells with hemoglobin, and kidneys that remove waste products from the blood.

The Origin of Craniates

In the late 1990s, paleontologists working in China discovered a vast supply of fossils of early chordates that appear to straddle the transition to craniates. The fossils were formed during the Cambrian explosion 530 million years ago, when many groups of animals were diversifying (see Chapter 32).

The most primitive of the fossils are the 3-cm-long *Haikouella* **(Figure 34.8)**. In many ways, *Haikouella* resembled a lancelet. Its mouth structure indicates that, like lancelets, it probably was a suspension feeder. However, *Haikouella* also had some of the characters of craniates. For example, it had a large and well-formed brain, small eyes, and muscle segments along the body as do the vertebrate fishes. It also had respiratory gills in its pharynx, which all the more-basal chordates lack. However, *Haikouella* did not have a skull or ear organs, suggesting that these characters emerged with further innovations to the chordate nervous system.

▲ **Figure 34.8 Fossil of an early chordate.** Discovered in 1999 in southern China, *Haikouella* had eyes and a brain but lacked a skull, a derived trait of craniates. The colors in the illustration are fanciful.

In other Cambrian rocks, paleontologists have found fossils of more advanced chordates, such as *Myllokunmingia* (see Figure 34.1). About the same size as *Haikouella*, *Myllokunmingia* had ear capsules and eye capsules, parts of the skull that surround these organs. Based on these and other characters, paleontologists have identified *Myllokunmingia* as a true craniate.

Hagfishes

The least derived craniate lineage that still survives is Myxini, the hagfishes **(Figure 34.9)**. Hagfishes have a skull made of cartilage, but they lack jaws and vertebrae. They swim in a snakelike fashion by using their segmental muscles to exert force against their notochord, which they retain in adulthood as a strong, flexible rod of cartilage. Hagfishes have a small brain, eyes, ears, and a nasal opening that connects with the pharynx. Their mouths contain tooth-like formations made of the protein keratin.

All of the 30 living species of hagfishes are marine. Measuring up to 60 cm in length, most are bottom-dwelling scavengers that feed on worms and sick or dead fish. Rows of slime glands on a hagfish's flanks secrete a substance that absorbs water, forming a slime that may repulse other scavengers when a hagfish is feeding (see Figure 34.9). When attacked by a predator, a hagfish can produce several liters of slime in less than a minute. The slime coats the gills of the attacking fish, sending it into retreat or even suffocating it. Several teams of biologists and engineers are investigating the properties of hagfish slime in hopes of producing an artificial slime that could act as a space-filling gel. Such a gel might be used, for instance, to curtail bleeding during surgery.

▲ **Figure 34.9 A hagfish.**

CONCEPT CHECK 34.2

1. What characteristics do hagfishes have that lancelets and tunicates lack?
2. Which extinct chordate is more closely related to humans, *Myllokunmingia* or *Haikouella*? Explain your answer.
3. **WHAT IF?** In several different animal lineages, organisms with heads first appeared roughly 530 million years ago. Does this finding constitute proof that having a head is favored by natural selection? Explain.

For suggested answers, see Appendix A.

CONCEPT 34.3
Vertebrates are craniates that have a backbone

During the Cambrian period, a lineage of craniates gave rise to vertebrates. With a more complex nervous system and a more elaborate skeleton than those of their ancestors, vertebrates became more efficient at two essential tasks: capturing food and avoiding being eaten.

Derived Characters of Vertebrates

After vertebrates branched off from other craniates, they underwent another gene duplication, this one involving a group of transcription factor genes called the *Dlx* family. The resulting additional genetic complexity may be associated with innovations in the vertebrate nervous system and skeleton, including a more extensive skull and a backbone composed of vertebrae. In some vertebrates, the vertebrae are little more than small prongs of cartilage arrayed dorsally along the notochord. In the majority of vertebrates, however, the vertebrae enclose the spinal cord and have taken over the mechanical roles of the notochord. Aquatic vertebrates also acquired dorsal, ventral, and anal fins stiffened by fin rays, which provide thrust and steering control when swimming after prey or away from predators. Faster swimming was supported by other adaptations, including a more efficient gas exchange system in the gills.

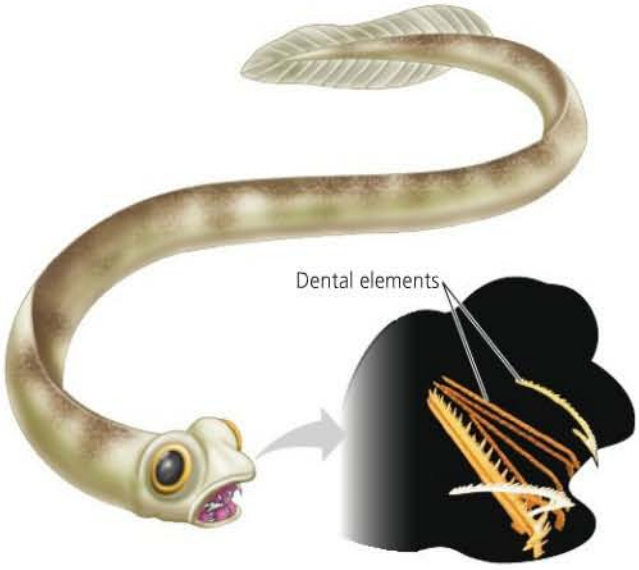
Lampreys

Lampreys (Petromyzontida) represent the oldest living lineage of vertebrates. Like hagfishes, lampreys may offer clues to early chordate evolution but have also acquired unique characters.

There are about 35 species of lampreys inhabiting various marine and freshwater environments (**Figure 34.10**). Most are parasites that feed by clamping their round, jawless mouth onto the flank of a live fish. They then use their rasping tongue to penetrate the skin of the fish and ingest the fish's blood.

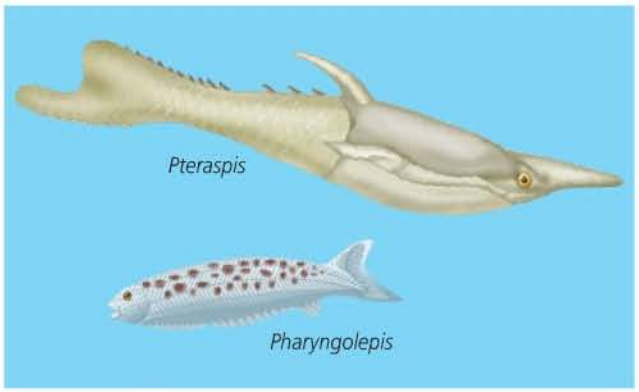
▲ **Figure 34.10 A sea lamprey.** Most lampreys use their mouth (enlarged, right) and tongue to bore a hole in the side of a fish. The lamprey then ingests the blood and other tissues of its host.

As larvae, lampreys live in freshwater streams. The larva is a suspension feeder that resembles a lancelet and spends much of its time partially buried in sediment. Some species of lampreys feed only as larvae; following several years in streams, they mature sexually, reproduce, and die within a few days. Most lampreys, however, migrate to the sea or lakes as they mature into adults. Sea lampreys (*Petromyzon marinus*) have invaded the Great Lakes over the past 170 years and have devastated a number of fisheries there.



The skeleton of lampreys is made of cartilage. Unlike the cartilage found in most vertebrates, lamprey cartilage contains no collagen. Instead, it is a stiff protein matrix. The notochord of lampreys persists as the main axial skeleton in the adult, as it does in hagfishes. However, lampreys also have a cartilaginous pipe around their rodlike notochord. Along the length of this pipe, pairs of cartilaginous projections related to vertebrae extend dorsally, partially enclosing the nerve cord.

Fossils of Early Vertebrates



After the ancestors of lampreys branched off from other vertebrates during the Cambrian period, many other lineages of vertebrates emerged. Like lampreys, the early members of these lineages lacked jaws, but the resemblance stopped there.

Conodonts were slender, soft-bodied vertebrates with prominent eyes controlled by numerous muscles. At the anterior end of their mouth, they had a set of barbed hooks made of dental tissues that were *mineralized* (composed of minerals such as calcium that provide rigidity) (**Figure 34.11**). Most conodonts were 3–10 cm in length, although some may have been as long as 30 cm. They probably hunted with the help of their large eyes, impaling prey on their mouth hooks. The food was then passed back to the pharynx, where a different set of dental elements sliced and crushed the food.

Conodonts were extremely abundant for over 300 million years. Their fossilized dental elements are so plentiful that they

▲ **Figure 34.11 A conodont.** Conodonts were early vertebrates that lived from the late Cambrian until the late Triassic. Unlike lampreys, conodonts had mineralized mouthparts, which they used for either predation or scavenging.

▲ **Figure 34.12 Jawless armored vertebrates.** *Pteraspis* and *Pharyngolepis* were two of many genera of jawless vertebrates that emerged during the Ordovician, Silurian, and Devonian periods.

have been used for decades by petroleum geologists as guides to the age of rock layers in which they search for oil. (These elements also gave conodonts their name, which means "cone teeth.")

Vertebrates with additional innovations emerged during the Ordovician, Silurian, and Devonian periods. These vertebrates had paired fins and an inner ear with two semicircular canals that provided a sense of balance. Although they, too, lacked jaws, they had a muscular pharynx, which they may have used to suck in bottom-dwelling organisms or detritus. They were also armored with mineralized bone, which covered varying amounts of their body **(Figure 34.12)**. The armor, which in some species included spines, may have offered protection from predators. Although there were many species of these jawless, armored swimming vertebrates, they all became extinct by the end of the Devonian period.

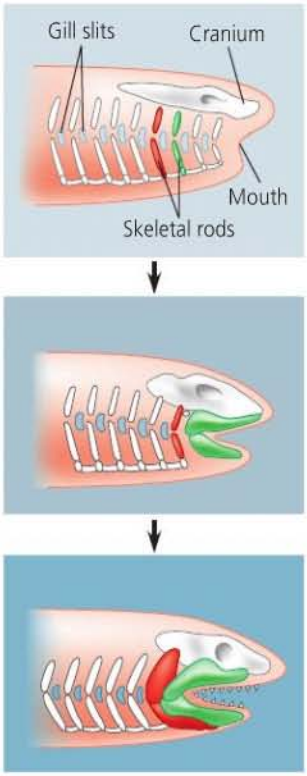
Origins of Bone and Teeth

The human skeleton is heavily mineralized bone, whereas cartilage plays a fairly minor role. But this was a later development in the history of vertebrates. As we've seen, the vertebrate skeleton evolved initially as a structure made of unmineralized cartilage. Its mineralization began only after lampreys diverged from other vertebrates.

What initiated the process of mineralization in vertebrates? One hypothesis is that mineralization was associated with a transition in feeding mechanisms. Early chordates probably were suspension feeders, like lancelets, but over time they became larger and were therefore able to ingest larger particles, including some small animals. The earliest known mineralized structures in vertebrates—conodont dental elements—were an adaptation that may have allowed these animals to become scavengers and predators. The armor seen in later jawless vertebrates was derived from dental mineralization. Thus, mineralization of the vertebrate body may have begun in the mouth. Only in more derived vertebrates did the endoskeleton begin to mineralize, starting with the skull. As you'll learn in the next section, more recent lineages of vertebrates underwent even further mineralization.

CONCEPT CHECK 34.3

1. How are differences in the anatomy of lampreys and conodonts reflected in each animal's feeding method?
2. **WHAT IF?** Suggest key roles that mineralized bone might have played in early vertebrates.



For suggested answers, see Appendix A.

CONCEPT 34.4 Gnathostomes are vertebrates that have jaws

Hagfishes and lampreys are survivors from the early Paleozoic era, when jawless craniates were common. Since then, jawless vertebrates have been far outnumbered by jawed vertebrates, known as **gnathostomes**. Living gnathostomes are a diverse group that includes sharks and their relatives, ray-finned fishes, lobe-fins, amphibians, reptiles (including birds), and mammals.

Derived Characters of Gnathostomes

Gnathostomes ("jaw mouth") are named for their jaws, hinged structures that, especially with the help of teeth, enable gnathostomes to grip food items firmly and slice them. According to one hypothesis, gnathostome jaws evolved by modification of the skeletal rods that had previously supported the

▶ **Figure 34.13 Hypothesis for the evolution of vertebrate jaws.** The skeleton of the jaws and their supports may have evolved from two pairs of skeletal rods (red and green) located between gill slits near the mouth. Pairs of rods anterior to those that formed the jaws were either lost or incorporated into the cranium or jaws.

▲ **Figure 34.14 Fossil of an early gnathostome.** The placoderm *Dunkleosteus* grew up to 10 m in length. A 2006 analysis of its jaw structure concluded that *Dunkleosteus* could exert a force of 8,000 pounds per square inch at the tip of its jaws.

anterior pharyngeal (gill) slits **(Figure 34.13)**. The remaining gill slits, no longer required for suspension feeding, remained as the major sites of respiratory gas exchange with the external environment.

Gnathostomes share other derived characters besides jaws. The common ancestors of all gnathostomes underwent an additional duplication of *Hox* genes, such that the single cluster present in early chordates became four. Other gene clusters also duplicated, and together these genetic changes probably allowed further complexity in the development of gnathostome embryos. The gnathostome forebrain is enlarged compared to that of other craniates, mainly in association with enhanced senses of smell and vision. An additional characteristic of aquatic gnathostomes (early versions of which were present in the head shields of some jawless vertebrates) is the **lateral line system**. These organs, which form a row along each side of the body, are sensitive to vibrations in the surrounding water.

Fossil Gnathostomes

Gnathostomes appeared in the fossil record in the mid-Ordovician period, about 470 million years ago, and steadily became more diverse. Their success probably lies in two features of their anatomy: Their paired fins and tail allowed them to swim efficiently after prey, and their jaws enabled them to grab prey or simply bite off chunks of flesh.

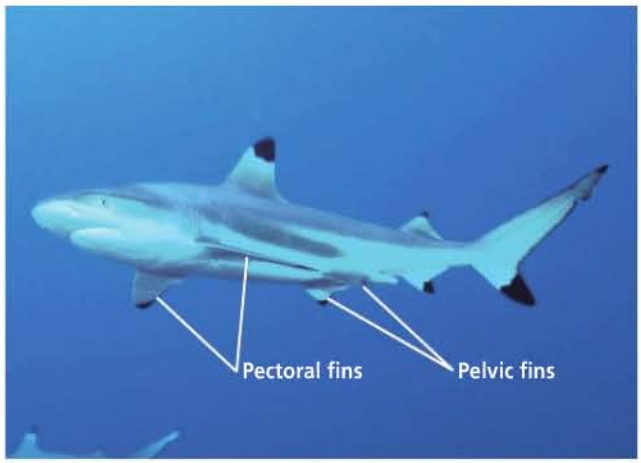
The earliest gnathostomes in the fossil record are an extinct lineage of armored vertebrates called **placoderms**, which means "plate-skinned." Most placoderms were less than a meter long, though some giants measured more than 10 m **(Figure 34.14)**. Another group of jawed vertebrates called **acanthodians** radiated during the Devonian period, and many new forms evolved in fresh and salt water. Acanthodians had disappeared by the end of the Devonian period, about 360 million years ago, and placoderms became extinct a few million years later, early in the Carboniferous.

Chondrichthyans (Sharks, Rays, and Their Relatives)

Sharks, rays, and their relatives include some of the biggest and most successful vertebrate predators in the oceans. They belong to the clade Chondrichthyes, which means "cartilage fish." As their name indicates, the **chondrichthyans** have a skeleton composed predominantly of cartilage, though often impregnated with calcium.

When the name Chondrichthyes was first coined in the 1800s, scientists thought that chondrichthyans represented an early stage in the evolution of the vertebrate skeleton and that mineralization had evolved only in more derived lineages (such as "bony fishes"). However, as conodonts and armored jawless vertebrates demonstrate, the mineralization of the vertebrate

skeleton had already begun before the chondrichthyan lineage branched off from other vertebrates. Moreover, bonelike tissues have been found in early chondrichthyans, such as the fin skeleton of a shark that lived in the Carboniferous period. Traces of bone can also be found in living chondrichthyans—in their scales, at the base of their teeth, and, in some sharks, in a thin layer on the surface of their vertebrae. Such findings strongly suggest that the restricted distribution of bone in the chondrichthyan body is a derived condition, emerging after chondrichthyans diverged from other gnathostomes.

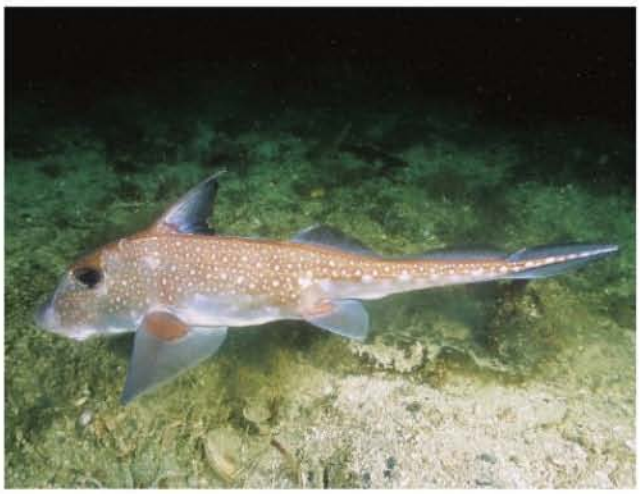


There are about 750 species of living chondrichthyans. The largest and most diverse group consists of the sharks, rays, and skates **(Figure 34.15a** and **b)**. A second group is composed of a few dozen species of ratfishes, or chimaeras **(Figure 34.15c)**.

Most sharks have a streamlined body and are swift swimmers, but they do not maneuver very well. Powerful movements of the trunk and the caudal (tail) fin propel them forward. The dorsal fins function mainly as stabilizers, and the paired pectoral (fore) and pelvic (hind) fins provide lift when the shark swims. Although a shark gains buoyancy by storing a large amount of oil in its huge liver, the animal is still more dense than water, and if it stops swimming it sinks. Continual swimming also ensures that water flows into the shark's mouth and out through the gills, where gas exchange occurs (sharks do not have lungs). However, some sharks and many skates and rays spend a good deal of time resting on the seafloor. When resting, they use muscles of their jaws and pharynx to pump water over the gills.

The largest sharks and rays are suspension feeders that consume plankton. Most sharks, however, are carnivores that swallow their prey whole or use their powerful jaws and sharp teeth to tear flesh from animals too large to swallow in one piece. Sharks have several rows of teeth that gradually move to the front of the mouth as old teeth are lost. The digestive tract of many sharks is proportionately shorter than that of many other vertebrates. Within the shark intestine is a *spiral valve*, a corkscrew-shaped ridge that increases surface area and prolongs the passage of food through the digestive tract.

Acute senses are adaptations that go along with the active, carnivorous lifestyle of sharks. Sharks have sharp vision but cannot distinguish colors. The nostrils of sharks, like those of most aquatic vertebrates, open into dead-end cups. They function only for olfaction (smelling), not for breathing. Sharks also have a pair of regions in the skin of their head that can detect electric fields generated by the muscle contractions of nearby animals. Like all (nonmammalian) aquatic vertebrates, sharks have no eardrums, structures that terrestrial vertebrates use to transmit sound waves in air to the auditory organs. Sound reaches a shark through water, and the animal's entire body transmits the sound to the hearing organs of the inner ear.



Shark eggs are fertilized internally. The male has a pair of claspers on its pelvic fins that transfer sperm into the reproductive tract of the female. Some species of sharks are **oviparous**; they lay eggs that hatch outside the mother's body. These sharks

(a) Blacktip reef shark (*Carcharhinus melanopterus*). Fast swimmers with acute senses, sharks have paired pectoral and pelvic fins.

(b) Southern stingray (*Dasyatis americana*). Most rays are bottom-dwellers that feed on molluscs and crustaceans. Some rays cruise in open water and scoop food into their gaping mouth.

(c) Spotted ratfish (*Hydrolagus colliei*). Ratfishes, or chimaeras, typically live at depths greater than 80 m and feed on shrimps, molluscs, and sea urchins. Some species have a poisonous spine at the front of their first dorsal fin.

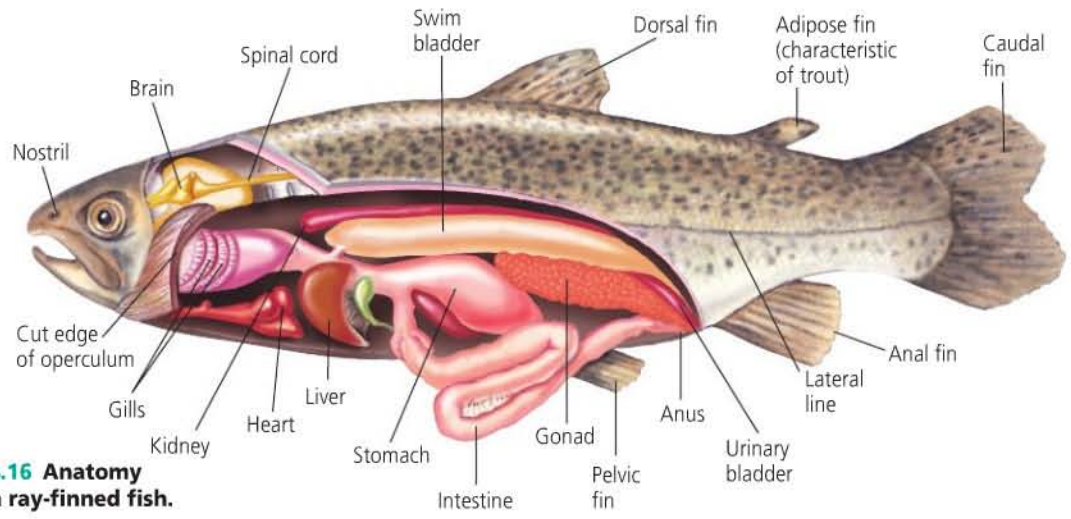
▲ **Figure 34.15 Chondrichthyans.**

release their eggs after encasing them in protective coats. Other species are **ovoviviparous**; they retain the fertilized eggs in the oviduct. Nourished by the egg yolk, the embryos develop into young that are born after hatching within the uterus. A few species are **viviparous**; the young develop within the uterus and obtain nourishment prior to birth by receiving nutrients from the mother's blood through a yolk sac placenta, by absorbing a nutritious fluid produced by the uterus, or by eating other eggs. The reproductive tract of the shark empties along with the excretory system and digestive tract into the **cloaca**, a common chamber that has a single opening to the outside.

Although rays are closely related to sharks, they have adopted a very different lifestyle. Most rays are bottom-dwellers that feed by using their jaws to crush molluscs and crustaceans. They have a flattened shape and use their greatly enlarged pectoral fins like water wings to propel themselves through the water. The tail of many rays is whiplike and, in some species, bears venomous barbs that function in defense.

Morphologically, chondrichthyans have changed little in over 300 million years. Today, however, they are severely threatened with overfishing: A recent report indicated that shark stocks in the northwest Atlantic had declined 75% over a 15-year period.

Ray-Finned Fishes and Lobe-Fins



The vast majority of vertebrates belong to the clade of gnathostomes called Osteichthyes. Like many other taxonomic names, the name Osteichthyes ("bony fish") was coined long before the advent of phylogenetic systematics. When it was originally defined, the group excluded tetrapods, but we now know that such a taxon would actually be paraphyletic (see Figure 34.2). Therefore, systematists today include tetrapods along with bony fishes in the clade Osteichthyes. Clearly, the name of the group does not accurately describe all of its members.

Unlike chondrichthyans, nearly all living **osteichthyans** have an ossified (bony) endoskeleton with a hard matrix of calcium phosphate. As discussed earlier, several lines of evidence suggest that the common ancestor of both chondrichthyans and osteichthyans was already highly ossified and that chondrichthyans subsequently lost much of this bone. However, some scientists dispute this conclusion, and until more fossils of early chondrichthyans and osteichthyans are unearthed, the question will remain open.

In this section, we'll discuss the aquatic osteichthyans known informally as fishes. Most fishes breathe by drawing water over four or five pairs of gills located in chambers covered by a protective bony flap called the **operculum** (Figure 34.16). Water is drawn into the mouth, through the pharynx, and out between the gills by movement of the operculum and contraction of muscles surrounding the gill chambers.

Most fishes can control their buoyancy with an air sac known as a **swim bladder**. Movement of gases from the blood to the swim bladder increases buoyancy, making the animal rise; transfer of gas back to the blood causes the animal to sink. Charles Darwin proposed that the lungs of tetrapods evolved from swim bladders, but, strange as it may sound, the opposite seems to be true. Osteichthyans in many early-branching lineages have lungs, which they use to breathe air as a supplement to gas exchange in their gills. The weight of evidence indicates that lungs arose in early osteichthyans; later, swim bladders evolved from lungs in some lineages.

In nearly all fishes, the skin is covered by flattened, bony scales that differ in structure from the tooth-like scales of sharks. Glands in the skin secrete a slimy mucus over the skin, an adaptation that reduces drag during swimming. Like the ancient aquatic gnathostomes mentioned earlier, fishes have a lateral line system, which is evident as a row of tiny pits in the skin on either side of the body.

▲ **Figure 34.16 Anatomy of a trout, a ray-finned fish.**

The details of fish reproduction vary extensively. Most species are oviparous, reproducing by external fertilization after the female sheds large numbers of small eggs. However, internal fertilization and birthing characterize other species.

Ray-Finned Fishes

Nearly all the aquatic osteichthyans familiar to us are among the over 27,000 species of **ray-finned fishes** (Actinopterygii) **(Figure 34.17)**. The fins, supported mainly by bony rays for which the group is named, are modified for maneuvering, defense, and other functions.

(a) Yellowfin tuna (*Thunnus albacares*), a fast-swimming, schooling fish that is commercially important worldwide

(b) Clownfish (*Amphiprion ocellaris*), a mutualistic symbiont of sea anemones

(c) Sea horse (*Hippocampus ramulosus*), unusual in the animal kingdom in that the male carries the young during their embryonic development

(d) Fine-spotted moray eel (*Gymnothorax dovii*), a predator that ambushes prey from crevices in its coral reef habitat

▲ **Figure 34.17 Ray-finned fishes (class Actinopterygii).**

Ray-finned fishes appear to have originated in fresh water and spread to the seas. (Adaptations that address the osmotic problems associated with the move to salt water are discussed in Chapter 44.) Numerous species of ray-finned fishes returned to fresh water at some point in their evolution. Some of them, including salmon and certain trout, replay their evolutionary round-trip from fresh water to seawater and back to fresh water during their life cycle.

Ray-finned fishes serve as a major source of protein for humans, who have harvested them for thousands of years. However, industrial-scale fishing operations appear to have driven some of the world's biggest fisheries to collapse. For example, after decades of abundant harvests, in the 1990s the catch of cod (*Gadus morhua*) in the northwest Atlantic plummeted to just 5% of its historic maximum, bringing codfishing there to a near halt. Despite ongoing restrictions on the fishery, cod populations have yet to recover to sustainable levels. Ray-finned fishes also face other pressures from humans, such as the diversion of rivers by dams. Changing water flow patterns can hamper the fishes' ability to obtain food and interferes with migratory pathways and spawning grounds.

Lobe-Fins

Ray-finned fishes evolved during the Devonian period, along with another major lineage of osteichthyans, the **lobe-fins** (Sarcopterygii). The key derived character of lobe-fins is the presence of rod-shaped bones surrounded by a thick layer of muscle in their pectoral and pelvic fins. During the Devonian, many lobe-fins lived in brackish waters, such as in coastal wetlands. There they probably used their lobed fins to swim and "walk" underwater across the substrate. Some Devonian lobe-fins were gigantic predators. It is not uncommon to find spike-shaped fossils of Devonian lobe-fin teeth as big as your thumb.

By the end of the Devonian period, lobe-fin diversity was dwindling, and today only three lineages survive. One lineage, the coelacanths (Actinistia), was thought to have become extinct 75 million years ago **(Figure 34.18)**. However,

▲ **Figure 34.18 A coelacanth (*Latimeria*).** These lobe-fins were found living off the coasts of southern Africa and Indonesia.

in 1938, fishermen caught a living coelacanth off the Comoros Islands in the western Indian Ocean. Coelacanths were found only in that area until 1999, when a second population was identified in the eastern Indian Ocean, near Indonesia. The Indonesian population may represent a second species.

The second lineage of living lobe-fins, the lungfishes (Dipnoi), is represented today by six species in three genera, all of which are found in the Southern Hemisphere. Lungfishes evolved in the ocean but today are found only in fresh water, generally in stagnant ponds and swamps. They surface to gulp air into lungs connected to their pharynx. Lungfishes also have gills, which are the main organs for gas exchange in Australian lungfishes. When ponds shrink during the dry season, some lungfishes can burrow into the mud and estivate (wait in a state of torpor; see Chapter 40).

The third lineage of lobe-fins that survives today is far more diverse than the coelacanths or the lungfishes. During the mid-Devonian, these organisms adapted to life on land and gave rise to vertebrates with limbs and feet, called tetrapods—a lineage that includes humans. The tetrapod clade is the topic of the next section.

CONCEPT CHECK 34.4

1. What derived characters do sharks and tuna share? What are some characteristics that distinguish tuna from sharks?
2. Describe key adaptations of aquatic gnathostomes.
3. **WHAT IF?** Imagine we could replay the history of life. Is it possible that a group of vertebrates that colonized land could have arisen from aquatic gnathostomes other than the lobe-fins? Explain.

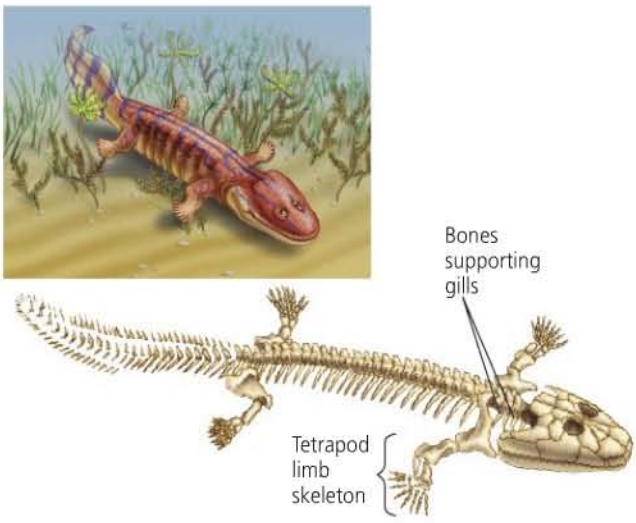
For suggested answers, see Appendix A.

CONCEPT 34.5
Tetrapods are gnathostomes that have limbs

One of the most significant events in vertebrate history took place about 360 million years ago, when the fins of some lobe-fins evolved into the limbs and feet of tetrapods. Until then, all vertebrates had shared the same basic fishlike anatomy. After tetrapods moved onto land, they took on many new forms, from leaping frogs to flying eagles to bipedal humans.

Derived Characters of Tetrapods

The most significant character of **tetrapods** gives the group its name, which means "four feet" in Greek. In place of pectoral and pelvic fins, tetrapods have limbs that can support their weight on land and feet with digits that allow them to transmit muscle-generated forces to the ground when they walk.



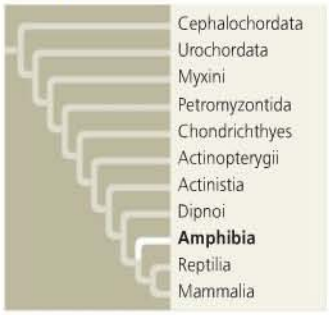
Life on land brought numerous other changes to the tetrapod body plan. In tetrapods, the head is separated from the body by a neck that originally had one vertebra on which the skull could move up and down. Later, with the origin of a second vertebra in the neck, the head could also swing from side to side. The bones of the pelvic girdle, to which the hind legs are attached, are fused to the backbone, permitting forces generated by the hind legs against the ground to be transferred to the rest of the body. Living tetrapods do not have gill slits; during embryonic development, the pharyngeal clefts instead give rise to parts of the ears, certain glands, and other structures.

As you will see, some of these characters were dramatically altered or lost in various lineages of tetrapods. In birds, for example, the pectoral limbs became wings, and in whales, the entire body converged toward a fishlike shape.

The Origin of Tetrapods

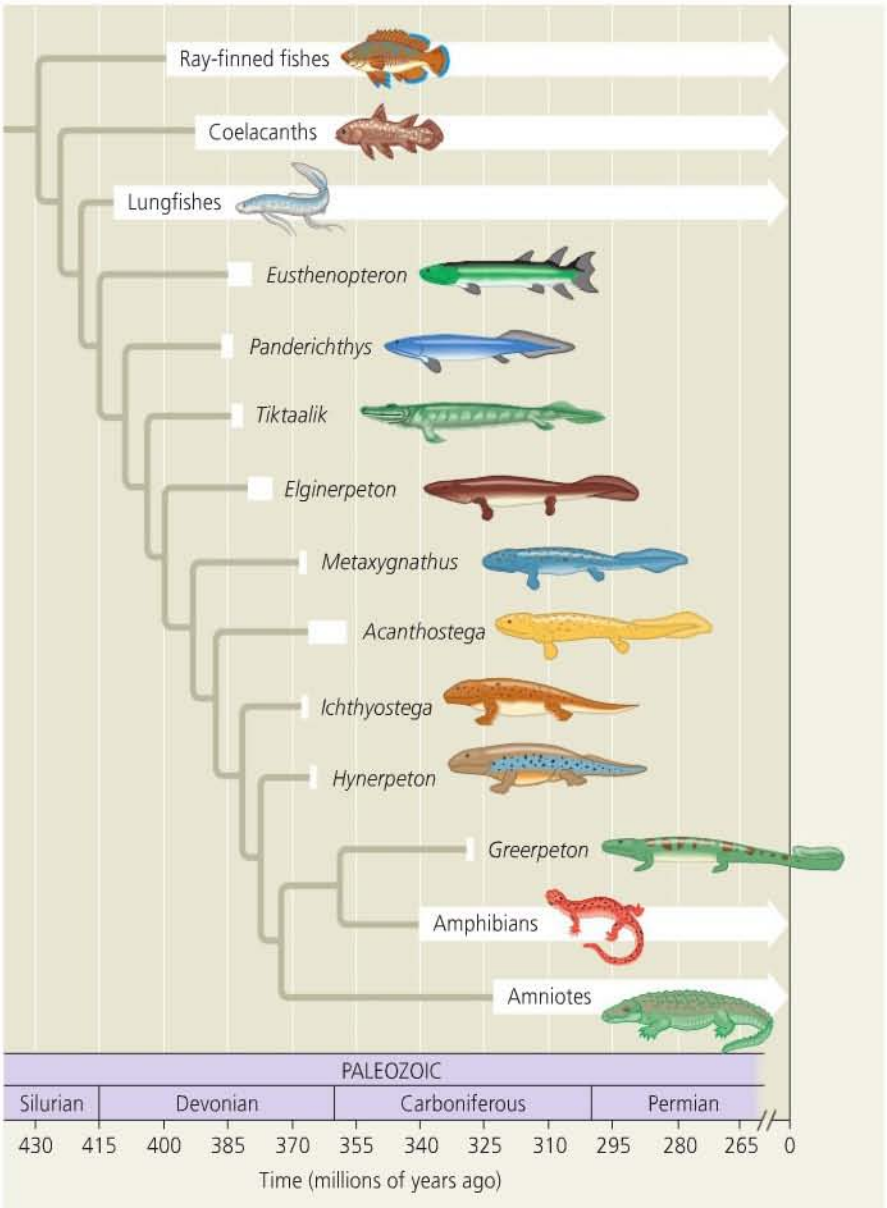
As you have read, the Devonian coastal wetlands were home to a wide range of lobe-fins. Those that entered particularly shallow, oxygen-poor water could use their lungs to breathe air. Some species probably used their stout fins to help them move across logs or the muddy bottom. Thus, the tetrapod body plan did not evolve "out of nowhere" but was simply a modification of a preexisting body plan.

In one lineage of lobe-fins, the fins became progressively more limb-like while the rest of the body retained adaptations for aquatic life. Consider *Acanthostega*, which lived in Greenland 365 million years ago and had fully formed legs, ankles, and digits **(Figure 34.19)**. This species was a close relative of tetrapods, yet it also retained adaptations for the water. It had



▲ **Figure 34.19 *Acanthostega*, a Devonian relative of tetrapods.** Along with the derived appendages of tetrapods, *Acanthostega* retained primitive aquatic adaptations, such as gills.

bones that supported gills, and its tail contained rays supporting a delicate fin that propelled it through water. Its pectoral and pelvic girdles and vertebrae were too weak to carry its body on land: *Acanthostega* may have slithered out of the water from time to time, but for the most part it was aquatic.



Extraordinary fossil discoveries over the past 20 years have allowed paleontologists to reconstruct with confidence the origin of tetrapods **(Figure 34.20)**. A great diversity of tetrapods emerged during the Devonian and Carboniferous periods, and some species reached 2 m in length. Judging from the morphology and locations of their fossils, most of these early tetrapods probably remained tied to the water, a feature they share with some members of a group of living tetrapods called amphibians.

Amphibians

The **amphibians** (class Amphibia) are represented today by about 6,150 species of salamanders (order Urodela, "tailed ones"), frogs (order Anura, "tail-less ones"), and caecilians (order Apoda, "legless ones").

There are only about 550 species of urodeles. Some are entirely aquatic, but others live on land as adults or throughout life. Most salamanders that live on land walk with

◀ **Figure 34.20 The origin of tetrapods.** The white bars on the branches of this diagram place known fossils in time; arrowheads indicate lineages that extend to today. The drawings of extinct forms are based on fossilized skeletons, but the colors are fanciful.

WHAT IF? *If the most recent common ancestor of* Hynerpeton *and later tetrapods originated 380 million years ago, what range of dates would include the origin of amphibians?*

(a) Order Urodela. Urodeles (salamanders) retain their tail as adults.

(b) Order Anura. Anurans, such as this poison dart frog, lack a tail as adults.

(c) Order Apoda. Apodans, or caecilians, are legless, mainly burrowing amphibians.

▲ **Figure 34.21 Amphibians.**

a side-to-side bending of the body, a trait inherited from the early terrestrial tetrapods **(Figure 34.21a)**. Paedomorphosis is common among aquatic salamanders; the axolotl, for instance, retains larval features even when it is sexually mature (see Figure 25.20).

Anurans, numbering about 5,420 species, are more specialized than urodeles for moving on land **(Figure 34.21b)**. Adult frogs use their powerful hind legs to hop along the terrain. A frog nabs insects and other prey by flicking out its long, sticky tongue, which is attached to the front of the mouth. Frogs display a great variety of adaptations that help them avoid being eaten by larger predators. Their skin glands secrete distasteful or even poisonous mucus. Many poisonous species have bright coloration, which predators apparently associate with danger (see Figure 54.5b). Other frogs have color patterns that camouflage them (see Figure 54.5a).

Apodans, the caecilians (about 170 species), are legless and nearly blind, and superficially they resemble earthworms **(Figure 34.21c)**. Their absence of legs is a secondary adaptation, as they evolved from a legged ancestor. Caecilians inhabit tropical areas, where most species burrow in moist forest soil. A few South American species live in freshwater ponds and streams.

Amphibian (derived from *amphibious,* meaning "both ways of life") refers to the life stages of many frog species that live first in water and then on land **(Figure 34.22)**. The larval stage of a frog, called a tadpole, is usually an aquatic herbivore with gills, a lateral line system resembling that of aquatic vertebrates, and a long, finned tail. The tadpole initially lacks

(a) The tadpole is an aquatic herbivore with a fishlike tail and internal gills.

(b) During metamorphosis, the gills and tail are resorbed, and walking legs develop. The adult frog will live on land.

(c) The adults return to water to mate. The male grasps the female, stimulating her to release eggs. The eggs are laid and fertilized in water. They have a jelly coat but lack a shell and would desiccate in air.

▲ **Figure 34.22 The "dual life" of a frog (*Rana temporaria*).**

legs; it swims by undulating its tail. During the metamorphosis that leads to the "second life," the tadpole develops legs, lungs, a pair of external eardrums, and a digestive system adapted to a carnivorous diet. At the same time, the gills disappear; the lateral line system also disappears in most species. The young frog crawls onto shore and becomes a terrestrial hunter. In spite of their name, however, many amphibians do not live a dual—aquatic and terrestrial—life. There are some strictly aquatic or strictly terrestrial frogs, salamanders, and caecilians. Moreover, salamander and caecilian larvae look much like the adults, and typically both the larvae and the adults are carnivorous.

Most amphibians are found in damp habitats such as swamps and rain forests. Even those adapted to drier habitats spend much of their time in burrows or under moist leaves, where humidity is high. Amphibians generally rely heavily on their moist skin for gas exchange with the environment. Some terrestrial species lack lungs and breathe exclusively through their skin and oral cavity.

Fertilization is external in most amphibians; the male grasps the female and spills his sperm over the eggs as the female sheds them (see Figure 34.22c). Amphibians typically lay their eggs in water or in moist environments on land. The eggs lack a shell and dehydrate quickly in dry air. Some amphibian species lay vast numbers of eggs in temporary pools, and egg mortality is high. In contrast, other species lay relatively few eggs and display various types of parental care. Depending on the species, either males or females may house eggs on their back **(Figure 34.23)**, in their mouth, or even in their stomach. Certain tropical tree frogs stir their egg masses into moist, foamy nests that resist drying. There are also some ovoviviparous and viviparous species that retain the eggs in the female reproductive tract, where embryos can develop without drying out.

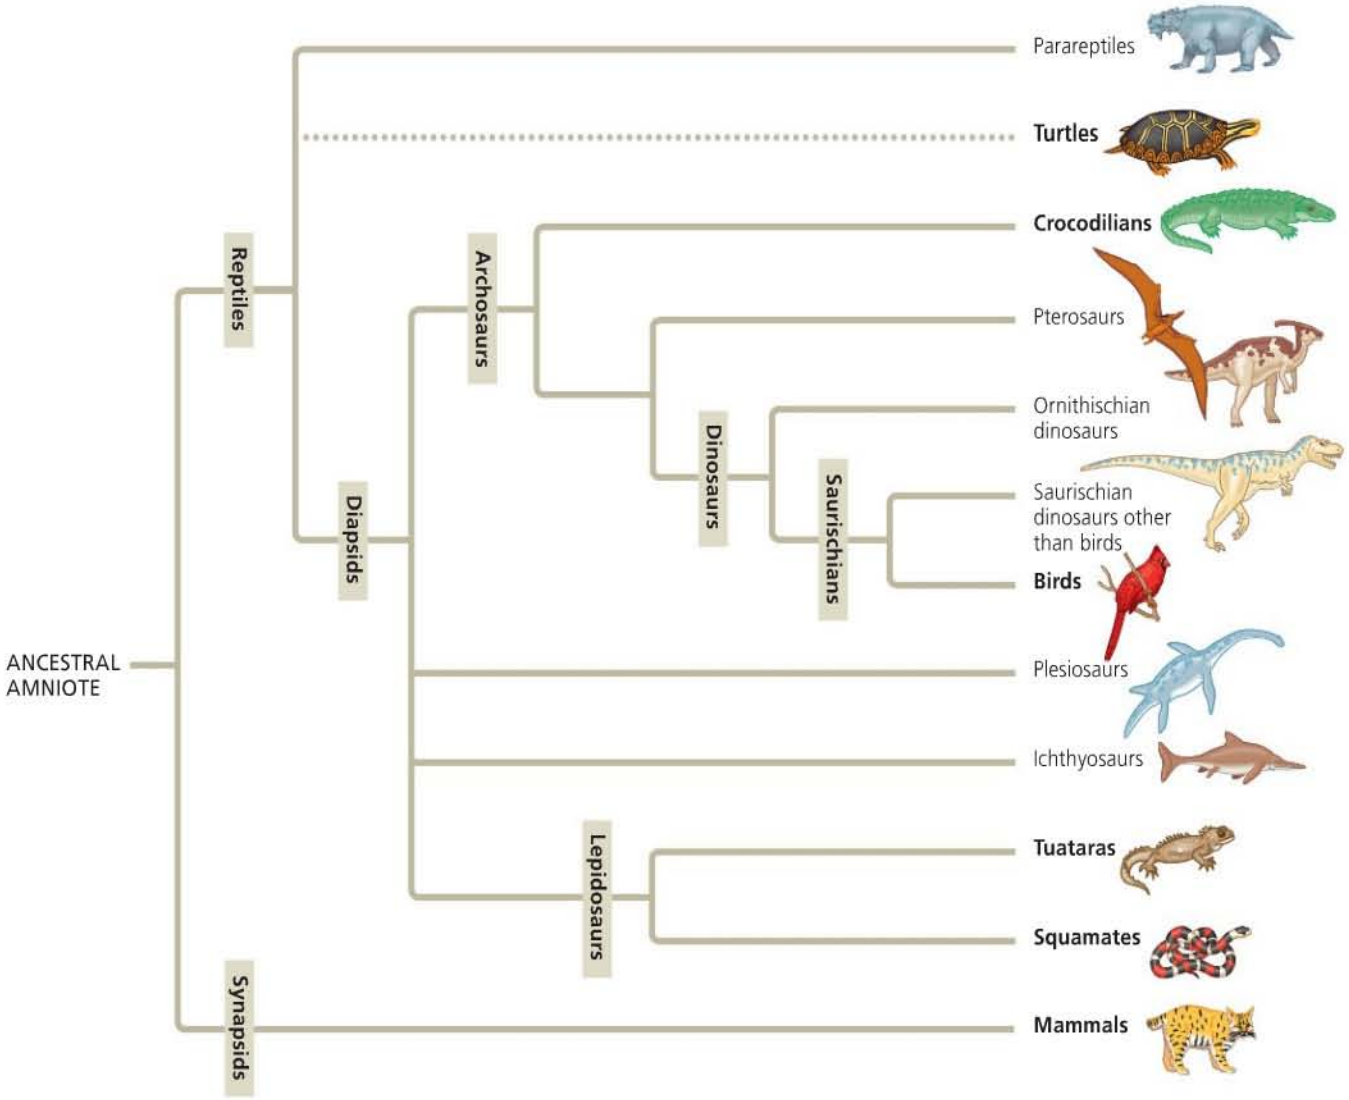
▲ **Figure 34.23 A mobile nursery.** A female pygmy marsupial frog, *Flectonotus pygmaeus,* incubates her eggs in a pouch of skin on her back, helping to protect the eggs from predators. When the eggs hatch, the female deposits the tadpoles in water where they begin life on their own.

Many amphibians exhibit complex and diverse social behaviors, especially during their breeding seasons. Frogs are usually quiet, but the males of many species vocalize to defend their breeding territory or to attract females. In some species, migrations to specific breeding sites may involve vocal communication, celestial navigation, or chemical signaling.

Over the past 25 years, zoologists have documented a rapid and alarming decline in amphibian populations in locations throughout the world. There appear to be several causes, including habitat loss, the spread of a fungal (chytrid) pathogen, climate change, and pollution. These and other factors have not only reduced populations, they have led to extinctions. A 2004 study indicates that since 1980, at least 9 amphibian species have become extinct. An additional 113 species have not been seen since that time and are considered "possibly extinct."

CONCEPT CHECK 34.5

1. Describe the origin of tetrapods and identify some of their key derived traits.
2. Some amphibians never leave the water, whereas others can survive in relatively dry terrestrial environments. Contrast the adaptations that facilitate these two lifestyles.
3. **WHAT IF?** Scientists think that amphibian populations may provide an early warning system of environmental problems. What features of amphibians might make them particularly sensitive to environmental problems?



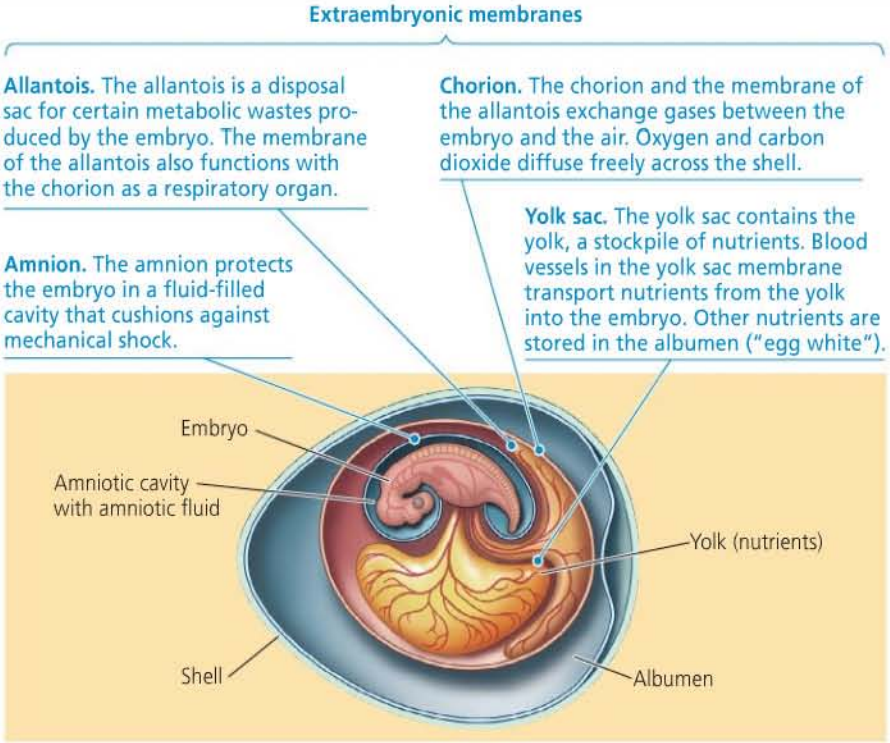
For suggested answers, see Appendix A.

CONCEPT 34.6
Amniotes are tetrapods that have a terrestrially adapted egg

The **amniotes** are a group of tetrapods whose extant members are the reptiles (including birds) and mammals (**Figure 34.24**, on the next page). During their evolution, amniotes acquired a number of new adaptations to life on land.

Derived Characters of Amniotes

Amniotes are named for the major derived character of the clade, the **amniotic egg**, which contains four specialized membranes: the amnion, the chorion, the yolk sac, and the allantois



▲ **Figure 34.24 A phylogeny of amniotes.** Extant groups are named at the tips of the branches in boldface type. The dotted line of the turtle branch indicates the uncertain relationship of turtles to other reptiles. Turtles may be a sister group to parareptiles (as indicated by some morphological data), or they may be diapsids more closely related to lepidosaurs (as indicated by other morphological analyses) or to archosaurs (as indicated by many molecular studies).

(Figure 34.25). Called *extraembryonic membranes* because they are not part of the body of the embryo itself, these membranes develop from tissue layers that grow out from the embryo. The amniotic egg is named for the amnion, which encloses a compartment of fluid that bathes the embryo and acts as a hydraulic shock absorber. The other membranes in the egg function in gas exchange, the transfer of stored nutrients to the embryo, and waste storage. The amniotic egg was a key evolutionary innovation for terrestrial life: It allowed the embryo to develop on land in its own private "pond," hence reducing the dependence of tetrapods on an aqueous environment for reproduction.

In contrast to the shell-less eggs of amphibians, the amniotic eggs of most reptiles and some mammals have a shell. The shells of bird eggs are calcareous (made of calcium carbonate) and inflexible, while the eggshells of many other reptiles are leathery and flexible. Either kind of shell significantly slows dehydration of the egg in air, an adaptation that helped amniotes to occupy a wider range of terrestrial habitats than amphibians, their closest living relatives. (Seeds played a similar role in the evolution of land plants, as we discussed in Chapter 30.) Most mammals have dispensed with the eggshell over the course of their evolution, and the embryo avoids desiccation by developing within the mother's body.

Amniotes acquired other key adaptations to life on land. For example, amniotes use their rib cage to ventilate their lungs. This method is more efficient than throat-based ventilation, which amphibians use as a supplement to breathing through

◀ **Figure 34.25 The amniotic egg.** The embryos of reptiles and mammals form four extraembryonic membranes: the amnion, chorion, yolk sac, and allantois. This diagram shows these membranes in the shelled egg of a reptile.

their skin. The increased efficiency of rib cage ventilation may have allowed amniotes to abandon breathing through their skin and develop less permeable skin, thereby conserving water.

Early Amniotes

The most recent common ancestor of living amphibians and amniotes likely lived about 370 million years ago. No fossils of amniotic eggs have been found from that time, which is not surprising given how delicate they are. Thus, it is not yet possible to say when the amniotic egg evolved, although it must have existed in the last common ancestor of living amniotes, which all have amniotic eggs.

What is evident from fossils of early amniotes and their closest relatives is that they could live in drier environments than did the first tetrapods. Some early amniotes were herbivores, as evidenced by their grinding teeth and other features; others were clearly predators.

Reptiles

The **reptile** clade includes tuataras, lizards, snakes, turtles, crocodilians, and birds, along with a number of extinct groups, such as plesiosaurs and ichthyosaurs (see Figure 34.24). Because all of the living reptile lineages are highly derived, none can serve as a straightforward model for the earliest reptiles, which lived some 320 million years ago. Nevertheless, comparative studies allow us to infer some of the derived characters that likely distinguished early reptiles from other tetrapods.

For example, unlike amphibians, reptiles have scales that contain the protein keratin (as does a human nail). Scales help protect the animal's skin from desiccation and abrasion. In addition, most reptiles lay their shelled eggs on land **(Figure 34.26)**. Fertilization must occur internally, before the eggshell is secreted. Many species of snakes and lizards are viviparous; in such species, the extraembryonic membranes form a kind

▲ **Figure 34.26 Hatching reptiles.** These bushmaster snakes (*Lachesis muta*) are breaking out of their parchment-like shells, a common type of shell among living reptiles other than birds.

of placenta that enables the embryo to obtain nutrients from its mother.

Reptiles such as lizards and snakes are sometimes described as "cold-blooded" because they do not use their metabolism extensively to control their body temperature. However, they do regulate their body temperature by using behavioral adaptations. For example, many lizards bask in the sun when the air is cool and seek shade when the air is too warm. A more accurate description of these reptiles is to say that they are **ectothermic**, which means that they absorb external heat as their main source of body heat. (This topic is discussed in more detail in Chapter 40.) By warming themselves directly with solar energy rather than through the metabolic breakdown of food, an ectothermic reptile can survive on less than 10% of the food energy required by a mammal of the same size. The reptile clade is not entirely ectothermic; birds are **endothermic**, capable of maintaining body temperature through metabolic activity.

The Origin and Evolutionary Radiation of Reptiles

The oldest reptilian fossils, found in rocks from Nova Scotia, date from the late Carboniferous period, about 310 million years ago. One of the first major groups of reptiles to emerge were the **parareptiles**, which were mostly large, stocky, quadrupedal herbivores. Some parareptiles had plates on their skin that may have provided them with defense against predators. Parareptiles died out by about 200 million years ago, at the end of the Triassic period.

As parareptiles were dwindling, another ancient clade of reptiles, the **diapsids**, was diversifying. One of the most obvious derived characters of diapsids is a pair of holes on each side of the skull, behind the eye socket. The diapsids are composed of two main lineages. One lineage gave rise to the **lepidosaurs**, which include tuataras, lizards, and snakes. This lineage also produced a number of marine reptiles, including the giant mososaurs. Some of these marine species rivaled today's whales in length; all of them are extinct. (We'll say more about living lepidosaurs shortly.)

The other diapsid lineage, the **archosaurs**, produced the crocodilians (which we'll discuss later), pterosaurs, and dinosaurs. **Pterosaurs**, which originated in the late Triassic, were the first tetrapods to exhibit flapping flight. The pterosaur wing was completely different from the wings of birds and bats. It consisted of a collagen-strengthened membrane that stretched between the trunk or hind leg and a very long digit on the foreleg. Well-preserved fossils show evidence of muscles, blood vessels, and nerves in the wing membranes, suggesting that pterosaurs could dynamically adjust their membranes to assist their flight.

The smallest pterosaurs were no bigger than a sparrow, and the largest had a wingspan of nearly 11 m. They appear to have converged on many of the ecological roles later played by birds; some were insect-eaters, others grabbed fish out of the ocean, and still others filtered small animals through thousands of fine needle-like teeth. But by the end of the Cretaceous period 65 million years ago, pterosaurs had become extinct.

On land, the **dinosaurs** diversified into a vast range of shapes and sizes, from bipeds the size of a pigeon to 45-m-long quadrupeds with necks long enough to let them browse the tops of trees. One lineage of dinosaurs, the ornithischians, were herbivores; they included many species with elaborate defenses against predators, such as tail clubs and horned crests. The other main lineage of dinosaurs, the saurischians, included the long-necked giants and a group called the **theropods**, which were bipedal carnivores. Theropods included the famous *Tyrannosaurus rex* as well as the ancestors of birds.

There is continuing debate about the metabolism of dinosaurs. Some researchers have pointed out that the Mesozoic climate over much of the dinosaurs' range was relatively warm and consistent, and they have suggested that the low surface-to-volume ratios of large dinosaurs combined with behavioral adaptations such as basking may have been sufficient for an ectotherm to maintain a suitable body temperature. However, some anatomical evidence supports the hypothesis that at least some dinosaurs were endotherms. Furthermore, paleontologists have found fossils of dinosaurs in both Antarctica and the Arctic; although the climate in these areas was milder when dinosaurs existed than it is today, it was cool enough that small dinosaurs may have had difficulty maintaining a high body temperature through ectothermy. The dinosaur that gave rise to birds was *certainly* endothermic, as are all birds.

Traditionally, dinosaurs were considered slow, sluggish creatures. Since the early 1970s, however, fossil discoveries and research have led to the conclusion that many dinosaurs were agile, fast moving, and, in some cases, social. Paleontologists have also discovered evidence that some dinosaurs built nests and brooded their eggs, as birds do today (see Figure 26.17).

All dinosaurs except birds became extinct by the end of the Cretaceous period. Their extinction may have been caused at least in part by the asteroid or comet impact you read about in Chapter 25. Some analyses of the fossil record are consistent with this idea in that they show a sudden decline in dinosaur diversity at the end of the Cretaceous. However, other analyses indicate that the number of dinosaur species had begun to decline several million years before the Cretaceous ended. Further fossil discoveries and new analyses will be needed to resolve this debate.

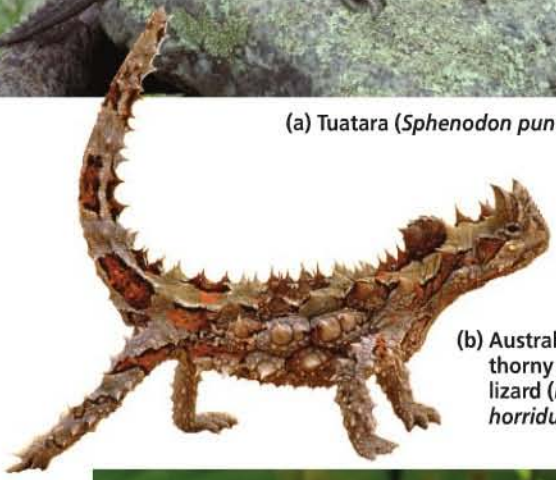
Lepidosaurs

One surviving lineage of lepidosaurs is represented by two species of lizard-like reptiles called tuataras **(Figure 34.27a)**. Fossil evidence indicates that tuatara relatives lived at least

220 million years ago. These organisms thrived on many continents well into the Cretaceous period, reaching up to a meter in length. Today, however, tuataras are found only on 30 islands off the coast of New Zealand. When humans arrived in New Zealand 750 years ago, the rats that accompanied them devoured tuatara eggs, eventually eliminating the reptiles on the main islands. The tuataras that remain on the outlying islands are about 50 cm long and feed on insects, small lizards, and bird eggs and chicks. They can live to be over 100 years old. Their future survival depends on whether their remaining habitats are kept rat-free.

The other major living lineage of lepidosaurs consists of the lizards and snakes, or squamates, which number about 7,900 species. Lizards are the most numerous and diverse reptiles (apart from birds) alive today **(Figure 34.27b)**. Most lizards are small; the Jaragua lizard, discovered in the Dominican Republic in 2001, is only 16 mm long—small enough to fit comfortably on a dime. In contrast, the Komodo dragon of Indonesia can reach a length of 3 m. It hunts deer and other large prey, delivering pathogenic bacteria with its bite. As its wounded prey weakens from the infection, the lizard slowly stalks it.

Snakes are legless lepidosaurs whose closest living relatives include the Komodo dragon **(Figure 34.27c)**. Today, some species of snakes retain vestigial pelvic and limb bones, which provide evidence of their ancestry.



Despite their lack of legs, snakes are quite proficient at moving on land, most often by producing waves of lateral bending that pass from head to tail. Force exerted by the bends against solid objects pushes the snake forward. Snakes can also move by gripping the ground with their belly scales at several points along the body, while the scales at intervening points are lifted slightly off the ground and pulled forward.

Snakes are carnivorous, and a number of adaptations aid them in hunting and eating prey. They have acute chemical sensors, and though they lack eardrums, they are sensitive to ground vibrations, which helps them detect the movements of prey. Heat-detecting organs between the eyes and nostrils of pit vipers, including rattlesnakes, are sensitive to minute temperature changes, enabling these night hunters to locate warm animals. Poisonous snakes inject their toxin through a pair of sharp, hollow or grooved teeth. The flicking tongue is not poisonous but helps fan odors toward olfactory (smell) organs on the roof of the mouth. Loosely articulated jawbones and elastic skin enable most snakes to swallow prey larger than the diameter of the snake's head (see Figure 23.14).

(b) Australian thorny devil lizard (*Moloch horridus*)

(c) Wagler's pit viper (*Tropidolaemus wagleri*)

(d) Eastern box turtle (*Terrapene carolina carolina*)

(e) American alligator (*Alligator mississippiensis*)

Turtles

Turtles are one of the most distinctive group of reptiles alive today. All turtles have a boxlike shell made of upper and lower shields that are fused to the vertebrae, clavicles (collarbones), and ribs **(Figure 34.27d)**. Most of the 307 known species of turtles have a hard shell, providing excellent defense against predators. The earliest fossils of turtles, dating from about 220 million years ago, have fully developed shells. In the absence of transitional fossils, clues to the origin of the turtle shell can be found in molecular data. Molecular analyses to date suggest that turtles are closely related to crocodiles and other Triassic archosaurs—organisms that had bony plates along their backbones and sometimes over their bodies. These plates may have become more extensive in the ancestors of turtles, over time resulting in a shell. If turtles are not closely related to archosaurs (the legend of Figure 34.24 discusses other possible relationships), new fossil discoveries will be needed to shed light on the origin of the turtle shell.

The earliest turtles could not retract their head into their shell, but mechanisms for doing so evolved independently in two separate branches of turtles. The side-necked turtles (pleurodires) fold their neck horizontally, while the vertical-necked turtles (cryptodires) fold their neck vertically.

Some turtles have adapted to deserts, and others live almost entirely in ponds and rivers. Still others have returned to the sea. Sea turtles have a reduced shell and enlarged forelimbs that function as flippers. They include the largest living turtles, the deep-diving leatherbacks, which can exceed a mass of 1,500 kg and feed on jellies. Leatherbacks and other sea turtles are endangered by being caught in fishing nets, as well as by development of the beaches where the turtles lay their eggs.

Alligators and Crocodiles

Alligators and crocodiles (collectively called crocodilians) belong to a lineage that reaches back to the late Triassic **(Figure 34.27e)**. The earliest members of this lineage were small terrestrial quadrupeds with long, slender legs. Later species became larger and adapted to aquatic habitats, breathing air through their upturned nostrils. Some Mesozoic crocodilians grew as long as 12 m and may have attacked dinosaurs and other prey at the water's edge.

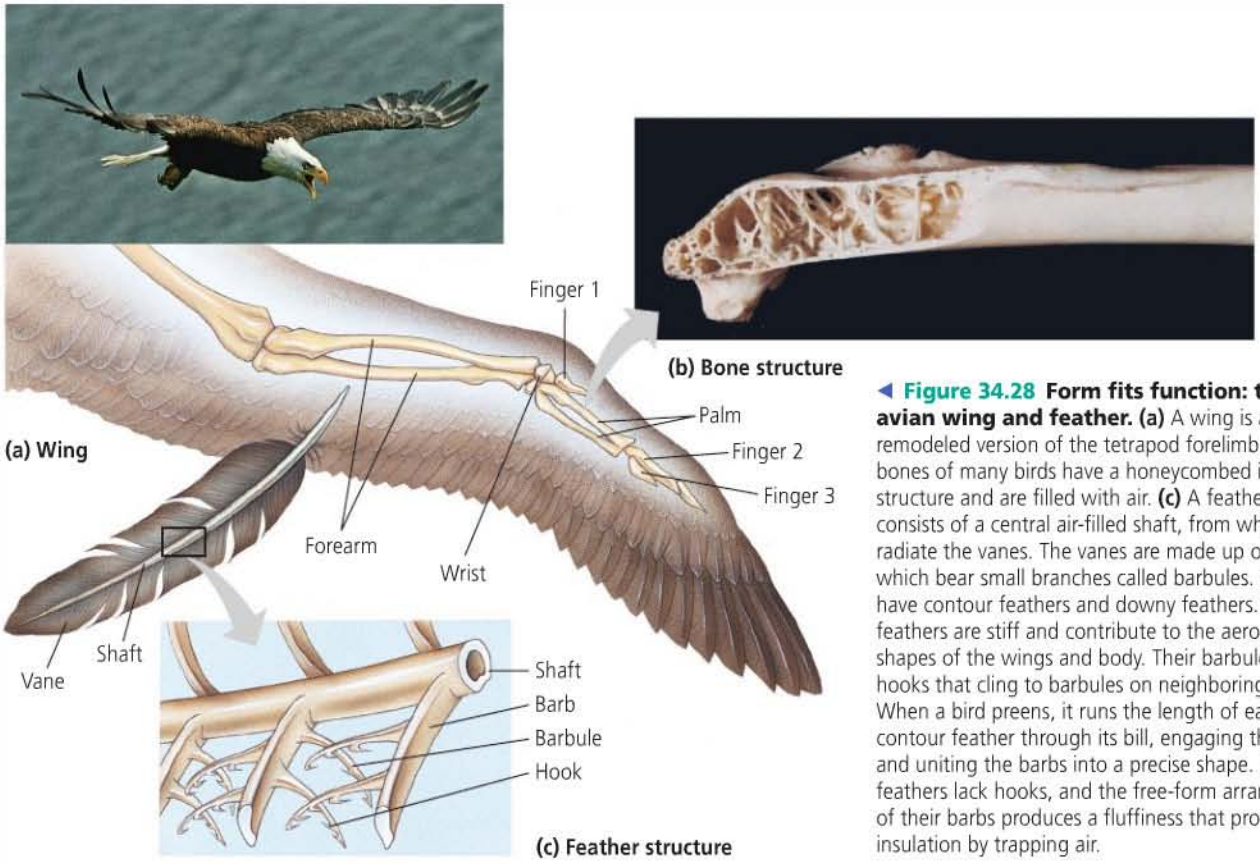
The 23 known species of living crocodilians are confined to warm regions of the globe. Alligators in the southeastern United States have made a comeback after spending years on the endangered species list.

Birds

There are about 10,000 species of birds in the world. Like crocodilians, birds are archosaurs, but almost every feature of their anatomy has been modified in their adaptation to flight.

Derived Characters of Birds Many of the characters of birds are adaptations that facilitate flight, including weight-saving modifications that make flying more efficient. For example, birds lack a urinary bladder, and the females of most species have only one ovary. The gonads of both females and males are usually small, except during the breeding season, when they increase in size. Living birds are also toothless, an adaptation that trims the weight of the head.

A bird's most obvious adaptations for flight are its wings and feathers **(Figure 34.28)**. Feathers are made of the protein β-keratin, which is also found in the scales of other reptiles. The shape and arrangement of the feathers form the wings into airfoils, and they illustrate some of the same principles of aerodynamics as the wings of an airplane. Power for flapping the wings comes from contractions of large pectoral (breast) muscles anchored to a keel on the sternum (breastbone). Some birds, such as eagles and hawks, have wings adapted for soaring on air currents and flap their wings only occasionally (see Figure 34.28); other birds, including hummingbirds, must flap continuously to stay aloft. Among the fastest birds are the appropriately named swifts, which can fly up to 170 km/hr.



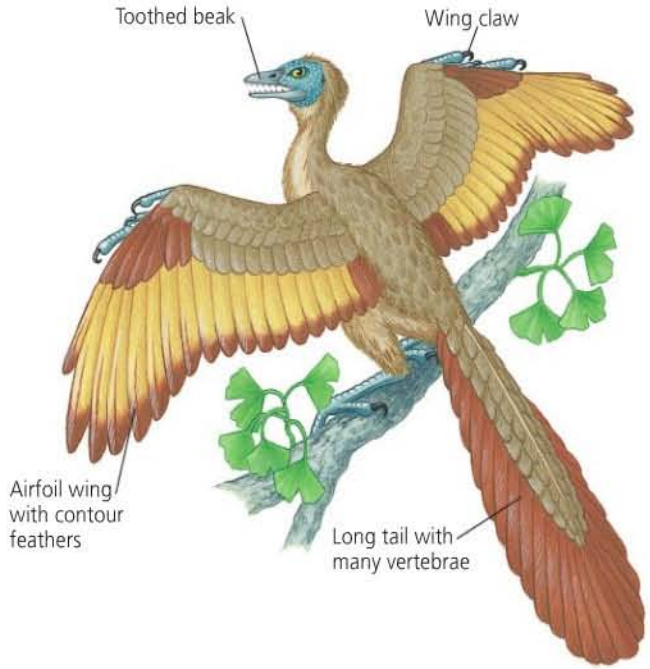
Flight provides numerous benefits. It enhances hunting and scavenging; many birds consume flying insects, an abundant, highly nutritious food resource. Flight also provides ready escape from earthbound predators and enables some birds to migrate great distances to exploit different food resources and seasonal breeding areas.

Flying requires a great expenditure of energy from an active metabolism. Birds are endothermic; they use their own metabolic heat to maintain a high, constant body temperature. Feathers and in some species a layer of fat provide insulation that enables birds to retain body heat. The lungs have tiny tubes leading to and from elastic air sacs that improve airflow and oxygen uptake. This efficient respiratory system and a circulatory system with a four-chambered heart keep tissues well supplied with oxygen and nutrients, supporting a high rate of metabolism.

Flight also requires both acute vision and fine muscle control. Birds have excellent eyesight. The visual and motor areas of the brain are well developed, and the brain is proportionately larger than those of amphibians and nonbird reptiles.

Birds generally display very complex behaviors, particularly during breeding season, when they engage in elaborate courtship rituals. Because eggs have shells by the time they are laid, fertilization must be internal. Copulation usually involves contact between the mates' vents, the openings to their cloacas. After eggs are laid, the avian embryo must be kept warm through brooding by the mother, the father, or both, depending on the species.

The Origin of Birds Cladistic analyses of birds and of reptilian fossils indicate that birds belong to the group of bipedal saurischians called theropods. Since the late 1990s, Chinese paleontologists have unearthed a spectacular trove of feathered theropod fossils that are shedding light on the origin of birds.



◀ **Figure 34.28 Form fits function: the avian wing and feather. (a)** A wing is a remodeled version of the tetrapod forelimb. **(b)** The bones of many birds have a honeycombed internal structure and are filled with air. **(c)** A feather consists of a central air-filled shaft, from which radiate the vanes. The vanes are made up of barbs, which bear small branches called barbules. Birds have contour feathers and downy feathers. Contour feathers are stiff and contribute to the aerodynamic shapes of the wings and body. Their barbules have hooks that cling to barbules on neighboring barbs. When a bird preens, it runs the length of each contour feather through its bill, engaging the hooks and uniting the barbs into a precise shape. Downy feathers lack hooks, and the free-form arrangement of their barbs produces a fluffiness that provides insulation by trapping air.

Several species of dinosaurs closely related to birds had feathers with vanes, and a wider range of species had filamentous feathers. Such findings imply that feathers evolved long before powered flight. Among the possible functions of these early feathers were insulation, camouflage, and courtship display.

How did flight evolve in the theropods? In one scenario, feathers may have enabled small, running dinosaurs chasing prey or escaping predators to gain extra lift as they jumped into the air. Or, small dinosaurs could have gained traction as they ran up hills by flapping their feathered fore limbs—a behavior seen in some birds today. In a third scenario, some dinosaurs could have climbed trees and glided, aided by feathers. Whether birds took to the air from the ground up or the trees down, an essential question being studied by scientists ranging from paleontologists to engineers is how their efficient flight stroke evolved.

By 150 million years ago, feathered theropods had evolved into birds. *Archaeopteryx*, which was discovered in a German limestone quarry in 1861, remains the earliest known bird **(Figure 34.29)**. It had feathered wings but retained ancestral characters such as teeth, clawed digits in its wings, and a long tail. *Archaeopteryx* flew well at high speeds, but unlike a present-day bird, it could not take off from a standing position. Fossils of later birds from the Cretaceous show a gradual loss of certain ancestral dinosaur features, such as teeth and clawed forelimbs, as well as the acquisition of innovations found in extant birds, including a short tail covered by a fan of feathers.

▲ **Figure 34.29 Artist's reconstruction of *Archaeopteryx*, the earliest known bird.** Fossil evidence indicates that *Archaeopteryx* was capable of powered flight but retained many characters of nonbird dinosaurs.

Living Birds Clear evidence of Neornithes, the clade that includes the 28 orders of living birds, can be found before the Cretaceous-Paleogene boundary 65.5 million years ago. Several

(a) Emu. This ratite lives in Australia.

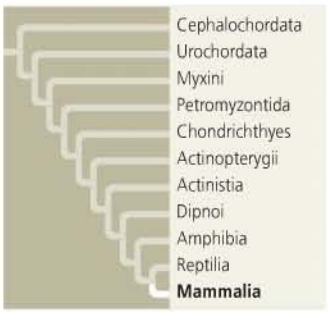
(b) Mallards. Like many bird species, the mallard exhibits pronounced color differences between the sexes.

(c) Laysan albatrosses. Like most birds, Laysan albatrosses have specific mating behaviors, such as this courtship ritual.

(d) Barn swallows. The barn swallow is a member of the order Passeriformes. Species in this order are called perching birds because the toes of their feet can lock around a branch or wire, enabling the bird to rest in place for long periods.

▲ **Figure 34.30 A small sample of living birds.**

groups of living and extinct birds include one or more flightless species. The **ratites** (order Struthioniformes), which consist of the ostrich, rhea, kiwi, cassowary, and emu, are all flightless. In ratites (from the Latin *ratitus*, flat-bottomed), the sternal keel is absent, and the pectoral muscles are not greatly enlarged **(Figure 34.30a)**. Penguins make up the flightless order Sphenisciformes, but, like flying birds, they have powerful pectoral muscles. They use these muscles to "fly" in the water: As they swim, they flap their flipper-like wings in a manner that resembles the flight stroke of a more typical bird. Certain species of rails, ducks, and pigeons are also flightless.



Although the demands of flight have rendered the general body forms of many flying birds similar to one another, experienced bird-watchers can distinguish species by their profile, flying style, behavior, colors, and beak shape **(Figure 34.30b–d)**. During avian evolution, the beak has taken on a variety of shapes suited to different diets. Foot structure, too, shows considerable variation. Various birds use their feet for perching on branches, grasping food, defense, swimming or walking, and even courtship (see Figure 24.4e).

CONCEPT CHECK 34.6

1. Describe three key amniote adaptations for life on land.
2. Identify four avian adaptations for flight.
3. **WHAT IF?** Suppose turtles are more closely related to lepidosaurs than to other reptiles. Redraw Figure 34.24 to show this relationship, and mark the node that represents the most recent common ancestor shared by all living reptiles. Defining the reptile clade as consisting of all descendants of that ancestor, list the reptiles.

For suggested answers, see Appendix A.

CONCEPT 34.7
Mammals are amniotes that have hair and produce milk

The reptiles we have been discussing represent one of two great lineages of amniotes. The other amniote lineage is our own, the **mammals** (class Mammalia). Today, there are more than 5,300 known species of mammals on Earth.

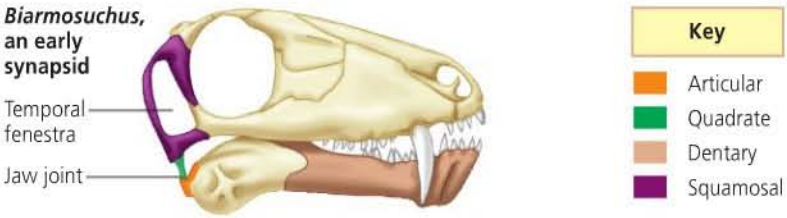
Derived Characters of Mammals

The distinctive character from which mammals derive their name is their mammary glands, which produce milk for offspring. All mammalian mothers nourish their young with

milk, a balanced diet rich in fats, sugars, proteins, minerals, and vitamins. Hair, another mammalian characteristic, and a fat layer under the skin help the body retain heat. Like birds, mammals are endothermic, and most have a high metabolic rate. Efficient respiratory and circulatory systems (including a four-chambered heart) support a mammal's metabolism. A sheet of muscle called the diaphragm helps ventilate the lungs.

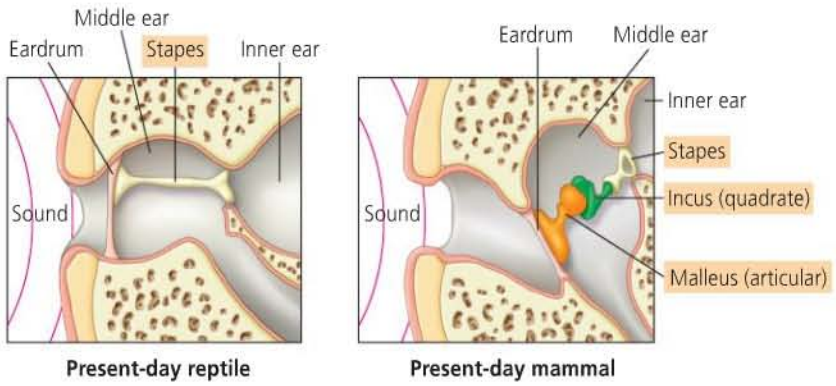
Like birds, mammals generally have a larger brain than other vertebrates of equivalent size, and many species are capable learners. And as in birds, the relatively long duration of parental care extends the time for offspring to learn important survival skills by observing their parents.

Differentiated teeth are another important mammalian trait. Whereas the teeth of reptiles are generally uniform in size and shape, the jaws of mammals bear a variety of teeth with sizes and shapes adapted for chewing many kinds of foods. Humans, like most mammals, have teeth modified for shearing (incisors and canine teeth) and for crushing and grinding (premolars and molars; see Figure 41.18).



Early Evolution of Mammals

Mammals belong to a group of amniotes known as **synapsids**. Early nonmammalian synapsids lacked hair, had a sprawling gait, and laid eggs. A distinctive characteristic of synapsids is the single temporal fenestra, a hole behind the eye socket on each side of the skull. Humans retain this feature; your jaw muscles pass through the temporal fenestra and anchor on your temple. Fossil evidence shows that the jaw was remodeled as mammalian features arose gradually in successive lineages of earlier synapsids (see Figure 25.6). In addition, two of the bones that formerly made up the jaw joint were incorporated into the mammalian middle ear **(Figure 34.31)**.



Synapsids evolved into large herbivores and carnivores during the Permian period, and for a time they were the dominant tetrapods. However, the Permian-Triassic extinctions took a heavy toll on them, and their diversity fell during the Triassic. Increasingly mammal-like synapsids emerged by the end of the Triassic 200 million years ago. While not true mammals, these synapsids had acquired a number of the derived characters that distinguish mammals from other amniotes. They were small and probably hairy, and they likely fed on insects at night. Their bones show that they grew faster than other synapsids, suggesting that they probably had a relatively high metabolic rate; however, they still laid eggs.

During the Jurassic period, the first true mammals arose and diversified into a number of lineages, many of which are extinct. Yet throughout the Mesozoic era, most mammals remained about the size of today's shrews. One possible explanation for their small size is that dinosaurs already occupied ecological niches of large-bodied animals.

By the early Cretaceous, the three major lineages of living mammals emerged: monotremes (egg-laying mammals), marsupials (mammals with a pouch), and eutherians (placental mammals). After the extinction of large dinosaurs, pterosaurs, and marine reptiles during the late Cretaceous period, mammals underwent an adaptive radiation, giving rise to large predators and herbivores as well as flying and aquatic species.

(a) In *Biarmosuchus*, the articular and quadrate bones formed the jaw joint.

(b) During the evolutionary remodeling of the mammalian skull, a new jaw joint formed between the dentary and squamosal bones (see Figure 25.6). No longer used in the jaw, the quadrate and articular bones became incorporated into the middle ear as two of the three bones that transmit sound from the eardrum to the inner ear.

◀ **Figure 34.31 The evolution of the mammalian ear bones.** *Biarmosuchus* was an early synapsid, a lineage that eventually gave rise to the mammals. Bones that transmit sound in the ear of mammals arose from the modification of bones in the jaw of nonmammalian synapsids.

▲ **Figure 34.32 Short-beaked echidna (*Tachyglossus aculeatus*), an Australian monotreme.** Monotremes have hair and produce milk, but they lack nipples. Monotremes are the only mammals that lay eggs (inset).

Monotremes

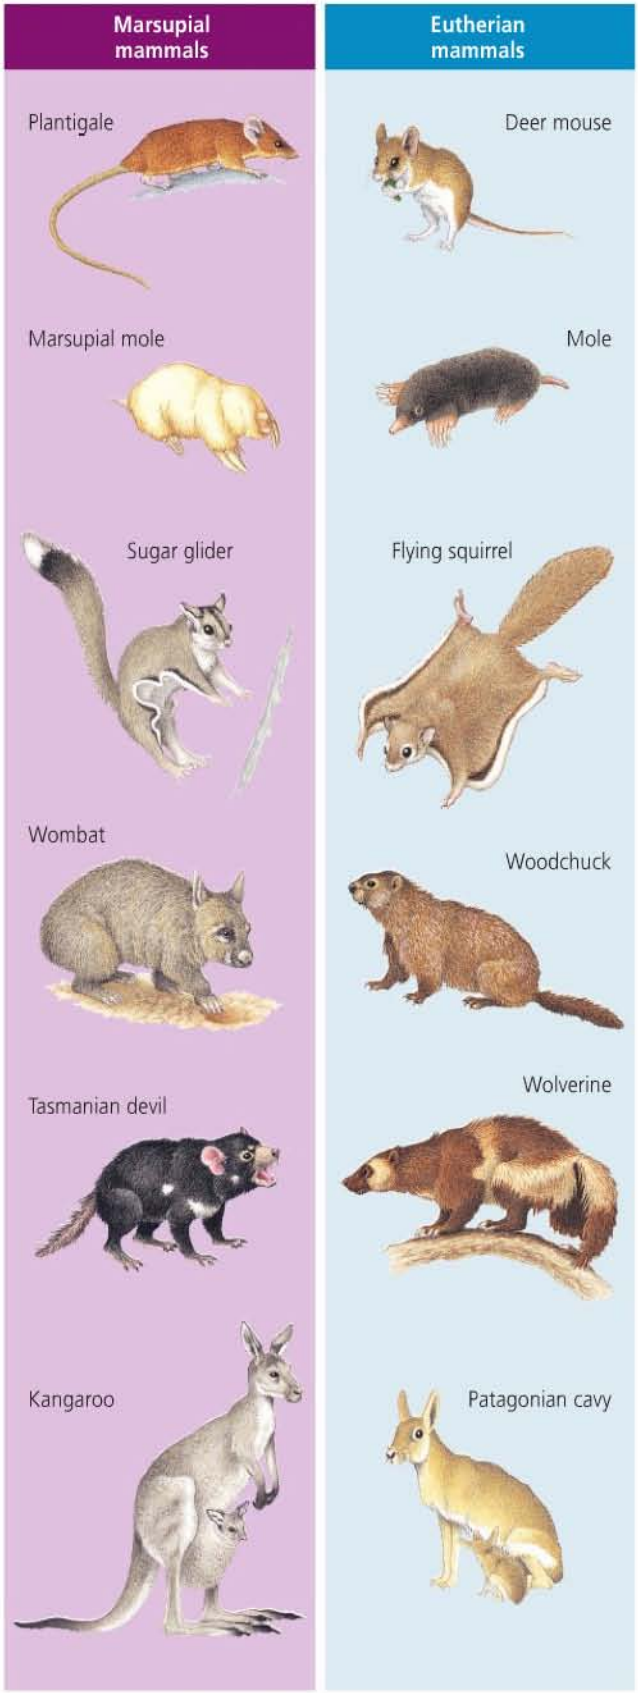
Monotremes are found only in Australia and New Guinea and are represented by one species of platypus and four species of echidnas (spiny anteaters). Monotremes lay eggs, a character that is ancestral for amniotes and retained in most reptiles **(Figure 34.32)**. Like all mammals, monotremes have hair and produce milk, but they lack nipples. Milk is secreted by glands on the belly of the mother. After hatching, the baby sucks the milk from the mother's fur.

Marsupials

Opossums, kangaroos, and koalas are examples of **marsupials**. Both marsupials and eutherians share derived characters not found among monotremes. They have higher metabolic rates and nipples that provide milk, and they give birth to live young. The embryo develops inside the uterus of the female's reproductive tract. The lining of the uterus and the extraembryonic membranes that arise from the embryo form a **placenta**, a structure in which nutrients diffuse into the embryo from the mother's blood.

A marsupial is born very early in its development and completes its embryonic development while nursing. In most species, the nursing young are held within a maternal pouch called a marsupium **(Figure 34.33a)**. A red kangaroo, for instance, is about the size of a honeybee at its birth, just 33 days after fertilization. Its back legs are merely buds, but its front legs are strong enough for it to crawl from the exit of its mother's reproductive tract to a pouch that opens to the front of her body, a journey that lasts a few minutes. In other species, the marsupium opens to the rear of the mother's body; in bandicoots this protects the young as their mother burrows in the dirt **(Figure 34.33b)**.

Marsupials existed worldwide during the Mesozoic era, but today they are found only in the Australian region and in North



(a) A young brushtail possum. The young of marsupials are born very early in their development. They finish their growth while nursing from a nipple (in their mother's pouch in most species).

(b) Long-nosed bandicoot. Most bandicoots are diggers and burrowers that eat mainly insects but also some small vertebrates and plant material. Their rear-opening pouch helps protect the young from dirt as the mother digs. Other marsupials, such as kangaroos, have a pouch that opens to the front.

▲ **Figure 34.33 Australian marsupials.**

and South America. The biogeography of marsupials is an example of the interplay between biological and geologic evolution (see Chapter 25). After the breakup of the supercontinent Pangaea, South America and Australia became island continents, and their marsupials diversified in isolation from the eutherians that began an adaptive radiation on the northern continents. Australia has not been in contact with another continent since early in the Cenozoic era, about 65 million years ago. In Australia, convergent evolution has resulted in a diversity of marsupials that resemble eutherians in similar ecological roles in other parts of the world **(Figure 34.34)**. In contrast, although South America had a diverse marsupial fauna throughout the Paleogene, it has experienced several migrations of eutherians. One of the most important migrations occurred about 3 million years ago, when North and South America joined at the Panamanian isthmus and extensive two-way traffic of animals took place over

▲ **Figure 34.34 Evolutionary convergence of marsupials and eutherians (placental mammals).** (Drawings are not to scale.)

the land bridge. Today, only three families of marsupials live outside the Australian region, and the only marsupials found in the wild in North America are a few species of opossum.

Eutherians (Placental Mammals)

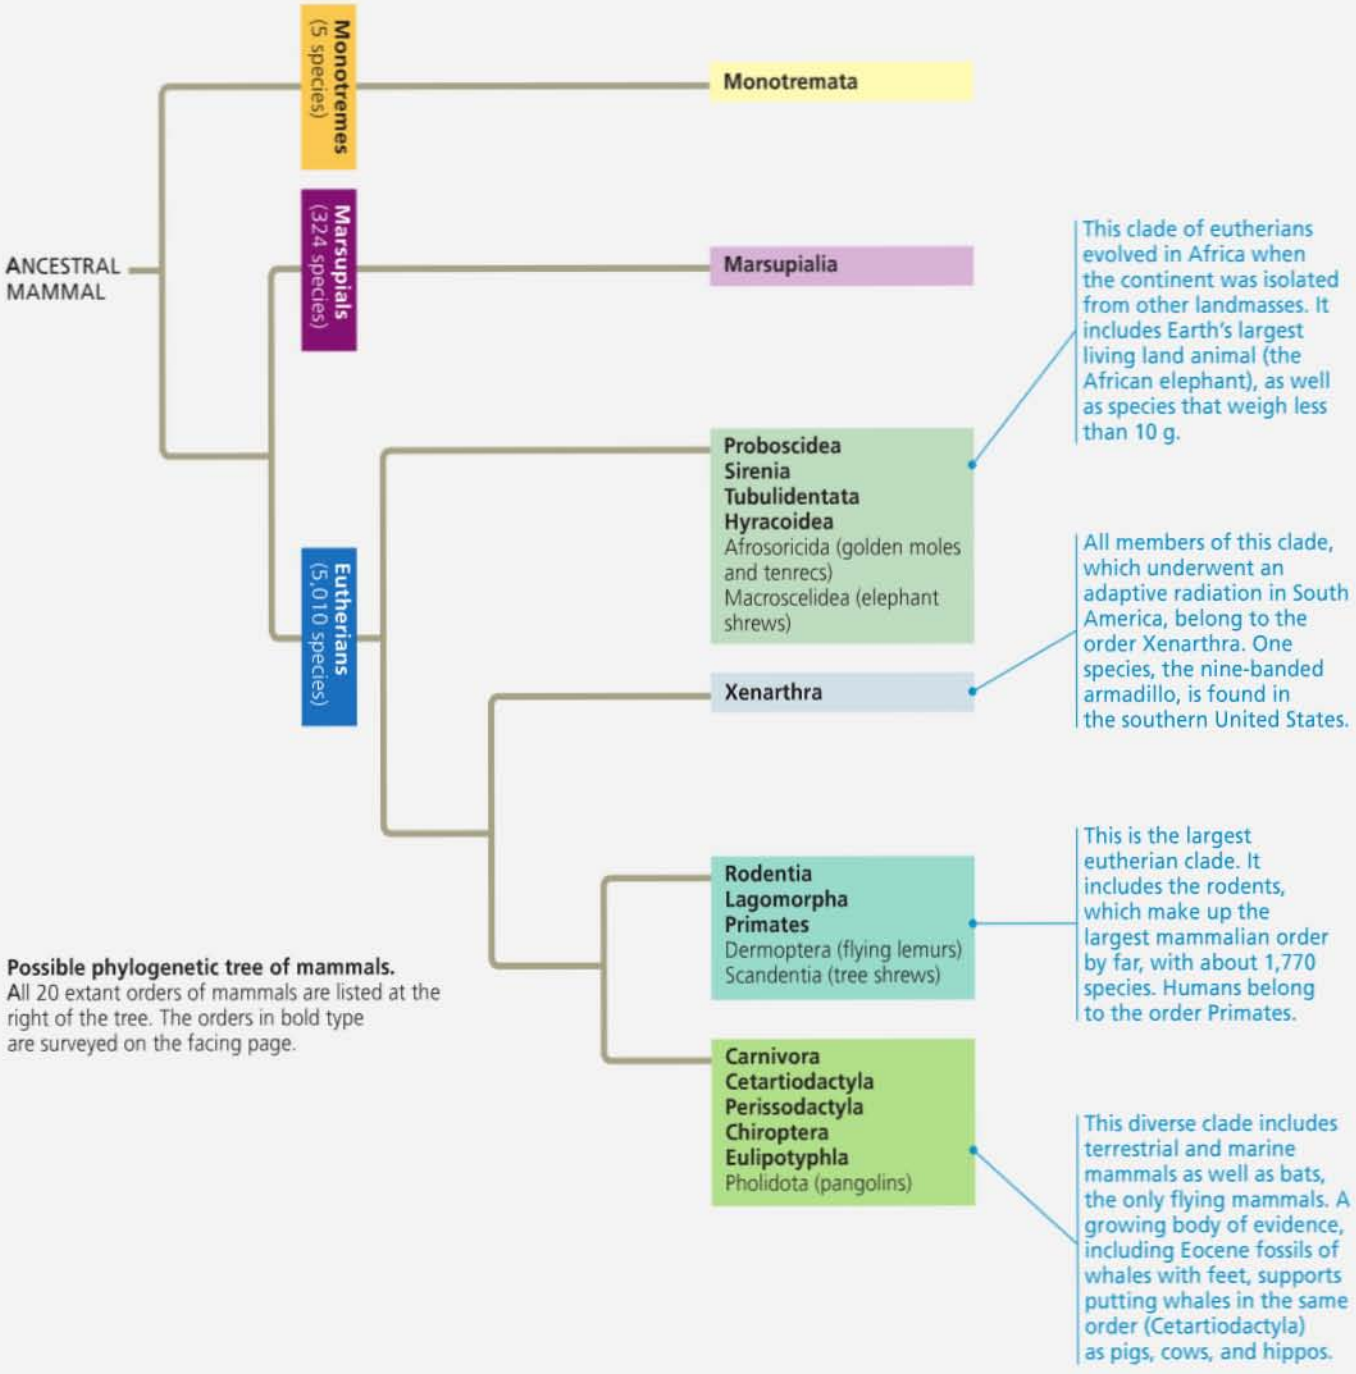
Eutherians are commonly called placental mammals because their placentas are more complex than those of marsupials. Eutherians have a longer pregnancy than marsupials. Young eutherians complete their embryonic development within the uterus, joined to their mother by the placenta. The eutherian placenta provides an intimate and long-lasting association between the mother and her developing young.

The major groups of living eutherians are thought to have diverged from one another in a burst of evolutionary change. The timing of this burst is uncertain: It is dated to 100 million years ago by molecular data and 60 million years ago by morphological data. **Figure 34.35**, on the next two pages, explores the major eutherian orders and their possible phylogenetic relationships with each other as well as with the monotremes and marsupials.

Primates

The mammalian order Primates includes the lemurs, the tarsiers, the monkeys, and the apes. Humans are members of the ape group.

Derived Characters of Primates Most primates have hands and feet adapted for grasping, and their digits have flat nails instead of the narrow claws of other mammals. There also are other characteristic features of the hands and feet, such as skin ridges on the fingers (which account for human fingerprints). Relative to other mammals, primates have a large brain and short jaws, giving them a flat face. Their forward-looking eyes are close together on the front of the face. Primates also exhibit relatively well-developed parental care and complex social behavior.



The earliest known primates were tree-dwellers, and many of the characteristics of primates are adaptations to the demands of living in the trees. Grasping hands and feet allow primates to hang onto tree branches. All living primates, except humans, have a big toe that is widely separated from the other toes, enabling them to grasp branches with their feet. All primates also have a thumb that is relatively moveable and separate from the fingers, but monkeys and apes have a fully **opposable thumb**; that is, they can touch the ventral surface (fingerprint side) of the tip of all four fingers with the ventral surface of the thumb of the same hand. In monkeys and apes other than humans, the opposable thumb functions in a grasping "power grip." In humans, a distinctive bone structure at the base of the thumb allows it to be used for more precise manipulation. The unique dexterity of humans represents descent with modification from our tree-dwelling ancestors. Arboreal maneuvering also requires excellent eye-hand coordination. The overlapping

Exploring Mammalian Diversity

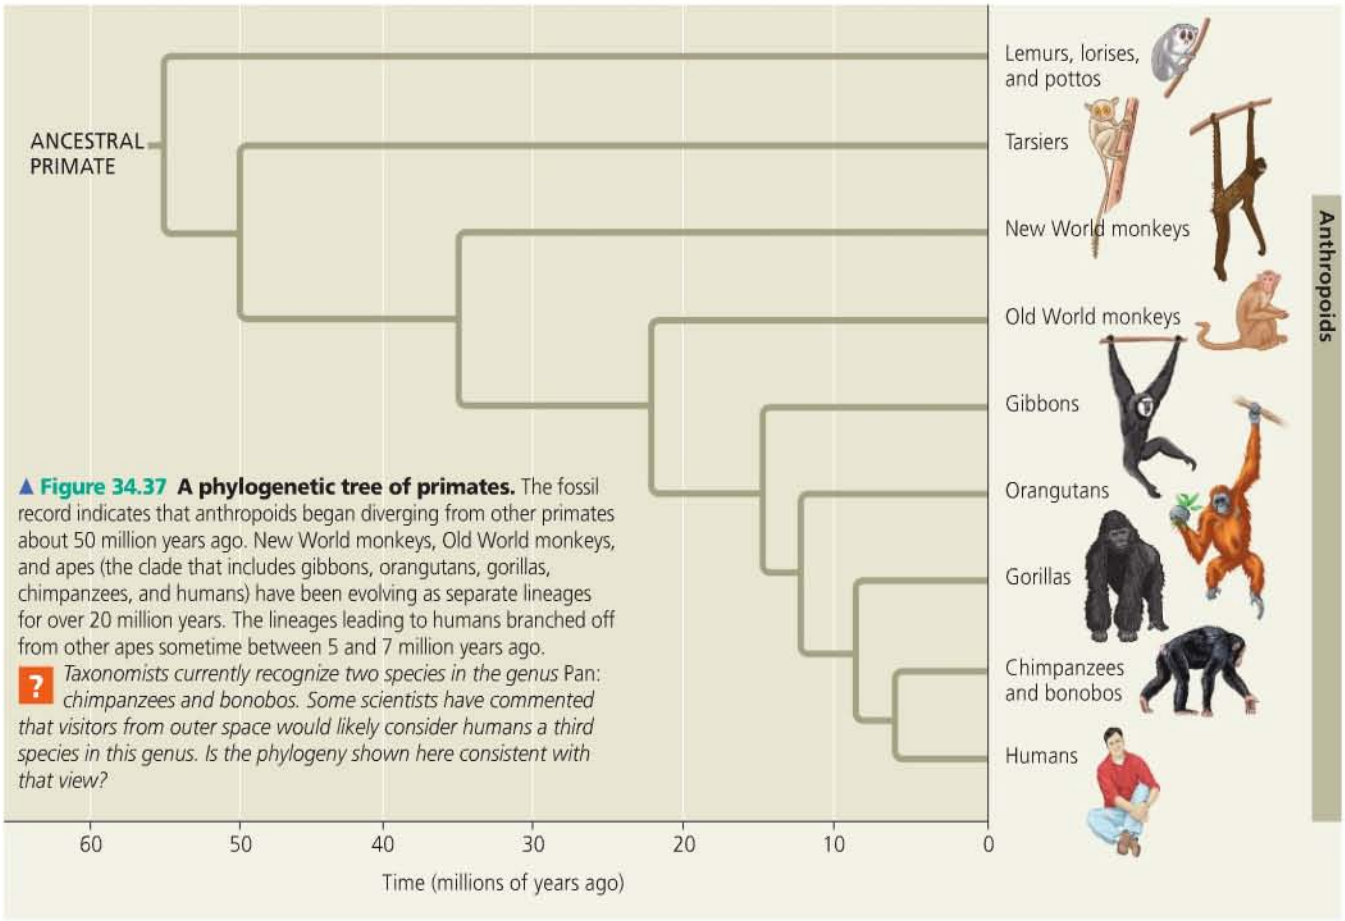
Phylogenetic Relationships of Mammals

Evidence from numerous fossils and molecular analyses indicates that monotremes diverged from other mammals about 180 million years ago and that marsupials diverged from eutherians (placental mammals) about 140 million years ago. Molecular systematics has helped to clarify the evolutionary relationships between the eutherian orders, though there is still no broad consensus on a phylogenetic tree. One current hypothesis, represented by the tree shown below, clusters the eutherian orders into four main clades.

Possible phylogenetic tree of mammals.
All 20 extant orders of mammals are listed at the right of the tree. The orders in bold type are surveyed on the facing page.

Orders and Examples	Main Characteristics
Monotremata Platypuses, echidnas  Echidna	Lay eggs; no nipples; young suck milk from fur of mother
Proboscidea Elephants  African elephant	Long, muscular trunk; thick, loose skin; upper incisors elongated as tusks
Sirenia Manatees, dugongs  Manatee	Aquatic; finlike forelimbs and no hind limbs; herbivorous
Xenarthra Sloths, anteaters, armadillos  Tamandua	Reduced teeth or no teeth; herbivorous (sloths) or carnivorous (anteaters, armadillos)
Lagomorpha Rabbits, hares, picas  Jackrabbit	Chisel-like incisors; hind legs longer than forelegs and adapted for running and jumping; herbivorous
Carnivora Dogs, wolves, bears, cats, weasels, otters, seals, walruses  Coyote	Sharp, pointed canine teeth and molars for shearing; carnivorous
Cetartiodactyla **Artiodactyls** Sheep, pigs, cattle, deer, giraffes  Bighorn sheep	Hooves with an even number of toes on each foot; herbivorous
Cetaceans Whales, dolphins, porpoises  Pacific white-sided porpoise	Aquatic; streamlined body; paddle-like forelimbs and no hind limbs; thick layer of insulating blubber; carnivorous

Orders and Examples	Main Characteristics
Marsupialia Kangaroos, opossums, koalas  Koala	Embryo completes development in pouch on mother
Tubulidentata Aardvarks  Aardvark	Teeth consisting of many thin tubes cemented together; eats ants and termites
Hyracoidea Hyraxes  Rock hyrax	Short legs; stumpy tail; herbivorous; complex, multichambered stomach
Rodentia Squirrels, beavers, rats, porcupines, mice  Red squirrel	Chisel-like, continuously growing incisors worn down by gnawing; herbivorous
Primates Lemurs, monkeys, chimpanzees, gorillas, humans  Golden lion tamarin	Opposable thumbs; forward-facing eyes; well-developed cerebral cortex; omnivorous
Perissodactyla Horses, zebras, tapirs, rhinoceroses  Indian rhinoceros	Hooves with an odd number of toes on each foot; herbivorous
Chiroptera Bats  Frog-eating bat	Adapted for flight; broad skinfold that extends from elongated fingers to body and legs; carnivorous or herbivorous
Eulipotyphla "Core insectivores": some moles, some shrews  Star-nosed mole	Diet consists mainly of insects and other small invertebrates



visual fields of the two forward-facing eyes enhance depth perception, an obvious advantage when brachiating (traveling by swinging from branch to branch in trees).

▶ **Figure 34.36** **Coquerel's sifakas (*Propithecus verreauxi coquereli*), a type of lemur.**

Living Primates There are three main groups of living primates: (1) the lemurs of Madagascar **(Figure 34.36)** and the lorises and pottos of tropical Africa and southern Asia; (2) the tarsiers, which live in Southeast Asia; and (3) the **anthropoids**, which include monkeys and apes and are found worldwide. The first group—lemurs, lorises, and pottos—probably resemble early arboreal primates. The oldest known anthropoid fossils, discovered in China in mid-Eocene strata about 45 million years old, indicate that tarsiers are more closely related to anthropoids than to the lemur group **(Figure 34.37)**. You can see in Figure 34.37 that monkeys do not constitute a monophyletic group.

Both New and Old World monkeys are thought to have originated in Africa or Asia. The fossil record indicates that New World monkeys first colonized South America roughly 25 million years ago. By that time, South America and Africa had drifted apart, and monkeys may have reached South America by rafting on logs or other debris from Africa. What is certain is that New World monkeys and Old World monkeys underwent separate adaptive radiations during their many millions of years of separation **(Figure 34.38)**. All species of New World monkeys are arboreal, whereas Old World monkeys include ground-dwelling as well as arboreal species. Most monkeys in both groups are diurnal (active during the day) and usually live in bands held together by social behavior.

▲ **Figure 34.37** **A phylogenetic tree of primates.** The fossil record indicates that anthropoids began diverging from other primates about 50 million years ago. New World monkeys, Old World monkeys, and apes (the clade that includes gibbons, orangutans, gorillas, chimpanzees, and humans) have been evolving as separate lineages for over 20 million years. The lineages leading to humans branched off from other apes sometime between 5 and 7 million years ago.

? *Taxonomists currently recognize two species in the genus* Pan: *chimpanzees and bonobos. Some scientists have commented that visitors from outer space would likely consider humans a third species in this genus. Is the phylogeny shown here consistent with that view?*

▼ **Figure 34.38 New World monkeys and Old World monkeys.**

(a) New World monkeys, such as spider monkeys (shown here), squirrel monkeys, and capuchins, have a prehensile tail and nostrils that open to the sides.

(b) Old World monkeys lack a prehensile tail, and their nostrils open downward. This group includes macaques (shown here), mandrils, baboons, and rhesus monkeys.

The other group of anthropoids consists of primates informally called apes **(Figure 34.39)**. The ape group includes the genera *Hylobates* (gibbons), *Pongo* (orangutans), *Gorilla* (gorillas), *Pan* (chimpanzees and bonobos), and *Homo* (humans). The apes diverged from Old World monkeys about 20–25 million years ago. Today, nonhuman apes are found exclusively in tropical regions of the Old World. With the exception of gibbons, living apes are larger than either New or Old World monkeys. All living apes have relatively long arms, short legs, and no tail. Although all nonhuman apes spend time in trees, only gibbons and orangutans are primarily arboreal. Social organization varies among the apes; gorillas and chimpanzees are highly social. Finally, compared to other primates, apes have a larger brain in proportion to their body size, and their behavior is more flexible. These two characteristics are especially prominent in the next group we'll consider, the hominins.

(a) Gibbons, such as this Muller's gibbon, are found only in southeastern Asia. Their very long arms and fingers are adaptations for brachiating (swinging by the arms from branch to branch).

(b) Orangutans are shy apes that live in the rain forests of Sumatra and Borneo. They spend most of their time in trees; note the foot adapted for grasping and the opposable thumb.

(c) Gorillas are the largest apes; some males are almost 2 m tall and weigh about 200 kg. Found only in Africa, these herbivores usually live in groups of up to about 20 individuals.

(d) Chimpanzees live in tropical Africa. They feed and sleep in trees but also spend a great deal of time on the ground. Chimpanzees are intelligent, communicative, and social.

(e) Bonobos are in the same genus (*Pan*) as chimpanzees but are smaller. They survive today only in the African nation of Congo.

▲ **Figure 34.39 Nonhuman apes.**

CONCEPT CHECK 34.7

1. Contrast monotremes, marsupials, and eutherians in terms of how they bear young.
2. Identify at least five derived traits of primates.
3. **WHAT IF?** Develop a hypothesis to explain why the diversity of mammals increased in the Cenozoic. Your explanation should consider mammalian adaptations as well as factors such as mass extinctions and continental drift.

For suggested answers, see Appendix A.

CONCEPT 34.8

Humans are mammals that have a large brain and bipedal locomotion

In our tour of Earth's biodiversity, we come at last to our own species, *Homo sapiens*, which is about 200,000 years old. When you consider that life has existed on Earth for at least 3.5 billion years, we are clearly evolutionary newcomers.

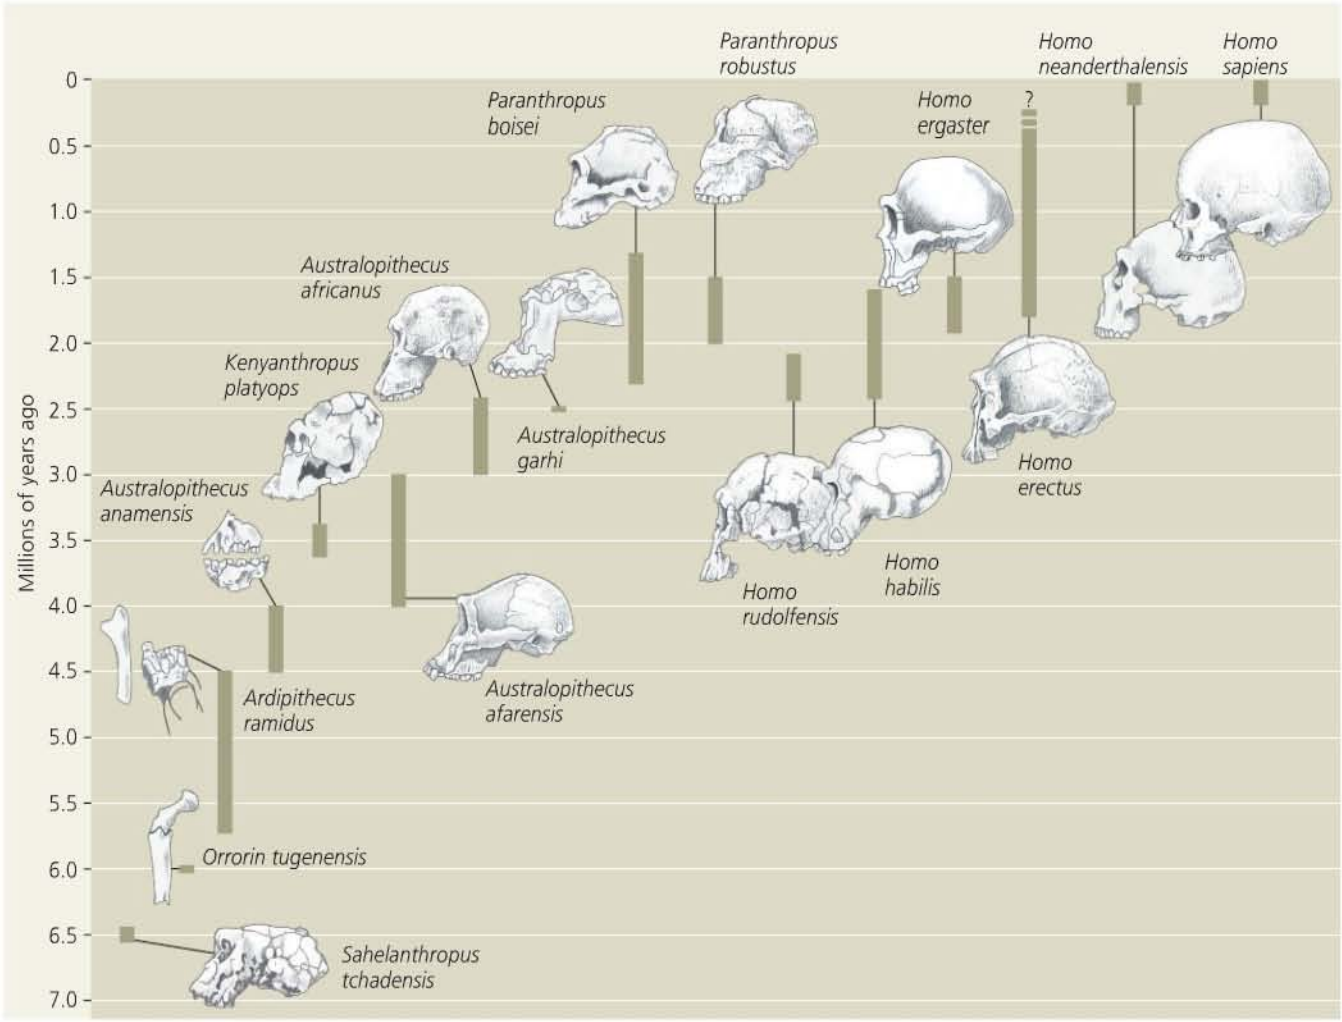
Derived Characters of Humans

Many characters distinguish humans from other apes. Most obviously, humans stand upright and are bipedal (walk on two legs). Humans have a much larger brain and are capable of language, symbolic thought, and the manufacture and use of complex tools. Humans also have reduced jawbones and jaw muscles, along with a shorter digestive tract.

At the molecular level, the list of derived characters of humans is growing as scientists compare the genomes of humans and chimpanzees. Although the two genomes are 99% identical, a disparity of 1% can translate into a large number of differences in a genome that contains 3 billion base pairs. Furthermore, changes in a small number of genes can have large effects. This point was highlighted by recent results showing that humans and chimpanzees differ in the expression of 19 regulatory genes. These genes turn other genes on and off and hence may account for many differences between humans and chimpanzees.

Bear in mind that such genomic differences—and whatever derived phenotypic traits they code for—separate humans from other *living* apes. But many of these new characters first emerged in our ancestors, long before our own species appeared. We will consider some of these ancestors to see how these characters originated.

The Earliest Hominins



The study of human origins is known as **paleoanthropology**. Paleoanthropologists have unearthed fossils of approximately 20 extinct species that are more closely related to humans than to chimpanzees. These species are known as **hominins** **(Figure 34.40)**. (Although a majority of anthropologists now use the term *hominin*, its older synonym, *hominid*, continues to be used by some). Since 1994, fossils of four hominin species dating from more than 4 million years ago have been discovered. The oldest of these hominins, *Sahelanthropus tchadensis*, lived about 6–7 million years ago.

Sahelanthropus and other early hominins shared some of the derived characters of humans. For example, they had reduced canine teeth, and some fossils suggest that they had relatively flat faces. They also show signs of having been more upright and bipedal than other apes. One clue to their upright stance can be found in the foramen magnum, the hole at the base of the skull through which the spinal cord exits. In chimpanzees, the foramen magnum is relatively far back on the skull, while in early hominins (and in humans), it is located underneath the skull. This position allows us to hold our head directly over our body, as apparently early hominins did as well. Leg bones of *Australopithecus anamensis*, a hominin that lived 4.5–4 million years ago, also suggest that early hominins were increasingly bipedal. (We will return to the subject of bipedalism later.)

Note that the characters that distinguish humans from other living apes did not all evolve in tight unison. While early hominins were showing signs of bipedalism, their brains remained small—about 400–450 cm^3 in volume, compared with an average of 1,300 cm^3 for *Homo sapiens*. The earliest hominins were also small overall (the 4.5-million-year-old *Ardipithecus ramidus* is estimated to have weighed only 40 kg) but had relatively large teeth and a lower jaw that projected beyond the upper part of their face. (Humans, in contrast, have a relatively flat face; compare your own face with those of the chimpanzees in Figure 34.39d.)

It's important to avoid two common misconceptions when considering these early hominins. One is to think of them as chimpanzees. Chimpanzees represent the tip of a separate branch of evolution, and they acquired derived characters of their own after they diverged from their common ancestor with humans.

Another misconception is to think of human evolution as a ladder leading directly from an ancestral ape to *Homo sapiens*. This error is often illustrated as a parade of fossil species that become progressively more like ourselves as they march across the page. If human evolution is a parade, it is a very disorderly one, with many groups breaking away to wander other evolutionary paths. At times, several hominin species coexisted. These species often differed in skull shape, body size, and diet (as inferred from their teeth). Ultimately, all but one lineage—the one that gave rise to *Homo sapiens*—ended in extinction. But when the characteristics of all hominins that lived over the past 6 million years are considered, *H. sapiens* appears not as the end result of a straight evolutionary path, but rather as the only surviving member of a highly branched evolutionary tree.

▲ **Figure 34.40 A timeline for some selected hominin species.** Most of these fossils come from sites in eastern and southern Africa. Note that at most times in hominin history, two or more hominin species were contemporaries. Some of the species are controversial, reflecting phylogenetic debates about the interpretation of skeletal details and biogeography.

Australopiths

The fossil record indicates that hominin diversity increased dramatically between 4 million and 2 million years ago. Many of the hominins from this period are collectively called australopiths. Their phylogeny remains unresolved on many points, but as a group, they are almost certainly paraphyletic. *Australopithecus anamensis*, mentioned earlier, links the australopiths to older hominins such as *Ardipithecus ramidus*.

Australopiths got their name from the 1924 discovery in South Africa of *Australopithecus africanus* ("southern ape of Africa"), which lived between 3 and 2.4 million years ago. With the discovery of more fossils, it became clear that *A. africanus* walked fully erect (was bipedal) and had human-like hands and teeth. However, its brain was only about one-third the size of the brain of a present-day human.

In 1974, in the Afar region of Ethiopia, paleoanthropologists discovered a 3.2-million-year-old *Australopithecus* skeleton that was 40% complete. "Lucy," as the fossil was named, was short—only about 1 m tall. Lucy and similar fossils have been considered sufficiently different from *Australopithecus africanus* to be designated as a separate species, *Australopithecus afarensis* (for the Afar region). Fossils discovered in the early 1990s show that *A. afarensis* existed as a species for at least 1 million years.

At the risk of oversimplifying, one could say that *A. afarensis* had fewer of the derived characters of humans above the neck than below. Lucy's head was the size of a softball, indicating a brain size about the same as that of a chimpanzee of Lucy's body size. *A. afarensis* skulls also have a long lower jaw. Skeletons of *A. afarensis* suggest these hominins were capable of arboreal locomotion, with arms that were relatively long in proportion to

body size (compared to the proportions in humans). However, fragments of pelvic and skull bones indicate that *A. afarensis* walked on two legs. Fossilized footprints in Laetoli, Tanzania, corroborate the skeletal evidence that hominins living at the time of *A. afarensis* were bipedal **(Figure 34.41)**.

Another lineage of australopiths consisted of the "robust" australopiths. These hominins, which included species such as *Paranthropus boisei*, had sturdy skulls with powerful jaws and large teeth, adapted for grinding and chewing hard, tough foods. They contrast with the "gracile" (slender) australopiths, including *A. afarensis* and *A. africanus*, which had lighter feeding equipment adapted for softer foods.

Combining evidence from the earliest hominins with the much richer fossil record of later australopiths makes it possible to formulate hypotheses about significant trends in hominin evolution. Let's consider two of these trends: the emergence of bipedalism and tool use.

(a) Lucy, a 3.24-million-year-old skeleton, represents the hominin species *Australopithecus afarensis*.

(b) The Laetoli footprints, more than 3.5 million years old, confirm that upright posture evolved quite early in hominin history.

(c) An artist's reconstruction of what *A. afarensis* may have looked like.

▲ Figure 34.41 Upright posture predates an enlarged brain in human evolution.

Bipedalism

Our anthropoid ancestors of 30–35 million years ago were still tree-dwellers. But by about 10 million years ago, the Himalayan mountain range had formed, thrust up in the aftermath of the Indian plate's collision with the Eurasian plate (see Figure 25.13). The climate became drier, and the forests of what are now Africa and Asia contracted. The result was an increased area of savanna (grassland) habitat, with fewer trees. For decades, paleoanthropologists have seen a strong connection between the rise of savannas and the rise of bipedal hominins. According to one hypothesis, tree-dwelling hominins could no longer move through the canopy, so natural selection favored adaptations that made moving over open ground more efficient.

Although some elements of this hypothesis survive, the picture now appears somewhat more complex. Although all recently discovered fossils of early hominins show some indications of bipedalism, none of these hominins lived in savannas. Instead, they lived in mixed habitats ranging from forests to open woodlands. Furthermore, whatever the selective pressure that led to bipedalism, hominins did not become more bipedal in a simple, linear fashion. Australopiths seem to have had various locomotor styles, and some species spent more time on the ground than others. Only about 1.9 million years ago did hominins begin to walk long distances on two legs. These hominins lived in more arid environments, where bipedal walking requires less energy than walking on all fours.

Tool Use

As you read earlier, the manufacture and use of complex tools is a derived behavioral character of humans. Determining the origin of tool use in hominin evolution is one of paleoanthropology's great challenges. Other apes are capable of surprisingly sophisticated tool use. Orangutans, for example, can fashion sticks into probes for retrieving insects from their nests. Chimpanzees are even more adept, using rocks to smash open food and putting leaves on their feet to walk over thorns. It's likely that early hominins were capable of this sort of simple tool use, but finding fossils of modified sticks or leaves that were used as shoes is practically impossible.

The oldest generally accepted evidence of tool use by hominins is 2.5-million-year-old cut marks on animal bones found in Ethiopia. These marks suggest that hominins cut flesh from the bones of animals using stone tools. Interestingly, the hominins whose fossils were found near the site where the bones were discovered had a relatively small brain. If these hominins, which have been named *Australopithecus garhi*, were indeed the creators of the stone tools used on the bones, that would suggest that stone tool use originated before the evolution of large brains in hominins.

Early *Homo*

The earliest fossils that paleoanthropologists place in our genus, *Homo*, are those of the species *Homo habilis*. These fossils, ranging in age from about 2.4 to 1.6 million years, show clear signs of certain derived hominin characters above the neck. Compared to the australopiths, *H. habilis* had a shorter jaw and a larger brain volume, about 600–750 cm^3. Sharp stone tools have also been found with some fossils of *H. habilis* (the name means "handy man").

Fossils from 1.9 to 1.5 million years ago mark a new stage in hominin evolution. A number of paleoanthropologists recognize these fossils as those of a distinct species, *Homo ergaster*. *Homo ergaster* had a substantially larger brain than *H. habilis* (over 900 cm^3), as well as long, slender legs with hip joints well adapted for long-distance walking **(Figure 34.42)**. The fingers were relatively short and straight, suggesting that *H. ergaster* did not climb trees like earlier hominins. *Homo ergaster* fossils have been discovered in far more arid environments than earlier hominins and have been associated with more sophisticated stone tools. Its smaller teeth also suggest that *H. ergaster* either ate different foods than australopiths (more meat and less plant material) or prepared some of its food before chewing, perhaps by cooking or mashing the food.

◀ Figure 34.42 Fossil and artist's reconstruction of *Homo ergaster*. This 1.7-million-year-old fossil from Kenya belongs to a young male *Homo ergaster*. This individual was tall, slender, and fully bipedal, and he had a relatively large brain.

Homo ergaster marks an important shift in the relative sizes of the sexes. In primates, a size difference between males and females is a major component of sexual dimorphism (see Chapter 23). On average, male gorillas and orangutans weigh about twice as much as females of their species. In chimpanzees and bonobos, males are only about 1.35 times as heavy as females, on average. In *Australopithecus afarensis*, males were 1.5 times as heavy as females. But in early *Homo*, sexual dimorphism was significantly reduced, and this trend continues through our own species: Human males average about 1.2 times the weight of females.

The reduced sexual dimorphism may offer some clues to the social systems of extinct hominins. In extant primates, extreme sexual dimorphism is associated with intense male-male competition for multiple females. In species that undergo more pair-bonding (including our own), sexual dimorphism is less dramatic. Male and female *H. ergaster* may therefore have engaged in more pair-bonding than earlier hominins did. This shift may have been associated with long-term care of the young by both parents. Human babies depend on their parents for food and protection much longer than do the young of other apes.

Fossils now generally recognized as *H. ergaster* were originally considered early members of another species, *Homo erectus*, and some paleoanthropologists still hold this position. *Homo erectus* originated in Africa and was the first hominin to migrate out of Africa. The oldest fossils of hominins outside Africa, dating back 1.8 million years, were discovered in 2000 in the former Soviet Republic of Georgia. *Homo erectus* eventually migrated as far as the Indonesian archipelago. Comparisons of *H. erectus* fossils with humans and studies of human DNA indicate that *H. erectus* became extinct sometime after 200,000 years ago.

Neanderthals

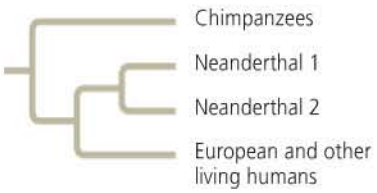
In 1856, miners discovered some mysterious human fossils in a cave in the Neander Valley in Germany. The 40,000-year-old fossils belonged to a thick-boned hominin with a prominent brow. The hominin was named *Homo neanderthalensis* and is commonly called a Neanderthal. Neanderthals were living in Europe and the Near East by 200,000 years ago, but never spread outside that region. They had a brain as large as that of present-day humans, buried their dead, and made hunting tools from stone and wood. But despite their adaptations and culture, Neanderthals apparently became extinct about 28,000 years ago.

At one time, many paleoanthropologists considered Neanderthals to be a stage in the evolution of *Homo erectus* into *Homo sapiens*. Now most have abandoned this view. One reason for this change concerns evidence from the analysis of

mitochondrial DNA **(Figure 34.43)**. The results suggest that Neanderthals may have contributed little to the gene pool of *H. sapiens*. However, preliminary results from a 2006 study that compared Neanderthal and human nuclear DNA appear to be consistent with limited gene flow between the two species. In addition, some researchers have argued that evidence of gene flow can be found in fossils that show a mixture of *H. sapiens* and Neanderthal characteristics. Further genetic analyses and fossil discoveries will be needed to resolve the ongoing debate over the extent of genetic exchange between the two species.

▼ Figure 34.43 Inquiry

Did Neanderthals give rise to European humans?



EXPERIMENT People have long been fascinated by Neanderthals and their relationship to *Homo sapiens*. Several fossils discovered in Europe have been interpreted by some researchers as showing a mixture of Neanderthal and human features, leading to the suggestion that European humans bred with or descended from Neanderthals. Igor Ovchinnikov and William Goodwin, then at the University of Glasgow, and their team used genetic methods to assess the relationship between Neanderthals and *H. sapiens*. The team extracted mitochondrial DNA (mtDNA) from a Neanderthal fossil (Neanderthal 1) and compared its sequence to an mtDNA sequence that other researchers had obtained three years earlier from a different Neanderthal fossil (Neanderthal 2). Mitochondrial DNA sequences were also obtained for a number of living humans from Europe, Africa, and Asia. The researchers then used Neanderthal and *H. sapiens* mtDNA sequences to construct a phylogenetic tree for Neanderthals and humans; data from chimpanzees were used to root the tree. This approach permitted the researchers to test the following hypothesis:

Hypothesis: Neanderthals gave rise to European humans.

Expected phylogeny:

RESULTS The two Neanderthal mtDNA sequences differed at 3.5% of the bases, whereas on average, the Neanderthal and *H. sapiens* mtDNA differed at 24% of the bases. The phylogenetic analysis yielded the following tree:

CONCLUSION The Neanderthals form one clade, and living humans form another, separate clade. Thus, it is not likely that Neanderthals gave rise to European humans. More generally, the results suggest that Neanderthals contributed little to the *H. sapiens* gene pool.

SOURCE I. V. Ovchinnikov et al., Molecular analysis of Neanderthal DNA from the northern Caucasus, *Nature* 404:490–493 (2000).

WHAT IF? DNA obtained from fossils can break down over time (obscuring the original sequence) or be contaminated by the DNA of other organisms. Do you think it is likely that these potential sources of error could have significantly affected the results obtained in this study? Explain.

Homo Sapiens

Evidence from fossils, archaeology, and DNA studies has led to a compelling hypothesis about how our own species, *Homo sapiens*, emerged and spread around the world.

Fossil evidence indicates that the ancestors of humans originated in Africa. Older species (perhaps *H. ergaster* or *H. erectus*) gave rise to later species, ultimately including *H. sapiens*. Furthermore, the oldest known fossils of our own species have been found at two different sites in Ethiopia and include specimens that are 195,000 and 160,000 years old **(Figure 34.44)**. These early humans lacked the heavy browridges of *H. erectus* and Neanderthals and were more slender than other hominins.

The Ethiopian fossils support inferences about the origin of humans from molecular evidence. As you saw in Figure 34.43, DNA analyses indicate that all living humans are more closely related to one another than to Neanderthals. Other studies on human DNA show that Europeans and Asians share a relatively recent common ancestor and that many African lineages branched off more ancient positions on the human family tree. These findings strongly suggest that all living humans have ancestors that originated as *H. sapiens* in Africa, which is further supported by analysis of mitochondrial DNA and Y chromosomes from members of various human populations.

The oldest fossils of *H. sapiens* outside Africa are from the Middle East and date back about 115,000 years. Studies of the human Y chromosome suggest that humans spread beyond Africa in one or more waves, first into Asia and then to Europe and Australia. The date of the first arrival of humans in the New World is uncertain, although the oldest generally accepted evidence puts that date at sometime before 15,000 years ago.

New findings continually update our understanding of the evolution of *H. sapiens*. For example, in 2004, researchers reported an astonishing find: skeletal remains of adult hominins dating from just 18,000 years ago and representing a previously unknown species, which they named *Homo floresiensis*. Discovered in a limestone cave on the Indonesian island of Flores, the individuals were much shorter and had a much smaller brain volume than *H. sapiens*—more similar, in fact, to an australopith. The researchers who discovered these fossils argue that the skeletons also display many derived traits, including skull thickness and proportions and teeth shape, suggesting the species is descended from the larger *H. erectus*. Not convinced, some researchers argued that the fossils represent a small *H. sapiens* who had a deformed, miniature brain, a condition called microcephaly.

However, a 2007 study found that the wrist bones of the Flores fossils are similar in shape to those of nonhuman apes and early hominins, but different from those of Neanderthals and of

▶ **Figure 34.44 A 160,000-year-old fossil of *Homo sapiens*.** This skull, discovered in Ethiopia in 2003, differs little from the skulls of living humans.

▲ **Figure 34.45 Art, a human hallmark.** The engravings on this 77,000-year-old piece of ochre, discovered in South Africa's Blombos Cave, are among the earliest signs of symbolic thought in humans.

H. sapiens. These researchers concluded that the Flores fossils represent a species whose lineage branched off before the origin of the clade that includes Neanderthals and humans. If further evidence supports the designation of *H. floresiensis* as a new hominin, one intriguing explanation for this species' apparent "shrinkage" is that isolation on the island may have resulted in selection for greatly reduced size. Such dramatic size reduction is well studied in other dwarf mammalian species that are endemic to islands; these include primitive pygmy elephants found in the same vicinity as the *H. floresiensis* specimen. Compelling questions that may yet be answered from the cache of anthropological and archeological finds on Flores include how *H. floresiensis* originated and whether it ever encountered *H. sapiens*, which also lived in Indonesia during the late Pleistocene.

The rapid expansion of our species (and the replacement of Neanderthals) may have been spurred by changes in human cognition as *H. sapiens* evolved in Africa. Evidence of sophisticated thought in *H. sapiens* includes a 2002 discovery in South Africa of 77,000-year-old art—geometric markings made on pieces of ochre **(Figure 34.45)**. And in 2004, archaeologists working in southern and eastern Africa found 75,000-year-old ostrich eggs and snail shells with holes neatly drilled through them. By 36,000 years ago, humans were producing spectacular cave paintings (see Figure 56.25a).

Clues to the cognitive transformation of humans can also be found within the human genome. For example, the gene *FOXP2* is thought to play a key role in human language. People who inherit mutated versions of the gene suffer from language impediments and have reduced activity in Broca's area in the brain (see Chapters 21 and 49). In 2002, geneticists compared the *FOXP2* gene in humans with the homologous gene in other mammals. They concluded that the gene experienced intense natural selection after the ancestors of humans and chimpanzees diverged. By comparing mutations in regions flanking the gene, the researchers estimated that this bout of natural selection occurred within the past 200,000 years. Of course, the human capacity for language involves many regions of the brain, and it is almost certain that many other genes are essential for language. But the evolution of *FOXP2* may be one genetic clue as to how our own species came to play its unique role in the world.

Our discussion of humans brings this unit on biological diversity to an end. But this organization isn't meant to imply that life consists of a ladder leading from lowly microorganisms to lofty humanity. Biological diversity is the product of branching phylogeny, not ladderlike "progress," however we choose to measure it. The fact that there are more species of ray-finned fishes alive today than all other vertebrates combined is a clear indication that our finned relatives are not outmoded underachievers that failed to leave the water. The tetrapods—amphibians, reptiles, and mammals—are derived from one lineage of lobe-finned vertebrates. As tetrapods diversified on land, fishes continued their branching evolution in the greatest portion of the biosphere's volume. Similarly, the ubiquity of diverse prokaryotes throughout the biosphere today is a reminder of the enduring ability of these relatively simple organisms to keep up with the times through adaptive evolution. Biology exalts life's diversity, past and present.

CONCEPT CHECK 34.8

1. Identify some characters that distinguish and contrast apes and hominins.
2. Provide an example in which different features of organisms in the hominin evolutionary lineage evolved at different rates.
3. **WHAT IF?** Some genetic studies suggest that the most recent common ancestor of *Homo sapiens* that lived outside of Africa spread from Africa about 50,000 years ago. Compare this date to the dates of fossils given in the text. Can both the genetic results and the dates ascribed to the fossils be correct? Explain.

For suggested answers, see Appendix A.

Chapter 34 Review

MEDIA Go to the Study Area at **www.masteringbio.com** for BioFlix 3-D Animations, MP3 Tutors, Videos, Practice Tests, an eBook, and more.

SUMMARY OF KEY CONCEPTS

Chordates: notochord; dorsal, hollow nerve cord; pharyngeal slits; post-anal tail

Craniates: two *Hox* gene clusters, neural crest

Vertebrates: *Dlx* genes duplication, backbone of vertebrae

Gnathostomes: hinged jaws, four *Hox* gene clusters

Osteichthyans: bony skeleton

Lobe-fins: muscular fins or limbs

Tetrapods: four limbs, neck, fused pelvic girdle

Amniotes: amniotic egg, rib-cage ventilation

Key Concept	Clade	Description
Concept 34.1 **Chordates have a notochord and a dorsal, hollow nerve cord (pp. 698–702)**	Cephalochordata (lancelets) 	Basal chordates; marine suspension feeders that exhibit four key derived characters of chordates
	Urochordata (tunicates) 	Marine suspension feeders; larvae display the derived traits of chordates
Concept 34.2 **Craniates are chordates that have a head (pp. 702–704)**	Myxini (hagfishes and relatives) 	Jawless marine organisms; have head that includes a skull and brain, eyes, and other sensory organs
Concept 34.3 **Vertebrates are craniates that have a backbone (pp. 704–705)**	Petromyzontida (lampreys) 	Jawless vertebrates; typically feed by attaching to a live fish and ingesting its blood
Concept 34.4 **Gnathostomes are vertebrates that have jaws (pp. 705–710)**	Chondrichthyes (sharks, rays, skates, ratfishes) 	Aquatic gnathostomes; have cartilaginous skeleton secondarily evolved from an ancestral mineralized skeleton
	Actinopterygii (ray-finned fishes) 	Aquatic gnathostomes; have bony skeleton and maneuverable fins supported by rays
	Actinistia (coelacanths) 	Ancient lineage of aquatic lobe-fins still surviving in Indian Ocean
	Dipnoi (lungfishes) 	Freshwater lobe-fins with both lungs and gills; sister group of tetrapods
Concept 34.5 **Tetrapods are gnathostomes that have limbs (pp. 710–713)**	Amphibia (salamanders, frogs, caecilians) 	Have four limbs descended from modified fins; most have moist skin that functions in gas exchange; many live both in water (as larvae) and on land (as adults)
Concept 34.6 **Amniotes are tetrapods that have a terrestrially adapted egg (pp. 713–720)** **MEDIA** Investigation How Does Bone Structure Shed Light on the Origin of Birds?	Reptilia (tuataras, lizards and snakes, turtles, crocodilians, birds)  	One of two groups of living amniotes; have amniotic eggs and rib-cage ventilation, which are key adaptations for life on land
Concept 34.7 **Mammals are amniotes that have hair and produce milk (pp. 720–728)** **MEDIA** Activity Characteristics of Chordates Activity Primate Diversity	Mammalia (monotremes, marsupials, eutherians)  	Evolved from synapsid ancestors; include egg-laying monotremes (echidnas, platypus); pouched marsupials (such as kangaroos, opossums); and eutherians (placental mammals such as rodents, primates)

CONCEPT 34.8

Humans are mammals that have a large brain and bipedal locomotion (pp. 728–733)

- **Derived Characters of Humans** Humans are bipedal and have a larger brain and reduced jaw compared to other apes.
- **The Earliest Hominins** Hominins—humans and species that are more closely related to humans than to chimpanzees—originated in Africa at least 6–7 million years ago. Early hominins had a small brain but probably walked upright.
- **Australopiths** Australopiths lived 4–2 million years ago. Some species walked upright and had human-like hands and teeth.
- **Bipedalism** Hominins began to walk long distances on two legs about 1.9 million years ago.
- **Tool Use** The oldest evidence of tool use—cut marks on animal bones—is 2.5 million years old.
- **Early *Homo*** *Homo ergaster* was the first fully bipedal, large-brained hominin. *Homo erectus* was the first hominin to leave Africa.
- **Neanderthals** Neanderthals lived in Europe and the Near East about 200,000—28,000 years ago.
- ***Homo Sapiens*** *Homo sapiens* appeared in Africa by about 195,000 years ago. Its spread to other continents about 115,000 years ago may have been preceded by genetic changes that enabled language and other aspects of cognition. Research into the origins and contemporaries of *Homo sapiens* is a lively area.

Activity Human Evolution

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Vertebrates and tunicates share
   a. jaws adapted for feeding.
   b. a high degree of cephalization.
   c. the formation of structures from the neural crest.
   d. an endoskeleton that includes a skull.
   e. a notochord and a dorsal, hollow nerve cord.
2. Some animals that lived 530 million years ago resembled lancelets but had a brain and a skull. These animals may represent
   a. the first chordates.
   b. a "missing link" between urochordates and cephalochordates.
   c. early craniates.
   d. marsupials.
   e. nontetrapod gnathostomes.
3. Which of the following could be considered the most recent common ancestor of living tetrapods?
   a. a sturdy-finned, shallow-water lobe-fin whose appendages had skeletal supports similar to those of terrestrial vertebrates
   b. an armored, jawed placoderm with two pairs of appendages
   c. an early ray-finned fish that developed bony skeletal supports in its paired fins
   d. a salamander that had legs supported by a bony skeleton but moved with the side-to-side bending typical of fishes
   e. an early terrestrial caecilian whose legless condition had evolved secondarily
4. Mammals and living birds share all of the following characteristics *except*
   a. endothermy.
   b. descent from a common amniotic ancestor.
   c. a dorsal, hollow nerve cord.
   d. an archosaur common ancestor.
   e. an amniotic egg.
5. Unlike eutherians, *both* monotremes and marsupials
   a. lack nipples.
   b. have some embryonic development outside the mother's uterus.
   c. lay eggs.
   d. are found in Australia and Africa.
   e. include only insectivores and herbivores.
6. Which clade does *not* include humans?
   a. synapsids
   b. lobe-fins
   c. diapsids
   d. craniates
   e. osteichthyans
7. As hominins diverged from other primates, which of the following appeared first?
   a. reduced jawbones
   b. language
   c. bipedal locomotion
   d. the making of stone tools
   e. an enlarged brain

EVOLUTION CONNECTION

8. Identify one characteristic that qualifies humans for membership in each of the following clades: eukaryotes, animals, deuterostomes, chordates, vertebrates, gnathostomes, amniotes, mammals, primates.

SCIENTIFIC INQUIRY

9. **DRAW IT** As a consequence of size alone, organisms that are large tend to have larger brains than organisms that are small. However, some organisms have brains that are considerably larger than expected for an animal of their size. There are high costs associated with the development and maintenance of brains that are large relative to body size.

   (a) The fossil record documents trends in which brains that are large relative to body size evolved in certain lineages, including hominins. In such lineages, what can you infer about the relative magnitude of the costs and benefits of large brains?

   (b) Hypothesize how natural selection might favor the evolution of large brains despite the high maintenance costs of such brains.

   (c) Data for 14 bird species are listed below. Graph the data, placing deviation from expected brain size on the *x*-axis and mortality rate on the *y*-axis. What can you conclude about the relationship between brain size and mortality?

Deviation from Expected Brain Size*	-2.4	-2.1	2.0	-1.8	-1.0	0.0	0.3	0.7	1.2	1.3	2.0	2.3	3.0	3.2
Mortality Rate	0.9	0.7	0.5	0.9	0.4	0.7	0.8	0.4	0.8	0.3	0.6	0.6	0.3	0.6

*Negative values indicate brain sizes smaller than expected; positive values indicate brain sizes larger than expected.

UNIT 6

Plant Form and Function

AN INTERVIEW WITH

Patricia C. Zambryski

Pat Zambryski opened the door to genetic engineering in plants by discovering how the bacterium *Agrobacterium tumefaciens* transfers DNA into the plants it infects, and her lab continues to provide insights into this process. She also has a second major research area: plasmodesmata, the channels through plant cell walls. Her work in this area is shedding light on cell-to-cell communication, plant development, and defenses against pathogens. Dr. Zambryski grew up in Montreal, Canada, where she graduated from McGill University, and she earned her Ph.D. from the University of Colorado. After postdoctoral research at the University of California, San Francisco (UCSF), she spent five years as a senior investigator at Ghent University in Belgium. A member of the National Academy of Sciences, Dr. Zambryski is currently a professor of plant and microbial biology at the University of California, Berkeley.

What were the subjects of your early research, leading up to your work with *Agrobacterium*?

In grad school at the University of Colorado, I worked on bacteriophage T4. To learn how to evaluate data and pose new questions in biology, it's good to work with a simple system like a phage or bacterium because you can do an experiment in one day and get the answer quickly. Especially in those days, before genetic engineering, if you were working with a multicellular eukaryote, a research project could take a long, long time. I used gel electrophoresis to separate and identify all the different proteins that this phage made, and I determined that specific groups of proteins were made at different times during infection.

Then I went to UCSF to do a post-doc. I was interested in working with animal tumor viruses. But after a few years I realized that there were thousands of people in that field—all working on the same small viruses, with tiny genomes that encoded just a few proteins! And I didn't feel like I could contribute something novel with so many people working on the same thing.

At the time, there was a powerful new method for using two-dimensional electrophoresis to separate all the proteins from cell extracts, and I was looking at the proteins made in a number of different biological systems. I was invited to visit a lab at Ghent University to use these 2-D gels to try to figure out what might be the gene product that enabled *Agrobacterium tumefaciens* to cause tumors in plants. While I was there, it occurred to me that this would be a very good biological system to study. Little was known about it, and it was a fascinating system of genetic transfer from a prokaryote to a eukaryote. So I got involved with tumors after all—but tumors in plants rather than animals!

It had already been discovered that there was a piece of DNA that *Agrobacterium* transferred into the plant it infected, but we didn't know the exact composition of that DNA, the nature of its borders with surrounding DNA, or how the transfer happened. Meanwhile, back at UCSF, people were just starting to do DNA cloning using phage lambda. When I returned there, my project was to clone the piece of *Agrobacterium* DNA that was inserted into the plant genome—the T DNA—and find out what the ends of the T DNA were.

I would spend summers in Ghent learning the biology of *Agrobacterium* and then return to UCSF to work on cloning the T DNA. Finally, after one summer, I decided to stay, and I spent the next five years at Ghent University. That's where a really big thing happened. I had figured out what the T-DNA ends were, and in Ghent I discovered that *any* DNA inserted between these ends (by recombinant DNA technology) would be transferred to plant cells and stably integrated into their genomes. It was the birth of genetic engineering in plants. [See Figure 20.25 to review how T DNA is used.]

For the genetic engineering of plants, how does the *Agrobacterium* system compare with a "gene gun"?

People generally prefer to use the *Agrobacterium* system because all the DNA carried between the ends of the T element is precisely integrated into the plant cell's DNA. *Agrobacterium* DNA transfer is more precise and significantly more efficient than shooting foreign DNA into plant cells using a gene gun, which fires tiny pellets coated with DNA. But for plants that are not susceptible to *Agrobacterium* infection, you have to use a gene gun.

What have you been studying recently in *Agrobacterium*?

Bacteria have various molecular systems that allow them to transport things out of the cell (secretion) or take things up. A major focus of our current research is one specific bacterial secretion system, called type IV, which is used by *Agrobacterium*. This system is used for translocating both DNA, as in bacterial conjugation, and proteins. In *Agrobacterium*, generation of a transferable T-DNA segment and expression of the type IV secretion system have evolved to occur only in the presence of a wounded plant cell. The wounded cell then is the recipient for DNA and protein transport. It turns out that type IV secretion systems are also used to secrete toxins into host cells by bacteria that are pathogenic for humans, such as those that cause whooping cough, stomach ulcers, and Legionnaires' disease. The system probably evolved first as a bacterial conjugation system and later developed the ability to transfer DNA and proteins to eukaryotic hosts, causing disease. Recall that in nature *Agrobacterium* causes disease—tumorous growths on plants.

How did you become interested in plasmodesmata, your other major area of research?

Although my background was mostly in microbiology, I was hired by a plant biology department, here at Berkeley. So I said to

myself, this is cool—maybe I should do some experiments with plants! But knowing almost nothing about plants, I decided to work on something about which little was known. So I started to work on plasmodesmata because I thought I could contribute to the field of plant intercellular communication. I didn't want to start with a well-studied system like photosynthesis!

What are plasmodesmata, and what is currently known about their function?

When adjacent plant cells need to communicate, information must be transferred across the thick cell walls that lie outside the plasma membrane. Plasmodesmata are plant-specific communication channels that span the cell walls and link the cytoplasm of adjacent cells; the plasma membrane of the two cells is continuous in these places. At first, it was thought that plasmodesmata were a fixed size, with apertures so narrow that only ions and small molecules such as sugars and hormones could pass through. However, it was also known that plant viruses could commandeer plasmodesmata, and it was discovered that these viruses encode proteins that open the channels enough to allow passage of the virus.

The big breakthrough in recent years has been the discovery that, even in plants not infected with a virus, the apertures of plasmodesmata are dynamic. And the apertures can open wide enough to allow the transport not only of small molecules but also of macromolecules such as RNA or protein. Also, the aperture size can change during development, both during embryonic development and during the development of new tissues and organs from regions of mature plants called meristems. This discovery has tremendous implications for how plant development proceeds. Immature tissues such as those found in embryos and meristems have very dilated plasmodesmata, suggesting that plasmodesma-mediated communication between cells is likely to be involved in the initiation and coordination of developmental processes.

What do you want to find out about plasmodesmata now?

We want to understand how the structure and function of plasmodesmata are regulated, both during embryonic development and in the life of the mature plant. To get at this, we have been searching for the genes that are responsible for this regulation. We've collected mutants that are deficient in regulating transport between cells of the embryo. We reasoned that we could not screen for mutants in mature plants because plasmodesmata are so important that any mutant would be a dead plant. Thus, we assay plasmodesmata function in so-called embryo defective lines that can be propagated as heterozygotes. The seedpods of heterozygote plants contain both wild-type and homozygous mutant embryos that develop enough to allow us to assay for plasmodesma-mediated transport. Once we identify the gene products affected by the mutations, we can study how these proteins affect the regulation of plasmodesmata in older plants, as well.

Fluorescent tracers are key tools in our research. Tracers of small molecular weight can move from cell to cell during all embryonic stages. However, larger tracers move freely only during the earlier stages. That means there is "down regulation" of plasmodesma apertures during embryonic development. So we used the large fluorescent tracers in a genetic screen for mutants that continued to traffic it at late embryonic stages. We screened 5,000 mutants in this way to find about 10 embryo-defective mutants of the sort we were looking for! Now we're cloning the genes affected, trying to identify their products, and seeing how they affect plasmodesmata.

How does the regulation of plasmodesma size benefit the plant?

In a tiny embryo, it makes sense for all the cells to be in communication with each other so that development is properly coordinated. Then, as cells differentiate and tissues and organs develop, groups of cells with related functions need to be in communication. Later, as cells and tissues develop unique functions, they may lose communication with adjacent regions. Cell differentiation occurs by regulation of gene expression, but development requires another layer of control on top of that—the control of what gene products can move cell to cell via plasmodesmata, which in turn coordinates development throughout the plant body.

Why do you and most other plant molecular biologists use *Arabidopsis thaliana* as a research organism?

You can grow thousands of these small plants in a small space, and they go from seed to seed in six weeks. *Arabidopsis* has a small genome, less than one twentieth the size of the corn or human genomes, making it easy to clone its genes. Its genome has been sequenced. The genetics are fabulous. Almost every gene has been tagged by T-DNA insertions to make mutants with particular phenotypes and to facilitate cloning of their affected genes. This plant is very convenient to work with for those reasons and more.

Along with laboratory research, do you enjoy teaching?

When I started teaching, I taught only graduate students, but I've found that I really enjoy teaching undergraduates, too. I teach a class with no prerequisites called "The Secret Life of Plants." I want the students to realize that plants are absolutely critical to our lives and also interesting in their own right. I want students to have enough understanding of science to read the popular press and form decisions about important issues such as global warming and genetically modified organisms (GMOs). We talk about basic biology that is unique to plants, but also about global warming, GMOs, biofuels, and medicinal plants, among other applied topics. Teaching that course is one of the most rewarding things I do.

I want the students to realize that plants are absolutely critical to our lives and also interesting in their own right.

35 Plant Structure, Growth, and Development

▲ **Figure 35.1 Why does this plant have two types of leaves?**

KEY CONCEPTS

35.1 The plant body has a hierarchy of organs, tissues, and cells

35.2 Meristems generate cells for new organs

35.3 Primary growth lengthens roots and shoots

35.4 Secondary growth adds girth to stems and roots in woody plants

35.5 Growth, morphogenesis, and differentiation produce the plant body

OVERVIEW

Plastic Plants?

Although the graceful fanwort (*Cabomba caroliniana*) **(Figure 35.1)** is an attractive addition to many aquariums, its most striking feature is its extreme *developmental plasticity*—its ability to alter its form in response to local environmental conditions. The underwater leaves are feathery, an adaptation that protects them from damage by lessening their resistance to moving water. In contrast, the surface leaves are pads that aid in flotation. Both leaf types have genetically identical cells, but dissimilar environments result in the turning on or off of different genes during leaf development. Such extreme developmental plasticity is much more common in plants than in animals and may help compensate for plants' inability to escape adverse conditions by moving.

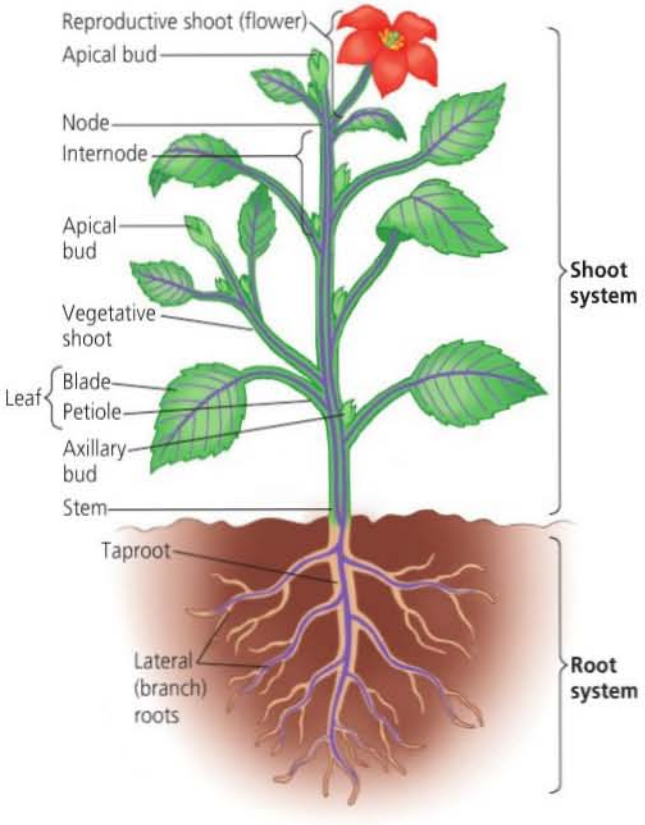
In addition to structural responses by an individual plant to a specific environment, entire species have by natural selection accumulated adaptations in **morphology**, or external form, that vary little among plants within the species. For example, most cactus species, regardless of local environment, have leaves that are so highly reduced—to spines—that the stems are the primary photosynthetic organs. This adaptation in leaf morphology enhances the survival and reproductive success of cacti because with reduced leaf surface areas, these desert plants lose less water.

Both genetic and environmental factors influence form in plants and animals, but the effect of environment is greater in plants. Consequently, plants typically vary much more within a species than do animals. All lions, for example, have four legs and are roughly the same size at maturity. In contrast, ginkgo trees vary greatly in the numbers, sizes, and positions of their roots, branches, and leaves. Lacking mobility, plants must be adapted to their environment in other ways. Thus, plant form is central to understanding how plants compete in nature.

This chapter focuses on how the body of a plant is formed, setting the stage for the rest of this unit on plant biology. Chapters 29 and 30 described the evolution and characteristics of nonvascular plants, seedless vascular plants, gymnosperms, and angiosperms (flowering plants). Here, in Unit Six, we'll focus primarily on vascular plants—especially angiosperms, because they account for about 90% of plant species and are of great importance to humans. As the world's population increases, the need for plants to supply food, fuel, fiber, medicine, lumber, and paper has never been greater, heightening the importance of understanding how plants grow and develop.

CONCEPT 35.1

The plant body has a hierarchy of organs, tissues, and cells



Plants, like most animals, have organs composed of different tissues, which in turn are composed of cells of different types. A **tissue** is a group of cells with a common function, structure, or both. An **organ** consists of several types of tissues that together carry out particular functions. In looking at the hierarchy of plant organs, tissues, and cells, we begin with organs because they are the most familiar and easily observed plant structures. As you learn about the hierarchy of plant structure, keep in mind how natural selection has produced plant forms, at all levels of organization, that fit plant function.

The Three Basic Plant Organs: Roots, Stems, and Leaves

The basic morphology of most vascular plants reflects their evolutionary history as terrestrial organisms that inhabit and draw resources from two very different environments—below ground and above ground. They must absorb water and minerals from below the ground surface and CO_2 and light from above the ground surface. The ability to acquire these resources arose from the evolution of three basic organs—roots, stems, and leaves. These organs form a **root system** and a **shoot system**, the latter consisting of stems and leaves **(Figure 35.2)**. With few exceptions, angiosperms and other vascular plants rely completely on both systems for survival. Roots are typically nonphotosynthetic and starve unless *photosynthates*, the sugars and other carbohydrates produced during photosynthesis, are imported from the shoot system. Conversely, the shoot system depends on the water and minerals that roots absorb from the soil.

Vegetative growth—production of nonreproductive leaves, stems, and roots—is only one stage in a plant's life. Many plants also undergo reproductive growth. In angiosperms, reproductive shoots bear flowers, which are composed of leaves that are highly modified for sexual reproduction. Later in this chapter, we'll discuss the transition from vegetative shoot formation to reproductive shoot formation.

In describing plant organs, we'll draw examples mainly from the two major groups of angiosperms: monocots and eudicots (see Figure 30.13).

▲ **Figure 35.2 An overview of a flowering plant.** The plant body is divided into a root system and a shoot system, connected by vascular tissue (purple strands in this diagram) that is continuous throughout the plant. The plant shown is an idealized eudicot.

Roots

A **root** is a multicellular organ that anchors a vascular plant in the soil, absorbs minerals and water, and often stores carbohydrates. Most eudicots and gymnosperms have a *taproot system*, consisting of one main vertical root, the **taproot**, that develops from an embryonic root. The taproot gives rise to **lateral roots**, also called branch roots (see Figure 35.2). In many angiosperms, the taproot stores sugars and starches that the plant will consume during flowering and fruit production. For this reason, root crops such as carrots, turnips, and beets are harvested before they flower. Taproot systems generally penetrate deeply and are therefore well adapted to deep soils where the groundwater is not close to the surface.

In seedless vascular plants and in most monocots, such as grasses, the embryonic root dies and does not give rise to a main root. Instead, many small roots grow from the stem. Such roots are said to be *adventitious* (from the Latin *adventicus*, extraneous), a term describing a plant organ that grows in an unusual location, such as roots arising from stems or leaves. Each small root forms its own lateral roots. The result is a *fibrous root system*—a mat of generally thin roots spreading out below the soil surface, with no root functioning as the main one (see Figure 30.13). Fibrous root systems usually do not penetrate deeply and are therefore best adapted to shallow soils or regions where rainfall is light and does not moisten the soil much below the surface layer. Most grasses have shallow roots, concentrated in the upper few centimeters of the soil. Because these shallow roots hold the topsoil in place, grass makes excellent ground cover for preventing erosion.

Although the entire root system helps anchor a plant, in most plants the absorption of water and minerals occurs primarily near the tips of roots, where vast numbers of tiny **root hairs** increase the surface area of the root enormously **(Figure 35.3)**.

◀ **Figure 35.3 Root hairs of a radish seedling.** Root hairs grow by the thousands just behind the tip of each root. By increasing the root's surface area, they greatly enhance the absorption of water and minerals from the soil.

Root hairs are short-lived and constantly replaced. A root hair is a thin, tubular extension of a root epidermal cell. It should not be confused with a lateral root, which is a multicellular organ. Despite their great surface area, root hairs, unlike lateral roots, contribute little to plant anchorage. Their main function is absorption.

Many plants have modified roots **(Figure 35.4)**. Some of these arise from roots, and others are adventitious, developing from stems or, in rare cases, leaves. Some modified roots provide more support and anchorage, whereas others store water and nutrients or absorb oxygen from the air.

▼ **Figure 35.4 Modified roots.**

◀ **Prop roots.** The aerial roots of maize (corn) are examples of prop roots, so named because they support tall, top-heavy plants. All roots of a mature maize plant are adventitious after the original roots die. The emerging roots shown here will eventually penetrate the soil.

▶ **Storage roots.** Many plants, such as the common beet, store food and water in their roots.

◀ **"Strangling" aerial roots.** The seeds of this strangler fig germinate in the branches of tall trees of other species and send numerous aerial roots to the ground. These snake-like roots gradually wrap around the host tree and objects such as this Cambodian temple ruin. Eventually, the host tree dies of shading by the fig leaves.

▲ **Pneumatophores.** Also known as air roots, pneumatophores are produced by trees such as mangroves that inhabit tidal swamps. By projecting above the water's surface, they enable the root system to obtain oxygen, which is lacking in the thick, waterlogged mud.

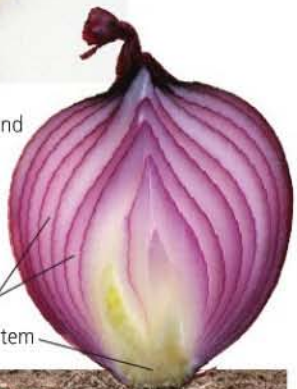
▼ **Buttress roots.** Aerial roots that look like buttresses support the tall trunks of some tropical trees, such as this ceiba tree in Central America.

Stems

A **stem** is an organ consisting of an alternating system of **nodes**, the points at which leaves are attached, and **internodes**, the stem segments between nodes (see Figure 35.2). In the upper angle (axil) formed by each leaf and the stem is an **axillary bud**, a structure that can form a lateral shoot, commonly called a branch. Most axillary buds of a young shoot are dormant (not growing). Thus, elongation of a young shoot is usually concentrated near the shoot tip, which consists of an **apical bud**, or terminal bud, with developing leaves and a compact series of nodes and internodes.

The proximity of the axillary buds to the apical bud is partly responsible for their dormancy. The inhibition of axillary buds by an apical bud is called **apical dominance**. By concentrating resources on elongation, the evolutionary adaptation of

apical dominance increases the plant's exposure to light. If an animal eats the end of the shoot, or if shading results in the light being more intense to the side of a plant than directly above, axillary buds break dormancy; that is, they start growing. A growing axillary bud gives rise to a lateral shoot, complete with its own apical bud, leaves, and axillary buds. Removing the apical bud usually stimulates the growth of axillary buds, resulting in more lateral shoots. That is why pruning trees and shrubs and pinching back houseplants will make them bushier.



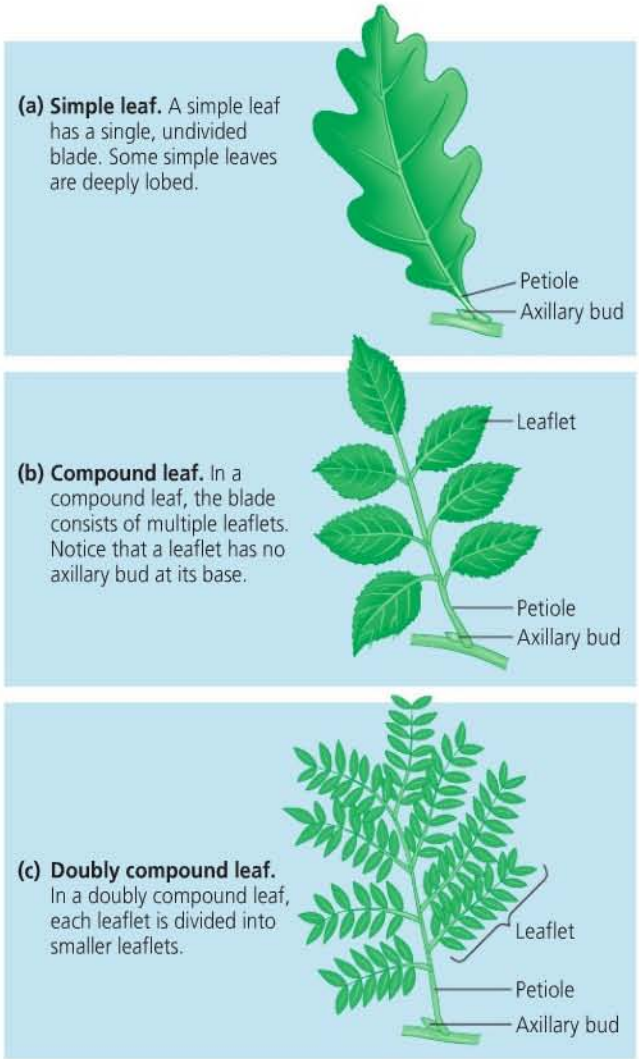
Some plants have stems with additional functions such as food storage and asexual reproduction. These modified stems, which include rhizomes, bulbs, stolons, and tubers, are often mistaken for roots **(Figure 35.5)**.

▼ Figure 35.5 Modified stems.

▼ Rhizomes. The base of this iris plant is an example of a rhizome, a horizontal shoot that grows just below the surface. Vertical shoots emerge from axillary buds on the rhizome.

▶ Bulbs. Bulbs are vertical underground shoots consisting mostly of the enlarged bases of leaves that store food. You can see the many layers of modified leaves attached to the short stem by slicing an onion bulb lengthwise.

▶ Stolons. Shown here on a strawberry plant, stolons are horizontal shoots that grow along the surface. These "runners" enable a plant to reproduce asexually, as plantlets form at nodes along each runner.



◀ Tubers. Tubers, such as these red potatoes, are enlarged ends of rhizomes or stolons specialized for storing food. The "eyes" of a potato are clusters of axillary buds that mark the nodes.

Leaves

In most vascular plants, the **leaf** is the main photosynthetic organ, although green stems also perform photosynthesis. Leaves vary extensively in form but generally consist of a flattened **blade** and a stalk, the **petiole**, which joins the leaf to the stem at a node (see Figure 35.2). Grasses and many other monocots lack petioles; instead, the base of the leaf forms a sheath that envelops the stem.

Monocots and eudicots differ in the arrangement of **veins**, the vascular tissue of leaves. Most monocots have parallel major veins that run the length of the blade. Eudicots generally have a branched network of major veins (see Figure 30.13).

In identifying angiosperms according to structure, taxonomists rely mainly on floral morphology, but they also use variations in leaf morphology, such as leaf shape, the branching pattern of veins, and the spatial arrangement of leaves. **Figure 35.6** illustrates a difference in leaf shape: simple versus compound. Many

▲ Figure 35.6 Simple versus compound leaves. One can distinguish simple leaves from compound leaves by looking for axillary buds. Leaves have axillary buds; leaflets do not.

very large leaves are compound or doubly compound. This structural adaptation may enable large leaves to withstand strong wind with less tearing. It may also confine some pathogens (disease-causing organisms and viruses) that invade the leaf to a single leaflet, rather than allowing them to spread to the entire leaf.

Almost all leaves are specialized for photosynthesis. However, some species have leaves with adaptations that enable them to perform additional functions, such as support, protection, storage, or reproduction **(Figure 35.7)**.

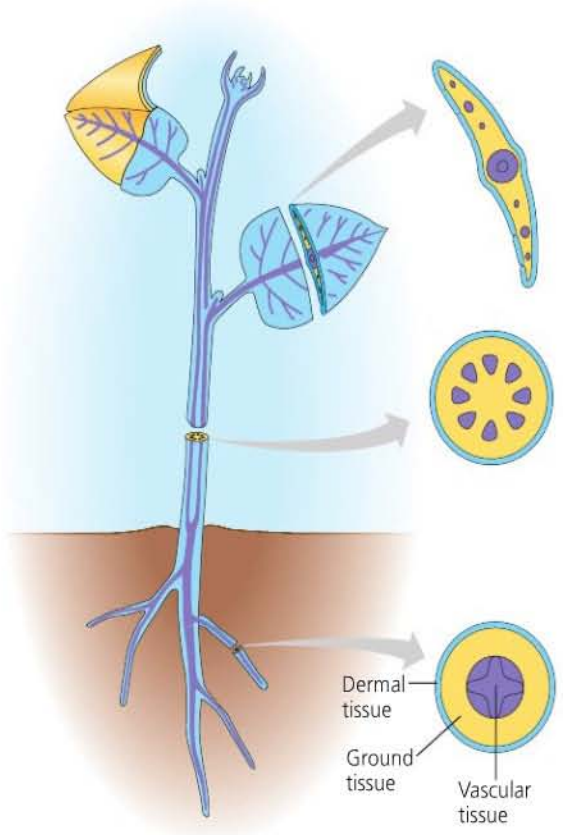
▼ Figure 35.7 Modified leaves.

▶ Tendrils. The tendrils by which this pea plant clings to a support are modified leaves. After it has "lassoed" a support, a tendril forms a coil that brings the plant closer to the support. Tendrils are typically modified leaves, but some tendrils are modified stems, as in grapevines.

◀ Spines. The spines of cacti, such as this prickly pear, are actually leaves; photosynthesis is carried out by the fleshy green stems.

◀ Storage leaves. Most succulents, such as this ice plant, have leaves modified for storing water.

▶ Reproductive leaves. The leaves of some succulents, such as *Kalanchoë daigremontiana*, produce adventitious plantlets, which fall off the leaf and take root in the soil.



▶ Bracts. Often mistaken for petals, the red parts of the poinsettia are actually modified leaves called bracts that surround a group of flowers. Such brightly colored leaves attract pollinators.

Dermal, Vascular, and Ground Tissues

Each plant organ—root, stem, or leaf—has dermal, vascular, and ground tissues. Each of these three categories forms a **tissue system**, a functional unit connecting all of the plant's organs. Although each tissue system is continuous throughout the plant, specific characteristics of the tissues and their spatial relationships to one another vary in different organs **(Figure 35.8)**.

The **dermal tissue system** is the plant's outer protective covering. Like our skin, it forms the first line of defense against physical damage and pathogens. In nonwoody plants, it is usually a single tissue called the **epidermis**, a layer of tightly packed cells. In leaves and most stems, the **cuticle**, a waxy coating on the epidermal surface, helps prevent water loss. In woody plants, protective tissues called **periderm** replace the epidermis in older regions of stems and roots. In addition to protecting the plant from water loss and disease, the epidermis has specialized characteristics in each organ. For example, a root hair is an extension of an epidermal cell near the tip of a root. *Trichomes*, hairlike outgrowths of the shoot epidermis, reduce water loss and reflect excess light. They can also provide defense against insects by forming a barrier or by secreting sticky fluids and toxic

▲ Figure 35.8 The three tissue systems. The dermal tissue system (blue) provides a protective cover for the entire body of a plant. The vascular tissue system (purple), which transports materials between the root and shoot systems, is also continuous throughout the plant, but is arranged differently in each organ. The ground tissue system (yellow), which is responsible for most of the plant's metabolic functions, is located between the dermal tissue and the vascular tissue in each organ.

compounds. For instance, the trichomes on aromatic leaves such as mint secrete oils that protect the plants from herbivores and disease. **Figure 35.9** describes an investigation of the relationship between trichome density on soybean pods and damage by beetles.

▼ Figure 35.9 Inquiry

Do soybean pod trichomes deter herbivores?

EXPERIMENT Bean leaf beetles (*Cerotoma trifurcata*) feed on developing legume pods, causing pod scarring and decreased seed quality. W. K. Lam and L. P. Pedigo, of Purdue University, investigated whether the stiff trichomes on soybean pods (*Glycine max*) physically deter these beetles. The researchers placed hungry beetles in muslin bags and sealed the bags around the pods of adjacent plants expressing different pod hairiness. The amount of damage to the pods was assessed after 24 hours.

Very hairy pod (10 trichomes/ mm^2) | Slightly hairy pod (2 trichomes/ mm^2) | Bald pod (no trichomes)

RESULTS Beetle damage to very hairy soybean pods was much lower compared with the other pod types.

Very hairy pod: 10% damage | Slightly hairy pod: 25% damage | Bald pod: 40% damage

CONCLUSION Soybean pod trichomes protect against beetle damage.

SOURCE W. F. Lam and L. P. Pedigo, Effect of trichome density on soybean pod feeding by adult bean leaf beetles (Coleoptera: Chrysomelidae), *Journal of Economic Entomology* 94(6):1459–1463 (2001).

WHAT IF? The pod trichomes of most soybean varieties are white, but some varieties have tawny-colored trichomes. Suppose that the effects of trichome density on beetle feeding were observed only in tawny-haired varieties. What might this finding suggest about how these trichomes deter beetles?

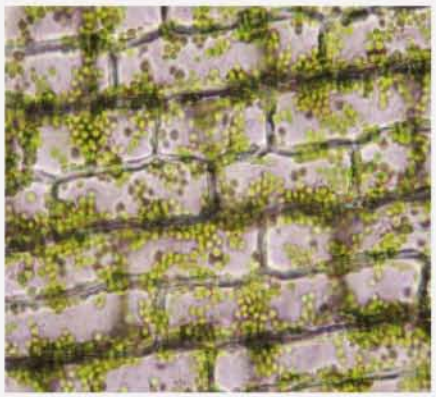
The **vascular tissue system** carries out long-distance transport of materials between the root and shoot systems. The two types of vascular tissues are xylem and phloem. **Xylem** conducts water and dissolved minerals upward from roots into the shoots. **Phloem** transports sugars, the products of photosynthesis, from where they are made (usually the leaves) to where they are needed—usually roots and sites of growth, such as developing leaves and fruits. The vascular tissue of a root or stem is collectively called the **stele** (the Greek word for "pillar"). The arrangement of the stele varies, depending on the species and organ. In angiosperms, for example, the root stele is a solid central *vascular cylinder* of xylem and phloem, whereas the stele of stems and leaves consists of *vascular bundles*, separate strands containing xylem and phloem (see Figure 35.8). Both xylem and phloem are composed of a variety of cell types, including cells that are highly specialized for transport or support.

Tissues that are neither dermal nor vascular are part of the **ground tissue system**. Ground tissue that is internal to the vascular tissue is known as **pith**, and ground tissue that is external to the vascular tissue is called **cortex**. The ground tissue system is not just filler. It includes various cells specialized for functions such as storage, photosynthesis, and support.

Common Types of Plant Cells

Like any multicellular organism, a plant is characterized by cellular differentiation, the specialization of cells in structure and function. Cellular differentiation may involve changes both in the cytoplasm and its organelles and in the cell wall. **Figure 35.10**, on the next two pages, focuses on the major types of plant cells: parenchyma cells, collenchyma cells, sclerenchyma cells, the water-conducting cells of the xylem, and the sugar-conducting cells of the phloem. Notice the structural adaptations in the different cells that make their specific functions possible. You may also wish to review Figures 6.9 and 6.28, which show basic plant cell structure.

CONCEPT CHECK 35.1



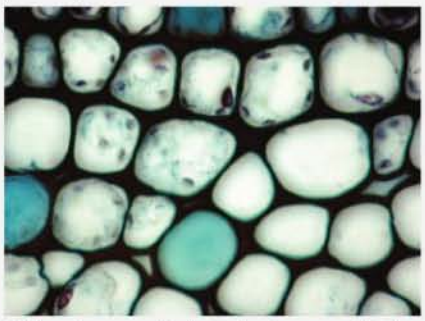
1. How does the vascular tissue system enable leaves and roots to function together in supporting growth and development of the whole plant?
2. When you eat the following, what plant structure are you consuming? (a) brussels sprouts; (b) celery sticks; (c) onions; (d) carrot sticks
3. Characterize the role of each of the three tissue systems in a leaf.
4. Describe at least three specializations in plant organs and plant cells that are adaptations to life on land.
5. **WHAT IF?** If humans were photoautotrophs, making food by capturing light energy for photosynthesis, how might our anatomy be different?

For suggested answers, see Appendix A.

▼ Figure 35.10

Exploring Examples of Differentiated Plant Cells

Parenchyma Cells

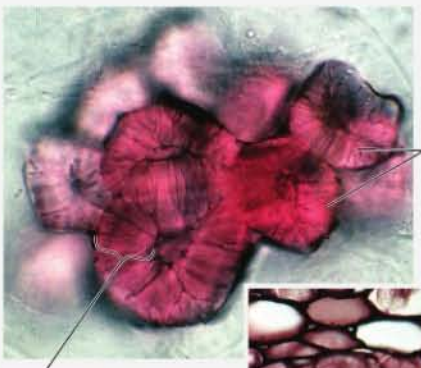


Parenchyma cells in *Elodea* leaf, with chloroplasts (LM)

60 µm

Mature **parenchyma cells** have primary walls that are relatively thin and flexible, and most lack secondary walls. (See Figure 6.28 to review primary and secondary cell walls.) When mature, parenchyma cells generally have a large central vacuole. Diagrams of "typical" plant cells often depict parenchyma cells because they are the least specialized structurally. Parenchyma cells perform most of the metabolic functions of the plant, synthesizing and storing various organic products. For example, photosynthesis occurs within the chloroplasts of parenchyma cells in the leaf. Some parenchyma cells in stems and roots have colorless plastids that store starch. The fleshy tissue of many fruits is composed mainly of parenchyma cells. Most parenchyma cells retain the ability to divide and differentiate into other types of plant cells under particular conditions—during wound repair, for example. It is even possible for scientists to grow an entire plant from a single parenchyma cell.

Collenchyma Cells

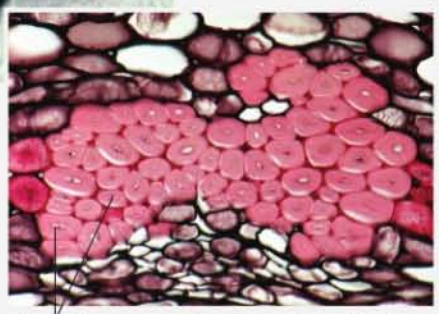


5 µm

Collenchyma cells (in *Helianthus* stem) (LM)

Grouped in strands or cylinders, **collenchyma cells** help support young parts of the plant shoot. Collenchyma cells have thicker primary walls than parenchyma cells, though the walls are unevenly thickened. Young stems and petioles often have strands of collenchyma cells just below their epidermis (for example, the "strings" of a celery stalk, which is a petiole). Collenchyma cells lack secondary walls, and the hardening agent lignin is absent from their primary walls. Therefore, these cells provide flexible support without restraining growth. At maturity, collenchyma cells are living and flexible, elongating with the stems and leaves they support—unlike sclerenchyma cells, which we discuss next.

Sclerenchyma Cells



5 µm

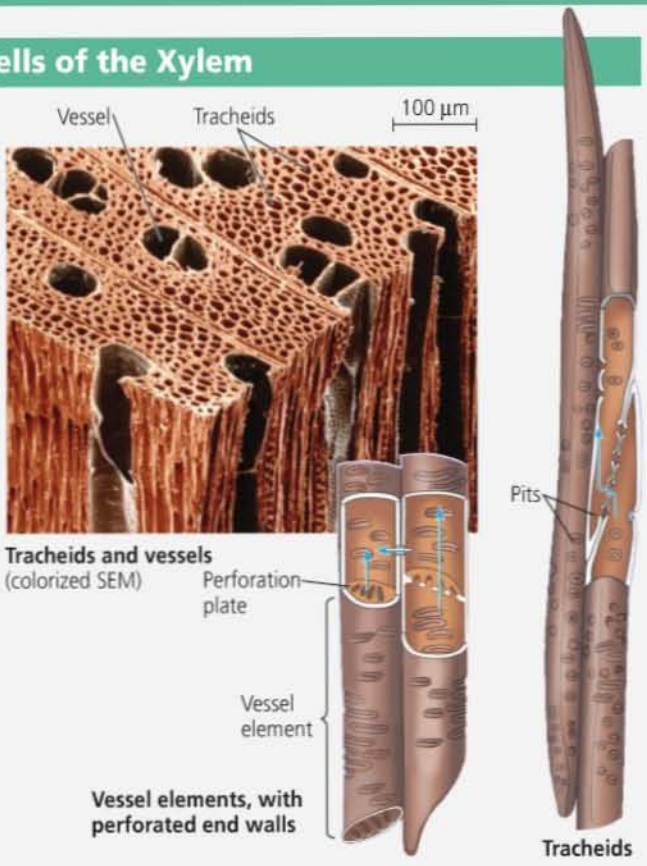
Sclereid cells in pear (LM)

Cell wall

25 µm

Fiber cells (cross section from ash tree) (LM)

Also functioning as supporting elements in the plant, but with thick secondary walls that are usually strengthened by lignin, **sclerenchyma cells** are much more rigid than collenchyma cells. Mature sclerenchyma cells cannot elongate, and they occur in regions of the plant that have stopped growing in length. Sclerenchyma cells are so specialized for support that many are dead at functional maturity, but they produce secondary walls before the protoplast (the living part of the cell) dies. The rigid walls remain as a "skeleton" that supports the plant, in some cases for hundreds of years.



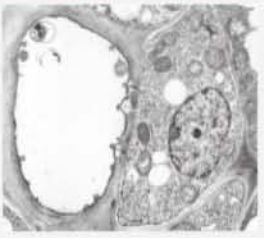
Two types of sclerenchyma cells, known as **sclereids** and **fibers**, are specialized entirely for support and strengthening. Sclereids, which are shorter than fibers and irregular in shape, have very thick, lignified secondary walls. Sclereids impart the hardness to nutshells and seed coats and the gritty texture to pear fruits. Fibers, which are usually arranged in threads, are long, slender, and tapered. Some are used commercially, such as hemp fibers for making rope and flax fibers for weaving into linen.

Water-Conducting Cells of the Xylem

The two types of water-conducting cells, **tracheids** and **vessel elements**, are tubular, elongated cells that are dead at functional maturity. Tracheids are found in the xylem of nearly all vascular plants. In addition to tracheids, most angiosperms, as well as a few gymnosperms and a few seedless vascular plants, have vessel elements. When the living cellular contents of a tracheid or vessel element disintegrate, the cell's thickened walls remain behind, forming a nonliving conduit through which water can flow. The secondary walls of tracheids and vessel elements are often interrupted by pits, thinner regions where only primary walls are present (see Figure 6.28 to review primary and secondary walls). Water can migrate laterally between neighboring cells through pits.

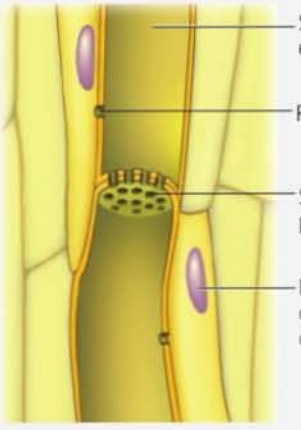
Tracheids are long, thin cells with tapered ends. Water moves from cell to cell mainly through the pits, where it does not have to cross thick secondary walls. The secondary walls of tracheids are hardened with lignin, which prevents collapse under the tensions of water transport and also provides support.

Vessel elements are generally wider, shorter, thinner walled, and less tapered than the tracheids. They are aligned end to end, forming long micropipes known as **vessels**. The end walls of the vessel elements have perforation plates that enable water to flow freely through the vessels.



Sugar-Conducting Cells of the Phloem

Unlike the water-conducting cells of the xylem, the sugar-conducting cells of the phloem are alive at functional maturity. In seedless vascular plants and gymnosperms, sugars and other organic nutrients are transported through long, narrow cells called sieve cells. In the phloem of angiosperms, these nutrients are transported through sieve tubes, which consist of chains of cells called **sieve-tube elements**, or sieve-tube members.



Though alive, sieve-tube elements lack a nucleus, ribosomes, a distinct vacuole, and cytoskeletal elements. This reduction in cell contents enables nutrients to pass more easily through the cell. The end walls between sieve-tube elements, called **sieve plates**, have pores that facilitate the flow of fluid from cell to cell along the sieve tube. Alongside each sieve-tube element is a nonconducting cell called a **companion cell**, which is connected to the sieve-tube element by numerous channels, plasmodesmata (see Figure 6.28). The nucleus and ribosomes of the companion cell serve not only that cell itself but also the adjacent sieve-tube element. In some plants, companion cells in leaves also help load sugars into the sieve-tube elements, which then transport the sugars to other parts of the plant.

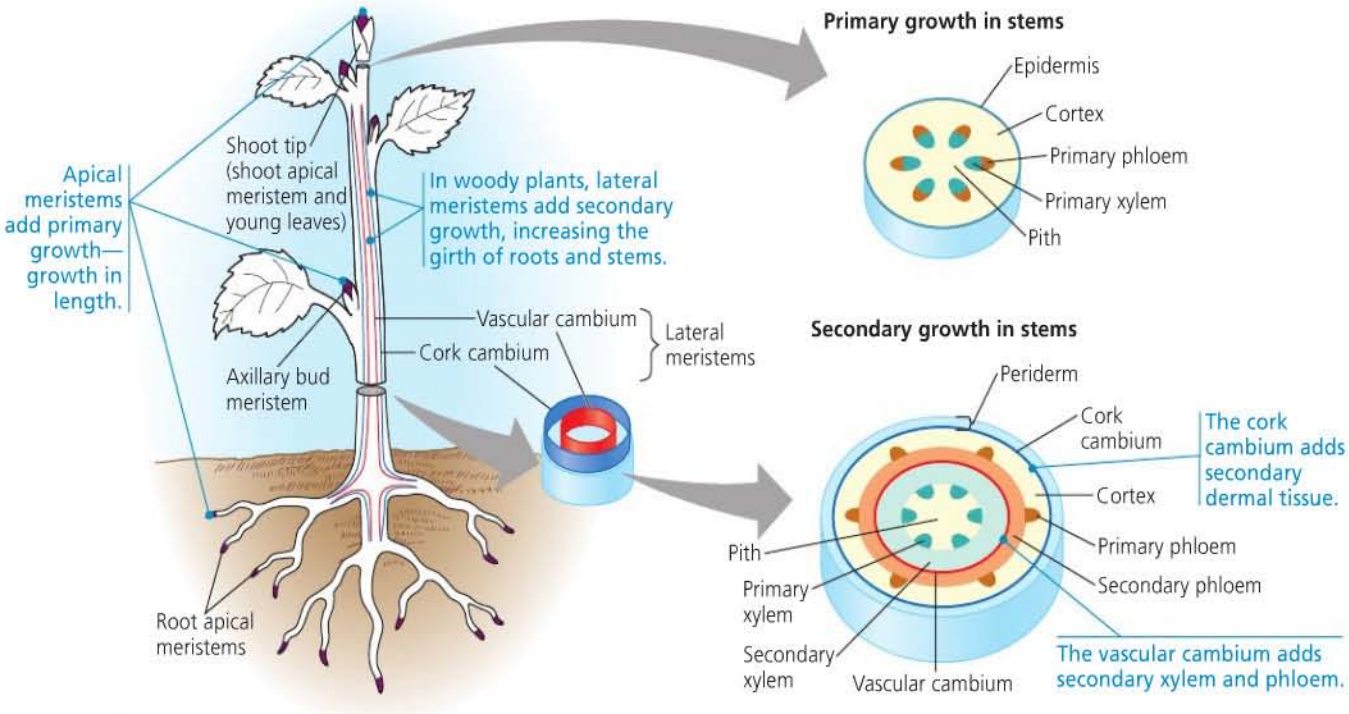
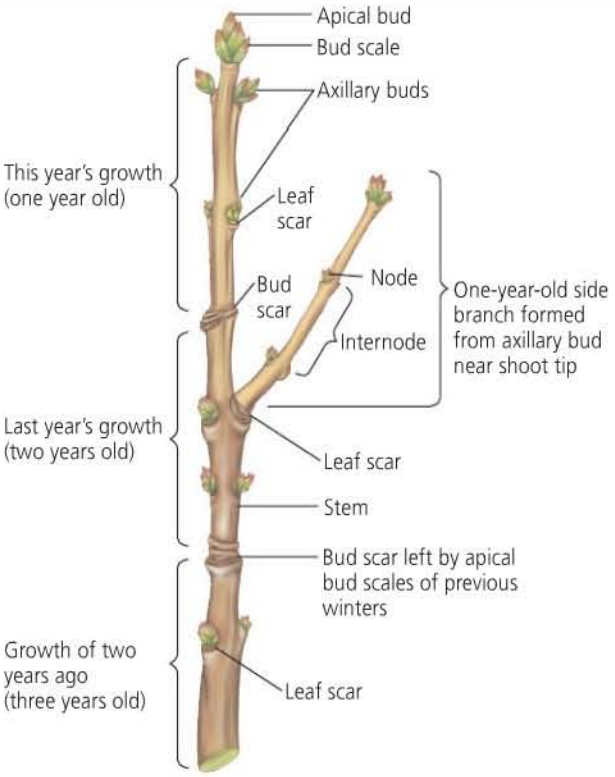
CONCEPT **35.2**

Meristems generate cells for new organs



So far, we have looked at the structure and arrangement of plant tissues and cells in mature organs. How does this organization arise? A major difference between plants and most animals is that plant growth is not limited to an embryonic or juvenile period. Instead, growth occurs throughout the plant's life, a process known as **indeterminate growth**. At any given time, a typical plant consists of embryonic, developing, and mature organs. Except for dormant periods, most plants grow continuously. In contrast, most animals and some plant organs—such as most leaves, thorns, and flowers—undergo **determinate growth**; that is, they stop growing after reaching a certain size.

Although plants continue to grow throughout their lives, they do die, of course. Based on the length of their life cycle, flowering plants can be categorized as annuals, biennials, or perennials. **Annuals** complete their life cycle—from germination to flowering to seed production to death—in a single year or less. Many wildflowers are annuals, as are most staple food crops, including legumes and cereal grains such as wheat and rice. **Biennials** generally require two growing seasons to complete their life cycle, flowering and fruiting only in their second year. Radishes and carrots are biennials, though they are usually harvested after the first year. **Perennials** live many years and include trees, shrubs, and some grasses. Some buffalo grass of the North American plains is thought to have been growing for 10,000 years from seeds that sprouted at the close of the last ice age. When a perennial dies, it is usually not from old age but from an infection or some environmental trauma, such as fire or severe drought.



Plants are capable of indeterminate growth because they have perpetually embryonic tissues called **meristems**. There are two main types: apical meristems and lateral meristems (**Figure 35.11**). **Apical meristems**, located at the tips of roots and shoots and in the axillary buds of shoots, provide additional cells that enable the plant to grow in length, a process known as **primary growth**. Primary growth allows roots to extend throughout the soil and shoots to increase their exposure to light. In herbaceous (nonwoody) plants, primary growth produces all, or almost all, of the plant body. Woody plants, however, also grow in girth in the parts of stems and roots that no longer grow in length. This growth in thickness, known as **secondary growth**, is caused by the activity of **lateral meristems** called the vascular cambium and cork cambium. These cylinders of dividing cells extend along the length of roots and stems. The **vascular cambium** adds layers of vascular tissue called secondary xylem (wood) and secondary phloem. The **cork cambium** replaces the epidermis with the thicker, tougher periderm.

The cells within meristems divide relatively frequently, generating additional cells. Some of these new cells remain in the meristem and produce more cells, while others differentiate and are incorporated into tissues and organs of the growing plant. Cells that remain as sources of new cells are called *initials*. The new cells displaced from the meristem, called *derivatives*, continue to divide until the cells they produce become specialized within developing tissues.

The relationship between primary and secondary growth is clearly seen in the winter twig of a deciduous tree. At the shoot

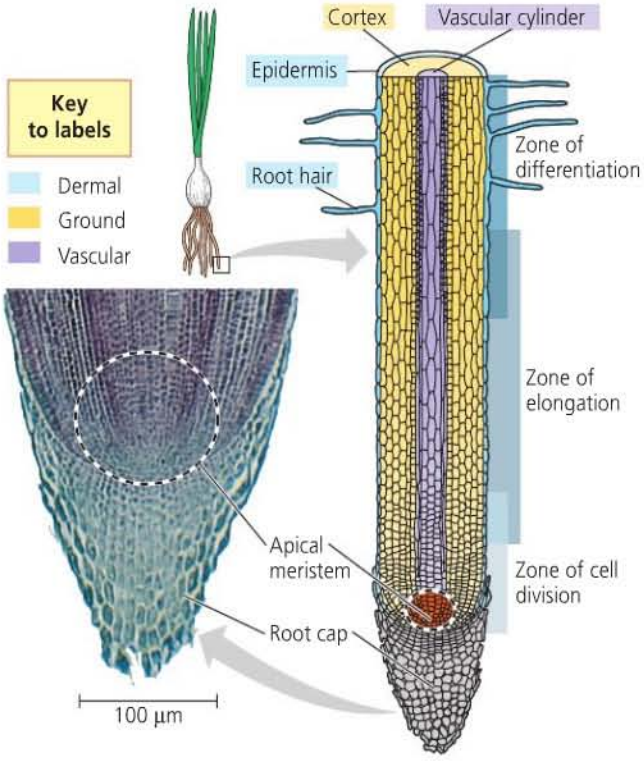
▲ **Figure 35.11 An overview of primary and secondary growth.**

▲ **Figure 35.12 Three years' growth in a winter twig.**

tip is the dormant apical bud, enclosed by scales that protect its apical meristem **(Figure 35.12)**. In spring, the bud sheds its scales and begins a new spurt of primary growth, producing a series of nodes and internodes. Along each growth segment, nodes are marked by scars that were left when leaves fell. Above each leaf scar is an axillary bud or a branch formed by an axillary bud. Farther down the twig are bud scars from the whorls of scales that enclosed the apical bud during the previous winter. During each growing season, primary growth extends the shoots, and secondary growth thickens the parts that formed in previous years.

CONCEPT CHECK 35.2

1. Distinguish between primary and secondary growth.
2. Cells in lower layers of your skin divide and replace dead cells sloughed from the surface. Why is it inaccurate to compare such regions of cell division to a plant meristem?
3. Roots and stems grow indeterminately, but leaves do not. How might this benefit the plant?
4. **WHAT IF?** Suppose a gardener picks some radishes and finds that they are too small. Since radishes are biennials, the gardener leaves the remaining plants in the ground, thinking that they will grow larger during their second year. Is this a good idea? Explain.



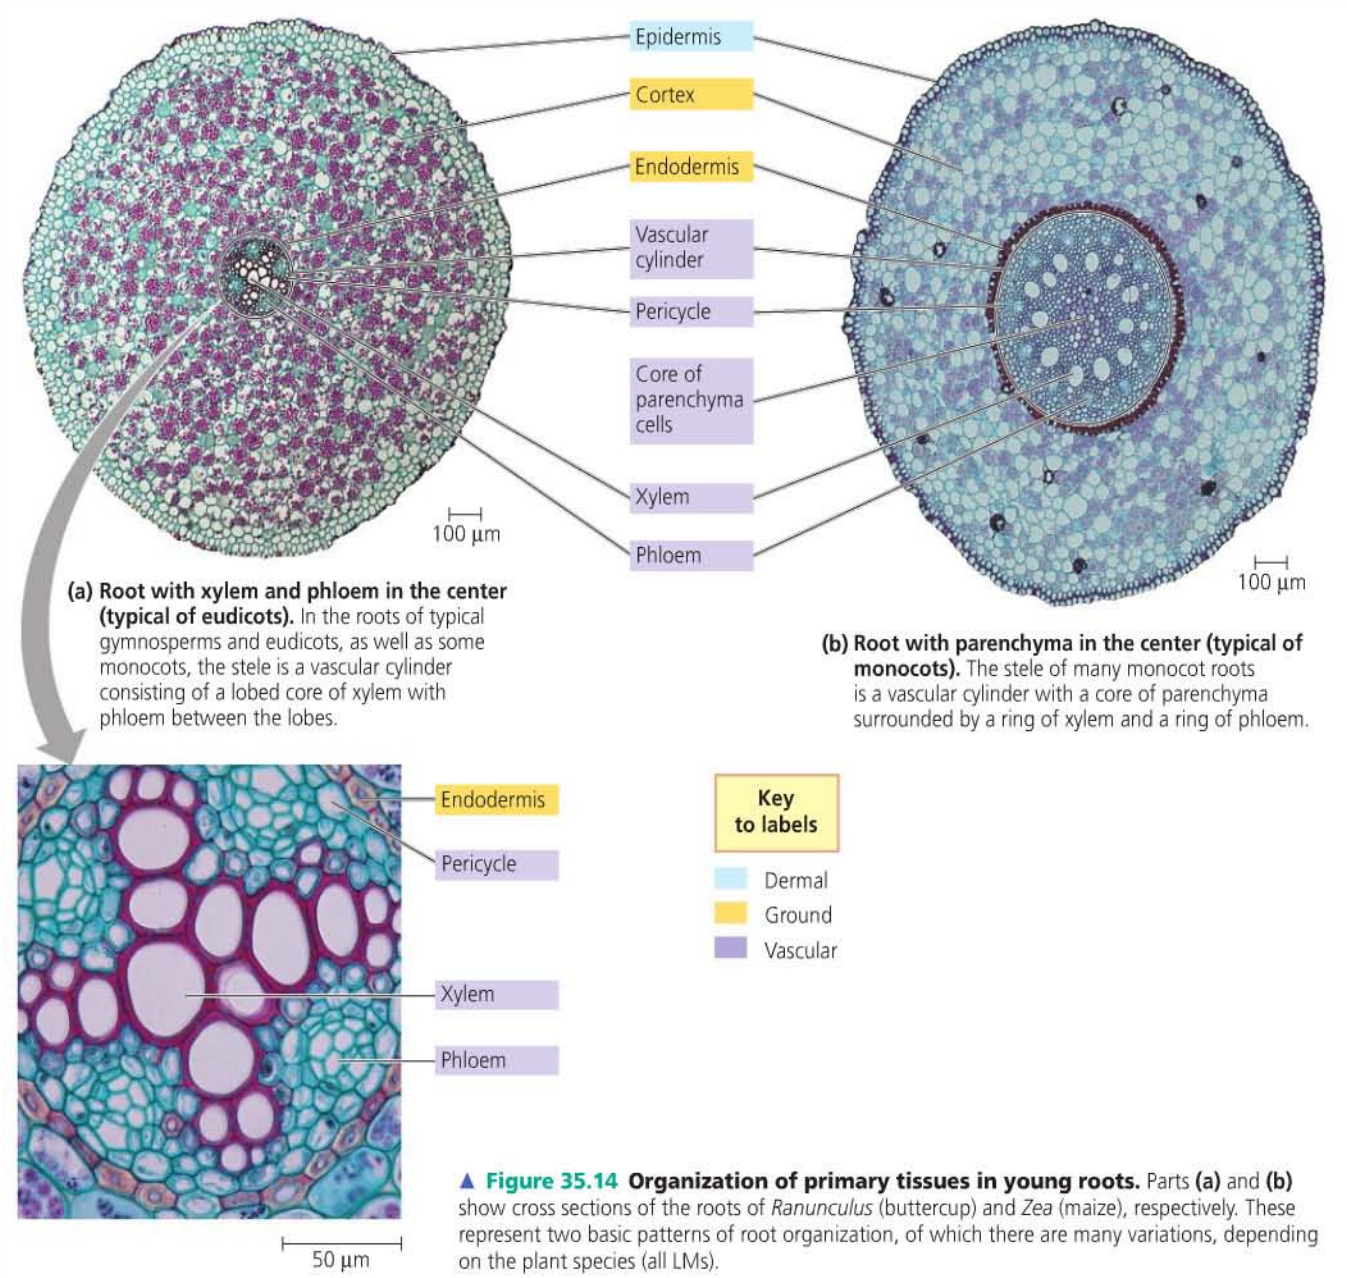
For suggested answers, see Appendix A.

CONCEPT 35.3 Primary growth lengthens roots and shoots

As you have learned, primary growth is growth in length, produced by apical meristems. Collectively, the results of this growth are called the **primary plant body**. In herbaceous plants, it is usually the entire plant. In woody plants, it consists only of the youngest parts, which are not yet woody. Although apical meristems lengthen both roots and shoots, there are differences in the primary growth of these two systems.

Primary Growth of Roots

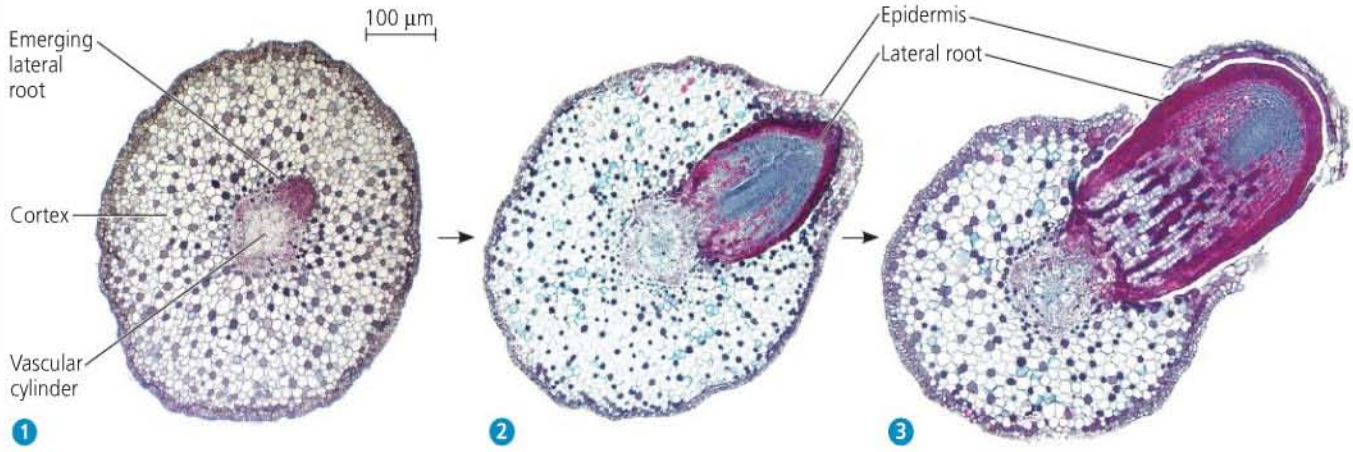
The tip of a root is covered by a thimble-like **root cap**, which protects the delicate apical meristem as the root pushes through the abrasive soil during primary growth. The root cap also secretes a polysaccharide slime that lubricates the soil around the tip of the root. Growth occurs just behind the tip in three zones of cells at successive stages of primary growth. Moving away from the tip, they are the zones of cell division, elongation, and differentiation **(Figure 35.13)**.



▲ **Figure 35.13 Primary growth of a root.** The light micrograph and diagram reveal the anatomical features of the tip of an onion root. Mitosis is concentrated in the zone of cell division, where the apical meristem and its immediate growth products are located. The apical meristem also maintains the root cap by generating new cells that replace those that are sloughed off. Most lengthening of the root occurs in the zone of elongation. Cells become functionally mature in the zone of differentiation. The zones grade into one another without sharp boundaries.

The three zones grade together, with no sharp boundaries. The *zone of cell division* includes the root apical meristem and its derivatives. New root cells are produced in this region, including the root cap. Typically, about a millimeter behind the tip of the root is the *zone of elongation*, where root cells elongate, sometimes to more than ten times their original length. Cell elongation in this zone pushes the tip farther into the soil. Meanwhile, the root apical meristem keeps adding cells to the younger end of the zone of elongation. Even before the root cells finish lengthening, many begin specializing in structure and function. In the *zone of differentiation*, or zone of maturation, cells complete their differentiation and become distinct cell types.

The primary growth of a root produces its epidermis, ground tissue, and vascular tissue. **Figure 35.14** shows in cross section the three primary tissue systems in the young roots of a eudicot (*Ranunculus*, buttercup) and a monocot (*Zea*, maize). Water and minerals absorbed from the soil must enter through the root's epidermis. Root hairs, which account for much of this absorption, enhance this process by greatly increasing the surface area of epidermal cells.



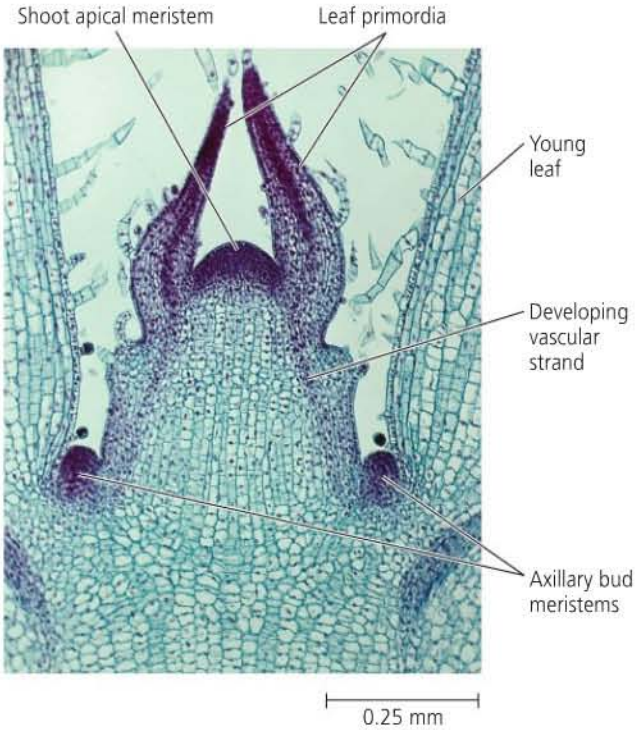
In most roots, the stele is a vascular cylinder, a solid core of xylem and phloem **(Figure 35.14a)**. In most eudicot roots, the xylem has a starlike appearance and the phloem occupies the indentations between the arms of the xylem "star." In many monocot roots, the vascular tissue consists of a central core of parenchyma cells surrounded by a ring of xylem and a ring of phloem **(Figure 35.14b)**. The central region is often called pith but should not be confused with stem pith, which is ground tissue.

(a) Root with xylem and phloem in the center (typical of eudicots). In the roots of typical gymnosperms and eudicots, as well as some monocots, the stele is a vascular cylinder consisting of a lobed core of xylem with phloem between the lobes.

(b) Root with parenchyma in the center (typical of monocots). The stele of many monocot roots is a vascular cylinder with a core of parenchyma surrounded by a ring of xylem and a ring of phloem.

▲ **Figure 35.14 Organization of primary tissues in young roots.** Parts **(a)** and **(b)** show cross sections of the roots of *Ranunculus* (buttercup) and *Zea* (maize), respectively. These represent two basic patterns of root organization, of which there are many variations, depending on the plant species (all LMs).

▲ **Figure 35.15 The formation of a lateral root.** A lateral root originates in the pericycle, the outermost layer of the vascular cylinder of a root, and grows out through the cortex and epidermis. In this series of light micrographs, the view of the original root is a cross section, while the view of the lateral root is a longitudinal section.

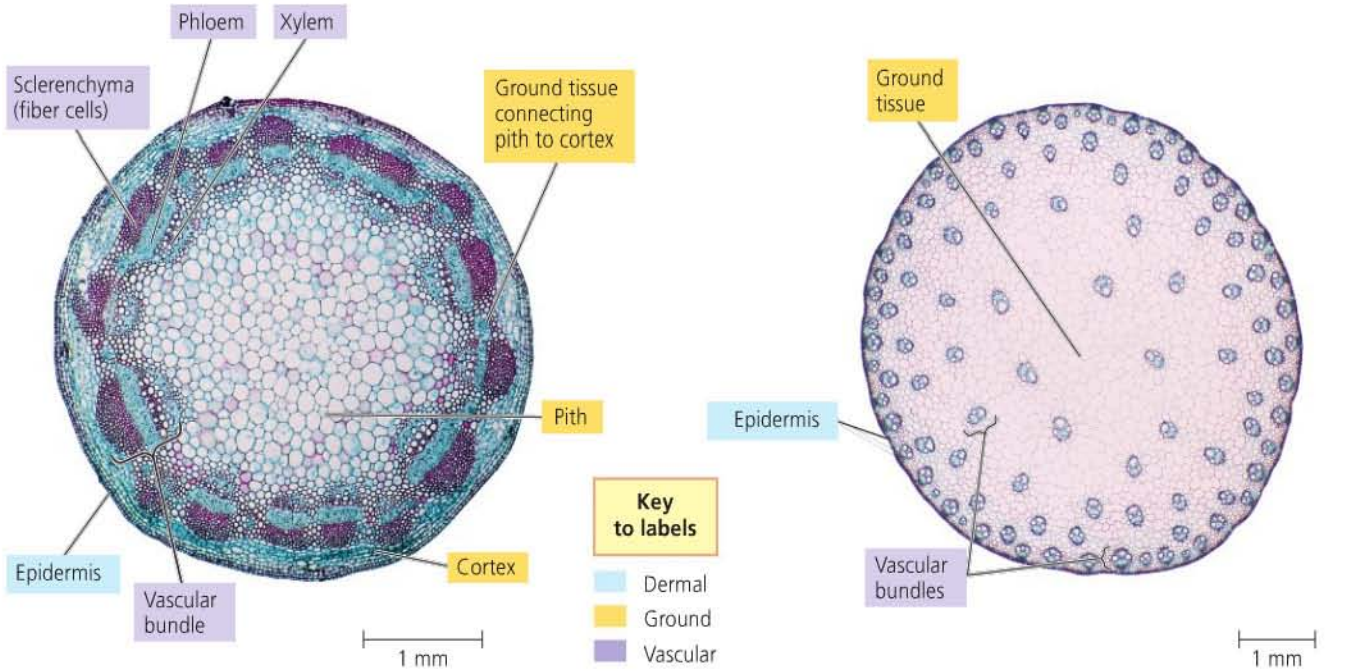


The ground tissue of roots, consisting mostly of parenchyma cells, fills the cortex, the region between the vascular cylinder and epidermis. Cells within the ground tissue store carbohydrates, and their plasma membranes absorb water and minerals from the soil. The innermost layer of the cortex is called the **endodermis**, a cylinder one cell thick that forms the boundary with the vascular cylinder. As you will see in Chapter 36, the endodermis is a selective barrier that regulates passage of substances from the soil into the vascular cylinder.

Lateral roots arise from the **pericycle**, the outermost cell layer in the vascular cylinder, which is adjacent to and just inside the endodermis (see Figure 35.14). A lateral root pushes through the cortex and epidermis until it emerges from the established root **(Figure 35.15)**. A lateral root cannot originate near the root's surface because its vascular system must be continuous with the vascular cylinder at the center of the established root.

Primary Growth of Shoots

A shoot apical meristem is a dome-shaped mass of dividing cells at the shoot tip **(Figure 35.16)**. Leaves develop from **leaf primordia** (singular, *primordium*), finger-like projections along the sides of the apical meristem. Axillary buds develop from islands of meristematic cells left by the apical meristem at the bases of the leaf primordia. Axillary buds can form lateral shoots at some later time (see Figure 35.12).



Within a bud, leaf primordia are spaced close together because the internodes are very short. Most shoot elongation is due to the lengthening of internode cells below the shoot tip. In some plants, including grasses, a few leaf cells are produced by areas of meristematic tissue separated from the apical meristem. These areas, called *intercalary meristems*, remain at the base of leaf blades and stem internodes. This morphological feature helps grasses tolerate grazing because the elevated part of the leaf blade can be removed without stopping growth.

▲ **Figure 35.16 The shoot tip.** Leaf primordia arise from the flanks of the dome of the apical meristem. This is a longitudinal section of the shoot tip of *Coleus* (LM).

Tissue Organization of Stems

The epidermis covers stems as part of the continuous dermal tissue system. Vascular tissue runs the length of a stem in vascular bundles. Unlike lateral roots, which arise from vascular tissue deep within a root and disrupt the vascular cambium, cortex, and epidermis as they emerge (see Figure 35.15), lateral shoots develop from axillary bud meristems on the stem's surface and disrupt no other tissues (see Figure 35.16). The vascular bundles of the stem converge with the root's vascular cylinder in a zone of transition located near the soil surface.

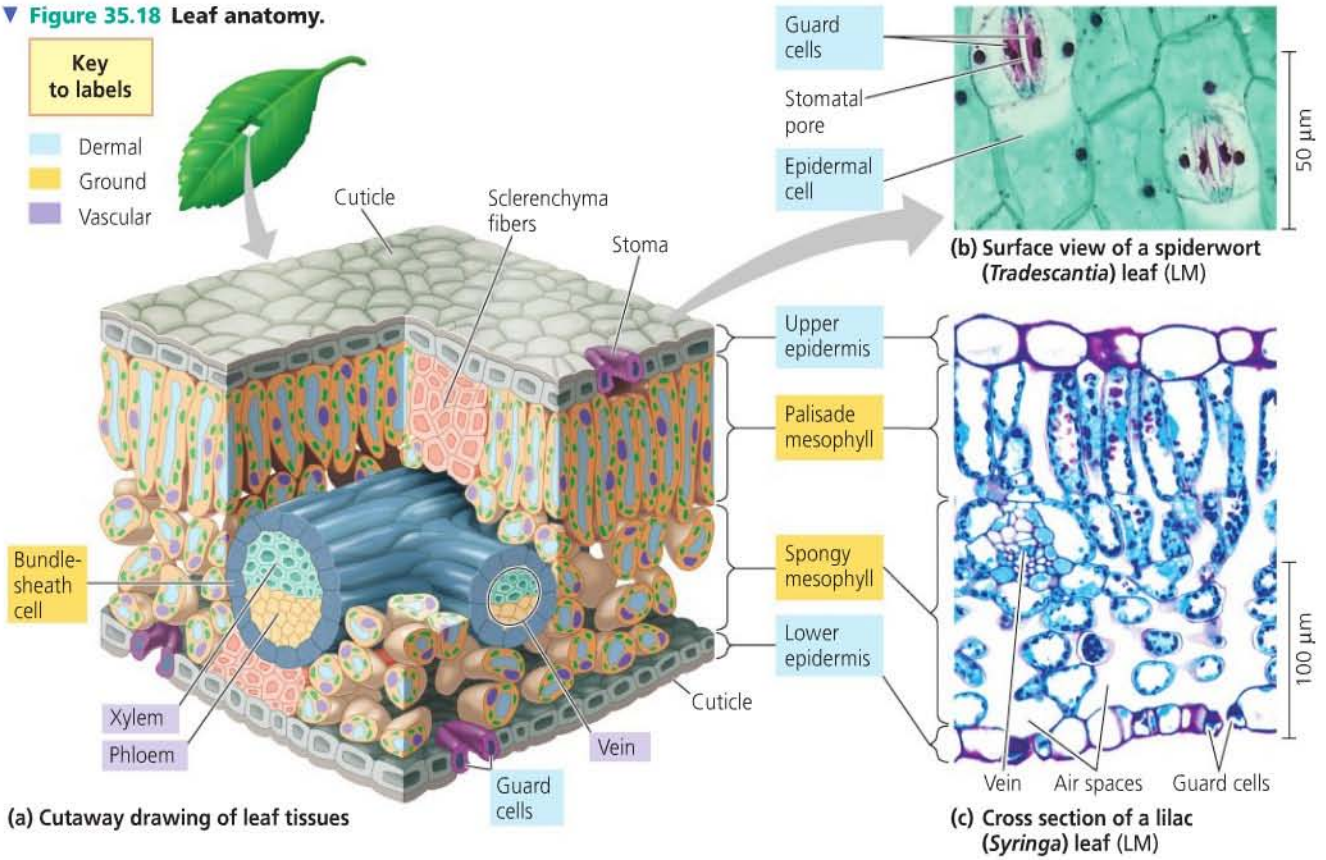
(a) Cross section of stem with vascular bundles forming a ring (typical of eudicots). Ground tissue toward the inside is called pith, and ground tissue toward the outside is called cortex (LM).

(b) Cross section of stem with scattered vascular bundles (typical of monocots). In such an arrangement, ground tissue is not partitioned into pith and cortex (LM).

▲ **Figure 35.17 Organization of primary tissues in young stems.**

? *Why aren't the terms* pith *and* cortex *used to describe the ground tissue of monocot stems?*

In most eudicot species, the vascular tissue consists of vascular bundles arranged in a ring **(Figure 35.17a)**. The xylem in each vascular bundle is adjacent to the pith, and the phloem in each bundle is adjacent to the cortex. In most monocot stems, the vascular bundles are scattered throughout the ground tissue, rather than forming a ring **(Figure 35.17b)**. In the stems of both monocots and eudicots, the ground tissue consists mostly of parenchyma cells. However, collenchyma cells just beneath the epidermis strengthen many stems. Sclerenchyma cells, especially fiber cells, also provide support in those parts of the stems that are no longer elongating.



Tissue Organization of Leaves

Figure 35.18 provides an overview of leaf structure. The epidermal barrier is interrupted by **stomata** (singular, *stoma*), which allow gas exchange between the surrounding air and the photosynthetic cells inside the leaf. In addition to regulating CO_2 uptake for photosynthesis, stomata are major avenues for the evaporative loss of water. The term *stoma* can refer to the stomatal pore or to the entire stomatal complex consisting of a pore flanked by two **guard cells**, which regulate the opening and closing of the pore. We'll discuss stomata in detail in Chapter 36.

The ground tissue of a leaf, a region called the **mesophyll** (from the Greek *mesos,* middle, and *phyll,* leaf), is sandwiched between the upper and lower epidermal layers. Mesophyll consists mainly of parenchyma cells specialized for photosynthesis. The leaves of many eudicots have two distinct areas: palisade mesophyll and spongy mesophyll. The *palisade mesophyll* consists of one or more layers of elongated parenchyma cells on the upper part of the leaf. The *spongy mesophyll* is below the palisade mesophyll. These parenchyma cells are more loosely arranged, with a labyrinth of air spaces through which CO_2 and oxygen circulate around the cells and up to the palisade region. The air spaces are particularly large in the vicinity of stomata, where gas exchange with the outside air occurs.

The vascular tissue of each leaf is continuous with the vascular tissue of the stem. *Leaf traces,* connections from vascular bundles in the stem, pass through petioles and into leaves. Veins are the leaf's vascular bundles, which subdivide repeatedly and branch throughout the mesophyll. This network brings xylem and phloem into close contact with the photosynthetic tissue, which obtains water and minerals from the xylem and loads its sugars and other organic products into the phloem for transport to other parts of the plant. The vascular structure also functions as a skeleton that reinforces the shape of the leaf. Each vein is enclosed by a protective *bundle sheath,* consisting of one or more layers of cells, usually parenchyma cells. Bundle sheath cells are particularly prominent in leaves of plants that undergo C_4 photosynthesis (see Chapter 10). Unlike stems and roots, leaves rarely undergo secondary growth, which is the topic of the next section.

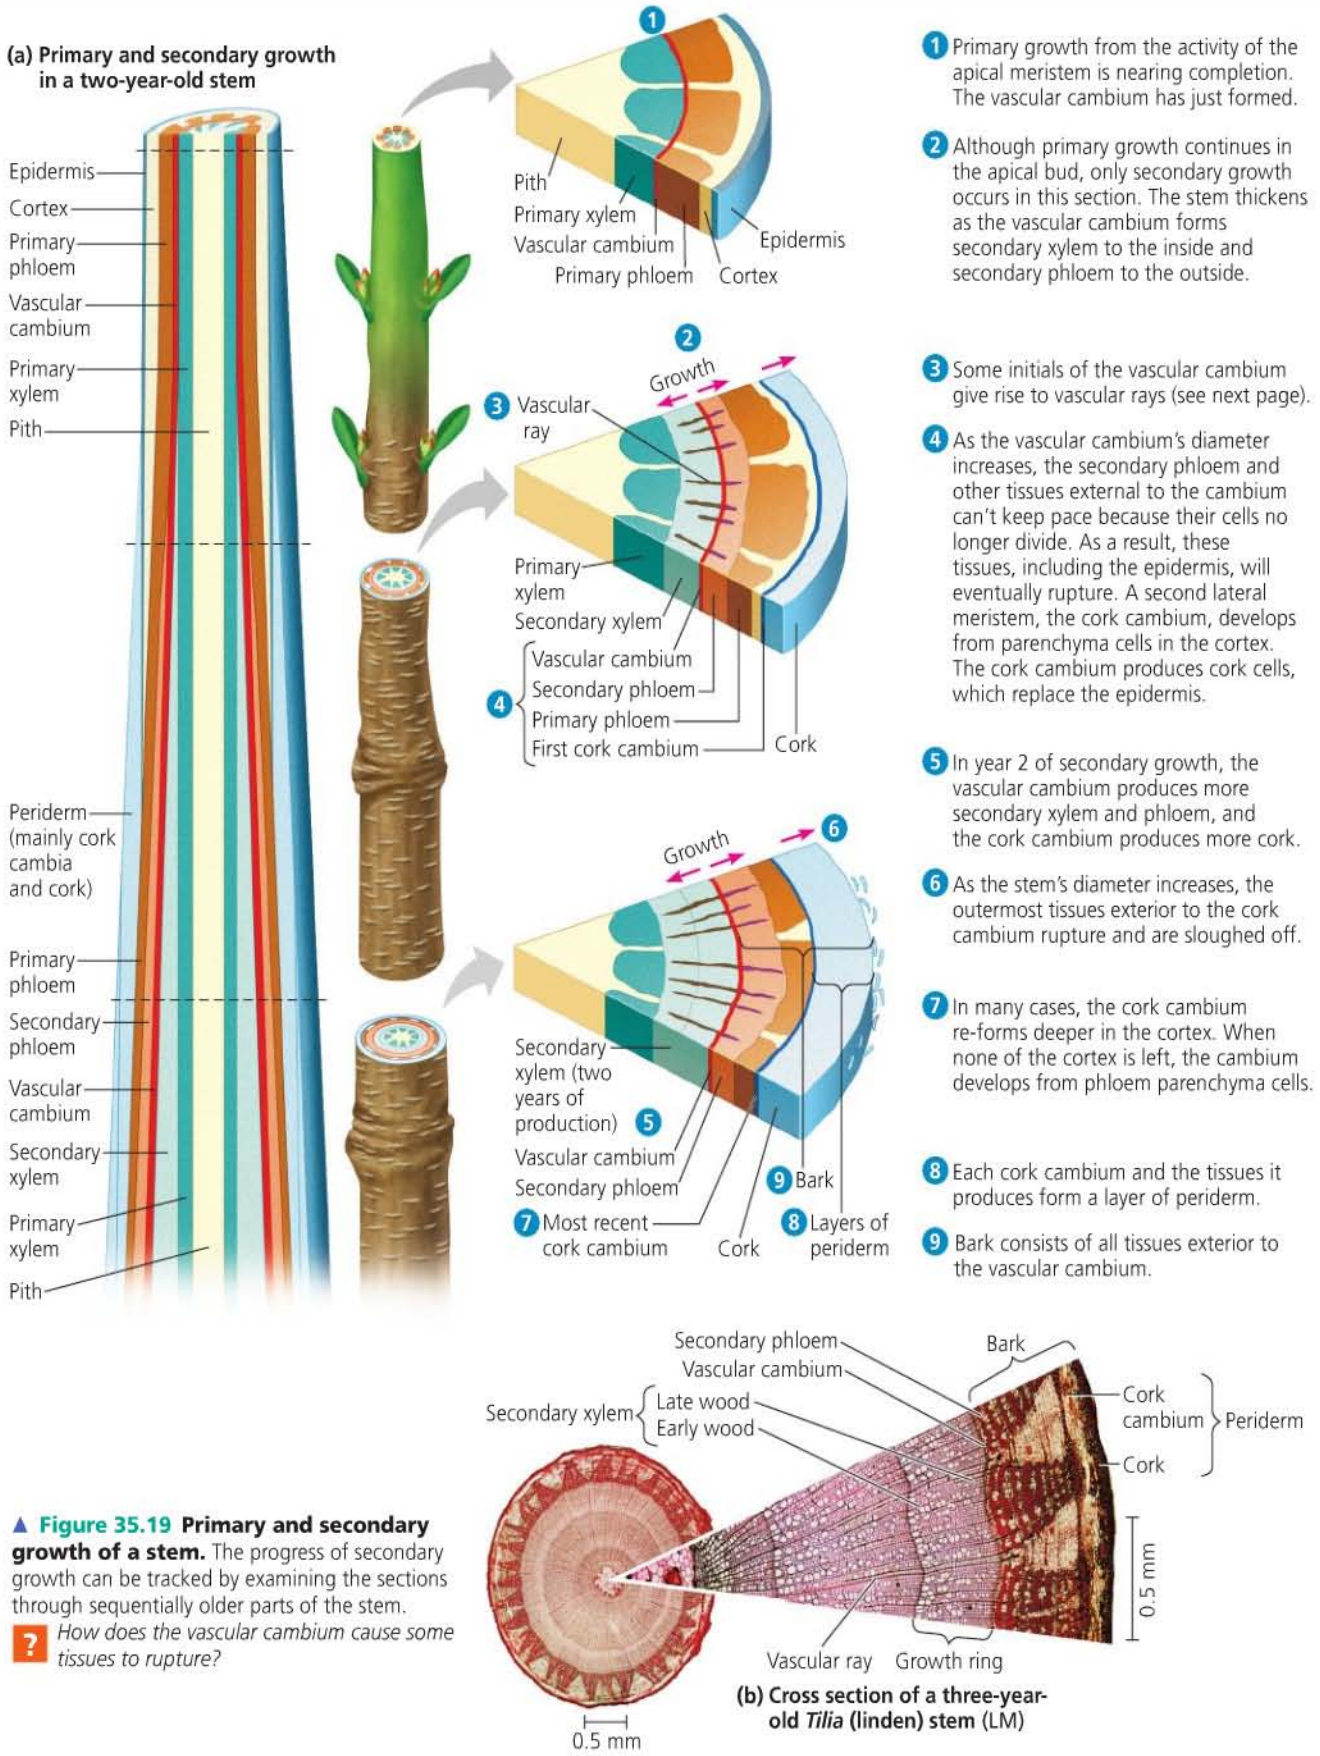
CONCEPT CHECK 35.3

1. Describe how roots and shoots differ in branching.
2. Contrast primary growth in roots and shoots.
3. When grazing animals are removed from grasslands, eudicots often replace grasses. Suggest a reason why.
4. **WHAT IF?** If a leaf is vertically oriented, would you expect its mesophyll to be divided into spongy and palisade layers? Explain.

For suggested answers, see Appendix A.

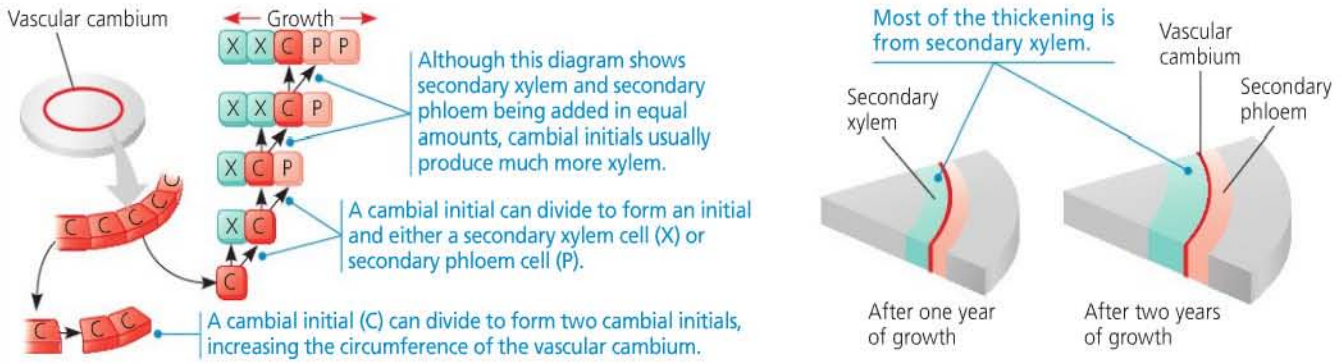
CONCEPT 35.4
Secondary growth adds girth to stems and roots in woody plants



As you have seen, primary growth arises from apical meristems and involves the production and elongation of roots, stems, and leaves. In contrast, secondary growth, the growth in thickness produced by lateral meristems, occurs in stems and roots of woody plants, but rarely in leaves. The **secondary plant body** consists of the tissues produced by the vascular cambium and cork cambium. The vascular cambium adds secondary xylem (wood) and secondary phloem, increasing vascular flow and support for the shoot system. The cork cambium produces a tough, thick covering consisting mainly of wax-impregnated cells that protect the stem from water loss and from invasion by insects, bacteria, and fungi. All gymnosperm species and many eudicot species have secondary growth, but it is rare in monocots.

Primary growth and secondary growth occur simultaneously. As primary growth adds leaves and lengthens stems and roots in the younger regions of a plant, secondary growth thickens stems and roots in older regions where primary growth has stopped. The process is similar in shoots and roots. **Figure 35.19**, on the next page, provides an overview of growth in a woody stem.

The Vascular Cambium and Secondary Vascular Tissue



The vascular cambium is a cylinder of meristematic cells, often only one cell thick. It increases in circumference and also adds layers of secondary xylem to its interior and secondary phloem to its exterior. Each layer has a larger diameter than the previous layer (see Figure 35.19). In this way, the vascular cambium thickens roots and stems.

In a typical woody stem, the vascular cambium consists of a continuous cylinder of undifferentiated parenchyma cells, located outside the pith and primary xylem and to the inside of the cortex and primary phloem. In a typical woody root, the vascular cambium forms to the exterior of the primary xylem and interior to the primary phloem and pericycle.

▲ **Figure 35.19 Primary and secondary growth of a stem.** The progress of secondary growth can be tracked by examining the sections through sequentially older parts of the stem.

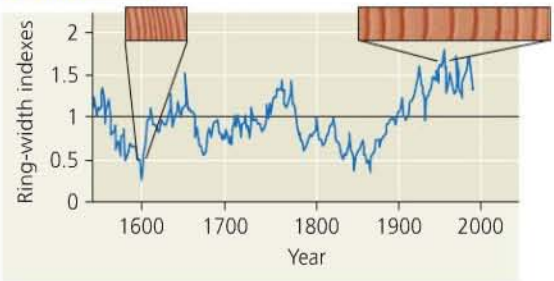
? *How does the vascular cambium cause some tissues to rupture?*

▲ **Figure 35.20 Secondary growth produced by the vascular cambium.**

Viewed in cross section, the vascular cambium appears as a ring of initials. As these meristematic cells divide, they increase the circumference of the vascular cambium and also add secondary xylem to the inside of the cambium and secondary phloem to the outside **(Figure 35.20)**. Some initials are elongated and are oriented with their long axis parallel to the axis of the stem or root. They produce cells such as the tracheids, vessel elements, and fibers of the xylem, as well as the sieve-tube elements, companion cells, parenchyma, and fibers of the phloem. The other initials are shorter and are oriented perpendicular to the axis of the stem or root. They produce *vascular rays*—radial files of cells that connect the secondary xylem with the secondary phloem. The cells of a vascular ray move water and nutrients between the secondary xylem and phloem, store carbohydrates, and aid in wound repair.

As secondary growth continues over many years, layers of secondary xylem (wood) accumulate, consisting mainly of tracheids, vessel elements, and fibers (see Figure 35.10). Gymnosperms have only tracheids, whereas almost all angiosperms have both tracheids and vessel elements. The walls of secondary xylem cells are heavily lignified and account for the hardness and strength of wood. In temperate regions, wood that develops early in the spring, known as early wood, usually consists of secondary xylem cells with relatively large diameters and thin cell walls (see Figure 35.19b). This structure maximizes delivery of water to new, growing leaves. Wood produced later in the growing season, during late summer or early fall, is known as late wood. It is composed of thick-walled cells that do not transport as much water but contribute more to stem support.

In temperate regions, the vascular cambium becomes dormant during winter, and after growth resumes in spring, there is a marked contrast between the large cells of the new early wood and the smaller cells of the late wood of the previous growing season. A year's growth appears as a distinct ring in cross sections of most tree trunks and roots. Therefore, researchers can estimate a tree's age by counting its annual rings. *Dendrochronology* (from the Greek *dendron,* trees) is the science of analyzing tree ring growth patterns. Rings can vary in thicknesses, depending on seasonal growth. Trees grow well in wet and warm years but may grow hardly at all in cold or dry years. Because a thick ring indicates a warm year and a thin ring indicates a cold or dry one, scientists can use ring patterns to study climate changes **(Figure 35.21)**.

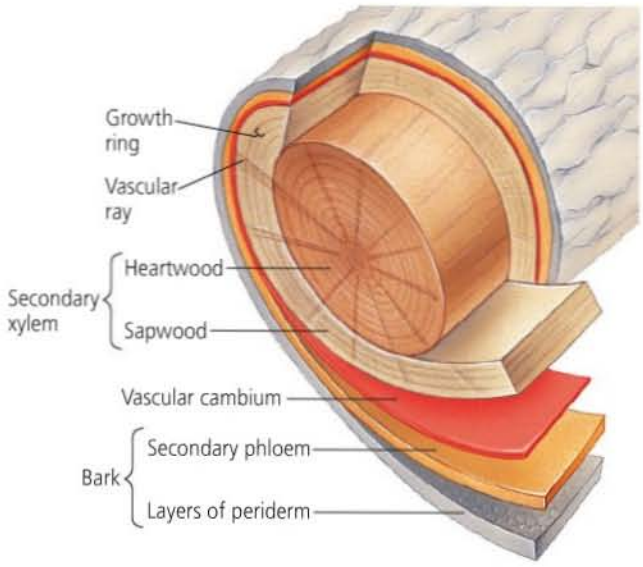


▼ Figure 35.21 Research Method

Using Dendrochronology to Study Climate

APPLICATION Dendrochronology, the science of analyzing tree rings, is useful in studying climate change. Most scientists attribute recent global warming to the burning of fossil fuels and release of CO_2 and other greenhouse gases, whereas a minority think it is a natural variation. Studying climate patterns requires comparing past and present temperatures, but instrumental climate records span only the last two centuries and apply only to some regions. By examining growth rings of Mongolian conifers dating back to the mid-1500s, G. C. Jacoby and Rosanne D'Arrigo, of the Lamont-Doherty Earth Observatory, and colleagues sought to learn whether Mongolia experienced similar warm periods in the past.

TECHNIQUE Researchers can analyze patterns of rings in living and dead trees. They can even study wood used for building long ago by matching samples with those from naturally situated specimens of overlapping age. Core samples, each about the diameter of a pencil, are taken from the bark to the center of the trunk. Each sample is dried and sanded to reveal the rings. By comparing, aligning, and averaging many samples from the Mongolian conifers, the researchers compiled a chronology. In this way, the trees served as a chronicle of environmental change.



RESULTS

This graph summarizes a composite record of ring-width indexes for the Mongolian conifers from 1550 to 1993. Higher indexes indicate wider rings and warmer temperatures. The highest growth period was from 1974 to 1993, and 17 of the 20 highest-growth years occurred since 1946, suggesting unusual warming during the 1900s.

As a tree or woody shrub ages, the older layers of secondary xylem no longer transport water and minerals (a solution called xylem sap). These layers are called *heartwood* because they are closer to the center of a stem or root **(Figure 35.22)**. The newest, outer layers of secondary xylem still transport xylem sap and are therefore known as *sapwood*. That is why a large tree can survive even if the center of its trunk is hollow **(Figure 35.23)**. Because each new layer of secondary xylem has a larger circumference, secondary growth enables the xylem to transport more sap each year, supplying an increasing number of leaves. Heartwood is generally darker than sapwood because of resins and other compounds that permeate the cell cavities and help protect the core of the tree from fungi and wood-boring insects.

Only the youngest secondary phloem, closest to the vascular cambium, functions in sugar transport. As a stem or root increases in circumference, the older secondary phloem is sloughed off, which is why secondary phloem does not accumulate as extensively as does secondary xylem.

▲ **Figure 35.22 Anatomy of a tree trunk.**

◀ **Figure 35.23 Is this tree living or dead?** The Wawona Sequoia tunnel in Yosemite National Park in California was cut in 1881 as a tourist attraction. This giant sequoia (*Sequoiadendron giganteum*) lived for another 88 years before it fell during a severe winter. It was 71.3 m tall and estimated to be 2,100 years old. Though conservation policies today would forbid the mutilation of such an important specimen, the Wawona Sequoia did teach a valuable botanical lesson: Trees do not need heartwood to survive.

The Cork Cambium and the Production of Periderm

During the early stages of secondary growth, the epidermis is pushed outward, causing it to split, dry, and fall off the stem or root. It is replaced by two tissues produced by the first cork cambium, a cylinder of dividing cells that arises in the outer cortex of stems (see Figure 35.19a) and in the outer layer of the pericycle in roots. One tissue, called *phelloderm*, is a thin layer of parenchyma cells that forms to the interior of the cork cambium. The other tissue consists of cork cells that accumulate to the exterior of the cork cambium. As cork cells mature, they deposit a waxy material called *suberin* in their walls and then die. The cork tissue then functions as a barrier that helps protect the stem or root from water loss, physical damage, and pathogens. Each cork cambium and the tissues it produces comprise a layer of periderm.

Because cork cells have suberin and are usually compacted together, most of the periderm is impermeable to water and gases, unlike the epidermis. In most plants, therefore, water and minerals are absorbed primarily in the youngest parts of roots. The older parts of roots anchor the plant and transport water and solutes between the soil and shoots. Dotting the periderm are small, raised areas called **lenticels**, in which there is more space between cork cells, enabling living cells within a woody stem or root to exchange gases with the outside air. Lenticels often appear as slits, as shown in Figure 35.19a.

The thickening of a stem or root often splits the first cork cambium, which loses its meristematic activity and differentiates into cork cells. A new cork cambium forms to the inside, resulting in another layer of periderm. As this process continues, older layers of periderm are sloughed off, as you can see in the cracked, peeling bark of many tree trunks.

Many people think that bark is only the protective outer covering of a woody stem or root. Actually, **bark** includes all tissues external to the vascular cambium. In an outward direction, its main components are the secondary phloem (produced by the vascular cambium), the most recent periderm, and all the older layers of periderm (see Figure 35.22).

CONCEPT CHECK 35.4

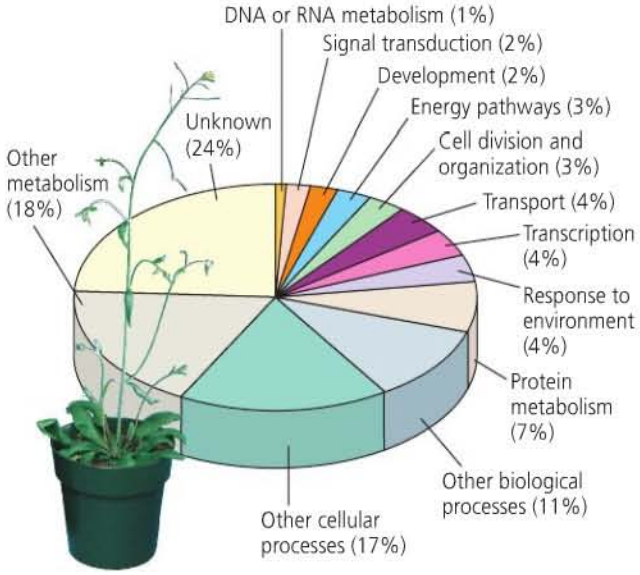
1. A sign is hammered into a tree 2 m from the tree's base. If the tree is 10 m tall and elongates 1 m each year, how high will the sign be after 10 years?
2. Stomata and lenticels are both involved in gas exchange. Why do stomata need to be able to close, but lenticels do not?
3. Would you expect a tropical tree to have distinct growth rings? Why or why not?
4. **WHAT IF?** If a complete ring of bark is removed around a tree trunk (a process called girdling), the tree usually dies. Explain why.

For suggested answers, see Appendix A.

CONCEPT **35.5**

Growth, morphogenesis, and differentiation produce the plant body

So far, we have described the development of the plant body from meristems. Here we will move from a description of plant growth and development to the mechanisms that underlie these processes.



Consider that a typical small plant may consist of billions of cells—some large, some small, some highly specialized and others not. The growth that occurs during the life of the plant results from both cell division and cell expansion. But what controls these two processes? Why do leaves stop growing upon reaching a certain size, whereas the cells of apical meristems keep dividing? Also, what controls cell specialization and the development of recognizable tissues and organs? Leaves arise from nodes; roots usually do not. Epidermis forms on the exterior of the leaf, and vascular tissue in the interior—never vice versa.

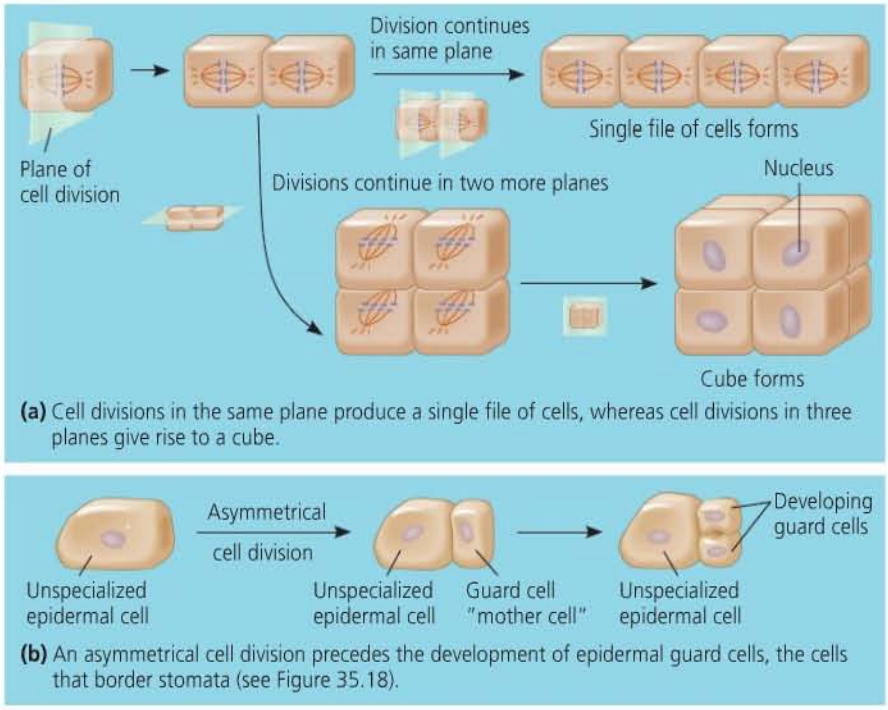
Each cell in the plant contains the same set of genes. The different patterns of gene expression among various cells cause the cellular differentiation that creates a diversity of cell types (see Chapter 18). Other processes lead to the development of body form and organization, called **morphogenesis**. The three developmental processes of growth, morphogenesis, and cellular differentiation act in concert to produce the body of a plant.

Molecular Biology: Revolutionizing the Study of Plants

Modern molecular techniques are helping plant biologists explore how growth, morphogenesis, and cellular differentiation give rise to a plant. In the current renaissance in plant biology, new laboratory methods and a focus on model organisms have catalyzed a research explosion. A major research focus is *Arabidopsis thaliana*, a weed of the mustard family that is small enough to allow researchers to cultivate thousands of plants in a few square meters of lab space. Its short generation span, about six weeks from germination to flowering, makes *Arabidopsis* an excellent model for genetic studies. It also has among the smallest genomes of all known plants. *Arabidopsis* was the first plant to have its entire genome sequenced—a six-year, multinational effort **(Figure 35.24)**. More recently, rice, a species of poplar, the common grape, and maize have had their entire genomes sequenced, too.

Arabidopsis has about 26,700 protein-encoding genes, but many of these are duplicates. There are probably fewer than 15,000 different types of genes, a number similar to that found in the fly *Drosophila*. Determining the function of many *Arabidopsis* genes has greatly expanded our understanding of plant development. To fill the gaps in our knowledge, plant biologists have launched an ambitious quest to determine the function of every one of the plant's genes. Toward this goal, they are attempting to create mutants for every gene in the genome of this species. We will discuss some of these mutants shortly, as we take a closer look at the molecular mechanisms that underlie growth, morphogenesis, and cellular differentiation. By identifying each gene's function and tracking every biochemical pathway, researchers aim to establish a blueprint for how plants develop, a major goal of systems biology. It may one day be possible to create a computer-generated "virtual plant" that enables researchers to visualize which plant genes are activated in different parts of the plant during the entire course of development.

▲ **Figure 35.24 *Arabidopsis thaliana* gene functions.** Due to its small size, rapid life cycle, and small genome, *Arabidopsis* was the first plant to have its entire genome sequenced (containing about 26,700 genes). The pie chart represents the proportion of *Arabidopsis* genes in different functional categories. (Data from TAIR, The *Arabidopsis* Information Resource, 2007.)



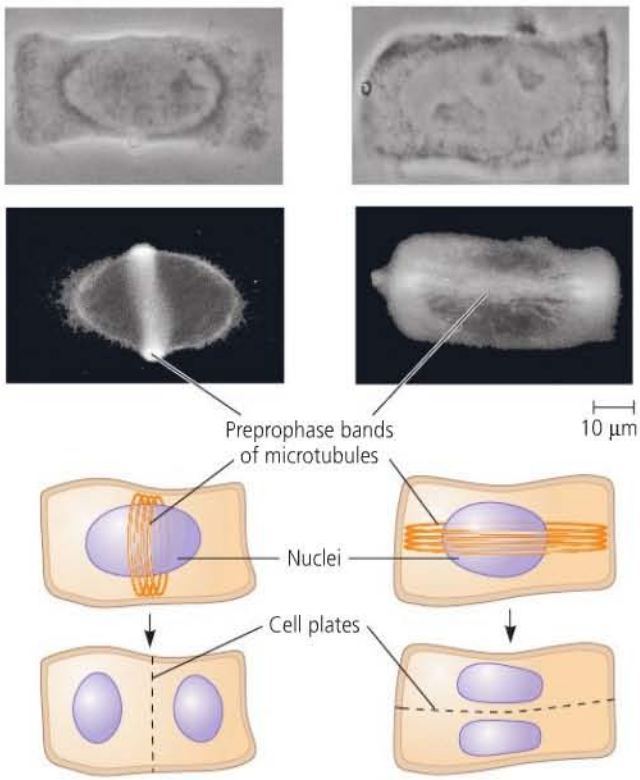
Growth: Cell Division and Cell Expansion

By increasing cell number, cell division in meristems increases the potential for growth. However, it is cell expansion, particularly cell elongation, that accounts for increase in size. The process of plant cell division is described more fully in Chapter 12 (see Figure 12.10), and Chapter 39 discusses the process of cell elongation (see Figure 39.8). Here we are more concerned with how these processes contribute to plant form.

The Plane and Symmetry of Cell Division

The plane (direction) and symmetry of cell division are immensely important in determining plant form. Imagine a single cell that is ready to undergo mitosis. If the planes of division of its descendants are parallel to the plane of the first cell division,

a single file of cells will be produced (Figure 35.25a). At the other extreme, if the planes vary randomly, a disorganized clump of cells results. Meanwhile, even though chromosomes are allocated to daughter cells equally during mitosis, the cytoplasm may divide asymmetrically. *Asymmetrical cell division*, in which one daughter cell receives more cytoplasm than the other during mitosis, is fairly common in plant cells and usually signals a key event in development. For example, the formation of guard cells typically involves both an asymmetrical cell division and a change in the plane of cell division. An epidermal cell divides asymmetrically, forming a large cell that remains an unspecialized epidermal cell and a small cell that becomes the guard cell "mother cell." Guard cells form when this small mother cell divides in a plane perpendicular to the first cell division (Figure 35.25b).

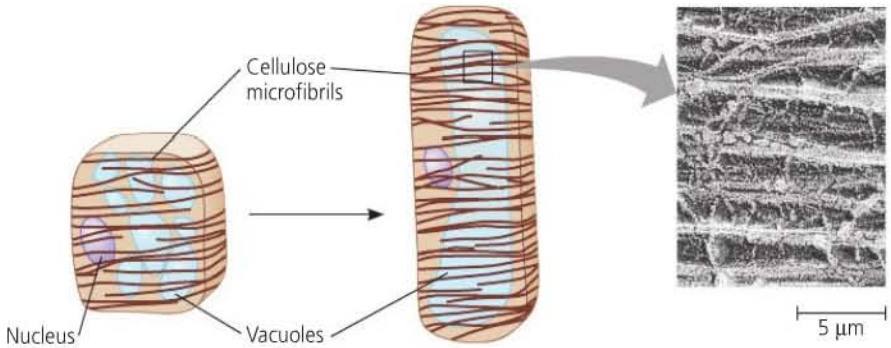


(a) Cell divisions in the same plane produce a single file of cells, whereas cell divisions in three planes give rise to a cube.

(b) An asymmetrical cell division precedes the development of epidermal guard cells, the cells that border stomata (see Figure 35.18).

▲ **Figure 35.25 The plane and symmetry of cell division influence development of form.**

The plane in which a cell divides is determined during late interphase. The first sign of this spatial orientation is a rearrangement of the cytoskeleton. Microtubules in the cytoplasm become concentrated into a ring that is called the **preprophase band** (Figure 35.26). The band disappears before metaphase, but it predicts the future plane of cell division. The "imprint" consists of an ordered array of actin microfilaments that remain after the microtubules disperse.



▲ **Figure 35.26 The preprophase band and the plane of cell division.** The location of the preprophase band predicts the plane of cell division. Although the cells shown on the left and right are similar in shape, they will divide in different planes. Each cell is represented by two light micrographs, one (top) unstained and the other (bottom) stained with a fluorescent dye that binds specifically to microtubules. The stained microtubules form a "halo" (preprophase band) around the nucleus in the outer cytoplasm.

Orientation of Cell Expansion

Before discussing how cell expansion contributes to plant form, it is useful to consider the difference in cell expansion between plants and animals. Animal cells grow mainly by synthesizing protein-rich cytoplasm, a metabolically expensive process. Growing plant cells also produce additional protein-rich material in their cytoplasm, but water uptake typically accounts for about 90% of expansion. Most of this water is packaged in the large central vacuole. Vacuolar sap is very dilute and nearly devoid of the energetically expensive macromolecules that are found in great abundance in the rest of the cytoplasm. Large vacuoles are therefore a "cheap" way of filling space, enabling a plant to grow rapidly and economically. Bamboo shoots, for instance, can elongate more than 2 m per week. Rapid extensibility of shoots and roots was an important evolutionary adaptation that increased their exposure to light and soil.

In a growing cell, enzymes weaken the cross-links in the cell wall, allowing it to expand as water diffuses into the vacuole by osmosis. Loosening of the wall occurs when hydrogen ions secreted by the cell activate cell wall enzymes that break the

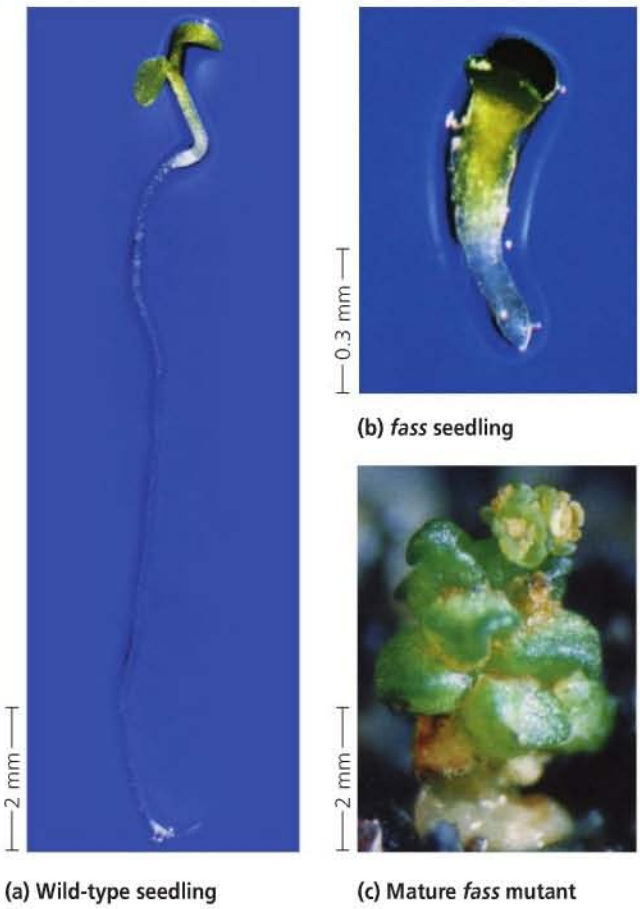
▶ **Figure 35.27 The orientation of plant cell expansion.** Growing plant cells expand mainly through water uptake. In a growing cell, enzymes weaken cross-links in the cell wall, allowing it to expand as water diffuses into the vacuole by osmosis; at the same time, more microfibrils are made. The orientation of cell growth is mainly in the plane perpendicular to the orientation of cellulose microfibrils in the wall. The microfibrils are embedded in a matrix of other (noncellulose) polysaccharides, some of which form the cross-links visible in the micrograph (TEM).

cross-links between polymers in the wall. This reduces constraint on the turgid cell, which can take up more water and expand. Small vacuoles, which accumulate most of this water, coalesce and form the cell's central vacuole.

Plant cells rarely expand equally in all directions. Their greatest expansion is usually oriented along the plant's main axis. For example, cells near the tip of the root may elongate up to 20 times their original length, with relatively little increase in width. The orientation of cellulose microfibrils in the innermost layers of the cell wall causes this differential growth. The microfibrils do not stretch, so the cell expands mainly perpendicular to the "grain" of the microfibrils, as shown in **Figure 35.27**.

As with the plane of cell division, microtubules play a key role in regulating the plane of cell expansion. It is the orientation of microtubules in the cell's outermost cytoplasm that determines the orientation of cellulose microfibrils, the basic structural units of the cell wall.

Microtubules and Plant Growth



Studies of *fass* mutants of *Arabidopsis* have confirmed the importance of cytoplasmic microtubules in cell division and expansion. The *fass* mutants have unusually squat cells with seemingly random planes of cell division. Their roots and stems have no ordered cell files and layers. Despite these abnormalities, *fass* mutants develop into tiny adult plants, but their organs are compressed longitudinally **(Figure 35.28)**.

The stubby form and disorganized tissue arrangement can be traced to the abnormal organization of microtubules. During interphase, the microtubules are randomly positioned, and preprophase bands do not form prior to mitosis (see Figure 35.26). As a result, there is no orderly "grain" of cellulose microfibrils in the cell wall to determine the direction of elongation (see Figure 35.27). This defect gives rise to cells that expand in all directions and divide haphazardly without respect to orientation.

Morphogenesis and Pattern Formation

A plant's body is more than a collection of dividing and expanding cells. Morphogenesis must occur for development to proceed properly; that is, cells must be organized into multicellular arrangements of tissues and organs. The development of specific structures in specific locations is called **pattern formation**.

Many developmental biologists postulate that pattern formation is determined by **positional information** in the form of signals that continuously indicate to each cell its location within a developing structure. According to this hypothesis, each cell within a developing organ responds to positional information from neighboring cells by differentiating into a particular cell type, oriented in a particular way. Biologists have accumulated

▲ **Figure 35.28 The *fass* mutant of *Arabidopsis* confirms the importance of cytoplasmic microtubules in plant growth.** The squat body of the *fass* mutant results from cell division and cell elongation being oriented randomly instead of in the direction of the normal plant axis.

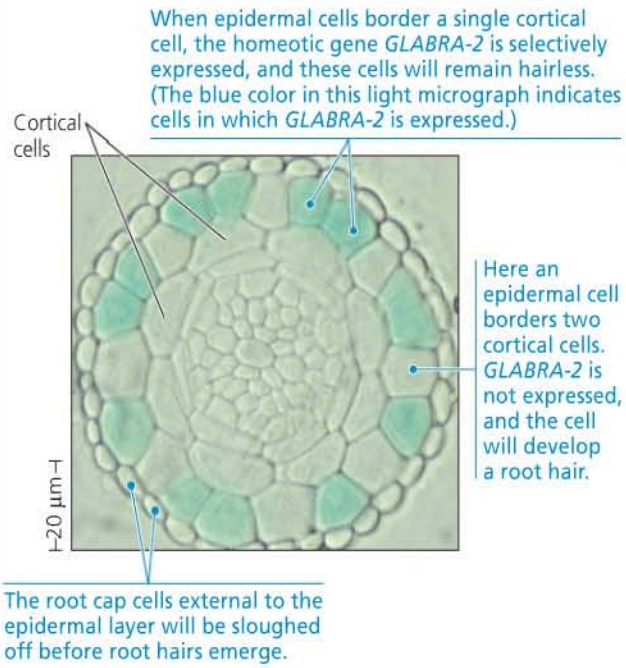
evidence that gradients of specific molecules, such as hormones, proteins, or mRNAs, provide positional information. For example, the diffusion of a growth-regulating molecule produced in the shoot apical meristem may "inform" the cells below of their distance from the shoot tip. Cells possibly "gauge" their radial positions within the developing organ by detecting a second chemical signal from the outermost cells. The gradients of these two substances would be sufficient for each cell to "get a fix" on its position relative to the longitudinal and radial axes of the developing organ. This hypothesis of diffusible chemical signals is just one that developmental biologists are testing.

One type of positional information is associated with **polarity**, the condition of having structural or chemical differences at opposite ends of an organism. Plants typically have an axis, with a root end and a shoot end. Such polarity is most obvious in morphological differences, but it is also manifest in physiological properties, including the unidirectional movement of the hormone auxin (see Chapter 39) and the emergence of adventitious roots and shoots from "cuttings." Adventitious roots form within the root end of a stem cutting, and adventitious shoots arise from the shoot end of a root cutting.

The first division of a plant zygote is normally asymmetrical, initiating polarization of the plant body into shoot and root. Once this polarity has been induced, it becomes exceedingly difficult to reverse experimentally. Therefore, the proper establishment of axial polarity is a critical step in a plant's morphogenesis. In the *gnom* mutant of *Arabidopsis,* the establishment of polarity is defective. The first cell division of the zygote is abnormal because it is symmetrical, and the resulting ball-shaped plant has neither roots nor leaves **(Figure 35.29)**.

Morphogenesis in plants, as in other multicellular organisms, is often under the control of homeotic genes, master regulatory genes that mediate many of the major events in an individual's development, such as the initiation of an organ (see Chapter 21). For example, the protein product of the homeotic gene *KNOTTED-1*, found in many plant species, is important in the development of leaf morphology, including the production of compound leaves. If the *KNOTTED-1* gene is expressed in greater quantity in the genome of tomato plants, the normally compound leaves become "supercompound" **(Figure 35.30)**.

◀ **Figure 35.29 Establishment of axial polarity.** The normal *Arabidopsis* seedling (left) has a shoot end and a root end. In the *gnom* mutant (right), the first division of the zygote was not asymmetrical; as a result, the plant is ball-shaped and lacks leaves and roots. The defect in *gnom* mutants has been traced to an inability to transport the hormone auxin in a polar manner.



▲ **Figure 35.30 Overexpression of a homeotic gene in leaf formation.** *KNOTTED-1* is a homeotic gene involved in leaf and leaflet formation. An increase in its expression in tomato plants results in leaves that are "super-compound" (right) compared with normal leaves (left).

Gene Expression and Control of Cellular Differentiation

Cells of a developing organism can synthesize different proteins and diverge in structure and function even though they share a common genome. If a mature cell removed from a root or leaf can dedifferentiate in tissue culture and give rise to the diverse cell types of a plant, then it must possess all the genes necessary to make any kind of plant cell (see Figure 20.16). This means that cellular differentiation depends, to a large extent, on the control of gene expression—the regulation of transcription and translation, resulting in the production of specific proteins. Researchers are beginning to unravel the molecular mechanisms that switch specific genes on and off at critical times during cellular differentiation (see Chapter 18).

The activation or inactivation of specific genes involved in cellular differentiation depends, to a large extent, on positional information—where a particular cell is located relative to other cells. For example, two distinct cell types are formed in the root epidermis of *Arabidopsis*: root hair cells and hairless epidermal cells. Cell fate is associated with the position of the epidermal cells. The immature epidermal cells that are in contact with two underlying cells of the root cortex differentiate into root hair cells, whereas the immature epidermal cells in contact with only one cortical cell differentiate into mature hairless cells. Differential expression of a homeotic gene called *GLABRA-2* (from the Latin *glaber,* bald) is required for appropriate root hair distribution. Researchers have demonstrated this by coupling the *GLABRA-2* gene to a "reporter gene" that causes every cell expressing *GLABRA-2* in the root to turn pale blue following a certain treatment **(Figure 35.31)**. The *GLABRA-2* gene is normally expressed only in epidermal cells that will not develop root hairs.

▲ **Figure 35.31 Control of root hair differentiation by a homeotic gene** (LM).

WHAT IF? *What would the roots look like if GLABRA-2 were rendered dysfunctional by a mutation?*

Location and a Cell's Developmental Fate

In the process of shaping an organ, patterns of cell division and cell expansion affect the differentiation of cells by placing them in specific locations relative to other cells. Thus, positional information underlies all the processes of development: growth, morphogenesis, and differentiation. One way to study the relationships among these processes is *clonal analysis*, in which the cell lineages derived from each cell in an apical meristem are mapped during organ development. Researchers use mutations to distinguish a specific meristematic cell from the neighboring cells in the shoot tip. All cells derived from the mutant cell by cell division will thereby be "marked." For example, a single cell in the meristem may have a mutation that prevents chlorophyll synthesis. This cell and all of its descendants will be "albino," and they will appear as a linear file of "albino" cells running down the long axis of the otherwise green shoot.

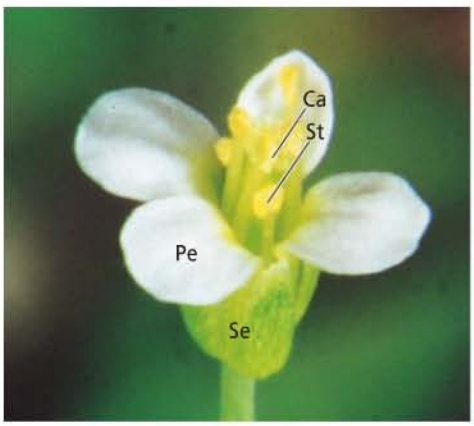
How early is a cell's developmental fate determined by its position in an embryonic structure? To some extent, the developmental fates of cells in the shoot tip are predictable very early. For example, clonal analysis has shown that almost all the cells derived from the outermost meristematic cells become part of the dermal tissue. However, we cannot pinpoint which meristematic cells will give rise to specific tissues and organs. Apparently random changes in rates and planes of cell division can reorganize the meristem. For example, the outermost cells *usually* divide perpendicularly to the surface of the shoot tip, adding cells to the surface layer. Occasionally, however, one of the outermost cells divides parallel to the surface of the shoot tip, placing one daughter cell beneath the surface, among cells derived from different lineages. Such exceptions indicate that meristematic cells are not dedicated early to forming specific tissues and organs. Instead, the cell's *final* position in an emerging organ determines what kind of cell it will become.

Shifts in Development: Phase Changes

Multicellular organisms generally pass through developmental phases. In humans, these are infancy, childhood, adolescence, and adulthood, with puberty as the dividing line between the nonreproductive and reproductive phases. Plants also pass through phases, developing from a juvenile phase to an adult vegetative phase to an adult reproductive phase. In animals, these developmental changes take place throughout the entire organism, such as when a larva develops into an adult animal. In contrast, plant developmental phases occur within a single region, the shoot apical meristem. The morphological changes that arise from these transitions in shoot apical meristem activity are called **phase changes**. During the transition from a juvenile phase to an adult phase, the most obvious morphological changes typically occur in leaf size and shape **(Figure 35.32)**. Juvenile

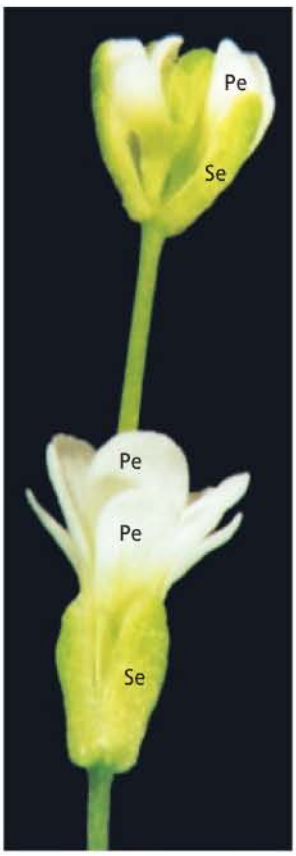
▲ **Figure 35.32 Phase change in the shoot system of *Acacia koa*.** This native of Hawaii has compound juvenile leaves, consisting of many small leaflets, and simple mature "leaves" (technically, highly modified petioles). This dual foliage reflects a phase change in the development of the apical meristem of each shoot. Once a node forms, the developmental phase—juvenile or adult—is fixed; that is, compound leaves do not mature into simple leaves.

nodes and internodes retain their juvenile status even after the shoot continues to elongate and the shoot apical meristem has changed to the adult phase. Therefore, any *new* leaves that develop on branches that emerge from axillary buds at juvenile nodes will also be juvenile, even though the apical meristem of the stem's main axis may have been producing mature nodes for years.



Phase changes are examples of developmental plasticity. The transition from juvenile to adult leaves is only one type of phase change. The transition in the fanwort (see Figure 35.1) from feathery underwater leaves to fan-shaped floating leaves is another example. Next we'll examine a common but nevertheless remarkable phase change—the transition of a vegetative shoot apical meristem into a floral meristem.

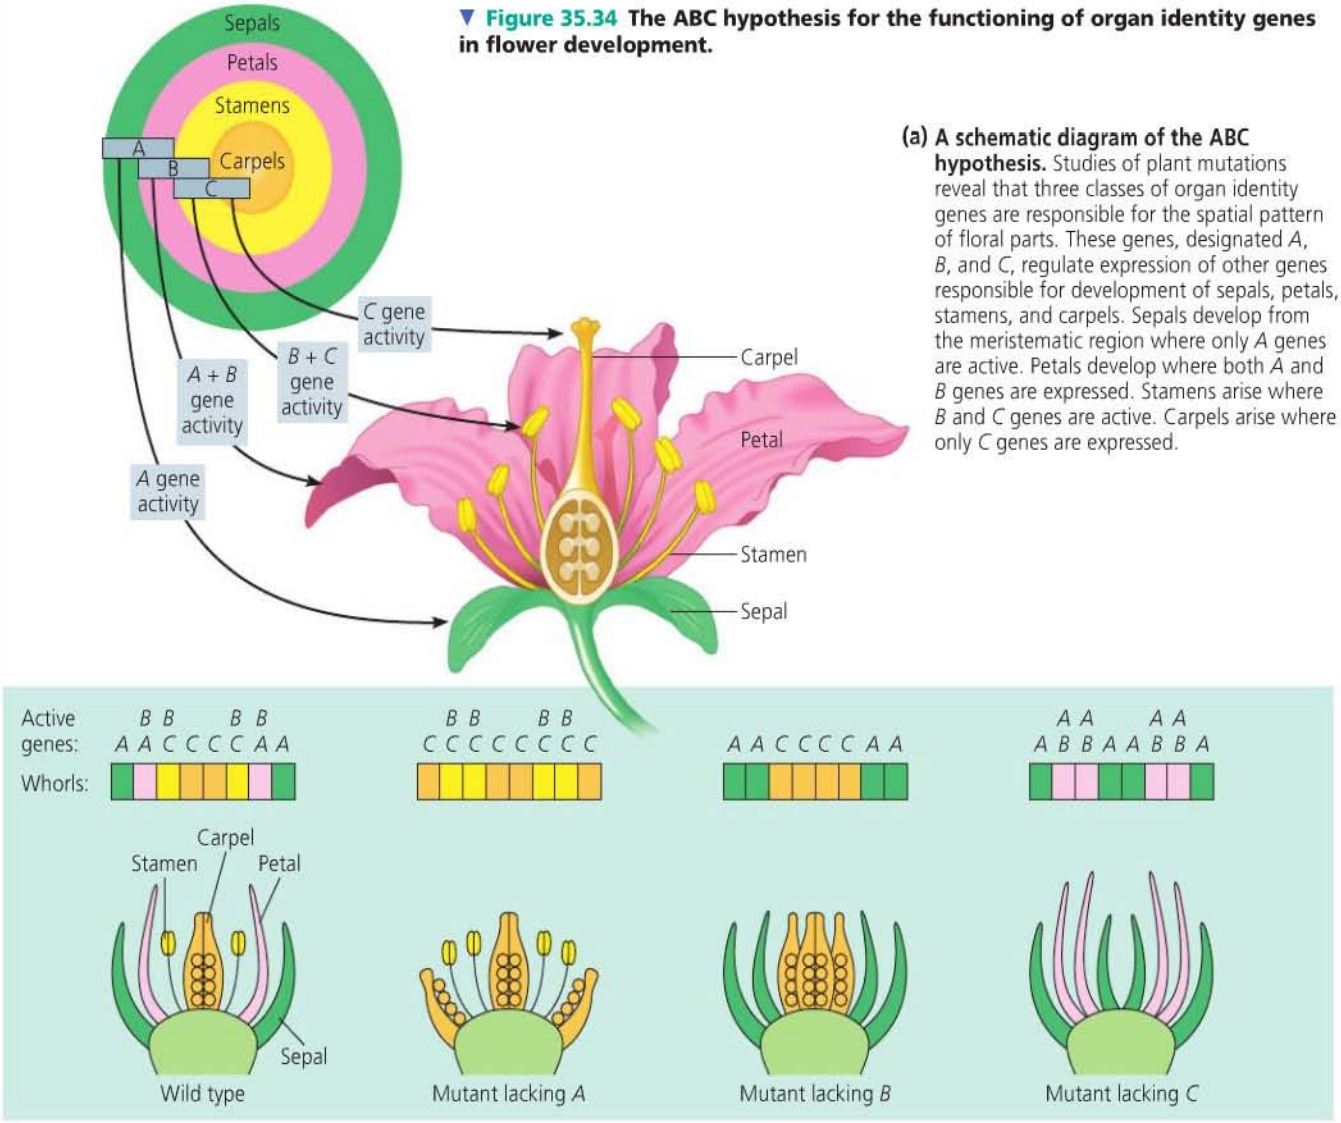
Genetic Control of Flowering



Flower formation involves a phase change from vegetative growth to reproductive growth. This transition is triggered by a combination of environmental cues, such as day length, and internal signals, such as hormones. (You will learn more about the roles of these signals in flowering in Chapter 39.) Unlike vegetative growth, which is indeterminate, floral growth is determinate: The production of a flower by a shoot apical meristem stops the primary growth of that shoot. The transition from vegetative growth to flowering is associated with the switching on of floral **meristem identity genes**. The protein products of these genes are transcription factors that regulate the genes required for the conversion of the indeterminate vegetative meristems to determinate floral meristems.

When a shoot apical meristem is induced to flower, the relative position of each primordium determines its development into a specific type of floral organ—a sepal, petal, stamen, or carpel (see Figure 30.7 to review basic flower structure). Viewed from above, the floral organs develop in four concentric circles, or whorls: Sepals form the fourth (outermost) whorl; petals form the third; stamens form the second; and carpels form the first (innermost) whorl. Plant biologists have identified several **organ identity genes** that regulate the development of this characteristic floral pattern. Organ identity genes, also called plant homeotic genes, code for transcription factors. Positional information determines which organ identity genes are expressed in a particular floral organ primordium. The result is the development of an emerging floral primordium into a specific floral organ. And just as a mutation in a fruit fly homeotic gene can cause legs to grow in place of antennae (see Figure 18.18), a mutation in a plant organ identity gene can cause abnormal floral development, such as petals growing in place of stamens, as shown in **Figure 35.33**.

By studying mutants with abnormal flowers, researchers have identified and cloned three classes of floral organ identity genes, and their studies are beginning to reveal how these genes function. The **ABC model** of flower formation, diagrammed in **Figure 35.34a**, identifies how these three classes of genes direct the formation of the four types of floral organs. According to the ABC model, each class of organ identity genes is switched on in two specific whorls of the floral meristem. Normally, *A* genes are switched on in the two outer whorls (sepals and petals); *B* genes are switched on in the two middle whorls (petals and stamens); and *C* genes are switched on in the two inner whorls (stamens and carpels). Sepals arise from those parts of the floral meristems in which only *A* genes are active; petals arise where *A* and *B* genes are active; stamens where *B* and *C* genes are active; and carpels where only *C* genes are active. The ABC model can account for the phenotypes of mutants lacking *A*, *B*, or *C* gene activity, with one addition: Where gene *A* activity is present, it inhibits *C*, and vice versa. If either *A* or *C* is missing, the other takes its place. **Figure 35.34b** shows the floral patterns of mutants lacking each of the three classes of organ identity



(a) Normal *Arabidopsis* flower. *Arabidopsis* normally has four whorls of flower parts: sepals (Se), petals (Pe), stamens (St), and carpels (Ca).

(b) Abnormal *Arabidopsis* flower. Researchers have identified several mutations of organ identity genes that cause abnormal flowers to develop. This flower has an extra set of petals in place of stamens and an internal flower where normal plants have carpels.

▶ **Figure 35.33 Organ identity genes and pattern formation in flower development.**

▼ Figure 35.34 The ABC hypothesis for the functioning of organ identity genes in flower development.

(a) A schematic diagram of the ABC hypothesis. Studies of plant mutations reveal that three classes of organ identity genes are responsible for the spatial pattern of floral parts. These genes, designated *A*, *B*, and *C*, regulate expression of other genes responsible for development of sepals, petals, stamens, and carpels. Sepals develop from the meristematic region where only *A* genes are active. Petals develop where both *A* and *B* genes are expressed. Stamens arise where *B* and *C* genes are active. Carpels arise where only *C* genes are expressed.

(b) Side view of flowers with organ identity mutations. The phenotype of mutants lacking a functional *A*, *B*, or *C* organ identity gene can be explained by combining the model in part (a) with the rule that if *A* or *C* activity is missing, the other activity occurs through all four whorls.

genes and depicts how the model accounts for the floral phenotypes. By constructing such hypotheses and designing experiments to test them, researchers are tracing the genetic basis of plant development.

In dissecting the plant to examine its parts, as we have done in this chapter, we must remember that the whole plant functions as an integrated organism. In the following chapters, you'll learn more about how materials are transported within vascular plants (Chapter 36), how plants obtain nutrients (Chapter 37), how plants reproduce (Chapter 38, focusing on flowering plants), and how plant functions are coordinated (Chapter 39). Remembering that structure fits function and that plant anatomy and physiology reflect evolutionary adaptations to the challenges of living on land will enhance your understanding of plants.

CONCEPT CHECK 35.5

1. What attributes of the weed *Arabidopsis thaliana* make it such a useful research organism?
2. How can two cells in a plant have vastly different structures even though they have the same genome?
3. Explain how the *fass* mutation in *Arabidopsis* results in a stubby plant rather than a normal elongated one.
4. **WHAT IF?** In some species, such as the magnolia on the cover of this book, sepals look like petals, and both are collectively called "tepals." Suggest an extension to the ABC model that could hypothetically account for the origin of tepals.

For suggested answers, see Appendix A.

Chapter 35 Review

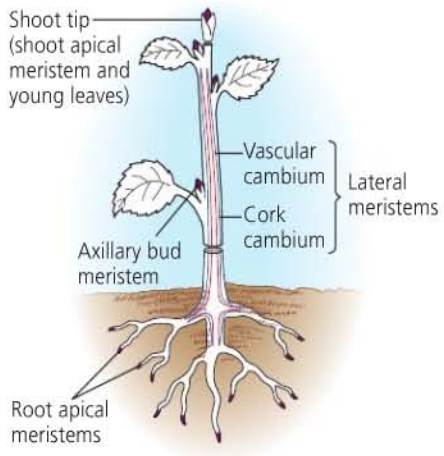
SUMMARY OF KEY CONCEPTS

CONCEPT 35.1

The plant body has a hierarchy of organs, tissues, and cells (pp. 738–745)



- **The Three Basic Plant Organs: Roots, Stems, and Leaves** Roots anchor the plant, absorb and conduct water and minerals, and store food. Shoots consist of stems, leaves, and (in angiosperms) flowers. Leaves are attached to the nodes of the stem and are the primary organs of photosynthesis. Axillary buds, located in axils of leaves and stems, give rise to shoot branches. Plant organs may be modified for specialized functions.
- **Dermal, Vascular, and Ground Tissues** Dermal tissue (epidermis and periderm), vascular tissue (xylem and phloem), and ground tissue are continuous throughout the plant, although in the various plant organs the three tissues differ in arrangement and in some specialized functions. Vascular tissues integrate the parts of the plant. Water and minerals move up from roots through the xylem. Sugar is exported from leaves or storage organs through the phloem.
- **Common Types of Plant Cells** Parenchyma cells, relatively unspecialized cells that retain the ability to divide, perform most of the plant's metabolic functions of synthesis and storage. Collenchyma cells, which have unevenly thickened walls, support young, growing parts of the plant. Sclerenchyma cells—fibers and sclereids—have thick, lignified walls that help support mature, nongrowing parts of the plant. Tracheids and vessel elements, the water-conducting cells of xylem, have thick walls and are dead at functional maturity. Sieve-tube elements are the sugar-transporting cells of phloem in angiosperms. Though alive at functional maturity, sieve-tube elements depend on neighboring companion cells.

MEDIA

CONCEPT 35.2

Meristems generate cells for new organs (pp. 746–747)

CONCEPT 35.3

Primary growth lengthens roots and shoots (pp. 747–751)

- **Primary Growth of Roots** The root apical meristem is located near the tip of the root, where it generates cells for the growing root axis and the root cap.
- **Primary Growth of Shoots** The apical meristem of a shoot is located in the apical bud, where it gives rise to a repetition of internodes and leaf-bearing nodes.

MEDIA

Activity Root, Stem, and Leaf Sections

Investigation What Are Functions of Monocot Tissues?

CONCEPT 35.4

Secondary growth adds girth to stems and roots in woody plants (pp. 751–754)

- **The Vascular Cambium and Secondary Vascular Tissue** The vascular cambium develops from parenchyma cells into a meristematic cylinder that produces secondary xylem and secondary phloem. Older layers of secondary xylem (heartwood) become inactive, while younger layers (sapwood) still conduct water. Only the youngest secondary phloem is active in conducting sugars.
- **The Cork Cambium and the Production of Periderm** The cork cambium gives rise to the secondary plant body's protective covering, or periderm, which consists of the cork cambium plus the layers of cork cells it produces. Bark consists of all the tissues external to the vascular cambium: secondary phloem and periderm.

MEDIA

Activity Primary and Secondary Growth

CONCEPT 35.5

Growth, morphogenesis, and differentiation produce the plant body (pp. 755–761)

- **Molecular Biology: Revolutionizing the Study of Plants** New techniques and model systems, including *Arabidopsis*, are catalyzing progress in understanding plants. *Arabidopsis* was the first plant to have its genome sequenced.
- **Growth: Cell Division and Cell Expansion** Cell division and cell expansion are the primary determinants of growth and form. A preprophase band determines where a cell plate will form in a dividing cell. Cytoskeleton orientation affects the direction of cell elongation by controlling the orientation of cellulose microfibrils in the cell wall.
- **Morphogenesis and Pattern Formation** Development of tissues and organs in specific locations depends on cells responding to positional information, such as polarity. Homeotic genes often control morphogenesis.
- **Gene Expression and Control of Cellular Differentiation** Despite having identical genomes, plant cells differentiate because of differential gene activation.

- **Location and a Cell's Developmental Fate** The way in which a plant cell differentiates is determined largely by the cell's position in the developing plant body.
- **Shifts in Development: Phase Changes** Internal or environmental cues may cause a plant to switch from one developmental phase to another—for example, from developing juvenile leaves to developing mature leaves. Such morphological changes are called phase changes.
- **Genetic Control of Flowering** Research on organ identity genes in developing flowers provides a model system for studying pattern formation. The ABC model identifies how three classes of organ identity genes control formation of sepals, petals, stamens, and carpels.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which structure is *incorrectly* paired with its tissue system?
   a. root hair—dermal tissue
   b. palisade mesophyll—ground tissue
   c. guard cell—dermal tissue
   d. companion cell—ground tissue
   e. tracheid—vascular tissue

2. In a root, a vessel element completes its development in which area of growth?
   a. zone of cell division
   b. zone of elongation
   c. zone of differentiation
   d. root cap
   e. apical meristem

3. Heartwood and sapwood consist of
   a. bark.
   b. periderm.
   c. secondary xylem.
   d. secondary phloem.
   e. cork.

4. Which of the following is *not* part of an older tree's bark?
   a. cork
   b. cork cambium
   c. lenticels
   d. secondary xylem
   e. secondary phloem

5. The phase change of an apical meristem from the juvenile to the mature vegetative phase is often revealed by
   a. a change in the morphology of the leaves produced.
   b. the initiation of secondary growth.
   c. the formation of lateral roots.
   d. a change in the orientation of preprophase bands and cytoplasmic microtubules in lateral meristems.
   e. the activation of floral meristem identity genes.

6. Which of the following arise from meristematic activity?
   a. secondary xylem
   b. leaves
   c. dermal tissue
   d. tubers
   e. all of the above

7. Pinching off the tops of snapdragons causes the plants to make many more flowers than they would if left alone. Why does the removal of the top cause more flowers to form?
   a. Removal of an apical meristem causes a phase transition from vegetative to floral development.
   b. Removal of an apical meristem causes cell division to become disorganized, as in the *fass* mutant of *Arabidopsis*.
   c. Removal of an apical meristem allows more nutrients to be delivered to floral meristems.
   d. Removal of an apical meristem causes outgrowth of lateral buds that produce extra branches, which ultimately produce flowers.
   e. Removal of an apical meristem allows the periderm to produce new lateral branches.

8. Which of these are *not* produced by the vascular cambium?
   a. sclerenchyma cells
   b. parenchyma cells
   c. sieve-tube elements
   d. root hairs
   e. vessel elements

9. The type of mature cell that a particular embryonic plant cell will become appears to be determined mainly by
   a. the selective loss of genes.
   b. the cell's final position in a developing organ.
   c. the cell's pattern of migration.
   d. the cell's age.
   e. the cell's particular meristematic lineage.

10. Based on the ABC model, what would be the structure of a flower that had normal expression of genes *A* and *C* and expression of gene *B* in all four whorls?
    a. carpel-petal-petal-carpel
    b. stamen-stamen-petal-petal
    c. sepal-carpel-carpel-sepal
    d. sepal-sepal-carpel-carpel
    e. carpel-carpel-carpel-carpel

11. **DRAW IT** On this cross section from a woody eudicot, label a growth ring, late wood, early wood, and a vessel element. Then draw an arrow in the pith-to-cork direction.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

12. Evolutionary biologists have coined the term *exaptation* to describe a common occurrence in the evolution of life: A limb or organ originally has a particular function but later fulfills a new function. What are some examples of exaptations in plant organs?

SCIENTIFIC INQUIRY

13. Write a paragraph explaining why mutants are useful for investigating the regulation of plant development. Include at least one specific example.

36 Resource Acquisition and Transport in Vascular Plants

▲ **Figure 36.1 Plants or pebbles?**

KEY CONCEPTS

36.1 Land plants acquire resources both above and below ground
36.2 Transport occurs by short-distance diffusion or active transport and by long-distance bulk flow
36.3 Water and minerals are transported from roots to shoots
36.4 Stomata help regulate the rate of transpiration
36.5 Sugars are transported from leaves and other sources to sites of use or storage
36.6 The symplast is highly dynamic

OVERVIEW

Underground Plants

The Kalahari Desert of southern Africa receives only about 20 cm of precipitation a year, almost exclusively during the summer months, when daytime temperatures reach a scorching 35–45°C (95–113°F). Many animals escape the desert heat by seeking shelter underground. A peculiar genus of perennial plants called stone plants (*Lithops*) has a similar, mostly subterranean lifestyle **(Figure 36.1)**. Except for the tips of two succulent leaves that are exposed to the surface, a stone plant lives entirely below ground. Each leaf tip has a region of clear, lens-like cells that allow light to penetrate to the photosynthetic tissues underground. These adaptations enable stone plants to conserve moisture and avoid the potentially harmful temperatures and high light intensities of the desert.

The remarkable growth habit of *Lithops* reminds us that the success of plants depends largely on their ability to gather and conserve resources from their environment. Through natural selection, many plant species have become highly proficient in acquiring resources that are especially limited in their environment, but there are often trade-offs in such specializations. For example, the mostly subterranean lifestyle of stone plants is good for the net acquisition of water but not for photosynthesis. As a result, stone plants grow very slowly.

This chapter begins by examining structural features of shoot and root systems that increase their efficiency in acquiring resources. Resource acquisition, however, is not the end of the story but only the beginning. Once acquired, resources must be transported to those parts of the plant where they are needed. The transport of materials, therefore, is critical for the integrated functioning of the whole plant. A central theme of this chapter is how three basic transport mechanisms—diffusion, active transport, and bulk flow—work together in vascular plants to transfer water, minerals, and the products of photosynthesis (sugars).

CONCEPT **36.1**

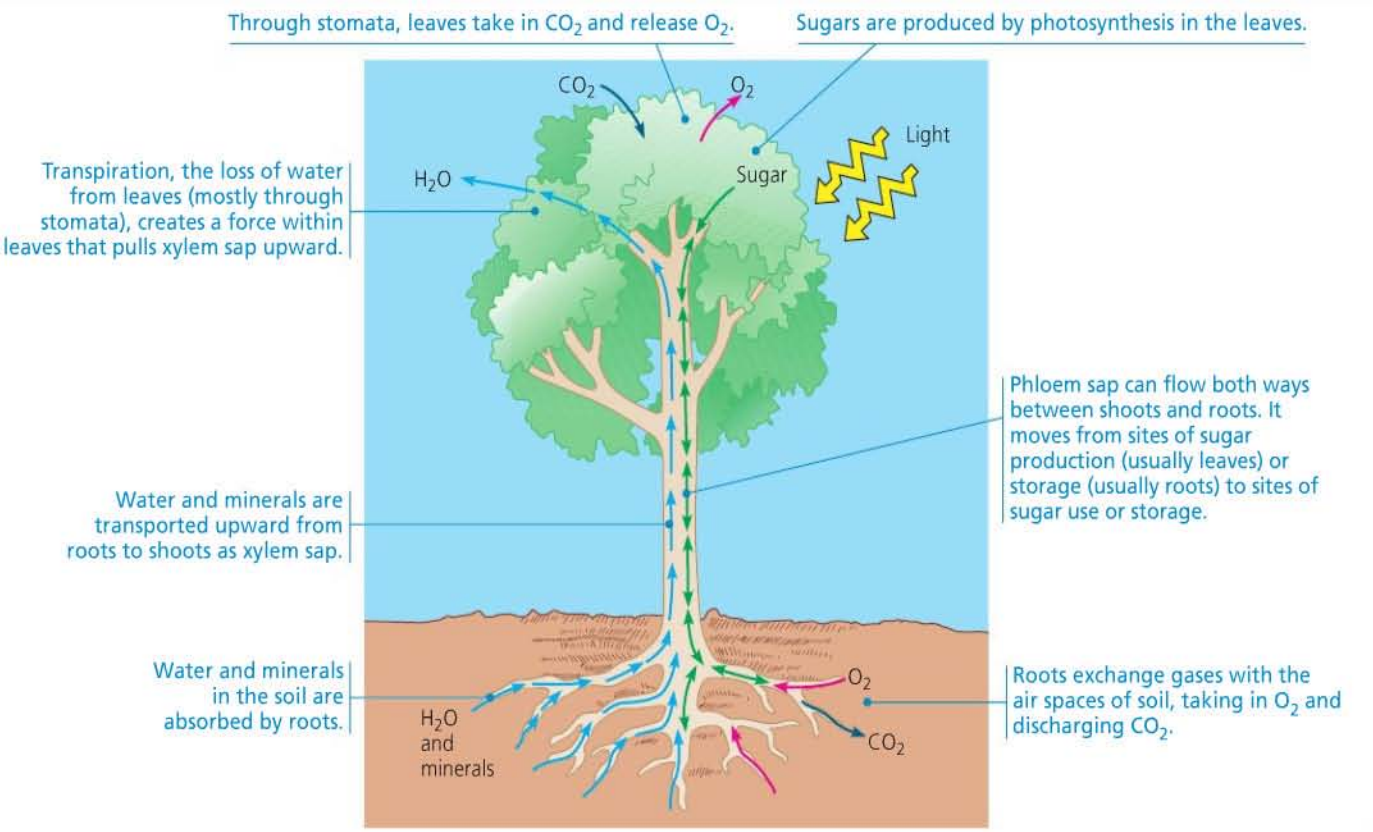
Land plants acquire resources both above and below ground

Land plants typically inhabit two worlds—above ground, where their shoot systems acquire sunlight and CO_2, and below ground, where their root systems acquire water and minerals. Without adaptations that allow acquisition and transport of these resources from these dual sites, plants could not have colonized land.

The algal ancestors of land plants absorbed water, minerals, and CO_2 directly from the water in which they lived. Transport in these algae was relatively simple because each cell was close to the source of these substances. The earliest land plants were nonvascular plants that grew photosynthetic shoots above the shallow fresh water in which they lived. These leafless shoots had waxy cuticles and few stomata, which allowed them to avoid excessive water loss while still permitting gas exchange for photosynthesis. The anchoring and absorbing functions of early land plants were assumed by the base of the stem or by threadlike rhizoids (see Figure 29.8).

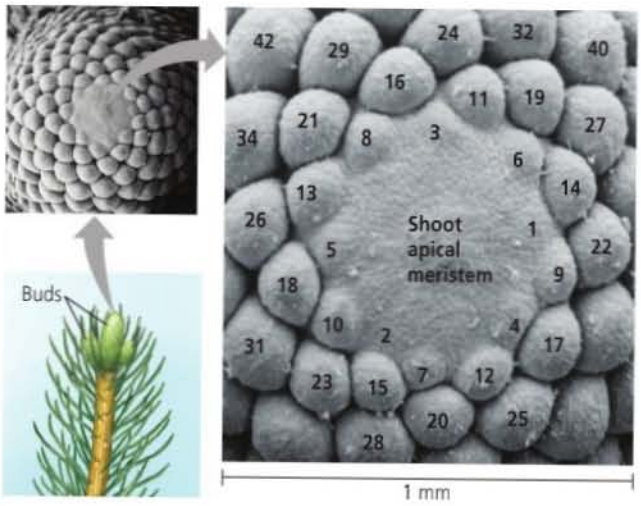
As land plants evolved and increased in number, competition for light, water, and nutrients intensified. Taller plants with broad, flat appendages had an advantage in absorbing light. This increase in surface area, however, resulted in more evaporation and therefore a greater need for water. Larger shoots also required more anchorage. These needs favored the production of multicellular, branching roots. Meanwhile, as greater shoot heights further separated the top of the photosynthetic shoot from the nonphotosynthetic parts below ground, natural selection favored plants capable of efficient long-distance transport of water, minerals, and products of photosynthesis.

The evolution of vascular tissue consisting of xylem and phloem made possible the development of extensive root and shoot systems that carry out long-distance transport (see Figure 35.10). The xylem transports water and minerals from roots to shoots. The phloem transports products of photosynthesis from where they are made or stored to where they are needed. **Figure 36.2** provides an overview of resource acquisition and transport in a vascular plant.



Because plant success depends on photosynthesis, evolution has resulted in many mechanisms for acquiring light from the sun, CO_2 from the air, and water from the ground. Perhaps just as important, land plants must minimize evaporative loss of water, particularly in environments where water is scarce. The adaptations of each species represent compromises between enhancing photosynthesis and minimizing water loss in the species' particular habitat. Later in the chapter, we'll discuss how plants minimize water loss. Here, we'll examine how the basic architecture of shoots and roots helps plants acquire resources.

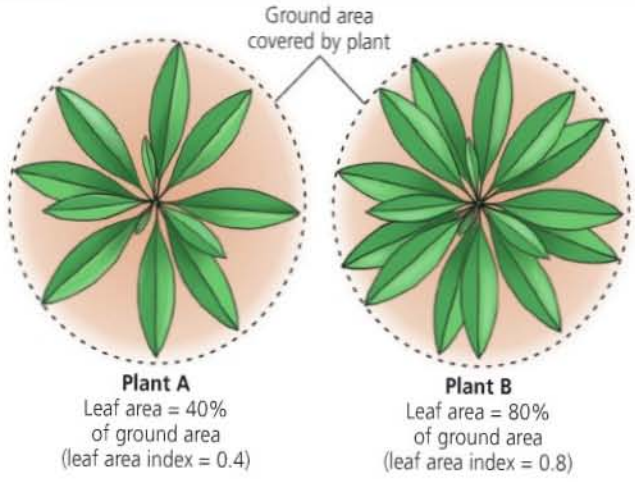
Shoot Architecture and Light Capture



In shoot systems, stems serve as supporting structures for leaves and as conduits for the transport of water and nutrients. Variations in shoot systems arise largely from the form and arrangement of leaves, the outgrowth of axillary buds, and the relative growth in stem length and thickness.

Leaf size and structure account for much of the outward diversity we see in plant form. Leaves range in length from the minuscule 1.3-mm leaves of the pygmy weed (*Crassula erecta*), a native weed of dry, sandy regions in the western United States, to the 20-m leaves of the palm *Raphia regalis*, a native of African rain forests. These species represent extreme examples of a general correlation observed between water availability and leaf size. The largest leaves are generally found in tropical rain forests, and the smallest are usually found in dry or very cold environments, where liquid water is scarce and evaporative loss from leaves is potentially more problematic.

The arrangement of leaves on a stem, known as **phyllotaxy**, is an architectural feature of immense importance in light capture.



▲ **Figure 36.2 An overview of resource acquisition and transport in a vascular plant.**

▲ **Figure 36.3 Emerging phyllotaxy of Norway spruce.** This SEM, taken from above a shoot tip, shows the pattern of emergence of leaves. The leaves are numbered, with 1 being the youngest. (Some numbered leaves are not visible in the close-up.)

? *With your finger, trace the progression of leaf emergence, starting with leaf number 29. What is the pattern?*

▲ **Figure 36.4 Leaf area index.** The leaf area index of a single plant is the ratio of the total area of the top surfaces of the leaves to the area of ground covered by the plant, as shown in this illustration of two plants viewed from the top.

? *Would a higher leaf area index always increase the amount of photosynthesis? Explain.*

Phyllotaxy is determined by the shoot apical meristem and is specific to each species **(Figure 36.3)**. A species may have one leaf per node (alternate, or spiral, phyllotaxy), two leaves per node (opposite phyllotaxy), or more (whorled phyllotaxy). Most angiosperms have alternate phyllotaxy, with leaves arranged in an ascending spiral around the stem, each successive leaf emerging about 137.5° from the site of the previous one. Why 137.5°? Mathematical analyses suggest that this angle allows each leaf to get the maximum exposure to light and reduces shading of the lower leaves by those above. In environments where intense sunlight can harm leaves, the greater shading provided by oppositely arranged leaves may be advantageous.

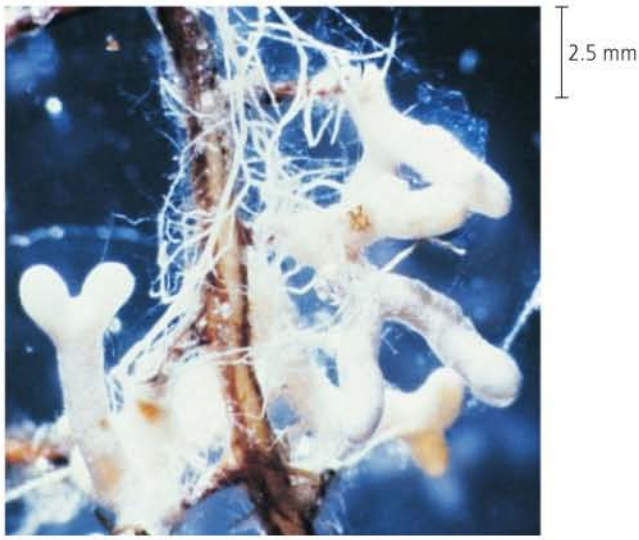
Plant features that reduce self-shading increase light capture. A useful measurement in this regard is the *leaf area index*, the ratio of the total upper leaf surface of a single plant or an entire crop divided by the surface area of the land on which the plant or crop grows **(Figure 36.4)**. Leaf area index values of up to 7 are common for many mature crops, and there is little agricultural benefit to leaf area indexes higher than this value. Adding more leaves increases shading of lower leaves to the point that they respire more than photosynthesize. When this happens, the nonproductive leaves or branches undergo programmed cell death and are eventually shed, a process called *self-pruning*.

Another factor affecting light capture is leaf orientation. Some plants have horizontally oriented leaves; others, such as grasses, have leaves that are vertically oriented. In low-light conditions, horizontal leaves capture sunlight much more effectively than vertical leaves. In grasslands or other sunny regions, however, horizontal orientation may expose upper leaves to intense light, injuring leaves and reducing photosynthesis. But if a plant's leaves are nearly vertical, light rays are essentially parallel to the leaf surfaces, so no leaf receives too much light, and light penetrates more deeply to the lower leaves.

Some other factors that contribute greatly to the outward appearance and ecological success of plants are bud outgrowth and stem elongation. Carbon dioxide and sunlight are resources that are more effectively exploited by branching. However, some plants, such as palms, generally do not branch, whereas others, such as grasses, have short stems with many branches. Why is there so much variation in shoot architecture? The reason is that plants have a finite amount of energy to devote to shoot growth. If they put most of that energy into branching, they have less to devote toward growing tall, and they are at increased risk of being shaded by taller plants. If they put all of their energy into being tall, they are not optimally exploiting the resources above ground. Natural selection has produced shoot architectures that optimize light absorption in the ecological niche plants naturally occupy.

Plant species also vary in stem thickness. Most tall plants require thick stems, which enable greater vascular flow to the leaves and mechanical support for them. Vines are an exception, relying on other structures (usually other plants) to raise their leaves higher. In woody plants, stems become thicker through secondary growth (see Figure 35.11).

Root Architecture and Acquisition of Water and Minerals



Just as carbon dioxide and sunlight are resources exploited by the shoot system, soil contains resources mined by the root system. The evolution of root branching enabled land plants to more effectively acquire water and nutrients from the soil, while also providing strong anchorage. The tallest plant species, including gymnosperms and eudicots, are typically anchored by

strong taproot systems with numerous branches (see Figure 35.2). Although there are exceptions, such as palms, most monocots do not reach treelike heights because their fibrous root systems do not anchor a tall plant as strongly as a taproot system (see Figure 30.13).

Recent evidence suggests that physiological mechanisms reduce competition within the root system of a plant. Cuttings from the stolons of buffalo grass (*Buchloe dactyloides*) developed fewer and shorter roots in the presence of cuttings from the same plant than they did in the presence of cuttings from another buffalo grass plant. Moreover, when cuttings from the same node were separated, their root systems eventually began competing with each other. Although the mechanism underlying this ability to distinguish self from nonself is unknown, avoiding competition between roots of the same plant for the same limited pool of resources certainly seems beneficial.

Evolution of mutualistic associations between roots and fungi was a critical step in the successful colonization of land by plants, especially given the poorly developed soils available at that time. The very specialized mutualistic associations between roots and fungi are called **mycorrhizae** (Figure 36.5). About 80% of extant land plant species form mycorrhizal associations (discussed in Chapters 31 and 37). Mycorrhizal hyphae endow the fungus and plant roots with an enormous surface area for absorbing water and minerals, particularly phosphate. As much as 3 m of hyphae can extend from each centimeter along a root's length, facilitating access to a far greater volume of soil than the root alone could penetrate.

Once acquired, resources must be transported to other parts of the plant that need them. In the next section, we'll examine the processes that enable resources such as water, minerals, and sugars to be transported throughout the plant.

▲ **Figure 36.5 A mycorrhiza, a mutualistic association of fungi and roots.** The white mycelium of the fungus ensheathes these roots of a pine tree. The branched, club-shaped roots are often characteristic of this association. The fungal hyphae provide an extensive surface area for the absorption of water and minerals.

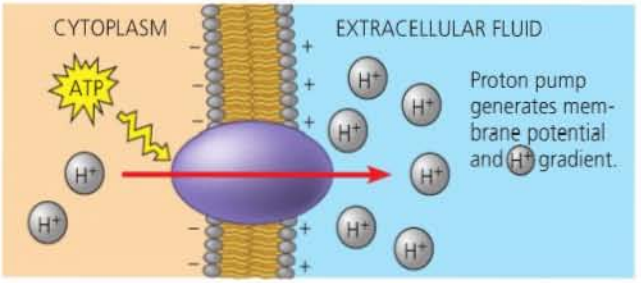
CONCEPT CHECK 36.1

1. Why is long-distance transport important for vascular plants?
2. What architectural features influence self-shading?
3. Why might a crop develop a mineral deficiency after being treated with a fungicide?
4. Some plants can detect increased levels of light reflected from leaves of encroaching neighbors. This detection elicits stem elongation, production of erect leaves, and reduced lateral branching. How do these responses help the plant compete?
5. **WHAT IF?** If you prune a plant's shoot tips, what will be the short-term effect on the plant's branching and leaf area index?

For suggested answers, see Appendix A.

CONCEPT 36.2

Transport occurs by short-distance diffusion or active transport and by long-distance bulk flow



Like animals, plants need to transport water and nutrients from one part of their body to another. How do they do this without a pumping mechanism like a heart? To answer this question, we must first look at the basic transport processes of plants.

Transport begins with the absorption of resources by plant cells. As in any organism, the selective permeability of the plasma membrane controls the movement of substances into and out of the cell. We examined the transport of solutes and water across plasma membranes in detail in Chapter 7. Here we'll review diffusion and active transport in the context of short-distance transport in plant cells, and then we'll look at long-distance transport through bulk flow.

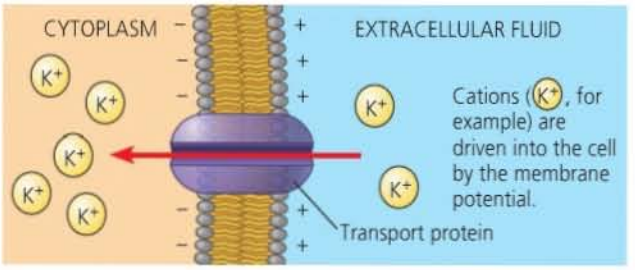
Diffusion and Active Transport of Solutes

Recall from Chapter 7 that a solute tends to diffuse down its electrochemical gradient, the combined effect of the solute's concentration gradient and the voltage (charge difference) across the membrane. Diffusion across a membrane is called *passive transport* because it happens without the cell directly using metabolic energy. *Active transport* is the pumping of a solute across a membrane against its electrochemical gradient. It is called "active" because the cell must expend energy, usually in the form of ATP, to transport a solute counter to the net direction in which the solute diffuses.

Most solutes cannot diffuse across the phospholipid bilayer of the membrane directly. Instead, they must pass through **transport proteins** embedded in the membrane. Transport proteins involved in active transport require energy to function,

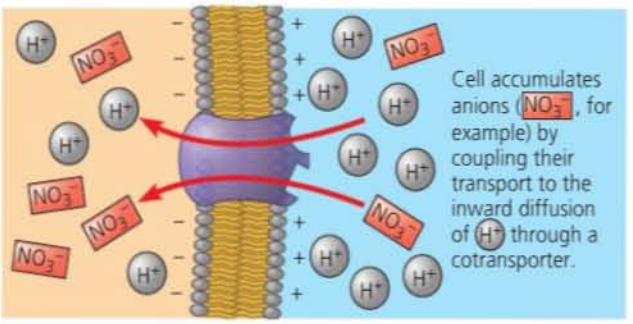
▲ **Figure 36.6 Proton pumps provide energy for solute transport.** By pumping H^+ out of the cell, proton pumps produce an H^+ gradient and a charge separation called a membrane potential. These two forms of potential energy can drive the transport of solutes.

whereas those engaged in passive transport do not. In some cases, transport proteins bind selectively to a solute on one side of the membrane and then change shape, releasing the solute on the opposite side. Other transport proteins provide selective channels across the membrane. For example, membranes of most plant cells have potassium channels that allow potassium ions (K^+) to pass but not other cations, such as sodium (Na^+). Some channels are gated, opening or closing in response to stimuli such as chemicals, pressure, or voltage. Later in this chapter, we'll discuss how K^+ channels in guard cells function in opening and closing stomata.



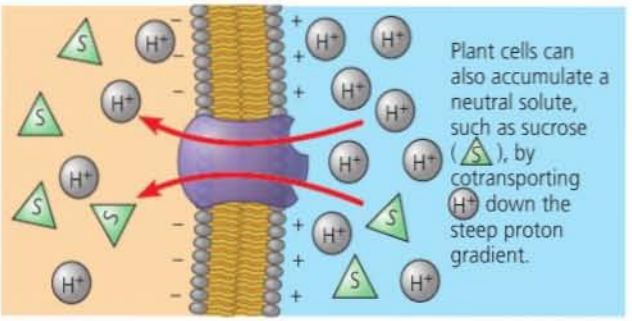
In active transport in plant cells, the most important transport proteins are **proton pumps**, which use energy from ATP to pump protons (H^+) out of the cell. This movement results in an H^+ gradient (proton gradient), with a higher H^+ concentration outside the cell than inside (**Figure 36.6**). The H^+ gradient across the membrane is a form of potential (stored) energy, and the flow of H^+ back into the cell can be harnessed to do work. The movement of H^+ out of the cell also makes the inside of the cell negative in charge relative to the outside. This charge separation across the membrane contributes to a voltage called a **membrane potential**, another form of potential energy that can be harnessed to perform cellular work.

Plant cells use the energy in the H^+ gradient and membrane potential to drive the active transport of many different solutes. For example, the membrane potential generated by proton pumps contributes to the absorption of K^+ by root cells (**Figure 36.7a**). In the mechanism called **cotransport**, a transport protein couples the diffusion of one solute (H^+) with active transport of another (NO_3^- in **Figure 36.7b**).



The "coattail" effect of cotransport is also responsible for absorption of neutral solutes, such as the sugar sucrose, by plant cells (**Figure 36.7c**). A sucrose-H^+ cotransporter couples movement of sucrose against its concentration gradient with movement of H^+ down its electrochemical gradient.

Diffusion of Water (Osmosis)



To survive, plants must balance water absorption and loss. The net absorption or loss of water by a cell occurs by **osmosis**, the

(a) Membrane potential and cation uptake

(b) Cotransport of an anion with H^+

(c) Cotransport of a neutral solute with H^+

▲ **Figure 36.7 Solute transport in plant cells.**

diffusion of water across a membrane (see Figure 7.12). What determines the direction of water movement? In an animal cell, if the plasma membrane is impermeable to the solutes, water will move from the solution with the lower solute concentration to the solution with the higher solute concentration. But a plant cell has an almost rigid cell wall, which adds another factor that affects osmosis: the physical pressure of the cell wall pushing back against the expanding protoplast (the living part of the cell, consisting of the nucleus, cytoplasm, and plasma membrane). The combined effects of solute concentration and physical pressure are incorporated into a quantity called the **water potential**.

Water potential determines the direction of water movement. The primary idea to keep in mind is that free water—water that is not bound to solutes or surfaces—moves *from regions of higher water potential to regions of lower water potential* if there is no barrier to its flow. For example, if a plant cell is immersed in a solution that has a higher water potential than the cell, water will move into the cell. As it moves, water can perform work, such as cell expansion. The word *potential*

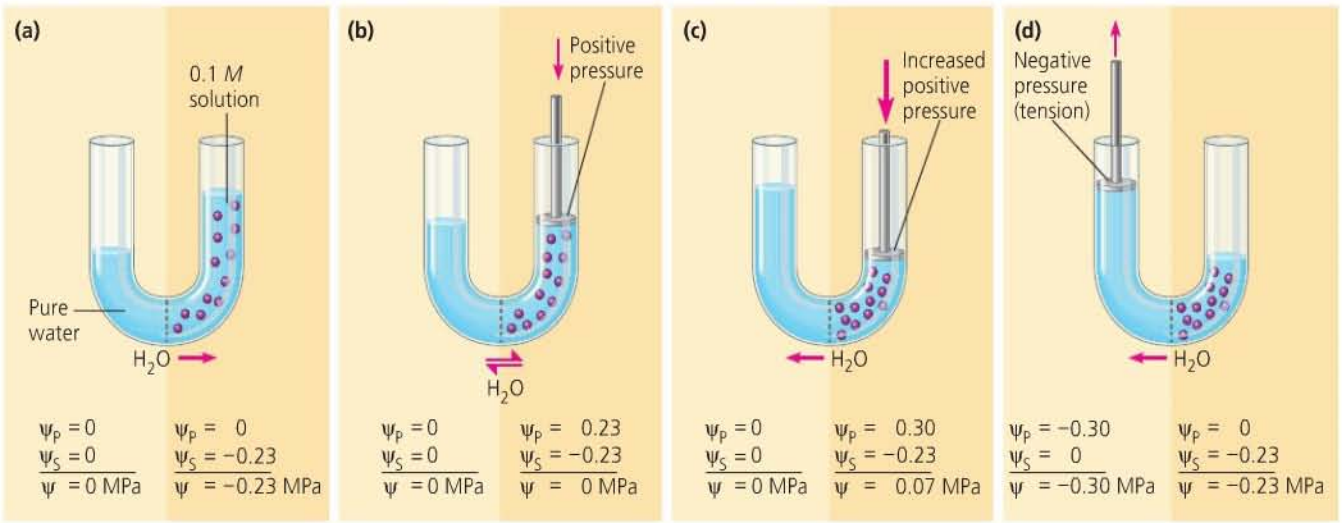
in the term *water potential* refers to water's potential energy—water's capacity to perform work when it moves from a region of higher water potential to a region of lower water potential.

Water potential is abbreviated by the Greek letter ψ (psi, pronounced "sigh"). Plant biologists measure ψ in units of pressure called **megapascals** (abbreviated **MPa**). Physicists have assigned the value of zero ($\psi = 0$ MPa) to the water potential of pure water in a container open to the atmosphere under standard conditions (at sea level and at room temperature). One MPa is equal to about 10 atmospheres of pressure. (An atmosphere is the pressure exerted at sea level by the volume of air extending through the entire height of the atmosphere—about 1 kg of pressure per square centimeter.) The internal pressure of a plant cell is approximately 0.5 MPa, about twice the air pressure inside an inflated car tire.

How Solutes and Pressure Affect Water Potential

Both pressure and solute concentration can affect water potential, as expressed in the *water potential equation*:

$$\psi = \psi_S + \psi_P$$



where ψ is the water potential, ψ_S is the solute potential (osmotic potential), and ψ_P is the pressure potential. The **solute potential** (ψ_S) of a solution is proportional to its molarity. Solute potential is also called **osmotic potential** because solutes affect the direction of osmosis. Solutes are dissolved chemicals, which in plants are typically mineral ions and sugars. By definition, the ψ_S of pure water is 0. But what happens when solutes are added? The solutes bind water molecules, reducing the number of free water molecules and lowering the capacity of the water to move and do work. Thus, adding solutes always lowers water potential, and the ψ_S of a solution is always negative. A 0.1 *M* solution of a sugar, for example, has a ψ_S of −0.23 MPa.

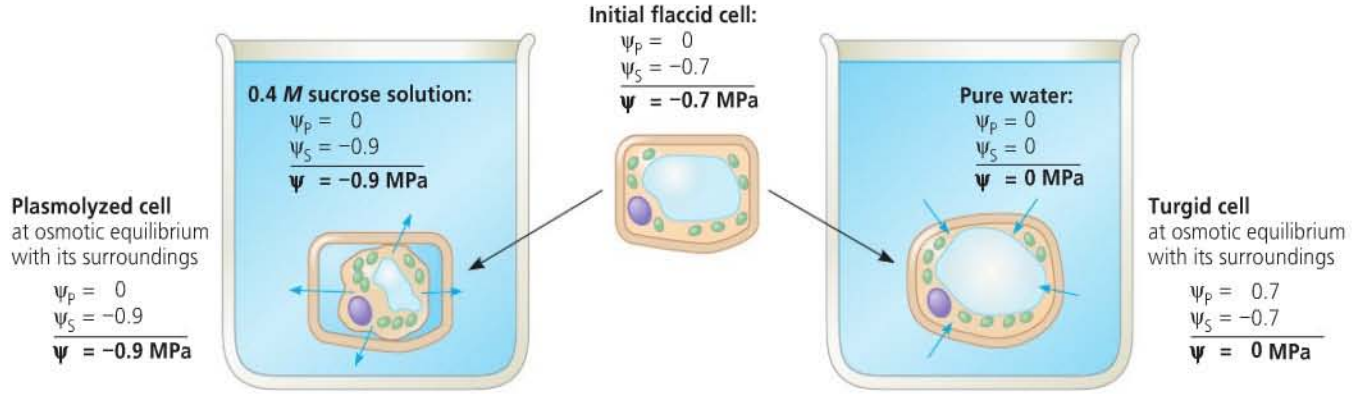
Pressure potential (ψ_P) is the physical pressure on a solution. Unlike ψ_S, ψ_P can be positive or negative relative to atmospheric pressure. For example, the water in the nonliving xylem cells (tracheids and vessel elements) of a plant is often under a negative pressure potential (tension) of less than −2 MPa. Conversely, much like the air in a balloon, the water in living cells is usually under positive pressure. Specifically, the cell contents press the plasma membrane against the cell wall, and the cell wall, in turn, presses against the protoplast, producing what is called **turgor pressure**.

Measuring Water Potential

Now let's put the water potential equation to use. We'll apply it to an artificial model and then to a living plant cell.

A U-shaped tube can be used to demonstrate water movement across a selectively permeable membrane **(Figure 36.8)**. As you consider this model, keep in mind the key point: *Water moves from regions of higher water potential to regions of lower water potential.* The two arms of the U-tube are separated by a membrane (shown as a vertical dashed line) that is permeable to water but not to solutes. If the right arm of the tube contains a 0.1 *M* solution ($\psi_S = -0.23$ MPa) and the left arm contains pure water ($\psi_S = 0$), and there is no physical pressure (that is, $\psi_P = 0$), the water potential ψ is equal to ψ_S. Thus, the ψ of the right arm is −0.23 MPa, whereas the ψ of the left arm (pure water) is 0 MPa. Because water moves from regions of higher water potential to regions of lower water potential, the net water movement will be from the left arm of the tube to

▲ **Figure 36.8 Water potential and water movement: an artificial model.** In this U-shaped apparatus, a membrane separates pure water (left arm) from a 0.1 *M* solution (right arm) containing a solute that cannot pass freely across the membrane. The values for ψ, ψ_S, and ψ_P in the left and right arms of the U-tube are given for *initial* conditions, *before* any net movement of water. **(a)** If no pressure is applied, ψ_S determines net movement of water. **(b)** Positive pressure (increased ψ_P) on the right raises ψ on the right, here making ψ the same in both arms, so eventually there is no net water movement. **(c)** Further increasing positive pressure on the right causes net water movement to the left. **(d)** Negative pressure reduces ψ_P. In this case, negative pressure on the left decreases ψ on the left, causing net water movement to the left.



the right arm, as shown in Figure 36.8a. But applying a positive physical pressure of +0.23 MPa to the solution in the right arm raises its water potential from a negative value to 0 MPa ($\psi = -0.23 + 0.23$). As shown in Figure 36.8b, there is now no net flow of water between this pressurized solution and the compartment of pure water. If we increase ψ_P to +0.30 MPa in the right arm, as in Figure 36.8c, then the solution has a water potential of +0.07 MPa ($\psi = -0.23 + 0.30$), and this solution will actually *lose* water to a compartment containing pure water. Whereas applying positive pressure increases ψ, applying negative pressure (tension) reduces ψ, as shown in Figure 36.8d. In this case, a negative pressure potential of −0.30 MPa reduces the ψ of the water compartment enough so that water is drawn from the solution on the right side.

Now let's consider how water potential affects absorption and loss of water by a living plant cell. First, imagine a cell that is **flaccid** (limp) as a result of losing water. The cell has a ψ_P of 0 MPa. Suppose this flaccid cell is bathed in a solution of higher solute concentration (more negative solute potential) than the cell itself **(Figure 36.9a)**. Since the external solution has the lower (more negative) water potential, water diffuses out of the cell. The cell's protoplast undergoes **plasmolysis**—that is, it shrinks and pulls away from the cell wall. If we place the same flaccid cell in pure water ($\psi = 0$ MPa) **(Figure 36.9b)**, the cell, because it contains solutes, has a lower water potential than the water, and water enters the cell by osmosis. The contents of the cell begin to swell and press the plasma membrane against the cell wall. The partially elastic wall, exerting turgor pressure, pushes back against the pressurized protoplast. When this pressure is enough to offset the tendency for water to enter because of the solutes in the cell, then ψ_P and ψ_S are equal, and $\psi = 0$. This matches the water potential of the extracellular environment: in this example, 0 MPa. A dynamic equilibrium has been reached, and there is no further net movement of water.

In contrast to a flaccid cell, a walled cell with a greater solute concentration than its surroundings is **turgid**, or very firm. When turgid cells in a nonwoody tissue push against each other, the tissue is stiffened. The effects of turgor loss are seen during **wilting**, when leaves and stems droop as a result of cells losing water **(Figure 36.10)**.

▲ **Figure 36.10 A wilted *Impatiens* plant regains its turgor when watered.**

(a) Initial conditions: cellular ψ > environmental ψ. The cell loses water and plasmolyzes. After plasmolysis is complete, the water potentials of the cell and its surroundings are the same.

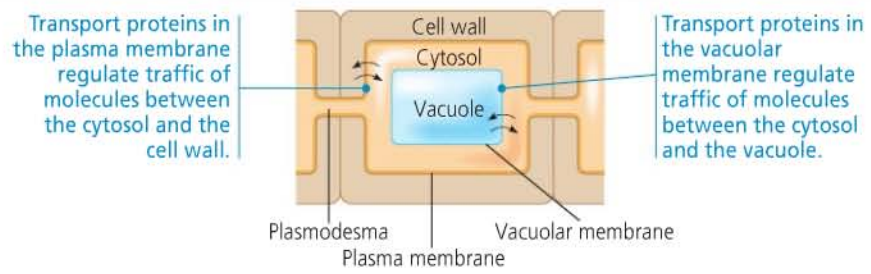
(b) Initial conditions: cellular ψ < environmental ψ. There is a net uptake of water by osmosis, causing the cell to become turgid. When this tendency for water to enter is offset by the back pressure of the elastic wall, water potentials are equal for the cell and its surroundings. (The volume change of the cell is exaggerated in this diagram.)

▲ **Figure 36.9 Water relations in plant cells.** In these experiments, identical cells, initially flaccid, are placed in two environments. (Protoplasts of flaccid cells are in contact with their walls but lack turgor pressure.) Blue arrows indicate initial net water movement.

Aquaporins: Facilitating Diffusion of Water

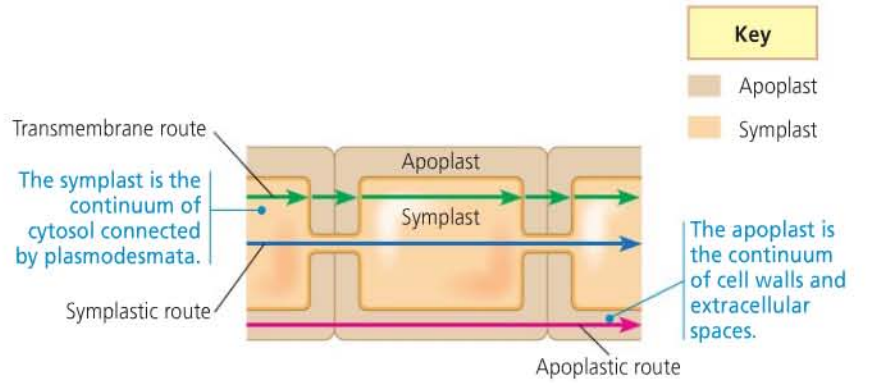
A difference in water potential determines the *direction* of water movement across membranes, but how do water molecules actually cross the membranes? Water molecules are small enough to diffuse across the phospholipid bilayer, even though the middle zone is hydrophobic (see Figure 7.2), but their movement is too rapid to be explained by unaided diffusion. Indeed, transport proteins called **aquaporins** facilitate the diffusion (see Chapter 7). These selective channels, which have been found most commonly in plants, affect the *rate* at which water diffuses down its water potential gradient. Evidence is accumulating that the rate of water movement through these proteins is regulated by phosphorylation of the aquaporin proteins, which can be induced by increases in cytoplasmic calcium ions or decreases in cytoplasmic pH. Recent evidence suggests that aquaporins may also facilitate absorption of CO_2 by plant cells.

Three Major Pathways of Transport



Transport within plants is also regulated by the compartmental structure of plant cells **(Figure 36.11a)**. Outside the protoplast is a cell wall (see Figures 6.9 and 6.28), consisting of a mesh of polysaccharides through which mineral ions diffuse readily. Because every plant cell is separated from its neighboring cells by cell walls, ions can diffuse across a tissue (or be carried passively by water flow) entirely through the **apoplast (Figure 36.11b)**, the continuum formed by cell walls, extracellular spaces, and the dead interiors of tracheids and vessels. However, it is the plasma membrane that directly controls the traffic of molecules into and out of the protoplast. Just as the cell walls form a continuum, so does the cytosol of cells, collectively referred to as the **symplast** (see Figure 36.11b). The cytoplasmic channels called **plasmodesmata** connect the cytoplasm of neighboring cells.

The compartmental structure of plant cells provides three routes for short-distance transport within a plant tissue or organ: the apoplastic, symplastic, and transmembrane routes (see Figure 36.11b). In the apoplastic route, water and solutes move along the continuum of cell walls and extracellular spaces. In the symplastic route, water and solutes move along the continuum of cytosol within a plant tissue. This route requires only one crossing of a plasma membrane. After entering one cell, substances can move from cell to cell via plasmodesmata. In the transmembrane route, water and solutes move out of one cell, across the cell wall, and into the neighboring cell, which may pass them to the next cell in the same way. The transmembrane route requires repeated crossings of plasma membranes as water and solutes exit one cell and enter the next. Substances may use more than one route. Scientists are debating which route, if any, is responsible for the most transport.



Bulk Flow in Long-Distance Transport

Diffusion and active transport are fairly efficient for short-distance transport within a cell and between cells. However, these processes are much too slow to function in long-distance transport within a plant. Although diffusion from one end of a cell to the other takes just seconds, diffusion from the roots to the top of a giant redwood would take decades or longer. Instead, long-distance transport occurs through **bulk flow**, the movement of a fluid driven by pressure.

Within tracheids and vessel elements of the xylem and within the sieve-tube elements (also called sieve-tube members) of the phloem, water and dissolved solutes move together in the same direction by bulk flow. The structures of these conducting cells of the xylem and phloem help to make bulk flow possible. If you have ever dealt with a partially clogged drain, you know that the volume of flow depends on the pipe's diameter. Clogs reduce the effective diameter of the drainpipe. Such experiences help us

(a) Cell compartments. The cell wall, cytosol, and vacuole are the three main compartments of most mature plant cells.

(b) Transport routes between cells. At the tissue level, there are three pathways: the transmembrane, symplastic, and apoplastic routes. Substances can transfer from one pathway to another.

▲ **Figure 36.11 Cell compartments and routes for short-distance transport.**

understand how the structures of plant cells specialized for bulk flow fit their function. As you learned in Chapter 35, mature tracheids and vessel elements are dead cells and therefore have no cytoplasm, and the cytoplasm of sieve-tube elements is almost devoid of internal organelles (see Figure 35.10). Like unplugging a kitchen drain, loss of cytoplasm in a plant's "plumbing" allows for efficient bulk flow through the xylem and phloem. Bulk flow is also enhanced by the perforation plates at the ends of vessel elements and the porous sieve plates connecting sieve-tube elements.

Diffusion, active transport, and bulk flow act in concert to transport resources throughout the whole plant. For example, bulk flow due to a pressure difference is the mechanism of long-distance transport of sugars in the phloem, but active transport of sugar at the cellular level maintains this pressure difference. In the next three sections, we'll examine in more detail the transport of water and minerals from roots to shoots, the control of evaporation, and the transport of sugars.

CONCEPT CHECK 36.2

1. If a plant cell immersed in distilled water has a ψ_S of −0.7 MPa and a ψ of 0 MPa, what is the cell's ψ_P? If you put it in an open beaker of solution that has a ψ of −0.4 MPa, what would be its ψ_P at equilibrium?
2. How would an aquaporin deficiency affect a plant cell's ability to adjust to new osmotic conditions?
3. How would the long-distance transport of water be affected if vessel elements and tracheids were alive at maturity? Explain.
4. **WHAT IF?** What would happen if you put plant protoplasts in pure water? Explain.

For suggested answers, see Appendix A.

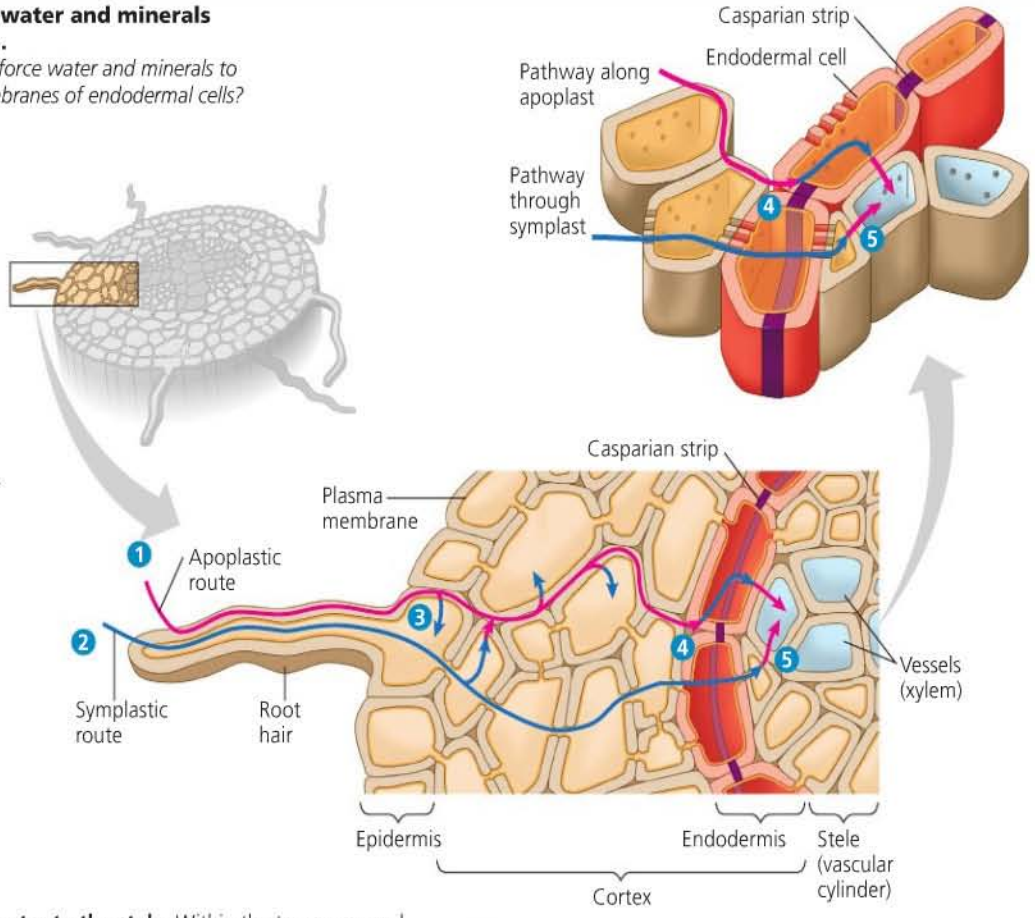
CONCEPT 36.3
Water and minerals are transported from roots to shoots

Picture yourself struggling to carry a very large container of water up several flights of stairs. Then consider the fact that water within a plant is transported effortlessly against the force of gravity. Up to 800 L (800 kg or 1,760 lb) of water reach the top of an average-sized tree every day. But trees and other plants have no pumping mechanism. So how is this feat accomplished? To answer this question, we'll follow each step in the journey of water and minerals from the tips of roots to the tips of shoots.

Absorption of Water and Minerals by Root Cells

Although all living plant cells absorb nutrients across their plasma membranes, the cells near the tips of roots are particularly important because most of the water and mineral absorption occurs there. In this region, the epidermal cells are permeable to water, and many are differentiated into root hairs, modified cells that account for much of the absorption of water by roots (see Figure 35.3). The root hairs absorb the soil solution, which consists of water molecules and dissolved mineral ions that are not bound tightly to soil particles. The soil solution flows into the hydrophilic walls of epidermal cells and passes freely along the cell walls and the extracellular spaces into the root cortex. This flow enhances the exposure of the cells of the cortex to the soil solution, providing a much greater membrane surface area for absorption than the surface area of the epidermis alone. Although the soil solution usually has a low mineral concentration, active transport enables roots to accumulate essential minerals, such as K^+, to concentrations hundreds of times higher than in the soil.

Transport of Water and Minerals into the Xylem



Water and minerals that pass from the soil into the root cortex cannot be transported to the rest of the plant until they enter the xylem of the stele, or vascular cylinder. The **endodermis**, the innermost layer of cells in the root cortex, surrounds the stele and functions as a last checkpoint for the selective passage of minerals from the cortex into the vascular tissue **(Figure 36.12)**. Minerals already in the symplast when they reach the endodermis continue through the plasmodesmata of endodermal cells and pass into the stele. These minerals were already screened by the plasma membrane they had to cross to enter the symplast in the epidermis or cortex. Those minerals that reach the endodermis via the apoplast encounter a dead end that blocks their passage into the stele. This barrier, located in the transverse and radial walls of each endodermal cell, is the **Casparian strip**, a belt made of suberin, a waxy material impervious to water and dissolved minerals (see Figure 36.12). Thus, water and minerals cannot cross the endodermis and enter the vascular tissue via the apoplast. The Casparian strip forces water and minerals that are passively moving through the apoplast to cross the plasma membrane of an endodermal cell and enter the stele via the symplast.

The endodermis, with its Casparian strip, ensures that no minerals can reach the vascular tissue of the root without crossing a selectively permeable plasma membrane. The endodermis also prevents solutes that have accumulated in the xylem from leaking back into the soil solution. The structure of the endodermis and its strategic location fit its function as an apoplastic barrier between the cortex and the stele. The endodermis helps roots to transport certain minerals preferentially from the soil into the xylem.

The last segment in the soil-to-xylem pathway is the passage of water and minerals into the tracheids and vessel elements of the xylem. These water-conducting cells lack protoplasts when mature and therefore are part of the apoplast. Endodermal cells, as well as living cells within the stele, discharge minerals

▼ Figure 36.12 Transport of water and minerals from root hairs to the xylem.

? *How does the Casparian strip force water and minerals to pass through the plasma membranes of endodermal cells?*

1 **Apoplastic route.** Uptake of soil solution by the hydrophilic walls of root hairs provides access to the apoplast. Water and minerals can then diffuse into the cortex along this matrix of walls.

2 **Symplastic route.** Minerals and water that cross the plasma membranes of root hairs can enter the symplast.

3 **Transmembrane route.** As soil solution moves along the apoplast, some water and minerals are transported into the protoplasts of cells of the epidermis and cortex and then move inward via the symplast.

4 **The endodermis: controlled entry to the stele.** Within the transverse and radial walls of each endodermal cell is the Casparian strip, a belt of waxy material (purple band) that blocks the passage of water and dissolved minerals. Only minerals already in the symplast or entering that pathway by crossing the plasma membrane of an endodermal cell can detour around the Casparian strip and pass into the stele, the vascular cylinder.

5 **Transport in the xylem.** Endodermal cells and also living cells within the stele discharge water and minerals into their walls (apoplast). The xylem vessels then transport the water and minerals upward into the shoot system.

from their protoplasts into their own cell walls. Both diffusion and active transport are involved in this transfer of solutes from symplast to apoplast, and the water and minerals are now free to enter the tracheids and vessels, where they are transported to the shoot system by bulk flow.

Bulk Flow Driven by Negative Pressure in the Xylem

Water and minerals from the soil enter the plant through the epidermis of roots, cross the root cortex, and pass into the stele. From there the **xylem sap**, the water and dissolved minerals in the xylem, gets transported long distances by bulk flow to the veins that branch throughout each leaf.

As noted earlier, bulk flow is much faster than diffusion or active transport. Peak velocities in the transport of xylem sap can range from 15 to 45 m/hr for trees with wide vessels. Leaves depend on this efficient delivery system for their supply of water. Plants lose an astonishing amount of water by **transpiration**, the loss of water vapor from leaves and other aerial parts of the plant. Consider the example of maize (commonly called corn in the United States). A single plant transpires 60 L (60 kg) of water during a growing season. A maize crop growing at a typical density of 60,000 plants per hectare transpires almost 4 million L of water per hectare every growing season (about 400,000 gallons of water per acre per growing season). Unless the transpired water is replaced by water transported up from the roots, the leaves will wilt, and the plants will eventually die. The flow of xylem sap also brings mineral nutrients to the shoot system.

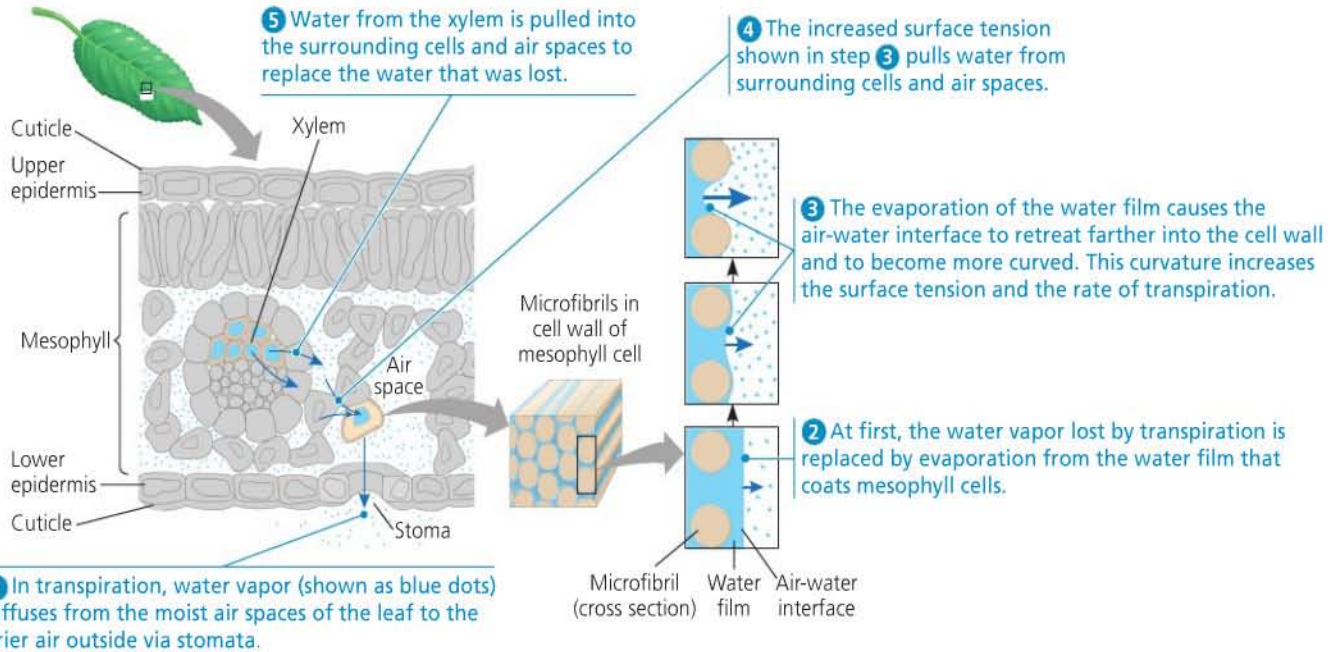
Xylem sap rises to heights of more than 100 m in the tallest trees. Is the sap mainly *pushed* upward from the roots, or is it mainly *pulled* upward by the leaves? Let's evaluate the relative contributions of these two mechanisms.

Pushing Xylem Sap: Root Pressure

At night, when there is almost no transpiration, root cells continue pumping mineral ions into the xylem of the stele. Meanwhile, the endodermis helps prevent the ions from leaking out. The resulting accumulation of minerals lowers the water potential within the stele. Water flows in from the root cortex, generating **root pressure**, a push of xylem sap. The root pressure

▲ **Figure 36.13 Guttation.** Root pressure is forcing excess water from this strawberry leaf.

sometimes causes more water to enter the leaves than is transpired, resulting in **guttation**, the exudation of water droplets that can be seen in the morning on the tips or edges of some plant leaves **(Figure 36.13)**. Guttation fluid should not be confused with dew, which is condensed atmospheric moisture.



In most plants, root pressure is a minor mechanism driving the ascent of xylem sap, at most pushing water only a few meters. The positive pressures produced are simply too weak to overcome the gravitational force of the water column in the xylem, particularly in tall plants. Many plants do not generate any root pressure. Even in plants that display guttation, root pressure cannot keep pace with transpiration after sunrise. For the most part, xylem sap is not pushed from below by root pressure but pulled by the leaves themselves.

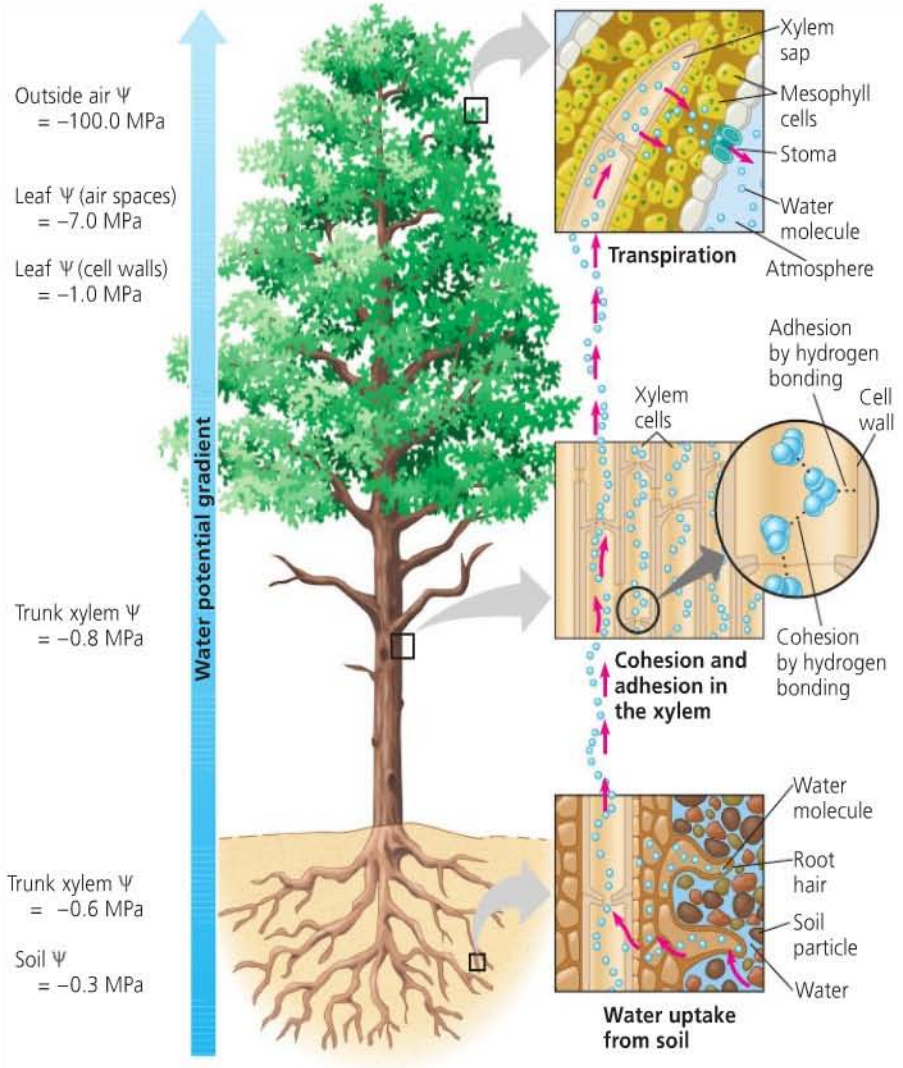
Pulling Xylem Sap: The Transpiration-Cohesion-Tension Mechanism

Material can be moved upward by positive pressure from below or negative pressure from above. Here we'll focus on how water is pulled by negative pressure potential in the xylem. As we investigate this mechanism of transport, we'll see that transpiration provides the pull and that the cohesion of water due to hydrogen bonding transmits the pull along the entire length of the xylem to the roots.

Transpirational Pull Stomata on a leaf's surface lead to a maze of internal air spaces that expose the mesophyll cells to the CO_2 they need for photosynthesis. The air in these spaces is saturated with water vapor because it is in contact with the moist walls of the cells. On most days, the air outside the leaf is drier; that is, it has a lower water potential than the air inside the leaf. Therefore, water vapor in the air spaces of a leaf diffuses down its water potential gradient and exits the leaf via the stomata. It is this loss of water vapor from the leaf by diffusion and evaporation that we call transpiration.

But how does loss of water vapor from the leaf translate into a pulling force for upward movement of water through a plant? The negative pressure potential that causes water to move up through the xylem develops at the surface of mesophyll cell walls in the leaf **(Figure 36.14)**. The cell wall acts like a very fine capillary network. Water adheres to the cellulose microfibrils and other hydrophilic components of the cell wall. As water evaporates from the water film that covers the cell walls of mesophyll cells, the air-water interface retreats farther into the cell wall. Because of the high surface tension of water, the curvature of the

▲ **Figure 36.14 Generation of transpirational pull.** Negative pressure (tension) at the air-water interface in the leaf is the basis of transpirational pull, which draws water out of the xylem.



interface induces a tension, or negative pressure potential, in the water. As more water evaporates from the cell wall, the curvature of the air-water interface increases and the pressure of the water becomes more negative. Water molecules from the more hydrated parts of the leaf are then pulled toward this area to reduce the tension. These pulling forces are transferred to the xylem because each water molecule is cohesively bound to the next by hydrogen bonds. Thus, transpirational pull depends on several of the properties of water discussed in Chapter 3: adhesion, cohesion, and surface tension.

The role of negative pressure potential in transpiration is consistent with the water potential equation because negative pressure potential (tension) *lowers* water potential (see Figure 36.8d). Because water moves from areas of higher water potential to areas of lower water potential, the more negative pressure potential at the air-water interface causes water in xylem cells to be "pulled" into mesophyll cells, which lose water to the air spaces, where it diffuses out through stomata. In this way, the negative water potential of leaves provides the "pull" in transpirational pull.

Cohesion and Adhesion in the Ascent of Xylem Sap The transpirational pull on xylem sap is transmitted all the way from the leaves to the root tips and even into the soil solution **(Figure 36.15)**. Cohesion and adhesion facilitate this long-distance transport by bulk flow. The cohesion of water due to hydrogen bonding makes it possible to pull a column of xylem sap from above without the water molecules separating. Water molecules exiting the xylem in the leaf tug on adjacent water molecules, and this pull is relayed, molecule by molecule, down the entire column of water in the xylem. Meanwhile, the strong adhesion of water molecules (again by hydrogen bonds) to the hydrophilic walls of xylem cells helps offset the downward force of gravity.

The upward pull on the sap creates tension within the xylem vessels and tracheids, which are like elastic pipes. Positive pressure causes an elastic pipe to swell, whereas tension pulls the walls of the pipe inward. On a warm day, a decrease in the diameter of a tree trunk can even be measured. As transpirational pull puts the vessels and tracheids under tension, their thick secondary walls prevent them from collapsing, much as wire rings maintain the shape of a vacuum-cleaner hose. The tension produced by transpirational pull lowers water potential in the root xylem to such an extent that water flows passively from the soil, across the root cortex, and into the stele.

Transpirational pull can extend down to the roots only through an unbroken chain of water molecules. Cavitation, the formation of a water vapor pocket, breaks the chain. It is more common in wide vessels than in tracheids and can occur during drought stress or when xylem sap freezes in winter. The air bubbles resulting from cavitation expand and block water channels of the xylem. The rapid expansion of air bubbles produces

▲ **Figure 36.15 Ascent of xylem sap.** Hydrogen bonding forms an unbroken chain of water molecules extending from leaves to the soil. The force driving the ascent of xylem sap is a gradient of water potential (ψ). For bulk flow over long distance, the ψ gradient is due mainly to a gradient of the pressure potential (ψ_P). Transpiration results in the ψ_P at the leaf end of the xylem being lower than the ψ_P at the root end. The ψ values shown at the left are a "snapshot." During daylight, they may vary, but the direction of the ψ gradient remains the same.

clicking noises that can be heard by placing sensitive microphones at the surface of the stem.

Root pressure enables small plants to refill blocked vessels in spring. In trees, though, root pressure is insufficient to push water to the top, so a vessel with a water vapor pocket usually cannot function in xylem sap transport. However, the chain of molecules can detour around the pocket through pits between adjacent tracheids or vessels. In addition, secondary growth adds a layer of new xylem each year. Only the youngest, outermost secondary xylem transports water. Although the older secondary xylem no longer transports water, it does provide support for the tree (see Figure 35.22).

Xylem Sap Ascent by Bulk Flow: *A Review*

The transpiration-cohesion-tension mechanism that transports xylem sap against gravity is an excellent example of how physical principles apply to biological processes. In the long-distance transport of water from roots to leaves by bulk flow, the movement of fluid is driven by a water potential difference at opposite ends of xylem tissue. The water potential difference is created at the leaf end of the xylem by the evaporation of water from leaf cells. Evaporation lowers the water potential at the air-water interface, thereby generating the negative pressure (tension) that pulls water through the xylem.

Bulk flow in the xylem differs from diffusion in some key ways. First, it is driven by differences in pressure potential (ψ_P); solute potential (ψ_S) is not a factor. Therefore, the water potential gradient within the xylem is essentially a pressure gradient. Also, the flow does not occur across plasma membranes of living cells, but instead within hollow, dead cells. Furthermore, it moves the entire solution together—not just water or solutes—and at much greater speed than diffusion.

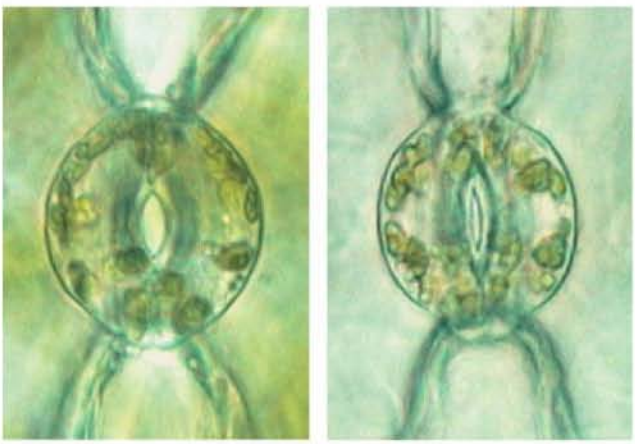
The plant expends no energy to lift xylem sap by bulk flow. Instead, the absorption of sunlight drives most of transpiration by causing water to evaporate from the moist walls of mesophyll cells and by lowering the water potential in the air spaces within a leaf. Thus, the ascent of xylem sap is ultimately solar powered.

CONCEPT CHECK 36.3

1. How do xylem cells facilitate long-distance transport?
2. A horticulturalist notices that when *Zinnia* flowers are cut at dawn, a small drop of water collects at the surface of the stump. However, when the flowers are cut at noon, no drop is observed. Suggest an explanation.
3. A scientist adds a water-soluble inhibitor of photosynthesis to a plant's roots, but photosynthesis is not reduced. Why?
4. **WHAT IF?** Suppose an *Arabidopsis* mutant lacking functional aquaporins has a root mass three times greater than that of wild-type plants. Suggest an explanation.

For suggested answers, see Appendix A.

CONCEPT 36.4
Stomata help regulate the rate of transpiration



Leaves generally have large surface areas and high surface-to-volume ratios. The large surface area enhances light absorption for photosynthesis. The high surface-to-volume ratio aids in CO_2 absorption during photosynthesis as well as in the release of O_2 as a by-product of photosynthesis. Upon diffusing through the stomata, CO_2 enters a honeycomb of air spaces formed by the spongy mesophyll cells (see Figure 35.18). Because of the irregular shapes of these cells, the leaf's internal surface area may be 10 to 30 times greater than the external surface area.

Although large surface areas and high surface-to-volume ratios increase the rate of photosynthesis, they also increase water loss by way of the stomata. Thus, a plant's tremendous requirement for water is largely a negative consequence of the shoot system's need for ample gas exchange for photosynthesis. By opening and closing the stomata, guard cells help balance the plant's requirement to conserve water with its requirement for photosynthesis **(Figure 36.16)**.

Stomata: Major Pathways for Water Loss

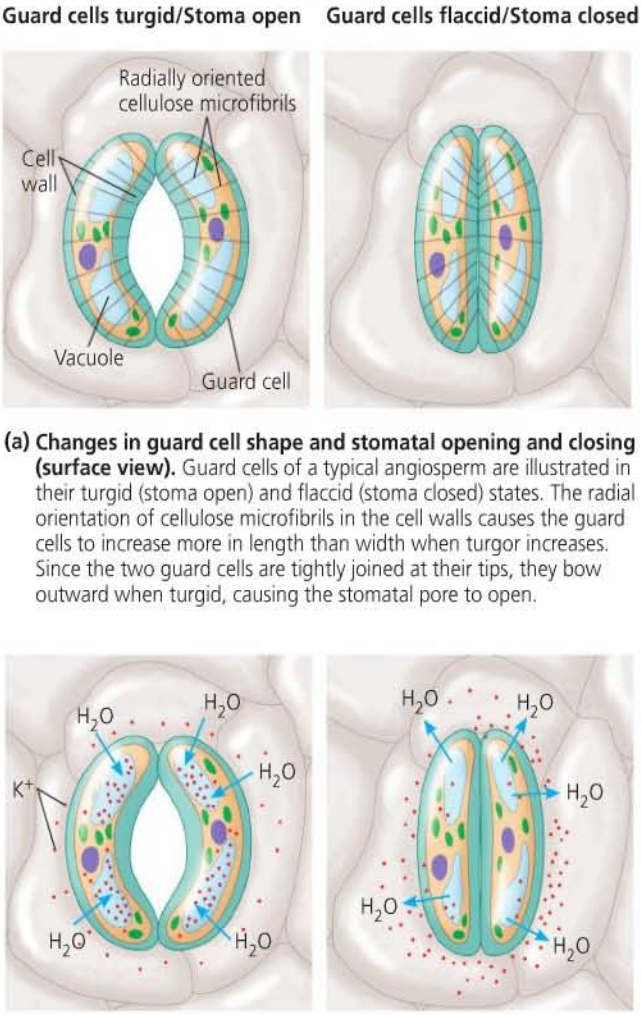
About 95% of the water a plant loses escapes through stomata, although these pores account for only 1–2% of the external leaf surface. The waxy cuticle limits water loss through the remaining surface of the leaf. Each stoma is flanked by a pair of guard cells. Guard cells control the diameter of the stoma by changing shape, thereby widening or narrowing the gap between the guard cell pair. Under the same environmental conditions, the amount of water lost by a leaf depends largely on the number of stomata and the average size of their pores.

The stomatal density of a leaf, which may be as high as 20,000 per square centimeter, is under both genetic and environmental control. For example, as a result of evolution by

▲ **Figure 36.16 An open stoma (left) and closed stoma (LMs).**

natural selection, desert plants have lower stomatal densities than do marsh plants. Stomatal density, however, is a developmentally plastic feature of many plants. High light exposures and low CO_2 levels during leaf development lead to increased density in many species. By measuring stomatal density of leaf fossils, scientists have gained insight into the levels of atmospheric CO_2 in past climates. A recent British survey found that stomatal density of many woodland species has decreased since 1927, when a similar survey was made. This survey is consistent with other findings that atmospheric CO_2 levels increased dramatically during the 1900s.

Mechanisms of Stomatal Opening and Closing



When guard cells take in water from neighboring cells by osmosis, they become more turgid. In most angiosperm species, the cell walls of guard cells are uneven in thickness, and the cellulose microfibrils are oriented in a direction that causes the guard cells to bow outward when turgid **(Figure 36.17a)**. This bowing outward increases the size of the pore between the guard cells. When the cells lose water and become flaccid, they become less bowed, and the pore closes.

The changes in turgor pressure in guard cells result primarily from the reversible absorption and loss of K^+. Stomata open when guard cells actively accumulate K^+ from neighboring epidermal cells **(Figure 36.17b)**. The flow of K^+ across the plasma membrane of the guard cell is coupled to the generation of a membrane potential by proton pumps. Stomatal opening correlates with active transport of H^+ out of the guard cell. The resulting voltage (membrane potential) drives K^+ into the cell through specific membrane channels (see Figure 36.7a). The absorption of K^+ causes the water potential to become more negative within the guard cells, and the cells become more turgid as water enters by osmosis. Because most of the K^+ and water are stored in the vacuole, the vacuolar membrane also plays a role in regulating guard cell dynamics. Stomatal closing results from a loss of K^+ from guard cells to neighboring cells, which leads to an osmotic loss of water. Aquaporins also help regulate the osmotic swelling and shrinking of guard cells.

Stimuli for Stomatal Opening and Closing

In general, stomata are open during the day and closed at night, preventing the plant from losing water under conditions when photosynthesis cannot occur. At least three cues contribute to stomatal opening at dawn: light, CO_2 depletion, and an internal "clock" in guard cells.

The light stimulates guard cells to accumulate K^+ and become turgid. This response is triggered by illumination of blue-light receptors in the plasma membrane of guard cells. Activation of these receptors stimulates the activity of proton pumps in the plasma membrane of the guard cells, in turn promoting absorption of K^+.

(a) Changes in guard cell shape and stomatal opening and closing (surface view). Guard cells of a typical angiosperm are illustrated in their turgid (stoma open) and flaccid (stoma closed) states. The radial orientation of cellulose microfibrils in the cell walls causes the guard cells to increase more in length than width when turgor increases. Since the two guard cells are tightly joined at their tips, they bow outward when turgid, causing the stomatal pore to open.

(b) Role of potassium in stomatal opening and closing. The transport of K^+ (potassium ions, symbolized here as red dots) across the plasma membrane and vacuolar membrane causes the turgor changes of guard cells. The uptake of anions, such as malate and chloride ions (not shown), also contributes to guard cell swelling.

▲ Figure 36.17 Mechanisms of stomatal opening and closing.

The stomata also open in response to depletion of CO_2 within the leaf's air spaces as a result of photosynthesis. As CO_2 concentrations decrease during the day, the stomata progressively open if sufficient water is supplied to the leaf.

A third cue, the internal "clock" in the guard cells, ensures that stomata continue their daily rhythm of opening and closing. This rhythm occurs even if a plant is kept in a dark location. All eukaryotic organisms have internal clocks that regulate cyclic processes. Cycles with intervals of approximately 24 hours are called **circadian rhythms**, which you'll learn more about in Chapter 39.

Environmental stresses, such as droughts, can cause stomata to close during the daytime. When the plant has a water deficiency, guard cells may lose turgor and close stomata. In addition, a hormone called abscisic acid, produced in roots and leaves in response to water deficiency, signals guard cells to

close stomata. This response reduces wilting but also restricts CO_2 absorption, thereby slowing photosynthesis. Since turgor is necessary for cell elongation, growth ceases. These are some reasons why droughts reduce crop yields.

Guard cells control the photosynthesis-transpiration compromise on a moment-to-moment basis by integrating a variety of internal and external stimuli. Even the passage of a cloud or a transient shaft of sunlight through a forest can affect the rate of transpiration.

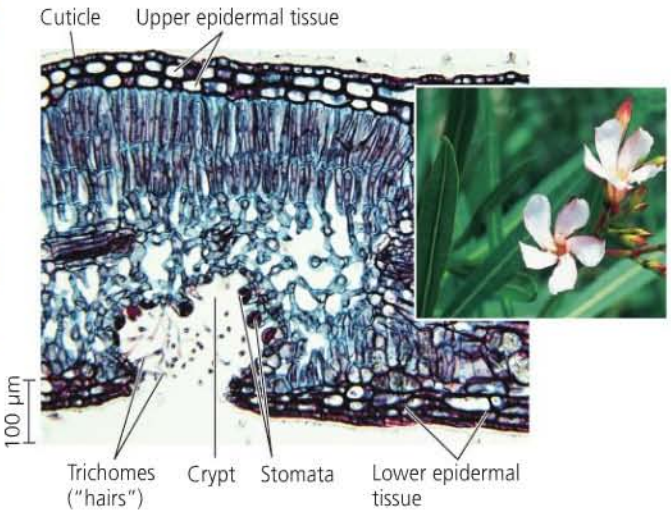
Effects of Transpiration on Wilting and Leaf Temperature

As long as most stomata remain open, transpiration is greatest on a day that is sunny, warm, dry, and windy because these environmental factors increase evaporation. If transpiration cannot pull sufficient water to the leaves, the shoot becomes slightly wilted as cells lose turgor pressure (see Figure 36.10). Although plants respond to such mild drought stress by rapidly closing stomata, some evaporative water loss still occurs through the cuticle. Under prolonged drought conditions, leaves can become severely wilted and irreversibly injured.

Transpiration also results in evaporative cooling, which can lower a leaf's temperature by as much as 10°C compared with the surrounding air. This cooling prevents the leaf from reaching temperatures that could denature enzymes involved in photosynthesis and other metabolic processes.

Adaptations That Reduce Evaporative Water Loss

Plants that are adapted to deserts and other regions with little moisture are called **xerophytes** (from the Greek *xero*, dry). The stone plants in Figure 36.1 are an example. **Figure 36.18**



▼ Figure 36.18 Some xerophytic adaptations.

▶ Ocotillo (*Fouquieria splendens*) is common in the southwestern region of the United States and northern Mexico. It is leafless during most of the year, thereby avoiding excessive water loss (right). Immediately after a heavy rainfall, it produces small leaves (below and inset). As the soil dries, the leaves quickly shrivel and die.

▼ Oleander (*Nerium oleander*), shown in the inset, is commonly found in arid climates. Its leaves have a thick cuticle and multiple-layered epidermal tissue that reduce water loss. Stomata are recessed in cavities called "crypts," an adaptation that reduces the rate of transpiration by protecting the stomata from hot, dry wind. Trichomes help minimize transpiration by breaking up the flow of air, allowing the chamber of the crypt to have a higher humidity than the surrounding atmosphere (LM).

▶ This is a close-up view of stems of old man cactus (*Cephalocereus senilis*), a Mexican desert plant. The long, white, hairlike bristles help reflect the sun.

shows others. Rain comes infrequently in deserts, but when it arrives the vegetation is transformed. Many species of desert plants avoid drying out by completing their short life cycles during the brief rainy seasons. Longer-lived species have unusual physiological or morphological adaptations that enable them to withstand the harsh desert conditions. Xerophytes are also found in other environments where access to liquid fresh water is problematic, such as frozen regions and seashores. Many xerophytes, such as cacti, have highly reduced leaves that resist excessive water loss; they carry out photosynthesis mainly in their stems. The stems of many xerophytes are fleshy because they store water for use during prolonged dry periods. Another adaptation to arid habitats is crassulacean acid metabolism (CAM), a specialized form of photosynthesis found in succulents of the family Crassulaceae and several other families (see Figure 10.20). Because the leaves of CAM plants take in CO_2 at night, the stomata can remain closed during the day, when evaporative stresses are greater.

As we have seen, plants face a dilemma: how to acquire as much CO_2 from the air as they can and at the same time retain as much water as possible. Stomata are the most important mediators of the conflicting demands of CO_2 acquisition and water retention.

CONCEPT CHECK 36.4

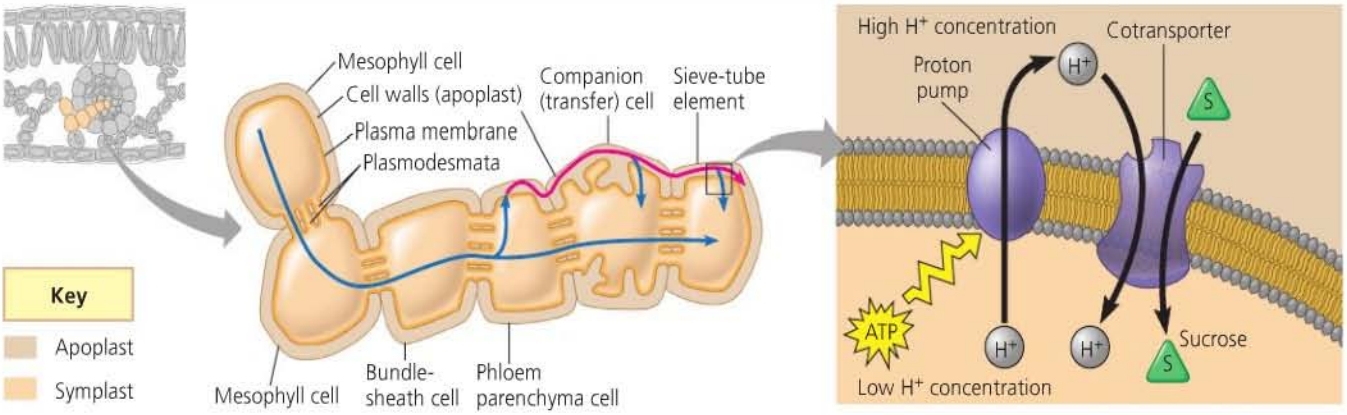
1. What are the stimuli that control the opening and closing of stomata?
2. The pathogenic fungus *Fusicoccum amygdali* secretes a toxin called fusicoccin that activates the plasma membrane proton pumps of plant cells and leads to uncontrolled water loss. Suggest a mechanism by which the activation of proton pumps could lead to severe wilting.
3. **WHAT IF?** If you buy cut flowers, why might the florist recommend cutting the stems underwater and then transferring the flowers to a vase while the cut ends are still wet?

For suggested answers, see Appendix A.

CONCEPT 36.5
Sugars are transported from leaves and other sources to sites of use or storage

You have read how water and minerals are absorbed by root cells, transported through the endodermis, released into the vessels and tracheids of the xylem, and carried to the tops of plants by the bulk flow driven by transpiration. However, transpiration cannot meet all the long-distance transport needs of the plant. The flow of water and minerals from soil to roots to leaves is largely in a direction opposite to the direction necessary for transporting sugars from mature leaves to lower parts of the plants, such as root tips that require large amounts of sugars for energy and growth. It is another tissue—the phloem—that transports the products of photosynthesis, a process called **translocation**.

Movement from Sugar Sources to Sugar Sinks



In angiosperms, the specialized cells that are conduits for translocation are the sieve-tube elements. Arranged end to end, they form long sieve tubes (see Figure 35.10). Between these cells are sieve plates, structures that allow the flow of sap along the sieve tube.

Phloem sap, the aqueous solution that flows through sieve tubes, differs markedly from xylem sap. By far the most prevalent solute in phloem sap is sugar, typically sucrose in most species. The sucrose concentration may be as high as 30% by weight, giving the sap a syrupy thickness. Phloem sap may also contain amino acids, hormones, and minerals.

In contrast to the unidirectional transport of xylem sap from roots to leaves, phloem sap moves from sites of sugar production to sites of sugar use or storage (see Figure 36.2). A **sugar source** is a plant organ that is a net producer of sugar, by photosynthesis or by breakdown of starch. A **sugar sink** is an organ that is a net consumer or depository of sugar. Growing roots, buds, stems, and fruits are sugar sinks. Although expanding leaves are sugar sinks, fully grown leaves, if well illuminated, are sugar sources. A storage organ, such as a tuber or a bulb, may be a source or a sink, depending on the season. When stockpiling carbohydrates in the summer, it is a sugar sink. After breaking dormancy in the spring, it is a sugar source because its starch is broken down to sugar, which is carried to the growing shoot tips.

Sinks usually receive sugar from the nearest sugar sources. The upper leaves on a branch, for example, may export sugar to the growing shoot tip, whereas the lower leaves may export sugar to the roots. A growing fruit may monopolize the sugar sources that surround it. For each sieve tube, the direction of transport depends on the locations of the sugar source and sugar sink that are connected by that tube. Therefore, neighboring sieve tubes may carry sap in opposite directions if they originate and end in different locations.

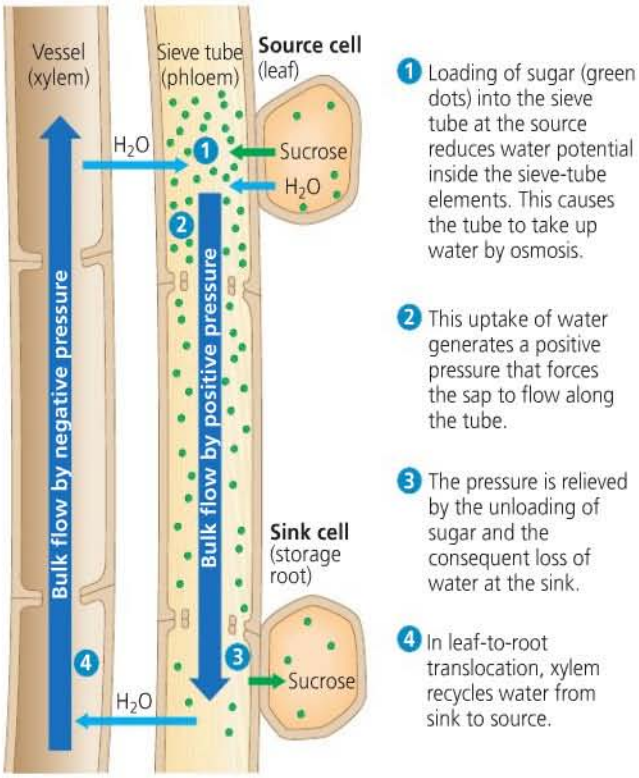
Sugar must be transported, or loaded, into sieve-tube elements before being exported to sugar sinks. In some species, it moves from mesophyll cells to sieve-tube elements via the symplast, passing through plasmodesmata. In other species, it moves by symplastic and apoplastic pathways. In maize leaves, for example, sucrose diffuses through the symplast from photosynthetic mesophyll cells into small veins. Much of it then moves into the apoplast and is accumulated by nearby sieve-tube elements, either directly or through companion cells

(a) Sucrose manufactured in mesophyll cells can travel via the symplast (blue arrows) to sieve-tube elements. In some species, sucrose exits the symplast near sieve tubes and travels through the apoplast (red arrow). It is then actively accumulated from the apoplast by sieve-tube elements and their companion cells.

(b) A chemiosmotic mechanism is responsible for the active transport of sucrose into companion cells and sieve-tube elements. Proton pumps generate an H^+ gradient, which drives sucrose accumulation with the help of a cotransport protein that couples sucrose transport to the diffusion of H^+ back into the cell.

▲ **Figure 36.19 Loading of sucrose into phloem.**

(Figure 36.19a). In some plants, the walls of the companion cells feature many ingrowths, enhancing solute transfer between apoplast and symplast. Such modified cells are called **transfer cells** (see Figure 29.5).



In many plants, sugar movement into the phloem requires active transport because sucrose is more concentrated in sieve-tube elements and companion cells than in mesophyll. Proton pumping and cotransport enable sucrose to move from mesophyll cells to sieve-tube elements **(Figure 36.19b)**.

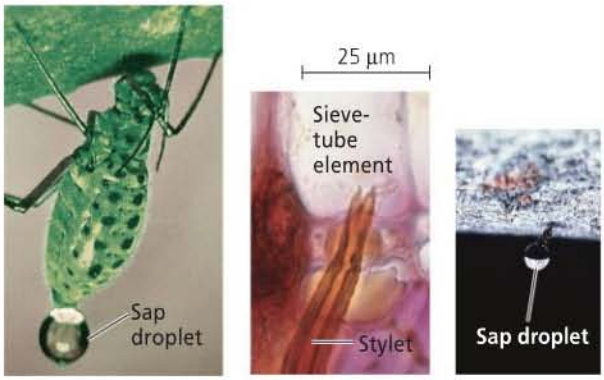
Sucrose is unloaded at the sink end of a sieve tube. The process varies by species and organ. However, the concentration of free sugar in the sink is always lower than in the sieve tube because the unloaded sugar is consumed during growth and metabolism of the cells of the sink or converted to insoluble polymers such as starch. As a result of this sugar concentration gradient, sugar molecules diffuse from the phloem into the sink tissues, and water follows by osmosis.

Bulk Flow by Positive Pressure: The Mechanism of Translocation in Angiosperms

Phloem sap flows from source to sink at rates as great as 1 m/hr, much faster than diffusion or cytoplasmic streaming, the circular flow of cytoplasm within cells. In studying angiosperms, researchers have concluded that phloem sap moves through a sieve tube by bulk flow driven by positive pressure, known as *pressure flow* **(Figure 36.20)**. The building of pressure at the source end and reduction of that pressure at the sink end cause water to flow from source to sink, carrying the sugar along.

The pressure flow hypothesis explains why phloem sap flows from source to sink, and experiments build a strong case for pressure flow as the mechanism of translocation in angiosperms **(Figure 36.21)**. However, studies using electron microscopes suggest that in nonflowering vascular plants, the pores between phloem cells may be too small or obstructed to permit pressure

▲ **Figure 36.20 Bulk flow by positive pressure (pressure flow) in a sieve tube.**



flow. Thus, it is not known if the model applies to all other vascular plants.

Sinks vary in energy demands and capacity to unload sugars. Sometimes there are more sinks than can be supported by sources. In such cases, a plant might abort some flowers, seeds, or fruits—a phenomenon called *self-thinning*. Removing sinks can also be a horticulturally useful practice. For example, since large apples command a much better price than small ones, growers sometimes remove flowers or young fruits so that their trees produce fewer but larger apples.

▼ Figure 36.21 Inquiry

Does phloem sap contain more sugar near sources than sinks?

EXPERIMENT The pressure flow hypothesis predicts that phloem sap near sources should have a higher sugar content than phloem sap near sinks. To test this aspect of the hypothesis, S. Rogers and A. J. Peel, at the University of Hull in England, used aphids that feed on phloem sap. An aphid probes with a hypodermic-like mouthpart called a stylet that penetrates a sieve-tube element. As sieve-tube pressure forced out phloem into the stylets, the researchers separated the aphids from the stylets, which then acted as taps exuding sap for hours. Researchers measured the sugar concentration of sap from stylets at different points between a source and sink.

Aphid feeding

Stylet in sieve-tube element

Separated stylet exuding sap

RESULTS The closer the stylet was to a sugar source, the higher its sugar concentration was.

CONCLUSION The results of such experiments support the pressure flow hypothesis, which predicts that sugar concentrations should be higher in sieve tubes closer to sugar sources.

SOURCE S. Rogers and A. J. Peel, Some evidence for the existence of turgor pressure in the sieve tubes of willow (*Salix*), *Planta* 126, no. 3:259–267 (1975).

WHAT IF? Spittle bugs are xylem sap feeders that use strong muscles to pump xylem sap through their guts. Could you isolate xylem sap from the excised stylets of spittle bugs?

CONCEPT CHECK 36.5

1. Compare and contrast the forces that move phloem sap and xylem sap over long distance.
2. Identify plant organs that are sugar sources, organs that are sugar sinks, and organs that might be either. Explain.
3. Why can xylem transport water and minerals using dead cells, whereas phloem requires living cells?
4. **WHAT IF?** Apple growers in Japan sometimes make a nonlethal spiral slash around the bark of trees destined for removal after the growing season. This practice makes the apples sweeter. Why?

For suggested answers, see Appendix A.

CONCEPT 36.6
The symplast is highly dynamic

Although we have been discussing transport in mostly physical terms, almost like the flow of solutions through pipes, plant transport is a dynamic process. That is, the transport needs of a plant cell typically change during its development. A leaf, for example, may begin as a sugar sink but spend most of its life as a sugar source. Also, environmental changes may trigger marked responses in plant transport processes. Water stress may activate signal transduction pathways that greatly alter the membrane transport proteins governing the overall transport of water and minerals. Because the symplast is living tissue, it is largely responsible for the dynamic changes in plant transport processes.

Plasmodesmata: Continuously Changing Structures

Plasmodesmata provide an example of the dynamic nature of the symplast. Biologists formerly thought of plasmodesmata as unchanging pore-like structures, based mostly on the static images from electron microscopy. Recently, however, new techniques have revealed that plasmodesmata are highly dynamic structures that can change in permeability and number. They can open or close rapidly in response to changes in turgor pressure, cytoplasmic calcium levels, or cytoplasmic pH. Although some form during cytokinesis, they can also form much later. Moreover, loss of function is common during differentiation. For example, as a leaf matures from a sink to a source, its plasmodesmata either close or are eliminated, causing phloem unloading to cease.

Early studies by plant physiologists and pathologists came to differing conclusions regarding pore sizes of plasmodesmata. Physiologists injected fluorescent probes of different molecular sizes into cells and recorded whether the molecules passed into adjacent cells. Based on these observations, they concluded that the pore sizes were approximately 2.5 nm—too small for macromolecules such as proteins to pass. In contrast, pathologists provided electron micrographs showing evidence of passage of viral particles with diameters of 10 nm or greater. One hypothesis to explain these discordant findings was that viruses can greatly dilate plasmodesmata.

Subsequently, it was learned that plant viruses produce *viral movement proteins* that do cause plasmodesmata to dilate, enabling viral RNA to pass between cells. More recent evidence shows that plant cells themselves regulate plasmodesmata as part of a dynamic communication network. Viruses subvert this network by mimicking the cell's regulators of plasmodesmata.

A high degree of cytoplasmic interconnectedness exists only within certain groups of cells and tissues, known as *symplastic domains*. Informational molecules, such as proteins and RNAs, coordinate development between cells within each symplastic

domain. If symplastic communication is altered by mutation, development can be grossly affected, as was shown by Patricia Zambryski and colleagues at the University of California, Berkeley **(Figure 36.22)**. (See the interview on pages 736–737.)

Electrical Signaling in the Phloem

Rapid, long-distance electrical signaling through the phloem is another dynamic feature of the symplast. Electrical signaling has been studied extensively in plants that have rapid leaf movements, such as the sensitive plant (*Mimosa pudica*) and Venus flytrap (*Dionaea muscipula*). However, its role in other species is less clear. Some studies have revealed that a stimulus in one part of a plant can trigger an electrical signal in the phloem that affects another part, such as eliciting a change in gene transcription, respiration, photosynthesis, phloem unloading, or hormonal levels. Thus, the phloem can serve a nerve-like function, allowing for swift electrical communication between widely separated organs.

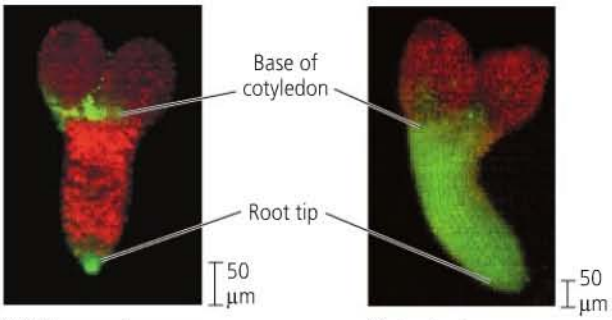
Phloem: An Information Superhighway

In addition to transporting sugars and conducting electrical signals, the phloem is a "superhighway" for the systemic transport of macromolecules and viruses. **Systemic** changes are those that spread throughout the body, affecting many or all of the body's systems or organs. Macromolecules translocated through the phloem include proteins and various types of RNA that enter the sieve tubes through plasmodesmata. Although plasmodesmata are often likened to the gap junctions between animal cells, their ability to traffic proteins and RNA is unique.

Systemic communication through the phloem helps integrate the functions of the whole plant. One classic example is the delivery of a flower-inducing signal from leaves to vegetative meristems. Another is a defensive response to localized infection, in which signals traveling through the phloem activate defense genes in noninfected tissues.

The coordinated transport of materials and information is central to plant survival. Plants acquire only so many resources in the course of their lifetimes. If these resources are not distributed and used in an optimal manner, the plant will not be able to compete well. Ultimately, the successful acquisition and conservation of resources and the integrated functioning of the whole plant are the most critical determinants of whether the plant will compete successfully.

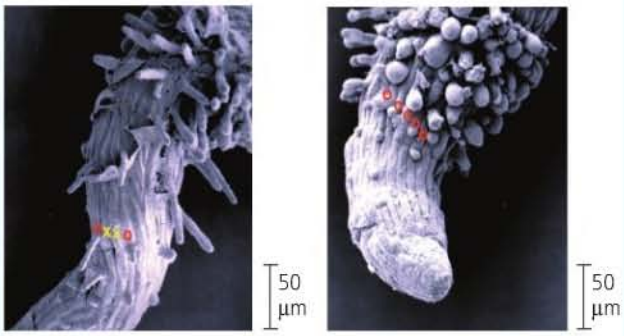
CONCEPT CHECK 36.6



1. What factors influence symplastic communication?
2. How do plasmodesmata differ from gap junctions?
3. **WHAT IF?** If plants were genetically modified to be unresponsive to viral movement proteins, would this be a good way to prevent spread of infection? Explain.

For suggested answers, see Appendix A.

▼ Figure 36.22 Inquiry



Do alterations in symplastic communication affect plant development?

EXPERIMENT Patricia Zambryski and colleagues at the University of California, Berkeley, loaded large and small fluorescent probes at the base of the cotyledon and the root tip of developing *Arabidopsis* embryos. Studies of wild-type embryos had revealed a period in the middle of embryogenesis when symplastic transport of the large probes ceased but transport of small probes continued. The researchers screened for mutants that still transported the large probes during this period and then analyzed their growth into seedlings. The light micrographs below contrast the movement of the large probes (green fluorescence) in a wild-type embryo and mutant embryo.

Wild-type embryo | Mutant embryo

RESULTS As shown in the scanning electron micrograph on the left, about half of the cell files in the wild type consisted of differentiated cells without root hairs (examples marked with yellow Xs). The mutant seedlings were developmentally retarded, with less cell differentiation than the wild-type seedlings. All cell files in a mutant seedling's root epidermis developed root hairs (examples marked with red circles).

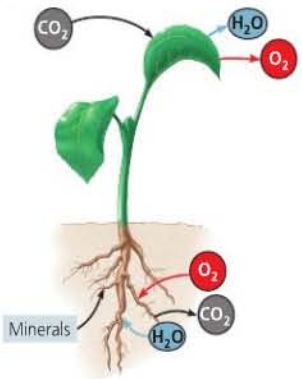
Wild-type seedling root tip | Mutant seedling root tip

CONCLUSION Isolation of the mutant and demonstration of its altered development support the hypothesis that maintaining symplastic domains is critical for proper plant development.

SOURCE I. Kim, F. Hempel, K. Sha, J. Pfluger, and P. Zambryski, Identification of a developmental transition in plasmodesmatal function during embryogenesis in *Arabidopsis thaliana*, *Development* 125:1261–1272 (2002).

WHAT IF? Suppose it was found that the mutation caused overproduction of an enzyme that cleaved the fluorescent molecule off the large probe midway through embryogenesis. Would you interpret the results differently?

Chapter 36 Review



MEDIA Go to the Study Area at **www.masteringbio.com** for BioFlix 3-D Animations, MP3 Tutors, Videos, Practice Tests, an eBook, and more.

SUMMARY OF KEY CONCEPTS

CONCEPT 36.1

Land plants acquire resources both above and below ground (pp. 764–767)

- **Shoot Architecture and Light Capture** Arrangement and size of leaves, branching, and stem thickness help shoots acquire CO_2 and light.
- **Root Architecture and Acquisition of Water and Minerals** Elongation, branching, and mycorrhizae help roots mine the soil for water and minerals.

CONCEPT 36.2

Transport occurs by short-distance diffusion or active transport and by long-distance bulk flow (pp. 767–772)

- **Diffusion and Active Transport of Solutes** Diffusion is the spontaneous movement down concentration gradients. Transport proteins aid diffusion across membranes. Proton pumps generate an H^+ gradient used to transport solutes.
- **Diffusion of Water (Osmosis)** Osmosis is the spontaneous movement of free water down its concentration gradient. Water flows across membranes from regions with higher water potential (ψ) to regions with lower ψ. Solutes decrease ψ. Pressure may increase or decrease ψ.
- **Three Major Pathways of Transport** The symplast is the cytoplasmic continuum linked by plasmodesmata. The apoplast is the continuum of cell walls and extracellular spaces.
- **Bulk Flow in Long-Distance Transport** Bulk flow is due to pressure differences at opposite ends of vessel elements and tracheids (for xylem sap) or sieve tubes (for phloem sap).

CONCEPT 36.3

Water and minerals are transported from roots to shoots (pp. 772–776)

- **Absorption of Water and Minerals by Root Cells** Root hairs and the extensive surface area of cortical cell membranes enhance uptake of water and minerals.
- **Transport of Water and Minerals into the Xylem** Water can cross the cortex via the symplast or apoplast, but minerals moving via the apoplast must finally cross the selective membranes of endodermal cells. The Casparian strip blocks apoplastic transfer of minerals to the stele.
- **Bulk Flow Driven by Negative Pressure in the Xylem** Transpiration lowers ψ in the leaf by producing a negative pressure potential (tension). This low ψ draws water from the xylem. Cohesion and adhesion of water transmit the pulling force to the roots.
- **Xylem Sap Ascent by Bulk Flow: *A Review*** Transpiration maintains movement of xylem sap against gravity.

MEDIA

BioFlix 3-D Animation Water Transport in Plants
MP3 Tutor Transpiration
Activity Transport of Xylem Sap

CONCEPT 36.4

Stomata help regulate the rate of transpiration (pp. 776–779)

- **Stomata: Major Pathways for Water Loss** Guard cells widen or narrow the diameter of stomatal pores. Genetic and environmental factors influence stomatal density.
- **Mechanisms of Stomatal Opening and Closing** When guard cells take up K^+, they bow outward, widening the pore. Stomatal closing involves the loss of K^+.
- **Stimuli for Stomatal Opening and Closing** Stomatal aperture is controlled by light, CO_2, water availability, the hormone abscisic acid, and circadian rhythm.
- **Effects of Transpiration on Wilting and Leaf Temperature** If water lost by transpiration is not replaced by absorption from roots, the plant will wilt. Cooling by transpiration can lower leaf temperature.
- **Adaptations That Reduce Evaporative Water Loss** Reduced leaves and CAM photosynthesis are examples of adaptations to arid environments.

MEDIA

Investigation How Is the Rate of Transpiration Calculated?

CONCEPT 36.5

Sugars are transported from leaves and other sources to sites of use or storage (pp. 779–781)

- **Movement from Sugar Sources to Sugar Sinks** Mature leaves are the main sources, though storage organs can be seasonal sources. Meristems and developing fruits and seeds are examples of sinks. Phloem loading and unloading depend on active transport of sucrose. Sucrose is cotransported with H^+, which diffuses down a gradient generated by proton pumps.
- **Bulk Flow by Positive Pressure: The Mechanism of Translocation in Angiosperms** Loading of sugar at the source and unloading at the sink maintain a pressure difference that keeps sap flowing through a sieve tube.

MEDIA

Activity Translocation of Phloem Sap

CONCEPT 36.6

The symplast is highly dynamic (pp. 781–782)

- **Plasmodesmata: Continuously Changing Structures** Plasmodesmata can change in number. When dilated, they can provide a passageway for macromolecules such as RNA and proteins.

▶ **Electrical Signaling in the Phloem** The phloem can conduct nerve-like electrical signals that propagate through the symplast and help to integrate whole-plant function.

▶ **Phloem: An Information Superhighway** Phloem helps integrate whole-plant function by transporting proteins, RNAs, and other macromolecules over long distances.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which of the following does *not* affect self-shading?
   a. leaf area index
   b. phyllotaxy
   c. self-pruning
   d. stem thickness
   e. leaf orientation

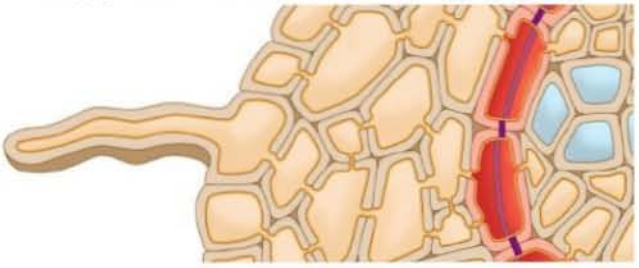
2. What would enhance water uptake by a plant cell?
   a. decreased ψ of the surrounding solution
   b. an increase in pressure exerted by the cell wall
   c. the loss of solutes from the cell
   d. an increase in ψ of the cytoplasm
   e. positive pressure on the surrounding solution

3. A plant cell with a ψ_S of −0.65 MPa maintains a constant volume when bathed in a solution that has a ψ_S of −0.30 MPa and is in an open container. The cell has a
   a. ψ_P of +0.65 MPa.
   b. ψ of −0.65 MPa.
   c. ψ_P of +0.35 MPa.
   d. ψ_P of +0.30 MPa.
   e. ψ of 0 MPa.

4. Which structure or compartment is *not* part of the apoplast?
   a. the lumen of a xylem vessel
   b. the lumen of a sieve tube
   c. the cell wall of a mesophyll cell
   d. an extracellular air space
   e. the cell wall of a root hair

5. Which of the following is an adaptation that enhances the uptake of water and minerals by roots?
   a. mycorrhizae
   b. cavitation
   c. active uptake by vessels
   d. rhythmic contractions by cortical cells
   e. pumping through plasmodesmata

6. Which of the following is *not* part of the transpiration-cohesion-tension mechanism for the ascent of xylem sap?
   a. loss of water from the mesophyll cells, which initiates a pull of water molecules from neighboring cells
   b. transfer of transpirational pull from one water molecule to the next, due to cohesion by hydrogen bonds
   c. hydrophilic walls of tracheids and vessels that help maintain the column of water against gravity
   d. active pumping of water into the xylem of roots
   e. lowering of ψ in the surface film of mesophyll cells due to transpiration



7. Photosynthesis ceases when leaves wilt, mainly because
   a. the chlorophyll of wilting leaves breaks down.
   b. flaccid mesophyll cells are incapable of photosynthesis.
   c. stomata close, preventing CO_2 from entering the leaf.
   d. photolysis, the water-splitting step of photosynthesis, cannot occur when there is a water deficiency.
   e. accumulation of CO_2 in the leaf inhibits enzymes.

8. Stomata open when guard cells
   a. sense an increase in CO_2 in the air spaces of the leaf.
   b. open because of a decrease in turgor pressure.
   c. become more turgid because of an addition of K^+, followed by the osmotic entry of water.
   d. close aquaporins, preventing uptake of water.
   e. accumulate water by active transport.

9. Movement of phloem sap from a source to a sink
   a. occurs through the apoplast of sieve-tube elements.
   b. may translocate sugars from the breakdown of stored starch in a root up to developing shoots.
   c. depends on tension, or negative pressure potential.
   d. depends on pumping water into sieve tubes at the source.
   e. results mainly from diffusion.

10. Which of these is *not* transported via the symplast?
    a. sugars
    b. mRNA
    c. DNA
    d. proteins
    e. viruses

11. **DRAW IT** Trace the uptake of water and minerals from root hairs to the vessels in a root, following a symplastic route and an apoplastic route. Label the routes.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

12. Large brown algae called kelps can grow as tall as 25 m. Kelps consist of a holdfast anchored to the ocean floor, blades that float at the surface and collect light, and a long stalk connecting the blades to the holdfast (see Figure 28.15). Specialized cells in the stalk, although nonvascular, transport sugar. Suggest a reason why these structures analogous to sieve-tube elements might have evolved in kelps.

SCIENTIFIC INQUIRY

13. Tomato and cotton plants wilt within a few hours of flooding their roots. Flooding leads to low oxygen conditions, increases in cytoplasmic calcium, and decreases in cytoplasmic pH. Suggest a hypothesis to explain how it leads to wilting.

SCIENCE, TECHNOLOGY, AND SOCIETY

14. In the arid southwestern United States, there has been growing criticism of water use for lawns and golf courses. Should such use be limited or even banned? Explain.

37 Soil and Plant Nutrition

▲ **Figure 37.1 Could this happen again?**

KEY CONCEPTS

37.1 Soil is a living, finite resource

37.2 Plants require essential elements to complete their life cycle

37.3 Plant nutrition often involves relationships with other organisms

OVERVIEW

"The Nation that Destroys Its Soil Destroys Itself"

President Franklin D. Roosevelt wrote these words in 1937 in referring to an ecological and human disaster that ravaged the southwestern Great Plains, a region that came to be called the Dust Bowl. The series of devastating dust storms was caused by a massive drought and decades of inappropriate farming techniques. Before the arrival of farmers, the Great Plains had been covered by hardy grasses that held the soil in place in spite of recurring droughts and torrential rains. But in the late 1800s and early 1900s, many homesteaders settled in the region, planting wheat and raising cattle. These land uses left the soil exposed to erosion by winds. A few years of drought made the problem worse. During the 1930s, huge quantities of fertile soil were blown away in "black blizzards," rendering millions of hectares of farmland useless **(Figure 37.1)**. In one of the worst dust storms, clouds of dust blew eastward to Chicago, where soil fell like snow, and even reached as far east as New York City and Washington, D.C. Hundreds of thousands of people in the Dust Bowl region were forced to abandon their homes and land, a plight immortalized in John Steinbeck's novel *The Grapes of Wrath*.

Soil mismanagement in various forms has been a recurrent problem throughout human history and continues to this day. More than 30% of the world's farmland has reduced productivity stemming from poor soil conditions, such as chemical contamination, mineral deficiencies, acidity, salinity, and poor drainage. As the world's population continues to grow, the demand for food increases. Because soil quality is a major determinant of crop yield, the need to manage soil resources prudently has never been greater.

Healthy soil improves plant growth by enhancing plant **nutrition**, the process by which an organism takes in and makes use of food substances. As discussed in Chapter 36, plants obtain nutrients from both the atmosphere and the soil. Using sunlight as an energy source, plants produce organic nutrients by reducing carbon dioxide to sugars through the process of photosynthesis. Land plants also take up water and various mineral nutrients from the soil through their root systems. In this chapter, we discuss the basic physical properties of soils and the factors that govern soil quality. We then explore why certain inorganic nutrients are essential for plant function. Finally, we examine some nutritional adaptations that have evolved in plants, often in relationships with other organisms.

CONCEPT 37.1

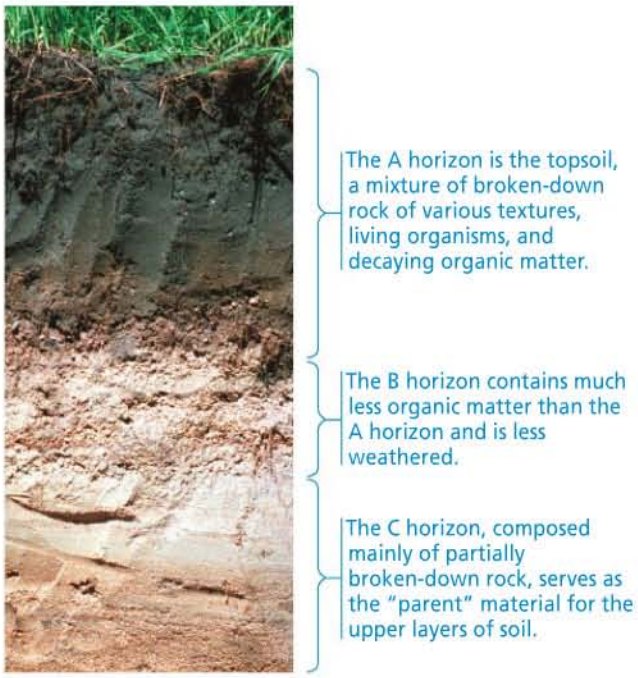
Soil is a living, finite resource

The upper layers of the soil, from which plants absorb nearly all of the water and minerals they require, contain a wide range of living organisms that interact with each other and with the physical environment. This complex ecosystem may take centuries to form but can be destroyed by human mismanagement in just a few years. To understand why soil must be conserved and why particular plants grow where they do, we must appreciate the basic physical properties of soil: its texture and composition.

Soil Texture

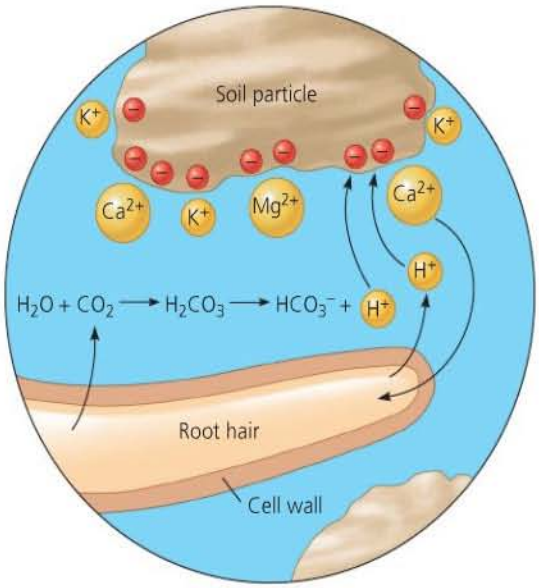
The texture of soil depends on the sizes of its particles. Soil particles can range from coarse sand (0.02–2 mm in diameter) to silt (0.002–0.02 mm) to microscopic clay particles (less than 0.002 mm). These different-sized particles arise ultimately from the weathering of rock. Water freezing in the crevices of rocks causes mechanical fracturing, and weak acids in the soil break rocks down chemically. When organisms penetrate the rock, they accelerate breakdown by chemical and mechanical means. Plant roots, for example, secrete acids that dissolve the rock, and their growth in fissures leads to mechanical fracturing. The mineral particles released by weathering become mixed with living organisms and **humus**, the remains of dead organisms and other organic matter, forming **topsoil**. The topsoil and other distinct soil layers, or **soil horizons**, are often visible where there is a road cut or deep hole **(Figure 37.2)**. The topsoil, or A horizon, can range in depth from millimeters to meters. We focus mostly on the properties of topsoil because it is the most important soil layer for the growth of most plants.

In the topsoil, plants are nourished by the soil solution, the water and dissolved minerals in the pores between soil particles. The pores also contain air pockets. After a heavy rainfall, water drains away from the larger spaces in the soil, but smaller spaces retain water because water molecules are attracted to the negatively charged surfaces of clay and other soil particles.



The topsoils that are the most fertile—supporting the most abundant growth—are **loams**, which are composed of roughly equal amounts of sand, silt, and clay. Loamy soils have enough small silt and clay particles to provide ample surface area for the adhesion and retention of minerals and water. Meanwhile, the large spaces between sand particles enable efficient diffusion of oxygen to the roots. Sandy soils generally don't retain enough water to support vigorous plant growth, and clayey soils tend to retain too much water. When soil does not drain adequately, the air is replaced by water, and the roots suffocate from lack of oxygen. Typically, the most fertile topsoils have pores that are about half water and half air, providing a good balance between aeration, drainage, and water storage capacity. The physical properties of soils can be adjusted by adding soil amendments, such as peat moss, compost, manure, or sand.

Topsoil Composition



A soil's composition encompasses its inorganic (mineral) and organic chemical components. The organic components include the many life-forms that inhabit the soil.

Inorganic Components

The surface charges of soil particles determine their ability to bind many nutrients. Most soil particles are negatively charged. Positively charged ions (cations)—such as potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+})—adhere to these particles and are therefore not easily lost by *leaching*, the percolation of water through the soil. Roots, however, do not absorb mineral cations directly from soil particles. Instead, they become available in the soil solution, through **cation exchange**. In this process, mineral cations are displaced from soil particles by other cations, particularly H^+, and enter the soil solution, which is then absorbed by root hairs **(Figure 37.3)**. A soil's capacity to exchange cations is determined by the number of

▲ **Figure 37.2 Soil horizons.**

▲ **Figure 37.3 Cation exchange in soil.**

? *Which are more likely to be leached from the soil by heavy rains—cations or anions? Explain.*

cation adhesion sites and by the pH. Soils with higher capacities generally have a larger reserve of mineral nutrients.

Negatively charged ions (anions)—such as the plant nutrients nitrate (NO_3^-), phosphate ($H_2PO_4^-$), and sulfate (SO_4^{2-})—are not bound tightly to the negatively charged soil particles and are therefore easily released. During heavy rain or irrigation, they are leached into the groundwater, making them unavailable for uptake by roots.

Organic Components

Humus is a major organic component of topsoil, consisting of organic material produced by the decomposition of dead organisms, feces, fallen leaves, and other organic matter by bacteria and fungi. Humus prevents clay particles from packing together and forms a crumbly soil that retains water but is still porous enough to aerate roots adequately. Humus also increases the soil's capacity to exchange cations and serves as a reservoir of mineral nutrients that return gradually to the soil as microorganisms decompose the organic matter.

Topsoil is also home to an astonishing number and variety of organisms. A teaspoon of topsoil has about 5 billion bacteria that cohabit with fungi, algae and other protists, insects, earthworms, nematodes, and plant roots. The activities of all these organisms affect the soil's physical and chemical properties. Earthworms, for example, consume organic matter and derive their nutrition from the bacteria and fungi growing on this material. They excrete wastes and move large amounts of material to the soil surface. In addition, they move organic matter into deeper layers of the soil. In effect, earthworms mix and clump the soil particles, allowing for better gaseous diffusion and retention of water. Plant roots also affect soil texture and composition. For example, by binding the soil, they reduce erosion, and by excreting acids, they lower soil pH.

Soil Conservation and Sustainable Agriculture

Ancient farmers recognized that yields on a particular plot of land decreased over the years. Moving to uncultivated areas, they observed the same pattern of reduced yields over time. Eventually, they realized that soil—if fertilized—was a renewable resource that enabled crops to be cultivated season after season at a fixed location. This sedentary agriculture facilitated a new way of life. Humans began to build permanent dwellings—the first villages. They also stored food for use between harvests, and food surpluses enabled some members of these early communities to specialize in nonfarming occupations. In short, soil management, by fertilization and other practices, helped prepare the way for the establishment of modern societies.

In this section, we'll discuss how farmers irrigate and modify soil to maintain good crop yields. The goal is **sustainable agriculture**, a commitment embracing a variety of farming methods that are conservation minded, environmentally safe, and profitable. We will also examine how problems such as erosion, soil compaction, and soil contamination are causing global soil degradation.

Irrigation

Because water is often the limiting factor in plant growth, perhaps no technology has increased crop yield as much as irrigation. However, irrigation is a huge drain on freshwater resources. Globally, about 75% of all freshwater use is devoted to agriculture. Many rivers in the southwestern United States have been reduced to trickles by the diversion of water for irrigation. The primary source of irrigation water, however, is not surface waters, such as rivers and lakes, but underground water reserves called *aquifers*. In some parts of the world, the rate of water removal is exceeding the natural refilling of the aquifers. The result is *land subsidence*, a gradual settling or sudden sinking of Earth's surface **(Figure 37.4)**. Land subsidence alters drainage patterns, causes damage to human-made structures, promotes loss of underground springs, and increases the risk of flooding.

◀ To emphasize the dramatic effects of land subsidence in California's San Joaquin Valley, geologist Joseph F. Poland (shown here in 1977) had signs posted to represent approximate altitudes of the land surface in 1925 and 1955.

▲ Sudden land subsidence resulting from the overuse of groundwater for irrigation triggered the formation of this sinkhole in Florida.

▲ **Figure 37.4 Land subsidence caused by excessive removal of groundwater.**

Irrigation, particularly from groundwater, can also lead to soil *salinization*—formation of soil too salty for cultivating plants. Salts dissolved in irrigation water accumulate in the soil as the water evaporates, making the water potential of the soil solution more negative. The water potential gradient from soil to roots is lowered, reducing water uptake (see Chapter 36).

Many forms of irrigation, such as the flooding of fields, are wasteful because much of the water evaporates. In order to use water efficiently, farmers must understand the water-holding capacity of their soil, the water needs of their crops, and the appropriate irrigation technology. One popular technology is *drip irrigation*, the slow release of water to soil and plants from perforated plastic tubing placed directly at the root zone. Because drip irrigation requires less water and reduces salinization, it is used in many arid agricultural regions.

Fertilization

In natural ecosystems, mineral nutrients are usually recycled by the decomposition of dead organic material and by the excretion of animal wastes. Agriculture, however, is unnatural. The lettuce in your salad, for example, contains minerals extracted from a farmer's field. As you excrete wastes, these minerals are now deposited far from their original source. Over many harvests, the farmer's field will become depleted of nutrients if they are not restored. Nutrient depletion is a major cause of global soil degradation. Farmers must reverse nutrient depletion by **fertilization**, the addition of mineral nutrients to the soil.

Today, most farmers in industrialized nations use fertilizers containing minerals that are either mined or prepared by energy-intensive processes. These fertilizers are usually enriched in nitrogen (N), phosphorus (P), and potassium (K)—the nutrients most commonly deficient in depleted soils. You may have seen fertilizers labeled with a three-number code, called the N-P-K ratio. A fertilizer marked "15-10-5," for instance, is 15% N (as ammonium or nitrate), 10% P (as phosphoric acid), and 5% K (as the mineral potash).

Manure, fishmeal, and compost are called "organic" fertilizers because they are of biological origin and contain decomposing organic material. Before plants can use organic material, however, it must be decomposed into the inorganic nutrients that roots can absorb. Whether from organic fertilizer or a chemical factory, the minerals a plant extracts are in the same form. However, organic fertilizers release them gradually, whereas minerals in commercial fertilizers are immediately available but may not be retained by the soil for long. Minerals not absorbed by roots are often leached from the soil by rainwater or irrigation. To make matters worse, mineral runoff into lakes may lead to explosions in algal populations that can deplete oxygen levels and decimate fish populations.

Adjusting Soil pH

Soil pH is another important factor influencing mineral availability because it affects cation exchange and the chemical form of minerals. Depending on the soil pH, a particular mineral may be bound too tightly to clay particles or may be in a chemical form that the plant cannot absorb. Most plants prefer slightly acidic soil because the high H^+ concentrations can displace positively charged minerals from soil particles, making them more available for absorption. Adjusting soil pH for optimal crop growth is tricky because a change in H^+ concentration may make one mineral more available but another mineral less available. At pH 8, for instance, plants can absorb calcium, but iron is almost completely unavailable. The soil pH should be matched to a crop's mineral needs. If the soil is too alkaline, adding sulfate will lower the pH. Soil that is too acidic can be adjusted by adding lime (calcium carbonate or calcium hydroxide).

When the soil pH dips to 5 or lower, toxic aluminum ions (Al^{3+}) become more soluble and are absorbed by roots, stunting root growth and preventing the uptake of calcium, a needed plant nutrient. Some plants can cope with high Al^{3+} levels by secreting organic anions that bind the Al^{3+} and render it harmless. However, low soil pH and Al^{3+} toxicity continue to pose serious problems, especially in tropical regions, where growing populations and food production pressures are often most acute.

Controlling Erosion

As happened most dramatically in the Dust Bowl, water and wind erosion can remove considerable amounts of topsoil. Erosion is a major cause of soil degradation because soil nutrients are carried far away by wind and streams. To limit erosion, farmers can take precautions such as planting rows of trees as windbreaks, terracing hillside crops, and cultivating in a contour pattern **(Figure 37.5)**. Crops such as alfalfa and wheat provide good ground cover and protect the soil better

▲ **Figure 37.5 Contour tillage.** These crops in Wisconsin are planted in rows that go around, rather than up and down, the hills. Contour tillage helps slow water runoff and topsoil erosion after heavy rains.

than maize and other crops that are usually planted in more widely spaced rows.

Erosion can also be reduced by a plowing technique called **no-till agriculture**. In traditional plowing, the entire field is tilled, or turned over. Although this practice helps control weeds, it also disrupts the meshwork of roots that holds the soil in place, leading to increased surface runoff and erosion. In no-till agriculture, a specialized plow creates narrow furrows for seeds and fertilizer. In this way, the field can be seeded with minimal disturbance of the soil, while also requiring less fertilizer.

Preventing Soil Compaction

Large heavy farm equipment causes a problem called soil compaction: Soil particles are pressed together, reducing pore space between them. Heavily compacted soils contain few large pores and have reduced rates of water absorption and drainage because the small pores that remain are less effective in moving water through the soil. Compaction also slows down gas exchange between roots and the soil. In addition, compaction reduces root growth by making it harder for them to penetrate the soil, thereby decreasing absorption of water and nutrients. The best cure for soil compaction is to avoid it by not farming soil that is too wet and by redesigning agricultural equipment with more and broader tires to redistribute the weight.

Phytoremediation

Some land areas are unfit for cultivation because toxic heavy metals or organic pollutants have contaminated the soil or groundwater. Traditionally, soil remediation, the detoxification of contaminated soils, has focused on nonbiological technologies, such as removing and storing contaminated soil in landfills, but these techniques are very costly and often disrupt the landscape. **Phytoremediation** is a nondestructive biotechnology that harnesses some plants' ability to extract soil pollutants and concentrate them in portions of the plant that can be easily removed for safe disposal. For example, alpine pennycress (*Thlaspi caerulescens*) can accumulate zinc in its shoots at concentrations 300 times higher than most plants can tolerate. The shoots can then be harvested and the contaminating zinc removed. Such plants show promise for cleaning up areas contaminated by smelters, mining operations, or nuclear testing. Phytoremediation is one form of the more general technology of bioremediation, which also includes the use of prokaryotes and protists to detoxify polluted sites (see Chapters 27 and 56).

In this section, we have discussed the importance of soil conservation for sustainable agriculture. Mineral nutrients are major factors contributing to soil fertility, but which minerals are most important, and why do plants need them? These are the topics of the next section.

CONCEPT CHECK 37.1

1. Explain how the phrase "too much of a good thing" can apply to watering and fertilizing plants.
2. Some lawn mowers collect clippings for easy disposal and to prevent clumps from inhibiting photosynthesis. What is a possible drawback of this practice with respect to plant nutrition?
3. **WHAT IF?** How would adding clay to loamy soil affect the soil's capacity to exchange cations and retain water? Explain.

For suggested answers, see Appendix A.

CONCEPT 37.2
Plants require essential elements to complete their life cycle

Watch a large plant grow from a tiny seed, and you cannot help wondering where all the plant mass comes from. Aristotle hypothesized that plants "ate" soil because they were seen to arise from the ground. In the 1640s, the Belgian physiologist Jan Baptista van Helmont tested the hypothesis that plants grow by consuming soil. He planted a small willow in a pot that contained 90.9 kg of soil. After five years, the plant weighed 76.8 kg, but only 0.06 kg of soil had disappeared from the pot. He concluded that the willow had grown mainly from the water he had added. A century later, the English physiologist Stephen Hales, armed with knowledge from recent advances in physics and chemistry that air is a substance with mass, postulated that plants are nourished mostly by air.

There is some truth to all three hypotheses because soil, water, and air all contribute to plant growth. The water content of a plant can be measured by comparing the mass of plant material before and after it is dried. Typically, 80–90% of a plant's fresh mass is water. We can also analyze the chemical composition of the dry residue. Organic substances generally account for about 96% of the dry mass. Thus, the inorganic nutrients from the soil, although essential for plant survival, contribute very little to the plant's total mass. The majority of a plant's dry mass is derived neither from water nor from soil minerals but from the CO_2 that is assimilated from the air during photosynthesis. Water also supplies most of the hydrogen atoms and some of the oxygen atoms incorporated into organic compounds by photosynthesis (see Figure 10.4). Most of the organic material of plants is carbohydrate, including the cellulose of cell walls. Thus, the components of carbohydrates—carbon, oxygen, and hydrogen—are the most abundant elements in a dried plant. Because many macromolecules contain nitrogen, sulfur, or phosphorus, these elements are also relatively abundant in plants.

Macronutrients and Micronutrients

The inorganic substances in plants contain more than 50 chemical elements. In studying the chemical composition of plants, we must distinguish elements that are essential from those that are merely present in the plant. A chemical element is considered an **essential element** only if it is required for a plant to complete its life cycle and produce another generation.

To determine which chemical elements are essential, researchers use **hydroponic culture**, in which plants are grown in mineral solutions instead of soil **(Figure 37.6)**. Such studies have helped identify 17 essential elements needed by all plants **(Table 37.1)**. Hydroponic culture is also used on a small scale to grow some greenhouse crops.

Nine of the essential elements are called **macronutrients** because plants require them in relatively large amounts. Six of these are the major components of organic compounds forming a plant's structure: carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulfur. The other three macronutrients are potassium, calcium, and magnesium. Of all the mineral nutrients, nitrogen contributes the most to plant growth and crop yields. Plants require nitrogen as a component of proteins, nucleic acids, chlorophyll, and other important organic molecules.

The remaining eight essential elements are known as **micronutrients** because plants need them in tiny quantities. They are chlorine, iron, manganese, boron, zinc, copper, nickel, and molybdenum. In some cases, sodium may be a ninth essential micronutrient: Plants that use the C_4 and CAM pathways of photosynthesis (see Chapter 10) require sodium ions to regenerate phosphophenolpyruvate, which is the CO_2 acceptor in these two types of carbon fixation.

Micronutrients function in plants mainly as cofactors, nonprotein helpers in enzymatic reactions (see Chapter 8). Iron, for example, is a metallic component of cytochromes, the proteins in the electron transport chains of chloroplasts and mitochondria. It is because micronutrients generally play catalytic roles that plants need only tiny quantities. The requirement for molybdenum, for instance, is so modest that there is only one atom of this rare element for every 60 million atoms of hydrogen in dried plant material. Yet a deficiency of molybdenum or any other micronutrient can weaken or kill a plant.

Symptoms of Mineral Deficiency

The symptoms of a deficiency depend partly on the mineral's function as a nutrient. For example, a deficiency of magnesium, a component of chlorophyll, causes *chlorosis*, yellowing of the leaves. In some cases, the relationship between a mineral deficiency and its symptoms is less direct. For instance, iron deficiency can cause chlorosis even though chlorophyll contains no iron, because iron ions are required as a cofactor in one of the enzymatic steps of chlorophyll synthesis.

Mineral deficiency symptoms depend not only on the role of the nutrient but also on its mobility within the plant. If a nutrient moves about freely, symptoms appear first in older organs because young, growing tissues have more "drawing power" for nutrients that are in short supply. For example, magnesium is relatively mobile and is shunted preferentially to young leaves. Therefore, a plant deficient in magnesium first shows signs of chlorosis in its older leaves. The mechanism for preferential routing is the source-to-sink translocation in phloem, as minerals move along with sugars to the growing tissues (see Figure 36.20). In contrast, a deficiency of a mineral that is relatively immobile affects young parts of the plant first. Older tissues may have adequate amounts that they retain during periods of short supply. For example, iron does not move freely within a plant, and an iron deficiency causes yellowing of young leaves before any effect on older leaves is visible. The mineral requirements of a plant may also change with the time of the year and the age of the plant. Young seedlings, for example, rarely show mineral deficiency symptoms because their mineral requirements are met largely by minerals released from stored reserves in the seed itself.

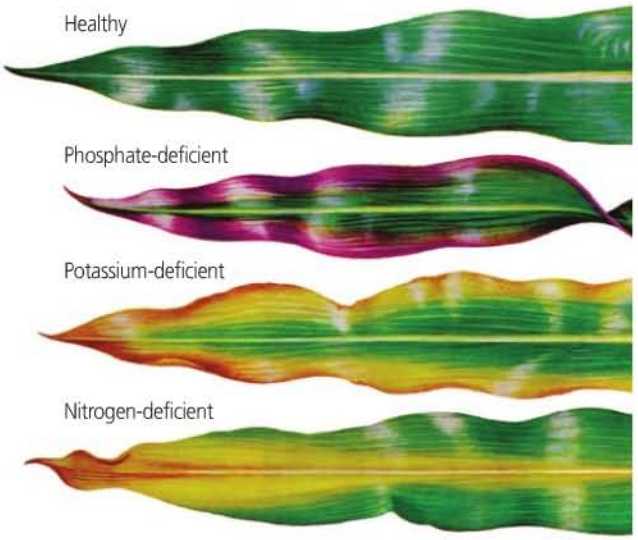
▼ Figure 37.6 Research Method

Hydroponic Culture

APPLICATION In hydroponic culture, plants are grown in mineral solutions without soil. One use of hydroponic culture is to identify essential elements in plants.

TECHNIQUE Plant roots are bathed in aerated solutions of known mineral composition. Aerating the water provides the roots with oxygen for cellular respiration. (Note: The flasks would normally be opaque to prevent algal growth.) A mineral, such as potassium, can be omitted to test whether it is essential.

Control: Solution containing all minerals



Experimental: Solution without potassium

RESULTS If the omitted mineral is essential, mineral deficiency symptoms occur, such as stunted growth and discolored leaves. By definition, the plant would not be able to complete its life cycle. Deficiencies of different elements may have different symptoms, which can aid in diagnosing mineral deficiencies in soil.

Table 37.1 Essential Elements in Plants

Element	Form Available to Plants	% Mass in Dry Tissue	Major Functions
Macronutrients			
Carbon	CO_2	45%	Major component of plant's organic compounds
Oxygen	CO_2	45%	Major component of plant's organic compounds
Hydrogen	H_2O	6%	Major component of plant's organic compounds
Nitrogen	NO_3^-, NH_4^+	1.5%	Component of nucleic acids, proteins, hormones, chlorophyll, coenzymes
Potassium	K^+	1.0%	Cofactor that functions in protein synthesis; major solute functioning in water balance; operation of stomata
Calcium	Ca^{2+}	0.5%	Important in formation and stability of cell walls and in maintenance of membrane structure and permeability; activates some enzymes; regulates many responses of cells to stimuli
Magnesium	Mg^{2+}	0.2%	Component of chlorophyll; activates many enzymes
Phosphorus	$H_2PO_4^-$, HPO_4^{2-}	0.2%	Component of nucleic acids, phospholipids, ATP, several coenzymes
Sulfur	SO_4^{2-}	0.1%	Component of proteins, coenzymes
Micronutrients			
Chlorine	Cl^-	0.01%	Required for water-splitting step of photosynthesis; functions in water balance
Iron	Fe^{3+}, Fe^{2+}	0.01%	Component of cytochromes; activates some enzymes
Manganese	Mn^{2+}	0.005%	Active in formation of amino acids; activates some enzymes; required for water-splitting step of photosynthesis
Boron	$H_2BO_3^-$	0.002%	Cofactor in chlorophyll synthesis; may be involved in carbohydrate transport and nucleic acid synthesis; role in cell wall function
Zinc	Zn^{2+}	0.002%	Active in formation of chlorophyll; activates some enzymes
Copper	Cu^+, Cu^{2+}	0.001%	Component of many redox and lignin-biosynthetic enzymes
Nickel	Ni^{2+}	0.001%	Cofactor for an enzyme functioning in nitrogen metabolism
Molybdenum	MoO_4^{2-}	0.0001%	Essential for mutualistic relationship with nitrogen-fixing bacteria; cofactor in nitrate reduction

Deficiencies of phosphorus, potassium, and especially nitrogen are most common. Micronutrient shortages are less common and tend to occur in certain geographic regions because of differences in soil composition. The symptoms of a mineral deficiency may vary between species but are often distinctive enough for a plant physiologist or farmer to diagnose the cause **(Figure 37.7)**. One way to confirm a diagnosis is to analyze the mineral content of the plant or soil. The amount of a micronutrient needed to correct a deficiency is usually quite small. For example, a zinc deficiency in fruit trees can usually be cured by hammering a few zinc nails into each tree trunk.

▶ **Figure 37.7 The most common mineral deficiencies, as seen in maize leaves.** Mineral deficiency symptoms may vary in different species. In maize, phosphate-deficient plants have reddish purple margins, particularly in young leaves. Potassium-deficient maize plants exhibit "firing," or drying, along tips and margins of older leaves. Nitrogen deficiency is evident in a yellowing that starts at the tip and moves along the center (midrib) of older leaves.

Moderation is important because overdoses of many nutrients can be detrimental or toxic to plants. Too much nitrogen, for example, can lead to excessive vine growth in tomato plants at the expense of good fruit production.

Improving Plant Nutrition by Genetic Modification: Some Examples

In exploring plant nutrition so far, we have discussed how farmers use irrigation, fertilization, and other means to tailor the soil to fit the needs of a crop. An opposite approach involves tailoring the plant by genetic engineering to better fit the soil. Here we highlight a few examples of how genetic engineering is improving plant nutrition and fertilizer usage.

Resistance to Aluminum Toxicity

As previously discussed, aluminum in acidic soils damages roots and greatly reduces crop yields. The major mechanism of aluminum resistance is the secretion of organic acids (such as malic acid and citric acid) by roots. These acids bind to free aluminum ions and lower aluminum levels in the soil. Luis Herrera-Estrella and colleagues, at the Research and Advanced Studies Center in Mexico, altered tobacco and papaya plants by introducing a citrate synthase gene from a bacterium into the plants' genomes. The resulting overproduction of citric acid increased aluminum resistance in these two crops.

Flood Tolerance

Waterlogged soil not only deprives roots of oxygen but also can injure plants as ethanol and other toxic products of alcoholic fermentation by soil microbes accumulate. In Asian countries, flooding during the monsoon season often destroys rice crops. Although most varieties of rice die after being submerged for a week, some types can survive weeks of flooding. A gene called *Submergence 1A-1* (*Sub1A-1*) is the main source of submergence tolerance in flood-resistant rice. Sub1A-1 proteins regulate the expression of genes that are normally activated under anaerobic conditions, such as those that code for alcohol dehydrogenase, an enzyme that breaks down ethanol. The heightened expression of *Sub1A-1* in flooding-intolerant varieties of rice increased the alcohol dehydrogenase levels of the plants and conferred tolerance to submergence.

Smart Plants

Agricultural researchers are developing ways to maintain crop yields while reducing fertilizer use. One approach is to genetically engineer "smart" plants that signal when a nutrient deficiency is imminent—but *before* damage has occurred. One type of smart plant takes advantage of a promoter (a DNA sequence that indicates where the transcription of a gene starts) that more readily binds RNA polymerase (the transcription enzyme) when the phosphorus content of the plant's tissues begins to decline. This promoter is linked to a "reporter" gene that leads to production of a light blue pigment in the leaf cells **(Figure 37.8)**. When leaves of these smart plants develop a blue tinge, the farmer knows it is time to add phosphate-containing fertilizer.

No phosphorus deficiency | Beginning phosphorus deficiency | Well-developed phosphorus deficiency

▲ **Figure 37.8 Deficiency warnings from "smart" plants.** Some plants have been genetically modified to signal an impending nutrient deficiency before irreparable damage occurs. For example, after laboratory treatments, the research plant *Arabidopsis* develops a blue color in response to an imminent phosphate deficiency.

So far, you have learned that soil, to support vigorous plant growth, must have an adequate supply of mineral nutrients, sufficient aeration, good water-holding capacity, low salinity, and a pH near neutrality. It must also be free of toxic concentrations of minerals and other chemicals. These physical and chemical features of soil, however, are just half the story. To understand soil fully, we must also consider its living components.

CONCEPT CHECK 37.2

1. Explain how Table 37.1 supports Stephen Hales's hypothesis.
2. Are some essential elements more important than others? Explain.
3. **WHAT IF?** The element silicon (Si) is absorbed by plants and increases the quality and yield of agricultural crops. Would this be sufficient evidence to consider it an essential plant nutrient?

For suggested answers, see Appendix A.

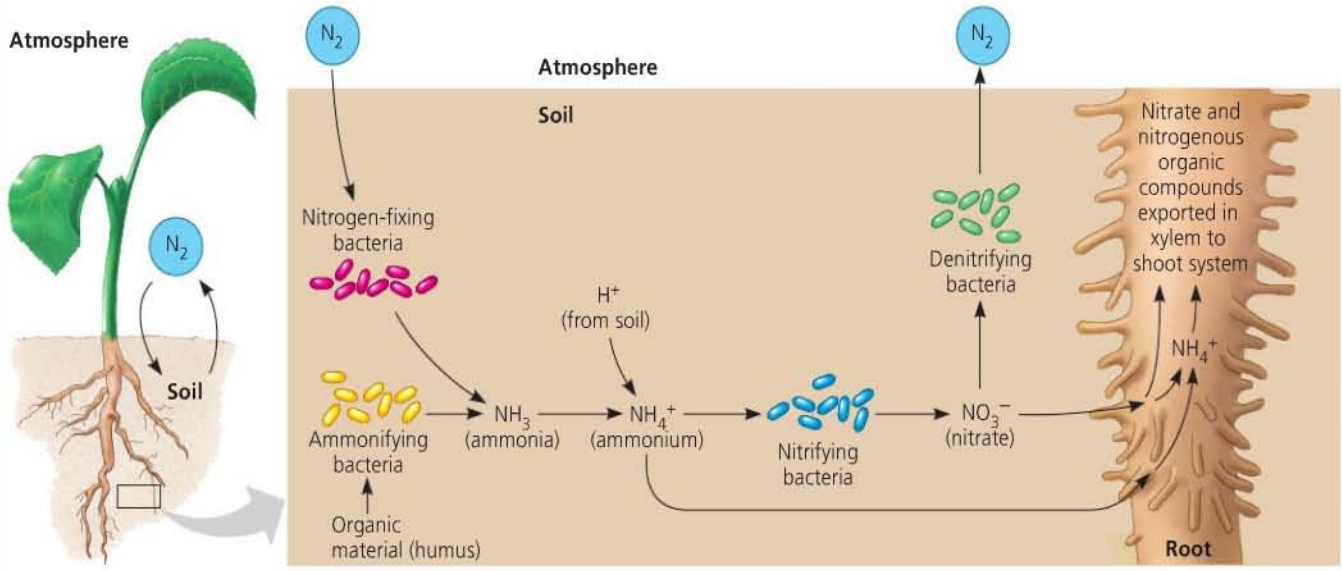
CONCEPT 37.3
Plant nutrition often involves relationships with other organisms

To this point, we have portrayed plants as exploiters of soil resources. But plants and soil have a two-way relationship. Dead plants provide much of the energy needed by soil-dwelling microorganisms, while secretions from living roots support a wide variety of microbes in the near-root environment. Here we'll focus on some mutualistic, or mutually beneficial, relationships between plants and soil bacteria or fungi. Then we'll look at some unusual plants that form nonmutualistic relationships with other plants or, in a few cases, with animals.

Soil Bacteria and Plant Nutrition

Some beneficial bacteria are found predominantly in the **rhizosphere**, the soil layer that is bound to the plant's roots. Others are decomposers, deriving nutrition from decaying organic material (humus) in the topsoil. Yet another class of important nitrogen-providing bacteria grow inside roots.

Rhizobacteria



Rhizobacteria are soil bacteria with especially large populations in the rhizosphere. Different soils vary greatly in the types and number of rhizobacteria they harbor. Microbial activity within a plant's rhizosphere is 10 to 100 times higher than in unbound soil because the roots secrete nutrients such as sugars, amino acids, and organic acids. Up to 20% of a plant's photosynthetic production fuels the organisms in this miniature ecosystem. As a result of diverse plant-microbe interactions, the composition of this microbial population often differs greatly from the surrounding soil and the rhizospheres of other plant species. Each rhizosphere contains a unique and complex cocktail of root secretions and microbial products.

Some rhizobacteria, known as *plant-growth-promoting rhizobacteria,* enhance plant growth by a variety of mechanisms. Some produce chemicals that stimulate plant growth. Others produce antibiotics that protect roots from disease. Still others absorb toxic metals or make nutrients more available to roots. Inoculation of seeds with plant-growth-promoting rhizobacteria can increase crop yield and reduce the need for fertilizers and pesticides. How do the bacteria benefit by interacting with plants? Root secretions supply most of the energy in the rhizosphere, so bacterial adaptations that help a plant thrive and secrete nutrients also help the bacteria.

Bacteria in the Nitrogen Cycle

Plants also have mutualistic relationships with several groups of bacteria that help make nitrogen more available. From a global perspective, no mineral nutrient is more limiting to plant growth than nitrogen, which is required in large amounts as a component of proteins and nucleic acids. The **nitrogen cycle**, discussed in Chapter 55, describes transformations of nitrogen and nitrogenous compounds in nature. Here we focus on processes leading directly to nitrogen assimilation by plants.

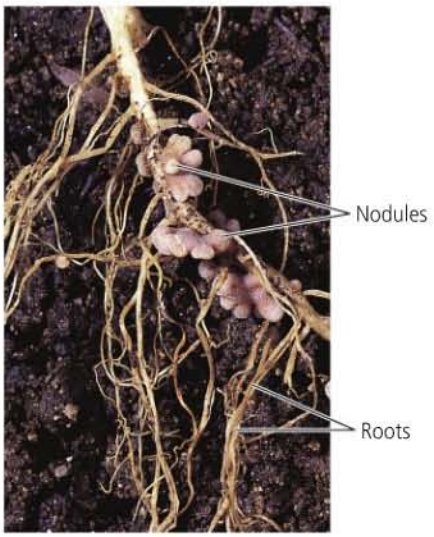
Unlike other soil minerals, ammonium ions (NH_4^+) and nitrate ions (NO_3^-) are not derived from the weathering of rocks. Although lightning produces small amounts of NO_3^- that get carried to the soil in rain, most soil nitrogen comes from the activity of bacteria **(Figure 37.9)**. *Ammonifying bacteria,* which are usually decomposers living in humus-rich soil, release ammonia (NH_3) by breaking down proteins and other organic compounds in humus. *Nitrogen-fixing bacteria* convert gaseous nitrogen (N_2) into NH_3, in a process we'll discuss shortly. In either case, the NH_3 produced picks up another H^+ in the soil solution to form NH_4^+, which plants can absorb. However, plants acquire nitrogen mainly in the form of NO_3^-. Soil NO_3^- is largely formed by a two-step process called *nitrification,* which consists of the oxidation of NH_3 to nitrite (NO_2^-), followed by oxidation of nitrite to nitrate (NO_3^-). Different types of *nitrifying bacteria* mediate each step. After the roots absorb NO_3^-, a plant enzyme reduces it back to NH_4^+, which other enzymes incorporate into amino acids and other organic compounds. Most plant species export nitrogen from roots to shoots via the xylem as NO_3^- or organic compounds synthesized in the roots. Some soil nitrogen is lost, particularly in anaerobic soils, when denitrifying bacteria convert NO_3^- to N_2, which diffuses into the atmosphere.

▲ **Figure 37.9 The roles of soil bacteria in the nitrogen nutrition of plants.** Ammonium is made available to plants by two types of soil bacteria: those that fix atmospheric N_2 (nitrogen-fixing bacteria) and those that decompose organic material (ammonifying bacteria). Although plants absorb some ammonium from the soil, they absorb mainly nitrate, which is produced from ammonium by nitrifying bacteria. Plants reduce nitrate back to ammonium before incorporating the nitrogen into organic compounds.

Nitrogen-Fixing Bacteria: A Closer Look

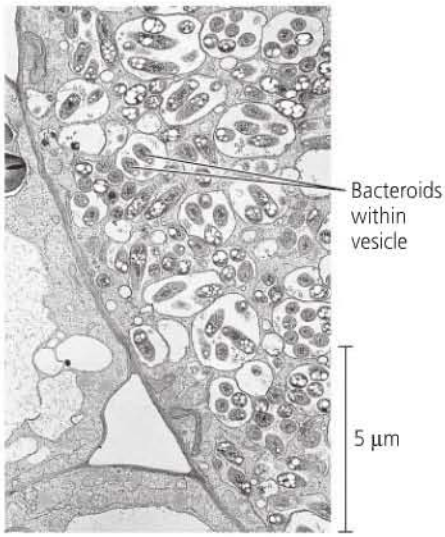
Although Earth's atmosphere is 79% nitrogen, plants cannot use free gaseous nitrogen (N_2) because there is a triple bond between the two nitrogen atoms, making the molecule almost inert. For atmospheric N_2 to be of use to plants, it must be reduced to NH_3 by a process called **nitrogen fixation**. All N_2-fixing organisms are prokaryotes, and some that carry out this process are free living (see Figure 37.9). In the particular case of N_2 fixation by the bacterium *Rhizobium,* the bacteria form an intimate association with the roots of legume plants (such as peas, soybeans, alfalfa, and clover) and markedly alter root structure. Although *Rhizobium* bacteria can be free living in the soil, they cannot fix N_2 in their free state, nor can legume roots fix N_2 without the bacteria.

The conversion of N_2 to NH_3 is a complicated, multistep process, but the reactants and products in nitrogen fixation can be summarized as follows:



$$N_2 + 8\,e^- + 8\,H^+ + 16\,ATP \rightarrow 2\,NH_3 + H_2 + 16\,ADP + 16\,\textcircled{P}_i$$

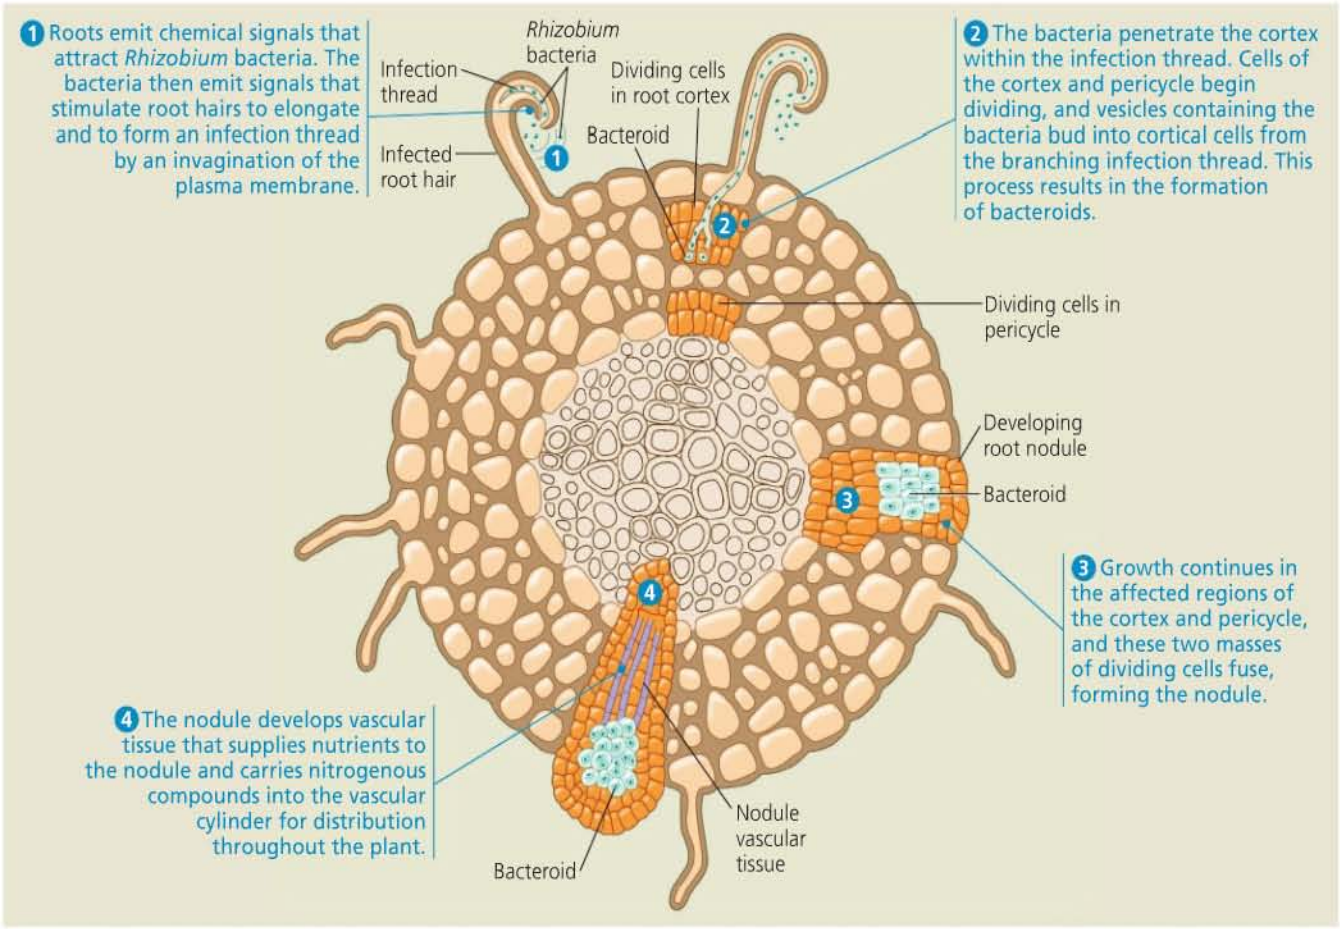
The enzyme complex nitrogenase catalyzes the entire reaction sequence, which reduces N_2 to NH_3 by adding electrons and H^+. Because the process of nitrogen fixation requires eight ATP molecules for each NH_3 synthesized, nitrogen-fixing bacteria require a rich supply of carbohydrates from decaying material, root secretions, or (in the case of *Rhizobium*) the vascular tissue of roots.



The specialized mutualism between *Rhizobium* bacteria and legume roots involves dramatic changes in root structure. Along a legume's roots are swellings called **nodules** composed of plant cells that have been "infected" by *Rhizobium* ("root living") bacteria **(Figure 37.10a)**. Inside the nodule, *Rhizobium* bacteria assume a form called **bacteroids**, which are contained within vesicles formed in the root cell **(Figure 37.10b)**. Legume-*Rhizobium* relationships generate more usable nitrogen for plants than all industrial fertilizers used today, and the mutualism provides the right amount of nitrogen at the right time at virtually no cost to the farmer. In addition to supplying the legume with nitrogen, this nitrogen fixation significantly reduces spending on fertilizers for subsequent crops.

The location of the bacteroids inside living, nonphotosynthetic cells is conducive to nitrogen fixation, which requires an anaerobic environment. Lignified external layers of root nodules also limit gas exchange. Some root nodules appear reddish because of a molecule called leghemoglobin (*leg-* for "legume"), an iron-containing protein that binds reversibly to oxygen (it is similar to the hemoglobin in human red blood cells). This protein is an oxygen "buffer," reducing the concentration of free oxygen and thereby providing an anaerobic environment for nitrogen fixation while regulating the oxygen supply for the intense cellular respiration required to produce ATP for nitrogen fixation.

Each legume species is associated with a particular strain of *Rhizobium.* **Figure 37.11** describes how a root nodule develops after bacteria enter through an "infection thread." The symbiotic relationship between a legume and nitrogen-fixing bacteria is mutualistic in that the bacteria supply the host plant with fixed nitrogen while the plant provides the bacteria with carbohydrates and other organic compounds. The root nodules use most of the ammonium produced to make amino



(a) Pea plant root. The bumps on this pea plant root are nodules containing *Rhizobium* bacteria. The bacteria fix nitrogen and obtain photosynthetic products supplied by the plant.

(b) Bacteroids in a soybean root nodule. In this TEM, a cell from a root nodule of soybean is filled with bacteroids in vesicles. The cells on the left are uninfected.

◀ **Figure 37.10 Root nodules on legumes.** The coordinated activities of the legume and the *Rhizobium* bacteria depend on a chemical dialogue between the mutualistic partners.

? *How is the relationship between legume plants and* Rhizobium *bacteria mutualistic?*

▲ **Figure 37.11 Development of a soybean root nodule.**
? *What plant tissue systems are modified by nodulation?*

acids, which are then transported up to the shoot through the xylem.

How does a legume species recognize a certain strain of *Rhizobium* among the many bacterial strains in the soil? And how does an encounter with that specific *Rhizobium* strain lead to development of a nodule? These two questions have led researchers to uncover a chemical dialogue between the bacteria and the root. Each partner responds to chemical signals from the other by expressing certain genes whose products contribute to nodule formation. By understanding the molecular biology underlying the formation of root nodules, researchers hope to learn how to induce *Rhizobium* uptake and nodule formation in crop plants that do not normally form such nitrogen-fixing mutualistic relationships.

Nitrogen Fixation and Agriculture

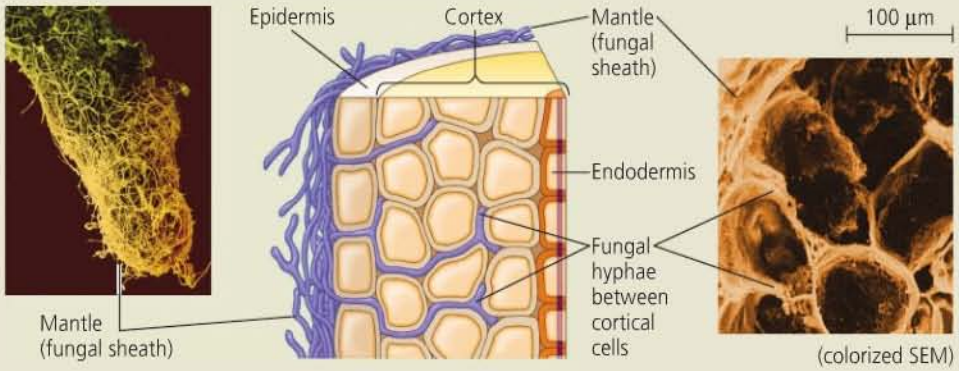
The agricultural benefits of mutualistic nitrogen fixation underlie most types of **crop rotation**. In this practice, a nonlegume such as maize is planted one year, and the following year alfalfa or some other legume is planted to restore the concentration of fixed nitrogen in the soil. To ensure that the legume encounters its specific *Rhizobium* strain, the seeds are soaked in a culture of the bacteria or dusted with bacterial spores before sowing. Instead of being harvested, the legume crop is often plowed under so that it will decompose as "green manure," reducing the need for manufactured fertilizers.

Many plant families besides legumes include species that benefit from mutualistic nitrogen fixation. For example, alder trees and certain tropical grasses host gram-positive bacteria of the actinomycete group (see Figure 27.18). Rice, a crop of great commercial importance, benefits indirectly from mutualistic nitrogen fixation. Rice farmers culture a free-floating aquatic fern, *Azolla*, which has mutualistic cyanobacteria that fix nitrogen. The growing rice eventually shades and kills the *Azolla*, and decomposition of this nitrogen-rich organic material increases the paddy's fertility.

Fungi and Plant Nutrition

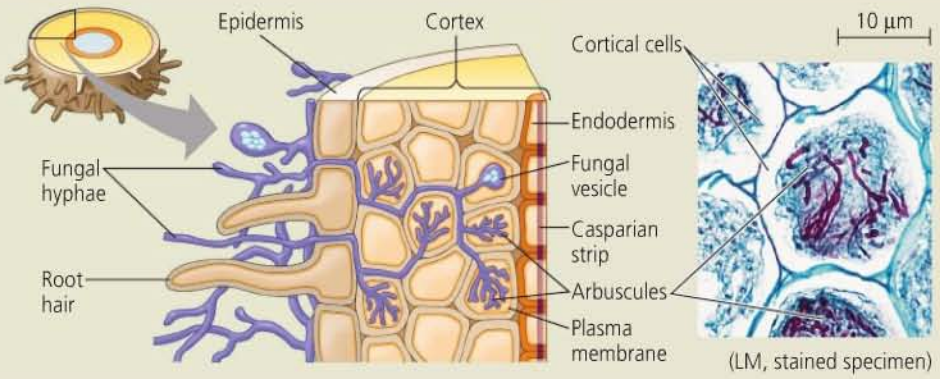
Certain species of soil fungi also form mutualistic relationships with roots and play a major role in plant nutrition. **Mycorrhizae** ("fungus roots") are mutualistic associations of roots and fungi (see Figures 31.15 and 36.5). The host

plant provides the fungus with a steady supply of sugar. Meanwhile, the fungus increases the surface area for water uptake and also supplies the plant with phosphate and other minerals absorbed from the soil. The fungi of mycorrhizae also secrete growth factors that stimulate roots to grow and branch, as well as antibiotics that help protect the plant from pathogens in the soil.



Mycorrhizae are not oddities; they are formed by most plant species. In fact, this plant-fungus mutualism might have been one of the evolutionary adaptations that helped plants initially colonize land (see Chapter 29). Indeed, fossilized roots from some of the earliest plants include mycorrhizae. In early terrestrial ecosystems, the soil was probably poor in nutrients. The fungi of mycorrhizae, which are more efficient at absorbing minerals than the roots themselves, would have helped nourish the pioneering plants.

The Two Main Types of Mycorrhizae



The major mutualistic symbioses of fungi and plants consist of two types: ectomycorrhizae and arbuscular mycorrhizae (sometimes called endomycorrhizae). In **ectomycorrhizae**, the mycelium (mass of branching hyphae; see Chapter 31) forms a dense sheath, or mantle, over the surface of the root **(Figure 37.12a)**. Fungal hyphae extend from the mantle into the soil, greatly increasing the surface area for water and mineral absorption. Hyphae also grow into the root cortex. These hyphae do not penetrate the root cells but form a network in the apoplast, or extracellular space, that facilitates nutrient exchange between the fungus and the plant. Compared with "uninfected" roots, ectomycorrhizae are generally thicker, shorter, and more branched. They typically do not form root hairs, which would be superfluous given the extensive surface area of the fungal mycelium. About 10% of plant families have species that form ectomycorrhizae, and the vast majority of these species are woody, including members of the pine, spruce, oak, walnut, birch, willow, and eucalyptus families.

In contrast, **arbuscular mycorrhizae** do not have a dense mantle ensheathing the root **(Figure 37.12b)**. Mycorrhizal associations start when microscopic soil hyphae respond to the presence of a root by growing toward it, establishing contact, and growing along its surface. Hyphae penetrate between epidermal cells and then enter the root cortex. These hyphae digest small patches of the cortical cell walls, but they do not actually pierce the plasma membrane and enter the cytoplasm. Instead, a hypha grows into a tube formed by invagination of the root cell's membrane. The process is analogous to poking a finger gently into a balloon without popping it; your finger is like the fungal hypha, and the balloon skin is like the root cell's membrane. After the fungal hyphae have penetrated in this way, some branch densely, forming structures called arbuscules ("little trees"), which are important sites of nutrient transfer between the fungus and the

(a) Ectomycorrhizae. The mantle of the fungal mycelium ensheathes the root. Fungal hyphae extend from the mantle into the soil, absorbing water and minerals, especially phosphate. Hyphae also extend into the extracellular spaces of the root cortex, providing extensive surface area for nutrient exchange between the fungus and its host plant.

(b) Arbuscular mycorrhizae (endomycorrhizae). No mantle forms around the root, but microscopic fungal hyphae extend into the root. Within the root cortex, the fungus makes extensive contact with the plant through branching of hyphae that form arbuscules, providing an enormous surface area for nutrient swapping. The hyphae penetrate the cell walls, but not the plasma membranes, of cells within the cortex.

▲ **Figure 37.12 Mycorrhizae.**

plant. Within the hyphae themselves, oval vesicles may form, possibly serving as food storage sites for the fungus. To the unaided eye, arbuscular mycorrhizae look like "normal" roots with root hairs, but a microscope reveals a mutualistic relationship of enormous importance to plant nutrition. Arbuscular mycorrhizae are much more common than ectomycorrhizae and are found in over 85% of plant species, including crop plants such as maize, wheat, and legumes.

Agricultural and Ecological Importance of Mycorrhizae

Roots can form mycorrhizal symbioses only if exposed to the appropriate species of fungus. In most ecosystems, these fungi are present in the soil, and seedlings develop mycorrhizae. But if seeds are collected in one environment and planted in foreign soil, the plants may show signs of malnutrition (particularly phosphorus deficiency) resulting from the absence of mycorrhizal partners. Treating seeds with spores of mycorrhizal fungi can sometimes help seedlings to form mycorrhizae and improve crop yield.

Mycorrhizal associations are also important in understanding ecological relationships. Invasive exotic plants sometimes colonize areas by disrupting interactions between native organisms. For example, garlic mustard (*Alliaria petiolata*), introduced into New England from Europe during the 1800s, has invaded woodlands throughout the eastern and middle United States, suppressing tree seedlings and other native plants. Kristina Stinson, of Harvard University, and colleagues have produced compelling evidence that its invasive properties may be related to an ability to slow the growth of other plant species by preventing the growth of arbuscular mycorrhizal fungi **(Figure 37.13)**.

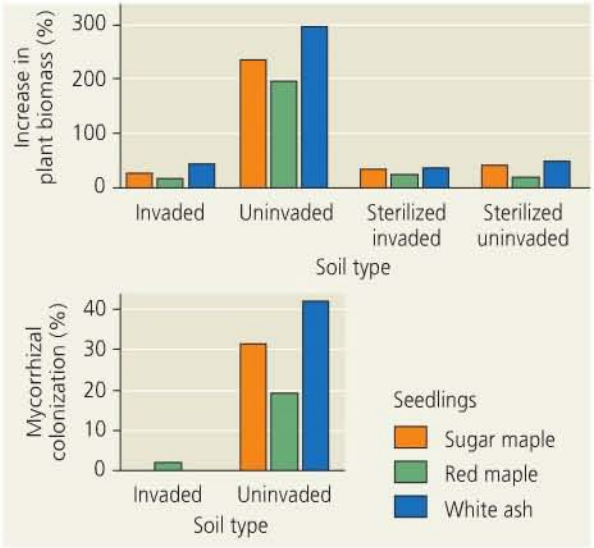
Epiphytes, Parasitic Plants, and Carnivorous Plants

Almost all plant species have mutualistic symbiotic relationships with soil fungi or bacteria or both. Though rarer, there are also plant species with nutritional adaptations that use other organisms in nonmutualistic ways. **Figure 37.14**, on the next page, provides an overview of three unusual adaptations: epiphytes, parasitic plants, and carnivorous plants.

CONCEPT CHECK 37.3

1. Why is the study of the rhizosphere critical to understanding plant nutrition?
2. How do soil bacteria and mycorrhizae contribute to plant nutrition?
3. **WHAT IF?** A peanut farmer finds that the older leaves of his plant are turning yellow following a long period of wet weather. Suggest a reason why.

For suggested answers, see Appendix A.



▼ Figure 37.13 Inquiry

Does the invasive weed garlic mustard disrupt mutualistic associations between native tree seedlings and arbuscular mycorrhizal fungi?

EXPERIMENT Kristina Stinson, of Harvard University, and colleagues investigated the effect of invasive garlic mustard on the growth of native tree seedlings and associated mycorrhizal fungi. In one experiment, they grew seedlings of three North American trees—sugar maple, red maple, and white ash—in four different soils. Two of the soil samples were collected from a location where garlic mustard was growing, and one of these samples was sterilized. The other two soil samples were collected from a location devoid of garlic mustard, and one was then sterilized. After four months of growth, the researchers harvested the shoots and roots and determined the dried biomass. The roots were also analyzed for percent colonization by arbuscular mycorrhizal fungi.

RESULTS Native tree seedlings grew more slowly and were less able to form mycorrhizal associations when grown either in sterilized soil or in unsterilized soil collected from a location that had been invaded by garlic mustard.

CONCLUSION The data support the hypothesis that garlic mustard suppresses growth of native trees by affecting the soil in a way that disrupts mutualistic associations between the trees and arbuscular mycorrhizal fungi.

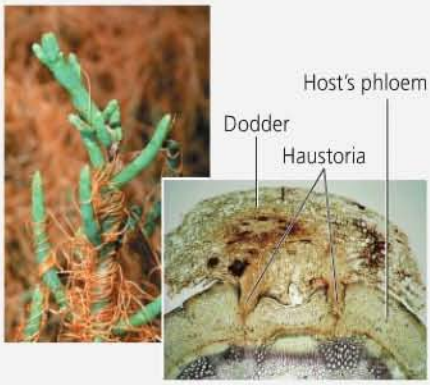
Exploring Unusual Nutritional Adaptations in Plants

Epiphytes

An **epiphyte** (from the Greek *epi,* upon, and *phyton,* plant) nourishes itself but grows on another plant, usually anchored to branches or trunks of living trees. Epiphytes absorb water and minerals from rain, mostly through leaves rather than roots. Some examples are staghorn ferns, bromeliads, and many orchids.

Staghorn fern, an epiphyte. This tropical fern (genus *Platycerium*) grows on large rocks, cliffs, and trees. It has two types of fronds: branched fronds resembling antlers and circular fronds that form a collar around the base of the fern.



Parasitic Plants

Unlike epiphytes, parasitic plants absorb sugars and minerals from their living hosts, although some parasitic species are photosynthetic.

Many species have roots that function as haustoria, nutrient-absorbing projections that enter the host plant.

Mistletoe, a photosynthetic parasite. Tacked above doorways during the holiday season, mistletoe (genus *Phoradendron*) lives in nature as a parasite on oaks and other trees.

Dodder, a nonphotosynthetic parasite. Dodder (genus *Cuscuta*), the orange "strings" on this pickleweed, draws its nutrients from the host. The cross section shows haustoria tapping the host's phloem (LM).

Indian pipe, a nonphotosynthetic parasite. Also called the ghost flower, this species (*Monotropa uniflora*) absorbs nutrients from the fungal hyphae of mycorrhizae of green plants.

Carnivorous Plants

Carnivorous plants are photosynthetic but obtain some nitrogen and minerals by killing and digesting insects and other small animals.

Carnivorous plants live in acid bogs and other habitats where soils are poor in nitrogen and other minerals. Various insect traps consist of modified leaves, usually equipped with glands that secrete digestive enzymes. Fortunately for animals, such turnabouts are rare!

Venus flytrap. Triggered by electrical impulses from sensory hairs, two leaf lobes close in half a second. Despite its common name, *Dionaea muscipula* usually catches ants and grasshoppers.

Pitcher plants. *Nepenthes*, *Sarracenia*, and other genera have water-filled funnels. The insects drown and are digested by enzymes.

Sundews. Sundews (genus *Drosera*) exude a sticky fluid that glitters like dew. Insects get stuck to the leaf hairs, which enfold the prey.

SUMMARY OF KEY CONCEPTS

CONCEPT 37.1

Soil is a living, finite resource (pp. 785–789)

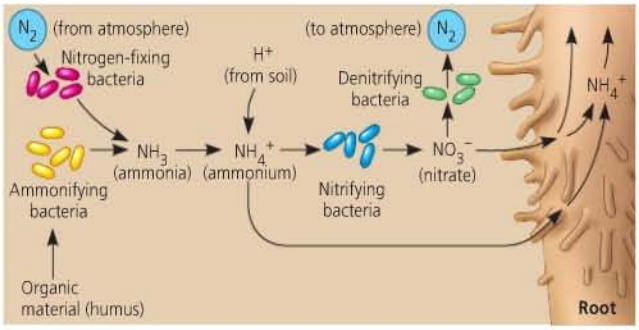
- **Soil Texture** Particles of various sizes derived from the breakdown of rock are found in soil. Soil particle size affects the availability of water, oxygen, and minerals in the soil.
- **Topsoil Composition** A soil's composition refers to its inorganic and organic components. Topsoil is a complex ecosystem teeming with bacteria, fungi, protists, animals, and the roots of plants.
- **Soil Conservation and Sustainable Agriculture** Some agricultural practices can deplete the mineral content of soil, tax water reserves, and promote erosion. The goal of soil conservation is to minimize this damage.

MEDIA

Activity How Plants Obtain Minerals from Soil
Investigation How Does Acid Precipitation Affect Mineral Deficiency?
GraphIt! Global Soil Degradation

CONCEPT 37.2

Plants require essential elements to complete their life cycle (pp. 789–792)



- **Macronutrients and Micronutrients** Macronutrients, elements required in relatively large amounts, include carbon, oxygen, hydrogen, nitrogen, and other major ingredients of organic compounds. Micronutrients, elements required in very small amounts, typically have catalytic functions as cofactors of enzymes.
- **Symptoms of Mineral Deficiency** Deficiency of a mobile nutrient usually affects older organs more than younger ones; the reverse is true for nutrients that are less mobile within a plant. Macronutrient deficiencies are most common, particularly deficiencies of nitrogen, phosphorus, and potassium.
- **Improving Plant Nutrition by Genetic Modification: Some Examples** Rather than tailoring the soil to match the plant, genetic engineers are tailoring the plant to match the soil.

CONCEPT 37.3

Plant nutrition often involves relationships with other organisms (pp. 792–798)

- **Soil Bacteria and Plant Nutrition** Many soil bacteria are decomposers, living on decaying organic material. Other soil bacteria, called rhizobacteria, derive their energy from the rhizosphere, a microbe-enriched ecosystem intimately associated with roots. Plant secretions support the energy needs of the rhizosphere. Some rhizobacteria produce antibiotics, whereas others make nutrients more available for plants. Most are free-living, but some live inside plants.

Plants satisfy most of their huge needs for nitrogen from the bacterial decomposition of humus and the fixation of gaseous nitrogen.

Nitrogen-fixing bacteria convert atmospheric N_2 to nitrogenous minerals that plants can absorb as a nitrogen source for organic synthesis. The most efficient mutualism between plants and nitrogen-fixing bacteria occurs in the nodules formed by *Rhizobium* bacteria growing in the roots of legumes. These bacteria obtain sugar from the plant and supply the plant with fixed nitrogen. In agriculture, legume crops are rotated with other crops to restore nitrogen to the soil.

- **Fungi and Plant Nutrition** Mycorrhizae are mutualistic associations of fungi and roots. The fungal hyphae of both ectomycorrhizae and arbuscular mycorrhizae absorb water and minerals, which they supply to their plant hosts.
- **Epiphytes, Parasitic Plants, and Carnivorous Plants** Epiphytes grow on the surfaces of other plants but acquire water and minerals from rain. Parasitic plants absorb nutrients from host plants. Carnivorous plants supplement their mineral nutrition by digesting animals.

Activity The Nitrogen Cycle

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Most of the mass of organic material of a plant comes from
   a. water.
   b. carbon dioxide.
   c. soil minerals.
   d. atmospheric oxygen.
   e. nitrogen.

2. Micronutrients are needed in very small amounts because
   a. most of them are mobile in the plant.
   b. most serve mainly as cofactors of enzymes.
   c. most are supplied in large enough quantities in seeds.
   d. they play only a minor role in the growth and health of the plant.
   e. only the most actively growing regions of the plants require micronutrients.

3. The rhizosphere would best be described as
   a. legume root swellings that are involved in nitrogen fixation.
   b. the part of the topsoil that supplies carbohydrates to plants.
   c. soil that is bound to roots and differs from the surrounding soil in containing many more microbes.
   d. the spherical soil horizon in which roots typically grow.
   e. all of the living organisms that inhabit the soil.

4. Some of the problems associated with intensive irrigation include all but
   a. mineral runoff.
   b. overfertilization.
   c. land subsidence.
   d. aquifer depletion.
   e. soil salinization.

5. A mineral deficiency is likely to affect older leaves more than younger leaves if
   a. the mineral is a micronutrient.
   b. the mineral is very mobile within the plant.
   c. the mineral is required for chlorophyll synthesis.
   d. the mineral is a macronutrient.
   e. the older leaves are in direct sunlight.

6. Two groups of tomatoes were grown under laboratory conditions, one with humus added to the soil and one a control without humus. The leaves of the plants grown without humus were yellowish (less green) compared with those of the plants grown in humus-enriched soil. The best explanation for this difference is that
   a. the healthy plants used the food in the decomposing leaves of the humus for energy to make chlorophyll.
   b. the humus made the soil more loosely packed, so water penetrated more easily to the roots.
   c. the humus contained minerals such as magnesium and iron, needed for the synthesis of chlorophyll.
   d. the heat released by the decomposing leaves of the humus caused more rapid growth and chlorophyll synthesis.
   e. the healthy plants absorbed chlorophyll from the humus.

7. The specific relationship between a legume and its mutualistic *Rhizobium* strain probably depends on
   a. each legume having a chemical dialog with a fungus.
   b. each *Rhizobium* strain having a form of nitrogenase that works only in the appropriate legume host.
   c. each legume being found where the soil has only the *Rhizobium* specific to that legume.
   d. specific recognition between the chemical signals and signal receptors of the *Rhizobium* strain and legume species.
   e. destruction of all incompatible *Rhizobium* strains by enzymes secreted from the legume's roots.

8. Mycorrhizae enhance plant nutrition mainly by
   a. absorbing water and minerals through the fungal hyphae.
   b. providing sugar to the root cells, which have no chloroplasts of their own.
   c. converting atmospheric nitrogen to ammonia.
   d. enabling the roots to parasitize neighboring plants.
   e. stimulating the development of root hairs.

9. We would expect the greatest difference in plant health between two groups of plants of the same species, one group with mycorrhizae and one group without mycorrhizae, in an environment
   a. where nitrogen-fixing bacteria are abundant.
   b. that has soil with poor drainage.
   c. that has hot summers and cold winters.
   d. in which the soil is relatively deficient in mineral nutrients.
   e. that is near a body of water, such as a pond or river.

10. Carnivorous adaptations of plants mainly compensate for soil that has a relatively low content of
    a. potassium.
    b. nitrogen.
    c. calcium.
    d. water.
    e. phosphate.

11. **DRAW IT** Draw a simple sketch of cation exchange, showing a root hair, a soil particle with anions, and a hydrogen ion displacing a mineral cation.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

12. Imagine taking the plant out of the picture in Figure 37.9. Write a paragraph explaining how soil bacteria could sustain the recycling of nitrogen *before* land plants evolved.

SCIENTIFIC INQUIRY

13. Acid precipitation has an abnormally high concentration of hydrogen ions (H^+). One effect of acid precipitation is to deplete the soil of nutrients such as calcium (Ca^{2+}), potassium (K^+), and magnesium (Mg^{2+}). Suggest a hypothesis to explain how acid precipitation washes these nutrients from the soil. How might you test your hypothesis?

SCIENCE, TECHNOLOGY, AND SOCIETY

14. About 10% of U.S. cropland is irrigated. Agriculture is by far the biggest user of water in arid western states, including Colorado, Arizona, and California. As the populations of these states grow, there is ongoing conflict between cities and farm regions over water. To ensure adequate water supplies for urban growth, cities are buying water rights from farmers. This is often the least expensive way to obtain more water, and it is possible for some farmers to make more money by selling water rights than by growing crops. Discuss the possible consequences of this trend. Is this the best way to allocate water? Why or why not?

38 Angiosperm Reproduction and Biotechnology

▲ **Figure 38.1 Why is this wasp trying to mate with this flower?**

KEY CONCEPTS

38.1 Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle

38.2 Flowering plants reproduce sexually, asexually, or both

38.3 Humans modify crops by breeding and genetic engineering

OVERVIEW

Flowers of Deceit

Male wasps of the species *Campsoscolia ciliata* often attempt to copulate with the flowers of the Mediterranean orchid *Ophrys speculum* **(Figure 38.1)**. During this encounter, a sac of pollen becomes glued to the insect's body. Eventually frustrated, the wasp flies off and deposits the pollen onto another *Ophrys* flower that has become the object of his misplaced ardor. *Ophrys* flowers offer no reward such as nectar to the male wasps, only sexual frustration. So what makes the male wasps so enamored of this orchid? The traditional answer has been that the shape of the orchid's largest petal and the frill of orange bristles around it vaguely resemble the female wasp. These visual cues, however, are only part of the deception: *Ophrys* orchids also emit chemicals with a scent similar to that produced by sexually receptive female wasps.

This orchid and its wasp pollinators are one example of the amazing ways in which angiosperms (flowering plants) reproduce sexually with spatially distant members of their own species. Sex, however, is not their only means of reproduction. Many species also reproduce asexually, creating offspring that are genetically identical to the parent.

An unusual aspect of the orchid and wasp example is that the insect does not profit from interacting with the flower. In fact, by wasting time and energy trying to copulate with it, the wasp is probably rendered less fit. More typically, a plant lures an animal pollinator to its flowers not with offers of sex but with rewards of energy-rich nectar or pollen. Thus, both plant and pollinator benefit; that is, the symbiotic relationship is mutualistic. Participating in mutualistic relationships with other organisms is very common in the plant kingdom. In fact, in recent evolutionary times, some flowering plants have formed mutualistic relationships with an animal that not only disperses their seeds but also provides the plants with water and mineral nutrients and vigorously protects them from encroaching competitors, pathogens, and predators. In return for these favors, the animal typically gets to eat a fraction of the plants' seeds and fruits. The plant symbionts involved in these remarkable mutualistic interactions are called crops; the animal symbionts are called humans.

Since the origins of crop domestication over 10,000 years ago, plant breeders have genetically manipulated the traits of a few hundred wild angiosperm species by artificial selection, transforming them into the crops we grow today. Genetic engineering has dramatically increased the variety of ways and the speed with which we can now modify plants.

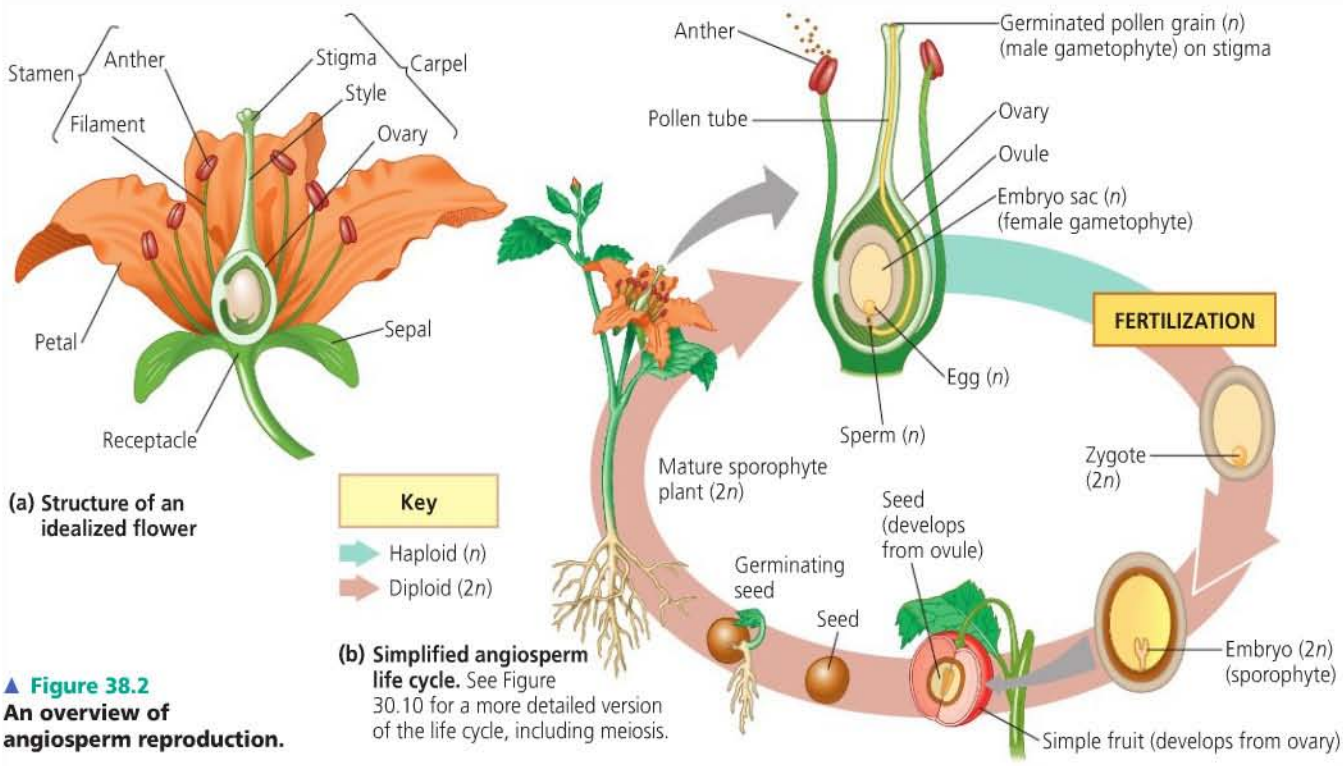
In Chapters 29 and 30, we approached plant reproduction from an evolutionary perspective, tracing the descent of land plants from algal ancestors. Here, we'll explore the reproductive biology of flowering plants in much greater detail because they are the most important group of plants in most terrestrial ecosystems and in agriculture. After discussing the sexual and asexual reproduction of angiosperms, we'll examine the role of humans in genetically altering crop species, as well as the controversies surrounding modern plant biotechnology.

CONCEPT **38.1**

Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle

The life cycles of plants are characterized by an alternation of generations, in which multicellular haploid (n) and diploid ($2n$)

generations take turns producing each other (see Figures 29.5 and 30.10). The diploid plant, the sporophyte, produces haploid spores by meiosis. These spores divide by mitosis, giving rise to the multicellular gametophytes, the male and female haploid plants that produce gametes (sperm and eggs). **Fertilization**, the fusion of gametes, results in diploid zygotes, which divide by mitosis and form new sporophytes. In angiosperms, the sporophyte is the dominant generation: It is larger, more conspicuous, and longer-lived than the gametophyte. Over the course of seed plant evolution, gametophytes became reduced in size and wholly dependent on the sporophyte for nutrients. Angiosperm gametophytes are the most reduced of all plants, consisting of only a few cells. **Figure 38.2** reviews the angiosperm life cycle, which is shown in more detail in Figure 30.10. The key derived traits of the angiosperm life cycle can be remembered as the "three Fs"—*f*lowers, double *f*ertilization, and *f*ruits. Since angiosperms, along with gymnosperms, are seed plants, a knowledge of seed structure and function is also critical to understanding the angiosperm life cycle.



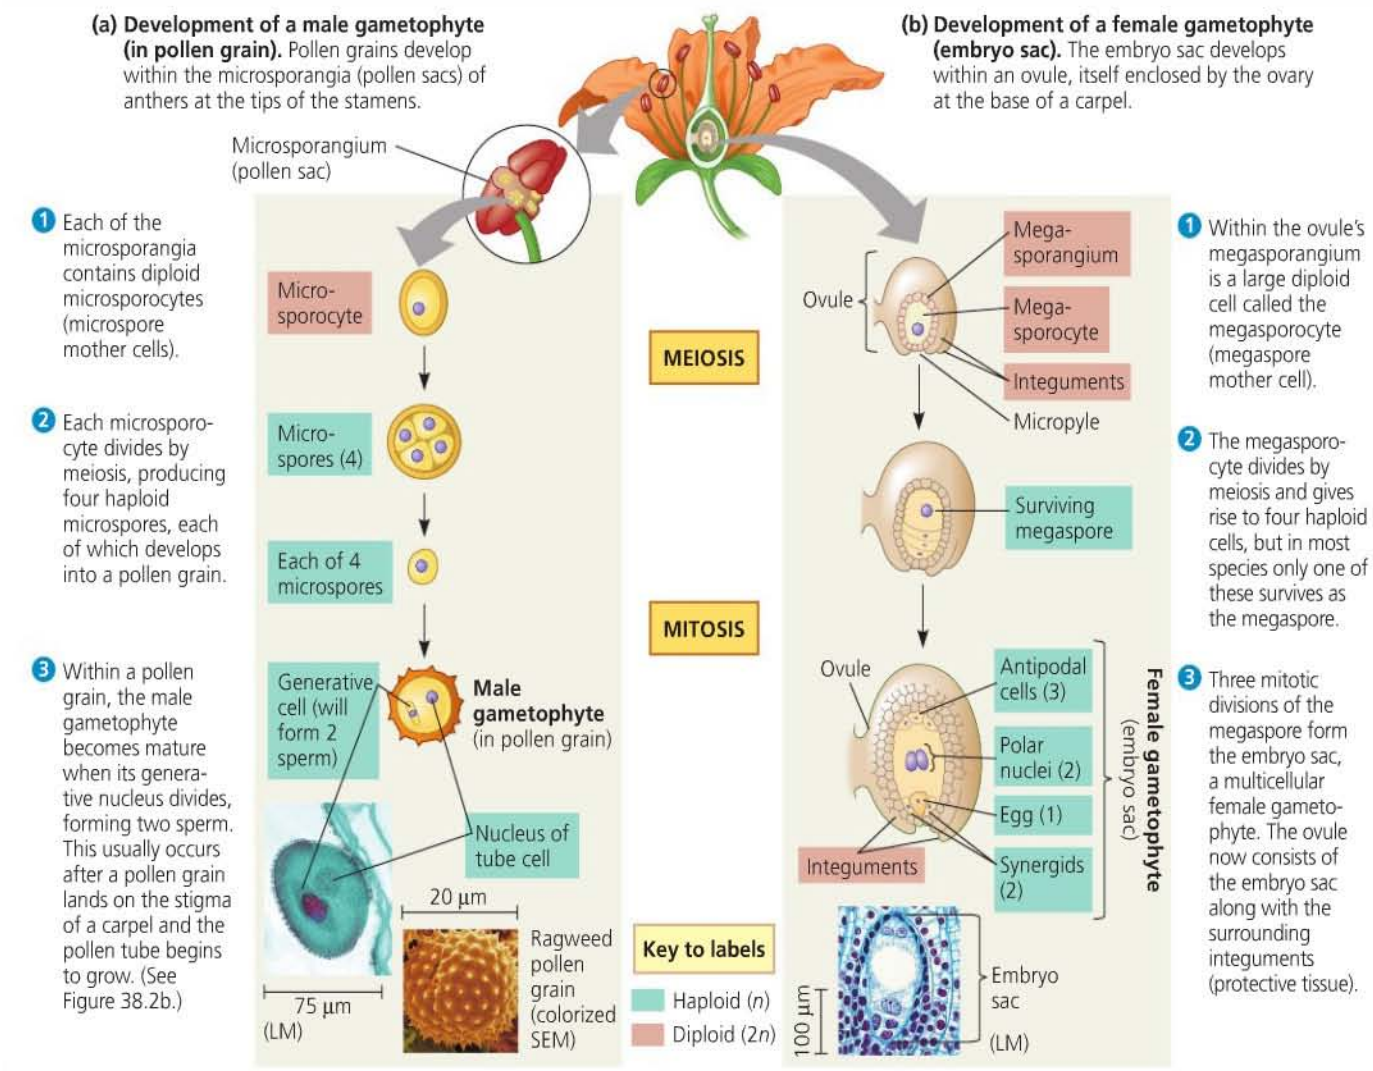
Flower Structure and Function

Flowers, the reproductive shoots of angiosperm sporophytes, are typically composed of four whorls of modified leaves called floral organs, which are separated by short internodes. Unlike vegetative shoots, flowers are determinate shoots. That is, they cease growing after the flower and fruit are formed.

Floral organs—**sepals, petals, stamens**, and **carpels**—are attached to a part of the stem called the **receptacle**. Stamens and carpels are reproductive organs, whereas sepals and petals are sterile. Sepals, which enclose and protect the floral bud before it opens, are usually green and more leaflike in appearance than the other floral organs. In many species, petals are more brightly colored than sepals and advertise the flower to insects and other pollinators.

A stamen consists of a stalk called the *filament* and a terminal structure called the **anther**; within the anther are chambers called microsporangia (pollen sacs) that produce pollen. A carpel has an **ovary** at its base and a long, slender neck called the **style**. At the top of the style is a generally sticky structure called the **stigma** that serves as a landing platform for pollen. Within the ovary are one or more **ovules**; the number of ovules depends on the species. The flower shown in Figure 38.2 has a single carpel, but many species have multiple carpels. In most species, two or more are fused into a single structure; the result is an ovary with two or more chambers, each containing one or more ovules. The term **pistil** is sometimes used to refer to a single carpel or a group of fused carpels.

Complete flowers have all four basic floral organs (see Figure 38.2a). Some species have **incomplete flowers**, lacking sepals, petals, stamens, or carpels. For example, most grass flowers lack petals. Some incomplete flowers are sterile, lacking functional stamens and carpels; others are *unisexual*, lacking either stamens or carpels. Flowers also vary in size, shape, color, odor, organ arrangement, and time of opening. Some are borne singly, while others are arranged in showy clusters called **inflorescences**. For example, a sunflower's central disk consists of hundreds of tiny incomplete flowers, and what look like petals are actually sterile flowers (see Figure 1.3). Much of floral diversity represents adaptation to specific pollinators.



▲ **Figure 38.2 An overview of angiosperm reproduction.**

Development of Male Gametophytes in Pollen Grains

Each anther contains four microsporangia, also known as pollen sacs. Within the microsporangia are many diploid cells called microsporocytes, or microspore mother cells **(Figure 38.3a)**. Each microsporocyte undergoes meiosis, forming four haploid **microspores**, each of which eventually gives rise to a haploid male gametophyte. Each microspore then undergoes mitosis, producing a male gametophyte consisting of only two cells: the *generative cell* and the *tube cell*. Together, these two cells and the spore wall constitute a **pollen grain**. The spore wall, which consists of material produced by both the microspore and the anther, usually exhibits an elaborate pattern unique to the species. During maturation of the male gametophyte, the generative cell passes into the tube cell and the spore wall is completed. The tube cell now has a completely free-standing cell inside it. After the microsporangium breaks open and releases the pollen, a pollen grain may be transferred to a receptive surface of a stigma. There, the tube cell produces the **pollen tube**, a long cellular protuberance that delivers sperm to the female gametophyte. Pollen tubes can grow very quickly, at rates of 1 cm/hr or more. As a pollen tube elongates through the style, the generative cell usually divides and produces two sperm cells, which remain inside the tube cell (see Figure 30.10). The pollen tube grows through the style and into the ovary, where it releases the sperm cells in the vicinity of the female gametophyte.

Development of Female Gametophytes (Embryo Sacs)

Among angiosperm species, there are over 15 variations in the development of the female gametophyte, also known as an **embryo sac**. We'll focus on just one. The entire process occurs within the carpel's ovary, in a tissue within each ovule called the megasporangium. Two *integuments* (layers of protective sporophytic tissue that will develop into the seed coat) surround each megasporangium except at a gap called the *micropyle*. Female gametophyte development begins when one cell in the megasporangium of each ovule, the *megasporocyte* (or megaspore mother cell), enlarges and undergoes meiosis, producing four haploid **megaspores (Figure 38.3b)**. Only one megaspore survives; the others disintegrate.

▲ **Figure 38.3 The development of male and female gametophytes in angiosperms.**

The surviving megaspore continues to grow, and its nucleus divides by mitosis three times without cytokinesis, resulting in one large cell with eight haploid nuclei. Membranes then partition this mass into a multicellular female gametophyte—the embryo sac. Three of the cells within the embryo sac are near the micropyle: the egg cell and two cells called synergids. The synergids flank the egg cell and help attract and guide the pollen tube to the embryo sac. At the opposite end of the embryo sac are three antipodal cells of unknown function. The remaining two nuclei, called polar nuclei, are not partitioned into separate cells but instead share the cytoplasm of the large central cell of the embryo sac. The ovule, which will eventually become a seed, now consists of the embryo sac and two surrounding integuments.

▼ **Figure 38.4**

Exploring Flower Pollination

Some angiosperm species can self-pollinate, but such species are limited to inbreeding in nature. Most angiosperm species rely on a living (biotic) or nonliving (abiotic) pollinating agent that can move pollen from the anther of a stamen of a flower on one plant to the stigma of a carpel of a flower on another plant. Approximately 80% of all angiosperm pollination is biotic, employing animal go-betweens. Among abiotically pollinated species, 98% rely on wind and 2% on water.

▲ Hazel staminate flowers (stamens only)

◀ Hazel carpellate flower (carpels only)

Abiotic Pollination by Wind

About 20% of all angiosperm species are wind-pollinated. Since their reproductive success does not depend on attracting pollinators, there was no selective pressure favoring colorful or scented flowers. Accordingly, the evolution of wind-pollinated species has resulted in flowers that are often small, green, and inconspicuous, and they produce neither nectar nor scent. Most temperate trees and grasses are wind-pollinated. The flowers of hazel (*Corylus avellana* shown here) and many other temperate, wind-pollinated trees appear in the early spring, when leaves are not present to interfere with pollen movement. The relative inefficiency of wind pollination is compensated for by production of copious amounts of pollen grains. Wind tunnel studies reveal that wind pollination is often more efficient than it appears because floral structures can create eddy currents that aid in pollen capture.

▲ Common dandelion under normal light

▶ Common dandelion under ultraviolet light

Pollination by Bees

About 65% of all flowering plants require insects for pollination; the percentage is even greater for major crops. Bees are the most important insect pollinators, and there is great concern in Europe and North America that honeybee populations have shrunk. Pollinating bees depend on nectar and pollen for food. Typically, bee-pollinated flowers have a delicate, sweet fragrance. Bees are attracted to bright colors, primarily yellow and blue. Red appears dull to them, but they can see ultraviolet radiation. Many bee-pollinated flowers, such as the common dandelion (*Taraxacum vulgare*), have markings called "nectar guides" that help insects locate the nectaries but are only visible to human eyes under ultraviolet light.

Pollination

In angiosperms, **pollination** is the transfer of pollen from an anther to a stigma. It is accomplished by wind, water, or animals **(Figure 38.4)**. In wind-pollinated species, including grasses and many trees, the release of enormous quantities of pollen compensates for the randomness of dispersal by the wind. At certain times of the year, the air is loaded with pollen grains, as anyone who is plagued with pollen allergies can attest. Some species of aquatic plants rely on water to disperse pollen. Most angiosperm species, however, depend on insects, birds, or other animal pollinators to transfer pollen directly from one flower to another flower. If pollination is successful, a pollen grain produces a pollen tube, which then grows down into the ovary via the style.

Pollination by Moths and Butterflies

▲ Moth on yucca flower

Moths and butterflies detect odors, and the flowers they pollinate are often sweetly fragrant. Butterflies perceive many bright colors, but moth-pollinated flowers are usually white or yellow, which stand out in low light (as at night). A yucca plant (shown here) is typically pollinated by a single species of moth with appendages that pack pollen onto the stigma. The moth then deposits eggs directly into the ovary. The larvae eat some developing seeds, but this cost is outweighed by the benefit of an efficient and reliable pollinator. If a moth deposits too many eggs, the flower aborts and drops off, selecting against individuals that overexploit the plant.

Pollination by Flies

Fly-pollinated flowers are reddish and fleshy, with an odor like rotten meat. Blowflies visiting carrion flowers (*Stapelia* species) mistake the flower for a rotting corpse and lay their eggs on it. In the process, the blowflies become dusted with pollen that they carry to other flowers. When the eggs hatch, the larvae find no carrion to eat and therefore die.

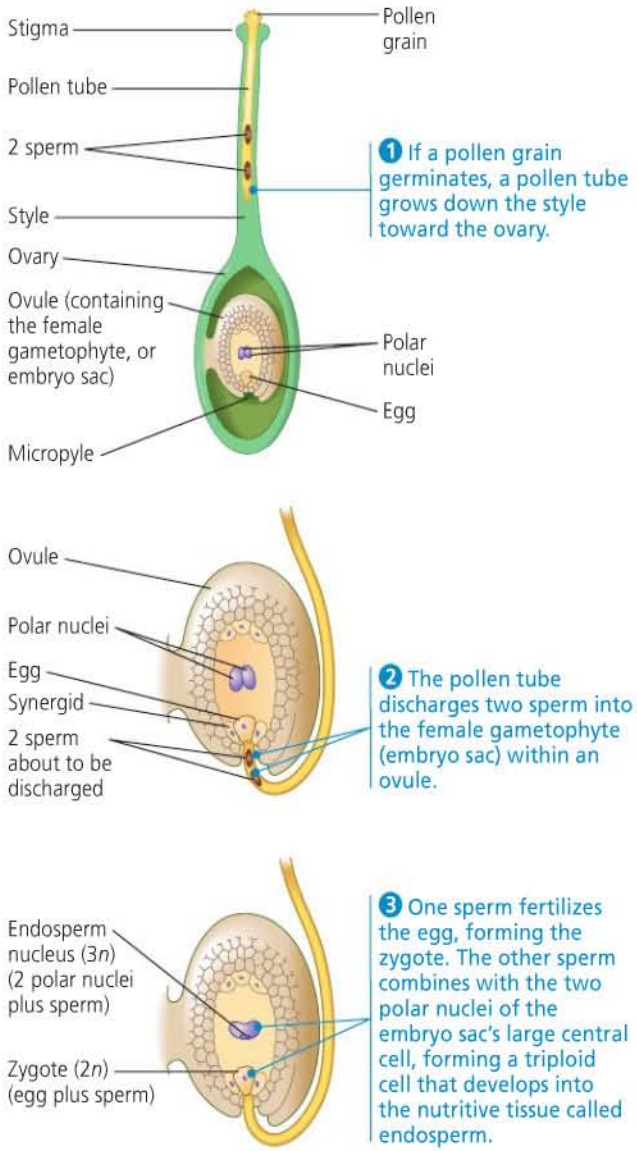
▲ Blowfly on carrion flower

Pollination by Birds

Bird-pollinated flowers, such as poro flowers, are usually large and bright red or yellow, but they have little odor. Since birds often do not have a well-developed sense of smell, there was no selective pressure favoring scent production. However, the flowers produce copious nectar that helps meet the high energy demands of the pollinating birds. Nectar is a sugary solution produced by nectaries at the base of many flowers. Nectar's primary function is to "reward" the pollinator. The petals of such flowers often fuse, forming a bent floral tube that fits the curved beak of the bird.

▲ Hummingbird drinking nectar of poro flower

? *What are the benefits and dangers to a plant of having a highly specific animal pollinator?*



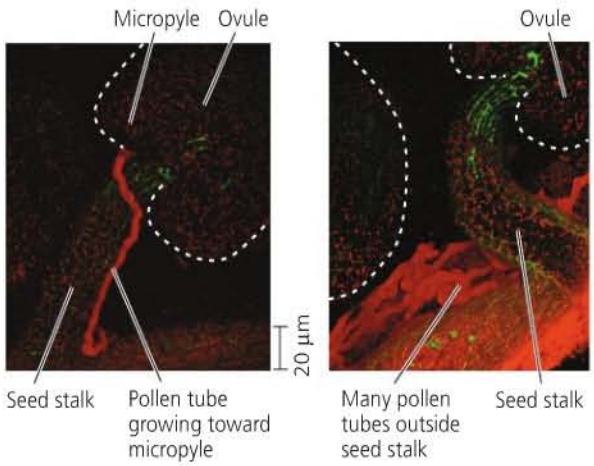
Pollination by Bats

Bat-pollinated flowers, like moth-pollinated flowers, are light-colored and aromatic, attracting their nocturnal pollinators. The lesser long-nosed bat (*Leptonycteris curasoae yerbabuenae*) feeds on the nectar and pollen of agave and cactus flowers in the southwestern United States and Mexico. In feeding, the bats transfer pollen from plant to plant. Long-nosed bats are on the federal list of endangered species.

▲ Long-nosed bat feeding on cactus flower at night

Double Fertilization

At the time of pollination, the living pollen grain typically consists of only the tube cell and the generative cell. After a pollen grain lands on a suitable stigma, it absorbs water and germinates by producing a pollen tube, which grows between the cells of the style toward the ovary **(Figure 38.5)**. The nucleus of the generative cell divides by mitosis and forms two sperm. Directed by a chemical attractant produced by the two synergids flanking the egg, the tip of the pollen tube enters the ovule through the micropyle and discharges its two sperm near or within the female gametophyte (embryo sac). A gradient in gamma-aminobutyric acid (GABA), a chemical that functions as a neurotransmitter in animal cells, may be the critical signal for attracting the pollen tube **(Figure 38.6)**.



▲ **Figure 38.5 Growth of the pollen tube and double fertilization.**

Upon reaching the female gametophyte, one sperm fertilizes the egg, forming the zygote. The other sperm combines with the two polar nuclei, forming a triploid ($3n$) nucleus in the center of the large central cell of the female gametophyte. This large cell will give rise to the **endosperm**, a food-storing tissue of the seed. The union of two sperm cells with different nuclei of the female gametophyte is called **double fertilization**. Dou-

▼ Figure 38.6 Inquiry

Do GABA gradients play a role in directing pollen tubes to the eggs in *Arabidopsis*?

EXPERIMENT Researchers at the University of Chicago found an *Arabidopsis* mutant (carrying a mutation called *pop2*) that failed to produce viable seeds because pollen tubes couldn't seem to "find" the egg. In wild-type *Arabidopsis*, the pollen tubes (thick red lines in the LMs below) have little trouble finding the egg, but in *pop2* mutants none of the numerous pollen tubes turn down the seed stalk toward the micropyle and the egg. The *pop2* mutation was mapped, and the wild-type allele was identified as coding for a protein related to gamma-aminobutyric acid (GABA) transaminase, an enzyme that breaks down GABA. The researchers tested the hypothesis that GABA plays a role in pollen tube guidance by measuring GABA levels in the flowers of *pop2* and wild-type flowers and by examining the effects of GABA on pollen tube growth *in vitro*.

RESULTS GABA levels were 113-fold higher in *pop2* flowers than in wild-type flowers. Other intermediates in the GABA pathway were unaffected by *pop2*. Measurements of GABA content in wild-type flowers revealed a gradient from the stigma (low) to the ovary (high), but this gradient was disrupted in the *pop2* mutant. *In vitro*, GABA stimulated pollen tube growth, although vast excesses were inhibitory.

CONCLUSION A GABA gradient helps guide the pollen tube to the egg in *Arabidopsis* flowers.

SOURCE R. Palinivelu et al., Pollen tube growth and guidance is regulated by *POP2*, an *Arabidopsis* gene that controls GABA levels, *Cell* 114: 47–59 (2003).

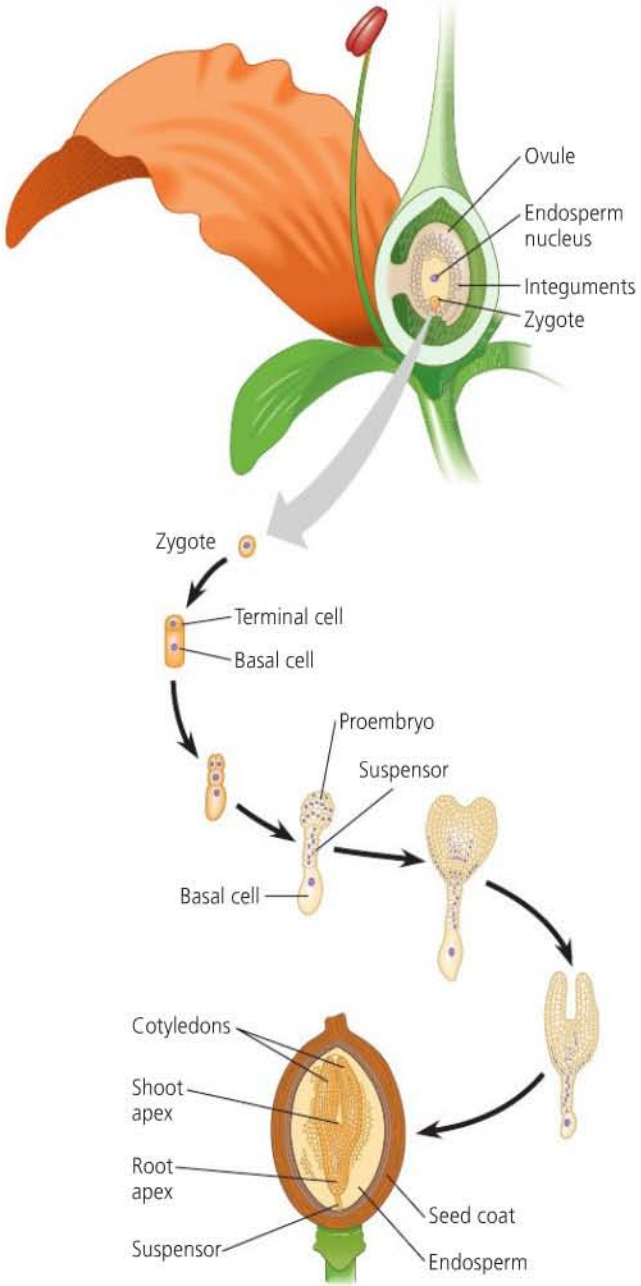
WHAT IF? What phenotypic effects would occur in a mutant that could not synthesize any GABA in its flowers?

ble fertilization ensures that the endosperm will develop only in ovules where the egg has been fertilized, thereby preventing angiosperms from squandering nutrients.

The tissues surrounding the female gametophyte have prevented researchers from directly observing fertilization in plants grown under normal conditions. Scientists have, however, isolated sperm from germinated pollen grains and eggs from female gametophytes and have observed the merging of plant gametes *in vitro* (in an artificial environment). The first cellular event that takes place after gamete fusion is an increase in the levels of cytoplasmic calcium ions (Ca^{2+}) in the egg, as also occurs during animal gamete fusion (see Chapter 47). Another similarity to animals is the establishment of a block to *polyspermy,* the fertilization of an egg by multiple sperm. Thus, sperm cannot fuse with zygotes even *in vitro.* In maize (*Zea mays*), for example, this barrier to polyspermy is established as early as 45 seconds after the initial sperm fusion with the egg.

Seed Development, Form, and Function

After double fertilization, each ovule develops into a seed, and the ovary develops into a fruit enclosing the seed(s). As the embryo develops from the zygote, the seed stockpiles proteins, oils, and starch to varying degrees, depending on the species. This is why seeds are such major sugar sinks—sites of sugar use and storage (see Chapter 36). Initially, these nutrients are stored in the seed's endosperm, although later in seed development, the main nutrient-storage sites for most species are the swelling cotyledons, or seed leaves, of the embryo.



Endosperm Development

Endosperm usually develops before the embryo does. After double fertilization, the triploid nucleus of the ovule's central cell divides, forming a multinucleate "supercell" that has a milky consistency. This liquid mass, the endosperm, becomes multicellular when cytokinesis partitions the cytoplasm by forming membranes between the nuclei. Eventually, these "naked" cells produce cell walls, and the endosperm becomes solid. Coconut "milk" and "meat" are examples of liquid and solid endosperm, respectively. The white fluffy part of popcorn is also solid endosperm.

In grains and most other species of monocots, as well as many eudicots, the endosperm stores nutrients that can be used by the seedling after germination. In other eudicot seeds (including those of beans), the food reserves of the endosperm are completely exported to the cotyledons before the seed completes its development; consequently, the mature seed lacks endosperm.

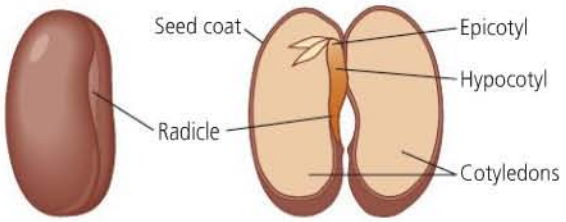
Embryo Development

The first mitotic division of the zygote splits the fertilized egg into a basal cell and a terminal cell **(Figure 38.7)**. The terminal cell eventually gives rise to most of the embryo. The basal cell continues to divide, producing a thread of cells called the *suspensor,* which anchors the embryo to the parent plant. The suspensor helps in transferring nutrients to the embryo from the parent plant and, in some species of plants, from the endosperm. As the suspensor elongates, it pushes the embryo deeper into the nutritive and protective tissues. Meanwhile, the terminal cell divides several times and forms a spherical proembryo (early embryo) attached to the suspensor. The cotyledons begin to form as bumps on the proembryo. A

▲ **Figure 38.7 The development of a eudicot plant embryo.** By the time the ovule becomes a mature seed and the integuments harden and thicken into the seed coat, the zygote has given rise to an embryonic plant with rudimentary organs.

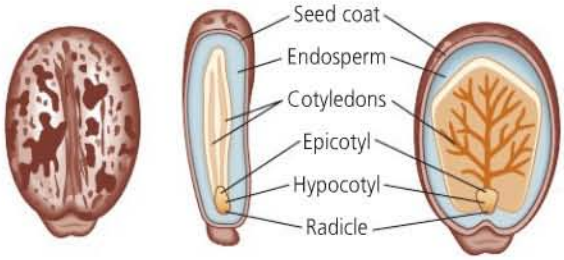
eudicot, with its two cotyledons, is heart-shaped at this stage. Only one cotyledon develops in monocots.

Soon after the rudimentary cotyledons appear, the embryo elongates. Cradled between the two cotyledons is the embryonic shoot apex, which includes the shoot apical meristem. At the opposite end of the embryo's axis, where the suspensor attaches, is the embryonic root apex, which includes the root apical meristem. After the seed germinates—indeed, for the rest of the plant's life—the apical meristems at the tips of shoots and roots sustain primary growth (see Figure 35.11).



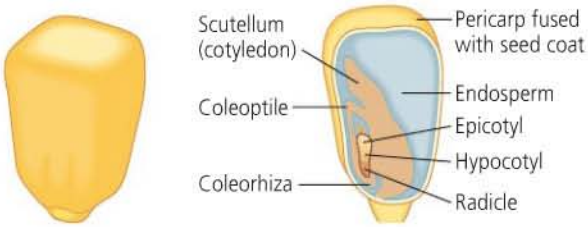
Structure of the Mature Seed

During the last stages of its maturation, the seed dehydrates until its water content is only about 5–15% of its weight. The embryo, which is surrounded by a food supply (cotyledons, endosperm, or both), enters **dormancy**; that is, it stops growing and its metabolism nearly ceases. The embryo and its food supply are enclosed by a hard, protective **seed coat** formed from the integuments of the ovule. In some species, dormancy is imposed by the presence of an intact seed coat rather than by the embryo itself.



You can take a closer look at one type of eudicot seed by splitting open the seed of a common garden bean. The embryo consists of an elongate structure, the embryonic axis, attached to fleshy cotyledons **(Figure 38.8a)**. Below where the cotyledons are attached, the embryonic axis is called the **hypocotyl** (from the Greek *hypo*, under). The hypocotyl terminates in the **radicle**, or embryonic root. The portion of the embryonic axis above where the cotyledons are attached and below the first pair of miniature leaves is the **epicotyl** (from the Greek *epi*, on, over). The epicotyl, young leaves, and shoot apical meristem are collectively called the *plumule*.

The cotyledons of the common garden bean are packed with starch before the seed germinates because they absorbed carbohydrates from the endosperm when the seed was developing. However, the seeds of some eudicot species, such as castor beans (*Ricinus communis*), retain their food supply in the endosperm and have very thin cotyledons **(Figure 38.8b)**. The cotyledons absorb nutrients from the endosperm and transfer them to the rest of the embryo when the seed germinates.



The embryo of a monocot has a single cotyledon **(Figure 38.8c)**. Members of the grass family, including maize and wheat, have a specialized cotyledon called a *scutellum* (from the Latin *scutella*, small shield, a reference to its shape). The scutellum, which has a large surface area, is pressed against the endosperm, from which it absorbs nutrients during germination. The embryo of a grass seed is enclosed by two protective sheathes: a **coleoptile**, which covers the young shoot, and a **coleorhiza**, which covers the young root.

(a) Common garden bean, a eudicot with thick cotyledons. The fleshy cotyledons store food absorbed from the endosperm before the seed germinates.

(b) Castor bean, a eudicot with thin cotyledons. The narrow, membranous cotyledons (shown in edge and flat views) absorb food from the endosperm when the seed germinates.

(c) Maize, a monocot. Like all monocots, maize has only one cotyledon. Maize and other grasses have a large cotyledon called a scutellum. The rudimentary shoot is sheathed in a structure called the coleoptile, and the coleorhiza covers the young root.

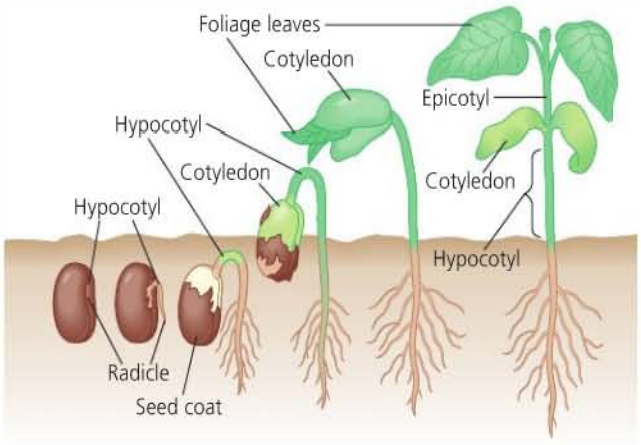
▲ **Figure 38.8 Seed structure.**

Seed Dormancy: An Adaptation for Tough Times

Dormancy (from the Latin word meaning "to sleep") is a condition of extremely low metabolic rate and suspension of growth and development. Environmental conditions required to break dormancy vary among species. Seeds of some species germinate as soon as they are in a suitable environment. Others remain dormant, even if sown in a favorable place, until an environmental cue causes them to break dormancy.

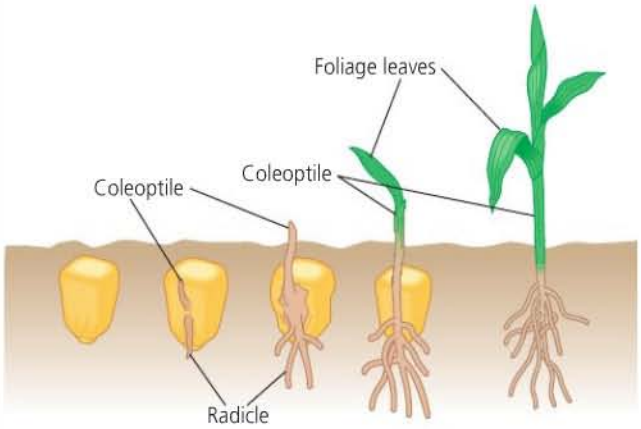
The requirement for specific cues to break seed dormancy increases the chances that germination will occur at a time and place most advantageous to the seedling. Seeds of many desert plants, for instance, germinate only after a substantial rainfall. If they were to germinate after a mild drizzle, the soil might soon become too dry to support the seedlings. Where natural fires are common, many seeds re-

quire intense heat or smoke to break dormancy; seedlings are therefore most abundant after fire has cleared away competing vegetation. Where winters are harsh, seeds may require extended exposure to cold. Seeds sown during summer or fall do not germinate until the following spring, ensuring a long growth season before the next winter. Some small seeds, such as those of some lettuce varieties, require light for germination and will break dormancy only if buried shallow enough for the seedlings to poke through the soil surface. Some seeds have coats that must be weakened by chemical attack as they pass through an animal's digestive tract and thus are usually carried a considerable distance before being defecated.



The length of time a dormant seed remains viable and capable of germinating varies from a few days to decades or even longer, depending on the plant species and environmental conditions. Most seeds are durable enough to last a year or two until conditions are favorable for germinating. Thus, the soil has a bank of ungerminated seeds that may have accumulated for several years. This is one reason vegetation reappears so rapidly after a fire, drought, flood, or other environmental disruption.

Seed Germination and Seedling Development

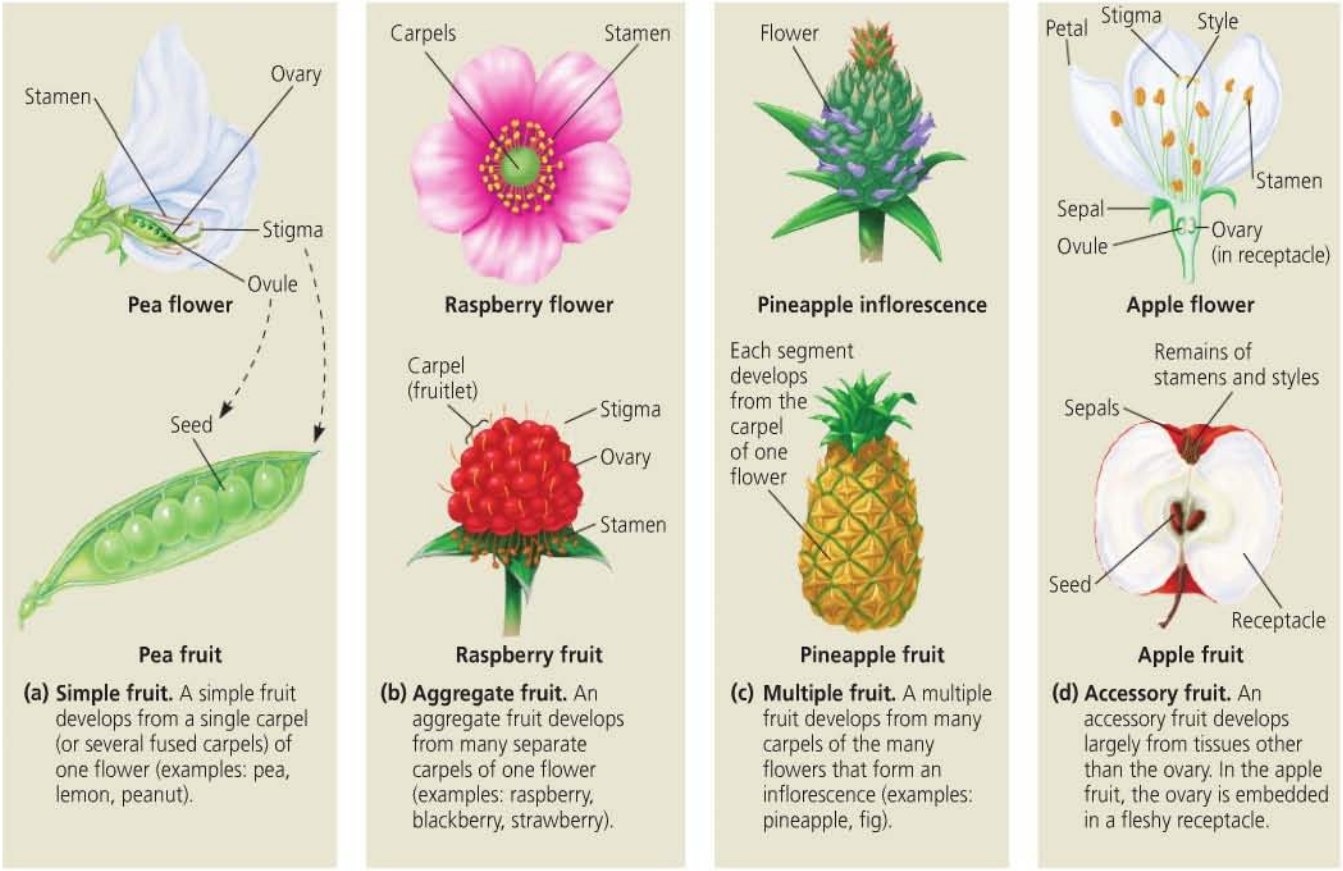


Germination depends on **imbibition**, the uptake of water due to the low water potential of the dry seed. Imbibing water causes the seed to expand and rupture its coat and also triggers metabolic changes in the embryo that enable it to resume growth. Following hydration, enzymes begin digesting the storage materials of the endosperm or cotyledons, and the nutrients are transferred to the growing regions of the embryo.

The first organ to emerge from the germinating seed is the radicle, the embryonic root. Next, the shoot tip must break through the soil surface. In garden beans and many other eudicots, a hook forms in the hypocotyl, and growth pushes the hook above ground **(Figure 38.9a)**. Stimulated by light, the hypocotyl straightens, raising the cotyledons and epicotyl. Thus, the delicate shoot tip and bulky cotyledons are pulled upward rather than being pushed tip-first through the abrasive soil. The epicotyl now spreads its first foliage leaves, which are true leaves, as distinguished from the cotyledons, or seed leaves. The foliage leaves expand, become green, and begin making food by photosynthesis. The cotyledons shrivel and fall away from the seedling, their food reserves having been exhausted by the germinating embryo.

Some monocots, such as maize and other grasses, use a different method for breaking ground when they germinate **(Figure 38.9b)**. The coleoptile, the sheath enclosing and protecting the embryonic shoot, pushes upward through the soil and into the air. The shoot tip then grows straight up through the tunnel provided by the tubular coleoptile and eventually breaks out through the coleoptile's tip.

(a) Common garden bean. In common garden beans, straightening of a hook in the hypocotyl pulls the cotyledons from the soil.



(b) Maize. In maize and other grasses, the shoot grows straight up through the tube of the coleoptile.

▲ **Figure 38.9 Two common types of seed germination.**
? *How do bean and maize seedlings protect their shoot systems as they push through the soil?*

Fruit Form and Function

While the seeds are developing from ovules, the ovary of the flower is developing into a **fruit**, which protects the enclosed seeds and, when mature, aids in their dispersal by wind or animals. Fertilization triggers hormonal changes that cause the ovary to begin its transformation into a fruit. If a flower has not been pollinated, fruit typically does not develop, and the entire flower usually withers and falls away.

During fruit development, the ovary wall becomes the pericarp, the thickened wall of the fruit. As the ovary grows, the other parts of the flower usually wither and are shed. For example, the pointed tip of a pea pod is the withered remains of the pea flower's stigma.

▲ **Figure 38.10 Developmental origin of fruits.**

Fruits are classified into several types, depending on their developmental origin. Most fruits are derived from a single carpel or several fused carpels and are called **simple fruits (Figure 38.10a)**. Some simple fruits are dry, such as a pea pod or a nut, whereas others are fleshy, such as a nectarine (see Figure 30.8). An **aggregate fruit** results from a single flower that has more than one separate carpel, each forming a small fruit **(Figure 38.10b)**. These "fruitlets" are clustered together on a single receptacle, as in a raspberry. A **multiple fruit** develops from an inflorescence, a group of flowers tightly clustered together. When the walls of the many ovaries start to thicken, they fuse together and become incorporated into one fruit, as in a pineapple **(Figure 38.10c)**.

In some angiosperms, other floral parts in addition to ovaries contribute to what we commonly call the fruit. Such fruits are called **accessory fruits**. In apple flowers, for example, the ovary is embedded in the receptacle, and the fleshy part of this simple fruit is derived mainly from the enlarged receptacle; only the apple core develops from the ovary **(Figure 38.10d)**. Another example is the strawberry, an aggregate fruit consisting of an enlarged receptacle embedded with tiny one-seeded fruits.

A fruit usually ripens about the same time that its seeds complete their development. Whereas the ripening of a dry fruit, such as a soybean pod, involves the aging and drying out of fruit tissues, the process in a fleshy fruit is more elaborate. Complex interactions of hormones result in an edible fruit that entices animals that help spread the seeds. The fruit's "pulp" becomes softer as a result of enzymes digesting components of the cell walls. The color usually changes from green to another color, such as red, orange, or yellow. The fruit becomes sweeter as organic acids or starch molecules are converted to sugar, which may reach a concentration of as much as 20% in a ripe fruit. **Figure 38.11** examines some mechanisms of fruit dispersal in more detail.

In this section, you have learned about the unique features of sexual reproduction in angiosperms—flowers, fruits, and double fertilization. As you will learn in the next section, many angiosperms also reproduce asexually.

CONCEPT CHECK 38.1

1. Distinguish between pollination and fertilization.
2. What is the advantage of seed dormancy?
3. Explain why the four types of fruits described in Figure 38.10 are not completely separate categories.
4. **WHAT IF?** If flowers had shorter styles, pollen tubes would more easily reach the embryo sac. Suggest an explanation for why very long styles have nevertheless evolved in most flowering plants.

For suggested answers, see Appendix A.

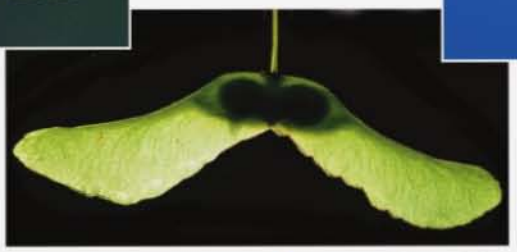
▼ Figure 38.11

Exploring Fruit and Seed Dispersal

A plant's life depends on finding fertile ground. But a seed that falls and sprouts beneath the parent plant stands little chance of competing successfully for nutrients. To prosper, seeds must be widely dispersed. Plants use biotic dispersal agents as well as abiotic agents such as water and wind.

Dispersal by Water

▶ Some buoyant seeds and fruits can survive months or years at sea. In coconut, the seed embryo and fleshy white "meat" (endosperm) are within a hard layer (endocarp) surrounded by a thick and buoyant fibrous husk.



Dispersal by Wind

▶ The winged seed of the tropical Asian climbing gourd *Alsomitra macrocarpa* glides through the air of the rain forest in wide circles when released.

▶ Some seeds and fruits have "parachutes" with an umbrella-like crown of intricately branched hairs, often produced in puffy clusters, such as these dandelion seeds. The slightest gust carries them aloft.

▶ The winged fruits of maples spin like helicopter blades, slowing descent and increasing the chance of being carried farther by horizontal winds.

▶ Some tumbleweeds break off at the ground and tumble across the terrain, scattering their seeds.

Dispersal by Animals

▶ The sharp, tack-like spines on the fruits of puncture vine (*Tribulus terrestris*) can pierce bicycle tires and injure animals, including humans. When these painful "tacks" are removed and discarded, the seeds are dispersed.

◀ Seeds in edible fruits are often dispersed in feces, such as the black bear feces shown here. Such dispersal may carry seeds far from the parent plant.

▶ Ants are chemically attracted to seeds with food bodies rich in fatty acids, amino acids, and sugars. The ants carry the seed to their underground nest, where the food body (the lighter-colored portion shown here) is removed and fed to larvae. Due to the seed's size, unwieldy shape, or hard coating, the remainder is usually left intact in the nest, where it germinates.

▶ Some animals, such as squirrels, hoard seeds or fruits in underground caches. If the animal dies or forgets the cache's location, the seeds may germinate.

CONCEPT **38.2**

Flowering plants reproduce sexually, asexually, or both

Imagine chopping off your finger and watching it develop into an exact copy of you. If this could actually occur, it would be an example of **asexual reproduction**, in which offspring are derived from a single parent without genetic recombination. The result would be a clone, an asexually produced, genetically identical organism. Asexual reproduction is common in angiosperms, as well as in other plants, and for some plant species it is the predominant mode of reproduction.

Mechanisms of Asexual Reproduction

Asexual reproduction in plants is typically an extension of the capacity for indeterminate growth. Plants, remember, have meristems, tissues of dividing, undifferentiated cells that can sustain or renew growth indefinitely. In addition, parenchyma cells throughout the plant can divide and differentiate into more specialized types of cells, enabling plants to regenerate lost parts. Detached vegetative fragments of some plants can develop into whole offspring; a severed stem, for instance, may develop adventitious roots and become a whole plant. Such **fragmentation**, the separation of a parent plant into parts that develop into whole plants, is one of the most common modes of asexual reproduction. The adventitious plantlets on *Kalanchoë* leaves exemplify an unusual type of fragmentation (see Figure 35.7). In another form of asexual reproduction in some species, the root system of a single parent gives rise to many adventitious shoots that become separate shoot systems. The result is a clone formed by asexual reproduction from one parent **(Figure 38.12)**. Such asexual propagation has produced the oldest of all known plant clones, a ring of creosote bushes in the Mojave Desert of California, estimated to be at least 12,000 years old.

▲ **Figure 38.12 Asexual reproduction in aspen trees.** Some aspen groves, such as those shown here, actually consist of thousands of trees descended by asexual reproduction. Each grove of trees derives from the root system of one parent. Notice that genetic differences between groves descended from different parents result in different timing for the development of fall color and the loss of leaves.

An entirely different mechanism of asexual reproduction has evolved in dandelions and some other plants. These plants can sometimes produce seeds without pollination or fertilization. This asexual production of seeds is called **apomixis** (from the Greek words meaning "away from the act of mixing") because there is no joining or, indeed, production of sperm and egg. Instead, a diploid cell in the ovule gives rise to the embryo, and the ovules mature into seeds, which in the dandelion are dispersed by windblown fruits. Thus, these plants clone themselves by an asexual process but have the advantage of seed dispersal, usually associated with sexual reproduction. Introducing apomixis into hybrid crops is a goal of great interest to plant breeders because apomixis would allow hybrid plants to pass on their desirable genomes intact to their offspring.

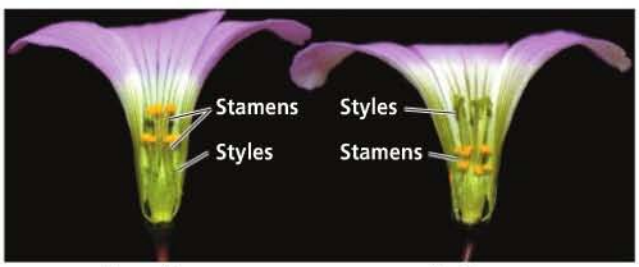
Advantages and Disadvantages of Asexual Versus Sexual Reproduction

An important advantage of asexual reproduction is that there is no need for a pollinator. This may be beneficial in situations where plants of the same species are sparsely distributed and unlikely to be visited by the same pollinator. Asexual reproduction also allows the plant to pass on all of its genetic legacy intact to its progeny. In contrast, when reproducing sexually, a plant passes on only half of its alleles. If a plant is superbly suited to a stable environment, asexual reproduction can be advantageous. A vigorous plant that is well adapted to its environment can clone many copies of itself, and if the environmental circumstances remain stable, these clones will also be genetically well adapted to the same environmental conditions under which the parent flourished.

Generally, the clones produced by asexual reproduction are not as frail as seedlings produced by sexual reproduction. The clones usually arise from mature vegetative fragments from the parent plant, which is why asexual reproduction in plants is also known as **vegetative reproduction**. In contrast, seed germination is a precarious stage in a plant's life. The tough seed gives rise to a fragile seedling that is exposed to predators, parasites, wind, and other hazards. In the wild, only a small fraction of seedlings endure long enough to become parents themselves. Production of enormous numbers of seeds compensates for the odds against individual survival and gives natural selection ample genetic variations to screen. However, this is a very expensive means of reproduction in terms of the resources consumed in flowering and fruiting.

Sexual reproduction generates variation in offspring and populations and can therefore be advantageous in unstable environments where evolving pathogens and fluctuating variables affect survival and reproductive success. In contrast, the genotypic uniformity of asexually produced plants puts them

at great risk of local extinction if there is a catastrophic environmental change, such as a new strain of disease. Moreover, seeds (which are almost always produced sexually) facilitate the dispersal of offspring to more distant locations. Finally, seed dormancy allows growth to be suspended until environmental conditions become more favorable.



While the great advantage of sexual reproduction is that it increases the genetic diversity of offspring, some flowers, such as garden peas, self-fertilize. This process, called "selfing," can be a desirable attribute in some crop plants because it ensures that a seed will develop. In many angiosperm species, however, mechanisms have evolved that make it difficult or impossible for a flower to fertilize itself, as we'll discuss next.

Mechanisms That Prevent Self-Fertilization

The various mechanisms that prevent self-fertilization contribute to genetic variety by ensuring that sperm and eggs come from different parents. In the case of **dioecious** species, plants cannot self-fertilize because different individuals have either staminate flowers (lacking carpels) or carpellate flowers (lacking stamens) **(Figure 38.13a)**. Other plants have flowers with functional stamens and carpels that mature at different times or are structurally arranged in such a way that it is unlikely that an animal pollinator could transfer pollen from an anther to a stigma of the same flower **(Figure 38.13b)**. However, the most common anti-selfing mechanism in flowering plants is **self-incompatibility**, the ability of a plant to reject its own pollen and sometimes the pollen of closely related individuals. If a pollen grain lands on a stigma of a flower on the same plant, a biochemical block prevents the pollen from completing its development and fertilizing an egg.

(a) Some species, such as *Sagittaria latifolia* (common arrowhead), are dioecious, having plants that produce only staminate flowers (left) or carpellate flowers (right).

Thrum flower Pin flower

(b) Some species, such as *Oxalis alpina* (alpine woodsorrel), produce two types of flowers on different individuals: "thrums," which have short styles and long stamens, and "pins," which have long styles and short stamens. An insect foraging for nectar would collect pollen on different parts of its body; thrum pollen would be deposited on pin stigmas, and vice versa.

▲ **Figure 38.13 Some floral adaptations that prevent self-fertilization.**

Researchers are unraveling the molecular mechanisms involved in self-incompatibility. This plant response is analogous to the immune response of animals in that both are based on the ability to distinguish the cells of "self" from those of "nonself." The key difference is that the animal immune system rejects nonself, as when the system mounts a defense against a pathogen or rejects a transplanted organ (see Chapter 43). Self-incompatibility in plants, in contrast, is a rejection of self.

Recognition of "self" pollen is based on genes for self-incompatibility, called *S*-genes. In the gene pool of a plant population, there can be dozens of alleles of an *S*-gene. If a pollen grain has an allele that matches an allele of the stigma on which it lands, the pollen tube fails to grow. Depending on the species, self-recognition blocks pollen tube growth by one of two molecular mechanisms: gametophytic self-incompatibility or sporophytic self-incompatibility.

In gametophytic self-incompatibility, the *S*-allele in the pollen genome governs the blocking of fertilization. For example, an S_1 pollen grain from an S_1S_2 parental sporophyte will fail to fertilize eggs of an S_1S_2 flower but will fertilize an S_2S_3 flower. An S_2 pollen grain will not fertilize either flower. Self-recognition of this kind involves the enzymatic destruction of RNA within a pollen tube. RNA-hydrolyzing enzymes are produced by the style and enter the pollen tube. If the pollen tube is a "self" type, these enzymes destroy its RNA.

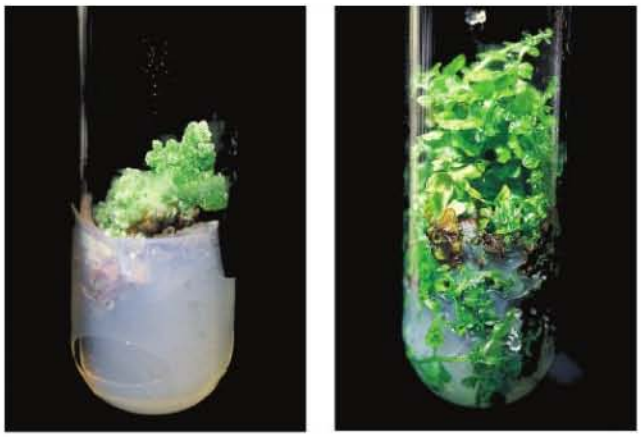
In sporophytic self-incompatibility, fertilization is blocked by *S*-allele gene products in tissues of the parental sporophyte that adhere to the pollen wall. For example, neither an S_1 nor S_2 pollen grain from an S_1S_2 parental sporophyte will fertilize eggs of an S_1S_2 flower or S_2S_3 flower, due to the S_1S_2 parental tissue attached to the pollen grain wall. Sporophytic incompatibility involves a signal transduction pathway in epidermal cells of the stigma that prevents germination of the pollen grain.

Some crops, such as peas, maize, and tomatoes, routinely self-pollinate with satisfactory results. However, plant breeders frequently hybridize different varieties of a crop plant to combine the best traits of the varieties and counter the loss of vigor that can often result from excessive inbreeding (see Chapter 14). To obtain hybrid seeds, plant breeders today must prevent self-fertilization either by laboriously removing the anthers from the parent plants that provide the seeds or by developing male-sterile plants. The latter option is increasingly common. Eventually, it may also be possible to impose self-incompatibility genetically on crop species that are normally self-compatible. Basic research on mechanisms of self-incompatibility may thus have agricultural applications.

Vegetative Propagation and Agriculture

With the objective of improving crops and ornamental plants, humans have devised various methods for asexual propagation of angiosperms. Most of these methods are based on the ability of plants to form adventitious roots or shoots.

Clones from Cuttings



Most houseplants, woody ornamentals, and orchard trees are asexually reproduced from plant fragments called cuttings. In some cases, shoot cuttings are used. At the cut end of the shoot, a mass of dividing, undifferentiated cells called a **callus** forms, and adventitious roots then develop from the callus. If the shoot fragment includes a node, then adventitious roots form without a callus stage. Some plants, including African violets, can be propagated from single leaves rather than stems. For other plants, cuttings are taken from specialized storage stems. For example, a potato can be cut up into several pieces, each with a vegetative bud, or "eye," that regenerates a whole plant.

Grafting

In a modification of vegetative reproduction from cuttings, a twig or bud from one plant can be grafted onto a plant of a closely related species or a different variety of the same species. Grafting makes it possible to combine the best qualities of different species or varieties into a single plant. The graft is usually done when the plant is young. The plant that provides the root system is called the **stock**; the twig grafted onto the stock is referred to as the **scion**. For example, scions from French varieties of vines that produce superior wine grapes are grafted onto root stocks of American varieties, which are more resistant to certain soil pathogens. The genes of the scion determine the quality of the fruit, so the quality is not diminished by the genetic makeup of the stock. In some cases of grafting, however, the stock can alter the characteristics of the shoot system that develops from the scion. For example, dwarf fruit trees, which allow for easier harvesting of the fruit, are made by grafting normal twigs onto stocks of dwarf varieties that retard the vegetative growth of the shoot system. Because seeds are produced by the part of the plant derived from the scion, they give rise to plants of the scion species when planted.

Test-Tube Cloning and Related Techniques

Plant biologists have adopted *in vitro* methods to create and clone novel plant varieties. It is possible to grow whole plants by culturing small pieces of tissue cut from the parent or even single parenchyma cells on an artificial medium containing nutrients and hormones **(Figure 38.14a)**. The cultured cells divide and form an undifferentiated callus. When the hormonal balance is manipulated in the culture medium, the callus can sprout shoots and roots with fully differentiated cells

(a) Just a few parenchyma cells from a carrot gave rise to this callus, a mass of undifferentiated cells.

(b) The callus differentiates into an entire plant, with leaves, stems, and roots.

▲ **Figure 38.14 Test-tube cloning of carrots.** (See also Figure 20.16.)

(Figure 38.14b). The test-tube plantlets can then be transferred to soil, where they continue their growth. A single plant can be cloned into thousands of copies by dividing calluses as they grow. This method is now used for propagating orchids and also a wide variety of horticulturally important trees and shrubs.

Plant tissue culture also facilitates genetic engineering. Most techniques for the introduction of foreign genes into plants require small pieces of plant tissue or single plant cells as the starting material. In plant biology, the term **transgenic** is used to describe genetically modified (GM) organisms that have been engineered to express a gene from another species. Test-tube culture makes it possible to regenerate GM plants from a single plant cell into which the foreign DNA has been incorporated. The techniques of genetic engineering are discussed in more detail in Chapter 20.

Some researchers couple a technique known as **protoplast fusion** with tissue culture methods to invent new plant varieties that can be cloned. Protoplasts are plant cells with their cell walls removed by treatment with enzymes (cellulases and pectinases) isolated from fungi **(Figure 38.15)**. Before protoplasts

◀ **Figure 38.15 Protoplasts.** These wall-less plant cells are prepared by treating cells or tissues with wall-degrading enzymes isolated from certain types of fungi. Researchers can fuse protoplasts from different species to make hybrids and can also culture the hybrid cells to produce a new plant (LM).

are cultured, they can be screened for mutations that may improve the plant's agricultural value. In some cases, it is possible to fuse two protoplasts from different plant species that would otherwise be reproductively incompatible and then culture the hybrid protoplasts. Each protoplast can regenerate a wall and eventually form a hybrid plantlet. One success of this method is a hybrid between a potato and a wild relative called black nightshade. The nightshade is resistant to an herbicide commonly used to kill weeds. The hybrids are also resistant, making it possible to "weed" a field with the herbicide without killing potato plants.

The *in vitro* culturing of plant cells and tissues is fundamental to most types of plant biotechnology. The other basic process is the production of transgenic plants through various methods of genetic engineering. In the next section, we take a closer look at plant biotechnology.

CONCEPT CHECK 38.2

1. Explain how both asexual and sexual "strategies" contribute to the reproductive success of plants.
2. The seedless banana, the world's most popular fruit, is losing the battle against two fungal epidemics. Why do such epidemics generally pose a greater risk to asexually propagated crops?
3. Given the seeming disadvantages of selfing as a reproductive "strategy" in nature, it is surprising that about 20% of angiosperm species primarily rely on selfing. Although fairly common in nature, self-fertilization has been called an "evolutionary dead end." Suggest a reason why selfing might be selected for in nature and yet still be an evolutionary dead end.
4. WHAT IF? Potatoes (*Solanum tuberosum*) and tomatoes (*Solanum lycopersicum*) are fairly closely related species. If you managed to cross the two, would it be possible to have a hybrid that makes potato-like tubers and tomato-like fruits on the same plant?

For suggested answers, see Appendix A.

CONCEPT 38.3
Humans modify crops by breeding and genetic engineering

Humans have intervened in the reproduction and genetic makeup of plants since the dawn of agriculture. Indeed, it is no exaggeration to say that maize is an unnatural monster created by humans. Left on its own in nature, maize would soon become extinct for the simple reason that it cannot spread its seeds. Maize kernels are not only permanently attached to the central axis (the "cob") but also permanently protected by tough, overlapping leaf sheathes (the "husk") **(Figure 38.16)**. These attributes arose by artificial selection by humans. (See Chapter 22 to review the basic concept of artificial selection.) Despite having no understanding of the scientific principles underlying plant breeding, Neolithic (late Stone Age) humans domesticated most of our crop species over a relatively short period about 10,000 years ago. But genetic modification began long before humans started altering crops by artificial selection. For example, the wheat species we rely on for much of our food evolved by the natural hybridization between different species of grasses. Such hybridization is common in plants and has long been exploited by breeders to introduce genetic variation for artificial selection and crop improvement.

▲ **Figure 38.16 Maize: a product of artificial selection.** Modern maize (bottom) was derived from teosinte (top). Teosinte kernels are tiny, and each row has a husk that must be removed to get at the kernel. The seeds are loose at maturity, allowing dispersal, which probably made harvesting difficult for early farmers. Neolithic farmers selected for larger cob and kernel size as well as the permanent attachment of seeds to the cob and the encasing of the entire cob by a tough husk.

Plant Breeding

The art of recognizing valuable traits is important in plant breeding. Breeders scrutinize their fields carefully and travel to other countries searching for domesticated varieties or wild relatives with desirable traits. Such traits occasionally arise spontaneously through mutation, but the natural rate of mutation is too slow and unreliable to produce all the mutations that breeders would like to study. Breeders sometimes hasten mutations by treating large batches of seeds or seedlings with X-rays, radiation, or chemicals.

When a desirable trait is identified in a wild species, the wild species is crossed with a domesticated variety. Generally, those progeny that have inherited the desirable trait from the wild parent have also inherited many traits that are not desirable for agriculture. The progeny that express the desired trait are again crossed with members of the domesticated species and their progeny examined for the desired trait. This process is continued until the progeny with the desired wild trait resemble the original domesticated parent in their other agricultural attributes.

While most breeders cross-pollinate plants of a single species, some breeding methods rely on hybridization between two distant species of the same genus. For example, a cross between two species of the genus *Musa* produced the familiar Cavendish banana. Distant crosses often result in the abortion of the hybrid seed during development. Very often the embryo begins to develop, but the endosperm does not. Hybrid embryos are sometimes rescued by surgically removing them from the ovule and culturing them *in vitro*.

Less commonly, distant hybridization is carried out between members of two different genera. A cross between wheat (*Triticum aestivum*) and rye (*Secale cereale*), for example, produced a novel grain called triticale, which contains a copy of all the chromosomes from both species. When triticale was first produced in the 1870s, it was considered little more than a botanical oddity. In the mid-1900s, however, plant breeders realized that triticale could potentially be developed into a crop with the yield and quality of bread wheat and with rye's tolerance of cold stress, moisture stress, and acidic soils. The early triticales were plagued with problems. These tall, late-maturing plants tended to fall over, were partially sterile, and were low yielding. They typically produced shriveled seeds that germinated poorly and were of poor quality for milling and baking. But through continued artificial selection, these problems were overcome, and triticale is now grown on more than 1 million hectares worldwide (1 ha = 2.47 acres). Some 600,000 ha are on the sandy, acidic soils of Poland, where the grain is used primarily for animal feed. It is nutritionally superior to rye, and the flour blends better with wheat in the baking of bread. Triticale grows well on *marginal land*, agriculturally inferior land that usually yields a poor return. If we are to feed the burgeoning world population in the 21st century, such marginal lands will have to become increasingly productive.

Plant Biotechnology and Genetic Engineering

Plant biotechnology has two meanings. In the general sense, it refers to innovations in the use of plants (or substances obtained from plants) to make products of use to humans—an endeavor that began in prehistory. In a more specific sense, biotechnology refers to the use of GM organisms in agriculture and industry. Indeed, in the last two decades, genetic engineering has become such a powerful force that the terms *genetic engineering* and *biotechnology* have become synonymous in the media.

Unlike traditional plant breeders, modern plant biotechnologists, using techniques of genetic engineering, are not limited to the transfer of genes between closely related species or varieties of the same species. For example, traditional breeding techniques could not be used to insert a desired gene from daffodil into rice because the many intermediate species between rice and daffodil and their common ancestor are extinct. In theory, if breeders had the intermediate species, over the course of several centuries they could probably introduce a daffodil gene into rice by traditional hybridization and breeding methods. With genetic engineering, however, such gene transfers can be done more quickly and without the need for intermediate species.

In the remainder of this chapter, we expand on discussions in Chapter 20 by examining the prospects and the controversies surrounding the use of genetically modified crops. The advocates of plant biotechnology believe that the genetic engineering of crop plants is the key to overcoming some of the most pressing problems of the 21st century, including world hunger and fossil fuel dependency.

Reducing World Hunger and Malnutrition

Currently, 800 million people on Earth suffer from nutritional deficiencies, with 40,000 dying each day of malnutrition, half of them children. There is much disagreement about the causes of such hunger. Some argue that food shortages arise from inequities in distribution and that the dire poor simply cannot afford food. Others regard food shortages as evidence that the world is overpopulated—that the human species has exceeded the carrying capacity of the planet (see Chapter 53). Whatever the social and demographic causes of malnutrition, increasing food production is a humane objective. Because land and water are the most limiting resources, the best option is to increase yields on the available land. Indeed, there is very little "extra" land that can be farmed, especially if the few remaining pockets of wilderness are to be preserved. Based on conservative estimates of population growth, farmers will have to produce 40% more grain per hectare to feed the human population in 2030. Plant biotechnology can help make these crop yields possible.

The commercial use of transgenic crops has been one of the most dramatic examples of rapid technology adoption in the history of agriculture. These crops include varieties and hybrids of cotton, maize, and potatoes that contain genes from the bacterium *Bacillus thuringiensis*. These "transgenes" encode a protein (*Bt* toxin) that is toxic to insect pests. The use of such plant varieties greatly reduces the need for chemical insecticides. The *Bt* toxin used in crops is produced in the plant as a harmless protoxin that only becomes toxic if activated by alkaline conditions, such as occur in the guts of insects. Because vertebrates have highly acidic stomachs, protoxin consumed by humans or farm animals is destroyed without becoming active.

Considerable progress has also been made in developing transgenic plants of cotton, maize, soybeans, sugar beets, and wheat that tolerate certain herbicides. The cultivation of these plants may reduce production costs by enabling farmers to "weed" crops with herbicides that do not damage the transgenic crop plants instead of by heavy tillage, which can cause soil erosion. Researchers are also engineering plants with enhanced resistance to disease. In one case, a transgenic papaya

◀ **Figure 38.17 Genetically modified papaya.** A ring spot virus has devastated papaya cultivation worldwide. However, a transgenic papaya variety rescued the industry in Hawaii. The genetically engineered papaya on the left is more resistant to ring spot virus than the nontransgenic papaya on the right.

▲ **Figure 38.18 "Golden Rice" and prevention of blindness associated with vitamin A deficiency.** Some 250,000 to 500,000 children go blind each year because of vitamin A deficiencies. The onset of blindness, indicated by a cloudy white spot in the eye, is a sign of severe underlying health problems: More than half of these children die within a year of becoming blind. The golden color and increased nutritional value of Golden Rice are attributable to its ability to make beta-carotene (provitamin A).

resistant to a ring spot virus was introduced into Hawaii, thereby saving its papaya industry **(Figure 38.17)**.

The nutritional quality of plants is also being improved. "Golden Rice," a transgenic variety carrying two daffodil genes, produces grain containing beta-carotene, a precursor of vitamin A. This rice was developed to prevent the blindness that occurs in those of the world's poor whose diet is deficient in vitamin A **(Figure 38.18)**. Recently, scientists have developed a new variety with much more beta-carotene than the original.

Reducing Fossil Fuel Dependency

Global sources of inexpensive fossil fuels, particularly oil, are rapidly being depleted. Moreover, climatologists attribute global warming mostly to the rampant burning of fossil fuels, such as coal and oil, and the resulting release of greenhouse gases. How can the world meet its energy demands in the 21st century in an economical and nonpolluting way? In certain localities, wind or solar power may become economically viable, but such alternative energy sources are unlikely to fill all the energy demands of the planet. Many scientists predict that the biomass from extremely fast-growing plants, such as switchgrass (*Panicum virgatum*) and poplar (*Populus trichocarpa*), could produce a sizable fraction of the world's energy needs in the not-too-distant future.

Under optimal conditions, poplars can grow 3–4 m each year, and switchgrass grows well under a wide variety of conditions found in regions where most types of agriculture are not economically viable. Scientists do not envisage the plant biomass being burned directly. Instead, the polymers in cell walls, such as cellulose and hemicellulose, which constitute the most abundant organic compounds on Earth, would be broken down into sugars by enzymatic reactions. These sugars, in turn, would be fermented into alcohol and distilled to yield **biofuels**.

The use of biofuels from plant biomass would reduce the net emission of the greenhouse gas CO_2. Whereas burning fossil fuels increases atmospheric CO_2 concentrations, biofuel crops reabsorb by photosynthesis the CO_2 emitted when biofuels are burned, creating a cycle that is carbon neutral. Plant breeders are trying to genetically engineer faster-growing poplar trees that produce more readily convertible biomass.

Biofuel technology does have its critics. For example, ecologist David Pimentel, of Cornell University, and geoengineer Tad Patzek, of UC Berkeley, have published estimates that more energy may be required to produce biofuels than would be produced from combustion of these products. Biofuel advocates, in turn, have questioned the accuracy of the data underlying these estimates.

The Debate over Plant Biotechnology

Much of the debate about GM organisms in agriculture is political, social, economic, or ethical and outside the scope of this book. But we *should* consider the biological concerns about GM crops. There are some biologists, particularly ecologists, who are concerned about the unknown risks associated with the release of GM organisms (GMOs) into the environment. The debate centers on the extent to which GMOs could harm human health or the environment. Those who want to proceed more slowly with agricultural biotechnology (or end it) are concerned about the unstoppable nature of the "experiment." If a drug trial produces unanticipated harmful results, the trial is stopped. But we may not be able to stop the "trial" of introducing novel organisms into the biosphere.

Chapter 20 introduced the key concerns regarding biotechnology in general. Here we take a closer look at some issues as they relate to plant biotechnology. Laboratory and field studies continue to examine the possible consequences of using GM crops, including the effects on human health and nontarget organisms and the potential for transgene escape.

Issues of Human Health

Many GMO opponents worry that genetic engineering may inadvertently transfer allergens, molecules to which some humans are allergic, from a species that produces an allergen to a plant used for food. However, biotechnologists are engaged in removing genes that encode allergenic proteins from soybeans and other crops. So far, there is no credible evidence that GM plants specifically designed for human consumption have adverse effects on human health. In fact, some GM foods are potentially healthier than non-GM foods. For example, *Bt* maize (the transgenic variety with the *Bt* toxin) contains 90% less of a cancer-causing and birth defect–causing mycotoxin than non-*Bt* maize. Called fumonisin, this toxin is highly resistant to degradation and has been found in alarmingly high concentrations in some batches of processed maize products, ranging from cornflakes to beer. Fumonisin is produced by a fungus (*Fusarium*) that infects insect-damaged maize. Because *Bt* maize generally suffers less insect damage than non-GM maize, it contains much less fumonisin.

Nevertheless, because of health concerns, GMO opponents lobby for the clear labeling of all foods containing products of GMOs. Some also argue for strict regulations against the mixing of GM foods with non-GM foods during food transport, storage, and processing. Biotechnology advocates, however, note that similar demands were not made when "transgenic" crops produced by traditional plant-breeding techniques were put on the market. There are, for example, some commercially grown varieties of wheat derived by traditional plant-breeding techniques that contain entire chromosomes (and thousands of genes) from rye.

Possible Effects on Nontarget Organisms

Many ecologists are concerned that the growing of GM crops might have unforeseen effects on nontarget organisms. One laboratory study indicated that the larvae (caterpillars) of monarch butterflies responded adversely and even died after eating milkweed leaves (their preferred food) heavily dusted with pollen from transgenic *Bt* maize. This study has since been discredited and affords a good example of the self-correcting nature of science. As it turns out, when the original researchers shook the male maize inflorescences onto the milkweed leaves in the laboratory, the filaments of stamens, opened microsporangia, and other floral parts also rained onto the leaves. Subsequent research found that it was these other floral parts, *not* the pollen, that contained *Bt* toxin in high concentrations. Unlike pollen, these floral parts would not be carried by the wind to neighboring milkweed plants when shed under natural field conditions. Only one *Bt* maize line, accounting for less than 2% of commercial *Bt* maize production (and now discontinued), produced pollen with high *Bt* toxin concentrations.

In considering the negative effects of *Bt* pollen on monarch butterflies, one must also weigh the effects of an alternative to the cultivation of *Bt* maize—the spraying of non-*Bt* maize with chemical pesticides. Recent studies have shown that such spraying was much more harmful to nearby monarch populations than was *Bt* maize production. Although the effects of *Bt* maize pollen on monarch butterfly larvae appear to be minor, the controversy has emphasized the need for accurate field testing of all GM crops and the importance of targeting gene expression to specific tissues to improve safety.

Addressing the Problem of Transgene Escape

Perhaps the most serious concern raised about GM crops is the possibility of the introduced genes escaping from a transgenic crop into related weeds through crop-to-weed hybridization. The fear is that the spontaneous hybridization between a crop engineered for herbicide resistance and a wild relative might give rise to a "superweed" that would have a selective advantage over other weeds in the wild and would be much more difficult to control in the field. Some crops *do* hybridize with weedy relatives, and crop-to-weed transgene escape is a possibility. Its likelihood depends on the ability of the crop and weed to hybridize and on how the transgenes affect the overall fitness of the hybrids. A desirable crop trait—a dwarf phenotype, for example—might be disadvantageous to a weed growing in the wild. In other instances, there are no weedy relatives nearby with which to hybridize; soybean, for example, has no wild relatives in the United States. However, canola, sorghum, and many other crops do hybridize readily with weeds.

Many different strategies are being pursued with the goal of preventing transgene escape. For example, if male sterility could be engineered into plants, these plants would still produce seeds and fruit if pollinated by nearby nontransgenic plants, but they would produce no viable pollen. A second approach involves genetically engineering apomixis into transgenic crops. When a seed is produced by apomixis, the embryo and endosperm develop without fertilization. The transfer of this trait to transgenic crops would therefore minimize the possibility of transgene escape via pollen because plants could be male-sterile without compromising seed or fruit production. A third approach is to engineer the transgene into the chloroplast DNA of the crop. Chloroplast DNA in many plant species is inherited strictly from the egg, so transgenes in the chloroplast cannot be transferred by pollen (see Chapter 15 to review maternal inheritance). A fourth approach for preventing transgene escape is to genetically engineer flowers that develop normally but fail to open. Consequently, self-pollination would occur, but pollen would be unlikely to escape from the flower. This solution would require modifications to flower design. Several floral genes have been identified that could be manipulated to this end.

The continuing debate about GMOs in agriculture exemplifies one of this textbook's recurring ideas: the relationship of science and technology to society. Technological advances almost always involve some risk of unintended outcomes. In plant biotechnology, zero risk is probably unattainable. Therefore, scientists and the public must assess on a case-by-case basis the possible benefits of transgenic products versus the risks that society is willing to take. The best scenario is for these discussions and decisions to be based on sound scientific information and rigorous testing rather than on reflexive fear or blind optimism.

CONCEPT CHECK 38.3

1. Compare traditional plant-breeding methods with genetic engineering.
2. Explain some benefits and risks of GM crops.
3. Why does *Bt* maize have less fumonisin than non-GM maize?
4. **WHAT IF?** In a few species, chloroplast genes are inherited only from sperm. How might this affect efforts to prevent transgene escape?

For suggested answers, see Appendix A.

Chapter 38 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 38.1

Flowers, double fertilization, and fruits are unique features of the angiosperm life cycle (pp. 801–811)

- The sporophyte, the dominant generation, produces spores that develop within flowers into male gametophytes (in pollen grains) and female gametophytes (embryo sacs).
- **Flower Structure and Function** Flowers function in sexual reproduction. The four floral organs are sepals, petals, stamens, and carpels. Pollen develops from microspores within the microsporangia of anthers; female gametophytes develop from megaspores within ovules. Pollination, which precedes fertilization, is the placing of pollen on the stigma of a carpel.
- **Double Fertilization** The pollen tube discharges two sperm into the female gametophyte; one sperm fertilizes the egg, while the other combines with the polar nuclei, giving rise to food-storing endosperm.

- **Seed Development, Form, and Function** The seed coat encloses the embryo along with a food supply stocked in either the endosperm or the cotyledons. Seed dormancy ensures that seeds germinate only when conditions for seedling survival are optimal. The breaking of dormancy often requires environmental cues, such as temperature or lighting changes.
- **Fruit Form and Function** The fruit protects the enclosed seeds and aids in wind dispersal or in the attraction of seed-dispersing animals.

CONCEPT 38.2

Flowering plants reproduce sexually, asexually, or both (pp. 812–815)

- **Mechanisms of Asexual Reproduction** Modes of asexual reproduction include fragmentation and the production of adventitious shoots.
- **Advantages and Disadvantages of Asexual Versus Sexual Reproduction** Asexual reproduction enables successful clones to spread; sexual reproduction generates the genetic variation that makes evolutionary adaptation possible.
- **Mechanisms That Prevent Self-Fertilization** Some plants reject pollen that has an *S*-gene matching an allele in the stigma cells. Recognition of "self" pollen triggers a signal transduction pathway leading to a block in growth of a pollen tube.
- **Vegetative Propagation and Agriculture** Cloning plants from cuttings is an ancient practice. Plants can be cloned from single cells, which can be genetically manipulated before being allowed to develop into a plant.

CONCEPT 38.3

Humans modify crops by breeding and genetic engineering (pp. 815–819)

- **Plant Breeding** Interspecific hybridization of plants is common in nature and has been used by breeders, ancient and modern, to introduce new genes into crops. After two plants are successfully hybridized, plant breeders select those progeny that have the desired traits.
- **Plant Biotechnology and Genetic Engineering** In genetic engineering, genes from unrelated organisms are incorporated into plants. Genetically modified (GM) plants have the potential of increasing the quality and quantity of food worldwide and may also become increasingly important as biofuels.
- **The Debate over Plant Biotechnology** There are concerns about the unknown risks of releasing GM organisms into the environment, but the potential benefits of transgenic crops need to be considered.

Activity Making Decisions About DNA Technology: Golden Rice

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. A plant that has small, green petals is most likely to be
   a. bee-pollinated.
   b. bird-pollinated.
   c. bat-pollinated.
   d. wind-pollinated.
   e. moth-pollinated.

2. A seed develops from
   a. an ovum.
   b. a pollen grain.
   c. an ovule.
   d. an ovary.
   e. an embryo.

3. A fruit is
   a. a mature ovary.
   b. a mature ovule.
   c. a seed plus its integuments.
   d. a fused carpel.
   e. an enlarged embryo sac.

4. Double fertilization means that
   a. flowers must be pollinated twice to yield fruits and seeds.
   b. every egg must receive two sperm to produce an embryo.
   c. one sperm is needed to fertilize the egg, and a second sperm is needed to fertilize the polar nuclei.
   d. the egg of the embryo sac is diploid.
   e. every sperm has two nuclei.

5. Some dioecious species have the XY genotype for male and XX for female. After double fertilization, what would be the genotypes of the embryos and endosperm nuclei?
   a. embryo X and endosperm XX or embryo Y and endosperm XY
   b. embryo XX and endosperm XX or embryo XY and endosperm XY
   c. embryo XX and endosperm XXX or embryo XY and endosperm XYY
   d. embryo XX and endosperm XXX or embryo XY and endosperm XXY
   e. embryo XY and endosperm XXX or embryo XX and endosperm XXY

6. Which statement concerning grafting is correct?
   a. Stocks and scions refer to twigs of different species.
   b. Stocks come from vines, but scions come from trees.
   c. Stocks provide root systems for grafting.
   d. Grafting creates new species.
   e. Stocks and scions must come from unrelated species.

7. Plant biotechnologists use protoplast fusion mainly to
   a. culture plant cells *in vitro*.
   b. asexually propagate desirable plant varieties.
   c. introduce bacterial genes into a plant genome.
   d. study the early events following fertilization.
   e. produce new hybrid species.

8. The basal cell from the zygote's first division develops into
   a. the suspensor that anchors the embryo and transfers nutrients.
   b. the proembryo.
   c. the endosperm that nourishes the developing embryo.
   d. the root apex of the embryo.
   e. two cotyledons in eudicots, but one in monocots.

9. The development of *Bt* crops raises concerns because
   a. *Bt* crops have been shown to be toxic to humans.
   b. pollen from these crops is harmful to monarch butterfly larvae in the field.
   c. if genes for *Bt* toxin "escape" to related weed species, the hybrid weeds could have harmful ecological effects.
   d. *Bacillus thuringiensis* is a pathogen of humans.
   e. *Bt* toxin reduces the nutritional quality of crops.

10. "Golden Rice" is a transgenic variety that
    a. is resistant to various herbicides, making it practical to weed rice fields with those herbicides.
    b. is resistant to a virus that commonly attacks rice fields.
    c. includes bacterial genes that produce a toxin that reduces damage from insect pests.
    d. produces larger, golden grains that increase crop yields.
    e. contains daffodil genes that increase vitamin A content.

11. **DRAW IT** Draw and label the parts of a flower.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

12. With respect to sexual reproduction, some plant species are fully self-fertile, others are fully self-incompatible, and some exhibit a "mixed strategy" with partial self-incompatibility. These reproductive strategies differ in their implications for evolutionary potential. How, for example, might a self-incompatible species fare as a small founder population or remnant population in a severe population bottleneck (see Chapter 23), as compared with a self-fertile species?

SCIENTIFIC INQUIRY

13. Critics of GM foods have argued that foreign genes may disturb normal cellular functioning, causing unexpected and potentially harmful substances to appear inside cells. Toxic intermediary substances that normally occur in very small amounts may arise in larger amounts, or new substances may appear. The disruption may also lead to loss of substances that help maintain normal metabolism. If you were your nation's chief scientific advisor, how would you respond to these criticisms?

Biological Inquiry: A Workbook of Investigative Cases Explore GM crops further with the case "Corn Under Construction."

SCIENCE, TECHNOLOGY, AND SOCIETY

14. Humans have engaged in genetic manipulation for millennia, producing plant and animal varieties through selective breeding and hybridization processes that significantly modify the genomes of organisms. Why do you think modern genetic engineering, which often entails introducing or modifying only one or a few genes, has met with so much public opposition? Should some forms of genetic engineering be of greater concern than others? Explain.

39 Plant Responses to Internal and External Signals

▲ **Figure 39.1 Can flowers tell you the time of day?**

KEY CONCEPTS

39.1 Signal transduction pathways link signal reception to response

39.2 Plant hormones help coordinate growth, development, and responses to stimuli

39.3 Responses to light are critical for plant success

39.4 Plants respond to a wide variety of stimuli other than light

39.5 Plants respond to attacks by herbivores and pathogens

OVERVIEW

Stimuli and a Stationary Life

Carolus Linnaeus, the father of taxonomy, was a keen naturalist and observer of plants. Linnaeus noted that certain plants opened and closed their flowers at particular times of the day, with these times varying from species to species. Therefore, one could deduce the approximate time of day according to which species had opened or closed its flowers. If the times of opening and closing were arranged in sequence, they could serve as a kind of floral clock, or *horologium florae,* as Linnaeus called it. **Figure 39.1** shows a modern simplified representation as a 12-hour clock face. Why does the timing vary? The time at which flowers open presumably reflects the time when their insect pollinators are most active, just one of many environmental factors that a plant must sense to compete successfully. Contrary to the common notion of plants as being almost inanimate, a plant's morphology and physiology are constantly tuned to its surroundings by complex interactions between environmental stimuli and internal signals.

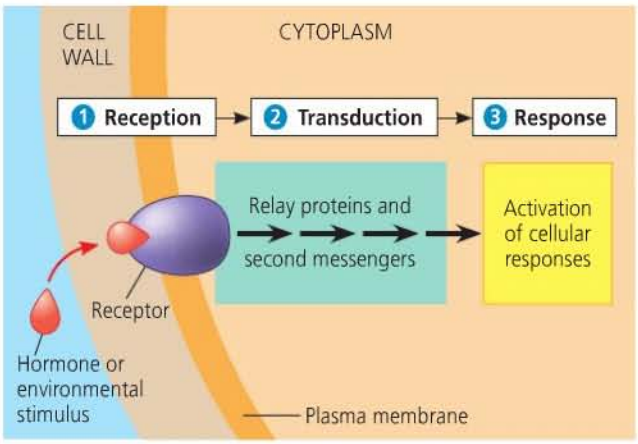
This chapter focuses on how plants respond to external and internal cues. At the organismal level, plants and animals respond to environmental stimuli by very different means. Animals, being mobile, respond mainly by behavioral mechanisms, moving toward positive stimuli and away from negative stimuli. Being stationary, a plant generally responds to environmental cues by adjusting its individual pattern of growth and development. For this reason, plants of the same species vary in body form much more than do animals of the same species. Before a plant can initiate growth responses to environmental signals, it must first detect the change in its environment. At the cellular level, the processes by which plants perceive environmental changes are as complex as those used by animal cells and are often homologous to them.

CONCEPT 39.1

Signal transduction pathways link signal reception to response

All organisms receive specific signals and respond to them in ways that enhance survival and reproductive success. For example, bees, which have UV-sensitive photoreceptors in their eyes, can discern nectar-guiding patterns on flower petals—patterns that are completely invisible to humans (see Figure 38.4). Plants, too, have cellular receptors that they use to detect important changes in their internal or external environments, whether the change is an increase in the concentration of a growth hormone, an injury from a caterpillar munching on leaves, or a decrease in day length as winter approaches.

For a stimulus to elicit a response, an organism must have cells with an appropriate receptor, a molecule affected by the stimulus. For example, humans' inability to see UV-reflecting floral patterns is due to our eyes lacking UV photoreceptors. Upon receiving a stimulus, a receptor initiates a signal transduction pathway, a series of biochemical steps that couples reception to response (see Chapter 11 to review general concepts of signal transduction). Plants are sensitive to a wide range of stimuli, each initiating a specific signal transduction pathway.



(a) Before exposure to light. A dark-grown potato has tall, spindly stems and nonexpanded leaves—morphological adaptations that enable the shoots to penetrate the soil. The roots are short, but there is little need for water absorption because little water is lost by the shoots.

(b) After a week's exposure to natural daylight. The potato plant begins to resemble a typical plant with broad green leaves, short sturdy stems, and long roots. This transformation begins with the reception of light by a specific pigment, phytochrome.

▲ **Figure 39.2 Light-induced de-etiolation (greening) of dark-grown potatoes.**

▲ **Figure 39.3 Review of a general model for signal transduction pathways.** As discussed in Chapter 11, a hormone or other kind of stimulus interacting with a specific receptor protein can trigger the sequential activation of relay proteins and also the production of second messengers that participate in the pathway. The signal is passed along, ultimately bringing about cellular responses. In this diagram, the receptor is on the surface of the target cell; in other cases, the stimulus interacts with receptors inside the cell.

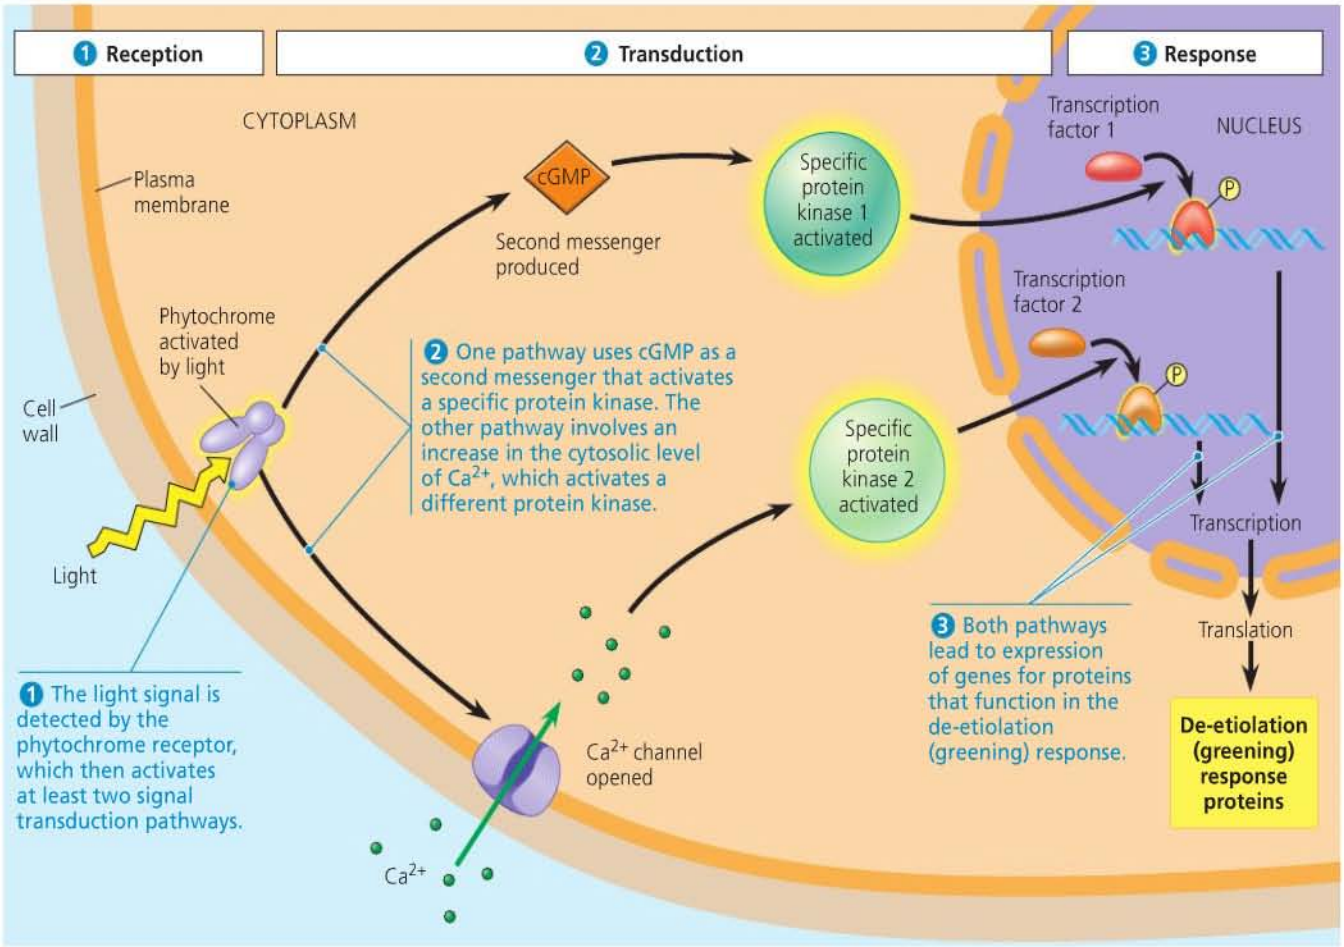
Consider a forgotten potato in the back corner of a kitchen cupboard. This modified underground stem, or tuber, has sprouted shoots from its "eyes" (axillary buds). These shoots, however, scarcely resemble those of a typical plant. Instead of sturdy stems and broad green leaves, these plants have ghostly pale stems and unexpanded leaves, as well as short, stubby roots **(Figure 39.2a)**. These morphological adaptations for growing in darkness, collectively referred to as **etiolation**, make sense if we consider that a young potato plant in nature usually encounters continuous darkness when sprouting underground. Under these circumstances, expanded leaves would be a hindrance to soil penetration and would be damaged as the shoots pushed through the soil. Because the leaves are unexpanded and underground, there is little evaporative loss of water and little requirement for an extensive root system to replace the water lost by transpiration. Moreover, the energy expended in producing green chlorophyll would be wasted because there is no light for photosynthesis. Instead, a potato plant growing in the dark allocates as much energy as possible to elongating its stems. This adaptation enables the shoots to break ground before the nutrient reserves in the tuber are exhausted. The etiolation response is one example of how a plant's morphology and physiology are tuned to its surroundings by complex interactions between environmental and internal signals.

When a shoot reaches the sunlight, the plant undergoes profound changes, collectively called **de-etiolation** (informally known as greening). Stem elongation slows; leaves expand; roots elongate; and the shoot produces chlorophyll. In short, it begins to resemble a typical plant **(Figure 39.2b)**. In this section, we will use this de-etiolation response as an example of how a plant cell's reception of a signal—in this case, light—is transduced into a response (greening). Along the way, we will explore how studies of mutants provide insights into the molecular details of the stages of cell-signal processing: reception, transduction, and response **(Figure 39.3)**.

Reception

Signals are first detected by receptors, proteins that undergo changes in shape in response to a specific stimulus. The receptor involved in de-etiolation is a type of *phytochrome*, a photoreceptor that we'll examine more closely later in the chapter. Unlike most receptors, which are built into the plasma membrane, the phytochrome that functions in the de-etiolation response is located in the cytoplasm. Researchers demonstrated the requirement for phytochrome in de-etiolation through studies of the tomato, a close relative of the potato. The *aurea* mutant tomato, which has lower-than-normal levels of phytochrome, greens less than wild-type tomatoes when exposed to light. (The name *aurea* comes from the Latin for "gold-colored." In the absence of chlorophyll, the yellow plant pigments called carotenoids are more obvious.) Researchers produced a normal de-etiolation response in individual *aurea* leaf cells by injecting phytochrome from other plants and then exposing the cells to light. Such experiments indicate that phytochrome functions in light detection during de-etiolation.

Transduction



Receptors can be sensitive to very weak environmental or chemical signals. Some de-etiolation responses are triggered by extremely low levels of light. For example, light levels equivalent to a few seconds of moonlight are sufficient to slow stem elongation in dark-grown oat seedlings. How is the information from these extremely weak signals amplified, and how is

their reception transduced into a specific response by the plant? The answer is **second messengers**—small molecules and ions in the cell that amplify the signal and transfer it from the receptor to other proteins that carry out the response. In de-etiolation, for example, each activated phytochrome molecule may give rise to hundreds of molecules of a second messenger, each of which may lead to the activation of hundreds of molecules of a specific enzyme. By such mechanisms, a second messenger in a signal transduction pathway rapidly amplifies the signal. In Chapter 11, we discussed several kinds of second messengers in general (see Figures 11.11 and 11.13). Here, we examine the particular roles of second messengers in de-etiolation. Refer to **Figure 39.4** frequently as you read the following description of this complex process.

Light causes phytochrome to undergo a change in shape that leads to increases in levels of the second messengers cyclic GMP (cGMP) and Ca^{2+}. One function of GMP is the activation of protein kinases, a diverse class of enzymes that influence the activation of other proteins by phosphorylation, a modification in which a phosphate group is attached to the protein at a specific site. Injection of cGMP into *aurea* tomato leaf cells induces a partial de-etiolation response, even without the addition of phytochrome, via the upper pathway in the figure. Changes in cytosolic Ca^{2+} levels also play an important role in phytochrome signal transduction. The concentration of Ca^{2+} is generally very low in the cytosol (about 10^{-7} *M*). But phytochrome activation can open Ca^{2+} channels and lead to a transient 100-fold increase in cytosolic Ca^{2+} levels. In other cases of signal transduction, both cGMP and cytosolic Ca^{2+} can influence the activity of specific ion channels, cytoskeletal proteins, and enzymes, including protein kinases.

Response

Ultimately, a signal transduction pathway leads to regulation of one or more cellular activities. In most cases, these responses involve the increased activity of particular enzymes. There are two main mechanisms by which a signaling pathway can enhance an enzymatic step in a biochemical pathway: transcriptional regulation and post-translational modification. Transcriptional regulation increases or decreases synthesis of the mRNA that codes for the enzyme. Post-translational modification activates existing enzyme molecules.

▲ **Figure 39.4 An example of signal transduction in plants: the role of phytochrome in the de-etiolation (greening) response.**

Transcriptional Regulation

As discussed in Chapter 18, the proteins we call *specific transcription factors* bind to specific regions of DNA and control the transcription of specific genes (see Figure 18.9). In the case of phytochrome-induced de-etiolation, several such transcription factors are activated by phosphorylation in response to the appropriate light conditions. The activation of some of these transcription factors depends on cGMP, whereas the activation of others requires Ca^{2+}.

The mechanism by which a signal promotes a new developmental course may depend on transcription factors that are activators (which *increase* transcription of specific genes) or repressors (which *decrease* transcription) or both. For example, consider *Arabidopsis* mutants that, except for their pale color, have a light-grown morphology when grown in the dark; they have expanded leaves and short, sturdy stems but are not green because the final step in chlorophyll production requires light directly. These mutants have defects in a repressor that inhibits the expression of other genes normally activated by light. When the repressor is eliminated by mutation, the pathway that it normally blocks proceeds. Thus, these mutants appear to have been grown in the light, except for their pale color.

Post-Translational Modification of Proteins

Although the syntheses of new proteins by transcription and translation are important molecular events associated with de-etiolation, so are post-translational modifications of existing proteins. Most often, existing proteins are modified by the phosphorylation of specific amino acids, which alters the protein's hydrophobicity and activity. Many second messengers, including cGMP, and some receptors themselves, including some forms of phytochrome, activate protein kinases directly. Often, one protein kinase will phosphorylate another protein kinase, which then phosphorylates another, and so on (see Figure 11.9). Such kinase cascades may link initial stimuli to responses at the level of gene expression, usually via the phosphorylation of transcription factors. By such mechanisms, many signal pathways ultimately regulate the synthesis of new proteins, usually by turning specific genes on or off.

Signal pathways must also have a means for turning off when the initial signal is no longer present, such as when a sprouting potato is put back into the cupboard. Protein phosphatases, enzymes that dephosphorylate specific proteins, are important in these "switch-off" processes. At any moment, a cell's activities depend on the balance of activity of many types of protein kinases and protein phosphatases.

De-Etiolation ("Greening") Proteins

What types of proteins are either newly transcribed or activated by phosphorylation during the de-etiolation process? Many are enzymes that function in photosynthesis directly; others are enzymes involved in supplying the chemical precursors necessary for chlorophyll production; still others affect the levels of plant hormones that regulate growth. For example, the levels of auxin and brassinosteroids, hormones that enhance stem elongation, decrease following phytochrome activation. That decrease explains the slowing of stem elongation that accompanies de-etiolation.

We have discussed the signal transduction involved in the de-etiolation response of a potato plant in some detail to give you a sense of the complexity of biochemical changes that underlie this one process. Every plant hormone and every environmental stimulus triggers one or more signal transduction pathways of comparable complexity. As with the *aurea* mutant tomato, techniques of molecular biology combined with genetic studies of mutants are helping researchers identify these various pathways. But molecular biology builds on a long history of careful physiological and biochemical investigations into how plants work. As you will read in the next section, classical experiments provided the first clues that transported signaling molecules called hormones are internal regulators of plant growth.

CONCEPT CHECK 39.1

1. What are the morphological differences between dark- and light-grown plants?
2. Explain how etiolation helps a seedling compete successfully.
3. Cycloheximide is a drug that inhibits protein synthesis. Predict what effect cycloheximide would have on de-etiolation.
4. **WHAT IF?** The sexual dysfunction drug Viagra inhibits an enzyme that breaks down cyclic GMP. If tomato leaf cells have a similar enzyme, would applying Viagra cause a normal de-etiolation of *aurea* mutant tomato leaves?

For suggested answers, see Appendix A.

CONCEPT 39.2
Plant hormones help coordinate growth, development, and responses to stimuli

A **hormone**, in the original meaning of the term, is a signaling molecule that is produced in tiny amounts by one part of an organism's body and transported to other parts, where it binds to a specific receptor and triggers responses in target cells and tissues. In animals, hormones are usually transported through the circulatory system, a criterion often included in definitions of the term.

The hormone concept originated from studies of animals and was adopted by plant physiologists in the early 1900s. Many

modern plant biologists, however, argue that it is too limiting to describe plant physiological processes using the narrow definitions established by animal physiologists. For example, plants don't have blood or a circulatory system to transport hormone-like signaling molecules. Moreover, some signaling molecules that are considered plant hormones act only locally. Finally, there are some signaling molecules in plants, such as sucrose, which typically occur in plants at concentrations that are hundreds of thousands times greater than a typical hormone. Nevertheless, they are transported through plants and activate signal transduction pathways that greatly alter the functioning of plants in a manner similar to a hormone. Thus, many plant biologists prefer the broader term *plant growth regulator* to describe organic compounds, either natural or synthetic, that modify or control one or more specific physiological processes within a plant. At this point in time, the terms *plant hormone* and *plant growth regulator* are used about equally, but for historical continuity we will use the term *plant hormone* and adhere to the criterion that plant hormones are active at very low concentrations.

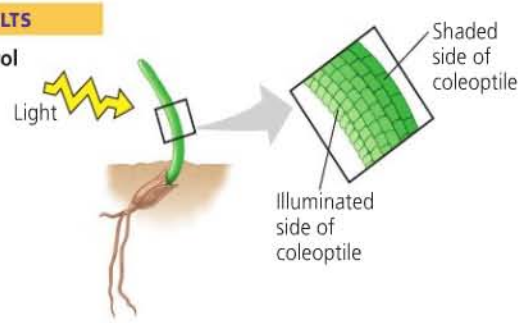
Virtually every aspect of plant growth and development is under hormonal control to some degree. A single hormone can regulate an amazingly diverse array of cellular and developmental processes. Conversely, multiple hormones can influence a single process.

The Discovery of Plant Hormones

The idea that chemical messengers exist in plants emerged from a series of classic experiments on how stems respond to light. As you know, the shoot of a houseplant on a windowsill grows toward light. If you rotate the plant, it soon reorients its growth until its leaves again face the window. Any growth response that results in plant organs curving toward or away from stimuli is called a **tropism** (from the Greek *tropos*, turn). The growth of a shoot toward light or away from it is called **phototropism**; the former is positive phototropism, the latter negative phototropism.

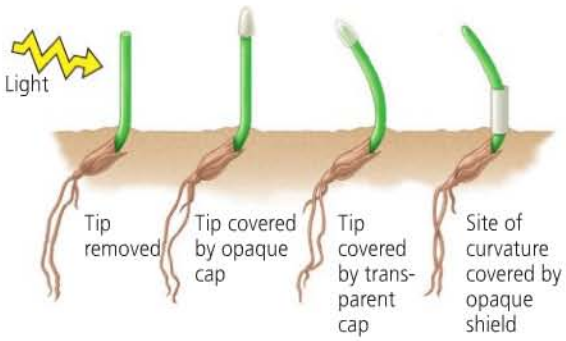
In a forest or other natural ecosystem where plants may be crowded, phototropism directs growing seedlings toward the sunlight that powers photosynthesis. What is the mechanism for this adaptive response? Much of what is known about phototropism has been learned from studies of grass seedlings, particularly oats. The shoot of a sprouting grass seedling is enclosed in a sheath called the coleoptile (see Figure 38.9b), which grows straight upward if the seedling is kept in the dark or if it is illuminated uniformly from all sides. If the growing coleoptile is illuminated from one side, it grows toward the light. This response results from a differential growth of cells on opposite sides of the coleoptile; the cells on the darker side elongate faster than the cells on the brighter side.

Charles Darwin and his son Francis conducted some of the earliest experiments on phototropism in the late 1800s **(Figure 39.5)**. They observed that a grass seedling could bend toward light only if the tip of the coleoptile was present. If the



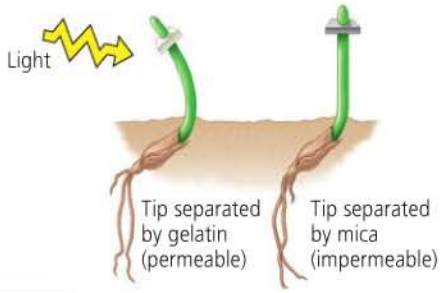
▼ Figure 39.5 Inquiry

What part of a grass coleoptile senses light, and how is the signal transmitted?



EXPERIMENT In 1880, Charles and Francis Darwin removed and covered parts of grass coleoptiles to determine what part senses light. In 1913, Peter Boysen-Jensen separated coleoptiles with different materials to determine how the signal for phototropism is transmitted.

RESULTS



Control

Darwin and Darwin: Phototropism occurs only when the tip is illuminated.

Boysen-Jensen: Phototropism occurs when the tip is separated by a permeable barrier but not an impermeable barrier.

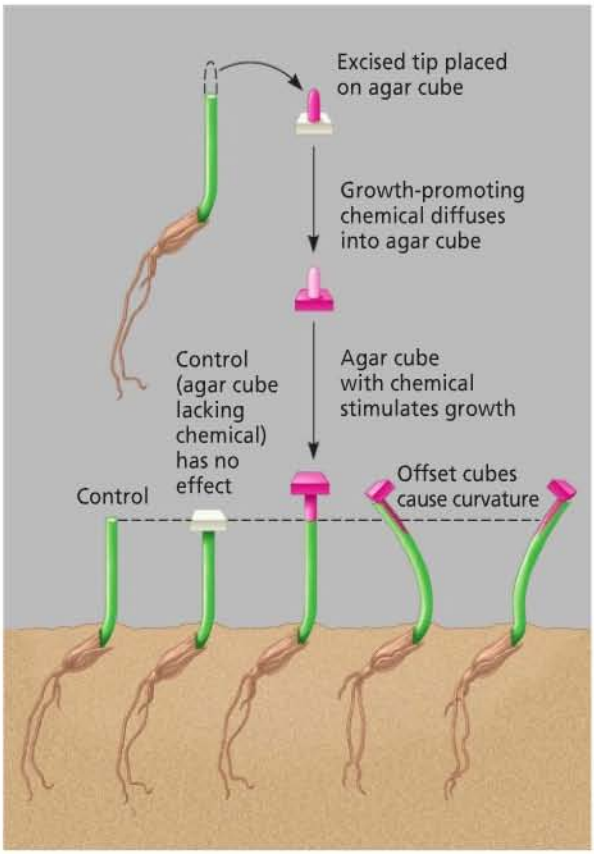
CONCLUSION The Darwins' experiment suggested that only the tip of the coleoptile senses light. The phototropic bending, however, occurred at a distance from the site of light perception (the tip). Boysen-Jensen's results suggested that the signal for the bending is a light-activated mobile chemical.

SOURCE C. R. Darwin, The power of movement in plants, John Murray, London (1880). P. Boysen-Jensen, Concerning the performance of phototropic stimuli on the *Avena* coleoptile, *Berichte der Deutschen Botanischen Gesellschaft* (Reports of the German Botanical Society) 31:559–566 (1913).

WHAT IF? How could you experimentally determine which colors of light cause the most phototropic bending?

tip was removed, the coleoptile did not curve. The seedling also failed to grow toward light if the tip was covered with an opaque cap; but neither a transparent cap over the tip nor an opaque shield placed below the coleoptile tip prevented the phototropic response. It was the tip of the coleoptile, the Darwins concluded, that was responsible for sensing light. However, they noted that the differential growth response that led to curvature of the coleoptile occurred some distance below the tip. The Darwins postulated that some signal was transmitted downward from the tip to the elongating region of the coleoptile. A few decades later, the Danish scientist Peter Boysen-Jensen demonstrated that the signal was a mobile chemical substance. He separated the tip from the remainder of the coleoptile by a cube of gelatin, which prevented cellular contact but allowed chemicals to pass. These seedlings responded normally, bending toward light. However, if the tip was experimentally separated from the lower coleoptile by an impermeable barrier, such as the mineral mica, no phototropic response occurred.

In 1926, Frits Went, a Dutch graduate student, extracted the chemical messenger for phototropism by modifying the experiments of Boysen-Jensen **(Figure 39.6)**. Went removed the coleoptile tip and placed it on a cube of agar, a gelatinous material. The chemical messenger from the tip, Went reasoned, should diffuse into the agar, and the agar block should then be able to substitute for the coleoptile tip. Went placed the agar blocks on decapitated coleoptiles that were kept in the dark. A block that was centered on top of the coleoptile caused the stem to grow straight upward. However, when the block was placed off center, the coleoptile began to bend away from the side with the agar block, as though growing toward light. Went concluded that the agar block contained a chemical produced in the coleoptile tip, that this chemical stimulated growth as it passed down the coleoptile, and that a coleoptile curved toward light because of a higher concentration of the growth-promoting chemical on the darker side of the coleoptile. For this chemical messenger, or hormone, Went chose the name auxin (from the Greek *auxein*, to increase). Auxin was later purified by Kenneth Thimann, at the California Institute of Technology, and its chemical structure found to be indoleacetic acid (IAA).



The classical hypothesis for what causes grass coleoptiles to grow toward light, based on the work of the Darwins, Boysen-Jensen, and Went, is that an asymmetrical distribution of auxin moving down from the coleoptile tip causes cells on the darker side to elongate faster than cells on the brighter side. But studies of phototropism by organs other than grass coleoptiles provide less support for this idea. There is no evidence that illumination from one side causes asymmetrical distribution of auxin in stems of sunflowers or other eudicots. There *is*, however, asymmetrical distribution of certain substances that may act as growth *inhibitors*, and these substances are more concentrated on the lighted side of a stem.

▼ Figure 39.6 Inquiry

Does asymmetrical distribution of a growth-promoting chemical cause a coleoptile to grow toward the light?

EXPERIMENT In 1926, Frits Went's experiment identified how a growth-promoting chemical causes a coleoptile to grow toward light. He placed coleoptiles in the dark and removed their tips, putting some tips on agar cubes that he predicted would absorb the growth-promoting chemical. On a control coleoptile, he placed a cube that lacked the chemical. On others, he placed cubes containing the chemical, either centered on top of the coleoptile to distribute the chemical evenly or offset to increase the concentration on one side.

RESULTS The coleoptile grew straight if the growth-promoting chemical was distributed evenly. If the chemical was distributed unevenly, the coleoptile curved away from the side with the cube, as if growing toward light, even though it was grown in the dark.

CONCLUSION Went concluded that a coleoptile curved toward light because its dark side had a higher concentration of the growth-promoting chemical, which he named auxin.

SOURCE F. Went, A growth substance and growth, *Recueils des Travaux Botaniques Néerlandais* (Collections of Dutch Botanical Works) 25:1–116 (1928).

WHAT IF? Triiodobenzoic acid (TIBA) inhibits auxin transport. If a tiny agar bead containing TIBA were placed off center on the tip of an intact coleoptile, which way would the coleoptile bend: toward the side with the bead or away from it? Explain.

A Survey of Plant Hormones

The early studies on phototropism that we have just discussed provided the basis for subsequent research on plant hormones. **Table 39.1** previews some major classes of plant hormones: auxin, cytokinins, gibberellins, brassinosteroids, abscisic acid, and ethylene. Many molecules in plants that function in defense against pathogens are probably plant hormones as well. (These molecules will be discussed later in the chapter.)

Plant hormones are produced in very low concentrations, but a tiny amount of hormone can have a profound effect on the growth and development of a plant organ. This implies that the hormonal signal must be amplified in some way. A hormone may act by altering the expression of genes, by affecting the activity of existing enzymes, or by changing properties of membranes. Any of these actions could redirect the metabolism and development of a cell responding to a small number of hormone molecules. Signal transduction pathways amplify the hormonal signal and connect it to a cell's specific responses.

In general, hormones control plant growth and development by affecting the division, elongation, and differentiation of cells. Some hormones also mediate shorter-term physiological responses of plants to environmental stimuli. Each hormone has multiple effects, depending on its site of action, its concentration, and the developmental stage of the plant.

Response to a hormone usually depends not so much on the amount of that hormone as on its relative concentration compared with other hormones. It is hormonal balance, rather than hormones acting in isolation, that may control growth and development. These interactions will become apparent in the following survey of hormone function.

Auxin

The term **auxin** is used for any chemical substance that promotes elongation of coleoptiles, although auxins have multiple

Table 39.1 Overview of Plant Hormones

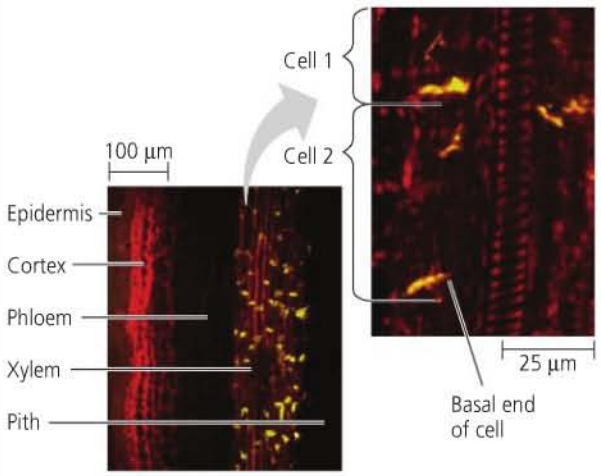
Hormone	Where Produced or Found in Plant	Major Functions
Auxin (IAA)	Shoot apical meristems and young leaves are the primary sites of auxin synthesis. Root apical meristems also produce auxin, although the root depends on the shoot for much of its auxin. Developing seeds and fruits contain high levels of auxin, but it is unclear whether it is newly synthesized or transported from maternal tissues.	Stimulates stem elongation (low concentration only); promotes the formation of lateral and adventitious roots; regulates development of fruit; enhances apical dominance; functions in phototropism and gravitropism; promotes vascular differentiation; retards leaf abscission.
Cytokinins	These are synthesized primarily in roots and transported to other organs, although there are many minor sites of production as well.	Regulate cell division in shoots and roots; modify apical dominance and promote lateral bud growth; promote movement of nutrients into sink tissues; stimulate seed germination; delay leaf senescence.
Gibberellins	Meristems of apical buds and roots, young leaves, and developing seeds are the primary sites of production.	Stimulate stem elongation, pollen development, pollen tube growth, fruit growth, and seed development and germination; regulate sex determination and the transition from juvenile to adult phases.
Brassinosteroids	These compounds are present in all plant tissues, although different intermediates predominate in different organs. Internally produced brassinosteroids act near the site of synthesis.	Promote cell expansion and cell division in shoots; promote root growth at low concentrations; inhibit root growth at high concentrations; promote xylem differentiation and inhibit phloem differentiation; promote seed germination and pollen tube elongation.
Abscisic acid (ABA)	Almost all plant cells have the ability to synthesize abscisic acid, and its presence has been detected in every major organ and living tissue; may be transported in the phloem or xylem.	Inhibits growth; promotes stomatal closure during drought stress; promotes seed dormancy and inhibits early germination; promotes leaf senescence; promotes desiccation tolerance.
Ethylene	This gaseous hormone can be produced by almost all parts of the plant. It is produced in high concentrations during senescence, leaf abscission, and the ripening of some types of fruits. Synthesis is also stimulated by wounding and stress.	Promotes ripening of many types of fruit, leaf abscission, and the triple response in seedlings (inhibition of stem elongation, promotion of lateral expansion, and horizontal growth); enhances the rate of senescence; promotes root and root hair formation; promotes flowering in the pineapple family.

functions in flowering plants. The natural auxin in plants is indoleacetic acid, or IAA, but several other compounds, including some synthetic ones, have auxin activity. Throughout this chapter, however, the term *auxin* is used specifically to refer to IAA. Although IAA was the first plant hormone to be discovered, much remains to be learned about auxin signal transduction and the regulation of auxin biosynthesis.

Auxin is transported down the stem from the shoot apex at a speed of about 10 mm/hr, much too fast for diffusion, although slower than translocation in phloem. Auxin seems to be transported directly through parenchyma tissue, from one cell to the next. In the shoot, it moves only from tip to base, not in the reverse direction. This unidirectional transport of auxin is called polar transport. Polar transport has nothing to do with gravity; experiments have shown that auxin travels upward when a stem or coleoptile segment is placed upside down. Rather, the polarity of auxin movement is attributable to the polar distribution of auxin transport protein in the cells. Concentrated at the basal end of a cell, the auxin transporters move the hormone out of the cell. The auxin can then enter the apical end of the neighboring cell **(Figure 39.7)**. Auxin has a variety of effects, including stimulating cell elongation and lateral root formation.

The Role of Auxin in Cell Elongation Although auxin affects several aspects of plant development, one of its chief functions is to stimulate elongation of cells within young developing shoots. The apical meristem of a shoot is a major site of auxin synthesis. As auxin from the shoot apex moves down to the region of cell elongation (see Figure 35.16), the hormone stimulates cell growth, probably by binding to a receptor in the plasma membrane. Auxin stimulates growth only over a certain concentration range, from about 10^{-8} to 10^{-4} *M*. At higher concentrations, auxin may inhibit cell elongation, probably by inducing production of ethylene, a hormone that generally inhibits elongation. We will return to this hormonal interaction when we discuss ethylene.

According to a model called the *acid growth hypothesis,* proton pumps play a major role in the growth response of cells to auxin. In a shoot's region of elongation, auxin stimulates the plasma membrane's proton (H^+) pumps. This pumping of H^+ increases the voltage across the membrane (membrane potential) and lowers the pH in the cell wall within minutes **(Figure 39.8)**. Acidification of the wall activates enzymes called **expansins** that break the cross-links (hydrogen bonds) between cellulose microfibrils and other cell wall constituents, loosening the wall's fabric. (Expansins can even weaken the integrity of filter paper made of pure cellulose.) Increasing the membrane potential enhances ion uptake into the cell, which causes osmotic uptake of water and increased turgor. Increased turgor and increased cell wall plasticity enable the cell to elongate.



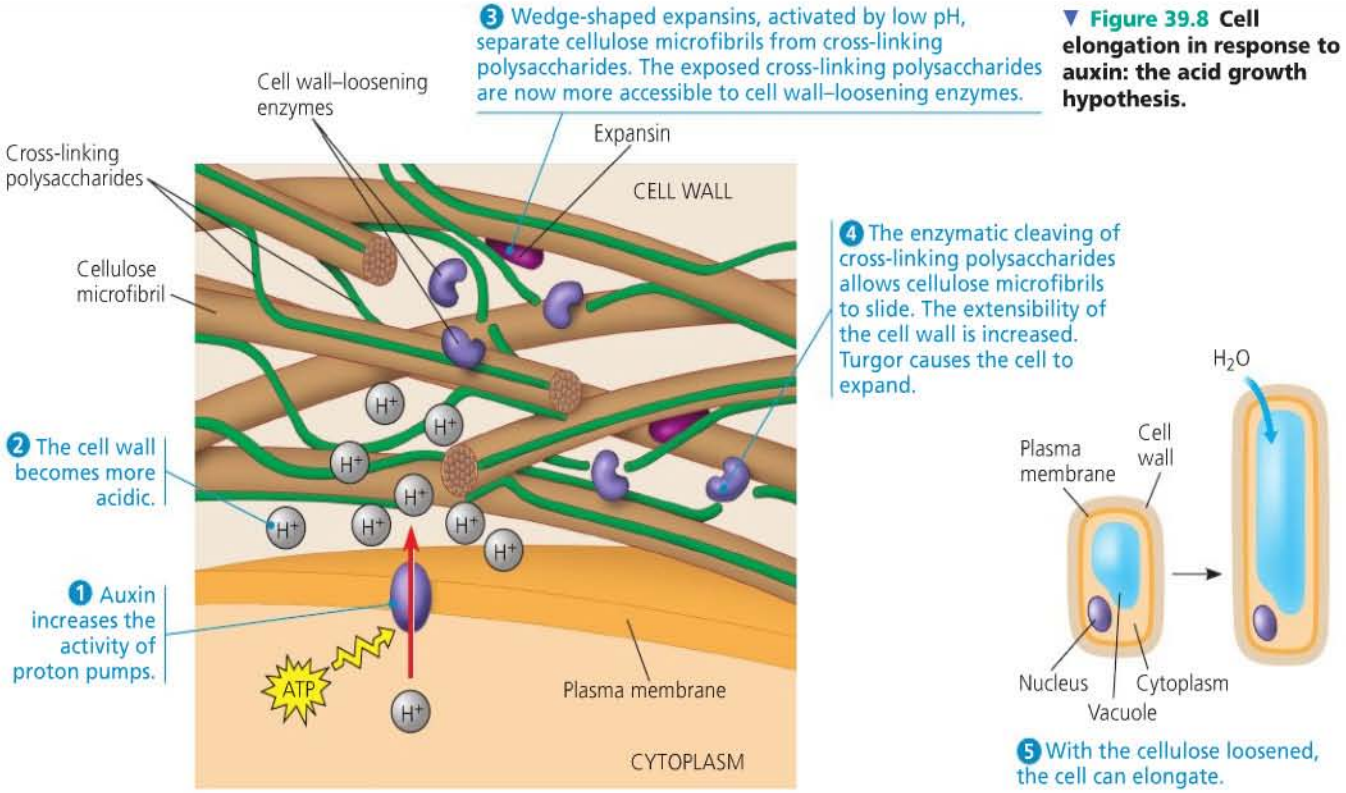
Auxin also rapidly alters gene expression, causing cells in the region of elongation to produce new proteins within minutes. Some of these proteins are short-lived transcription factors that repress or activate the expression of other genes. For sustained growth after this initial spurt, cells must make more cytoplasm and wall material. Auxin also stimulates this sustained growth response.

Figure 39.7 Inquiry

What causes polar movement of auxin from shoot tip to base?

EXPERIMENT To investigate how auxin is transported unidirectionally, Leo Gälweiler and colleagues designed an experiment to identify the location of the auxin transport protein. They used a greenish yellow fluorescent molecule to label antibodies that bind to the auxin transport protein. Then they applied the antibodies to longitudinally sectioned *Arabidopsis* stems.

RESULTS The light micrograph on the left shows that auxin transport proteins are not found in all stem tissues, but only in the xylem parenchyma. In the light micrograph on the right, a higher magnification reveals that these proteins are primarily localized at basal ends of the cells.



CONCLUSION The results support the hypothesis that concentration of the auxin transport protein at the basal ends of cells mediates the polar transport of auxin.

SOURCE L. Gälweiler et al., Regulation of polar auxin transport by AtPIN1 in *Arabidopsis* vascular tissue, *Science* 282:2226–2230 (1998).

WHAT IF? If auxin transport proteins were equally distributed at both ends of the cells, would polar auxin transport still be possible? Explain.

Lateral and Adventitious Root Formation Auxins are used commercially in the vegetative propagation of plants by cuttings. Treating a detached leaf or stem with rooting powder containing auxin often causes adventitious roots to form near the cut surface. Auxin is also involved in the branching of roots. Researchers found that an *Arabidopsis* mutant that exhibits extreme proliferation of lateral roots has an auxin concentration 17-fold higher than normal.

▼ Figure 39.8 Cell elongation in response to auxin: the acid growth hypothesis.

Auxins as Herbicides Certain synthetic auxins, including 2,4-dichlorophenoxyacteic acid (2,4-D), are widely used as herbicides. Monocots, such as maize and turfgrass, can rapidly inactivate such synthetic auxins. However, eudicots cannot and therefore die from hormonal overdose. Spraying cereal fields or turf with 2,4-D eliminates eudicot (broadleaf) weeds.

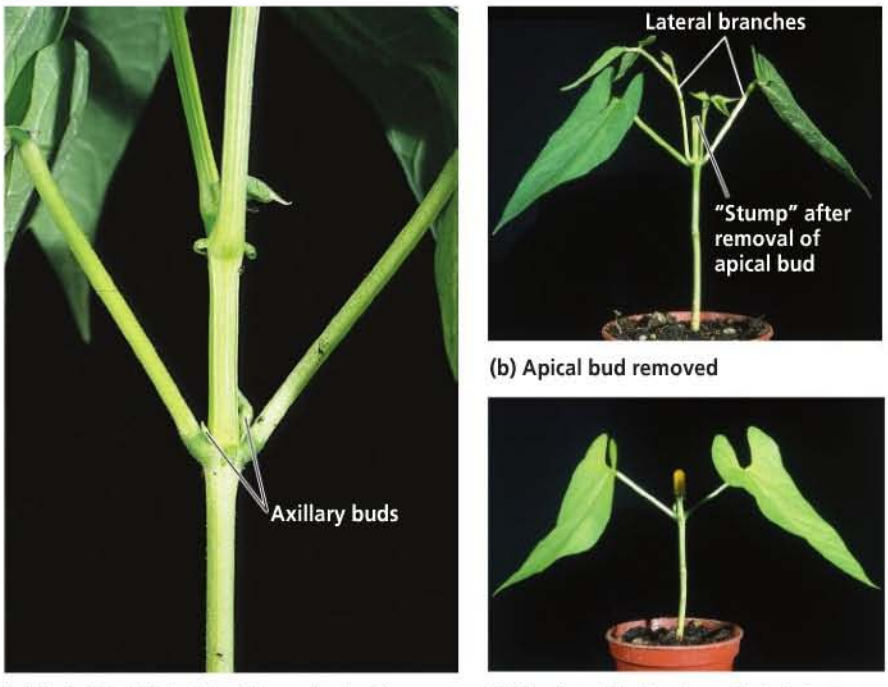
Other Effects of Auxin In addition to stimulating cell elongation during primary growth, auxin affects secondary growth by increasing cambial activity and influencing the differentiation of cambial initials (see Figure 35.20).

Developing seeds produce auxin, which promotes fruit growth. In greenhouses, seed production is often poor because of the lack of insect pollinators, resulting in poorly developed tomato fruits. However, spraying synthetic auxins on greenhouse-grown tomato vines induces normal fruit development without pollination, making the greenhouse-cultivated tomato fruits commercially viable.

Cytokinins

Trial-and-error attempts to find chemical additives that would enhance the growth and development of plant cells in tissue culture led to the discovery of **cytokinins**. In the 1940s, Johannes van Overbeek, working at the Cold Spring Harbor Laboratory in New York, found he could stimulate the growth of plant embryos by adding coconut milk, the liquid endosperm of a coconut's giant seed, to his culture medium. A decade later, Folke Skoog and Carlos O. Miller, at the University of Wisconsin, Madison, induced cultured tobacco cells to divide by adding degraded DNA samples. The active ingredients of both experimental additives turned out to be modified forms of adenine, a component of nucleic acids. These growth regulators were named cytokinins because they stimulate cytokinesis, or cell division. The most common natural cytokinin is zeatin, so named because it was discovered first in maize (*Zea mays*). Although much remains to be learned about cytokinin synthesis and signal transduction, the effects of cytokinins on cell division and differentiation, apical dominance, and aging are well documented.

Control of Cell Division and Differentiation Cytokinins are produced in actively growing tissues, particularly in roots, embryos, and fruits. Cytokinins produced in roots reach their target tissues by moving up the plant in the xylem sap. Acting in concert with auxin, cytokinins stimulate cell division and influence the pathway of differentiation. The effects of cytokinins on cells growing in tissue culture provide clues about how this class of hormones may function in an intact plant. When a piece of parenchyma tissue from a stem is cultured in the absence of cytokinins, the cells grow very large but do not divide. But if cytokinins are added along with auxin, the cells divide. Cytokinins alone have no effect. The ratio of cytokinins to auxin controls cell differentiation. When the concentrations of these two hormones are at certain levels, the mass of cells continues to grow, but it remains a cluster of undifferentiated cells called a callus (see Figure 38.14). If cytokinin levels increase, shoot buds develop from the callus. If auxin levels increase, roots form.



Control of Apical Dominance Cytokinins, auxin, and other factors interact in the control of apical dominance, the ability of the apical bud to suppress the development of axillary buds **(Figure 39.9a)**. Until recently, the leading hypothesis to explain the hormonal regulation of apical dominance—the direct inhibition hypothesis—proposed that auxin and cytokinins act antagonistically in regulating axillary bud growth. According to this view, auxin transported down the shoot from the apical bud directly inhibits axillary buds from growing, causing a shoot to lengthen at the expense of lateral branching. Meanwhile, cytokinins entering the shoot system from roots counter the action of auxin by signaling axillary buds to begin growing. Thus, the ratio of auxin and cytokinins was viewed as the critical factor in controlling axillary bud inhibition.

Many observations are consistent with the direct inhibition hypothesis. If the apical bud, the primary source of auxin, is removed, the inhibition of axillary buds is removed and the plant becomes bushier **(Figure 39.9b)**. Applying auxin to the cut surface of the decapitated shoot resuppresses the growth of the lateral buds **(Figure 39.9c)**. Mutants that overproduce cytokinins or plants treated with cytokinins also tend to be bushier than normal. However, one prediction of the direct inhibition hypothesis *not* supported by experiment is that decapitation, by removing the primary source of auxin, should lead to a decrease in the auxin levels of axillary buds. Biochemical studies have in fact revealed the opposite: Auxin levels actually *increase* in the axillary buds of decapitated plants. The direct inhibition hypothesis, therefore, does not account for all experimental findings. It is likely that plant biologists have not uncovered all the pieces of this puzzle.

Anti-Aging Effects Cytokinins retard the aging of certain plant organs by inhibiting protein breakdown, stimulating RNA and protein synthesis, and mobilizing nutrients from surrounding tissues. If leaves removed from a plant are dipped in a cytokinin solution, they stay green much longer than otherwise. Cytokinins also slow the deterioration of leaves on intact plants. Because of this anti-aging effect, florists use cytokinin sprays to keep cut flowers fresh.

Gibberellins

In the early 1900s, farmers in Asia noticed that some rice seedlings in their paddies grew so tall and spindly that they toppled over before they could mature and flower. In 1926, Japanese plant pathologist Ewiti Kurosawa discovered that a fungus of the genus *Gibberella* caused this "foolish seedling disease." By the 1930s, Japanese scientists had determined that the fungus caused hyperelongation of rice stems by secreting a chemical, which was given the name **gibberellin**. In the 1950s, researchers discovered that plants also produce gibberellins (GAs). Since that time, scientists have identified more than 100 different gibberellins that occur naturally in plants, although a much smaller number occur in each plant species. "Foolish rice" seedlings, it seems, suffer from an overdose of gibberellins normally found in plants in lower concentrations. Gibberellins have a variety of effects, such as stem elongation, fruit growth, and seed germination.

(a) Apical bud intact (not shown in photo)

(b) Apical bud removed

(c) Auxin added to decapitated stem

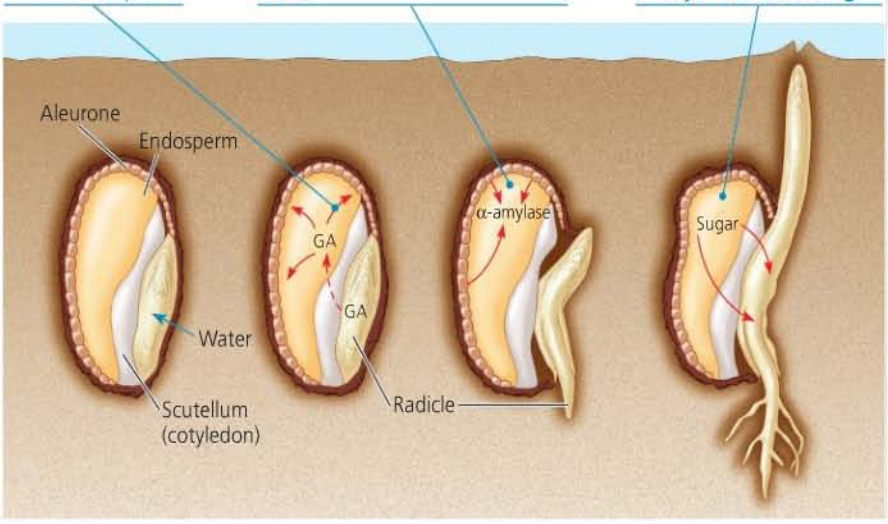
▲ **Figure 39.9 Apical dominance. (a)** The inhibition of growth of axillary buds, possibly influenced by auxin from the apical bud, favors elongation of the shoot's main axis. **(b)** Removal of the apical bud from the same plant enables lateral branches to grow. **(c)** Applying a gelatin capsule containing auxin to the stump prevents the lateral branches from growing.

Stem Elongation The major sites of gibberellin production are roots and young leaves. Gibberellins stimulate stem and leaf growth but have little effect on roots. In stems, they stimulate cell elongation *and* cell division. One hypothesis proposes that they activate enzymes that loosen cell walls, facilitating entry of expansin proteins. Thus, gibberellins act in concert with auxin to promote stem elongation.

The effects of gibberellins in enhancing stem elongation are evident when certain dwarf (mutant) varieties of plants are treated with gibberellins. For instance, some dwarf pea plants (including the variety Mendel studied; see Chapter 14) grow tall if treated with gibberellins. But there is often no response if the gibberellins are applied to wild-type plants. Apparently, these plants already produce

an optimal dose of the hormone. The most dramatic example of gibberellin-induced stem elongation is *bolting*, rapid growth of the floral stalk **(Figure 39.10a)**.

Fruit Growth In many plants, both auxin and gibberellins must be present in order for fruit to develop. The most important commercial application of gibberellins is in the spraying of Thompson seedless grapes **(Figure 39.10b)**. The hormone makes the individual grapes grow larger, a trait valued by the consumer. The gibberellin sprays also make the internodes of the grape bunch elongate, allowing more space for the individual grapes. By enhancing air circulation between the grapes, this increase in space also makes it harder for yeasts and other microorganisms to infect the fruits.



(a) Some plants develop in a rosette form, low to the ground with very short internodes, as in the *Arabidopsis* plant shown at the left. As the plant switches to reproductive growth, a surge of gibberellins induces bolting: Internodes elongate rapidly, elevating floral buds that develop at stem tips (right).

(b) The Thompson seedless grape bunch on the left is from an untreated control vine. The bunch on the right is growing from a vine that was sprayed with gibberellin during fruit development.

◀ Figure 39.10 Effects of gibberellins on stem elongation and fruit growth.

Germination The embryo of a seed is a rich source of gibberellins. After water is imbibed, the release of gibberellins from the embryo signals the seed to break dormancy and germinate. Some seeds that require particular environmental conditions to germinate, such as exposure to light or low temperatures, break dormancy if they are treated with gibberellins. Gibberellins support the growth of cereal seedlings by stimulating the synthesis of digestive enzymes such as α-amylase that mobilize stored nutrients **(Figure 39.11)**.

▲ Figure 39.11 Mobilization of nutrients by gibberellins during the germination of grain seeds such as barley.

Brassinosteroids

Brassinosteroids are steroids and therefore chemically similar to cholesterol and the sex hormones of animals. They induce cell elongation and division in stem segments and seedlings at concentrations as low as 10^{-12} *M*. They also retard leaf abscission (leaf drop) and promote xylem differentiation. These effects are so qualitatively similar to those of auxin that it took several years for plant physiologists to determine that brassinosteroids were not types of auxins.

Evidence from molecular biology established brassinosteroids as plant hormones. Joanne Chory and colleagues at the Salk Institute in San Diego were interested in mutant *Arabidopsis* with morphological features similar to those of light-grown plants, even though the mutants were grown in the dark. The researchers discovered that the mutation affects a gene that normally codes for an enzyme similar to one involved in steroid synthesis in mammals. They also found that this brassinosteroid-deficient mutant could be restored to the wild-type phenotype by applying brassinosteroids in the lab.

Abscisic Acid

In the 1960s, one research group studying the chemical changes that precede bud dormancy and leaf abscission in deciduous trees and another team investigating chemical changes preceding abscission of cotton fruits isolated the same compound, **abscisic acid** (ABA).

Ironically, ABA is no longer thought to play a primary role in bud dormancy or leaf abscission, but it is very important in other functions. Unlike the growth-stimulating hormones we have studied so far—auxin, cytokinins, gibberellins, and brassinosteroids—ABA *slows* growth. ABA often antagonizes the actions of growth hormones, and the ratio of ABA to one or more growth hormones determines the final physiological outcome. We will consider here two of ABA's many effects: seed dormancy and drought tolerance.

Seed Dormancy Seed dormancy increases the likelihood that seeds will germinate only when there are sufficient amounts of light, temperature, and moisture for the seedlings to survive (see Chapter 38). What prevents seeds dispersed in autumn from germinating immediately, only to die in the winter? What mechanisms ensure that such seeds do not germinate until spring? For that matter, what prevents seeds from germinating in the dark, moist interior of the fruit? The answer to these questions is ABA. The levels of ABA may increase 100-fold during seed maturation. The high levels of ABA in maturing seeds inhibit germination and induce the production of certain proteins that help the seeds withstand the extreme dehydration that accompanies maturation.

Many types of dormant seeds germinate when ABA is removed or inactivated. The seeds of some desert plants break dormancy only when heavy rains wash ABA out of them. Other seeds require light or prolonged exposure to cold to inactivate ABA. Often, the ratio of ABA to gibberellins determines whether the seed remains dormant or germinates, and adding ABA to seeds that are primed to germinate makes them dormant again. Inactivated ABA or low levels of ABA can lead to precocious (early) germination **(Figure 39.12)**. For example, a maize mutant with grains that germinate while still on the cob lacks a functional transcription factor required for ABA to induce expression of certain genes. Precocious germination of red mangrove seeds, due to low ABA levels, is actually an adaptation that helps the young seedlings to plant themselves in the soft mud below the parent tree.

Drought Tolerance ABA is the primary internal signaling molecule that enables plants to withstand drought. When a plant begins to wilt, ABA accumulates in leaves and causes stomata to close rapidly, reducing transpiration and preventing further water loss. By affecting second messengers such as calcium, ABA causes potassium channels in the plasma membrane of guard cells to open, leading to a massive loss of potassium ions from the cells. The accompanying osmotic loss of water reduces guard cell turgor and leads to closing of the stomatal pores (see Figure 36.17). In some cases, water shortage stresses the root system before the shoot system, and ABA transported from roots to leaves may function as an "early warning system." Many mutants that are especially prone to wilting are deficient in ABA production.

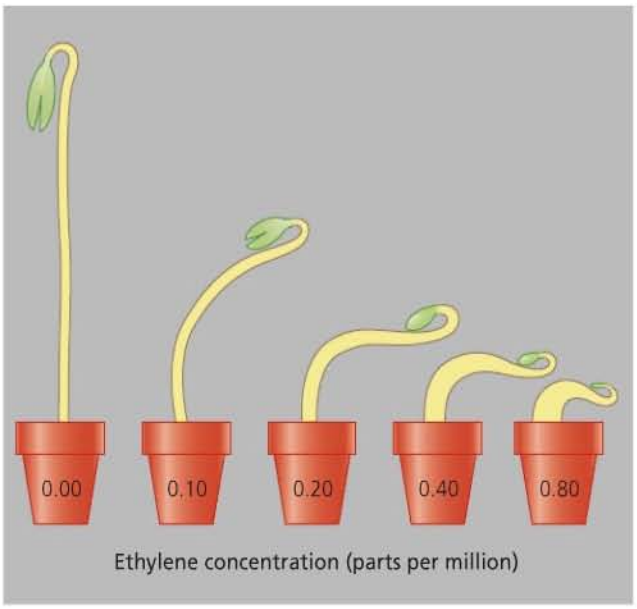
◀ Red mangrove (*Rhizophora mangle*) seeds produce only low levels of ABA, and their seeds germinate while still on the tree. In this case, early germination is a useful adaptation. When released, the radicle of the dart-like seedling deeply penetrates the soft mudflats in which the mangroves grow.

▲ Precocious germination in this maize mutant is caused by lack of a functional transcription factor required for ABA action.

▲ **Figure 39.12 Precocious germination of wild-type mangrove and mutant maize seeds.**

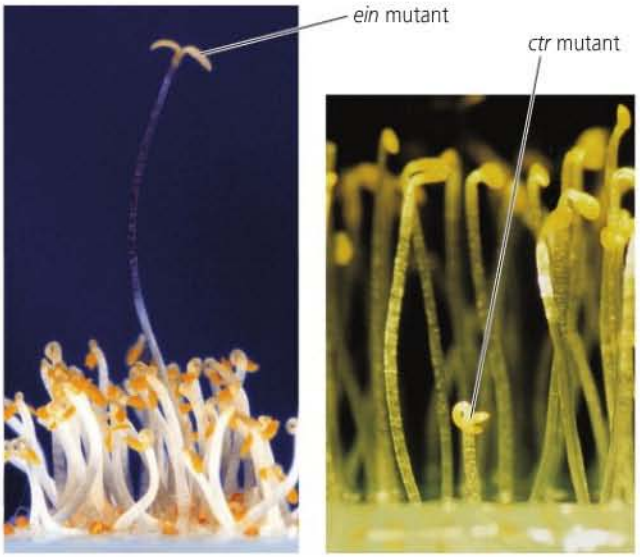
Ethylene

During the 1800s, when coal gas was used as fuel for streetlights, leakage from gas pipes caused nearby trees to drop leaves prematurely. In 1901, the Russian scientist Dimitry Neljubow demonstrated that the gas **ethylene** was the active factor in the coal gas. The idea that ethylene is a plant hormone was not widely accepted, however, until the advent of gas chromatography simplified identification.



Plants produce ethylene in response to stresses such as drought, flooding, mechanical pressure, injury, and infection. Ethylene is also produced during fruit ripening and programmed cell death and in response to high concentrations of externally applied auxin. Indeed, many effects previously ascribed to auxin, such as inhibition of root elongation, may be due to auxin-induced ethylene production. We will focus here on four of ethylene's many effects: response to mechanical stress, senescence, leaf abscission, and fruit ripening.

The Triple Response to Mechanical Stress Imagine a pea seedling pushing upward through the soil, only to come up against a stone. As it pushes against the obstacle, the stress in its delicate tip induces the seedling to produce ethylene. The hormone then instigates a growth maneuver known as the **triple response** that enables the shoot to avoid the obstacle. The three



parts of this response are a slowing of stem elongation, a thickening of the stem (which makes it stronger), and a curvature that causes the stem to start growing horizontally. As the effects of the initial ethylene pulse lessen, the stem resumes vertical growth. If it again contacts a barrier, another burst of ethylene is released, and horizontal growth resumes. However, if the upward touch detects no solid object, then ethylene production decreases, and the stem, now clear of the obstacle, resumes its normal upward growth. It is ethylene that induces the stem to grow horizontally rather than the physical obstruction itself; when ethylene is applied to normal seedlings growing free of physical impediments, they still undergo the triple response **(Figure 39.13)**.

Studies of *Arabidopsis* mutants with abnormal triple responses are an example of how biologists identify a signal transduction pathway. Scientists isolated ethylene-insensitive (*ein*) mutants, which fail to undergo the triple response after exposure to ethylene **(Figure 39.14a)**. Some types of *ein* mutants are insensitive to ethylene because they lack a functional ethylene receptor. Mutants of a different sort undergo the triple response even out of soil, in the air, where there are no physical obstacles. Some of these mutants have a regulatory defect that causes them to produce ethylene at rates 20 times normal. The phenotype of such ethylene-overproducing (*eto*) mutants can be restored to wild-type by treating the seedlings with inhibitors of ethylene synthesis. Other mutants, called constitutive triple-response (*ctr*) mutants, undergo the triple response in air but do not respond to inhibitors of ethylene synthesis **(Figure 39.14b)**. (Constitutive genes are genes that are continually expressed in all cells of an organism.) In *ctr mutants*, ethylene signal transduction is permanently turned on, even though ethylene is not present.

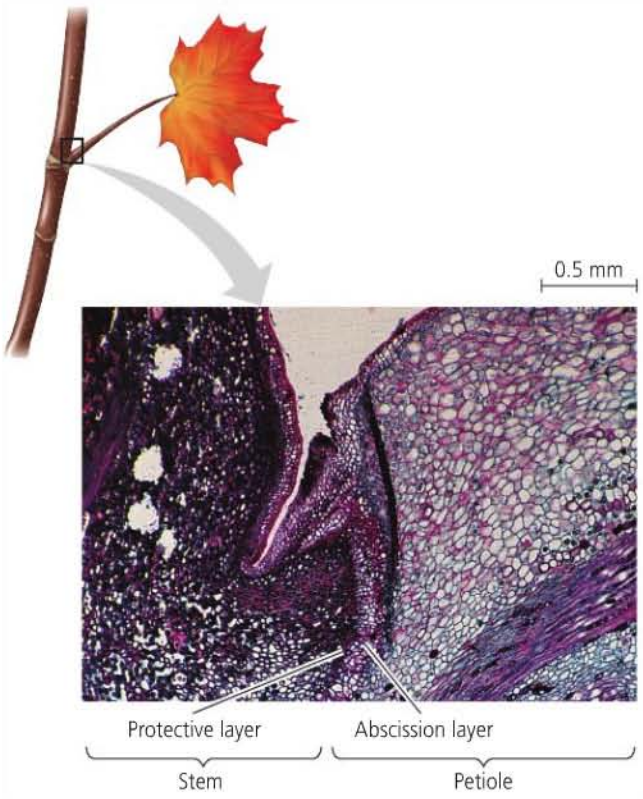
The affected gene in *ctr* mutants codes for a protein kinase. The fact that this mutation *activates* the ethylene response suggests that the normal kinase product of the wild-type allele is a *negative* regulator of ethylene signal transduction. Here is one hypothesis for how the pathway works in wild-type plants: Binding of the hormone ethylene to the ethylene receptor leads to inactivation of the kinase; and inactivation of this negative regulator allows synthesis of the proteins required for the triple response.

▲ **Figure 39.13 The ethylene-induced triple response.** In response to ethylene, a gaseous plant hormone, germinating pea seedlings grown in the dark undergo the triple response—slowing of stem elongation, stem thickening, and horizontal stem growth. The response is greater with increased ethylene concentration.

(a) *ein* mutant. An ethylene-insensitive (*ein*) mutant fails to undergo the triple response in the presence of ethylene.

(b) *ctr* mutant. A constitutive triple-response (*ctr*) mutant undergoes the triple response even in the absence of ethylene.

▲ **Figure 39.14 Ethylene triple-response *Arabidopsis* mutants.**



Senescence Consider the shedding of a leaf in autumn or the death of an annual after flowering. Or think about the final step in differentiation of a vessel element, when its living contents are destroyed, leaving a hollow tube behind. Such events involve **senescence**—the programmed death of certain cells or organs or the entire plant. Cells, organs, and plants genetically programmed to die on a schedule do not simply shut down cellular machinery and await death. Instead, at the molecular level, the onset of programmed cell death, called **apoptosis**, is a very busy time in a cell's life, requiring new gene expression (see Figure 11.19). During apoptosis, newly formed enzymes break down many chemical components, including chlorophyll, DNA, RNA, proteins, and membrane lipids. The plant salvages many of the breakdown products. A burst of ethylene is almost always associated with the programmed destruction of cells, organs, or the whole plant.

Leaf Abscission The loss of leaves from deciduous trees helps prevent desiccation during seasonal periods of climatic stress

that severely limit the availability of water to the roots. Before dying leaves abscise, many essential elements are salvaged from them and stored in stem parenchyma cells. These nutrients are recycled back to developing leaves the following spring. Autumn leaf color is due to newly made red pigments as well as yellow and orange carotenoids (see Chapter 10) that were already present in the leaf and are rendered visible by the breakdown of the dark green chlorophyll in autumn.

When an autumn leaf falls, the breaking point is an abscission layer that develops near the base of the petiole **(Figure 39.15)**. The small parenchyma cells of this layer have very thin walls, and there are no fiber cells around the vascular tissue. The abscission layer is further weakened when enzymes hydrolyze polysaccharides in the cell walls. Finally, the weight of the leaf, with the help of wind, causes a separation within the abscission layer. Even before the leaf falls, a layer of cork forms a protective scar on the twig side of the abscission layer, preventing pathogens from invading the plant.

A change in the ratio of ethylene to auxin controls abscission. An aging leaf produces less and less auxin, rendering the cells of the abscission layer more sensitive to ethylene. As the influence of ethylene on the abscission layer prevails, the cells produce enzymes that digest the cellulose and other components of cell walls.

▲ **Figure 39.15 Abscission of a maple leaf.** Abscission is controlled by a change in the ratio of ethylene to auxin. The abscission layer is seen in this longitudinal section as a vertical band at the base of the petiole. After the leaf falls, a protective layer of cork becomes the leaf scar that helps prevent pathogens from invading the plant (LM).

Fruit Ripening Immature fleshy fruits are generally tart, hard, and green—features that help protect the developing seeds from herbivores. After ripening, the mature fruits help *attract* animals that disperse the seeds (see Figures 30.8 and 30.9). In many cases, a burst of ethylene production in the fruit triggers the ripening process. The enzymatic breakdown of cell wall components softens the fruit, and the conversion of starches and acids to sugars makes the fruit sweet. The production of new scents and colors helps advertise ripeness to animals, which eat the fruits and disperse the seeds.

A chain reaction occurs during ripening: Ethylene triggers ripening, and ripening triggers more ethylene production—a rare example of positive feedback in physiology (see Figure 1.13). The result is a huge burst in ethylene production. Because ethylene is a gas, the signal to ripen spreads from fruit to fruit. If you pick or buy green fruit, you may be able to speed ripening by storing the fruit in a paper bag, allowing ethylene to accumulate. On a commercial scale, many kinds of fruits are ripened in huge storage containers in which ethylene levels are enhanced. In other cases, fruit producers take measures to slow ripening caused by natural ethylene. Apples, for instance, are stored in bins flushed with carbon dioxide. Circulating the air prevents ethylene from accumulating, and carbon dioxide inhibits synthesis of new ethylene. Stored in this way, apples picked in autumn can still be shipped to grocery stores the following summer.

Given the importance of ethylene in the postharvest physiology of fruits, the genetic engineering of ethylene signal transduction pathways has potential commercial applications. For example, by engineering a way to block the transcription of one of the genes required for ethylene synthesis, molecular biologists have created tomato fruits that ripen on demand. These fruits are picked while green and will not ripen unless ethylene gas is added. As such methods are refined, they will reduce spoilage of fruits and vegetables, a problem that ruins almost half the produce harvested in the United States.

Systems Biology and Hormone Interactions

As we have discussed, plant responses often involve the interactions of many hormones and their signal transduction pathways. The study of hormone interactions can be a complex problem. For example, flooding of deepwater rice leads to a 50-fold increase in internal ethylene levels and rapid stem elongation. But ethylene's role in this response is a small part of the story. Flooding also leads to an increase in sensitivity to gibberellins that is mediated by a decrease in ABA levels. Thus, stem elongation results from an interaction of these three hormones and their signal transduction pathways.

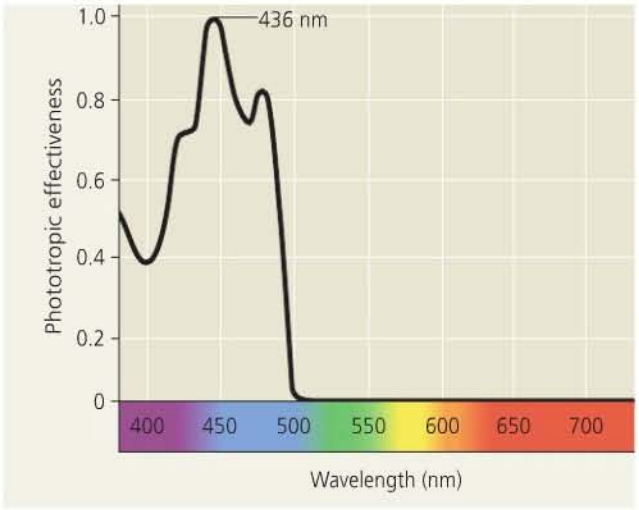
Imagine yourself as a molecular biologist assigned the task of genetically engineering a deepwater rice plant so that it grows even faster when submerged. Would the best molecu-

lar target for genetic manipulation be an enzyme that inactivates ABA? An enzyme that produces more gibberellins? An ethylene receptor? It is difficult to predict. And this is by no means an unusual problem. Virtually every plant response discussed in this chapter is of comparable complexity. Because of this pervasive and unavoidable issue of complex interactions, many plant biologists are promoting a new, systems-based approach to plant biology.

Chapter 1 provided a general description of systems biology, which attempts to discover and understand biological properties that emerge from the interactions of many system elements (for example, mRNAs, proteins, hormones, and metabolites). Using genomic techniques, biologists can now identify all the genes in a plant. As of early 2008, the genomes of several plant species have been sequenced, including the research plant *Arabidopsis*, rice (*Oryza sativa*), a species of poplar (*Populus trichocarpa*), grape (*Vitus vinifera*), and maize (*Zea mays*). Moreover, using microarray and proteomic techniques (see Chapters 20 and 21), scientists can determine which genes are activated or inactivated during development or in response to an environmental change. However, simply identifying all the genes and proteins (system elements) in an organism is comparable to listing all the parts of an airplane. Although such a list provides a catalog of components, it is not sufficient for understanding the complexity underlying the integrated system. What plant biologists really need to know is how all these system elements interact.

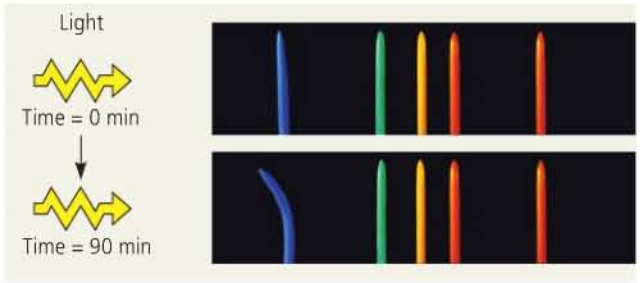
A systems-based approach may greatly alter how plants are studied. One vision is laboratories equipped with high-throughput robotic scanners that record which genes in a plant's genome are activated in which cells and under what conditions. New hypotheses and avenues of research will emerge from analysis of these comprehensive data sets. Ultimately, one goal of systems biology is to model an entire living plant. Armed with such detailed knowledge, a biologist attempting to genetically engineer faster stem elongation in rice could proceed much more efficiently. The ability to model a living plant could make it possible to predict the result of a genetic manipulation before setting foot in the laboratory.

CONCEPT CHECK 39.2



1. Suggest a physiological reason for the old adage "One bad apple spoils the bunch."
2. Suggest a reason why cut flowers such as carnations are often treated with cytokinins prior to shipping.
3. Fusicoccin is a fungal toxin that stimulates the plasma membrane H^+ pumps of plant cells. How may it affect the growth of isolated stem sections?
4. **WHAT IF?** If a plant has the double mutation *ctr* and *ein*, what would be its triple-response phenotype? Explain your answer.

For suggested answers, see Appendix A.



CONCEPT 39.3
Responses to light are critical for plant success

Light is an especially important environmental factor in the lives of plants. In addition to being required for photosynthesis, light cues many key events in plant growth and development. Effects of light on plant morphology are what plant biologists call **photomorphogenesis**. Light reception also allows plants to measure the passage of days and seasons.

Plants can detect not only the presence of light but also its direction, intensity, and wavelength (color). A graph called an **action spectrum** depicts the relative effectiveness of different wavelengths of radiation in driving a particular process. For example, the action spectrum for photosynthesis has two peaks, one in red light and one in blue light (see Figure 10.9b). This is because chlorophyll absorbs light primarily in the red and blue portions of the visible spectrum. Action spectra are useful in studying *any* process that depends on light, such as phototropism **(Figure 39.16)**. By

(a) This action spectrum illustrates that only light wavelengths below 500 nm (blue and violet light) induce curvature.

(b) These photographs of coleoptiles were taken before and after 90-minute exposures to light sources of the colors indicated.

▲ **Figure 39.16 Action spectrum for blue-light-stimulated phototropism in maize coleoptiles.** Phototropic bending toward light is controlled by phototropin, a photoreceptor sensitive to blue and violet light, particularly blue light.

comparing action spectra of various plant responses, researchers determine which responses are mediated by the same photoreceptor (pigment). They also compare action spectra with absorption spectra of pigments; a close correspondence for a given pigment suggests that the pigment is the photoreceptor mediating the response. Action spectra reveal that red and blue light are the most important colors in regulating a plant's photomorphogenesis. These observations led researchers to two major classes of light receptors: **blue-light photoreceptors** and **phytochromes**, photoreceptors that absorb mostly red light.

Blue-Light Photoreceptors

Blue light initiates a variety of responses in plants, including phototropism, the light-induced opening of stomata (see Figure 36.16), and the light-induced slowing of hypocotyl elongation that occurs when a seedling breaks ground. The biochemical identity of the blue-light photoreceptor was so elusive that in the 1970s, plant physiologists began to call this putative receptor "cryptochrome" (from the Greek *kryptos*, hidden, and *chrom*, pigment). In the 1990s, molecular biologists analyzing *Arabidopsis* mutants found that plants use at least three different types of pigments to detect blue light. *Cryptochromes*, molecular relatives of DNA repair enzymes, are involved in the blue-light-induced inhibition of stem elongation that occurs, for example, when a seedling first emerges from the soil. *Phototropin* is a protein kinase involved in mediating phototropic curvatures, such as those studied in grass seedlings by the Darwins, and in chloroplast movements in response to light. There is currently much debate about whether phototropin or a carotenoid-based photoreceptor called *zeaxanthin* is the major blue-light photoreceptor involved in blue-light-mediated stomatal opening.

Phytochromes as Photoreceptors

When introducing signal transduction in plants earlier in the chapter, we discussed the role of the plant pigments called phytochromes in the de-etiolation process. Phytochromes regulate many plant responses to light. Let's look at two more examples: seed germination and shade avoidance.

Phytochromes and Seed Germination

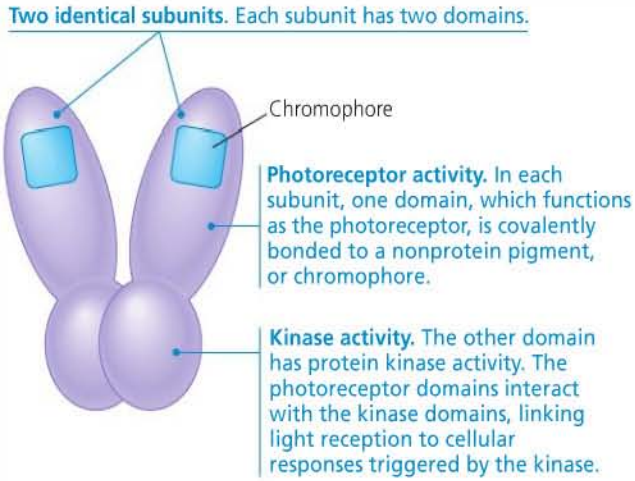
Studies of seed germination led to the discovery of phytochromes. Because of limited nutrient reserves, many types of seeds, especially small ones, germinate only when the light environment and other conditions are near optimal. Such seeds often remain dormant for many years until light conditions change. For example, the death of a shading tree or the plowing of a field may create a favorable light environment.

In the 1930s, scientists at the U.S. Department of Agriculture determined the action spectrum for light-induced germination of lettuce seeds. They exposed water-swollen seeds to a few minutes of monochromatic (single-colored) light of various wavelengths and then stored the seeds in the dark. After two days, the researchers counted the number of seeds that had germinated under each light regimen. They found that red light of wavelength 660 nm increased the germination percentage of lettuce seeds maximally, whereas far-red light—that is, light of wavelengths near the upper edge of human visibility (730 nm)—*inhibited* germination compared with dark controls **(Figure 39.17)**. What happens when the lettuce seeds are subjected to a flash of red

▼ Figure 39.17 Inquiry

How does the order of red and far-red illumination affect seed germination?

EXPERIMENT Scientists at the U.S. Department of Agriculture briefly exposed batches of lettuce seeds to red light or far-red light to test the effects on germination. After the light exposure, the seeds were placed in the dark, and the results were compared with control seeds that were not exposed to light.

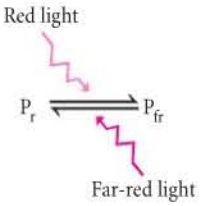


RESULTS The bar below each photo indicates the sequence of red light exposure, far-red light exposure, and darkness. The germination rate increased greatly in groups of seeds that were last exposed to red light (left). Germination was inhibited in groups of seeds that were last exposed to far-red light (right).

CONCLUSION Red light stimulated germination, and far-red light inhibited germination. The final light exposure was the determining factor. The effects of red and far-red light were reversible.

SOURCE H. Borthwick et al., A reversible photoreaction controlling seed germination, *Proceedings of the National Academy of Sciences, USA* 38:662–666 (1952).

WHAT IF? Phytochrome responds faster to red light than to far-red. If the seeds had been placed in white light instead of the dark after their red and far-red light treatments, would the results have been different?



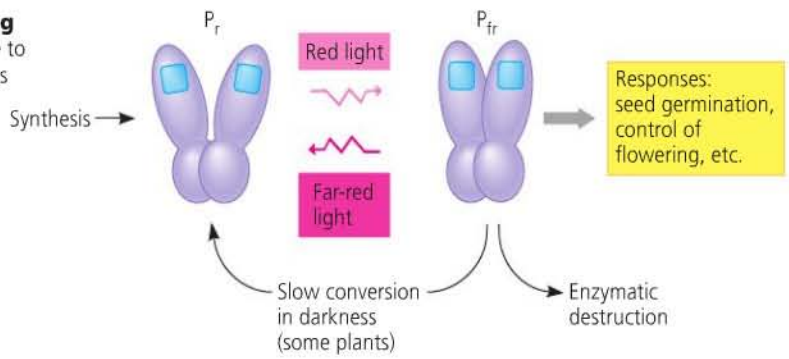
▲ **Figure 39.18 Structure of a phytochrome.**

light followed by a flash of far-red light or, conversely, to far-red light followed by red light? The *last* flash of light determines the seeds' response. In other words, the effects of red and far-red light are reversible.

The photoreceptors responsible for the opposing effects of red and far-red light are phytochromes. A phytochrome has two identical subunits, each consisting of a polypeptide component covalently bonded to a nonpolypeptide *chromophore*, the light-absorbing part of the subunit **(Figure 39.18)**. So far, researchers have identified five phytochromes in *Arabidopsis*, each with a slightly different polypeptide component.

The chromophore of a phytochrome is photoreversible, reverting back and forth between two isomeric forms, depending on the color of light provided (see Figure 4.7 to review isomers). In its P_r isomer form, a phytochrome absorbs red (r) light maximally, whereas in its P_{fr} isomer form, it absorbs far-red (fr) light:

This $P_r \rightleftharpoons P_{fr}$ interconversion is a switching mechanism that controls various light-induced events in the life of the plant **(Figure 39.19)**. P_{fr} is the form of phytochrome that triggers many of a plant's developmental responses to light. For example, P_r in lettuce seeds exposed to red light is converted to P_{fr}, stimulating the cellular responses that lead to germination. When red-illuminated seeds are then exposed to far-red light, the P_{fr} is converted back to P_r, inhibiting the germination response.



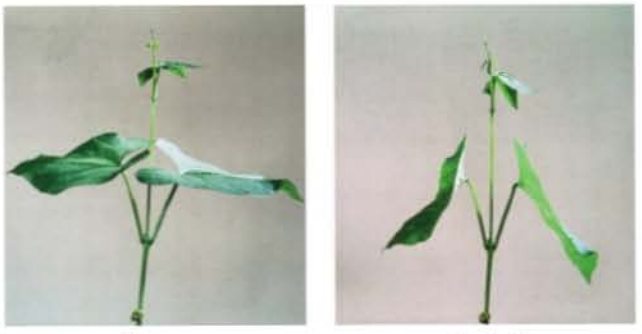
How does phytochrome switching explain light-induced germination in nature? Plants synthesize phytochrome as P_r, and if seeds are kept in the dark, the pigment remains almost entirely in the P_r form (see Figure 39.19). Sunlight contains both red light and far-red light, but the conversion to P_{fr} is faster than the conversion to P_r. Therefore, the ratio of P_{fr} to P_r increases in the sunlight. When seeds are exposed to adequate sunlight, the production and accumulation of P_{fr} will trigger their germination.

Phytochromes and Shade Avoidance

The phytochrome system also provides the plant with information about the *quality* of light. Because sunlight includes both red and far-red radiation, during the day the $P_r \rightleftharpoons P_{fr}$ interconversion reaches a dynamic equilibrium, with the ratio of the two phytochrome forms indicating the relative amounts of red and far-red light. This sensing mechanism enables plants to adapt to changes in light conditions. Consider, for example, the "shade avoidance" response of a tree that requires relatively high light intensity. If other trees in a forest shade this tree, the phytochrome ratio shifts in favor of P_r because the forest canopy screens out more red light than far-red light. This is because the chlorophyll pigments in the leaves of the canopy absorb red light and allow far-red light to pass. The shift in the ratio of red to far-red light induces the tree to allocate more of its resources to growing taller. In contrast, direct sunlight increases the proportion of P_{fr}, which stimulates branching and inhibits vertical growth.

In addition to helping plants detect light, phytochrome helps a plant to keep track of the passage of days and seasons. To understand phytochrome's role in these timekeeping processes, we must first examine the nature of the plant's internal clock.

▶ **Figure 39.19 Phytochrome: a molecular switching mechanism.** Absorption of red light causes the P_r to change to the P_{fr}. Far-red light reverses this conversion. In most cases, it is the P_{fr} form of the pigment that switches on physiological and developmental responses in the plant.



Biological Clocks and Circadian Rhythms

Many plant processes, such as transpiration and the synthesis of certain enzymes, oscillate during the course of a day. Some of these cyclic variations are responses to the changes in light levels, temperature, and relative humidity that accompany the 24-hour cycle of day and night. One can control these external factors by growing plants in growth chambers under rigidly maintained conditions of light, temperature, and humidity. But even under artificially constant conditions, many physiological processes in plants, such as the opening and closing of stomata and the production of photosynthetic enzymes, continue to oscillate with a frequency of about 24 hours. For example, many legumes lower their leaves in the evening and raise them in the morning **(Figure 39.20)**. A bean plant continues these "sleep movements" even if kept in constant light or constant darkness; the leaves are not simply responding to sunrise and sunset. Such cycles, with a frequency of about 24 hours and not directly controlled by any known environmental variable, are called **circadian rhythms** (from the Latin *circa*, approximately, and *dies*, day), and they are common to all eukaryotic life. Your pulse rate, blood pressure, temperature, rate of cell division, blood cell count, alertness, urine composition, metabolic rate, sex drive, and response to medications all fluctuate in a circadian manner.

Current research indicates that the molecular "gears" of the circadian clock are internal, rather than a daily response to some subtle but pervasive environmental cycle, such as geomagnetism or cosmic radiation. Organisms, including plants and humans, continue their rhythms even when placed in deep mine shafts or when orbited in satellites, conditions that alter these subtle geophysical periodicities. However, daily signals from the environment can entrain (set) the circadian clock to a period of precisely 24 hours.

If an organism is kept in a constant environment, its circadian rhythms deviate from a 24-hour period (a period is the duration of one cycle). These free-running periods, as they are called, vary from about 21 to 27 hours, depending on the particular rhythmic response. The sleep movements of bean plants, for instance, have a period of 26 hours when the plants are kept in the free-running condition of constant darkness. Deviation of the free-running period from exactly 24 hours does not mean that biological clocks drift erratically. Free-running clocks are still keeping perfect time, but they are not synchronized with the outside world.

Noon Midnight

▲ **Figure 39.20 Sleep movements of a bean plant (*Phaseolus vulgaris*).** The movements are caused by reversible changes in the turgor pressure of cells on opposing sides of the pulvini, motor organs of the leaf.

How do biological clocks work? In attempting to answer this question, we must distinguish between the clock and the rhythmic processes it controls. For example, the leaves of the bean plant in Figure 39.20 are the clock's "hands" but are not the essence of the clock itself. If bean leaves are restrained for several hours and then released, they will reestablish the position appropriate for the time of day. We can interfere with a biological rhythm, but the underlying clockwork continues.

Researchers are tracing the clock to a molecular mechanism that may be common to all eukaryotes. A leading hypothesis is that biological timekeeping may depend on the synthesis of a protein that regulates its own production through feedback control. This protein may be a transcription factor that inhibits transcription of the gene that encodes the transcription factor itself. The concentration of this transcription factor may increase during the first half of the circadian cycle and then decline during the second half as a result of inhibiting its own production.

Researchers have recently used a novel technique to identify clock mutants of *Arabidopsis*. One prominent circadian rhythm in plants is the daily production of certain photosynthesis-related proteins. Molecular biologists traced the cause of this rhythm to the promoter that initiates the transcription of the genes for these photosynthesis proteins. To identify clock mutants, scientists spliced the gene for an enzyme responsible for the bioluminescence of fireflies, called luciferase, to the promoter. When the biological clock turned on the promoter in the *Arabidopsis* genome, it also turned on the production of luciferase. The plants began to glow with a circadian periodicity. Clock mutants were then isolated by selecting specimens that glowed for a longer or shorter time than normal. The genes altered in some of these mutants affect proteins that normally bind photoreceptors. Perhaps these particular mutations disrupt a light-dependent mechanism that sets the biological clock.

The Effect of Light on the Biological Clock

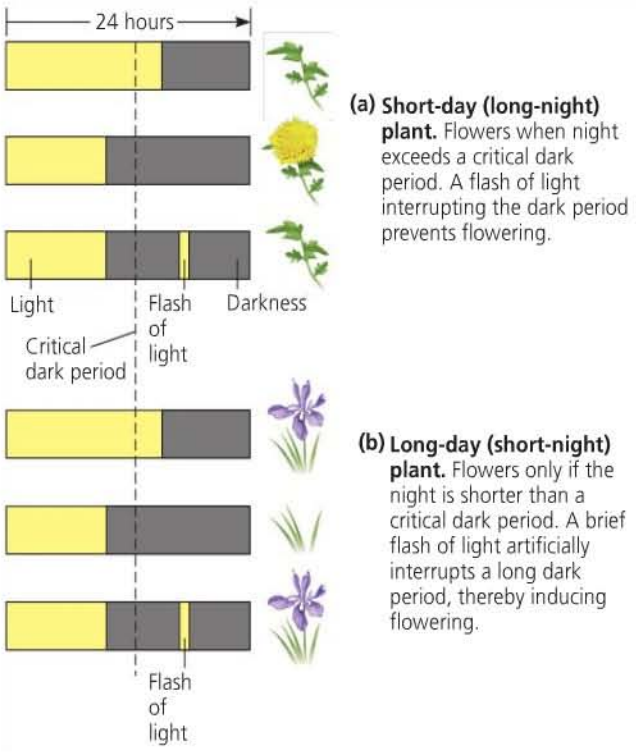
As we have discussed, the free-running period of the circadian rhythm of bean leaf movements is 26 hours. Consider a bean plant placed at dawn in a dark cabinet for 72 hours: Its leaves would not rise again until 2 hours after natural dawn on the second day, 4 hours after natural dawn on the third day, and so on. Shut off from environmental cues, the plant becomes desynchronized. Desynchronization happens to humans when we cross several time zones in an airplane; when we reach our destination, the clocks on the wall are not synchronized with our internal clocks. All eukaryotes are probably prone to jet lag.

The factor that entrains the biological clock to precisely 24 hours every day is light. Both phytochrome and blue-light photoreceptors can entrain circadian rhythms in plants, but our understanding of how phytochrome does this is more complete. The mechanism involves turning cellular responses on and off by means of the $P_r \rightleftharpoons P_{fr}$ switch.

Consider again the photoreversible system in Figure 39.19. In darkness, the phytochrome ratio shifts gradually in favor of the P_r form, partly as a result of turnover in the overall phytochrome pool. The pigment is synthesized in the P_r form, and enzymes destroy more P_{fr} than P_r. In some plant species, P_{fr} present at sundown slowly converts to P_r. In darkness, there is no means for the P_r to be reconverted to P_{fr}, but upon illumination, the P_{fr} level suddenly increases again as P_r is rapidly converted. This increase in P_{fr} each day at dawn resets the biological clock: Bean leaves reach their most extreme night position 16 hours after dawn.

In nature, interactions between phytochrome and the biological clock enable plants to measure the passage of night and day. The relative lengths of night and day, however, change over the course of the year (except at the equator). Plants use this change to adjust activities in synchrony with the seasons.

Photoperiodism and Responses to Seasons



Imagine the consequences if a plant produced flowers when pollinators were not present or if a deciduous tree produced leaves in the middle of winter. Seasonal events are of critical importance in the life cycles of most plants. Seed germination, flowering, and the onset and breaking of bud dormancy are all stages that usually occur at specific times of the year. The environmental stimulus that plants use most often to detect the time of year is the photoperiod, the relative lengths of night and day. A physiological response to photoperiod, such as flowering, is called **photoperiodism**.

Photoperiodism and Control of Flowering

An early clue to how plants detect seasons came from a mutant variety of tobacco, Maryland Mammoth, which grew tall but failed to flower during summer. It finally bloomed in a greenhouse in December. After trying to induce earlier flowering by varying temperature, moisture, and mineral nutrition, researchers learned that the shortening days of winter stimulated this variety to flower. If the plants were kept in light-tight boxes so that lamps could manipulate "day" and "night," flowering occurred only if the day length was 14 hours or shorter. It did not flower during summer because at Maryland's latitude, the summer days were too long.

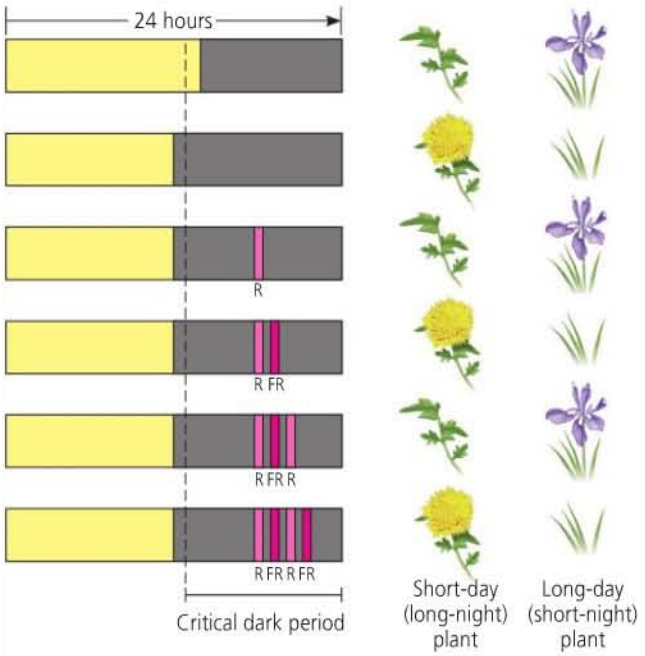
The researchers called Maryland Mammoth a **short-day plant** because it apparently required a light period *shorter* than a critical length to flower. Chrysanthemums, poinsettias, and some soybean varieties are also short-day plants, which generally flower in late summer, fall, or winter. Another group of plants flower only when the light period is *longer* than a certain number of hours. These **long-day plants** generally flower in late spring or early summer. Spinach, for example, flowers when days are 14 hours or longer. Radishes, lettuce, irises, and many cereal varieties are also long-day plants. **Day-neutral plants**, such as tomatoes, rice, and dandelions, are unaffected by photoperiod and flower when they reach a certain stage of maturity, regardless of day length.

Critical Night Length In the 1940s, researchers learned that flowering and other responses to photoperiod are actually controlled by night length, not day length. Many of these scientists worked with cocklebur (*Xanthium strumarium*), a short-day plant that flowers only when days are 16 hours or shorter (and nights are at least 8 hours long). These researchers found that if the daytime portion of the photoperiod is broken by a brief exposure to darkness, there is no effect on flowering. However, if the nighttime part of the photoperiod is interrupted by even a few minutes of dim light, cocklebur will not flower, and this turned out to be true for other short-day plants as well **(Figure 39.21a)**. Cocklebur is unresponsive to day length, but it requires at least 8 hours of continuous darkness to flower. Short-day plants are really long-night plants, but the older term is embedded firmly in the jargon of plant physiology. Similarly, long-day plants are actually short-night plants. A long-day plant grown on photoperiods of long nights that would not normally induce flowering will flower if the period of continuous darkness is interrupted by a few minutes of light **(Figure 39.21b)**. Notice that we distinguish long-day from short-day plants *not* by

▲ **Figure 39.21 Photoperiodic control of flowering.**

an absolute night length but by whether the critical night length sets a maximum (long-day plants) or minimum (short-day plants) number of hours of darkness required for flowering. In both cases, the actual number of hours in the critical night length is specific to each species of plant.

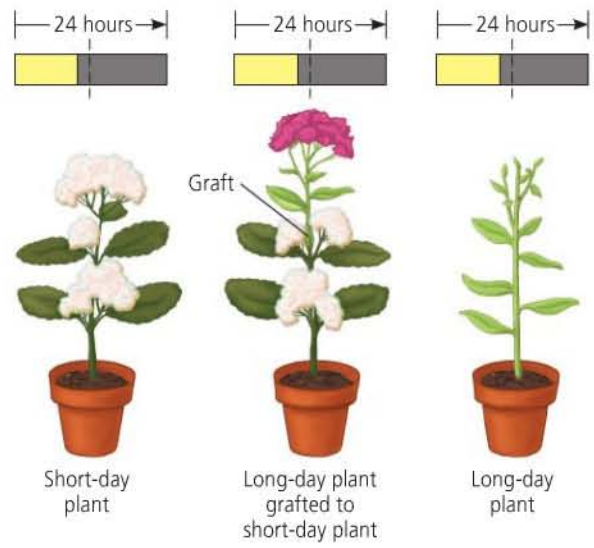
Red light is the most effective color in interrupting the nighttime portion of the photoperiod. Action spectra and photoreversibility experiments show that phytochrome is the pigment that detects the red light **(Figure 39.22)**. For example, if a flash of red (R) light during the dark period is followed by a flash of far-red (FR) light, then the plant detects no interruption of night length. As in the case of phytochrome-mediated seed germination, red/far-red photoreversibility occurs.



Plants detect night length very precisely; some short-day plants will not flower if night is even 1 minute shorter than the critical length. Some plant species always flower on the same day each year. It appears that plants use their biological clock, entrained by night length with the help of phytochrome, to tell the season of the year. The floriculture (flower-growing) industry applies this knowledge to produce flowers out of season. Chrysanthemums, for instance, are short-day plants that normally bloom in fall, but their blooming can be stalled until Mother's Day in May by punctuating each long night with a flash of light, thus turning one long night into two short nights.

Some plants bloom after a single exposure to the photoperiod required for flowering. Other species need several successive days of the appropriate photoperiod. Still other plants respond to a photoperiod only if they have been previously exposed to some other environmental stimulus, such as a period of cold temperatures. Winter wheat, for example, will not flower unless it has been exposed to several weeks of temperatures below 10°C. The use of pretreatment with cold to induce flowering is called **vernalization** (from the Latin for "spring"). Several weeks after winter wheat is vernalized, a photoperiod with long days (short nights) induces flowering.

A Flowering Hormone?



Although flowers form from apical or axillary bud meristems, it is leaves that detect changes in photoperiod and produce signaling molecules that cue buds to develop as flowers. In many short-day and long-day plants, exposing just one leaf to the appropriate photoperiod is enough to induce flowering. Indeed, as long as one leaf is left on the plant, photoperiod is detected and floral buds are induced. If all leaves are removed, the plant is insensitive to photoperiod.

Classic experiments revealed that the floral stimulus could move across a graft from an induced plant to a noninduced plant and trigger flowering in the latter. Moreover, the flowering stimulus appears to be the same for short-day and long-day plants, despite the differing photoperiodic conditions required for leaves to send this signal **(Figure 39.23)**. The hypothetical signaling molecule for flowering, called **florigen**, is still unidentified after 70 years, possibly because plant scientists had focused on small hormone-like molecules. As discussed in Chapter 36, large macromolecules, such as mRNA and proteins, can move by the

▲ **Figure 39.22 Reversible effects of red and far-red light on photoperiodic response.** A flash of red (R) light shortens the dark period. A subsequent flash of far-red (FR) light cancels the red flash's effect.

? *How would a single flash of full-spectrum light affect each plant?*

▲ **Figure 39.23 Experimental evidence for a flowering hormone.** If grown individually under short-day conditions, a short-day plant will flower and a long-day plant will not. However, both will flower if grafted together and exposed to short days. This result indicates that a flower-inducing substance (florigen) is transmitted across grafts and induces flowering in both short-day and long-day plants.

WHAT IF? *If flowering were inhibited in both parts of the grafted plants, what would you conclude?*

symplastic route via plasmodesmata (see Figure 36.11) and regulate plant development. Could florigen be a macromolecule? Plant biologists are now excited about this possibility. *Arabidopsis* is a long-day plant that requires a functional *CONSTANS* gene to flower under long days. Brian Ayre and Robert Turgeon, of Cornell University, noted that *Arabidopsis* plants flowered only when *CONSTANS* was expressed in the leaf, a finding consistent with the observation that florigen is made only in leaves. They provided further evidence for a role for the CONSTANS protein in floral signaling when they grafted *Arabidopsis* plants that contained no CONSTANS protein onto plants synthesizing CONSTANS in their leaves. This elegant experiment showed that CONSTANS, or another factor that it interacts with, can move through the graft junction to signal flowering in the parts of the plant that formerly were devoid of the protein. More recent evidence suggests that CONSTANS turns on a gene called *FLOWERING LOCUS T* (*FT*) in the leaf and that the FT protein travels to the shoot apical meristem and initiates flowering.

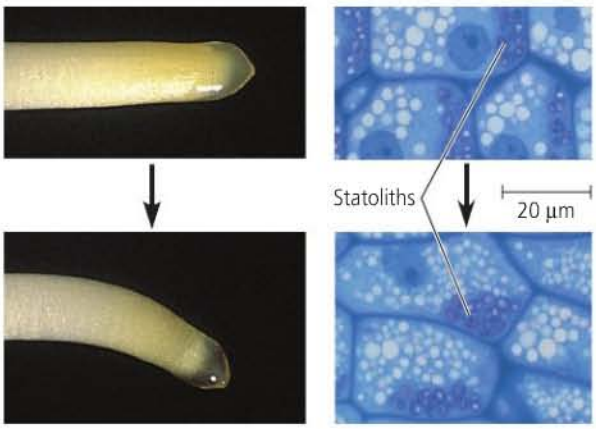
Meristem Transition and Flowering

Whatever combination of environmental cues (such as photoperiod or vernalization) and internal signaling molecules (such as the FT protein) is necessary for flowering, the outcome is the transition of a bud's meristem from a vegetative state to a flowering state. This transition requires changes in the expression of genes that regulate pattern formation. Meristem identity genes that induce the bud to form a flower instead of a vegetative shoot must first be switched on. Then the organ identity genes that specify the spatial organization of the floral organs—sepals, petals, stamens, and carpels—are activated in the appropriate regions of the meristem (see Figure 35.34). Research on flower development is progressing rapidly, and one goal is to identify the signal transduction pathways that link such cues as photoperiod and hormonal changes to the gene expression required for flowering.

CONCEPT CHECK 39.3

1. If an enzyme in field-grown soybean leaves is most active at noon and least active at midnight, is its activity under circadian regulation?
2. A guard absentmindedly turns on the lights in a greenhouse one night, but the plants still flower on schedule. Suggest two reasons why they were not affected by the interruption of darkness.
3. Some vine seedlings grow toward darkness until reaching an upright structure. This adaptation helps them "find" a shaded object to climb. How might you test whether this negative phototropism is mediated by blue-light photoreceptors or by phytochrome?
4. **WHAT IF?** If a plant flowers in a controlled chamber with a daily cycle of 10 hours of light and 14 hours of darkness, is it a short-day plant? Explain.

For suggested answers, see Appendix A.



CONCEPT 39.4
Plants respond to a wide variety of stimuli other than light

Plants can neither migrate to a watering hole when water is scarce nor seek shelter from wind. A seed landing upside down in the soil cannot maneuver itself into an upright position. Because of their immobility, plants must adjust to a wide range of environmental circumstances through developmental and physiological mechanisms, and natural selection has refined these responses. Light is so important in the life of a plant that we devoted the entire previous section to a plant's reception of and response to this one environmental factor. In this section, we examine responses to some of the other environmental stimuli that a plant commonly encounters.

Gravity

Because plants are solar-powered organisms, it is not surprising that mechanisms for growing toward sunlight have evolved. But what environmental cue does the shoot of a young seedling use to grow upward when it is completely underground and there is no light for it to detect? Similarly, what environmental factor prompts the young root to grow downward? The answer to both questions is gravity.

Place a plant on its side, and it adjusts its growth so that the shoot bends upward and the root curves downward. In their responses to gravity, or **gravitropism**, roots display positive gravitropism **(Figure 39.24a)** and shoots exhibit negative

(a) Over the course of hours, a horizontally oriented primary root of maize bends gravitropically until its growing tip becomes vertically oriented (LMs).

(b) Within minutes after the root is placed horizontally, plastids called statoliths begin settling to the lowest sides of root cap cells. This settling may be the gravity-sensing mechanism that leads to redistribution of auxin and differing rates of elongation by cells on opposite sides of the root (LMs).

▲ **Figure 39.24 Positive gravitropism in roots: the statolith hypothesis.**

gravitropism. Gravitropism occurs as soon as a seed germinates, ensuring that the root grows into the soil and the shoot grows toward sunlight, regardless of how the seed is oriented when it lands. Auxin plays a key role in gravitropism.

Plants may detect gravity by the settling of **statoliths**, specialized plastids containing dense starch grains, to the lower portions of cells (**Figure 39.24b**, on the previous page). In roots, statoliths are located in certain cells of the root cap. According to one hypothesis, the aggregation of statoliths at the low points of these cells triggers redistribution of calcium, which causes lateral transport of auxin within the root. The calcium and auxin accumulate on the lower side of the root's zone of elongation. Because these chemicals are dissolved, they do not respond to gravity but must be actively transported to one side of the root. At high concentration, auxin inhibits cell elongation, an effect that slows growth on the root's lower side. The more rapid elongation of cells on the upper side causes the root to curve as it grows. This tropism continues until the root grows straight down.

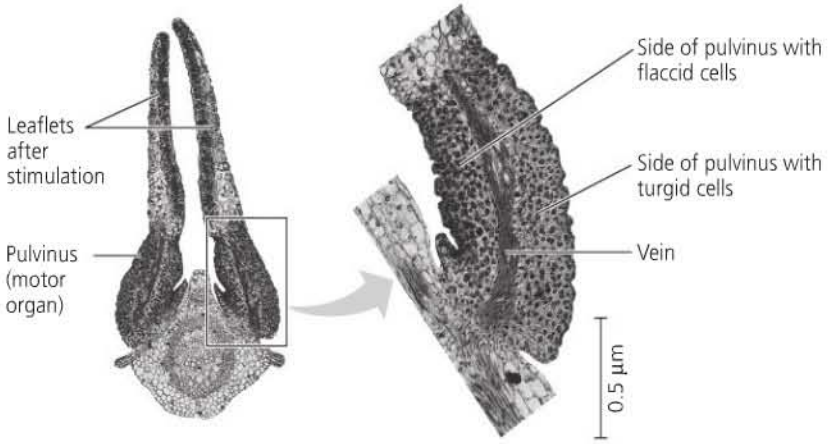
Plant physiologists are refining the "falling statolith" hypothesis of root gravitropism, based on new experiments. For example, mutants of *Arabidopsis* and tobacco that lack statoliths are still capable of gravitropism, though the response is slower than in wild-type plants. It could be that the entire cell helps the root sense gravity by mechanically pulling on proteins that tether the protoplast to the cell wall, stretching the proteins on the "up" side and compressing the proteins on the "down" side of the root cells. Dense organelles, in addition to starch granules, may also contribute by distorting the cytoskeleton as they are pulled by gravity. Statoliths, because of their density, may enhance gravitational sensing by a mechanism that works more slowly in their absence.

Mechanical Stimuli

A tree growing on a windy mountain ridge usually has a shorter, stockier trunk than a tree of the same species growing in a more sheltered location. The advantage of this stunted morphology is that it enables the plant to hold its ground against strong gusts of wind. The term **thigmomorphogenesis** (from the Greek *thigma*, touch) refers to the changes in form that result from mechanical perturbation. Plants are very sensitive to mechanical stress: Even the act of measuring the length of a leaf with a ruler alters its subsequent growth. Rubbing the stems of a young plant a couple of times daily results in plants that are shorter than controls **(Figure 39.25)**. Mechanical stimulation activates a signal transduction pathway involving an increase in cytosolic Ca^{2+} that mediates the activation of specific genes, some of which code for proteins that affect cell wall properties.

Some plant species have become, over the course of their evolution, "touch specialists." Acute responsiveness to mechanical stimuli is an integral part of these plants' "life strategies."

▲ **Figure 39.25 Altering gene expression by touch in *Arabidopsis*.** The shorter plant on the left was rubbed twice a day. The untouched plant (right) grew much taller.



Most vines and other climbing plants have tendrils that coil rapidly around supports (see Figure 35.7). These grasping organs usually grow straight until they touch something; the contact stimulates a coiling response caused by differential growth of cells on opposite sides of the tendril. This directional growth in response to touch is called **thigmotropism**, and it allows the vine to take advantage of whatever mechanical supports it comes across as it climbs upward toward a forest canopy.

Other examples of touch specialists are plants that undergo rapid leaf movements in response to mechanical stimulation. For example, when the compound leaf of the sensitive plant *Mimosa pudica* is touched, it collapses and its leaflets fold together **(Figure 39.26)**. This response, which takes only a second or two, results from a rapid loss of turgor in cells within pulvini, specialized motor organs located at the joints of the leaf. The motor cells suddenly become flaccid after stimulation because they lose potassium, which causes water to leave the cells by osmosis. It takes about 10 minutes for the cells to regain their turgor and restore the "unstimulated" form of the leaf. The function of the sensitive plant's behavior invites speculation. Perhaps by folding its leaves and reducing its surface area when jostled by strong winds, the plant conserves water. Or perhaps because the collapse of the leaves exposes thorns on the stem, the rapid response of the sensitive plant discourages herbivores.

A remarkable feature of rapid leaf movements is the mode of transmission of the stimulus through the plant. If one leaflet on a sensitive plant is touched, first that leaflet responds, then the adjacent leaflet responds, and so on, until all the leaflet pairs have folded together. From the point of stimulation, the signal that produces this response travels at a speed of about 1 cm/sec. An electrical impulse, traveling at the same rate, can

(a) Unstimulated state (leaflets spread apart) (b) Stimulated state (leaflets folded)

(c) Cross section of a leaflet pair in the stimulated state (LM). The curvature of a pulvinus (motor organ) is caused when motor cells on one side of the pulvinus lose water and become flaccid while cells on the opposite side retain their turgor.

▲ **Figure 39.26 Rapid turgor movements by the sensitive plant (*Mimosa pudica*).**

be detected by attaching electrodes to the leaf. These impulses, called **action potentials**, resemble nerve impulses in animals, though the action potentials of plants are thousands of times slower. Action potentials, which have been discovered in many species of algae and plants, may be widely used as a form of internal communication. For example, in the Venus flytrap (*Dionaea muscipula*), action potentials are transmitted from sensory hairs in the trap to the cells that respond by closing the trap (see Figure 37.14). In the case of *Mimosa pudica*, more violent stimuli, such as touching a leaf with a hot needle, causes *all* the leaves and leaflets on a plant to droop, but this systemic response involves the spread of signaling molecules released from the injured area to other parts of the shoot.

Environmental Stresses

Occasionally, certain factors in the environment change severely enough to have a potentially adverse effect on a plant's survival, growth, and reproduction. Environmental stresses, such as flooding, drought, or extreme temperatures, can have a devastating impact on crop yields in agriculture. In natural ecosystems, plants that cannot tolerate an environmental stress either will succumb or will be outcompeted by other plants, and they will become locally extinct. Thus, environmental stresses are an important factor in determining the geographic ranges of plants. Here, we will consider some of the more common **abiotic** (nonliving) stresses that plants encounter. In the last section of this chapter, we will examine the defensive responses of plants to common **biotic** (living) stresses, such as pathogens and herbivores.

Drought

On a bright, warm, dry day, a plant may be stressed by a water deficiency because it is losing water by transpiration faster than the water can be restored by uptake from the soil. Prolonged drought can stress crops and the plants of natural ecosystems for weeks or months. Severe water deficit, of course, will kill a plant, as you may know from experience with neglected houseplants. But plants have control systems that enable them to cope with less extreme water deficits.

Many of a plant's responses to water deficit help the plant conserve water by reducing the rate of transpiration. Water deficit in a leaf causes guard cells to lose turgor, a simple control mechanism that slows transpiration by closing stomata (see Figure 36.17). Water deficit also stimulates increased synthesis and release of abscisic acid in the leaf; this hormone helps keep stomata closed by acting on guard cell membranes. Leaves respond to water deficit in several other ways. Because cell expansion is a turgor-dependent process, water deficits inhibit the growth of young leaves, as does the accumulation of abscisic acid. This response minimizes the transpirational loss of water by slowing the increase in leaf surface. When the leaves of many grasses and other plants wilt from a water deficit, they roll into a shape that reduces transpiration by exposing less leaf surface to dry air and wind. Although these leaf responses conserve water, they reduce photosynthesis, which is one reason why a drought diminishes crop yield.

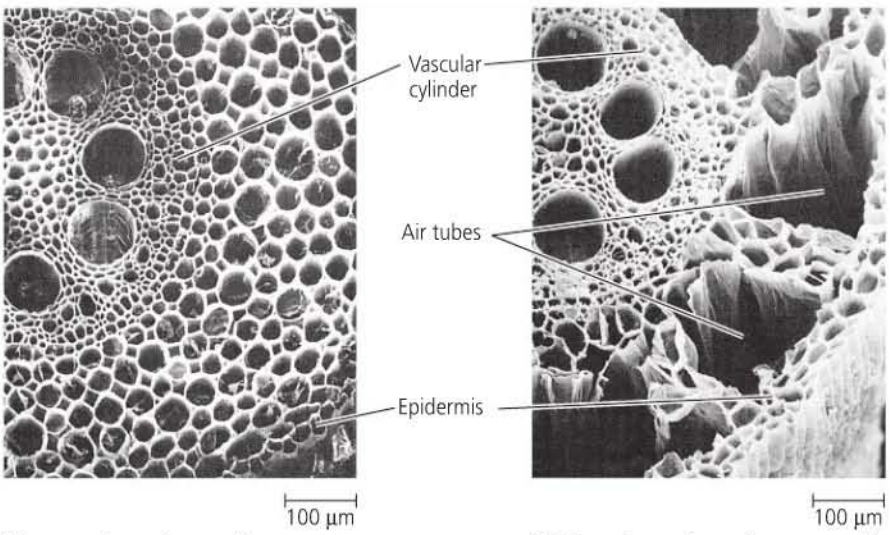
Root growth also responds to water deficit. During a drought, the soil usually dries from the surface down. This inhibits the growth of shallow roots, partly because cells cannot maintain the turgor required for elongation. Deeper roots surrounded by soil that is still moist continue to grow. Thus, the root system proliferates in a way that maximizes exposure to soil water.

Flooding

Too much water is also a problem for a plant. An overwatered houseplant may suffocate because the soil lacks the air spaces that provide oxygen for cellular respiration in the roots. Some plants are structurally adapted to very wet habitats. For example, the submerged roots of mangroves, which inhabit coastal marshes, are continuous with aerial roots exposed to oxygen (see Figure 35.4). But how do less specialized plants cope with oxygen deprivation in waterlogged soils? Oxygen deprivation stimulates the production of ethylene, which causes some cells in the root cortex to undergo apoptosis. The destruction of these cells creates air tubes that function as "snorkels," providing oxygen to the submerged roots **(Figure 39.27)**.

Salt Stress

An excess of sodium chloride or other salts in the soil threatens plants for two reasons. First, by lowering the water potential of the soil solution, salt can cause a water deficit in plants even though the soil has plenty of water. As the water potential of the soil solution becomes more negative, the water potential gradient from soil to roots is lowered, thereby reducing water uptake (see Chapter 36). The second problem with saline soil is that sodium and certain other ions are toxic to plants when their concentrations are relatively high. The selectively permeable membranes of root cells impede the uptake of most harmful ions, but this only aggravates the problem of acquiring water from soil that is rich in solutes. Many plants can respond to moderate soil salinity by producing solutes that are well tolerated at high concentrations: These mostly organic compounds keep the water potential of cells more negative than that of the soil solution without admitting toxic quantities of salt. However, most plants cannot survive salt stress for long. The exceptions are halophytes, salt-tolerant plants with adaptations such as salt glands that pump salts out across the leaf epidermis.



Heat Stress

As is true for other organisms, excessive heat harms and even kills a plant by denaturing its enzymes and damaging its metabolism. One function of transpiration is evaporative cooling. On a warm day, for example, the temperature of a leaf may be 3–10°C below the ambient air temperature. Hot, dry weather also tends to dehydrate many plants; the closing of stomata in response to this stress conserves water but then sacrifices evaporative cooling. This dilemma is one reason why very hot, dry days take a toll on most plants.

Most plants have a backup response that enables them to survive heat stress. Above a certain temperature—about 40°C for most plants in temperate regions—plant cells begin synthesizing **heat-shock proteins**, which help protect other proteins from heat stress. This response also occurs in heat-stressed animals and microorganisms. Some heat-shock proteins are chaperone proteins (chaperonins), which function in unstressed cells as temporary scaffolds that help other proteins fold into their functional shapes (see Chapter 5). In their roles as heat-shock proteins, perhaps these molecules bind to other proteins and help prevent their denaturation.

Cold Stress

One problem plants face when the temperature of the environment falls is a change in the fluidity of cell membranes. Recall from Chapter 7 that a biological membrane is a fluid mosaic, with proteins and lipids moving laterally in the plane of the membrane. When a membrane cools below a critical point, it loses its fluidity as the lipids become locked into crystalline structures. This alters solute transport across the membrane and also adversely affects the functions of membrane proteins. Plants respond to cold stress by altering the lipid composition of their membranes. For example, membrane lipids increase in their proportion of unsaturated fatty acids, which have shapes that help keep membranes fluid at lower temperatures by impeding crystal formation (see Figure 7.5b). Such membrane modification requires from several hours to days, which is one reason why unseasonably cold temperatures are generally more stressful to plants than the more gradual seasonal drop in air temperature.

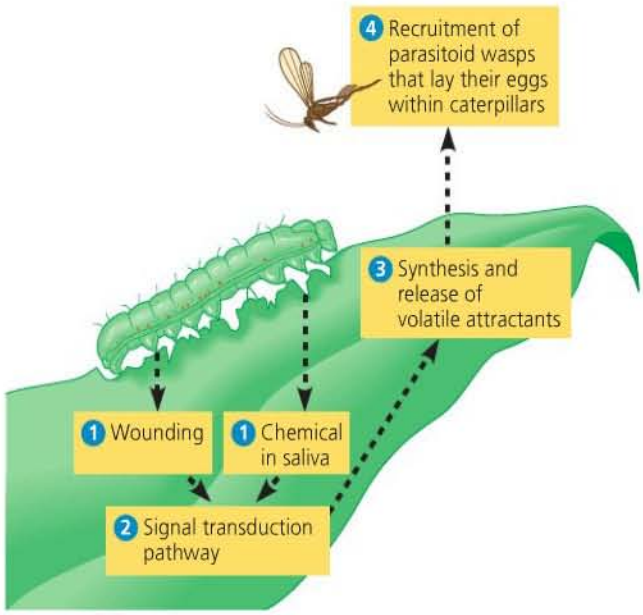
▲ **Figure 39.27 A developmental response of maize roots to flooding and oxygen deprivation.** **(a)** A cross section of a control root grown in an aerated hydroponic medium. **(b)** A root grown in a nonaerated hydroponic medium. Ethylene-stimulated apoptosis (programmed cell death) creates the air tubes (SEMs).

Freezing is a more severe version of cold stress. At subfreezing temperatures, ice forms in the cell walls and intercellular spaces of most plants. The cytosol generally does not freeze at the cooling rates encountered in nature because it contains more solutes than the very dilute solution found in the cell wall, and solutes lower the freezing point of a solution. The reduction in liquid water in the cell wall caused by ice formation lowers the extracellular water potential, causing water to leave the cytoplasm. The resulting increase in the concentration of ions in the cytoplasm is harmful and can lead to cell death. Whether the cell survives depends largely on how well it resists dehydration. In regions with cold winters, native plants are adapted to cope with freezing stress. For example, before the onset of winter, the cells of many frost-tolerant species increase cytoplasmic levels of specific solutes, such as sugars, that are well tolerated at high concentrations and that help reduce the loss of water from the cell during extracellular freezing. The unsaturation of membrane lipids also increases, thereby maintaining proper levels of membrane fluidity.

CONCEPT CHECK 39.4

1. Thermal images are photographs of the heat emitted by an object. Researchers have used thermal imaging of plants to isolate mutants that overproduce abscisic acid. Suggest a reason why these mutants are warmer than wild-type plants under conditions that are normally nonstressful.
2. A greenhouse worker finds that potted chrysanthemums nearest to the aisles are often shorter than those in the middle of the bench. Explain this "edge effect," a common problem in horticulture.
3. Plants normally subjected to drought stress are often more resistant to freezing stress than plants that are not drought adapted. Suggest a reason why.
4. **WHAT IF?** If you removed the root cap from a root, would the root still respond to gravity? Explain.

For suggested answers, see Appendix A.



CONCEPT 39.5
Plants respond to attacks by herbivores and pathogens

Plants do not exist in isolation but interact with many other species in their communities. Some interspecific interactions—for example, the associations of plants with fungi in mycorrhizae (see Figure 37.12) or with pollinators (see Figure 38.4)—are mutually beneficial. Most of a plant's interactions with other organisms, however, do not benefit the plant. As primary producers, plants are at the base of most food webs and are subject to attack by a wide range of plant-eating (herbivorous) animals. A plant is also subject to infection by diverse viruses, bacteria, and fungi that can damage tissues or even kill the plant. Plants counter these threats with defense systems that deter herbivory and prevent infection or combat pathogens that infect the plant.

Defenses Against Herbivores

Herbivory—animals eating plants—is a stress that plants face in any ecosystem. Plants prevent excessive herbivory by using both physical defenses, such as thorns, and chemical defenses, such as the production of distasteful or toxic compounds. For example, some plants produce an unusual amino acid called *canavanine*, named for one of its sources, the jackbean (*Canavalia ensiformis*). Canavanine resembles arginine, one of the 20 amino acids that organisms incorporate into their proteins. If an insect eats a plant containing canavanine, the molecule is incorporated into the insect's proteins in place of arginine. Because canavanine is different enough from arginine to adversely affect the shape and hence the function of the proteins, the insect dies.

Some plants even "recruit" predatory animals that help defend the plant against specific herbivores. For example, insects called parasitoid wasps inject their eggs into their prey, including caterpillars feeding on plants (see Figure 54.1). The eggs hatch within the caterpillars, and the larvae eat through their organic containers from the inside out. The plant, which benefits from the destruction of the herbivorous caterpillars, has an active role in this drama. A leaf damaged by caterpillars releases volatile compounds that attract parasitoid wasps. The stimulus for this response is a combination of physical damage to the leaf caused by the munching caterpillar and a specific compound in the caterpillar's saliva **(Figure 39.28)**.

▲ **Figure 39.28 A maize leaf "recruiting" a parasitoid wasp as a defensive response to an armyworm caterpillar, an herbivore.**

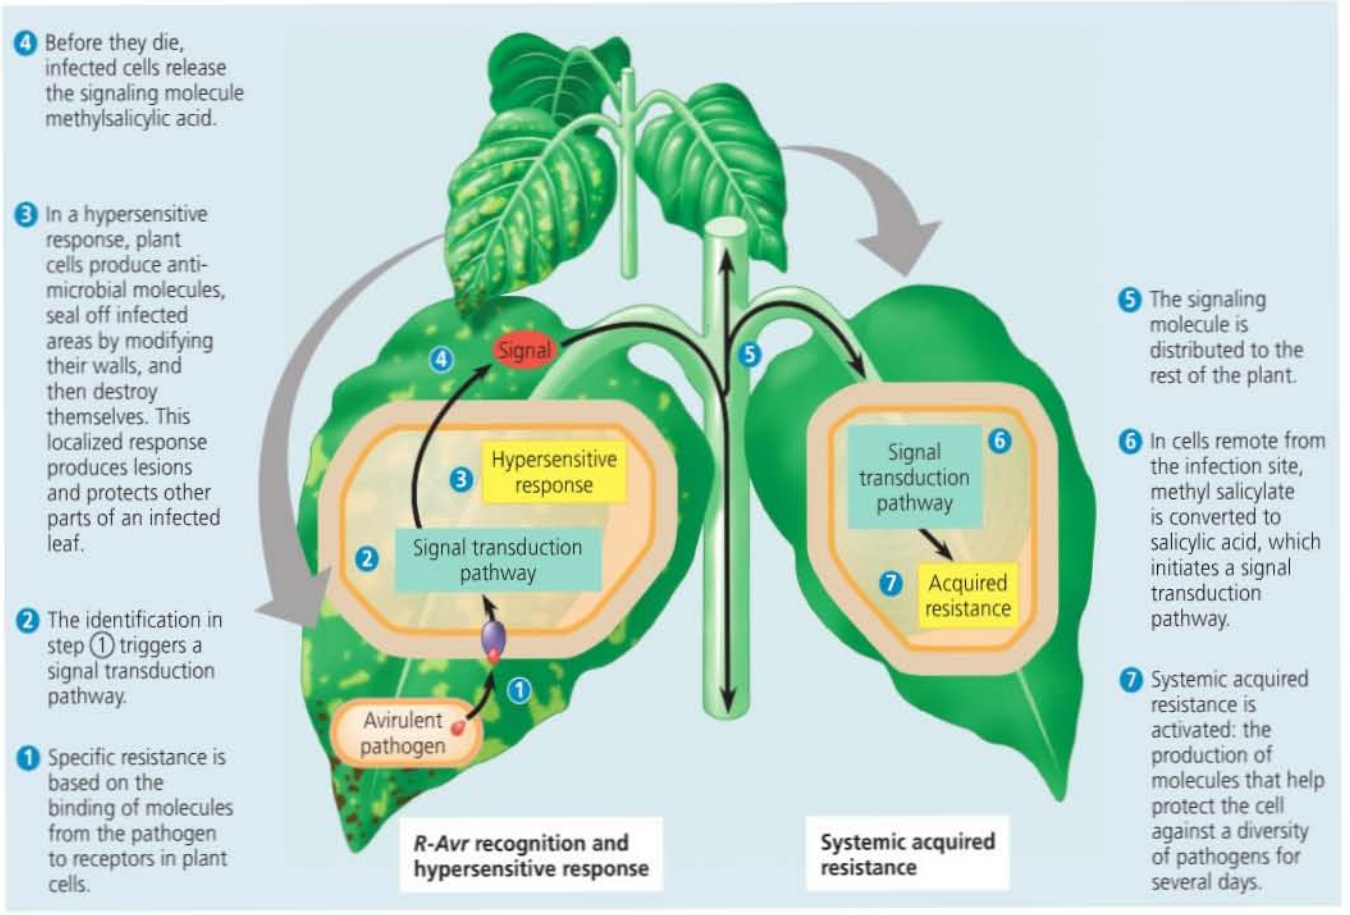
The volatile molecules a plant releases in response to herbivore damage can also function as an "early warning system" for nearby plants of the same species. For example, lima bean plants infested with spider mites release a cocktail of volatile chemicals, including methyljasmonic acid, that signal "news" of the attack to neighboring, noninfested lima bean plants. In response to these chemicals, noninfested lima bean leaves express defense genes. Volatile chemicals released from leaves that are mechanically wounded in experiments do not have the same effect. As a result of the activation of specific genes by these released volatile chemicals, noninfested neighbors become less susceptible to spider mites and more attractive to another species of mite that preys on spider mites. Iris Kappers and her colleagues at Wageningen University, in the Netherlands, transgenically engineered *Arabidopsis* plants to produce two volatile chemicals that normally are not made by *Arabidopsis* but which have been found to attract carnivorous predatory mites in other plants. The predatory mites were now also attracted to the genetically modified *Arabidopsis*, a finding that could have implications for the genetic engineering of insect resistance in crop plants.

Defenses Against Pathogens

A plant's first line of defense against infection is the physical barrier presented by the epidermis of the primary plant body and the periderm of the secondary plant body (see Figure 35.19). This first defense system, however, is not impenetrable. Viruses, bacteria, and the spores and hyphae of fungi can still enter the plant through wounds or through the natural openings in the epidermis, such as stomata. Once a pathogen invades, the plant mounts a chemical attack as a second line of defense that destroys the pathogens and prevents their spread from the site of infection. This second defense system is enhanced by the plant's ability to recognize certain pathogens.

Plants can recognize invading pathogens and defend against them. Successful pathogens cause disease because they evade recognition or suppress the host's defense mechanisms. Pathogens against which a plant has little specific defense are said to be **virulent** pathogens. They are the exceptions, for if they were not, then hosts and pathogens would soon perish together. A kind of "compromise" has evolved between plants and most of their pathogens. In such cases, the pathogen gains enough access to its host to enable it to perpetuate itself without severely damaging or killing the plant. Strains of pathogens that only mildly harm but do not kill the host plant are said to be **avirulent** pathogens.

Gene-for-gene recognition is a widespread form of plant disease resistance that involves recognition of pathogen-derived molecules by the protein products of specific plant disease resistance (*R*) genes. There are many pathogens, and plants have many *R* genes—*Arabidopsis* has at least several hundred. An R protein usually recognizes only a single corresponding pathogen molecule that is encoded by one of a pathogen's avirulence (*Avr*) genes. Despite their name, Avr proteins are harmful to the plant; they are thought to redirect the host's metabolism to the advantage of the pathogen. The recognition of pathogen-derived molecules called *elicitors* by R proteins triggers signal transduction pathways leading to the activation of an arsenal of defense responses. These include the **hypersensitive response**—the genetically programmed death of infected cells—as well as tissue reinforcement and antibiotic production at the infection site. Pathogen invasion can also trigger **systemic acquired resistance**, a long-lasting systemic response that primes the plant for resisting a broad spectrum of pathogens. Local and systemic responses to pathogens require extensive genetic reprogramming and commitment of cellular resources. Therefore, a plant activates these defenses only after detecting an invading pathogen.



The Hypersensitive Response

The hypersensitive response is a defense response that causes cell and tissue death near the infection site, thereby restricting the spread of a pathogen. After the cells at the infection site mount a chemical defense and seal off the area, they destroy themselves. The hypersensitive response is initiated when pathogen elicitors bind to R proteins, altering the selective permeability of the plasma membrane and stimulating the production of *phytoalexins*, which are toxic compounds with general fungicidal and bactericidal properties. The hypersensitive response also induces production of *PR proteins* (pathogenesis-related proteins), many of which are enzymes that hydrolyze components in the cell walls of the pathogens. Infection also stimulates the cross-linking of molecules within the cell wall and the deposition of lignin, responses that set up a local barricade that slows the spread of the pathogen to other parts of the plant.

We can see the result of a hypersensitive response as lesions on a leaf. As "sick" as such a leaf appears, it will still survive, and its defensive response will help protect the rest of the plant **(Figure 39.29)**.

Systemic Acquired Resistance

The hypersensitive response is localized and specific, a containment response based on gene-for-gene (*R-Avr*) recognition between host and pathogen. However, as noted previously, pathogen invasions can also produce signaling molecules that "sound the alarm" of infection to the whole plant. The resulting systemic acquired resistance, which is associated with the systemic expression of defense genes, is nonspecific, providing protection against a diversity of pathogens that lasts for days. The search for a signaling molecule that moves from the infection site to elicit the systemic acquired resistance led to the

▲ **Figure 39.29 Defense responses against an avirulent pathogen.**

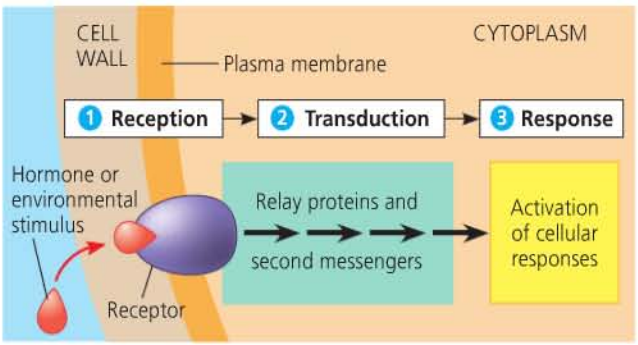
identification of *methylsalicylic acid* as the most likely candidate. Methylsalicylic acid is produced around the infection site and carried by the phloem throughout the plant, where it is converted to **salicylic acid** in areas remote from the sites of infection. Salicylic acid activates a signal transduction pathway that induces the production of PR proteins and resistance to pathogen attack (see Figure 39.29).

A modified form of salicylic acid, acetylsalicylic acid, is the active ingredient in aspirin. Centuries before aspirin was sold as a pain reliever, some cultures had learned that chewing the bark of a willow tree (*Salix*) would lessen the pain of a toothache or headache. With the discovery of systemic acquired resistance, biologists have finally learned one function of salicylic acid in plants. Aspirin is a natural medicine in the plants that produce it, but with effects entirely different from the medicinal action in humans who consume the drug.

Plant biologists investigating disease resistance and other evolutionary adaptations of plants are getting to the heart of how a plant responds to internal and external signals. These scientists, along with thousands of other plant biologists working on other questions and millions of students experimenting with plants in biology courses, are all extending a centuries-old tradition of curiosity about the green organisms that feed the biosphere.

CONCEPT CHECK 39.5

1. What are some drawbacks of spraying fields with general-purpose insecticides?
2. Chewing insects mechanically damage plants and lessen the surface area of leaves for photosynthesis. In addition, these insects make plants more vulnerable to pathogen attack. Suggest a reason why.
3. Many fungal pathogens get their food by causing plant cells to become leaky, thereby releasing nutrients into the intercellular spaces. Would it benefit the fungus to kill the host plant in a way that results in all the nutrients leaking out?
4. **WHAT IF?** Suppose a scientist finds that a population of plants growing in a breezy location is more prone to herbivory by insects than a population of the same species growing in a sheltered area. Suggest a hypothesis to account for this observation.



For suggested answers, see Appendix A.

Chapter 39 Review

SUMMARY OF KEY CONCEPTS

CONCEPT 39.1
Signal transduction pathways link signal reception to response (pp. 821–824)

CONCEPT 39.2
Plant hormones help coordinate growth, development, and responses to stimuli (pp. 824–835)

- **The Discovery of Plant Hormones** Researchers discovered auxin by identifying the compound responsible for transmitting a signal downward through coleoptiles, from the tips to the elongating regions, during phototropism.
- **A Survey of Plant Hormones** Auxin, produced primarily in the apical meristem of the shoot, stimulates cell elongation in different target tissues. Cytokinins stimulate cell division. Gibberellins, produced in roots and young leaves, stimulate growth in leaves and stems. Brassinosteroids, chemically similar to the sex hormones of animals, induce cell elongation and division. Abscisic acid maintains dormancy in seeds. Ethylene helps control fruit ripening.
- **Systems Biology and Hormone Interactions** Interactions between hormones and their signal transduction pathways make it difficult to predict what effect a genetic manipulation will have on a plant. Systems biology seeks a comprehensive understanding of plants that will permit successful modeling of plant functions.

Investigation What Plant Hormones Affect Organ Formation?

CONCEPT 39.3
Responses to light are critical for plant success (pp. 835–841)

- **Blue-Light Photoreceptors** Various blue-light photoreceptors control the responses of hypocotyl elongation, stomatal opening, and phototropism.
- **Phytochromes as Photoreceptors**

- **Biological Clocks and Circadian Rhythms** Free-running circadian cycles are approximately 24 hours long but are entrained to exactly 24 hours by the day/night cycle.
- **The Effect of Light on the Biological Clock** Phytochrome conversion marks sunrise and sunset, providing the clock with environmental cues.
- **Photoperiodism and Responses to Seasons** Some developmental processes, including flowering in many species, require a certain photoperiod. A critical night length sets a minimum (in short-day plants) or maximum (in long-day plants) number of hours of darkness required for flowering.

MEDIA

Activity Flowering Lab

CONCEPT 39.4
Plants respond to a wide variety of stimuli other than light (pp. 841–845)

- **Gravity** Gravitropism is a growth response to gravity. Roots show positive gravitropism, and stems show negative gravitropism. Plastids called statoliths may enable plant roots to detect gravity.
- **Mechanical Stimuli** Growth in response to touch is called thigmotropism. Rapid leaf movements involve transmission of electrical impulses called action potentials.
- **Environmental Stresses** During drought, plants respond to water deficit by reducing transpiration. Enzymatic destruction of cells creates air tubes that help plants survive oxygen deprivation during flooding. Plants respond to salt stress by producing solutes tolerated at high concentrations, keeping the water potential of cells more negative than the soil solution. Heat-shock proteins help plants survive heat stress. Altering lipid composition of membranes is a response to cold stress.

CONCEPT 39.5
Plants respond to attacks by herbivores and pathogens (pp. 845–847)

- **Defenses Against Herbivores** In addition to physical defenses such as thorns, plants defend themselves chemically by producing distasteful or toxic compounds, as well as airborne attractants that bring animals that destroy herbivores.
- **Defenses Against Pathogens** A pathogen is avirulent if it has a specific *Avr* gene corresponding to a particular *R* allele in the host plant. A hypersensitive response against an avirulent pathogen seals off the infection and destroys both pathogen and host cells in the region of the infection. Systemic acquired resistance is a generalized defense response in organs distant from the infection site.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Which of the following does *not* occur in a signal transduction pathway?
   a. stimulation of the receptor by a relay molecule
   b. production of second messengers such as cGMP
   c. expression of specific genes
   d. activation of protein kinases
   e. phosphorylation of transcription factors

2. Auxin enhances cell elongation in all of these ways *except*
   a. increased uptake of solutes.
   b. gene activation.
   c. acidification of the cell wall, causing denaturation of growth-inhibiting cell wall proteins.
   d. increased activity of plasma membrane proton pumps.
   e. cell wall loosening.

3. Charles and Francis Darwin discovered that
   a. auxin is responsible for phototropic curvature.
   b. auxin can pass through agar.
   c. light destroys auxin.
   d. light is perceived by the tips of coleoptiles.
   e. red light is most effective in causing phototropic curvatures.

4. Which hormone is *incorrectly* paired with its function?
   a. auxin—promotes stem growth through cell elongation
   b. cytokinins—initiate programmed cell death
   c. gibberellins—stimulate seed germination
   d. abscisic acid—promotes seed dormancy
   e. ethylene—inhibits cell elongation

5. The hormone that helps plants respond to drought is
   a. auxin.
   b. gibberellin.
   c. cytokinin.
   d. ethylene.
   e. abscisic acid.

6. The signaling molecule for flowering might be released earlier than normal in a long-day plant exposed to flashes of
   a. far-red light during the night.
   b. red light during the night.
   c. red light followed by far-red light during the night.
   d. far-red light during the day.
   e. red light during the day.

7. If a long-day plant has a critical night length of 9 hours, which 24-hour cycle would prevent flowering?
   a. 16 hours light/8 hours dark
   b. 14 hours light/10 hours dark
   c. 15.5 hours light/8.5 hours dark
   d. 4 hours light/8 hours dark/4 hours light/8 hours dark
   e. 8 hours light/8 hours dark/light flash/8 hours dark

8. If a scientist discovers an *Arabidopsis* mutant that does not store starch in plastids but has normal gravitropic bending, what aspect of our understanding of gravitropism would need to be reevaluated?
   a. the role of auxin in gravitropism
   b. the role of calcium in gravitropism
   c. the role of statoliths in gravitropism
   d. the role of light in gravitropism
   e. the role of differential growth in gravitropic bending

9. How may a plant respond to *severe* heat stress?
   a. by orienting leaves to increase evaporative cooling
   b. by producing ethylene, which kills some cortex cells and creates air tubes for ventilation
   c. by initiating a systemic acquired resistance response
   d. by increasing the proportion of unsaturated fatty acids in cell membranes, reducing their fluidity
   e. by producing heat-shock proteins, which may protect the plant's proteins from denaturing

10. In systemic acquired resistance, salicylic acid probably
    a. destroys pathogens directly.
    b. activates defenses throughout the plant before infection spreads.
    c. closes stomata, thus preventing the entry of pathogens.
    d. activates heat-shock proteins.
    e. sacrifices infected tissues by hydrolyzing cells.

11. **DRAW IT** Indicate the response to each condition by drawing a straight seedling or one with the triple response.

	Control	Ethylene added	Ethylene synthesis inhibitor
Wild-type			
Ethylene insensitive (*ein*)			
Ethylene overproducing (*eto*)			
Constitutive triple response (*ctr*)

EVOLUTION CONNECTION

12. Coevolution is defined as the evolution of reciprocal adaptations in two species, with each species adapting its interaction with the other. In this context, explain the coevolutionary relationship between a plant and an avirulent pathogen.

SCIENTIFIC INQUIRY

13. A plant biologist observed a peculiar pattern when a tropical shrub was attacked by caterpillars. After a caterpillar ate a leaf, it would skip over nearby leaves and attack a leaf some distance away. Simply removing a leaf did not deter caterpillars from eating nearby leaves. The biologist suspected that an insect-damaged leaf sent out a chemical that signaled nearby leaves. How could the researcher test this hypothesis?

SCIENCE, TECHNOLOGY, AND SOCIETY

14. Describe how our knowledge about the control systems of plants is being applied to agriculture or horticulture, giving three examples.

UNIT 7

Animal Form and Function

AN INTERVIEW WITH

Masashi Yanagisawa

While still in graduate school, Masashi Yanagisawa became famous for discovering endothelins, local regulators that are the most potent constrictors of blood vessels known. Later he discovered orexins, which regulate food intake and wakefulness. He received his M.D. and Ph.D. degrees from the University of Tsukuba, Japan. Since 1996, Dr. Yanagisawa has been a professor and Howard Hughes Medical Institute Investigator at the University of Texas Southwestern Medical Center at Dallas, where he holds the Patrick E. Haggerty Distinguished Chair in Basic Biomedical Science. The recipient of many awards, he is also a member of the National Academy of Sciences.

How did you get to be a medical scientist?

Even as a small child, I wanted to be a scientist. And in Japan, you really have to decide what you want to do before college; it's a European-style system. My decision to enter medical school, which is a 6-year undergraduate program there, was influenced by something my father told me. He said—this was the late 1970s—that biology would be very exciting in the coming era and that if I wanted to do biology, going to medical school was not a bad choice. I believed him, and I decided to go to medical school.

Until then, basic biology hadn't genuinely excited me, partly because of a bias at that time in Japan, where biology was regarded as a science discipline for "humanities people." And high-school biology mostly meant traditional taxonomy and lots of memorization. But in medical school, I was exposed to cutting-edge biology and found it very exciting, and I did some informal research internships that confirmed my interest in basic research. Clinical medicine excited me as well—it's impressive to see a patient improve dramatically.

The decision about what to do after medical school was probably the most difficult I've faced in my life. Should I continue with clinical training or go directly into basic research? An experience I had toward the end of medical school helped me make up my mind. When I was on rotation in the OB-GYN department, there was a patient—a young woman—suffering from a terminal case of ovarian cancer. Her abdominal cavity was full of cancer cells; no surgery could help. The doctors were discussing how aggressively to treat her with chemotherapy. At that time in Japan, most terminal cancer patients were not told of their condition. So this patient didn't know about her own condition and certainly didn't know about her options. Immediately after that, I had a chance to go to Australia in an exchange program, and there I was assigned to surgery and oncology. Their philosophy was totally different: The patient was at the center. The young me was very moved. If I had been a more aggressive person, I might have decided to try to change clinical practice in Japan, but I wasn't like that. I just decided not to go through clinical training, but instead to enroll in a Ph.D. program in pharmacology.

Why did you choose pharmacology?

Actually, pharmacology itself didn't matter. I was considering various programs all over Japan, but eventually I realized that I wanted to work under Tomoh Masaki, who happened to be a professor in pharmacology at Tsukuba. It was his open style of running his lab that appealed to me. I felt I could be a semi-independent researcher in his lab. My first research project was in Masaki's lifelong research area, the biochemistry of contractile proteins in muscles. My specific goal was to clone the gene for the large polypeptide subunit of the muscle protein myosin. I was sent off to another institution for almost a year to learn DNA cloning and other molecular techniques.

I finished the myosin project, but I strongly wanted to do something more medically oriented. So I started to look for an interesting topic. Many researchers were talking about a newly identified factor made by the endothelium (lining) of blood vessels that caused the vessel walls to relax. This was clearly a hot topic. I went to the library to browse through the scientific literature. (Remember, this was the pre-Internet era, so browsing meant actually flipping pages—very time-consuming!) I was lucky to find one abstract describing a mysterious vascular constricting factor that was secreted into culture medium when endothelial cells were cultured. This seemed interesting—and a promising research topic for me because the abstract authors hadn't gone on to identify the factor. I thought I could do this. In my lab and neighboring labs, I had all the techniques and teachers I needed for the project.

The great thing about my mentor, Masaki, is that he supported me in this project, even though it was outside his field; he gave me half a year to try it. Amazingly, within a few months I had purified the factor, a 21-amino-acid peptide. When I sequenced the peptide, it turned out to be previously unknown. When we injected the peptide into rats, their blood pressure shot up, because their blood vessels were being constricted. We called the peptide endothelin. It's a local regulator, a signaling molecule that acts on muscle cells lying just outside the blood-vessel endothelium. Endothelin recognizes its target cells by means of specific receptor proteins on the target cell surface. The binding of endothelin, the "ligand," to its receptor triggers a signal-transduction pathway that leads to muscle cell contraction. I stayed on as a post-doc and cloned the gene for the endothelin receptor, which is a G protein-coupled receptor (GPCR). [See Chapter 11 to review cell signaling.]

How did all the publicity arising from your work influence your career path?

My endothelin discoveries had attracted attention to me. I realized that I wanted to be in the United States, which seemed to be the center of the world for biology. I also wanted more independence as a researcher. Unfortunately, to be head of a laboratory in Japan, you had to be a full professor, which meant 37 years old at least. I was then about 27, and 10 years seemed too long to wait! This department offered me a lot of support, and it was an easy decision to come here.

What did you work on once you got here?

I wanted to learn more about how endothelin functioned, so we genetically engineered strains

of mice each lacking a component of the endothelin system—"knock-out" mice. We got some surprising results. The effects of endothelin go way beyond the vascular system. We learned that this protein has a fundamental role in certain stages of embryonic development. In the embryo, it's made by cells derived from a structure called the neural crest and is necessary for normal development of the intestine and several other organs. In adults, genes for endothelins (there are actually several) and their receptors are expressed in many, many places, and they seem to be doing a variety of things outside the vascular system.

Let's talk about the orphan receptor project, which led to orexin. Why is your approach called "reverse" pharmacology?

In the past, scientists usually went from the discovery of an intercellular signaling molecule, such as a hormone, to the eventual discovery of its receptor and the pathway leading to the response in target cells. For example, insulin was discovered years ago as a blood sugar-lowering hormone, and it was only later that the insulin receptor and the cellular pathway were identified. But the sequencing of the human genome has made the reverse approach possible. Now we can directly identify the genes for receptor proteins, especially for GPCRs, which all have very similar sequences. The human genome has more than 1,000 such genes. Many encode sensory receptors, especially for smell, but there are probably 400 or so encoding receptors that sense something internally. Out of these receptors, the ligands of more than 100 haven't been identified yet—these are the "orphan" receptors.

The genes encoding the ligands we're interested in—the peptides called neuropeptides because they are often made by neurons—can be extremely hard to find. We decided to search for novel neuropeptides that, like endothelin, had GPCRs. We developed a strategy to screen orphan receptors for peptide ligands—and we had beginners' luck. Orexin was found as the ligand for one of the first receptors we tested.

How did you find out what orexin did in the body?

The first clue was that both the orexin gene and its receptor gene are expressed only in the brain, and orexin is produced by neurons located only in the lateral hypothalamus. This part of the brain was known to play a role in appetite, which was immediately very exciting. Our next experiment was to inject orexin into the brains of mice, which then ate much more than the control mice. Shortly afterwards, we discovered that when you withhold a mouse's food, more orexin mRNA is made in its lateral hypothalamus. So that seemed to be the story: The animal gets hungry, somehow signals to its orexin neurons, more orexin is made, and the animal eats more. We got the name orexin from the Greek word for appetite.

Next, as usual, we engineered mice with the orexin gene or orexin receptor gene knocked out. Our hypothesis was that a mouse without orexin would have less appetite and become leaner. But we were wrong. It turned out that the mice lacking orexin were, if anything, chubbier. Now we know the reason was that orexin knock-out mice had a reduced appetite but also an even more reduced metabolic rate, so the net effect was that they became fatter.

That's when my instinct as a whole-animal physiologist kicked in. The orexin system must be doing something more important than the subtle effect we'd seen, I thought. Then I realized that observing the mice during the day was probably a mistake. Physiological research is usually done in the daytime for human convenience. But mice are nocturnal, so observing them during the day and concluding anything about their behavior is like sneaking into someone's home at night and concluding that humans are a lazy, sleepy species. So to observe the eating behavior of our mice at night, we set up a night-vision camera. And we discovered a weird phenomenon: A mouse would be running around, and all of a sudden it would fall to the side and stop moving for a minute or two and then suddenly get up and behave as if nothing had happened.

This strange behavior and subsequent tests told us that the mice had the sleep disorder called narcolepsy, which until then had been a mystery. People with narcolepsy have normal 24-hour sleep-wake cycles, but their wakeful periods are fragmented, and they go into REM sleep suddenly and inappropriately. My standard joke is this: When I'm giving a boring seminar in a dimly lit room, it's normal for a few in the audience to doze off. But if I start to doze off during my own talk, that's abnormal. That kind of thing can happen to a narcolepsy patient without medication. What's fundamentally abnormal is the regulation of sleep-state transitions. It turns out that people with narcolepsy don't have orexin-secreting neurons; these neurons disappear during adolescence, presumably from an autoimmune attack. Their orexin genes are OK.

So what's the connection between appetite regulation and sleep regulation?

It's well known that when animals are hungry they are more active; that's an important physiological adaptation. When an animal is hungry, it has to go out and hunt or seek for food, while protecting itself from danger. In the lab, if you don't feed a mouse, it becomes more awake and active. But an orexin-deficient animal doesn't do that, suggesting that orexin may be a crucial part of a connection between the brain's roles in regulating feeding and sleep.

What advice do you have for students aspiring to be biologists?

I always say that identifying a good research question is more difficult than solving it. The question should be important and feasible to answer. Something else I tell my students is this: In every class you attend, try to ask at least one meaningful question. If you can't come up with one, then you're not taking the class seriously enough. That's a mode of study very different from just knowledge absorption. To be a scientist, you have to question everything.

Our hypothesis was that a mouse without orexin would have less appetite and become leaner. But we were wrong.

40 Basic Principles of Animal Form and Function

▲ **Figure 40.1 How does a jackrabbit keep from overheating?**

KEY CONCEPTS

40.1 Animal form and function are correlated at all levels of organization

40.2 Feedback control loops maintain the internal environment in many animals

40.3 Homeostatic processes for thermoregulation involve form, function, and behavior

40.4 Energy requirements are related to animal size, activity, and environment

OVERVIEW

Diverse Forms, Common Challenges

The outer ears of the jackrabbit (*Lepus alleni*) in **Figure 40.1** are thin and remarkably large. They provide this hare with an acute sense of hearing, a primary defense against predators. The ears also help the jackrabbit shed excess heat. Blood flowing through each ear's network of vessels transfers heat to the surrounding air. At times, however, blood flow in the ear could be a liability. When the air is hot, blood passing through the ears could absorb heat, raising body temperature to dangerous levels. So how does a big-eared jackrabbit survive in the midday desert heat? To answer this question, we need to look more closely at the biological form, or **anatomy**, of the animal.

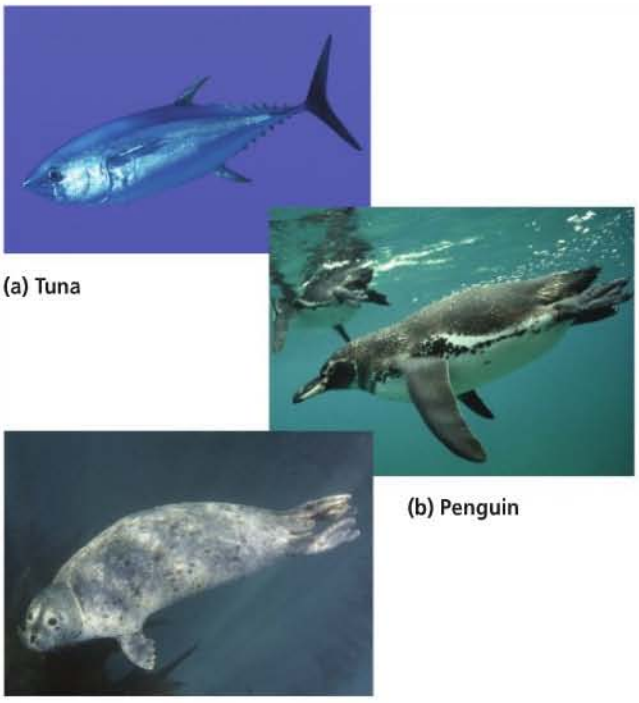
Over the course of its life, a jackrabbit faces the same fundamental challenges as any other animal, whether hydra, hawk, or human. All animals must obtain oxygen and nutrients, fight off infection, and produce offspring. Given that they share these basic requirements, why do species vary so enormously in makeup, complexity, organization, and appearance? The answer is that natural selection favors, over many generations, the variations appearing in a population that best meet the animal's needs. The solutions to the challenges of survival vary among environments and species, but for the jackrabbit and other animals, they frequently result in a close match of form to function.

Because form and function are correlated, examining anatomy often provides clues to **physiology**—biological function. In the case of the jackrabbit, researchers noted that its large pink-tinged ears turn pale when the air temperature exceeds 40°C (104°F), the normal temperature of the jackrabbit's body. The color change reflects a temporary narrowing of blood vessels in response to a hot environment. With their blood supply reduced, the ears can absorb heat without overheating the rest of the body. When the air cools, blood flow resumes, and the large ears again help release excess heat.

In this chapter, we will begin our study of animal form and function by examining the levels of organization in the animal body and the systems for coordinating the activities of distinct body parts. Next, we will discuss how animals regulate their internal environment, using body temperature regulation to introduce and illustrate the concept of homeostasis. Finally, we will explore how anatomy and physiology relate to an animal's interactions with the environment and its management of energy use.

CONCEPT 40.1

Animal form and function are correlated at all levels of organization



An animal's size and shape are fundamental aspects of form that significantly affect the way an animal interacts with its environment. Although we may refer to size and shape as elements of a "body plan" or "design," this does not imply a process of conscious invention. The body plan of an animal is the result of a pattern of development programmed by the genome, itself the product of millions of years of evolution.

Physical Constraints on Animal Size and Shape

Many different body plans have arisen during the course of evolution, but the variations fall within certain bounds. Physical laws that govern strength, diffusion, movement, and heat exchange limit the range of animal forms.

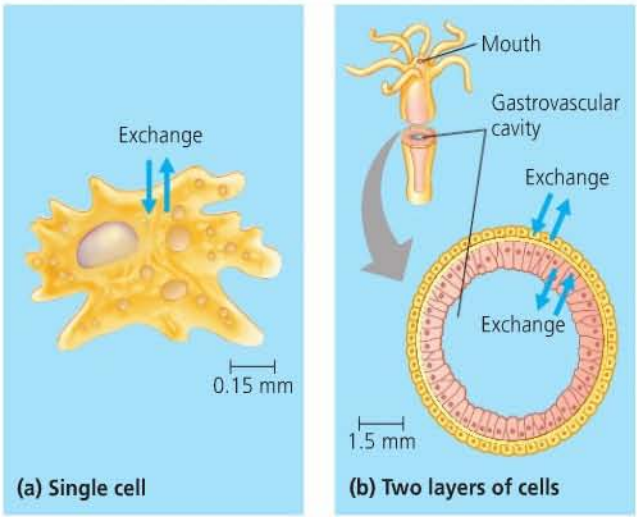
As an example of how physical laws constrain evolution, let's consider how some properties of water limit the possible shapes for animals that are fast swimmers. Water is about a thousand times denser than air and also far more viscous. Thus, any bump on an animal's body surface that causes drag impedes a swimmer more than it would a runner or flyer. Tuna and other fast ray-finned fishes can swim at speeds up to 80 km/hr (50 mph). Sharks, penguins, dolphins, and seals are also fast swimmers. As apparent in the examples in **Figure 40.2**, such animals share a streamlined body contour: a shape that is fusiform, meaning tapered on both ends. The similar shape found in these speedy fishes, birds, and mammals is an example of convergent evolution (see Chapter 22). Natural selection often shapes similar adaptations when diverse organisms face the same environmental challenge, such as the resistance of water to fast travel.

Physical laws also influence animal body plans with regard to maximum size. As body dimensions increase, thicker skeletons are required to maintain adequate strength. This limitation affects internal skeletons, such as those of vertebrates, as well as external skeletons, such as those of insects and other arthropods. In addition, as bodies increase in size, the muscles required for locomotion must represent an ever-larger fraction of the total body mass. At some point, mobility becomes limited. By considering the fraction of body mass in leg muscles and the effective force such muscles generate, scientists can estimate maximum running speed for a wide range of body plans. Such calculations indicate that the dinosaur *Tyrannosaurus rex*, over 6 m tall, probably could reach speeds of 30 km/hr (19 mph), as fast as a professional soccer player but not quite the thunderous sprint depicted in the movie *Jurassic Park*.

(a) Tuna

(b) Penguin

(c) Seal



▲ **Figure 40.2 Convergent evolution in fast swimmers.**

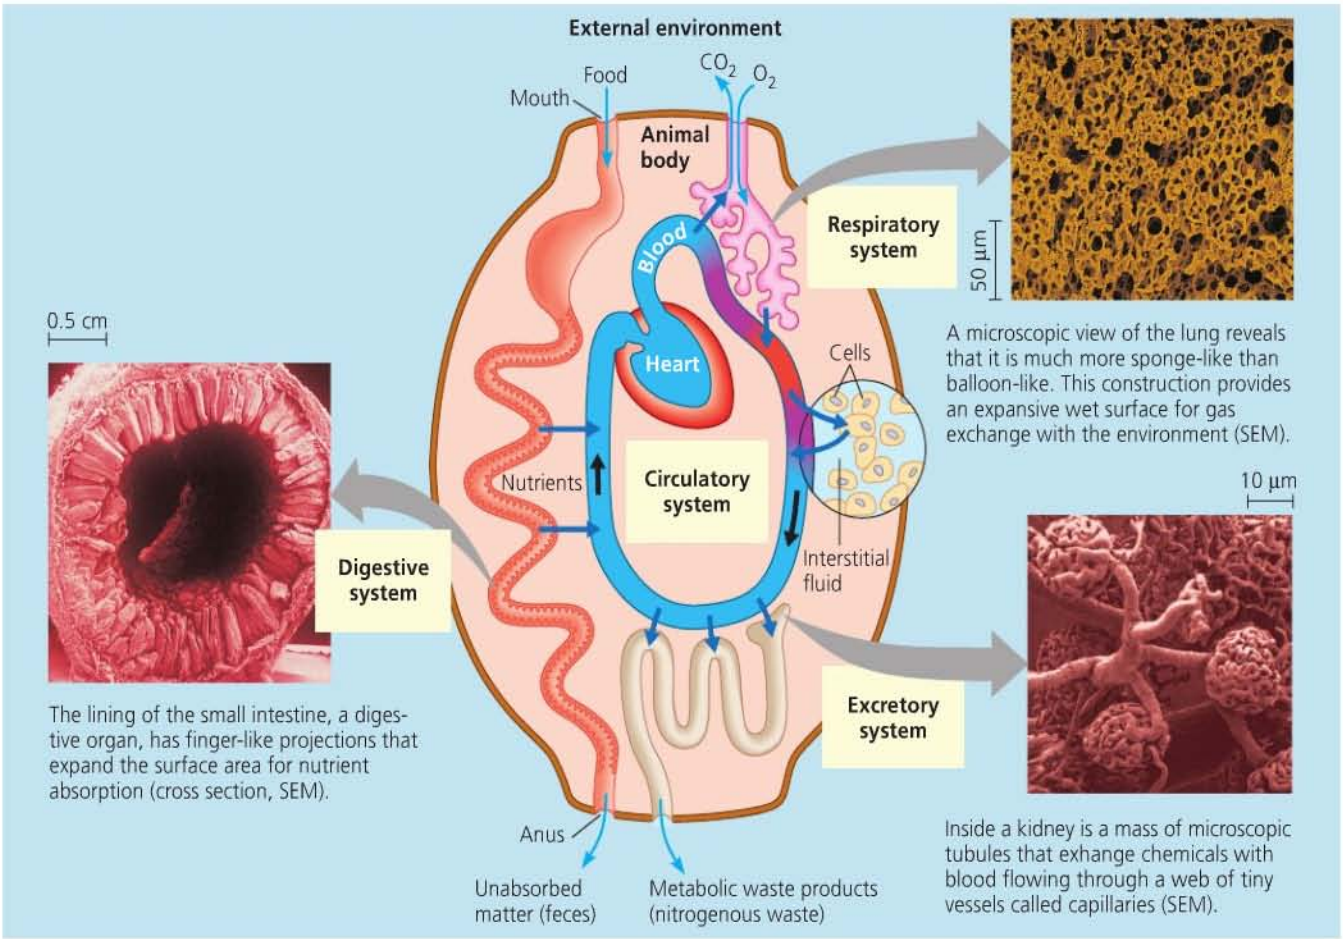
Exchange with the Environment

Animals need to exchange materials with their environment, and this need imposes limitations on their body plans (as it does for all other multicellular organisms). Exchange occurs as substances dissolved in an aqueous medium move across the plasma membrane of each cell. The rates of exchange for nutrients, waste products, and gases are proportional to membrane surface area. In contrast, the amount of material that must be exchanged to sustain life is proportional to volume.

The opportunity for exchange is strongly influenced by cell number. A single-celled organism, such as the amoeba in **Figure 40.3a**, has a sufficient membrane surface area in contact with its environment to carry out all necessary exchange. In contrast, an animal is composed of many cells, each with its own plasma membrane across which exchange must occur. A multicellular organization therefore works only if every cell has access to a suitable aqueous environment, either inside or outside of the animal's body.

Many animals with a simple internal organization have body plans that enable direct exchange between the external environment and nearly all cells. For example, a pond-dwelling hydra, which has a saclike body plan, has a body wall only two cell layers thick **(Figure 40.3b)**. Because its gastrovascular cavity

▲ **Figure 40.3 Contact with the environment. (a)** In a single-celled organism, such as an amoeba, the entire surface area contacts the environment. **(b)** Although all animals are multicellular, some have a simple organization in which all or nearly all cells contact the environment. For example, a hydra's body consists of two layers of cells. As fluid moves in and out of the hydra's mouth, every body cell can exchange material directly with the aqueous environment.



opens to the external environment, both the outer and inner layers of cells are constantly bathed by pond water. Another common design that maximizes exposure to the surrounding medium is a flat body shape. Consider, for instance, a parasitic tapeworm, which can reach several meters in length (see Figure 33.12). A thin, flat shape places most cells of the worm in direct contact with its specialized environment—the nutrient-rich intestinal fluid of a vertebrate host.

Most animals have a much more complex internal organization than that of a hydra or a tapeworm. Composed of compact masses of cells, these animals have outer surfaces that are relatively small compared with their volumes. As cell number increases, the ratio of the outer surface area of the animal to its total volume steadily decreases (see Figure 6.8). As an extreme comparison, the ratio of outer surface to volume for a whale is hundreds of thousands of times smaller than that for a water flea (*Daphnia*). Nevertheless, every cell in the whale must be bathed in fluid and have access to oxygen, nutrients, and other resources. How is this accomplished?

In whales and most other animals, extensively branched or folded surfaces are the evolutionary adaptation that enables sufficient exchange with the environment **(Figure 40.4)**. In almost all cases, these surfaces lie within the body, protecting delicate exchange tissues from abrasion or dehydration and allowing for streamlined body contours. In humans, the digestive, respiratory, and circulatory systems rely on exchange surfaces within the body that in each system have a total area more than 25 times that of the skin.

Internal body fluids link exchange surfaces to body cells. In all animals, the spaces between cells are filled with fluid, often called **interstitial fluid** (from the Latin for "stand between"). Complex body plans also include a circulatory fluid, such as blood. Exchange between the interstitial fluid and circulatory fluid enables cells throughout the body to obtain nutrients and get rid of wastes (see Figure 40.4).

Despite the greater challenges of exchange with the environment, complex body plans have distinct benefits over simple ones. For example, an external skeleton can protect against

▲ **Figure 40.4 Internal exchange surfaces of complex animals.** This diagram provides an overview of chemical exchange between an animal body and the environment. Most animals have surfaces that are specialized for exchanging chemicals with the surroundings. These exchange surfaces are usually internal but are connected to the environment via openings on the body surface (the mouth, for example). The exchange surfaces are finely branched or folded, giving them a very large area. The digestive, respiratory, and excretory systems all have such exchange surfaces. The circulatory system carries chemicals transported across these surfaces throughout the body.

? *In what sense are exchange surfaces such as the lining of the digestive system both internal and external?*

predators, and sensory organs can provide detailed information on the animal's surroundings. Internal digestive organs can break down food gradually, controlling the release of stored energy. In addition, specialized filtration systems can adjust the composition of the internal fluid that bathes the animal's body cells. In this way, an animal can maintain a relatively stable internal environment while living in a variable external environment. A complex body plan is especially advantageous for animals living on land, where the external environment may be highly variable.

Hierarchical Organization of Body Plans

Cells form an animal's body through their emergent properties. Recall from Chapter 1 that emergent properties arise through successive levels of structural and functional organization. Cells are organized into **tissues**, groups of cells of similar appearance and a common function. In all but the simplest animals (such as sponges), different tissues are further organized into functional units called **organs**. Groups of organs that work together provide an additional level of organization and coordination and make up an **organ system** (Table 40.1). Thus, for example, the skin is an organ of the integumentary system, which protects against infection and helps regulate body temperature.

Organs often contain tissues with distinct physiological roles. In some cases, the roles are different enough that we consider the organ to belong to more than one organ system. The pancreas, for instance, produces enzymes critical to the function of the digestive system and also regulates the level of sugar in the blood as a vital part of the endocrine system.

Just as viewing the hierarchy of the body's organization from the "bottom up" (from cells to organ systems) reveals emergent properties that underlie organ systems, a view of the hierarchy from the "top down" makes clear the multilayered basis of specialization. Consider the digestive system, which in humans consists of the mouth, pharynx, esophagus, stomach, small and large intestines, accessory organs, and anus. Each organ has specific roles in digestion. One important function of the stomach, for example, is to initiate the breakdown of proteins. This process requires a churning powered by stomach muscles, as well as digestive juices secreted by the stomach lining. Production of digestive juices, in turn, requires several highly specialized cell types, one of which generates concentrated hydrochloric acid.

The specialization characteristic of complex body plans is based on varied combinations of a limited set of cell and tissue types. For example, lungs and blood vessels have distinct functions but are lined by tissues that are of the same basic type and therefore share many properties. To introduce these shared properties, we next survey the major tissue types in vertebrates. In later chapters, we'll discuss how the tissues described here contribute to the functions of each organ system.

Tissue Structure and Function

Animal tissues fall into four main categories: epithelial tissue, connective tissue, muscle tissue, and nervous tissue. We explore the structure and function of each type in **Figure 40.5** and in the accompanying text, on the next four pages.

Table 40.1 Organ Systems: Their Main Components and Functions in Mammals

Organ System	Main Components	Main Functions
Digestive	Mouth, pharynx, esophagus, stomach, intestines, liver, pancreas, anus	Food processing (ingestion, digestion, absorption, elimination)
Circulatory	Heart, blood vessels, blood	Internal distribution of materials
Respiratory	Lungs, trachea, other breathing tubes	Gas exchange (uptake of oxygen; disposal of carbon dioxide)
Immune and lymphatic	Bone marrow, lymph nodes, thymus, spleen, lymph vessels, white blood cells	Body defense (fighting infections and cancer)
Excretory	Kidneys, ureters, urinary bladder, urethra	Disposal of metabolic wastes; regulation of osmotic balance of blood
Endocrine	Pituitary, thyroid, pancreas, adrenal, and other hormone-secreting glands	Coordination of body activities (such as digestion and metabolism)
Reproductive	Ovaries or testes, and associated organs	Reproduction
Nervous	Brain, spinal cord, nerves, sensory organs	Coordination of body activities; detection of stimuli and formulation of responses to them
Integumentary	Skin and its derivatives (such as hair, claws, skin glands)	Protection against mechanical injury, infection, drying out; thermoregulation
Skeletal	Skeleton (bones, tendons, ligaments, cartilage)	Body support, protection of internal organs, movement
Muscular	Skeletal muscles	Locomotion and other movement

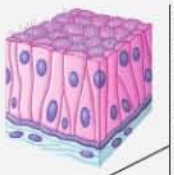
Epithelial Tissue

Occurring as sheets of cells, **epithelial tissue** covers the outside of the body and lines organs and cavities within the body. The close packing of epithelial cells, often involving tight junctions (see Figure 6.32), enables epithelial tissue to function as a barrier against mechanical injury, pathogens, and fluid loss. The cells of an epithelial tissue, or **epithelium** (plural, *epithelia*), also form active interfaces with the environment. For example, the epithelium that lines the nasal passages has a critical function in olfaction, the sense of smell.

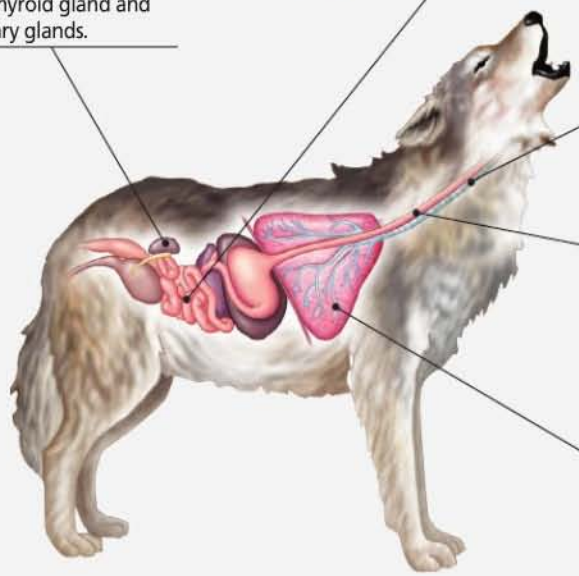
Epithelial cell shape may be *cuboidal* (like dice), *columnar* (like bricks standing on end), or *squamous* (like floor tiles). In addition, cells may be arranged in a *simple epithelium* (single cell layer), a *stratified epithelium* (multiple tiers of cells), or a *pseudostratified epithelium* (a single layer of cells varying in height). As shown in Figure 40.5, different cell shapes and arrangements correlate with distinct functions. For example, columnar epithelia, which have cells with relatively large cytoplasmic volumes, are often located where secretion or active absorption is important.

▼ **Figure 40.5**

Exploring Structure and Function in Animal Tissues



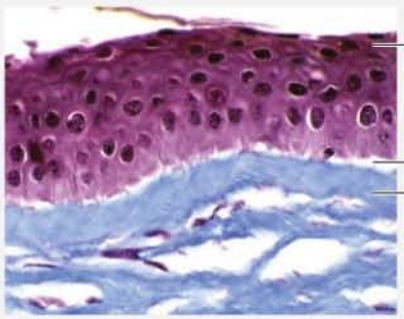
Epithelial Tissue



Cuboidal epithelium, with dice-shaped cells specialized for secretion, makes up the epithelium of kidney tubules and many glands, including the thyroid gland and salivary glands.

Simple columnar epithelium lines the intestines. This epithelium secretes digestive juices and absorbs nutrients.

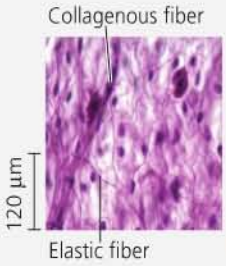
Pseudostratified ciliated columnar epithelium forms a mucous membrane that lines portions of the respiratory tract of many vertebrates. The beating cilia move the film of mucus along the surface.



Stratified squamous epithelium regenerates rapidly by cell division near the basal lamina (see below). The new cells are pushed outward, replacing cells that are sloughed off. This epithelium is commonly found on surfaces subject to abrasion, such as the outer skin and linings of the esophagus, anus, and vagina.

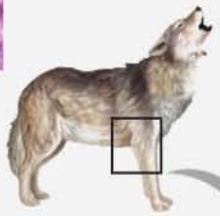
Simple squamous epithelium, which is thin and leaky, functions in the exchange of material by diffusion. This type of epithelium lines blood vessels and the air sacs of the lungs, where diffusion of nutrients and gases is critical.

All epithelia are polarized, meaning that they have two different sides. The *apical* surface faces the lumen (cavity) or outside of the organ and is therefore exposed to fluid or air. It is this surface that is often covered with specialized projections. For example, the epithelium of the small intestine is covered with microvilli, projections that increase the surface area available for absorbing nutrients (see Figure 40.4). The opposite side of each epithelium is the *basal* surface. The basal surface is attached to a *basal lamina*, a dense mat of extracellular matrix, which separates the epithelium from the underlying tissue.

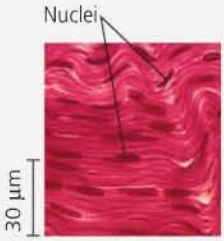


(All photos in figure are LMs.)

Connective Tissue

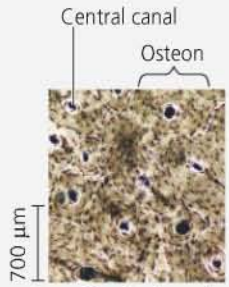


The most common functions of **connective tissues** are to bind and support other tissues in the body (see Figure 40.5). Connective tissue consists of a sparse population of cells scattered through an extracellular matrix. The matrix generally consists of a web of fibers embedded in a uniform foundation that may be liquid, jellylike, or solid. This variation in matrix structure is reflected in the six major types of connective tissue in vertebrates: loose connective tissue, cartilage, fibrous connective tissue, adipose tissue, blood, and bone.

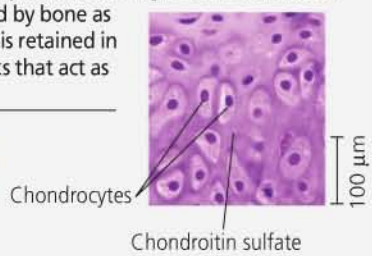


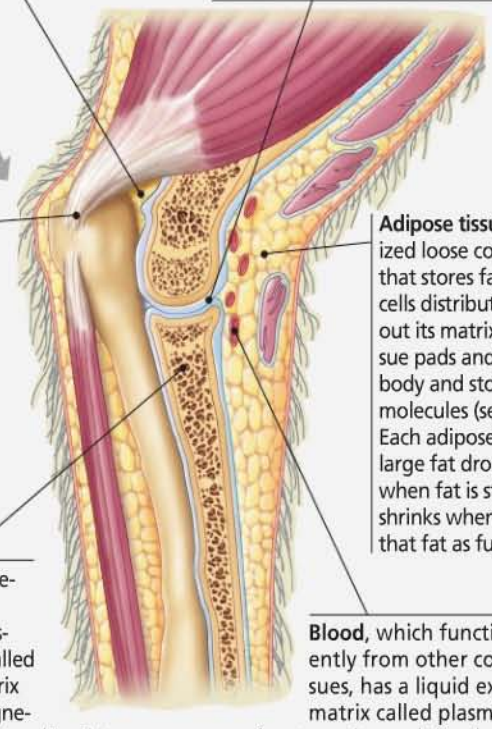
Connective tissue fibers, which are made of protein, are of three kinds: collagenous, elastic, and reticular. *Collagenous fibers* provide strength combined with flexibility. They are made of collagen, probably the most abundant protein in the animal kingdom. Collagenous fibers are nonelastic and do not tear easily when pulled lengthwise. *Elastic fibers* are easily stretched but are also resilient, snapping back to their original length when tension is released. Shaped as long threads, elastic fibers are made of a protein called elastin. *Reticular fibers* are very thin and branched. Composed of collagen and continuous with collagenous fibers,

Connective Tissue

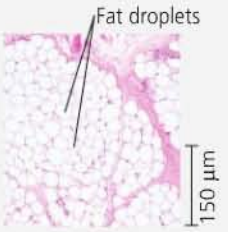


The most widespread connective tissue in the vertebrate body is *loose connective tissue*. Collagenous, elastic, and reticular fibers in this tissue type bind epithelia to underlying tissues and hold organs in place.



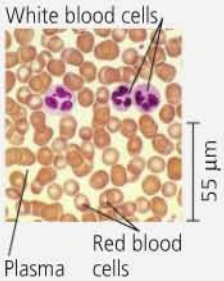


Fibrous connective tissue is dense with collagenous fibers. The fibers form parallel bundles, which maximize nonelastic strength. Fibrous connective tissue is found in **tendons**, which attach muscles to bones, and in **ligaments**, which connect bones at joints.



The skeleton of most vertebrates is made of **bone**, a mineralized connective tissue. Bone-forming cells called *osteoblasts* deposit a matrix of collagen. Calcium, magnesium, and phosphate ions combine into a hard mineral within the matrix. The combination of hard mineral and flexible collagen makes bone harder than cartilage without being brittle. The microscopic structure of hard mammalian bone consists of repeating units called *osteons*. Each osteon has concentric layers of the mineralized matrix, which are deposited around a central canal containing blood vessels and nerves.

Cartilage has an abundance of collagenous fibers embedded in a rubbery matrix made of a protein-carbohydrate complex called chondroitin sulfate. Cells called *chondrocytes* secrete the collagen and chondroitin sulfate that make cartilage a strong yet flexible support material. Many vertebrate embryos have cartilaginous skeletons, but most of the cartilage is replaced by bone as the embryo matures. Cartilage is retained in some locations, such as the disks that act as cushions between vertebrae.



Adipose tissue is a specialized loose connective tissue that stores fat in adipose cells distributed throughout its matrix. Adipose tissue pads and insulates the body and stores fuel as fat molecules (see Figure 4.6). Each adipose cell contains a large fat droplet that swells when fat is stored and shrinks when the body uses that fat as fuel.

Blood, which functions differently from other connective tissues, has a liquid extracellular matrix called plasma. Consisting of water, salts, and dissolved proteins, plasma contains erythrocytes (red blood cells), leukocytes (white blood cells), and cell fragments called platelets. Red cells carry oxygen; white cells function in defense; and platelets aid in blood clotting.

Continued on next page

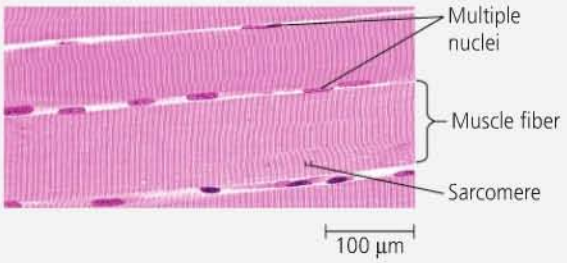
they form a tightly woven fabric that joins connective tissue to adjacent tissues. If you pinch a fold of skin on the back of your hand, the collagenous and reticular fibers prevent the tissue from being pulled far from the bone; the elastic fibers then restore the skin to its original shape when you release your grip.

The connective tissue that holds many tissues and organs together and in place contains scattered cells of varying function. Of these cells, two types predominate: fibroblasts and macrophages. **Fibroblasts** secrete the protein ingredients of the extracellular fibers. **Macrophages** are cells that roam the maze of fibers, engulfing both foreign particles and the debris of dead cells by phagocytosis (see Chapter 6).

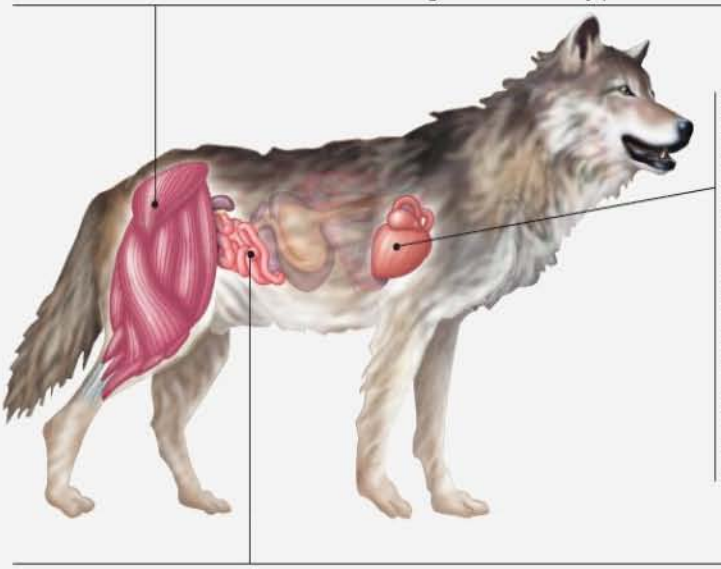
Muscle Tissue

The tissue responsible for nearly all types of body movement is **muscle tissue**. All muscle cells consist of filaments containing the proteins actin and myosin, which together enable muscles to contract. Muscle is the most abundant tissue in many animals, and muscle activity accounts for much of the energy-consuming cellular work in an active animal. Figure 40.5 shows the three types of muscle tissue in the vertebrate body: skeletal, cardiac, and smooth muscle.

Nervous Tissue

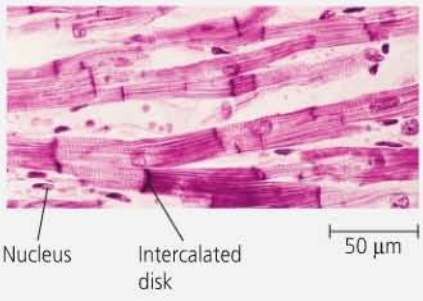


The function of **nervous tissue** is to sense stimuli and transmit signals in the form of nerve impulses from one part of the animal to another. Nervous tissue contains **neurons**, or nerve cells, which have extensions called axons that are uniquely specialized to transmit nerve impulses (see Figure 40.5). It also includes different forms of **glial cells**, or **glia**, which help nourish, insulate, and replenish neurons. In many animals, a concentration of nervous tissue forms a brain, an information-processing center. As we will discuss next, neurons have a critical role in managing many of the animal's physiological functions.



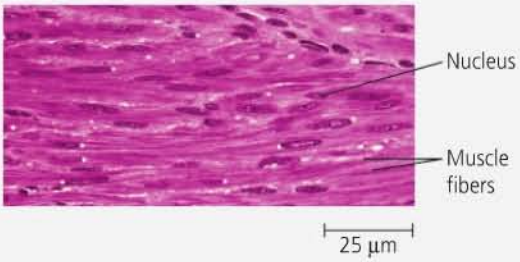
▼ **Figure 40.5 (continued)**

Exploring Structure and Function in Animal Tissues



Muscle Tissue

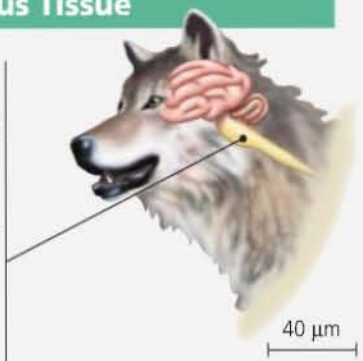
Attached to bones by tendons, **skeletal muscle** is responsible for voluntary movements. Skeletal muscle consists of bundles of long cells called muscle fibers. The arrangement of contractile units, or sarcomeres, along the length of the fibers gives the cells a striped (striated) appearance under the microscope. For this reason, skeletal muscle is also called *striated muscle*. Adult mammals have a fixed number of muscle cells; building muscle does not increase the number of cells but rather enlarges those already present.



Cardiac muscle forms the contractile wall of the heart. It is striated like skeletal muscle and has contractile properties similar to those of skeletal muscle. Unlike skeletal muscle, however, cardiac muscle carries out an unconscious task: contraction of the heart. Cardiac muscle fibers branch and interconnect via intercalated disks, which relay signals from cell to cell and help synchronize the heartbeat.

Smooth muscle, so named because it lacks striations, is found in the walls of the digestive tract, urinary bladder, arteries, and other internal organs. The cells are spindle-shaped. Controlled by different kinds of nerves than those controlling skeletal muscles, smooth muscles are responsible for involuntary body activities, such as churning of the stomach or constriction of arteries.

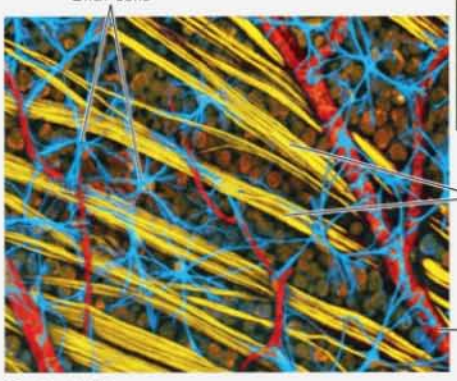
Coordination and Control



An animal's tissues, organs, and organ systems must act in conjunction with one another. For example, during long dives the harbor seal in Figure 40.2 slows its heart rate, collapses its lungs, and lowers its body temperature while propelling itself forward with its hind flippers. Coordinating activity across an animal's body in this way requires communication. What signals are used? How do the signals move within the body? There are two sets of answers to these questions, reflecting the two major systems for control and coordination: the endocrine system and the nervous system **(Figure 40.6)**. In the endocrine system, signaling molecules released into the bloodstream by endocrine cells reach all locations in the body. In the nervous system, neurons transmit information between specific locations.

The signaling molecules broadcast throughout the body by the endocrine system are called **hormones**. Different hormones cause distinct effects, and only cells that have receptors for a particular hormone respond **(Figure 40.6a)**. Depending on which cells have receptors for that hormone, the hormone may have an effect in just a single location or in sites throughout the body. Cells, in turn, can express more than one receptor type. Thus, cells in the ovaries and testes are regulated not only by sex hormones but also by metabolic hormones. Such hormones include insulin, which controls the level of glucose in the blood by binding to and regulating virtually every cell outside of the brain.

Hormones are relatively slow acting. It takes many seconds for insulin and other hormones to be released into the bloodstream and be carried throughout the body. Hormone effects are often long-lasting, however, because hormones remain in the bloodstream and target tissue for seconds, minutes, or even hours.



Nervous Tissue

Nerve cells (neurons) are the basic units of the nervous system. A neuron consists of a cell body and two or more extensions called dendrites and axons. Dendrites transmit signals from their tips toward the rest of the neuron. Axons, which are often bundled together into nerves, transmit signals toward another neuron or toward an effector, a structure such as a muscle cell that carries out a body response. The supporting glial cells help neurons function properly.

(Confocal LM)

15 µm

▲ **Figure 40.6 Signaling in the endocrine and nervous systems.** Endocrine cells secrete specific hormones—signaling molecules (shown as red dots)—into the bloodstream. Only cells expressing the corresponding receptor receive and respond to the signal. Nerve cells (neurons) generate signals that travel along axons. Only cells that form a specialized junction with the axon of an activated neuron receive and respond to the signal.

In the nervous system, a signal is not broadcast throughout the entire body. Instead, each signal, called a nerve impulse, travels to a target cell along a dedicated communication line, consisting mainly of the neuron extensions called axons **(Figure 40.6b)**. Four types of cells receive nerve impulses: other neurons, muscle cells, endocrine cells, and exocrine cells. Unlike the endocrine system, the nervous system conveys information by the *pathway* the signal takes. For example, a person can distinguish different musical notes because each note's frequency activates different neurons connecting the ear to the brain.

Signaling in the nervous system usually involves more than one type of signal. Nerve impulses travel within axons, sometimes over long distances, as changes in voltage. But in many cases, passing signals from one neuron to another involves very short-range chemical signals. Overall, transmission is extremely fast; nerve impulses take only a fraction of a second to reach the target and last only a fraction of a second.

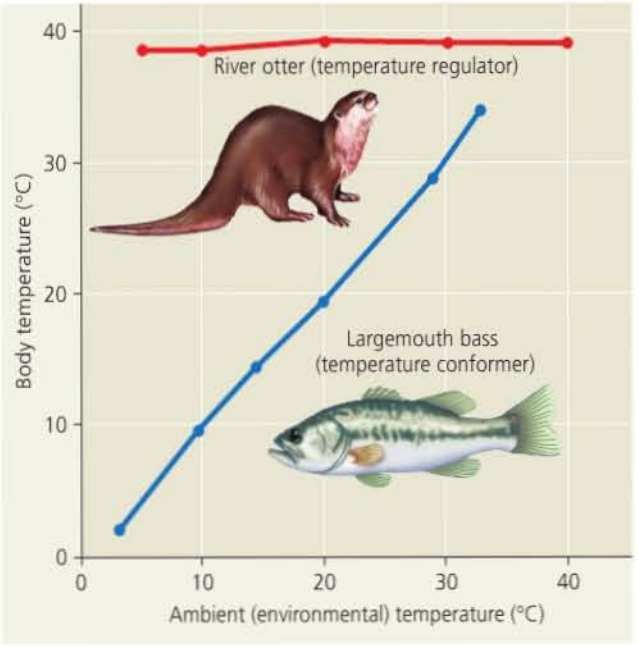
Because the two major communication systems of the body differ in signal type, transmission, speed, and duration, they are adapted to different functions. The endocrine system is well suited for coordinating gradual changes that affect the entire body, such as growth and development, reproduction, metabolic processes, and digestion. The nervous system is well suited for directing immediate and rapid responses to the environment, especially in controlling fast locomotion and behavior. Both systems contribute to maintaining a stable internal environment, our next topic of discussion.

CONCEPT CHECK 40.1

1. What properties are shared by all types of epithelia?
2. Under what temperature conditions would it benefit a jackrabbit to flatten its ears against its body? Explain.
3. **WHAT IF?** Suppose you are standing at the edge of a cliff and you suddenly slip—you barely manage to keep your balance to keep from falling. As your heart races, you feel a burst of energy, due in part to a surge of blood into dilated (widened) vessels in your muscles and an upward spike in the level of glucose in your blood. Why might you expect that this "fight-or-flight" response requires both the nervous system and the endocrine system?

For suggested answers, see Appendix A.

CONCEPT 40.2
Feedback control loops maintain the internal environment in many animals



Imagine that your body temperature soared every time you took a hot shower or drank a freshly brewed cup of coffee. Managing the state of the internal environment is a major challenge for the animal body. Faced with environmental fluctuations, animals manage their internal environment by either regulating or conforming.

Regulating and Conforming

An animal is said to be a **regulator** for a particular environmental variable if it uses internal control mechanisms to regulate internal change in the face of external fluctuation. For example, the river otter in **Figure 40.7** is a regulator for temperature, keeping its body at a temperature that is largely independent of that of the water in which it swims.

An animal is said to be a **conformer** for a particular environmental variable if it allows its internal condition to conform to external changes in the variable. For instance, the largemouth bass in Figure 40.7 conforms to the temperature of the lake in which it lives. As the water warms or cools, so do the cells of the bass. Some animals conform to more constant environments. For example, many marine invertebrates, such as spider crabs of the genus *Libinia*, let their internal solute concentration conform to the relatively stable solute concentration (salinity) of their ocean environment.

Regulating and conforming represent extremes on a continuum. An animal may regulate some internal conditions while allowing others to conform to the environment. For example, even though the bass conforms to the temperature of the surrounding water, the solute concentration in its blood

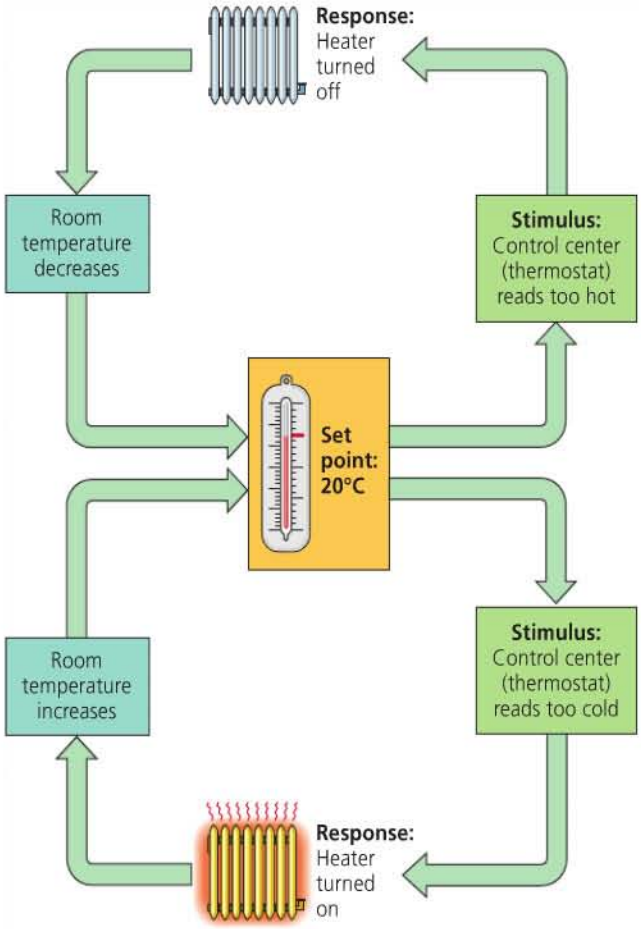
▲ **Figure 40.7 The relationship between body and environmental temperatures in an aquatic temperature regulator and an aquatic temperature conformer.** The river otter regulates its body temperature, keeping it stable across a wide range of environmental temperatures. The largemouth bass, meanwhile, allows its internal environment to conform to the water temperature.

and interstitial fluid differs from the solute concentration of the fresh water in which it lives. This difference occurs because the fish's anatomy and physiology enable it to regulate internal changes in solute concentration. (You will learn more about the mechanisms of this regulation in Chapter 44.)

Homeostasis

The steady body temperature of a river otter and the stable concentration of solutes in a freshwater bass are examples of **homeostasis**, which means "steady state," or internal balance. In achieving homeostasis, animals maintain a relatively constant internal environment even when the external environment changes significantly.

Like many animals, humans exhibit homeostasis for a range of physical and chemical properties. For example, the human body maintains a fairly constant body temperature of about 37°C (98.6°F) and a pH of the blood and interstitial fluid within 0.1 pH unit of 7.4. The body also regulates the solute concentration of glucose in the bloodstream so that it does not fluctuate for long from about 90 mg of glucose per 100 mL of blood.



Mechanisms of Homeostasis

Before exploring homeostasis in animals, let's first consider a nonliving example: the regulation of room temperature (Figure 40.8). Let's assume we want to keep a house at 20°C (68°F), a comfortable temperature for normal activity. We adjust a control device—the thermostat—to 20°C and allow a thermometer in the thermostat to monitor temperature. If the room temperature falls below 20°C, the thermostat responds by turning on the heating system. Heat is produced until the room reaches 20°C, at which point the thermostat switches off the heater. Whenever the temperature in the room again drifts below 20°C, the thermostat activates another heating cycle.

Like a home heating system, an animal achieves homeostasis by maintaining a variable, such as body temperature or solute concentration, at or near a particular value, or **set point**. Fluctuations in the variable above or below the set point serve as the **stimulus**. A receptor, or **sensor**, detects the stimulus and triggers a **response**, a physiological activity that helps return the variable to the set point. In the home heating example, a drop in temperature below the set point acts as a stimulus, the thermometer serves as the sensor, and the heater produces the response.

Feedback Loops in Homeostasis

Like the regulatory circuit shown in Figure 40.8, homeostasis in animals relies largely on **negative feedback**, a response that reduces, or "damps," the stimulus. For example, when you exercise vigorously, you produce heat, which increases body temperature. Your nervous system detects this increase and triggers sweating. As you sweat, the evaporation of moisture from your skin cools your body, helping return your body temperature to its set point.

▲ **Figure 40.8 A nonliving example of negative feedback: control of room temperature.** Regulating room temperature depends on a control center (a thermostat) that detects temperature change and activates mechanisms that reverse that change.

? *How would adding an air conditioner to the system contribute to homeostasis?*

Homeostasis is a dynamic equilibrium, the interplay between external factors that tend to change the internal environment and internal control mechanisms that oppose such changes. Note that physiological responses to stimuli are not instantaneous, just as switching on a furnace does not immediately warm a house. As a result, homeostasis reduces but doesn't eliminate changes in the internal environment. Additional fluctuation occurs if a variable has a **normal range**—an upper and lower limit—rather than a single set point. This is equivalent to a heating system that begins producing heat when the room temperature drops to 19°C (66°F) and stops heating when the temperature reaches 21°C (70°F). Regardless of whether there is a set point or a normal range, homeostasis is enhanced by mechanisms that reduce fluctuations, such as insulation in the case of temperature and physiological buffers in the case of pH.

Although positive-feedback loops also occur in animals, these circuits do not usually contribute to homeostasis. Unlike negative feedback, **positive feedback** triggers mechanisms that amplify rather than diminish the stimulus. During childbirth, for instance, the pressure of the baby's head against receptors near the opening of the mother's uterus stimulates the uterus to contract. These contractions result in greater pressure against the opening of the uterus, heightening the contractions and thereby causing even greater pressure, until the baby is born. In this way, the positive feedback helps drive processes to completion.

Alterations in Homeostasis

The set points and normal ranges for homeostasis can change under various circumstances. In fact, so-called *regulated changes* in the internal environment are essential to normal body functions. For example, many animals have a lower body temperature when asleep than when awake. Some regulated changes are associated with a particular stage in life, such as the radical shift in hormone balance that occurs during puberty. Other regulated changes are cyclic, such as the variation in hormone levels responsible for women's menstrual cycles (see Figure 46.14). Over the short term, homeostatic mechanisms maintain the set point in effect during a particular interval. Over the longer term, homeostasis allows regulated change in the set point and therefore in the body's internal environment.

One way in which the normal range of homeostasis may change is through **acclimatization**, the process by which an animal adjusts to changes in its external environment. For example, when an elk or other mammal moves from sea level to a much higher elevation, changes that occur over several days facilitate activity at lowered oxygen concentrations. These changes include increased blood flow in the lungs and increased production of red blood cells that carry oxygen. Note that acclimatization, a temporary change during an animal's lifetime, should not be confused with adaptation, a process of change in a population brought about by natural selection acting over many generations.

CONCEPT CHECK 40.2

1. Is it accurate to define homeostasis as a constant internal environment? Explain.
2. Describe the difference between negative feedback and positive feedback.
3. **WHAT IF?** If you were deciding where to locate the thermostat in a house, what considerations would govern your decision? How do these factors relate to the location of many homeostatic control sensors in the human brain?

For suggested answers, see Appendix A.

CONCEPT 40.3
Homeostatic processes for thermoregulation involve form, function, and behavior

In this section, we will examine the regulation of body temperature as an example of how form and function work together in regulating an animal's internal environment. Later chapters in this unit will discuss other physiological systems involved in maintaining homeostasis.

Thermoregulation is the process by which animals maintain an internal temperature within a tolerable range. Thermoregulation is critical to survival because most biochemical and physiological processes are very sensitive to changes in body temperature. For every 10°C (18°F) decrease in temperature, the rates of most enzyme-mediated reactions decrease two- to threefold. Increases in temperatures speed up reactions but cause some proteins to become less active. For instance, the oxygen carrier molecule hemoglobin becomes less effective at binding oxygen as temperature increases. Membranes can also change properties, becoming increasingly fluid or rigid as temperatures rise or fall, respectively.

Each animal species has an optimal temperature range. Thermoregulation helps keep body temperature within that optimal range, enabling cells to function effectively even as the external temperature fluctuates.

Endothermy and Ectothermy

Internal metabolism and the external environment provide the sources of heat for thermoregulation. Birds and mammals are mainly **endothermic**, meaning that they are warmed mostly by heat generated by metabolism. A few nonavian reptiles, some fishes, and many insect species are also mainly endothermic. In contrast, amphibians, lizards, snakes, turtles, many fishes, and most invertebrates are mainly **ectothermic**, meaning that they gain most of their heat from external sources.

Animals that are mainly endothermic are known as endotherms; those that are mainly ectothermic are known as ectotherms. Keep in mind, though, that endothermy and ectothermy are not mutually exclusive modes of thermoregulation. For example, a bird is mainly endothermic, but it may warm itself in the sun on a cold morning, much as an ectothermic lizard does.

Endothermic animals can maintain stable body temperatures even in the face of large environmental temperature fluctuations. For example, few ectotherms are active in the below-freezing weather that prevails during winter over much of Earth's surface, but many endotherms function very well in these conditions **(Figure 40.9a)**. In a cold environment, an endotherm generates enough heat to keep its body substantially warmer than its surroundings. In a hot environment, endothermic vertebrates have

(a) A walrus, an endotherm

(b) A lizard, an ectotherm

▲ **Figure 40.9 Endothermy and ectothermy.**

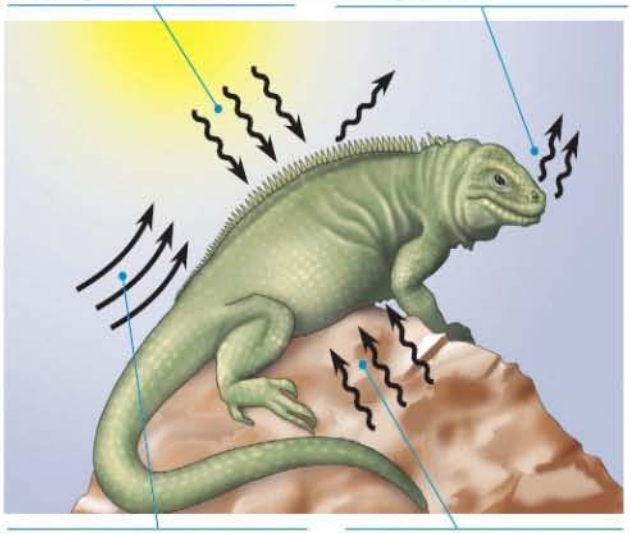
mechanisms for cooling the body, enabling them to withstand heat loads that are intolerable for most ectotherms.

Because their heat source is largely environmental, ectotherms generally need to consume much less food than endotherms of equivalent size—an advantage if food supplies are limited. Ectotherms also usually tolerate larger fluctuations in their internal temperatures. Although ectotherms do not generate enough heat for thermoregulation, many adjust body temperature by behavioral means, such as seeking out shade or basking in the sun **(Figure 40.9b)**. Overall, ectothermy is an effective and successful strategy in most environments, as shown by the abundance and diversity of ectothermic animals.

Variation in Body Temperature

Animals can have either a variable or a constant body temperature. An animal whose body temperature varies with its environment is called a *poikilotherm* (from the Greek *poikilos*, varied). In contrast, a *homeotherm* has a relatively constant body temperature. For example, the largemouth bass is a poikilotherm, and the river otter is a homeotherm (see Figure 40.7).

From the descriptions of ectotherms and endotherms, it might seem that all ectotherms are poikilothermic and all endotherms are homeothermic. Actually, there is no fixed relationship between the source of heat and the stability of body temperature. For example, many ectothermic marine fishes and invertebrates inhabit waters with such stable temperatures that their body temperature varies less than that of endotherms such as humans and other mammals. Conversely, the body temperature of a few endotherms varies considerably. For example, bats and hummingbirds may periodically enter an inactive state in which they maintain a lower body temperature.

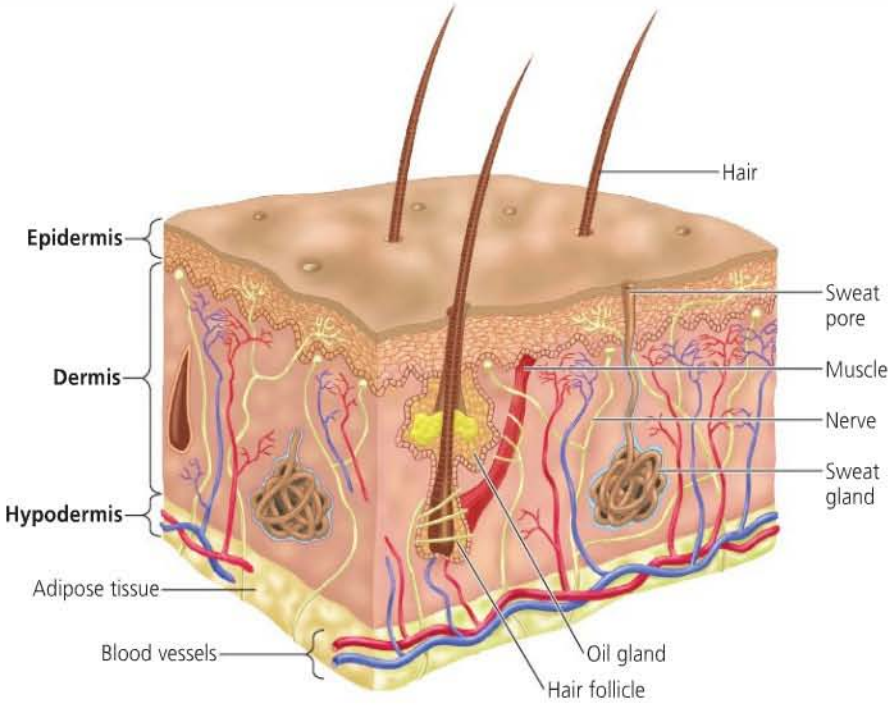


It is a common misconception that ectotherms are "cold-blooded" and endotherms are "warm-blooded." Ectotherms do not necessarily have low body temperatures. In fact, when sitting in the sun, many ectothermic lizards have higher body temperatures than mammals. Thus, the terms *cold-blooded* and *warm-blooded* are misleading and have been dropped from the scientific vocabulary.

Balancing Heat Loss and Gain

Thermoregulation depends on an animal's ability to control the exchange of heat with its environment. Any organism, like any object, exchanges heat by four physical processes: conduction, convection, radiation, and evaporation. **Figure 40.10** distinguishes these processes, which account for the flow of heat

Radiation is the emission of electromagnetic waves by all objects warmer than absolute zero. Radiation can transfer heat between objects that are not in direct contact, as when a lizard absorbs heat radiating from the sun.



Evaporation is the removal of heat from the surface of a liquid that is losing some of its molecules as gas. Evaporation of water from a lizard's moist surfaces that are exposed to the environment has a strong cooling effect.

Convection is the transfer of heat by the movement of air or liquid past a surface, as when a breeze contributes to heat loss from a lizard's dry skin, or blood moves heat from the body core to the extremities.

Conduction is the direct transfer of thermal motion (heat) between molecules of objects in direct contact with each other, as when a lizard sits on a hot rock.

▲ **Figure 40.10 Heat exchange between an organism and its environment.**

▲ **Figure 40.11 Mammalian integumentary system.** The skin and its derivatives serve important functions in mammals, including protection and thermoregulation.

both within an organism and between an organism and its external environment. Note that heat is always transferred from an object of higher temperature to one of lower temperature.

The essence of thermoregulation is maintaining rates of heat gain that equal rates of heat loss. Animals do this through mechanisms that either reduce heat exchange overall or that favor heat exchange in a particular direction. In mammals, several of these mechanisms involve the **integumentary system**, the outer covering of the body, consisting of the skin, hair, and nails (claws or hooves in some species). A key organ of this system is the skin, which consists of the epidermis and the dermis **(Figure 40.11)**. The epidermis is the outermost layer of skin and is composed mostly of dead epithelial cells that continually flake and fall off. New cells pushing up from lower layers replace the cells that are lost. The inner layer, the dermis, contains hair follicles, oil and sweat glands, muscles, nerves, and blood vessels. Beneath the skin lies the hypodermis, a layer of adipose tissue that includes fat-storing cells as well as blood vessels.

Insulation

A major thermoregulatory adaptation in mammals and birds is insulation, which reduces the flow of heat between an animal and its environment. Sources of insulation include hair, feathers, and layers of fat formed by adipose tissue.

Many animals that rely on insulation to reduce overall heat exchange also adjust their insulating layers to help thermoregulate. Most land mammals and birds, for example, react to cold by raising their fur or feathers. This action traps a thicker layer of air, thereby increasing the insulating power of the fur or feather layer. To repel water that would reduce the insulating capacity of feathers or fur, some animals secrete oily substances, such as the oils that birds apply to their feathers during preening. Lacking feathers or fur, humans must rely primarily on fat for insulation. "Goose bumps" are a vestige of hair raising inherited from our furry ancestors.

Insulation plays a particularly important role in thermoregulation by marine mammals, such as whales and walruses. These animals swim in water colder than their body core temperature, and many species spend at least part of the year in nearly freezing polar seas. The problem of thermoregulation is made worse by the fact that the transfer of heat to water occurs 50 to 100 times more rapidly than heat transfer to air. Just under the skin, marine mammals have a very thick layer of insulating fat called blubber. The insulation blubber provides is so effective that marine mammals maintain body core temperatures of about 36–38°C (97–100°F) without requiring much more food energy than land mammals of similar size.

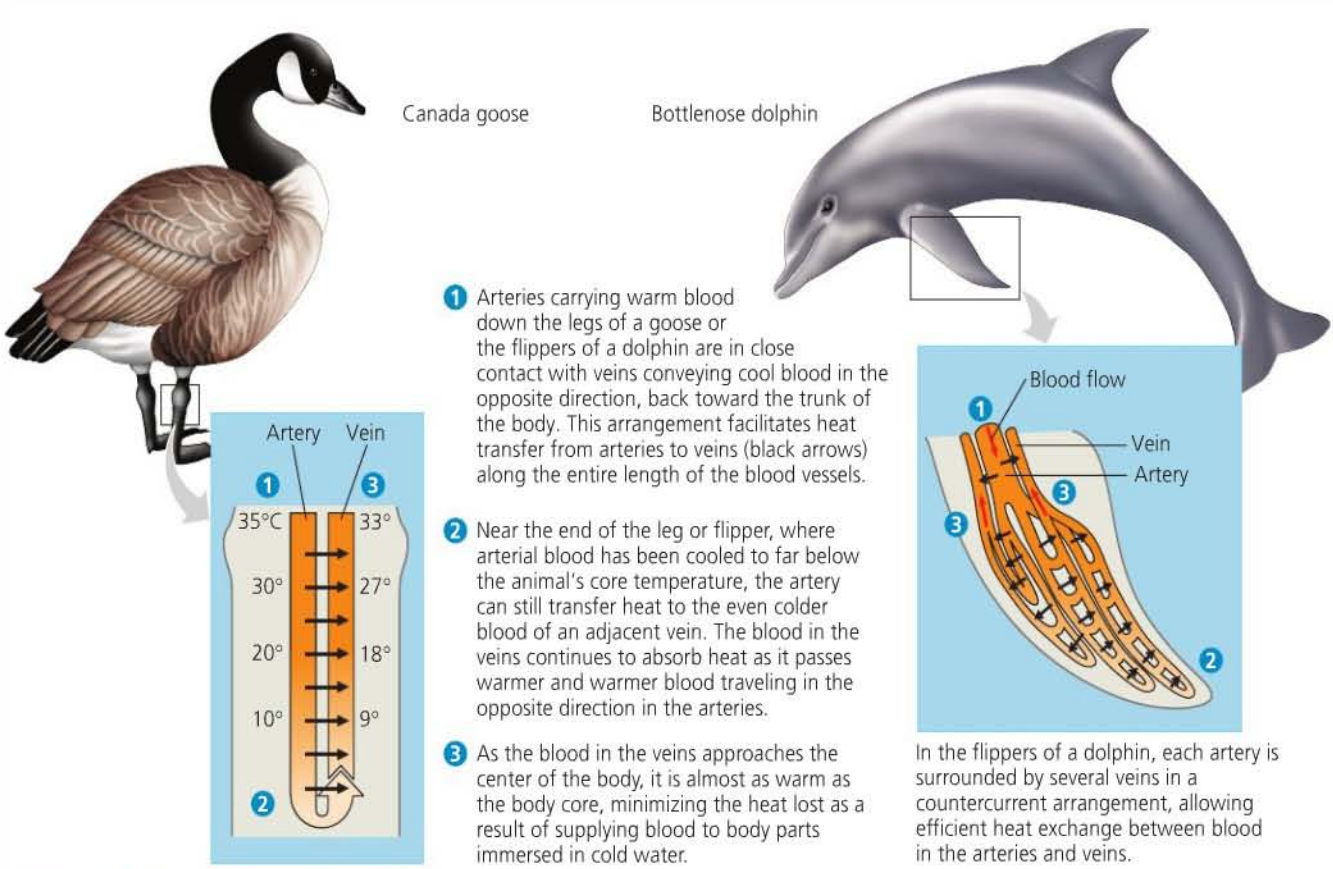
Circulatory Adaptations

Circulatory systems provide a major route for heat flow between the interior and exterior of the body. Adaptations that regulate the extent of blood flow near the body surface or that trap heat within the body core play a significant role in thermoregulation.

In response to changes in the temperature of their surroundings, many animals alter the amount of blood (and hence heat) flowing between their body core and their skin. Nerve signals that relax the muscles of the vessel walls result in *vasodilation*, an increase in the diameter of superficial blood vessels (those near the body surface). As a consequence of the increase in vessel diameter, blood flow in the skin is elevated. In endotherms, vasodilation usually warms the skin and increases the transfer of body heat to the environment by radiation, conduction, and convection (see Figure 40.10). The reverse process, *vasoconstriction*, reduces blood flow and heat transfer by decreasing the diameter of superficial vessels. It is vasoconstriction in blood vessels of the ear that allows the jackrabbit shown in Figure 40.1 to avoid overheating on hot desert days.

Like endotherms, some ectotherms control heat exchange by regulating blood flow. For example, when the marine iguana of the Galápagos Islands swims in the cold ocean, its superficial blood vessels will undergo vasoconstriction. This

process routes more blood to the central core of the body, conserving body heat.



In many birds and mammals, reduction of heat loss relies on **countercurrent exchange**, the flow of adjacent fluids in opposing directions that maximizes transfer rates of heat or solutes. Heat transfer involves an antiparallel arrangement of blood vessels called a *countercurrent heat exchanger*. When tissues are organized this way, arteries and veins are located adjacent to each other. As warm blood passes through arteries, it transfers heat to the colder blood returning from the extremities in the veins. Because the arteries and veins have countercurrent blood flow—blood flowing in opposite directions—heat transfer occurs along the entire length of the exchanger. **Figure 40.12** illustrates countercurrent heat exchange in a goose and dolphin.

Certain sharks, bony fishes, and insects also use countercurrent heat exchange. Although most sharks and fishes are temperature conformers, countercurrent heat exchangers are found in some large, powerful swimmers, including great white sharks, bluefin tuna, and swordfish. By keeping the main swimming muscles several degrees warmer than tissues near the animal's surface, this adaptation enables the vigorous, sustained activity that is characteristic of these animals. Similarly, many endothermic insects (bumblebees, honeybees, and some moths) have a countercurrent exchanger that helps maintain a high temperature in the thorax, where flight muscles are located.

In controlling heat gain and loss, some species regulate the extent of blood flow to the countercurrent exchanger. By allowing blood to pass through the heat exchanger or diverting it to other blood vessels, these animals alter the rate of heat loss as their physiological state or environment changes. For example, insects flying in hot weather run the risk of overheating because of the large amount of heat produced by working flight muscles. In some species, the countercurrent mechanism can be "shut down," allowing muscle-produced heat to be lost from the thorax to the abdomen and then to the environment.

Cooling by Evaporative Heat Loss

Many mammals and birds live in places where thermoregulation requires cooling as well as warming. If environmental temperature is above body temperature, animals gain heat from the environment as well as from metabolism, and evaporation is the only way to keep body temperature from rising rapidly. Terrestrial animals lose water by evaporation across the skin and when they breathe. Water absorbs considerable heat when it evaporates (see Chapter 3); this heat is carried away from the body surface with the water vapor.

▲ **Figure 40.12 Countercurrent heat exchangers.** A countercurrent exchange system traps heat in the body core, thus reducing heat loss from the extremities, particularly when they are immersed in cold water or in contact with ice or snow. In essence, heat in the arterial blood emerging from the body core is transferred directly to the returning venous blood instead of being lost to the environment.

Thermoregulation in some animals is aided by adaptations that can greatly augment this cooling effect. Panting is important in birds and many mammals. Some birds have a pouch richly supplied with blood vessels in the floor of the mouth; fluttering the pouch increases evaporation. Pigeons, for example, can use evaporative cooling to keep body temperature close to 40°C (104°F) in air temperatures as high as 60°C (140°F), as long as they have sufficient water. Sweating or bathing moistens the skin and enhances evaporative cooling. Many terrestrial mammals have sweat glands controlled by the nervous system (see Figure 40.11).

Behavioral Responses

Both endotherms and ectotherms control body temperature through behavioral responses. Many ectotherms maintain a nearly constant body temperature through relatively simple behaviors. More extreme behavioral adaptations in some animals include hibernation or migration to a more suitable climate.

All amphibians and most reptiles other than birds are ectothermic. Therefore, these organisms control body temperature mainly by behavior. When exposed to air, most amphibians lose heat rapidly by evaporation from their moist body surfaces, making it difficult to keep sufficiently warm. However, an amphibian can maintain a satisfactory body temperature simply by moving to a location where solar heat is available. When the surroundings are too warm, amphibians seek shady spots or other cooler microenvironments.

Like amphibians, reptiles other than birds use behavior as their dominant means of thermoregulation. When cold, they seek warm places, orienting themselves toward heat sources and expanding the portion of their body surface exposed to the heat source (see Figure 40.9b). When hot, they move to cool areas or turn in another direction. Many reptiles keep their body temperatures very stable over the course of a day by shuttling back and forth between warm and cool spots.

Many terrestrial invertebrates can adjust internal temperature by the same behavioral mechanisms used by vertebrate ectotherms. The desert locust, for example, must reach a certain temperature to become active, and on cold days it orients in a direction that maximizes the absorption of sunlight. Other terrestrial invertebrates have certain postures that enable them to maximize or minimize their absorption of heat from the sun **(Figure 40.13)**.

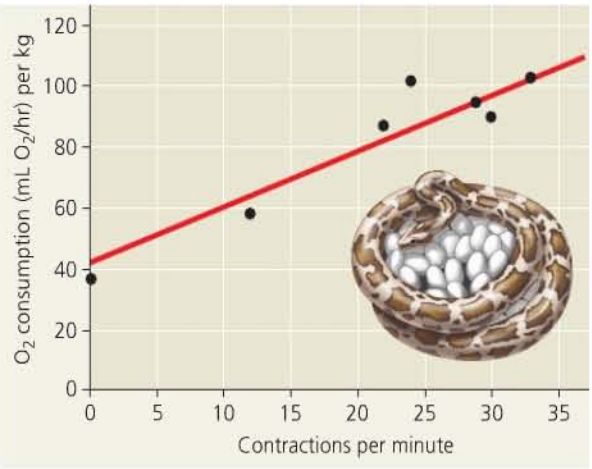
Honeybees use a thermoregulatory mechanism that depends on social behavior. In cold weather, they increase heat production and huddle together, thereby retaining heat. They maintain a relatively constant temperature by changing how densely they huddle. Individuals move between the cooler outer edges of the cluster and the warmer center, thus circulating and distributing the heat. Even when huddling, honeybees must expend considerable energy to keep warm during long periods of cold weather, and this is the main function of storing large quantities of fuel in the hive in the form of honey.

◀ Figure 40.13
Thermoregulatory behavior in a dragonfly.
This dragonfly's "obelisk" posture is an adaptation that minimizes the amount of body surface exposed to the sun. This posture helps reduce heat gain by radiation.

Honeybees also control the temperature of their hive by transporting water to the hive in hot weather and fanning with their wings, promoting evaporation and convection. Thus, a colony of honeybees uses many of the mechanisms of thermoregulation seen in individual organisms.

Adjusting Metabolic Heat Production

Because endotherms generally maintain body temperatures considerably higher than that of the environment, they must counteract constant heat loss. Endotherms can vary heat production to match changing rates of heat loss. For example, heat production—*thermogenesis*—is increased by such muscle activity as moving or shivering. In some mammals, certain hormones can cause mitochondria to increase their metabolic activity and produce heat instead of ATP. This *nonshivering thermogenesis* takes place throughout the body, but some mammals also have a tissue called *brown fat* in the neck and between the shoulders that is specialized for rapid heat production. Through shivering and nonshivering thermogenesis, mammals and birds in cold environments can increase their metabolic heat production by as much as five to ten times the levels that occur in warm conditions. For example, chickadees, birds with a body mass of only 20 g, can remain active and hold body temperature nearly constant at 40°C (104°F) in environmental temperatures as low as −40°C (−40°F), as long as they have adequate food.



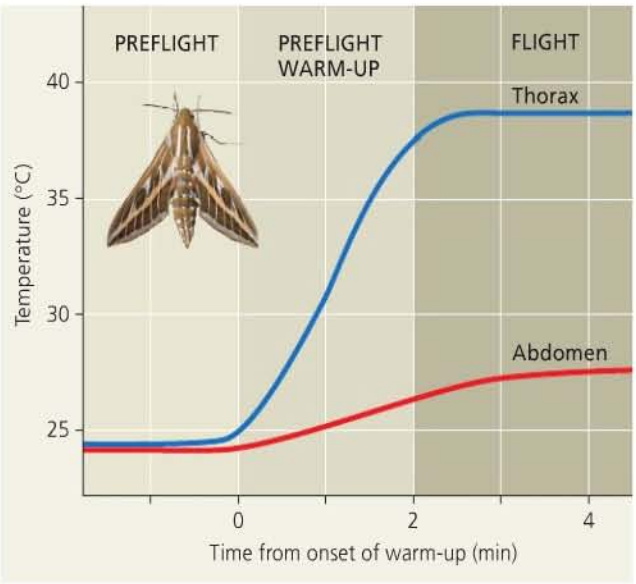
A few large reptiles become endothermic in particular circumstances. In the early 1960s, Herndon Dowling, at the Bronx Zoo in New York, documented this phenomenon for a female Burmese python (*Python molurus bivittatus*). Placing temperature-recording devices along the snake's coils, Dowling found that the snake maintained a body temperature roughly 6°C (10°F) above that of the surrounding air during the month when she was incubating eggs. Where did the heat come from? To answer this question, Dowling carried out studies together with a graduate student, Allen Vinegar, and his research supervisor, Victor Hutchison **(Figure 40.14)**. What they found was that pythons, like mammals, can generate heat

▼ Figure 40.14 Inquiry

How does a Burmese python generate heat while incubating eggs?

EXPERIMENT Herndon Dowling and colleagues at the Bronx Zoo in New York observed that when a female Burmese python incubated eggs by wrapping her body around them, she raised her body temperature and frequently contracted the muscles in her coils. To learn if the contractions were elevating her body temperature, they placed the python and her eggs in a chamber. They varied the chamber's temperature and monitored the python's muscle contractions and her oxygen uptake, a measure of her rate of cellular respiration.

RESULTS The python's oxygen consumption increased when the temperature in the chamber decreased. Her oxygen consumption also changed with the rate of muscle contraction:



CONCLUSION Because oxygen consumption generates heat through cellular respiration and increases linearly with the rate of muscle contraction, the researchers concluded that the muscle contractions, a form of shivering, were the source of the Burmese python's elevated body temperature.

SOURCE V. H. Hutchison, H.G. Dowling, and A. Vinegar, Thermoregulation in a brooding female Indian python, *Python molurus bivittatus*, *Science* 151:694–696 (1966).

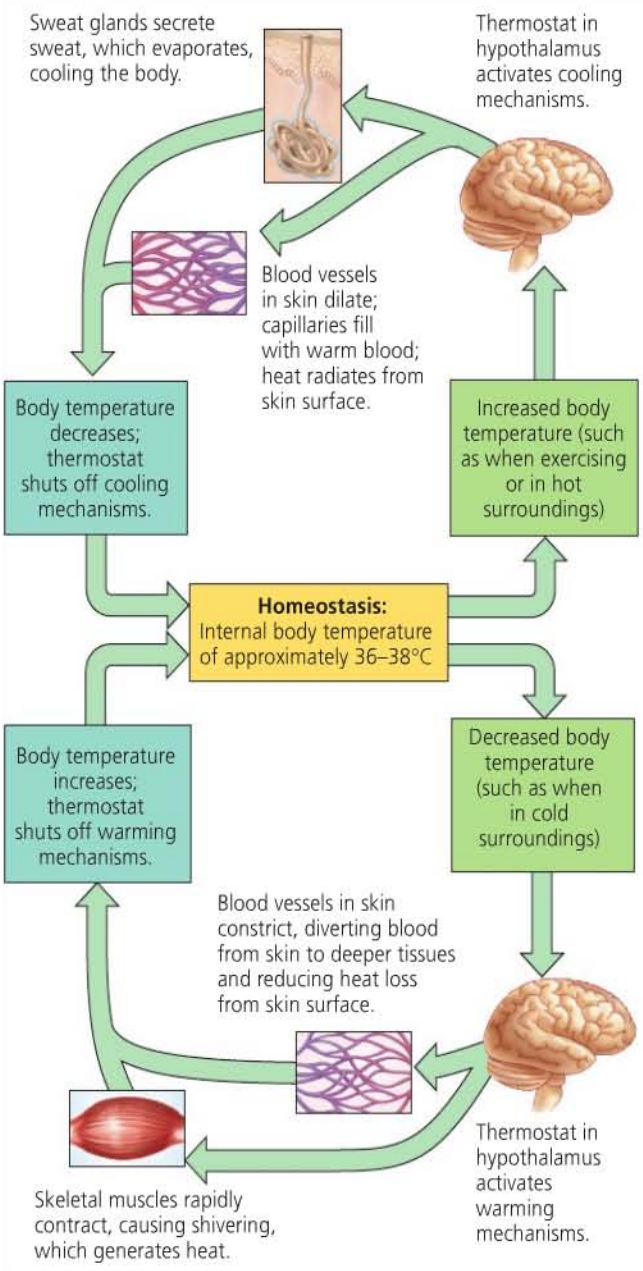
WHAT IF? Suppose you varied air temperature and measured oxygen consumption for a female Burmese python without a clutch of eggs. Since she would not show shivering behavior, how would the snake's oxygen consumption vary with environmental temperature?

through spasmodic muscle contraction—in other words, shivering. These findings and others have led to new insights into thermoregulation in reptiles and contributed to the idea, still under debate, that certain groups of dinosaurs were endothermic (see Chapter 34).

As mentioned earlier, many species of flying insects, such as bees and moths, are endothermic—the smallest of all endotherms. The capacity of such endothermic insects to elevate body temperature depends on powerful flight muscles, which

▲ **Figure 40.15 Preflight warm-up in the hawkmoth.** The hawkmoth (*Manduca sexta*) is one of many insect species that use a shivering-like mechanism for preflight warm-up of thoracic flight muscles. Warming up helps these muscles produce enough power to let the animal take off. Once airborne, flight muscle activity maintains a high thoracic temperature.

generate large amounts of heat when operating. Many endothermic insects warm up by shivering before taking off. As they contract their flight muscles in synchrony, only slight wing movements occur, but considerable heat is produced. Chemical reactions, and hence cellular respiration, speed up in the warmed-up flight "motors," enabling these insects to fly even on cold days or at night **(Figure 40.15)**.



Acclimatization in Thermoregulation

Acclimatization contributes to thermoregulation across many animal species. In birds and mammals, acclimatization to seasonal temperature changes often includes adjusting the amount of insulation—by growing a thicker coat of fur in the winter and shedding it in the summer, for example. These changes help endotherms keep a constant body temperature throughout the year.

Acclimatization in ectotherms often includes adjustments at the cellular level. Cells may produce variants of enzymes that have the same function but different optimal temperatures. Also, the proportions of saturated and unsaturated lipids in membranes may change; unsaturated lipids help keep membranes fluid at lower temperatures (see Figure 7.5). Some ectotherms that experience subzero body temperatures protect themselves by producing "antifreeze" compounds that prevent ice formation in the cells. In the Arctic and Southern (Antarctic) oceans, these compounds in the body fluids of certain fishes enable survival where water temperatures can be as low as −2°C (28°F), below the freezing point of unprotected body fluids (about −1°C, or 30°F).

Physiological Thermostats and Fever

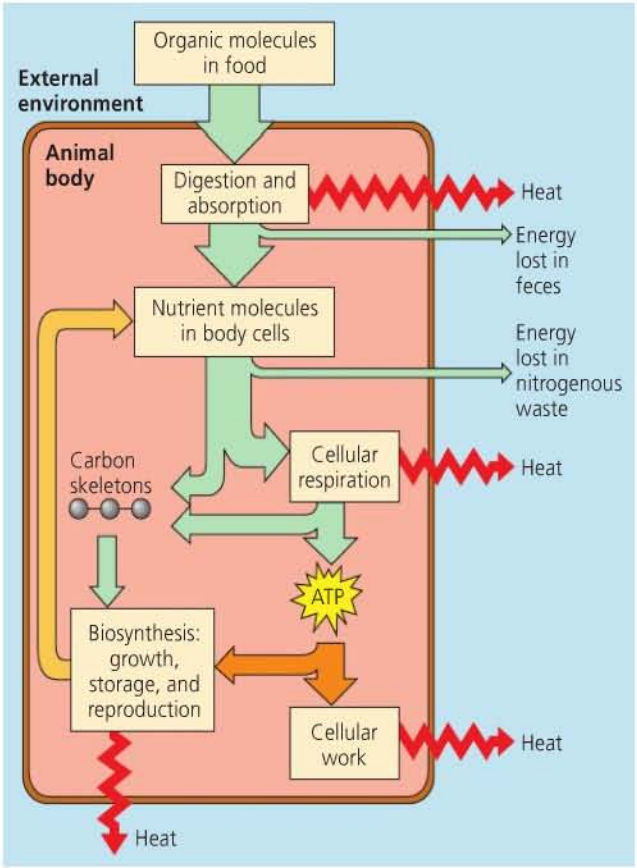
The regulation of body temperature in humans and other mammals is brought about by a complex system based on feedback mechanisms. The sensors for thermoregulation are concentrated in a brain region called the **hypothalamus**. The hypothalamus contains a group of nerve cells that functions as a thermostat, responding to body temperatures outside a normal range by activating mechanisms that promote heat loss or gain **(Figure 40.16)**. Warm receptors signal the hypothalamic thermostat when temperatures increase; cold receptors signal when temperatures decrease. At body temperatures below the normal range, the thermostat inhibits heat loss mechanisms and activates heat-saving ones such as the constriction of certain blood vessels and the raising of fur, while stimulating heat-generating mechanisms (shivering and nonshivering thermogenesis). In response to elevated body temperature, the thermostat shuts down heat retention mechanisms and promotes body cooling by vasodilation, sweating, or panting. Because the same blood vessel supplies the hypothalamus and ears, an ear thermometer records the temperature detected by the hypothalmic thermostat.

▲ **Figure 40.16 The thermostatic function of the hypothalamus in human thermoregulation.**

In the course of certain bacterial and viral infections, mammals and birds develop fever, an elevated body temperature. A variety of experiments have shown that fever reflects an increase in the set point for the biological thermostat. For example, artificially raising the temperature of the hypothalamus in an infected animal reduces fever in the rest of the body.

Although only endotherms develop fever, lizards exhibit a related response. When infected with certain bacteria, the desert iguana (*Dipsosaurus dorsalis*) seeks a warmer environment and then maintains a body temperature that is elevated by 2–4°C (4–7°F). Similar observations in fishes, amphibians, and even cockroaches indicate broad evolutionary conservation of this response to certain infections.

Having explored thermoregulation in depth, we'll now consider some other energy-consuming processes and the different ways that animals allocate, use, and conserve energy.



CONCEPT CHECK 40.3

1. What mode of heat exchange is involved in "wind chill," when moving air feels colder than still air at the same temperature?
2. Flowers differ in how much sunlight they absorb. Why might this matter to a hummingbird seeking nectar on a cool morning?
3. **WHAT IF?** Suppose at the end of a hard run on a hot day you find that there are no drinks left in the cooler. If, out of desperation, you dunk your head into the cooler, how might the ice-cold water affect the rate at which your body temperature returns to normal?

For suggested answers, see Appendix A.

CONCEPT 40.4
Energy requirements are related to animal size, activity, and environment

Like other organisms, animals require chemical energy for growth, repair, activity, and reproduction. The overall flow and transformation of energy in an animal—its **bioenergetics**—determines nutritional needs and is related to an animal's size, activity, and environment.

▲ **Figure 40.17 Bioenergetics of an animal: an overview.**

Energy Allocation and Use

As we have discussed in other chapters, organisms can be classified by how they obtain chemical energy. Most autotrophs, such as plants, use light energy to build energy-rich organic molecules and then use those organic molecules for fuel. Heterotrophs, such as animals, must obtain their chemical energy from food, which contains organic molecules synthesized by other organisms.

Animals use chemical energy harvested from the food they eat to fuel metabolism and activity **(Figure 40.17)**. Food is digested by enzymatic hydrolysis (see Figure 5.2b), and nutrients are absorbed by body cells. Most energy-containing molecules are used to generate ATP. ATP produced by cellular respiration and fermentation (see Chapter 9) powers cellular work, enabling cells, organs, and organ systems to perform the functions that keep an animal alive. Energy in the form of ATP is also used in biosynthesis, which is needed for body growth and repair, synthesis of storage material such as fat, and production of gametes. The production and use of ATP generates heat, which the animal eventually gives off to its surroundings.

Quantifying Energy Use

How much of the total energy an animal obtains from food does it need just to stay alive? How much energy must be expended to walk, run, swim, or fly from one place to another? What fraction of the energy intake is used for reproduction? Physiologists answer such questions by measuring the rate at which an animal uses chemical energy and how this rate changes in different circumstances.

▲ **Figure 40.18 Measuring rate of oxygen consumption in a running pronghorn.** A researcher collects respiratory data from a pronghorn running on a treadmill at 40 km/hr.

The amount of energy an animal uses in a unit of time is called its **metabolic rate**—the sum of all the energy-requiring biochemical reactions over a given time interval. Energy is measured in joules or in calories (cal) and kilocalories (kcal). (A kilocalorie equals 1,000 calories. The unit Calorie, with a capital C, as used by many nutritionists, is actually a kilocalorie.)

Metabolic rate can be determined in several ways. Because nearly all of the chemical energy used in cellular respiration eventually appears as heat, metabolic rate can be measured by monitoring an animal's rate of heat loss. For this approach, researchers use a calorimeter, which is a closed, insulated chamber equipped with a device that records an animal's heat loss. Metabolic rate can also be determined from the amount of oxygen consumed or carbon dioxide produced by an animal's cellular respiration **(Figure 40.18)**. To calculate metabolic rate over longer periods, researchers record the rate of food consumption, the energy content of the food (about 4.5–5 kcal per gram of protein or carbohydrate and about 9 kcal per gram of fat), and the chemical energy lost in waste products (feces and nitrogenous waste).

Minimum Metabolic Rate and Thermoregulation

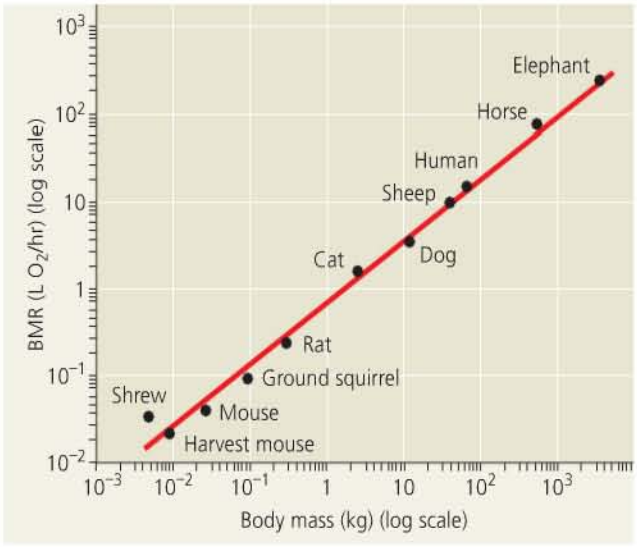
Animals must maintain a minimum metabolic rate for basic functions such as cell maintenance, breathing, and heartbeat. Researchers measure this minimum metabolic rate differently for endotherms and ectotherms. The minimum metabolic rate of a nongrowing endotherm that is at rest, has an empty stomach, and is not experiencing stress is called the **basal metabolic rate (BMR)**. BMR is measured

under a "comfortable" temperature range—a range that requires no generation or shedding of heat above the minimum. The minimum metabolic rate of ectotherms is determined at a specific temperature because changes in the environmental temperature alter body temperature and therefore metabolic rate. The metabolic rate of a fasting, nonstressed ectotherm at rest at a particular temperature is called its **standard metabolic rate (SMR)**.

Comparisons of minimum metabolic rates reveal that endothermy and ectothermy have distinct energy costs. The BMR for humans averages 1,600–1,800 kcal per day for adult males and 1,300–1,500 kcal per day for adult females. These BMRs are about equivalent to the rate of energy use by a 75-watt light bulb. In contrast, SMR calculations reveal that an American alligator at rest consumes only about 60 kcal per day at 20°C (68°F). Since this represents less than ⅒ the energy used by a comparably sized adult human, the lower energetic requirement of ectothermy is readily apparent.

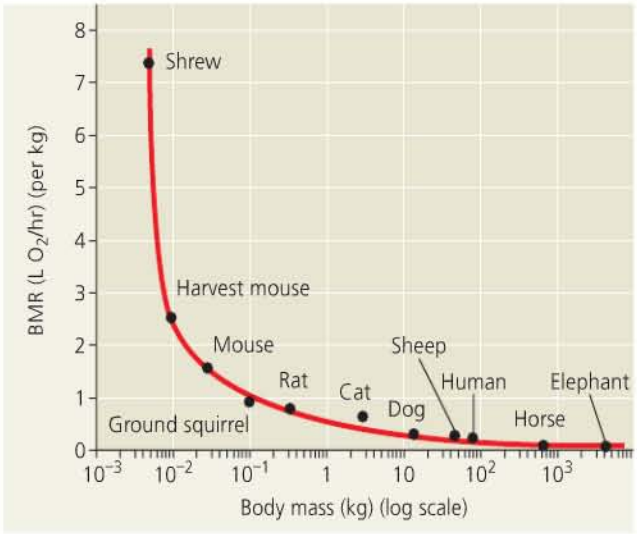
Influences on Metabolic Rate

Metabolic rate is affected by many factors besides whether the animal is an endotherm or an ectotherm. Some key factors are age, sex, size, activity, temperature, and nutrition. Here we'll examine the effects of size and activity.



Size and Metabolic Rate

An intriguing, yet largely unanswered, question in animal biology has to do with the relationship between body size and metabolic rate. Larger animals have more body mass and therefore require more chemical energy. Remarkably, the relationship between overall metabolic rate and body mass is constant across a wide range of sizes and forms, as illustrated for various mammals in **Figure 40.19a**. For creatures ranging in size from bacteria to blue whales, metabolic rate is roughly proportional to body mass to the three-quarter power ($m^{3/4}$).



The relationship of metabolic rate to size profoundly affects energy consumption by body cells and tissues. As shown in **Figure 40.19b**, the energy it takes to maintain each gram of body weight is inversely related to body size. Each gram of a mouse, for instance, requires about 20 times as many calories as a gram of an elephant, even though the whole elephant uses far more calories than the whole mouse. The smaller animal's higher metabolic rate per gram demands a greater rate of oxygen delivery. Correlated with its higher metabolic rate per gram, the smaller animal has a higher breathing rate, blood volume (relative to its size), and heart rate. Also, it must eat much more food per unit of body mass.

The reason for the inverse relationship of metabolic rate per unit of body mass to body size is still a subject of debate. One hypothesis is that for endotherms the smaller the animal, the greater the energy cost of maintaining a stable body temperature. In effect, the smaller an animal is, the greater its surface-to-volume ratio is and thus the faster it loses heat to (or gains heat from) the surroundings. Logical as this hypothesis seems, it does not explain the fact that the inverse relationship between metabolic rate per gram and size is also observed in ectotherms, which do not use metabolic heat to maintain body temperature.

Bioenergetic considerations associated with body size provide a clear example of how trade-offs shape the evolution of body plans. As body size becomes smaller, each gram of tissue increases in energy cost. As body size increases, energy costs per gram of tissue lessen, but an ever-larger fraction of body tissue is required for exchange, support, and locomotion.

(a) Relationship of basal metabolic rate (BMR) to body size for various mammals. From shrew to elephant, size increases 1 millionfold.

(b) Relationship of BMR per kilogram of body mass to body size for the same mammals as in (a).

▲ Figure 40.19 The relationship of metabolic rate to body size.

Activity and Metabolic Rate

For both ectotherms and endotherms, activity greatly affects metabolic rate. Even a person reading quietly at a desk or an insect twitching its wings consumes energy beyond the BMR or SMR. Maximum metabolic rates (the highest rates of ATP use) occur during peak activity, such as lifting heavy weights, sprinting, or high-speed swimming. In general, the maximum metabolic rate an animal can sustain is inversely related to the duration of activity.

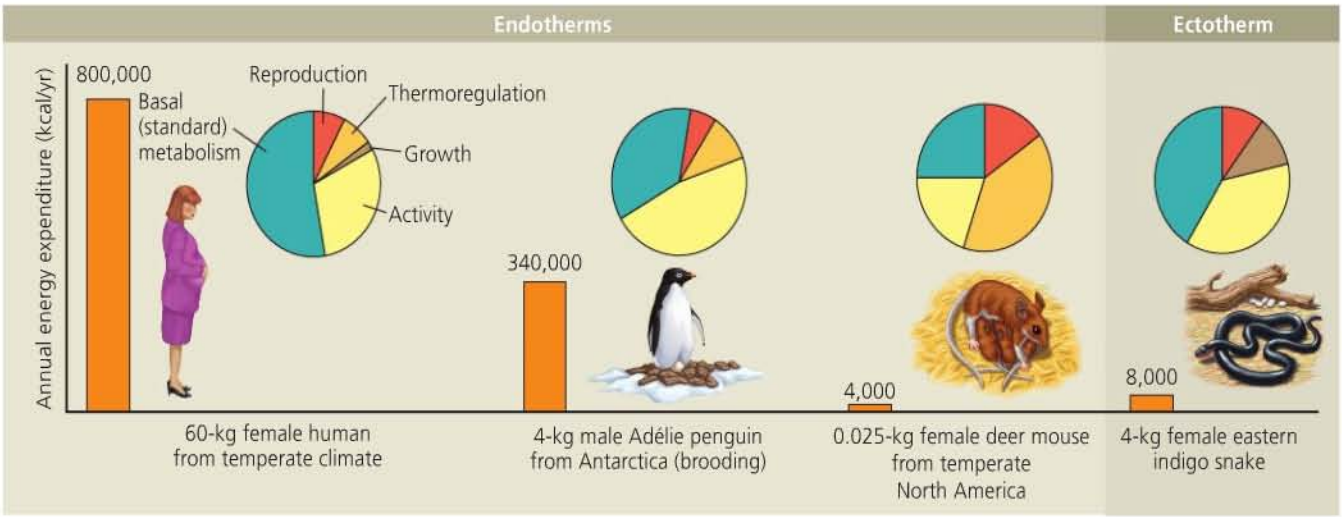
For most terrestrial animals, the average daily rate of energy consumption is 2 to 4 times BMR (for endotherms) or SMR (for ectotherms). Humans in most developed countries have an unusually low average daily metabolic rate of about 1.5 times BMR—an indication of their relatively sedentary lifestyles.

Energy Budgets

As we have seen, the ways in which animals use the chemical energy of food depend on environment, behavior, size, and thermoregulation. To understand how these influences affect bioenergetics in animal bodies, let's consider typical annual energy "budgets" of four terrestrial vertebrates varying in size and thermoregulatory strategy: a 60-kg female human, a 4-kg male Adélie penguin, a 25-g (0.025-kg) female deer mouse, and a 4-kg female eastern indigo snake **(Figure 40.20)**. Reproduction is included in these energy budgets because it can greatly influence energy allocation and is critical to species survival.

The female human, an endothermic mammal, spends the largest fraction of her annual energy budget for BMR and relatively little for activity and thermoregulation. The small amount of growth, about 1%, is equivalent to adding about 1 kg of body fat or 5–6 kg of other tissues. (Growth is not shown in the budgets for the penguin and deer mouse because these animals don't typically gain weight year to year after they are adults.) The cost of nine months of pregnancy and several months of breast-feeding is only 5–8% of the mother's annual energy requirements.

A male penguin spends the largest fraction of his energy for activity because he must swim to catch food. Being well insulated and fairly large, he has relatively low costs of thermoregulation in spite of living in the cold Antarctic. His reproductive costs, about 6% of annual energy expenditures, come mainly from incubating eggs (brooding) and bringing food to his chicks. Like most birds, penguins do not grow after they become adults.



Despite living in a temperate climate, the female deer mouse spends a large fraction of her energy budget for temperature regulation. Because of the high surface-to-volume ratio that goes with small size, deer mice lose body heat rapidly and must constantly generate metabolic heat to maintain body temperature.

In contrast with these endothermic animals, the ectothermic snake has no thermoregulation costs. Like most snakes, she grows continuously throughout her life. In the example in Figure 40.20, the snake added about 750 g of new body tissue in a year. She also produced about 650 g of eggs. The snake's economical ectothermic strategy is revealed by her very low energy expenditure, only ⅛ the energy expended by the similarly sized endothermic penguin.

For all the animals in Figure 40.20, locomotion and other activities are a major part of the energy budget. Some animals can conserve energy by temporarily decreasing their activity to a very low level, a process we will consider next.

Torpor and Energy Conservation

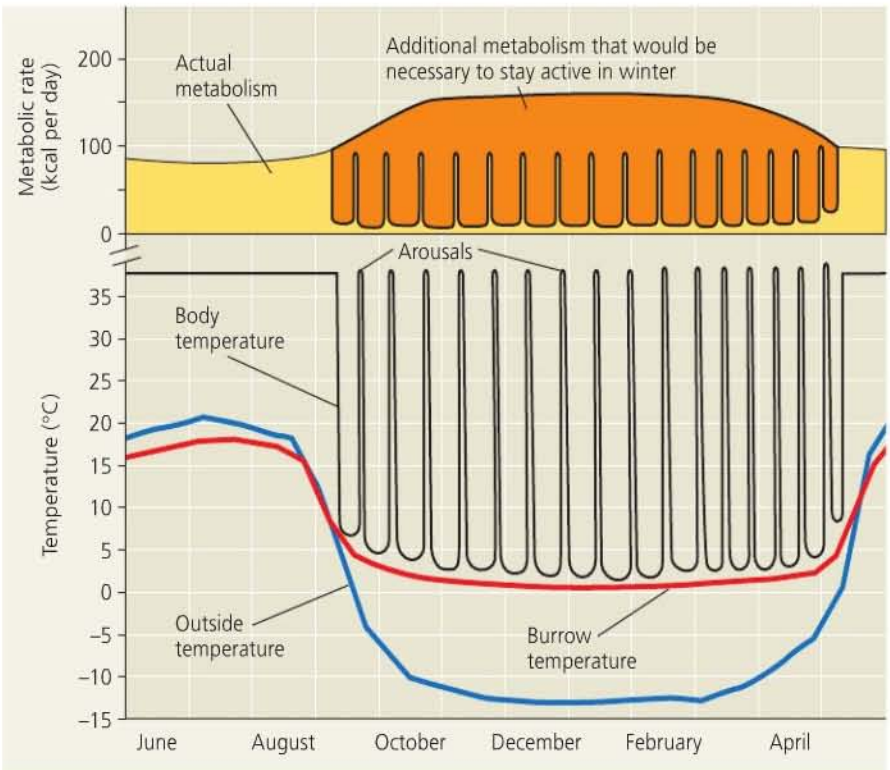
Despite their many adaptations for homeostasis, animals may encounter conditions that severely challenge their abilities to balance their heat, energy, and materials budgets. For example, at certain seasons or times of day, temperatures may be extremely high or low, or food may be unavailable. **Torpor**, a physiological

▲ **Figure 40.20 Energy budgets for four animals.** The slices of the pie charts indicate annual energy expenditures for various functions.

state in which activity is low and metabolism decreases, is an adaptation that enables animals to save energy while avoiding difficult and dangerous conditions.

Hibernation is long-term torpor that is an adaptation to winter cold and food scarcity. When vertebrate endotherms (birds and mammals) enter hibernation, their body temperatures decline as their body's thermostat is turned down. The temperature reduction may be dramatic: Some hibernating mammals cool to as low as 1–2°C (34–35°F), and a few even drop slightly below 0°C (32°F) in a supercooled (unfrozen) state. The resulting energy savings are huge; metabolic rates during hibernation can be much lower than if the animal attempted to maintain normal body temperatures of 36–38°C (97–100°F). Consider, for example, a Belding's ground squirrel (*Spermophilus beldingi*) living in the high mountains of California **(Figure 40.21)**. Instead of spending 150 kcal per day to maintain body temperature in winter weather, a hibernating squirrel spends an average of only 5–8 kcal per day. As a result, hibernators such as the ground squirrel can survive through the winter on limited supplies of energy stored in the body tissues or as food cached in a burrow. Similarly, the slow metabolism and inactivity of *estivation*, or summer torpor, enables animals to survive long periods of high temperatures and scarce water supplies.

Many small mammals and birds exhibit a daily torpor that seems to be adapted to feeding patterns. For instance, some bats feed at night and go into torpor in daylight. Chickadees and hummingbirds feed during the day and often go into torpor on cold nights; the body temperature of chickadees drops as much as 10°C (18°F) at night, and the temperature of hummingbirds can fall 25°C (45°F) or more. All endotherms that use daily torpor are relatively small; when active, they have high metabolic rates and thus very high rates of energy consumption.



From discussing body shape to considering energy conservation, this chapter has focused on the whole animal. We explored common tissue types that make up organs and organ systems. We also investigated how body plans provide for exchange, how size affects metabolic rate, and how some animals maintain a constant internal environment. For much of the rest of this unit, we'll see how specialized organs and organ systems enable animals to meet the basic challenges of life.

CONCEPT CHECK 40.4

1. If a mouse and a small lizard of the same mass (both at rest) were placed in experimental chambers under identical environmental conditions, which animal would consume oxygen at a higher rate? Explain.
2. Which animal must eat a larger proportion of its weight in food each day: a house cat or an African lion caged in a zoo? Explain.
3. **WHAT IF?** If you monitored energy allocation in the penguin in Figure 40.20 for just a few months, the "growth" category might now be a significant part of the pie chart, even though adult penguins don't change in size from year to year. What limitation in such energy budget studies does this lead you to consider?

For suggested answers, see Appendix A.

▶ **Figure 40.21 Body temperature and metabolism during hibernation in Belding's ground squirrels.**

WHAT IF? *Propose two different hypotheses about the environmental change that triggers hibernation. Then suppose that, during one year, the outside temperatures dropped steadily a month earlier than normal. For each hypothesis, what effect on the timing of hibernation would you expect?*

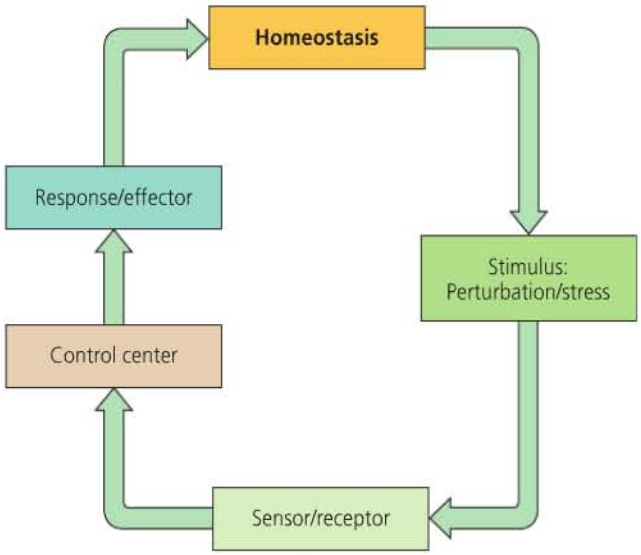
SUMMARY OF KEY CONCEPTS

CONCEPT 40.1

Animal form and function are correlated at all levels of organization (pp. 852–860)

- **Physical Constraints on Animal Size and Shape** The ability to perform certain actions, such as fast swimming, depends on an animal's size and shape. Convergent evolution reflects different species' independent adaptations to a similar environmental challenge.
- **Exchange with the Environment** Each cell of an animal must have access to an aqueous environment. Simple two-layered sacs and flat shapes maximize exposure to the surrounding medium. More complex body plans have highly folded internal surfaces specialized for exchanging materials.
- **Hierarchical Organization of Body Plans** Animals are composed of cells. Groups of cells with a common structure and function make up tissues. Different tissues make up organs, which together make up organ systems.
- **Tissue Structure and Function** Epithelial tissue covers the outside of the body and lines internal organs and cavities. Connective tissues bind and support other tissues. Muscle tissue contracts in response to nerve signals. Nervous tissue transmits nerve signals throughout the animal.
- **Coordination and Control** The endocrine and nervous systems function as the two means of communication between distinct locations in the body. The endocrine system broadcasts signaling molecules called hormones everywhere via the bloodstream, but only certain cells are responsive. The nervous system uses dedicated cellular circuits involving electrical and chemical signals to send information to specific locations.



MEDIA

Activity Overview of Animal Tissues
Activity Epithelial Tissue
Activity Connective Tissue
Activity Muscle Tissue
Activity Nervous Tissue

CONCEPT 40.2

Feedback control loops maintain the internal environment in many animals (pp. 860–862)

- **Regulating and Conforming** Animals cope with environmental fluctuations by regulating certain internal variables while allowing others to conform to external changes.
- **Homeostasis** Homeostasis describes an animal's internal steady state. It is a balance between external changes and the animal's internal control mechanisms that oppose the changes. The interstitial fluid surrounding an animal's cells is usually very different from the external environment. Homeostatic mechanisms moderate changes in the internal environment and usually involve negative feedback. These mechanisms enable regulated change.

Regulated change in the internal environment is essential to normal body functions. Acclimatization involves temporary changes in homeostasis in response to alterations in the environment.

MEDIA

Activity Regulation: Negative and Positive Feedback

CONCEPT 40.3

Homeostatic processes for thermoregulation involve form, function, and behavior (pp. 862–868)

- An animal maintains its internal temperature within a tolerable range by processes of thermoregulation.
- **Endothermy and Ectothermy** Endotherms are warmed mostly by heat generated by metabolism. Ectotherms get most of their heat from external sources. Endothermy requires an animal to expend more energy.
- **Variation in Body Temperature** Body temperature varies in poikilotherms and is relatively constant in homeotherms.
- **Balancing Heat Loss and Gain** Conduction, convection, radiation, and evaporation account for heat exchange. Thermoregulation involves physiological and behavioral adjustments that balance heat gain and loss. Insulation, vasodilation, vasoconstriction, and countercurrent heat exchange alter the rate of heat exchange. Panting, sweating, and bathing increase evaporation, cooling the body. Both ectotherms and endotherms adjust the rate of heat exchange with their surroundings by behavioral responses. Some animals can even adjust their rate of metabolic heat production.
- **Acclimatization in Thermoregulation** Many mammals and birds adjust the amount of body insulation in response to changes in environmental temperature. Ectotherms undergo a variety of changes at the cellular level to acclimatize to shifts in temperature.
- **Physiological Thermostats and Fever** Mammals regulate their body temperature by complex negative-feedback mechanisms that involve several organ systems, including the nervous, circulatory, and integumentary systems.

CONCEPT 40.4

Energy requirements are related to animal size, activity, and environment (pp. 868–872)

- **Energy Allocation and Use** Animals obtain chemical energy from food, storing it for short-term use in ATP.
- **Quantifying Energy Use** An animal's metabolic rate is the total amount of energy it uses in a unit of time. Metabolic rates for birds and mammals, which maintain a fairly constant body temperature using metabolic heat (endothermy), are generally higher than those for most fishes, nonavian reptiles, amphibians, and invertebrates, which rely mostly on external sources of heat for maintaining body temperature (ectothermy).
- **Minimum Metabolic Rate and Thermoregulation** Under similar conditions and for animals of the same size, BMR, the minimum metabolic rate of endotherms, is substantially higher than SMR, the standard metabolic rate of ectotherms.
- **Influences on Metabolic Rate** Minimum metabolic rate per gram is inversely related to body size among similar animals. Activity increases metabolic rate.
- **Energy Budgets** Animals use energy for basal (or standard) metabolism, activity, homeostasis (such as temperature regulation), growth, and reproduction.
- **Torpor and Energy Conservation** Torpor involves a decrease in metabolic rate, conserving energy during environmental extremes. Animals may enter torpor in winter (hibernation), summer (estivation), or during sleep periods (daily torpor).

Investigation How Does Temperature Affect Metabolic Rate in *Daphnia*?

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Compared with a smaller cell, a larger cell of the same shape has
   a. less surface area.
   b. less surface area per unit of volume.
   c. the same surface-to-volume ratio.
   d. a smaller average distance between its mitochondria and the external source of oxygen.
   e. a smaller cytoplasm-to-nucleus ratio.

2. The epithelium best adapted for a body surface subject to abrasion is
   a. simple squamous.
   b. simple cuboidal.
   c. simple columnar.
   d. stratified columnar.
   e. stratified squamous.

3. Which of the following is not an adaptation for reducing the rate of heat exchange between an animal and its environment?
   a. feathers or fur
   b. vasoconstriction
   c. nonshivering thermogenesis
   d. countercurrent heat exchanger
   e. blubber or fat layer

4. Which of the following animals uses the highest percent of its energy budget for homeostatic regulation?
   a. a hydra
   b. a marine jelly (an invertebrate)
   c. a snake in a temperate forest
   d. a desert insect
   e. a desert bird

5. Consider the energy budgets for a human, an elephant, a penguin, a mouse, and a snake. The _____ would have the highest total annual energy expenditure, and the _____ would have the highest energy expenditure per unit mass.
   a. elephant; mouse
   b. elephant; human
   c. human; penguin
   d. mouse; snake
   e. penguin; mouse

6. An animal's inputs of energy and materials would exceed its outputs
   a. if the animal is an endotherm, which must always take in more energy because of its high metabolic rate.
   b. if it is actively foraging for food.
   c. if it is hibernating.
   d. if it is growing and increasing its mass.
   e. never; homeostasis makes these energy and material budgets always balance.

7. **DRAW IT** Draw a model of the control loop(s) required for driving an automobile at a fairly constant speed over a hilly road. Assuming that either the driver or a cruise control device is the control center, indicate each feature that represents a sensor, input, or response.

For Self-Quiz answers, see Appendix A.

MEDIA Visit the Study Area at **www.masteringbio.com** for a Practice Test.

EVOLUTION CONNECTION

8. The biologist C. Bergmann noted that mammals and birds living at higher latitudes are on average larger and bulkier than related species found at lower latitudes. Suggest an evolutionary hypothesis for this observation.

SCIENTIFIC INQUIRY

9. Eastern tent caterpillars (*Malacosoma americanum*) live in large groups in silk nests, or tents, which they build in trees. They are among the first insects to be active in early spring, when daily temperature fluctuates from freezing to very hot. Over the course of a day, they display striking differences in behavior: Early in the morning, they rest in a tightly packed group on the tent's east-facing surface. In midafternoon, they are on its undersurface, each caterpillar hanging by a few of its legs. Propose a hypothesis to explain this behavior. How could you test it?

SCIENCE, TECHNOLOGY, AND SOCIETY

10. Medical researchers are investigating artificial substitutes for various human tissues. Why might artificial blood or skin be useful? What characteristics would these substitutes need in order to function well in the body? Why do real tissues work better? Why not use the real tissues if they work better? What other artificial tissues might be useful? What problems do you anticipate in developing and applying them?

41 Animal Nutrition

▲ **Figure 41.1 How does a lean fish help a bear make fat?**

KEY CONCEPTS

41.1 An animal's diet must supply chemical energy, organic molecules, and essential nutrients

41.2 The main stages of food processing are ingestion, digestion, absorption, and elimination

41.3 Organs specialized for sequential stages of food processing form the mammalian digestive system

41.4 Evolutionary adaptations of vertebrate digestive systems correlate with diet

41.5 Homeostatic mechanisms contribute to an animal's energy balance

OVERVIEW

The Need to Feed

Dinnertime has arrived for the Kodiak bear in **Figure 41.1** (and for the salmon, though in quite a different sense). The skin, muscles, and other parts of the fish will be chewed into pieces, broken down by acid and enzymes in the bear's digestive system, and finally absorbed as small molecules into the body of the bear. Such a process is what is meant by animal **nutrition**: food being taken in, taken apart, and taken up.

Although a diet of fish plucked from a waterfall is not common, all animals eat other organisms—dead or alive, piecemeal or whole. Unlike plants, animals rely on their food for both the energy and the organic molecules used to assemble new molecules, cells, and tissues. Despite this shared need, animals have diverse diets. **Herbivores**, such as cattle, parrotfish, and termites, dine mainly on plants or algae. **Carnivores**, such as sharks, hawks, and spiders, mostly eat other animals. Bears and other **omnivores** (from the Latin *omni*, all) don't in fact eat everything, but they do regularly consume animals as well as plants or algae. We humans are typically omnivores, as are cockroaches and crows.

The terms *herbivore*, *carnivore*, and *omnivore* represent the kinds of food an animal usually eats. Keep in mind, however, that most animals are opportunistic feeders, eating foods outside their standard diet when their usual foods aren't available. For example, deer are herbivores, but in addition to feeding on grass and other plants, they occasionally eat insects, worms, or bird eggs. Note as well that microorganisms are an unavoidable "supplement" in every animal's diet.

Animals must eat. But to survive and reproduce, they must also balance their consumption, storage, and use of food. Bats, for example, store energy, largely in the form of body fat, for periods of hibernation. Eating too little food, too much food, or the wrong mixture of foods can endanger an animal's health. In this chapter, we will survey the nutritional requirements of animals, explore some of the diverse evolutionary adaptations for obtaining and processing food, and investigate the regulation of energy intake and expenditure.

CONCEPT 41.1

An animal's diet must supply chemical energy, organic molecules, and essential nutrients

The activities of cells, tissues, organs, and whole animals depend on sources of chemical energy in the diet. This energy, after being converted to ATP, powers processes ranging from DNA replication and cell division to vision and flight. To meet the continuous requirement for ATP, animals ingest and digest nutrients, such as carbohydrates, proteins, and lipids, for use in cellular respiration and energy storage.

In addition to providing fuel for ATP production, an animal's diet must supply the raw materials needed for

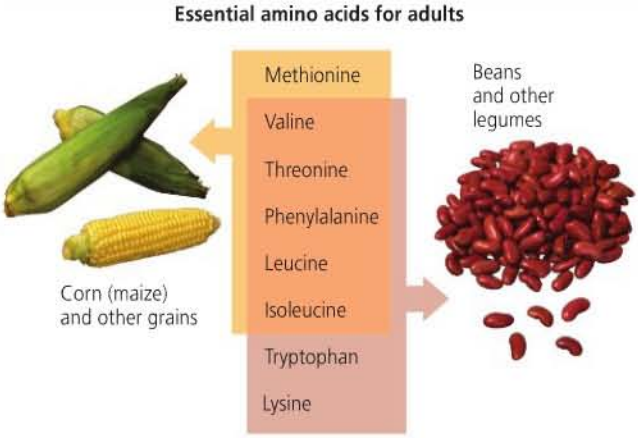
biosynthesis. To build the complex molecules it needs to grow, maintain itself, and reproduce, an animal must obtain two types of organic precursors from its food. Animals need a source of organic carbon (such as sugar) and a source of organic nitrogen (usually amino acids from the digestion of protein). Starting with these materials, animals can construct a great variety of organic molecules.

The materials that an animal's cells require but cannot synthesize are called **essential nutrients**. Obtained from dietary sources, these nutrients include both minerals and preassembled organic molecules. Some nutrients are essential for all animals, whereas others are needed only by certain species. For instance, ascorbic acid (vitamin C) is an essential nutrient for humans and other primates, guinea pigs, and some birds and snakes, but not for most other animals.

Overall, an adequate diet thus satisfies three nutritional needs: chemical energy for cellular processes, organic building blocks for carbohydrates and other macromolecules, and essential nutrients.

Essential Nutrients

There are four classes of essential nutrients: essential amino acids, essential fatty acids, vitamins, and minerals.



Essential Amino Acids

Animals require 20 amino acids to make proteins. The majority of animal species can synthesize about half of these amino acids, as long as their diet includes organic nitrogen. The remaining amino acids must be obtained from food in prefabricated form and are therefore called **essential amino acids**. Most animals, including adult humans, require eight amino acids in their diet (infants also need a ninth, histidine).

A diet that provides insufficient amounts of one or more essential amino acids causes protein deficiency, the most common type of malnutrition among humans. The victims are usually children, who, if they survive infancy, often have impaired physical and sometimes mental development.

The proteins in animal products such as meat, eggs, and cheese are "complete," which means that they provide all the essential amino acids in their proper proportions. In contrast, most plant proteins are "incomplete," being deficient in one or more essential amino acids. Corn (maize), for example, is deficient in tryptophan and lysine, whereas beans are lacking in methionine. To prevent protein deficiency, vegetarian diets must therefore include combinations of plant products that together provide all of the essential amino acids **(Figure 41.2)**.

Some animals have adaptations that help them through periods when their bodies demand extraordinary amounts of protein. In penguins, for example, muscle protein provides a source of amino acids for making new proteins when feathers are replaced after molting **(Figure 41.3)**.

▲ **Figure 41.2 Essential amino acids from a vegetarian diet.** In combination, corn and beans provide an adult human with all essential amino acids.

▲ **Figure 41.3 Storing protein for growth.** Penguins, such as this Adélie from Antarctica, must make an abundance of new protein when they molt (grow new feathers). Because of the temporary loss of their insulating coat of feathers, penguins cannot swim—or feed—when molting. What is the source of amino acids for production of feather protein? Before molting, a penguin greatly increases its muscle mass. The penguin then breaks down the extra muscle protein, which supplies the amino acids for growing new feathers.

Essential Fatty Acids

Animals can synthesize most, but not all, of the fatty acids they need. The **essential fatty acids**, the ones they cannot make, are certain fatty acids that are unsaturated (containing one or more double bonds; see Figure 5.12). For example, humans require linoleic acid to make some membrane phospholipids. Because seeds, grains, and vegetables in the diets of humans and other animals generally furnish ample quantities of essential fatty acids, deficiencies in this class of nutrients are rare.

Vitamins

Vitamins are organic molecules with diverse functions that are required in the diet in very small amounts. Vitamin B_2, for example, is converted in the body to FAD, a coenzyme used in many metabolic processes, including cellular respiration (see Figure 9.12). For humans, 13 essential vitamins have been identified. Depending on the vitamin, the required amount ranges from about 0.01 to 100 mg per day.

Vitamins are classified as water-soluble or fat-soluble **(Table 41.1)**. The water-soluble vitamins include the B complex, which are compounds that generally function as coenzymes, and vitamin C, which is required to produce connective tissue. Among the fat-soluble vitamins are vitamin A, which is incorporated into visual pigments of the eye, and vitamin K, which functions in blood clotting. Another is vitamin D, which aids in calcium absorption and bone formation. Our dietary requirement for vitamin D is variable because we synthesize this vitamin from other molecules when the skin is exposed to sunlight.

For people with poorly balanced diets, taking vitamin supplements that provide recommended daily levels is certainly reasonable. It is much less clear whether massive doses of vitamins confer any health benefits or are, in fact, safe. Moderate overdoses of water-soluble vitamins are probably harmless because excesses of these vitamins are excreted in urine. However, excesses of

Table 41.1 Vitamin Requirements of Humans

Vitamin	Major Dietary Sources	Major Functions in the Body	Symptoms of Deficiency or Extreme Excess
Water-Soluble Vitamins			
Vitamin B_1 (thiamine)	Pork, legumes, peanuts, whole grains	Coenzyme used in removing CO_2 from organic compounds	Beriberi (nerve disorders, emaciation, anemia)
Vitamin B_2 (riboflavin)	Dairy products, meats, enriched grains, vegetables	Component of coenzymes FAD and FMN	Skin lesions such as cracks at corners of mouth
Niacin (B_3)	Nuts, meats, grains	Component of coenzymes NAD^+ and $NADP^+$	Skin and gastrointestinal lesions, nervous disorders **Liver damage**
Vitamin B_6 (pyridoxine)	Meats, vegetables, whole grains	Coenzyme used in amino acid metabolism	Irritability, convulsions, muscular twitching, anemia **Unstable gait, numb feet, poor coordination**
Pantothenic acid (B_5)	Most foods: meats, dairy products, whole grains, etc.	Component of coenzyme A	Fatigue, numbness, tingling of hands and feet
Folic acid (folacin) (B_9)	Green vegetables, oranges, nuts, legumes, whole grains	Coenzyme in nucleic acid and amino acid metabolism	Anemia, birth defects **May mask deficiency of vitamin B_{12}**
Vitamin B_{12}	Meats, eggs, dairy products	Coenzyme in nucleic acid metabolism; maturation of red blood cells	Anemia, nervous system disorders
Biotin	Legumes, other vegetables, meats	Coenzyme in synthesis of fat, glycogen, and amino acids	Scaly skin inflammation, neuromuscular disorders
Vitamin C (ascorbic acid)	Fruits and vegetables, especially citrus fruits, broccoli, cabbage, tomatoes, green peppers	Used in collagen synthesis (such as for bone, cartilage, gums); antioxidant; aids in detoxification; improves iron absorption	Scurvy (degeneration of skin, teeth, blood vessels), weakness, delayed wound healing, impaired immunity **Gastrointestinal upset**
Fat-Soluble Vitamins			
Vitamin A (retinol)	Provitamin A (beta-carotene) in deep green and orange vegetables and fruits; retinal in dairy products	Component of visual pigments; maintenance of epithelial tissues; antioxidant; helps prevent damage to cell membranes	Blindness and increased death rate **Headache, irritability, vomiting, hair loss, blurred vision, liver and bone damage**
Vitamin D	Dairy products, egg yolk; also made in human skin in presence of sunlight	Aids in absorption and use of calcium and phosphorus; promotes bone growth	Rickets (bone deformities) in children, bone softening in adults **Brain, cardiovascular, and kidney damage**
Vitamin E (tocopherol)	Vegetable oils, nuts, seeds	Antioxidant; helps prevent damage to cell membranes	Degeneration of the nervous system
Vitamin K (phylloquinone)	Green vegetables, tea; also made by colon bacteria	Important in blood clotting	Defective blood clotting **Liver damage and anemia**

fat-soluble vitamins are deposited in body fat, so overconsumption may result in accumulating toxic levels of these compounds.

Minerals

Dietary **minerals** are inorganic nutrients, such as zinc and potassium, that are usually required in small amounts—from less than 1 mg to about 2,500 mg per day **(Table 41.2)**. Mineral requirements vary among animal species. For example, humans and other vertebrates require relatively large quantities of calcium and phosphorus for building and maintaining bone. In addition, calcium is necessary for the functioning of nerves and muscles, and phosphorus is an ingredient of ATP and nucleic acids. Iron is a component of the cytochromes that function in cellular respiration (see Figure 9.13) and of hemoglobin, the oxygen-binding protein of red blood cells. Many minerals are cofactors built into the structure of enzymes; magnesium, for example, is present in enzymes that split ATP. Vertebrates need iodine to make thyroid hormones, which regulate metabolic rate. Sodium, potassium, and chloride ions are important in the functioning of nerves and in maintaining osmotic balance between cells and the surrounding body fluid.

Table 41.2 Mineral Requirements of Humans

	Mineral	Major Dietary Sources	Major Functions in the Body	Symptoms of Deficiency*
Greater than 200 mg per day required	Calcium (Ca)	Dairy products, dark green vegetables, legumes	Bone and tooth formation, blood clotting, nerve and muscle function	Retarded growth, possibly loss of bone mass
	Phosphorus (P)	Dairy products, meats, grains	Bone and tooth formation, acid-base balance, nucleotide synthesis	Weakness, loss of minerals from bone, calcium loss
	Sulfur (S)	Proteins from many sources	Component of certain amino acids	Symptoms of protein deficiency
	Potassium (K)	Meats, dairy products, many fruits and vegetables, grains	Acid-base balance, water balance, nerve function	Muscular weakness, paralysis, nausea, heart failure
	Chlorine (Cl)	Table salt	Acid-base balance, formation of gastric juice, nerve function, osmotic balance	Muscle cramps, reduced appetite
	Sodium (Na)	Table salt	Acid-base balance, water balance, nerve function	Muscle cramps, reduced appetite
	Magnesium (Mg)	Whole grains, green leafy vegetables	Cofactor; ATP bioenergetics	Nervous system disturbances
	Iron (Fe)	Meats, eggs, legumes, whole grains, green leafy vegetables	Component of hemoglobin and of electron carriers in energy metabolism; enzyme cofactor	Iron-deficiency anemia, weakness, impaired immunity
	Fluorine (F)	Drinking water, tea, seafood	Maintenance of tooth (and probably bone) structure	Higher frequency of tooth decay
	Zinc (Zn)	Meats, seafood, grains	Component of certain digestive enzymes and other proteins	Growth failure, skin abnormalities, reproductive failure, impaired immunity
	Copper (Cu)	Seafood, nuts, legumes, organ meats	Enzyme cofactor in iron metabolism, melanin synthesis, electron transport	Anemia, cardiovascular abnormalities
	Manganese (Mn)	Nuts, grains, vegetables, fruits, tea	Enzyme cofactor	Abnormal bone and cartilage
	Iodine (I)	Seafood, dairy products, iodized salt	Component of thyroid hormones	Goiter (enlarged thyroid)
	Cobalt (Co)	Meats and dairy products	Component of vitamin B_{12}	None, except as B_{12} deficiency
	Selenium (Se)	Seafood, meats, whole grains	Enzyme cofactor; antioxidant functioning in close association with vitamin E	Muscle pain, possibly heart muscle deterioration
	Chromium (Cr)	Brewer's yeast, liver, seafood, meats, some vegetables	Involved in glucose and energy metabolism	Impaired glucose metabolism
	Molybdenum (Mo)	Legumes, grains, some vegetables	Enzyme cofactor	Disorder in excretion of nitrogen-containing compounds

*All of these minerals are also harmful when consumed in excess.

Ingesting large amounts of some minerals can upset homeostatic balance and cause toxic side effects. For example, liver damage due to iron overload affects as much as 10% of the population in some regions of Africa where the water supply is especially iron-rich. Many individuals in these regions have a genetic alteration in mineral metabolism that increases the toxic effects of iron overload. In a different example, excess salt (sodium chloride) is not toxic but can contribute to high blood pressure. This is a particular problem in the United States, where the typical person consumes enough salt to provide about 20 times the required amount of sodium. Packaged (prepared) foods often contain large amounts of sodium chloride, even if they do not taste very salty.

Dietary Deficiencies

Diets that fail to meet basic needs can lead to either undernourishment or malnourishment. **Undernourishment** is the result of a diet that consistently supplies less chemical energy than the body requires. In contrast, **malnourishment** is the long-term absence from the diet of one or more essential nutrients. Both have negative impacts on health and survival.

Undernourishment

When an animal is undernourished, a series of events unfold: The body uses up stored fat and carbohydrates; the body begins breaking down its own proteins for fuel; muscles begin to decrease in size; and the brain may become protein-deficient. If energy intake remains less than energy expenditures, the animal will eventually die. Even if a seriously undernourished animal survives, some of the damage may be irreversible.

Because adequate amounts of just a single staple such as rice or corn can provide sufficient calories, human undernourishment is most common when drought, war, or another crisis severely disrupts the food supply. In sub-Saharan Africa, where the AIDS epidemic has crippled both rural and urban communities, approximately 200 million children and adults cannot obtain enough food.

Sometimes undernourishment occurs within well-fed populations as a result of eating disorders. For example, anorexia nervosa leads individuals, usually female, to starve themselves compulsively.

Malnourishment

The potential effects of malnourishment include deformities, disease, and even death. For example, cattle, deer, and other herbivores may develop fragile bones if they graze on plants growing in soil that lacks phosphorus. Some grazing animals obtain the missing nutrients by consuming concentrated sources of salt or other minerals **(Figure 41.4)**. Among carnivores, recent experiments reveal that spiders can adjust for dietary deficiencies by switching to prey that restores nutritional balance.

▲ **Figure 41.4 Obtaining essential nutrients by eating antlers.** A caribou, an arctic herbivore, chews on discarded antlers from another animal. Because antlers contain calcium phosphate, this behavior is common among herbivores living where soils and plants are deficient in phosphorus. Animals require phosphorus to make ATP, nucleic acids, phospholipids, and components of bones.

Like other animals, humans sometimes suffer from malnourishment. Among populations subsisting on simple rice diets, individuals are often afflicted with vitamin A deficiency, which can cause blindness or death. To overcome this problem, scientists have engineered a strain of rice to synthesize beta-carotene, the orange-colored source of vitamin A that is abundant in carrots. The potential benefit of this "Golden Rice" is enormous because, at present, 1 to 2 million young children worldwide die every year from vitamin A deficiency.

Assessing Nutritional Needs

Determining the ideal diet for the human population is an important but difficult problem for scientists. As objects of study, people present many challenges. Unlike laboratory animals, humans are genetically diverse. They also live in settings far more varied than the stable and uniform environment that scientists use to facilitate comparisons in laboratory experiments. Ethical concerns present an additional barrier. For example, it is not acceptable to investigate the nutritional needs of children in a way that might harm a child's growth or development.

The methods used to study human nutrition have changed dramatically over time. To avoid harming others, several of the researchers who discovered vitamins a century ago used themselves as subject animals. Today, an important approach is the study of genetic defects that disrupt food uptake, storage, or use. For example, a genetic disorder called hemochromatosis causes iron buildup in the absence of any abnormal iron consumption or exposure. Fortunately, this common disorder is remarkably easy to treat: Drawing blood regularly removes enough iron from the body to restore homeostasis. By studying the defective genes that can cause the disease, scientists have learned a great deal about the regulation of iron absorption.

Many insights into human nutrition have come from *epidemiology*, the study of human health and disease at the population level. By tracking the causes and distribution of a disease among many individuals, epidemiologists can identify potential nutritional strategies for preventing and controlling diseases and disorders. For example, researchers discovered that dietary intake of the vitamin folic acid substantially reduces the frequency of neural tube defects, which are a serious and sometimes fatal type of birth defect.

Neural tube defects occur when tissue fails to enclose the developing brain and spinal cord. In the 1970s, studies revealed that these defects were more frequent in children born to women of low socioeconomic status. Richard Smithells, of the University of Leeds, thought that malnutrition among these women might be responsible. As described in **Figure 41.5**, he found that vitamin supplementation greatly reduced the risk of neural tube defects. In other studies, he obtained evidence that folic acid (B_9) was the specific vitamin responsible, a finding confirmed by other researchers. Based on this evidence, the FDA in 1998 began to require that folic acid be added to enriched grain products used to make bread, cereals, and other foods. Follow-up studies have documented the effectiveness of this program in reducing the frequency of neural tube defects. Thus, at a time when microsurgery and sophisticated diagnostic imaging dominate the headlines, simple dietary changes such as folic acid supplements or consumption of Golden Rice may be among the greatest contributors to human health.

▼ Figure 41.5 Inquiry

Can diet influence the frequency of birth defects?

EXPERIMENT Richard Smithells, of the University of Leeds, examined the effect of vitamin supplementation on the risk of neural tube defects. Women who had had one or more babies with such a defect were put into two study groups. The experimental group consisted of those who were planning a pregnancy and began taking a multivitamin at least four weeks before attempting conception. The control group, who were not given vitamins, included women who declined them and women who were already pregnant. The numbers of neural tube defects resulting from the pregnancies were recorded for each group.

RESULTS

Group	Number of infants/fetuses studied	Infants/fetuses with a neural tube defect
Vitamin supplements (experimental group)	141	1 (0.7%)
No vitamin supplements (control group)	204	12 (5.9%)

CONCLUSION This study provided evidence that vitamin supplementation protects against neural tube defects, at least in pregnancies after the first. Follow-up trials demonstrated that folic acid alone provided an equivalent protective effect.

Inquiry in Action Read and analyze the original paper in *Inquiry in Action: Interpreting Scientific Papers.*

WHAT IF? Subsequent studies were designed to learn if folic acid supplements prevent neural tube defects during first-time pregnancies. To determine the required number of subjects, what additional information did the researchers need?

CONCEPT CHECK 41.1

1. All 20 amino acids are needed to make animal proteins. Why aren't they all essential to animal diets?
2. Explain why vitamins are required in much smaller amounts than carbohydrates.
3. **WHAT IF?** If a zoo animal shows signs of malnutrition, how might a researcher determine which nutrient is lacking?

For suggested answers, see Appendix A.

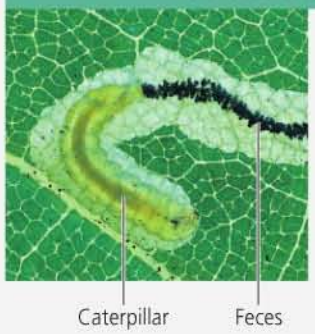
CONCEPT 41.2

The main stages of food processing are ingestion, digestion, absorption, and elimination

In this section, we turn from nutritional requirements to the mechanisms by which animals process food. Food processing can be divided into four distinct stages: ingestion, digestion, absorption, and elimination. The first stage, **ingestion**, is the act of eating. Food can be ingested in many liquid and solid forms. **Figure 41.6** surveys and classifies the principal feeding mechanisms that have evolved among animals. Given the variation in food sources, it is not surprising that strategies for extracting resources from food also differ widely among animal species. We will focus, however, on the shared processes, pausing periodically to consider some adaptations to particular diets or environments.

In **digestion**, the second stage of food processing, food is broken down into molecules small enough for the body to absorb. This stage is necessary because animals cannot directly use the proteins, carbohydrates, nucleic acids, fats, and phospholipids in food. One problem is that these molecules are too large to pass through membranes and enter the cells of the animal. In addition, the large molecules in food are not all identical to those the animal needs for its particular tissues and functions. When large molecules in food are broken down into their components, however, the animal can use these smaller mol-

▼ Figure 41.6



Exploring Four Main Feeding Mechanisms of Animals

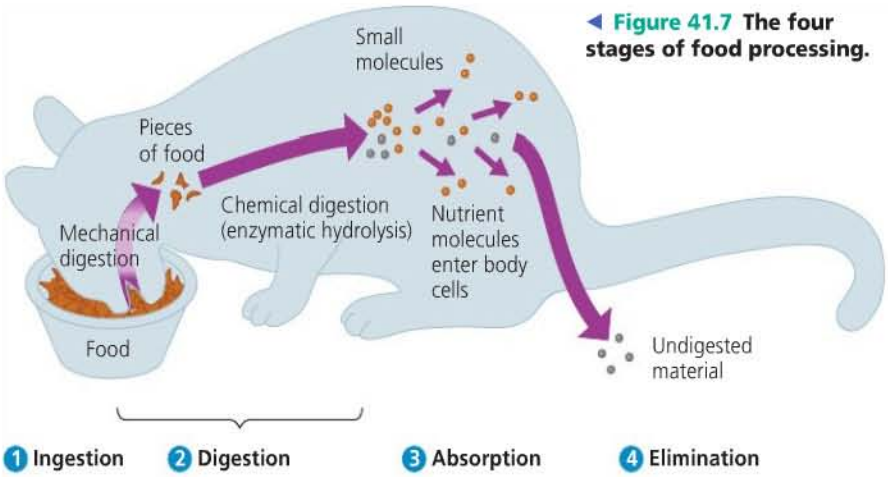
Suspension Feeders

Many aquatic animals are **suspension feeders**, which sift small food particles from the water. For example, attached to the upper jaw of this humpback whale are comb-like plates called baleen, which strain small invertebrates and fish from enormous volumes of water. Clams and oysters are also suspension feeders. They use their gills to trap tiny morsels; cilia then sweep the food particles to the mouth in a film of mucus.

Substrate Feeders

Substrate feeders are animals that live in or on their food source. This leaf miner caterpillar, the larva of a moth, is eating through the soft tissue of an oak leaf, leaving a dark trail of feces in its wake. Some other substrate feeders include maggots (fly larvae), which burrow into animal carcasses.

Fluid Feeders



Fluid feeders suck nutrient-rich fluid from a living host. This mosquito has pierced the skin of its human host with hollow, needle-like mouthparts and is consuming a blood meal (colorized SEM). Similarly, aphids are fluid feeders that tap the phloem sap of plants. In contrast to such parasites, some fluid feeders actually benefit their hosts. For example, hummingbirds and bees move pollen between flowers as they fluid-feed on nectar.

Bulk Feeders

Most animals, including humans, are **bulk feeders**, which eat relatively large pieces of food. Their adaptations include tentacles, pincers, claws, poisonous fangs, jaws, and teeth that kill their prey or tear off pieces of meat or vegetation. In this amazing scene, a rock python is beginning to ingest a gazelle it has captured and killed. Snakes cannot chew their food into pieces and must swallow it whole—even if the prey is much bigger than the diameter of the snake. They can do so because the lower jaw is loosely hinged to the skull by an elastic ligament that permits the mouth and throat to open very wide. After swallowing its prey, which may take more than an hour, the python will spend two weeks or more digesting its meal.

◀ **Figure 41.7 The four stages of food processing.**

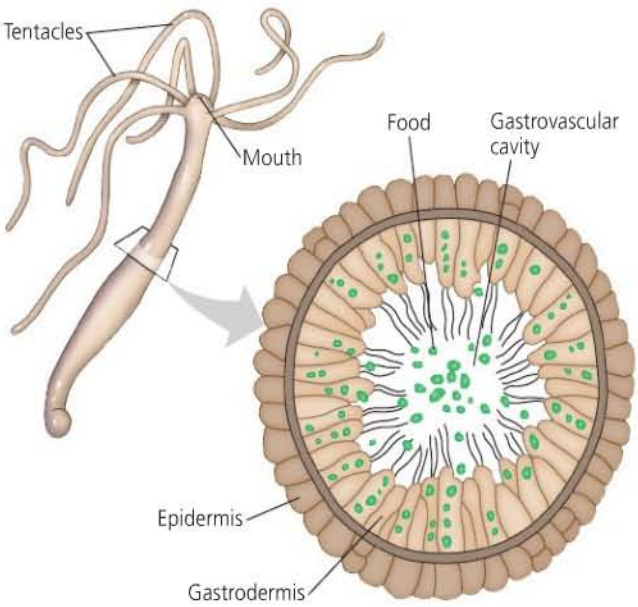
ecules to assemble the large molecules it needs. For example, although fruit flies and humans have very different diets, both convert proteins in their food to the same 20 amino acids from which they assemble all of the proteins specific for their species.

Recall from Chapter 5 that a cell makes a macromolecule or fat by linking together smaller components; it does so by removing a molecule of water for each new covalent bond formed. Chemical digestion by enzymes reverses this process by breaking bonds with the addition of water (see Figure 5.2). This splitting process is called **enzymatic hydrolysis**. A variety of enzymes catalyze the digestion of large molecules in food. Polysaccharides and disaccharides are split into simple sugars; proteins are broken down into amino acids; and nucleic acids are cleaved into nucleotides. Enzymatic hydrolysis also releases fatty acids and other components from fats and phospholipids. Such chemical digestion is typically preceded by mechanical digestion—by chewing, for instance. Mechanical digestion breaks food into smaller pieces, increasing the surface area available for chemical processes.

The last two stages of food processing occur after the food is digested. In the third stage, **absorption**, the animal's cells take up (absorb) small molecules such as amino acids and simple sugars. **Elimination** completes the process as undigested material passes out of the digestive system. **Figure 41.7** reviews the four stages of food processing.

Digestive Compartments

In our overview of food processing, we have seen that digestive enzymes hydrolyze the same biological materials (such as proteins, fats, and carbohydrates) that make up the bodies of the animals themselves. How, then, are animals able to digest food without digesting their own cells and tissues? The evolutionary adaptation found across a wide range of animal species is the processing of food within specialized compartments. Such compartments can be intracellular, in the form of food vacuoles, or extracellular, as in digestive organs and systems.



Intracellular Digestion

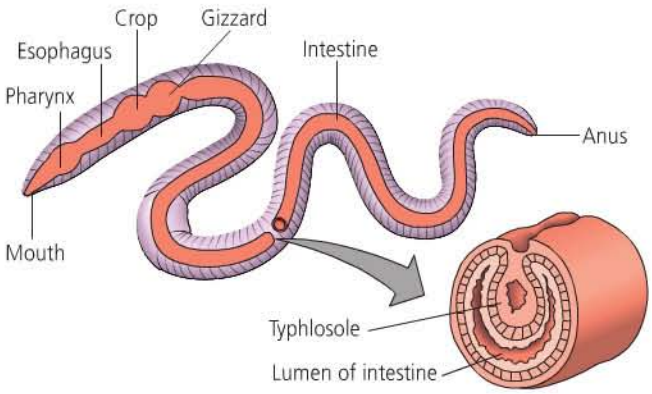
Food vacuoles—cellular organelles in which hydrolytic enzymes break down food—are the simplest digestive compartments. The hydrolysis of food inside vacuoles, called **intracellular digestion**, begins after a cell engulfs solid food by phagocytosis or liquid food by pinocytosis (see Figure 7.20). Newly formed food vacuoles fuse with lysosomes, organelles containing hydrolytic enzymes. This fusion of organelles brings food together with the enzymes, allowing digestion to occur safely within a compartment enclosed by a protective membrane. A few animals, such as sponges, digest their food entirely by this intracellular mechanism (see Figure 33.4).

Extracellular Digestion

In most animals, at least some hydrolysis occurs by **extracellular digestion**, the breakdown of food in compartments that are continuous with the outside of the animal's body. Having one or more extracellular compartments for digestion enables an animal to devour much larger sources of food than can be ingested by phagocytosis.

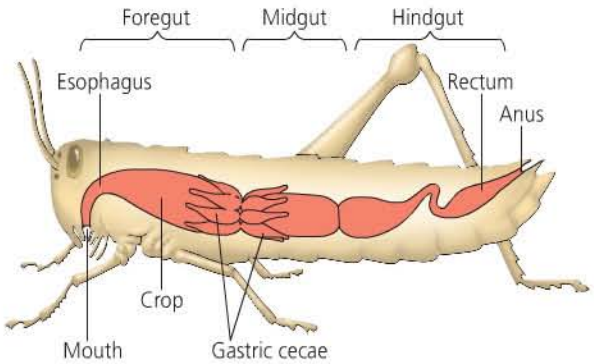
Many animals with relatively simple body plans have a digestive compartment with a single opening **(Figure 41.8)**. This pouch, called a **gastrovascular cavity**, functions in digestion as well as in the distribution of nutrients throughout the body (hence the *vascular* part of the term). The carnivorous

▲ **Figure 41.8 Digestion in a hydra.** Digestion begins in the gastrovascular cavity and is completed intracellularly after small food particles are engulfed by specialized cells of the gastrodermis.



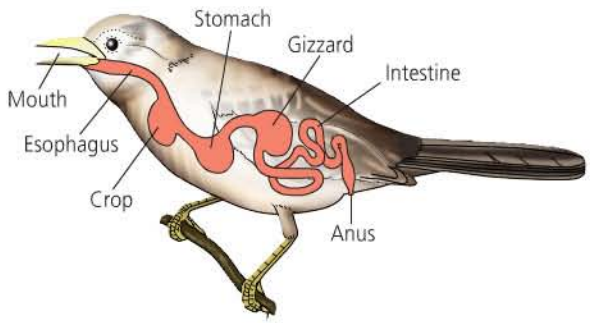
cnidarians called hydras provide a good example of how a gastrovascular cavity works. A hydra uses its tentacles to stuff captured prey through its mouth into its gastrovascular cavity. Specialized gland cells of the hydra's gastrodermis, the tissue layer that lines the cavity, then secrete digestive enzymes that break the soft tissues of the prey into tiny pieces. Other cells of the gastrodermis engulf these food particles, and most of the actual hydrolysis of macromolecules occurs intracellularly, as in sponges. After a hydra has digested its meal, undigested materials that remain in the gastrovascular cavity, such as exoskeletons of small crustaceans, are eliminated through the same opening by which food entered. Many flatworms also have a gastrovascular cavity with a single opening (see Figure 33.10).

In contrast with cnidarians and flatworms, most animals have a digestive tube extending between two openings, a mouth and an anus. Such a tube is called a **complete digestive tract** or, more commonly, an **alimentary canal**. Because food moves along the alimentary canal in a single direction, the tube can be organized into specialized compartments that carry out digestion and nutrient absorption in a stepwise fashion **(Figure 41.9)**. An animal with an alimentary canal can ingest food while earlier meals are still being digested, a feat that is likely to be difficult or inefficient for animals with gastrovascular cavities. In the next section, we'll explore the spatial and functional organization of an alimentary canal.



CONCEPT CHECK 41.2

1. Distinguish the overall structure of a gastrovascular cavity from that of an alimentary canal.
2. In what sense are nutrients from a recently ingested meal not really "inside" your body prior to the absorption stage of food processing?
3. **WHAT IF?** Thinking in broad terms, what similarities can you identify between digestion in an animal body and the breakdown of gasoline in an automobile? (You don't have to know about auto mechanics.)



For suggested answers, see Appendix A.

(a) Earthworm. The alimentary canal of an earthworm includes a muscular pharynx that sucks food in through the mouth. Food passes through the esophagus and is stored and moistened in the crop. Mechanical digestion occurs in the muscular gizzard, which pulverizes food with the aid of small bits of sand and gravel. Further digestion and absorption occur in the intestine, which has a dorsal fold, the typhlosole, that increases the surface area for nutrient absorption.

(b) Grasshopper. A grasshopper has several digestive chambers grouped into three main regions: a foregut, with an esophagus and crop; a midgut; and a hindgut. Food is moistened and stored in the crop, but most digestion occurs in the midgut. Gastric cecae, (singular, ceca), pouches extending from the beginning of the midgut, function in digestion and absorption.

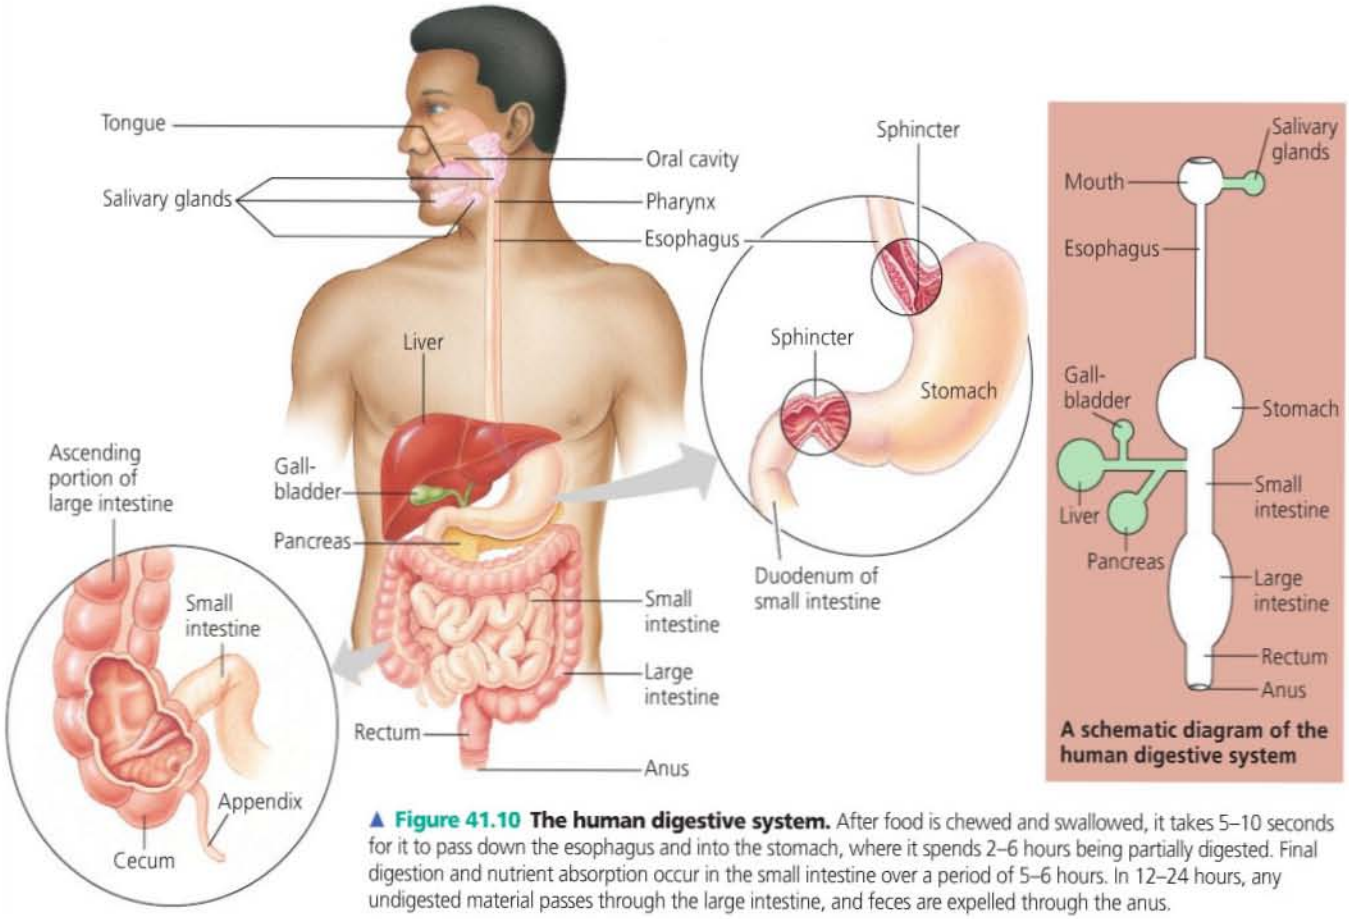
(c) Bird. Many birds have three separate chambers—the crop, stomach, and gizzard—where food is pulverized and churned before passing into the intestine. A bird's crop and gizzard function very much like those of an earthworm. In most birds, chemical digestion and absorption of nutrients occur in the intestine.

▲ **Figure 41.9 Variation in alimentary canals.**

CONCEPT **41.3**

Organs specialized for sequential stages of food processing form the mammalian digestive system

Because most animals, including mammals, have an alimentary canal, we can use the mammalian digestive system as a representative example of the general principles of food processing. In mammals, the digestive system consists of the alimentary canal and various accessory glands that secrete digestive juices through ducts into the canal (**Figure 41.10**). The accessory glands of the mammalian digestive system are three pairs of salivary glands, the pancreas, the liver, and the gallbladder.



Food is pushed along the alimentary canal by **peristalsis**, alternating waves of contraction and relaxation in the smooth muscles lining the canal. It is peristalsis that enables us to process and digest food even while lying down. At some of the junctions between specialized compartments, the muscular layer forms ringlike valves called **sphincters**. Acting like drawstrings to close off the alimentary canal, sphincters regulate the passage of material between compartments.

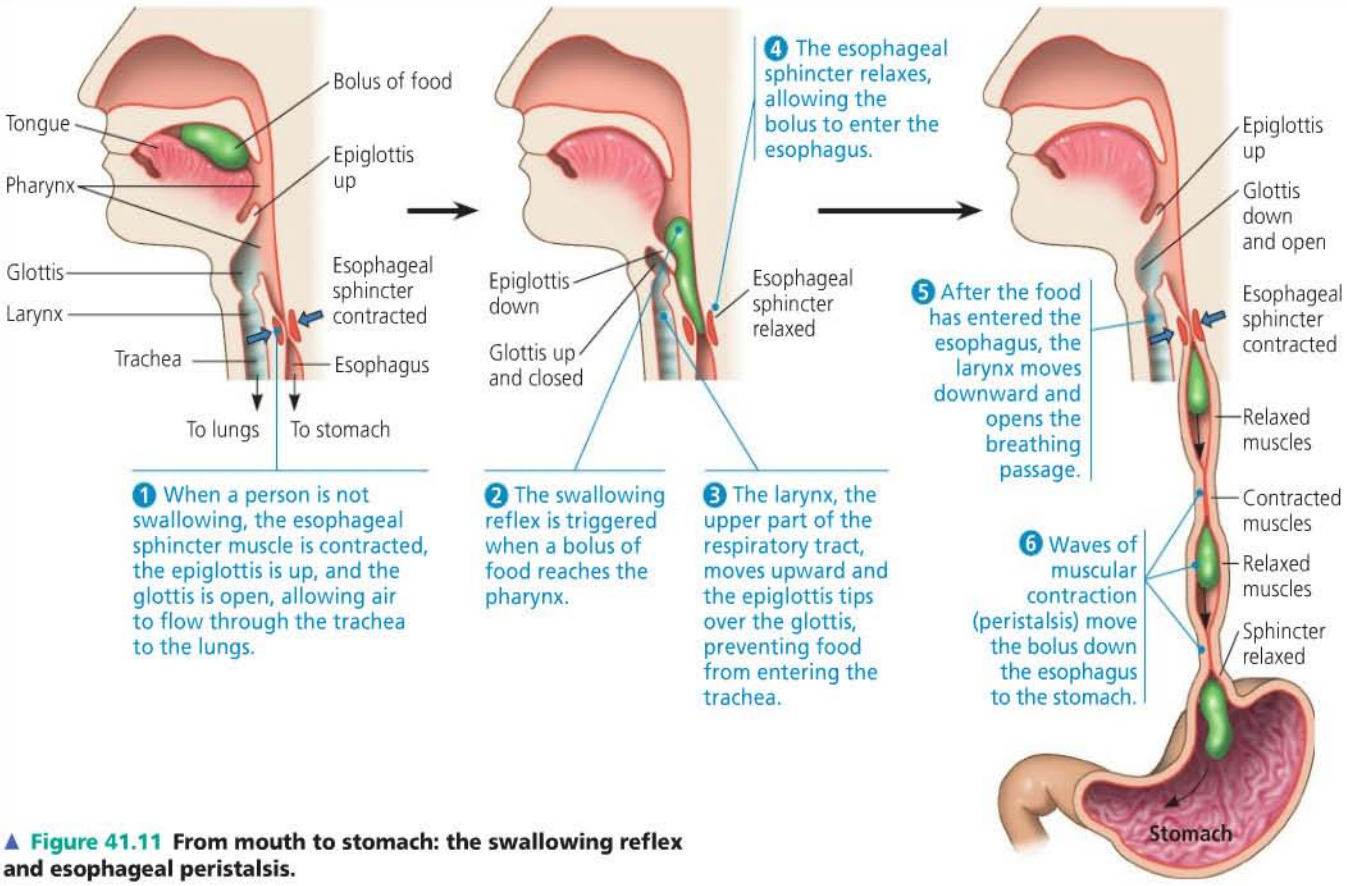
Using the human digestive system as a model, let's now follow a meal through the alimentary canal. As we do so, we'll examine in more detail what happens to the food in each digestive compartment along the way.

The Oral Cavity, Pharynx, and Esophagus

Ingestion and the initial steps of digestion occur in the mouth, or **oral cavity**. Mechanical digestion begins as teeth of various shapes cut, smash, and grind food, making the food easier to swallow and increasing its surface area. Meanwhile, the presence of food stimulates a nervous reflex that causes the **salivary glands** to deliver saliva through ducts to the oral cavity. Saliva may also be released before food enters the mouth, triggered by a learned association between eating and the time of day, a cooking odor, or another stimulus.

Saliva initiates chemical digestion while also protecting the oral cavity. **Amylase**, an enzyme in saliva, hydrolyzes starch (a glucose polymer from plants) and glycogen (a glucose polymer from animals) into smaller polysaccharides and the disaccharide maltose. Mucin, a slippery glycoprotein (carbohydrate-protein complex) in saliva, protects the lining of the mouth from abrasion. Mucin also lubricates food for easier swallowing. Additional components of saliva include buffers, which help prevent tooth decay by neutralizing acid, and antibacterial agents (such as lysozyme; see Figure 5.19), which protect against microorganisms that enter the mouth with food.

▲ **Figure 41.10 The human digestive system.** After food is chewed and swallowed, it takes 5–10 seconds for it to pass down the esophagus and into the stomach, where it spends 2–6 hours being partially digested. Final digestion and nutrient absorption occur in the small intestine over a period of 5–6 hours. In 12–24 hours, any undigested material passes through the large intestine, and feces are expelled through the anus.



Much as a doorman screens and assists people entering a building, the tongue aids digestive processes by evaluating ingested material and then enabling its further passage. When food arrives at the oral cavity, the tongue plays a critical role in distinguishing which foods should be processed further (see Chapter 50 for a discussion of the sense of taste). After food is deemed acceptable and chewing commences, tongue movements manipulate the food, helping shape it into a ball called a **bolus**. During swallowing, the tongue provides further help, pushing the bolus to the back of the oral cavity and into the pharynx.

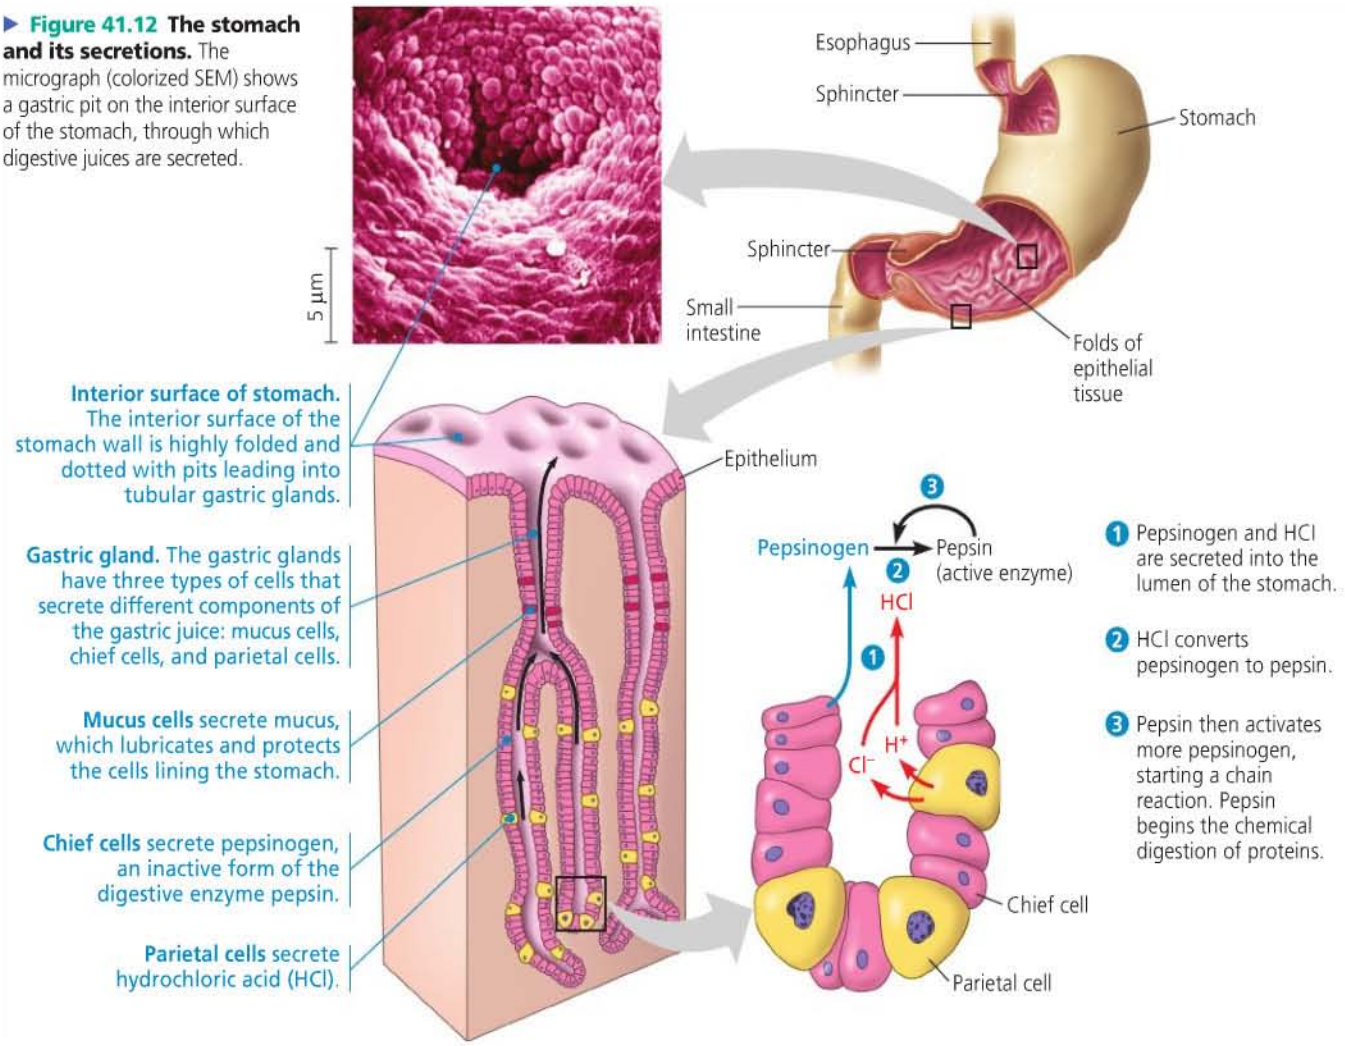
The **pharynx**, or throat region, opens to two passageways: the esophagus and the trachea (windpipe). The **esophagus** connects to the stomach, whereas the trachea leads to the lungs. Swallowing must therefore be carefully choreographed to keep food from entering and blocking the airway. When you swallow, a flap of cartilage called the *epiglottis* prevents food from entering the trachea by covering the *glottis*—the vocal cords and the opening between them. Guided by the movements of the *larynx*, the upper part of the respiratory tract, this swallowing mechanism directs each bolus into the entrance of the esophagus (**Figure 41.11**, steps 1–4). If the swallowing reflex fails, food or liquids can reach the windpipe and cause choking, a blockage of the trachea. The resulting lack of airflow into the lungs can be fatal if the material is not dislodged by vigorous coughing or a forced upward thrust of the diaphragm (the Heimlich maneuver).

The esophagus contains both striated and smooth muscle (see Figure 40.5). The striated muscle is situated at the top of the esophagus and is active during swallowing. Throughout the rest of the esophagus, smooth muscle functions in peristalsis. The rhythmic cycles of contraction move each bolus to the stomach (see Figure 41.11, step 6). As with other parts of the digestive system, the form of the esophagus fits its function and varies among species. For example, fishes have no lungs to bypass and therefore have a very short esophagus. And it will come as no surprise that giraffes have a very long esophagus.

Digestion in the Stomach

The **stomach** is located just below the diaphragm in the upper abdominal cavity. A few nutrients are absorbed from the stomach into the bloodstream, but the stomach primarily stores food and continues digestion. With accordion-like folds and a very elastic wall, it can stretch to accommodate about 2 L of food and fluid. The stomach secretes a digestive fluid called **gastric juice** and mixes this secretion with the food through a churning action. This mixture of ingested food and digestive juice is called **chyme**.

▲ **Figure 41.11 From mouth to stomach: the swallowing reflex and esophageal peristalsis.**



Chemical Digestion in the Stomach

Two components of gastric juice carry out chemical digestion. One is hydrochloric acid (HCl), which disrupts the extracellular matrix that binds cells together in meat and plant material. The concentration of HCl is so high that the pH of gastric juice is about 2, acidic enough to dissolve iron nails. This low pH not only kills most bacteria but also denatures (unfolds) proteins in food, increasing exposure of their peptide bonds. The exposed bonds are attacked by the second component of gastric juice—a **protease**, or protein-digesting enzyme, called **pepsin**. Unlike most enzymes, pepsin works best in a strongly acidic environment. By breaking peptide bonds, it cleaves proteins into smaller polypeptides. Further digestion to individual amino acids occurs in the small intestine.

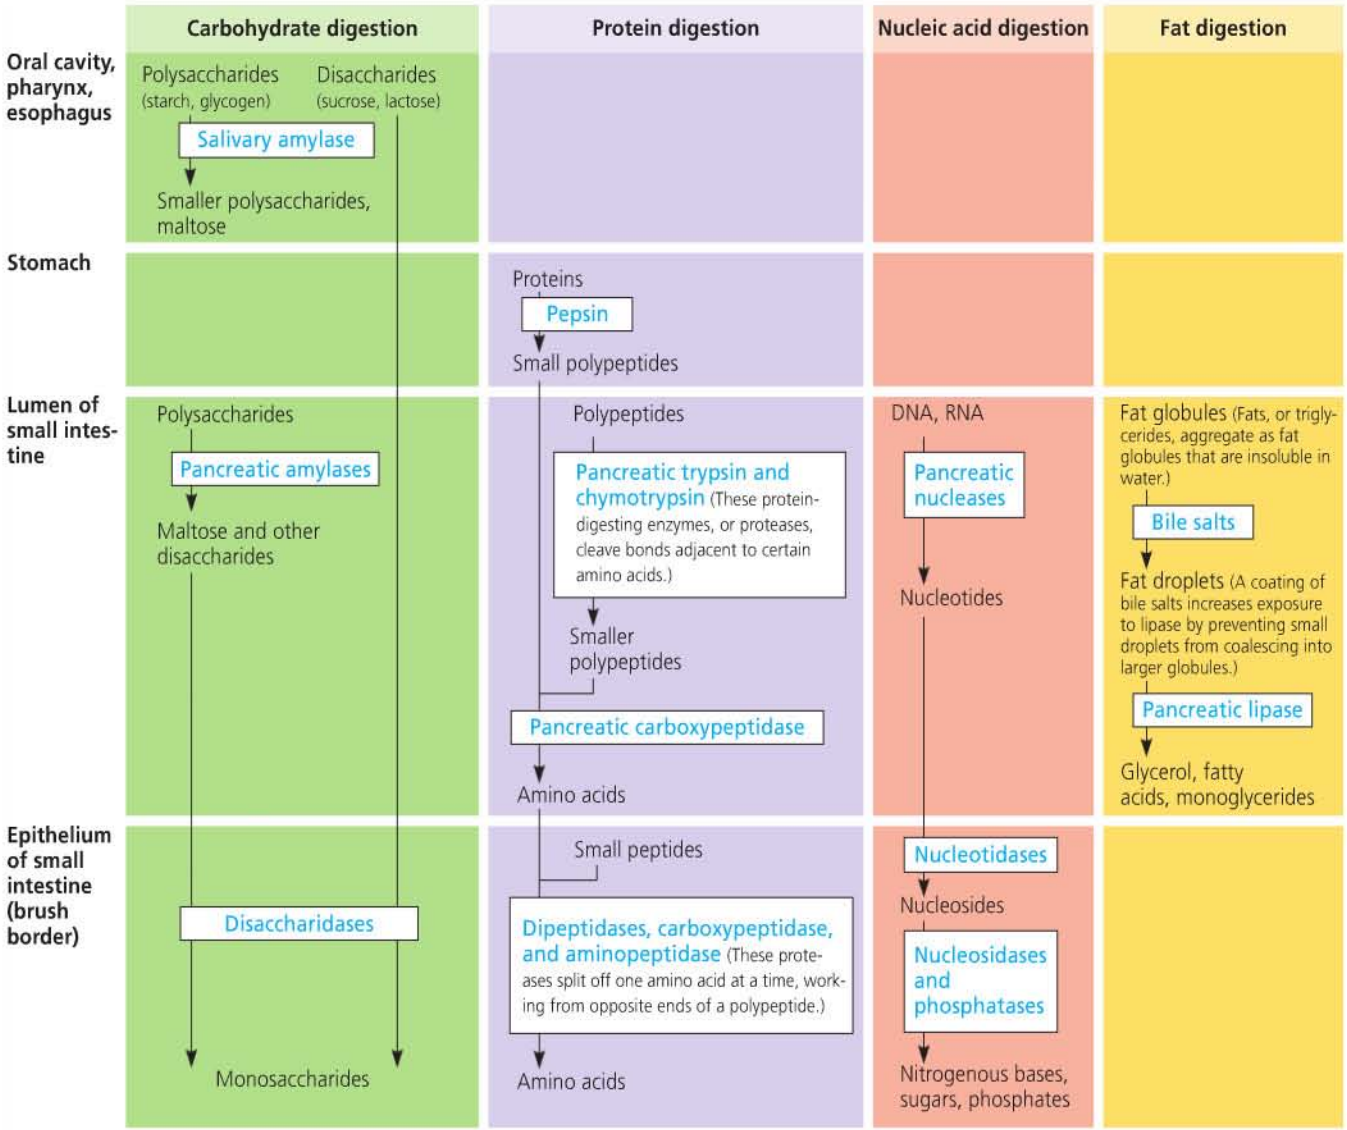
Why doesn't gastric juice destroy the stomach cells that make it? The answer is that the ingredients of gastric juice are kept inactive until they are released into the lumen (cavity) of the stomach. The components of gastric juice are produced by cells in the gastric glands of the stomach **(Figure 41.12)**. *Parietal cells* secrete hydrogen and chloride ions, which form hydrochloric acid (HCl). Using an ATP-driven pump, the parietal cells expel hydrogen ions into the lumen at very high concentration. There the hydrogen ions combine with chloride ions that diffuse into the lumen through specific membrane channels. Meanwhile, *chief cells* release pepsin into the lumen in an inactive form called **pepsinogen**. HCl converts pepsinogen to active pepsin by clipping off a small portion of the molecule and exposing its active site. Through these processes, both HCl and pepsin form in the lumen of the stomach, not within the cells of the gastric glands.

After hydrochloric acid converts a small amount of pepsinogen to pepsin, a second chemical process helps activate the remaining pepsinogen. Pepsin, like HCl, can clip pepsinogen to expose the enzyme's active site. This generates more pepsin, which activates more pepsinogen, forming more active enzyme. This series of events is an example of positive feedback.

When HCl and pepsin form within the stomach lumen, why aren't the cells that line the stomach damaged? Actually, these cells are vulnerable to gastric juice as well as to acid-tolerant pathogens in food. However, the stomach lining protects against self-digestion by secreting **mucus**, a viscous and slippery mixture of glycoproteins, cells, salts, and water. In addition, cell division adds a new epithelial layer every three days, replacing cells

▶ **Figure 41.12 The stomach and its secretions.** The micrograph (colorized SEM) shows a gastric pit on the interior surface of the stomach, through which digestive juices are secreted.

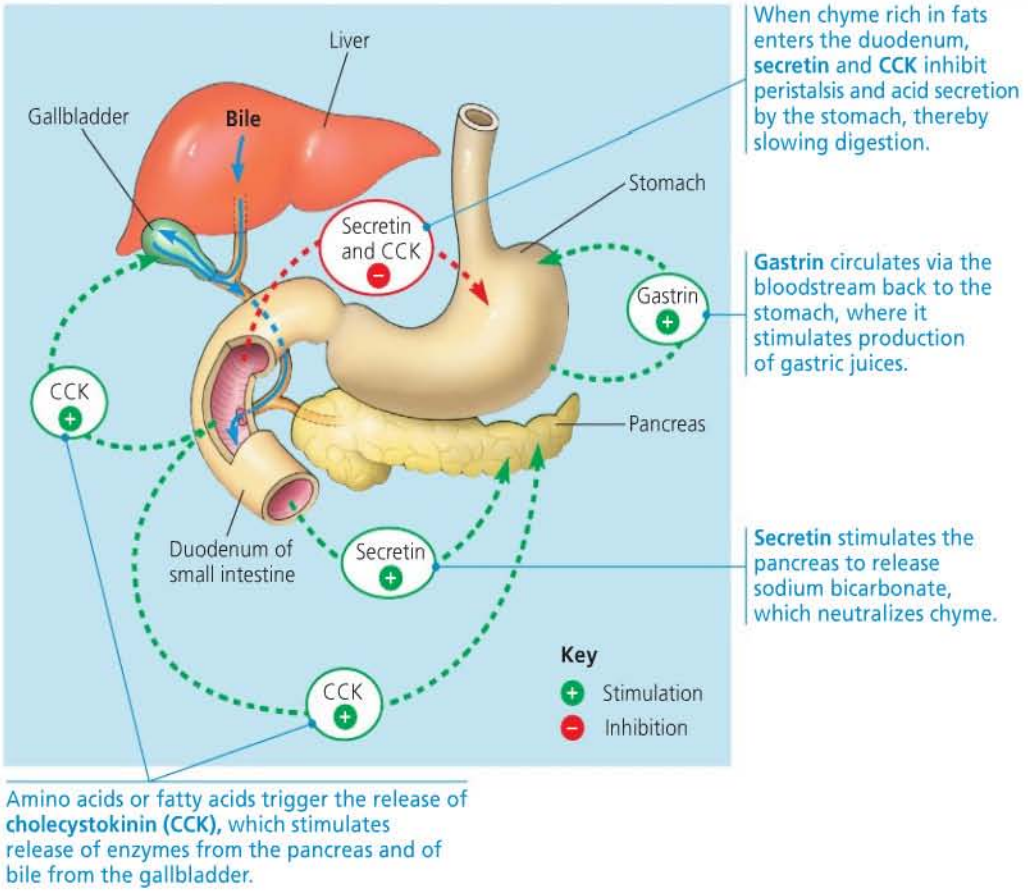
eroded by digestive juices. Despite these defenses, damaged areas of the stomach lining called gastric ulcers may appear. For decades, scientists thought they were caused by psychological stress and resulting excess acid secretion. In 1982, however, researchers Barry Marshall and Robin Warren, at Royal Perth Hospital in Australia, reported that infection by the acid-tolerant bacterium *Helicobacter pylori* causes ulcers. They also demonstrated that an antibiotic treatment could cure most gastric ulcers. For these findings, they were awarded the Nobel Prize in 2005.



Stomach Dynamics

Chemical digestion by gastric juice is accompanied by the churning action of the stomach. This coordinated series of muscle contractions and relaxations mixes the stomach contents about every 20 seconds. As a result of mixing and enzyme action, what begins as a recently swallowed meal becomes the acidic, nutrient-rich broth known as chyme. Most of the time, the stomach is closed off at both ends (see Figure 41.10). The sphincter between the esophagus and the stomach normally opens only when a bolus arrives. Occasionally, however, a person experiences acid reflux, a backflow of chyme from the stomach into the lower end of the esophagus. The resulting irritation of the esophagus is commonly but inaccurately called "heartburn."

The sphincter located where the stomach opens to the small intestine helps regulate the passage of chyme into the small intestine, allowing only one squirt at a time. The mixture of acid, enzyme, and partially digested food typically leaves the stomach 2–6 hours after a meal.



Digestion in the Small Intestine

Most enzymatic hydrolysis of macromolecules from food occurs in the **small intestine** (Figure 41.13). Over 6 m long in

▲ **Figure 41.13 Enzymatic hydrolysis in the human digestive system.**

? *Pepsin is resistant to the denaturing effect of the low pH environment of the stomach. Thinking about the different digestive processes that occur in the small intestine, what adaptation do you think the digestive enzymes in that compartment share?*

▶ **Figure 41.14 Hormonal control of digestion.** Many animals go for long intervals between meals and do not need their digestive systems to be active continuously. Hormones released by the stomach and duodenum help ensure that digestive secretions are present only when needed. Like all hormones, they are transported through the bloodstream. In the case of gastrin, the target is the organ that secretes the hormone.

humans, the small intestine is the alimentary canal's longest compartment. Its name refers to its small diameter, compared with that of the large intestine. The first 25 cm or so of the small intestine forms the **duodenum**, a major crossroad in digestion. It is here that chyme from the stomach mixes with digestive juices from the pancreas, liver, and gallbladder, as well as from gland cells of the intestinal wall itself. Hormones released by the stomach and duodenum control the digestive secretions into the alimentary canal **(Figure 41.14)**.

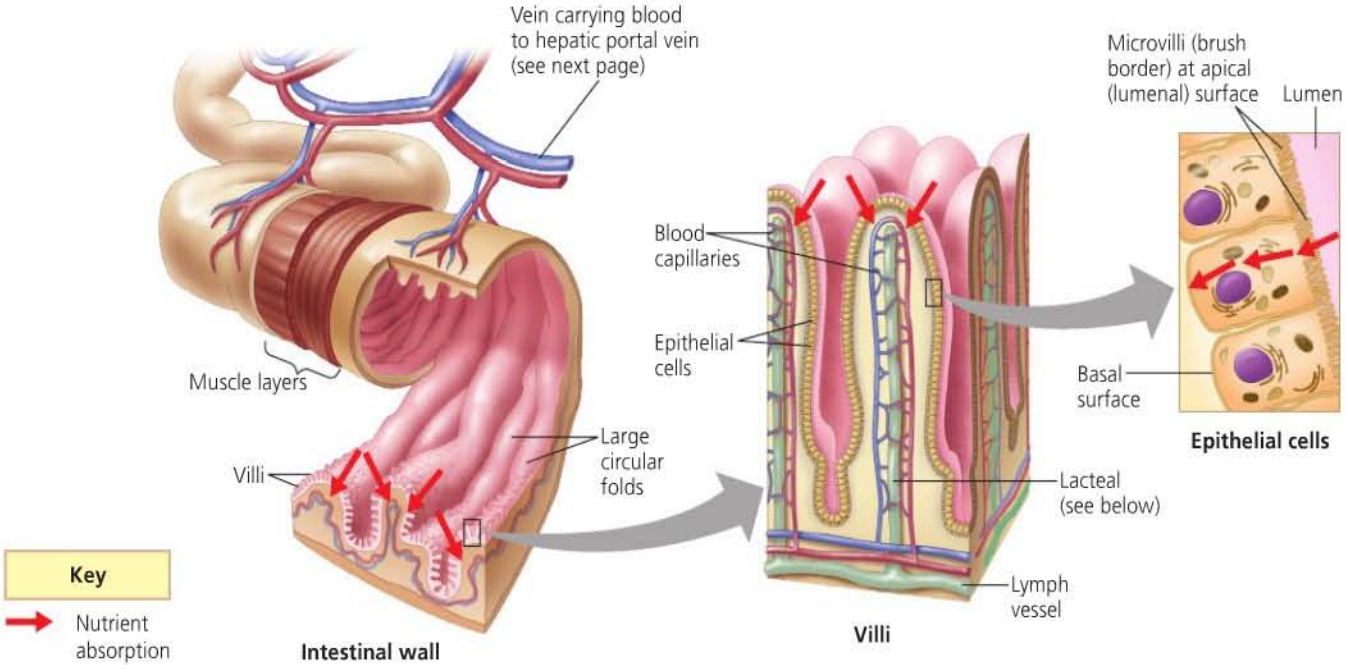
Pancreatic Secretions

The **pancreas** aids chemical digestion by producing an alkaline solution rich in bicarbonate as well as several enzymes. The bicarbonate neutralizes the acidity of chyme and acts as a buffer. Among the pancreatic enzymes are trypsin and chymotrypsin, proteases secreted into the duodenum in inactive forms (see Figure 41.13). In a chain reaction similar to activation of pepsin, they are activated when safely located in the extracellular space within the duodenum.

Bile Production by the Liver

Digestion of fats and other lipids begins in the small intestine and relies on the production of **bile**, a mixture of substances that is made in the **liver**. Bile contains bile salts, which act as detergents (emulsifiers) that aid in digestion and absorption of lipids. Bile is stored and concentrated in the **gallbladder**.

The liver has many vital functions in addition to bile production. As we shall see shortly, it also breaks down toxins that enter the body and helps balance nutrient utilization. Bile production itself is integral to another task of the liver: the destruction of red blood cells that are no longer fully functional. In producing bile, the liver incorporates some pigments that are by-products of red blood cell disassembly. These bile pigments are then eliminated from the body with the feces.



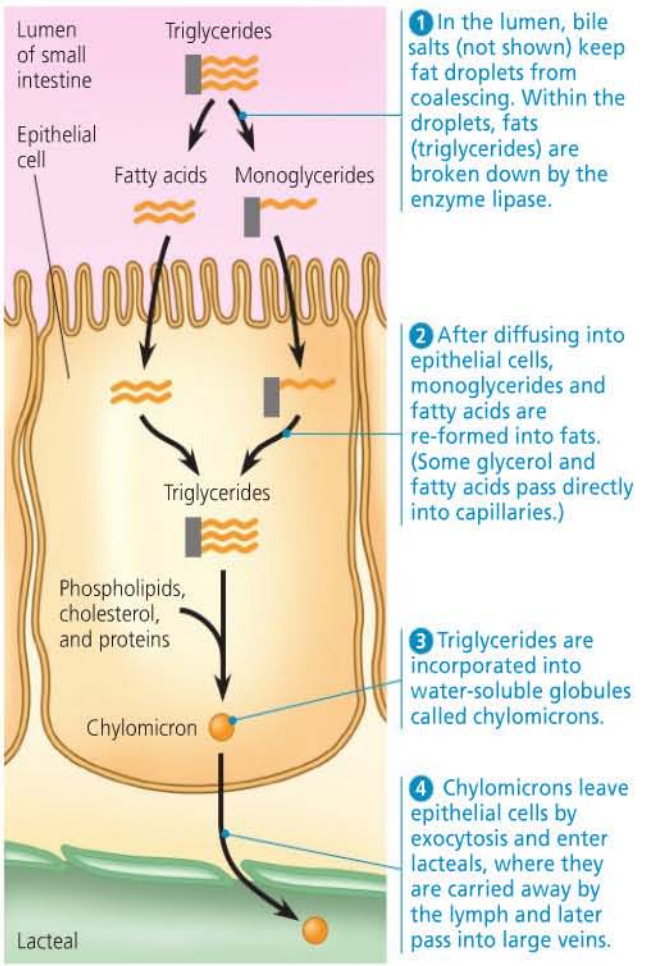
Secretions of the Small Intestine

The epithelial lining of the duodenum is the source of several digestive enzymes (see Figure 41.13). Some are secreted into the lumen of the duodenum, whereas others are bound to the surface of epithelial cells.

While enzymatic hydrolysis proceeds, peristalsis moves the mixture of chyme and digestive juices along the small intestine. Most digestion is completed in the duodenum. The remaining regions of the small intestine, called the *jejunum* and *ileum*, function mainly in the absorption of nutrients and water.

Absorption in the Small Intestine

To reach body tissues, nutrients in the lumen must first cross the lining of the alimentary canal. Most of this absorption occurs in the small intestine. This organ has a huge surface area—300 m^2, roughly the size of a tennis court. Large folds in the lining have finger-like projections called **villi**. In turn, each



▲ **Figure 41.15 The structure of the small intestine.**

? *Tapeworms sometimes infect humans, anchoring themselves to the wall of the small intestine. Based on how digestion is compartmentalized along the alimentary canal, what digestive functions would you expect these parasites to have?*

epithelial cell of a villus has on its apical surface many microscopic appendages, or **microvilli**, that are exposed to the intestinal lumen **(Figure 41.15)**. The many side-by-side microvilli give the intestinal epithelium a brush-like appearance—reflected in the name *brush border*. The enormous surface area presented by microvilli is an adaptation that greatly increases the total capacity for nutrient absorption.

Depending on the nutrient, transport across the epithelial cells can be passive or active. The sugar fructose, for example, moves by facilitated diffusion down its concentration gradient from the lumen of the small intestine into the epithelial cells. From there, fructose exits the basal surface and is absorbed into microscopic blood vessels, or capillaries, at the core of each villus. Other nutrients, including amino acids, small peptides, vitamins, and most glucose molecules, are pumped against concentration gradients by the epithelial cells of the villus. This active transport allows much more absorption of nutrients than would be possible with passive diffusion alone.

Although many nutrients leave the intestine through the bloodstream, some products of fat (triglyceride) digestion take a different path. After being absorbed by epithelial cells, fatty acids and monoglycerides (glycerol joined to a single fatty acid) are recombined into triglycerides within those cells. These fats are then coated with phospholipids, cholesterol, and proteins, forming water-soluble globules called **chylomicrons (Figure 41.16)**. These globules are too large to pass through the membranes of capillaries. Instead, they are transported into a **lacteal**, a vessel at the core of each villus (see Figures 41.15 and 41.16). Lacteals are part of the vertebrate lymphatic system, which is a network of vessels that are filled with a clear fluid called lymph. Starting

▲ **Figure 41.16 Absorption of fats.** Because fats are insoluble in water, adaptations are needed to digest and absorb them. Bile salts maintain a small droplet size, exposing more surface for enzymatic hydrolysis to fatty acids and monoglycerides. These molecules can diffuse into epithelial cells, where fats are reassembled and incorporated into water-soluble chylomicrons that enter the bloodstream via the lymphatic system.

at the lacteals, lymph containing the chylomicrons passes into the larger vessels of the lymphatic system and eventually into large veins that return the blood to the heart.

In contrast with the lacteals, the capillaries and veins that carry nutrient-rich blood away from the villi all converge into the **hepatic portal vein**, a blood vessel that leads directly to the liver. From the liver, blood travels to the heart and then to other tissues and organs. This arrangement serves two major functions. First, it allows the liver to regulate distribution of nutrients to the rest of the body. Because the liver can interconvert many organic molecules, blood that leaves the liver may have a very different nutrient balance than the blood that entered via the hepatic portal vein. For example, blood exiting the liver usually has a glucose concentration very close to 90 mg per 100 mL, regardless of the carbohydrate content of a meal. Second, the arrangement allows the liver to remove toxic substances before the blood circulates broadly. The liver is the primary site for the detoxification of many organic molecules, including drugs, that are foreign to the body.

Absorption in the Large Intestine

The alimentary canal ends with the **large intestine**, which includes the colon, cecum, and rectum. The small intestine connects to the large intestine at a T-shaped junction, where a sphincter controls the movement of material. One arm of the T is the 1.5-m-long **colon** (Figure 41.17), which leads to the rectum and anus. The other arm forms a pouch called the **cecum** (see Figure 41.10). The cecum is important for fermenting ingested material, especially in animals that eat large amounts of plant material. Compared with many other mammals, humans have a relatively small cecum. The **appendix**, a finger-like extension of the human cecum, has a minor and dispensable role in immunity.

A major function of the colon is to recover water that has entered the alimentary canal as the solvent of digestive juices. About 7 L of fluid are secreted into the lumen of the alimentary canal each day. Together, the small intestine and colon reabsorb about 90% of the water that enters the alimentary canal. Since there is no biological mechanism for active transport of water, water absorption in the colon occurs by osmosis that results when ions, particularly sodium, are pumped out of the lumen.

The **feces**, the wastes of the digestive system, become increasingly solid as they are moved along the colon by peristalsis. It takes approximately 12–24 hours for material to travel the length of the colon. If the lining of the colon is irritated—by a viral or bacterial infection, for instance—less water than normal may be reabsorbed, resulting in diarrhea. The opposite problem, constipation, occurs when the feces move along the colon too slowly. An excess of water is reabsorbed, and therefore the feces become compacted.

A rich flora of mostly harmless bacteria resides in the human colon, contributing approximately one-third of the dry weight of feces. One inhabitant is *Escherichia coli*, a favorite research organism of molecular biologists (see Chapter 18). Because *E. coli* is so common in human digestive systems, its presence in lakes and streams is a useful indicator of contamination by untreated sewage. Within the intestine, *E. coli* and other bacteria live on unabsorbed organic material. As by-products of their metabolism, many colon bacteria generate gases, including methane and hydrogen sulfide, which has an offensive odor. These gases and ingested air are expelled through the anus. Some of the bacteria produce vitamins, such as biotin, vitamin K, and several B vitamins, including folic acid. These vitamins, absorbed into the blood, supplement our dietary intake of vitamins.

Besides bacteria, feces contain undigested material, including cellulose fiber. Although it has no caloric value to humans, fiber helps move food along the alimentary canal.

The terminal portion of the large intestine is the **rectum**, where feces are stored until they can be eliminated. Between the rectum and the anus are two sphincters, the inner one being involuntary and the outer one being voluntary. Periodically (once a day or so in most individuals), strong contractions of the colon create an urge to defecate.

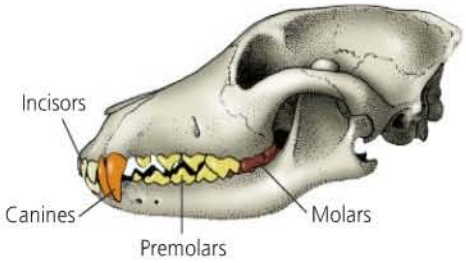
We have followed a meal from one opening (the mouth) of the alimentary canal to the other (the anus). Next we'll see how some digestive adaptations may have evolved.

◀ **Figure 41.17 Digital image of a human colon.** This CAT scan image was produced by integrating two-dimensional sectional views of the large intestine.

CONCEPT CHECK 41.3

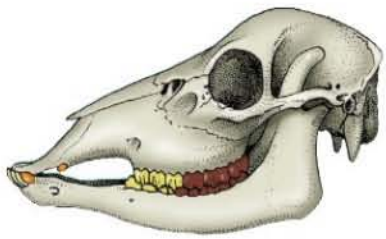
1. In the zero-gravity environment of space, how does food swallowed by an astronaut reach his or her stomach?
2. What step in food processing occurs more readily for fats than for proteins and carbohydrates?
3. **WHAT IF?** Some early experiments involved obtaining samples of digestive juices and observing digestion outside the body. If you mixed gastric juice with crushed food, how far would the process of digestion proceed?

For suggested answers, see Appendix A.



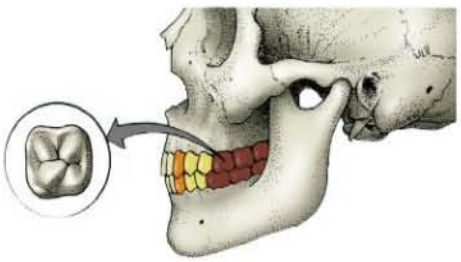
CONCEPT **41.4**

Evolutionary adaptations of vertebrate digestive systems correlate with diet



The digestive systems of mammals and other vertebrates are variations on a common plan, but there are many intriguing adaptations, often associated with the animal's diet. To highlight how form fits function, we'll examine a few of them.

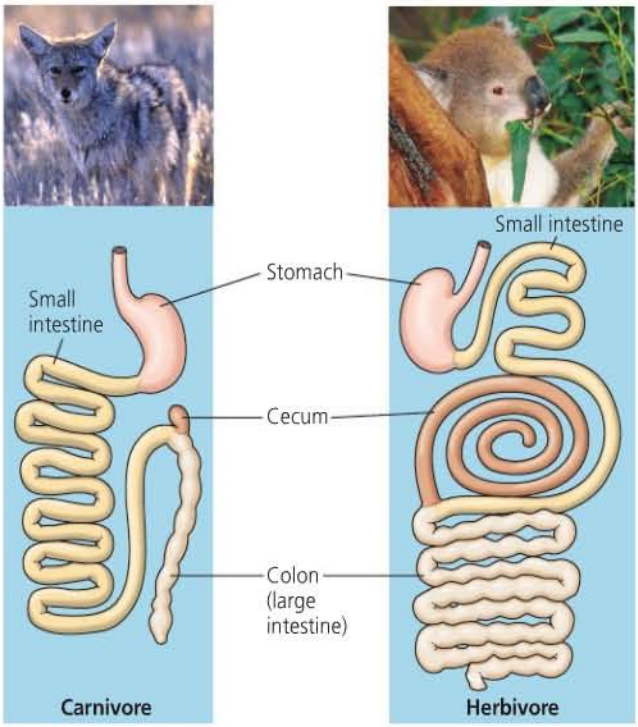
Some Dental Adaptations



Dentition, an animal's assortment of teeth, is one example of structural variation reflecting diet. Consider the dentition of carnivorous, herbivorous, and omnivorous mammals in **Figure 41.18**. The evolutionary adaptation of teeth for processing different kinds of food is one of the major reasons mammals have been so successful. Nonmammalian vertebrates generally have less specialized dentition, but there are interesting exceptions. For example, poisonous snakes, such as rattlesnakes, have fangs, modified teeth that inject venom into prey. Some fangs are hollow, like syringes, whereas others drip the poison along grooves on the surfaces of the teeth. Other teeth are absent. Combined with an elastic ligament that permits the mouth to open very wide, these anatomical adaptations allow prey to be swallowed whole, as in the astonishing scene in Figure 41.6.

(a) Carnivore. Carnivores, such as members of the dog and cat families, generally have pointed incisors and canines that can be used to kill prey and rip or cut away pieces of flesh. The jagged premolars and molars crush and shred food.

(b) Herbivore. In contrast, herbivorous mammals, such as horses and deer, usually have teeth with broad, ridged surfaces that grind tough plant material. The incisors and canines are generally modified for biting off pieces of vegetation. In some herbivorous mammals, canines are absent.



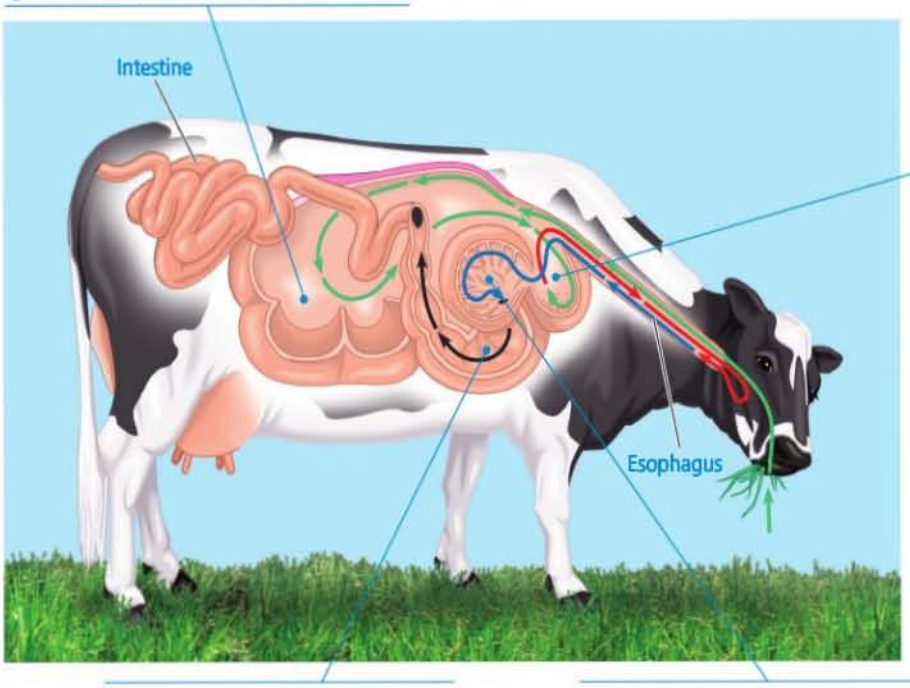
(c) Omnivore. Humans, being omnivores adapted for eating both vegetation and meat, have a relatively unspecialized dentition consisting of 32 permanent (adult) teeth. From the midline to the back along one side of one jaw, there are two bladelike incisors for biting, a pointed canine for tearing, two premolars for grinding, and three molars for crushing.

▲ **Figure 41.18 Dentition and diet.**

Stomach and Intestinal Adaptations

Large, expandable stomachs are common in carnivorous vertebrates, which may go for a long time between meals and must eat as much as they can when they do catch prey. A 200-kg African lion can consume 40 kg of meat in one meal!

The length of the vertebrate digestive system is also correlated with diet. In general, herbivores and omnivores have longer alimentary canals relative to their body size than do carnivores **(Figure 41.19)**. Vegetation is more difficult to digest than meat because it contains cell walls. A longer digestive tract furnishes more time for digestion and more surface area for the absorption of nutrients.



▲ **Figure 41.19 The alimentary canals of a carnivore (coyote) and herbivore (koala).** Although these two mammals are about the same size, the koala's intestines are much longer, enhancing processing of fibrous, protein-poor eucalyptus leaves from which it obtains virtually all its food and water. Extensive chewing chops the leaves into tiny pieces, increasing exposure to digestive juices. In the long cecum, symbiotic bacteria convert the shredded leaves to a more nutritious diet.

Mutualistic Adaptations

Some digestive adaptations involve mutualistic symbiosis, a mutually beneficial interaction between two species (see Chapter 54). For example, microorganisms help herbivores digest plants. Much of the chemical energy in herbivore diets comes from the cellulose of plant cell walls, but animals do not produce enzymes that hydrolyze cellulose. Instead, many vertebrates (as well as termites, whose wood diets are largely cellulose) house large populations of mutualistic bacteria and protists in fermentation chambers in their alimentary canals. These microorganisms have enzymes that can digest cellulose to simple sugars and other compounds that the animal can absorb. In many cases, the microorganisms also use the sugars from digested cellulose to produce a variety of nutrients essential to the animal, such as vitamins and amino acids.

The location of mutualistic microbes in alimentary canals varies, depending on the type of herbivore. For example:

- The hoatzin, an herbivorous bird that lives in the South American rain forests, has a large, muscular crop (an esophageal pouch; see Figure 41.9) that houses mutualistic microorganisms. Hard ridges in the wall of the crop grind plant leaves into small fragments, and the microorganisms break down cellulose.
- Horses and many other herbivorous mammals house mutualistic microorganisms in a large cecum, the pouch where the small and large intestines connect.
- In rabbits and some rodents, mutualistic bacteria live in the large intestine as well as in the cecum. Since most nutrients are absorbed in the small intestine, nourishing by-products of fermentation by bacteria in the large intestine are initially lost with the feces. Rabbits and rodents recover these nutrients by *coprophagy* (from the Greek, meaning "dung eating"), feeding on some of their feces and then passing the food through the alimentary canal a second time. The familiar rabbit "pellets," which are not reingested, are the feces eliminated after food has passed through the digestive tract twice.
- The koala, an Australian marsupial, also has an enlarged cecum, where mutualistic bacteria ferment finely shredded eucalyptus leaves (see Figure 41.19).
- The most elaborate adaptations for an herbivorous diet have evolved in the animals called **ruminants**, which include deer, sheep, and cattle **(Figure 41.20)**.

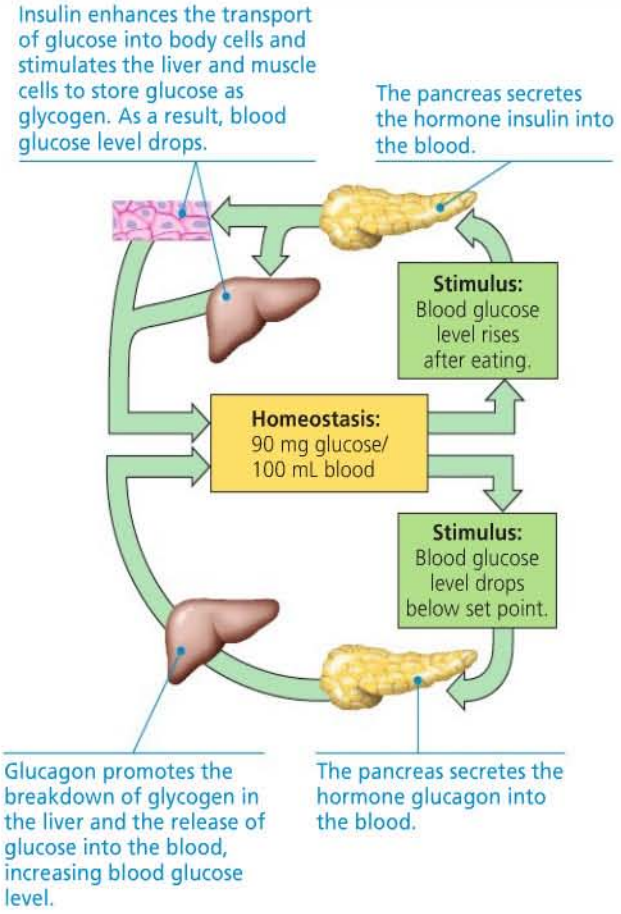
1 Rumen. When the cow first chews and swallows a mouthful of grass, boluses (green arrows) enter the rumen.

2 Reticulum. Some boluses also enter the reticulum. In both the rumen and the reticulum, mutualistic prokaryotes and protists (mainly ciliates) go to work on the cellulose-rich meal. As by-products of their metabolism, the microorganisms secrete fatty acids. The cow periodically regurgitates and rechews the cud (red arrows), which further breaks down the fibers, making them more accessible to further microbial action.

3 Omasum. The cow then reswallows the cud (blue arrows), which moves to the omasum, where water is removed.

4 Abomasum. The cud, containing great numbers of microorganisms, finally passes to the abomasum for digestion by the cow's own enzymes (black arrows).

▲ **Figure 41.20 Ruminant digestion.** The stomach of a ruminant has four chambers. Because of the microbial action in the chambers, the diet from which a ruminant actually absorbs its nutrients is much richer than the grass the animal originally eats. In fact, a ruminant eating grass or hay obtains many of its nutrients by digesting the mutualistic microorganisms, which reproduce rapidly enough in the rumen to maintain a stable population.



Although we have focused our discussion on vertebrates, adaptations related to digestion are also widespread among other animals. Some of the most remarkable examples are the giant tubeworms that live at deep-sea hydrothermal vents (see Figure 52.18). These worms, which thrive at pressures as high as 260 atmospheres in water that reaches a remarkable 400°C (752°F), have no mouth or digestive system. Instead, they rely entirely on mutualistic bacteria to generate energy and nutrients from the carbon dioxide, oxygen, hydrogen sulfide, and nitrate available at the vents. Thus, for invertebrates and vertebrates alike, mutualistic symbiosis has evolved as a general strategy for expanding the sources of nutrition available to animals.

Having examined how animals optimize their extraction of nutrients from food, we will next turn to the challenge of balancing the use of these nutrients.

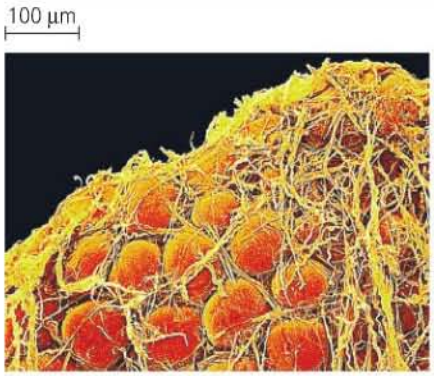
CONCEPT CHECK 41.4

1. What are the two advantages of a longer alimentary canal for processing plant material that is difficult to digest?
2. What features of an animal's digestive system make it an attractive habitat for mutualistic microorganisms?
3. **WHAT IF?** "Lactose-intolerant" people have a shortage of lactase, the enzyme that breaks down lactose in milk. As a result, they sometimes develop cramps, bloating, or diarrhea after consuming dairy products. Suppose such a person ate yogurt, which contains bacteria that produce lactase. Why might you expect that eating yogurt would provide at best only temporary relief of the symptoms?

For suggested answers, see Appendix A.

▲ **Figure 41.21 Homeostatic regulation of cellular fuel.** After a meal is digested, glucose and other monomers are absorbed into the blood from the digestive tract. The human body regulates the use and storage of glucose, a major cellular fuel. Notice that these regulatory loops are examples of the negative feedback control described in Chapter 40.

CONCEPT 41.5
Homeostatic mechanisms contribute to an animal's energy balance



As discussed in Chapter 40, the energy obtained from food balances the expenditure of energy for metabolism, activity, and storage. In concluding our overview of nutrition, we'll examine some ways in which animals achieve this balance.

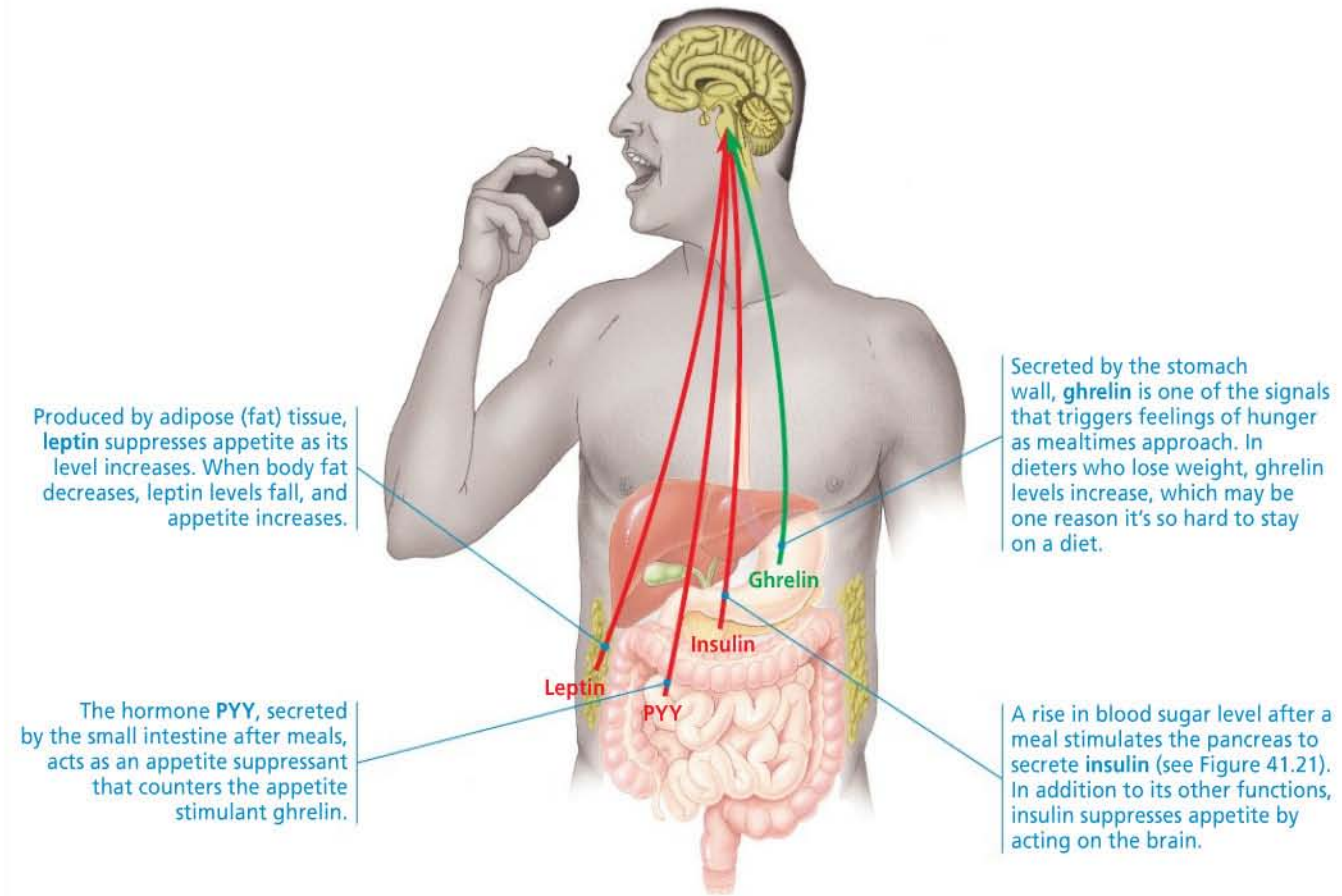
Energy Sources and Stores

In deriving energy from their diet, animals make use of certain fuel sources before others. Nearly all of an animal's ATP generation is based on the oxidation of energy-rich organic molecules—carbohydrates, proteins, and fats—in cellular respiration. Although any of these substances can be used as fuel, most animals "burn" proteins only after exhausting their supply of carbohydrates and fats. Fats are especially rich in energy; oxidizing a gram of fat liberates about twice the energy liberated from a gram of carbohydrate or protein.

When an animal takes in more energy-rich molecules than it breaks down, the excess is converted to storage molecules. In humans, the primary sites of storage are liver and muscle cells. Excess energy from the diet is stored there in the form of glycogen, a polymer made up of many glucose units (see Figure 5.6b). When fewer calories are taken in than are expended—perhaps because of sustained heavy exercise or lack of food—glycogen is oxidized. The hormones insulin and glucagon maintain glucose homeostasis by tightly regulating glycogen synthesis and breakdown **(Figure 41.21)**.

Adipose (fat) cells represent a secondary site of energy storage in the body. If glycogen depots are full and caloric intake exceeds caloric expenditure, the excess is usually stored as fat. When more energy is required than is generated from the diet, the human body generally expends liver glycogen first and then draws on muscle glycogen and fat. Most healthy people have enough stored fat to sustain them through several weeks without food.

◀ **Figure 41.22 Fat cells from the abdomen of a human.** Strands of connective tissue (yellow) hold the fat-storing adipose cells in place (colorized SEM).



Overnourishment and Obesity

Overnourishment, the consumption of more calories than the body needs for normal metabolism, causes obesity, the excessive accumulation of fat **(Figure 41.22)**. Obesity, in turn, contributes to a number of health problems, including the most common type of diabetes (type 2), cancer of the colon and breast, and cardiovascular disease that can lead to heart attacks and strokes. It is estimated that obesity is a factor in about 300,000 deaths per year in the United States alone.

Researchers have discovered several homeostatic mechanisms that help regulate body weight. Operating as feedback circuits, these mechanisms control the storage and metabolism of fat. Several hormones regulate long-term and short-term appetite by affecting a "satiety center" in the brain **(Figure 41.23)**. A network of neurons relays and integrates information from the digestive system to regulate hormone release.

Mutations that cause mice to be chronically obese played a key role in advancing our understanding of the satiety pathway. Mice with mutations in the *ob* or *db* gene eat voraciously and become much more massive than normal. Doug Coleman, a researcher at the Jackson Laboratory in Maine, investigated how *ob* and *db* mutations disrupt normal control of appetite **(Figure 41.24)**. Based on his experiments, Coleman deduced that the *ob* gene is required to produce the satiety factor, and the *db* gene is required to respond to the factor.

Cloning of the *ob* gene led to the demonstration that it produces a hormone, now known as leptin (from the Greek *lepto*, thin). The *db* gene encodes the leptin receptor. Leptin and the leptin receptor are key components of the circuitry that regulates appetite over the long term. Leptin is a product of adipose cells, so levels rise when body fat increases, cuing the

▲ **Figure 41.23 A few of the appetite-regulating hormones.** Secreted by various organs and tissues, the hormones reach the brain via the bloodstream. The hormones act on a region of the brain that in turn controls the "satiety center," which generates the nervous impulses that make us feel either hungry or satiated ("full"). The green arrow indicates an appetite stimulant; red arrows represent appetite suppressants.

▼ Figure 41.24 Inquiry

What are the roles of the *ob* and *db* genes in appetite regulation?

EXPERIMENT Margaret Dickie, Katherine Hummel, and Doug Coleman, of the Jackson Laboratory in Bar Harbor, Maine, discovered that mice with a mutant *ob* gene or a mutant *db* gene eat voraciously and grow much more massive than mice with the wild-type (nonmutant) forms of both genes (designated ob^+, db^+).

Obese mouse with mutant *ob* gene (left) next to wild-type mouse.

To explore further the roles of the two genes, Coleman measured the body masses of pairs of young mice with various genotypes and then surgically linked the circulatory systems of each pair. This procedure ensured that any factor circulating in the bloodstream of either mouse would be transferred to the other. After several weeks, he again measured the mass of each mouse.

RESULTS

Genotype pairing (red type indicates mutant genes; bar indicates pairing)	Average body mass (g)	
	Starting	Ending
ob^+, db^+	20.3	23.6
ob^+, db^+	20.8	21.4
ob, db^+	27.6	47.0
ob, db^+	26.6	44.0
ob, db^+	29.4	39.8
ob^+, db^+	22.5	25.5
ob, db^+	33.7	18.8
ob^+, *db*	30.3	33.2

CONCLUSION Because an *ob* mouse gains less weight when surgically joined with an ob^+ mouse than when joined with an *ob* mouse, Coleman concluded that the *ob* mouse fails to make a satiety factor but can respond to the factor when it is present. To explain the weight loss in an *ob* mouse that receives circulating factors from a *db* mouse, he reasoned that the *db* mutation blocks the response to the satiety factor but not its production. Subsequent molecular studies demonstrated the validity of both parts of Coleman's conclusion. The ob^+ gene product is leptin, the satiety factor, whereas the db^+ gene product is the leptin receptor. Thus, mice with the *ob* mutation cannot produce leptin, and mice with the *db* mutation produce leptin but cannot respond to it.

SOURCE D. L. Coleman, Effects of parabiosis of obese with diabetes and normal mice. *Diabetologia* 9:294–298 (1973).

WHAT IF? Suppose you collected blood from a wild-type mouse and a *db* mouse. Which would you expect to have a higher concentration of leptin, the satiety factor, and why?

brain to suppress appetite (see Figure 41.23). Conversely, loss of fat decreases leptin levels, signaling the brain to increase appetite. In this way, the feedback signals provided by leptin maintain body fat levels within a set range.

Our understanding of leptin may lead to treatments for obesity, but uncertainties remain. For one thing, leptin has complex functions, including a role in how the nervous system develops. Also, most obese people have an abnormally high leptin level, which somehow fails to elicit a response from the brain's satiety center. Clearly, there is much to learn in this important area of human physiology.

Obesity and Evolution

Though fat hoarding can be a health liability, it may have been an advantage in our evolutionary past. Our ancestors on the African savanna were hunter-gatherers who probably survived mainly on seeds and other plant products, a diet only occasionally supplemented by hunting game or scavenging meat from animals killed by other predators. In such a feast-or-famine existence, natural selection may have favored those individuals with a physiology that induced them to gorge on rich, fatty foods on those rare occasions when such treats were abundantly available. Such individuals with genes promoting the storage of high-energy molecules during feasts may have been more likely than their thinner friends to survive famines. So perhaps our present-day taste for fats is partly an evolutionary vestige of less nutritious times.

The relationship between fat storage and evolutionary adaptation in animals is sometimes complex. Consider the plump offspring of the seabirds called petrels **(Figure 41.25)**. Their parents must fly long distances to find food. Most of the food that they bring to their chicks is very rich in lipids. The fact that fat has twice as many calories per gram as other

▲ **Figure 41.25 A plump petrel.** Too heavy to fly, the petrel chick (right) will have to lose weight before it takes wing. In the meantime, its stored fat provides energy during times when its parent fails to bring enough food.

fuels minimizes the number of foraging trips. However, growing baby petrels need lots of protein for building new tissues, and there is relatively little in their oily diet. To get all the protein they need, young petrels have to consume many more calories than they burn in metabolism and consequently become obese. Their fat depots nevertheless help them survive periods when parents cannot find enough food. When food is not scarce, chicks at the end of the growth period weigh much more than their parents. The youngsters must then fast for several days to lose enough weight to be capable of flight.

In the next chapter, we'll see that obtaining food, digesting it, and absorbing nutrients are parts of a larger story. Provisioning the body also involves distributing nutrients (circulation) and exchanging respiratory gases with the environment.

CONCEPT CHECK 41.5

1. Explain how people can become obese even if their intake of dietary fat is relatively low compared with carbohydrate intake.
2. After reviewing Figure 41.23, explain how PYY and leptin complement each other in regulating body weight.
3. **WHAT IF?** Suppose you were studying two groups of obese people with genetic abnormalities in the leptin pathway. In one group, the leptin levels are abnormally high; in the other group, they are abnormally low. How would each group's leptin levels change if both groups were placed on a low-calorie diet for an extended period? Explain.

For suggested answers, see Appendix A.

Chapter 41 Review

MEDIA Go to the Study Area at **www.masteringbio.com** for BioFlix 3-D Animations, MP3 Tutors, Videos, Practice Tests, an eBook, and more.

SUMMARY OF KEY CONCEPTS

- Animals have diverse diets. Herbivores mainly eat plants; carnivores mainly eat other animals; and omnivores eat both. Animals must balance consumption, storage, and use of food.

CONCEPT 41.1

An animal's diet must supply chemical energy, organic molecules, and essential nutrients (pp. 875–880)

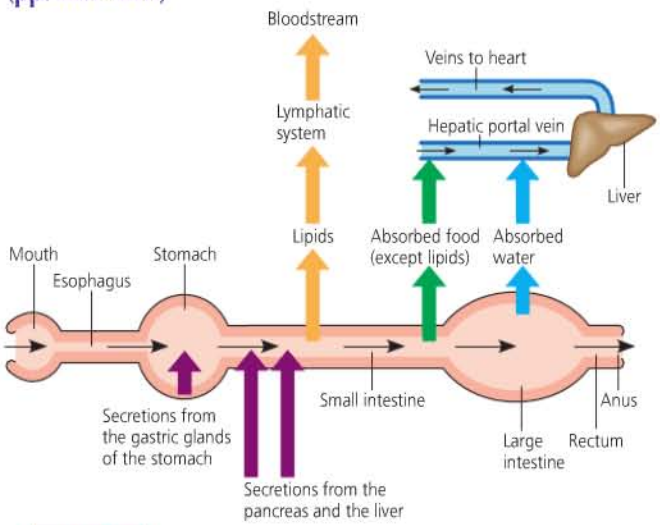
- Animals need fuel to produce ATP, carbon skeletons for biosynthesis, and essential nutrients—nutrients that must be supplied in preassembled form.
- **Essential Nutrients** Essential nutrients include essential amino acids, essential fatty acids, vitamins, and minerals. Essential amino acids are those an animal cannot synthesize. Essential fatty acids are unsaturated. Vitamins are organic molecules required in small amounts. Minerals are inorganic nutrients, usually required in small amounts.
- **Dietary Deficiencies** Undernourished animals have diets deficient in calories. Malnourished animals are missing one or more essential nutrients.
- **Assessing Nutritional Needs** Studies of genetic defects and the study of disease at the population level help researchers determine human dietary requirements.

MEDIA

Activity Analyzing Food Labels

CONCEPT 41.2

The main stages of food processing are ingestion, digestion, absorption, and elimination (pp. 880–883)



- Food processing in animals involves ingestion (eating), digestion (enzymatic breakdown of large molecules), absorption (uptake of nutrients by cells), and elimination (passage of undigested materials out of the body in feces).
- Suspension feeders sift small particles from the water. Substrate feeders eat as they tunnel through their food. Fluid feeders suck nutrient-rich fluids from a living host. Most animals are bulk feeders, eating large pieces of food.
- **Digestive Compartments** In intracellular digestion, food particles are engulfed by endocytosis and digested within food vacuoles that have fused with lysosomes. Most animals use extracellular digestion: Enzymatic hydrolysis occurs outside cells in a gastrovascular cavity or alimentary canal.

CONCEPT 41.4

Evolutionary adaptations of vertebrate digestive systems correlate with diet (pp. 891–893)

- **Some Dental Adaptations** Dentition generally correlates with diet.
- **Stomach and Intestinal Adaptations** Herbivores generally have longer alimentary canals than carnivores, reflecting the longer time needed to digest vegetation.
- **Mutualistic Adaptations** Many herbivores have fermentation chambers where microorganisms digest cellulose.

CONCEPT 41.5

Homeostatic mechanisms contribute to an animal's energy balance (pp. 893–896)

- **Energy Sources and Stores** Vertebrates store excess calories as glycogen in the liver and muscles and as fat. These energy stores can be tapped when an animal expends more calories than it consumes.
- **Overnourishment and Obesity** Overnourishment, the consumption of more calories than the body needs for normal metabolism, can lead to the serious health problem of obesity. Several hormones regulate appetite by affecting the brain's satiety center. Studies of the hormone leptin may lead to treatments for obesity.
- **Obesity and Evolution** The problem of maintaining a healthy weight partly stems from our evolutionary past, when fat hoarding may have been important for survival.

TESTING YOUR KNOWLEDGE

SELF-QUIZ

1. Individuals whose diet consists primarily of corn would likely become
   a. obese.
   b. anorexic.
   c. overnourished.
   d. undernourished.
   e. malnourished.

2. Which of the following animals is *incorrectly* paired with its feeding mechanism?
   a. lion—substrate feeder
   b. baleen whale—suspension feeder
   c. aphid—fluid feeder
   d. clam—suspension feeder
   e. snake—bulk feeder

3. The mammalian trachea and esophagus both connect to the
   a. large intestine.
   b. stomach.
   c. pharynx.
   d. rectum.
   e. epiglottis.

4. Which of the following enzymes works most effectively at a very low pH?
   a. salivary amylase
   b. trypsin
   c. pepsin
   d. pancreatic amylase
   e. pancreatic lipase

5. Which of the following organs is *incorrectly* paired with its function?
   a. stomach—protein digestion
   b. oral cavity—starch digestion
   c. large intestine—bile production
   d. small intestine—nutrient absorption
   e. pancreas—enzyme production

6. After surgical removal of an infected gallbladder, a person must be especially careful to restrict dietary intake of
   a. starch.
   b. protein.
   c. sugar.
   d. fat.
   e. water.

7. The mutualistic microorganisms that help nourish a ruminant live mainly in specialized regions of the
   a. large intestine.
   b. liver.
   c. small intestine.
   d. pharynx.
   e. stomach.

8. If you were to jog a mile a few hours after lunch, which stored fuel would you probably tap?
   a. muscle proteins
   b. muscle and liver glycogen
   c. fat stored in the liver
   d. fat stored in adipose tissue
   e. blood proteins

9. **DRAW IT** Make a flowchart of the events that occur after partially digested food leaves the stomach. Use the following terms: bicarbonate secretion, circulation, decrease in acid, secretin secretion, increase in acid, signal detection. Next to each term, indicate the compartment(s) involved. You may use a term more than once.

For Self-Quiz answers, see Appendix A.

OVERVIEW

Trading Places

The animal in **Figure 42.1** may look like a creature from a science fiction film, but it's actually an axolotl, a salamander native to shallow ponds in central Mexico. The feathery red appendages jutting out from the head of this albino adult are gills. Although external gills are uncommon in adult animals, they help satisfy the need shared by all animals to exchange substances with their environment.

Exchange between an axolotl or any other animal and its surroundings ultimately occurs at the cellular level. The resources that animal cells require, such as nutrients and oxygen (O_2), enter the cytoplasm by crossing the plasma membrane. Metabolic by-products, such as carbon dioxide (CO_2), exit the cell by crossing the same membrane. In unicellular organisms, exchange occurs directly with the external environment. For most multicellular organisms, however, direct exchange between every cell and the environment is not possible. Instead, these organisms rely on specialized systems that carry out exchange with the environment and that transport materials between sites of exchange and the rest of the body.

The reddish color and branching structure of the axolotl's gills reflect the intimate association between exchange and transport. Tiny blood vessels lie close to the surface of each filament in the gills. Across this surface, there is a net diffusion of O_2 from the surrounding water into the blood and of CO_2 from the blood into the water. The short distances involved allow diffusion to be rapid. Pumping of the axolotl's heart propels the oxygen-rich blood from the gill filaments to all other tissues of the body. There, more short-range exchange occurs, involving nutrients and O_2 as well as CO_2 and other wastes.

Because internal transport and gas exchange are functionally related in most animals, not just axolotls, we will examine both circulatory and respiratory systems in this chapter. We will explore the remarkable variation in form and organization of these systems by considering examples from a number of species. We will also highlight the roles of circulatory and respiratory systems in maintaining homeostasis under a range of physiological and environmental stresses.

CONCEPT 42.1

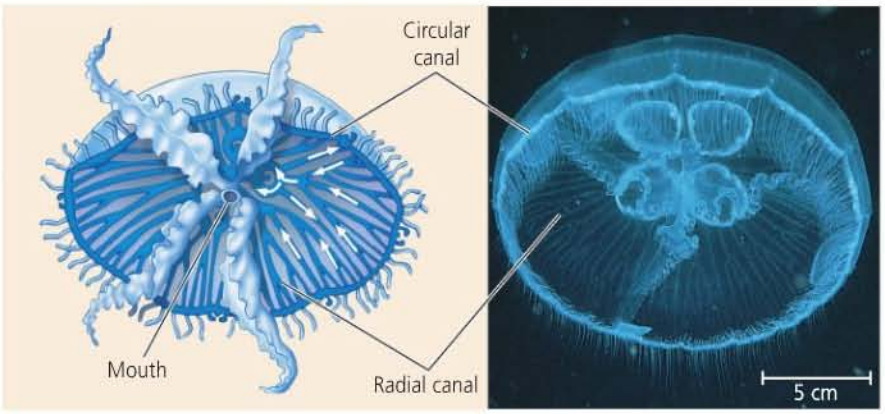
Circulatory systems link exchange surfaces with cells throughout the body

The molecular trade that animals carry out with their environment—gaining O_2 and nutrients while shedding CO_2 and other waste products—must ultimately involve every cell in the body. As you learned in Chapter 7, small, nonpolar molecules such as O_2 and CO_2 can move between cells and their immediate surroundings by diffusion. But diffusion is very slow for distances of more than a few millimeters. That's because the time it takes for a substance to diffuse from one

place to another is proportional to the *square* of the distance. For example, if it takes 1 second for a given quantity of glucose to diffuse 100 μm, it will take 100 seconds for the same quantity to diffuse 1 mm, and almost 3 hours to diffuse 1 cm. This relationship between diffusion time and distance places a substantial constraint on the body plan of any animal.

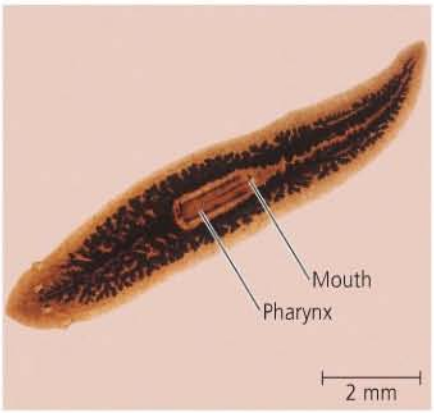
Given that diffusion is rapid only over small distances, how does each cell of an animal participate in exchange? Natural selection has resulted in two general solutions to this problem. The first solution is a body size and shape that keep many or all cells in direct contact with the environment. Each cell can thus exchange materials directly with the surrounding medium. This type of body plan is found only in certain invertebrates, including sponges, cnidarians, and flatworms. The second solution, found in all other animals, is a circulatory system that moves fluid between each cell's immediate surroundings and the tissues where exchange with the environment occurs.

Gastrovascular Cavities



Let's begin by looking at animals that lack a distinct circulatory system. In hydras and other cnidarians, a central gastrovascular cavity functions both in digestion and in the distribution of substances throughout the body. As was shown for a hydra in Figure 41.8, a single opening maintains continuity between the fluid inside the cavity and the water outside. As a result, both the inner and outer tissue layers are bathed by fluid. Only the cells of the inner layer have direct access to nutrients, but since the body wall is a mere two cells thick, the nutrients must diffuse only a short distance to reach the cells of the outer layer. Thin branches of a hydra's gastrovascular cavity extend into the animal's tentacles. Some cnidarians, such as jellies, have gastrovascular cavities with a much more elaborate branching pattern **(Figure 42.2a)**.

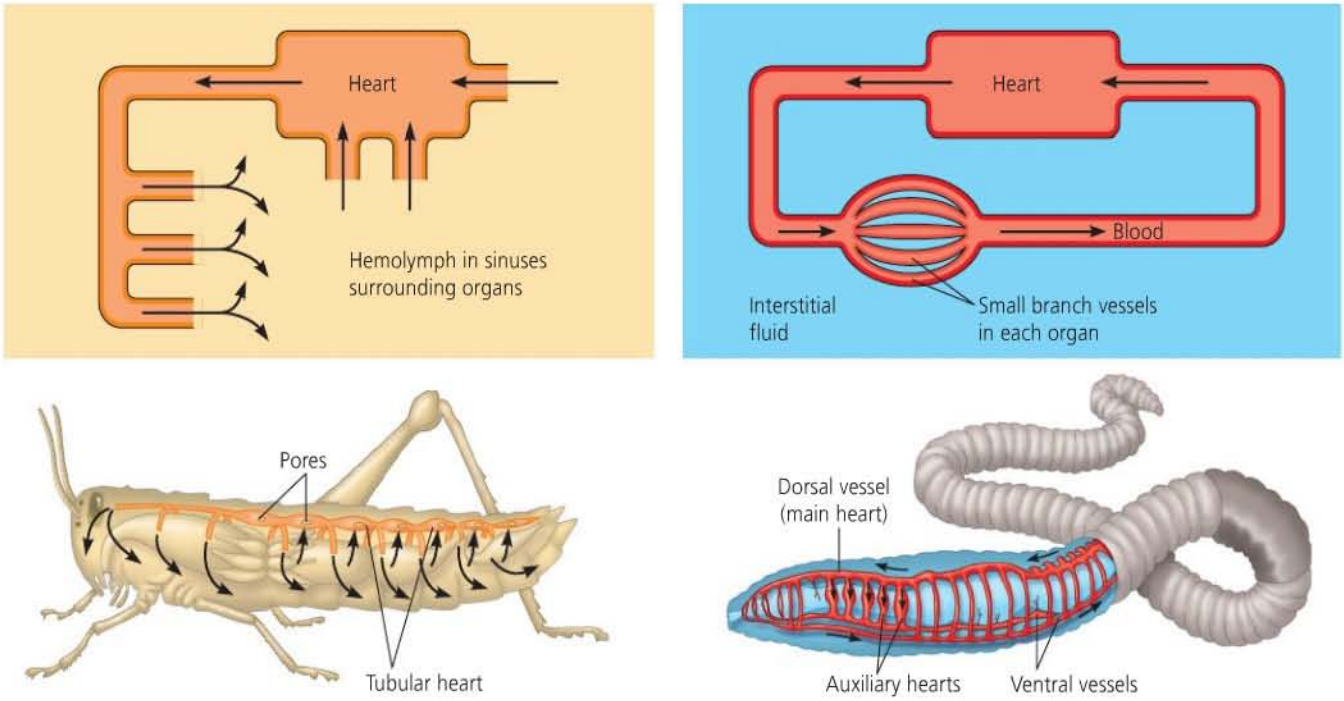
Planarians and most other flatworms also survive without a circulatory system. Their combination of a gastrovascular cavity and a flat body is well suited for exchange with the environment **(Figure 42.2b)**. A flat body optimizes diffusional exchange by increasing surface area and minimizing diffusion distances.



Open and Closed Circulatory Systems

For animals with many cell layers, diffusion distances are too great for adequate exchange of nutrients and wastes by a gastrovascular cavity. In these organisms, a circulatory system minimizes the distances that substances must diffuse to enter or leave a cell. By transporting fluid throughout the body, the circulatory system functionally connects the aqueous environment of the body cells to the organs that exchange gases, absorb nutrients, and dispose of wastes. In mammals, for example, O_2 from inhaled air diffuses across only two layers of cells in the lungs before reaching the blood. The circulatory system, powered by the heart, then carries the oxygen-rich blood to all parts of the body. As the blood streams throughout the body tissues in tiny blood vessels, O_2 in the blood again diffuses only a short distance before entering the interstitial fluid that directly bathes the cells.

A circulatory system has three basic components: a circulatory fluid, a set of interconnecting tubes, and a muscular pump, the **heart**. The heart powers circulation by using metabolic energy to elevate the hydrostatic pressure of the circulatory fluid, which then flows through a circuit of vessels and back to the heart.



(a) The moon jelly *Aurelia*, a cnidarian. The jelly is viewed here from its underside (oral surface). The mouth leads to an elaborate gastrovascular cavity that consists of radial arms (canals) leading to and from a circular canal. Ciliated cells lining the canals circulate fluid within the cavity as indicated by the arrows.

(b) The planarian *Dugesia*, a flatworm. The mouth and pharynx on the ventral side lead to the highly branched gastrovascular cavity, stained dark brown in this specimen (LM).

▲ **Figure 42.2 Internal transport in gastrovascular cavities.**

WHAT IF? *Suppose a gastrovascular cavity were open at two ends, with fluid entering one end and leaving the other. How would this affect the gastrovascular cavity's function?*

(a) An open circulatory system. In an open circulatory system, such as that of a grasshopper, the circulatory fluid, called hemolymph, is the same as interstitial fluid. The heart pumps hemolymph through vessels into sinuses, fluid-filled spaces where materials are exchanged between the hemolymph and cells. Hemolymph returns to the heart through pores, which are equipped with valves that close when the heart contracts.

(b) A closed circulatory system. Closed circulatory systems circulate blood entirely within vessels, so the blood is distinct from the interstitial fluid. Chemical exchange occurs between the blood and the interstitial fluid, as well as between the interstitial fluid and body cells. In an earthworm, the dorsal vessel functions as the main heart, pumping blood forward by peristalsis. Near the worm's anterior end, five pairs of vessels loop around the digestive tract and function as auxillary hearts.

▲ **Figure 42.3 Open and closed circulatory systems.**

Arthropods and most mollusks have an **open circulatory system**, in which the circulatory fluid bathes the organs directly **(Figure 42.3a)**. In these animals, the circulatory fluid, called **hemolymph**, is also the interstitial fluid. Contraction of one or more hearts pumps the hemolymph through the circulatory vessels into interconnected sinuses, spaces surrounding the organs. Within the sinuses, chemical exchange occurs between the hemolymph and body cells. Relaxation of the heart draws hemolymph back in through pores, and body movements help circulate the hemolymph by periodically squeezing the sinuses. The open circulatory system of larger crustaceans, such as lobsters and crabs, includes a more extensive system of vessels as well as an accessory pump.

In a **closed circulatory system**, blood is confined to vessels and is distinct from the interstitial fluid **(Figure 42.3b)**. One or more hearts pump blood into large vessels that branch into smaller ones coursing through the organs. Materials are exchanged between the smallest vessels and the interstitial fluid bathing the cells. Annelids (including earthworms), cephalopods (including squids and octopuses), and all vertebrates have closed circulatory systems.

The fact that both open and closed circulatory systems are widespread among animals suggests that there are advantages to each system. The lower hydrostatic pressures associated with open circulatory systems make them less costly than closed systems in terms of energy expenditure. In some invertebrates, open circulatory systems serve additional functions. For example, in spiders, the hydrostatic pressure generated by the open circulatory system provides the force used to extend the animal's legs.

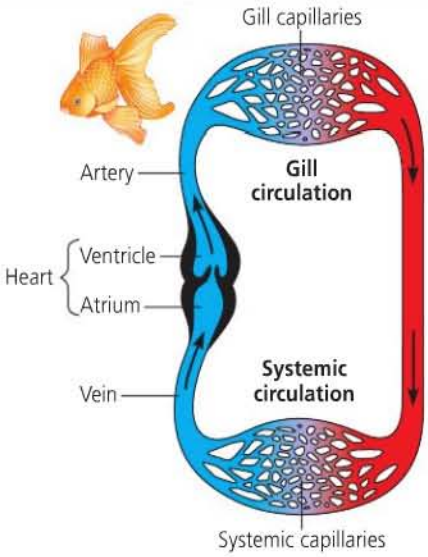
The benefits of closed circulatory systems include relatively high blood pressures, which enable the effective delivery of O_2 and nutrients to the cells of larger and more active animals. Among the molluscs, for instance, closed circulatory systems are found in the largest and most active species, the squids and octopuses. Closed systems are also particularly well suited to regulating the distribution of blood to different organs, as you'll learn later in this chapter. In examining closed circulatory systems in more detail, we will focus on the vertebrates.

Organization of Vertebrate Circulatory Systems

The closed circulatory system of humans and other vertebrates is often called the **cardiovascular system**. Blood circulates to

and from the heart through an amazingly extensive network of vessels: The total length of blood vessels in an average human adult is twice Earth's circumference at the equator!

Arteries, veins, and capillaries are the three main types of blood vessels. Within each type, blood flows in only one direction. **Arteries** carry blood away from the heart to organs throughout the body. Within organs, arteries branch into **arterioles**, small vessels that convey blood to the capillaries. **Capillaries** are microscopic vessels with very thin, porous walls. Networks of these vessels, called **capillary beds**, infiltrate each tissue, passing within a few cell diameters of every cell in the body. Across the thin walls of capillaries, chemicals, including dissolved gases, are exchanged by diffusion between the blood and the interstitial fluid around the tissue cells. At their "downstream" end, capillaries converge into **venules**, and venules converge into **veins**, the vessels that carry blood back to the heart.



Arteries and veins are distinguished by the *direction* in which they carry blood, not by the O_2 content or other characteristics of the blood they contain. Arteries carry blood from the heart *toward* capillaries, and veins return blood to the heart *from* capillaries. There is one exception: the portal veins, which carry blood between pairs of capillary beds. The hepatic portal vein, for example, carries blood from capillary beds in the digestive system to capillary beds in the liver (see Chapter 41). From the liver, blood passes into the hepatic veins, which conduct blood toward the heart.

Natural selection has modified the cardiovascular systems of different vertebrates in accordance with their level of activity. For example, animals with higher metabolic rates generally have more complex circulatory systems and more powerful hearts than animals with lower metabolic rates. Similarly, within an animal, the complexity and number of blood vessels in a particular organ correlate with that organ's metabolic requirements.

The hearts of all vertebrates contain two or more muscular chambers. The chambers that receive blood entering the heart are called **atria** (singular, *atrium*). The chambers responsible for pumping blood out of the heart are called **ventricles**. The number of chambers and the extent to which they are separated from one another differ substantially among groups of vertebrates, as we will discuss next. These important differences reflect the close fit of form to function.

Single Circulation

In bony fishes, rays, and sharks, the heart consists of two chambers: an atrium and a ventricle. The blood passes through the heart once in each complete circuit, an arrangement called **single circulation** (Figure 42.4). Blood entering the heart collects in the atrium before transfer to the ventricle. Contraction of the ventricle pumps blood to the gills, where there is a net diffusion of O_2 into the blood and of CO_2 out of the blood. As

▲ **Figure 42.4 Single circulation in fishes.** Fishes have a two-chambered heart and a single circuit of blood flow.

blood leaves the gills, the capillaries converge into a vessel that carries oxygen-rich blood to capillary beds throughout the body. Blood then returns to the heart.

In single circulation, blood that leaves the heart passes through two capillary beds before returning to the heart. When blood flows through a capillary bed, blood pressure drops substantially, for reasons we will explain shortly. The drop in blood pressure in the gills of a bony fish, ray, or shark limits the rate of blood flow in the rest of the animal's body. As the animal swims, however, the contraction and relaxation of its muscles help accelerate the relatively sluggish pace of circulation.

Double Circulation

As shown in **Figure 42.5**, on the next page, the circulatory systems of amphibians, reptiles, and mammals have two distinct circuits, an arrangement called **double circulation**. The pumps for the two circuits serve different tissues but are combined into a single organ, the heart. Having both pumps within a single heart simplifies coordination of the pumping cycles.

One pump, the right side of the heart, delivers oxygen-poor blood to the capillary beds of the gas exchange tissues, where there is a net movement of O_2 into the blood and of CO_2 out of the blood. This part of the circulation is called a **pulmonary circuit** if the capillary beds involved are all in the lungs, as in reptiles and mammals. It is called a **pulmocutaneous circuit** if it includes capillaries in both the lungs and the skin, as in many amphibians.

After the oxygen-enriched blood leaves the gas exchange tissues, it enters the other pump, the left side of the heart. Contraction of the heart propels this blood to capillary beds in organs and tissues throughout the body. Following the exchange of O_2 and CO_2, as well as nutrients and waste products, the

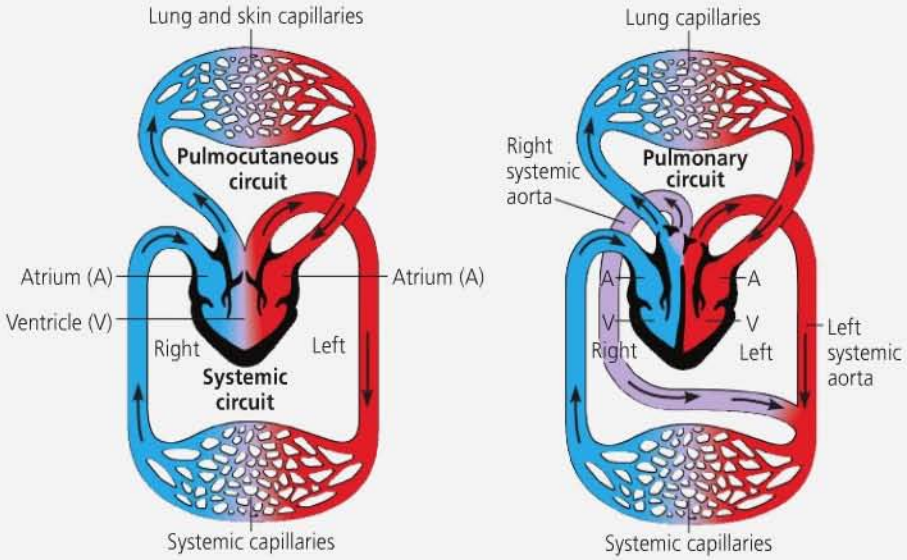
▼ Figure 42.5

Exploring Double Circulation in Vertebrates

Amphibians

Amphibians have a three-chambered heart and two circuits of blood flow: pulmocutaneous and systemic.

Reptiles (Except Birds)



Lizards, snakes, and turtles have a three-chambered heart, with a septum partially dividing the single ventricle. In crocodilians, the septum is complete and the heart is four-chambered.

Mammals and Birds

Mammals and birds have a four-chambered heart. In birds, the major vessels near the heart are slightly different than shown, but the pattern of double circulation is essentially the same.

Systemic circuits include all body tissues except the primary gas exchange tissues. Note that circulatory systems are depicted as if the animal is facing you: The right side of the heart is shown on the left, and vice versa.

now oxygen-poor blood returns to the heart, completing the **systemic circuit**.

Double circulation provides a vigorous flow of blood to the brain, muscles, and other organs because the heart repressurizes the blood destined for these tissues after it passes through the capillary beds of the lungs or skin. Indeed, blood pressure is often much higher in the systemic circuit than in the gas exchange circuit. This contrasts sharply with single circulation, in which, as you read earlier, blood flows directly from the respiratory organs to other organs, under reduced pressure.

Adaptations of Double Circulatory Systems

Having considered the general properties of double circulation, let's examine the adaptations found in the hearts of different vertebrate groups that have this type of circulation. As you read, refer to the illustrations in Figure 42.5.

Amphibians Frogs and other amphibians have a heart with three chambers: two atria and one ventricle. A ridge within the ventricle diverts most (about 90%) of the oxygen-poor blood from the right atrium into the pulmocutaneous circuit and most of the oxygen-rich blood from the left atrium into the systemic circuit. When underwater, a frog adjusts its circulation, for the most part shutting off blood flow to its temporarily ineffective lungs. Blood flow continues to the skin, which acts as the sole site of gas exchange while the frog is submerged.

Reptiles (Except Birds) Turtles, snakes, and lizards have a three-chambered heart, with a septum partially dividing the ventricle into separate right and left chambers. In alligators, caimans, and other crocodilians, the septum is complete, but the pulmonary and systemic circuits are connected where the arteries exit the heart. When a crocodilian is underwater, arterial valves divert most of the blood flow from the pulmonary circuit to the systemic circuit through this connection.

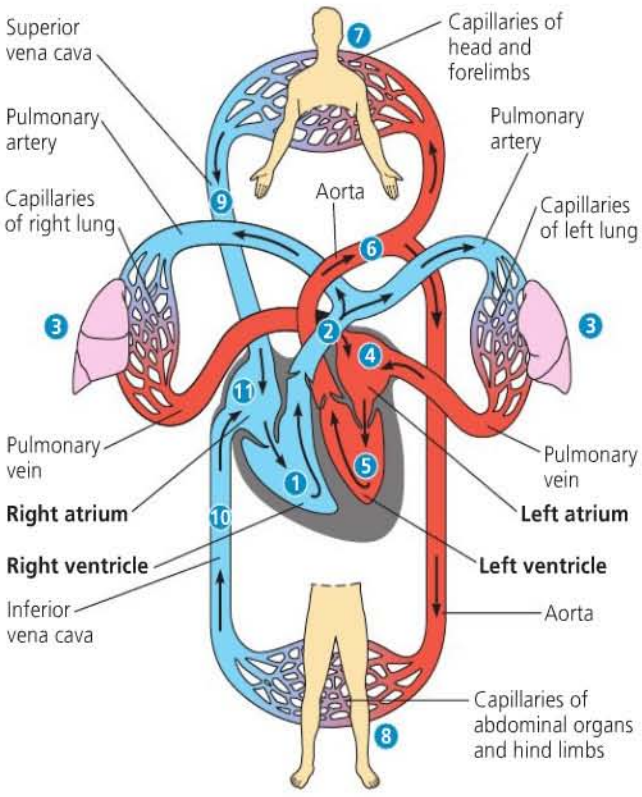
Mammals and Birds In all mammals and birds, the ventricle is completely divided, such that there are two atria and two ventricles. The left side of the heart receives and pumps only

oxygen-rich blood, while the right side receives and pumps only oxygen-poor blood.

A powerful four-chambered heart is a key adaptation that supports the endothermic way of life characteristic of mammals and birds. Endotherms use about ten times as much energy as equal-sized ectotherms; therefore, their circulatory systems need to deliver about ten times as much fuel and O_2 to their tissues (and remove ten times as much CO_2 and other wastes). This large traffic of substances is made possible by separate and independently powered systemic and pulmonary circuits and by large hearts that pump the necessary volume of blood. As we discussed in Chapter 34, mammals and birds descended from different tetrapod ancestors, and their four-chambered hearts evolved independently—an example of convergent evolution.

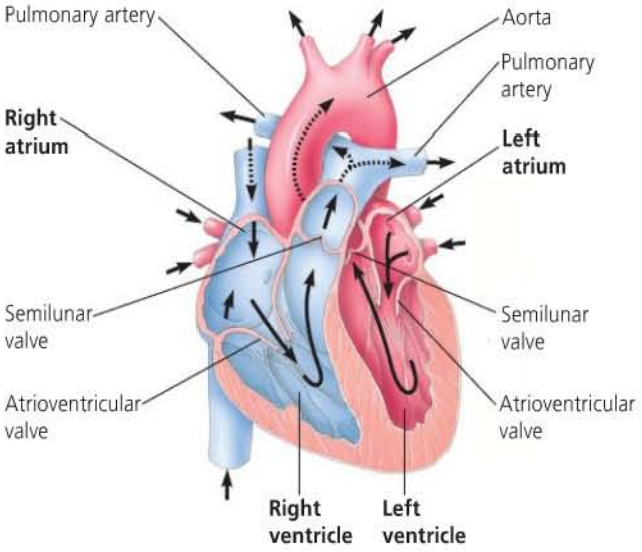
CONCEPT CHECK 42.1

1. How is the flow of hemolymph through an open circulatory system similar to the flow of water through an outdoor fountain?
2. Three-chambered hearts with incomplete septa were once viewed as being less adapted to circulatory function than mammalian hearts. What advantage of such hearts did this viewpoint overlook?
3. **WHAT IF?** The heart of a human fetus has a hole between the left and right ventricles. In some cases, this hole does not close completely before birth. If the hole weren't surgically corrected, how would it affect the O_2 content of the blood entering the systemic circuit from the heart?



For suggested answers, see Appendix A.

CONCEPT 42.2 Coordinated cycles of heart contraction drive double circulation in mammals



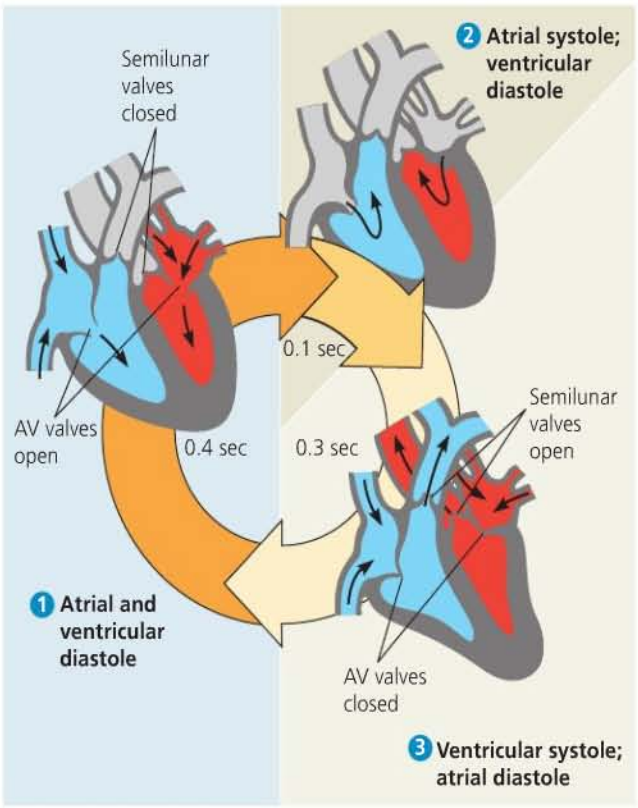
The timely delivery of O_2 to the body's organs is critical: Brain cells, for example, die within just a few minutes if their O_2 supply is interrupted. How does the mammalian cardiovascular system meet the body's continuous but variable demand for O_2? To answer this question, we need to consider how the parts of the system are arranged and how each part functions.

Mammalian Circulation

Let's first examine the overall organization of the mammalian cardiovascular system, beginning with the pulmonary circuit. (The circled numbers refer to corresponding locations in **Figure 42.6**). ❶ Contraction of the right ventricle pumps blood to the lungs via ❷ the pulmonary arteries. As the blood flows through ❸ capillary beds in the left and right lungs, it loads O_2 and unloads CO_2. Oxygen-rich blood returns from the lungs via the pulmonary veins to ❹ the left atrium of the heart. Next, the oxygen-rich blood flows into ❺ the left ventricle, which pumps the oxygen-rich blood out to body tissues through the systemic circuit. Blood leaves the left ventricle via ❻ the aorta, which conveys blood to arteries leading throughout the body. The first branches from the aorta are the coronary arteries (not shown), which supply blood to the heart muscle itself. Then branches lead to ❼ capillary beds in the head and arms (forelimbs). The aorta then descends into the abdomen, supplying oxygen-rich blood to arteries leading to ❽ capillary beds in the abdominal organs and legs (hind limbs). Within the capillaries, there is a net diffusion of O_2 from the blood to the tissues and of CO_2 produced by cellular respiration into the blood. Capillaries rejoin, forming venules, which convey blood to veins. Oxygen-poor blood from the head, neck, and forelimbs is channeled into a large vein, ❾ the superior vena cava. Another large vein, ❿ the inferior vena cava, drains blood from the trunk and hind limbs. The two venae cavae empty their blood into ⓫ the right atrium, from which the oxygen-poor blood flows into the right ventricle.

▲ **Figure 42.6 The mammalian cardiovascular system: an overview.** Note that the dual circuits operate simultaneously, not in the serial fashion that the numbering in the diagram suggests. The two ventricles pump almost in unison; while some blood is traveling in the pulmonary circuit, the rest of the blood is flowing in the systemic circuit.

▲ **Figure 42.7 The mammalian heart: a closer look.** Notice the locations of the valves, which prevent backflow of blood within the heart. Also notice how the atria and left and right ventricles differ in the thickness of their muscular walls.



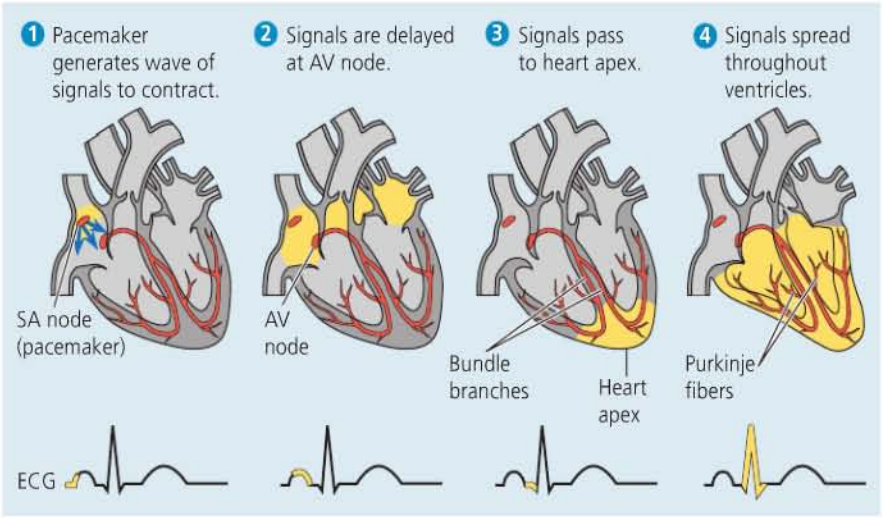
The Mammalian Heart: *A Closer Look*

Using the human heart as an example, let's now take a closer look at how the mammalian heart works (Figure 42.7). Located behind the sternum (breastbone), the human heart is about the size of a clenched fist and consists mostly of cardiac muscle (see Figure 40.5). The two atria have relatively thin walls and serve as collection chambers for blood returning to the heart. Much of the blood entering the atria flows into the ventricles while all heart chambers are relaxed. Contraction of the atria transfers the remainder before the ventricles begin to contract. The ventricles have thicker walls and contract much more forcefully than the atria—especially the left ventricle, which pumps blood to all body organs through the systemic circuit. Although the left ventricle contracts with greater force than the right ventricle, it pumps the same volume of blood as the right ventricle during each contraction.

The heart contracts and relaxes in a rhythmic cycle. When it contracts, it pumps blood; when it relaxes, its chambers fill with blood. One complete sequence of pumping and filling is referred to as the **cardiac cycle**. The contraction phase of the cycle is called **systole**, and the relaxation phase is called **diastole** (Figure 42.8). The volume of blood each ventricle pumps per minute is the **cardiac output**. Two factors determine cardiac output: the rate of contraction, or **heart rate** (number of beats per minute), and the **stroke volume**, the amount of blood pumped by a ventricle in a single contraction. The average stroke volume in humans is about 70 mL. Multiplying this stroke volume by a resting heart rate of 72 beats per minute yields a cardiac output of 5 L/min—about equal to the total volume of blood in the human body. During heavy exercise, cardiac output increases as much as fivefold.

Four valves in the heart prevent backflow and keep blood moving in the correct direction (see Figures 42.7 and 42.8). Made of flaps of connective tissue, the valves open when pushed from one side and close when pushed from the other. An **atrioventricular (AV) valve** lies between each atrium and ventricle. The AV valves are anchored by strong fibers that prevent them from turning inside out. Pressure generated by the powerful contraction of the ventricles closes the AV valves, keeping blood from flowing back into the atria. **Semilunar valves** are located at the two exits of the heart: where the aorta leaves the left ventricle and where the pulmonary artery leaves the right ventricle. These valves are pushed open by the pressure generated during contraction of the ventricles. When the ventricles relax, pressure built up in the aorta closes the semilunar valves and prevents significant backflow. You can follow these events either with a stethoscope or by pressing your ear tightly against the chest of a friend (or a friendly dog). The sound pattern is "lub-dup, lub-dup, lub-dup." The first heart sound ("lub") is created by the recoil of blood against the closed AV valves. The second sound ("dup") is produced by the recoil of blood against the closed semilunar valves.

If blood squirts backward through a defective valve, it may produce an abnormal sound called a **heart murmur**. Some



▲ **Figure 42.8 The cardiac cycle.** For an adult human at rest with a heart rate of about 72 beats per minute, one complete cardiac cycle takes about 0.8 second. 1 During a relaxation phase (atria and ventricles in diastole), blood returning from the large veins flows into the atria and ventricles through the AV valves. 2 A brief period of atrial systole then forces all blood remaining in the atria into the ventricles. 3 During the remainder of the cycle, ventricular systole pumps blood into the large arteries through the semilunar valves. Note that during all but 0.1 second of the cardiac cycle, the atria are relaxed and are filling with blood returning via the veins.

people are born with heart murmurs; in others, the valves may be damaged by infection (from rheumatic fever, for instance). When a valve defect is severe enough to endanger health, surgeons may implant a mechanical replacement valve. However, not all heart murmurs are caused by a defect, and most valve defects do not reduce the efficiency of blood flow enough to warrant surgery.

Maintaining the Heart's Rhythmic Beat

In vertebrates, the heartbeat originates in the heart itself. Some cardiac muscle cells are autorhythmic, meaning they contract and relax repeatedly without any signal from the nervous system. You can even see these rhythmic contractions in tissue that has been removed from the heart and placed in a dish in the laboratory! Because each of these cells has its own intrinsic contraction rhythm, how are their contractions coordinated in the intact heart? The answer lies in a group of autorhythmic cells located in the wall of the right atrium, near where the superior vena cava enters the heart. This cluster of cells is called the **sinoatrial (SA) node**, or *pacemaker*, and it sets the rate and timing at which all cardiac muscle cells contract. (In contrast to vertebrates, some arthropods have pacemakers located in the nervous system, outside the heart.)

▲ **Figure 42.9 The control of heart rhythm.** The sequence of electrical events in the heart is shown at the top; the corresponding components of an electrocardiogram (ECG) are highlighted below in gold. In step 4, the portion of the ECG to the right of the gold "spike" represents electrical activity that reprimes the ventricles for the next round of contraction.

The SA node generates electrical impulses much like those produced by nerve cells. Because cardiac muscle cells are electrically coupled through gap junctions (see Figure 6.32), impulses from the SA node spread rapidly within heart tissue. In addition, these impulses generate currents that are conducted to the skin via body fluids. The medical test called an **electrocardiogram** (**ECG** or, sometimes, **EKG**) uses electrodes placed on the skin to detect and record these currents. The resulting graph has a characteristic shape that represents the stages in the cardiac cycle **(Figure 42.9)**.

Impulses from the SA node first spread rapidly through the walls of the atria, causing both atria to contract in unison. During atrial contraction, the impulses originating at the SA node reach other autorhythmic cells that are located in the wall between the left and right atria. These cells form a relay point called the **atrioventricular (AV) node**. Here the impulses are delayed for about 0.1 second before spreading to the walls of the ventricles. This delay allows the atria to empty completely before the ventricles contract. Then, the signals from the AV node are conducted throughout the ventricular walls by specialized muscle fibers called bundle branches and Purkinje fibers.

Physiological cues alter heart tempo by regulating the SA node. Two sets of nerves, the sympathetic and parasympathetic nerves, are largely responsible for this regulation. These nerves function like the spurs and reins used in riding a horse: One set speeds up the pacemaker, and the other set slows it down. For example, when you stand up and start walking, the sympathetic nerves increase your heart rate, an adaptation that enables your circulatory system to provide the additional O_2 needed by the muscles that are powering your activity. If you then sit down and relax, the parasympathetic nerves decrease your heart rate, an adaptation that conserves energy. Hormones secreted into the blood also influence the pacemaker. For instance, epinephrine, the "fight-or-flight" hormone secreted by the adrenal glands, causes the heart rate to increase. A third type of input that affects the pacemaker is body temperature. An increase of only 1°C raises the heart rate by about 10 beats per minute. This is the reason your heart beats faster when you have a fever.

Having examined the operation of the circulatory pump, we turn in the next section to the forces and structures that influence blood flow in the vessels of each circuit.

CONCEPT CHECK 42.2

1. Explain why blood in the pulmonary veins has a higher O_2 concentration than blood in the venae cavae, which are also veins.
2. Why is it important that the AV node delay the electrical impulse moving from the SA node and the atria to the ventricles?
3. **WHAT IF?** After exercising regularly for several months, you find that your resting heart rate has decreased. Given that your body now requires fewer cardiac cycles in a given time, what other change in the function of your heart at rest would you expect to find? Explain.

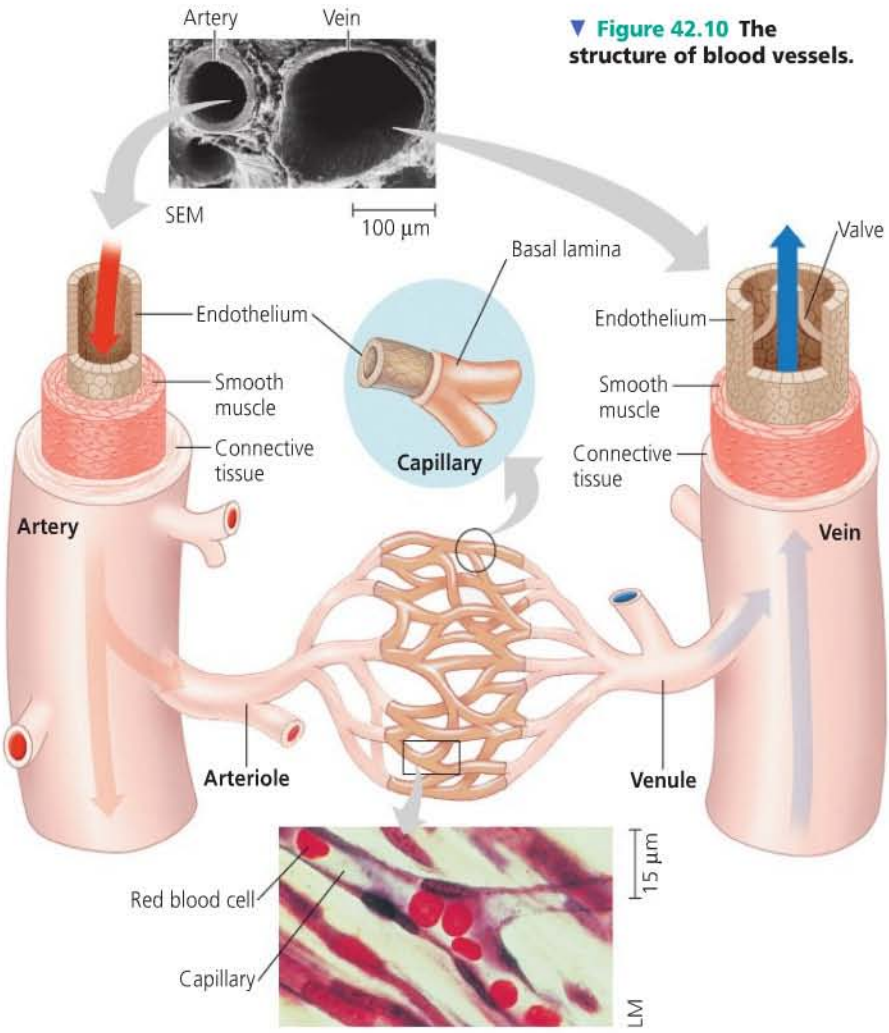
For suggested answers, see Appendix A.

CONCEPT 42.3

Patterns of blood pressure and flow reflect the structure and arrangement of blood vessels

The vertebrate circulatory system enables blood to deliver oxygen and nutrients and remove wastes throughout the body. In doing so, the circulatory system relies on a branching network of vessels much like the plumbing system that delivers fresh water to a city and removes its wastes. Furthermore, the same physical principles that govern the operation of plumbing systems apply to the functioning of blood vessels.

Blood Vessel Structure and Function

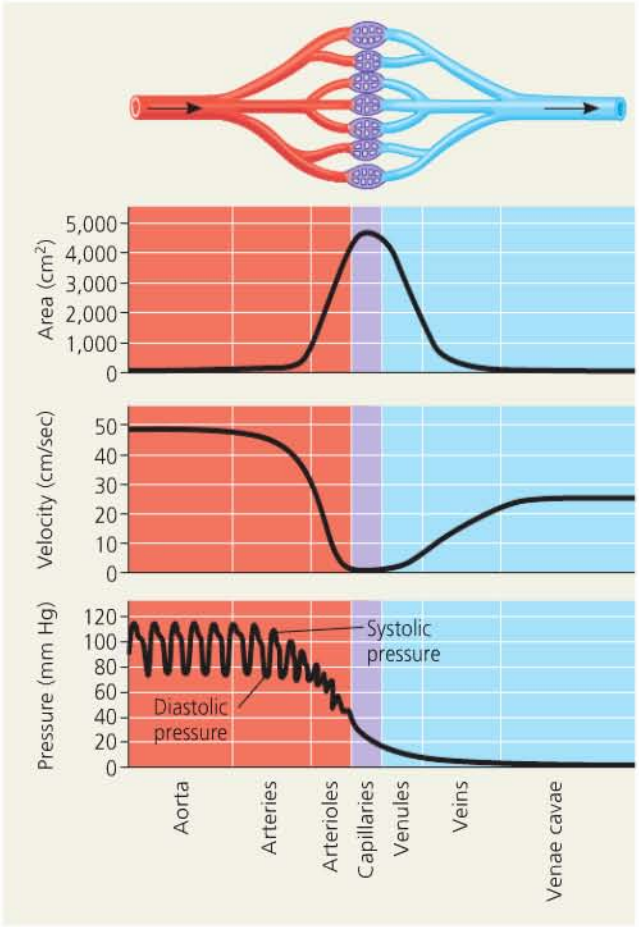


Blood vessels contain a central lumen (cavity) lined with an **endothelium**, a single layer of flattened epithelial cells. The smooth surface of the endothelium minimizes resistance to the flow of blood. Surrounding the endothelium are layers of tissue that differ among capillaries, arteries, and veins, reflecting the specialized functions of these vessels.

Capillaries are the smallest blood vessels, having a diameter only slightly greater than that of a red blood cell **(Figure 42.10)**. Capillaries also have very thin walls, which consist of just the endothelium and its basal lamina. This structural organization facilitates the exchange of substances between the blood in capillaries and the interstitial fluid.

The walls of arteries and veins have a more complex organization than those of capillaries. Both arteries and veins have two layers of tissue surrounding the endothelium: an outer layer of connective tissue containing elastic fibers, which allow the vessel to stretch and recoil, and a middle layer containing smooth muscle and more elastic fibers. However, arteries and veins differ in important ways. For a given blood vessel diameter, an artery has a wall about three times as thick as that of a vein (see Figure 42.10). The thicker walls of arteries are very strong, accommodating blood pumped at high pressure by the heart, and their elastic recoil helps maintain blood pressure when the heart relaxes between contractions. Signals from the nervous system and hormones circulating in the blood act on the smooth muscles in arteries, controlling blood flow to different parts of the body. The thinner-walled veins convey blood back to the heart at a lower velocity and pressure. Valves in the veins maintain a unidirectional flow of blood in these vessels (see Figure 42.10).

Blood Flow Velocity



To understand how blood vessel diameter influences blood flow, consider how water flows through a thick hose connected to a faucet. When the faucet is turned on, water flows at the same velocity everywhere in the hose. However, if a narrow nozzle is attached to the end of the hose, the water will exit the nozzle at a much greater velocity. Because water doesn't compress under pressure, the volume of water moving through the nozzle in a given time must be the same as the volume moving through the rest of the hose. The cross-sectional area of the nozzle is smaller than that of the hose, so the water speeds up in the nozzle.

▼ **Figure 42.10 The structure of blood vessels.**

An analogous situation exists in the circulatory system, but blood *slows* as it moves from arteries to arterioles to capillaries. Why? The reason is that the number of capillaries is enormous. Each artery conveys blood to so many capillaries that the *total* cross-sectional area is much greater in capillary beds than in the arteries or any other part of the circulatory system **(Figure 42.11)**. The result is a dramatic decrease in velocity from the arteries to the capillaries: Blood travels 500 times slower in the capillaries (about 0.1 cm/sec) than in the aorta (about 48 cm/sec).

The reduced velocity of blood flow in capillaries is critical to the function of the circulatory system. Capillaries are the only vessels with walls thin enough to permit the transfer of substances between the blood and interstitial fluid. The slower flow of blood through these tiny vessels allows time for exchange to occur. After passing through the capillaries, the blood speeds up as it enters the venules and veins, which have smaller total cross-sectional areas (see Figure 42.11).

▲ **Figure 42.11 The interrelationship of cross-sectional area of blood vessels, blood flow velocity, and blood pressure.** Owing to an increase in total cross-sectional area, blood flow velocity decreases markedly in the arterioles and is lowest in the capillaries. Blood pressure, the main force driving blood from the heart to the capillaries, is highest in the aorta and other arteries.

Blood Pressure

Blood, like all fluids, flows from areas of higher pressure to areas of lower pressure. Contraction of a heart ventricle generates blood pressure, which exerts a force in all directions. The force directed lengthwise in an artery causes the blood to flow away from the heart, the site of highest pressure. The force exerted against the elastic wall of an artery stretches the wall, and the recoil of arterial walls plays a critical role in maintaining blood pressure, and hence blood flow, throughout the cardiac cycle. Once the blood enters the millions of tiny arterioles and capillaries, the narrow diameter of these vessels generates substantial resistance to flow. This resistance dissipates much of the pressure generated by the pumping heart by the time the blood enters the veins.

Changes in Blood Pressure During the Cardiac Cycle

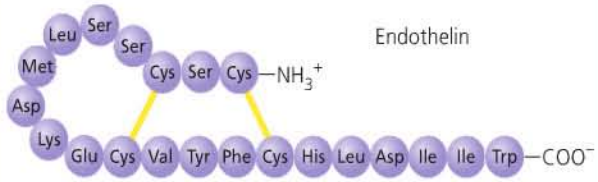
Arterial blood pressure is highest when the heart contracts during ventricular systole. The pressure at this time is called **systolic pressure** (see Figure 42.11). The spikes in blood pressure caused by the powerful contractions of the ventricles stretch the arteries. By placing your fingers on your wrist, you can feel a **pulse**—the rhythmic bulging of the artery walls with each heartbeat. The surge of pressure is partly due to the narrow openings of arterioles impeding the exit of blood from the arteries. Thus, when the heart contracts, blood enters the arteries faster than it can leave, and the vessels stretch from the rise in pressure. During diastole, the elastic walls of the arteries snap back. As a consequence, there is a lower but still substantial blood pressure when the ventricles are relaxed (**diastolic pressure**). Before enough blood has flowed into the arterioles to completely relieve pressure in the arteries, the heart contracts again. Because the arteries remain pressurized throughout the cardiac cycle (see Figure 42.11), blood continuously flows into arterioles and capillaries.

Regulation of Blood Pressure

Blood pressure fluctuates over two different time scales. The first is the oscillation in arterial blood pressure during each cardiac cycle (see bottom graph in Figure 42.11). Blood pressure also fluctuates on a longer time scale in response to signals that change the state of smooth muscles in arteriole walls. For example, physical or emotional stress can trigger nervous and hormonal responses that cause smooth muscles in arteriole walls to contract, a process called **vasoconstriction**. When that happens, the arterioles narrow, thereby increasing blood pressure upstream in the arteries. When the smooth muscles relax, the arterioles undergo **vasodilation**, an increase in diameter that causes blood pressure in the arteries to fall.

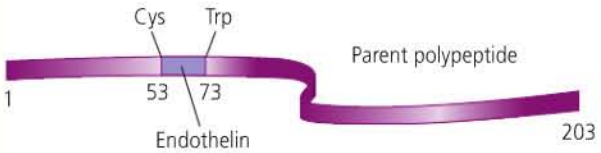
Vasoconstriction and vasodilation are often coupled to changes in cardiac output that also affect blood pressure. This

coordination of regulatory mechanisms maintains adequate blood flow as the body's demands on the circulatory system change. During heavy exercise, for example, the arterioles in working muscles dilate, causing a greater flow of oxygen-rich blood to the muscles. By itself, this increased flow to the muscles would cause a drop in blood pressure (and therefore blood flow) in the body as a whole. However, cardiac output increases at the same time, maintaining blood pressure and supporting the necessary increase in blood flow.



Recent experiments have identified the molecules that serve as signals for vasodilation and vasoconstriction. Three scientists in the United States—Robert Furchgott, Louis Ignarro, and Ferid Murad—demonstrated that the gas nitric oxide (NO) serves as a major inducer of vasodilation in the cardiovascular system. Their research was honored with a Nobel Prize in 1998. Independent studies by Masashi Yanagisawa, then a graduate student at the University of Tsukuba in Japan, identified a peptide, **endothelin**, as a potent inducer of vasoconstriction **(Figure 42.12)**. As discussed in the interview with Dr. Yanagisawa on pages 850–851, his findings led to fundamental discoveries about signals that regulate not only blood vessel diameter but also the embryonic development of the digestive system.

▼ Figure 42.12 Inquiry



How do endothelial cells control vasoconstriction?

EXPERIMENT In 1988, Masashi Yanagisawa set out to identify the endothelial factor that triggers vasoconstriction in mammals. He isolated endothelial cells from blood vessels and grew them in liquid medium. Then he collected the liquid, which contained substances secreted by the cells. Next, he bathed a small piece of an artery in the liquid. The artery tissue contracted, indicating that the cells grown in culture had secreted a factor that causes vasoconstriction. Using biochemical procedures, Yanagisawa separated the substances in the fluid on the basis of size, charge, and other properties. He then tested each substance for its ability to cause arterial contraction. After several separation steps and many tests, he purified the vasoconstriction factor.

RESULTS The vasoconstriction factor, which Yanagisawa named **endothelin**, is a peptide that contains 21 amino acids. Two disulfide bridges between cysteines stabilize the peptide structure.

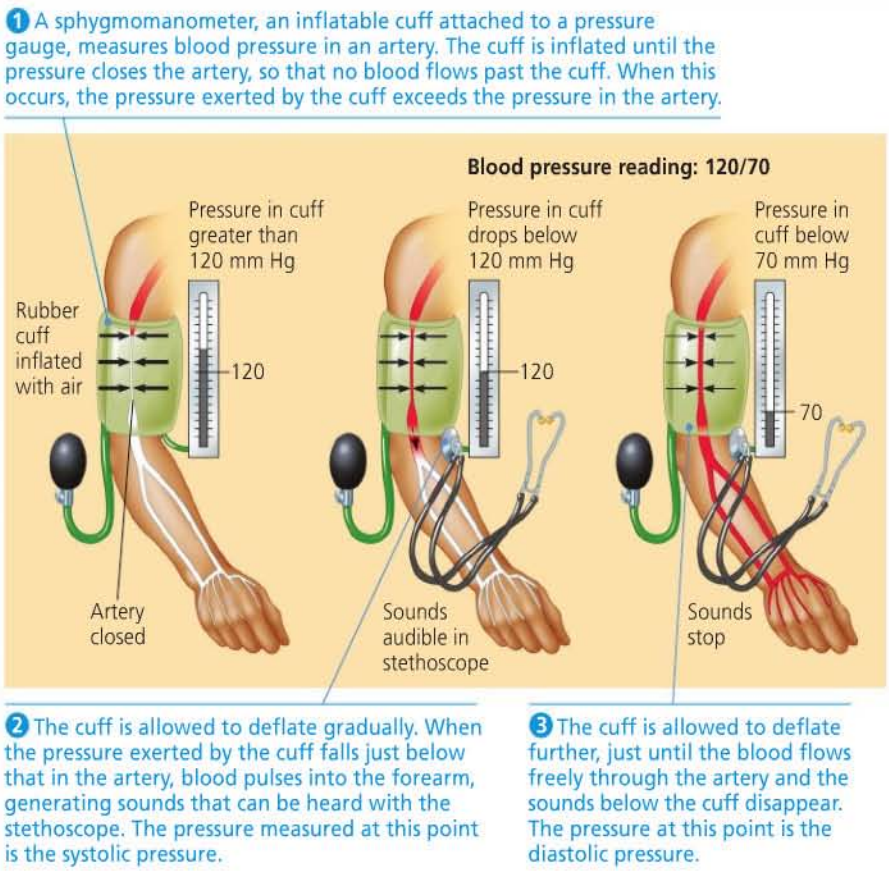
Using the amino acid sequence of the peptide as a guide, Yanagisawa identified the endothelin gene. The polypeptide encoded by the gene is much longer than endothelin, containing 203 amino acids. The amino acids in endothelin extend from position 53 (Cys) to position 73 (Trp) in the longer polypeptide:

Yanagisawa also showed that treating endothelial cells with other substances already known to promote vasoconstriction, such as the hormone epinephrine, led to increased production of endothelin mRNA.

CONCLUSION Endothelial cells produce and translate endothelin mRNA in response to signals, such as hormones, that circulate in the blood. The resulting polypeptide is cleaved to form active endothelin, the substance that triggers vasoconstriction. Yanagisawa and colleagues subsequently demonstrated that endothelial cells also make the enzyme that catalyzes this cleavage.

SOURCE M. Yanagisawa et al., A novel potent vasoconstrictor peptide produced by vascular endothelial cells, *Nature* 332:411–415 (1988).

WHAT IF? Given what you know about epithelial tissue organization (see Figure 40.5) and the function of endothelin, what would you predict about the location of endothelin secretion with regard to endothelial cell surfaces?

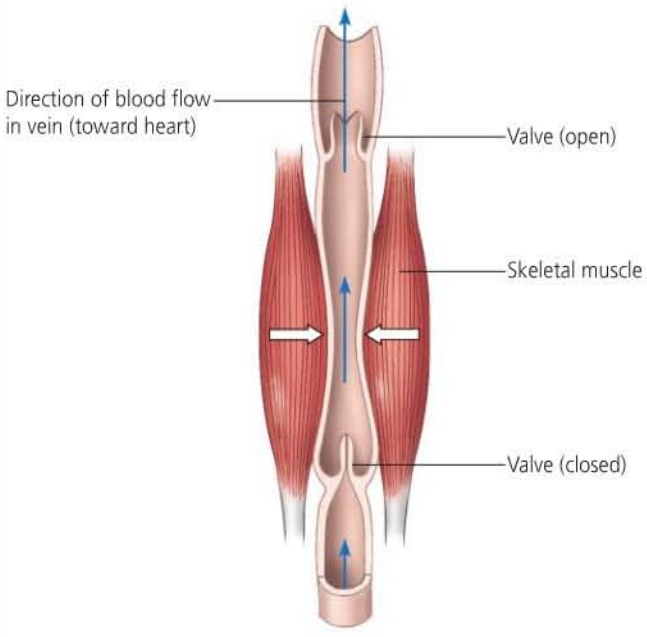


Blood Pressure and Gravity

Blood pressure is generally measured for an artery in the arm at the same height as the heart **(Figure 42.13)**. For a healthy 20-year-old human at rest, arterial blood pressure in the systemic circuit is typically about 120 millimeters of mercury (mm Hg) at systole and 70 mm Hg at diastole, a combination designated 120/70. (Arterial blood pressure in the pulmonary circuit is six to ten times lower.)

Gravity has a significant effect on blood pressure. When you are standing, for example, your head is roughly 0.35 m higher than your chest, and the arterial blood pressure in your brain is about 27 mm Hg less than that near your heart. If the blood pressure in your brain is too low to provide adequate blood flow, you will likely faint. By causing your body to collapse to the ground, fainting effectively places your head at the level of your heart, quickly increasing blood flow to your brain.

The challenge of pumping blood against gravity is particularly great for animals with very long necks. A giraffe, for example, requires a systolic pressure of more than 250 mm Hg near the heart. When a giraffe lowers its head to drink, one-way valves and sinuses, along with feedback mechanisms that reduce cardiac output, prevent this high pressure from damaging its brain. We can calculate that a dinosaur with a neck nearly 10 m long would have required even greater systolic pressure—nearly 760 mm Hg—to pump blood to its brain when its head was fully raised. However, calculations based on anatomy and inferred metabolic rate suggest that dinosaurs did not have a heart powerful enough to generate such high pressure. Based on this evidence as well as studies of neck bone structure, some biologists have concluded that the long-necked dinosaurs fed close to the ground rather than on high foliage.

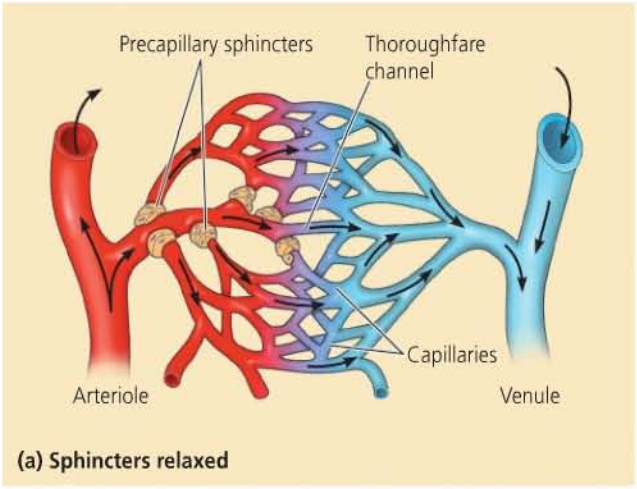


Gravity is also a consideration for blood flow in veins, especially those in the legs. Although blood pressure in veins is relatively low, several mechanisms assist the return of venous blood to the heart. First, rhythmic contractions of smooth muscles in

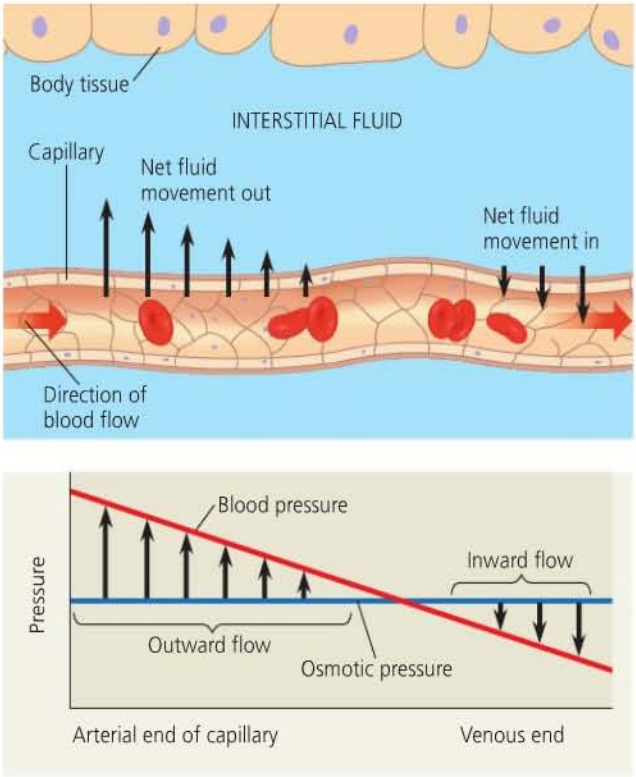
▲ **Figure 42.13 Measurement of blood pressure.** Blood pressure is recorded as two numbers separated by a slash. The first number is the systolic pressure; the second is the diastolic pressure.

the walls of venules and veins aid in the movement of the blood. Second, and more important, the contraction of skeletal muscles during exercise squeezes blood through the veins toward the heart **(Figure 42.14)**. This is why periodically walking up and down the aisle during a long airplane flight helps prevent potentially dangerous blood clots from forming in veins. Third, the change in pressure within the thoracic (chest) cavity during inhalation causes the venae cavae and other large veins near the heart to expand and fill with blood.

In rare instances, runners and other athletes can suffer heart failure if they stop vigorous exercise abruptly. When the leg muscles suddenly cease contracting and relaxing, less blood returns to the heart, which continues to beat rapidly. If the heart is weak or damaged, this inadequate blood flow may cause the heart to malfunction. To reduce the risk of stressing the heart excessively, athletes are encouraged to follow hard exercise with moderate activity, such as walking, to "cool down" until their heart rate approaches its resting level.



▲ **Figure 42.14 Blood flow in veins.** Skeletal muscle contraction squeezes and constricts veins. Flaps of tissue within the veins act as one-way valves that keep blood moving only toward the heart. If you sit or stand too long, the lack of muscular activity may cause your feet to swell as blood pools in your veins.



Capillary Function

At any given time, only about 5–10% of the body's capillaries have blood flowing through them. However, each tissue has many capillaries, so every part of the body is supplied with blood at all times. Capillaries in the brain, heart, kidneys, and liver are usually filled to capacity, but at many other sites the blood supply varies over time as blood is diverted from one destination to another. For example, blood flow to the skin is regulated to help control body temperature, and blood supply to the digestive tract increases after a meal. During strenuous exercise, blood is diverted from the digestive tract and supplied more generously to skeletal muscles and skin. This is one reason why exercising heavily immediately after eating a big meal may cause indigestion.

Given that capillaries lack smooth muscles, how is blood flow in capillary beds altered? There are two mechanisms, both of which rely on signals that regulate flow into capillaries. One mechanism involves contraction of the smooth muscle in the wall of an arteriole, which reduces the vessel's diameter and decreases blood flow to the adjoining capillary beds. When the smooth muscle relaxes, the arterioles dilate, allowing blood to enter the capillaries. The other mechanism for altering flow,

▲ **Figure 42.15 Blood flow in capillary beds.** Precapillary sphincters regulate the passage of blood into capillary beds. Some blood flows directly from arterioles to venules through capillaries called thoroughfare channels, which are always open.

▲ **Figure 42.16 Fluid exchange between capillaries and the interstitial fluid.** This diagram shows a hypothetical capillary in which osmotic pressure is constant along its length. At the arterial end, where blood pressure exceeds osmotic pressure, fluid flows out of the capillary into the interstitial fluid. At the venous end, the blood pressure is less than osmotic pressure, and fluid flows from the interstitial fluid into the capillary. In many capillaries, blood pressure may be higher or lower than osmotic pressure throughout the entire length of the capillary.

shown in **Figure 42.15**, involves the action of *precapillary sphincters*, rings of smooth muscle located at the entrance to capillary beds. The signals that regulate blood flow include nerve impulses, hormones traveling throughout the bloodstream, and chemicals produced locally. For example, the chemical histamine released by cells at a wound site causes smooth muscle relaxation, dilating blood vessels and increasing blood flow. The dilated vessels also provide disease-fighting white blood cells greater access to invading microorganisms.

As you have read, the critical exchange of substances between the blood and interstitial fluid takes place across the thin endothelial walls of the capillaries. Some substances are carried across the endothelium in vesicles that form on one side by endocytosis and release their contents on the opposite side by exocytosis. Small molecules, such as O_2 and CO_2, simply diffuse across the endothelial cells or through the openings within and between adjoining cells. These openings also provide the route for transport of small solutes such as sugars, salts, and urea, as well as for bulk flow of fluid into tissues driven by blood pressure within the capillary.

While blood pressure tends to drive fluid out of the capillaries, the presence of blood proteins tends to pull fluid back into the capillaries. Many blood proteins (and all blood cells) are too large to pass readily through the endothelium, and they remain in the capillaries. The proteins, especially albumin, create an osmotic pressure difference between the capillary interior and the interstitial fluid. In places where the blood pressure is greater than the osmotic pressure difference, there is a net loss of fluid from the capillaries. In contrast, where the osmotic pressure difference exceeds the blood pressure, there is a net movement of fluid from the tissues into the capillaries **(Figure 42.16)**.

Fluid Return by the Lymphatic System

Throughout the body, only about 85% of the fluid that leaves the capillaries because of blood pressure reenters them as a result of osmotic pressure. Each day, this imbalance results in a loss of about 4 L of fluid from capillaries to the surrounding tissues. There is also some leakage of blood proteins, even though the capillary wall is not very permeable to large molecules. The lost fluid and proteins return to the blood via the **lymphatic system**, which

includes a network of tiny vessels intermingled among capillaries of the cardiovascular system. After entering the lymphatic system by diffusion, the fluid is called **lymph**; its composition is about the same as that of interstitial fluid. The lymphatic system drains into large veins of the circulatory system at the base of the neck (see Figure 43.7). As you read in Chapter 41, this joining of the lymphatic and circulatory systems functions in the transfer of lipids from the small intestine to the blood.

The movement of lymph from peripheral tissues to the heart relies on much the same mechanisms that assist blood flow in veins. Lymph vessels, like veins, have valves that prevent the backflow of fluid. Rhythmic contractions of the vessel walls help draw fluid into the small lymphatic vessels. In addition, skeletal muscle contractions play a role in moving lymph.

Disorders that interfere with the lymphatic system highlight its role in maintaining proper fluid distribution in the body. Disruptions in the movement of lymph often cause edema, swelling resulting from the excessive accumulation of fluid in tissues. Severe blockage of lymph flow, as occurs when certain parasitic worms lodge in lymph vessels, results in extremely swollen limbs or other body parts, a condition known as elephantiasis.

Along a lymph vessel are organs called **lymph nodes**. By filtering the lymph and by housing cells that attack viruses and bacteria, lymph nodes play an important role in the body's defense. Inside each lymph node is a honeycomb of connective tissue with spaces filled by white blood cells. When the body is fighting an infection, these cells multiply rapidly, and the lymph nodes become swollen and tender (which is why your doctor may check for swollen lymph nodes in your neck, armpits, or groin when you feel sick). Because lymph nodes have filtering and surveillance functions, doctors may examine the lymph nodes of cancer patients to detect the spread of diseased cells.

In recent years, evidence has appeared suggesting that the lymphatic system also has a role in harmful immune responses, such as those responsible for asthma. Because of these and other findings, the lymphatic system, largely ignored until the 1990s, has become a very active and promising area of biomedical research.

CONCEPT CHECK 42.3

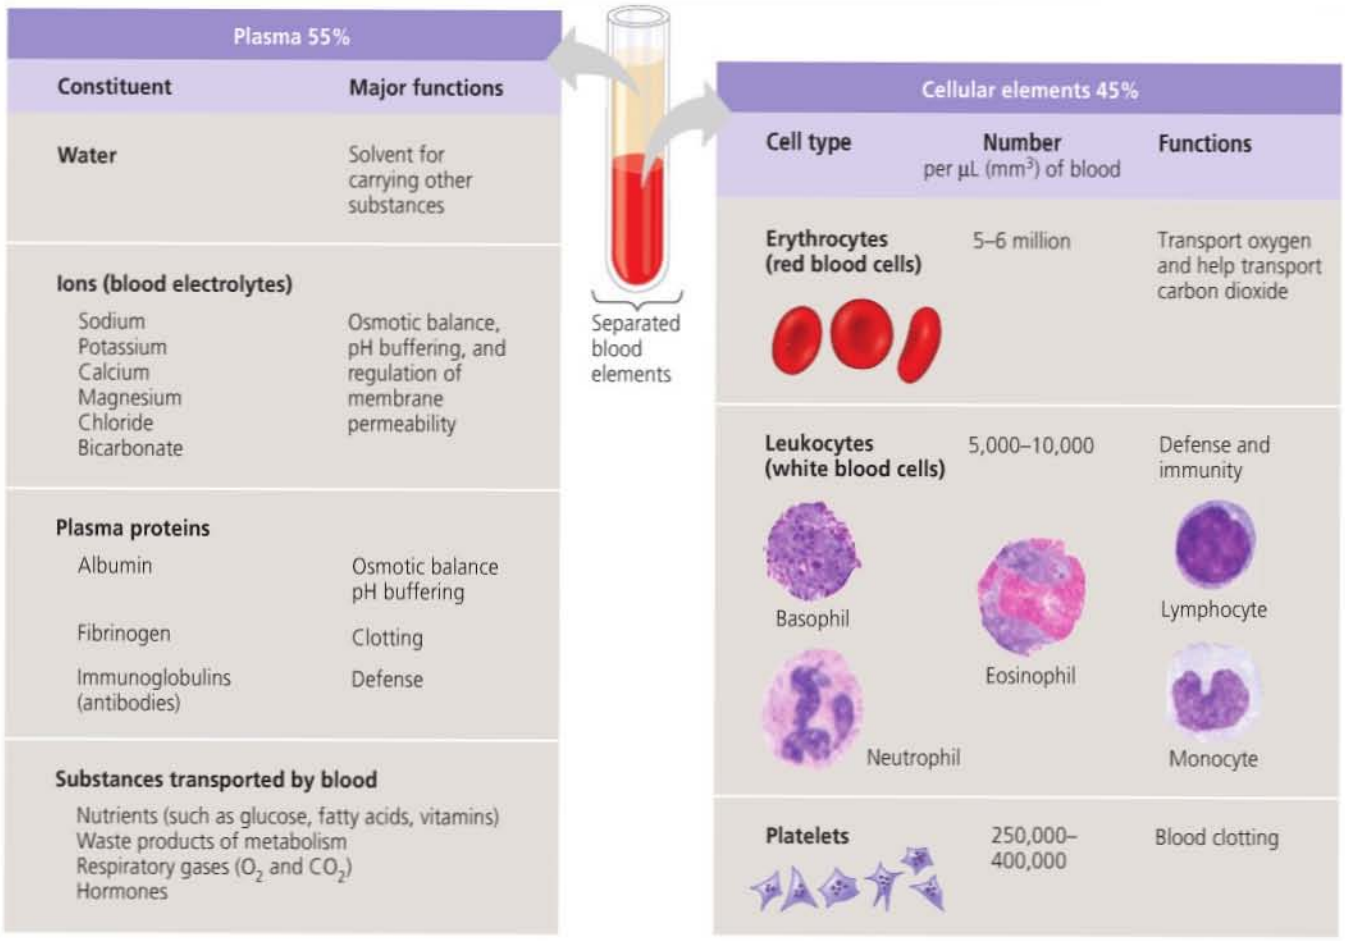
1. What is the primary cause of the low velocity of blood flow through capillaries?
2. What short-term changes in cardiovascular function might best enable skeletal muscles to help an animal escape from a dangerous situation?
3. **WHAT IF?** If you had additional hearts distributed throughout your body, what would be one likely advantage and one likely disadvantage?

For suggested answers, see Appendix A.

CONCEPT 42.4 Blood components function in exchange, transport, and defense

As we discussed earlier, the fluid transported by an open circulatory system is continuous with the fluid that surrounds all of the body cells and therefore has the same composition. In contrast, the fluid in a closed circulatory system can be much more highly specialized, as is the case for the blood of vertebrates.

Blood Composition and Function



Vertebrate blood is a connective tissue consisting of cells suspended in a liquid matrix called **plasma**. Dissolved in the plasma are ions and proteins that, together with the blood cells, function in osmotic regulation, transport, and defense. Separating the components of blood using a centrifuge reveals that cellular elements (cells and cell fragments) occupy about 45% of the volume of blood (**Figure 42.17**, on the next page). The remainder is plasma.

Plasma

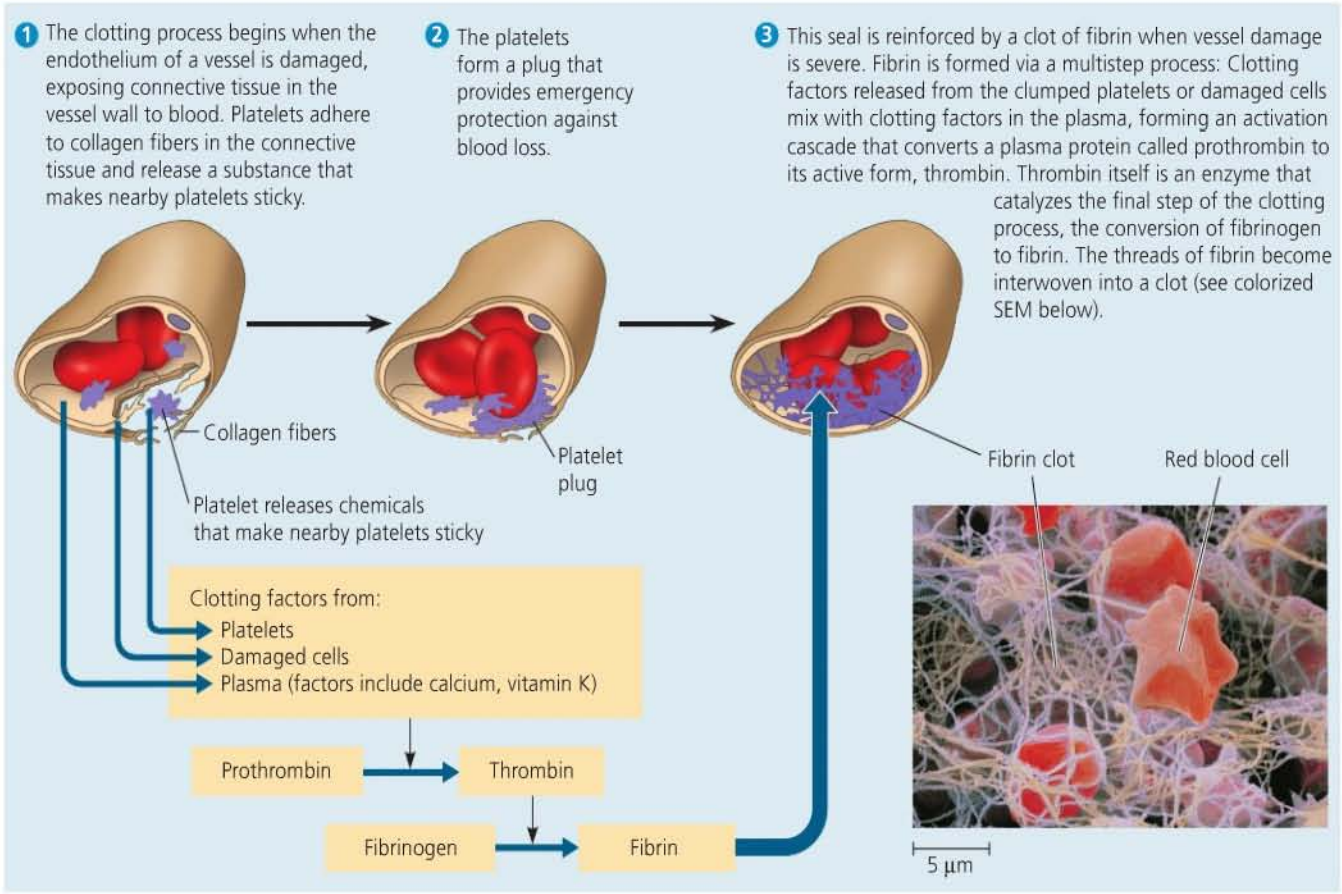
Among the many solutes in plasma are inorganic salts in the form of dissolved ions, sometimes referred to as blood electrolytes (see Figure 42.17). Although plasma is about 90% water, the dissolved salts are an essential component of the blood. Some of these ions buffer the blood, which in humans normally has a pH of 7.4. Salts are also important in maintaining the osmotic balance of the blood. In addition, the concentration of ions in plasma directly affects the composition of the interstitial fluid, where many of these ions have a vital role in muscle and nerve activity. To serve all of these functions, plasma electrolytes must be kept within narrow concentration ranges, a homeostatic function we will explore in Chapter 44.

Plasma proteins act as buffers against pH changes, help maintain the osmotic balance between blood and interstitial fluid, and contribute to the blood's viscosity (thickness). Particular plasma proteins have additional functions. The immunoglobulins, or antibodies, help combat viruses and other foreign agents that invade the body (see Chapter 43). Others are escorts for lipids, which are insoluble in water and can travel in blood only when bound to proteins. A third group of plasma proteins are clotting factors that help plug leaks when blood vessels are injured. (The term *serum* refers to blood plasma from which these clotting factors have been removed.)

Plasma also contains a wide variety of other substances in transit from one part of the body to another, including nutrients, metabolic wastes, respiratory gases, and hormones. Plasma has a much higher protein concentration than interstitial fluid, although the two fluids are otherwise similar. (Capillary walls, remember, are not very permeable to proteins.)

▲ **Figure 42.17 The composition of mammalian blood.**

Cellular Elements



Suspended in blood plasma are two classes of cells: red blood cells, which transport O_2, and white blood cells, which function in defense (see Figure 42.17). Blood also contains **platelets**, fragments of cells that are involved in the clotting process.

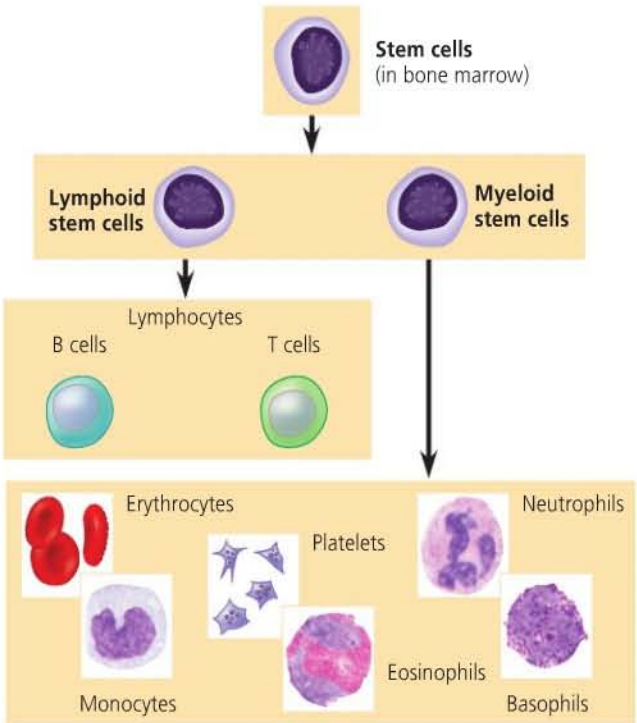
Erythrocytes Red blood cells, or **erythrocytes**, are by far the most numerous blood cells. Each microliter (µL, or mm^3) of human blood contains 5–6 million red cells, and there are about 25 trillion of these cells in the body's 5 L of blood. Their main function is O_2 transport, and their structure is closely related to this function. Human erythrocytes are small disks (7–8 µm in diameter) that are biconcave—thinner in the center than at the edges. This shape increases surface area, enhancing the rate of diffusion of O_2 across their plasma membranes. Mature mammalian erythrocytes lack nuclei. This unusual characteristic leaves more space in these tiny cells for **hemoglobin**, the iron-containing protein that transports O_2 (see Figure 5.21). Erythrocytes also lack mitochondria and generate their ATP exclusively by anaerobic metabolism. Oxygen transport would be less efficient if erythrocytes were aerobic and consumed some of the O_2 they carry.

Despite its small size, an erythrocyte contains about 250 million molecules of hemoglobin. Because each molecule of hemoglobin binds up to four molecules of O_2, one erythrocyte can transport about a billion O_2 molecules. As erythrocytes pass through the capillary beds of lungs, gills, or other respiratory organs, O_2 diffuses into the erythrocytes and binds to hemoglobin. In the systemic capillaries, O_2 dissociates from hemoglobin and diffuses into body cells.

Leukocytes The blood contains five major types of white blood cells, or **leukocytes**. Their function is to fight infections. Some are phagocytic, engulfing and digesting microorganisms as well as debris from the body's own dead cells. As we will see in Chapter 43, other leukocytes, called lymphocytes, develop into specialized B cells and T cells that mount immune responses against foreign substances. Normally, 1 µL of human blood contains about 5,000–10,000 leukocytes; their numbers increase temporarily whenever the body is fighting an infection. Unlike erythrocytes, leukocytes are also found outside the circulatory system, patrolling both interstitial fluid and the lymphatic system.

Platelets Platelets are pinched-off cytoplasmic fragments of specialized bone marrow cells. They are about 2–3 µm in diameter and have no nuclei. Platelets serve both structural and molecular functions in blood clotting.

▲ **Figure 42.18 Blood clotting.**



Blood Clotting

The occasional cut or scrape is not life-threatening because blood components seal the broken blood vessels. A break in a blood vessel wall exposes proteins that attract platelets and initiate coagulation, the conversion of liquid components of blood to a solid clot. The coagulant, or sealant, circulates in an inactive form called fibrinogen. Clotting involves the conversion of fibrinogen to its active form, **fibrin**, which aggregates into threads that form the framework of the clot. The formation of fibrin is the last step in a series of reactions triggered by the release of clotting factors from platelets **(Figure 42.18)**. A genetic mutation that affects any step of the clotting process causes hemophilia, a disease characterized by excessive bleeding and bruising from even minor cuts and bumps.

Anticlotting factors in the blood normally prevent spontaneous clotting in the absence of injury. Sometimes, however, clots form within a blood vessel, blocking the flow of blood. Such a clot is called a **thrombus**. We will explore how a thrombus forms and the danger that it poses later in this chapter.

Stem Cells and the Replacement of Cellular Elements

Erythrocytes, leukocytes, and platelets all develop from a common source: multipotent **stem cells** that are dedicated to replenishing the body's blood cell populations **(Figure 42.19)**.

▲ **Figure 42.19 Differentiation of blood cells.** Some of the multipotent stem cells differentiate into lymphoid stem cells, which then develop into B cells and T cells, two types of lymphocytes that function in the immune response (see Chapter 43). All other blood cells differentiate from myeloid stem cells.

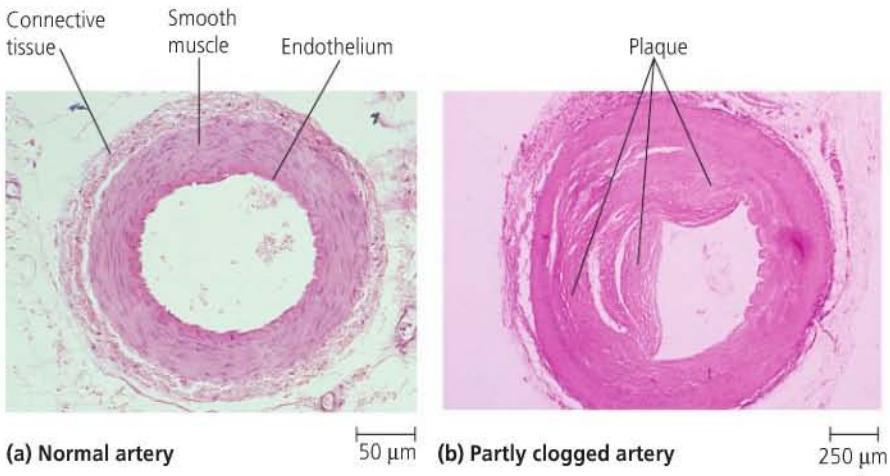
The stem cells that produce blood cells are located in the red marrow of bones, particularly the ribs, vertebrae, sternum, and pelvis. Multipotent stem cells are so named because they have the ability to form multiple types of cells—in this case, the myeloid and lymphoid cell lineages. When any stem cell divides, one daughter cell remains a stem cell while the other takes on a specialized function.

Throughout a person's life, erythrocytes, leukocytes, and platelets formed from stem cell divisions replace the worn-out cellular elements of blood. Erythrocytes, for example, usually circulate for only three to four months before being replaced; the old cells are consumed by phagocytic cells in the liver and spleen. The production of new erythrocytes involves recycling of materials, such as the use of iron scavenged from old erythrocytes in new hemoglobin molecules.

A negative-feedback mechanism, sensitive to the amount of O_2 reaching the body's tissues via the blood, controls erythrocyte production. If the tissues do not receive enough O_2, the kidneys synthesize and secrete a hormone called **erythropoietin (EPO)** that stimulates erythrocyte production. If the blood is delivering more O_2 than the tissues can use, the level of EPO falls and erythrocyte production slows. Physicians use synthetic EPO to treat people with health problems such as anemia, a condition of lower-than-normal hemoglobin levels. Some athletes inject themselves with EPO to increase their erythrocyte levels, although this practice, a form of blood doping, has been banned by the International Olympic Committee and other sports organizations. In recent years, a number of well-known runners and cyclists have tested positive for EPO-related drugs and have forfeited both their records and their right to participate in future competitions.

Cardiovascular Disease

More than half of all human deaths in the United States are caused by cardiovascular diseases—disorders of the heart and blood vessels. Cardiovascular diseases range from a minor disturbance of vein or heart valve function to a life-threatening disruption of blood flow to the heart or brain. The tendency to develop particular cardiovascular diseases is inherited but is also strongly influenced by lifestyle. Smoking, lack of exercise, and a diet rich in animal fat each increase the risk of a number of cardiovascular diseases.



Atherosclerosis

One reason cardiovascular diseases cause so many deaths is that they often aren't detected until they disrupt critical blood flow. An example is **atherosclerosis**, the hardening of the arteries by accumulation of fatty deposits. Healthy arteries have a smooth inner lining that reduces resistance to blood flow. Damage or infection can roughen the lining and lead to inflammation. Leukocytes are attracted to the damaged lining and begin to take up lipids, including cholesterol. A fatty deposit, called a plaque, grows steadily, incorporating fibrous connective tissue and additional cholesterol. As the plaque grows, the walls of the artery become thick and stiff, and the obstruction of the artery increases **(Figure 42.20)**.

Atherosclerosis sometimes produces warning signs. Partial blockage of the coronary arteries, which supply oxygen-rich blood to the heart muscle, may cause occasional chest pain, a condition known as angina pectoris. The pain is most likely to be felt when the heart is laboring hard during physical or emotional stress, and it signals that part of the heart is not receiving enough O_2. However, many people with atherosclerosis are completely unaware of their condition until catastrophe strikes.

Heart Attacks and Stroke

If unrecognized and untreated, the result of atherosclerosis is often a heart attack or a stroke. A **heart attack**, also called a *myocardial infarction*, is the damage or death of cardiac muscle tissue resulting from blockage of one or more coronary arteries. Because the coronary arteries are small in diameter, they are especially vulnerable to obstruction. Such blockage can destroy cardiac muscle quickly because the constantly beating heart muscle cannot survive long without O_2. If the

▶ **Figure 42.20 Atherosclerosis.** These light micrographs contrast **(a)** a cross section of a normal (healthy) artery with **(b)** that of an artery partially blocked by an atherosclerotic plaque. Plaques consist mostly of fibrous connective tissue and smooth muscle cells infiltrated with lipids.

heart stops beating, the victim may nevertheless survive if a heartbeat is restored by cardiopulmonary resuscitation (CPR) or some other emergency procedure within a few minutes of the attack. A **stroke** is the death of nervous tissue in the brain due to a lack of O_2. Strokes usually result from rupture or blockage of arteries in the head. The effects of a stroke and the individual's chance of survival depend on the extent and location of the damaged brain tissue.

Heart attacks and strokes frequently result from a thrombus that clogs an artery. A key step in thrombus formation is the rupture of plaques by an inflammatory response, analogous to the body's response to a cut infected by bacteria (see Figure 43.8). A fragment released by plaque rupture is swept along in the bloodstream, sometimes lodging in an artery. The thrombus may originate in a coronary artery or an artery in the brain, or it may develop elsewhere in the circulatory system and reach the heart or brain via the bloodstream.

Treatment and Diagnosis of Cardiovascular Disease

One major contributor to atherosclerosis is cholesterol. Cholesterol travels in the blood plasma mainly in the form of particles consisting of thousands of cholesterol molecules and other lipids bound to a protein. One type of particle—**low-density lipoprotein (LDL)**, often called "bad cholesterol"—is associated with the deposition of cholesterol in arterial plaques. Another type—**high-density lipoprotein (HDL)**, or "good cholesterol"—appears to reduce the deposition of cholesterol. Exercise decreases the LDL/HDL ratio. Smoking and consumption of certain processed vegetable oils called *trans fats* (see Chapter 5) have the opposite effect. Many individuals at high risk for cardiovascular disease are treated with drugs called statins, which lower LDL levels and thereby reduce the frequency of heart attacks.

The recent recognition that inflammation has a central role in atherosclerosis and thrombus formation is changing the diagnosis and treatment of cardiovascular disease. For example, aspirin, which blocks the inflammatory response, has been found to help prevent the recurrence of heart attacks and stroke. Researchers have also focused attention on C-reactive protein (CRP), which is produced by the liver and found in the blood during episodes of acute inflammation. Like a high level of LDL cholesterol, the presence of significant amounts of CRP in blood is a useful predictor of cardiovascular disease.

Hypertension (high blood pressure) is yet another contributor to heart attack and stroke as well as other health problems. According to one hypothesis, chronic high blood pressure damages the endothelium that lines the arteries, promoting plaque formation. The usual definition of hypertension in adults is a systolic pressure above 140 mm Hg or a diastolic pressure above 90 mm Hg. Fortunately, hypertension is simple to diagnose and can usually be controlled by dietary changes, exercise, medication, or a combination of these approaches.

CONCEPT CHECK 42.4

1. Explain why a physician might order a white cell count for a patient with symptoms of an infection.
2. Clots in arteries can cause heart attacks and strokes. Why, then, does it make sense to treat hemophiliacs by introducing clotting factors into their blood?
3. **WHAT IF?** Nitroglycerin (the key ingredient in dynamite) is sometimes prescribed for heart disease patients. Within the body, the nitroglycerin is converted to nitric oxide. Why would you expect nitroglycerin to relieve chest pain in these patients?

For suggested answers, see Appendix A.

CONCEPT 42.5

Gas exchange occurs across specialized respiratory surfaces

In the remainder of this chapter, we will focus on the process of **gas exchange**. Although this process is often called respiratory exchange or respiration, it should not be confused with the energy transformations of cellular respiration. Gas exchange is the uptake of molecular O_2 from the environment and the discharge of CO_2 to the environment.

Partial Pressure Gradients in Gas Exchange

To understand the driving forces for gas exchange, we must calculate **partial pressure**, which is simply the pressure exerted by a particular gas in a mixture of gases. To do so, we need to know the pressure that the mixture exerts and the fraction of the mixture represented by a particular gas. Let's consider O_2 as an example. At sea level, the atmosphere exerts a downward force equal to that of a column of mercury (Hg) 760 mm high. Therefore, atmospheric pressure at sea level is 760 mm Hg. Since the atmosphere is 21% O_2 by volume, the partial pressure of O_2 is 0.21×760, or about 160 mm Hg. This value is called the *partial pressure* of O_2 (abbreviated P_{O_2}) because it is the portion of atmospheric pressure contributed by O_2. The partial pressure of CO_2, P_{CO_2}, is much less, only 0.29 mm Hg at sea level.

Calculating partial pressure for a gas dissolved in liquid, such as water, is also straightforward. When water is exposed to air, the amount of a gas that dissolves in the water is proportional to its partial pressure in the air and its solubility in water. Equilibrium is reached when gas molecules enter and leave the solution at the same rate. At equilibrium, the partial pressure of the gas in the solution equals the partial pressure of the gas in the air. Therefore, the P_{O_2} in water exposed to air at sea level must be 160 mm Hg, the same as that in the atmosphere. However, the *concentrations* of O_2 in the air and water differ substantially because O_2 is much less soluble in water than in air.

Once we have calculated partial pressures, we can readily predict the net result of diffusion at gas exchange surfaces: A gas always diffuses from a region of higher partial pressure to a region of lower partial pressure.

Respiratory Media

The conditions for gas exchange vary considerably, depending on whether the respiratory medium—the source of O_2—is air or water. As already noted, O_2 is plentiful in air, making up about 21% of Earth's atmosphere by volume. Compared to water, air is much less dense and less viscous, so it is easier to move and to force through small passageways. As a result, breathing air is relatively easy and need not be particularly efficient. Humans, for example, extract only about 25% of the O_2 in the air we inhale.

Gas exchange with water as the respiratory medium is much more demanding. The amount of O_2 dissolved in a given volume of water varies but is always less than in an equivalent volume of air: Water in many marine and freshwater habitats contains only 4–8 mL of dissolved O_2 per liter, a concentration roughly 40 times less than in air. The warmer and saltier the water is, the less dissolved O_2 it can hold. Water's lower O_2 content, greater density, and greater viscosity mean that aquatic animals such as fishes and lobsters must expend considerable energy to carry out gas exchange. In the context of these challenges, adaptations have evolved that in general enable aquatic animals to be very efficient in gas exchange. Many of these adaptations involve the organization of the surfaces dedicated to exchange.

Respiratory Surfaces

Specialization for gas exchange is apparent in the structure of the respiratory surface, the part of an animal's body where gas exchange occurs. Like all living cells, the cells that carry out gas exchange have a plasma membrane that must be in contact with an aqueous solution. Respiratory surfaces are therefore always moist.

The movement of O_2 and CO_2 across moist respiratory surfaces takes place entirely by diffusion. The rate of diffusion is proportional to the surface area across which it occurs and inversely proportional to the square of the distance through which molecules must move. In other words, gas exchange is fast when the area for diffusion is large and the path for diffusion is short. As a result, respiratory surfaces tend to be large and thin.

The structure of a respiratory surface depends mainly on the size of the animal and whether it lives in water or on land, but it is also influenced by metabolic demands for gas exchange. Thus, an endotherm generally has a larger area of respiratory surface than a similar-sized ectotherm.

In some relatively simple animals, such as sponges, cnidarians, and flatworms, every cell in the body is close enough to the external environment that gases can diffuse quickly between all

(a) Marine worm. Many polychaetes (marine worms of the phylum Annelida) have a pair of flattened appendages called parapodia on each body segment. The parapodia serve as gills and also function in crawling and swimming.

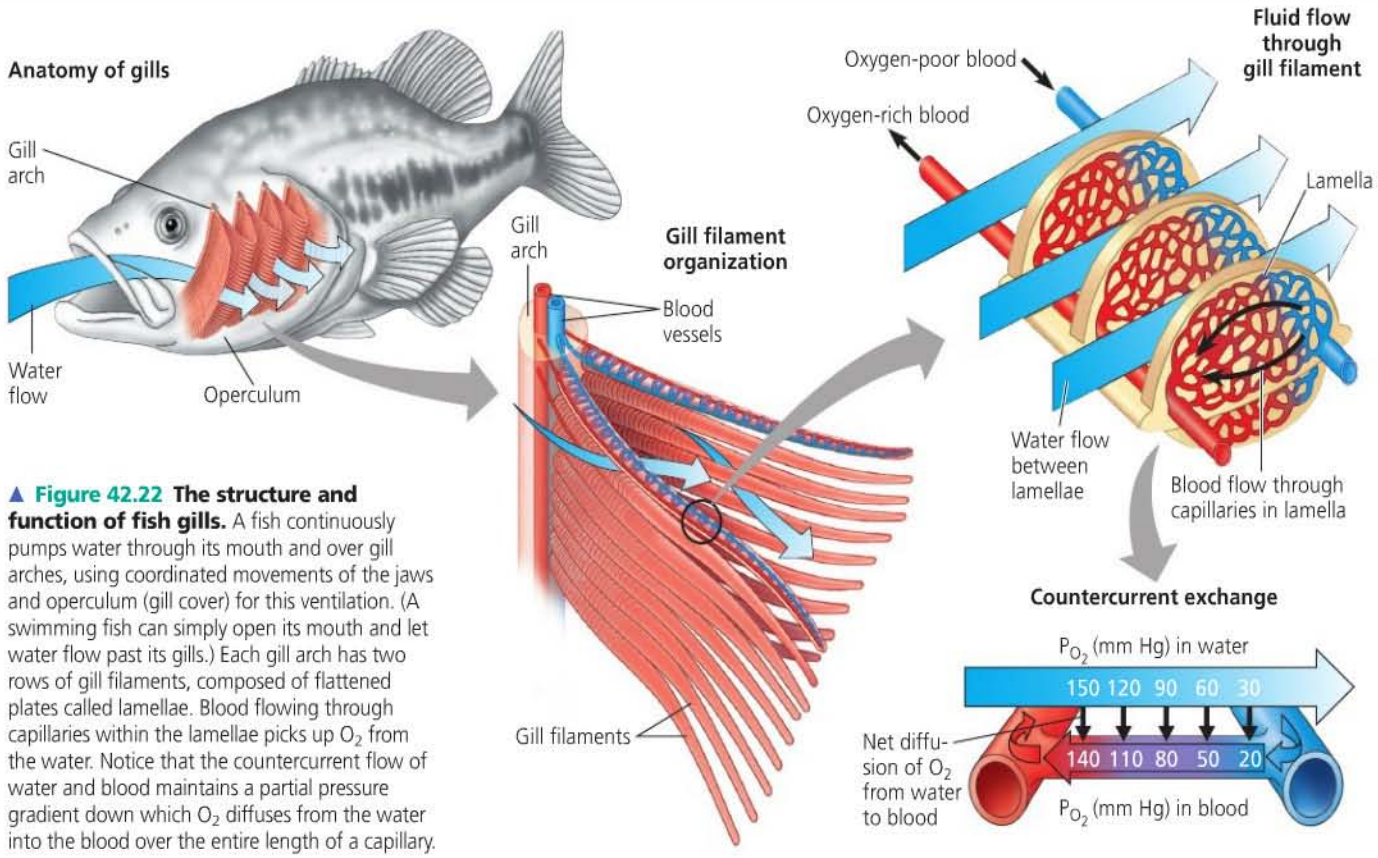
(b) Crayfish. Crayfish and other crustaceans have long, feathery gills covered by the exoskeleton. Specialized body appendages drive water over the gill surfaces.

(c) Sea star. The gills of a sea star are simple tubular projections of the skin. The hollow core of each gill is an extension of the coelom (body cavity). Gas exchange occurs by diffusion across the gill surfaces, and fluid in the coelom circulates in and out of the gills, aiding gas transport. The surfaces of a sea star's tube feet also function in gas exchange.

▲ **Figure 42.21 Diversity in the structure of gills, external body surfaces that function in gas exchange.**

cells and the environment. In many animals, however, the bulk of the body's cells lack immediate access to the environment. The respiratory surface in these animals is a thin, moist epithelium that constitutes a respiratory organ.

The skin serves as a respiratory organ in some animals, including earthworms and some amphibians. Just below the skin, a dense network of capillaries facilitates the exchange of gases between the circulatory system and the environment. Because the respiratory surface must remain moist, earthworms and many other skin-breathers can survive for extended periods only in damp places.



The general body surface of most animals lacks sufficient area to exchange gases for the whole organism. The solution is a respiratory organ that is extensively folded or branched, thereby enlarging the available surface area for gas exchange. Gills, tracheae, and lungs are three such organs.

Gills in Aquatic Animals

Gills are outfoldings of the body surface that are suspended in the water. As illustrated in **Figure 42.21**, on the facing page, the distribution of gills over the body can vary considerably. Regardless of their distribution, gills often have a total surface area much greater than that of the rest of the body.

Movement of the respiratory medium over the respiratory surface, a process called **ventilation**, maintains the partial pressure gradients of O_2 and CO_2 across the gill that are necessary for gas exchange. To promote ventilation, most gill-bearing animals either move their gills through the water or move water over their gills. For example, crayfish and lobsters have paddle-like appendages that drive a current of water over the gills, whereas mussels and clams move water with cilia. Octopuses and squids ventilate their gills by taking in and ejecting water, with the side benefit of locomotion by jet propulsion. Fishes use the motion of swimming or coordinated movements of the mouth and gill covers to ventilate their gills. In both cases, a current of water enters the mouth, passes through slits in the pharynx, flows over the gills, and then exits the body **(Figure 42.22)**.

The arrangement of capillaries in a fish gill allows for **countercurrent exchange**, the exchange of a substance or heat between two fluids flowing in opposite directions. In a fish gill, this process maximizes gas exchange efficiency. Because blood flows in the direction opposite to that of water passing over the gills, at each point in its travel blood is less saturated with O_2 than the water it meets (see Figure 42.22). As blood enters a gill capillary, it encounters water that is completing its passage through the gill. Depleted of much of its dissolved O_2, this water nevertheless has a higher P_{O_2} than the incoming blood, and O_2 transfer takes place. As the blood continues its passage, its P_{O_2} steadily increases, but so does that of the water it encounters, since each successive position in the blood's travel corresponds to an earlier position in the water's passage over the gills. Thus, a partial pressure gradient favoring the diffusion of O_2 from water to blood exists along the entire length of the capillary.

▲ **Figure 42.22 The structure and function of fish gills.** A fish continuously pumps water through its mouth and over gill arches, using coordinated movements of the jaws and operculum (gill cover) for this ventilation. (A swimming fish can simply open its mouth and let water flow past its gills.) Each gill arch has two rows of gill filaments, composed of flattened plates called lamellae. Blood flowing through capillaries within the lamellae picks up O_2 from the water. Notice that the countercurrent flow of water and blood maintains a partial pressure gradient down which O_2 diffuses from the water into the blood over the entire length of a capillary.

Countercurrent exchange mechanisms are remarkably efficient. In the fish gill, more than 80% of the O_2 dissolved in the water is removed as it passes over the respiratory surface. Countercurrent exchange also contributes to temperature regulation (see Chapter 40) and to the functioning of the mammalian kidney, as we will see in Chapter 44.

Gills are generally unsuitable for an animal living on land. An expansive surface of wet membrane exposed directly to air currents in the environment would lose too much water by evaporation. Furthermore, the gills would collapse as their fine filaments, no longer supported by water, would cling together. In most terrestrial animals, respiratory surfaces are enclosed within the body, exposed to the atmosphere through narrow tubes.

Tracheal Systems in Insects
