Diode Lasers

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Definition

As the name suggests, the active medium in a diode laser is a semiconductor diode. These lasers are mostly pumped electrically by applying voltage across the diode. The electron and holes from the two-doped sides of the diode recombine on the application of voltage leading to the generation of light.

Principle of Operation

Diode lasers use p-i-n diode, where p-region is a positively doped semiconductor having excess positively charged entities (holes), n is a

negatively doped semiconductor having excess negatively charged entities (electrons), while i is the intrinsic layer which is uncharged. When a voltage is applied across the p-i-n diode, the positive voltage drives the holes from the p-region toward the n-region, while the negative voltage on the n-region drives the electrons toward the p-region (Fig. 1). The electrons and holes recombine in the i-region resulting in the generation of light. This electron hole recombination in itself does not cause lasing. However when the diode is kept inside a cavity, population inversion happens for a wavelength, which belongs to one of the longitudinal modes of the cavity and lasing is observed. In diode lasers the cavity is a waveguide made on the semiconductor crystal. The light is confined in the waveguide, and the two ends of the crystal are cleaved and polished to act as reflectors (Fig. 1).

Material

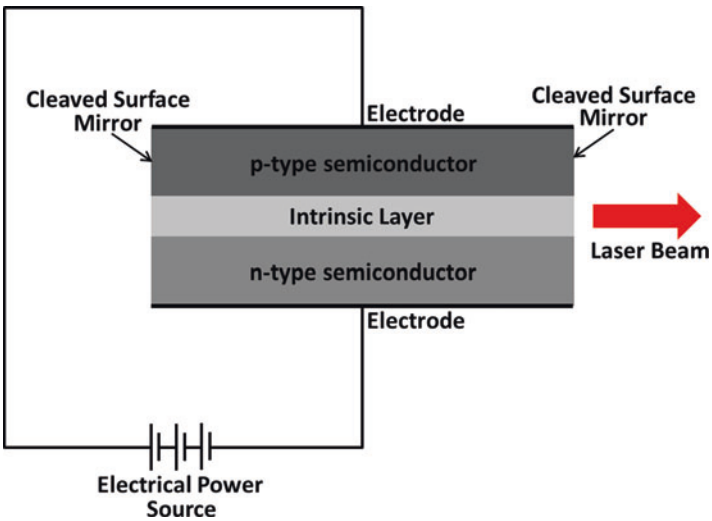
Diode lasers are fabricated using special semiconductor materials. Most of the naturally available semiconducting materials such as silicon and germanium have atomic orientation which does not allow the energy from the electron hole recombination to be emitted as light. Only those semiconductors where electron hole recombination results in the generation of a photon can be used in fabricating diode laser. III/V type semiconductors such as gallium arsenide or indium phosphide are suited for this purpose.

Beam Quality

The output beam from the laser diodes usually is elliptical with higher divergence in one axis as compared to the other. This is because the cavity for laser diodes is asymmetrical, wider in one direction and narrower in the other. Due to diffraction the beams come out more divergent along the axis, which is narrower and less divergent along the axis, which is wider. This elliptical orientation of the laser diode beam is usually corrected using cylindrical lens.

Output Power

Diode lasers can have output powers ranging from hundreds of microwatts to tens of kilowatts. The low output power laser diodes have good beam quality, which is obtained by making a narrow waveguide. To increase output power, laser diodes



Diode Lasers, Fig. 1 Schematic of the diode laser

with a wider waveguide are used. The output from multiple laser diodes is then combined together using additional optics to increase output power in the range of kilowatts.

Emission Wavelengths

The diode lasers' emission wavelength ranges from near UV to mid-IR with the shortest wavelength being 375 nm to the longest wavelength of 3,330 nm. The most common output wavelengths of emission are in 760–980 nm, 1,310 nm, and 1,550 nm.

Applications

Diode lasers are cheap and compact and provide high output power. This makes them ideal for various applications. They are extensively used in telecommunications as their output power can be easily modulated. They are also used in a variety of other equipments such as range finders, barcode readers, DVD players, laser pointers, etc. High-power diode lasers are used in industrial applications such as seam welding, heat treating, and brazing. High-power diode lasers are also used as pumping sources for solid-state lasers. Diode lasers have been so successful that they are now replacing other types in almost every area of application of lasers.

In the area of ophthalmology, diode lasers are being used in retinal photodynamic therapy where a light-sensitive medicine is injected into the bloodstream. Once the medicine reaches the macula, light from the diode laser is shined into the eye. The medicine is activated by the laser light and creates blood clots in the abnormal blood vessels. This slows the scar tissue growth in the retina, thus reducing the damage to the cells in the macula. Another similar application of diode laser is the retinal photocoagulation, where the heat generated from the laser shined into the retina and blocks the abnormal blood vessel.

Diode laser technology is still an active area of research where new techniques are being developed to achieve compact design, improved beam quality, and higher power with greater conversion efficiency. With these advances diode lasers are expected to be used for various new applications in different areas of science and technology, including ophthalmology.

Synonyms

Dioptre

Definition

A diopter ([D] or [dpt]) is a unit of measurement of the optical power of a lens or curved mirror, which is equal to the reciprocal of the focal length measured in meters (unit is 1/m). For example, a 2 diopter lens focuses an object at infinity to an image plane at a distance of 0.5 m. The term was proposed by French ophthalmologist Ferdinand Monoyer in 1872 based on the term dioptrice by Johannes Kepler.

Synonyms

Graves' orbitopathy; Thyroid associated orbitopathy (TAO); Thyroid eye disease (TED)

Definition

Graves' disease is an acquired autoimmune phenomenon with a genetic predisposition characterized by the production of thyroid-stimulating immunoglobulins (TSIs). TSIs are autoantibodies that mimic the function of thyroid-stimulating hormone (TSH) by binding to TSH receptors in the follicles of the thyroid. Once TSI is bound, the TSH receptor is activated and transmits nuclear signals to increase production and secretion of thyroid hormone leading to a hyperthyroid state. The TSIs also cause hyperplasia and hypertrophy of the follicular tissue leading to diffuse goiter clinically. It is the most common cause of hyperthyroidism in the developed world.

The adjusted annual incidence rate is 16 females and 3 males per 100,000 people. The most common associated ocular findings include a dry, gritty ocular sensation, excessive tearing, photophobia, diplopia, and a pressure sensation behind the eye. Although Graves' disease is a common cause of thyroid eye disease, autoimmune thyroid disease can present with hypothyroidism (e.g., Hashimoto's thyroiditis) or with antibodies (e.g., TPO or TSIg) but normal thyroid function (euthyroid Graves' orbitopathy).

Diplopia, or seeing double, occurs when thyroid antibodies bind to the fibroblasts in the extraocular muscles and produce secondary inflammation. This causes a conversion to adipocytes which build up in the muscles and cause inflammation. The inflammation then compresses veins, prevents drainage, and subsequently causes edema. Hence this diplopia is generally restrictive rather than paralytic. Inflammation and edema in the extraocular muscles cause gaze abnormalities as muscle function is directly affected. The inferior rectus muscle is the most commonly involved extraocular muscle, and therefore, diplopia is most often encountered upon lateral upgaze. Eye elevation can also be limited secondary to fibrosis of the muscle. The second most commonly affected muscle is the medial rectus; however, multiple muscles can be affected and are not necessarily disturbed symmetrically. Diplopia is usually intermittent but can become chronic. The most common order of involvement for extraocular muscles in thyroid eye disease includes the inferior rectus, medial rectus, superior rectus, and lateral rectus. Patching, prism wear, or strabismus surgery are reasonable symptomatic treatments.

While orbital radiotherapy has been shown to treat refractory diplopia, radiation comes with its own set of risks and should be evaluated on a case-by-case basis. For patients with increasing diplopia, attempting to suppress the immune system with a trial of oral corticosteroids can be initiated.

Synonyms

Demyelinating disease; MS

Definition

Multiple sclerosis (MS) is a chronic, inflammatory, autoimmune, demyelinating disease of the central nervous system (CNS). Patients with MS may present with or develop diplopia. One of the most common presentations is a lesion of the medial longitudinal fasciculus (MLF) known as an internuclear ophthalmoplegia (INO). An INO may be seen in up to 25% of patients with MS. This lesion affects the connection between the abducens nerve nucleus and the contralateral medial rectus subnucleus of the third cranial nerve. Adduction of the affected side is impaired on horizontal gaze, and there is typically a dissociated horizontal abducting nystagmus in the fellow eye. Convergence may be spared if the near pathway located more rostrally is intact. Bilateral INO is often due to MS and patients may develop a concomitant exotropia with either monocular or binocular INO. Patients with MS can also have demyelinating pontine lesions that involve the abducens nucleus and MLF (i.e., the one-and-a-half syndrome). Involvement of the sixth nerve fascicle in the pons might also produce binocular horizontal diplopia in MS. Other isolated cranial nerve palsies of the third and fourth nerves however are less common in MS. Brain stem lesions may also produce skew deviation and binocular vertical diplopia.

Definition

Several systemic myopathies cause ocular motility disorders but most do not. Most myopathies are systemic or genetic diseases, and the motility problems are bilateral, insidious in the onset, and symmetric. Therefore, diplopia is rarely a presenting complaint as it usually requires an asymmetric lesion. These disorders include various forms of chronic progressive external ophthalmoplegia (CPEO). Four myopathies are specifically known to cause ocular motility disorders from a young age: Kearns-Sayre syndrome, oculopharyngeal muscular dystrophy, myotonic dystrophy, and myotubular myopathy. Kearns-Sayre syndrome is a mitochondrial myopathy in which the ophthalmoplegia appears between the ages of 5 and 20. Oculopharyngeal muscular dystrophy is an autosomal dominant disease that mainly affects patients with a French-Canadian descent and presents around the age of 40. Ptosis is generally a more common feature of this disorder. Myotonic dystrophy is a trinucleotide (CTG) repeat disorder. While the congenital form is more severe, the classic form begins in adolescence or adulthood with eccentric gaze holding difficulty, slow saccades, and ptosis. Finally, myotubular myopathy is an X-linked disorder in which patients exhibit ptosis and extraocular muscle weakness.

Synonyms

Vertebrobasilar atherothrombotic disease (VBATD); Vertebrobasilar insufficiency (VBI)

Definition

Vertebrobasilar system disease is a vasculopathy that affects the vertebral arteries and/or the basilar artery. Most commonly this arises because of total or partial occlusion secondary to atherosclerotic changes, thrombosis, arterial dissection, vasculitis, or embolic occlusion. Additionally, diplopia can also be caused by dolichoectasia or elongation/distension of these vessels. Given that these arteries directly or indirectly feed the midbrain, pons, medulla, and part of the occipital lobe, neuro-ophthalmic manifestations of this disease are common. Patients with VBI can experience transient diplopia when cranial nerves 3, 4, or 6 are affected, from internuclear or supranuclear brain stem disorders, or from skew deviation. Typically patients with VBI have other neurologic symptoms that help localize to the brain stem.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Monocular polyopia

Definition

Diplopia is a another name for double vision. There are two main types of diplopia: monocular and binocular. Monocular diplopia occurs under monocular viewing conditions with one eye only and binocular diplopia occurs under binocular viewing. If either eye is covered and the double vision still persists, then it is likely to be monocular diplopia and generally not of neurologic origin (some exceptions like cerebral polyopia and palinopsia occur however). Monocular, or non-strabismic, diplopia can be caused by several optical problems.

As stated above, the noticeable form of the condition is mostly optical in nature. Most commonly, dry eyes, astigmatism, and spherocylindrical refractive errors are to blame. Sometimes, monocular diplopia can arise from an extrapupillary aperture as seen in a surgical or laser iridectomy or iridotomy. The lens can be the culprit as seen in cataracts or lens displacements/subluxations. Corneal etiologies for monocular diplopia include keratoconus (a degenerative, cone-shaped cornea due to genetic, cellular, and environmental conditions) and lower level and higher level aberrations that may be due to corneal or lenticular etiologies. Chalazion producing lid

and cornea pressure can also cause monocular diplopia. The pinhole might be useful in eliminating monocular diplopia and establishing an intraocular etiology for the symptoms.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Diplopia, or double vision, can be caused by multiple mechanisms. There are several situations in which diplopia is caused by restriction in the extraocular muscles (EOM). Congenital fibrosis of the EOM (e.g., medial rectus muscle restriction causing esotropia in children) can produce ophthalmoplegia and diplopia. Orbital myositis, a form of idiopathic orbital inflammation, is a benign, noninfectious condition that typically presents with pain, periorbital edema, erythema, and diplopia. Nonsteroidal anti-inflammatory or corticosteroid drugs are the mainstay for therapy. Thyroid eye disease may also produce restrictive diplopia. In Graves' disease thyroid-stimulating immunoglobulins bind to the thyroid producing hyperthyroidism but also cross-react with fibroblasts in the orbit causing a conversion to adipocytes. These accumulate and cause an inflammatory response and affect EOM. In trauma situations, a medial orbital wall or orbital floor fracture could cause entrapment of the medial rectus or inferior rectus muscles respectively. Postsurgical esotropia is an iatrogenic restrictive damage to EOM that may cause diplopia after sinus surgery.

Disciform disease with endotheliitis; Disciform edema; HSV endotheliitis; HSV keratitis; Keratitis disciformis

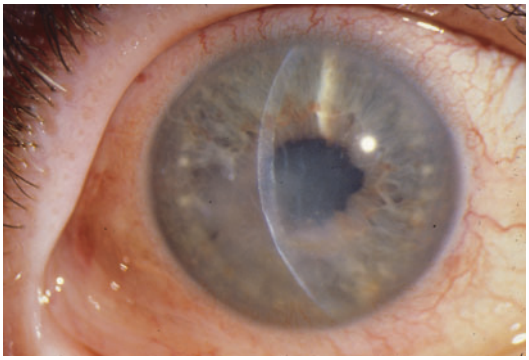
Definition

Herpes simplex virus (HSV)-induced disciform keratitis is a non-necrotizing keratitis of the cornea thought to be due to a delayed hypersensitivity reaction that manifests primarily as a localized endotheliitis with disk-shaped stromal and epithelial edema in a central or paracentral distribution (Krachmer et al. 2006; O'Day 2006).

Etiology

The main route of infection with HSV is through direct contact with mucous membranes. Ocular infection can occur as primary or recurrent episodes although HSV keratitis is thought to occur more commonly in recurrences. Primary ocular HSV typically presents as a blepharoconjunctivitis, while recurrent infection can occur on almost any ocular tissue including the eyelid, conjunctiva, cornea, iris, uveal tract, trabecular meshwork, retina, and optic nerve. In addition to endotheliitis, other manifestations of HSV with corneal involvement include epithelial keratitis, neurotrophic keratopathy, interstitial stromal keratitis (non-necrotizing), and necrotizing stromal keratitis (O'Day 2006).

Disciform keratitis is thought to be an immunologically driven reaction to the herpes simplex virus although there is some debate about the role of live virus in this reaction. The principle mediators are CD4(+) Th1 cells in addition to neutrophils and antigen-presenting cells. Cytokines such as interleukin 2 (IL-2), IL-12, and interferon gamma as well as IL-1alpha and IL-6 have been demonstrated to have activity in the inflammatory reaction (Inoue 2008). This immune reaction presents clinically with disk-shaped areas of epithelial and stromal edema with underlying fine keratic precipitates and is commonly associated with an iridocyclitis which may cloud the diagnosis (Fig. 1). The stromal edema and keratic precipitates appear out of proportion to the degree of anterior chamber reaction and can help distinguish the disciform keratitis from uveitis associated with secondary corneal decompensation. Although typically self-limited, ophthalmic steroids can speed recovery (O'Day 2006). Rarely,



Disciform Keratitis, Herpes Simplex Virus Causing, Fig. 1 Disciform keratitis. Note the clear periphery and well-demarcated areas of disk-shaped edema with underlying keratic precipitates (Image Credit: Dr. Richard K. Forsterp MD)

chronic endotheliitis may lead to intractable corneal edema secondary to the loss of endothelial cells, with resultant permanent scarring and neovascularization (Krachmer et al. 2006; Yanoff and Duker 2009).

Occurrence

HSV-1 exposure increases with age. Exposure is almost universal by the age 60 and was found on autopsy in the trigeminal ganglion 89.1% of the time by polymerase chain reaction (PCR). Although the virus may remain latent and without associated pathology, HSV keratitis is the most common cause of cornea-derived blindness in developed nations. The global incidence of Herpes keratitis is estimated to be approximately 1.5 million new cases each year (Farooq and Shulka 2012).

Classification

HSV disciform keratitis has traditionally been considered a stromal non-necrotizing keratitis and was included among the stromal keratitis in the Herpetic Eye Disease Study (Wilhelmus et al. 1994). However, HSV disciform keratitis is more appropriately described as an endotheliitis as the inflammatory reaction occurs primary at the level of the endothelium. This is supported by the observation that keratic precipitates (KP) are found on the endothelium only in areas of stromal edema and by the lack of stromal inflammation. More recent classifications now differentiate the types of HSV keratitis as primarily an epithelial disease with dendritiform lesions or neurotrophic ulcers, stromal necrotizing and non-necrotizing keratitis, or endotheliitis. Three forms of HSV endotheliitis are described: disciform, diffuse, and linear (Krachmer et al. 2006).

Disciform degeneration

Definition

Disciform scar is an area of subretinal fibrosis or subretinal pigment epithelial (RPE) fibrosis. It is often located in the macula and is the end stage of neovascular age-related macular degeneration (AMD) Retina and vitreous (2014–2015).

Pathogenesis

Age-related macular degeneration (AMD) is the leading cause of worldwide blindness among the elderly. Clinically, AMD is classified into two types: the non-neovascular "dry" or atrophic form and the neovascular "wet" form.

The typical clinical sign of "dry" AMD is drusen, which are small yellowish deposits underneath the retina, found between the RPE and Bruch's membrane. In 15–20% of patients, the condition progresses to the "wet" or neovascular form. The natural history of wet AMD advances further to a cicatricial stage referred to as a disciform scar.

The hallmark of the neovascular form of AMD is the formation of choroidal neovascularization (CNV). These neovascular vessels originate from the choroidal capillaries, which progress and penetrate the outer aspect of Bruch's membrane. The neovascular complex continues to grow in the sub-RPE and subretinal space. The neovascular complex is accompanied by the growth of fibroblasts, resulting thus in proliferation of a fibrovascular complex within the inner aspect of Bruch's membrane. This complex can disrupt and destroy the normal architecture of the choriocapillaris, the Bruch's membrane, the RPE, and the photoreceptors Retina and vitreous (2014–2015) .

Ultimately, if left untreated, within several months, this process results in a 4–8 mm diameter fibrotic scar underlying the macula. On examination disciform scar appears as dull, white fibrous tissue which may include a vascular component. It can present concomitantly with CNV or replace the latter over time. Patients complain about central scotoma with severe central vision loss in the affected eye. However, peripheral visual acuity is usually retained.

To this current moment, no efficient treatment has been found to treat this condition Retina and vitreous (2014–2015).

Abbe number; Wavelength-dependent refractive index

Definition

The refractive index of transparent media is dependent on wavelength, as illustrated in Fig. 1. As white light is incident upon a surface, the angle of refraction through the surface will depend on wavelength: the shorter wavelengths will refract more strongly than the longer wavelengths. This causes the separation of white light into its elemental colors through a prism, crystal, or water

droplets giving rise to a rainbow as shown in Fig. 2. The wavelength dependence of the refractive index also means that the eye and ophthalmic lenses have different focal lengths for different colors, leading to axial chromatic aberration (see ▶ Chromatic Aberration: Definition).

The dispersion of a material is quantified with the Abbe number, as defined below:

$$V = \frac{n_d - 1}{n_F - n_C}$$

where n_d, n_F, and n_C are a material's refractive index for wavelengths of 587.6, 486.1, and 656.3 nm, corresponding to helium *d*, hydrogen *F*, and *C* lines, respectively (Smith 2000).

Synonyms

Aberrant lash

Definition

Distichiasis is a condition where an extra row of eyelashes emerge at or slightly behind the meibomian gland orifices (Vagefi et al. 2011). In order from posterior to anterior lid margin, the normal anatomic structures are palpebral conjunctiva, mucocutaneous junction, gray line, meibomian glands, and eyelashes. Distichiasis can be congenital or more commonly acquired.

Congenital distichiasis is a rare condition that occurs when primary epithelial germ cells destined to differentiate into a meibomian gland of the tarsus develop into a complete pilosebaceous unit. The condition is inherited in an autosomal dominant manner with high penetrance, but it has

variable expressivity (Kanski 2007). Frequently, patients with congenital distichiasis will also be identified as having lymphedema-distichiasis syndrome. These individuals have distichiasis with lower extremity lymphedema that is usually asymmetric. These patients may also present with cardiac anomalies or a cleft lip (Boon and Vikkula 2012).

Aberrant lashes in congenital distichiasis can develop as either a partial or complete second row. In congenital cases, the aberrant lashes tend to be thinner and shorter than normal cilia. At a young age, the lashes tend to be finer and well tolerated. However, the lashes tend to be directed posteriorly and with time and age become coarser and can lead to corneal epithelial breakdown.

Acquired distichiasis is occurs when metaplasia of the meibomian glands leads to the formation of a hair follicle. This process is secondary to trauma or chronic irritation from inflammatory conditions of the eyelids or conjunctiva. Common causes include late stage cicatrizing conjunctivitis, chemical injury, Stevens-Johnson syndrome, ocular cicatricial pemphigoid, other chronic ocular surface diseases like blepharitis, or ocular rosacea. Aberrant lashes in these cases can also be directed posteriorly toward the cornea and cause epithelial breakdown. Acquired distichiasis usually becomes symptomatic.

DNA, Disorders with Retinal Phenotype, Associated with Mitochondrial DNA (mt-DNA) Mutations

Eran Pras
The Matlow's Ophthalmo-Genetic Laboratory, Assaf Harofeh Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Ramat Aviv, Israel

Synonyms

Mitochondrial-related retinal degenerations (MRDs)

Definition

Mitochondrial retinal degeneration (MRD) is a heterogeneous group of multisystem disorders including retinal involvement, which associates with mitochondrial DNA (mt-DNA) mutations (Merin 2005). The various subtypes of MRDs are commonly subdivided according to their accompanying systemic findings. The retina may manifest a spectrum of clinical appearances (phenotypes) ranging from peripheral involvement similar to retinitis pigmentosa (RP) to

macular involvement only. Nevertheless, based on the retinal findings alone, the distinction of a specific genetic etiology could not be made.

Etiology

The exact mechanisms for retinal involvement in mt-DNA mutations are not fully understood. Most researchers tie this propensity with dysfunction of important mitochondrial roles for cell function and survival including adenosine triphosphate (ATP) production, control of cellular metabolism, and regulation of the programmed cell death mechanism, i.e., apoptosis. As a high-energy-demand organ, the retina is particularly susceptible to the consequence of mitochondrial damage. The phenotype of most MRDs is influenced not only by the specific mt-DNA mutation but the contribution of other factors such as the mutant load (degree of heteroplasmy), age of onset, and the impact of other nuclear genes.

Clinical Presentations

The clinical manifestations of many MRDs share a significant phenotypic overlap, which may prohibit ready distinction of a specific genetic etiology based on clinical parameters alone (Merin 2005; Grönlund et al. 2010). To further complicate matters, a given mt-DNA mutation may associate with a spectrum of phenotypes. Below is a list of the major MRD subtypes. Their classification relies mainly on accompanying systemic findings rather than their retinal appearance.

- **Neurogenic weakness**, **ataxia**, **and retinitis pigmentosa** (**NARP**) – the term NARP highlights the major signs of the syndrome. It results from a point mt-DNA mutation T8993C (or T8993G), in the mitochondrial complex V subunit gene ATPase 6. Notably for this mutation, the ratio of the mutant DNA to all mt-DNA usually determines the clinical manifestation. An individual has a normal phenotype if the "mutant load" is less than 60%, while NARP associates with >60% "mutation load." When the "mutation load" exceeds 80%, a more severe phenotype termed Leigh syndrome may develop.

  The retinal phenotype is consistent with retinitis pigmentosa.
- **Leigh syndrome** – also designated maternally inherited Leigh syndrome (MILS), has a more severe and fulminant course than NARP which usually results with death at infancy. It is considered as a degenerative disorder involving the basal ganglia and brain stem. The child is born with hypotonia, psychomotor abnormalities, lactic acidosis, seizures, and ataxia.
- **Mitochondrial encephalomyopathy, lactic acidosis, and stroke** (**MELAS**) – the term highlights the main signs of the syndrome. The most common mutation causing MELAS is A3243G, but other mutations were also described (A3271G). Neurological abnormalities are the most common manifestations with variable phenotypic expressivity ranging from stroke-like episodes, mental retardation, and sensorineural hearing loss. Other systemic abnormalities such as lactic acidosis, myopathy, or diabetes were also described. The brain lesions may be slowly progressive. Headache is usually the first symptom followed by hemianopsia, psychosis, and aphasia with a later occurrence of seizures. The retinal phenotype may vary from peripheral involvement with atypical RP to maculopathy alone.
- **Maternally inherited diabetes and deafness** (**MIDD**) – as indicated by the name, MIDD is characterized by diabetes and sensorineural hearing loss (Murphy et al. 2008). The most common mutation described in MIDD is the same A3243G mutation described for MELAS despite the different appearances of the syndromes. The disease commonly starts at early adulthood with high-tone frequency hearing loss, which usually precedes the onset of diabetes. In most cases, a non-insulin-dependent diabetes mellitus (NIDDM) without overweight develops.

  In contrast to the peripheral retinal involvement in MELAS, the main ocular feature in MIDD is a localized pattern dystrophy of the macula.

- **Kearns-Sayre syndrome** (**KSS**) – is characterized by chronic progressive ocular motility deficit (CPEO, chronic progressive extraocular ophthalmoplegia) and pigmentary retinopathy of the "salt and pepper" type which may progress to exhibit full-blown RP appearance in late stages. The ophthalmoplegia usually starts with strabismus or eyelid drop (ptosis) which progresses to complete (or almost total) paresis of the extraocular muscles. Accompanying multisystem abnormalities may include various CNS dysfunctions (ataxia, mental retardation, sensorineural hearing loss, high CSF protein content) and cardiac conduction block. KSS usually starts at early age (adolescence) and usually results in early death.

  The disorder associates with large deletions, duplications, or rearrangement of mt-DNA.
- **Myoclonic epilepsy and ragged red fibers syndrome** (**MERRF**). The acronym highlights the more common findings in MERRF which include myoclonus, ataxia, and the appearance of ragged red fibers on muscle biopsy. Other less frequent features include hearing loss, exercise intolerance, peripheral neuropathy, dementia, optic atrophy, and a mild retinal pigmentary disorder. The most common mutation A8344G is present in 80–90% of the patients with MERRF and encodes for the mt-RNA Lys gene.

Diagnostics

The diagnosis of MRD is established on clinical and laboratory grounds (Merin 2005; Haas et al. 2008). A common symptom of mitochondrial disease is fatigue. Typically, there is an increased blood lactate/pyruvate ratio following exercise. Maternal inheritance is characteristic, as mt-DNA is almost exclusively inherited from the mitochondria of the maternal oocyte during embryogenesis. These features, alongside any of the clinical presentations listed above, raise the likelihood for MRD. Confirmation of the diagnosis can be supported by muscle biopsy, MRI studies, and molecular screening for mt-DNA mutations.

Therapy and Prophylaxis

At present, no medication has been proven to alter the course of MRD. Evidence for the effectiveness of dietary supplementation, antioxidants, and vitamins remains controversial. There are a variety of reproductive options available for women with mt-DNA mutations including genetic counseling, ovum donation, antenatal diagnosis (by CVS biopsy), and preimplantation genetic diagnosis.

Prognosis

Generally, MRDs are considered progressive incurable disorders which may result in severe debilitating conditions or even death.

Epidemiology

MRDs are very rare, with an estimated occurrence rate approximating 1 out of 8,000–10,000 individuals.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Doll's eye movement; Oculocephalic reflex

Definition

The doll's eye maneuver is executed by quickly turning the patient's head horizontally from side to side or vertically up and down while holding the eyelids open. If the reflex is intact (positive doll's head maneuver), then the eyes demonstrate conjugate movement in the opposite direction of the head movement; however, if the reflex is not intact (negative doll's head maneuver), then the eyes remain stationary (Hickey 2003).

Purpose

This maneuver evaluates the functioning of the brain stem vestibular ocular reflexes and can help differentiate between supranuclear (e.g., cortical or subcortical dysfunction) in vertical or horizontal gaze palsies in both conscious and unconscious patients (Hickey 2003; McInery 2009).

Principle

Stimulation of the vestibular system by passive head movement causes eye movement without the involvement of the cortex. Upon turning of the head, afferent nerve fibers from the vestibular system stimulate specific ocular motor cranial nerve nuclei located in the brain stem, allowing for conjugate eye movement in the opposite direction of head movement (Haines 2012). More specifically, the movement of the head in the vertical direction will stimulate the trochlear and oculomotor nerves, whereas the movement of the head in the horizontal direction stimulates the abducens and oculomotor nerves. A negative doll's head maneuver indicates damage of the infranuclear pathway (Hickey 2003). On the other hand, a positive oculocephalic reflex in combination with a vertical or horizontal gaze palsy indicates that the lesion is supranuclear (McInery 2009).

Indication

The doll's head maneuver is used to test the brain stem functioning in comatose patients and neonates, and it can also be used in the initial evaluation of supranuclear versus infranuclear strabismus or other gaze palsies (McInery 2009; Venes 2013).

Contraindication

In the presence of cervical fracture or injury, this maneuver should not be performed (Hickey 2003).

Advantage/Disadvantage

The primary advantage to this maneuver is that it is a quick method of assessing brain stem function in a comatose patient. However, this test can only

be a preliminary evaluation because it does not provide precise localization of lesions or deficits (Hickey 2003).

Synonyms

Koerber-Salus-Elschnig syndrome; Parinaud's syndrome; Pretectal syndrome; Sylvian aqueduct syndrome

Definition

The dorsal midbrain syndrome is also known as the Parinaud syndrome, named after the notable nineteenth century French ophthalmologist Henri Parinaud who was the first to describe the cardinal clinical features of the disorder. The syndrome classically consists of a supranuclear paralysis of vertical gaze (predominantly upgaze initially but later downgaze may become involved), convergence-retraction nystagmus, and impaired pupillary constriction to light stimuli but normal to near reaction (i.e., light-near dissociation).

Etiology

Lesions of the dorsal midbrain (pretectal area) may also variably affect the medial longitudinal fasciculus (MLF), the superior colliculus, the pretectal nucleus, and the posterior commissure. Damage to these structures produces the classic signs associated with the syndrome. The most common causes are pineal mass (e.g., pinealoma, dysgerminoma, metastasis), vascular lesions (e.g., ischemia, hemorrhage, infarct, or arteriovenous malformations,), demyelinating disease (e.g., multiple sclerosis),

trauma, obstructive hydrocephalus or shunt failure, metabolic disorders (Wilson disease), and infectious (e.g., Whipple disease, tuberculosis, infective endocarditis, neurosyphilis) or inflammatory (e.g., neurosarcoidosis) etiologies.

Clinical Presentation

Vertical gaze (particularly upgaze) palsy is common in the dorsal midbrain syndrome. Patients may initially have a difficult time looking upwards voluntarily and eventually experience significant difficulty following an object upwards with their eyes. The absence of convergence and pupillary constriction reflexes can also be noted (with preservation of the near-pupillary response), as the neural projections that control these eye movements synapse at the site of the lesion implicated in the syndrome. Patients frequently complain of difficulty reading or double vision (diplopia) since both convergence and accommodation are disrupted.

In contrast, horizontal gaze is typically preserved because the ocular motor pathways controlling horizontal eye movements utilize nuclei and ascending tracts projecting from the rostral pons and not the midbrain. The vestibulo-ocular reflex is also preserved because the necessary neuronal connections for this reflex arise rostrally in the brain stem, away from the site of the lesion.

Convergence-Retraction Nystagmus

Convergence-retraction nystagmus is a classic dorsal midbrain sign and is best observed when patients attempt upward saccades, as when following a downward-moving optokinetic drum. The eyes then converge and retract into the orbit from co-contraction of the medial, superior, and inferior recti muscles bilaterally in attempted upgaze.

Eyelid Retraction

In patients with dorsal midbrain syndrome, the upper eyelids may be retracted. When this occurs, the superior sclera can be seen above the limbus (Collier sign). The cause of this sign is probably damage to levator inhibitory fibers in the posterior commissure.

Diagnostics

Magnetic resonance imaging (MRI) of the brain with and without gadolinium enhancement is typically the best initial neuroimaging study, but computed tomography (CT) scan of the brain without contrast may be faster in the traumatic or emergent setting. Lumbar puncture and serologic testing (e.g., syphilis) may be necessary for other etiologies if neuroimaging is negative.

Differential Diagnosis

Pineal tumors, progressive supranuclear palsy, bilateral Brown superior oblique tendon sheath syndrome, congenital upgaze limitation, transtentorial herniation, infections (encephalitis, cysticercosis), Wernicke encephalopathy, stroke – ischemic or hemorrhagic, and multiple sclerosis. Thyroid ophthalmopathy and myasthenia may mimic the ophthalmoplegia of the dorsal midbrain syndrome.

Therapy

Treatment should be directed against the underlying cause.

Prognosis

Prognosis for dorsal midbrain syndrome depends on the underlying etiology.

Epidemiology

Dorsal midbrain syndrome is a rare disorder that occurs in patients of all ages, and various etiologies may be more common in younger (e.g., demyelinating) or older (e.g., ischemic) patients.

Double Convexity Deformity

Gary Joseph Lelli[1], Ryan St Clair[2] and Christopher Zoumalan[3]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Ophthalmology, Division of Ophthalmic Plastic, Reconstructive and Orbital Surgery, Weill Cornell Medical College, New York, NY, USA
[3]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Definition

Age-related changes to the eyelid-cheek junction, resulting in replacement of the youthful single convex contour of the lower eyelid and midface unit by a double convex contour with anterior bulging of the postseptal lower eyelid fat, descent of the midface, and volumetric deficiency in the region of the orbitomalar ligament (Baker 1999; Aston et al. 2009; de Castro and Boehm 2009).

Etiology

In youth, the lower eyelid and midface forms a single convexity, beginning at the inferior margin of the lower eyelid in the pretarsal region and extending inferiorly to the lateral oral commissure and angle of the mandible. By the third decade, the suborbital orbicularis oculi fat (SOOF) and the cheek fat pad typically descend, resulting in a soft tissue paucity inferior to the inferior orbital rim. In addition, with increased age, the globe moves inferiorly in the orbit, causing anterior bulging of the postseptal lower eyelid fat. The combination of bulging postseptal lower eyelid fat, soft tissue paucity at the inferior orbital rim, and inferiorly displaced SOOF and cheek fat pad form the classic double-convexity deformity.

Clinical Presentation

Patients present with a cosmetically unacceptable change in the contour of the lower eyelid and midface, typically in the third and fourth decade of life.

Diagnostics

The diagnosis of double-convexity deformity is made by clinical examination of the eyelid-cheek junction.

Differential Diagnosis

Differential diagnosis includes

Thyroid eye disease
Orbital tumor
Preseptal cellulitis
Allergic dermatitis/contact allergy to the eyelids

Therapy

Surgical correction of the double-convexity deformity may involve a variety of techniques and should be tailored to the patient's particular anatomy, with the goal of repositioning lower eyelid and midface soft tissues into a more aesthetically pleasing youthful configuration. Various surgical techniques in addition to lower eyelid blepharoplasty have been described such as arcus marginalis release, fat mobilization, and/or orbicularis oculi resuspension. Hyaluronic acid and non-hyaluronic acid filler

injection may also play a role in reconstructing mid-facial contour. Fat grafting is an option for volumetric rejuvenation in selected patients.

Prognosis

Double-convexity deformity is typically progressive with age, but does not result in functional compromise. Outcomes after surgical correction are variable and depend on the surgical technique employed.

Epidemiology

Unknown

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

The "double ring sign" is a characteristic configuration of the optic nerve head that is observed upon funduscopic examination in patients with optic nerve hypoplasia (ONH). The sign appears as a peripapillary yellowish, mottled halo that surrounds the hypoplastic optic disk. In ONH, there is a decreased number of optic nerve axons with normal amount of supporting tissue. The outer ring of the double ring sign represents the junction between sclera and lamina cribrosa, while the inner ring is the termination of the retinal pigment epithelium (RPE). The inner ring often appears whitish due to the glial and connective tissue around the retinal vessels. In ONH, the size of the smaller optic nerve plus the peripapillary halo may be roughly the size of a healthy optic disk. Other features that may be apparent include tortuous non-dilated retinal veins, decreased foveal reflex, and decreased thickness of the retinal nerve fiber layer. ONH on exam can range from dramatic findings if the optic disk appears to be one-half or less of the normal size and is accompanied by the double ring sign to much more subtle changes, necessitating detailed evaluation of the nerve under higher magnification before diagnosis can be confirmed.

Etiology

ONH is a congenital malformation of prenatal origin. ONH may present during evaluation of a unilateral visual defect, an examination of

strabismus, nystagmus, amblyopia, or unusual appearance of optic disk. ONH may present unilaterally or bilaterally with variable effect on vision. While there is no single unifying theory to explain the pathophysiology underlying ONH, the usage of certain recreational substances as LSD and ethanol (fetal alcohol syndrome) and certain classes of therapeutic drugs such as anticonvulsants and diuretics has been associated with the disorder, as has diabetes mellitus in expectant mothers. ONH is often accompanied by developmental delay, cerebral palsy, seizures, and a variety of neurodevelopmental and central nervous system (CNS) abnormalities and pathologies. One hypothesis for the etiology of ONH is excess apoptosis during embryonic ganglion cell and axonal development from abnormal mitochondrial function and energy metabolism. Another hypothesis is that ONH is the outcome of an initially reduced number of retinal precursor cells that eventually become retinal ganglion cells. The most important intervention in ONH may be the identification of associated endocrinopathies or CNS abnormalities to allow for early treatment and minimization of complications.

Occurrence

The double ring sign is quite common among patients with ONH but not always present and is not necessary for the diagnosis. ONH is the most common optic disk anomaly seen in clinical practice. The disorder itself occurs between 4% and 13% among children in US schools for the blind. In Finland, the prevalence of ONH has been estimated at 1.5 per 100,000 individuals (and a 4% prevalence among visually impaired children). In Sweden, the prevalence has been estimated to be at least 7 per 100,000 births.

Classification

Histopathologic sign.

Names in previous usage include Hutchinson-Tay choroiditis and Holthouse-Batten chorioretinitis.

Definition

DHRD is an autosomal-dominant degenerative retinal disease characterized by drusen (small round deposits of extracellular material located between the basement membrane of the retinal pigment epithelium (RPE) and the collagenous layer of Bruch's membrane). Those primarily at the macula coalesce in time to form a central solid plaque at the level of Bruch's membrane surrounded by smaller drusen deposited in a radial distribution (Brown et al. 2006). Drusen are also located characteristically in the nasal retina and around the optic disk (Fig. 1).

Etiology

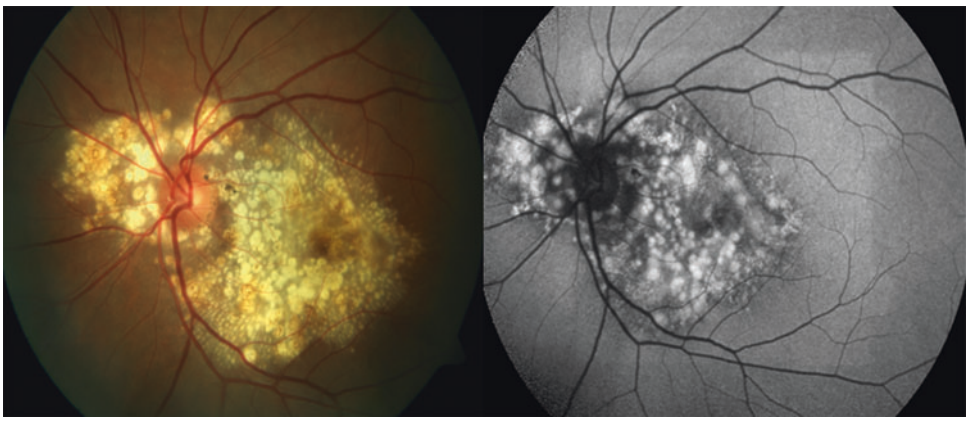
DHRD is caused by a single heterozygous pArg345Trp (R345W) mutation in the fibulin 3 gene, also known as the EGF-containing fibulin-like extracellular matrix protein 1 (EFEMP1), an extracellular protein localized to RPE (Stone et al. 1999). Not all patients with early onset retinal drusen have a mutation in the fibulin 3 gene, but with an autosomal-dominant history and the typical radial drusen as well as nasal and peridisc distribution of drusen, this makes it much more likely that they will be mutation positive.

Clinical Presentation

DHRD may be identified by examining members from a family with known DHRD, or patients may be asymptomatic, but referred because of early onset drusen. Onset of symptoms of delayed dark adaptation can occur before onset of distortion, blurring, or scotomata, which do not usually occur before the third to fifth decade (Haimovici et al. 2002). Early-onset macular drusen may be sparse at first; the distribution of the drusen in the nasal retina and around the optic disk together with a positive family history should arouse suspicion of DHRD. The macular drusen demonstrate a symmetrical bilateral radial distribution with increasing density of central deposition and coalesce to form the characteristic honeycomb pattern of RPE, developing a central plaque with supervening atrophic change and hyperpigmentation. Choroidal neovascularization may also develop.

Diagnosis

The diagnosis is suggested by early-onset drusen with a positive family history and typical fundus findings, and in the majority with the specific phenotype, a mutation in the EFEMP1 gene will be identified.



Doyne's Honeycomb Dystrophy, Fig. 1 Color photograph (**a**) and autofluorescence (**b**) of a patient with EFEMP1-positive DHRD. Note the characteristic feature of drusen nasal to and surrounding the optic disk

Differential Diagnosis

Drusen seen in early age-related macular degeneration particularly with a family history
- Early-onset drusen
- Sorsby fundus dystrophy
- Pattern dystrophy
- Stargardt disease
- Best disease
- North Carolina macular dystrophy

Prophylaxis

There is no current prophylaxis, but advice regarding a good diet and smoking cessation is likely to be of benefit. Prophylactic photocoagulation aimed at reducing the number of drusen has been tried with some success (Lenassi et al. 2013).

Therapy

There is currently no established therapy for DHRD; however, intravitreal anti-vascular endothelial growth factor therapy is currently the most likely to be helpful in treating associated choroidal neovascularization (Sohn et al. 2011). As with other inherited retinal degenerations, genetic counseling should be offered prior to mutational analysis.

Prognosis

The majority of patients will not experience noticeable visual deterioration usually until the fourth or fifth decade. Visual loss is gradual until the RPE atrophy involves the foveal zone. Sudden vision loss may occur following choroidal neovascularization.

Epidemiology

DHRD equally affects both men and women. There are no clear prevalence data.

Drugs, Ocular, Absorption of

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

Absorption of a topical drug depends on its bioavailability. Increasing the amount of time the drug spends on the corneal surface improves drug absorption. This is influenced by the drug delivery system, which include gels, ointments, inserts, soft contact lenses, and collagen shields. Other factors that affect ocular drug absorption are nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and drug diffusion across the cornea and conjunctiva. Absorption can also increase by disrupting the corneal epithelium.

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Anisocoria is defined as a difference in the size (diameter) of the two pupils. Common causes of anisocoria include iris damage (e.g., iris trauma or intraocular surgery), ocular sympathetic lesions (i.e., the Horner syndrome), and parasympathetic lesions (e.g., third nerve palsy, Adie tonic pupil). This chapter deals with drugs that cause anisocoria.

Etiology

Drugs that cause pharmacologic mydriasis include ocular parasympatholytics and sympathomimetics. These include topical, nasal, and sometimes systemic (which may have inadvertent contact with the eye) agents. Mydriatic parasympatholytic agents include tropicamide, scopolamine, cyclopentolate, and atropine derivatives, while sympathomimetics include epinephrine and norepinephrine. Miotic agents include topical pilocarpine and exposure to parasympathomimetics (e.g., anticholinesterases). Systemic agents used for motion sickness (e.g., transdermal scopolamine) or nebulized inhalation agents (e.g., ipratropium bromide) might also be inadvertently administered to the eye causing pharmacologic anisocoria.

Differential Diagnosis and Evaluation

The differential diagnosis of pharmacologic anisocoria includes Horner syndrome, third nerve palsy, iris damage, and Adie pupil. Topical pilocarpine 1% will not constrict a fully pharmacologically dilated pupil and can be used as a differentiating test for neurogenic etiologies for a dilated pupil (e.g., atropine exposure).

Classification

Side effect of pharmacotherapy.

Synonyms

Hallucinogen; Psychedelic drug

Definition

Psychedelic drugs may cause visual hallucinations as part of the "psychedelic experience." This might include distortions of vision, hearing, thought, emotion, and perception. Perceptual distortions in particular may affect the senses of sight, sound, touch, smell, and taste, producing hallucinations, which are perceptions without external stimulation of the relevant sensory organ.

Hallucinations may be the primary effect of a drug or a side effect of use. Some drugs associated with visual hallucinations include:

- Hallucinogens (e.g., dimethyltryptamine, harmine, ketamine hydrochloride, LSD, mescaline, nitrous oxide, phencyclidine hydrochloride (PCP), psilocybin, tetrahydrocannabinol (THC))
- Stimulants (e.g., amphetamine, cocaine, methylphenidate, atropine, scopolamine, cyclopentolate)
- Anti-Parkinsonian agents (amantadine hydrochloride, anticholinergic drugs, bromocriptine, levodopa, lisuride, mesulergine, pergolide mesylate)
- Antidepressants (amitriptyline hydrochloride, amoxapine, bupropion hydrochloride, doxepin hydrochloride, imipramine hydrochloride, lithium carbonate and phenelzine sulfate)

Classification

Primary effect or side effect of pharmacotherapy.

[2]The Oxford Eye Hospital, Oxford, UK
[3]Nuffield Laboratory of Ophthalmology, University of Oxford, Oxford, UK

Synonyms

Druse – singular form

Definition

Drusen are discrete whitish-yellow deposits of abnormal material located deep to the retina between the basal lamina of the retinal pigment epithelium (RPE) and Bruch's membrane. Varying widely in number, size, and shape, drusen can be confined to the macula region or involve large portions of the retina. The presence of drusen is suggestive of age-related macular degeneration although other diseases such as familial dominant drusen or basil laminar drusen also can be associated with drusen.

Dry Eye: Definition

Jessica Selter
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Dysfunctional tear syndrome; Keratoconjunctivitis sicca

Definition

Dry eye is a common condition involving abnormalities of the tear film due to insufficient tear production or increased tear evaporation (Lemp et al. 2007). Symptoms include ocular discomfort such as dryness, foreign body sensation, or burning in the eye, visual disturbances, and tear instability. Dry eye is one of the leading causes of patient visits to ophthalmologists (Asbell and Lemp 2006).

Synonyms

Duchenne muscular dystrophy associated with pigmentary retinopathy; Duchenne muscular dystrophy associated with proliferative retinopathy

Definition

Duchenne muscular dystrophy is the most common X-linked neuromuscular disorder with an incidence of 1 in 3,500 live male births. It is characterized by progressive proximal muscular weakness, loss of ambulation, and early death. The disease typically manifests before 3 years of age with 95% of patients wheelchair-bound by the age of 12 years, rarely reaching the third decade of life. Duchenne muscular dystrophy is caused by a mutation of the dystrophin gene located on the short arm of the X chromosome at Xp21.

The retina contains three of the seven known isoforms of dystrophin including full-length dystrophin (Dp427), Dp260, and Dp71. The Dp260 isoform localizes at the retinal photoreceptor terminal (in the outer plexiform layer); its deficiency results in abnormal neurotransmission between photoreceptor cells and ON bipolar cells. The Dp71 isoform localizes in the inner limiting

membrane and around retinal blood vessels, playing an unclear role in retinal vascular permeability.

Patients with Duchenne muscular dystrophy may demonstrate abnormal scotopic electroretinogram (ERG) configuration, termed electronegative ERG, in which the scotopic a-wave and b-wave amplitude ratio is greater than 1. The severity of this unique ERG configuration varies based on the precise genetic mutation. The electronegative ERG configuration, similar to that seen in congenital stationary night blindness patients and other ocular diseases, indicates defective neurotransmission between photoreceptor cells and ON bipolar cells. However, in contrast to other X-linked disorders with a reduced scotopic b-wave ERG amplitude, color vision, photopic ERG amplitudes, visual acuity, and extraocular muscle function usually remain normal in patients with Duchenne muscular dystrophy. Patients classically have a relatively normal fundoscopic exam, with a slight tendency toward focal macular hyperpigmentation. Rarely, massive proliferative retinopathy may occur, leading to rapid and severe loss of vision. This atypical phenomenon is thought to be the end result of a vasoendothelial growth factor-mediated response resulting from a combination of cardiac hypoperfusion, the absence of an anti-vasogenic effect of dystrophin and anemia.

[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Forced duction test

Definition

The forced duction test is a test of extraocular muscle (EOM) function that can be used to differentiate between EOM weakness (i.e., paresis) and restriction (e.g., entrapment, enlargement, infiltration, or fibrosis of muscle). If the EOM is acutely paretic, it will move easily when pushed or pulled during the forced duction. A restricted EOM on the other hand will not move freely.

Purpose

The forced duction test is very important for the diagnosis of EOM palsies or restriction in some cases of acute strabismus.

Principle

First, topical anesthetic (e.g., tetracaine) is instilled at the area where the conjunctiva will be grasped. The patient is told to cover one eye (manually or with an occluder) and to look in the

direction of the muscle that is suspected to be impaired. The examiner then uses forceps for globe fixation at the limbus and attempts to move the eye or by pushing on the deviated eye with a cotton-tipped swab or pulling the conjunctiva with forceps. If the examiner is unable to move the eye freely then this is a positive forced duction and supports restriction of EOM.

Indication

Indications for forced duction testing may include trauma, endocrine, congenital restrictions (Brown syndrome, Duane syndrome, strabismus fixus, congenital fibrosis of extraocular muscles), postoperative restrictions of motility (after strabismus procedures, orbital surgery, repair of retinal detachment), transposition procedures, and orbital diseases such as tumors and inflammation.

Contraindication

The forced duction test is contraindicated in the case of confirmed or suspected open globe injury.

Advantage/Disadvantage

The forced duction test is generally short and relatively painless. It increases diagnostic accuracy and helps in deciding which surgical strategy to employ. Some patients will not cooperate with this test; however, and the vagal response may be stimulated leading to syncope. For these patients, the test is best done in the operating room before surgery. Furthermore, the test can be painful for some patients and difficult to interpret. In addition, patients with chronic paretic lesions may develop a contracture and produce a false-positive forced duction test.

Synonyms

Duplex ultrasound

Definition

Duplex ultrasonography is a two-step ("duplex") imaging modality that is a combination of pulsed Doppler ultrasonography and brightness-mode

(B-mode) ultrasonography. It depicts a gray-scale (brightness scale) image of underlying tissue that is used to visualize the architecture of the body part (via grayscale ultrasound) and a color-Doppler ultrasound that helps visualize movement in a structure such as arterial blood flow via spectral analysis.

Purpose

Using the frequency of the original sound wave and the frequency of a received echo, duplex ultrasonography can calculate the velocity of moving red blood cells. Increased velocity of blood usually indicates narrowing of an artery or a form of resistance such as atherosclerotic plaque. Hence, it can be used to detect the presence and severity of vascular stenosis or occlusion and may provide valuable information for operative planning.

Principle

A duplex ultrasonography scanning device uses a pulsed Doppler beam to calculate frequency shifts in a specific area (the sample volume) by determining from what depth reflected echoes are received. The transducer is gated to only receive echoes from the specified area along the path of the pulsed Doppler beam. The depth of the sample volume is determined from the B-mode image.

Indication

Duplex ultrasonography is a minimally invasive way to determine vascular pathology in central and peripheral veins and arteries before further testing or surgery is involved. Thus, it can be utilized in a variety of suspected local and systemic vascular-related conditions such as deep vein thrombosis (DVT). An ophthalmologic application, for example, is the visualization of carotid arteries to identify occlusion, stenosis, and ulceration at the bifurcation of the carotid arteries in amaurosis fugax (a transient monocular visual loss that can be due to reduced blood flow reaching the eye).

Contraindication

Generally, there are very few contraindications for duplex ultrasonography. Depending on the body site of use, there may be some practical limitations, however. For example, evaluation of the abdominal aorta using this technique may be complicated by a large abdomen, a significant amount of bowel gas, open wounds, fresh sutures, or dialysis catheters.

Advantage/Disadvantage

The main advantage of duplex ultrasonography is the accuracy and minimally invasive nature with which it can be used to map vascular disease. Furthermore, it is safer and simpler than other techniques, which makes it one of the first line studies in vascular surgical planning. The main disadvantage is that it is a more time-consuming method than other arterial studies. Additionally, the sensitivity of duplex ultrasonography is lower than conventional and magnetic resonance angiography.

Synonyms

Cerebral venous sinus thrombosis (CVST)

Definition

Cerebral venous sinus thrombosis (CVST) refers to the presence of a thrombus (blood clot) in the dural venous sinuses. These sinuses are critical for draining blood from the brain.

Etiology

CVST of the lateral or sagittal sinus or small cortical veins can occur due to complications of oral contraceptives, pregnancy, inflammatory bowel disease, infections such as meningitis, dehydration, postpartum or postoperative states, and patients who have thrombophilic or hypercoagulable conditions as in pancreatic or colon cancer, cachexia in infants, cyanotic congenital heart disease, antiphospholipid antibody syndrome, polycythemia, Behçet disease, sickle-cell anemia, protein C or S deficiencies, factor V Leiden mutation, homocysteinemia, antithrombin III deficiency, paroxysmal nocturnal hemoglobinuria, and prothrombin G20210 mutation (especially with oral contraceptive use). Certain drugs including tamoxifen, erythropoietin, and bevacizumab are also risk factors for development of thrombosis.

Clinical Presentation

Patients experiencing CVST may present with headaches (most frequent symptom), seizures, and focal neurologic signs such as paraparesis. As intracranial pressure increases due to obstruction of cerebrospinal fluid (CSF) flow back to venous circulation, the patient may complain of nausea, vomiting, and headaches. Papilledema may also be seen and CVST can mimic the presentation of idiopathic intracranial hypertension (IIH).

Cavernous Sinus Thrombosis

Patients with cavernous sinus thrombosis may present with chemosis, proptosis, and cranial nerve III, IV, V (ophthalmic), or VI findings. If the thrombus spreads to the inferior petrosal sinus, then cranial nerve VI, IX, X, or XI findings may be present.

Diagnostics

Computerized tomography (CT) imaging may be normal in patients with dural sinus thrombosis unless venous hemorrhage has occurred. Thrombosis of the venous sinuses is best apparent with magnetic resonance venography (MRV) or computerized tomographic venography (CTV). Alternatively, catheter angiography may still be required to visualize CVST. In the case of superior sagittal sinus occlusion, hemorrhagic infarcts or edematous congestion in the frontal or parietal lobes may be observed. Cerebrospinal fluid (CSF) pressure is increased and fluid may contain traces of blood. With transverse sinus occlusion, hemorrhagic infarct of the temporal lobe with edema may be observed. A "corkscrew" appearance of surface veins is seen with chronic thrombosis.

Differential Diagnosis

Stroke
Hemorrhage

Therapy

Systemic anticoagulation is typically recommended for CVST.

Prognosis

With appropriate treatment, dural sinus thrombosis generally may resolve successfully or be appropriately controlled medically. Total mortality is about 9.4% but approximately 88% of survivors make a substantial recovery. The rate of recurrence of CVST is low and is estimated at 2.8% (Dentali et al. 2006).

Epidemiology

Dural sinus thrombosis is a rare condition accounting for less than 1% of all strokes with peak incidence in adults in the third decade of life. Exact incidence is unknown but five to eight cases per year can be expected in a tertiary care center. It is more common in women than in men (Einhäupl et al. 2006).

[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Color blindness; Incomplete achromatopsia

Definition

Dyschromatopsia, meaning "color confusion", is a form of color blindness, a diminished or impaired ability to see certain colors. In contrast,

complete loss of color vision is termed achromatopsia. Thus, dyschromatopsia is sometimes known as incomplete achromatopsia. In individuals with color blindness, the ability to perceive one or more primary colors is either defective (anomalous) or absent (anopia).

Etiology

Dyschromatopsia can either be congenital or acquired, though it is most frequently an inherited condition. A congenital color vision defect is typically red-green in nature, while acquired defects are generally blue-yellow in character. The hereditary bases for tritanopia and tritanomaly are related to chromosome 7 and are autosomal dominant. Protanopia/protanomaly and deuteranopia/deuteranomaly are X-linked recessive disorders.

Clinical Presentation

Dyschromatopsia can be classified as anomalous trichromatism or congenital dichromatism. Each of these classifications has several subtypes depending on which color is affected. The two major types of color blindness that patients present with are red-green and blue-yellow forms.

Anomalous Trichromatism

In anomalous trichromatism, all three cones for red, blue, and green color perception are present but in abnormal proportions or with altered spectral sensitivity. Individuals who have this condition can distinguish fully saturated colors but have difficulty distinguishing colors at low saturation. Perception for one or two of the three primary colors is partially impaired. Individuals who have defective red color appreciation due to abnormal red cone distributions are termed protanomalous individuals. Those who have defective green and blue perception are termed deuteranomalous and tritanomalous, respectively. Protanomaly and deuteranomaly correspond to red-green color blindness, while tritanomaly corresponds to blue-yellow blindness.

Congenital Dichromatism

In congenital dichromatism, patients present with a total inability to perceive one of the three primary colors because of complete absence of the necessary photoreceptors. Such individuals are called dichromats. Naming convention follows that for anomalous trichromatism, those who have a complete red perception defect have protanopia and green and blue defects are called deuteranopia and tritanopia, respectively. Protanopia and deuteranopia correspond to major difficulty distinguishing between red and green hues, while tritanopia, extremely rare, corresponds to a total lack of blue retinal receptors.

Diagnostics

The diagnosis of dyschromatopsia can often be confirmed by color vision testing. The Farnsworth-Munsell (FM) 100 hue test and Farnsworth's panel D-15 can detect both red-green and blue-yellow defects. The city university test is derived from the 100 hue test and can also be used. Ishihara color plates (which are designed to detect red-green defects) and Hardy-Rand-Ritter (HRR) polychromatic plates (better for both red-green and blue-yellow defects) are more convenient for use in the clinic setting but are less sensitive and specific.

Differential Diagnosis

- Kjer dominant optic atrophy (if tritan color defect and slightly subnormal vision)
- Optic nerve disease (if errors in testing are characteristic of red-green blindness)
- Retinal disease (blue-yellow blindness errors)
- Glaucomatous optic neuropathy (initially causes blue/yellow deficits)
- Various effects of drugs (example is xanthopsia in digoxin toxicity)

Therapy

Currently there is no therapy available.

Prognosis

Congenital forms of color blindness remain static over time.

Epidemiology

Some incidence figures for dyschromatopsia are as high as 13% of the population. The X-linked color blindness occurs much more frequently in males than females with about 8% of males and less than 1% of females affected. Red-green disorders are X-linked recessive and thus mostly found in males, whereas both men and women can have tritan (blue-yellow) disorders. Protan disorders are present in about 1% of males. Deuteranomaly (red-green blindness) is the most common type of color blindness and affects approximately 5% of European males. Tritan disorders are extremely rare.

[2]Department of Clinical Ophthalmology, UCL Institute of Ophthalmology (IO), London, UK
[3]Department of Ophthalomology, Moorfields Eye Hospital, Institute of Ophthalmology, University College London, London, UK

Synonyms

Presumed tuberculous retinal periphlebitis

Definition

Eales' disease is an uncommon, idiopathic inflammatory retinal vasculopathy that mainly affects the peripheral retina of otherwise healthy young adults in their second to fourth decade of life. The disease was first described in 1880–1882 by Henry Eales as a noninflammatory condition in young healthy male patients who presented with recurrent vitreous retinal hemorrhages and epistaxis. Subsequently, the condition has been redefined as a primarily inflammatory condition (Biswas et al. 2002).

The disease is characterized by an obliterative, progressive, peripheral retinal vasculitis, predominately periphlebitis that can lead to large areas of peripheral retinal non-perfusion, severe retinal ischemia, and neovascularization, resulting in repeat vitreous hemorrhages with or without retinal detachment. In some patients there are associated retinitis and vitritis, but in others there is very little or no inflammation.

Etiology

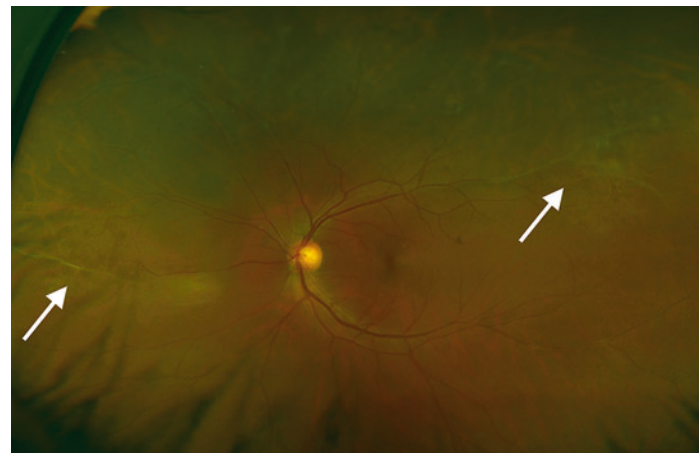
Eales' disease remains an idiopathic condition, though several underlying conditions have been proposed, resulting in a variable clinical presentation. Hypersensitivity to tuberculin protein has been heavily implicated in the pathogenesis of Eales' disease, and investigations using polymerase chain reaction (PCR) techniques have documented the presence of the mycobacterium tuberculosis genome in the vitreous fluid of more than 50% of Eales' disease patients. This has led some researchers to suggest renaming Eales' disease as presumed tuberculous retinal periphlebitis. Other factors linked to developing Eales' disease include the presence of human leukocyte antigens (HLAs) B5, DR1, and DR4; oxidative stress due to increased concentrations of reactive oxygen species, especially inducible nitric oxide; and possible associations with hypercoagulable states such as factor V Leiden thrombophilia and proliferative responses against retinal S-antigen (Biswas et al. 2013).

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Clinical Presentation

Eales' disease occurs most often in young individuals, predominantly but not exclusively men in the second to fourth decade of life. Symptoms and clinical signs may be unilateral at presentation but eventually become bilateral in most cases. Typical symptoms include floaters secondary to vitritis or mild vitreous hemorrhage. Severe visual loss can occur with significant vitreous hemorrhage. There are three clinical hallmark characteristics to Eales' disease: retinal phlebitis (vasculitis), peripheral capillary non-perfusion, and recurrent vitreous hemorrhages (Figs. 1 and 2). Vitritis is present in some but not all eyes. Retinal phlebitis appears as mid-peripheral venous dilation, peripheral perivascular exudates, hemorrhages, and sheathing. Overlying vitritis can be seen in the area of active vasculitis, and the inflammatory reaction can result in cystoid macular edema and further vision loss. Capillary non-perfusion areas can be seen as peripheral areas with "ghost" vessels (obliterated thin white vessels). A demarcation line between the non-affected and affected peripheral retina can frequently be seen with some angiopathic changes such as microaneurysms, venular shunts, hard exudates, or cotton wool spots. Vitreous hemorrhage is most commonly caused by bleeding from neovascularization of the optic disk or retina secondary to the capillary non-perfusion, which may be very extensive.

The natural history of the disease is variable. Hemorrhages are usually the result of



Eales' Disease, Fig. 1 Eales' disease. Note the extensive areas of vascular occlusion and retina hemorrhages (*arrows*)

Eales' Disease, Fig. 2 Fluorescein angiography of patient in Fig. 1 demonstrating the large areas of retinal ischemia with neovascularization (*arrow*)

neovascularization, and these leaking vessels tend to regress (and regrow) spontaneously with resultant formation of a contractile scar tissue that can lead to traction retinal detachment. Patients who do not develop retinal detachments can achieve a stable state, where following recanalization, formation of capillary shunts, and tissue atrophy, the process of neovascularization, with the resultant vitreous hemorrhages, cease.

Diagnosis

Clinical examination will demonstrate peripheral retinal vasculitis with large areas of retinal ischemia, retinal hemorrhages, neovascularization, and vitritis in some. Fluorescein angiography (FA) is useful in identifying patterns of staining and diffuse leakage that correspond to the presence of peripheral vasculitis which may progress to cause areas of retinal ischemia and subsequent neovascularization. Areas of hypofluorescence with bordering engorged capillaries and venous shunts are seen in ischemic areas. Neovascularization can usually be seen along the area of retinal ischemia or the optic disk. Ultrasonography is needed to rule out the presence of a retinal detachment when vitreous hemorrhage obscures the fundal view.

Exposure to *M. tuberculosis* should be investigated in all cases suspected of Eales' disease (e.g., QuantiFERON gold, T-spot, Mantoux test, chest X-ray).

Differential Diagnosis

The main differential diagnoses are other retinal vasculitic diseases and other retinal diseases resulting in retinal neovascularization. Systemic diseases related to retinal vasculitis which may result in ischemia and neovascularization include tuberculous uveitis with vasculitis, Behçet disease, syphilis, sarcoidosis, systemic lupus erythematosus, and granulomatosis with polyangiitis. However, a careful history, clinical examination, and targeted diagnostic tests (blood investigations) will help rule out most of these causes.

Proliferative retinopathies without vasculitis include diabetes mellitus, sickle cell disease, branch and central vein occlusion, and previous retinopathy of prematurity.

Therapy

Corticosteroids when there are associated inflammatory signs (e.g., vitritis), together with antituberculous therapy and laser treatment to ischemic areas when there is neovascularization, are the mainstay of therapy in Eales' disease. In eyes with active vasculitis and vitritis, systemic corticosteroids are initiated to control the inflammatory reaction (prednisolone 1 mg/kg of body weight). The known association of Eales' disease with *M. tuberculosis* requires consideration of tuberculosis treatment, and in cases with a positive tuberculosis test, such treatment should be given for a period of 6–9 months even in the absence of clinically active systemic tuberculosis.

Retinal laser photocoagulation to areas of non-perfused retina and early vitrectomy for recurrent vitreous hemorrhages should be considered in the presence of neovascularization (Dehghan et al. 2005). The aim of photocoagulation is to reduce the ischemic drive that leads to the formation of neovascularization and induces new vessel regression in approximately 90% of cases (Gopal and Abraham 1985). Laser is given in a segmental scattered pattern to the areas of capillary non-perfusion. In the presence of optic disk neovascularization and extensive peripheral ischemia, panretinal photocoagulation is applied.

The use of intraocular bevacizumab has been suggested for inducing regression of neovascularization or in the management of traction retinal detachments, as an adjunctive treatment to vitreoretinal surgery. However, reports of an increased risk of progressive retinal ischemia require combining intravitreal bevacizumab with retinal laser photocoagulation in order to reduce the ongoing ischemic drive.

Prognosis

As Eales' disease is a peripheral retinal disease, many patients have a good visual outcome, even in the presence of extensive peripheral vascular occlusion. Satisfactory visual outcome has also been observed in eyes receiving laser photocoagulation, especially when combined with early vitrectomy. However, once advanced disease has occurred, including traction retinal detachment, macular ischemia, rubeosis iridis, neovascular glaucoma, and optic nerve atrophy, the visual prognosis is poor.

Epidemiology

While there is no racial predilection for Eales' disease, it has been mainly reported in India and parts of the Middle East. In these regions the prevalence of the disease was found to be up to 1 in 200–250 patients in India, as compared to one in 4800 in Great Britain (Gadkari et al. 1992). The disease mainly affects males (approximately 97% of cases) in their second to fourth decade of life.

Synonyms

Diabetic retinopathy; Early treatment of diabetic retinopathy study; ETDRS; Focal grid laser; Focal laser

Definition

The Early Treatment of Diabetic Retinopathy Study (ETDRS) was a randomized, prospective, multicenter, clinical trial designed to evaluate the role of aspirin and argon laser photocoagulation in patients with nonproliferative and early proliferative diabetic retinopathy (Ferris, study53.asp).

The Diabetic Retinopathy Study (DRS) previously showed that panretinal photocoagulation reduced the risk of severe vision loss (SVL 5/200 or worse vision) by 50% over 5 years in patients with high-risk proliferative diabetic retinopathy (DRS Report 8 1981). High-risk proliferative retinopathy was defined as either:

1. New blood vessel growth within one disk diameter of the optic disk (neovascularization of the disk) greater than one-fourth of a disk area in size with or without vitreous hemorrhage

2. Any new blood vessels on or near the optic disk with vitreous hemorrhage
3. New blood vessels in the retina (neovascularization elsewhere, NVE) greater than one-half disk area in size with vitreous hemorrhage (DRS Report 8 1981)

Given this finding, the ETDRS was only open to patients with less than high-risk PDR.

ETDRS preceded optical coherence tomography, so all grading of retinopathy was done either by fundus photographs, intravenous fluorescence angiography, or clinical exam with contact lens biomicroscopy or indirect fundoscopy. This limited the ability to detect and measure small amounts of macular edema. Macular edema was defined as clinically significant if it met one of the following three criteria:

1. Thickening of the retina within 500 um of the foveal center
2. Hard exudates within 500 um of the foveal center associated with thickening of the adjacent retina
3. An area of thickening greater in size than the one disk area located within one disk diameter of the foveal center

Moderate vision loss (MVL) was defined as a doubling of the visual angle or a loss of 15 letters on the logarithmic ETDRS vision chart (Basic and clinical science course retina and vitreous 2002–2003).

The ETDRS divided nonproliferative diabetic retinopathy into five groups:

1. No retinopathy.
2. Mild NPDR: Microaneurysms, venous loops, retinal hemorrhages, or hard exudates.
3. Moderate NPDR: Mild NPDR with cotton-wool spots and intraretinal microvascular abnormalities (IRMA) defined as abnormal blood vessels limited to the retina. Any neovascularization extending into the vitreous, on the optic nerve, or retinal surface was considered proliferative diabetic retinopathy.
4. Severe NPDR: Any one of the following without proliferative retinopathy (the 4-2-1 rule).
   More than 20 intraretinal hemorrhages in each of four quadrants
   Venous beading in two or more quadrants
   Prominent IRMA
5. Very Severe NPDR: Two of the above findings.

Quadrants were any one of four mid-periphery fields compared to seven standard 30° photographs. Grading was done by comparing to standard photographs (Ryan 2006).

Aims

- To test the effectiveness of aspirin and argon laser photocoagulation on progression of early diabetic retinopathy to visual loss and blindness
- To determine the optimal time to treat patients with photocoagulation
- To monitor the effects of photocoagulation treatment and diabetes on vision
- To follow the natural history of diabetic retinopathy and use that information to identify risk factors and to test etiologic hypotheses in diabetic retinopathy (Ferris, study53.asp)

Outcomes

The primary outcome was the percentage of patients with MVL at 4 years. Secondary outcomes included percentage of patients with severe vision loss (5/200) for 4 months or greater and progression of retinopathy.

Methods

A total of 3,711 patients were recruited and followed for a minimum of 4 years (Ferris, study53.asp). The study recruited patients from December 1979 to July 1985. The results were presented at the American Academy of

Ophthalmology meeting in New Orleans in 1989 (Ferris, study53.asp 2000; Kupfer, alert-etdrs.asp).

Enrolment Criteria

Patient ages ranged from 18 to 70 years old. Diabetic retinopathy varied from mild nonproliferative to mild proliferative retinopathy in both eyes. Best corrected visual acuity was 20/40 or better, unless macular edema was present, in which case 20/200 vision or better was allowed. No patients could have any history of prior photocoagulation (Ferris, study53.asp 2000).

All patients had one eye randomly assigned to observation or immediate focal grid photocoagulation. Patients were also randomly assigned to 650 mg aspirin or placebo (Ferris, study53.asp 2000).

Results

- Focal grid laser reduced the risk of moderate to severe vision loss in clinically significant macular edema by 50%. The 3-year risk of MVL without focal laser was 32% (Ryan 2006). Panretinal photocoagulation (PRP) was not effective in treating macular edema and led to a mild decrease in central and peripheral vision (Kupfer, alert-etdrs.asp).
- There was a low rate of severe vision loss at 5 years in both non-high-risk proliferative retinopathy treated with scatter photocoagulation (2.5%) and when treatment was delayed until the development of high-risk proliferative retinopathy (4%). Therefore, it was concluded that treatment could be delayed until high-risk characteristics developed, provided close follow-up can be maintained (Kupfer, alert-etdrs.asp).
- Treatment with 605 mg aspirin daily had no effect, either on the risk of vitreous hemorrhage or the progression of retinopathy (Kupfer, alert-etdrs.asp).
- Follow-up: Based on the ETDRS data, the recommended time for follow-up visits was determined for NPDR. The risk of developing HRPDR in 1 year was 0.8% for mild NPDR and 48.5% for severe NPDR. At 5 years, the risk was 14.3% and 74.4%, respectively. This was supported by the Wisconsin Epidemiological Study of Diabetic Retinopathy (WESDR) (Ryan 2006). Therefore, the following recommendations were made for follow-up on diabetic screening based on grading of retinopathy:
  - No retinopathy: annual exam
  - Mild/Moderate NPDR without macular edema: 6–12 months
  - Mild/Moderate NPDR with macular edema but not CSME: 4–6 months
  - Severe or very severe NPDR: 3–4 month exam (Ryan)

Conclusions

The Early Treatment of Diabetic Retinopathy Study (ETDRS) was a major study that revolutionized the treatment of diabetic eye disease in the 1980s. While many of its contributions are now of historical importance, several important conclusions were reached by the study.

These include:

1. The use of aspirin in diabetic retinopathy did not affect the development or treatment of clinically significant macular edema nor did it affect the development of or response to therapy for proliferative diabetic retinopathy. There were no adverse effects, including no difference in the rate of vitreous hemorrhages. Therefore, aspirin is neither indicated nor contraindicated (Ryan 2006).
2. The timing of early panretinal photocoagulation (PRP): Patients with high-risk proliferative diabetic retinopathy (PDR) should be treated with PRP laser. Patients with non-high-risk PDR may be considered for early laser. PRP laser for patients with mild to moderate nonproliferative diabetic retinopathy was not indicated by the study.
3. The value of focal laser in the treatment of clinically significant macular edema: focal grid laser significantly reduced the rate of MVL in patients with CSME.

In addition, the study established:

(A) A grading system for grading diabetic retinopathy
(B) The use of logarithmic eye charts for checking visual acuity

These contributions have greatly affected future studies; however. the study and its results are limited in modern practice by the lack of optical coherence tomography (not commercially available until 20 years later) and anti-VEGF (Vascular endothelial growth factor) drugs, the two pillars of modern diabetic macular edema management.

Before ETDRS, the prognosis for patients with proliferative diabetic retinopathy was blindness within 5 years for more than 50% of patients. Rates of blindness in ETDRS patients following the development of proliferative retinopathy are remarkably lower. Legal blindness is reduced to less than 5% in 5 years for patients with proliferative retinopathy. Severe vision loss is reduced to 1%.

Echinococcus granulosus (Echinococcosis), Orbital

Pete Setabutr
Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA

Synonyms

Hydatid cyst

Definition

Human parasitosis caused by *Echinococcus granulosus*. Formation of hydatid cysts occurs most commonly in the liver, lungs, and central nervous system.

Etiology

Zoonosis caused by larvae or cestodes of the *E. granulosus* genus. The definitive hosts are dogs and other carnivores; cysts (metacestode stage) develop in sheep and cows. The larval stage develops in humans.

Clinical Presentation

In primary disease, patients usually present with unilateral findings. Usually found behind the globe or in the superior orbit causing slowly progressive proptosis. The cysts tend to grow slowly and cause orbital signs such as chemosis, pain, motility deficits, eyelid edema, optic nerve edema, vision loss, and optic atrophy. Rarely extension through the orbital roof into the intracranial cavity, or through orbital walls into the paranasal sinuses, may be seen.

Diagnostics

Clinical examination and orbital imaging with CT, MRI, and/or ultrasound. CT scan shows a well-defined, hypodense cystic lesion, with thin walls, and fine ring enhancement. May be unilocular or polycystic (5%). On MRI lesions appear low intensity on T1 and high intensity on T2. Capsular enhancement of the lesion is seen on T1 with gadolinium. Systemic eosinophilia is seen in 20–25%, and serologic testing may be negative in 50–60%.

Differential Diagnosis

Dermoid cyst, abscess, intraorbital hematoma, lymphangioma, teratoma, encephalocele, mucocele

Prophylaxis

Avoidance of endemic areas, hand hygiene, animal control measures, and possible immunization of animal hosts.

Therapy

Surgical excision without rupture of lesion is often difficult. Surgical excision with decompression and irrigation with hypertonic saline is used in many cases. Preoperative albendazole as preventative therapy for 14–28 days has been advocated. Concurrent treatment with anti-helminthic agents, such as albendazole, may be indicated.

Prognosis

Spillage of contents of cysts can lead to inflammatory reactions and systemic recurrence. Vision loss may be seen with delayed presentation, diagnosis, or severe disease.

Epidemiology

Endemic in cattle- and sheep-raising regions such as East and North Africa, Central Europe, the Middle East, India, Latin America, South America, Australia, and New Zealand. Orbital hydatid cysts are rarely encountered and comprise just 0.3–1% of all hydatid cysts. In endemic areas, hydatid cysts may be the cause of 5–26% of cystic orbital masses. The majority of patients are younger than 20 years of age. There is no gender predilection.

Synonyms

Transient cerebral blindness; Transient cortical blindness

Definition

Eclampsia is a potentially life-threatening condition in pregnant women consisting of hypertension, generalized edema, proteinemia, and seizures. The prequel to eclampsia is preeclampsia, also known as pregnancy-induced hypertension (PIH), which consists of just the first three symptoms. Onset is usually after the 20th week of gestation. Visual complaints occur in approximately 40% of patients with preeclampsia. The most common complaints are blurring of vision, photopsias, scotomas, and diplopia. Other ocular manifestations include retinopathy, serous retinal detachments, optic neuropathy, and occipital cortical blindness. The most common ophthalmoscopic findings are retinal arteriolar narrowing, retinal hemorrhages, exudates, retinal vascular thrombosis, and retinal edema. Optic nerve changes associated with this condition include optic atrophy, papilledema, and anterior ischemic neuropathy. Transient visual loss, posterior reversible encephalopathy syndrome (PRES), or cortical blindness occurs in about 1–15% of patients with preeclampsia or eclampsia. In contrast to ischemic infarction, PRES is typically reversible and patients with PRES from eclampsia may recover vision between 2 h and 21 days with treatment.

Etiology

Petechial hemorrhage and focal edema develop from endothelial dysfunction, dysregulation of vascular autoregulatory mechanisms, and ischemia from vasospasm. Recovery of vision follows successful treatment and resolution of cerebral edema and underlying eclampsia with magnesium sulfate, fluid restriction, and blood pressure control.

Occurrence

The occurrence of transient visual loss or cerebral blindness is between 1% and 15% of patients with preeclampsia, PIH, or eclampsia. It is more common in very young and very old mothers, in first-time mothers, and in mothers with existing systemic disease such as diabetes, chronic hypertension, and renal disease.

Ectasia, Corneal

Gustavo Bonfadini
Department of Ophthalmology, Rio de Janeiro Eye Bank – INTO, Rio de Janeiro, RJ, Brazil

Synonyms

Iatrogenic ectasia; Keratectasia; Keratoectasia

Definition

Corneal ectasia is a progressive non-inflammatory group of disorders affecting corneal stroma with thinning and steepening that occurs pathologically or post-operatively, leading to irregular astigmatism with subsequent higher-order aberrations (HOA). This condition can be caused by iatrogenic surgery as keratoplasty and excimer laser corneal refractive surgery (Seiler et al. 1998), degenerative disease (keratoconus, pellucid marginal corneal degeneration) (Rabinowitz 1998), congenital anomaly (keratoglobus) or mechanical trauma, and injury of the cornea.

Histology

A hallmark in all ectatic diseases is stromal thinning. A recent histological study did not found any classic pathognomonic signs of keratoconus (KC), like the Bowman's layer disruption, but found the presence of thinning of collagen fibrils and decreased interfibrillar distance in the eyes with iatrogenic keratectasia (IK) (Meghpara et al. 2008). A high amount of tissue removed by the refractive procedure was associated with greater corneal biomechanical destabilization, increased corneal steepening, and a worse prognosis.

Immunohistochemical examinations revealed different expression patterns of α1-proteinase inhibitor and matrix metalloproteinases (MMP) in KC and IK eyes. KC showed lower levels of α1-proteinase inhibitor and higher levels of MMP-1 compared to normal eyes. Expression patterns in IK eyes were similar to those in normal eyes. These discrepancies suggest that KC and IK are two different entities.

Molecular Diagnostics

Recently, a few inflammatory mediators have been reported to be elevated in the tear fluid and sera of keratoconus patients (Jun et al. 2011), but there are no valid clinical molecular diagnostics available at the moment. In spite of inflammatory mediators being found in keratoconus, several issues are still to be elucidated as clinical and histological findings show little evidence of this inflammation and there is no significant cell infiltration or neovascularization, suggesting that the findings of inflammatory markers merely correspond to epiphenomena, a possibility already suggested by Lema et al. (2009).

Electron Microscopy

In keratoconus eyes, electron microscopy shows decreased thickness of the cornea with fewer lamellae. The collagen fibrils in the lamellae are thickened mildly and the space between fibrils is increased. Epithelial cells showed signs of degeneration and accumulation of ferritin (Fleischer's ring). In the stroma, a reduction of collagen lamellae and deposits beneath the keratocytes can be found. Also in Descemet's layer ruptures were found (Vogt's striae). In iatrogenic keratectasia eyes, collagen fibril thinning and decreased interfibril distance were observed in the stromal bed.

Clinical Diagnosis

There are many topography (front surface curvature), tomography (epithelial and stromal thickness profiles), and biomechanical indices published that have been used to distinguish keratoconus and ectatic corneas from normal corneas (Fontes et al. 2011). Placido disc–based corneal topography is sensitive to detect abnormal front curvature patterns of ectatic diseases in eyes with relatively normal distance-corrected visual acuity and unremarkable biomicroscopy (Ambrosio and Randleman 2013). A major application of topography is the detection and management of corneal ectasia, principally keratoconus; screening for corneal ectasia is especially important prior to refractive surgery. In the early stage, ectatic diseases are difficult to detect without a complete corneal study: topography, tomography with pachymetric map, and biomechanical parameters. Recognizing the development of ectasia early in the process is critical to maximize patient outcomes.

Differential Diagnosis

Corneal thickness profile is different in ectatic corneas so that the increase in thickness is more abrupt in these cases than in normal. Secondly, the differential diagnosis between different corneal ectatic diseases has to be made (e.g., keratoconus vs. pellucid marginal corneal degeneration).

Treatment

After corneal ectasia is established, to prevent progression, eye rubbing should be avoided. As corneal ectasia progresses and irregular astigmatism increases, many patients are no longer able to achieve satisfactory vision with spectacle correction. Corneal collagen cross-linking (CXL) may stabilize ectasia, but only indicated after progression has been documented. Visual improvement can be addressed with spectacles, rigid contact lenses, intracorneal ring segment implantation, and keratoplasty.

Synonyms

Choroidal coloboma; Chorioretinal coloboma; Fundus coloboma; Macular coloboma; Retinal coloboma; Retinochoroidal coloboma

Definition

A congenital defect, characterized by the absence of normal retina, retinal pigment epithelium, and choroid.

Etiology

Congenital ocular colobomata are caused by impaired embryogenesis. During embryogenesis, at around day 30 of gestation, the ventral surface of the optic vesicle and stalk invaginates leading to the formation of a double-layered optic cup. This invagination gives rise to the optic fissure, allowing blood vessels from the vascular mesoderm to enter the developing eye. Fusion of the edges of this fissure starts centrally around day 33 of gestation and proceeds anteriorly toward the rim of the optic cup and posteriorly along the optic stalk, with completion by 7 weeks. Failure of part of the fetal fissure to close results in the clinical entity recognized as coloboma which may affect one or more areas of the eye including the eyelid, cornea, iris, ciliary body, lens, retina, choroid, and optic nerve. Maternal exposure to alcohol and an excess amount or deficiency of vitamin A during these stages of embryonic development are risk factors. The molecular mechanisms controlling these tissue events are largely unknown although the involvement of homeobox genes such as PAX2, MSH-C, and sonic hedgehog has been described. Associations with chromosomal abnormalities or multisystem disorders, such as trisomy 13, the Aicardi syndrome, and *Goldenhar's syndrome,* have been reported (Regillo 2012).

Clinical Presentation

The extent of the defect depends on the location of the coloboma and the ocular structures involved. Incomplete or inadequate closure produces a coloboma of the iris, ciliary body, choroid, or optic disk, depending on the extent of the failed closure and secondary attempts to close the defect. When the damage is severe *microphthalmia* or *anophthalmia* may result. If the fetal fissure fails to close posteriorly, then a chorioretinal coloboma affecting the retinal pigment epithelium (RPE), neurosensory retina, or choroid may occur. The defect is essentially a bare sclera with the overlying RPE, retina, or choroid missing. In some cases, although the retina is present, it is hypoplastic and gliotic.

Usually, a chorioretinal coloboma is asymptomatic despite significant upper visual field defects as the patient is unaware of the congenital defects. Chorioretinal coloboma is usually associated with *iris coloboma* and is bilateral in more than 60% of cases. If the iris is indeed involved an inferonasal keyhole, pupil may be seen. Chorioretinal colobomata are glistening white or yellow defects, varying in size, with distinct borders that are inferior or inferonasal to the optic disk and may extend to involve the macula. The margin of the coloboma is often pigmented, and the defect can extend from the iris to the choroid and produce an inferonasal gap (Barnard 2012).

Chorioretinal colobomata increase the risk of retinal detachment, occurring in one third of cases (Schubert et al. 2005), choroidal neovascularization at its margins and cataract. Involvement of the macula, extended involvement of the retina, or refractive errors may all lead to secondary amblyopia.

Diagnosis

Physical exam may reveal congenital defects in the eyelids or iris and are typically seen after birth. Genetic counseling, when indicated, may help identify chromosomal abnormalities and systemic syndromes associated with chorioretinal coloboma (Gregory-Evans et al. 2004).

Differential Diagnosis

Ocular trauma, chorioretinal scars, *staphyloma*, and North Carolina macular dystrophy.

Prophylaxis

Avoiding alcohol intake and excess exposure or vitamin A deficiency during pregnancy is

recommended. When indicated, genetic counseling may help identify hereditary chromosomal abnormalities.

Therapy

No cure is currently available for chorioretinal coloboma. Patients with bilateral coloboma or unilateral coloboma plus one other systemic abnormality should be referred to a genetics specialist to evaluate for systemic disorders. Interval monitoring for *retinal detachment* and choroidal neovascularization should be performed with a dilated fundus exam approximately every 6–12 months or sooner if indicated. Measures such as patching should be taken to maximize visual potential of the affected side as there is often normal retina present, and refractive error is often present putting patients at risk for amblyopia. Correction of refractive error, if present, should be performed. Choroidal or retinal detachment that may occur later in life should be treated accordingly.

Monocular precautions should be strongly considered for any patient with unilateral coloboma and resulting decreased visual acuity on the affected side. Low vision (vision rehabilitation) may be of aid, if indicated.

Prognosis

The most important predictor of visual outcome is the preservation of normal foveal anatomy. However, retinal detachment, choroidal neovascularization, and cataract may further compromise the visual outcome (Olsen 1997).

Epidemiology

Most cases of chorioretinal coloboma are sporadic. The exact frequency of isolated chorioretinal coloboma is most probably underestimated as mild cases have a tendency to escape detection; however the estimated incidence is 0.2 per 10,000 live births. The most frequent type of coloboma is iris coloboma followed by combined iris and choroidal coloboma (Regillo 2012).

Ectodermal Dysplasia

Jeffrey J. Mattingly and Gene Kim
Ruiz Department of Ophthalmology and Visual Sciences, Robert Cizik Eye Clinic, University of Texas Medical School at Houston, Houston, TX, USA

Definition

Heterogeneous group of congenital syndromes in which ectoderm-derived tissues are altered or absent.

Overview

Ectodermal dysplasias consist of congenital abnormalities in derivatives of the surface ectoderm. Although the pathogenesis is not fully understood, many described mutations affect components of cell-to-cell communication such as ligands, receptors, or transcription factors. Resultant disruptions in cell signaling prevent in utero induction of the surface ectoderm, leading to the absence or functional impairment of adult tissues. Concordantly, ocular pathology results from the loss of superficial structures or their normal functions. Mutations are generally associated with the p63 gene.

Structure

During development the surface ectoderm is induced by neighboring mesenchyme and mesoderm to form the epidermis, hair, nails, teeth, and subcutaneous glands. It also contributes to limb formation and the branchial apparatus that forms much of the face and neck.

The formation of the eye begins with interaction between surface ectoderm and the early forebrain leading to formation of an optic cup that organizes the rest of the embryologic process (see Fig. 1). The mesoderm of the optic cup creates the choroid and sclera, while the neuroectoderm forms the retina and optic nerve. The surface ectoderm produces the ocular surface, including the corneal epithelium, bulbar and palpebral conjunctiva, meibomian glands, lacrimal glands, and nasolacrimal ducts. It also gives off a bud in early development that becomes the crystalline lens.

Function

The overall role of the surface ectoderm derivatives is to form the body's protective external barrier. The epidermis prevents microbes and other pathogens from entering the body and maintains fluid and electrolyte homeostasis in cooperation with the sweat glands, which use evaporation to mediate thermoregulation. Surface ectoderm is also a precursor to hair, nails, tooth enamel, and their surrounding structures.

Like the epidermis, the corneal epithelium and bulbar and palpebral conjunctiva mediate innate immunity and act as a first barrier to the eye. The structures that form each of the three tear film layers are derived from surface ectoderm. The aqueous layer is produced by lacrimal glands and contains electrolytes and antibacterial proteins. The lipid layer is created by meibomian glands which prevent tear evaporation. The mucin layer is created by the conjunctival epithelium that creates a dispersive, hydrophilic layer. Drainage occurs via the nasolacrimal sac and duct.

Clinical Relevance

The estimated incidence of ectodermal dysplasia is 7 per 10,000 births. That number includes many syndromes with a wide array of phenotypes that can involve non-ectodermal structures. The skin, hair, teeth, and nails are the most common sources of signs and symptoms, leading to both cosmetic and functionally debilitating defects. Facial and oral defects such as anodontia or cleft lip and palate require surgical correction, as do limb abnormalities such as ectrodactyly. Genitourinary anomalies may precipitate renal failure, and mortality can occur in hyperthermia secondary to hypohidrosis.

Ocular manifestations can be progressive and particularly burdensome. Deficient tear production leads to xerophthalmia and defective drainage leads to excess tearing or epiphora. Limbal stem cell deficiency causes poor corneal epithelium which can lead to chronic epithelial defects, corneal infections, corneal scar, and, in late stages, corneal perforation. Less frequently, cases have been noted with cataracts and other ocular pathology outside the surface ectoderm such as macular degeneration.

Ectopia Lentis

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Lens dislocation; Lens ectopy

Definition

A displacement, partial or complete, of the crystalline lens resulting from defective zonule formation. Such anatomical conditions give rise to an anterior displacement into the anterior chamber and a posterior displacement into the vitreous body.

A subluxation represents partially displaced lens still remaining within the lens space.

Etiology

Causes for a lens luxation are, for example, myopia magna with overexpansion of zonule formation, trauma (most common cause), or intraocular tumors. A possible cause is a genetical hypoplasia of zonule formation (Marfan's syndrome, Marchesani syndrome, Ehlers-Danlos syndrome, pseudoexfoliation syndrome, homocystinurie). A secondary ectopia may result from degeneration of the zonula formation by uveitis (iridocyclitis) or cataracta hypermatura.

Clinical Presentation

Symptoms of a lens displacement may become clinically apparent as diplopic images or lower visual acuity because of missed refraction of the lens (refractive myopia). If there is an anterior displacement, an acute attack of glaucoma with pain and cloudy vision is possible. An intraocular inflammation (endophthalmitis) or raising intraocular pressure can result from posterior displacement.

Diagnostics

- Visual acuity
- Slit-lamp examination
- Intraocular pressure
- Dilated fundus examination
- Echography
- Laboratory evaluation (suspicion of hereditary condition)
- If Marfan's syndrome suspected: cardiac evaluation, eyes axial length measurement
- If homocystinuria is suspected: special serum and urine examination

Differential Diagnosis

- Pseudoexfoliation
- Glaucoma
- Cataracta traumatica

Prophylaxis

In addition to regular ocular examinations, a well-timed cataract surgery for patients suffering, for example, from mature cataracts is reasonable. If the patient suffers from a currently active uveitis disease, a sufficient pharmacological therapy is important.

Therapy

An immediate surgery procedure is considered to be the only efficient therapy. The individual surgical treatment depends on the initial situation and localization of the displaced lens.

In addition to that, an anti-inflammatory treatment is indispensable.

If there is any suspicion of a general disease, a comanagement with the patient's internist or pediatrician is important.

Prognosis

The visual damage varies with the degree of lens displacement, etiologic abnormality, and age of onset.

In case of appearance of the lens dislocation during childhood, the prevention of an amblyopia is vital.

Epidemiology

The actual incidence in general population is currently unknown. In general, it can be said that the ectopia lentis is a rare clinical diagnosis. One cannot detect an age-related distribution of the affected patient, so that age cannot be ascertained as a risk factor for lens dislocation. Considering the gender distribution, the literature reports an overbalance of male patients.

[2]Ruiz Department of Ophthalmology and Visual Sciences, Robert Cizik Eye Clinic, University of Texas Medical School at Houston, Houston, TX, USA

Synonyms

EEC syndrome; Split foot syndrome with clefting; Split hand

Definition

A combination of characteristic findings including ectrodactyly of the hands or feet, bilateral cleft lip and palate, and ectodermal dysplasia. Ectrodactyly refers to abnormal, fused, or extra fingers or toes. All abnormalities are due to dysplasia of ectodermally derived structures.

Etiology

The defects are due to mutations at a variety of possible chromosomes all affecting the p63 gene. This gene is a transcription factor active during embryogenesis that plays a role in stem cell differentiation. The mutation is usually autosomal dominant but can also be sporadic. It has variable expressivity and incomplete penetrance. Sporadic cases are usually more severe than familial cases.

Clinical Presentation

Patients present with a variety of clinical manifestations. Urogenital abnormalities include a wide spectrum of problems such as small-volume bladder, painful micturition, and recurrent infections. The skin and hair can be dry and hypopigmented. The hair can be sparse and slow growing in some patients. One of the most concerning features is a lack of sweat glands, which can lead to hyperthermia and death. The nails are often dystrophic with pitting and transverse ridges. Patients universally have many dental carries and often have secondary dentition malformations. Conductive hearing loss is often noted in patients due to missing or malformed ossicles. Ectrodactyly is often present in the upper or lower extremities. Many patients also have a bilateral cleft lip and/or palate.

The eyes are affected in several ways. The most common problem is poor functioning meibomian glands that lead to a poor lipid tear film resulting in dry eye. The second most common ocular problem is obstruction or malformation of the lacrimal drainage system. This causes excessive tearing or epiphora. With continued blockage of the tear duct, dacryocystitis, an inflammation or infection of the lacrimal sac, can occur. Both dry eye and tear stasis can cause recurring infections of both the eye and ocular adnexa. The corneal limbal stem cells constantly regenerate the corneal epithelium. Corneal scarring, ulceration, neovascularization, perforation, and progressive loss of vision are also common problems that can be attributed to corneal limbal stem cell deficiency that is common in ectodermal dysplasia. Abnormalities of the crystalline lens are not found in EEC despite its ectodermal origin.

Diagnosis

A diagnosis of EEC is made clinically. Two of the three major features are required. These include (1) some form of ectodermal dysplasia, (2) ectrodactyly, and (3) cleft lip or palate.

Differential Diagnosis

- Orofacial clefting and ectrodactyly with no signs of ectodermal dysplasia:
  - Ectrodactyly-cleft palate syndrome
- Ectodermal dysplasia and only *one* of the other major features:
  - Oligosymptomatic EEC
  - Rapp-Hodgkin syndrome
  - Ankyloblepharon ectodermal dysplasia and clefting syndrome
- Mental retardation with ectodermal dysplasia and orofacial clefting:
  - Ectodermal dysplasia, cleft palate, and mental retardation syndrome
- Ectodermal dysplasia and ectrodactyly but no orofacial clefting:
  - Lacrimo-auricular-dento-digital syndrome

Prophylaxis

Genetic screening and meeting with a genetic counselor is recommended to discuss the 50% possibility of passing the mutation on to future generations.

Therapy

Therapy for EEC involves a plastic surgeon repairing dysplastic features such as a cleft lip or palate and dysplastic hands and feet. A renal ultrasound should be recommended to look for any urogenital malformations, and extensive dental work may be needed. If hypohidrosis is present, it is important to educate the patient and family on methods to regulate body temperature and to avoid long periods of heat exposure.

Ophthalmic treatment goals should be focused on protecting the eyes and preserving vision. Most patient's ocular manifestations involve the ocular surface. Artificial tears and surface lubrication, both lipid and aqueous based, can be used for dry eye. For patients with poor drainage and excessive tears a dacryocystorhinostomy (DCR) can be performed. These patients are also susceptible to ophthalmic infections and should be

monitored closely. If an infection is diagnosed, topical antibiotic drops are effective for ocular infections, and systemic antibiotics drops are needed for ocular adnexal infections. Supportive ocular surface care with soft contact lenses, artificial tears, or mild steroids is beneficial to prevent corneal scarring and vision loss. Corneal transplants have a better prognosis if most of the corneal limbal stem cells are intact. If there is significant loss of corneal limbal stem cells and poor corneal epithelium, a combined cadaveric limbal stem cell transplant and corneal transplant, or keratoprosthesis may be the only option.

Prognosis

Progressive loss of vision and overheating causes the greatest morbidity. Hyperthermia due to the absence of sweat glands can lead to seizures, coma, and death. Patients with EEC rarely have intellectual disabilities and can be expected to live a full and productive life with close management.

Epidemiology

Rare, but the true prevalence is unknown. There is no correlation with race, sex, or socioeconomic status.

Edema, Eyelid

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Eyelid edema is swelling of the eyelids that can result from a variety of causes.

Etiology

Periorbital edema most commonly occurs from allergy, angioedema, or localized lymphedema. Eyelid edema may be caused by both local and systemic conditions.

Classification/Occurrence

Local inflammatory diseases may cause eyelid edema. Contact dermatitis is one of the most common causes of cutaneous eyelid inflammation and is due to allergy or irritation from exposure to chemicals via direct application or contamination from the fingers and hands. Angioedema is an abrupt, usually bilateral, deep dermal swelling mediated by a type I allergic reaction. In addition, rosacea, allergy, or insect bites may also cause eyelid edema.

Local infections such as bacterial (blepharitis, hordeolum, chalazion), viral (herpes simplex, herpes zoster), and parasitic or protozoal infections (trichiniasis, filariasis, onchocerciasis, trypanosomiasis, and malaria) can cause eyelid edema. Preseptal or orbital cellulitis as well as intraocular infections may also cause periorbital edema.

In addition, eyelid edema may be a reflection of systemic disease including hypoalbuminemia, renal disease, and congestive heart failure causing bilateral, boggy, nontender, nondiscolored soft-tissue swelling. In addition, myxedema, dermatomyositis, lymphoproliferative disease, superior vena cava syndrome, drug eruption, and certain collagen vascular diseases may be associated with eyelid edema. Generalized or regional edema as well as other signs and symptoms consistent with each respective disease should also be present.

Other causes include blunt trauma, where a history of trauma is present, and eyelid swelling is self-limited. Tumors that involve the eye may rarely cause eyelid edema including hemangiomas of the lid as well as certain ocular or orbital neoplasms. In addition, lymphedema may be present after the lymphatic drainage system from the eyelid is interrupted.

Edinger-Westphal Nucleus

Definition

The Edinger-Westphal complex, also known as the Edinger-Westphal nuclei (EWN), is a group of neuron cell bodies that lie under the aqueduct

of Sylvius in the midbrain, just posterior to the oculomotor motor nuclei (of cranial nerve III) in the midbrain. Each EWN receives bilateral input from interneurons of the pretectal area (olivary pretectal nucleus) via the posterior commissure, which in turn receive afferent input from light-sensitive W-type ganglion cells of the retina whose axons run in the optic nerve (cranial nerve II). The EWN serves as the site of origin for cholinergic preganglionic parasympathetic fibers that run along the oculomotor nerve (cranial nerve III) and synapse in the ciliary ganglion in the orbit. From the ciliary ganglion, postsynaptic parasympathetic fibers run with the short ciliary nerves to provide motor innervation to the smooth muscle of the iris pupillary sphincter, leading to pupillary constriction in response to light (the pupillary light reflex). Pupillary constriction also occurs when looking at a near object along with convergence and accommodation (i.e., the near synkinesis reflex). This pathway involves fibers from the nucleus of Perlia (of the occipitomesencephalic tract) that synapse in the EWN and eventually make their way to the ciliary muscle to increase lens thickness and refractive power for focusing on a near object.

[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

The efferent visual system is composed of the ocular motor pathways ("infranuclear" pathways) that originate from cranial nerve nuclei III, IV, and VI of the midbrain and brainstem. These three cranial nerves control the extraocular muscles of the eye. Internuclear pathways (e.g., medial longitudinal fasciculus) coordinate ocular motor nuclei activity along with the infranuclear pathways to produce conjugate eye movements (matched rotation of the eyes in the orbit to stabilize the visual world) such as vertical and horizontal saccades (rapid relocation of gaze fixation), smooth pursuit (slow, involuntary following of moving target), vestibular movements (initiated by input from semicircular canals responding to head movement), and convergence (involved in depth perception and near synkinesis). This system works with the afferent visual system to keep the target of visual fixation on the macula (area of retina responsible for high-acuity vision).

Cranial Nerve III: Oculomotor Nerve

The nuclei of the oculomotor nerves lie in the midbrain at the level of the superior colliculus, ventral to the cerebral aqueduct and periaqueductal gray. The oculomotor nerve provides ipsilateral motor innervation to most of the extraocular muscles of the eye except the superior oblique (innervated by CN IV) and lateral rectus muscles (innervated by CN VI). The extraocular muscles innervated by CN III are the inferior oblique, medial rectus, superior rectus, and inferior rectus. A CN III palsy results in a "down and out" position of the eye due to loss of function of all muscles except the superior oblique and lateral rectus muscles, controlled by the trochlear and abducens nerves, respectively.

Cranial Nerve IV: Trochlear Nerve

The trochlear nerve nucleus provides contralateral motor innervation to the superior oblique muscle, which abducts, depresses, and internally rotates (intents) the eye. The trochlear nucleus is also located in the midbrain, caudally to the oculomotor nucleus at the level of the inferior colliculus.

Cranial Nerve VI: Abducens Nerve

The abducens nerve provides motor innervation to the ipsilateral lateral rectus muscle that produces abduction. The abducens nucleus, located in the caudal pons, is also critically involved in horizontal conjugate movements of the eye. When activated by the paramedian pontine reticular formation (PPRF), the nucleus not only activates the ipsilateral lateral rectus muscle via the abducens nerve but also sends excitatory projections via the medial longitudinal fasciculus (MLF) to the contralateral oculomotor nucleus that controls the medial rectus muscle. In this way, the abducens nucleus is the final common pathway

for the control of voluntary and involuntary horizontal conjugate eye movements.

Angioid streaks – Ehlers-Danlos syndromes

Introduction

Ehlers-Danlos syndromes (EDS) comprise a heterogeneous group of diseases of the connective tissue. The features of EDS were first described by Hippocrates in 400 BC. The syndrome is named after two physicians, Edvard Ehlers from Denmark and Henri-Alexandre Danlos from France, who described it at the turn of the twentieth century (Parapia and Jackson 2008; Georgalas et al. 2009).

EDS is caused by a defect in the structure, production, or processing of collagen or proteins that interact with collagen. This disease is characterized by fragility of the soft connective tissues and widespread manifestations in the skin, ligaments, joints, blood vessels, and internal organs. The clinical spectrum varies from mild skin and joint hyperlaxity to severe physical disability and life-threatening vascular complications. The overall incidence is 1 in 5,000 births, with higher rate among blacks. There is no cure yet for EDS, and treatment is supportive (Georgalas et al. 2009; Ryan et al. 2013).

Among these patients it is common to find angioid streaks on ophthalmologic examination.

Definition

Angioid streaks were initially described in 1889 by Doyne. They were described as irregular radial lines spreading from the optic nerve to the retinal periphery in a patient with retinal hemorrhages due to blunt trauma. Knapp was the first to use the term "angioid streaks" since the funduscopic appearance of the lines was similar to that of blood vessels. In 1917 Kofler correctly determined that angioid streaks represented changes at the level of Bruch's membrane (Parapia and Jackson 2008).

Histopathologic studies have demonstrated that angioid streaks represent irregular dehiscence in the thickened and calcified Bruch's membrane (Georgalas et al. 2009).

Systemic Conditions Associated with Angioid Streaks

Associations have been found between angioid streaks and systemic conditions such as pseudoxanthoma elasticum (Gronblad-Strandberg syndrome), Paget's disease, sickle cell anemia, acromegaly, and fibrodysplasia hyperelastica (Ehlers-Danlos syndrome). However angioid streaks may also occur in patients without associated systemic disease (Parapia and Jackson 2008; Georgalas et al. 2009; Ryan et al. 2013).

Etiology

Klein proposed a dual mechanism for the development of Bruch's membrane angioid streaks including a primary abnormality in the fibers of Bruch's membrane and increased deposits of metal salts or an increasing tendency for their pathologic deposition (Parapia and Jackson 2008; Georgalas et al. 2009).

The deposition of calcium may cause Bruch's membrane to become more brittle and increases the likelihood of developing choroidal rupture.

Furthermore it has been shown that tissue metalloproteinase, specifically MMP-9 which is known to induce basement membrane destruction and angiogenesis, was found in higher concentrations in the excised Bruch's membrane in areas of choroidal neovascularization in some eyes with angioid streaks (Georgalas et al. 2009; Ryan et al. 2013; Schubert 2014–2015).

In the early stages, angioid streaks consist of partial breaks of the calcified Bruch's membrane with thinning of the RPE, without any significant anatomic changes in the overlying retinal layers. In advanced stages, a full-thickness break of Bruch's membrane may occur followed by atrophy of the choriocapillaris, RPE, and photoreceptors. Fibrovascular proliferation from the choroid may occur through the Bruch's membrane break resulting in choroidal neovascularization and subsequent development of a disciform scar (Parapia and Jackson 2008; Georgalas et al. 2009; Ryan et al. 2013; Schubert 2014–2015).

Clinical Presentation

Angioid streaks usually originate adjacent to the optic nerve and may either radiate out or surround it concentrically and appear as irregular lines of varying width. The subretinal lines can range in diameter from 50 to 500 μm. The color of angioid streaks varies and depends on fundus pigmentation and the degree of the atrophy of the overlying RPE. Thus, angioid streaks are reddish in light-colored individuals, while in patients who have darker background pigmentation, they are usually medium to dark brown (Georgalas et al. 2009; Schubert 2014–2015).

Angioid streaks remain unchanged or may increase in length and width over time. There are no clinical studies determining the rate of their propagation in correlation with time. New streaks may be formed adjacent to old lesions and adjacent RPE and choriocapillaris may develop atrophy (Parapia and Jackson 2008).

Additional fundus findings in this condition include optic disc drusen, peripheral round atrophic scars, and a lighter orange appearance against the darker orange color of the normal RPE and choroid. At the interface between the abnormal light color and the normal darker color, the fundus has a fine, stippled appearance referred to as peau d'orange ("the skin of an orange"). Small, round retinal pigmented dots, known as crystalline dots, are also frequently present in the mid-peripheral retina (Parapia and Jackson 2008; Georgalas et al. 2009; Ryan et al. 2013).

Usually patients remain asymptomatic, and angioid streaks are an incidental finding during a routine ophthalmological investigation, unless the macula is involved with the development of traumatic rupture of the Bruch's membrane or choroidal neovascularization.

In cases with macular involvement, patients usually report metamorphopsia, blurred vision, or decreased central vision (Parapia and Jackson 2008).

Rupture of Bruch's membrane in cases of blunt head or ocular trauma may be followed by subretinal hemorrhages. It has been reported that up to 15% of patients with angioid streaks develop significant visual loss after mild head injury (Parapia and Jackson 2008; Georgalas et al. 2009).

The most common significant complication of angioid streaks is the development of choroidal neovascularization CNV, which is often bilateral, and the incidence varies between 72% and 86% in numerous studies. CNV usually is asymmetric with a mean interval of 18 months between the development of CNV in the first and fellow eye.

The risk of developing CNV increases with age. The wider and longer are the angioid streaks

the higher the risk for CNV and especially if the lesions are located in a distance less than one optic disc diameter from the fovea (Parapia and Jackson 2008; Georgalas et al. 2009; Ryan et al. 2013).

The standard outcome is poor if CNV in the macular region remains untreated because it leads to further extensive formation of subfoveal scarring causing severe loss of visual acuity. More than 50% of such patients eventually become legally blind with very poor visual acuity.

Diagnosis

Usually the diagnosis of angioid streaks is made on funduscopic examination, but ophthalmological imaging, in particular fluorescein angiography (FA), may be helpful in detecting angioid streaks and associated choroidal neovascularization when the findings are subtle (Parapia and Jackson 2008; Ryan et al. 2013; Schubert 2014–2015).

Fluorescein Angiography (FA)

FA demonstrates irregular hyperfluorescence of the angioid streaks during the early phase followed by varying degrees of staining during late phases. In some individuals with deeply pigmented choroidal tissue, the angioid streaks may be difficult to detect angiographically, whereas in light-pigmented individuals, fluorescein angiography may aid in the identification of the angioid streaks prior to their clinical detection. Fluorescein leakage is evident when CNV is present (Parapia and Jackson 2008; Georgalas et al. 2009).

Fundus Autofluorescence (FAF)

FAF imaging uses light emission from lipofuscin in RPE cells and is considered to reflect RPE metabolic activity. Fundus autofluorescence often demonstrates hypo-autofluorescence representing RPE atrophy, which can be seen more extensively than that seen on fundus ophthalmoscopy or FA. It is a useful noninvasive tool to monitor the progression of the RPE damage and choroidal neovascularization (Parapia and Jackson 2008; Georgalas et al. 2009; Schubert 2014–2015).

Indocyanine Green Angiography (ICGA)

ICGA is useful among patients with some scarring that may obscure the presence of active CNV. In these cases ICG angiography demonstrates the neovascularization more clearly than fluorescein angiography. It shows the hyperfluorescent lines with "pinpoints" in brighter areas of hyperfluorescence that are enhanced through the late stages suggesting the presence of CNV.

Spectral Domain Optical Coherence Tomography (SD OCT)

SD OCT has been shown to be helpful in detecting abnormalities in Bruch's membrane as well as the presence of subretinal fibrosis and deposits that can be difficult to demonstrate on FAF, FA, or ICGA (Parapia and Jackson 2008; Georgalas et al. 2009).

Treatment

There is no known prophylactic treatment for the formation of angioid streaks. The use of safety glasses may be advised for patients with angioid streaks because their eyes are particularly susceptible to choroidal rupture even after minor blunt injury. Treatment strategies are only directed to treat eyes with choroidal neovascularization, since untreated CNV results in poor visual outcomes.

Laser Photocoagulation

In the past prophylactic therapy of angioid streaks with thermal laser in order to prevent CNV development has failed and in some cases even induced CNV formation. Some studies have shown that

laser treatment for extrafoveal CNV related to angioid streaks resulted in better visual outcome than untreated eyes. On the other hand, results of photocoagulation for the treatment of foveal CNV demonstrate a high recurrence rate of up to 77% and poor overall visual outcomes (Parapia and Jackson 2008; Georgalas et al. 2009).

Transpupillary Thermotherapy (TTT)

TTT employs diode laser beam of 810 nm wavelength, with a lower threshold to avoid producing a thermal burn. This treatment has a better penetration to the choriocapillaris and is less damaging to the RPE. However a retrospective study investigating the use of TTT in treatment of subfoveal choroidal neovascularization found no significant long-term benefit in reducing the growth of the CNV or in visual improvement.

Photodynamic Therapy (PDT)

Data from both retrospective and prospective case series of eyes treated with PDT demonstrate variability and contradictory results on visual outcomes (Georgalas et al. 2009; Schubert 2014–2015).

In conclusion, from all previous studies and case reports, it is evident that despite the initial encouraging results from the application of PDT for the treatment of foveal CNV, the end results did not fulfill the initial expectations. However some may consider PDT as an adjuvant therapy that does not prevent, but slows down the natural course of CNV.

Macular Translocation

This surgical technique was introduced by Machemer and Steinhorst in 1993, which was applicable prior to the use of anti-vascular endothelial growth factor (VEGF) treatments for CNV.

This surgical technique involves moving the macular neuroretina to lie on top of an area of RPE without previous CNV. Several techniques have been described including a limited translocation as well as a 360° translocation where the entire retina is rotated. However, this is a complex, difficult, long-lasting operation with serious complications which can threaten the patient's vision.

In the few studies that employed this technique, varying short-term visual acuity improvement has been reported, but one should keep in mind that the number of eyes treated was limited.

Anti-VEGF Treatment

Laser photocoagulation, TTT, and PDT have not been as successful in reducing the degree of visual loss compared with the visual outcomes following anti-VEGF therapy. Treatments with anti-VEGF therapies such as bevacizumab or ranibizumab have demonstrated a marked reduction in the incidence of severe visual acuity loss in the treated eyes compared to the untreated eyes, though follow-up is short and randomized trials are lacking.

Further investigations involving combination therapy are needed before determining its added benefit over monotherapy with anti-VEGF treatment alone (Parapia and Jackson 2008; Georgalas et al. 2009).

Prognosis

As described above, patients with angioid streaks usually are asymptomatic unless complications such as macular choroidal neovascularization develop. In case of macular involvement, the prognosis is often poor, with higher than 50% of eyes progressing to legal blindness without treatment (Georgalas et al. 2009; Ryan et al. 2013; Schubert 2014–2015).

EDS I: classic type, gravis type; EDS II: mild classic type, mitis type; EDS IV: vascular type, arterial type, ecchymotic type, Sack-Barabas type; EDS VI: kyphoscoliotic type, ocular-scoliotic type, Nevo Syndrome, Brittle Cornea Syndrome (variant of Ehlers-Danlos Type VI)

Definition

Ehlers-Danlos syndrome (EDS) is a rare, inherited disorder caused by defective collagen synthesis. It is part of a large heterogeneous group of connective tissue disorders characterized by skin and joint hyperextensibility and easy bruisability with poor scar formation. Over 10 distinct clinical subtypes exist based on biochemical, genetic, and clinical variations; those subtypes with ocular manifestations are included in Table 1, below (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Etiology

All forms of EDS result from defective synthesis and metabolism of elastin, proteoglycans, and

Ehlers-Danlos Syndrome, Gene Linkage of Disease, Table 1 A summary of Ehlers-Danlos Syndrome classifications and associated gene linkage

Type	Prevalence	Systemic findings	Ocular manifestations	Gene linkage
EDS type I	1 in 20,000	EDS type I is the most common severe form. The skin is easily hyperextensible and bruisable.	Epicanthal folds are a common finding. Eyelids can be easily stretched and everted. Retinal detachment has also been reported.	*COL5A1* (9q34.3), *COL5A2* (2q32.2) or *COL1A1* (17q21.33).
EDS type II	1 in 20,000	EDS type II resembles type I but has milder clinical findings and is hence called the "mitis" type. It has similar prevalence as EDS type I.	Epicanthal folds are a common finding.	*COL5A1* (9q34.3) or *COL5A2* (2q32.2).
EDS type IV	1 in 200,000	EDS type IV is related to abnormalities in medium-sized arterial vessels.	Ocular complications involve carotid-cavernous fistulas giving rise to ocular bruits, proptosis, conjunctival hyperemia and chemosis, blurred vision, diplopia, and orbital pain. Further perfusion compromise can cause ocular ischemia.	*COL3A1* (2q32.2)
EDS type VI	1 in 100,000	EDS type VI is characterized by severe kyphoscoliosis, generalized joint laxity, and skin involvement.	Globe rupture and rhegmatogenous retinal detachment may occur as a result of minor trauma or spontaneously. Other ocular manifestations in EDS type VI include myopia, thin, blue sclerae, and microcornea with normal intraocular pressure. These features make this subtype of most interest to ophthalmologists.	*PLOD1* (1p36.22)

macromolecular proteins in the extracellular matrix of various tissues, the most abundant of which is collagen. In majority of EDS cases, mutations in a wide variety of genes cause altered structure, synthesis, posttranslational modifications, or stability of involved collagen molecules. This leads to decreased synthesis of collagen, defective collagen fibril crosslinking, or decreased function of involved collagen-processing enzymes, such as lysyl hydroxylase 1 in EDS type VI.

EDS type I is caused by an autosomal dominant mutation in collagen alpha-1(V) (*COL5A1* [9q34.3]), collagen alpha-2(V) (*COL5A2* [2q32.2]), or rarely in collagen alpha-1(I) (*COL1A1* [17q21.33]) genes. These genes code for the alpha chain in type V and type I collagen. The mutations result in defective production of type V and type I collagen. EDS type II is caused by an autosomal dominant mutation in collagen alpha-1(V) (*COL5A1* [9q34.3]) or collagen alpha-2(V) (*COL5A2* [2q32.2]) genes only.

EDS type IV is caused by an autosomal dominant, or rarely autosomal recessive, heterozygous mutation in the type III collagen gene (*COL3A1* [2q32.2]). This mutation causes structural defects in pro-alpha-chains of type III procollagen.

EDS type VI is caused by an autosomal recessive homozygous or compound heterozygous mutation in the *PLOD1* (1p36.22). This gene codes for lysyl hydroxylase 1 – an enzyme responsible for the formation of hydroxylysyl groups in collagen molecules. These groups become important attachment sites for carbohydrates in collagen molecules. The *PLOD1* mutation results in reduced stability of collagen intermolecular crosslinking (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Clinical Presentation

Patients with EDS may present with dry eyes, steep corneas, pathologic myopia, and abnormal vitreous. Epicanthal folds are identified with classical EDS type I and II. Keratoglobus is associated with EDS type VI.

An association between EDS and ectopia lens has been reported; collagen type IV is present in zonular fibers but the molecular mechanisms underlying such weakness are unclear and may be related to myopic change.

In EDS type VI, a variant also known as brittle cornea syndrome, patients demonstrate a biochemical defect other than lysyl hydroxylase. Associated with keratoglobus or keratoconus, minor trauma may cause rupture of the globe with risk of retinal detachment due to increased corneal and scleral fragility and thinning. Corneas with significant anterior bulging may experience Descemet membrane detachment, resulting in the appearance of a thin cornea with corneal haze. A thin sclera appears blue due to relatively increased transparency and visualization of underlying uvea.

Systemically, characteristic findings are hypermobile joints and hyperextensible skin. Cardiovascular disease involves bleeding diathesis, dissecting aneurysms, spontaneous rupture of large blood vessels, and mitral valve prolapse. Other systemic features include kyphoscoliosis, diaphragmatic hernia, carotid-cavernous fistula, and diverticula of the gastrointestinal and respiratory tracts (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Diagnosis

Diagnosis of the different subtypes of EDS is based on careful evaluation of clinical features and use of laboratory tests. Classical type EDS (type I and II) is diagnosed based on clinical examination. Diagnosis of EDS type IV (vascular type) may be more definitively confirmed by genetic testing for mutations in *COL3A1* or a skin biopsy indicating collagen changes in cultured fibroblasts. Urinary enzyme assay can help establish the diagnosis of EDS type VI (kyphoscoliotic type) (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Differential Diagnosis

Other non-EDS disorders with similar clinical presentation should be considered and excluded in the patient workup. Marfan syndrome may present with infantile kyphoscioliosis also seen in EDS type VI. Larsen's syndrome resembles the arthrochalasis type of EDS due to similar joint hypermobility. Cutix laxa may resemble the skin involvement and loss of elasticity in dermatosparaxis type of EDS (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Prophylaxis

Genetic counseling should be given to all patients on mode of inheritance and risk of having children with EDS. Prenatal diagnosis of all EDS types with specific molecular defects may be a useful screening tool. Biochemical and genetic screening may elucidate defects in type III collagen in relatives at risk. Patients with vascular EDS should be advised to avoid contact sports and to manage high blood pressure. Arteriography and arterial lines should also be avoided (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Therapy

Correct diagnosis of EDS and specific subtype should be established if possible before appropriate management plan is formulated. The kyphoscoliotic type of EDS may improve with administration of vitamin C by compensating for enzyme deficiencies; no metabolic or genetic therapy is effective in other forms of EDS.

Management of ocular manifestations is challenging due to poor wound healing or approximation. In EDS type VI, in particular, management of spontaneous globe rupture necessitates a careful surgical approach due to corneoscleral fragility; epikeratoplasty allows addition of donor corneal tissue for stability while preserving host cornea, although reports are few (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Prognosis

Life expectancy is comparable to the general population except for patients with EDS type IV, in which it is decreased to approximately 50 years of age (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Epidemiology

Incidence of EDS has been estimated to be about 1 in 5000 births and worldwide prevalence to be about 1.5 million people (Lorenz and Moore 2006; Kanski and Bowling 2011; Krachmer et al. 2011; Chaudhuri and Vanathi 2012; Goldman and Schafer 2012).

Electrical Evoked Response (EER); Phosphene

Definition

The electrically evoked potential (EEP) is the electrical activity in the visual cortex (V1) that is triggered by trans-corneal electrical stimulation. The psychophysical description of visual perception, reported by subjects who undergo electrical stimulation of the globe, is called phosphene.

This is in distinction from electrical activity in the visual cortex that is generated in response to light stimuli (visually evoked potential, VEP).

Purpose

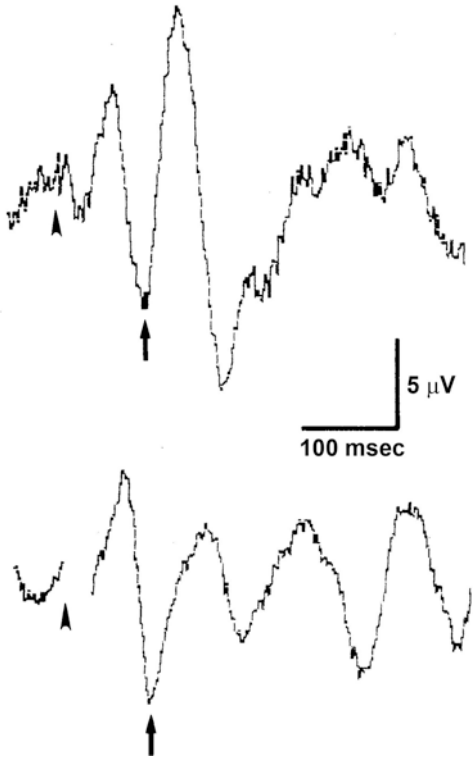
The electrically evoked potential (EEP) is used to assess the functional integrity of the visual nervous system, including the retinal ganglion cells, optic nerves, visual pathways, and primary visual cortex (V1) in cases where simple visual stimuli cannot be used (Dorfman et al. 1987).

Principle

The visual system, like any other sensory modality, depends upon electrical activity that is generated in the receptors (hair cells in the ear, photoreceptors in the retina) in response to a physical stimulus (sound, light). The information conveyed to the appropriate region in the brain from any physical stimulus is a pattern of electrical activity, which is further processed in the brain leading eventually to perception. Therefore, any pattern of electrical activity transmitted from the eyes to the primary visual cortex (V1) regardless of its physical source is perceived as light.

Electrical activity in the visual pathways that is elicited by stimuli other than light, such as physical pressure or by electrical stimulation, will all be interpreted in the brain as reflecting light stimuli, which are called phosphenes.

The electrically evoked potential (EEP) is elicited by trans-corneal electrical excitation while recording electrical activity from the visual cortex using scalp electrodes placed over the occipital lobe in a pattern similar to that used to record the visually evoked potential (VEP). Trans-



Electrically Evoked Potentials, Fig. 1 Electrical evoked potential and visual evoked potential, obtained by stimulating the same eye in a healthy volunteer, are compared. Timing of stimuli is marked by an arrowhead and the preeminent negative wave by an arrow.

corneal electrical excitation can be achieved with a bipolar corneal electrode or by a monopolar electrode placed on the cornea, while the ground electrode is placed either on the forehead or the temporal skin. The cornea needs to be anesthetized in order to prevent any discomfort to the patient (Potts et al. 1968; Gekeler et al. 2006).

Figure 1 compares visually evoked potential (VEP) elicited by flashlight stimuli to electrically evoked potential (EEP) that was elicited by square 5-ms pulses of 500 μA applied to the cornea using a bipolar corneal electrode. The VEP and EEP were recorded by stimulating the same eye. Recording from the visual cortex was done using a bipolar recording configuration. The active electrode was placed along the midline about 3 cm above the inion, the reference electrode was placed 5 cm further up along the midline, and an ear-clip served as ground electrode. The small gap in the trace of the EEP is the photoelectric artifact. Arrowheads denote timing of stimuli, and arrows point to the first negative wave. The pattern of the VEP and EEP differ; the EEP is composed of several consecutive waves, while the VEP is more robust and is composed of a negative wave followed by a positive wave.

Indication

The electrically evoked potential (EEP) was suggested for the following:

1. Very opaque optical media: in cases when bright light stimuli are not sufficient to test potential visual function, the EEP can be used to assess the functional integrity of the visual pathways from the eyes through the lateral geniculate nuclei and to the primary visual cortex (V1).
2. Candidates for implantation of retinal neuroprosthesis: Electrical neuroprosthetic devices have been developed and approved for clinical use in blind patients suffering from advanced retinitis pigmentosa. Evaluation of the integrity of the visual nervous pathways before surgical implantation of the prosthesis is imperative for assessment of the potential for visual restoration. A bright flash VEP and ERG can be used but in very advanced cases of retinitis pigmentosa, even intensely bright flashes may not elicit a measurable cortical response. In these cases, trans-corneal electrical stimulation can be used to check for detection of phosphenes or more objectively for recording the EEP to indicate whether electrical stimulation can elicit brain activity.

Contraindication

Severe damage to the cornea.

Advantage/Disadvantage

Advantage: test optic nerve function, bypassing photoreceptors.

Disadvantage: not clear which retinal elements are stimulated, may be moderately uncomfortable.

Light-induced retinal damage; Phototoxicity

Definition

Electromagnetic radiation is any form of energy generated by electromagnetic process, ranging between x-rays to microwaves. The visible range of electromagnetic radiation is characterized by wavelength spectrum that spans from 400 nm (purple blue) to 700 nm (red). Whereas light in the visible range is essential for physiological visual function, exposure to excessive electromagnetic energy of any wavelength can result in tissue damage to the retina through one of several general mechanisms, including photochemical, thermal, or mechanical injury. The particular mechanism activated depends on the wavelength, duration of exposure, and energy of electromagnetic radiation.

1. Photochemical damage: reflects excessive activation of the phototransduction cascade in the rod photoreceptors leading to apoptosis of the retinal pigment epithelial (RPE) cells and photoreceptors. Photochemical retinal damage, first described in albino rats, depends upon light intensity, its color, duration of light exposure, body temperature of animal, and other parameters and is characterized by irreversible reduction in the ERG amplitudes associated with degeneration and loss of photoreceptors and RPE cells. The pathological mechanism of this photochemical injury is yet to be elucidated, but several hypotheses have been speculated, including light-induced oxidative stress and metabolic stress.

   To date, no clinical correlate of this kind of retinal injury has been described in humans.
2. Thermal damage: occurs when light is absorbed by non-visual pigments in the retina such as melanin, hemoglobin, or lipofuscin and causes local temperature rise and thermal stress to the tissue. The local heat response can result in denaturation of proteins, loss of tertiary structure of proteins and macromolecules, and loss of membrane structure. Higher energy levels can cause photocoagulation of tissue.

   In clinical ophthalmology, the principle of controlled photothermal retinal damage is commonly applied for the treatment of retinal conditions including laser retinopexy around

retinal breaks or laser photocoagulation for leaking blood vessels.

3. Mechanical damage: occurs when excessive energy from electromagnetic radiation generates tensile forces in the tissue, leading to formation of cavitation and structural tissue disruption.

In ophthalmology, pulsed lasers that produce photodisruption of tissue are used for producing precise holes or cuts, particularly in the anterior segment. For example, the pulsed Nd:YAG laser is commonly used to perform capsulotomy when visually significant opacification of the posterior lens capsule occurs after surgical cataract extraction. However, pulsed lasers can be lethal to the RPE and carry a high risk of collateral damage to the retina and therefore are rarely employed for procedures of the posterior segment.

Synonyms

Arden ratio; Standing potential of the eye; The corneo-fundal potential

Definition

The electrooculogram (EOG) is an electrophysiological test to assess the standing potential of the eye that normally exists between the cornea and Bruch's membrane at the back of the eye. This potential, also called corneo-fundal potential, is largely derived from the activity of the retinal pigment epithelium (RPE) and depends upon the functional and morphological integrity of the RPE as well as on the interactions between the RPE and the photoreceptors. Since the standing potential of the eye cannot be measured directly in humans, the clinical EOG is used to measure the effects of the state of adaptation upon the standing potential. The EOG voltage is measured first in darkness and then during adaptation to bright background. The ratio between the maximal EOG voltage under light-adapted conditions and the minimal value measured in darkness is called the Arden ratio and was shown to be a reliable measure of the integrity of the RPE and the interactions between the RPE and the photoreceptors.

Purpose

The purpose of recording the electrooculogram in clinical electrodiagnosis of vision is to assess the integrity of the RPE and the interaction between the RPE and photoreceptors. This is achieved by measuring the dependence of the EOG upon the state of adaptation. Therefore, the EOG belongs to the ensemble of electrophysiological tests (ERG, EOG, and Visual Evoked Potentials (VEP)) that are used in electrodiagnosis of visual disorders for assessing retinal function in health and in disease.

Since the electooculogram is a useful tool to track eye movements, it is used for additional purposes including:

1. Following reading strategies in children suffering from learning disabilities.
2. Studying strategies for scanning pictures.
3. Tracking eye movements during sleep to assess sleep disorders.
4. Monitoring fixation quality in experiments involving visual task performance.

Principle

The eye is an electrical dipole in which the cornea is constantly positive compared to the back of the eye. The corneo-fundal potential originates from the metabolic activity of several epithelial tissues within the eye, including the cornea, lens, and RPE, but the RPE component, called the Trans Epithelial Potential (TEP), is the dominant one and is the only one that changes with the state of adaptation. Typically, the standing potential of the eye substantially decreases during dark adaptation, reaching its lowest potential after 8–12 min, a minimum called "dark trough." When a bright background light of about 100 cd/m^2 for dilated eyes and 400 cd/m^2 for non-dilated eyes is turned on, the resting potential gradually rises, reaching a peak in about 9–12 min followed by a slow decline toward baseline level. The standing potential in the dark reflects differential permeability to ions of the apical and basal membranes of the RPE, mainly to potassium ions, and the activity of ionic transporters. The slow rise of the standing potential under background conditions reflects depolarization of the basal membrane of the RPE which is believed to reflect increase in permeability to chloride channels in the basal RPE membrane. Conflicting results from animal models argue about the role of the bestrophin protein in the rise of the standing potential during background light.

The EOG is measured clinically by a pair of electrodes attached to the skin on the left and right sides of the eyes. The patient is instructed to shift gaze, without moving the head, between two red LEDs lighted sequentially to the left and right of the center of fixation. The two target LEDs are separated by about 30°, 15° on each side of the central fixation. With the cornea being positive compared to the back of the eye, horizontal eye movements shift the electrical potential measured between these electrodes in a square wave pattern. In a typical electrodiagnostic setup, the patient first performs the EOG under background conditions for 2–3 min, followed by complete darkness for about 15 min. Then, the background light is turned on and the patient continues with the test for an additional 15 min. Eye movements between the LED targets are typically repeated for 10–15 s every minute.

The amplitude of the voltage changes during eye movements depends upon the resistance of the electrodes, their distance from the eye, and the performance of the task by the patient. To overcome technical variability, Geoffrey Arden suggested in 1962 to measure the "dark trough" and the "light peak" in order to calculate the "light peak" to the "dark trough" ratio, thereby circumventing any technical factors. In visually normal subjects, the value of Arden ratio should be 2.0 (200%) or higher. An Arden ratio lower than 1.8 (180%) is considered abnormal for individuals under the age of 60 years, and a ratio of less than 1.7 (170%) is abnormal for individuals over 60 years of age.

A normal EOG test is shown in the figure. The volunteer performed eye movement for 15 s in about every minute, and the voltage difference of the square wave was plotted as data points in the upper panel. The dark fall toward the "dark trough" in the EOG amplitude during the 15-min dark period followed by the light rise during 15 min of bright background toward the "light peak" are clearly evident. Two examples of the square wave produced by the eye movements between the two red LEDs are shown in the figure; one was recorded during the "dark trough" and the other during the "light peak." In this particular example, the Arden ratio (light peak divided by dark rough) was 4.53 (453%).

Over the years, several attempts were made to use pharmacological approach to affect the transepithelial potential of the RPE directly. Intravenous infusion of hyperosmotic solution and acetazolamide or bicarbonate solution induced a decrease in the EOG voltage. By combining measurements of the EOG light rise with a pharmacologically induced change in the EOG, a better localization of the underlying pathological process can be achieved. Thus, in cases of retinitis pigmentosa, the EOG light rise is absent while acetazolamide-induced decrease in EOG amplitude persists indicating that the source of the abnormal EOG resides in the photoreceptors and not in the RPE.

Indication

The electooculogram is a useful adjunct to electroretinography (ERG) and is typically used for specific indications. It reflects a pan-retinal response and is generally affected in diffuse disorders of the RPE and the photoreceptors. It may be abnormal in conditions characterized by rod dysfunction, chorioretinal atrophy, and inflammation. However, in most of these cases, an abnormal EOG is associated with an abnormal ERG, and there is no need for EOG testing to make a diagnosis.

The hallmark of dissociation between EOG and ERG is Best vitelliform macular dystrophy, which is the most common indication for EOG testing. In Best disease, the "light peak" of the EOG is reduced, giving rise to an Arden ration considerably lower than 1.8 (180%), whereas the ERG is normal because the peripheral retina functions normally. Other diseases associated with abnormal EOG in the presence of normal ERG include autosomal recessive bestrophinopathy, fundus flavimaculatus, and pattern dystrophy of the RPE. The EOG may also be markedly depressed in acute zonal occult outer retinopathy (AZOOR).

Another important use of the EOG is in separating retinitis pigmentosa (RP) and allied disorders from congenital stationary night blindness. It may also be helpful in RP cases that are characterized by a very slow progress of photoreceptor degeneration, and the fundus appearance is atypical for the disease. With patients complaining of difficulties at night and the ERG responses not dramatically reduced in amplitude, a progressive photoreceptor degeneration disorder can be misdiagnosed as stationary night blindness. The EOG is a decisive test since the Arden ratio is subnormal in RP and normal in stationary night blindness.

Contraindication

There is no contraindication for the use of EOG in terms of patient safety. However, for a patient suffering from severe photophobia, the light phase of the test may be too difficult to bear, and the EOG test is useless. Additionally, patients with difficulties in eye movements cannot comply with the EOG procedure and should not be subjected to the test.

Advantage/Disadvantage

The test is noninvasive and provides valuable information in certain cases of retinal disorders.

The validity of EOG results depends on accurate and consistent tracking of the fixation lights, while moving the eyes only and avoiding any head movements for over at least 30 min, and thus this test is not appropriate for young children and for elderly patients. The test also depends on a minimum degree of light adaptation and may not be reliable in patients with severe photophobia who cannot open their eyes during the background phase of the test.

The electrical response of the retina to a light stimulus

Definition

The visual system processes visual information as patterns of electrical activity. The photoreceptors of the retina transform the physical stimulus (light) into electrical signals that are preprocessed by the retinal neurons before being transferred via the optic nerve to the visual cortex of the brain for further processing. The electrical activity generated in the different types of retinal neurons in response to a light stimulus gives rise to radial extracellular currents that can be recorded by a corneal electrode. This electrical signal is called the electroretinogram (ERG).

The full-field ERG (ff-ERG) response, which is mostly used for electrodiagnosis of retinal disorders, is a summated wave of three major components. The cornea-positive P-I arises from potential change across the retinal pigment epithelium (RPE) reflecting changes in the electrolyte composition of the extracellular space of the retina. The cornea-positive P-II component is generated by electrical activity in post-photoreceptor cells, mainly in the ON-center bipolar cells, and the cornea-negative P-III component reflecting light-induced electrical activity in the photoreceptors. There are additional contributions to the ERG, but these are minor and recorded only under special conditions. The summation of the three ERG components results in the general ERG pattern seen in response to a light stimulus, consisting of an initial negative a-wave, followed by a positive b-wave, and ending with a slow positive c-wave. However, under normal clinical testing conditions, the c-wave is practically absent, and therefore the ff-ERG trace is composed of a negative a-wave followed by a positive b-wave. With bright light stimulus, fast oscillations of small amplitude can be identified on the rising phase of the b-wave. It is customary to use the amplitude and implicit time (latency) of the a-wave for assessment of photoreceptor function and the amplitude and implicit time (latency) of the b-wave as indicators for ON-center bipolar cells' function and for signal transmission between the photoreceptors and the bipolar cells. The fast oscillatory potentials are generated by neural networks in the inner retina between bipolar cells, amacrine cells, and ganglion cells and are very sensitive to the integrity of retinal blood circulation.

Purpose

The ERG is used as an objective method to reliably monitor retinal function in order to identify retinal disorders, to assess severity of retinal diseases, to monitor disease progression, and to track retinal function during treatment. By controlling the color and intensity of light stimulation, the conditions of illumination and pattern of stimulation, the ERG can be used to separate between the function of the rod system from that of the cone system and to isolate the contribution of the peripheral retina from that of the macular region. Furthermore, the ERG can serve to identify the retinal structures that are affected by the pathological process, e.g., photoreceptors, bipolar cells, inner retinal neurons, and ganglion cells. Thus, ERG measurement is an important procedure within the ensemble of electrophysiological tests (ERG, EOG, Visual Evoked Potentials (VEP)) that are used in centers for electrodiagnosis of visual disorders.

Principle

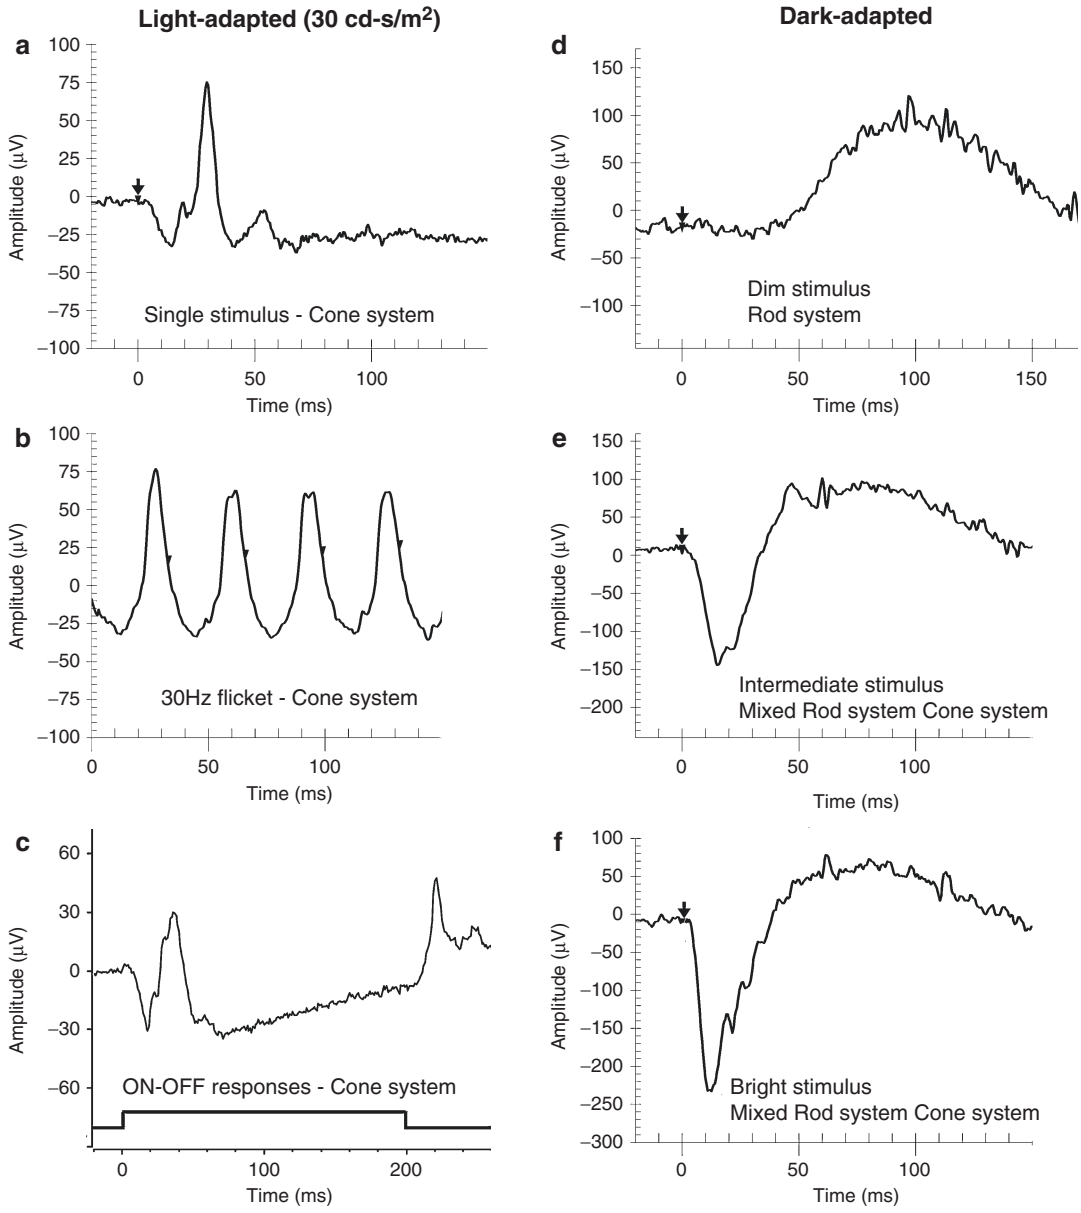
The visual pigment molecules located in the outer segments of the photoreceptors absorb impinging light and, through a cascade of reactions termed the phototransduction process, generate an electrical signal that is transmitted via chemical and electrical synapses to horizontal cells and bipolar cells, which in turn transmit electrical signals to amacrine cells and ganglion cells in the inner retinal layers. The axons of ganglion cells form the optic nerve that carries visual information coded by action potentials to the visual cortex of the brain for further processing. Light-induced electrical activities of retinal neurons generate extracellular radial currents that summate and flow from the retina through the vitreous to the cornea and return to the back of the eye to form the basis for the corneal electroretinogram. Therefore, any resistance to electrical current flow in this pathway, such as silicone oil fill in the vitreous cavity, will be expressed in reduction of the ERG signal down to non-measurable levels even if the retina functions normally.

The most common procedure to record the ERG in clinical settings involves the use of three electrodes, an active corneal electrode, a reference electrode, and a ground electrode. The recorded signal is amplified and filtered by an appropriate data acquisition system. To obtain maximal ERG signals and enable reliable comparison between subjects, full pupillary mydriasis is needed.

The choice of corneal electrodes varies between visual electrodiagnostic centers and depends upon the clinical consideration and patient cooperation. The Burian-Allen bipolar contact lens electrode is the one giving the largest response and the least noisy one, but it is not disposable and requires cleaning and disinfection between recording sessions. Commonly used disposable electrodes include the Dawson, Trick, and Litzkow (DTL) electrode, the gold foil electrode, ERG jet electrode, and others. Some centers use skin electrodes, especially for children and infants in which the active electrode is placed on the skin below the eye. In this case, the recorded signal is typically of small amplitude and high level of electrical noise, and therefore averaging of many repetitions is required for reliable assessment of retinal function.

The waveform of the ERG depends upon the pattern (color, intensity, and duration) of the photic stimulation and upon the conditions of visual adaptation. A dome producing a full-field homogenous stimulus is used to elicit full-field ERG responses that reflect the summed activity of the entire retina and can be used to separate the activity of the rod system from that of the cone system and the cone ON pathway from the cone OFF pathway as shown in Fig. 1. The most useful procedure for ff-ERG recording is described in the ff-ERG standard that is supported by the International Society for Clinical Electrophysiology of Vision (ISCEV), but many visual electrodiagnostic centers adopt a modified version of this standard.

A white background of 30 cd/m^2 saturates the rod system, thus isolating the responses of the cone system (Fig. 1 left column). For reliable assessment of the cone system's function, light adaptation of 10 min is needed. The retinal electrical response to a single flash or to a 30 Hz flicker of stimuli (Fig. 1a, b respectively) serves as good indicators for the functional integrity of the cone system. After at least 20 min of dark adaption, the rod system recovers to about 90% level, and the dark-adapted ERG responses can be recorded (Fig. 1, right column). Under these conditions, the retinal response to a dim white or blue light stimulus is used to assess the function of the rod system (Fig. 1d), while bright white light stimuli elicit ERG responses, which reflect the combined contributions of the rod system and the cone system (Fig. 1e, f), with predominant contribution by the rod system. In some visual electrodiagnostic centers, stimuli of very high intensity (energy) are sometimes used to elicit ERG responses when retinal function assessment is needed in cases of opaque optic media. Additionally, very bright stimuli are used in order to elicit ERG response of saturated a-wave that can be used to derive information about the responsiveness to light of rods or cones.



Electroretinogram, Fig. 1 Full field (ff)-ERG responses from a subject with normal vision. Light-adapted ff-ERG responses are recorded under background illumination of 30 cd/m^2 using single flash of 3 cd-s/m^2 strength (**A**) or 30Hz flicker of 3 cd-s/m^2 strength (**B**). A long-duration (200 msec) stimulus of 200 cd/m^2 (**C**) is used to separate the response of the cone ON-pathway from the cone OFF-pathway. Rod function is assessed from dim blue flash delivered after at least 20 minutes of adaptation to darkness (**D**). Mixed Rod-Cone function is represented by the responses to flashes of intermediate (3 cd-s/m^2) and bright (30 cd-s/m^2) strengths (**E** and **F** respectively)

The full-field ERG recording procedure can be further modified in cases when the ON and OFF pathways of the cone system need to be separated, such as in complete and incomplete congenital stationary night blindness and in melanoma-associated retinopathy (MAR). In these cases, a long duration (200 ms) stimulus is used under light-adapted conditions (Fig. 1c), to generate a

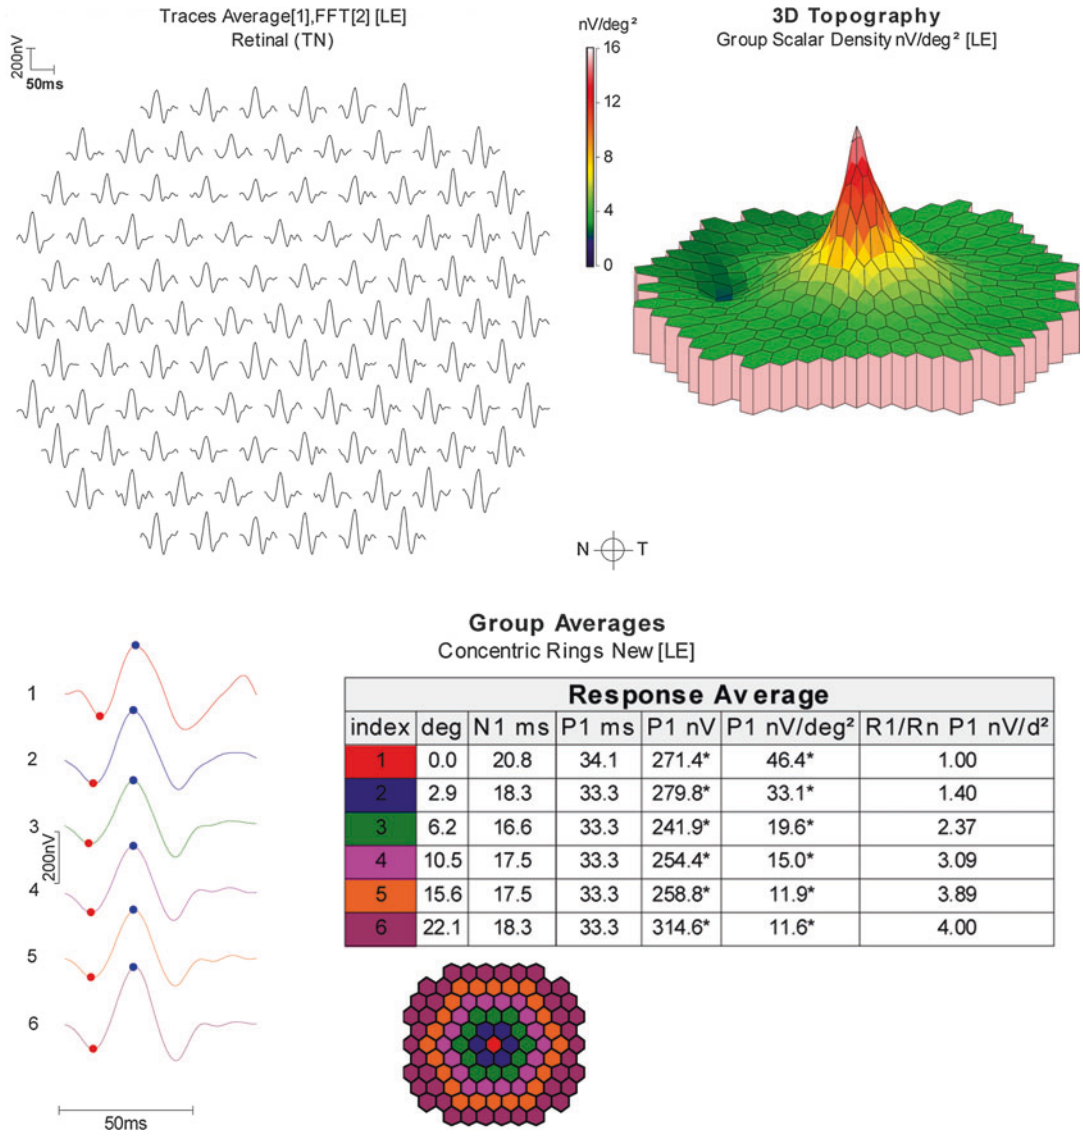
two-component response. The initial response to light onset is composed of an a-wave followed by a b-wave reflecting light-induced activity in the cones and the cones' ON-center bipolar cells. This is the ON-pathway response. At light offset, another positive wave is recorded, called the d-wave, reflecting the activation of cones' OFF-center bipolar cells and the termination of electrical activity in the cones. This is the OFF-pathway response.

Changing test parameters such as the duration, color, and intensity of the light stimulus and/or of the background, the duration of dark adaptation and pattern of the stimulus are used for recording of specific responses to assess function of specific retinal structures, e.g., ganglion cells in the macula (pattern-reversal ERG), ganglion cells in the entire retina (photopic negative response, PhNR), absolute rod sensitivity (scotopic threshold response, STR), and isolated function of the S-cones' system.

Since the ff-ERG is a global response reflecting the summated activity of the entire retina; it is noteworthy that focal retinal lesions will not be identified by a reduced ERG response unless at least 20% of the retina is damaged. Therefore, the ff-ERG is used in suspected pan-retinal disorders, such as photoreceptor degeneration, night blindness, melanoma- or cancer-associated retinopathy, and more. In order to obtain ERG responses that are more sensitive to local retinal damage, the multifocal ERG (mf-ERG) procedure was developed. In this procedure, the light stimulus viewed by the patient comprises an array of hexagons (typically 103 or 61) flickering individually between dark and light at a pseudorandom sequence. The size of the hexagons increases gradually with increasing distance from the center of the array to inversely fit the gradient of the retinal cone density decreasing from the foveal center. In this manner, the focal response of each hexagon is expected to be of similar amplitude in volunteers with normal vision. During stimulation, a single corneal electrode continuously records the electrical potential at the cornea in response to the flickering array of hexagons. Upon termination of the test, the electrophysiological system derives the local ERG responses by comparing mathematically the response at a given time frame to the hexagons' illumination pattern at that time frame relative to that at a previous time frame. With this analysis, an electroretinographical map of the stimulated retinal region is derived as shown in Fig. 2. During the recording procedure, the average screen illumination is stable, similar to the room light, and therefore the ERG responses reflect local function of the cone system. Figure 2 shows mf-ERG data from a volunteer with normal vision, using 103 hexagons flickering between 400 and 0 cd/m^2, covering the central 48° of the retina, roughly parallel to the 24-2 visual field test. The individual responses of the 103 hexagons (Fig. 2, upper left) represent the average ERG response at each hexagon. These responses are recalculated as amplitude density (response amplitude divided by hexagon area) in order to derive the colored 3D surface map (Fig. 2, upper right) indicating high activity of cone system in the center (fovea) that tapers off to a steady low value at eccentricities ranging from 5 to 24° reflecting the normal retinal distribution of the cone system in the human retina. With the assumption that the cone system reduces similarly along radial paths originating at the fovea and extending to large eccentricities, it is customary to sum the activity at concentric rings and calculate it as amplitude density by dividing the ring amplitude by the ring area (Fig. 2 bottom left). The attached table indicates the eccentricity of each ring, implicit times of N1 and P1 waves, average amplitude for each ring, amplitude density for each ring, and ring ratios. Excellent patient cooperation and stable fixation are necessary for reliable results of the mf-ERG procedure. Good fixation is verified by localization of a small depression in the 3D map (Fig. 2 upper right panel), about 15–20° nasal to the fovea, representing the blind spot at the optic disk. The mf-ERG is sensitive to local retinal damage and is used to test maculopathies and cases presenting with local scotomas in the central visual field (24-2).

Indication

Any patient that complains of visual disturbances that cannot be explained by routine tests available



Electroretinogram, Fig. 2 Multifocal ERG measurement from a subject with normal vision. The central 48° of the retina are illuminated by 103 hexagons, and the retinal response is analyzed and presented as the trace array (*upper left*). The 3D plot of the retinal response generated by each hexagon (*upper right*) clearly shows the peak amplitude density of the fovea, and the slight depression in the nasal retina representing the optic disk. The trace array is divided into 6 rings centered on the fovea (central hexagon). The rings' ERG responses, shown in the lower left side, represent the average response to each hexagon in the ring. The Table lists for each ring, the average eccentricity from the fovea, implicit time of N1 and P1, P1 average amplitude, P1 amplitude density and ring ratio relative to Ring1, the central one

in the ophthalmic clinic may potentially benefit from ERG testing.

The most common indications for ERG testing are:

1. Visual difficulties at night – assess scotopic function using ff-ERG.
2. Photophobia in daytime – assess photopic function using ff-ERG.

3. Unexplained loss of visual field – test first with ff-ERG, and if normal, try mf-ERG.
4. Symptoms of flashes, shimmering lights – use ff-ERG to test for cancer-associated retinopathy (CAR), melanoma-associated retinopathy (MAR), or other types of autoimmune retinopathy (AIR).
5. Test for chloroquine (Plaquenil) toxicity using mf-ERG.
6. Unexplained reduction in visual acuity or subjective complaints of decreased central vision – use mf-ERG to test for maculopathy.
7. Asymptomatic relatives of patients with known inherited photoreceptor degeneration – use ff-ERG to test for the disorder.
8. Separate fundus albipunctata from fundus punctata albescens using ff-ERG.
9. Evaluation of retinal function prior to a complex eye surgery – use ff-ERG; sometimes bright flash ERG is needed.

Contraindication

There are no contraindications for the use of ERG and no known patient safety concerns. However, there are several contraindications for specific procedures. A patient suffering from epilepsy should not be tested with 30 Hz flicker at light-adapted ff-ERG procedure or with mf-ERG. Patients with corneal wounds and patients after corneal surgery including photorefractive surgery (especially Laser In Situ Keratomileusis (LASIK)) should not be tested with the corneal contact lens electrode. Patients with severe eye infection should be tested with a disposable electrode.

Advantage/Disadvantage

Advantages

1. Objective test of retinal function
2. Can be used to monitor reliably over time disease progression, efficacy of treatment, and drug toxicity
3. Can separate photopic function from scotopic function
4. Can separate function of peripheral retina from that of macular region
5. Allow assessment of function in specific retinal structures, e.g., photoreceptors, bipolar cells, inner retinal neurons, and ganglion cells

Disadvantages

1. Intersubject variability
2. Intra-subject variability between consecutive recording sessions

Elschnig Spots

Sign of Acute and Chronic Hypertensive Choroidopathy

Ayala Polack, Luba Rodov and Yoel Greenwald
Department of Ophthalmology, Kaplan Medical Center, Rehovot, Israel

Synonyms

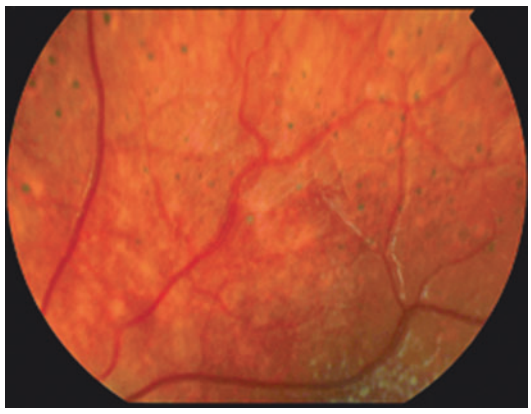
Ischemic infarct of the choroid

Definition

Elschnig spots are changes in the retinal pigment epithelium from non-perfused areas of the choriocapillaris in hypertensive choroidopathy. Their appearance is pale or yellow and tends to have defined margins. When an Elschnig spot heals, a scar develops, and a pigment spot is left surrounded by a depigmented pale halo (Fig. 1).

Etiology

Acute and chronic hypertension may manifest in the eye as hypertensive retinopathy and choroidopathy. The effects of hypertension on the choroid are related to the anatomic and functional differences found in the choroidal vasculature, as compared with the retinal vasculature. Sympathetic innervation of the choroid makes terminal arterioles more susceptible to vasoconstriction, and the lack of autoregulation increases susceptibility to elevated perfusion pressures. Circulating vasoconstrictive factors such as angiotensin II, adrenaline, and vasopressin can initiate vasoconstriction of the choroid and choriocapillaris, leading to focal ischemia. Fenestrations in the choroidal capillaries and the consequent lack of a blood-ocular barrier allow free passage of macromolecules. As a result the overlying retinal pigment epithelium (RPE) and the outer blood-retinal barrier may be compromised. In the acute phase, this can lead to a local leakage of fluid from the choroid into the subretinal space forming serous detachments (Bourke et al. 2004; DellaCroce and Vitale 2008; Ugarte et al. 2008).



Elschnig Spots, Fig. 1 Elschnig spots in the mid-periphery, seen at 4 months after presentation of malignant hypertension in a child (Courtesy of D.A. Morisson et al.)

Elschnig spots develop from damage to the retinal pigment epithelium overlying a local area of ischemia in the choriocapillaris caused by choroidal infarcts (Shah et al. 2011). Elschnig spots are commonly observed in the posterior pole. These changes are different from the more superficial retinal infarcts ("cotton wool spots") and retinal hard exudates observed in accelerated and chronic hypertension. Over time an Elschnig spot heals leaving a pigment spot surrounded by a depigmented pale halo (Bourke et al. 2004; DellaCroce and Vitale 2008; Ugarte et al. 2008; Shah et al. 2011).

Fluorescein angiography (FA) is used to confirm ophthalmoscopic suspicion of hypertensive choroidopathy. Early in their development, Elschnig spots display hyperfluorescence on FA because of leakage from focal compromise to the blood-retina barrier. After the initial damage heals, the hyperfluorescent FA pattern changes to be more consistent with a window defect from overlying RPE atrophy (Bourke et al. 2004; Ugarte et al. 2008).

Hypertension control and management needs to be the first goal of treatment, but carotid ischemia and temporal arteritis should also be considered.

Occurrence

Hypertensive choroidopathy and Elschnig spots occur later than the retinal vascular changes (hypertensive retinopathy) of arteriolar narrowing and arteriovenous crossing changes in chronic hypertension. These advanced abnormalities are observed more commonly in younger patients with acute increases in blood pressure and are associated with a poor prognosis in the untreated hypertensive patient. Hypertensive choroidopathy has been reported in association with toxemia of pregnancy, chronic glomerulonephritis, pheochromocytoma, and malignant hypertension (Bourke et al. 2004; DellaCroce and Vitale 2008; Ugarte et al. 2008; Shah et al. 2011).

Emmetropia: Definition

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Definition

Emmetropia is the term used to describe the condition of absence of refractive errors. That means that an object point located at infinity is sharply imaged to the retinal plane in absence of accommodation. Refractive correction (e.g., spectacle correction, contact lenses) is not required. In practice emmetropia is defined for a range of ±0.25 diopters or refraction.

Emphysema (Ocular), of Orbit and Eyelids, in Blowout Fractures

Gary Joseph Lelli[1], Ryan St Clair[2] and Christopher Zoumalan[3]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Ophthalmology, Division of Ophthalmic Plastic, Reconstructive and Orbital Surgery, Weill Cornell Medical College, New York, NY, USA
[3]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Synonyms

Pneumo-orbitism

Definition

Presence of air in the orbit and/or periorbital tissues following orbital wall fracture.

Etiology

Orbital blowout fractures occur when an impact raises intraorbital pressure to the point where the thin bones of the orbital floor and medial wall are "blown out," pushing orbital contents into the maxillary or ethmoid sinus (Nerad et al. 2001). Orbital emphysema most commonly results from an orbital blowout fracture (63% of cases; Key et al. 2008). The resulting communication with the paranasal sinuses allows air to accumulate in the orbital space. Sudden onset of orbital emphysema after Valsalva maneuvers (laughing, sneezing, nose blowing) is occasionally reported and is believed to result from the formation of a one-way valve across the fracture site, permitting air to enter the orbit, but not to leave it. Orbital emphysema has also been reported after sinus surgery.

Emphysema (Ocular), of Orbit and Eyelids, in Blowout Fractures, Fig. 1 Orbital emphysema with air pockets noted in the subconjunctival space of the superior forniceal space

Emphysema (Ocular), of Orbit and Eyelids, in Blowout Fractures, Fig. 2 CT scan of patient in Fig. 1, demonstrating intraorbital (preseptal and postseptal) emphysema

Clinical Presentation

Classically, patients who have had recent trauma to the orbit, face, or head present with sudden onset of one or more of the following after nose blowing, laughing, or other Valsalva actions: periorbital swelling, pain, lid distension, diplopia, and blurred vision. On examination, patients may demonstrate decreased visual acuity; ophthalmoplegia; a tense, hard globe; and proptosis. Emphysema may be palpable within the eyelids as crepitus and may be visible in the subconjunctival space (Fig. 1). Intraocular pressure (IOP) is usually elevated. If high intraorbital air pressure results in decreased perfusion to the retina or optic nerve, an afferent pupillary defect may be present (Muhammad and Simpson 1996).

Orbital emphysema may also present as an incidental finding on radiographic assessment; it is detected in up to 50% of orbital fractures on CT scan (Fig. 2; Key et al. 2008).

Diagnostics

The diagnosis of orbital emphysema can usually be made from history and physical examination alone. However, distinguishing orbital emphysema from retrobulbar hemorrhage can be difficult; therefore, the diagnosis should be supported by orbital CT scan. IOP should be measured by tonometry, and an assessment of extraocular muscle function should be made.

Differential Diagnosis

Differential diagnosis includes:

Retrobulbar hemorrhage
Orbital cellulitis

Preseptal cellulitis
Thyroid orbitopathy
Benign or malignant orbital tumor
Orbital inflammatory syndrome

Prophylaxis

Patients with recent orbital and facial trauma, with or without radiographic evidence of orbital wall fracture, should be advised to avoid nose blowing, heavy lifting, laughing, and other Valsalva activities.

Therapy

Orbital emphysema without visual loss is a benign, self-limited condition, which usually resolves in about 2 weeks. Mildly elevated IOP with no associated visual deficits can be observed or treated medically with IOP-reducing topical agents. However, compressive orbital emphysema with rapidly decreasing visual acuity is an emergency and must be treated promptly to avoid ischemic damage to the retina and optic nerve. Surgical decompression is achieved via lateral canthotomy and cantholysis, which expands the orbital volume and lowers intraorbital pressure. In rare cases, intraorbital needle aspiration may be necessary to relieve compression (Key et al. 2008).

Antibiotics may reduce the incidence of orbital cellulitis in cases of orbital emphysema; however, the benefit of antibiotics remains unproven (Key et al. 2008).

Prognosis

Orbital emphysema is generally a benign, self-limiting condition with an excellent visual prognosis (Muhammad and Simpson 1996). Nearly all reported cases of orbital emphysema with subsequent optic nerve compression showed complete recovery of visual acuity.

Epidemiology

Orbital emphysema is most commonly seen after orbital floor and/or medial wall fractures. It is detected in up to 50% of orbital wall fractures on CT scan (Key et al. 2008). Very few cases of orbital emphysema with optic nerve compression have been reported.

Encircling Buckle

Michael R. Martinez
Department of Ophthalmology, Tel Aviv Medical Center, Tel Aviv, Israel

Synonyms

Scleral buckle

Definition

Scleral buckling is an ophthalmic surgical technique that has been successfully employed to repair rhegmatogenous retinal detachments for over 50 years. The scleral buckle alters the shape

of the eye, depending on the type of material and explant used to achieve scleral indentation to approximate the detached retina and to achieve functional closure of all retinal breaks, to allow normal physiological processes and to maintain an attached retina.

Encircling buckle is defined as a 360° encircling, circumferential silicon band passed around the circumference of the globe and beneath the rectus muscles.

Indication

An encircling buckle is used in cases of rhegmatogenous retinal detachment with single or multiple defects and also in patients with early proliferative vitreoretinopathy and very extensive scleromalacia. Extensive retinal detachment which breaks is difficult to detect. Another indication for using encircling buckle is retinal detachment due to dialysis.

Contraindication

Retinal breaks significantly posterior to the equator are difficult to approach due to anatomic location. Patients with significant vitreoretinal proliferation and vitreous traction are difficult to treat only with scleral buckle reducing the rates of success; these patients can be approached by a combination of scleral buckle with vitrectomy. Opaque media obscures a good visualization of the retinal tears and good placement of the scleral buckle.

Techniques and Principles

1. A circumferential 360° peritomy with radial relieving incisions is made.
2. Slinging of rectus muscles employing a special muscle hook, a large bridle suture (2–0 silk) is passed under the rectus muscle to stabilize the globe.
3. Careful indented examination under anesthesia of the whole peripheral retina is now carried out to determine the location of the retinal breaks; every break is marked on the sclera.
4. Retinopexy is required to produce an enduring bond between the retina and the retinal pigment epithelium. Cryotherapy is used to create this, under direct visualization of indirect ophthalmoscope; after localizing the retinal break, we indent the sclera with the cryoprobe, and after revalidation of position over the break, the cryoprobe is activated. After a few seconds, one observes whitening of the retina. If the tear is small, one application can be enough; most of the times several cryotherapy applications should be made to ensure complete retinopexy.
5. Next, the tire and band are threaded together under the recti and mattress sutures. Ensure that both limbs of all the mattress sutures are above the buckle as it is not uncommon to leave one under the encirclement by mistake.
6. Scleral sutures are placed in each quadrant to accommodate the encircling silicone tire and its silicon band. The anterior suture bite is placed at the estimated location of the ora serrata, and the posterior bite is placed far posteriorly, at a spot dictated by the width of the tire, the desired amount of indentation, and the location of tears. Frequently, this distance is equal to twice the distance from the anterior bite to the marked posterior edge of the retinal break. Calipers are used to ensure accurate bite separation. The sutures need to be placed halfway through the sclera to prevent perforation.
7. Subretinal fluid drainage is required in the majority of cases.
8. Tighten the mattress sutures over the tire to create a local indent.
9. The ends of an encircling band are joined with a silicone Watzke silicone sleeve, tantalum clip, or suture; a Watzke sleeve is a small Silastic tube designed to secure the ends and allow adjustment of the tension in the band.
10. The ends of the band are pulled to create the encircling indent. A 6-mm shortening will produce approximately a 1-mm indent, irrespective of the size of the globe.

Final examination of the retina needs to be done to evaluate height of the buckle, correct positioning over the break, and perfusion of central retinal artery.

Trimming of any protruding edges needs to be done to reduce the risk of buckle extrusion; also good closure of Tenon's capsule and conjunctiva needs to be achieved.

Outcome

A favorable anatomic reattachment is achieved in 90% of cases; although, there is a significant discrepancy between favorable anatomic correction and functional visual outcomes, this can be correlated with macular involvement.

Complications

Two different groups of complications can be present, intraoperative and postoperative complications.

Intraoperative complications such as scleral perforations in the process of anchor scleral sutures and penetration of the globe are usually heralded by the sudden appearance of subretinal fluid at either end of the suture bite; it can lead to choroidal hemorrhage.

If the surgeon decides to do a drainage procedure, it should be performed with subtle care to prevent hemorrhage, retinal incarceration, and iatrogenic retinal holes. In the setting of a high encircling buckle and a horseshoe tear, "fishmouthing" of retinal breaks can be present, in which the open break will prevent a complete retinal reattachment.

In postoperative complications, the most important one is anatomic failure, followed by increased intraocular pressure, choroidal detachment, and late periocular infection and implant extrusion, because the various materials used in scleral buckle technique (sutures, bands) are foreign bodies.

Another common complication is formation of epiretinal membranes; macular pucker has been reported from 2% to 17% of successfully treated retinal detachments. Failure of the retina to reattach or recurrent retinal detachment can be due to proliferative vitreoretinopathy.

Due to the configuration of circumferential scleral buckle, an altered refractive error can occur, usually causing a myopic change due to changes in axial length; every 1 mm of average increase in axial length can cause a −2.50 diopters of myopic shift.

Synonyms

Intraocular infection

Definition

Infectious inflammation of the ocular cavities and internal structures of the eyeball.

Histology

Inflammatory infiltrates in the vitreous and the retina mainly consist of polymorphonuclear leucocytes. These infiltrates release proteolytic enzymes that destroy all intraocular structures with exception of basal membranes. The underlying pathogen cannot be identified by histology. For acute postoperative endophthalmitis, common bacteria are coagulase-negative *Staphylococci* spp., *Staphylococcus aureus*, *Streptococci* spp., and gram-negative bacteria, for late-onset postoperative endophthalmitis propionibacteria and fungi, and for endogenic endophthalmitis fungi (esp. *Candida albicans* and *Aspergillus* spp.) and *Bacillus* spp (Anon 2005).

Immunohistochemistry

Immunohistochemistry does not play a role in the diagnostics of endophthalmitis.

Electron Microscopy

Remains of the lens capsule or an explanted IOL can be analyzed using scanning electron microscopy (SEM) or transmission electron microscopy (TEM). Though the use of electronic microscopy allows the collection of data related to the physiopathology of the infection, this method is not usually part of the diagnostic routine analyzing the pathogen (Adán et al. 2008).

Molecular Diagnosis

As with any infection, the cornerstone of management of postsurgical endophthalmitis includes identification of the responsible organism. In addition to gram staining and cultures to investigate the underlying microbial organism, samples of aqueous and vitreous can also be analyzed by using polymerase chain reaction (PCR) testing. This technique can increase the laboratory rate of identifying the pathogen. Samples of both aqueous and vitreous should be collected and stored at minus 20° for PCR at the time of the diagnostic tap (Seal et al. 2008).

Differential Diagnosis

An acute postoperative endophthalmitis is rarely misdiagnosed due to often typical anamnestic data and typical clinical appearance. Differential diagnosis includes ocular or systemic sterile inflammatory or malignant conditions that result in an anterior, intermediate, posterior, or panuveitis. The term masquerade syndrome is used for malignant diseases manifesting as an intraocular inflammation of unknown origin. In persistent or refractory ocular inflammation in middle-aged patients, primary intraocular lymphoma should be considered.

Endothelial Degeneration

▶ Endothelial Dystrophies
▶ Endothelial Failure

Endothelial Degenerations

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Endothelial dystrophy; Fuchs dystrophy; Posterior corneal dystrophies

Definition

Endothelial degeneration is the degradation of the innermost layer of the cornea, the endothelium (Krachmer and Palay 2006). The cornea is composed of several layers: epithelium, Bowman's layer, stroma, Descemet's membrane, and endothelium. The endothelium is typically one cell layer thick and serves to regulate water in the corneal stroma. Damage to this cell layer may result in reduced fluid flow and corneal swelling. This corneal degeneration, or dystrophy, may have hereditary influence and typically cannot be repaired. Descemet's membrane also may be involved with disease. Types of corneal dystrophy involving the endothelium include Fuchs dystrophy, congenital hereditary endothelial dystrophy, and posterior polymorphous corneal dystrophy.

Endothelial Dystrophies

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Corneal dystrophy; Endothelial degeneration

Definition

Endothelial dystrophy is the degeneration of the innermost layer of the cornea, the endothelium (Kanski and Bowling 2011). Endothelial dystrophy is a subset of a larger group of corneal diseases called corneal dystrophy. Corneal dystrophy refers to a group of inherited diseases that typically are bilateral, symmetric, progressive, and unrelated to environmental factors (Krachmer et al. 2011). Three major types of endothelial dystrophy include Fuchs dystrophy, posterior

polymorphous dystrophy, and congenital hereditary endothelial dystrophy (Yanoff and Duker 2014). Fuchs dystrophy is a bilateral accelerated loss of endothelial cells, with damage and progression of the disease leading to vision loss and even corneal blindness. Posterior polymorphous dystrophy is a rare and asymptomatic condition where the endothelium cells display epithelial characteristics. Congenital hereditary endothelial dystrophy develops perinatal with a focal or generalized absence of the endothelium.

Etiology

Endothelial dystrophies have been found to have both sporadic and hereditary autosomal causes (Kanski and Bowling 2011). Majority of Fuchs dystrophy tends to be sporadic, while it may have an autosomal-dominant presentation in some families. Congenital hereditary endothelial dystrophy has two main forms, CHED1 (autosomal dominant, 20p11.2–q11.2) and CHED2 (autosomal recessive, 20p13) (Krachmer et al. 2011). Inheritance for posterior polymorphous dystrophy is usually autosomal dominant (three genes, three forms PPCD1–3).

Clinical Presentation

Patients with endothelial dystrophy may present with mild reduction in visual acuity and blurred vision (Krachmer et al. 2011). These diseases progress slowly and symptoms may not become apparent initially. Fuchs dystrophy may be accompanied by worse vision in the morning and improvement over the day (Kanski and Bowling 2011). Ocular pain may also be a factor in some patients due to increased corneal edema and bullae formation. Congenital hereditary endothelial dystrophy develops in the perinatal period.

Diagnosis

Endothelial dystrophy diagnosis requires a thorough clinical evaluation (Kanski and Bowling 2011). A thorough patient history and slit-lamp examination are required. Given a patient's family history, genetic testing may aid in the diagnosis of a particular dystrophy.

On slit-lamp examination, patients with Fuchs may be found to have increased stromal thickness, tiny dark spots revealed as disruption of the regular endothelial mosaic, and a "beaten bronze" endothelium secondary to melanin deposition (Krachmer et al. 2011). Though not part of the clinical diagnosis, histology of the cornea would reveal bullae and corneal edema. Posterior polymorphous dystrophy may reveal signs of subtle vesicular endothelial lesions, band-like lesions, or diffuse opacities. Congenital hereditary endothelial dystrophy has perinatal onset and presents with bilateral, symmetrical, diffuse corneal edema ranging from a bluish-gray ground glass appearance to total opacification.

Differential Diagnosis

Keratoconus, bullous keratopathy, herpetic stromal keratitis, uveitis, congenital stromal dystrophy, pigment dispersion syndrome, and iridocorneal endothelial dystrophy.

Prophylaxis

No known prevention.

Therapy

General treatment for most endothelial dystrophies involves symptomatic and conservative management early on with topical sodium chloride 5% drops or ointment, reduction of intraocular pressure, or even use of a hair dryer in the morning to accelerate corneal dehydration (Yanoff and Duker 2014). Bandage contact lenses are another means for providing comfort due to bullae irritation (Kanski and Bowling 2011) For Fuchs dystrophy, progression of the disease may necessitate surgical procedures, specifically

penetrating or deep lamellar endothelial keratoplasty. Descemet's stripping endothelial keratoplasty (DSEK) or Descemet's stripping automated endothelial keratoplasty (DSAEK) have grown in popularity and are found to have improved results for mild/moderate Fuchs dystrophy. Descemet's membrane endothelial keratoplasty (DMEK) is also emerging as a new surgical treatment for endothelial disease. For posterior polymorphous dystrophy, most disease remains stable (Krachmer et al. 2011). Some patients may require corneal transplantation.

Therapy for congenital hereditary endothelial dystrophy involves penetrating keratoplasty. This procedure has a strong chance for success if performed early for the child. Surgical delay may result in dense amblyopia.

Prognosis

There is no treatment to reverse the progression of endothelial dystrophy (Yanoff and Duker 2014). For posterior polymorphous dystrophy, the majority of patients have stable disease and may remain asymptomatic (Krachmer et al. 2011). Patients requiring surgical intervention may have recurrence. The prognosis overall for recipients of PKP and DSEK is quite excellent (Kanski and Bowling 2011). However, surgical procedures to replace the endothelium carry a risk of graft rejection. Postoperative follow-up is necessary to prevent and treat rejection.

Epidemiology

Endothelial dystrophies affect women and men equally (Yanoff and Duker 2014). However, Fuchs dystrophy affects women roughly four times more than men. Dystrophies may affect all ages. Fuchs in particular affects 4% of the population over 40 years of age (Krachmer et al. 2011). The incidence, prevalence, and sex distribution of posterior polymorphous dystrophy and congenital hereditary endothelial dystrophy are unknown (Yanoff and Duker 2014).

Endothelial Failure

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Endothelial degeneration

Definition

Corneal endothelial failure occurs with irreversible and compromised endothelial function resulting in severe corneal edema. The endothelium in a healthy individual regulates active water transport away from the corneal stroma toward the aqueous. Early corneal edema may be marked by symptoms of blurry vision as the cornea begins to accumulate fluid and blisters (bullae) secondary to

impaired endothelial function. No medical treatment can promote endothelial regeneration once it has begun to deteriorate. Worsening cell damage due to trauma or disease, such as Fuchs dystrophy, may result in irreversible endothelial failure. Medical management of irreversible endothelial failure involves endothelial replacement with corneal transplantation.

Endothelial Graft Rejection

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Corneal graft rejection

Definition

Corneal transplantation is the most common form of tissue transplantation (Levin and Albert 2010). Transplant typically is conducted for corneal dystrophy, bullous keratopathy, infection, or failed grafts. Endothelial rejection is the most common form of graft rejection (Brightbill et al. 2009). Immune rejection of corneal grafts is the leading cause of graft failure (Krachmer et al. 2011).

Etiology

While graft rejection is triggered by major histocompatibility antigens for most forms of solid-tissue/organ transplantation, histocompatibility matching of donor tissue for the recipient is variably conducted in the cornea (Levin and Albert 2010). The normal cornea expresses low levels of histocompatibility antigens, specifically HLA antigens. Current studies are inconclusive regarding the benefit of conducting HLA matching for corneal transplants. Of note, minor histocompatibility antigens have demonstrated a role in triggering graft rejection. The pathophysiology of rejection involves antigen presentation to T cells. T cell activation results in graft destruction.

Several causes and risk factors have been found to be associated with endothelial graft rejection. The two most common risk factors are stromal neovascularization and host bed inflammation (Levin and Albert 2010). Corneal neovascularization is linked to high graft rejection, with elevated levels of blood vessels correlating with endothelial rejection (Levin and Albert 2010). Corneal inflammation, both at time of transplant and even prior, is associated with significantly decreased graft survival. Alternative causes for graft rejection are ocular surface diseases, such as severe dry eye, or injury.

Occurrence

Over 70,000 corneal transplants are conducted each year worldwide (Levin and Albert 2010). The average onset for endothelial rejection is 8 months (Brightbill et al. 2009).Rejection may begin as early as 2 weeks or as late as 20 years after transplant. Of the transplants into uncomplicated graft beds, about 20–40% of grafts experience one episode of immune rejection (Levin and Albert 2010). In this normal-risk transplant, only 10% of patients experience rejection by postoperative 1-year mark.

In high-risk, complicated graft beds, 50–90% of grafts fail even with immune suppression (Levin and Albert 2010). These graft beds are complicated by inflammation and neovascularization.

Classification

There are three types of corneal graft rejection: epithelial, stromal, and endothelial (Levin and

Albert 2010). Endothelial graft rejection is the most common. Endothelial surface precipitates can be observed in groups or a classic linear line (Khodadoust line) (Brightbill et al. 2009). This line begins at the periphery of the graft and continues centrally. Endothelial rejection can then result in increased edema and inflammation.

Presenting symptoms include decreased vision, irritation, and eye redness (Krachmer et al. 2011). Edema and signs of precipitates on the donor endothelium are signs of graft rejection. Corticosteroids are the primary treatment for acute cornea allograft rejection. Endothelial rejection can be treated with topical, periocular, and/or systemic corticosteroids.

Enucleation

Gary Joseph Lelli[1] and Christopher Zoumalan[2]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA

Definition

Enucleation is the surgical removal of the eyeball from the orbit.

Indications

There are several indications for enucleation (Moshfeghi et al. 2000). The most common are as follows:

1. Trauma
2. Intraocular malignancy
3. Blind, painful eye
4. All other causes

Trauma

Trauma is a common indication for enucleation and cause of blindness in the USA (AAO 2008). When caring for a traumatized and possibly ruptured globe, it is common practice for surgeons to make all attempts to repair the globe primarily. Sparing the patient primary enucleation serves many purposes. First it allows any subsequent enucleation to be performed under planned and controlled conditions. Also, it allows time for the patient to realize that the traumatized eye is no longer functional. Then he or she can be adequately informed and proper consent obtained as the patient might be disoriented, medicated, or even unconscious in the immediate posttraumatic period. However, if primary repair of the globe is not possible, as may

be seen following gunshot wounds, primary enucleation may be indicated.

Once a traumatized globe has been repaired but it is determined that it will no longer provide useful vision, the decision must be made as to remove that eye or not. If no useful vision is maintained, some surgeons recommend enucleation of the traumatized eye to protect the fellow eye from sympathetic ophthalmia. This rare form of granulomatous uveitis can cause severe visual loss in the fellow or "sympathizing" eye. If the decision is made to enucleate for prevention of sympathetic ophthalmia, it should be performed within 2 weeks of the trauma. Also, although there is a perceived advantage of enucleation over evisceration for prevention of sympathetic ophthalmia, this has never been proven. In fact, cases of sympathetic ophthalmia have been reported after both procedures.

Intraocular Malignancy

Until the late twentieth century, enucleation was the only generally accepted treatment for intraocular malignancy. Although there are now eye-sparing treatments in use, enucleation remains very common. Choroidal melanoma, the most common primary intraocular malignancy of adults, and retinoblastoma, the most common primary intraocular malignancy of childhood, may require enucleation. Also enucleation should be considered for any other intraocular neoplasm with malignant potential that fails to respond to conventional therapy, has metastatic potential, or has resulted in a blind, painful eye.

Blind, Painful Eye

There are numerous causes of a blind, painful eye. Trauma, neovascular glaucoma, chronic retinal detachment, chronic angle-closure glaucoma, retinopathy of prematurity, uveitis, and tumors can all lead to a blind, painful eye. When conservative measures such as topical medications, cyclodestructive therapy, or retrobulbar injection of alcohol or thorazine have failed to control the pain, removal of the eye is considered. Enucleation and evisceration can both be reasonable options and should be chosen on an individualized basis.

Other Indications

Phthisis bulbi, microphthalmia, and improvement of cosmesis are other common indications for enucleation.

Techniques and Principles

Enucleation is usually carried out under general anesthesia (Stewart 1995). A retrobulbar injection of local anesthetic with epinephrine can be used for intraoperative hemostasis and pain control. After creating a 360° conjunctival peritomy, the extraocular muscles are isolated and transected, and the optic nerve is clamped and severed. An orbital implant of sufficient volume is usually placed within the orbital space to account for volumetric changes. The EOMs are usually secured onto the implant, and it is covered by approximating Tenon's capsule and overlying conjunctiva. A conformer is then placed to retain the anatomy of the fornices. After adequate healing, a custom-made prosthesis (i.e., artificial eye) is placed.

Outcomes

The goal of enucleation is to remove the source of pathology while delivering an acceptable cosmetic outcome. Depending on the indication for enucleation, appropriate pathology specimens are obtained and further treatment, both locally and systemically, may be indicated. An ocular prosthesis is usually fitted by an ocularist 6 weeks postoperatively in order to provide a good cosmetic result.

Complications

Complications can occur intraoperatively and postoperatively. Intraoperative complications include removal of the wrong eye, a slipped extraocular muscle, and orbital hemorrhage. Postoperatively, hemorrhage, edema, and infection can complicate the early course while enophthalmos, superior sulcus deformity, and implant exposure and extrusion can occur months to years after the initial surgery.

Ephelis

- ▶ Ephelis (Freckle), of the Eyelid

Ephelis (Freckle), Conjunctival Disease

Saeed Alwadani
Department of Ophthalmology, King Saud University, Riyadh, Saudi Arabia

Synonyms

Benign epithelial melanosis; Complexion-associated melanosis; Freckle

Definition

An ephelis (freckle) is a benign conjunctival epithelial hyperpigmentation characterized by an increase of melanin in the basal keratinocytes, and no melanocytic hyperplasia is present.

Etiology

The etiology of complexion-associated melanosis remains unclear, but available data suggests it may vary according to the skin pigmentation. It is considered to be a normal phenomenon in heavily pigmented individuals, whereas in light skin population, it can be considered abnormal. Chronic sun exposure could also be related to the development of this entity. This condition can also be congenital in nature.

Clinical Presentation

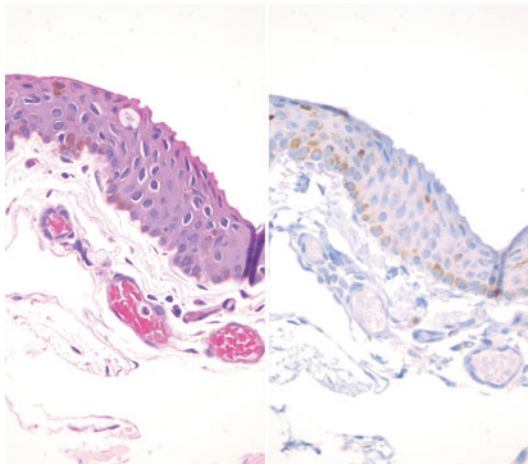
Ephelis appears at an early age. Usually, it is an asymptomatic, flat, brown patch with circumscribed pigmentation, occurring mainly at the perilimbal area. It fans out to lighter color, at the periphery, toward the fornix.

Diagnosis

Histopathological evaluation shows increased pigmentation of the epithelial basal layer and normal melanocytes (Fig. 1). There are no cytological atypia, nested pattern, or increase in number of melanocytes.

Differential Diagnosis

1. Nevus
2. Ocular melanocytosis
3. Primary acquired melanosis without atypia or benign acquired melanosis
4. Primary acquired melanosis with atypia
5. Melanoma



Ephelis (Freckle), Conjunctival Disease, Fig. 1 Histopathological finding

The ephelis or freckle is clinically and histopathologically indistinguishable from benign acquired melanosis.

Therapy

In general, ephelis does not require treatment if recognized in the appropriate setting. However, few cases may be somehow confusing because of the degree of pigmentation or increased growth and require biopsy.

Prognosis

Ephelis is benign and is not a precursor of malignant melanoma.

Epidemiology

It is more common in dark-skinned individuals.

Ephelis (Freckle), of the Eyelid

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Ephelides; Ephelis; Freckle

Definition

A tan, flat macule on sun-exposed skin.

Etiology

Ephelides are a result of hyperpigmentation of the basal layer of the epidermis. The number of melanocytes is not increased, but melanin production is increased in the basal keratinocytes. Freckles tend to be inherited as an autosomal dominant trait and related to sun exposure (Albert and Jakobiec 2008).

Clinical Presentation

Ephelides are small circumscribed macules with uniform pigmentation on sun-exposed areas, occasionally on the eyelids or conjunctiva. Ephelides present during childhood and increase

in size and number in the summer months and lighten in the winter months (Albert and Jakobiec 2008).

Diagnostics

Excisional biopsy in not necessary but may provide definitive diagnosis in questionable cases. The number of melanocytes of the epidermis is not increased, but the melanosomes are larger.

Differential Diagnosis

Lentigo simplex
Lentigo, senile
Nevus, melanocytic
Malignant melanoma

Prophylaxis

Avoidance of sun exposure and sunscreens may prevent increased pigmentation.

Therapy

Treatment is not necessary. Chemical peels, cryotherapy, and laser treatments can be used to make the ephelides less pronounced.

Prognosis

Excellent. Patients in the same demographic tend to be more susceptible to skin cancers, so routine skin examinations are encouraged.

Epidemiology

Common and can be found on most individuals in varying degrees. They tend to be more pronounced in temperate climates.

Definition

Epibulbar tumors are neoplasms found on the surface of the eye that arise from the conjunctiva, the cornea, or the limbus. In adults, the most common epibulbar tumors are melanoma (malignant tumor of conjunctival melanocytes), lymphoma (most commonly conjunctival MALT), and squamous cell carcinoma (maligant tumor of conjunctiva with squamous cell differentiation). Choristomas, growth of normal tissue in an abnormal location, are the most common epibulbar tumors in children and include dermoids and dermolipomas. Additional pediatric tumors include papillomas (benign epithelial tumor), nevi (benign conjunctival melanocyte proliferation), and rhabdomyosarcoma (malignant tumor with skeletal muscle differentiation).

Synonyms

Epidermal cyst; Epidermal inclusion cyst; Milia; Molluscum contagiosum; Pilar cyst; Sebaceous cyst; Trichilemmal cyst; Xanthelasma

Definition

Benign, fluid-filled lesions affecting the superficial layers of the skin. Varieties include epidermal inclusion cysts, milia, molluscum contagiousum, pilar or trichilemmal cysts, and xanthelasma (Shields and Shields 1999; Albert and Jakobiec 2008).

Characteristics

Epidermal inclusion cysts are the most common epidermal cysts. They are slow-growing, solitary, round, smooth, elevated lesions with a surface layer of epidermis that tend to occur on the face, scalp, neck, and trunk. They frequently occur on the upper eyelids. They are thought to originate from occluded pilosebaceous follicles or surface

epidermis. Rupture of the cyst wall may cause a foreign body granulomatous reaction, and infection may lead to abscess formation. Treatment of choice is surgical excision.

Milia are multiple small umbilicated firm lesions that occur spontaneously or arise after trauma, radiation, or a herpes zoster infection. They are common in newborn infants. They are thought to be follicular retention cysts caused by the blockage of pilosebaceous follicles. Surgical excision is the treatment of choice or treatment with retinoic acid cream for multiple lesions.

Pilar or trichilemmal cysts occur in areas containing hair follicles, occasionally found in the eyebrow region. The cysts are filled with desquamated epithelium and can demonstrate calcification.

Molluscum contagiosum is a viral infection from the DNA poxvirus and can involve the eyelid margin. Typical lesions are characterized by a waxy nodule with central umbilication. They may be associated with a follicular conjunctivitis. Transmission in children can occur by direct contact or fomites, and sexual transmission is more common in adults. Numerous exuberant lesions may present in patients with acquired immunodeficiency syndrome. Treatment involves observation, excision, cryotherapy, or curettage. Topical or intravenous cidofovir may be required in immunosuppressed individuals.

Xanthelasma are yellowish plaques in the inner medial canthal regions of the upper and lower eyelids. Lesions involve lipid-laden macrophages in the dermis and subdermal tissues. They can occur in patients with normal serum cholesterol but may be associated with systemic hypercholesterolemia and lipid disorders. Treatments include surgical excision and laser ablation (Shields and Shields 1999; Albert and Jakobiec 2008).

Skin

Definition

The epidermis is a cutaneous structure characterized by stratified squamous epithelium that covers the external surface of the body (Weedon 2009).

Structure

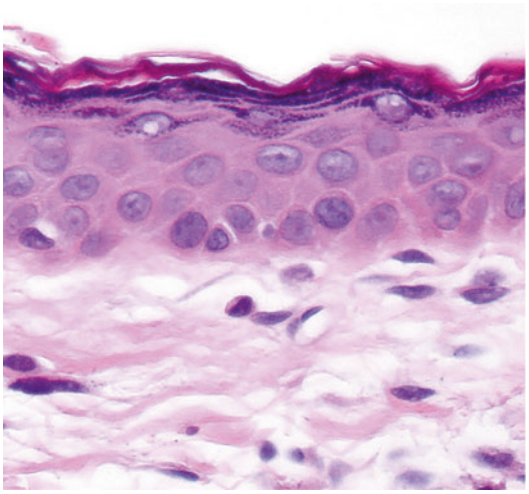
The skin is composed of keratinocytes and melanocytes forming a binary system (Javier and Ackerman 2001). The squamous epithelial cells (keratinocytes) are continuously regenerating with the cells undergoing terminal differentiation and death. Epidermal folds (*rete ridges*) invaginate into the dermis, while the latter one projects upward in between these ridges, forming the *dermal papilla.* The epidermis is separated from the dermis by a basement membrane, a complex, multilayered structure that gives rise to the epidermis structure (Haake and Polakowska 1993). The *basal layer* rests on the basement membrane, and it has the proliferating cells of the epidermis. Only around 17% of the basal cell population divides. These cells leave the layer to undergo terminal differentiation, while some immediately die by apoptosis due to intrinsic program or imbalance of signaling factors (McGowan and Coulombe 2000). Cells that enter the *prickle cell layer* which is four to ten cells thick are destined to differentiate; they acquire more cytoplasm and well-formed keratin filaments which are essential for the epithelial cells to tolerate stress (McGowan and Coulombe 2000). The desmosomes, prickles or intercellular attachments, develop here. As the cells are migrating toward the outer surface, they produce keratohyalin granules, forming the *granular layer* which is one to three cells thick. These cells lose their organelles and, subsequently, their function. They become flattened and form a dense, compacted keratinous layer known as *stratum corneum*. Finally, the superficial flake-like layer desquamates.

Function

The skin is now well known to be more than a protective and mechanical barrier. The keratinocytes in addition to the production of keratin are responsible for the biosynthesis of cytokines. Melanocytes produce a brown pigment (melanin) that represents an important endogenous protector against harmful UV sunlight. Langerhans cells are the epidermal dendritic cells that process and present antigens to lymphoid cells. Although Merkel cell function remains unclear, they reside within the basal layer and may serve mechanoreceptors or provide some sort of neuroendocrine function to the skin (Kumar et al. 2005).

Clinical Relevance

Several triggers such as UV light, stress, trauma, and surgery may affect the skin homeostasis and result in clinical conditions including wrinkles and hair loss, blisters and rashes, and life-threatening cancers and disorders of immune regulation. For example, chronic sun exposure may predispose to the development of a variety of



Epidermis, Fig. 1 Histological section of epidermis, H&E 400X

premalignant and malignant cutaneous neoplasms. Therapy with certain medications can also present with skin manifestations such rash or exanthemas, secondary to toxicity. Lastly, systemic and immune-related diseases including diabetes mellitus, lupus erythematosus, and amyloidosis, among others, may also have important manifestations in the skin (Kumar et al. 2005) (Fig. 1).

Choristoma

Definition

These lesions are etiologically choristomas, i.e., masses of histologically normal-appearing tissue in an abnormal location. They are the most common epibulbar and orbital tumors in children, but may present at any age (Shields et al. 1984, 2004). They are formed during development as the suture lines of the skull close, during which time dermal or epidermal tissue may be pinched off to form cysts. They may displace structures in the globe and cause visual impairment due to optic nerve compression or restricting ocular motility (Cavazza et al. 2011).

Episcleritis: Overview

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Definition

Episcleritis is inflammation of the tissue between the conjunctiva and sclera.

Etiology

Episcleritis is largely idiopathic. Collagen vascular disease, vasculitis, rosacea, atopy, herpes simplex, herpes zoster, gout, keratoconjunctivitis sicca, and atopic keratoconjunctivitis hold associations with episcleritis (Goldstein and Tessler 2009; Pearlstein 2011). One-third of cases are associated with an underlying disease (Goldstein and Tessler 2009). It may also follow administration of certain drugs like erlotinib, pamidronate disodium, risedronate, and topiramate (Pearlstein 2011).

Clinical Presentation

Episcleritis is a harmless and benign condition that presents acutely. Many individuals are asymptomatic, but some do experience minor discomfort and in rare cases severe pain (Goldstein and Tessler 2009; Pearlstein 2011). In cases of severe pain, it is more likely scleritis than episcleritis. Visual acuity is unaffected by this condition (Pearlstein 2011). Discharge may or may not be present, but when present is only watery (Pearlstein 2011). Purulent or mucopurulent discharge is not associated with episcleritis. Episcleritis should not be misunderstood as a mild form of scleritis.

The inflammation can be localized to the episclera by the vascular pattern. The episclera vascular plexus is straight and radial. The conjunctiva and sclera are freely anastomosing, and the conjunctiva plexus is mobile when moving the conjunctiva (Kanski and Bowling 2011; Pearlstein 2011). Another way to distinguish the condition is to give 2.5% phenylephrine, which blanches the conjunctiva vasculature. Ten percent phenylephrine can be used also, which will blanch the conjunctiva and superficial episcleral capillary plexus and leaves the deep vasculature alone that is inflamed in cases of scleritis. It may be beneficial to use red-free light when observing the vascular plexus pattern (Pearlstein 2011).

There are two presenting forms of episcleritis: simple and nodular. The simple form shows sectoral or diffuse redness from vascular congestion often in an interpalpebral distribution. This further distinguishes episcleritis from scleritis, as scleritis often has upper temporal quadrant distribution (Kanski and Bowling 2011). In 67% of cases, the inflammation will be sectoral and 33% will have diffuse inflammation (Pearlstein 2011). Episcleritis typically peaks in <12 h and then will slowly self-resolve over 6–10 days.

The nodular form of episcleritis presents one or more nodules in addition to simple episcleritis findings. These nodules are tender and in some cases can be found in the interpalpebral fissure (Kanski and Bowling 2011). These nodules can be differentiated from scleritis nodules by narrow,

bright slit beams. The episcleritis nodules will show the outer reflection displaced, while the inner reflection on the sclera and visceral episclera will be undisturbed (Pearlstein 2011). Scleritis nodules will show both inner and outer reflections as displaced (Pearlstein 2011). These nodules are also not phlyctenule, which are mobile as part of the conjunctiva (Goldstein and Tessler 2009).

Diagnosis

No laboratory diagnostics are available.

Differential Diagnosis

- Scleritis
- Conjunctivitis
- Phlyctenular conjunctivitis

Prophylaxis

Most cases are idiopathic. Control of underlying systemic or ocular disease is important.

Therapy

There is typically no intervention needed for episcleritis. In some cases, episcleritis presents with systemic diseases, and those systemic diseases should be treated as needed. Patients can be advised that cold compresses and cold artificial tears may help relieve symptoms. In severe cases, a systemic oral NSAID like flurbiprofen 100 mg three times daily may be used (Goldstein and Tessler 2009; Pearlstein 2011). In prescribing NSAIDs, it is not known if therapy should stop after symptoms resolve or to continue on afterward. Corticosteroid use is not recommended as these can lead to rebound episodes with more intense episcleritis with each recurrence (Goldstein and Tessler 2009; Pearlstein 2011).

Prognosis

Episcleritis typically resolves spontaneously. The peak occurs <12 h after onset and will improve over 5–10 days to where it will be completely resolved in 2–3 weeks (Goldstein and Tessler 2009; Kanski and Bowling 2011; Pearlstein 2011). Nodules will also resolve, but may take up to 4–5 weeks (Goldstein and Tessler 2009; Pearlstein 2011). Recurrence is a concern as 60% will recur around 2 months later and will continue in this pattern for 3–6 years (Pearlstein 2011). In some reported cases, these recurrent attacks have occurred for up to 30 years (Watson 2008). When associated with systemic disease, the recurrence is often delayed and at random intervals (Pearlstein 2011). Recurrence may lead to the random array and random sizes of the episclera tissue to rearrange into a more ordered pattern. This may cause the blue color of the uveal tissue to be seen, but does not represent scleral thinning (Pearlstein 2011). Otherwise, the structure of the eye is not damaged (Watson 2008). Complications are uncommon, but can include mild anterior uveitis, transient peripheral corneal infiltrates, and corneal dellen.

Epidemiology

The prevalence of episcleritis is not well known since most patients do not seek treatment since episcleritis is benign and resolves quickly. It is believed that 0.08% of hospital visits are due to episcleritis (Pearlstein 2011). Some studies have shown no association with gender, while some cite higher risk in females (Kanski and Bowling 2011; Pearlstein 2011).

Corneal abrasion; Corneal defect; Corneal erosion; Epithelial abrasion; Epithelial erosion

Definition

Focal area of epithelial (outermost corneal layer) loss; can be due to mechanical trauma, corneal dryness, neurotrophic cornea, postsurgical changes, or any other of a variety of etiologies

Etiology

Corneal epithelial defects are one of the most commonly seen ocular pathologies in the general patient population (Reidy 2013–2014). Corneal epithelial defects are a focal loss of the corneal epithelium and can occur by a variety of means:

- Mechanical trauma (e.g., fingernail scratch, contact lens overuse, foreign body in the lid/fornices, trichiasis/distichiasis, chemical exposure)
- Exposure (e.g., neurotrophic diseases causing incomplete lid closure (commonly cranial nerve seven palsy), restrictive eyelid diseases, proptosis, decreased consciousness in drug abuse or comatose state, blepharoplasty, lagophthalmos)
- Ultraviolet burns (e.g., welding, prolonged sun exposure off reflective surfaces)
- Local corneal dryness and systemic disorders leading to corneal dryness (e.g., dry eye syndrome, thyroid eye disease, Sjogren's syndrome, vitamin A deficiency)
- Limbal stem cell deficiency (failure to regenerate epithelial cells, occurs from a variety of causes, e.g., chemical burns, postocular surgery, ocular autoimmune degenerations)

- Topical anesthetic abuse
- Neurotrophic keratopathy (corneal hypoesthesia or anesthesia caused, most frequently, by damage to the trigeminal nerve, also HSV, VZV, and topical drop toxicity, among others (Wilson 2009))

Corneal defects are frequently accompanied by pain, tearing, and foreign body sensation of the affected eye (the exception being neurotrophic keratopathy) which are commonly alleviated by the instillation of topical anesthetic. They can also be accompanied by photophobia, pain with blinking and pain with eye movement. Conjunctival injection is frequently present on the ipsilateral side of the corneal defect. Periorbital skin or lid changes are present variably given the etiology of the defect (e.g., skin burns with chemical exposures, periorbital trauma in post-motor vehicle collision defects, poor lid closure in exposure defects).

When visualizing corneal defects, fluorescein dye is instilled either as a liquid drop (mixed with a topical anesthetic) or via a fluorescein impregnated paper strip after the instillation of topical anesthetic. The dye is visualized using a cobalt-blue filter which causes the dye to fluoresce a bright green color. Fluorescein does not stain intact corneal epithelium but does stain corneal stroma, thus demarcating the area of the epithelial loss. The distribution, size, and shape of the corneal defect will vary depending on the etiology (e.g., thin, linear defect for fingernail scratch, whole corneal surface defect for an extensive chemical burn, inferior corneal irregular defect for lid abnormalities/lagophthalmos).

A thorough history is required to determine the etiology of the corneal defect. Similarly, a thorough exam of both eyes is needed because in many cases of systemic diseases or trauma, both eyes can be affected.

Occurrence

Corneal epithelial defects accounted for 10% of all eye-related emergency room visits in the early 1990s (Shields and Sloane 1991). They are a common, and frequently overlooked, ocular pathology. Specific occurrences vary by etiology of epithelial defect.

Classification

Corneal disease, corneal trauma

Definition

Epithelial dystrophy is a bilateral disease that affects the outermost layer of the cornea and is characterized by intraepithelial cysts and

abnormal basement membrane, leading to recurrent epithelial erosions, which can be painful and cause blurred vision. There are three subtypes of epithelial dystrophy including EBMD which is the most common anterior corneal dystrophy seen by the comprehensive ophthalmologist, Meesman's epithelial dystrophy, and the Lisch epithelial corneal dystrophy. EBMD is often sporadic but may be inherited in an autosomal dominant fashion; point mutations in the TGFB1 gene have been associated in a minority of cases.

Epithelial Erosions

Katherine Giuliano
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Corneal abrasion; Corneal erosion; Recurrent corneal erosion

Definition

Epithelial erosion is the detachment of the outermost corneal epithelial cells from the underlying Bowman's layer. It occurs as a result of corneal trauma, dystophy, or disease. The primary symptom of erosion is pain, as the loss of surface epithelium exposes sensory nerve fibers (ciliary nerves from the ophthalmic division of the trigeminal nerve). Other symptoms include foreign body sensation, photophobia, and blurred vision. Recurrent corneal erosion refers to repeated episodes of epithelial erosion.

Definition

Epidermoid cyst is a benign, slow-growing, round, firm, subcutaneous tumor lesion that can be congenital or secondary to trauma or surgery (Shields and Shields 2008; Kronis et al. 1988). It tends to occur at the outer upper portion of the upper eyelid and also in the superotemporal region of the orbit. They are filled with cheesy, foul-smelling keratin debris and lined by keratinizing stratified squamous epithelium that resembles normal epidermis (Figs. 1 and 2) (Yanoff and Sassani 2009; Eagle 2011).

Epitheliopathy

Alan Fremder Utria
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Definition

Epitheliopathy refers to any disease that affects the epithelial cells of the eye. The cornea, conjunctiva, ciliary bodies, iris, lens, and retina all contain epithelial cells and may be affected by disease or disorder. Due to its location, the cornea is the most susceptible to insults that may result in epitheliopathy.

Synonyms

ESR; Sed rate

Definition

An erythrocyte sedimentation rate (ESR) is a hematology test that is a nonspecific indicator of inflammation. The ESR can be used to diagnose or to monitor the course of treatment in inflammatory disease. In healthy blood, sedimentation of erythrocytes (erythrocytes gradually separate from plasma and settle to the bottom of a container) occurs slowly (due to negative surface change), while during inflammatory disease, the rate of sedimentation is more rapid. ESR is measured as a rate (distance in millimeters that erythrocytes have fallen from the plasma meniscus over time defined in mm per hour).

Giant cell arteritis (GCA, also known as temporal arteritis) is typically associated with

elevated ESR. An ESR is usually measured by the Westergren method. It is considered to be elevated if above 40 mm/h and is elevated in up to 85% of patients with GCA. Age increases the ESR however and one empiric calculation of normal is age and gender based. For men, age divided by 2 and for women age +10 divided by 2 are common empiric formulas for defining normal. An elevated ESR however is nonspecific and can be seen in other conditions that may involve changes in plasma proteins such as rheumatic fever, hypercholesterolemia, rheumatoid arthritis, lupus, anemia, macrocytosis, inflammatory disease, viral hepatitis, tuberculosis, cancer, multiple myeloma, increased plasma fibrinogen, and increased plasma globulins. A decreased sedimentation rate, on the other hand, could indicate the presence of sickle cells, microcytosis, increased plasma viscosity, spherocytosis, or polycythemia.

ETDRS chart

Definition

The ETDRS chart has been introduced as a standardized visual acuity (VA) testing chart for the ▶ Early Treatment of Diabetic Retinopathy Study (ETDRS). It uses 14 lines of 5 ▶ Sloan letter optotypes in each line in logarithmic progression. The space between lines and letters is proportionally equal keeping the effect of contour interaction constant. The threshold VA corresponds to the line in which 3 out of 5 optotypes were correctly identified. Alternatively, a by-letter scoring system (−0.02 logMAR credited for each letter correctly read) can be used. The testing distance can be varied; the corresponding visual acuity can be read easily from the chart. The chart is mounted on a box that is backlit by fluorescent tubes. For repeated measurements, the chart itself can be exchanged, providing different letters for different eyes.

Its easy design, its high standardization (logarithmic progression, backlit box), and the opportunity of

using the chart at different distances – especially at a short distance for low-vision testing – have established the ETDRS chart as the standard chart for testing visual acuity. In particular, shortcomings of its predecessor the traditional ▶ Snellen chart such as unequal design of the different lines and non-logarithmic progression were overcome.

Evisceration

Christopher Zoumalan[1] and Gary Joseph Lelli[2]
[1]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Definition

Evisceration involves the removal of the internal contents of the eyeball, leaving the sclera, extraocular muscles, and optic nerve intact (2008).

Indications

There are several indications for evisceration. The most common are as follows:

1. Blind painful eye
2. Suppurative endophthalmitis

Blind Painful Eye

There are numerous causes of a blind painful eye. Trauma, neovascular glaucoma, chronic retinal detachment, chronic angle closure glaucoma, retinopathy of prematurity, uveitis, and tumors can all lead to a blind painful eye. When conservative measures such as topical medications, cyclodestructive therapy, or retrobulbar injection of alcohol or thorazine have failed to control the pain, removal of the eye must be considered. Enucleation and evisceration can both be reasonable options and should be chosen based on the surgical goals of the patient and surgeon. Evisceration holds several advantages over enucleation:

1. There is less disruption of orbital anatomy.
2. Potential for better motility of the prosthesis.
3. Less-invasive procedure better tolerated by those with significant comorbidities.
4. Superior treatment for endophthalmitis.

Suppurative Endophthalmitis

In suppurative endophthalmitis, evisceration is commonly used over enucleation as removal of the ocular contents, and therefore, by definition, the infection can be undertaken without invasion of the orbit. As a result, the risk for spread of infection to the orbit or intracranial space is reduced.

Contraindications

Evisceration has several contraindications as well as known disadvantages to enucleation. First and most importantly, any potential for or known presence of intraocular tumor is an absolute contraindication to evisceration. If removal of the eye is indicated in these cases, enucleation must be done to ensure complete removal of the mass (if possible) and also provide for a complete specimen for pathologic evaluation.

Another important contraindication is the risk of sympathetic ophthalmia. This rare form of granulomatous uveitis can cause severe visual loss in the fellow or "sympathizing" eye. Eyes indicated for removal after penetrating trauma or multiple surgical procedures theoretically have an increased risk of sympathetic ophthalmia and

should undergo enucleation rather than evisceration. It is currently recommended that enucleation be carried out within two weeks of the trauma to help reduce the likelihood of sympathetic ophthalmia. Although there is a perceived advantage of enucleation over evisceration for prevention of sympathetic ophthalmia, this has never been proven (Moshfeghi et al. 2000).

Lastly, the shape of the eye needs to be taken into consideration prior to surgery. Eyes that are phthisical or have undergone scleral buckling, for example, are poor candidates for evisceration. The procedure itself and implant placement can be very difficult in these cases.

Techniques and Principles

Evisceration is usually carried out under general anesthesia; however, retrobulbar infusion of local anesthetic and monitored anesthesia care (MAC) can be used. Evisceration can be performed with or without keratectomy. The ocular contents are removed completely leaving bare sclera and overlying conjunctiva. An implant of sufficient volume is centered within the globe. The globe is then closed. A conformer can be placed to retain the anatomy of the fornices if needed. In cases of endophthalmitis, some surgeons will avoid placement of an implant given the setting of active infection (Stewart 1995).

Outcomes

The goal of evisceration is to remove the source of ocular pathology while delivering an acceptable cosmetic outcome. A prosthesis is placed in addition to the implant after adequate healing time to achieve good motility, normal eyelid shape and position, as well as normal volume and surface appearance.

Complications

Complications can occur intraoperatively and postoperatively. Intraoperative complications include evisceration of the wrong eye, orbital hemorrhage, and difficulty with intrascleral implant placement. Postoperatively, hemorrhage, edema, and infection can complicate the early course, while enophthalmos, superior sulcus deformity, and implant exposure and extrusion can occur months to years after the initial surgery. Most importantly, as mentioned above, the risks of undiagnosed intraocular tumor and of postoperative sympathetic ophthalmia are rare but potentially devastating complications.

Excimer Laser Photoablation

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]

[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany

[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Exciplex laser photoablation

Definition

Removal of corneal tissue using an excimer laser that emits very concentrated light in the ultraviolet (UV) region of the spectrum (193 nm) (Azar 2007).

Epidemiology

Worldwide an estimated number of over 30 million corneal excimer laser photoablations are performed each year. Around 95% are laser in situ keratomileusis (LASIK) procedures and 5% are advanced surface ablations (ASA).

History

Laser vision correction has grown with tremendous speed over the years since the first applications on human corneas in the 1990s. In addition to the choice of ASA or lamellar treatments like LASIK, the surgeon now has to select a laser profile for myopic, hyperopic, or astigmatic treatment. Wavefront-guided, wavefront-optimized (aspheric), and topography-guided ablation are the most advanced and frequently used profiles in current practice (Kohnen et al. 2007).

Clinical Features

Standard or planoscan treatment profile has been used for many years and produces very predictable results. The nature of the corneal reshaping, however, can lead to the induction of other complex optical aberrations after this type of ablation. Therefore, patients with higher optical errors, larger pupils, or with preexisting higher optical aberrations (HOA) may be better suited to another treatment profile.

Aspheric treatment profile is based on subjective refraction and corneal topography. It incorporates some elements of wavefront-guided treatment. The essential advantage is that the corneal reshaping is done in a more selective way resulting in excellent optical correction but without inducing spherical aberration. By not inducing this particular aberration, patients achieve better mesopic visual performance. This treatment profile is an option for patients with larger pupil size in dim light in the presence of minimal preexisting higher order aberrations and also for patients who have higher degrees of pre existing spherical aberration without substantial amounts of other HOA.

Wavefront-guided treatment profile is sometimes referred to as personalized or customized treatment profile. Assessment of the corneal wavefront is based on the principle that if an eye had no imperfections at all, a single point of light passing to the retina would not scatter and be seen as a tiny single point of light at the retina. But as no optical system is perfect, some individual light scattering occurs in every eye. A wavefront-guided treatment profile is able to correct HOA and is an option for patients with larger pupil size and marked HOA.

Topography-guided treatment profile or TopoLink profile is also based on subjective refraction and corneal topography and is an option for patients with corneal irregularities or underlying irregular corneal astigmatism (Kohnen 2008).

Tests

In advance to every corneal photoablative surgery, the excimer laser energy level is tested into appropriate substrate materials, the so-called "fluence test." Laser fluence is a measure of the energy density and is described as the amount of energy applied per unit area with each single pulse in mJ/cm2. Minimum fluence required for proper ablation is approximately 50 mJ/cm^2.

Differential Diagnosis

Today, corneal photoablation is solely performed with the excimer laser.

Etiology

The term "photoablation" refers to the greek term "phos" (light) and the latin term "ablatio" (removal).

Treatment

Excimer laser corneal photoablation is approximately 0.3–0.5 μm per pulse. Using modern excimer lasers with high pulse frequencies, photoablation is performed in less than 60 s per eye even treating higher ametropias. Though the tissue immediately adjacent to the excimer laser photoablation pulse may increase in temperature to about 40°, modern flying spot lasers seem not to produce significant increase in surface temperatures.

Excimer Lasers

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]

[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany

[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Exciplex laser

Definition

A gas LASER (light amplification by stimulated emission of radiation) in which a very short electrical pulse excites a mixture containing a halogen such as fluorine and a rare gas such as argon or krypton that emits very concentrated light in the ultraviolet (UV) region of the spectrum (193 nm). The term excimer is an acronym of "excited" and "dimer" with regard to the laser-active medium. A dimer is a molecule consisting of two identical atoms or molecules.

Epidemiology

Today, an estimated number of 5000–1,0000 excimer lasers are used worldwide for an estimated number of over 30 million refractive surgical procedures each year.

History

The first excimer laser was used in 1970 by N. Bassow, V. A. Danilychew, and Y. M. Popow at the P. N. Lebedew Physics Institute in Moscow, Russia. The first commercial excimer laser was

built in 1977 by Lambda Physics. In 1983, following initial reports by S. L. Trokel and R. Srinivasan that this laser could reshape the cornea without collateral thermal damage, animal experiments were pursued by M. B. McDonald, S. L. Trokel, and T. Seiler. The early excimer lasers were designed to perform slits in the cornea to simulate incisional surgery, but this was soon abandoned. After introduction of the Munnerlyn formula, photorefractive keratectomy (PRK) was introduced. This was followed by primate experiments and human clinical trials, ultimately gaining FDA approval of PRK for use on human eyes in 1995. LASIK (laser in situ keratomileusis) soon became the dominant procedure, and wave front technology and aspheric ablations led to customized treatments. Videokeratography, femtosecond laser-assisted flap creation, and advances in wave front technology played an important role in advancing the field resulting in its widespread worldwide acceptance today.

Clinical Features

Modern excimer lasers work with pulse frequencies of 100–1000 Hz and a spot diameter around 1 mm. An entire laser weights around 500–1000 kg, amount of space needed is around 4 × 4 m, and the minimum prize in $ is at least six digit.

Tests

Thorough examination of the eyes and workup of the patient's anamnesis is mandatory to rule out several exclusion criteria for excimer laser refractive surgery. See also chapters PRK, LASEK, and LASIK.

Differential Diagnosis

Other LASERs that are used for ophthalmic surgical procedures:

- Femtosecond laser
- Nd:YAG (neodymium-doped yttrium aluminum garnet) laser
- Argon laser
- Diode laser
- Carbon dioxide laser

Etiology

See "History" section above.

Treatment

Almost all types of corneal refractive procedures use an excimer laser. Some novel techniques like SMILE (small-incision *femtosecond* lenticule extraction) or FLEx (femtosecond lamellar extraction) work with femtosecond laser technology and do not implement an excimer laser for corneal ablation. For detailed illustration of the different surgical procedures, refer to chapters PRK, LASIK, Epi-LASIK, and LASEK.

[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil
[3]Department of Ophthalmology, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Biopsy

Definition

Surgical removal of a lesion whereby the tumor is removed completely, utilizing an elliptical or other circumferential surgical pattern surrounding the lesion, in order to prevent recurrence or to avoid leaving any tumor behind.

Purpose

To fully remove a lesion in question to prevent recurrence or achieve cure or both. An excisional biopsy is also often used if a deep inflammatory lesion or malignancy is suspected.

Principle

First, the tissue surrounding the lesion is anesthetized with local anesthetic with epinephrine. A sharp incision is fashioned circumferentially around the lesion, usually with an eliptical pattern and preferably in relaxed skin tension lines. A rim of normal tissue, around 1–2 mm (more if the surgeon suspects an aggressive malignancy) is typically included to secure the diagnoses of clear margins. Including the adjacent normal tissue also aids in histopathologic characterization of the abnormal tissue (Nerad 2001; Albert and Jakobiec 2008).

Indication

A wide excisional biopsy is highly warranted in any lesion suspicious for malignancy, such as melanoma. Benign lesions with high recurrence rate also may warrant an excisional biopsy in order to prevent recurrence.

Contraindication

Lesions that can be removed with simpler techniques, such as a shave biopsy. Abnormal bleeding times, due to therapeutic or pathological causes, may also preclude safe excisional biopsy. An excisional biopsy may also be avoided if the lesion is intimately associated with vital structures and excision risks functional or structural damage.

Advantages/Disadvantages

Removal of the whole lesion may increase the likelihood of a complete cure and may eliminate the need for further surgery. Disadvantages of this type of biopsy include: possibly larger tissue area removal, potential for higher bleeding complications, possible structural or functional damage to the area, and a potential for an unacceptable cosmetic result if not performed properly (Nerad 2001; Albert and Jakobiec 2008).

Exposure Keratitis/Keratopathy

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Lagophthalmic keratitis

Definition

Exposure keratopathy is a noninfectious inflammation of the cornea that results after incomplete lid closure or lagophthalmos (Kanski and Bowling 2011). The cornea remains unprotected from drying despite normal tear production.

Etiology

The most frequent cause of lagophthalmos associated with exposure keratopathy is facial nerve palsy (Kaiser and Friedman). Facial nerve palsy may be idiopathic or secondary to surgery for acoustic neuromas or parotid gland tumors. Lagophthalmos may also be caused by reduced muscle tone, as may be observed in comas. Nocturnal lagophthalmos is noted for some patients (Kanski and Bowling 2011). Mechanical trauma and burns may cause eyelid scarring, limiting eyelid closure. Increased skin tightness due to eczema, taut skin, solar keratosis, and even blepharoplasty may result in lagophthalmos. Globe position may also play a factor. The end result of persistent lagophthalmos is drying of the cornea and inflammation leading to exposure keratopathy.

Occurrence

Exposure keratitis can affect individuals of all ages and equally males and females. Of note, it has become a growing concern in ICU care. Some reports have revealed the incidence of exposure keratitis to range from 20% to 42%, ranging from 2 to7 days in the ICU setting (Rosenberg and Eisen 2008).

Classification

Exposure keratopathy is diagnosed in the absence of an infectious etiology (Kanski and Bowling 2011). Limited eyelid closure is associated with the disease. Patients will present with symptoms of dry eye, itching, burning, decreased vision, and foreign body sensation. Physical exam and slit lamp will reveal punctate epithelial changes, epithelial breakdown. Severe findings include stromal melting with possible corneal perforation and secondary infection.

The extent of disease guides the type of treatment that may be pursued. Reversible exposure may be treated with artificial tears during the day and ointment during the night (Kanski and Bowling 2011). Bandage silicone rubber or scleral contact lenses may be of aid to some patients. Temporary tarsorrhaphy or occlusive dressings may be necessary. In cases where permanent

exposure is of concern, permanent tarsorrhaphy is a treatment option. Alternative treatment methods include placement of gold weights into the upper lid (especially in cases with facial nerve palsy). Orbital involvement may necessitate orbital decompression.

Exposure Staining, Keratoconjunctivitis Sicca

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Ocular surface staining

Definition

Exposure staining is defined as the use of dyes, like fluorescein, rose bengal, and lissamine green, to stain and identify damaged corneal and conjunctival epithelial cells (Holland et al. 2013).

Purpose

Keratoconjunctivitis sicca, or dry eye syndrome, may result in corneal and conjunctival epithelial cell damage (Kanksi and Bowling 2011). The use of ocular surface staining allows for identification of devitalized and desiccated corneal and conjunctival tissue under slit-lamp examination.

Principle

The principle of exposure staining is to visually identify extent of epithelial cell damage on examination. Fluorescein enters and dyes damaged corneal and conjunctival epithelial cells (Kanksi and Bowling 2011) Rose bengal is a dye that has a high affinity for injured or dead epithelial cells that have lost their protective mucous layer. Lissamine green has a similar staining pattern to rose bengal.

Indication

The pattern of staining may aid in the diagnosis and assessment of dry eye syndrome. Fluorescein staining has shown to be of use for staining of diseased cornea, while rose bengal and lissamine green have been more useful for staining diseased conjunctiva (Holland et al. 2013).

Patients presenting with symptoms of dry eyes (itching, burning, redness, decreased vision, foreign body sensation) necessitate a slit-lamp examination and ocular surface staining. Staining may reveal several findings. For example, interpalpebral staining of the cornea and conjunctiva is found during tear deficiency (Kanksi and Bowling 2011). A superior limbic keratoconjunctivitis may be indicated on a superior conjunctival stain. Inferior stains may rather hint exposure keratitis or blepharitis.

Contraindication

Ocular staining is well tolerated by patients, and there are no contraindications other than adverse reactions/stinging to the particular stain.

Advantage/Disadvantage

Ocular staining has several advantages for determining the extent of keratoconjunctivitis sicca. The greatest advantage is its low risk potential (Holland et al. 2013). Fluorescein staining is highly tolerable and does not cause stinging in the patient. However, it may stain contact lenses, and patients should be warned that their eyes may remain yellow for a short period of time. A disadvantage may also be that the fluorescein tear film may obscure accurate corneal staining measurements (Bron et al. 2003). Tear film assessments prior to application may improve staining measurements.

Rose bengal dye may cause stinging that can last up to a day. A topical anesthetic should be applied prior to its use (Holland et al. 2013).

Lissamine green, however, carries a similar staining profile as rose bengal and is not associated with stinging (Holland et al. 2013). It is better tolerated by patients and has grown in its popularity in clinical practice.

External Hordeolum (Stye)

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Stye

Definition

It is an acute bacterial infection resulting in a painful, nodular lesion on the external anterior eyelid.

Etiology

An external hordeolum is an acute bacterial infection of one or more sebaceous glands of Zeis or apocrine sweat glands of Moll. The most common cause is *Staphylococcus aureus*. Hordeolum is associated with chronic blepharitis, meibomian gland dysfunction, and acne.

Clinical Presentation

A hordeolum presents as an acute, painful, erythematous, subcutaneous, nodular abscess on the margin of the anterior eyelid. One or more lesions appear and can sometimes involve the entire lid margin. Swelling and crusting of the eyelid and mucopurulent discharge from the eye may be present. Symptoms include localized pain, tenderness, burning, irritation, blurred vision, photophobia, and tearing. Rarely, the infection may spread to adjacent tissue, secondarily causing preseptal cellulitis.

Diagnosis

Diagnosis is based on clinical appearance and symptoms. No additional tests are necessary for diagnosis.

Differential Diagnosis

It may be difficult to differentiate a hordeolum from an acute chalazion. However, a chronic chalazion will be firm and nontender, in contrast with a hordeolum, which is acute, painful, and self-limiting. Blepharitis and preseptal cellulitis should also be considered in the differential. With a history of recurrent hordeola, suspicion for neoplasm may be increased, particularly sebaceous gland carcinoma, basal cell carcinoma of the eyelid, and squamous cell carcinoma of the eyelid. Histopathologic examination of tissue will be able to differentiate between these neoplasm diagnoses (Weisenthal et al. 2013).

Prophylaxis

Proper daily eyelid hygiene with warm compresses can prevent the development of a hordeolum and minimize blepharitis and meibomian gland dysfunction, both of which are risk factors for hordeolum. Appropriate hand washing can decrease infection.

Therapy

The main medical management is eyelid hygiene. Warm compresses with gentle massage for at least 10 min, four times a day, can facilitate drainage and are generally sufficient for complete resolution. A hordeolum should not be forcefully ruptured to prevent further spread of the infection. Topical antibiotics usually are not effective but are prescribed if there is associated blepharoconjunctivitis. Systemic antibiotics are administered if there is secondary preseptal cellulitis. Treat concomitant blepharitis to minimize recurrence of hordeola. If there is no resolution with medical therapy, incision and drainage can be performed through the skin and orbicularis. A sample can be sent for histopathologic examination to rule out malignancy (Krachmer et al. 2011).

Prognosis

A hordeolum is usually self-limiting, resolving within 1–2 weeks. They may recur. Secondary complications, although rare, include preseptal cellulitis and a systemic infection.

Epidemiology

Hordeola are common, more so in adults compared to children. The incidence and prevalence are unknown. There does not appear to be a racial or gender predominance.

Extraperiosteal Route

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Synonyms

Subperiosteal orbitotomy

Definition

An orbitotomy designed to access the subperiosteal or extraperiosteal space of an orbital wall.

Indications

This is often performed for drainage of a subperiosteal abscess that may be continuous from the frontal, ethmoid, or maxillary sinus, for orbital fracture repair, or for bony decompression of the orbit.

Contraindication

Contraindications include need for access to lesions not in the subperiosteal space or for patients who are not medically stable for surgery.

Techniques and Principles

This procedure is generally performed in the operating room under sedation or general anesthesia. The subperiosteal space of the inferior and superior orbit may be accessed through a transcutaneous incision through the lower or upper eyelid, respectively. In the upper eyelid, the incision may go through the transeptal plane if necessary, or just superior to the septum, depending on the area of interest. A vertical eyelid splitting procedure may be used if a broader exposure is desired. The inferior extraperiosteal space may also be accessed through a lower eyelid transconjunctival approach. Medially, for drainage of a subperiosteal abscess from the ethmoids, fracture repair of the medial wall, or medial wall decompression, a transcaruncular or frontoethmoidal, or Lynch, incision may be taken to access this area (Cockerham et al. 2001; Levine 2003; Mohadjer and Hartstein 2006). The medial and inferior subperiosteal spaces may also be accessed endoscopically during sinus surgery for decompression or abscess drainage (Nerad 2001; Tsirbas et al. 2005). For lateral subperiosteal access, a lateral orbitotomy is performed (Cockerham et al. 2001; Levine 2003; Mohadjer and Hartstein 2006).

Outcome

Access to the subperiosteal spaces of each orbital wall for drainage of an abscess, bony decompression, or fracture repair.

Complications

Risks of extraperiosteal orbitotomy include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, and need for additional procedures.

Eye Banking

Sana Idrees
The George Washington University, Washington, DC, USA

Definition

Eye banking has evolved over the years from a simple collection and distribution system to a technically demanding and scientifically sophisticated system. In the mid-1970s, an eye bank was a refrigerator where whole eyes were stored at 4 °C until they were used in the operating room for corneal transplantation. Since then, corneal preservation techniques have improved the quality of donor tissue and increased the supply of available donor corneas to meet the increasing demand. Advances in corneal transplantation techniques have led to an increase in corneal transplants and expansion of the indications for transplantation. Patients who were previously considered to be poor prognostic candidates for corneal transplantation are now considered acceptable candidates (Doughman 1998). Today, eye banks provide ocular tissues, including glycerol-preserved corneas and scleral tissue, for multiple procedures, including penetrating keratoplasty, Descemet's stripping endothelial keratoplasty (DSEK), and femtosecond laser-enabled keratoplasty (Heck and Montoya 2011).

The first eye bank was formally established in New York in 1944. Over time, a body of medical standards and regulations has evolved to keep up to date with advancements in eye banking. The goal of these regulations is to insure the highest standard of eye tissue for human transplantation,

while maintaining an adequate donor pool. The Eye Bank Association of America (EBAA) developed the first medical standards of eye banking, which were formally adopted in 1980 (Glasser 2011).

Eye banking involves educating potential donors before death, counseling their next of kin at the time of death, harvesting and preserving the tissue, and finally distributing the tissue to the recipient's surgeon. An eye bank is a complex network of technicians, surgeons, enucleators, medical examiners, and administrators. The process of eye banking is essential to prevent the spread of infectious disease and malignancy from donor to recipient. If microorganisms are transplanted from the donor eye, endophthalmitis may develop and could ultimately result in loss of the eye. Recipient deaths have been reported in cases of rabies virus and Creutzfeldt-Jacob disease transmission. The threat of human immunodeficiency virus (HIV) transmission from donor corneas of patients with acquired immunodeficiency syndrome (AIDS) has been a major concern given the isolation of HIV from the tears, conjunctival epithelium, and cornea of these individuals (Doughman 1998). Additionally, the optical and mechanical integrity of the of the transplanted tissue may be compromised in donors with corneal dystrophies or degenerations, and eye banks are involved in detecting these and other similar abnormalities prior to distribution of tissue to transplant recipients (Glasser 2011).

Eyelid Erythema

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Eyelid erythema is redness of the eyelids that can result from any condition that irritates, inflames, or infects the eyelid.

Etiology

The delicate, thin skin around the eyes has a rich blood and nerve supply and is susceptible to developing erythema due to many different conditions. The most common causes of eyelid erythema include allergies, inflammation, infection, and trauma.

Classification/Occurrence

Allergies, a very common cause of red eyelids, may be local such as a reaction to a chemical or more generalized such as hay fever. Contact dermatitis occurs frequently from cosmetics, shampoos, soaps, or substances on the hand and fingers that are rubbed inadvertently onto the periocular skin. Notably, preservatives in ophthalmic medications such as benzalkonium chloride and thiomerosal are also potential causes of contact dermatitis.

Other dermatoses may cause eyelid erythema with associated scaling such as seborrheic dermatitis, psoriasis, and atopic dermatitis. Systemic diseases such as cutaneous sarcoidosis can also present with erythematous, scaly plaques, and discoid lupus erythematosus has classically shiny erythematous plaques with punctate, follicular scale that may be seen in the periocular region.

Infections or inflammations of the eyelid margin are also frequent causes of eyelid erythema. These conditions include blepharitis, chalazion, and hordeolum. Other infectious causes may include herpes zoster with its associated painful vesicles in a dermatomal pattern.

Trauma to the periocular region including burns, blunt, or penetrating injury may also lead to eyelid erythema associated with other signs of injury.

Synonyms

Avulsion; Contusion; Hematoma; Lacerations

Definition

Trauma to the eyelid involving damage to the eyelid skin, muscles, connective tissue, mucous membrane, or adnexal structures (Nerad 2001).

Etiology

Eyelid trauma is caused by blunt or penetrating injury. Blunt trauma may result from causes such

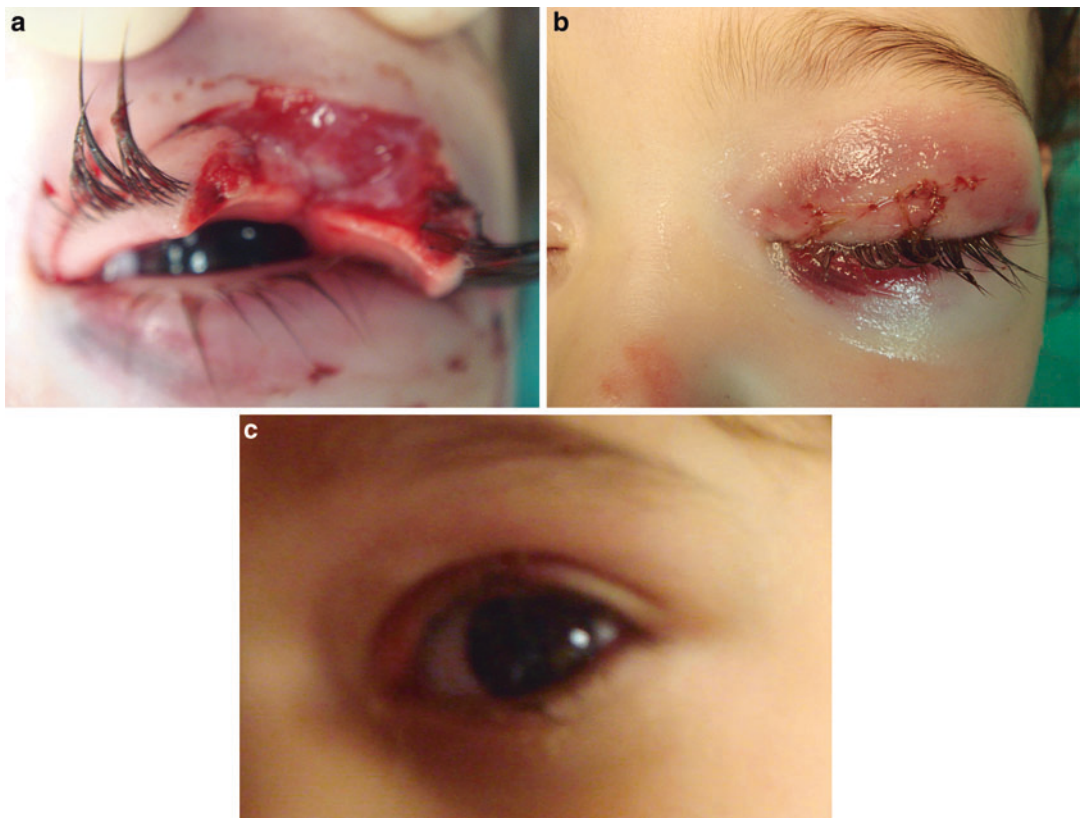
as a motor vehicle accident, assault, or a fall. Laceration or penetrating trauma to the eyelid is seen in the context of assault with sharp object, as well as bite injuries.

Clinical Presentation

Injury to the eyelid or periocular area can be an isolated incident but most often occurs in the setting of multisystem trauma. The physician's primary role is to rule out life-threatening injury and stabilize the patient. Sight-threatening injuries should then be addressed. The eyelid wound is explored to identify injured anatomic structures and the extent of damage. Fat present in the wound implies violation of the orbital septum and consequently, damage to the levator palpebrae superioris muscle is suspected. Full thickness eyelid trauma increases initial suspicion of globe injury. Tissue loss in the context of eyelid trauma is extremely rare but becomes more common with injuries in which the patient has been dragged, such as motorcycle accidents. Shrinkage of tissue is more common. Avulsion of the medial or lateral canthal tendons most often occurs in the setting of blunt trauma. The anterior and posterior arms of the lower eyelid medial canthal tendon are particularly susceptible. With any injury to the medial aspect of the upper or lower eyelid, the ophthalmic examination should inspect for canalicular involvement (Fig. 1a) (Weiner and Bedrossian 2002).

Diagnostics

Examination of the patient's eye precedes examination of the eyelid. Following the eye exam, a



Eyelid Trauma, Fig. 1 (**a**) Initial injury. Eyelid trauma was caused by a fall against a stroller. (**b**) Immediate postoperative result. (**c**) Two week postoperative result.

thorough clinical examination via direct inspection of the wound is the physician's most important tool to determine the location, extent, and severity of the injury. A suspicion of a foreign body in the wound warrants imaging of the region. CT scanning of the orbit is the first line imaging protocol. If the medial aspect of the eyelid is involved, the canalicular system is inspected by careful probing. Damage to the levator is suspected when orbital fat is present within the wound and can be evaluated by measuring the levator excursion of the upper eyelid.

Differential Diagnosis

Trauma to the orbit, periocular trauma.

Prophylaxis

Injury to the eyelid can be prevented by the use of protective eyewear and polycarbonate eye glasses.

Therapy

The goal of treatment is to return normal function and cosmesis to the eyelid. Trauma to the eyelid should be repaired within 48–72 h following injury. The well-vascularized eyelid allows for somewhat delayed closure as it is at lower risk for infection. Some clinicians utilize broad spectrum oral antibiotics until wound treatment is initiated. A general medical history should include inquiry regarding recent tetanus injections. Repair of the wound involves reapproximating tissues to their appropriate anatomic locations. If the levator muscle is found to be damaged, it is sutured to the anterior border of the tarsus. Furthermore, if canalicular trauma is involved, the canalicular system should be explored, repaired, and intubated with silicone tubes. Medial or lateral canthal tendon avulsions are repaired by reinserting the appropriate limb of the canthal tendon to its bony insertion (Fig. 1b, c).

Prognosis

Given the highly vascular nature of the eyelid, wounds heal with minimal scarring and eyelid asymmetry.

Epidemiology

Eyelid injury predominantly occurs in males aged 20–30 (Savar et al. 2008).

[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

Upper lid loading

Definition

Eyelid weight insertion is a lid loading technique using an implanted device to counter lagophthalmos associated with facial paralysis.

Indication

Facial paralysis places the eye at risk for incomplete closure voluntarily and during blinking due to paralysis of the orbicularis oculi and the unopposed action of the levator palpebrae superioris. Inadequate corneal protection results in exposure keratitis and corneal ulceration and, in severe cases, may result in blindness. In addition, chronic facial paralysis may result in ectropion of the lower lid, brow ptosis, and decreased tear production, further contributing to corneal injury. Co-existing corneal anesthesia, dry eye, and absent Bell's phenomenon put patients at greater risk of ocular complications. The most common causes of facial paralysis include Bell's palsy, tumors such as acoustic neuroma, trauma to the seventh cranial nerve, cerebral vascular accidents, and complications of previous facial or neurosurgical surgery.

Various implanted devices have been tried to counteract the action of the levator including silicone bands, palpebral springs, and lid magnets. However, due to complications of breakage, erosion, and extrusion, their use is currently limited.

Upper lid loading with gold weight insertion is now the most commonly performed procedure for the treatment of paralytic lagophthalmos due to its safety, predictability, and low cost. It was first described in 1958 by Illig and further refined in its design and surgical technique over the past several decades. Weighting of the upper lid results in increased gravitational pull on the lid and with relaxation of the levator on attempted eye closure, the eyelid passively closes by gravitational effect. Gold has the advantage of combining considerable density with malleability, being relatively inert and providing a good color match for the skin. In addition, gold weight insertion is associated with the fewest number of complications and is reversible.

Contraindication

Eyelid weight procedures are indicted for long-standing cases of facial paralysis or when the chance of recovery is low. If early spontaneous recovery of the nerve function is predicted, aggressive lubrication with temporary tarsorrhaphy should be considered. The procedure is also contraindicated in cases of gold allergy.

Techniques and Principles

The appropriate gold weight size is selected preoperatively by taping various sizes of weights to the upper eyelid to determine which size best achieves adequate relaxed eyelid closure while limiting eyelid ptosis in primary gaze. Once the appropriate weight is determined, a customized weight is made for the patient, taking into account the overall size of the lid and the curvature of the globe.

A standard upper eyelid incision closure is made through skin and orbicularis muscle. The gold weight is then positioned in a pocket overlying the tarsal plate. The implant is then sutured to the tarsal plate in order to reduce the risk of migration and extrusion.

Outcome

Gold weight implantation does not restore the normal blink reflex but reduces lagophthalmos and corneal exposure by improving voluntary eye closure.

Complications

Complications of gold eyelid weights include undercorrection, overcorrection (ptosis), allergy or foreign body reaction, cosmetic deformity, corneal astigmatism, infection, migration, and extrusion.

Facial Diplegia, Guillain-Barré Syndrome

Jason E. Hale[4], Sumayya J. Almarzouqi[1], Andrew G. Lee[1,2,3,4,5] and Michael L. Morgan[1,6]

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Facial diplegia refers to facial nerve paralysis of both sides of the face. It can be a finding in patients with Guillain-Barre Syndrome (GBS), an infection-triggered polyneuropathy disorder affecting the peripheral nervous system.

Differential Diagnosis

Other diseases that can present with facial diplegia include Bell's palsy (which is usually unilateral), chronic inflammatory demyelinating polyneuropathy (CIDP), sarcoidosis, severe vitamin B1 deficiency, acute arsenic poisoning, n-hexane (glue-sniffing) neuropathy, vasculitis, Lyme disease, porphyria, tick paralysis, leptomeningeal disease, and paraneoplastic disease.

Diagnosis

The diagnosis of GBS is based on clinical presentation. Key features that favor a diagnosis of GBS include relative symmetry of ascending polyneuropathy (e.g., muscle weakness and sensory impairment), cranial nerve involvement (including Miller Fisher variant), areflexia, autonomic dysfunction, normal body temperature, and elevated CSF protein levels with normal cell count (albuminocytologic dissociation).

Pathogenesis

The pathogenesis of GBS is believed to be autoimmune. Following an infection, antibodies generated in the immune response cross-react with components of peripheral nerves, particularly

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

myelin-producing Schwann cells. This phenomenon is known as molecular mimicry, and the result is secondary demyelination and dysfunction of peripheral nerves. *Campylobacter jejuni*, which often causes a diarrheal illness, is a common precipitating infection in GBS. Other infectious etiologies include viruses, other bacteria, and some immunizations.

Clinical

GBS usually progresses over a period of about 2 weeks. GBS that progresses longer than 8 weeks is more consistent with chronic inflammatory demyelinating polyradiculoneuropathy (CIDP).

Treatment

Supportive care is of utmost importance in individuals suffering from GBS, particularly for respiratory failure. Severe autonomic dysfunction often requires close monitoring in an ICU setting, with particular attention given to blood pressure control, arrhythmias, ileus, urinary retention, and other autonomic functions. Neuropathic pain is common and can be treated with medications like gabapentin or carbamazepine.

Plasma exchange can be done to remove the presumptive autoimmune antibodies from the blood, and intravenous immune globulin (IVIG) can be administered to inhibit production of more autoimmune antibodies by B cells. Both of these therapies can help increase recovery time.

Prognosis

The prognosis varies by severity of illness. Poor prognostic factors include older age, rapid onset (less than 7 days), severe muscle weakness, need for ventilator support, and a preceding diarrheal illness.

Femtosecond Laser

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

F

Synonyms

Ultrashort pulse laser, Ultrafast laser

Definition

A femtosecond (fs) laser is a laser which emits optical ▶ pulses with *ultrashort pulses*, between a few and hundreds of fs (1 fs $= 10^{-15}$ s).

Epidemiology

Today, almost a dozen of different companies offer fs laser devices for ophthalmic surgical use. Fs laser technology has now been used in an estimated number of five million plus surgical procedures worldwide.

History

The first studies regarding fs laser technology were published in the 1980s investigating the interaction of the fs laser with retinal tissue in the animal model. The human cornea was treated for the first time in 1994 (Kautek et al. 1994). Since 2001, different fs laser systems were introduced on the market, and fs laser technology was

basically used as an alternate for the mechanical microkeratome in laser in situ keratomileusis (Kohnen et al. 2010).

Clinical Features

The fs laser works with a wavelength of 1030–1050 nm as this wavelength is suitable for corneal procedures due to very low light absorption or dispersion. The laser achieves its surgical effect through a process termed "photodisruption." When the intensity of the focused laser beam exceeds the threshold of 10^{10}–10^{11} W/cm^2, changes occur in the absorption characteristics of the tissue, and the phenomena of "laser-induced optical breakdown" occur. A plasma of free electrons and ions is generated. When energy is removed from the system, these electrons and ions recombine to form a gas (cavitation bubble) that expands rapidly within the tissue. Expanding of the gas produces a cleavage of the tissue surrounding the focal point of the laser. If these laser spots are placed close together side to side, lamellar cuts can be generated; if the spots are stacked on top of each other, vertical cuts can be generated.

Tests

Before each clinical application, this type of laser usually performs a self-test.

Differential Diagnosis

Other important laser systems used for ophthalmic surgical procedures are, e.g., the excimer laser, the Nd:YAG (neodymium-doped yttrium aluminum garnet) laser, the argon laser, the diode laser, or the carbon dioxide laser.

Etiology

The term "femto" originates from Danish "femten" which means "fifteen." One femtosecond is 10^{-15} s.

The word "LASER" is short for light amplification by stimulated emission of radiation.

Treatment

Fs laser technology is implemented in corneal refractive surgery and recently also in cataract surgery. Common applications are used as a laser keratome for laser in situ keratomileusis, for lamellar or penetrating keratoplasty (especially for differentiated cut configurations like the "top-hat" or "mushroom" configuration), for creating intrastromal tunnels for intracorneal ring segment implantation, for astigmatic keratotomy, or for femtosecond lenticule extraction (where extraction of a fs laser-generated lenticule replaces excimer laser photoablation) (Kook et al. 2009). Recent research also implicates fs laser technology for capsulorhexis and fs laser-assisted phacofragmentation.

Synonyms

Fine needle aspiration (FNA)

Definition

A procedure used to remove a small amount of an unknown lesion by aspirating through a syringe. This allows a small tissue sample, often in patients with known lymphoproliferative disease, metastatic disease, or secondary tumors from adjacent sinus spread.

Indications

To safely obtain a tissue sample without a surgical orbitotomy. This technique may be reserved for patients with blind eyes, who may be poor surgical candidates or when immediate biopsy result is required.

Contraindication

Relative contraindication for tumors that may be near vital structures (i.e., optic nerve) or patients unable to tolerate procedure. FNA is also contraindicated for tumors that may metastasize if violated (some lacrimal gland tumors, melanomas, etc.) and should be avoided (Tijl and Koornneef 1991).

Techniques and Principles

This procedure may be done in the office. The patient is given an injection of local anesthetic. Then, a 4-cm 22 gauge needle is passed transcutaneously or transconjunctively to the suspicious lesion and cells are aspirated. Occasionally, it is performed via computed tomography (CT) or ultrasound guidance for improved localization (Tijl and Koornneef 1991).

Outcome

A small sample size is obtained while avoiding surgery.

Complications

The sample size may be insufficient, and further FNA or surgery may be required. Pain, infection, swelling, and bruising may occur. Rarely there may be hemorrhage or hematoma. A retrobulbar bleed, while possible, is a rare complication.

Fluorescein, as Diagnostic Agent

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Definition

Fluorescein angiography (FA) is a diagnostic modality that utilizes intravenous sodium fluorescein to image retinal and choroidal blood vessels (Gass 1997; Johnson et al. 2006).

Purpose

Fluorescein angiography provides photographic documentation on the location and condition of retinal and choroidal blood vessels, allowing clinicians to diagnose and treat retinal and choroidal diseases.

Principle

Fluorescein angiography is based on the ability of sodium fluorescein to absorb photons of light in the blue wavelength (465–490 nm) of light and subsequently emit them in the yellow-green wavelength (520–530 nm) of light. Following intravenous injection, sodium fluorescein shortly appears within the eye and outlines the location of retinal and choroidal blood vessels. The documentation of this fundus appearance is accomplished with a special FA camera, which harbors a blue wavelength outbound filter over its light source and a yellow wavelength inbound filter over its objective lens. Fluorescein angiography images appear in black and white (Fig. 1).

The specific technique of FA involves intravenously injecting sodium fluorescein through a peripheral site (usually the antecubital vein) followed immediately by photographing the fundus oculi with the FA camera. Within 8 to 12 seconds of the injection, sodium fluorescein appears within the choroidal vasculature followed almost immediately within the retinal arteries (arterial phase). Over the next 30 s, sodium fluorescein traverses the retinal capillaries and flows via a laminar fashion into the retinal veins (laminar venous phase). Eventually, both retinal arteries and veins are completely filled (arteriovenous phase). The angiogram finishes over the next 15 min as sodium fluorescein recirculates throughout the body and the fluorescent images in the fundus fade.

Pathologic findings on FA reflect an abnormal ability of sodium fluorescein to accumulate in areas of the eye where it should not be, or inability to be present in areas where it should, such as retinal and choroidal vessels. These abnormalities are referred to as hyperfluorescence and hypofluorescence, respectively. (Autofluorescence is the ability of a fundus object to fluoresce even without any injection of sodium fluorescein.)

Fluorescein, as Diagnostic Agent, Fig. 1 Fluorescein angiography of the ocular fundus

During a normal FA, sodium fluorescein cannot pass through the retinal pigment epithelium or tight junctions of the retinal vessels and so cannot enter the subretinal, intraretinal, or vitreous spaces. However, pathologic conditions often alter these natural barriers, and sodium fluorescein appears to leaks into abnormal locations. The increased presence of sodium fluorescein produces a signal brighter than expected (hyperfluorescence). When sodium fluorescein cannot fill a vascular structure like it normally should (i.e., an occluded retinal or choroidal vessel), the decreased amount of sodium fluorescein produces a signal darker than expected (hypofluorescence). Hyperfluorescence and hypofluorescence can also be observed when less or more of an obscuring substance is present over a normal pattern of fluorescence and produces a brighter or darker image, respectively. Common intraocular substances that influence the brightness of fluorescence in such a manner include blood, pigment, lipid, and fibrosis.

Indications

Common indications for FA include diabetic macular edema, age-related macular degeneration,

branch and central retinal artery or vein occlusions, proliferative diabetic retinopathy, infectious and inflammatory retinochoroidal diseases, and posterior segment neoplasms. However, FA may be helpful and considered for any ocular disease that involves the vascular supply of the retina and choroid or that affects the integrity of the blood-retinal barrier.

Contraindications

Fluorescein angiography is contraindicated in patients who have had a prior severe reaction to fluorescein, including urticaria and anaphylaxis. It should also be used with caution in patients with hepatic or renal compromise as they may display decreased clearance of the drug. Patients with a protein-deficient state can experience an effectively higher level of free fluorescein due to decreased serum protein and may require a reduction in dosage of fluorescein.

Advantages/Disadvantages

Advantages of FA are many since it is safe, well tolerated, and easily performed in a clinic setting and provides valuable information in the diagnosis and treatment of many retinal and choroidal diseases. Potential disadvantages of FA include its limited ability to image the choroidal circulation and its potential side effect profile, including the ability to induce nausea, vasovagal reactions, urticaria, and anaphylaxis.

[6]Department of Ophthalmology, College of Medicine, Texas A&M University, College Station, TX, USA

Synonyms

Saccadic nystagmus

Definition

Ocular flutter is defined as involuntary, back-to-back, rapid, horizontal saccades without an intersaccadic interval.

Etiology

Ocular flutter is commonly associated with cerebellar or brainstem disease but can occur in the setting of postviral encephalopathy. One hypothesis is that ocular flutter is a disorder of the saccadic pause neurons, but this has not been proven.

Clinical Presentation

Patients may present with symptoms of benign encephalitis – ataxia and rapid ocular movement while the eyes are closed.

Diagnostics

Neuroimaging of the posterior fossa is typically the first-line evaluation of ocular flutter. Lumbar puncture may be required in some cases (e.g., postinfectious). Some cases are paraneoplastic in origin, and a search for underlying neoplasm may be indicated.

Differential Diagnosis

Opsoclonus, nystagmus

Therapy

Treatment is dependent upon the underlying disease.

Prognosis

Prognosis depends on the etiology of the flutter.

Epidemiology

Ocular flutter is typically postinfectious or paraneoplastic but can affect any age, either gender, and any ethnic group.

Foldable IOL

Definition

A foldable intraocular lens is literally folded to half its size. It makes an insertion of the IOL into the eye through a small incision possible. Incision may be as small as 1.8 mm. Once a foldable IOL is placed, it unfolds to its full regular size.

Epidemiology

Today the vast majority of worldwide implanted IOLs are foldable IOLs. PMMA IOLs are used only in special cases.

History

The first foldable IOLs were developed in the 1950s. They were made of hydrogel and implanted in animals by M. Dreifus. Later in the 1970s, E. Epstein implanted these IOLs in human eyes. The first foldable silicone IOL was used in 1978 by J. Zhou. In the 1980s, foldable IOLs conquered the market. Until that time, PMMA IOLs were the standard IOLs requiring a 5–7 mm incision after extracapsular surgery (Werner 2008; Auffahrt 2008). As implantation was often performed in the ciliary sulcus, a so-called windshield-wiper effect was noticed. This referred to a pigment dispersion of the posterior pigment epithelium of the iris due to mobility of the IOL. This type of post-operative complication became rare as foldable IOLs were implanted with injector systems into the capsular bag in the 1990s. Today, also phakic IOLs like the iris-supported Artiflex/Veriflex IOL or anterior chamber angle-supported AcrySof are implanted with injector systems.

Clinical Features

A foldable IOL is made of silicone or hydrophobic or hydrophilic acrylic. Foldable IOLs have numerous advantages over rigid PMMA IOLs (Kohnen et al. 2009):

- The IOL can be implanted or injected via a small incision and is therefore less traumatic.
- Placement of the IOL is easier and more accurate.
- Low risk of tilting of the IOL.
- Faster wound healing due to small incision size.
- Less surgical induced astigmatism due to small incision size.

Tests

In the scope of a biomicroscopic examination, it is not possible to determine whether a foldable or non-foldable IOL is implanted in the eye.

Differential Diagnosis

Either aphakic, pseudophakic, or phakic IOL is manufactured as foldable models.

Etiology

Today, all different types of IOLs – monofocal, multifocal, accommodative, toric, and blue light filter – are available on the market.

Fornices

Benjamin P. Erickson
Department of Ophthalmology, Bascom Palmer Eye Institute, Miami, FL, USA

Definition

Loose arches of redundant conjunctival tissue posterior to the upper and lower eyelids.

F

Structure

The conjunctiva of the fornices joins the palpebral (tarsal) and bulbar segments and consists of non-keratinized cuboidal epithelial cells with prominent microvillae. It overlies a substantia propria rich in lympthoid tissue and accessory lacrimal glands (glands of Krause) (Song et al. 2006).

The apex of the superior fornix is located approximately 10–13 mm above the superior lid margin when the eyes are open and 25 mm above the margin when they are closed (Bedrossian 2006). It is suspended by ligaments originating from the levator/superior rectus complex. The lacrimal gland ductules drain into the superolateral fornix. The deepest extent of the inferior fornix is 9–10 mm below the inferior lid margin. It is maintained by ligaments originating from the inferior rectus sheath. The lateral fornix extends to the globe equator. The plica semilunaris and caruncle take the place of the fornices medially.

Function

The redundant tissue of the conjunctival fornices permits unimpeded movement of the globe in all directions. The highest concentration of mucin-producing goblet cells is contained within the fornices. The glands of Krause (along with the glands of Wolfring along the antimarginal border of the tarsal plates) are responible for the basal secretion of aquous tears. The fornices therefore play a critical role in ocular surface health.

Clinical Relevance

Forshorneting of the fornices and symblepharon may occur with autoimmune disorders such as Stevens-Johnson syndrome (SJS) and ocular-cicatricial pemphigoid (OCP), chemical burns, surgical trauma, trachoma, and other forms of cicatrizing conjunctitivits. In severe cases, prompt intervention is required to prevent diplopia, lid malposition, xerosis, and corneal blindness.

Deep fornices are required after enucleation and evisceration in order to support an adequately sized prosthesis. Fornix contraction is often treated with mucus or amiotic membrane grafts (Solomon et al. 2003; Demirci et al. 2010).

Giant fornix syndrome is typically seen in older individuals with chronic ocular surface inflammation (Rose 2004). Profound redundancy of the fornices contributes to the trapping of mucoid material and colonization with *Staphylococcus aureus*. This results in chronic or recurrent ocular discharge and conjunctivitis that is refractory to conventional treatements. Difinitive treatment is with resection of the excess conjunctiva.

Synonyms

Fourth cranial nerve palsy; Trochlear nerve palsy

Definition

The fourth cranial nerve, or trochlear nerve, innervates the superior oblique ocular muscle. Its nucleus lies in the midbrain caudal to the oculomotor nucleus, dorsal to the medial longitudinal fasciculus, and at the level of the inferior colliculus (Lee and Brazis 2003). The fourth nerve travels inferior and posteriorly, exits dorsally, and decussates at the anterior medullary velum, passing between the posterior cerebral artery and the superior cerebellar artery in the subarachnoid, before entering the orbit through the superior orbital fissure and innervating the superior oblique muscle. Any lesion along this pathway can result in a fourth nerve palsy (FNP). An FNP manifests as an ipsilateral hypertropia in primary position, worse in contralateral gaze, and ipsilateral head tilt. There is also often objective and subjective ipsilateral excyclotorsion. As with all ocular motor cranial neuropathies, there are a wide range of known etiologies (i.e., neoplasms, infections, metabolic disorders, and ischemia), but the most common causes of isolated fourth nerve palsies are traumatic, congenital, and microvascular etiologies (Lee and Brazis 2003; Brazis 2009). The distinction between isolated and non-isolated FNP (i.e., other neurological signs and symptoms are present) is important since cases of isolated FNP often do not need further neurological workup or neuroimaging.

Etiology

In most series of FNP, the most common cause is head trauma accounting for up to 40% of all cases (Keane 1993; Mollan et al. 2009; Von Noorden et al. 1986). The fourth cranial nerve is the longest and thinnest of all the cranial nerves and is thus most susceptible to shearing injury at the free margin of the tentorium cerebella and can be damaged even in cases of relatively mild head trauma. In cases of traumatic FNP, the diplopia will typically have a clear temporal relationship to the previous head trauma, does not progress, and is often neurologically isolated. Trauma is also a common cause of bilateral FNP, and in these cases, there might not be as large of a primary position hypertropia (HT) as in a unilateral FNP. Instead there might be a reversing HT in right and left gaze or alternating HT in alternating head tilts and a larger than expected ($>10^{\circ}$) amount of excyclotorsion (Brazis 2009).

Congenital FNP is another common etiology (Lee and Brazis 2003; Brazis 2009) and may be subtle in childhood and worsen in adulthood due to decompensation (thought to be a breakdown of vertical fusion rather than progressive superior oblique dysfunction). These types of patients often complain of neck pain from chronic head tilting and may have facial asymmetry or sternocleidomastoid hypertrophy. Old photographs of the patient showing a long-standing head tilt will often help in establishing this diagnosis, and large vertical fusional amplitudes (greater than 6–8 prism diopters) in primary gaze are more suggestive of congenital cases. The excyclotorsion is often asymptomatic in congenital FNP cases but symptomatic in acquired cases.

Microvascular ischemia can cause isolated FNP including diabetes mellitus and hypertension (Lee and Brazis 2003). Most vasculopathic FNPs resolve in 3–6 months, and progression or lack of resolution should prompt consideration for neuroimaging and other evaluations. Other less common causes of isolated FNP include midbrain lacunar infarction, increased intracranial pressure (e.g., pseudotumor cerebri, subarachnoid hemorrhage), and posterior fossa tumors – however, these etiologies are typically associated with other neurological and clinical findings.

Clinical Presentation

The principle presenting symptom in patients with unilateral FNP is binocular vertical diplopia that is often accompanied by a compensatory contralateral head tilt (Lee and Brazis 2003; Brazis 2009). The head tilt minimizes the vertical diplopia by moving the eye away from the paretic superior oblique muscle's field of action. Rarely, however, some patients with an FNP may adopt an ipsilateral head tilt to increase rather than decrease the

vertical deviation, which produces a greater distance between the two images and an increased ability for some patients to ignore the second image. The superior oblique muscle (SOM), which is innervated by the fourth cranial nerve, has three functions that are dependent on the position of gaze: (1) primary function in primary position, incyclotorsion (or intorsion) of the eye; (2) secondary function, depression (or infraduction) of the globe when the eye is in the adducted position; and (3) tertiary function, abduction of the eye (Lee and Brazis 2003; Brazis 2009). The direct antagonist of the superior oblique muscle is the ipsilateral inferior oblique muscle. With a fourth nerve palsy, there may be **underaction** of the ipsilateral superior oblique muscle and thus apparent **overaction** of the ipsilateral inferior oblique muscle, which acts (among other functions) to elevate the eye. Therefore, a hypertropia will be observed in the affected eye which is greater in contralateral gaze (due to overaction of the ipsilateral inferior oblique in adduction) and head tilt toward the affected eye.

Excyclotorsion of the affected eye, due to weakness of the incyclotorsion action of the superior oblique, is another potential symptom of FNP. It can be observed objectively on fundus exam or can be measured subjectively using a double Maddox rod. Anatomically, the fovea is usually about one-third of a disk diameter below the center of the optic disk. If the fovea is lower than expected, excyclotorsion is present. In the double Maddox rod test, a Maddox rod is placed in front of each eye in a trial frame with the grooves oriented vertically (producing parallel horizontal lines when the patient looks at a light source). If the lines are not parallel, cyclotorsion is present and the patient is asked to adjust the rods until the lines are oriented parallel on the horizontal axis. If excyclotorsion is present, the patient will turn the OD Maddox rod counterclockwise or the OS Maddox rod clockwise.

Bilateral FNP, accounting for 10–30% of all cases, is usually the result of trauma but can also be caused by increased intracranial pressure, Chiari I, tumor, or other intracranial pathologies (Keane 1993; Mollan et al. 2009; Von Noorden et al. 1986). In primary gaze, there is often minimal ocular misalignment due to the bilateral nature of involved muscles (a bilateral HT cancels out). Due to decreased superior oblique muscle abduction, an esotropia may be present in either eye that is worse on downgaze, classified as a V-pattern esotropia if there is a 15 prism diopter or greater difference between upgaze and downgaze (Brazis 2009). This often complicates the diagnosis and is often deceptively suggestive of sixth nerve palsy. The hypertropia may also alternate such that it is contralateral to the direction of gaze and ipsilateral to the direction of head tilt. There is often a large angle of excyclotorsion ($>10^{\circ}$) that is accompanied by prominent torsional diplopia. In any patient with excyclotorsion greater than 10°, bilateral superior oblique palsy should be suspected.

Diagnostics

The initial evaluation of any patient presenting with a unilateral vertical misalignment involves using the Parks-Bielschowsky three-step test to determine the paretic muscle (Lee and Brazis 2003). Only eight muscles are involved in vertical ocular alignment: the right superior rectus (RSR), the right inferior rectus (RIR), the right superior oblique (RSO), the right inferior oblique (RIO), the left superior rectus (LSR), the left inferior rectus (LIR), the left superior oblique (LSO), and the left inferior oblique (LIO). Each of the three steps of the Parks-Bielschowsky test is designed to eliminate one or more of the muscles listed above such that after all three steps are performed, only one muscle is isolated as the affected or paretic muscle.

The first step of the test involves determining the side and size of the hypertropia in primary position. For example, if there is a right hypertropia (RHT), the paretic muscle can be either of the right eye depressors (RIR, RSO) or either of the left eye elevators (LSR, LIO). Conversely, in the case of left hypertropia, the paretic muscles can be the LIR or LSO or RSR or RIO.

The second step involves determining whether the hypertropia is worse on right or left gaze. The recti muscles have a greater vertical action when

the eye is in an abducted position, while the oblique muscles have a greater vertical action when the eye is in an adducted position. Thus, for the affected or hypertrophic eye, the paretic muscle should be a vertical rectus muscle if the hypertropia worsens in abduction or an oblique muscle if the hypertropia worsens in adduction. For example, for a right hypertropia, if the RHT worsens on right gaze, the paretic muscle is the RIR or LIO. If the right hypertropia worsens on left gaze, the paretic muscle is either the RSO or LSR.

The third step is to determine whether the hypertropia is worse on right or left head tilt. The superior muscles (SR, SO) intort the eye, while the inferior muscles (IR, IO) extort the eye. In a head tilt, the eye ipsilateral to the direction of the tilt (i.e., right eye in right head tilt or left eye in left head tilt) will intort (through action of the SR and SO), and the contralateral eye will extort (through action of the IO and IR). Thus, the hypertropia, or vertical deviation, will be increased in a head tilt ipsilateral to the affected eye if one of the intorting muscles is paretic (SR or SO). Likewise, the hypertropia will be increased in a head tilt contralateral to the affected eye if one of the extorting muscles is paretic (IR or IO).

Thus, after the conclusion of the three steps, only one muscle should remain as the affected, or paretic, muscle through the process of elimination. An additional "fourth step" can be added to test for the presence of any torsion using the double Maddox rod.

If the superior oblique muscle is determined to be the paretic muscle, the next step involves determining whether the cranial nerve deficit is isolated or non-isolated (Lee and Brazis 2003; Brazis 2009). If the FNP is non-isolated, neuroimaging, preferably magnetic resonance imaging (MRI) of the brain and orbits with and without contrast and fat suppression, is required and should be directed at the anatomical location of neurological pathology. Important etiologies of non-isolated FNP can include intracranial malignancy, intracranial hemorrhage, infarction, demyelinating disease, cavernous sinus thrombosis, orbital apex syndrome, and toxic/nutritional polyneuropathy. In patients with an isolated, acute FNP, it is important to first consider the more common congenital, traumatic, and microvascular etiologies. In cases of isolated presumed vasculopathic FNP, if symptoms and signs do not improve or worsen after months of observation, the initial diagnosis should be questioned and the patient must undergo neuroimaging, preferably MRI as stated above. Computed tomography (CT) scanning should be utilized in cases of suspected bone trauma or hemorrhage. It is also important to re-evaluate for syndromes that can initially mimic a fourth nerve palsy such as myasthenia gravis, giant cell arteritis (in an older patient), skew deviation, and thyroid eye disease.

F

Differential Diagnosis

Several conditions can initially mimic a fourth nerve palsy but often progress to produce other neurological and/or orbital findings (Lee and Brazis 2003; Brazis 2009). Restrictive strabismus can be produced by a variety of orbital processes (e.g., Graves ophthalmopathy, orbital tumors, orbital fracture, orbital pseudotumor) that are often accompanied by orbital signs such as proptosis, chemosis, and conjunctival injection. Myasthenia gravis can mimic any painless ophthalmoplegia and is often accompanied by ptosis and fatigability. Temporal arteritis can also manifest as ophthalmoplegia and is commonly associated with scalp tenderness, temporal nodularity, and/or jaw claudication. Skew deviation, resulting from pathology of the vestibule-ocular pathways, manifests as any type of vertical misalignment and can present with hypotropia, excyclotorsion, and a head tilt. The vertical misalignments are often position dependent in skew deviation and position independent in fourth nerve palsy. A change in vertical misalignment during an upright to supine test is highly sensitive and specific for skew deviation. Skew deviation is also commonly associated with more symptoms and signs of brainstem pathology.

Prophylaxis

Non-applicable

Therapy

Treatment should be directed toward the underlying etiology of the trochlear nerve palsy. In general, isolated FNPs that are traumatic, congenital, or microvascular most often resolve and should be observed several months before further intervention is considered (Lee and Brazis 2003; Brazis 2009). Surgery, usually consisting of inferior oblique weakening (myomectomy with disinsertion, recession, etc.) or less commonly a superior oblique strengthening procedure, is considered only after conservative measures fail, an etiologic diagnosis has been established, and there has been stability of the ocular misalignment for a period of at least 6 months. A trial of base-down prism over the hypertrophic eye is usually attempted prior to surgery; however, this method does not correct torsional diplopia, and many patients find prism correction unsatisfactory if they have a large torsional component. Patching one eye can be beneficial in patients who defer surgery but should be used with caution in children that fall in the amblyopic age range.

Fovea, Foveal Avascular Zone (FAZ)

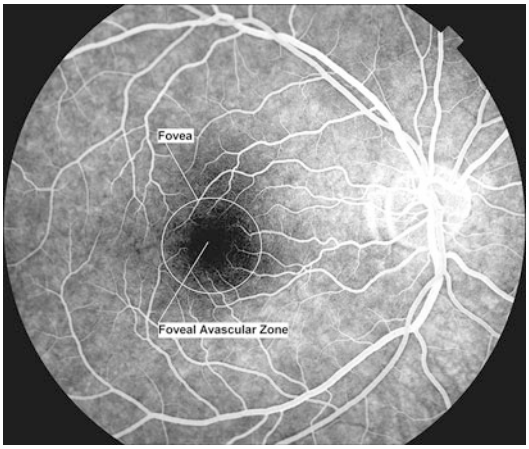
William J. Wirostko
Eye Institute- Medical College of WI, Milwaukee, WI, USA

Definition

Anatomical area of retina with highest visual acuity that is responsible for central vision.

Basic Characteristics

The clinical fovea appears as a circular area of the retina (approximately 1.5 mm in diameter) lying approximately 17° (4500–5000 μm) directly temporal to the optic nerve (Gass 1997; Massey 2006). It is responsible for central and color vision. It contains all cone cell types with the various color opsin pigments. It also contains a central 400 μm area devoid of retinal capillaries, which is called the foveal avascular zone. This foveal avascular zone is likely vascularized in utero but becomes nonvascularized shortly before birth. The exact center of the fovea is the foveal pit, also called the umbo (Miller 2006; Thumann et al. 2006; Schubert 2009). In this region, the retina is very thin, and no neurons are present. Cone cells in this region are of minimal size with a hexagonal shape and a very high density of approximately 200,000 cells per mm^2. No blue cones are present in the umbo, probably because they are large, susceptible to chromatic aberration from the lens, and consequently have low visual acuity potential. Rods are likewise absent, probably because they also have low visual acuity potential. Retinal pigment



Fovea, Foveal Avascular Zone (FAZ), Fig. 1 Fluorescein angiography demonstrating fovea and foveal avascular zone

epithelial cells in the fovea are taller, more narrow, and contain more pigment than retinal pigment epithelial cells in other areas of the fundus (Miller 2006). Surrounding the umbo, various structures radiate away through the retina in an oblique fashion, including cone axons and Henle fibers. All of these findings in the fovea likely represent evolutionary adjustments to maximize visual acuity by minimizing the amount of light and image scatter that occurs as photons traverse the retinal layers before reaching the photoreceptors (Fig. 1).

Foveola

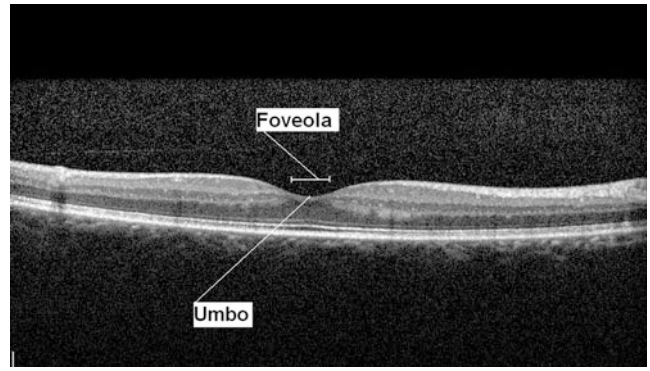
William J. Wirostko
Eye Institute- Medical College of WI, Milwaukee, WI, USA

Definition

The anatomic central floor of the fovea.

Basic Characteristics

The foveola is the anatomic central floor of the fovea (Gass 1997; Gunton et al. 2005; Schubert 2009). It measures approximately 350 μm in diameter, lies within the foveal avascular zone, and contains the foveal pit (umbo). Since the foveola is located in the center of the fovea, the retina here is thin (only approximately 150 μm thick) and displays no overlying retinal ganglion cells. The geometrical center of the foveola is called the foveal pit or umbo. This is where maximal visual acuity is achieved with photoreceptors in this region, predominantly cone cells, being packed together very tightly with a density as high as 385,000 cells per mm^2. Their inner segments are linked together as the external limiting membrane of the retina, and their inner fibers and axons travel radially and peripherally as fibers of Henle in the outer plexiform layer. Peripheral to the foveola, retinal



Foveola, Fig. 1 Optical coherence tomography of fovea demonstrating foveola and umbo

thickness slopes upward as nuclei of the second- and third-order neurons along with those of Mueller cells appear. Retinal pigment epithelium cells directly under the foveola are taller, narrower, and contain more melanin granules per unit than elsewhere in the fundus (Yanoff and Fine 2002).

Development of the foveola begins very early in gestation with retinal cell division ceasing by 14 weeks gestational age. At 32 weeks gestational age, a depression in the retina appears as ganglion cells and inner retinal layers migrate peripherally. A single layer of ganglion cells and inner retinal layers is often still present at birth. This may explain the generally poor vision of neonates. Foveola formation usually completes by 11 months through 15 months postterm, at which time the ganglion and inner retinal cells have completely migrated out of the fovea. Maturation of the foveola continues over the subsequent 30 months as cone cells increase their densities by becoming longer and thinner, as well as pushing rod cells peripherally (Gunton et al. 2005).

A reduced foveola depression can be due to various developmental abnormalities, retinal diseases, or retinal dysplasias. Conditions associated with foveolar developmental aplasia or hypoplasia include albinism, aniridia, achromatopsia, X-linked hemeralopia, and microphthalmos. Foveola hypoplasia can also occur as an isolated condition (Querques et al. 2009). The foveolar depression can become blunted in the presence of retinal edema from various retinal vascular disorders, including diabetes, retinal vein occlusion, hypertensive retinopathy, and uveitis, among others. Foveola depression can also be distorted or blunted in cases of vitreomacular traction. Finally, foveomacular dysplasias can develop secondary to retinal colobomas and congenital toxoplasmosis (Yanoff and Fine 2002).

Retinal-vitreous attachments in the center of the fovea are very strong due to a thin internal limiting membrane. This logically explains the tendency for macular hole formation during periods of forceful anterior-posterior vitreous traction (Gass 1997; Yanoff and Fine 2002) (Fig. 1).

Definition

Foville syndrome was initially described by Achille-Louis-Francois Foville, a French physician, in 1859 (Brogna et al. 2012). The crossed syndromes have been variously described and sometimes have conflicting or overlapping features in the literature. For this chapter, we use the definitions of Millard-Gubler (nuclear facial palsy and contralateral hemiparesis), Foville (facial palsy, conjugate horizontal gaze paralysis, and contralateral hemiparesis), Weber (oculomotor palsy and contralateral hemiparesis), and Raymond-Cestan (internuclear ophthalmoplegia and contralateral hemiparesis) that were abstracted from the original reports by Silverman et al. (1995). These syndromes demonstrate important principles in brainstem localization including cranial neuropathies contralateral to hemibody motor or sensory disturbances, medial longitudinal fasciculus and internuclear ophthalmoplegia, horizontal nuclear conjugate gaze palsies, and the corticobulbar innervation of the facial nerve nucleus.

Causes

It is caused by a unilateral lesion located in the dorsal pontine tegmentum in the caudal third of the pons (e.g., occlusion of a pontine branch of the basilar artery, tumors in the dorsal pons, hemorrhage, or demyelination) (Liu et al. 2010).

Presentation (Liu et al. 2010; Kline and Foroozan 2013; Neuro-Ophthalmology, BCSC/American Academy of Ophthalmology)

1. Ipsilateral horizontal gaze palsy (from nucleus of VI or parapontine reticular formation (PPRF))
2. Ipsilateral CN VII facial palsy
3. Contralateral hemiparesis (corticospinal tract)

Marcus Neuffer
Department of Ophthalmology, Keesler Medical Center, Biloxi, MS, USA

Synonyms

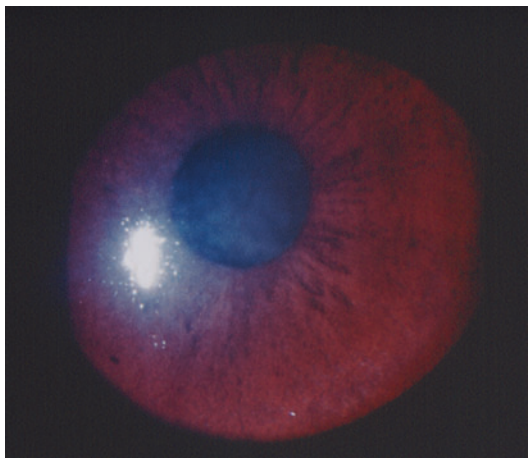
Central cloudy dystrophy of François

Definition

François disease is a nonprogressive bilateral corneal dystrophy characterized by central round opacities separated by clear linear areas (Figs.1, 2, and 3).

Etiology

Inheritance is autosomal dominant.



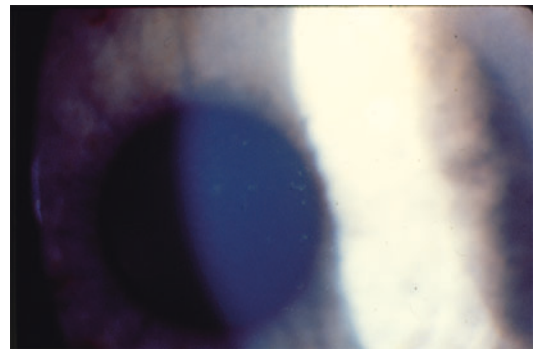
François, Central Cloudy Dystrophy, Fig. 1 Central polygonal opacities that fade peripherally

Clinical Presentation

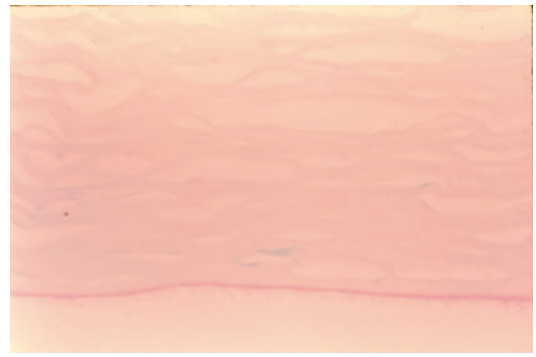
Patients are asymptomatic. Examination of the cornea reveals central polygonal opacities separated by clear lines and less prominent anteriorly and peripherally. The stroma is of normal thickness, erosion does not occur, and there is no loss of sensation. Appearance of the cornea is similar to crocodile shagreen (Krachmer et al. 2011).

Diagnostics

Light microscopy demonstrates staining of glycosaminoglycans and a rippling appearance of the deep stroma. Confocal microscopy can reveal highly refractile deposits in the anterior stroma with multiple dark striae in the posterior stroma (Weiss et al. 2008).



François, Central Cloudy Dystrophy, Fig. 2 Higher magnification of opacities



François, Central Cloudy Dystrophy, Fig. 3 Light microscopy demonstrating glycosaminoglycan deposition

Differential Diagnosis

Differential diagnosis includes corneal edema, posterior crocodile shagreen, fleck corneal dystrophy, posterior amorphous corneal dystrophy, pre-Descemet corneal dystrophy, and congenital hereditary stromal dystrophy.

Prophylaxis

There is no known prophylaxis.

Therapy

Patients are generally asymptomatic and treatment is not necessary required (Krachmer et al. 2011).

Prognosis

Prognosis is good and patients do not experience any pain or vision loss.

Epidemiology

The inheritance is autosomal dominant. The condition is rare and the exact prevalence is unknown.

Free Caps, LASIK Complication

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Free flaps

Definition

A free cap is a complication of LASIK in which instead of a flap with hinge, there is a complete resection of the flap. Usually this occurs due to unintended complete section or loss of suction.

Immunohistochemistry

As free caps are caused by mechanical factors (microkeratomes), no immunohistochemical process is involved.

Differential Diagnosis

Every other LASIK complication includes incomplete cuts, buttonholing, flap perforation, epithelial defects, wound dehiscence, irregular ablation, flap wrinkling, or slicing.

Free Radicals

Tanja M. Rabsilber and Mike P. Holzer
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Definition

Free radicals are atoms, molecules, or ions with unpaired electrons that may have positive, negative, or zero charge. They influence many biological processes – some of them are essential for life, while others may lead to cell damage and death. The free radical theory of aging assumes that accumulation of free radical cell damage over time leads to mutation, cancer, and aging (Muller et al. 2007).

Structure

Pigmented molecules absorb visible and ultraviolet light which changes their energy level and leads to an electron loss. A free radical forms when a neighboring molecule gains this extra electron. In case of oxygen, the new molecule is called superoxide (Miller and Scott 2004).

Function

Free radicals may disrupt cell and mitochondrial membranes and nucleic acid and destroy tissue (Miller and Scott 2004). Fortunately, antioxidants such as superoxide dismutases, catalases and peroxiredoxins, glutathione, and vitamin C and E function as scavengers and protect molecules, cells, and tissues from oxidative damage (Miller and Scott 2004; Gutteridge and Halliwell 2010).

Clinical Relevance

Different tissues can develop light damages, depending on the light wavelength (mainly ultraviolet), intensity, and exposure time (Miller and Scott 2004):

1. Lid: epidermal keratoses; malignant skin changes
2. Cornea: superficial punctate keratitis (snow blindness); spheroidal degeneration
3. Lens: cataract
4. Retina: maculopathy

Frequency of Light Wave

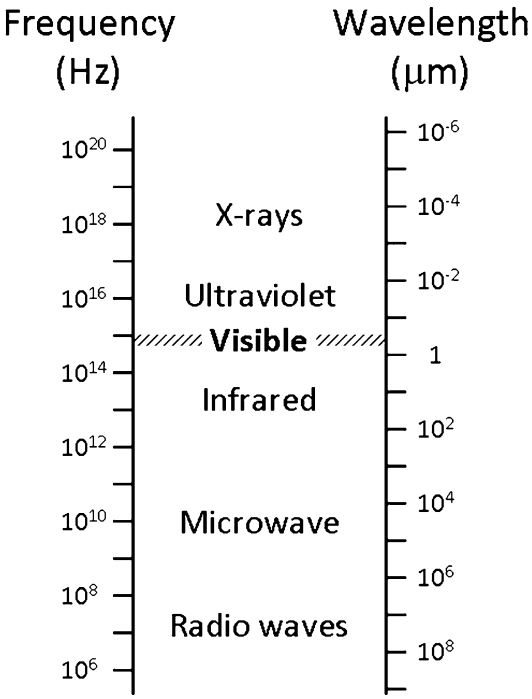
Len Zheleznyak
Center for Visual Science, The Institute of Optics, University of Rochester, Rochester, NY, USA

Synonyms

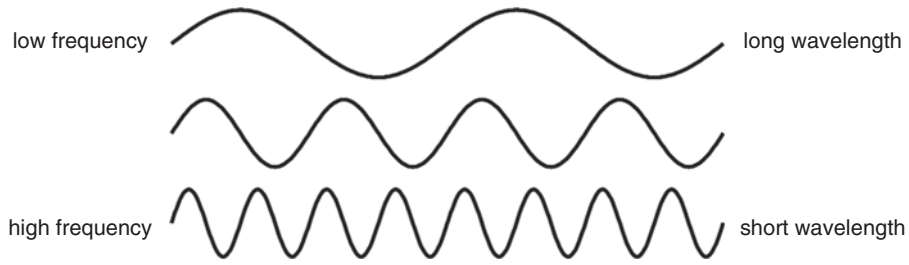
Electromagnetic spectrum; Inversely proportional to wavelength

Definition

Frequency is generally defined as the number of cycles per unit time. Figure 1 illustrates sinusoidal waves of various frequencies in cycles per second. The unit for temporal frequency is Hertz (Hz) or cycles per second. In optical physics, frequency refers to the rate of oscillation of the electromagnetic field per unit second. The electromagnetic spectrum is shown in Fig. 2. Frequency is mathematically defined as follows:



Frequency of Light Wave, Fig. 2 The electromagnetic spectrum



Frequency of Light Wave, Fig. 1 Illustration of sinusoidal waves with frequencies scaling by factors of 1, 2, and 4 (from *top* to *bottom*)

$$v = \frac{c}{\lambda}$$

where ν is the frequency, λ is the wavelength, and c is the speed of light in a vacuum (approximately 3×10^8 meters per second).

Fresnel

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Definition

Augustin Jean Fresnel (pronounce *freɪˈnɛl*) was born on 10 May 1788 in Broglie (†14 July 1827 in Ville-d'Avray near Paris) and was a French Physicist and Engineer, who gave a major impact on wave theory of light and optics. A series of terms are named after Fresnel, e.g., Fresnel lens, Fresnel prism, and Fresnel diffraction theory (or Fresnel formulas). The Fresnel lens reduces the amount of material required compared to a conventional lens by dividing the lens into a set of concentric annular sections with stepwise discontinuities in between.

Cross-References

▶ Fresnel Prisms

Fresnel Prisms

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Definition

Fresnel (pronounce *freɪˈnɛl*) prisms are constructed as a series of very narrow adjacent prisms on a thin sheet typically made of plastic. The advantages to using Fresnel prisms are that they are lightweight and very convenient to use. They are available in powers of 1–40 prism diopters and due to flexibility it can be placed over conventional lenses. One disadvantage of Fresnel prisms is that higher-power prisms (more than 10–12 prism diopters) introduce glare and chromatic aberration.

Fuchs Heterochromic Iridocyclitis, Glaucoma

Sarwat Salim
Medical College of Wisconsin, Milwaukee, WI, USA

Synonyms

Uveitic glaucoma; Uveitis, iridocyclitis

Definition

Fuchs heterochromic iridocyclitis (FHI) is a unilateral condition characterized by mild anterior uveitis, iris heterochromia, cataract, and glaucoma. FHI remains a clinical diagnosis without any well-established diagnostic test.

Etiology and Mechanism

The exact etiology of FHI remains unknown, but several associations have been proposed (Allingham et al. 2005). Decreased innervation to iris stroma with resultant hypopigmentation and the presence of Horner's syndrome in some patients with FHI suggest the possibility of sympathetic dysfunction as an underlying etiology. A possible link with toxoplasmosis has also been proposed from studies reporting the presence of chorioretinal scars in a significantly higher proportion of eyes with FHI; however, no evidence by cellular immunity, enzyme-linked immunosorbent assays, or immunofluorescence antibody tests has been found. In one study measuring IgG antibodies against rubella, herpes simplex virus, varicella zoster virus, or *Toxoplasma gondii* in 46 patients, 13/14 patients with FHI had intraocular antibody production against rubella only, and none of the controls had positive rubella titers. Consequently, the authors proposed an association between rubella and FHI (de Groot-Mijnes et al. 2006).

The mechanism of secondary glaucoma in FHI is thought to be similar to that of chronic open-angle glaucoma, given an open and normal-appearing angle on gonioscopy. In other cases, active trabeculitis with various types of inflammatory cells may cause obstruction of aqueous outflow facility. Fine rubeotic vessels have been described in the angle and histology reports have indicated sclerosis of the trabecular meshwork and presence of an inflammatory membrane over the angle. Other mechanisms include lens-induced glaucoma, steroid-induced glaucoma, and secondary angle-closure glaucoma from peripheral anterior synechiae (Salim and Shields 2008).

Epidemiology

The prevalence of FHI is reported to be 2–11% of all uveitides. It usually presents in the third or fourth decade of life. There is no race or sex predilection. Glaucoma is the most sight-threatening complication of FHI with a prevalence of 9–59%.

Clinical Presentation

FHI, reportedly the most underdiagnosed form of iridocyclitis, typically lacks the usual symptoms of inflammation, including pain, photophobia, and redness. Patients may remain asymptomatic for many years and often present with reduced vision secondary to cataract formation. Glaucoma often presents as a late complication of FHI.

Clinical Examination

Iris heterochromia (Fig. 1) is present in a majority of patients, with the lighter-colored iris usually, but not invariably, being the affected eye. Iris heterochromia is more difficult to detect in dark-complected individuals. Iris nodules, both Koeppe and Busacca, may be present and may cause diagnostic confusion with other uveitides.

Fuchs Heterochromic Iridocyclitis, Glaucoma, Fig. 1 Iris heterochromia (lighter iris) and pseudophakia in an eye affected with FHI

Keratic precipitates (KP) tend to involve the entire endothelial surface of the cornea and appear fine and stellate. Iridocyclitis is mild with minimal flare and cells and runs a protracted course. Posterior synechiae are often absent, which helps differentiate FHI from other uveitides. Posterior subcapsular cataract formation is common in the affected eye. Glaucomatous optic nerve cupping and associated visual field loss may be seen with uncontrolled intraocular pressure (IOP). The drainage angle is open on gonioscopy in most cases. Posterior segment findings, including chorioretinal lesions and vitritis, may be present.

Differential Diagnosis

The main differential diagnosis is Posner-Schlossman syndrome or glaucomatocyclitic crisis, characterized by unilateral IOP spikes with mild anterior chamber inflammation. These eyes may also have a certain degree of heterochromia but often have higher IOP elevations. Unlike FHI, the inflammation in this condition responds to corticosteroid therapy with resolution of elevated IOP spikes. Herpes simplex uveitis (and other uveitides) should be considered as it may present with iris heterochromia and inflammation with diffuse KP. Other causes of iris heterochromia include Waardenburg's syndrome, congenital Horner's syndrome, and ocular melanosis and should also be ruled out.

Management and Prognosis

Iridocyclitis does not respond to corticosteroid therapy with most patients generally having a good prognosis despite persistent low grade inflammation. A short course of steroids may be used to differentiate FHI from Posner-Schlossman syndrome, but long-term use is not recommended. The outcomes of cataract extraction are reported to be equivalent or better in FHI when compared with other forms of chronic uveitides. Glaucoma management is challenging with 73% of cases failing with maximal medical therapy (La Hey et al. 1993). Laser trabeculoplasty is ineffective in these eyes, given the underlying inflammation and alterations in the angle anatomy from peripheral anterior synechiae, neovascularization of the angle, or presence of an inflammatory membrane covering the angle recess (Salim and Shields 2008). Glaucoma filtration surgery, even with antimetabolites, has limited success over time because of excessive scarring. Glaucoma drainage implants have higher success rates and are the preferred initial surgical intervention (Sung and Barton 2004). The course of glaucoma is not altered by cataract extraction.

Fuchs Superficial Marginal Keratitis

Michael Coleman
Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Bilateral inflammatorydisorder that results in progressive peripheral corneal thinning and pseudopterygium formation (Bierly et al. 1992; Brilakis et al. 2004).

Clinical Presentation

Patients usually present in the second to fourth decade of life. They classically complain of intermittent and recurrent episodes of ocular irritation and photophobia (Bierly et al. 1992). On exam, corneal inflammation with associated stromal thinning and marginal infiltrates are found. This stromalysis may quiet with time or progress to perforation (Goldberg et al. 1996). Pseudopterygium formation usually results once the inflammation has resolved (Kotecha and Raber 2001; Keenan et al. 2011). These patients usually have decreased visual acuity related to irregular astigmatism, which will require hard contact lens for correction.

Diagnosis

Clinical evidence of corneal thinning, inflammation, and neovascularization is typical. Given the rarity of this disease, it must be viewed as a diagnosis of exclusion. Patients should be worked up for systemic vasculitis, collagen vascular disease, severe dry eye, and infectious keratitis. Once infectious keratitis and autoimmune diseases have been ruled out, then this can be considered as a diagnosis.

Differential Diagnosis

1. Mooren's ulcer
2. Peripheral ulcerative keratitis
3. Terrien's marginal degeneration

Therapy

Visual rehabilitation can be done with glasses or hard contact lens (scleral lens may be required). Observation is the mainstay of treatment unless the globe integrity is becoming compromised. Immunosuppression with systemic or topical therapy can be considered in cases with significant ocular inflammation and patient discomfort (Kotecha and Raber 2001; Keenan et al. 2011). Treatment with vitamin C and doxycycline has been proposed as a way to slow down stromalysis and corneal thinning (Keenan et al. 2011).

If perforation is impending, tectonic patch grafting can be performed with cornea or corneoscleral patches (Bierly et al. 1992; Kotecha and Raber 2001; Brilakis et al. 2004; Keenan et al. 2011). Recurrences can occur after grafting.

Prognosis

Patients lead a quality of life comparable to the general population and most retain good vision as the central cornea is spared. Only in the severe cases do patients typically lose lines of best corrected visual acuity.

Epidemiology

Rare

Fuchs' Corneal Dystrophy

► Fuchs' Dystrophy Disease

Fuchs' Dystrophy Disease

Aazim A. Siddiqui[1] and Allen O. Eghrari[2]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MA, USA

Synonyms

Endoepithelial corneal dystrophy; Fuchs' corneal dystrophy; Fuchs' endothelial corneal dystrophy; Late hereditary endothelial dystrophy

Definition

Fuchs' dystrophy is a progressive, late-onset degeneration of the cornea characterized by focal excrescences of Descemet's membrane known as *guttae*, resulting in loss of endothelial barrier function, stromal edema, and, in late stages, painful epithelial bullae (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Etiology

Corneal decompensation in Fuchs' dystrophy originates in disease of the corneal endothelium and subsequent misregulation of fluid balance within the cornea. Causative genetic mutations coding for an ion cotransporter (SLC4A11), a transcription control factor (TCF8), a lipoxygenase (LOXHD1), and an intronic variant in TCF4 have been identified, but the precise pathogenic process has yet to be identified. Hereditary transmission is multifactorial and often autosomal dominant, with severe disease phenotype associated with acquisition of a disease allele from both parents (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Clinical Presentation

Patients initially present with bilateral, painless blurry vision upon waking that improves during

the day. It is most commonly identified in females of middle age. Slit-lamp biomicroscopy reveals central guttae in early stages which coalesce and develop in the periphery over time. The development of corneal edema correlates with progression in a number of guttae (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Diagnosis

Diagnosis of Fuchs' dystrophy is primarily made by the identification of guttae with slit-lamp biomicroscopy. The presence of guttae and endothelial cell density attenuation can be confirmed with specular microscopy. Corneal pachymetry is a useful modality to follow progression and severity as edema increases over time (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Differential Diagnosis

Posterior polymorphous corneal dystrophy and iridocorneal endothelial syndrome present with punched out lesions or beaten-metal appearance of the corneal endothelium which may be confused for guttae. The eyes with posttraumatic deposition of pigment on the corneal endothelium, anterior uveitis, and herpetic keratouveitis may also present with a similar appearance.

Corneal edema and epithelial bullae are characteristic features of aphakic or pseudophakic bullous keratopathy. Interstitial keratitis presents with corneal edema but with increased vascularity; Fuchs' dystrophy is by nature not an inflammatory disease (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Prophylaxis

There are no clinically proven methods of prophylaxis for Fuchs' dystrophy. Smoking increases the risk of development of corneal guttae and should be avoided (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Therapy

Medical management of Fuchs' dystrophy addresses symptoms of corneal edema and painful bullae and consists of topical hypertonic saline, hairdryer use to dehydrate the precorneal tear film, and therapeutic soft contact lenses.

Definitive treatment of disease is surgical. Penetrating keratoplasty, historically the mainstay of treatment, has given way in the past decade to endothelial keratoplasty. Descemet's stripping endothelial keratoplasty and Descemet's membrane endothelial keratoplasty allow a more stable intraoperative anterior chamber and faster postoperative healing (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Prognosis

Endothelial cell loss, formation of guttae, and development of corneal edema are gradual processes that progress over years, with family studies showing an average of 20 years from identification of mild disease to diffuse corneal decompensation (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Epidemiology

Regions of highest prevalence with Fuchs' dystrophy include North America and Europe, at approximately 4% of individuals over 40 years of age. Significantly lesser frequency of disease is seen in Asia and South America. While mild disease is seen with the above frequency, only 0.1% experience epithelial edema and bullae formation (Waring et al. 1978; Reinhard and Larkin 2008; Lisch and Seitz 2011).

Full-Thickness Eyelid Biopsy

Jeremiah Tao[1], Betina Wachter[2] and Julio Echegoyen[3]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil
[3]Department of Ophthalmology, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Biopsy; Lid biopsy

Definition

Removal of a complete section of the eyelid by incising all layers.

Indication

To fully remove a lesion while achieving proper cosmetic repair and to maintain normal lid margin architecture. Typically full thickness eyelid biopsy is performed when a lesion involves or is in close proximity to the eyelid margin, and removal of the lesion alone would result in an eyelid defect such as a notch or keratinization past the normal mucocutaneous junction.

Contraindication

Tumors that are very superficial or far from the eyelid margin may be poor candidates for full thickness eyelid biopsy. Additionally, for medial eyelid tumors, full thickness procedures risk damage to the canaliculi and lacrimal drainage apparatus.

Techniques and Principles

The tissue surrounding the lesion is anesthetized with local anesthetic with epinephrine. A scalpel or scissors is used to incise the eyelid full thickness on either side of the lesion. The vertical extent usually extends completely through the tarsus to avoid lid contour abnormalities on closure (Fig. 1). Typically, a pentagonal excision pattern is employed around the lesion. This type of excision pattern allows for a proper approximation of the lid edges resulting in satisfactory cosmetic repair. A rim of normal tissue, around

Full-Thickness Eyelid Biopsy, Fig. 1 Intraoperative photo of full thickness excision

1-5 mm (depending on the level of suspicion for malignancy), is usually included in an attempt to fully excise the lesion (Nerad 2001; Albert and Jakobiec 2008).

Outcomes

Excellent aesthetic and functional results are achieved with proper pentagonal wedge procedures. The lesion may be removed completely, theoretically increasing the likelihood of a cure if the lesion is malignant.

Complications

Bleeding and blood loss may occur since the marginal arcades are usually violated. Also meticulous margin approximation is necessary to avoid lid margin contour abnormalities. Usually, only up to one third of the lid extent may be closed primarily. Larger defects may need more advanced closure techniques.

Fundamental Considerations Regarding the Optic Nerve

Christoph Faschinger
Universitäts-Augenklinik, Graz, Styria, Austria

Synonyms

Optic disc; Optic nerve head; Papilla nervi optici

Definition

The optic nerve head (papilla nervi optici) is the visible part of all those retinal ganglion cell fibers conglomerating as a bundle and leaving the eye. The optic nerve fibers penetrate the sclera through multiple perforations of varying sizes, known as the lamina cribrosa (sieve sheets). Behind the globe, the fibers continue as the myelinated optic nerve, surrounded by meninges along its passage through the orbit and up where the optic nerves cross (optic chiasm). The optic nerve head is divided into four parts: the nerve fibers, the prelaminar, laminar, and retrolaminar parts.

The Optic Nerve Head = The Papilla

Various parameters need to be evaluated:

1. Size/area. The size/area of the papilla varies between individuals, and is defined as the tissue within the borders of Elschnig's scleral ring. In Caucasians, the area ranges from 1.6 to 2.8 mm^2. Smaller optic nerves are described as micropapillae, larger ones as macropapillae. The size is important, because it is always compared to the size of the excavation (or cup) of the optic nerve head. Small papillae may have no or only a very small excavation, whereas large papillae often also have larger excavations, without pathological changes being present. A narrow scleral canal in small optic nerve heads can lead to an indistinct

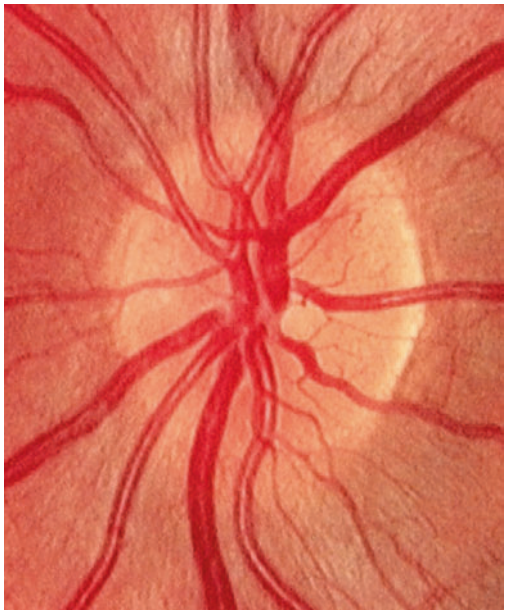
border, and a crowded disc. The size of the papilla is also dependent on ethnicity: Africans and Afro-Caribbeans have larger papillae on average.

2. Shape. A normal optic nerve head is vertically oval. A skew torted disc is a rotation of >15°, and a tilted disc is a disc with an angulation in the anterior-posterior axis. These findings are common in high myopia, often in combination with astigmatism and/or amblyopia.
3. Neuroretinal rim-size/-area. The papilla can have a central excavation, which remains stationary, and is considered physiological. The shape of this excavation is round to slightly horizontally oval. The size of the excavation determines the neuroretinal rim: Total disc area – excavation area. The vertical and horizontal diameter of the excavation is compared with the respective diameters of the optic disc, and a quotient of excavation vs. papillary diameter, or cup/disc ratio, is determined. The neuroretinal rim must be intact around the circumference of the disc, and in healthy subjects often demonstrates the following characteristic: Broadest inferiorly, followed by superior and nasal, and narrowest temporally. The first letters of the mentioned areas form the "ISNT"-rule: if this rule is followed, then glaucoma damage *isn't* present. There is also an ISNT-light: Inferior may not be narrower than superior. Only 5% of the population have a C/D ratio of >0.6. An asymmetry of the cup/disc ratio of >0.2 should raise suspicion of glaucoma. The excavation in glaucoma enlarges from the inner, central side, either concentrically, or more often, supero- or inferotemporally as a notch. Vertical cup-disc ratio and size of the disc are highly heritable. Instead of the cup/disc ratio, the rim/disc ratio (radial width of the neuroretinal rim at its thinnest point compared to the diameter of the disc in the same axis) can be evaluated.
4. Color. The neuroretinal rim has a yellowish-pink appearance. Yellowing of the crystalline lens (cataract) may give a false yellow appearance of a pale disc. Occlusion of the fine blood vessels leads to a pale white appearance (i.e., optic atrophy due to vascular insufficiency, inflammation, or pressure from tumors)
5. Vessels. The central retinal artery and vein emerge from the center, or slightly superonasally of the papilla, and usually splits into four main branches to supply the four quadrants of the inner retina. In glaucoma, the vessels are shifted nasally. The loss of surrounding neuroretinal tissue can lead to the vessels lying free and forming a bridge to the disc margin. If the excavation leads to undermining of the margin, the vessels can take on a bayonet shaped kink.
6. Disc margin hemorrhages. These are microinfarctions and occur very rarely in healthy individuals (<2%). These hemorrhages are usually streak-like within one disc diameter of the disc margin, but can also occur within the disc. They are often found supero- or inferotemporally. These bleeds can be easily missed, and must be looked for actively. Red free light will show them up as dark streaks which are more readily visualized. After approximately 2 months they have disappeared. In glaucoma they are seen more often (4% in primary open-angle glaucoma, 40% in normal tension glaucoma), and are pathognomonic for progression of glaucoma damage. If the neuroretinal rim has been lost, no more disc hemorrhages will occur.
7. Peripapillary tissue. Tissue atrophy usually occurs temporally, but can also be circumferential. The so-called beta zone is an atrophy of receptor cells, retinal pigment epithelium, and small choroidal vessels at the edge of the disc. The alpha zone lies peripheral to this, with hyper- or hypopigmentation. The beta zone can enlarge in glaucoma.
8. Retinal nerve fiber layer. The neurons of all retinal ganglion cells congregate towards the optic disc and follow an arcuate path. A horizontal raphe forms the border between superior and inferior fibers. The longer the fiber, the deeper it lies. In glaucoma, the fibers can undergo generalized or sectoral decrease, which can be demonstrated as wedge shaped defects from the disc margin with red free light.

Lamina Cribrosa

The lamina cribrosa is formed by connective tissue and is regarded as the main site of glaucoma damage, since the retinal nerve fibers make a 90° bend at the disc margin, and then move through the pores of the lamina cribrosa, which are slightly offset. The pores have different sizes: usually larger superiorly and inferiorly, and thus possibly less support for the fibers. The lamina cribrosa is angled at the edge of the disc, and can change elastically, depending on intraocular and intracranial pressure, bending forward or backward, creating stress and strain. With age the elasticity decreases. This can impair the axoplasmic flow in both directions.

The more atrophic the nerve fiber layer, the more pores become visible. The excavation thus does not only become wider, but deeper as well.



Fundamental Considerations Regarding the Optic Nerve, Fig. 1 Normal optic disc with centrally located vessels and no excavation (cup)

Drusen

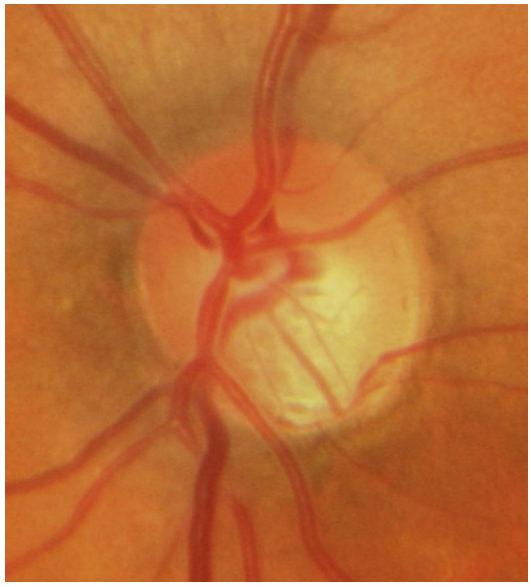
Drusen are waste products of nerve fiber metabolism, which can become increasingly deposited if not adequately removed. They can occur superficially in the area of the nerve fiber layer or in the deeper prepapillary area. They are usually dynamic and can change size and position, and are commoner in smaller discs.

Congenital Malformations

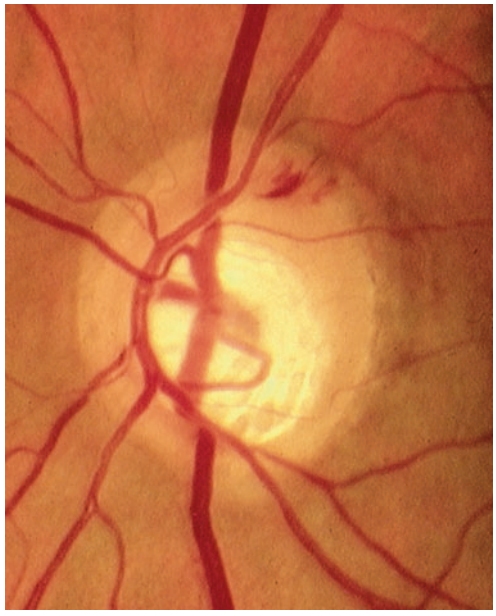
The optic nerve forms as a protrusion of the brain. An incomplete closure of the optic cup leads to an inferior chorioretinal coloboma, and occasionally to an optic nerve coloboma as well. A giant "excavation" with all vessels seeming to arise from the disc margin, and the disc lying in the center, is described as a "morning glory" anomaly, due to the resemblance with a flower. Small deep defects are called optic pits, which can be associated with a canal towards the macular region, and lead to macular edema.

Remnants of embryonic material (glial tissue, Bergmeister papilla) or hyaloid arteries can be present.

Fundamental Considerations Regarding the Optic Nerve, Fig. 2 Normal optic disc fulfilling the ISNT rule: the neuroretinal rim is thickest inferiorly, followed by superiorly, nasally, and finally temporally



Fundamental Considerations Regarding the Optic Nerve, Fig. 3 Glaucomatous disc with loss of the neuroretinal rim (notch) from 5 to 6 o'clock



Fundamental Considerations Regarding the Optic Nerve, Fig. 4 Glaucomatous disc with loss of neuroretinal rim inferotemporally and a hemorrhage at 1 o'clock

A hypoplasia of the optic nerve is exceedingly rare. Too few nerve fibers are present.

Within the eye, nerve fibers are generally not myelinated. Rarely one can find myelinated fibers close to the disc, which are not pathological (Figs. 1, 2, 3, and 4).

Fundus Albipunctatus

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Fundus albipunctatus cum hemeralopia

Definition

Fundus albipunctatus is a rare autosomal-recessive form of congenital stationary night. First described by Lauber in 1910, fundus albipunctatus is remarkable for fundus exam findings showing many discrete white-yellow lesions deep in the retina. These distinct whitish-yellow lesions start in a ring-like formation around the macula and extending into the periphery. The macula itself is usually spared. Patients experience impaired night vision, but visual acuity, visual fields, and color vision are normal. Because nyctalopia is congenital, some patients may not even be symptomatic. Although the retinal lesions can change with time from a fleck-like appearance to a more numerous dot-like appearance, no retinal degenerative changes occur. Central visual acuity remains good into middle age. Approximately half of patients with fundus albipunctatus will develop a progressive cone macular dystrophy later in life, usually over the age of 40.

Fundus albipunctatus has distinctive electrophysiological findings. Dark adaptometry shows significantly delayed cone and rod adaptation but, given enough time, eventually reaches normal threshold. With full-field electroretinogram (ERG), the rod scotopic response after normal dark adaptation of 30–40 min is reduced. If dark adaptation is extended out to three to four times normal, the scotopic full-field ERG response normalizes. Photopic full-field ERG responses are normal or very mildly reduced unless cone macular dystrophy is present. Electroretinogram (ERG) responses with normal dark adaptation are also reduced but will normalize with prolonged dark adaptation.

Etiology

Some cases of fundus albipunctatus are caused by mutations in the RDH5 gene located on chromosome 12q13-14. The RDH5 gene encodes an enzyme, 11-cis retinol dehydrogenase, found in the retinal pigment epithelium (RPE) that is important in the conversion of 11-cis retinol to 11-cis retinal needed for the synthesis of rhodopsin. Impairment of 11-cis retinol dehydrogenase results in prolonged regeneration of visual pigment. Some patients have not been found to have mutations in RDH5 gene, suggesting other genes may also play a role in the development of fundus albipunctatus.

Occurrence

Fundus albipunctatus is a rare autosomal recessive disorder.

Classification

Fundus albipunctatus is classified as a subtype of congenital stationary night blindness (CSNB).

It is important to differentiate fundus albipunctatus from retinitis punctata albescens, a progressive tapetoretinal degeneration that has a very similar appearance in younger patients but is progressive and can result in blindness. Included in the differential diagnosis of fundus albipunctatus are canthaxanthine retinopathy, basal laminar drusen, cystinosis, oxalosis, and other causes of acquired nyctalopia such as vitamin A deficiency.

Fundus Flavimaculatus (Stargardt Disease/Juvenile Macular Degeneration)

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Juvenile macular degeneration; Juvenile macular dystrophy; Stargardt disease; Stargardt macular dystrophy

Definition

In 1909, Stargardt described a group of patients with bilateral atrophic-appearing changes within the macula with surrounding whitish-yellow flecks that extended out into the periphery. In 1963, Franceschetti used the term "fundus flavimaculatus" to describe a group of patients with fleck-like lesions in the retina with or without macular changes. The similarities of the fleck-like lesions with Stargardt disease and fundus flavimaculatus had led to discussion that the two diseases may actually be the same with overlapping clinical findings. However, some still use the term "Stargardt disease" to describe patients usually presenting at a younger age with atrophic macular changes with surrounding fleck-like lesions and "fundus flavimaculatus" to describe adult patients with fleck-like changes in the retina with no macular involvement.

If thought of as one disease, Stargardt disease/fundus flavimaculatus is probably best defined as a bilateral, autosomal recessive disease characterized by fleck-like lesions in the retina with or without atrophic macular changes and having a characteristic "dark choroid" on fluorescein angiogram.

Etiology

Mutations in the ABCR gene on chromosome 1 were identified in patients with Stargardt disease and fundus flavimaculatus in 1997. The ABCR gene encodes an ATP-binding cassette transporter protein, ABCA4, that is found in photoreceptor outer segments of both rods and cones. It is thought that this protein transports vitamin A derivatives across intracellular membranes. ABCR gene was renamed to the ABCA4 gene which stands for ABC cassette, subfamily A, member 4. The ABCA4 gene has significant sequence variability, with various heterozygotic sequences being disease causing for Stargardt disease/fundus flavimaculatus. Interestingly, other mutations in the ABCA4 gene have been shown to cause retinitis pigmentosa and cone dystrophies.

Clinical Presentation

Patients with Stargardt disease/fundus flavimaculatus usually present in the first or second decade of life with decreased central visual acuity, although this is variable. Dilated fundus exam may show subtle foveal pigmentary abnormalities sometimes described as a "beaten bronze appearance." Atrophic changes at the level of the retinal pigment epithelium (RPE) may also be present in the macula. Many patients have fleck-like lesions around the fovea that extend into the periphery. These fleck-like lesions have been described as linear, ovoid, or pisiform (fish-like) in shape and may change over time. As the retinal findings evolve, visual acuity usually deteriorates to about the 20/200 level, although this is variable.

Fluorescein angiography (FA) shows the characteristic finding of a "dark choroid" thought to be due to accumulation of lipofuscin at the level of the RPE which leads to blockage of normal choroidal fluorescence. A "bull-eye" type of fluorescence can sometimes be seen in the macula with central dark hypofluorescence surrounded by a ring of hyperfluorescent spots.

Electrophysiologic testing with full-field electroretinogram (ERG) shows variable responses ranging from normal to subnormal with impaired rod and cone responses.

Diagnosis

The diagnosis of Stargardt disease/fundus flavimaculatus is supported by a family history suggesting autosomal recessive inheritance pattern, clinical exam findings of fleck-like lesions with or without macular atrophy, and characteristic "dark choroid" findings and possible bull-eye-like macular changes seen on FA. Recently genetic testing for the ABCA4 gene has become available and also can help support the diagnosis of Stargardt disease/fundus flavimaculatus.

Differential Diagnosis

Differential diagnosis should include other disorders with flecked lesions of the retina such as drusen, multiple vitelliform lesions, fundus albipunctatus, and peau d'orange retinal findings seen with pseudoxanthoma elasticum.

Prophylaxis

Genetic testing and genetic counseling are available for those families affected by Stargardt disease/fundus flavimaculatus.

Therapy

No known treatments exist. Patients may benefit from low vision referral and genetic counseling.

Prognosis

Although variable, visual acuity usually stabilizes around 20/200 level.

Epidemiology

It is estimated that approximately 1 in 10,000 has Stargardt disease/fundus flavimaculatus.

Fundus Salt and Pepper

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Pigmentary retinopathy

Definition

A disturbance or insult to the retina or retinal pigment epithelium (RPE) can result in pigmentary changes in the retina. Salt-and-pepper fundus is a nonspecific term to describe areas of hypopigmentation due to atrophic retinal changes (salt) with pigmentary alterations from pigment migration (pepper) in large portions of the retina. A number of disorders, dystrophies, infections, or toxicities can result in salt-and-pepper fundus changes.

Etiology

Salt-and-pepper pigmentary retinal changes can be seen with many ocular disorders. These include congenital infections, retinal dystrophies, systemic metabolic disorders, and ocular drug toxicities. Many of the severe pigmentary retinopathies are genetic in origin with onset seen in childhood:

Congenital/acquired infections:
- Rubella retinopathy secondary to congenital infection
- Syphilitic retinopathy secondary to congenital or acquired infection
- Diffuse unilateral subacute neuroretinitis (DUSN)
- Toxoplasmotic retinochoroiditis
- Herpetic retinopathies

Retinal dystrophies:
- Retinitis pigmentosa (rod-cone dystrophy)
- Leber congenital amaurosis
- Usher syndrome
- Goldmann-Favre syndrome

Systemic metabolic disorders:
- Bardet-Biedl syndrome
- Alström syndrome
- Refsum syndrome
- Abetalipoproteinemia (Bassen-Kornzweig syndrome)
- Neuronal ceroid lipofuscinosis

Systemic mitochondrial retinopathy:
- Kearns-Sayre syndrome
- Chronic progressive external ophthalmoplegia (CPEO)

Autoimmune paraneoplastic retinopathy:
- Cancer-associated retinopathy (CAR)
- Melanoma-associated retinopathy (MAR)

Drug toxicities – pigmentary changes can be seen with long-term use and/or high doses:
- Thioridazine
- Chlorpromazine
- Chloroquine
- Hydroxychloroquine
- Quinine

Trauma/postsurgical:
- Traumatic retinopathy due to old commotio retinae
- Pigmentary changes following retinal detachments

Occurrence

The onset of pigmentary changes is dependent on the etiology. Many causes of pigmentary retinopathies may have manifestations in childhood as seen with Leber congenital amaurosis or congenital rubella. Others may not develop until later in life such as changes from acquired syphilis or associated with CAR. Affected individuals may have other ocular symptoms such as nyctalopia, peripheral field loss, nystagmus, or impaired vision. Systemic changes may also be present with some disorders with pigmentary retinopathy. Many pigmentary retinopathies are slowly progressive.

Classification

Identifying the etiology of pigmentary alterations can be challenging. Electrophysiology can play a pivotal role in establishing a diagnosis. For example, electroretinograms (ERGs) will be severely affected in patients with Usher syndrome or Leber congenital amaurosis but normal or only mildly affected in congenital rubella. A detailed family, medical, and ocular history, a through ocular exam, and systemic evaluation for other manifestations that may be associated with systemic disorders may aid in the diagnosis. Directed lab studies may also help in diagnosis, for example, Refsum syndrome is characterized by abnormally elevated serum phytanic acid levels.

Furrow Degeneration, Senile

Michael Coleman
Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Furrow degeneration; Idiopathic furrow degeneration; Senile furrow; Senile marginal atrophy; Senile marginal degeneration

Definition

Peripheral thinning is seen in the avascular zone between arcus senilis and the limbal vascular arcades (Farjo and Sugar (n.d.); Palay 2011; Tuft (n.d.)).

Etiology

Furrow degeneration is a corneal thinning in the periphery of the cornea that commonly occurs in association with arcus senilis. A fragmentation of peripheral corneal collagen results in a non-inflammatory depression at the corneal limbus (Farjo and Sugar (n.d.); Palay 2011; Tuft (n.d.)).

Clinical Presentation

Patients are typically asymptomatic. The corneal thinning is usually seen on routine eye exam between the corneal arcus and the limbus. The thinning is usually mild and there are no signs of inflammation or neovascularization. Occasionally the thinning can induce astigmatism.

Diagnosis

There is a zone of clearing between the corneal arcus and the corneal limbus (Tuft (n.d.)). The epithelium is intact and the cornea does not show any signs of neovascularization or inflammation (Farjo and Sugar (n.d.); Palay 2011; Tuft (n.d.)).

Differential Diagnosis

1. Terrien's marginal degeneration
2. Pellucid marginal degeneration
3. Dellen

Treatment/Prognosis

Asymptomatic. No treatment necessary unless significant astigmatism is induced.

Epidemiology

Incidence increases with age.

Gardner Syndrome: Retinal Pigment Epithelium Hypertrophy

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Synonyms

Familial adenomatous polyposis

Definition

Variant of familial adenomatous polyposis characterized by pigmented fundus ocular lesions, adenomatous polyposis of the small and large intestines, and other various neoplasms, including osteomas, fibromas, and desmoid tumors (Buettner 2006; Gass 1997; Humayun and Traboulsi 1999).

Etiology

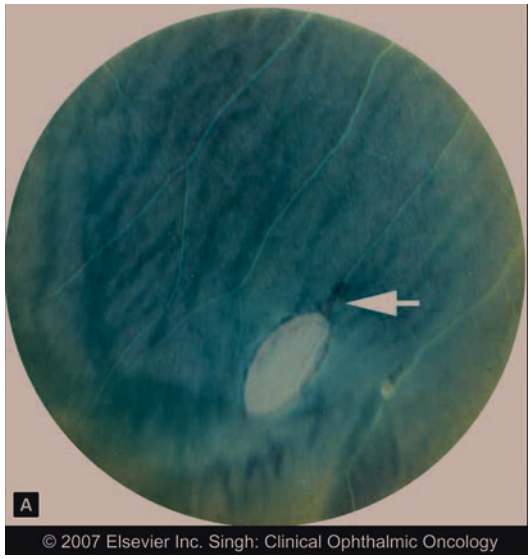
Autosomal dominantly inherited mutation in the APC gene (tumor suppressor gene) located on the long arm of chromosome 5 (5q21) (Online Mendelian Inheritance of Man).

Clinical Presentation

Although over 80% of patients with Gardner syndrome have pigmented fundus lesions, the majority of patients are visually asymptomatic. Their pigmented fundus lesions are identified most often either during general routine ophthalmoscopy or during ophthalmic screening for familial adenomatous polyposis. Ophthalmoscopically, the pigmented fundus lesions of Gardner syndrome are flat, ovoid, variably pigmented subretinal lesions with a hypopigmented halo or depigmented tail. They can be differentiated from typical congenital hypertrophy of the retinal pigment epithelium (CHRPE) in the normal population by their smaller, more ovoid or pisciform, more variegated, multiple, and bilateral appearance. Histologically, the pigmented fundus lesions of Gardner syndrome are adenomas or hamartomas of retinal pigment epithelium since they can demonstrate multiple layers of abnormal hypertrophic retinal pigment epithelium cells. Occasionally, the abnormal hypertrophic cells of the pigmented fundus lesions occupy the full thickness of the retina (Fig. 1).

Patients with Gardner syndrome typically develop polyps in their small and large intestinal during their third decade of life. If left untreated,

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9



Gardner Syndrome: Retinal Pigment Epithelium Hypertrophy, Fig. 1 Color fundus photograph demonstrating pigmented fundus lesion characteristic for Gardner syndrome (From: Singh AD, Damato BE, Pe'er J, Murphree L, Perry JD (eds) (2007) Clinical Ophthalmic Oncology. Elsevier, Philadelphia. With permission)

the gastrointestinal polyps can progress to adenocarcinoma by the fifth decade of life.

Diagnostics

Pigmented fundus lesions of Gardner syndrome are best detected with a dilated fundus exam and scleral depression. Any abnormal pigmentation of the fundus should be documented with fundus photography. Lesions demonstrating thickness should be measured using ocular echography. If four or more lesions characteristic for the pigmented fundus lesions of Gardner syndrome are seen in one or both eyes, the patient should receive genetic studies looking for the APC mutation. Diagnosis of Gardner syndrome is confirmed by documenting adenomatous polyposis of the small and large intestine during either esophagogastroduodenoscopy or colonoscopy.

Differential Diagnosis

Differential diagnosis of pigmented fundus lesions of Gardner syndrome includes isolated congenital hypertrophy of retinal pigment epithelium, choroidal nevus, choroidal melanoma, choroidal melanocytoma, hyperplasia of retinal pigment epithelium, and dark subretinal blood.

Prophylaxis

Although no prophylaxis against Gardner syndrome is currently available, routine fundus examination can be helpful for detecting Gardner syndrome in asymptomatic individuals. Routine dilated fundus examination with scleral depression is recommended for all patients with a family history of familial adenomatous polyposis.

Therapy

Management of pigmented fundus lesions in Gardner syndrome is observation. Treatment of intestinal polyps and adenocarcinoma is determined under the care of a gastroenterologist.

Prognosis

Visual prognosis of Gardner syndrome is excellent, as the pigmented fundus lesions of the retinal pigment epithelium are typically asymptomatic. Survival prognosis of Gardner syndrome is determined by the intestinal manifestations of the disease.

Epidemiology

Unclear

Synonyms

Gasserian ganglion; Semilunar ganglion; Trigeminal ganglion

Definition

Afferent sensory fibers of the trigeminal nerve originate from cell bodies within the *trigeminal ganglion*. A fold of dura, named Meckel cave, houses the sensory trigeminal ganglion also known as the gasserian or semilunar ganglion. Two of the three branches (V1 and V2) of the trigeminal nerve serve solely as sensory nerves whereas the mandibular division (V3) of the trigeminal nerve has both motor and sensory fibers.The sensory root of CN V exits the pons ventrally and fans out to form the

trigeminal ganglion meanwhile the motor fibers of CN V remain separated. Three separate sensory divisions then come off the trigeminal ganglion and continue as the ophthalmic nerve (V1), maxillary nerve (V2), and mandibular nerve (V3).

Geometrical Optics

Timo Eppig
Institute of Experimental Ophthalmology, Saarland University, Homburg, Germany

Synonyms

Ray optics

Definition

Geometrical optics is a method to describe light propagation by definition of light rays which are perpendicular to wave fronts. A ray is a simplified model of the path of a wave or photon within an optical system which can be calculated by ray tracing using the laws of refraction and reflection. Ray tracing is sufficient for most calculations in ophthalmology and basic optical aberration calculation. Most intraocular lens calculation formulas are based on geometric optical considerations.

Ghost Cell Glaucoma

Christoph Kniestedt[1] and Marc Töteberg-Harms[2]
[1]TAZZ Talacker Augenzentrum Zurich, Zürich, Switzerland
[2]Department of Ophthalmology, University Hospital Zurich, Zürich, Switzerland

Definition

Degenerated red blood cells (ghost cells) cause secondary open-angle glaucoma by blocking the outflow through the trabecular meshwork (Campbell et al. 1976). After a vitreous hemorrhage, red blood cells degenerate (Campbell et al. 1976).

They lose their intracellular hemoglobin and appear as small and tan-colored intraocular bodies with some denatured clumped hemoglobin called *Heinz bodies* (Campbell et al. 1976). The ghost cells migrate into the anterior chamber through a disrupted anterior hyaloid face. Ghost cells are more rigid compared to normal red blood cells, which is a major reason for obstruction of the trabecular meshwork (Campbell et al. 1976; Quigley and Addicks 1980).

Etiology

A disruption in the anterior hyaloid membrane by previous intraocular surgery (e.g., vitrectomy, cataract surgery) or by trauma causes the pathway to the anterior chamber. One to three months after a vitreous hemorrhage, ghost cells appear in the anterior chamber (Montenegro and Simmons 1995).

Clinical Presentation

Intraocular pressure is elevated typically 1–3 months after a vitreous bleeding (Montenegro and Simmons 1995).

Diagnosis

IOP is unilaterally elevated in the eye with previous vitreous hemorrhage. Circulating ghost cells are visible in the anterior chamber. Signs of inflammation like superficial conjunctival injection or intraocular flare are absent. Gonioscopically, ghost cells could be found mainly in the inferior hemicircumference on the trabecular meshwork. Old red blood cells may be found in the vitreous.

Differential Diagnosis

- Uveitis anterior
- Status post-hyphema

Therapy

Local antiglaucomatous therapy should be initiated. Upon failure, irrigation of the anterior chamber, vitrectomy, or trabeculectomy to control IOP are treatment options, which can be discussed with the patient.

Prognosis

Heinz bodies may be washed out over time and ghost cell glaucoma may resolve.

Epidemiology

Ghost cell glaucoma is very rare.

Giant Papillary (Contact Lens-Induced) Conjunctivitis Disease

Sana Idrees
The George Washington University, Washington, DC, USA

Synonyms

Contact lens-induced conjunctivitis

Definition

Giant papillary conjunctivitis (GPC) An inflammatory response of the superior tarsal conjunctiva to the prolonged presence of a foreign body on the ocular surface.

Etiology

The condition was first observed in contact lens wearers. Ocular prostheses, exposed suture ends, extruded scleral buckles, filtering blebs, corneal foreign bodies, limbal dermoids, and tissue adhesives have also been implicated (Ehlers and Donshik 2008). The condition is most commonly seen in contact lens wearers, particularly patients who wear soft contact lenses (Manzouri et al. 2006). It can occur with hydroxyethyl methacrylate (HEMA) or silicone polymer hydrogel contact lenses. However, it can also occur with rigid contact lenses of either polymethyl metacrylate (PMMA) or gas-permeable polymers (Ehlers and Donshik 2008).

The development of giant papillary conjunctivitis is attributed to a combination of mechanical irritation of the superior limbus and a hypersensitivity reaction to material adherent to the contact lenses, sutures, or ocular prostheses (Dunn and Heidemann 2011). A study on Rhesus monkeys demonstrated that coated contact lenses lead to cellular infiltration of the conjunctiva with eosinophils and plasma cells. This reaction was not noted in virgin contact lenses or lenses from non-GPC contact lens wearers. Additionally, the tears of patients with active GPC have been found to have elevated levels of immunoglobulin and various cytokine levels. These findings suggest that there may be an antigen on coated contact lenses contributing to the immune reaction in GP-C. The presence of neutrophil chemotactic factor released from injured conjunctival cells supports the theory that a mechanical cause may also be involved (Ehlers and Donshik 2008). Minimizing the build-up of lens deposits appears to reduce the chance of developing mechanical and immunologic stimuli for the condition. The frequency of contact lens replacement is a significant variable in the development of giant papillary conjunctivitis. Individuals on a 1-day to 3-week replacement cycle were less likely to develop this condition than individuals on a longer replacement schedule (Dunn and Heidemann 2011).

In some cases, giant papillary conjunctivitis appears to be related to thimerosal exposure. Lens care solutions used in most reported cases contained thimerosal. However, only a minority of patients exhibited reactions to thimerosal on patch testing. The incidence of giant papillary conjunctivitis is decreasing as most contact lens solutions no longer contain thimerosal. Hypoxia of the epithelium beneath the lens may be associated, which would be expected to be most significant beneath the superior lid (Arffa 1997).

Clinical Presentation

Giant papillary conjunctivitis may present as early as 3 weeks to 8 months after the start of soft contact lens use and 14 months to 8 years after the start of hard contact lens use (Dunn and Heidemann 2011). Classic symptoms of GPC include decreased contact lens tolerance, increased mucus production, and excessive contact lens displacement, usually superiorly (Ehlers and Donshik 2008). Early symptoms of giant papillary conjunctivitis include inner canthus mucus discharge in the morning and itching upon removal of the contact lenses. During the early stages of the disease, the conjunctiva may appear normal. The symptoms become more marked as

the disease progresses. The patient may begin to experience a foreign body sensation, conjunctival injection, photophobia, tearing, and crusting. Blurry vision may also be a symptom of the disease secondary to mucus coating of the lens and increased lens mobility and instability. During this stage of the disease, the superior tarsal conjunctiva becomes thickened and hyperemic. Small papillae develop initially, which progress in size and number over time to become giant papillae (Manzouri et al. 2006).

The papillae of giant papillary conjunctivitis are defined as greater than 0.3 mm in diameter. Giant papillae are defined as being greater than 1.0 mm in diameter (Dunn and Heidemann 2011). The distribution of the giant papillae varies depending upon the type of lens worn. Soft contact lens wearers develop papillae along the superior edge of the tarsal plate initially and progress to involve the entire central area of the tarsal conjunctiva. Hard contact lenses tend to be smaller, and wearers of these lenses develop papillae closer to the margin of the superior lid (Manzouri et al. 2006). These papillae tend to be fewer in number with a crater-like or flattened appearance (Dunn and Heidemann 2011). Ocular prostheses tend to cause a generalized papillary reaction. Filtering blebs and exposed sutures cause a more localized GPC, usually centered around the bleb or exposed suture (Ehlers and Donshik 2008). Subepithelial opacities are often present, and a pannus may be noted beneath the abnormal epithelium (Arffa 1997). The bulbar conjunctiva and the inferior fornix usually appear normal. In the advanced stages of the disease, patients may become increasingly intolerant of their contact lenses (Manzouri et al. 2006).

Diagnosis

A history of contact lens use with details of contact lens age, type, and frequency of replacement should be taken. For diagnosis, slit-lamp examination of the superior tarsal conjunctiva by eversion of the upper lids reveals hyperemia and injection of the upper tarsal conjunctiva, making the vascular arcade difficult to discern. Additionally, large papillae greater than 0.3 mm can be visualized on the superior tarsal conjunctiva (Ehlers and Donshik 2008). Fluorescein staining of the superior corneal epithelium of the papillae may be punctate, extending from the limbus in a V pattern toward the visual axis (Arffa 1997).

Differential Diagnosis

Differential diagnosis includes vernal keratoconjunctivitis. Contact lens history and patient age may be helpful in distinguishing these conditions as vernal keratoconjunctivitis is uncommon after the early twenties (Manzouri et al. 2006). Additionally, patients with vernal keratoconjunctivitis frequently have a history of allergic rhinitis, atopic dermatitis, and asthma (Dunn and Heidemann 2011).

Prophylaxis

The development of giant papillary conjunctivitis can be reduced by meticulous contact lens hygiene, and frequent replacement of lenses to minimize lens surface deposits (Dunn and Heidemann 2011).

Therapy

The goal of therapy in giant papillary conjunctivitis is resolution of the burning, itching, and excess mucus production that characterize the condition. Reduction or cessation of contact lens use for 2–4 weeks is the primary treatment for giant papillary conjunctivitis (Ehlers and Donshik 2008). After resolution of the signs and symptoms of GPC, lens wear can be reinstituted by refitting, switching to alternate better tolerated lenses, or avoiding solutions containing thimerosal (Arffa 1997). Studies have shown that changing to a different contact lens polymer allows over 80% of GPC patients to continue contact lens wear (Ehlers and Donshik 2008). For patients who may be significantly handicapped by the

discontinuation of contact lens use, including individuals with keratoconus or anisometropia, modification of their contact lens care routine and wear schedule may help to relieve many of the symptoms of giant papillary conjunctivitis. Because of the well-established relationship between lens deposits and giant papillary conjunctivitis, the use of daily disposable soft contact lenses or frequent replacement contact lenses is the best solution. Individuals for whom this may be cost-prohibitive or who require specialty lenses or rigid-gas permeable lenses should adopt a daily lens care regime, including use of a surfactant cleaner and "rub" routine. Disinfection of the lenses with hydrogen peroxide is the least likely method to further traumatize the conjunctiva (Dunn and Heidemann 2011).

When discontinuation of contact lens wear and refitting with frequent replacement contact lenses is unsuccessful, the conjunctival inflammation may be managed pharmacologically with the goal of reducing histamine release and local inflammation (Ehlers and Donshik 2008). Topical mast cell stabilizers, such as cromolyn sodium, have been shown to be effective in resolution of early giant papillary conjunctivitis when combined with lens hygiene. This class of medications stabilizes the mast cell membrane and inhibits type I hypersensitivity reactions. Cromolyn sodium can be applied with continued contact lens use. If the condition does not improve, discontinuation of contact lens wear may be necessary with gradual reintroduction after resolution of symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as suprofen, have been shown to reduce papillae and symptoms associated with the condition. NSAIDs appear to work by inhibiting mast-cell stimulated prostaglandin biosynthesis. Treatment with topical corticosteroids can be beneficial in the acute phase of giant papillary conjunctivitis to reduce tarsal hyperemia and inflammation. The need for corticosteroids is an indication of severity of disease, and contact lens use should be discontinued until corticosteroids are no longer necessary (Dunn and Heidemann 2011). If corneal epithelial changes do not resolve with discontinuation of lens wear, surgical treatment options may be necessary. In some cases, limbal or conjunctival autografts have successfully restored the corneal surface (Arfa 1997).

Prognosis

If contact lens wear is discontinued, the prognosis is good, and the disease may resolve within a few weeks to several months. Early recognition and treatment of the condition is important for ensuring contact lens comfort and the individuals continued ability to wear contact lenses (Dunn and Heidemann 2011). If left untreated, the disease continues to progress. The epithelium thickens, becomes grayer, and involves an increasingly greater area of the conjunctiva. The pannus progresses centrally and vascularization of the deep stroma may develop. Superficial stromal scarring may also be present and recurrent ulceration can occur (Arffa 1997).

Epidemiology

An estimated 1–5% of soft contact lens wearers and 1% of hard contact lens wearers have clinically significant signs and symptoms of giant papillary conjunctivitis. The incidence of giant papillary conjunctivitis is generally considered to be higher amongst extended wear contact lens users compared to daily wear soft lens wearers. The syndrome can occur at any age and is seen with equal frequency between males and females (Dunn and Heidemann 2011).

Glands of Krause, Glands of Moll, Glands of Wolfring, Glands of Zeis

Katherine G. Gold[1] and Tara Uhler[2]
[1]Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA
[2]Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Accessory lacrimal glands; Apocrine or sweat glands of the eyelid; Sebaceous glands of the eyelid

Definition

Glands of Krause

Exocrine and aqueous secreting accessory lacrimal glands located in the lamina propria of the conjunctival fornices (superior > inferior).

Glands of Wolfring

Exocrine and aqueous secreting accessory lacrimal glands located above the superior border of the upper lid tarsus.

Glands of Moll

Specialized apocrine sweat glands located at the base of the lashes anterior to the Meibomian glands.

Glands of Zeis

Modified sebaceous holocrine glands located at the base of eyelash follicles.

Structure

Glands of Krause and Wolfring possess a histologic structure similar to the lacrimal gland.

Glands of Moll are tubular, large apocrine gland.

Glands of Zeis are unilobular sebaceous gland units associated with follicles.

Function

The eyelid glands produce the tear film which nourishes, lubricates, and protects the ocular surface.

- Glands of Krause and Wolfring are responsible for aqueous tear secretion.
- Glands of Moll and Zeis secrete part of the lipid component of the tear film. Moll's secretions have been found to have bacteriolytic properties as well and may play a role in local immune defense.

Clinical Relevance

Abnormal functioning of any of the glands may lead to dry eye conditions. Cysts and carcinomas of these glands may occur.

- Glands of Krause and Wolfring are affected in Sjogren syndrome and graft-versus-host disease.
- Glands of Moll can develop ductal cysts, including apocrine hidrocystomas (smooth cysts arising from the glands of Moll); they can also develop apocrine carcinoma.
- Glands of Zeis can develop an acute infection of the sebaceous material within these glands resulting in an external hordeolum; sebaceous carcinoma may arise in these glands.

Glare Testing

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Disability glare testing

Definition

Methods of psychophysical quantification of the effects of ▶ glare on visual function. In clinical use, "glare testing" is synonymous with measuring the effects of straylight-induced effects on visual function. Typically, a ▶ contrast sensitivity test is repeated after introducing glare by a defined glare source. The difference between the measurement without and with glare denotes the glare effect, also referred to as glare sensitivity or disability glare. There are multiple chart-based tests or view-in devices in use. The C-Quant™ (Oculus Optikgeräte) is the most basic method for the psychophysical quantification of straylight effects.

Questionnaires for the psychometric quantification of glare-induced subjective disturbances and devices for adaptometry also measure glare effects but are generally not considered glare tests.

Cross-References

- ▶ Glare, General

Glare, General

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Disability glare

Definition

A subjective disturbance of vision induced by too high luminances or luminance differences across the visual field. A reduction of visual functions due to glare is common (disability glare) but not a necessary feature of glare.

Basic Characteristics

There are different types of glare: (1) *adaptation glare* due to (momentary) mis-adaption to the actual luminance, e.g., changing from a dark to a brightly lit room after dark adaptation; (2) *absolute glare*, if no adaptation is possible, e.g., glare by sunlight; and (3) *simultaneous glare*, if luminances are distributed inequally within visual field and straylight causes a contrast reduction

(veiling) of the retinal image. The latter form is the clinically most important form of glare and often meant if clinicians refer to "glare." A glare source of defined luminance and size acts at a certain glare angle. The glare source can either be the light source itself (e.g., the sun, headlights) or objects that reflect the light of a light source (e.g., a newspaper that reflects bright light).

Globe, Displacement of, in Orbital Disorders

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Synonyms

Proptosis (for forward displacement of the globe)

Definition

Displacement of the globe from its normal anatomical location due to various orbital processes.

Etiology and Occurrence

Globe displacement may result from a wide variety of neoplastic, inflammatory, infectious, traumatic, and vascular conditions. Any mass lesion of the orbit may cause proptosis or displacement of the eye including primary tumors such as lacrimal epithelial tumors (pleomorphic adenoma, adenoid cystic carcinoma), mesenchymal tumors (fibrous histiocytoma, rhabdomyosarcoma), and neurogenic tumors (sphenoid wing meningioma, optic nerve glioma, neurofibroma, schwannoma). In addition, metastatic lesions, representing 2–3% of all orbital tumors, are usually characterized by a rapid onset of orbital symptoms including globe displacement. The most common primary sites of metastatic carcinoma to the orbit are the breast, lung, prostate, gastrointestinal tract, and kidney.

Lymphoproliferative diseases are uncommon in the orbit and account for 5% of all orbital mass lesions. Lymphoid lesions include lymphoproliferative reactive and atypical diseases and lymphomas. Malignant orbital lymphomas are usually located in the anterior orbit and may mold to the globe and adjacent structures.

Inflammatory diseases are the most common orbital lesions which can cause globe displacement. Most notably Graves' disease, which accounts for 50% of all orbital lesions, causes exophthalmos or forward displacement of the globe. Other inflammatory causes include idiopathic orbital inflammation (pseudotumor), myositis, and Wegener's granulomatosis.

Other causes of globe displacement include infectious processes (orbital cellulitis), trauma (orbital fractures), and structural disorders (dermoid cysts, mucoceles). In addition, vascular lesions are an important cause of globe displacement including capillary hemangioma, cavernous hemangioma, lymphangioma, and arteriovenous fistula.

Classification

The direction of globe displacement may carry diagnostic significance and can be classified by the following locations:

- Inferior displacement: fibrous dysplasia, frontal mucocele, lymphoma, neuroblastoma, neurofibroma, schwannoma, subperiosteal hematoma, thyroid orbitopathy
- Superior displacement: lacrimal sac tumors, lymphoma, maxillary sinus tumors, metastatic tumors
- Lateral displacement: ethmoid mucocele, lacrimal sac tumors, metastatic tumors, nasopharyngeal tumors, rhabdomyosarcoma
- Medial displacement: lacrimal fossa tumors, sphenoid wing meningioma

Diagnostics

A complete medical and ophthalmic history including time course of the disease, past trauma, and systemic illnesses should be elicited. A careful and complete ophthalmic exam including external and periorbital inspection for lid findings (edema, ptosis, retraction) and assessment for a palpable mass should be completed. Hertel exophthalmometry should be done to measure the degree of anterior displacement, and motility should be assessed. Imaging by computed tomography or magnetic resonance imaging is almost always indicated.

Goblet Cells, Mucin Tear Secretion by

Daniel Montenegro and Nadeem Fatteh
Department of Ophthalmology, Kresge Eye Institute, Wayne State University, Detroit, MI, USA

Synonyms

Mucus-secreting cells

Definition

Cells recognized as a source of mucus for the tear-film complex.

Structure

Conjunctival goblet cells appear in histological sections as oval-shaped cells containing rich amounts of intracytoplasmic mucus (Doughty 2012). Cytoplasmic staining is characteristically periodic acid-Schiff (PAS) positive, reflecting the high density of glycosylated glycoproteins within these cells (Doughty 2012). Goblet cell location

varies depending on their degree of maturation with more mature cells residing near the apical surface of the conjunctival epithelium; the distribution of goblet cells is related to differences in exposure, with cell numbers being higher in the superior and inferior bulbar conjunctiva compared to the interpalpebral conjunctiva (Doughty 2012).

Function

Goblet cells comprise the main source of mucus secreted into the tear-film complex (Inatomi et al. 1996; Doughty 2012; Gipson 2004). Mucus secretion is influenced by environmental and autonomic factors (Plugfelder 2011). A gel-forming mucin, MUC5AC, secreted by conjunctival goblet cells assists in the maintenance of a moist and lubricated ocular surface (Inatomi et al. 1996). Secreted mucins are negatively charged and move freely over similarly negatively charged membrane-associated mucins of the conjunctival and corneal epithelium also known as *glycocalyx* (Gipson 2004). It is believed that repellent forces between these two mucin layers promote debris removal from the surface epithelium, hence their recognition as an integral component of the lacrimal function unit (Plugfelder 2011).

Clinical Relevance

Ocular surface diseases are associated with drying, increased deposition of keratin in the conjunctival epithelium, reduced goblet cell density, and reduced secretion of gel-forming mucins (Plugfelder 2011; Doughty 2012). A broad group of entities are associated with impaired goblet cell function. These include tear-film dysfunction, Stevens-Johnson syndrome, and ocular cicatricial pemphigoid (Sangwan and Tseng 2001).

Goldenhar Syndrome

Suzanne K. Jadico and Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Facio-auriculo-vertebral spectrum; First and second branchial arch syndrome; Oculo-auriculo-vertebral spectrum

Definition

Congenital syndrome of the first and second brachial arches that includes malformations of the eyes, ears, mandible, and cervical spine.

Etiology

Because there has been no agreement on the minimal diagnostic criteria, Goldenhar syndrome may be more appropriately termed oculo-auriculo-vertebral spectrum (OAVS). This nomenclature emphasizes the continuum of ocular, auricular, and vertebral anomalies also referred to as hemifacial microsomia, facio-auriculo-vertebral

syndrome, otomandibular dysostosis, Goldenhar syndrome, or first and second branchial arch anomalies.

In most cases, OAVS appears to occur sporadically; however, family histories suggest an autosomal dominant or recessive inheritance in several documented cases. Possible loci have been suggested at 14q22 and 5p15.33-pter. Mutations in the SALL1 gene at 16q12.1 can result in an OAVS phenotype (Tasse et al. 2007). In addition, some researchers suggest that this condition may result from a somatic mutation or disruption during embryogenesis which interferes with the development of the first two brachial arches. Also, there has been speculation of its association with maternal diabetes and with thalidomide or retinoic acid intake during pregnancy. The teratogen thalidomide appears to result in OAVS anomalies particularly when the drug is ingested during weeks 6–8 of gestation (Gorlin et al. 1990).

Clinical Presentation

Patients with the OAV spectrum have unilateral or bilateral hemifacial microsomia, including decreased jaw and cheek growth, microtia, pretragal skin tags or blind fistulas, hearing loss, and facial weakness. Patients may also have vertebral, neurologic, cardiovascular, and genitourinary abnormalities, in addition to characteristic ophthalmic abnormalities (Alecksic et al. 1975).

Ocular manifestations include epibulbar dermoid (78%), lipodermoid (47%), upper eyelid coloboma (24%), Duane syndrome, and, less commonly, corneal hypoesthesia, microcornea, microphthalmia, anophthalmia, ocular coloboma, iris atrophy, and anterior polar cataract. An absent, abnormal, or ectopic caruncle may predict nasal involvement and help to make a diagnosis of OAVS (Spierer and Wygnanski-Jaffe 2011).

Epibulbar dermoids (Fig. 1) usually occur in the inferotemporal quadrant, straddling the limbus, and are covered by conjunctiva. They are mixed tissue choristomas and can have hair shafts protruding from the surface. They occur bilaterally in 25% of patients. These dermoids can cause amblyopia either by direct obstruction of the visual axis or, more commonly, by anisometropic amblyopia resulting from induced astigmatism (Baum and Feingold 1973).

Goldenhar Syndrome, Fig. 1 Photograph of an inferotemporal, limbal epibulbar dermoid (Courtesy of Dr. Alex V. Levin, Wills Eye Institute)

Lipodermoids are reported less frequently, occurring either alone or in association with an epibulbar dermoid. They are most commonly located over the lateral rectus muscle or in the superotemporal quadrant, do not invade the cornea, and are often bilateral. They may infiltrate extraocular muscles and restrict eye movement (Baum and Feingold 1973).

Diagnostics

The minimum criteria for the clinical diagnosis of OAVS are the presence of at least two of the following: otic hypoplasia, hemifacial microsomia, lateral facial cleft, epibulbar dermoid and/or upper eyelid coloboma, and vertebral anomalies.

Differential Diagnosis

Treacher Collins-Franceschetti syndrome
Pierre Robin syndrome
Hemifacial microsomia
Cervico-oculo-acoustic syndrome
Townes-Brocks syndrome
Microtia-anotia syndrome
Aplasia cutis with epidermal dermoids

Oculo-auriculo-frontonasal syndrome
Goltz syndrome

Prophylaxis

Prenatal ultrasound may identify facial and ocular anomalies.

Therapy

Amblyopia should be treated appropriately. Surgical excision, usually via superficial keratectomy, is indicated for epibulbar dermoid tumors that exhibit continued growth, ocular irritation, amblyopia unresponsive to glasses and occlusion, or unacceptable cosmesis. Oculoplastic repair of upper eyelid colobomas are usually performed after the first year of life. Although lipodermoid may represent a cosmetic concern, surgery is often difficult, and it is best to restrict excision to the surface of the mass.

Prognosis

Individuals typically have a normal life span and normal intelligence.

Epidemiology

Incidence estimated to be 1 in 5,600 births.

Gonococcal Conjunctivitis

Vishwanath Srinagesh
Sinai Hospital, Krieger Eye Institute, Baltimore, MD, USA

Definition

Inflammation of the conjunctiva caused by *Neisseria gonorrhoeae* infection.

Etiology

Gonococcal conjunctivitis may be acquired through direct genital-eye transmission, genital-hand-eye contact, or maternal-neonate transmission during vaginal delivery.

Clinical Presentation

Gonococcal conjunctivitis is characterized by hyperacute onset of purulent exudates, conjunctival chemosis and hyperemia, and eyelid swelling. It may also be associated with the formation of membranes and preauricular lymphadenopathy. Keratitis is the most frequent cause of sight-threatening complication and occurs in 15–40% of cases.

Notable signs of corneal involvement include marginal infiltrates, epithelial haze, epithelial defects, and peripheral infectious keratitis. If left untreated, keratitis may progress to ulceration and eventually perforation.

In neonates, symptoms are typically bilateral and begin within 2–5 days after parturition.

Diagnosis

In cases of neonatal gonococcal conjunctivitis, a prenatal history is vital and cervical specimens should be taken from the mother for culture. A full ocular and general physical exam should be performed to diagnose and assess the extent of disease.

Conjunctival scrapings submitted for Gram and Giemsa staining should reveal intracellular gram-negative diplococci present inside neutrophils.

Conjunctival swabs should also be planted on chocolate agar in a CO_2-enriched atmosphere or Thayer-Martin media.

Differential Diagnosis

Differential diagnosis includes chemical conjunctivitis, chlamydial and other nongonococcal bacterial conjunctivitis, and herpetic conjunctivitis.

Prophylaxis

Prophylactic recommendations include tetracycline (1%) drops and erythromycin (0.5%) ointment. Silver nitrate drops are used less commonly as they may cause chemical conjunctivitis and do not provide prophylaxis against chlamydia.

Therapy

The mainstay of treatment of gonococcal disease is systemic antibiotics. Due to increasing prevalence of penicillin-resistant *N. gonorrhoeae*, ceftriaxone is prescribed as first-line treatment. Gonococcal conjunctivitis without ulceration may be treated with a one-time, intramuscular dose of ceftriaxone (1 g). Patients with corneal ulceration should be admitted to the hospital and treated with intravenous ceftriaxone (1 g IV every 12 h) for 3 days. Patients with a penicillin allergy may be treated with spectinomycin (2 g IM) or ciprofloxacin (500 mg bid for 5 days).

Non-disseminated neonatal conjunctivitis is treated with a single intravenous or intramuscular ceftriaxone (25–50 mg/kg or up to 125 mg). Alternatively, cefotaxime may be prescribed as an intramuscular or intravenous injection (100 mg/kg). In disseminated infections, hourly saline irrigation of the conjunctiva may be initiated to clear discharge. If clinical signs of corneal involvement are present, topical erythromycin or gentamicin ointment or a topical flouroquinolone should be considered. Patients should also be treated for chlamydia with systemic erythromycin (12.5 mg/kg oral or IV qid for 14 days) as coinfection can occur and systemic involvement, such as pneumonitis and otitis media, can lead to significant morbidity.

Prognosis

Prognosis is excellent if treatment is started while infection is localized. Visual prognosis may be limited in patients with significant corneal involvement with subsequent scarring and/or perforation.

Disseminated gonococcal infection with meningitis, pneumonia, and sepsis resulting in death is a rare complication in neonates.

Epidemiology

The incidence of neonatal gonococcal conjunctivitis is estimated at approximately 100 per 100,000 in the United States.

Non-neonatal infections are most common in adolescents and young adults.

Gorlin Syndrome

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Basal cell nevus syndrome; Nevoid basal cell carcinoma syndrome

Definition

A rare autosomal dominant disorder characterized by multiple nevoid basal cell carcinomas early in life. It is a multisystemic disease involving multiple organ systems (American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Etiology

Tumors are indistinguishable from noninherited forms of basal cell carcinoma, arising from the basal cell layer of the epithelium. The gene though to be responsible for Gorlin syndrome is the patched gene (PTCH), found on 9q22.3-q31. It is thought to be a tumor suppressor with one germline defect in affected families. Complete penetrance with variable expressivity is observed (Gorlin 1995; Bale 1997; Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Clinical Presentation

Gorlin syndrome may present with multiple basal cell carcinomas at a young age. Eyelid basal cell carcinomas occur in 25% of cases and are indistinguishable from noninherited forms of basal cell carcinoma.

Other ophthalmic findings in Gorlin syndrome include congenital cataracts, orbital cysts, hypertelorism, colobomas, and medullated nerve fiber layer of the retina. Other features include mandibular cysts, macrocephaly, frontal bossing, polydactyly, palmar or plantar pits, and medulloblastoma (Gorlin 1995; Bale 1997; Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Diagnostics

Excisional biopsies of suspect lesions are histologically indistinguishable from basal cell carcinoma. Imaging is necessary when clinically correlated, including MRI of the brain, dental radiography, and a skeletal survey (Gorlin 1995; Bale 1997; Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Differential Diagnosis

Xeroderma Pigmentosa

Prophylaxis

Patients with Gorlin syndrome may be extremely susceptible to ionizing radiation and sun exposure. Patient should be counseled to avoid sun exposure (Gorlin 1995; Bale 1997; Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Therapy

Surgical excision is recommended for a patient with a limited number of lesions. Topical 5-fluorouracil with or without topical tretinoin may be useful for patients with extensive lesions. Oral isotretinoin may be an option for patients who are at high risk for developing many additional lesions.

Prognosis

Patients may have multiorgan involvement and will need care by appropriate specialists, including dermatologists, dentists, oncologists, cardiologists, and orthopedic surgeons.

Epidemiology

Incidence is rare and occurring in about 1 per 50,000–150,000 people and in 0.7% of patients with basal cell carcinoma. Fair skinned patients with substantial sun exposure may be more susceptible (Shields and Shields 1999; American Academy of Ophthalmology 2006–2007; Albert and Jakobiec 2008).

Gradenigo-Lannois syndrome; Petrous apicitis

Definition

Gradenigo syndrome is a rare but sometimes serious infectious/inflammatory syndrome, associated with localized inflammation at the apex of the petrous temporal bone, a location in which the trigeminal (CN V) nerve is closely related to abducens nerve (CN VI) and facial (CN VII) and vestibulocochlear (CN VIII) nerves.

Etiology

Causes include inflammation (e.g., petrositis secondary to otitis and mastoiditis), infection typically due to aerobic microorganisms, extradural abscess, tumors (e.g., cholesteatoma, chordoma, meningioma, nasopharyngeal carcinoma, metastatic disease), and skull base fracture.

Clinical Presentation

Gradenigo syndrome is characterized by a clinical triad: retro-orbital pain in the distribution of the ophthalmic division of trigeminal nerve (CN V), diplopia due to abducens nerve (CN VI) palsy, and otorrhea due to suppurative otitis media. Facial (CN VII) palsy and deafness, due to compromise of vestibulocochlear nerve (CN VIII), also may manifest as components of the syndrome.

History

It was first described by Giuseppe Gradenigo in 1904, as a serious complication of otitis media. In the postantibiotic era, infection is a much less common cause of the syndrome.

Diagnosis

The diagnosis of Gradenigo syndrome is a clinical diagnosis supported by either computed tomography (CT) or magnetic resonance imaging (MRI) findings.

Differential Diagnosis

The differential diagnosis of Gradenigo syndrome includes Ramsay Hunt syndrome (geniculate Herpes Zoster), neoplastic disorders involving petrous bone, and closed head trauma.

Therapy

High-dose antibiotic treatments, both systemic and topical, are recommended for infectious etiologies. Treatment, in severe cases failing maximum medical therapy, may also require more aggressive and radical surgical intervention (e.g., apical petrosectomy) to debulk the infection.

Prognosis

Earlier diagnosis and treatment may limit disease progression and more severe and potentially life-threatening complications.

Epidemiology

The incidence of infectious Gradenigo syndrome in the United States has been reduced by earlier diagnosis and treatment with broad-spectrum antibiotics but may still be as high as 2 per 100,000 individuals with acute otitis media. Gradenigo syndrome however remains a problem in lesser-developed countries.

Graft-Versus-Host Disease: Overview

Jiawei Zhao
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Definition

Graft-versus-host disease (GVHD) is a major complication from allogeneic hematological stem cell transplantation. It is a systemic inflammatory condition due to attack of host tissue by immunocompetent cells from the donor (Albert et al. 2008).

Etiology

GVHD is the recognition of allogeneic differences and destruction of host peptides by immune cells of the donor. Activation of donor immune cells leads to secretion of IL-2, resulting in clonal expansion and proliferation of T lymphocytes (Albert et al. 2008).

Acute GVHD is due to conditioning regimen (radiation and/or chemotherapy) that damages host tissue (Albert et al. 2008). This leads to production of pro-inflammatory cytokines such as IL-1 and TNF-α that increase expression of human leukocyte antigen (HLA) alloantigens and adhesion molecules on the surface of host cells, activating donor type 1 helper T cell (Albert et al. 2008).

Chronic GVHD is predominantly a type 2 helper T cell response with lymphoproliferation, increased IgE synthesis, and production of IL-4 and IL-10 (Albert et al. 2008). In contrast to acute GVHD, donor antigen-presenting cells are also involved in the pathogenesis (Albert et al. 2008).

Clinical Presentation

Acute GVHD develops within 100 days of transplantation and chronic GVHD develops after day 100 (Albert et al. 2008). Ocular GVHD can affect all layers of the eye including the lid, meibomian gland, vitreous, and choroid, but it mainly affects ocular surface and lacrimal gland (Hasanain et al. 2013). Acute ocular GVHD often presents with conjunctival hyperemia, chemosis, and pseudomembrane formation (Hasanain et al. 2013). Chronic GVHD often presents with keratoconjunctivitis sicca along with chronic blepharitis and meibomian gland dysfunction (Hasanain et al. 2013). Sterile conjunctivitis, cicatricial lagophthalmos, and retinal microvascular occlusive disease are also commonly observed (Hessen and Akpek 2012).

Diagnosis

Acute ocular GVHD is diagnosed by clinical presentation. Diagnosis of chronic ocular GVHD needs to be confirmed by (1) biopsy or Schirmer test and (2) involvement of at least one other organ (Hasanain et al. 2013).

Differential Diagnosis

Infection, total body irradiation, ocular toxicity of chemotherapy, immunosuppressive therapy, meibomian gland dysfunction, and keratoconjunctivitis sicca are due to other causes.

Prophylaxis

One major prophylaxis method is optimal HLA-matching between donor and recipient. Donor T cell depletion through alemtuzumab (anti-CD52) and anti-thymocyte globulin can also prevent GVHD, but this increases the rate of graft failure, relapse of malignancy, infections, and Epstein-Barr virus-associated lymphoproliferative disorder (Hasanain et al. 2013). Pharmacologic agents that can be used are the combined use of calcineurin inhibitors with low doses of methotrexate (Hasanain et al. 2013). Reduced intensity conditioning regimens reduce tissue damage and thus lower intensity of cytokine storm (Hasanain et al. 2013).

Therapy

Treatment options for ocular GVHD include lubrication with artificial non-preserved phosphate-free tears (Hessen and Akpek 2012); tear preservation with punctal occlusion (silicone plugs or thermal cauterization) (Hessen and Akpek 2012); reduction of inflammation with short-term, low-frequency application of topical steroids and long-term control with topical cyclosporine eye drops (Hessen and Akpek 2012); prevention of tear evaporation with warm compresses and ointments such as erythromycin (Hessen and Akpek 2012); epithelial support with autologous serum eye drops, contact lenses (bandage soft contact lenses, scleral lenses, or prosthetic replacement of ocular surface ecosystem), or sutureless amniotic membrane; and surgery for severe cases of ocular surface disruption (Hessen and Akpek 2012).

Prognosis

Mortality due directly or indirectly to acute GVHD may reach 50% (Albert et al. 2008). Acute GVHD leading directly to chronic GVHD has the worse prognosis compared to chronic GVHD with a remission period after acute GVHD and de novo chronic GVHD (Hasanain et al. 2013). Presence of pseudomembranous conjunctivitis is associated with poor prognosis (Hasanain et al. 2013).

Epidemiology

Acute and chronic GVHD develops in approximately 40% and 30–70%, respectively, in HLA-matched patients (Hessen and Akpek 2012). Ocular manifestations occur in 60–90% of patients with chronic GVHD but are uncommon in acute GVHD (Hessen and Akpek 2012).

Gram-Negative Bacteria

Khaled Tuwairqi
Wilmer Eye Institute, Baltimore, MD, USA
Department of Ophthalmology, University of Utah, Salt Lake City, UT, USA

Definition

A group of microorganisms that will not retain a crystal violet stain on gram staining method.

Structure

As opposed to gram-positive bacteria, gram-negative bacteria maintain the cell wall shape by a thin layer of peptidoglycan that is surrounded by an outer membrane. The outer membrane provides an important role in the protection from host environment, and it is linked to the peptidoglycan through lipoproteins. Lipid A is a component of the outer membrane which acts as a strong activator of the innate immune system. Few kinds of proteins that are found on the outer membrane play a role in the virulence of these organisms. Periplasmic space is an area that is found between the inner and outer membranes that many enzymatic processes will take place at. Other structures which could also be found in the gram-positive bacteria include capsule which is useful in the protection from phagocytosis, pili that are used by bacteria for adherence or sexual reproduction and flagellum for movement.

Function

Certain types of bacteria are found in the normal flora of human bodies. In the ocular flora, gram-negative bacteria that could be isolated include *Haemophilus* species, *Neisseria* species, and *Pseudomonas* species. Recent studies suggested that normal flora could help minimize the inflammations, act as a barrier against harmful pathogens, maintain the immune system, inhibit the apoptosis, and accelerate the wound repair.

Clinical Relevance

Many ocular infections have been related to gram-negative bacteria. These infections could involve any part of the eye and vary in their course and treatment. Keratitis, dacryocystitis, cellulitis, conjunctivitis, corneal ulcer infections, and endophthalmitis are examples of ocular diseases that could be a result of gram-negative bacterial pathology.

Gram-Positive Bacteria

Khaled Tuwairqi
Wilmer Eye Institute, Baltimore, MD, USA
Department of Ophthalmology, University of Utah, Salt Lake City, UT, USA

Definition

A group of microorganisms that will stain crystal violet on gram staining method.

Structure

The main theme for the gram-positive bacteria is a thick layer of peptidoglycan that will provide protection and maintain the cell wall shape and structure. Additionally, few bacteria have lipoteichoic acid and teichoic acid in their walls. The main functions of teichoic acid are to further strengthen the cell wall, help in the sequestration of calcium ion, and act as an activator of innate immune system. Other structures which could be found regardless of the bacteria gram stain include capsule which is useful in the protection from phagocytosis, pili that are used by bacteria for adherence or sexual reproduction and flagellum for movement.

Function

Certain types of bacteria are found in the normal flora of human bodies. In the ocular flora, gram-positive bacteria that could be isolated include *Staphylococci*, *Corynebacterium*, *Streptococcus* species, and *Propionibacterium* species. Recent studies showed that this flora could help minimize the inflammations, act as a barrier against harmful pathogens, maintain the immune system, inhibit the apoptosis, and accelerate the wound repair.

Clinical Relevance

Many ocular infections have been related to gram-positive bacteria. These infections could involve any part of the eye and vary in their course and treatment. Hordeolum, blepharitis, keratitis, dacryocystitis, cellulitis, conjunctivitis, corneal ulcer infections, and endophthalmitis are examples of ocular diseases that could be a result of gram-positive bacterial pathology.

Synonyms

Dysthyroidal/thyroid-associated orbitopathy; Graves' orbitopathy; Thyroid eye disease

Definition

Graves disease (GD) is an autoimmune condition associated with hyperthyroidism. Thyroid eye disease (TED) is a disease of the orbit that typically presents with upper eyelid retraction, lid lag, swelling, erythema, conjunctivitis, and proptosis and can be associated with GD but is not unique to GD-related hyperthyroidism.

Epidemiology

GD occurs four times more often in females than in males. However, the prognosis for males is typically worse. Risk factors include age greater than 50, rapid onset of symptoms under 3 months, cigarette smoking, diabetes, hyperthyroidism, hyperlipidemia, and peripheral vascular disease.

History

Robert James Graves first described the disorder in 1835. The disease was associated with thyroid goiter and exophthalmos of the eye.

Clinical Features

TED is characterized by unilateral or bilateral upper eyelid retraction, lid lag in downward bilateral or unilateral proptosis, ophthalmoplegia, and sometimes compressive optic neuropathy.

Tests

After a complete ocular history and physical examination, if TED is suspected, then thyroid function studies (e.g., TSH, T3, T4) should be performed. Thyroid antibodies (e.g., TPO and TSIG antibodies) might also be helpful especially for confirming autoimmune hypothyroidism or in euthyroid patients. Orbital imaging including ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) of the orbit can be done if there is diagnostic uncertainty. The distinctive radiographic sign of TED is enlargement of the extraocular muscles typically with sparing of the tendon. The most common order of involvement for the extraocular muscles in TED is inferior rectus, then medial rectus, then superior rectus, and lastly the lateral rectus muscles.

Differential Diagnosis

Previous eyelid surgeries
Third, fourth, or sixth cranial nerve palsy
Myasthenia gravis
Parinaud syndrome

Etiology

GD is a systemic autoimmune disorder in which antibodies are produced against the receptor for thyroid stimulating hormone (TSH). The abnormally high production of T3 and T4 may lead to an enlargement of the thyroid gland, seen as a goiter. It is postulated that the TSH receptor antibodies share a similar antigen that is present on the extraocular muscles. Therefore, TSH receptor and other thyroid-related antibodies bind to extraocular muscles and cause TED.

Diagnosis

GD is a clinical syndrome supported by laboratory and radiographic testing.

Treatment

The patient should consult with a medical internist or endocrinologist for management of the autoimmune thyroid disease. Conservative treatment for exposure keratopathy includes artificial tears and lubricating ointment. Elevation of the head of the bed might be useful for lid and orbital edema. Prednisone can be used to treat inflammatory TED and might reduce proptosis, corneal ulceration, acute disturbing double vision, and visual loss from optic neuropathy. Patients with compressive optic neuropathy due to TED however may require surgical decompression. In general, the surgical treatment of TED should follow a stepwise approach with orbital decompression first as this might change the pattern of strabismus, then strabismus surgery second as this might alter the lid position, and then eyelid surgery last.

Synonyms

Dysthyroid ophthalmopathy; Thyroid eye disease; Thyroid-associated orbitopathy

Definition

Graves' disease is an autoimmune inflammatory disorder that affects orbital and periorbital tissue. It is associated with hyperthyroidism at some point in most patients, although in less than 10% of cases, patients are hypothyroid or euthyroid.

Clinical Presentation

Graves' disease is always a bilateral process, although it is often asymmetrical. Many of the clinical signs and symptoms arise from soft tissue enlargement in the orbit including both extraocular muscles and adipose tissue. Patients under 40 years of age typically have a predominance of fat expansion, while patients over 60 years of age often have more extraocular muscle swelling. Although multiple muscles may be involved, the inferior rectus is the most common, followed by the medial rectus.

The most common symptoms include orbital pain or discomfort, diplopia, lacrimation, photophobia, and dry eye symptoms. The clinical

characteristic signs include lid retraction with temporal flare, lid lag, exophthalmos, restrictive extraocular myopathy, erythema of the periorbital tissues, or conjunctiva and corneal exposure. Three to five percent of cases are sight threatening due to optic nerve compression or corneal decompensation.

In patients with hyperthyroidism, pretibial myxedema and acropachy, which manifests as clubbing of the fingers or toes, may occur. The course of ophthalmopathy does not necessarily parallel the state of thyroid dysfunction.

Diagnosis

Diagnosis of thyroid abnormalities can be made with thyroid studies. Measurement of circulating thyrotropin-receptor antibodies may have diagnostic value due to their high specificity and sensitivity for Graves' disease. Orbital imaging with computed tomography (CT) or magnetic resonance imaging (MRI) may show fusiform extraocular muscle enlargement with sparing of the tendons and/or an increase in orbital fibroadipose tissue. Neuroimaging is particularly useful to evaluate optic nerve compression by enlarged muscles, especially at the orbital apex, known as apical crowding.

Differential Diagnosis

Orbital inflammatory syndrome, preseptal or orbital cellulitis, sarcoidosis, orbital metastases, dorsal midbrain syndrome, carotid-cavernous fistula.

Prophylaxis

Primary prevention of the disease is not feasible. However, the strongest modifiable risk factor is cigarette smoking, with a 7.7 odds ratio of developing the disease in smokers versus nonsmokers. Early and accurate control of thyroid dysfunction may also be important.

Therapy

Thyroid dysfunction should be treated if present with antithyroid medications or radioactive iodine. However, radioiodine therapy can cause progression of ophthalmopathy in about 15% of patients, especially in smokers and patients with severe hyperthyroidism, which may be prevented with concomitant treatment with oral prednisone.

Specific treatment depends on the severity of the disease. Patients with mild disease only require supportive therapy including ocular lubrication for dry eye or temporary prisms for diplopia.

For more severe disease, therapy is directed toward decreasing inflammation or acute orbital congestion with systemic corticosteroids or orbital radiotherapy, particularly for impaired motility.

Approximately 20% of patients require surgical intervention. Surgery is generally considered only after stabilization of the disease. Orbital decompression surgery is often done to restore normal globe position by expanding the orbital bony volume. Strabismus surgery and eyelid surgery to correct eyelid retraction may be indicated to correct diplopia and for cosmesis. If multiple surgeries are indicated, orbital decompression is done first, followed by strabismus surgery and then eyelid surgery.

Urgent intervention without waiting for stabilization may be needed to treat or prevent optic neuropathy or corneal decompensation by high-dose systemic corticosteroids, orbital radiotherapy, or orbital decompression.

Prognosis

Generally there is an initial active phase lasting 1–2 years, followed by stabilization. Only 5–10% of patients have reactivation of inflammation over their lifetime.

Smokers have a poorer prognosis, a longer duration of disease, and are less likely to respond to immunosuppressive therapy. Other poor prognostic features include male gender, older age,

rapidly progressive disease, and presence of dermopathy.

Epidemiology

Graves' disease has an annual incidence of 16 women and 3 men per 100,000 population. Two age peaks of incidence are observed in the fifth and seventh decade of life, varying slightly between men and women.

Groenouw Dystrophy Type 1 Disease

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

Granular corneal dystrophy type I

Definition

First described by German ophthalmologist Arthur Groenouw in 1890; Groenouw Dystrophy Type 1 is a bilateral, progressive, noninflammatory corneal condition marked by the development of focal anterior stromal opacities in a granular pattern.

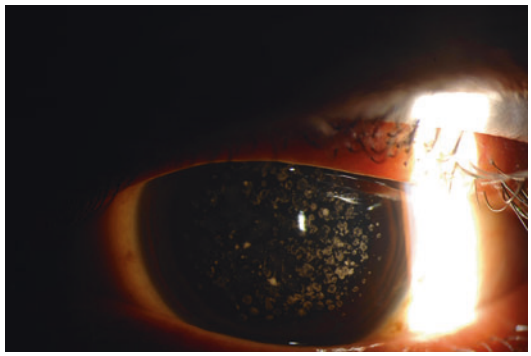
Etiology

A mutation in the TGFBI gene from Arg to Trp at position 555 in Chromosome 5q31 codes for keratoepithelin and is causative for Groenouw Dystrophy. It is inherited through autosomal dominant inheritance.

Clinical Presentation

Groenouw Dystrophy Type 1 often presents in childhood, affecting males and females equally. Patients are initially comfortable but may develop photophobia from light scattering and/or discomfort from recurrent corneal erosions. Visual acuity may be maintained for decades, until the disease has progressed to an advanced state.

On physical examination, central, fine, granular "bread crumb-," snowflake-, or ring-like lesions with empty intervening spaces present in the anterior stroma (Fig. 1). The peripheral cornea is often spared. With slit-lamp examination, lesions are opaque with direct illumination but translucent with retroillumination. Superficial



Groenouw Dystrophy Type 1 Disease, Fig. 1 Corneal photograph of a 37-year-old male with Groenouw Dystrophy Type 1, confirmed with genetic testing for the common TGFBI mutation

lesions may be associated with negative fluorescein staining.

Diagnosis

Diagnosis is primarily conducted by slit-lamp biomicroscopy. While focal lesions are generally round, lines may radiate from the individual lesions and should not be confused for lattice lines. Genetic testing for TGFBI mutations is commercially available and can help to differentiate Groenouw Dystrophy Type 1 from Avellino corneal dystrophy but is not necessary for diagnosis.

Histological evaluation of the cornea, conducted if corneal transplant is required, reveals strong, bright red staining of hyaline deposits with Masson Trichrome and weak staining with period acid-Schiff. These deposits may be eosinophilic, rod-like or trapezoidal in shape, and are appreciated anteriorly but can be deposited throughout the stroma.

Differential Diagnosis

Groenouw Dystrophy I differs clinically from Avellino corneal dystrophy (or granular-lattice corneal dystrophy) in that it is without lattice lines, although ray-like features in granular deposits may be deceiving in appearance. Both conditions originate from mutations in *TGFBI*. While both conditions demonstrate staining with Masson trichrome, amyloid deposits in Avellino corneal dystrophy stain positively with Congo Red. Laboratory genetic testing is beneficial in cases of a diagnostic dilemma.

Prophylaxis

None. Groenouw Dystrophy Type 1 is inherited; no known genetic therapy exists at this time.

Therapy

Many patients have few symptoms, requiring no treatment. Lubrication is helpful in the setting of recurrent corneal erosions.

In cases of advanced disease, surgical intervention is based on lesion depth, which can be measured with anterior segment optical coherence tomography. Superficial keratectomy or epithelial scraping can be utilized to address subepithelial deposits. Argon-fluoride excimer laser ablation may reduce or eliminate deposits in the anterior stroma, although vision may be limited by posterior lesions. Deep anterior lamellar keratoplasty or penetrating keratoplasty may be utilized in the setting of deep lesions.

Prognosis

Visual acuity is generally well maintained until middle age, but patients may present with severe disease at an earlier age, particularly those homozygotic for the mutation in TGFBI. Stromal haze may develop between hyaline granules in advanced disease, affecting visual acuity.

Phototherapeutic keratectomy in early-to-middle age maintains corneal transplantation as a future surgical option. Recurrence of Groenouw corneal dystrophy following corneal transplantation is common and independent of the size or type of graft. Lesions often re-appear superficially but may differ from primary presentation, appearing peripherally.

Epidemiology

Rare.

Guerin (Maxillary) Fracture

Gary Joseph Lelli[1], Dara Liotta[2] and Ashutosh Kacker[2]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Otorhinolaryngology, Weill College of Medicine of Cornell University, New York, NY, USA

Synonyms

Horizontal fracture; Le Fort I fracture; Maxillary fracture

Definition

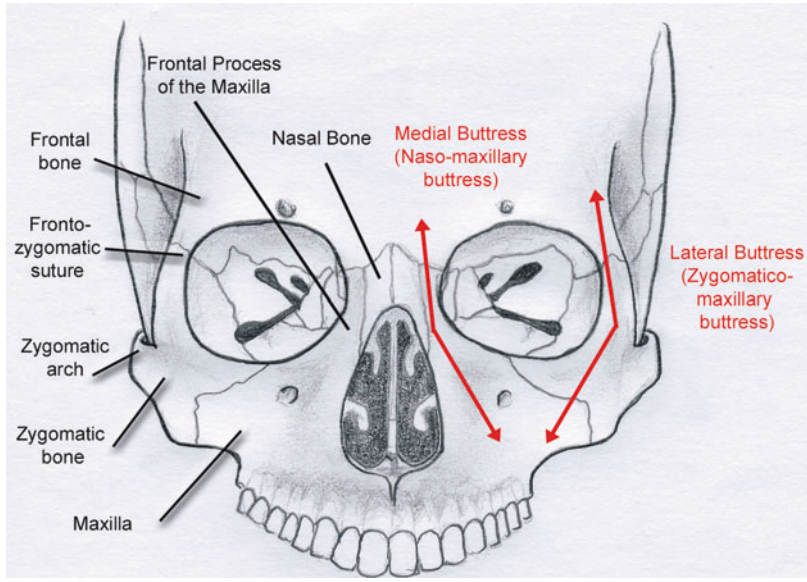
In 1901, Rene Le Fort categorized fracture patterns of the Maxilla resulting from a single blow to cadevaric skulls. The fracture lines, or "linea minoros resistentiae," described by Le Fort in 1901 are the basis for the modern Le Fort classification. The midface is attached to the cranium by three vertical buttresses that help distribute masticatory forces and stabilize the midface: the medial buttress (frontomaxillary buttress) and lateral buttress (zygomatico-maxillary buttress) anteriorly and the pterygomaxillary buttress posteriorly. The fractures described by Le Fort disrupt these buttresses. A Guerin fracture is equivalent to a Le Fort I fracture (also known as a horizontal fracture) and is a single horizontal fracture through the maxilla that passes through the septum medially, extending laterally through the pyriform rims, passing below the zygomatico-maxillary suture line, and transecting the pterygomaxillary junction to interrupt the pterygoid plates (Cummings 2005). Guerin fractures result in a mobile hard palate. It is important to realize that pure Guerin fractures are uncommon in clinical practice, and most midfacial fractures are an amalgam of various types of midfacial fractures (Figs. 1, 2, 3, and 4).

Etiology

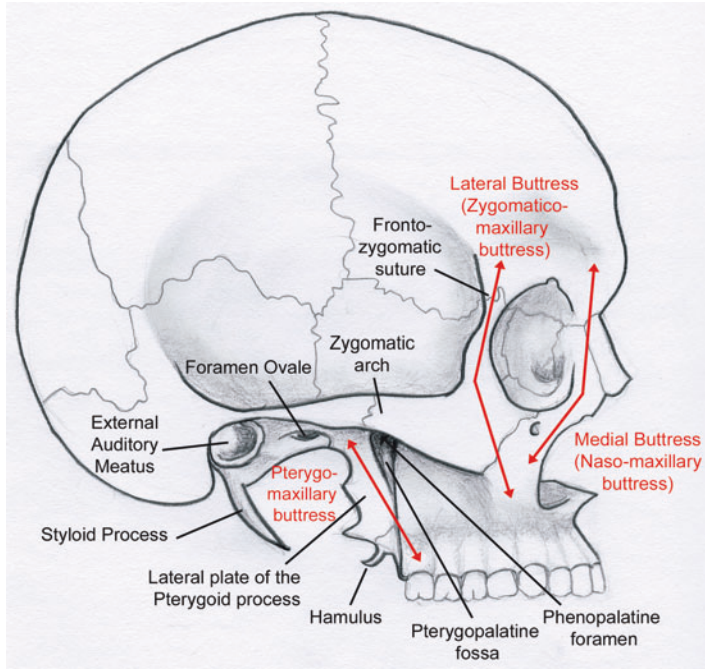
Guerin fractures are generally the result of blunt-force trauma to the midface. More specifically, Guerin fractures are most likely to occur after a blow to the inferior aspect of the maxilla, the maxillary alveolar ridge, directed downward. Common causes include motor vehicle accidents, interpersonal altercations, assaults, falls, and sports-related injuries.

Clinical Presentation

In the case of isolated Guerin fracture, overt clinical signs can be minimal (Papel 2002). Intraoral ecchymosis, lacerations, or palpable step-offs may be appreciated. The mobile bone

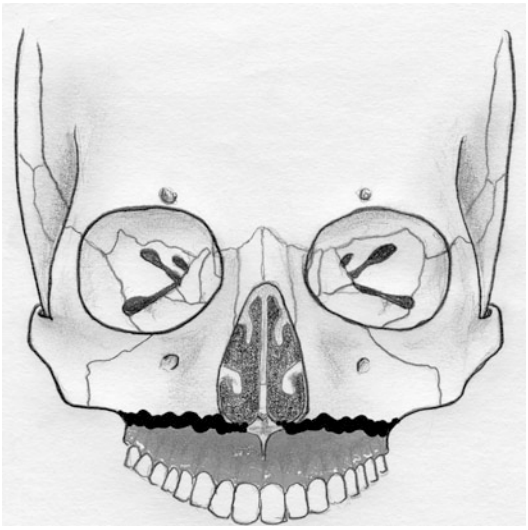


Guerin (Maxillary) Fracture, Fig. 1 Anteroposterior view of the vertical buttresses of the facial skeleton

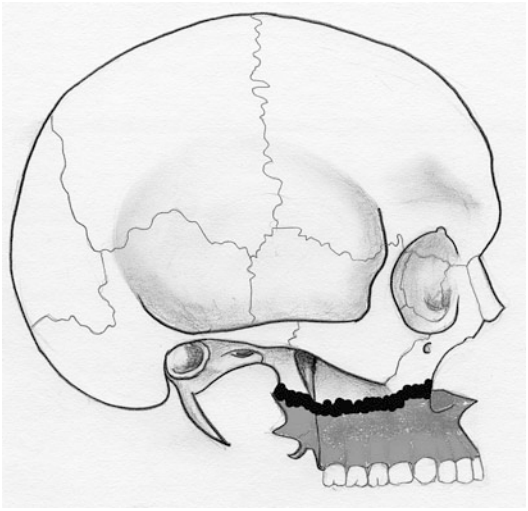


Guerin (Maxillary) Fracture, Fig. 2 Lateral view of the vertical buttresses of the facial skeleton

fragment resulting from a Guerin fracture tends to be driven posteroinferiorly along the slope of the skull base, resulting in malocclusion and an anterior open bite with posterior molars contacting before incisors. There may be crepitus at the gingival buccal sulcus from subcutaneous emphysema. Mobility of the hard palate at the pyriform rims can generally be appreciated. Palatal fractures and fractures of the dentoalveolar ridge may also occur. Significant facial edema is



Guerin (Maxillary) Fracture, Fig. 3 Anteroposterior view of a Guerin fracture (Le Fort I fracture or horizontal fracture). The *shaded area* represents the resultant mobile bone fragment



Guerin (Maxillary) Fracture, Fig. 4 Lateral view of a Guerin fracture. The *shaded area* represents the resultant mobile bone fragment

common with midfacial fractures, and it is important to keep in mind that presence of a Guerin fracture does not rule out presence of additional maxillofacial injuries.

Diagnostics

Maxillary fractures often occur as the result of significant trauma, and evaluation should begin with airway control and hemodynamic stabilization. Serious intracranial injury may be seen in up to 38% of patients with midfacial fractures; serious ophthalmologic injury may be seen in up to 28% of patients. Spinal cord injury should be ruled out, and any overt globe injury should be evaluated. A thorough history and physical, including a complete head and neck exam, may then be performed. With any midfacial fracture, suspicion for CSF rhinorrhea and/or otorrhea should be high. Examination of dental occlusion is important. Maxillofacial CT scan is considered the modality of choice for diagnosis of Guerin fractures.

Differential Diagnosis

Le Fort II fracture, Le Fort III fracture, naso-orbital-ethmoid fracture, zygomatico-maxillary complex fracture, palatal fracture.

Prophylaxis

The use of restraints, seat belts, and protective headgear can help prevent maxillary fractures.

Therapy

Treatment of ocular and CNS injuries should precede treatment of Le Fort fracture in the presence of a stable airway. Proper repair of complex midfacial fractures may require a surgical airway. When palatal fractures are present, the repair generally requires a custom-made reducing splint adapted to the palatal fragments and wired to the maxillary teeth. Palatal fractures should be reduced before plating of other maxillary fractures to ensure that proper dental occlusion is ultimately restored. Proper plating of Guerin fractures first requires mobilization of the resultant bone fragment and application of intermaxillary fixation

(Stewart 2005). Reconstruction and plating of disrupted facial buttresses is an important part of restoring normal occlusion and vertical height of the midface and stabilizing the midfacial skeleton against masticatory forces. Perioperative antibiotics should be considered in patients with facial fractures.

Prognosis

Long-term prognosis after repair of Guerin fractures is excellent. Postoperative infection rates are low and generally resolve with oral antibiotics.

Epidemiology

Maxillary (Guerin) fractures are most common in men aged 21–40.

Gul Schematic Eye

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Schematic eyes are used in theoretically modeling the real human eye as an optical instrument. The most popular schematic eye currently used is the Gullstrand model eye, which was proposed by Allvar Gullstrand and for which he received Nobel Prize in 1911. This model assumes all the ocular surfaces to be spherical and mentions their radius of curvatures. The model also mentions the thickness and refractive indices of different media inside the eye (the refractive indices are defined for 587 nm wavelength).

It was well known even at the time of Gullstrand that the representation of the eye as an optical system made up of spherical surfaces and homogeneous refractive index medium is a simplification. The profiles of all the ocular surfaces in reality are aspheric, and the refractive indices can have a spatial variation (gradient refractive index). The Gullstrand's model however has been popular in the vision science area over the last century as it serves well for paraxial calculations. There are four different Gullstrand model eyes that are currently being used.

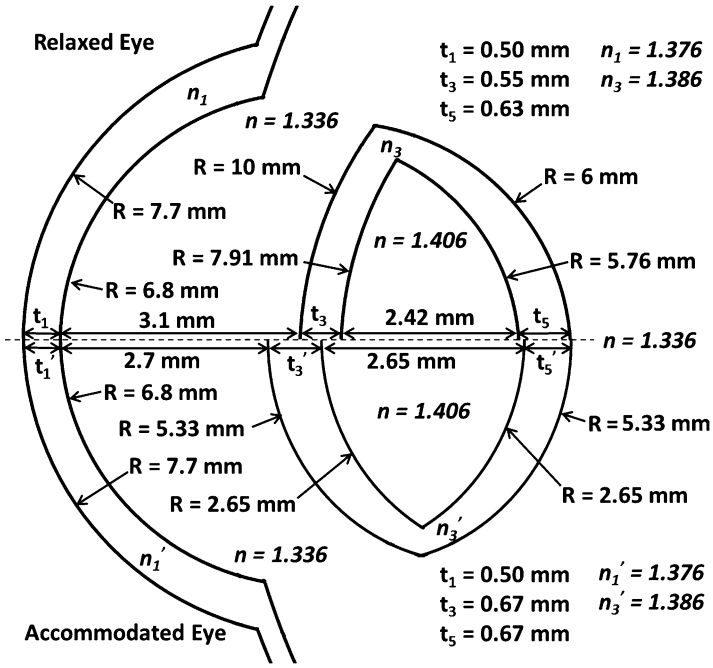
1. Gullstrand exact eye or Gullstrand eye #1
2. Simplified Gullstrand eye or Gullstrand eye #2
3. Gullstrand-Emsley eye
4. Gullstrand-Legrand eye

Gullstrand Exact Eye

Gullstrand exact eye is a detailed representation of the eye; it assumes the eye's optical system to be having six surfaces. The cornea in this model is described to be a two-surface element with finite thickness. The lens is described to

Gul Schematic Eye, Table 1 Structural parameters of Gullstrand exact eye

	Relaxed eye			Accommodated eye		
Surface	Radius (mm)	Thickness (mm)	Refractive index	Radius (mm)	Thickness (mm)	Refractive index
Anterior cornea	7.7	0.5	1.376	7.7	0.5	1.376
Posterior cornea	6.8	3.1	1.336	6.8	2.7	1.336
Anterior lens surface	10	0.55	1.386	5.33	0.67	1.386
Anterior lens nucleus	7.91	2.42	1.406	2.65	2.65	1.406
Posterior lens surface	−5.76	0.63	1.386	−2.65	0.67	1.386
Anterior lens nucleus	−6	17.18	1.336	−5.33	16.8	1.336
Image	−17.2			−17.2		



Gul Schematic Eye, Fig. 1 Gullstrand exact eye schematic

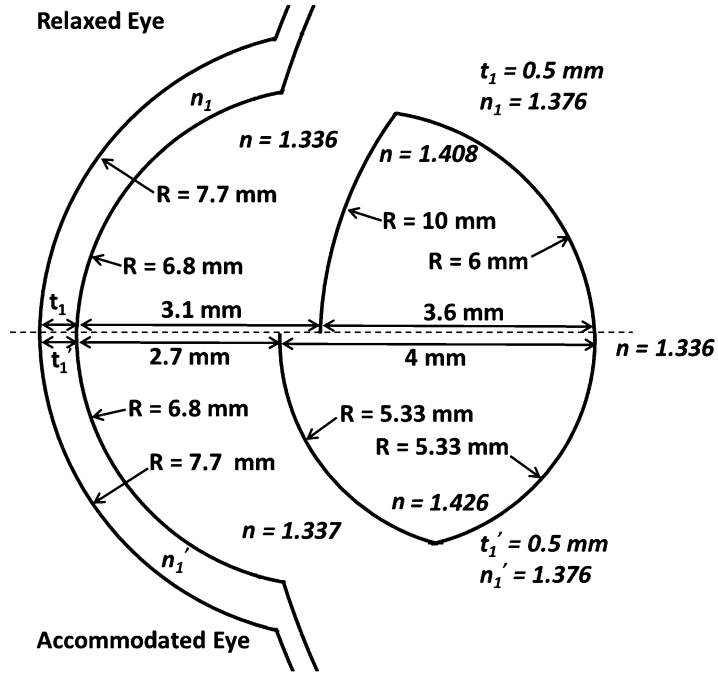
have an inner nucleus and outer shell thus making it a four-surface element. The model describes the eye in both relaxed and accommodated states. Table 1 gives the details on the dimensions and refractive indices for the relaxed and accommodated Gullstrand exact eye. Figure 1 shows the schematic of the Gullstrand exact eye.

Simplified Gullstrand Eye

This model is a simplified version of the Gullstrand exact eye, which assumes the eye's optical system to have four surfaces. The cornea in this model is the same as in the exact eye, while the crystalline lens is simplified to a two-surface element. Table 2 shows the structural parameters of

Gul Schematic Eye, Table 2 Structural parameters of simplified Gullstrand eye

	Relaxed eye			Accommodated eye		
Surface	Radius (mm)	Thickness (mm)	Refractive index	Radius (mm)	Thickness (mm)	Refractive index
Anterior cornea	7.70	0.50	1.376	7.70	0.50	1.376
Posterior cornea	6.80	3.10	1.336	6.80	2.70	1.336
Anterior lens surface	10.00	3.60	1.408	5.33	4.00	1.426
Posterior lens surface	−6.00	17.18	1.336	−5.33	13.82	1.336
Image	−17.20			−17.20		



Gul Schematic Eye, Fig. 2 Relaxed simplified Gullstrand eye schematic

this model. Figure 2 shows the schematic of the simplified Gullstrand eye.

Gullstrand-Emsley Eye

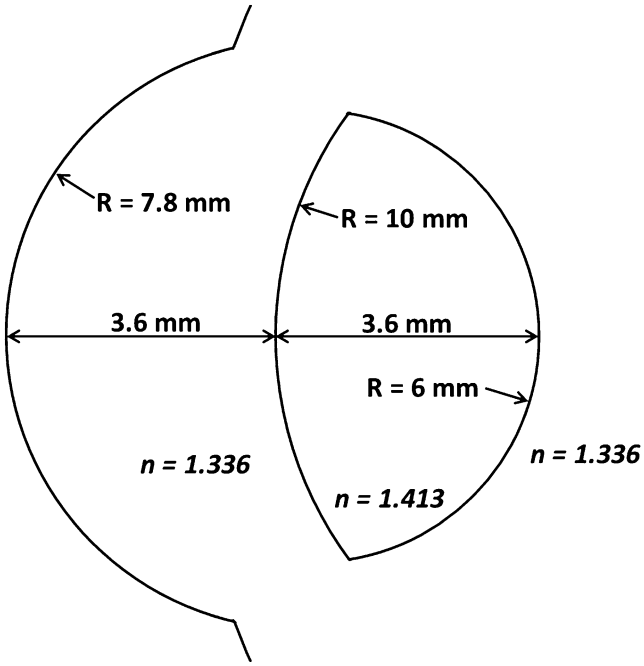
This model further simplifies the Gullstrand model by providing a three-surface representation of the eye where the cornea is assumed to be a single surface and the lens is assumed to be a two-surface optical element. Accommodated state of the eye is not described in the model. Table 3 shows the structural parameters of the model, while Fig. 3 shows the schematic of the Gullstrand-Emsley model eye.

Gullstrand-Legrand Eye

Gullstrand-Legrand eye is perhaps the most widely used Gullstrand model and is inspired from the simplified Gullstrand eye. As in simplified Gullstrand eye, this model also assumes the eye's optical system to have four surfaces,

Gul Schematic Eye, Table 3 Structural parameters of Gullstrand-Emsley eye

Surface	Radius (mm)	Thickness (mm)	Refractive index
Cornea	7.8	3.6	1.336
Anterior lens surface	10	7.2	1.413
Posterior lens surface	−6	17	1.336
Image	–		



Gul Schematic Eye, Fig. 3 Schematic of the Gullstrand-Emsley eye

Gul Schematic Eye, Table 4 Structural parameters of Gullstrand-Legrand eye

	Relaxed eye			Accommodated eye		
Surface	Radius (mm)	Thickness (mm)	Refractive index	Radius (mm)	Thickness (mm)	Refractive index
Anterior cornea	7.8	0.55	1.377	7.7	0.55	1.377
Posterior cornea	6.5	3.05	1.337	6.5	2.65	1.337
Anterior lens surface	10.2	4	1.42	6	4.5	1.42
Posterior lens surface	−6	16.6	1.336	−5.5	14.23	1.336
Image	−17.2			−17.2		

two for the cornea and two for the crystalline lens. The curvature, thickness, and refractive index values however are different. This model also describes both relaxed and accommodated states. Table 4 shows the structural parameters of the model. Figure 4 shows the schematic of the Gullstrand-Legrand model eye.

Synonyms

Bacterial conjunctivitis; Pink eye

Definition

Haemophilus influenzae is a causative bacterial agent responsible for acute and purulent conjunctivitis, or inflammation of the conjunctiva.

Structure

Haemophilus influenzae is a small pleomorphic, gram-negative coccobacillus (Cherry et al. 2014). This organism is nonmotile, non-spore forming, and facultatively anaerobic. H influenzae is unique in that it requires growth supplementation, factor X and V. There are roughly eight biotypes and six serotypes (Tindall 2008). The eight biotypes are categorized by the presence or absence of indole, urease, and ornithine decarboxylase. The serotypes (a–f) are based upon the type of polysaccharide capsule around the organism. Unencapsulated forms of the organism also exist. These unencapsulated forms typically cause a variety of mucosal infections, including conjunctivitis (Cherry et al. 2014).

Function

The bacteria colonize the human respiratory tract (Tindall 2008). Asymptomatic colonization may be present. Transmission occurs through direct contact with or inhalation of respiratory secretions. Mucosal infections involve movement of H influenzae through the nasal ostia to the sinuses and up the Eustachian tubes (Cherry et al. 2014). Infection of the eye may occur

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

following this transmission after an episode of sinusitis or otitis media.

Clinical Relevance

Prior to the development of H influenzae type b vaccine, H influenzae was an important cause for several bacterial infections (Tindall 2008). Related ophthalmic diseases include conjunctivitis and orbital cellulitis. H influenzae carries increased transmission and risk among pediatric populations. Children are at increased risk in centers such as day-care or nurseries.

Diagnosis of conjunctivitis secondary to H influenzae is made via clinical presentation and laboratory findings. Patients with a recent history of upper respiratory infection, sinusitis, or sinus surgery are at increased risk for H influenzae-associated conjunctivitis (Tindall 2008). Patients may have symptoms of eye redness, pain, blurred vision. Laboratory findings include positive gram stain and culture growth. Of note, chocolate agar medium is required for this organism.

Once identified, treatment for conjunctivitis is topical fluoroquinolone eye drops ranging from four times per day to hourly depending on disease severity (Tindall 2008).

Definition

A hallucination is a sensory perception lacking the appropriate real external stimulus of that sensory system, including any of the five senses. Visual hallucinations (VH), in particular, might occur as the result of various underlying neurological etiologies, or they might occur as an isolated instance without defect of cognition or mental function.

Etiology

A hallucination, simple or complex, can be a symptom of many underlying causes.

Hallucinations may be present as a symptom of a dementia (e.g., Alzheimer's), confusion (e.g., epilepsy, delirium, stroke, alcohol withdrawal), or psychiatric etiologies (e.g., schizophrenia, narcolepsy). Hallucinations with these origins might involve multiple sensory systems (multimodal hallucinations) as well as other symptoms of the underlying mental illness.

Drugs as well as some metabolic disorders have been known to cause visual hallucinations. Drugs, such as MDMA or 3,4-methylenedioxymethamphetamine (aka "ecstasy") or lysergic acid diethylamide (LSD), are "hallucinogens" that can result in VH or other perception disturbances. Likewise, dopamine agonists, serotonin agonists, atropine, and other prescription drugs can also result in VH. Metabolic disorders such as Niemann-Pick disease, α-mannosidosis, or urea cycle defects have been known to cause VH.

Patients with intact mental and cognitive function who experience visual hallucinations may fall into one of three main pathophysiologic groupings of VH: (1) release hallucinations (e.g., Charles Bonnet syndrome due to visual loss), (2) seizures (e.g., temporal or occipital lobe seizures), and (3) migraine aura (see ▶ Charles Bonnet Syndrome: Overview, and ▶ Occipital Seizures: Transient Visual Loss).

History

The description of what is clinically considered a hallucination is prevalent in the earliest known medical writings. However, the first modern use of the term hallucination was defined by Jean-Etienne Esquirol in his book *Des Maladies Mentales* in 1837.

Clinical Presentation

Depending on the type of VH, presentation can range from seeing spots and patterns to seeing complex visual images as detailed as people or animals. Various etiologies can result in a large variety of associated symptoms with VH including migraine hallucinations (visual aura) with a severe unilateral headache or complex VH with few other associated symptoms (see ▶ Peduncular Hallucinosis).

Treatments

Treatments for VH should be directed at the underlying etiology.

Prognosis

The expected recovery of the VH depends on the underlying etiology and its respective treatments.

Epidemiology

Recent studies combining surveys from various countries, including the United States, Germany, and Italy, have determined the prevalence of VH in the general population to be 7.3%. When drug-induced VH and VH as a result of physical illness were excluded from this combination of surveys, the general population still exhibited a VH prevalence of 6%. VH is also known to be a common symptom in psychotic disorders, such as schizophrenia (27%) or bipolar and affective disorder (15%). There has been contradictory information regarding the prevalence of VH in men versus women in the general public. With regard to age, there is a bimodal distribution of the greatest incidence of VH during a lifetime: first in late adolescence/early adulthood and second in late life. The late adolescent/early adulthood peak is related to the higher incidence of psychosis, while the late in life peak correlates with a higher incidence of brain and eye diseases with VH as a symptom.

Synonyms

Leprosy

Definition

Chronic granulomatous inflammation of the peripheral nerves, skin, and mucus membranes caused by the intracellular bacteria *Mycobacterium leprae*.

Etiology

Hansen's disease is caused by the *M. leprae* bacteria which is only mildly contagious. The intracellular bacteria infect the eye and other parts of the body by direct inoculation and primarily reside in peripheral, cutaneous nerves. *M. leprae* shows a predilection for the cutaneous Schwann cells and grows best at lower temperatures of 27–30 °C. *M. leprae* down-regulates myelin gene expression in nerves and this process eventually results in peripheral neuropathy. *M. leprae* also causes a chronic granulomatous inflammation that damages local organs and structures (Nunzi and Massone 2012).

The spectrum of disease, classified by the Ridley-Jopling classification system, depends on the patient's unique immune system and response to the bacteria, which is determined by each patient's human leukocyte antigen (HLA) composition. Responses range from tuberculoid leprosy (TT), characterized by a strong inflammatory response and few bacteria, to lepromatous leprosy (LL) marked by minimal inflammatory response

and ample bacteria. Any inflammatory response with signs of both TT and LL leprosy is designated as "borderline." There are also two subtypes of leprosy-related inflammatory responses: type 1, primarily T-cell-mediated delayed hypersensitivity, and type 2, primarily B-cell-mediated humoral response based on antigen-antibody complex deposition. TT is associated with a type 1 reaction and LL is associated with a type 2 reaction. While most patients have predominantly a type 1 or type 2 inflammatory response, a switch in the type of inflammation, known as a "reversal reaction," can occur spontaneously during the disease course or as a result of the initiation of multidrug therapy (Hussein and Schwab 2013).

Clinical Presentation

Clinically, it is generally rather easy to distinguish between the polar forms of tuberculoid leprosy and lepromatous leprosy. Tuberculoid leprosy presents with mostly local symptoms confined to the skin. These lesions are hypopigmented macules with raised edges and no nerve sensation resulting in anhidrosis and anesthesia. In contrast, lepromatous leprosy presents with systemic symptoms and is much more severe than the tuberculoid form. There is greater nerve involvement and subsequently greater disability. Signs and symptoms of lepromatous leprosy are a result of nerve demyelination and chronic granulomatous inflammation and differ depending on the body part affected. There are confluent papules and nodules and diffuse infiltration of the skins resulting in leonine facies and madarosis (Eichelmann et al. 2013). Diffuse deposition of immune complexes can lead to fever, malaise, painful erythematous skin nodules, and multi-organ involvement, including the eye. It is far more common for patients with lepromatous leprosy to have ocular involvement than tuberculous leprosy patients (Yanoff and Duker 2009).

Peripheral neuropathy and granulomatous inflammation are responsible for the ocular pathology present in patients with Hansen's disease. Neuropathy can affect both motor and sensory nerves. In the ocular adnexa and ocular surface, demyelination of superficial branches of cranial nerves V and VII cause ectropion, lagophthalmos, and anesthetic corneas with decreased blink reflex, leading to greater susceptibility to exposure keratitis and corneal ulceration (Nunzi and Massone 2012). Denervation of the lacrimal gland results in xerophthalmia or aqueous tear deficiency dry eye. Nonreactive pinpoint pupils occur with denervation of iris dilator muscles and parasympathetic denervation causes difficulties in accommodation. Thickened edematous corneal nerves on exam are pathognomonic of leprosy (Hussein and Schwab 2013).

Granulomatous inflammation in the ocular adnexa leads to destruction of hair follicles and meibomian glands resulting in eyebrow loss, madarosis, and lipid deficiency dry eyes. Dacryocystitis occurs with bacterial invasion of the nasolacrimal duct. Within the eye, miliary lepromas cause punctate keratitis and subepithelial immune infiltrates that can coalesce and obscure vision. Corneal lepromas occur at the limbus or sclera, most commonly at the cooler interpalpebral fissure, and can extend across the cornea. Scleral thinning, scleromalacia, and staphylomas occur with chronic granulomatous inflammation. Iris pearls are pathognomonic for ocular leprosy, arising near the pupil edge, and can coalesce, detach, and obstruct the angle. Recurrent iritis can result in iris atrophy and synechia (scar) formation (Hussein and Schwab 2013). Ultimately, mild chronic uveitis and complex cataract formation is the principal cause of blindness (Nunzi and Massone 2012).

Diagnosis

Hansen's disease can be clinically diagnosed if a patient has not completed a treatment regimen for leprosy and has one or more of three cardinal signs including (1) a hypopigmented or erythematous skin lesion with sensory loss, (2) a thickened peripheral nerve, or (3) a positive skin smear or acid-fast bacilli observed in a biopsy. The diagnostic sensitivity of all three cardinal signs that are present has been shown to be as high as 97%. Corneal scrapings can confirm ocular

involvement as well as anterior chamber or vitreous taps showing acid-fast bacilli (Eichelmann et al. 2013).

Differential Diagnosis

Tuberculosis
Brucellosis
Sarcoidosis

Prophylaxis

M. leprae is mildly communicable and thought to be spread from person to person via respiratory droplets. Overcrowding and prolonged contact with infected individuals are known risk factors for developing the disease (Hussein and Schwab 2013). Armadillos are the only other known reservoirs for *M. leprae* and thus avoidance should be advised though transmission is rare (Eichelmann et al. 2013).

The BCG vaccine, developed against *Mycobacterium tuberculosis* has been shown to bestow up to 50% protection against *Mycobacterium leprae*. When heat-inactivated *M. leprae* organisms are added to the vaccine, up to 64% resistance is conferred (Eichelmann et al. 2013).

Therapy

Primary therapy includes rifampicin and dapsone for 6 months for tuberculous leprosy. In patients with lepromatous leprosy, clofazimine is added to the regimen and therapy is extended to 12 months (Hussein and Schwab 2013). A combination of medications is used to prevent emergence of drug resistance and quickly reduce the chances of transmission. Second-line therapy includes minocycline, ofloxacin, and clarithromycin, which have been shown to be more efficacious, yet use is limited due to higher cost. Initiation of multidrug therapy often results in a "reversal reaction," a brisk inflammatory response that needs to be controlled with a prolonged course of systemic prednisone or thalidomide (Eichelmann et al. 2013).

Prognosis

Prognosis is dependent on the stage of disease and extent of neuropathy at the time of diagnosis. Ocular pathology increases with disease duration; therefore, early diagnosis and treatment leads to a better outcome (Malik et al. 2011).

Epidemiology

In 2011 almost 220,000 new cases of leprosy were detected worldwide, the vast majority in Southeast Asia (Global 2012). Sight-threatening ocular complications are seen in approximately 20% of patients, the vast majority being patients with lepromatous leprosy (Malik et al. 2011).

Haptic

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Intraocular lens haptics

Definition

Haptic means relating to or based on the sense of touch. With regard to the design of an intraocular lens, haptic is the part of the lens that does not take part in focusing light but holds the lens in place (Kohnen and Koch 2009).

Epidemiology

Every intraocular lens (IOL) consists of an optic and a haptic.

Clinical Features

IOL haptics material can be made of polypropylene, polyvinylidene fluoride homopolymer, polyamide, PMMA, silicone, or acrylic. If the optic of the IOL is made of the same material as the haptic, the IOL is a single-piece IOL, if haptic and optic are made of two different materials, the IOL is a three-piece IOL. Generally, "plate"-haptics, "C"-haptics, "loop"-haptics, and "three"- or "four"-point haptics are differentiated. The term angulation refers to the angle between the optic of the IOL and the haptic (Werner 2008; Kohnen et al. 2009).

Tests

In biomicroscopic evaluation of an implanted IOL, the type of haptic can usually be assessed.

Differential Diagnosis

Every intraocular lens has an optic and a haptic.

Etiology

The term haptik refers to Greek "haptein" which means "to touch."

Treatment

In scope of aphakic, pseudophakic, or phakic IOL implantation, the haptic is inserted in the capsular bag, ciliary sulcus, anterior chamber angle, or enclavated in the iris.

Hard Palate Graft

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Eyelid spacer graft; Tarsal substitute

Definition

Free graft of hard palate taken from the oral cavity and transplanted to the lower eyelid as a spacer graft and substitute for posterior lamellar (conjunctiva and tarsus) replacement, and as a posterior and middle lamellar (orbital septum) stent in postsurgically retracted lower eyelids.

Indication

Utilized in lower eyelid reconstruction for posterior lamella (conjunctiva and tarsus), inadequacy secondary to eyelid cancer excision, trauma, or congenital defects. Also, used as a posterior/middle lamellar stent in the repair of postsurgical lower eyelid retraction and scleral show.

Contraindication

Patients with significant oral disease may not be adequate donors. Hard palate is usually avoided as a tarsal replacement in the upper eyelid because of the presence of keratinized epithelium, which can abrade the cornea.

Techniques and Principles

Assessment of the degree of posterior lamellar inadequacy or the degree of lower eyelid retraction and scleral show is performed and the proper graft size determined. The graft is harvested from the hard palate between the midline raphe and the gingival surface of the teeth, avoiding the soft palate posteriorly. The donor site is left to heal by secondary intention; however, placement of a prefabricated dental stent can help minimize postoperative discomfort. The graft is then trimmed and thinned with scissors to the desired size. The graft is sutured in place, mucosal surface toward the globe, with absorbing sutures to reconstruct the posterior lamellar defect. In cases of lower eyelid retraction, the graft is sutured to the lower border of the tarsus superiorly and the cut edge of conjunctiva inferiorly. The lower eyelid is usually placed on upward stretch for 1 week with Frost sutures to facilitate healing and avoid corrugation of the graft.

Outcome

The hard palate graft undergoes a variable degree of contraction postoperatively but usually provides for long-term posterior lamellar replacement and/or middle lamellar support.

Complications

Graft failure and slough with contraction and failure to reconstruct the eyelid are possible. Donor site infection is also possible. Corneal irritation and possible abrasion from the keratinized epithelium, particularly when utilized as a tarsal replacement, can occur.

Heerfordt's Syndrome

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Synonyms

Uveoparotid fever

Definition

Heerfordt's syndrome is a rare form of sarcoidosis in which patients present with fever, uveitis, parotitis, and/or seventh nerve palsy.

Etiology

As a rare form of sarcoidosis, the etiology for Heerfordt's syndrome disease is unknown. The disease process involves T-cell-mediated granulomatous inflammation.

Clinical Presentation

Heerfordt's syndrome usually presents acutely in younger patients with uveitis, fever, parotitis, and cranial nerve palsy, usually involving the seventh cranial nerve. With this facial nerve palsy, the patient may have incomplete closure of the eyelids on the affected side and may be unable to purse one's lips. The patient's parotid glands are generally firm and nontender. Patients may also have enlargement of the submandibular and lacrimal glands.

Patients may have other system signs of sarcoidosis such as skin lesions, pulmonary disease, and other less common manifestations such as neurological disease, arthritis, bone cysts, renal disease, lymphadenopathy, splenomegaly, liver disease, and cardiac arrhythmias. Pulmonary disease can manifest as bilateral asymptomatic hilar lymphadenopathy, diffuse reticulonodular infiltrates, or even pulmonary fibrosis which may result in pulmonary hypertension and cor pulmonale. Skin lesions may manifest as erythema nodosum, scattered plaques or nodules, lupus pernio, or deposits in long-standing scars.

Patients with Heerfordt's syndrome also may have ocular involvement most often presenting as uveitis. However, other ocular manifestations include keratoconjunctivitis sicca, conjunctival nodules, and, very rarely, scleral or orbital lesions. Patients can have an acute anterior uveitis or a chronic granulomatous uveitis. Patients with intermediate uveitis may present with snowballs. Other patients may have periphlebitis which would appear as yellowish or gray-white perivenous sheathing which can sometimes also involve the optic nerve. Severe periphlebitis will result in perivenous exudates called candlewax drippings. Although rare, choroidal infiltrates can present as many small, pale yellow "punched out" infiltrates, multiple large confluent lesions with amoeboid

margins, or exceedingly rarely as solitary choroidal granulomas. Other ocular findings can include retinal granulomas, peripheral retinal neovascularization secondary to retinal capillary drop out, a nummular keratitis, and optic nerve involvement. Optic nerve involvement could include focal granulomas by the optic nerve, papilledema secondary to central nervous system involvement, or persistent disk edema associated with vitreous or retinal involvement.

Diagnosis

Although only 6% of patients with sarcoidosis present with parotid involvement, the additional presenting symptoms of fever, uveitis, and facial nerve palsy make Heerfordt's syndrome extremely likely. Ultrasound-guided biopsy of the enlarged parotid glands may be utilized for histologic diagnosis, but other involved glands may be biopsied instead.

For a diagnosis of sarcoidosis, enzyme assays of angiotensin-converting enzyme (ACE) and lysozyme levels in addition to biopsy are common methods used to arrive at this diagnosis of exclusion. Lung biopsy is the highest yield (90%). This is so even in asymptomatic patients with a normal chest X-ray. In patients with conjunctivitis with conjunctival nodules, biopsies are positive 70% of the time. In enlarged lacrimal glands, biopsies are positive 75% of the time, but in un-enlarged lacrimal glands, biopsy yield can be as low as 25%. Pulmonary function tests would show a restrictive lung disease pattern. A strongly positive Mantoux test to a tuberculin unit would make a diagnosis of sarcoidosis less likely. Chest radiographs will be abnormal in patients with general sarcoidosis 90% of the time.

Differential Diagnosis

The constellation of signs and symptoms of fever, parotitis, seventh nerve palsy, and uveitis makes Heerfordt's Syndrome extremely likely. However, other diagnoses such as lymphoma should be ruled out with ultrasound biopsy of the enlarged parotid glands.

Differential diagnosis of posterior segment sarcoidosis is organized into small choroidal lesions, large choroidal infiltrates, and periphlebitis. Small choroidal lesions could also be tuberculosis, birdshot chorioretinopathy, or multifocal choroiditis with panuveitis. Findings of large choroidal infiltrates could also be large cell lymphoma, Harada disease, serpiginous choroidopathy, or metastatic tumor. Finally, other causes of periphlebitis could be Behcet syndrome, tuberculosis, or cytomegalovirus retinitis.

Prophylaxis

There is no prophylaxis for this disease.

Therapy

Therapy would be the same for sarcoidosis, generally high-dose steroids such as starting the patient on 60 mg per day of prednisone. Topical and/or periocular steroids would also be used for any anterior uveitis. If the patient has posterior uveitis, then the systemic steroids given for the systemic involvement in Heerfordt's syndrome would be of benefit as well. The patient may also require immunosuppressive agents such as methotrexate, cyclosporine, or azathioprine. Cyclophosphamide and infliximab have been shown to be useful in refractory disease as well.

Prognosis

Prognosis is generally good if patient has timely diagnosis and treatment. However, if the patient also presents with the multifocal choroiditis, then visual prognosis is especially guarded as the patient may develop choroidal neovascularization resulting in loss of central vision or a chorioretinal scar.

Epidemiology

Only 6% of patients with sarcoidosis present with parotid involvement. When the patient also has the other constellation of signs and symptoms of fever, uveitis, and/or facial nerve palsy, then the disease is called Heerfordt's syndrome. In regard to sarcoidosis, patients are more commonly of African rather than Caucasian descent. Patients with Heerfordt's syndrome are more commonly younger patients who present acutely.

Hemochromatosis

Aazim A. Siddiqui[1] and Allen O. Eghrari[2]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MA, USA

Synonyms

Hanot-Chauffard syndrome; Iron overload

Definition

Hemochromatosis is a systemic disorder of iron overload leading to eventual organ dysfunction.

Etiology

Primary hemochromatosis is the most common type of hemochromatosis and is due to autosomal recessive missense mutations on short arm of chromosome 6 in *HFE*. This gene encodes for an MHC class 1-like molecule that binds with transferrin receptor and affects hepcidin homeostasis. The subsequent defect of this pathway leads to increased iron absorption in the upper gastrointestinal tract, leading to iron deposition in parenchymal cells of the liver, heart, pancreas, joints, and endocrine organs.

The C282Y mutation is the most frequently identified causative genetic lesion, for which homozygosity confers the disease state. Patients heterozygous for this allele are carriers but generally do not demonstrate clinical disease. The exception is the compound heterozygote; carriers who also have the H63D mutation, prevalent among individuals of North Italian descent, may develop a milder form of iron overload. The homozygous C282Y mutation affects 5 in 1000 individuals with northern European descent.

Secondary hemochromatosis may also occur due to iron overload from external sources such as multiple blood transfusions, thalassemia, sickle cell anemia, or increased iron intake.

Occurrence

Hemochromatosis is a systemic disease with multi-organ involvement. Clinical symptoms generally appear between 40 and 60 years of age and primarily in homozygous males.

Externally, the location of deposits is found most frequently in an interpalpebral distribution. It may be found at the lid margins and is often present in both the upper and lower lids. Discoloration of the bulbar conjunctivae has been reported to occur in approximately 20% of patients, and rust-colored deposits may be appreciated within insertions of the recti muscles and sclera. The intervening conjunctival lymphatic channels render a radially striated appearance of the deposited pigments (Lazzaro et al. 1998).

In the cornea, iron deposits appear as fine dusting of the subepithelial and anterior stromal space, inferiorly greater than superiorly. A clear zone of 1.5 mm appears between deposits and the limbus. In an otherwise normal eye, these deposits are more broadly distributed in contrast to the iron lines seen with aging (Hudson-Stahli line), at the base of the cone in keratoconus (Fleischer ring), at the edge of a filtering bleb (Ferry line), or at the head of a pterygium (Stocker line).

Histopathological evaluation of eyes in patients with hemochromatosis postmortem reveals scattered iron granules deposited in the ciliary body, sclera, and iris, with an absence of iron in the choroid or retina. Although iron deposition has been noted in the peripapillary retinal pigment epithelium, these cases also have sparing of the neurosensory retina and choroid (Roth and Foos 1972).

Systemically, the diagnosis of hemochromatosis is often accompanied by arthralgia, fatigue, amenorrhea, infertility, and impotence and associated with hepatomegaly and cirrhosis. Approximately 85% of cirrhotic patients also develop secondary diabetes (known as "bronze diabetes") and are at risk for associated intraocular retinopathy. Dermatologic manifestation includes a characteristic bronze appearance of the skin.

Classification

Hemochromatosis may be primary (hereditary hemochromatosis, HH) or secondary (acquired hemochromatosis) in origin. This should be distinguished from hemosiderosis secondary to an iron-based intraocular foreign body.

Hereditary Hemorrhagic Telangiectasia (Osler-Weber-Rendu Disease)

Michael Coleman
Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Osler-Weber-Rendu syndrome

Definition

It is a familial syndrome characterized by the presence of multiple superficial telangiectasias (skin, lips, oral cavity, fingers, nasopharynx, and conjunctiva) combined with arteriovenous malformations (AVMs) of the internal organs (lung, brain, gastrointestinal tract, liver, and spinal cord) (Goldberg and Bullock 1990; Ferri et al. 2014).

Etiology

HHT is a rare autosomal dominant disorder that leads to dysplasia of blood vessels throughout the body (Goldberg and Bullock 1990; Ferri et al. 2014). Gene mutations lead to endothelial cell loss and weakness in the perivascular connective tissue with subsequent dilatation of the vessel wall. Most commonly, HHT patients have mutations in the endoglin and activin A receptor-like kinase 1 (ALK1) genes. Endoglin, SMAD4, and ALK1 are involved in cell surface signaling via the transforming growth factor-β (TGF-β) receptor complex (Morelli 2011; Rinaldi et al. 2011).

Type	Gene with associated mutation
HHT type I	Endoglin
HHT type II	ALK1
HHT type III	Unknown
Juvenile polyposis and HHT (JPHT)	SMAD4

Clinical Presentation

Classically, patients present with recurrent epistaxis or gastrointestinal bleeds due to telangiectasias of the nasopharynx or AVMs in the GI system. Epistaxis is the most common clinical manifestation (90% of affected patients), followed by gastrointestinal bleeding (20–40%) and pulmonary arteriovenous malformations (15–20%) (Morelli 2011; Rinaldi et al. 2011). This autosomal dominant disease produces a syndrome of multiple orocutaneous telangiectasias, especially on the face, lips, tongue, oral mucosa, conjunctiva, retina, and choroid, with associated internal AVMs. The cutaneous or mucosal lesions are typically bright red, non-pulsatile, and blanch under direct pressure.

Ocular symptoms are rarely the basis for the patient presentation to the ophthalmologist office. Patients can present with recurrent subconjunctival hemorrhages, bloody tears, conjunctival vascular tumors, or decreased vision secondary to macular edema as a result of a retinal vein occlusion, generalized retinopathy, or leaking retinal or choroidal telangiectasias in and around the macula (Goldberg and Bullock 1990; Morelli 2011; Rinaldi et al. 2011; Ferri et al. 2014).

Diagnosis

Curaçao Criteria:

- Spontaneous recurrent epistaxis
- Multiple telangiectasias (face, mouth, lips)
- Internal arteriovenous malformations
- First-degree relative with HHT

Diagnosis is defined by the presence of three criteria; two criteria give a possible diagnosis; and less than two criteria make the diagnosis unlikely (Rinaldi et al. 2011).

Differential Diagnosis

1. Recurrent subconjunctival hemorrhages
   (a) Conjunctival tumors
   (b) Amyloidosis
2. Conjunctival telangiectasia
   (a) Age-related vascular changes
   (b) Vascular arteriovenous malformations (AVMs)
   (c) Ataxia telangiectasia
3. Bloody tears
   (a) Lacrimal sac tumors or stones
   (b) Conjunctival inflammatory lesions (pyogenic granuloma)
   (c) Conjunctival/corneal tumors

Prophylaxis

Surveillance monitoring of ferritin levels and CBC to monitor for occult bleeds. These patients should be followed closely by their internists to monitor their AVMs, as they may increase in number and size as the patient ages.

Therapy

Therapy is targeted at leaking retinal or choroidal telangiectasia if vision is affected. Caution with intraocular surgery as these patients may have a higher risk of choroidal hemorrhage.

Prognosis

Patient's lifetime prognosis depends on the severity of vascular dysplasia. Visual prognosis depends on the extent of retinal and choroidal vascular abnormalities. If there is no retinal vessel dysplasia, visual acuity will remain normal.

Epidemiology

The incidence is estimated to be between 1 in 8,000 and 1 in 16,500 (Ferri et al. 2014). Approximately 1.2 million people suffer from HHT (Ferri et al. 2014). The frequency is equal between male and female.

Hereditary sensory and autonomic neuropathy

Definition

Collection of similar but distinct inherited neurodegenerative conditions characterized by progressive loss of peripheral sensation.

Etiology

Hereditary sensory neuropathies (HSNs), or hereditary sensory autonomic neuropathies (HSANs), arise from any of several mutations in several distinct genes. To date they are classified into five main subtypes (HSN/HSAN types I–V):

1. HSAN I

   The first and most common group of HSNs is characterized by autosomal dominant mutations of either the *SPTLC1* (serine palmitoyltransferase long-chain subunit 1) or the *RAB7* (a late endosomal GTPase protein) genes (Klein and Dyck 2005). The *SPTLC1* gene encodes a subunit of serine palmitoyltransferase (SPT), an important enzyme for the production of certain fats called sphingolipids. The mutations of this gene make SPT with reduced function, leading to a decrease in sphingolipids. Sphingolipids are found in myelin, and this decrease in sphingolipids disrupts myelin formation, resulting in loss of efficiency of nerve cells and eventually cell death (Klein and Dyck 2005). The RAB7 protein is a small GTPase late endosomal protein involved in axonal vesicular transport. The mutations of the *RAB7* gene negatively affect retrograde tubular extensions, resulting in axonal atrophy and degeneration (Klein and Dyck 2005). The net effect of reduced myelinated fibers and axonal degradation is loss of sensory neural signal transmission and reduced motor neuron signal transmission, typically manifesting in loss of pain sensation in the distal parts of the lower limbs. The onset of these symptomatic deficits ranges from the second decade to fifth decade (Katirji and Koontz 2012).
2. HSAN II, Congenital sensory neuropathy

   HSAN II is an autosomal recessive disorder that has been linked to its own tentative *HSN2* gene located on chromosome 12 (Klein and Dyck 2005). Current research suggests a role for this HSN2 protein in nerve growth. The mutation of this gene is phenotypically characterized by marked demyelination as well as loss of unmyelinated fibers, causing lack of sensation and chronic ulcerations in the upper and lower extremities. The onset of HSAN II is in infancy or early childhood (Siddique et al. 2007).
3. HSAN III, Familial dysautonomia

   Familial dysautonomia, one of the more common forms of autosomal recessive HSAN, is most prevalent in Jewish infants and children and has been linked to the *IKBKAP* gene on chromosome 9 (Klein and Dyck 2005). The mutations on this gene have been found to disrupt production of a functional IKAP protein. Although the exact mechanism through which these mutations cause sensory neuropathy in the effected population is not known, inhibited development and maintenance of neuronal cells have been implicated in the neuropathologic progression of the disorder (Siddique et al. 2007). It is also characterized by autonomic dysfunction, hindered physical development, and reduction or the absence of sympathetic nerve endings (Klein and Dyck 2005). The disorder has a typical onset in infancy, often with premature death during infancy or childhood (Katirji and Koontz 2012).

4. HSAN IV, Congenital insensitivity to pain with anhidrosis

   HSAN IV, or the disorder commonly known as congenital insensitivity to pain with anhidrosis, is an autosomal recessive disorder linked to the *TRKA* gene (chromosome 1, encoding the TrkA protein), which is believed to be important for neurite outgrowth and development of embryonic sympathetic and sensory neurons (Klein and Dyck 2005). The mechanism of action of the TrkA protein, a transmembrane tyrosine kinase, is through the signal transduction of nerve growth factor (NGF). Defects in this protein appear to cause an absence of unmyelinated fibers, including those to sweat glands, causing anhidrosis (Pina-Garza 2013). The disorder has onset at infancy (Katirji and Koontz 2012).
5. HSAN V, Congenital insensitivity to pain with partial anhidrosis

   HSAN V shares many features of HSAN IV including congenital insensitivity to pain as well as partial anhidrosis. It has recently been declared its own category due to its selective reduction in unmyelinated nerve fibers, unlike in HSAN IV, which is characterized by the absence of these fibers (Katirji and Koontz et al. 2012). HSAN V is linked to mutations on the *NGFB* (for nerve growth factor-β) and *TRKA* genes, both of which are implicated in the development and maintenance of sensory neurons (Klein and Dyck 2005). NGF-β protein is a signaling molecule that binds to TrkA during development in order to promote differentiation and survival of nerve cells, the lack of which could explain disruption of proper sensory neuron innervation and insensitivity to pain in people with HSAN V (Siddique et al. 2007).

Clinical Presentation

The symptoms of the hereditary sensory neuropathies can be characterized into two broad groups of autosomal dominant (HSAN I) and autosomal recessive (HSAN II–V) disorders.

Dominant: The clinical onset for HSAN I is typically the second or later decades, manifesting initially as diminished sensation in the distal portions of the lower limbs with progressive degeneration over time (Lloyd and Chaudhry 2011). Some patients experience spontaneous pain from these regions, including lancinating or burning pain from the feet, which is exacerbated by excessive use. The characteristic loss of sensation from the distal lower limbs eventually causes loss of pain and temperature sensation, leading to a variety of complications in these areas (Katirji and Koontz 2012). Common features include deep foot ulcerations, cellulitis, osteomyelitis, and foot bone resorption (Klein and Dyck 2005).

Recessive: The clinical features of autosomal recessive HSAN (II–V) disorders typically present in infancy or early childhood (Siddique et al. 2007). Similar loss of sensory modality as in the autosomal dominant disorders is found in the distal parts of both the upper and lower limbs, as well as in the trunk. There is often complete loss or depression of tendon reflexes in all limbs (Klein and Dyck 2005). In conjunction with loss of neuropathic joint degeneration, the loss of pain and temperature sensation often leads to complications such as ulcerations, bone fractures, infections, and bone resorption in all the distal limbs (Pina-Garza 2013). Patients may also exhibit autosomal dysfunction such as anhidrosis. This can also cause a cohort of problems affecting gastrointestinal function in the form of abnormal esophageal peristalsis, oropharyngeal incoordination, gastroesophageal reflux, and chronic lung disease (Klein and Dyck 2005). In addition, the combination of dysautonomic functions such as alacrima with corneal insensitivity from peripheral sensory deficits predisposes HSAN patients to ulceration and scarring of the cornea or neurotrophic keratopathy (Katirji and Koontz 2012). Other features of more severely affected patients with congenital HSANs include mental retardation and premature death (Klein and Dyck 2005).

Diagnosis

The diagnosis of HSAN involves both the recognition and the degree of sensory and autonomic

dysfunction in patients. All the HSAN disorder types show complete penetrance, but exhibit wide variability in terms of their clinical presentation. A simple way to test sensory axonal neuropathy is via the histamine test to examine axonal integrity (Katirji and Koontz 2012). A lack of normal axon flare response to intradermal histamine injection can suggest deterioration of unmyelinated C-fibers, a characteristic common to most HSAN patients. Other sensory and autonomic deficits in patients can be matched to the constellation of clinical features of each HSAN type for diagnosis. Genetic testing for known genes should be administered to establish a more definitive diagnosis whenever possible (Klein and Dyck 2005).

Differential Diagnosis

Electrodiagnostic testing of sensory nerves, glucose tolerance test, and laboratory testing can help to differentiate HSAN from other sensory neuropathies (Lloyd and Chaudhry 2011). Charcot-Marie-Tooth (CMT) disease may closely resemble HSAN, yet HSAN patients typically present with more severe sensory deficits and less motor deficits than CMT patients (Katirji and Koontz 2012). Sudomotor testing and skin biopsy can further confirm autonomic and small-fiber sensory involvement, respectively, while amyloidosis and vasculitis can be excluded via nerve biopsy (Lloyd and Chaudhry 2011).

Prophylaxis

Genetic counseling of at-risk family members of HSAN patients should be implemented. Patients should maintain constant vigilance in order to minimize injuries to peripheral limbs, skin, and bones.

Therapy

There is currently no gene therapy or treatment available for any of the known HSAN types. The goal of the therapy for HSAN, therefore, remains symptomatic and geared toward the prevention of self-mutilation to avoid the development of debilitating deformities such as ulcers and stress fractures in the upper and lower limbs (Klein and Dyck 2005). Patients should be carefully inspected daily for injuries to hands and feet. Early recognition and proper use of antiseptic techniques may help prevent osteomyelitis and amputations. Sharp pains can be partially relieved through careful selection of drugs, such as certain combinations of antiepileptics and antidepressants. For autosomal recessive HSAN subtypes (HSAN II–V), which show infantile onset, treatment of self-mutilation can also involve smoothing of teeth and early habit-reversal behavioral therapy for self-injurious behaviors (Lloyd and Chaudhry 2011).

Prognosis

The development of HSAN type I can be better managed given the later onset of symptoms with proper training and precautions to prevent self-mutilation. With the infantile onset of symptoms for affected individuals with the autosomal recessive disease, management of HSAN types II–V remains more difficult. Smoothing of teeth, habit-reversal behavioral therapy, and the use of braces have helped improve the outcome of patients (Lloyd and Chaudhry 2011).

Epidemiology

HSAN is a rare disease and its prevalence varies with each subtype. The lack of prospective epidemiologic studies makes it difficult to determine the prevalence of the disease as a whole, although the gene frequency for the more common recessive form HSAN III (familial dysautonomia) has been estimated to be at 0.01 per 100,000 Jews in the United States (Siddique et al. 2007).

Herpes Simplex Stromal Keratitis

► Stromal Keratitis (Herpetic)

Herpes Simplex Virus

Adam T. Gerstenblith and Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

HSV

Definition

Double-stranded DNA viruses with two closely related subtypes, HSV-1 and HSV-2.

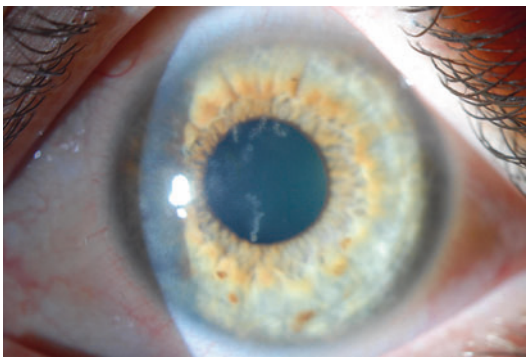
Etiology

Transmission occurs when live virus encounters exposed mucosal surfaces or skin breaks. Primary infection is often asymptomatic but may manifest as a mild fever and upper respiratory illness. HSV survives in a latent form in the central nervous system (CNS) of its host; HSV-1 most commonly resides in the trigeminal ganglia and causes ocular disease through reactivation.

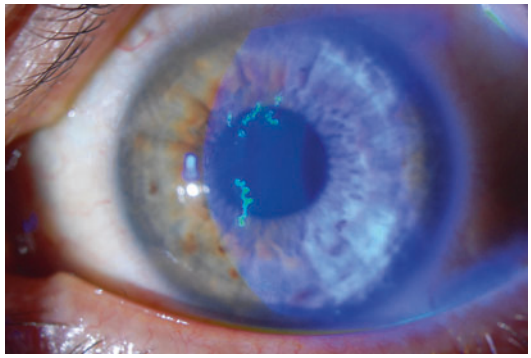
Clinical Presentation

Recurrent HSV has a predilection for the cornea. The most common manifestation is reduced corneal sensation and epithelial keratitis with a central, dendritic ulcer with terminal bulbs (Figs. 1 and 2). Patients present with tearing, blurred vision, and mild irritation or foreign body sensation. Complications include secondary bacterial infection, neurotrophic keratopathy, and corneal scarring.

Less commonly, stromal disciform keratitis is present. Patients experience blurred vision and photophobia. Findings include a central zone of stromal and epithelial edema, folds in Descemet's membrane, and a ring of stromal haze resulting from deposition of viral antigen and immune complexes in the stroma. Associated findings may include anterior uveitis with endothelial keratic precipitates, increased intraocular pressure, and



Herpes Simplex Virus, Fig. 1 Slit lamp photograph demonstrating classic dendritic ulcer in a patient with corneal disease secondary to reactivation of HSV-1 (Courtesy of Dr. Christopher J. Rapuano, Wills Eye Institute)



Herpes Simplex Virus, Fig. 2 Photograph, with a cobalt blue filter in place, of the same ulcers stained with fluorescein (Courtesy of Dr. Christopher J. Rapuano, Wills Eye Institute)

corneal neovascularization or ghost vessels. Complications include corneal scarring, glaucoma, cataract, and iris atrophy.

Acute retinal necrosis (ARN) results from reactivation in the retina. It typically occurs in *immunocompetent* individuals. Findings include granulomatous anterior uveitis, occlusive retinal vasculitis involving arteries and veins, retinitis and retinal necrosis in the periphery with circumferential spread, vitritis, and optic neuropathy. Complications include retinal breaks, detachments, and proliferative vitreoretinopathy.

Diagnosis

The true dendritic ulcer is pathognomonic. HSV may be isolated from corneal scrapings, cultured from corneal tissue, or identified by polymerase chain reaction performed on samples of the tears, epithelium, or anterior chamber fluid. Serology is of limited use given the high prevalence of positivity in the general population.

Differential Diagnosis

The differential diagnosis of dendritic or disciform keratitis includes:

Herpes zoster keratitis
Healing corneal abrasion
Keratoconjunctivitis sicca
Acanthamoeba keratitis
Toxic keratopathies secondary to topical medication
Bacterial or fungal keratitis
Interstitial keratitis

ARN from HSV infection may mimic:

Behçet disease
Fungal endophthalmitis
Cytomegalovirus retinitis
Syphilis
Sarcoidosis
Toxoplasmosis
Retinitis associated with collagen vascular diseases (e.g., systemic lupus erythematosus)

Prophylaxis

Maintenance therapy with oral acyclovir or valacyclovir reduces recurrence, but this effect is lost when the medication is stopped.

Therapy

Treatment includes antivirals, often in combination with a topical steroid. Dendritic keratitis may be treated with topical antivirals like trifluridine or vidarabine. Systemic antivirals, such as acyclovir or valacyclovir, are as effective as topical formulations and avoid the corneal toxicity. Stromal keratitis is treated similarly. Topical antibiotic ointments may prevent secondary bacterial infection, especially when topical corticosteroids are employed. For ARN, inpatient admission with intravenous antivirals is usually indicated and helps prevent ARN in the fellow eye. In severe cases, systemic steroids may limit the damage from retinal inflammation. Performed after the acute infection, laser retinopexy may prevent detachments. Patients must be evaluated for CNS involvement including life-threatening herpetic encephalitis.

Prognosis

Dendritic keratitis usually heals with relatively little scarring. Complications result with repeated recurrences or in undiagnosed or ineffectively treated cases. Disciform keratitis usually has favorable resolution; if associated with stromal keratouveitis, the course is often prolonged and unpredictable with repeated scarring and vision loss. ARN carries a very poor visual prognosis.

Epidemiology

HSV-1 seropositivity increases with age; 80% are positive by age 60, and it is estimated that one-third of the world's population is afflicted with some form of recurrent HSV-1 infection.

Disease secondary to reinfection or reactivation of latent varicella zoster virus (VZV)

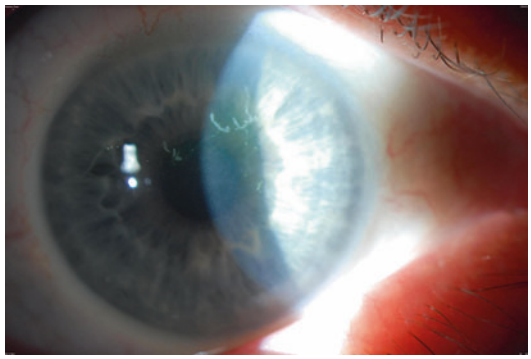
Etiology

VZV causes a primary infection (varicella, chickenpox); reactivation of latent virus in the neural ganglia causes herpes zoster (HZ), most commonly seen in older or immunocompromised patients. Subclinical reactivations and reinfections occur throughout life but are limited by VZV-specific cell-mediated immunity.

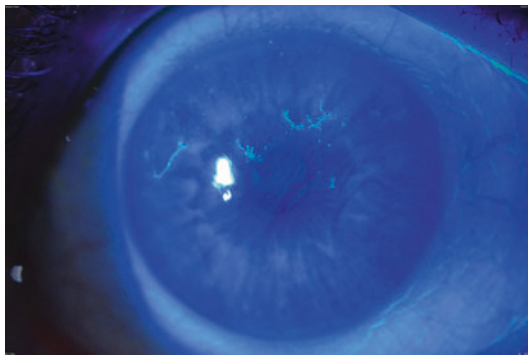
The pathophysiology of postherpetic neuralgia (PHN), persistent pain following HZ, remains unclear. It appears to be a disease of the CNS resulting in abnormal sensory processing and development of pain response to nonpainful stimuli.

Clinical Presentation

After a few days of fever, headache, malaise, and dysesthesia, a characteristic rash develops and involves one to three adjacent dermatomes of the



Herpes Zoster, Fig. 1 Slit lamp photograph demonstrating pseudodendritic lesion, without terminal end bulbs, in a patient with HZO (Courtesy of Dr. Christopher J. Rapuano, Wills Eye Institute)



Herpes Zoster, Fig. 2 Photograph, with a cobalt blue filter in place, of the same pseudodendrites stained with fluorescein (Courtesy of Dr. Christopher J. Rapuano, Wills Eye Institute)

affected ganglia. If an attack is limited, a rash might not develop (zoster sine herpete). More typically, grouped vesicles progress to pustules which may be hemorrhagic and crust after 7–10 days. Commonly affected dermatomes are those of the thorax (T3–L3) and those served by the trigeminal nerve. In herpes zoster ophthalmicus (HZO), damage from the infection or immune-mediated response can result in significant anterior or posterior segment complications (Figs. 1 and 2).

Viremia with dissemination (more than 20 pustules at sites nonadjacent to the primarily affected dermatomes) to cutaneous and extracutaneous sites is much more likely in immunocompromised patients who may develop visceral involvement of the lungs, liver, and brain. Neurologic complications of HZ include motor neuropathies, encephalitis, meningoencephalitis, myelitis, and Guillain-Barré syndrome. Of note, weeks to months after HZO, a cerebral vasculopathy with contralateral hemiparesis can occur and carries a mortality rate of 25%. The most common neurologic complication is PHN which can be particularly incapacitating.

Diagnosis

The characteristic pain and rash are usually sufficient for diagnosing HZ. Scrapings from a vesicle base can be sent for staining (Tzanck smear), cytology, PCR, or culture, and immunodiagnostic methods can confirm acute or recurrent VZV infection. Laboratory confirmation may help in unclear cases like zoster sine herpete. Although 90% of adults have detectable titers, only 5% without disease have titers of 1:640 or higher.

Differential Diagnosis

Herpes simplex virus (HSV).

Prophylaxis

Varicella virus vaccine is recommended for nonpregnant individuals aged 12 months or older without history of chickenpox or with negative serology. Theoretically, the vaccine could be used to prevent HZ by boosting immunity in patients who previously had varicella. HZ has occurred in vaccinees, especially those who had a rash. Unlike community-acquired infection with high levels of viremia and rash, vaccination usually produces little or no viremia. Thus, it is less likely for virus to become latent in the ganglia, and the incidence of HZ may decrease in the future. However, there is concern that initial vaccination may alter the epidemiology of HZ and, without widespread use, shift the prevalence of

varicella infection to an older population prone to complications not usually seen in children.

Therapy

If started within 72 h after the rash appears, antivirals such as acyclovir, valacyclovir, and famciclovir may limit viral replication, accelerate healing, and decrease the early pain of HZ. However, long-term (beyond 6 months) reduction in PHN has not been proven. Aggressive pain control and antidepressants such as amitriptyline or nortriptyline in older patients may reduce PHN by modifying the CNS effect. Topical agents like capsaicin cream may be of some benefit, but studies are inconclusive since the cream itself causes burning. Referral to a pain management clinic may be useful.

Steroids may improve the quality of life in the early stages but appear to have no long-term effect on PHN in HZ. Their judicious use, along with antivirals in older patients with moderate to severe pain and without contraindications, remains controversial in HZ. However, in HZO, carefully monitored use of steroids may reduce the complications from the inflammatory response. Current recommendations for acute HZO include antiviral, steroids, antidepressant, and pain medication.

HZ in patients younger than 45 years of age should trigger an investigation for HIV or other causes of impaired immunity. Immunocompromised patients must be treated with intravenous antivirals and monitored closely; they have a significantly increased risk of disseminated disease and poorer prognosis.

Prognosis

The major predictor of the severity of infection is the ability of the immune response to limit spread of the virus. The course is more severe and prolonged in immunosuppressed patients who also have an increased risk of dissemination.

If the side of the tip of the nose is involved, 50–85% of patients develop ocular complications, but roughly half of patients without Hutchinson's sign also have serious ocular involvement.

Increased age and prodromal symptoms are associated with increased PHN. PHN also appears to be increased in HZO compared to HZ elsewhere.

Epidemiology

HZ occurs in 20% of infected individuals with trigeminal nerve involvement in approximately 15% of cases. Incidence increases with age and immunosuppression.

Varicella zoster virus

Definition

Herpes zoster ophthalmicus (HZO) is a recurrent infection with varicella zoster virus (VZV) affecting the first division of the trigeminal nerve.

Etiology

Herpes zoster infection may result from reactivation of a latent virus in the sensory ganglion or reinfection from contact with an exogenous viral source. The virus has an incubation period of a few days to 2 weeks from the time of exposure (Pavan-Langston 2005). In HZO, the virus affects the ophthalmic division of the trigeminal nerve, which divides into the nasociliary, frontal, and lacrimal branches (Lee and Liesegang 2011). A depressed cell-mediated immune response, such as in the elderly, HIV-infected individuals, organ transplant recipients, and individuals with malignancies, increases the risk of herpes zoster development (Gerstenblith and Rabinowitz 2012).

Clinical Presentation

Dermal, Extraocular Muscle, and Orbital Involvement

Herpes zoster ophthalmicus may present initially with a prodrome of headache, fever, malaise, blurred vision, eye pain, and red eye. The prodrome is followed by dermatomal pain and paresthesias 24–48 h later. The affected dermatome in herpes zoster ophthalmicus is the first division of the fifth cranial nerve. Hyperemic, hyperesthetic edema of the involved dermatome develops 2–3 days later, which develops into a skin rash. The rash initially develops as a macular rash, which becomes papular and then vesicular within 24 h. These vesicles continue to form for the following 3–5 days. Over the next 2–3 weeks, the vesicles become turbid and crust over, usually forming hemorrhagic scabs. In immunocompromised individuals, the vesicles may persist for weeks (Lee and Liesegang 2011). Herpes zoster affects the epidermis through the corium and forms deep eschars that may leave residual pitting or permanent scars (Pavan-Langston 2005). The rash is characteristically unilateral and does not involve the lower eyelid. Involvement of the tip of the nose from the nasociliary branch of the trigeminal nerve is known as the Hutchinson sign. The Hutchinson sign predicts higher risk of ocular involvement. Less commonly, the maxillary and mandibular divisions of the trigeminal nerve may also be involved, affecting the lower eyelid, cheek, and jaw of the involved side (Gerstenblith and Rabinowitz 2012). Hematogenous spread of the virus may result in crops of vesicles in remote sites. Visceral dissemination commonly affects the lungs and gastrointestinal tract and can be a severe complication (Lee and Liesegang 2011).

HZV skin and ocular ulcerations may result in complications of ptosis, lid retraction, or sloughing of lashes and lid tissues. Lid changes secondary to HZO include trichiasis, ectropion, entropion, madarosis, or poliosis. Contraction of the eyelids may lead to chronic corneal exposure and scarring (Lee and Liesegang 2011). Cranial nerve III, IV, and VI palsies are not uncommon, but they tend to resolve completely regardless of initial severity. Other possible palsies secondary to HZV include internuclear ophthalmoplegia, isolated iris sphincter paralysis, and Horner's syndrome. The associated palsies and orbital edema may be due to perineuritis and perivasculitis from generalized orbit inflammation. Most palsies will resolve spontaneously. Acute dacryoadenitis may develop, presenting with severe ocular pain and red eye. Elderly and immunocompromised individuals are at risk of developing superior orbital syndrome with complicating meningoencephalitis (Pavan-Langston 2005).

Conjunctivitis

Herpes zoster ophthalmicus can affect virtually any ocular structure. Ocular inflammation may present during acutely or months later, and become recurring. Conjunctivitis may present as a watery follicular reaction with or without petechial reaction and regional adenopathy. It may also present as a necrotizing membranous inflammation (Pavan-Langston 2005). A vesicular eruption can occur on the conjunctiva, leading to

rupture and possible hemorrhagic changes of the tissue. Severe conjunctival changes can lead to conjunctival scarring and symblepharon formation (Lee and Liesegang 2011). Conjunctival changes can spread to the puncta, leading to scarring, punctal occlusion, and epiphora (Lee and Liesegang 2011).

Episcleritis and Scleritis

Episcleritis or a scleritis can manifest acutely or even months later after resolution of the zoster vesicles. Episcleritis is typically seen early in the disease course, but it is not uncommon for it to persist for up to and beyond 3 months (Lee and Liesegang 2011). Scleritis that is flat and diffuse or focal with nodular elevations is a common finding in HZO. The nodular form of scleritis may lead to scleral thinning and staphyloma formation (Pavan-Langston 2005). Scleritis has a tendency to progress toward the perilimbal region of the cornea, which can result in a peripheral limbal vasculitis. Sclerokeratitis usually develops approximately 1 month after HZO onset (Lee and Liesegang 2011).

Keratitis and Pseudodendrites

Corneal disease may follow several days to months after the acute rash presentation and may last for years. Corneal manifestations of herpes zoster ophthalmicus may present as diffuse superficial punctate keratitis or multiple small migratory epithelial dendritiform lesions in the initial stages. Larger pseudodendrites, presenting as raised mucus plaques on the cornea or conjunctiva, SPK, immune stromal keratitis, and neurotrophic keratitis will follow (Gerstenblith and Rabinowitz 2012). VZV DNA shedding duration is highly variable, age dependent, and may relate to immune status (Pavan-Langston 2005).

Corneal zoster involvement presents initially as coarse punctate epithelial keratitis with blotchy, swollen, epithelial cells. They are usually multiple, small, raised, and focally located along the periphery, and they can be stained with rose Bengal stain. Within a few days, multiple dendritic or stellate lesions of the involved epithelial cells develop, and they are typically found along the periphery of the cornea. They can be differentiated from herpes simplex associated dendrites by their superficial involvement, blunt dendrites, lack of central ulceration, and minimal staining with fluorescein and rose Bengal (Lee and Liesegang 2011).

Stromal Immune Disease

Anterior stromal infiltrates may develop as isolated or multiple patches of hazy, granular, dry infiltrates under the Bowman's layer, usually appearing 10 days after the onset of disease. The infiltrates typically underlie previous epithelial lesions. They may represent stromal reaction to viral antigen or direct viral cytotoxicity (Lee and Liesegang 2011). Other immune reactions that may develop include necrotizing interstitial keratitis with neovascularization, Wessely rings, or limbal vasculitis. When interstitial keratitis is associated with herpes zoster infection, there is increased risk of deep neovascularization with lipid deposition and fibrovascular scarring (Pavan-Langston 2005).

Keratouveitis and Endotheliitis

One week into the disease course, sudden onset of Descemet's folds and subsequent epithelial and stromal edema may develop. The folds may be localized or diffuse with underlying keratic precipitates and associated uveitis. This reaction may be due to direct viral invasion of the endothelium. The immune reaction may be manifest as a mild disciform keratitis or as a severe granulomatous inflammatory reaction (Lee and Liesegang 2011).

Corneal Mucus Plaques

Corneal mucus plaques typically develop months after acute HZO in a quiescent or minimally smoldering eye. They develop suddenly as coarse gray-white branching elevated lesions on the surface of edematous epithelial cells. They have sharp margins and lack terminal branches. They tend to stain well with rose Bengal but minimally with fluorescein. Mucus plaques vary in size and are migratory in nature. The etiology is unclear but may represent an immune reaction or result from mechanical causes, such as neurotrophic changes or an abnormal epithelial receptor site. VZV viral DNA has been detected within the

lesions by polymerase chain reaction (PCR), which may suggest an infectious etiology (Lee and Liesegang 2011).

Disciform Keratitis

Disciform keratitis presents weeks to months after acute HZO. It appears as a deep central or peripheral disk-shaped area of stromal edema. There are typically minimal infiltrates and the epithelium remains intact. A relatively quiescent eye may show multiple sites of corneal edema. Disciform keratitis of HZO may be associated with immune rings, most commonly seen in the central or paracentral cornea (Lee and Liesegang 2011).

Neuroparalytic Keratopathy and Neurotrophic Ulcers

Herpes zoster keratitis may result in markedly diminished corneal sensation, with 60% of patients experiencing moderate to complete corneal anesthesia (Pavan-Langston 2005). Diminished corneal sensation resolves in most, though some may never regain normal sensation. Approximately 20% of patients are estimated to have decreased corneal sensitivity at 1 year after onset of HZO (Lee and Liesegang 2011). The more intact the corneal sensation the better the prognosis for the cornea. The neuroparalysis of herpes zoster develops secondary to the destructive VZV ganglionitis and aqueous tear deficiency due to loss of the nasolacrimal reflex. Corneal anesthesia may develop with the acute illness or over the next 2–3 weeks. One of the most dangerous forms of herpes zoster keratitis is anesthetic epithelial breakdown due to permanent corneal anesthesia. One fourth of patients with HZO develop clinical signs of neurotrophic keratitis, which may begin as a dull or irregular corneal surface with mild punctate epithelial keratitis. Diffuse epithelial edema or haze with fine intraepithelial vesicles may follow. Reduced blink frequency and an unstable tear film further aggravate this condition. Oval epithelial defects may develop in the palpebral fissure or lower corneal region, which progress to corneal melting and subsequent thinning (Pavan-Langston 2005). Complications, such as superinfection, corneal thinning, corneal perforation, and fibrovascular scarring, may occur and suggest a worse prognosis (Lee and Liesegang 2011).

Iridocyclitis

Frequency of anterior uveal tract involvement is second only to the cornea. Involvement may present acutely, months later, or both. Symptoms include pain, decreased vision, and photophobia. Patient may have signs of ciliary hyperemia, keratic precipitates, and iris edema. Anterior peripheral and posterior synechia formation with a fibrinous exudate may be present in more severe cases. Herpes zoster iritis develops from a diffuse infiltrate of the iris stroma. Striate keratopathy, vascular dilation, sphincter damage, and sectoral iris atrophy have been characterized in herpes zoster ophthalmicus. Occlusion of iris vessels at the sites of iris atrophy has been noted by fluorescein angiography (Pavan-Langston 2005). Ischemic occlusive vasculitis associated with ciliary body inflammation, segmental iris distortion, and sectoral iris atrophy may be the cause of zoster iritis (Lee and Liesegang 2011).

Up to 40% of patients with HZO develop anterior uveitis. The inflammation may be granulomatous or nongranulomatous, and it is usually associated with keratic precipitates and corneal edema. Less commonly, the uveitis of HZO may occur independent of corneal involvement (Lee and Liesegang 2011). Zoster iritis may lead to development of a hypopyon, hyphema, heterochromia iridis, sympathetic ophthalmia, hypotony, and phthisis. Herpes zoster associated uveitis may result from an immune reaction to the antigenic residua of the virus or to new virus production. Twenty-five percent of patients with VZV uveitis progress to develop posterior pole complications. These complications include cystoid macular edema, epiretinal membranes, papillitis, and retinal fibrosis and detachment (Pavan-Langston 2005). In a retrospective study, secondary glaucoma developed in 56% of patients with HZO associated uveitis (Lee and Liesegang 2011).

Glaucoma

HZO may cause an imbalance between the decreased aqueous production and outflow

blockage by these mechanisms, leading to intraocular pressures ranging from abnormally low to severe secondary glaucoma. The alteration may result from extension of VZV to the trabecular meshwork or a severe ischemic vasculitis (Lee and Liesegang 2011). Elevated intraocular pressure secondary to herpes zoster ophthalmicus may be acute or transient, or it may become a chronic problem. Glaucoma is the most common secondary complication of VZV uveitis (Pavan-Langston 2005). The inflammatory glaucoma associated with HZO uveitis may result from multiple mechanisms. The trabecular meshwork may be blocked by cellular debris, iris pigment, or blood. Peripheral anterior synechiae may interfere with aqueous fluid drainage. Posterior synechiae may cause a pupillary block. Additionally, the trabecular meshwork may undergo structural changes (Lee and Liesegang 2011).

Acute Postherpetic Neuralgia and Postherpetic Itch

Though the skin rash of herpes zoster ophthalmicus usually resolves within 2–3 weeks, patients may be troubled by persistent pain in the involved dermatome. Herpes zoster ophthalmicus may manifest with multiple different types of pain or discomfort. Postherpetic neuralgia may cause a constant aching or burning pain, a sudden lancinating pain, or nonpainful stimuli may be perceived as painful. Postherpetic itch is a constant or intermittent itching in the involved area. These conditions may manifest as sleep disturbances, anorexia, constipation, and depression. Maximal recovery is typically achieved by 2 years after the acute illness. The initial pain of herpetic neuralgia has been attributed to acute swelling of the trigeminal neuralgia associated with a neural vasculitis, nerve and axon necrosis, focal hemorrhage, and periocular tissue inflammation. Cases of severe pain may have associated sympathetic hyperactivity, including tachypnea, tachycardia, diaphoresis, and mydriasis (Pavan-Langston 2005).

Zoster Sine Herpete

Zoster sine herpete (ZSH) is a reactivated VZV infection that causes only neurologic symptoms, including dermatomal neuralgia or neuropathy, and occasional ocular inflammation. By definition, ZSH does not cause a rash. A facial palsy (Bell's palsy), granulomatous iritis, and disciform keratitis may develop as a result of ZSH (Pavan-Langston 2005).

Diagnosis

The diagnosis of herpes zoster ophthalmicus is made by clinical impression based upon the characteristic signs and symptoms of the infection. However, herpes zoster can mimic other diseases, such as herpes simplex and impetigo, so laboratory testing is needed on occasion. These tests include morphologic and immunomorphologic tests, viral isolation, serologic tests, and cellular immunity tests (Lee and Liesegang 2011).

The simplest morphologic test is the Tzanck smear, which can identify a herpes virus but cannot distinguish it from the various different types of herpes viruses. Various stains can be used to confirm the presence of multinucleated giant cells and the characteristic acidophilic intranuclear inclusions in epithelial cell scrapings. These stains include hematoxylin & eosin, Giemsa, Papanicolaou, Wright, and toluidine blue (Lee and Liesegang 2011). Immunologic tests include immunofluorescent and immunoenzyme stains. Direct immunofluorescence assay can be used to confirm suspicion of herpes zoster infection as it is sensitive and specific with the benefit of lower cost and rapid execution time (Pavan-Langston 2005). Polymerase chain reaction (PCR) technique is rapid and very sensitive, but it is difficult to distinguish between active disease, inactive viral particles, and recurrent disease with this test (Lee and Liesegang 2011).

The definitive technique for VZV identification is by culture of vesicular fluid. The virus can be cultured from skin vesicles and ocular lesions for up to 7 days after their appearance in an immunocompetent individual and longer in an immunocompromised patient. However, culture growth of the virus is slow. Varicella zoster virus titers will rise after a zoster infection. Serologic evaluations include a number of different assays to measure

anti-VZV antibodies for indication of prior or recurrent infections. Serologic assays include fluorescent antibody staining for membrane antigen, immune adherence hemagglutination assay, passive hemagglutination, immunofluorescence, complement fixation, radioimmunoassay, immunoblot, and enzyme-linked immunosorbent assay (ELISA). HIV serologic testing should be considered in individuals less than 50 years of age who develop herpes zoster infection as HIV-positive individuals can be asymptomatic (Pavan-Langston 2005).

Differential Diagnosis

The differential diagnosis should include herpes simplex virus. The two can be distinguished by their regional involvement. The rash of herpes simplex virus is not dermatomal and crosses the midline. It typically affects young individuals (Gerstenblith and Rabinowitz 2012).

Herpes zoster ophthalmicus may closely mimic varicella zoster dermatitis. In severe cases, skin and periocular involvement may resemble bacterial orbital cellulitis (Pavan-Langston 2005).

Prophylaxis

A high-potency live attenuated Oka/Merck VZV vaccine was approved by the US FDA in 2006 for the prevention of herpes zoster in immunocompetent individuals 60 years of age or older. The shingles prevention study found that the vaccine reduced the overall incidence of herpes zoster by 51%. It also found that the vaccine reduced the burden of illness by 61% and the incidence of postherpetic neuralgia by 66%. It is estimated that the vaccine will effectively prevent 250,000 cases of herpes zoster in the USA each year. Studies are underway to determine the effectiveness of the vaccine in immunocompromised individuals. It is not yet known what the duration of the vaccine's protective effect is and whether a booster vaccine will be necessary to maintain the vaccine's efficacy (Lee and Liesegang 2011).

Therapy

Medical Treatment

Treatment of VZV is mainly supportive, treating the symptoms of the infection. Therapy includes hydration, nonaspirin antipyretics, cool baths, and careful hygiene to prevent superinfection of the skin lesions. Antiviral agents may be used in treatment. Acyclovir, valacyclovir, and famciclovir are FDA-approved for herpes zoster, and they are guanosine analogs that interfere with viral replication. A systemic review of 12 randomized controlled trials concluded that valacyclovir and famciclovir therapy has resulted in significant reduction in the risk of pain associated with HZO and should be the preferred therapeutic drugs given their efficacy in pain control and convenient dosing regimen (McDonald et al. 2012). Immunocompromised individuals may require intravenous acyclovir to prevent or treat the complications of disseminated disease. Oral acyclovir shortens the duration of the disease. Antivirals accelerate cutaneous lesion healing and decrease new lesion formation. However, controversy exists with regards to the use of oral antiviral drugs for localized zoster. Zoster immune globulin is not effective once the disease is contracted. However, it may confer passive immunity within 96 h of exposure in individuals at risk for severe infection (Lee and Liesegang 2011). Characteristics of patients at increased risk of complications include prematurity, age over 50 years, immunocompromise, severe pain at presentation, and increased area of skin involvement (Pavan-Langston 2005). Topical acyclovir was found to be effective in controlling herpes zoster keratouveitis compared to steroids, resulting in fewer recurrences and shorter recovery times. Shorter disease durations and decreased recurrence rates would likely result in decreased incidence of ocular damage and visual loss. The combination of acyclovir and steroids has been shown to result in prolonged treatment durations and higher recurrence rates (McGill et al. 1983)

Corticosteroids in combination with antivirals have been shown to have a moderate but statistically significant acceleration in cutaneous healing and acute pain alleviation than antiviral drugs

alone. Corticosteroids have not been shown to have any benefit in postherpetic neuralgia (Lee and Liesegang 2011). Topical steroids are useful in treatment of zoster vasculitis manifestations, including scleritis, stromal keratitis, interstitial keratitis, and uveitis. Corticosteroids suppress nonspecific inflammation and immune-mediated diseases, including anterior stromal infiltrates, stromal disciform reaction, corneal mucous plaques, sclerokeratitis, serpiginous ulceration, and keratouveitis. The role of systemic corticosteroids in acute HZO is controversial. Given the well-known adverse side effect profile and risk of disseminated infectious disease, the use of systemic corticosteroids should be limited to immunocompetant, nondiabetic patients experiencing vasculitic complications of HZO, such as severe scleritis and uveitis (Pavan-Langston 2005).

Development of corneal ulcers may be prevented with adequate preservative-free lubrication, topical antibiotic prophylaxis, and lateral tarsorrhaphy. Lower punctal plugs may be used to increase natural lubrication. If these measures are unsuccessful and the corneal epithelium is at risk of a break or an ulcer develops, soft contact lenses with continued lubrication and antibiotic prophylaxis should be initiated. If the corneal ulcer begins to melt, cyanoacrylate gluing is indicated. Neovascularization should be allowed to occur as a component of the healing process (Pavan-Langston 2005).

Acute neuralgia typically responds moderately well to mild analgesics. Postherpetic neuralgia and itch have been shown to be prevented or greatly inhibited by treatment initiated at the onset of acute illness with a combination of an antiviral, such as famciclovir or valacyclovir, with a tricyclic antidepressant or anticonvulsant and strong analgesic (Pavan-Langston 2005). There is no data to suggest that any tricyclic antidepressant is more efficacious than another in pain management. Selection of a drug for postherpetic neuralgia treatment is made based upon each drug's individual side effect profile (Lee and Liesegang 2011). A combination of neuroleptic agents can be used as an alternative to tricyclic antidepressants, but patients should be monitored for side effects of tardive dyskinesia and other extrapyramidal reactions. Anticonvulsants, such as pregabalin, gabapentin, and zonisamide, are very effective at controlling postherpetic neuralgia as single agents. Tricyclic antidepressants and anticonvulsants can be combined in patients who don't respond to a single agent. If the combination is still not effective, slow-release opioids, such as oxycodone-SR, can be added or used as a single agent (Pavan-Langston 2005).

Topical capsaicin has been tried as a way of depleting substance P from the small sensory peripheral and central neurons involved in pain sensation. It has not been shown to be effective as a single agent but may have some benefit as an adjuvant treatment (Pavan-Langston 2005). A variety of topical compounded growth factors have been beneficial in epithelial healing of neurotrophic keratopathy, such as autologous serum, substance-P-derived peptide, and insulin-like growth factor (Lee and Liesegang 2011). Lidocaine skin patches can be applied to the forehead or scalp and have been effective in treating postherpetic neuralgia and postherpetic itching. Diphenhydramine has been effective in reducing symptoms of postherpetic itching in many patients (Pavan-Langston 2005).

Frontal and nasal nerve blocks are effective in cases of severe pain associated with acute HZO that is not controlled by other drugs. Bupivacaine, epinephrine, and clonidine are injected at the frontal and nasal branch levels of the ophthalmic nerve. The injections are typically effective for 5 days and can be repeated. A stellate ganglion block may be effective if given within 14 days of rash onset. The stellate ganglion block consists of a 1% lidocaine and 0.5% bupivacaine mixture injected at the C5-6 vertebrae level with the head extended (Pavan-Langston 2005).

Surgical Treatment

Surgery is most commonly indicated in HZO for exposure keratopathy and anesthetic cornea. Punctal plugs may be sufficient if lid closure is adequate but the tear meniscus is low. More severe forms of HZO may lead to significant scarring or partial destruction of the eyelid, leading to impairment of normal lid closure. In cases where the lid

tissue is intact, a lateral or medial and lateral tarsorrhaphy may be adequate to protect the globe. If lid tissue has been lost, plastic reconstruction may be indicated (Pavan-Langston 2005).

A partial tarsorrhaphy is indicated in partial or total corneal anesthesia where the epithelium is unhealthy or prone to recurrent breakdown. A therapeutic contact lens may be used in these cases with adequate lubrication. In cases where corneal melting occurs, the area should be sealed with cyanoacrylate glue, and a Plano T therapeutic lens should be inserted to cover the rough surface of the glue. Over time, the cornea heals under the glue, and the glue dislodges spontaneously. Adequate alternatives, though more extensive surgical procedures, include pulling down a conjunctival flap if it has not been too scarred by the disease, placing a conjunctival transplant from the contralateral eye, or placing an amniotic membrane transplant (Pavan-Langston 2005).

Keratoplasty may be successful in a cornea that has scarred but maintained a reasonable amount of sensation. Anesthetic eyes tend to heal poorly and transplanted eyes are prone to melting and superinfection, making them poor candidates for keratoplasty (Pavan-Langston 2005). Deep anterior lamellar keratoplasty (DALK), penetrating keratoplasty (PK), and prosthokeratoplasty may be done in cases of severe scarring (Lee and Liesegang 2011). If keratoplasty is performed, a lateral tarsorrhaphy should be done to protect the graft (Pavan-Langston 2005).

Prognosis

The presence of Hutchinson's sign is a poor prognostic indicator due to the increased risk of ocular complications secondary to the extensive intraocular innervations of the nasociliary branch. Ocular involvement has no known correlation with age, gender, or severity of the zoster associated skin rash. The disease may present with acute, chronic, or relapsing phases. The visual outcome is highly variable. However, the visual prognosis in immunocompromised individuals tends to be significantly worse (Lee and Liesegang 2011).

Epidemiology

The frequency of herpes zoster affecting the trigeminal nerve is 9–16% and involvement of the ophthalmic branch varies in frequency from 8% to 56%. Of individuals with herpes zoster of the ophthalmic division of the trigeminal nerve, approximately 50–72% will have involvement of ocular structures, develop chronic disease, and sustain moderate to severe vision loss (Pavan-Langston 2005).

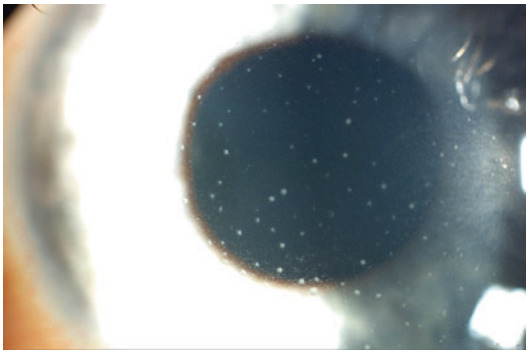
Definition

Intraocular pressure rise secondary to FUS leading to optic nerve damage

Etiology

Several, mostly infectious, causative agents have been discussed. In the last years, rubella came to the focus of attention as antibodies to rubella have been found in aqueous humor (Quentin and Reiber 2004), and an epidemiologic study showed a reduction of FUS since vaccination for rubella was introduced (Birnbaum et al. 2007). Mechanism of raised intraocular pressure (IOP) is thought to be mixed, on the one hand due to trabecular meshwork damage and thus increased outflow resistance due to the chronic inflammation and on the other hand by angle closure due to peripheral anterior synechiae or vascular membrane formation (Moura Filho and Liesegang 2010). Local corticosteroids may promote glaucoma.

Friederike Mackensen: deceased.



Heterochromic Cyclitis Fuchs' Glaucoma, Fig. 1

Clinical Presentation

The classic clinical phenotype of Fuchs' uveitis syndrome (FUS) is unilateral mild anterior to intermediate uveitis, no pain or redness, insidious onset (typically discovered when the patient attends to an eye care provider due to other reasons) with chronic course, responding little or not at all to topical corticosteroids, stellate or mixed (fine, small roundish, and stellate) keratic precipitates (KP) (see Fig. 1) in a diffuse distribution, in a young patient, diffuse iris transillumination defects and/or heterochromia, early cataract formation, whitish vitreous cell deposits, and lack of posterior synechiae or macular edema. Typical complications of FUS are cataract and glaucoma.

Diagnosis

The diagnosis is mainly a clinical one (see above). OCT can be used to exclude macular edema. Confocal microscopy can help detect low-grade stellate KP, and anterior chamber tap can show elevated antibodies to rubella to further confirm the diagnosis (Quentin and Reiber 2004; de Visser et al. 2008).

Differential Diagnosis

The differential diagnosis of FUS includes conditions with hypopigmentary heterochromia and raised IOP such as glaucomatocyclitic crisis and

herpetic uveitis or pigment dispersion syndrome. The iris atrophy of FUS can also help in differentiating it from other uveitis forms in which atrophy, if present, is associated with full-thickness sector atrophy. Anterior chamber tap can help to exclude infectious origins as herpetic virus.

Prophylaxis

Glaucoma is often resistant to treatment and should actively be screened for at least every 6 months in patients with Fuchs' uveitis syndrome. Local corticosteroids should be avoided as they show no effect and may promote glaucoma and cataract formation.

Therapy

No anti-inflammatory treatment is known to change the course of FUS. Local corticosteroids may only be warranted if used as a diagnostic means to differentiate from other uveitic forms. Medical and surgical treatment for reducing intraocular pressure should be especially aggressive in these patients. Compliance may be an issue. Cataract surgery and – if necessary for dense vitreous opacities – vitrectomy can be performed without immunosuppressive treatment.

Prognosis

Generally the prognosis depends on the development of glaucoma which is the most common cause of permanent vision loss in FUS patients. If glaucoma does not develop, vision can be reduced by cataract formation or dense vitreous opacities which can be removed surgically with near-normal operation risks.

Epidemiology

FUS is a rare entity found in about 7% of all patients and 11% of anterior uveitis patients in a tertiary care setting (Jakob et al. 2009). It is frequently first diagnosed in the second to third decade of life. In this cohort it was more frequent in male patients. Glaucoma can develop in 15–59% of cases. Cataract formation is frequent.

Hidradenoma, Clear Cell (Eccrine Acrospiroma)

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Adenoma of the clear cell type; Clear cell hidradenoma; Clear cell myoepithelioma; Cystic hidradenoma; Eccrine acrospiroma; Eccrine poroma; Eccrine sweat gland adenoma; Nodular cell hidradenoma; Porosyringoma

Definition

A solid cystic cutaneous nodule arising from the duct and secretory coil of eccrine sweat glands.

Etiology

Clear cell hidradenomas may be due to impaired drainage of eccrine sweat glands within the dermis.

Clinical Presentation

Flesh colored, solid or cystic intradermal nodules, typically 5–30 mm, covered by intact skin. Pressure applied to the lesion may produce tenderness in 20% of patients. They present in middle age and frequently occur on the head, but can occur anywhere on the body (Shields and Shields 1999; Albert and Jakobie 2008; Rabady et al. 2008).

Diagnostics

Excisional biopsy provides definitive diagnosis. Histopathologically, clear cell hidradenoma demonstrates a well circumscribed dermal lesion composed of lobules of epithelial cells in a biphasic pattern. The first layer is composed of round cells with clear cytoplasm, and the other layer is composed of spindle shaped cells with eosinophilic cytoplasm (Shields and Shields 1999; Albert and Jakobie 2008; Rabady et al. 2008).

Differential Diagnosis

Seborrheic Keratosis
Squamous Cell Carcinoma
Trichilemmoma

Prophylaxis

No preventative measures are known.

Therapy

Surgical excision provides definitive diagnosis. Solitary eccrine spiradenomas are typically benign. Multiple large eccrine spiradenomas may be treated with carbon dioxide laser.

Prognosis

Excellent. Malignant eccrine spiradenoma has been reported on the eyelids, and malignant eccrine porocarcinomas have been reported to metastasize to viscera, lymph nodes, and bone.

Epidemiology

Unknown.

Cross-References

Hidrocystoma, Apocrine

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Apocrine cystadenoma; Cyst of Moll

Definition

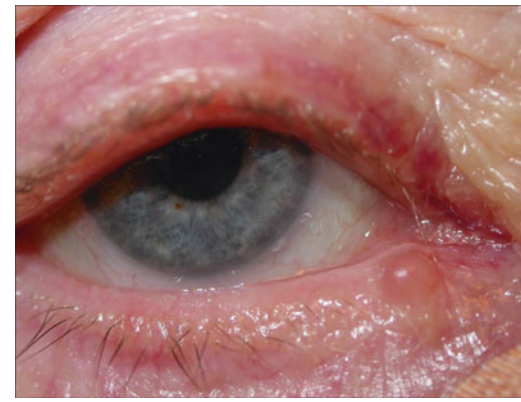
Benign cystic proliferations of the apocrine secretory glands (apocrine glands of the eyelids known as glands of Moll) (Nesi et al. 1998; Albert and Jakobiec 2008; Shields and Shields 2008).

Etiology

Unknown but blockage of the gland drainage ducts may lead to cyst formation.

Clinical Presentation

Usually appear as a solitary, soft, dome-shaped, slow growing papules or nodules with a cystic consistency, which can be translucent or frequently blue (Fig. 1). They are located most frequently on the eyelids margin, especially near the medial canthus.



Hidrocystoma, Apocrine, Fig. 1 Apocrine hidrocystoma on the right lower eyelid

Diagnostics

By typical clinical appearance; however, histologic examination often is required to establish a specific and definitive diagnosis.

Differential Diagnosis

Differential Diagnosis includes ► syringoma, ► blue nevus, eccrine hidrocystoma, ► basal cell carcinoma, ► malignant melanoma

Prophylaxis

Unknown.

Therapy

Surgical excision; remotion of the cyst wall is recommended to prevent recurrence. Multiple lesions can also be treated with trichloroacetic acid and CO_2 laser.

Prognosis

Benign lesions which are usually asymptomatic.

Epidemiology

Most lesions occur in adults or in the elderly; a few cases have been observed in both childhood and adolescence, both sexes are equally affected.

Higher-Order Aberrations, Refractive Surgery

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Higher-order optical aberrations induced by refractive surgery

Definition

Monochromatic aberrations besides defocus and astigmatism that are induced by refractive-surgical procedures.

Basic Characteristics

With the opportunity of the measurement of the ocular wavefront error using wavefront sensors, it became obvious that refractive surgical procedures aiming at reducing ocular lower-order aberrations (LOA) also induce higher-order aberrations (HOA) (Applegate et al. 1996; Marcos et al. 2001; Bühren et al. 2004). While HOA in the normal human eye have a rather insignificant contribution to visual function, refractive surgery-induced HOA can lead to severe optical disturbances like haloes, ghost images, loss of contrast, and blurry vision (Chalita et al. 2004; Bühren et al. 2009a). Like in the normal eye, spherical aberration and coma are the dominant HOA, however, at significantly elevated levels. It has been shown that there is a linear relationship between the attempted spherical equivalent and the amount of spherical aberration (Marcos et al. 2001). The reason for the induction of HOA in LASIK is primarily the loss of laser fluence at the corneal periphery (Bühren et al. 2010) while coma is induced by decentration of the ablation (Bühren et al. 2010). Other reasons are the biomechanical response of the cornea to flap creation (Porter et al. 2003; Potgieter et al. 2005) and to incisions in radial keratotomy and implant surgery (Applegate et al. 1996; Bühren et al. 2004) as well as wound healing reactions (Bühren et al. 2009b). In current state-of-the-art refractive surgery novel technology such as aspheric ("wavefront-optimized") ablation profiles, the HOA induction can be efficiently minimized (Bühren et al. 2010).

In case of HOA-borne symptoms, the effect of HOA can be reduced by application of pupil-constricting eye drops such as pilocarpine or brimonidine (Bühren et al. 2005).

High-Pressure Glaucoma

Oliver Schwenn
Bürgerhospital, Frankfurt am Main, Germany

Synonyms

Primary open-angle glaucoma (with elevated intraocular pressure)

Definition

High-pressure glaucoma is a subcategory of primary open-angle glaucoma with the adjunctive characteristic of elevated IOP.

Etiology

The main initializing event resides in the region of the trabecular meshwork, increasing aqueous outflow resistance and IOP.

Clinical Presentation

High-pressure glaucoma is usually insidious in onset, slowly progressive, and painless. Because central visual acuity is relatively unaffected until late in the disease, visual loss may be significant before symptoms are noted, especially in asymmetrical or unilateral cases.

Diagnosis

IOP $\geq$21 mmHg, optic nerve head with typical glaucomatous damage, visual field with progressive glaucomatous defects, wide open anterior chamber angle.

Differential Diagnosis

Other forms of elevated intraocular pressure combined with the typical features of ONH damage.

Therapy

The treatment is primarily medical with topical medications that reduce the aqueous humor production or facilitating its outflow. The inefficient reduction of the IOP requires a laser or an incisional surgical procedure such as laser trabeculoplasty, filtration surgery, insertion of aqueous drainage implants, or cyclodestructive procedures.

Prognosis

Most patients with POWG will retain useful vision for their entire lives. However, the incidence of blindness has been variously reported and has been estimated at 27% unilateral und 9% bilateral at 20 years following diagnosis in a certain population of patients. The age and severity at diagnosis are clearly important prognostic factors. Other prognostic factors are level of IOP, life expectance, family history, insufficient health care, decreased central corneal thickness, and myopia.

Epidemiology

Glaucoma is one of the leading causes of irreversible visual loss worldwide. The mean prevalence is estimated to be 1.96%. It has been estimated that by 2010, almost 45 million people will have open-angle glaucoma worldwide. Almost half (47%) of these people will reside in Asia, while 24% will be European. Individuals of African and Caribbean heritage have an increased risk of developing high-pressure glaucoma.

Holmium YAG Laser, Thermokeratoplasty

Jiaxi Ding and Hoon Jung
Department of Ophthalmology, Ross Eye Institute, State University of New York at Buffalo, Buffalo, NY, USA

Definitions

Thermokeratoplasty is the application of thermal energy to alter corneal curvature. This can be achieved by electrically heating a wire (conductive thermokeratoplasty) or via laser technology. Laser thermokeratoplasty (LTK) has the advantage of more targeted and controlled heat delivery, thereby avoiding spikes outside therapeutic temperature zones which cause necrosis, keratocyte damage, and increased wound-healing time. Numerous types of lasers for LTK have been explored, including carbon dioxide, hydrogen fluoride, erbium-glass, cobalt-magnesium fluoride, and, more notably, holmium:YAG (Ho:YAG) (Stasi and Azar 2007). Ho:YAG lasers are subcategorized as contact probe or noncontact type.

Indications

The idea of thermokeratoplasty has been described in literature dating back to 1879 with Gayet's use for keratoconus. Other reported applications include Lans in 1898 for corneal astigmatism, Terrien in 1900 for Terrien's marginal degeneration, O'Connor in 1933 for high myopic astigmatism, and Fyodorov of Moscow in 1981 for hyperopia (Stasi and Azar 2007). In modern refractive practice, the most established indication for holmium:YAG laser thermokeratoplasty (Ho:YAG LTK) by both the contact and noncontact types is mild to moderate hyperopia. Other indications described in literature include astigmatism associated with hyperopia and myopia. The use of LTK for myopia is still an ongoing investigation. LTK may be used to treat refractive error which is primary in nature as well as that induced by or residual from prior eye surgery (Eggink et al. 2000; Stasi and Azar 2007).

Contraindications

Contraindications to LTK are along similar guidelines of poor candidacy for refractive surgery in general. Pregnant or nursing women are prone to fluctuations. Autoimmune or connective tissue disease, such as systemic lupus erythematosus, polyarteritis nodosa, and rheumatoid arthritis, is at higher risk of prolonged inflammation, poor wound healing, and even corneal melt with perforation. The ocular surface in cicatricial disorders, severe dry eye or atopic disease, and chemical burns are also potentially problematic for wound

healing. Other conditions which may be considered relative contraindications for LTK include herpetic keratitis, corneal scarring or dystrophy within the central optical zone, glaucoma, amblyopia, insulin-dependent diabetes, and systemic immunodeficiency (Stasi and Azar 2007).

Techniques and Principles

The concept behind thermokeratoplasty is based within the corneal ultrastructure of collagen fibrils packed into parallel lamellae in a bedding of glycosaminoglycans. By dry weight, collagen comprises 71% of stroma. Therefore, changes in the chemical structure of collagen with heat application will subsequently alter macro-level cornea and topography.

The specific response of corneal collagen to heat depends on the intensity of temperature rise. Low amounts of corneal heating induce transient changes, if any at all. Collagen shrinkage, which is a disruption to the hydrogen bonds of its tertiary structure, occurs within a narrow range of 55–58 °C for humans. Beyond 78 °C, the contraction effect transitions to collagen relaxation as cross-links are hydrolyzed. Further heating beyond this point leads to necrosis and tissue destruction (Stasi and Azar 2007).

Thermokeratoplasty utilizes collagen contraction from heating into the 60 °C therapeutic zone to achieve a refractive effect of corneal flattening. Centrally applied heat causes central flattening, inducing an overall hyperopic shift that may be desirable in conditions such as myopia and keratoconus. Conversely, peripheral heating in either an annular or radial pattern induces central steepening that is applicable for treatment of hyperopia. A third function of thermokeratoplasty is the astigmatic effect of heating at only a specified meridian. For example, steepness at the 90° axis can be countered by applying heat to the periphery of the flatter 180° meridian, thus generating central steepening at the 180° meridian and neutralizing the original astigmatism (Stasi and Azar 2007). In general, the refractive effect is proportional to the number of burns performed.

The contact probe type of Ho:YAG LTK is made by Summit Technology (Waltham, MA). It employs infrared energy (2.06 μm) with pulse power of 19 mJ at 300 μs duration and repetition frequency of 15 Hz. Heat delivered through the probe's tip results in a subsequent cone-shaped zone of corneal shrinkage with approximate parameters of 700 μm diameter at the surface of corneal touch and 450 μm depth of penetration (Stasi and Azar 2007).

Sunrise Technologies (Fremont, CA) produces a noncontact type of Ho:YAG LTK. It operates at 2.13 μm wavelength which pulses at 250 μs duration with frequency of 5 Hz. The laser system is mounted to a slit lamp and able to deliver one to eight treatment spots simultaneously, each about 600 μm in size. To increase refractive effect, a second ring of treatment spots can be placed in addition to the first round. Alternatively, energy intensity and spot size can also be adjusted to alter treatment effect (Stasi and Azar 2007).

On the horizon is low-energy noncontact Ho:YAG LTK with intraoperative wavefront monitoring. This combination of Sunrise Hyperion laser with Shack-Hartmann wavefront sensor (Wavefront Sciences COAS) was first used at Cole Eye Institute in Cleveland, Ohio. Its advantage over conventional LTK is lower-energy application which reduces corneal tissue necrosis, regression, and induced subsequent astigmatism. Thus far, the real-time dynamic wavefront readings do not interfere with laser delivery and appears promising for future relay of wavefront information into intraoperative treatment strategy (Stasi and Azar 2007).

Outcomes

Contact Ho:YAG LTK

Contact type of Ho:YAG LTK can be used for mild to moderate hyperopia. In general, there is a transient phase of overcorrection initially after treatment which is followed by regression of this myopic shift and finally stabilization at 4–6 months postoperatively. Tutton and Cherry's study in 1996 placed two rings of eight laser spots

at 6.5 mm and 9 mm from the central visual axis for up to +4.0 D of hyperopia in 22 eyes. An average of +2.10 D of hyperopic correction was achieved in 17 eyes with no induced astigmatism. However, significant astigmatism (1.25–2.50 D) was produced in 23% of eyes requiring further astigmatic LTK correction. In this series, regression occurred in approximately 50% of cases by 2 years post-LTK, but they reported that many patients read remarkably well in the first few months (Tutton and Cherry 1996). Several other trials also experienced significant regression and lack of treatment predictability.

In regard to hyperopic astigmatism, LTK generates an overall myopic shift in the spherical equivalent of roughly half the amount of the astigmatic correction. In an investigation by Thompson of 26 eyes with astigmatism ranging from 1.5 to 4.0 D, the mean astigmatic correction achieved at 6 months post-op was 1.7 D. This method involved applying four spots, two on each side of the flat meridian at an 8.5 μM ablation zone (Stasi and Azar 2007).

Ho:YAG LTK can also be used as a secondary procedure on eyes with prior ocular surgery such as cataract extraction (CE), photorefractive keratectomy (PRK), laser-assisted in situ keratomileusis (LASIK), and penetrating keratoplasty (PK). Eggink et al. conducted a study that reported efficacy regarding LTK treatment of PRK overcorrection on seven patients with postoperative hyperopia and nine patients with astigmatism. They reported success for both of these conditions, achieving spherical correction of the hyperopia, although two of the seven eyes had induced astigmatism. As for astigmatic correction, the amount of correction was generally reduced with increasing diameter size of the treatment zone, and all eyes with significant improvement demonstrated overcorrection in the first initial postoperative phase. Overall, these authors offered holmium LTK as a useful option for the treatment of astigmatism and overcorrection hyperopia after PRK. However, the results are prone to low predictability and induced astigmatism (Eggink et al. 2000). In 1995, Hennekes reported his experience of astigmatic LTK on eyes with previous CE, PRK, and PK. Results included regression to almost baseline within 1 week and marked overshoot in astigmatic power of about 15 D. The author cautioned against over-interpretation of this small case series, but did express a probable higher propensity for large regression of astigmatic LTK in eyes with large corneal or corneoscleral full-thickness scars (Hennekes 1995).

Noncontact Ho:YAG LTK

Phase IIa and III US trials were conducted on 612 eyes from 379 patients to investigate the treatment of hyperopia with noncontact Ho:YAG LTK. The study aimed to achieve emmetropia in the 3–6 month postoperative period since refractive regression was highest during the first 3 months (0.3 D per month) but essentially leveled off by 6 months thereafter (0.02–0.06 D per month). This goal was accomplished in 62.5% of eyes which were within 1.00 D of emmetropia. The remaining eyes were all undercorrected, and retreatment was performed in ten of these patients. This extended US trial overall concluded that noncontact Ho:YAG LTK is a safe and effective method to correct mild to moderate (+0.75 to +2.50 D) hyperopia with very low risk of complications. An additional advantage of the noncontact system is preservation of untouched cornea allowing future laser in LASIK, PRK, and contact lens use (Stasi and Azar 2007).

Canadian investigators further pursued a phase III clinical trial of noncontact Ho:YAG LTK in 38 eyes with +0.77 D to +2.50 D of hyperopia and up to 1.00 D of astigmatism. At the final 2-year follow-up, 100% of eyes were within 1.0 D of intended refractive state and 92% within 0.5 D. The authors concluded noncontact Ho:YAG LTK as a safe and effective treatment of low hyperopia with predictable refractive results despite a tendency toward regression by 2 years (Rocha et al. 2003).

Astigmatic and myopic correction with noncontact Ho:YAG LTK is still ongoing investigations. Koch et al. described treatment of up to 4.0 D of astigmatism but with only 6 months of follow-up. In the case of myopia, there is an added challenge of central corneal haze and/or

opacification from the treatment which may be vision impairing, unlike that of mid-peripheral hyperopic and astigmatic treatments (Stasi and Azar 2007).

Complications

In general, higher temperatures of thermokeratoplasty not only alter collagen structure but also induce inflammation, corneal vascularization, epithelial thinning, and irregularity as well as stromal scarring (Stasi and Azar 2007). Other potential problems include persistent epithelial defects, infectious keratitis, recurrent erosions, corneal edema, pain, transient elevation in intraocular pressure, and mild foreign body sensation (Stasi and Azar 2007). Overall, Ho:YAG LTK is considered safe with most complications relating to failure to achieve primary goal of the procedure, namely, regression, induced astigmatism, and undercorrection (Hennekes 1995; Tutton and Cherry 1996; Eggink et al. 2000; Rocha et al. 2003; Stasi and Azar 2007).

Holmium-YLF Solid-State Laser

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Definition

Holmium YLiF4 (Ho:YLF) is a solid-state laser with a Ho^{3+} ion doped in yttrium lithium fluoride crystal as the active medium. Holmium-doped solid-state lasers are one of the popular approaches for generating 2 μm laser radiation where Ho:YLF lasers are mainly suited for low pulse repetition frequency (few 10s of Hz) Q-switched application.

Emission Wavelength

The specific emission wavelength for Ho:YLF lasers is 2064 nm.

Pumping Method

Most popular method for pumping these lasers is to use thulium-doped lasers, which in turn are pumped by diode lasers.

Medical Applications

Water has an absorption peak at 2064 nm; hence, Ho-YLF laser is highly absorbed by biological tissue resulting in low penetration depth. When a tissue is irradiated with Ho-YLF laser, due to its low penetration depth, the damage to the surrounding tissue is minimal. Therefore, these lasers are suited for making clean and precise incision and tissue ablation.

Homocystinuria

Jörg Stürmer
Kantonsspital Winterthur, Brauerstrasse, Winterthur, Switzerland
Augenklinik Kantonsspital, Winterthur, Switzerland

Definition

The term "homocystinuria" designates a biochemical abnormality, not a specific disease entity. There are many causes of homocystinuria. All affect one of the transsulfation pathways that convert the sulfur atom of methionine into the sulfur atom of cysteine. This pathway is the chief route of disposal of methionine.

Etiology

The most common defect, cystathionine β-synthase (CBS) deficiency, results in high concentrations of serum methionine (Kaye and The Committee on Genetics 2006a, b). One form of CBS deficiency is responsive to vitamin B6. Other metabolic variants of homocystinuria include defects of Vitamin B12 uptake or activation and tetrahydrofolate reductase deficiency. Two mechanisms probably explain most of the clinical symptoms seen: Firstly abnormal (hyper) coagulation because of "sticky" platelets; and secondly direct toxicity of homocysteine and its metabolites, causing endothelial cell damage.

Clinical Presentation

Clinical problems include multiple, recurrent thromboembolism. Arterial or venous thromboses may involve the cerebral, pulmonary, renal, and myocardial circulation. Patients may also show developmental delays/mental retardation, seizures, psychiatric disturbances, osteoporosis with bone deformities, scoliosis, high palatal arch, muscle weakness with a shuffling gait, and a marfanoid habitus. Ectopia lentis is the outstanding ophthalmic feature of homocystinuria and is detected in approximately 90% of patients. Ectopia lentis has been detected in patients of all age groups. Other reported ophthalmic complications of homocystinuria include retinal detachment, microphthalmos, optic atrophy, peripheral cystoid retinal degeneration, retinal artery occlusion, band keratopathy, and secondary glaucoma.

The potential for early clinical diagnosis is limited. Ocular abnormalities, because of their distinctive lens displacement, may lead to the diagnosis. The diagnosis should be considered in any child or young adult with thromboembolism affecting both the large and small arteries as well as the veins, particularly in association with developmental disabilities, mental retardation, or skeletal findings. Most patients, however, have nonspecific features so that definitive testing involving the measurement of serum or urine amino acids is not accomplished before the expression of more severe clinical symptoms.

Diagnostics

The specific enzymatic defect should be identified. However, all heritable forms of homocysteinuria exhibit autosomal recessive inheritance. Prenatal diagnosis is available for CBS deficiency using cultured chorionic villus cells or amniotic fluid cells to measure the activity of the enzyme. The chromosome map location is 21q22. More than 90 different disease-associated mutations of the CBS gene have been identified. The vast majority of these mutations are "private" mutations that occur in only a single or a very small number of families. The most prevalent mutations are the G307S and I278T mutations. Affected patients vary widely in the extent to which they manifest clinical abnormalities, suggesting considerable genetic heterogeneity. Some of the variability is accounted for by the

relative reduction of enzymatic activity. Absent to relatively low residual activity (up to 10%) of CBS has been noted among different families. However, there are reports of individuals with the identical genotype resulting in a different phenotype within the same family.

Differential Diagnosis

As some of the patients with homocystinuria express a marfanoid habitus, the main differential diagnosis is Marfan syndrome (Summers et al. 2006). Patients affected by Marfan syndrome do not exhibit developmental delays or mental retardation. Seizures or psychiatric diseases are also rare in Marfan syndrome. Measuring blood methionine levels will easily distinct Marfan syndrome from homocystinuria. As ectopia lentis together with glaucoma and cataracts are the main ophthalmological findings, all diseases with ectopic lenses (i.e., Stickler syndrome, Ehlers-Danlos syndrome, Weill–Marchesani syndrome, autosomal dominant ectopia lentis, and autosomal recessive ectopia lentis with or without ectopic pupils) have to be considered in the differential diagnosis.

Prophylaxis

Newborn screening using the bacterial inhibition assay (BIA) test or direct methionine assay may be used to detect increased concentrations of blood methionine. Normal values for serum methionine concentration are noted to be less than 2 mg/dl. Approximately 1 in 5000 infants is found to have blood methionine concentration more than 2 mg/dl. Increased concentrations of methionine may be minimal during the first 3 days of life until there is adequate protein intake (milk feedings). This is especially true in patients who are responsive to vitamin B6, who usually have some residual enzyme activity. It may therefore be preferable to screen for this disorder at 2–4 weeks of age. Early discharge at 24 h or even 18 h results in many missed cases and decreases screening effectiveness.

Recent evidence has shown that carriers (heterozygotes) for homocystinuria have an increased risk of thromboembolic events. Therefore, genetic counseling and screening should be offered to relatives of persons with homocystinuria.

Therapy

Treatment seems to reduce the risk of thromboembolic episodes. Because this is the major cause of mortality and morbidity in these patients, the survival rate may improve with early, effective treatment. Treatment depends on the underlying cause of homocystinuria. As first step, pyridoxine (vitamin B6) responsiveness should be ascertained, because approximately 50% of patients respond to large doses of this vitamin. Nonresponsive patients with CBS deficiency should be treated with methionine-restricted, cystine supplemented diet. Folic acid and betaine therapy may also be helpful with all patients. In the disorders of cobalamin metabolism and transport in which methylmalonic acid and homocystein appear in the urine, hydroxycobalamin treatment (vitamin B12) may be beneficial. Aspirin and dipyridamole have also been used to decrease the occurrence of thromboembolic phenomena. These thromboembolic phenomena are more prone to occur during anesthesia, surgical procedures, and prolonged immobilization.

The management of the main ophthalmic complication (ectopia lentis) is not easy (Harrison et al. 1998). Recurrent lens dislocation in the anterior chamber is the main indication for surgery followed by pupillary block glaucoma. Prophylactic peripheral iridectomy was not successful in preventing lens dislocation into the anterior chamber in 5/45 patients in one larger series. Other ocular complications include optic atrophy, iris atrophy, anterior staphylomas, lenticular, and corneal opacities.

Prognosis

Death has been reported within the first year of life. Approximately 50% of untreated individuals

die by 25 years of age; death is frequently a result of thromboembolic events. Developmental delay is reported in 65–80% of untreated individuals.

The incidence of the mental retardation may be prevented or reduced by treatment. For patients with classic (homozygous) homocystinuria, early treatment with good biochemical control (lifetime plasma-free homocysteine < 11 μmol/l) seems to prevent mental retardation, ectopia lentis seems to be delayed, and the incidence of seizures is reduced. Programs continue to evaluate the efficacy of screening and early treatment. Improvement in screening to decrease the numbers of missed cases is important.

Epidemiology

Although homocystinuria is a rare disorder, carriers of the condition represent a much larger population. If one assumes a worldwide incidence of 1 in 300,000 individuals, the expected carrier frequency is 1 in 135. Because carriers are more prone to thromboembolic events, ascertainment of these individuals via identification of an affected person needs to be emphasized to primary health care professionals.

Horizontal Eyelid Shortening

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Lateral canthoplasty; Lateral tarsal strip

Definition

In cases of horizontal laxity of the eyelid, surgically shortening and tightening the eyelid in its horizontal dimension, usually via a lateral tarsal strip procedure.

Indication

Horizontal eyelid shortening and tightening is indicated when horizontal eyelid laxity is present, often in combination with involutional ectropion, involutional entropion, and/or floppy eyelid syndrome. Horizontal laxity can be diagnosed clinically by utilizing the snap and distraction tests.

Contraindication

Any shortening of the eyelid should be conservatively performed. Aggressive resection of tissue can cause problems with secondary rounding and phimosis of the lateral canthal angle.

Techniques and Principles

After the degree of horizontal eyelid laxity is determined with the snap and distraction tests, surgery to horizontally shorten and tighten the eyelid is undertaken. Simple block excision away from the canthus can be performed for horizontal shortening; however, shortening is usually performed as part of the lateral tarsal strip procedure. A canthotomy and cantholysis are performed to allow free mobility of the eyelid. A tarsal strip is then fashioned by denuding the epithelium of the strip along the eyelid margin and posterior lamella; the anterior lamella is then recessed leaving a tarsal strip devoid of epithelial tissue. Conservative shortening of the strip may be performed at this point if desired, particularly in cases of floppy eyelid syndrome. A double-armed suture is then passed in a horizontal mattress fashion through the superior and inferior aspects of the tarsal strip. The upper and lower limbs of the suture are then passed so as to incorporate a purchase of periosteum of the inner aspect of the lateral orbital rim in the region of Whitnall's tubercle. This mattress suture is then tied under surgical tension. The skin incision from the lateral canthotomy is then closed.

Outcome

This maneuver results in horizontal tightening of the eyelid with improved eyelid position.

Complications

Aggressive resection of eyelid tissue at the lateral canthus can cause problems with secondary rounding and phimosis of the lateral canthal angle. Weakening of the orbicularis oculi muscle may occur if there is injury to the zygomatic branch of the facial nerve.

Synonyms

Lateral gaze center; Paramedian pontine reticular formation and abducens nucleus

Definition

The horizontal gaze center is a functional unit of neurons that generate coordinated, conjugate horizontal eye movements. Primarily, it includes the paramedian pontine reticular formation (PPRF) and the abducens nucleus in the pons. The PPRF is located on the medial aspect of the pontine reticular formation about 2 mm from the midline. The PPRF receives input through polysynaptic connections from the vestibular nuclei and contralateral frontal lobe for saccades. In addition, the PPRF contains most of the burst neurons that generate horizontal saccades. Neurons from the PPRF project to the ipsilateral abducens nucleus where they synapse with motor neurons of the lateral rectus and internuclear neurons. These interneurons send signals via the medial longitudinal fasciculus (MLF) to the contralateral medial rectus motor neurons resulting in a conjugate lateral gaze. Activation of the right PPRF will result in rightward gaze and activation of the left PPRF results in left horizontal gaze. Lesions in the PPRF may thus impair or limit horizontal conjugate eye movement.

The PPRF also projects saccade-related neurons to the cerebellum and reticulospinal neurons which mediate head movements and eye-head coordination.

Horner-Trantas Dots

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Definition

Horner-Trantas dots are collections of eosinophils and cellular debris along the limbus of patients with limbal vernal keratoconjunctivitis.

Etiology

Horner-Trantas dots occur in the limbal vernal keratoconjunctivitis subset of vernal conjunctivitis.

Clinical Presentation

Limbal vernal keratoconjunctivitis is more common among black patients. On slit-lamp examination, one would find intraepithelial and subepithelial deposits of eosinophils and cellular debris at the limbus of the cornea.

Diagnosis

Horner-Trantas dots can be diagnosed by finding white intraepithelial and subepithelial deposits at the limbus in patients with limbal vernal keratoconjunctivitis.

Differential Diagnosis

The differential diagnosis for Horner-Trantas dots are staphylococcal hypersensitivity or infectious corneal infiltrates.

Prophylaxis

There is no prophylaxis for Horner-Trantas dots.

Therapy

Horner-Trantas dots are not themselves treated as they do not become visually significant. However, the treatment for vernal keratoconjunctivitis is antihistamine, mast cell stabilizers, or even steroid topical agents.

Prognosis

The prognosis for Horner-Trantas dots is very good as they do not become visually significant. As the limbal vernal keratoconjunctivitis is treated and controlled, the Horner-Trantas dots will subside.

Epidemiology

Vernal conjunctivitis is usually seen in younger patients. Specifically, limbal vernal keratoconjunctivitis is more common among black patients.

Hudson-Stähli Line

Michael Coleman
Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Iron line

Definition

Intracellular iron deposition in the corneal epithelial cells which appears as a horizontal line of faint yellow to dark-brown discoloration in the inferior aspect of the cornea (Farjo and Sugar (n.d.)).

Etiology

Iron deposition is a result of pooling of tears in the regions of topographic irregularities, which allows iron from the tear film to be deposited within the epithelium over time (Palay 2011).

Clinical Presentation

Faint yellow to brown horizontal line found close to where the lid margins of the upper and lower lids meet when blinking (Farjo and Sugar (n.d.); Palay 2011). The prevalence increases with age and it is best seen using either cobalt blue or ultraviolet light. For this reason you may first notice it during a slit-lamp examination using fluorescein and cobalt blue illumination (Farjo and Sugar (n.d.); Palay 2011).

Diagnosis

This is a clinical diagnosis. The faint yellow to brown line is found on close examination of the corneal epithelium using the slit lamp with either white light or cobalt blue light.

Differential Diagnosis

1. Vortex keratopathy
2. Iron lines related to previous corneal surgeries
3. Previous corneal trauma
4. Epithelial melanosis related to limbal pigmented cells (e.g., melanoma)

Prognosis

Incidence is higher in the older population, but it is not visually significant.

Epidemiology

The line is seen in 29–90% of persons aged 60 years or more and it can be unilateral in 50% of people.

Hughes Procedure/Modified Hughes Procedure, in Eyelid Repair

Ronald Mancini and Helene Chokron Garneau
Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA

Synonyms

Lid sharing procedure; Tarsoconjunctival graft

Definition

Eyelid sharing procedure for extensive lower eyelid reconstruction, entailing advancement of a tarsoconjunctival flap from the upper eyelid to reconstruct a posterior lamella defect of the lower eyelid.

Indication

Utilized for the reconstruction of extensive (usually greater than 50%) lower eyelid defects, which involve the eyelid margin. Provides vascularized posterior lamellar tissue for full thickness eyelid reconstruction.

Contraindication

An intact healthy upper eyelid is required for the reconstruction. The flap will remain closed for several weeks obstructing vision out of the ipsilateral eye, therefore a seeing contralateral eye is required for vision. The Hughes flap should be avoided in monocular patients or in children at risk of amblyopia development.

Techniques and Principles

Extensive lower eyelid defects require reconstruction for comfort and protection of the eye. On occasion, these extensive lower eyelid defects mandate utilization of an otherwise normal upper eyelid for reconstruction in the form of a Hughes procedure.

Surgery begins with an assessment of the defect size. By grasping the proximal and distal cut ends of the eyelid with forceps and removing any slack, the defect size can be accurately measured. The upper eyelid is everted over a Desmarres retractor and the upper eyelid tarsus inspected. As much upper eyelid tarsus as possible should be left in place to ensure adequate structural support for normal upper eyelid function remains. An incision with a scalpel through

tarsus only, 4 mm below its upper border, will leave a large amount of tarsus in situ in the upper eyelid while providing approximately 4 mm of tarsal tissue to be grafted into the lower eyelid. The dissection is then carefully carried superiorly in a subconjunctival plane avoiding any buttonholes in the conjunctiva, which could compromise vascular supply to the graft. Care should be taken to leave as little Mullers muscle as possible on the tarsoconjunctival flap as this can contribute to upper eyelid retraction after flap separation. The dissection is carried superiorly towards the fornix until the tarsoconjunctival is freely mobile; back-cuts are created medially and laterally to facilitate mobilization. The tarsoconjunctival flap is then advanced into the lower eyelid posterior lamellar defect. The distal and proximal cut ends of the tarsus are sutured to the tarsus of the advancement flap with interrupted longer-lasting absorbable sutures such as vicryl or dexon. Care should be taken to assure the sutures are passed in a lamellar fashion to avoid any potential exposure to and/or abrasion of the cornea. The anterior lamellar is then reconstructed with either a local myocutaneous advancement flap or full thickness skin graft (e.g., upper eyelid, postauricular, preauricular, supraclavicular, etc.) depending on the size of the anterior lamellar defect and status of and laxity of the surrounding tissues.

The tarsoconjunctival flap is left closed to ensure adequate vascularization for several weeks. The tarsoconjunctival flap is then severed 1–2 mm above the anticipated new lower eyelid margin to allow for some degree of contraction. The residual conjunctiva of the flap is then repositied into the superior fornix and trimmed if necessary.

Outcomes

This is a two-stage procedure, which can often achieve a functional lower eyelid capable of providing adequate protection of the globe when extensive tissue loss is present. The reconstructed eyelid is devoid of lashes.

Complications

One of the most common complications of the procedure is upper eyelid retraction, which can on occasion warrant repair. The risk of this complication is theoretically reduced if Mullers muscle is not incorporated in the transposition flap thereby avoiding advancement of the muscle with subsequent retraction. Overly aggressive tarsal resection of the upper eyelid can result in destabilization and subsequent malposition of the upper eyelid. Lower eyelid malpositions such as entropion or ectropion can also occur.

Human Herpes Virus

Brooks P. Applewhite and Jonathan Lester
Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Herpesviridae; HHV; Human herpesvirus

Definition

Herpesviridae are a ubiquitous family of large, enveloped, double-stranded DNA viruses with linear genomes and icosahedral capsids. Human

herpes viruses (HHVs) are particularly notable for their capacity to establish acute, latent, and recurrent infection within a host (Whitley 2012).

Etiology

There are eight known human herpes viruses (HHVs). The HHVs are grouped into three subfamilies given their different viral characteristics, pathogenesis, and disease manifestations. HHV infections are most commonly benign, but HHVs can also cause significant morbidity and mortality, especially in the immunocompromised (Murray et al. 2013).

Human herpes virus-1 (HHV-1) and human herpes virus-2 (HHV-2) are known as herpes simplex virus type 1 and type 2, respectively. These viruses belong to the *Alphaherpesvirinae* subfamily, characterized by their primarily cellular target of mucoepithelial cells and viral spread through direct contact with active, virus-shedding lesions (e.g., cold sores) of mucous and epithelial membranes (Murray et al. 2013). Both HSV-1 and HSV-2 establish latency in neuronal cells, while the former (HSV-1) may also remain latent within cells of the cornea. In regard to ocular disease, HSV-1 and HSV-2 gain access to the trigeminal sensory ganglion during primary infection, where then the virus may enter a latent state and reemerge later on in its lytic phase (Tuli and Kubal 2014).

Human herpes virus (HHV-3), or varicella-zoster virus (VZV), also belongs to the *Alphaherpesvirinae* subfamily. VZV establishes latency in neurons, but targets T cells and mucoepithelial cells. In addition to close contact, VZV is transmissible via respiratory droplets (Murray et al. 2013). VZV, similar to HSV-1 and HSV-2, gains access to the trigeminal ganglion via retrograde migration from the skin during primary infection where the virus subsequently remains latent (Tuli and Kubal 2014).

Human herpes virus-4 (HHV-4) is known as Epstein-Barr virus (EBV). EBV, also called kissing disease, belongs to the *Gammaherpesvirinae* subfamily and is transmissible through saliva. EBV primarily targets B cells and epithelial cells and can establish latency or even immortalized infections within B cells (Murray et al. 2013).

Human herpes virus-8 (HHV-8), commonly known as Kaposi sarcoma-related virus, also belongs to the *Gammaherpesvirinae* subfamily and is the least prevalent of the HHVs. Similar to EBV, HHV-8 establishes latency within B cells. It differs, however, insofar as HHV-8 is transmitted through close, often sexual, contact and primarily targets lymphocytes (Murray et al. 2013).

Cytomegalovirus (CMV), or human herpes virus-5 (HHV-5), belongs to the *Betaherpesvirinae* subfamily, primarily targeting monocytes, granulocytes, lymphocytes, and epithelial cells. Transmitted through a host of mechanisms, including close contact, congenital transmission, tissue transplant, tears, and transfusions, CMV establishes latency in monocytes and myeloid stem cells (Murray et al. 2013).

Along with cytomegalovirus (CMV/HHV-5), human herpes viruses-6 (HHV-6), or herpes lymphotropic virus, and human herpes virus-7 (HHV-7) also belong to the *Betaherpesvirinae* subfamily. HHV-6 and HHV-7 are similar in that they both are known to primarily target lymphocytes and establish latency in T cells, and both are transmitted via saliva (Murray et al. 2013).

Human herpes virus-infected tissues usually correspond with predictable anatomic locations, as the primary cellular targets of each virus are relatively specific. HHV tropism can be highly restricted, given the nature of tissue-specific receptors. HHV replication begins upon cell surface receptor interaction with viral glycoproteins, virus-cell fusion, and release of the nucleocapsid into the cytoplasm (Murray et al. 2013).

Of the human herpes viruses, ocular diseases and complications typically arise from HSV-1, HSV-2, VZV, EBV, and CMV (Pavan-Langston 2008).

Clinical Presentation

Similar to the rest of the body, human herpes virus infections of the eye typically correspond to specific anatomic locations as a result of restrictive

tropism of HHV glycoproteins for tissue-specific receptors (Murray et al. 2013).

Herpes simplex infections (HSV-1 and HSV-2) of the eye usually present as disease of the anterior segment. Ocular HSV infections can present with a diverse and very difficult array of complications rooted in both infectious and immune pathogenic mechanisms and may occur as primary infection of a nonimmune host or recurrent infection in an immune or previously immune host (Pavan-Langston 2008).

Primary HSV disease can occur in neonates, children, and adults. In neonates, HSV ocular infection most typically arises as an acute conjunctivitis with frequently associated ulcerative keratitis. HSV ulcerative keratitis of the neonate may be diffuse with characteristic microdendrites, serpiginous epithelial defects, or less ominously as a punctate keratitis. Other detrimental primary, neonatal ocular HSV complications that occur in an acute or subacute timeframe are necrotizing chorioretinitis, optic neuritis, cataracts, and strabismus resulting from CNS damage or phthisis bulbi (Barnes et al. 2010).

Primary ocular HSV infection in children and adults usually arises 3–9 days after exposure and most commonly presents as an acute periorbital skin infection. Primary ocular HSV infection may also present as a keratoconjunctivitis, conjunctivitis, blepharitis, and, uncommonly, iridocyclitis (Barnes et al. 2010). Although very few infected individuals present with overt disease, those who do may have periorbital dermatitis or blepharitis with severe vesicular lesions and hemorrhagic blisters, pseudomembranous follicular conjunctivitis, geographic ulceration, corneal ulceration, and iritis (Tuli and Kubal 2014). Keratitis will develop in the majority of patients and is initially characterized by punctate staining that converts to multiple diffuse microdendritic epithelial defects or serpiginous ulcers within the first day (Barnes et al. 2010).

Recurrent ocular herpes can occur in the forms of blepharitis, conjunctivitis, geographical or dendritic keratitis, sterile corneal neurotrophic ulcerations, trabeculitis, endotheliitis, iridocyclitis, and stromal keratitis (interstitial keratitis, immune rings, limbal vasculitis, and disciform keratitis) (Barnes et al. 2010).

Acute and recurrent varicella-zoster virus (VZV/HHV-3) infection of the eye, also known as herpes zoster ophthalmicus (HZO), can be a devastating ocular disease with many complications. HZO can impact a vast number of ocular tissues, with complications including but not limited to pseudodendritic keratitis, disciform or neurotrophic keratitis, punctate epithelial keratitis, corneal stroma infiltrates, diffuse iridocyclitis, iris atrophy, scleritis and episcleritis, secondary glaucoma, canalicular scarring, neuro-ophthalmic involvement with nerve palsy or hemiplegia, and postherpetic neuralgia (Barnes et al. 2010).

The most common ocular manifestation of cytomegalovirus (CMV) infection is chorioretinitis, the prevalence and severity of which have declined dramatically since the advent of HAART (highly active antiretroviral therapy) in preventing patient progression from HIV to AIDS (Pavan-Langston 2008). Cytomegalovirus infection of the anterior segment, either alone or in conjunction with CMV retinitis, may manifest as a follicular conjunctivitis, iritis, or as asymptomatic linear and stellate endothelial deposits most frequently found in a reticular pattern within the inferior cornea (Pavan-Langston 2008).

While associated with infectious mononucleosis, Hodgkin's disease, African Burkitt's lymphoma, and nasopharyngeal carcinoma, Epstein-Barr virus (EBV/HHV-4) is also associated with anterior segment and neuro-ophthalmic disease. Manifestations of EBV ocular infection may include: papilledema, optic neuritis, cranial nerve palsies, follicular or hemorrhagic conjunctivitis, nodular or flat scleritis, infectious dendritic epithelial keratitis or stromal keratitis, and extranodal natural killer/T-cell lymphomas of the eye (Pavan-Langston 2008).

Diagnostics

Diagnosing viral infections of the eye is usually done by clinical observation alone. When in need of objective data, four common methods are utilized: (1) examination of skin, corneal, or conjunctival scrapings (of the human herpes viruses, this method is most used for HSV-1 and HSV-2);

(2) immunologic and molecular assays; (3) viral culture; and (4) detection of circulating antibodies. Another strategy, used almost exclusively in herpetic ocular disease, is histopathologic analysis of corneal tissue post keratoplasty. Additionally, polymerase chain reaction (PCR) can successfully detect HSVs and VZV in the tear film and corneas of infected patients (Tuli and Kubal 2014).

Differential Diagnosis

The differential diagnosis of all the human herpes viruses is diverse and extensive and with much overlap. Important associations to consider on a differential include human herpes viruses with similar presentations, other forms of microbial keratitis (other viruses, bacteria, and fungi), and much other inflammatory, autoimmune, or oncologic pathology with similar presentation (Barnes et al. 2010).

Prophylaxis

There are many antiviral prophylactic means to help with frequent recurrences, especially for use in patients with bilateral disease, stromal disease, and to assist in high-risk and stressful periods such as other illness, fever, chemotherapy, and ocular surgeries (Pavan-Langston 2008). Prophylaxis for a particular HHV and given symptomatology is relatively specific and warrants investigation of most current, evidence-based best practices. For example, various combinations of antivirals, such as acyclovir, famciclovir, valacyclovir, and a handful of others, should only be used as prophylaxis with certain HHV pathologies and conditions, often in conjunction with other medications like topical steroids or even specialized, therapeutic contacts. With other HHVs, medications, and interventions like these have no prophylactic value (Tuli and Kubal 2014).

The role and implications of vaccines for ocular HHV diseases, such as in the development of an HSV vaccine, is controversial given the failures of many systemic vaccines to induce local ocular immune responses. Yet, in another instance, evidence of vaccine efficacy is more robust regarding the prevention of varicella-zoster infections and progression to herpes zoster ophthalmicus (Pavan-Langston 2008).

Therapy

A wide range of therapies are systematically used in the treatment of ocular human herpes viruses (HHVs), specifically tailored to the HHV infection and its physical manifestation within a given patient. Common treatments include classes of systemic and ocular antivirals, steroids, antibiotics, sympathomimetic and parasympathomimetic agents, immunomodulators, lubricants, glues, analgesics, therapeutic lenses, and others in addition to surgical interventions like penetrating keratoplasty, tarsorrhaphy, and more (Pavan-Langston 2008). Interventions for a given patient with a particular HHV infection and associated symptomatology should be diagnosed and treatment with specific, current, evidence-based interventions provided.

Prognosis

Patient prognosis is highly dependent upon the infectious etiology and can vary greatly with type of human herpes virus (HHV) infection and location of the infection, among many other factors such as general patient health and immunocompetence.

Epidemiology

Human herpes viruses (HHVs), HHV-8 aside, are a ubiquitous family of virus. In regards to HHVs with significant impacts on eye health, herpes simplex viruses (HSV-1 and HSV-2) are the most common cause of corneal blindness in the resource-rich world, with approximately 500,000 cases diagnosed in the United States annually. Ocular manifestations of the disease are largely

caused by HSV-1. Multiple recurrences, however, are far more common with oral or genital HSV infections than with the ocular form of the disease (Pavan-Langston 2008).

Herpes zoster is recurrent infection with varicella-zoster virus (VZV). Up to 20% of the world's population will have herpes zoster in their lifetime, with up to 50% of those who reach 90 years of age having zoster at some point in life. Herpes zoster has a predilection for females over males, with incidence rates increasing with age and highest among individuals over 80 years of age. Furthermore, herpes zoster incidence is four times greater in Whites when compared to Black and Asian ethnic groups. The incidence of herpes zoster is also greater in patient populations with organ transplants, HIV infection, and cancer (Pavan-Langston 2008).

Asymptomatic cytomegalovirus (CMV) is very common among the immunocompetent, with 50–100% of all individuals having antibody presence indicative of previous CMV infection. CMV is the most common virus to be transmitted in utero, with an incidence of 2.2% of all live births. The incidence of CMV among patients with HIV/AIDS has decreased dramatically since the advent of HAART (highly active antiretroviral therapy), dropping from 7.34 cases per 100 patient years in the pre-HARRT era of 1993–1996 to 0.75 cases per 100 patient years or lower since (Pavan-Langston 2008).

Epstein-Barr virus (EBV) has a very high prevalence, with 90% of individuals positive for EBV antibodies by 30 years of age. Half to 85% of children under the age of 4 living in lower socioeconomic conditions are positive for EBV-specific antibodies, and 26–82% of college students are positive (Pavan-Langston 2008).

Human Papilloma Viruses, Ocular Infection

Brooks P. Applewhite and Jonathan Lester
Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Conjunctival papilloma; HPV; Human papillomavirus; Infectious papilloma; *Papillomaviridae*; Verrucous lesion; Wart

Definition

A wide and ubiquitous group of DNA viruses with over 100 strains, 9 of which most commonly result in benign ocular papillomatous lesions of the conjunctiva, eyelid margin, and skin of the eyelids

Etiology

Human papilloma viruses (HPVs) are members of the Papillomaviridae family, a group of nonenveloped viruses characterized by double-stranded circular DNA and enclosed in an icosahedral capsid measuring approximately 55 nm in diameter (Douglas 2012). HPVs cause disease through aberrant cell growth. Some strains are considered to be high risk, associated with high-grade squamous intraepithelial lesions and genital tract cancers, and others low risk given their association with warts and other low-grade squamous intraepithelial lesions.

In regard to ocular disease, HPV strains 6 and 11 are most commonly involved in infections of mucous membranes and less frequently HPVs 16, 18, and 33. HPV strains 1–4 most commonly infect skin sites. Papilloma infection with multiple subtypes has also been described (Pavan-Langston 2008).

Infection is spread between individuals through fomites and direct contact with a given site, although conjunctival inoculation through this means of transmission is still under investigation. Further autoinoculation may occur and the resultant spread can lead to multicentric HPV infection. For neonates, direct contact with infected maternal tissues or fluids is a suggested mode of transmission (Douglas 2012).

The role of human papilloma virus in neoplastic transformation of ocular epithelial cells is unclear. While studies have noted that HPVs are found in approximately one third of samples of normal conjunctival tissue, other studies have identified the presence of HPV mRNA at a higher frequency in ocular lesions of patients with conjunctival intraepithelial neoplasia. Other studies have also shown that HPV infection may be associated with a number of other neoplastic and non-neoplastic ocular diseases, including in situ squamous cell carcinoma, invasive squamous cell carcinoma, sporadic retinoblastoma, climatic droplet keratopathy, and scarred corneas (Pavan-Langston 2008).

Clinical Presentation

Human papilloma viruses typically cause benign ocular changes in the form of fleshy, red-pink, sessile (broad-based), or pedunculated (narrow-based) lesions with "fingerlike" projections (Lang 2000). Lesions of the conjunctiva are more commonly reddish in color and those of the skin, grayish. Pedunculated lesions are more often found in children and frequently arise in the fornix and sessile lesions in adults and the bulbar conjunctiva, respectively, but either may occur in any age group and in any part of the conjunctiva. Papillomatous HPV lesions may also arise on the skin of the eyelids and on or within the lacrimal sacs, puncta, ducts, or canaliculi (Palazzi 2008). The limbal or corneal surfaces may become involved, but this is unusual and could be related

to other disease processes including superficial punctate keratitis or pannus formation (Pavan-Langston 2008).

HPV papillomas of the bulbar or palpebral conjunctiva commonly lead to continuous foreign-body sensation. Other symptoms less commonly experienced include irritation, mild to moderate itching, tearing, mucoid discharge, hyperemia, blurred vision, and photophobia. Larger lesions have the propensity to cause punctate epithelial erosions or diffuse keratitis, given the interference with eyelid apposition and tear-film integrity. Occasionally, however, no symptoms are experienced at all (Palazzi 2008).

In immunocompromised patients, HPV ocular infection may be more significant. Infectious papillomas may be larger, multiple, and/or bilateral (Pavan-Langston 2008).

Diagnostics

Diagnosis is commonly made by clinical observation and confirmed with biopsy. Histopathology indicative of HPV infection includes papillomatosis with hyperkeratosis, parakeratosis, and acanthosis. Keratinocytes are commonly large and vacuolated with a notable large halo surrounding the basophilic nuclei. Conjunctival papillomas consist of multiple branching fronds, each with a vascular core, all arising from a single broad (sessile) or narrow (pedunculated) base (Palazzi 2008).

Differential Diagnosis

The differential diagnosis includes both benign and malignant lesions. As such, emphasis is placed on the importance of histopathologic analysis to avoid misdiagnosis of malignant tumors, especially in older patients (Palazzi 2008).

Differential diagnosis:

- Capillary hemangioma
- Pyogenic granuloma
- Squamous cell carcinoma
- Sebaceous cell carcinoma

Prophylaxis

Recurrences of virally induced conjunctival papillomas and cutaneous warts are common. The immunomodulating effects of cimetidine, a histamine2 receptor antagonist commonly used for peptic ulcer disease, have demonstrated significant regression of diffuse HPV-induced papillomatosis. Recommended oral cimetidine dosing is 30 mg/kg/day divided into three doses, taken for 4 months (Palazzi 2008).

The quadrivalent HPV vaccine may also help provide protection against the ocular effects of strains 6, 11, 16, and 18 (Pavan-Langston 2008).

Therapy

Many HPV-induced papillomas spontaneously regress over the course of 1–2 years, and observation is often deemed suitable for asymptomatic individuals or those with only mild symptoms (Pavan-Langston 2008).

Primary therapy consists of surgical excision, cryotherapy, or both. The use of both modalities helps reduce the frequency of further seeding and recurrence, which is common. One surgical strategy to avoid seeding and recurrence includes initial cryotherapy followed by lesion elevation and excision at the papilloma stalk base with inclusion of a small area of normal surrounding tissue and subsequent double freeze-thaw cryotherapy to the excised area. Specifically, papillomas of the lid may be treated with electrodesiccation or heat cautery (Pavan-Langston 2008).

Topical agents, like the antimetabolite mitomycin C (MMC) or the immunotherapeutic interferon alfa-2b (IFN α-2b), may also be considered as adjunctive or alternative therapies for diffuse, large, or recurrent lesions. Complications, however, have been seen with excessive MMC use or when used with open conjunctival wounds, and punctal plugs are recommended to prevent damage to nasopharyngeal tissues. While considered a relatively safe and successful alternative treatment for conjunctival papillomas, IFN α-2b is considered to be a suppressive, not curative, therapy and long-term follow-up is required. Moreover,

superficial keratitis may be a possible side effect of IFN α-2b, but seems otherwise a relatively benign, topical drug (Palazzi 2008).

Prognosis

HPV-associated ocular papillomas are largely benign, but recurrence is frequent, and histopathologic confirmation is recommended, especially in adults, to avoid misdiagnosis of malignancies. Adults with long-standing papillomatous lesions should be treated and monitored, as some papillomas may demonstrate malignant transformation. Lesions in children and young adults are nearly always benign (Palazzi 2008).

Epidemiology

Nongenital HPV prevalence data ranges from 3% to 20%, but greater prevalence is noted among HIV-positive and other immunocompromised populations (Douglas 2012). HPV-associated infectious ocular papillomas are more frequently diagnosed in males. There is no predilection for ethnicity. Studies report the frequency of HPV DNA in conjunctival papillomas as ranging from 50% to 100% (Palazzi 2008).

Hurler-Scheie Syndrome

Sana Idrees
The George Washington University, Washington, DC, USA

Synonyms

MPS I-HS

Definition

Hurler-Scheie syndrome is a lysosomal storage disorder, more specifically a type I mucopolysaccharidosis. It is an inherited disorder, resulting from mutations in the lysosomal enzyme α-1-iduronidase. The deficiency leads to intracellular and extracellular accumulation of the glycosaminoglycans (GAGs) dermatan and heparan sulfate, resulting in cell death, tissue damage, and excessive secretion of these GAGs in urine. Hurler-Scheie syndrome is an intermediate form of the disease between the severe Hurler's syndrome and the milder Scheie syndrome. They are thought to have inherited one Hurler and one Scheie gene from each parent (Srinivasan et al. 2011). Both Hurler and Scheie syndromes are autosomal recessive (Arrfa 1997).

Hurler syndrome manifests at 6–12 years of age. They develop gargoyle-like coarse facial features, hypertelorism, skeletal deformities, short stature, large head circumference, communicating hydrocephalus, mental retardation, cardiac complications, and hepatosplenomegaly (Srinivasan et al. 2011). Corneal clouding is a prominent feature of the disease, and its features develop within the first few days to months of birth. Initially the cornea may be clear, but soon afterward it develops an avascular noninflammatory clouding (Arrfa 1997). The opacities are initially fine gray punctate opacities found in the anterior stroma, which progress to involve the posterior stroma and endothelium, forming a diffuse ground-glass haze (Waheed and Azar 2005). The thickness of the cornea may increase secondary to the glycosaminoglycans (Arrfa 1997). Other ocular complications include retinal pigmentary degeneration, glaucoma, optic nerve swelling, and optic atrophy. Corneal transplantation success may be limited by the retinal manifestations of the disease. Most Hurler syndrome patients die within the first decade of life (Srinivasan et al. 2011).

Scheie syndrome is a rare disorder characterized by joint stiffness and deformity of the hands, carpal tunnel syndrome, and aortic valve disease. It is caused by a different defect in the same enzyme affected in Hurler's syndrome, α-1-iduronidase. Ocular signs include progressive severe corneal clouding that is more marked at the periphery but may affect the entire cornea (Arrfa 1997). Proteoglycan material deposits in the stromal lamella, which is characteristic of all mucopolysaccharidoses. The histologic appearance of the cornea in Scheie syndrome is characterized by epithelial breaks with peg-like undulations, marked attenuation of Bowman's layer, and fibrous long-spacing collagen (Srinivasan et al. 2011). They may also develop pigmentary retinopathy, optic atrophy, and glaucoma (Arrfa 1997). Symptoms of Scheie syndrome present between 5 and 15 years of age. These patients have normal height and intelligence (Srinivasan et al. 2011).

Patients with Hurler-Scheie syndrome have an intermediate phenotype between Hurler and Scheie syndrome. They typically have normal intelligence and mild facial changes. Ocular manifestations of the disease include corneal opacification due to accumulation of dermatan and heparan sulfate and retinopathy. They tend to die in their twenties or later secondary to cardiopulmonary disease (Srinivasan et al. 2011).

Hurricane (Vortex) Keratopathy

Zaiba Malik
Wright State University School of Medicine, Dayton, OH, USA

Synonyms

Blizzard keratopathy; Vortex keratopathy

Definition

Whorl or vortex pattern given to pattern of corneal surface growth in states of increased replicative epithelial turnover.

Etiology

Turnover of corneal epithelium from stem cells located at limbus.

Clinical Presentation

Most often seen at the epithelium of corneal grafts. Also seen after long-term topical steroid use or deposition of substances like pigment, iron, drug metabolites, and glycogen. In addition seen in patients with no corneal graft but evidence of chronic epithelia breakdown and healing. Whorl pattern is sustained as long as the stimulus for increased cell turnover is maintained. Once the stimulus is eliminated, the pattern tends to resolve spontaneously.

Diagnostics

Highlighted with fluorescein staining of cornea under slit-lamp biomicroscopy

Differential Diagnosis

Differential diagnosis includes corneal verticillata and crystalline keratopathy.

Prophylaxis

Removal of epithelial cell turnover stimulus.

Prognosis

Good.

Epidemiology

Not enough studies.

Hyaluronic Acid, for Dry Eye

Deepak Raja
Department of Ophthalmology, University of Central Florida, College of Medicine, Orlando, FL, USA
Orlando Eye Institute, Orlando, FL, USA

Synonyms

Ophthalmic Viscosurgical Device (OVD)

Definition

Glycosaminoglycan disaccharide composed of repeated units of D-glucuronic acid and *N*-acetyl-

D-glucosamine. It is found in many human tissues including synovial fluid, skin, cartilage, and the vitreous.

Etiology

Studies suggest that hyaluronic acid promotes migration of corneal epithelial cells, but not necessarily proliferation (Gomes et al. 2004).

Clinical Presentation

It can be helpful for cases of moderate to severe ocular surface disease.

Prophylaxis

Hyaluronic acid can be used to lubricate the cornea during ophthalmic surgery.

Therapy

Hyaluronic acid (HA) is a viscoelastic agent often used to lubricate the cornea for ophthalmic surgeries. For patients with moderate to severe dry eyes, 0.4% hyaluronic acid eye drops have been effective in improving the signs and symptoms of dry eyes (Kinoshita et al. 2013). Results have been more dramatic with a hypotonic solution of 0.4% HA(150 mOsm/L) than an isotonic solution (300 mOsm/L) (Koh et al. 2013).

Prognosis

When used as a chronic outpatient treatment for keratoconjunctivitis sicca, 0.4% HA was found to improve tear-break-up time, fluorescein and Rose Bengal staining, Schirmer I scores, tear osmolarity, impression cytology, and patient symptoms. Hyaluronic acid may cause higher-order aberrations due to light scatter for the first 5 min after instillation (Lester et al. 2000).

Hydrodissection

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Cortical cleaving hydrodissection

Definition

Hydrodissection and hydrolineation describe lens surgery techniques. This step in cataract surgery succeeds the corneal incision and capsulorrhexis stages.

Hydrodissection causes the dissection of the lens from the cortex which is performed to enable the following emulsification of the lens.

Epidemiology

Hydrodissection has become an integral part of microincisional lens surgery. Because cataract surgery is among the most often performed operation, the frequency of hydrodissection technique is very high today.

History

In 1984, Faust performed first the hydrodissection by placing a cannula beneath a "beer-can" capsulotomy opening.

In 1990, Sheperd reintroduced this technique after the development of the continuous curvilinear capsulorrhexis. He described the method of irrigating fluid into the nuclear-cortical plane and thus allowing nuclear rotation and crosshatch sculpting.

After that, Anis developed the part of hydrodelineation which describes the injection of irrigation fluid into the nucleus to isolate the inner nucleus from epinucleus.

In conclusion, Fine eventually established the hydrodissection technique and named it "cortical cleaving hydrodissection."

Clinical Features

Hydrodissection and hydrodelineation are performed with the same cannula.

Tests

Preoperative requirements compromise an ophthalmological examination of both eyes to determine the nature or severity of cataract. Also visual acuity, refraction, and workup of the patient's anamnesis should be practiced to eliminate possible exclusion criteria for cataract surgery with the phacoemulsification technique.

Differential Diagnosis

Apart from hydrodissection, one can apply the hydrodelineation technique to separate the epinucleus from the endonucleus. Another related method is the viscodissection, used in cases of hard nuclei.

Etiology

See "History" section above.

Treatment

The hydrodissection should be performed through the main incision. BSS fluid is injected under the anterior capsular rim advanced toward the equator using a 25- or 27-gauge blunt cannula attached to a 2 ml syringe. The successful hydrodissection induces a wave of dissection toward the equator and subsequently a wave in the opposite direction under the posterior capsule. Injection should be made in different independent points to prevent, for example, a capsular block syndrome.

Afterward the nucleus should be freely rotating in the capsular bag.

Hydrophilic Acrylic Intraocular Lens

Daniel Kook[1], Mehdi Shajari[2] and Thomas Kohnen[2]
[1]Department of Ophthalmology, Ludwig-Maximilians University, Munich, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Hydrophilic acrylic IOL; Hydrophilic polyacrylic IOL

Definition

Artificial lens made of transparent hydrophilic acrylic that is implanted in the eye and performs in focusing images. Hydrophilic means that this type of IOL has a strong affinity for water.

Epidemiology

Most of the worldwide-implanted IOLs are made of acrylic today. The most common acrylic IOL however is made of hydrophobic acrylate.

History

See also entries "► Intraocular Lens" and "► Acrylic Intraocular Lens." The first hydrophilic acrylic IOL was implanted in 1983 in Perth, Australia.

Clinical Features

Hydrophilic acrylic IOLs are manufactured from polyhydroxyethyl methacrylate (pHEMA) and have a refractive index of 1.47. Their water content is between 18% and 36%. These lenses are smaller in the dry state and swell on hydration (Barrett et al. 1986; Werner 2008). Advantages of this type of IOL are that they are less harmful to the corneal endothelium, they fold and unfold faster, IOL material is highly compressible due to its water content, mechanical properties are not temperature dependent, IOLs provide very good optical clarity, and they are not expensive. In patients after trauma with underlying uveitis, hydrophilic acrylic IOLs display better biocompatibility than hydrophobic acrylic IOLs. Disadvantages are their high flexibility and reduced tensile strength and high rates of decentration as they lack adhesive property to the lens capsule. Also, the rate of posterior capsule opacification is higher than in hydrophobic acrylic IOLs (Auffahrt 2008).

Tests

During the decades, hydrophilic acrylic IOLs have undergone extensive research and testing in Europe, Asia, and the USA and have been proven safe for the treatment of cataracts and refractive errors.

Differential Diagnosis

Foldable IOLs may also be made of hydrophobic acrylic or silicone.

Etiology

The term hydrophilic refers to Greek "hydor" = water and "philein" = to love. The term acrylic refers to the Latin word "acer" or the Greek word "ákros" that mean "sharp" due to the smell of acrylic acid.

Treatment

See also entries "► Cataract Surgery" and "► Refractive Surgery" describing different IOL implantation techniques.

See also entries "▶ Intraocular Lens" and "▶ Acrylic Intraocular Lens." The first acrylic IOL was implanted in 1983.

Clinical Features

Hydrophobic acrylic IOLs are made of copolymer of phenylethyl acrylate and phenylethyl methacrylate. They have a refractive index of 1.55 and their water content is below 1%. Advantages of hydrophobic acrylic are the reduced rate of posterior capsule opacification and the higher refractive index that results in thinner lens thickness. Disadvantages are their tacky nature to surgical instruments, their susceptibility to mechanical damage, and their reduced optical clarity compared to hydrophilic acrylic IOLs (Kohnen and Koch 2009; Auffahrt 2008; Werner 2008).

Tests

During the decades, hydrophobic acrylic IOLs have undergone extensive research and testing in Europe, Asia, and the USA and have been proven safe for the treatment of cataracts and refractive errors.

Differential Diagnosis

Foldable IOLs may also be made of hydrophilic acrylic or silicone.

Etiology

The term hydrophobic refers to Greek "hydor" = water and "phobos" = fear. The term acrylic refers to the Latin word "acer" or the Greek

word "ákros" that mean "sharp" due to the smell of acrylic acid.

Treatment

See also entries "▶ Cataract Surgery" and "▶ Refractive Surgery" describing different IOL implantation techniques.

Hydrops, Keratoconus

David Shiple
Ophthalmic Consultants of Vermont, South Burlington, VT, USA
Flaum Eye Institute, University of Rochester, University of Rochester Medical Center, Rochester, NY, USA

Synonyms

Acute hydrops keratoconus; Corneal edema

Definition

Acute hydrops is caused by a rupture in Descemet's membrane that allows an influx of aqueous into the cornea.

Etiology

Hydrops is often seen or discussed in the context of keratoconus. Keratoconus is a progressive ectasia, or thinning, of the corneal stromal tissue. As the cornea thins, it becomes structurally weaker and progressively will come forward with increasing astigmatism. This bulging forward can be demonstrated by Munson's sign, Rizzuti sign, or serial topography or keratometry. This progression puts stress and strain on Descemet's membrane and endothelium. In patients with advanced keratoconus, breaks in Descemet's membrane may occur, providing channels for the aqueous humor to pass into the stroma, resulting in marked corneal edema. This is known as acute hydrops and presents clinically as a sudden onset of pain and loss of vision.

Descemet's membrane is the basement membrane of the corneal endothelium. Descemet's membrane is composed mainly of type IV and VIII collagen and does not regenerate after injury. It is synthesized by endothelial cells and assembled at the basal surface. Ultrasound biomicroscopy of keratoconic eyes with acute

hydrops reveals intrastromal clefts connected to the anterior chamber, which separate the stroma from the ruptured Descemet's membrane. These clefts may develop simultaneously or immediately after the rupture of Descemet's membrane (Abbey and Yoo 2010). There is also separation between the stroma and Descemet's membrane caused by these clefts. This extra level of separation represents a focal area of Descemet's detachment. This could lead to delayed closure and slower resolution of stromal edema.

If acute hydrops occurs, patients will present with a sudden onset of blurry vision and intense foreign body sensation with photophobia. As the corneal swells, there can be secondary epithelial breakdown and risk for secondary corneal infection. Slit-lamp biomicroscopy demonstrates diffuse opacification of the corneal stroma and injection of the conjunctiva. The corneal stroma may appear protuberant and very thickened. There may also be epithelial breakdown over the area of stromal edema.

The opacification often resolves without intervention over the course of 6–10 weeks, but scarring commonly occurs after the edema resolves. In the acute phase, patients may have some relief from hypertonic drops or ointment as well as cycloplegic agents. As the edema improves, comfort and clarity of the cornea improve. However, residual scarring occurs along with changes to astigmatism. Non-resolution of the opacification, poor best corrected visual acuity, unstable contact lens, and contact lens intolerance are all indications for penetrating keratoplasty. A history of acute hydrops can be a contraindication to performing a deep anterior lamellar keratoplasty (DALK) for keratoconus.

Histopathology of post-keratoplasty corneal buttons 4 months after the onset of hydrops demonstrated significant stromal edema. The rupture and detachment of Descemet's membrane resulted in the formation of ledges or ridges (Stone et al. 1976). As the detached areas heal, new endothelium migrates and covers the exposed areas of stroma. The areas of ledges are covered as well. During this time, the endothelium regenerates basement membrane.

Hydrops is often seen or discussed in the context of keratoconus. However, other causes of spontaneous breaks of Descemet's membrane include obstetric forceps injury, congenital glaucoma, Terrien marginal degeneration, and pellucid marginal degeneration. Allergy and eye rubbing are risk factors for the development of hydrops.

Patients with congenital glaucoma are often referred to the ophthalmologist because of corneal edema. Because infants have immature and growing collagen that makes up the cornea and sclera, increased intraocular pressure can result in profound ocular enlargement. As the corneal diameter increases, collagen fibers in Descemet's membrane are exposed to the increased tension. As the cornea stretches, Descemet's membrane and the overlying corneal endothelium may tear. This results in aqueous access to corneal stroma and cornea edema or acute hydrops. With time, edema resolves and endothelial cells migrate over the breaks and lay down new basement membrane. Following this, ridges develop along the separated edges of Descemet's membrane and can be seen clinically. This line of double striae is called Haab's striae.

Children with congenital glaucoma often present due to the cornea edema that causes the triad of epiphora, blepharospasm, and photophobia. Other presenting findings of children with congenital glaucoma include progressive unilateral myopia.

Occurrence

It occurs in approximately 3% of keratoconic eyes (Tuft and Buckley 1994).

Classification

Hydrops is an acute event with variable amount of corneal swelling and symptoms of discomfort. Although the break usually heals within 6–10 weeks and the corneal edema clears, a variable amount of stromal scarring may develop. Hydrops is not typically classified, but can be followed with serial examinations, with corneal thickness maps (anterior segment ocular coherence tomography, ultrasound pachymetry,

Pentacam), or by following corneal curvature with topography.

Hyperacuity (Vernier Acuity)

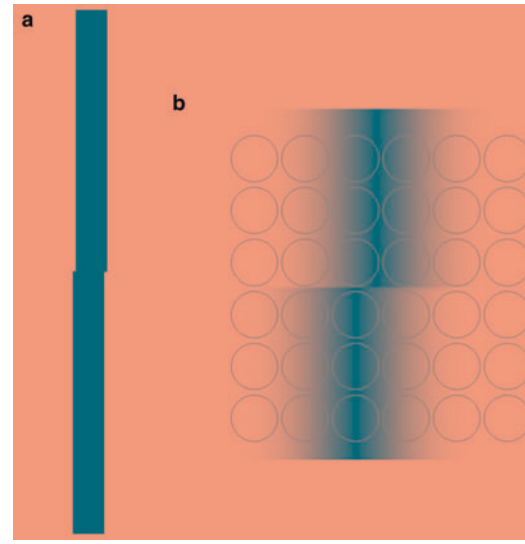
Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Nonius acuity; Vernier acuity

Definition

Under optimum conditions, spatial offsets of 2″ to 6″ can be recognized in high-contrast targets. Because the angle of the offset is finer than expected from the spacing of foveal photoreceptors, this type of visual acuity is called hyperacuity. One example of hyperacuity is Vernier acuity, which is determined by recognizing a just notable break in two lines vertically aligned (Fig. 1a). One explanation for the much higher resolution is the detection of contrasts above and below the break (Fig. 1b). There are other forms of hyperacuity such as spatial interval acuity and the detection of a single point relative to a circle.



Hyperacuity (Vernier Acuity), Fig. 1 Vernier acuity. (**a**) Setup with two vertically aligned bars with horizontal offset. (**b**) Different stimulation of cones in the region above and below the break allows detection of the break even in case of a vertical offset below the cone spacing

Hypercalcemia: Corneal Changes

Brooks P. Applewhite and Jonathan Lester
Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Calcific band keratopathy; Hypercalcemia-induced band keratopathy; Metabolic band keratopathy

Definition

Hypercalcemic states can induce a form of corneal degeneration characterized by a horizontal band of intracellular calcium deposits, typically at Bowman's layer, confined to the interpalpebral fissure (Chang et al. 2011).

Etiology

Calcific band keratopathy is a common corneal degenerative condition that can present at any age. While often the secondary result of chronic corneal diseases like uveitis and juvenile rheumatoid arthritis, band keratopathy may also occur secondarily to elevated serum calcium or phosphate (Woodard et al. 2014). Hypercalcemic states that lead to corneal changes may originally be induced by a number of systemic conditions, including but not limited to sarcoidosis, metastatic neoplasms to bone, vitamin D toxicity, hyperparathyroidism, and secondary hyperparathyroidism to chronic renal failure (Woodard et al. 2014).

The exact mechanism of calcium salt precipitation and deposition within the cornea is unclear. Theories include the following: (1) aberrations of normal corneal metabolism lead to increased tissue pH and calcium precipitation; (2) evaporation of tears results in calcium salt deposition within the interpalpebral zone; and (3) carbon dioxide release leads to pH increase and subsequent calcium deposition (Woodard et al. 2014). In the case of hypercalcemia-induced band keratopathy, calcium is deposited as hydroxyapatite salt intracellularly and can be found upon histopathologic examination both intranuclearly and intracytoplasmically. Fine basophilic granules typically present first at the level of Bowman's layer. The granules eventually coalesce and then fragment Bowman's layer, in time replacing the superficial corneal stroma. Throughout the subepithelial tissue, hyaline-like material is deposited among the calcium precipitate, which gives the appearance of Bowman's layer duplication. Moreover, a fibrous pannus may also develop as a result of the calcification that further disrupts the Bowman's layer-epithelium interface, leading to atrophy of the epithelium (Chang et al. 2011).

In cases of chronic ocular inflammation, the lesion may begin centrally. With band keratopathy resulting from hypercalcemia, however, the peripheral form of the disease is observed in which the lesion periphery is well demarcated and separated from the limbus by a lucent zone. The lucent zone is thought to be the result of either the buffering capacity of limbal vessels preventing calcium salt precipitation or that the limbal region simply lacks Bowman's layer. As the multifocal deposits coalesce, clear circles void of calcium salts can be seen where penetrating corneal nerves traverse Bowman's layer (Chang et al. 2011).

Calcium lesions in hypercalcemia-induced band keratopathy progress slowly over months to years. Patients diagnosed with dry eye, however, can progress much more rapidly on the order of weeks given increased tear calcium concentration and that dry eye may encourage calcium deposition near the corneal surface (Chang et al. 2011).

Clinical Presentation

Visible on ophthalmologic exam, patients frequently present with calcium deposits in the form of a horizontal band that typically originates near the corneal periphery at the 3 and 9 o'clock positions and progresses centrally (Chang et al. 2011). While patients in the early stages of calcific band keratopathy secondary to hypercalcemia may be asymptomatic, later stages result in decreased vision, pain, persistent foreign body sensation, photophobia, tearing, or recurrent corneal erosions (Chang et al. 2011).

Diagnostics

Diagnosis is commonly made by clinical observation. Typically, the associated disease causing calcific band keratopathy is already known. In patients for whom the etiology is unknown, ocular and systemic causes should be sought through

history taking, ocular examination, and laboratory studies. A thorough history, including questions regarding vitamin, calcium, and alternative supplement intake, should be elicited. Physicians may consider obtaining serum calcium, phosphorus, uric acid, and renal function measurements, as well as labs for parathyroid hormone (PTH) and angiotensin-converting enzyme (ACE), when trying to establish a potential systemic cause of calcific band keratopathy (Chang et al. 2011).

Differential Diagnosis

The differential diagnosis for general and disease-associated causes of band keratopathy is extensive and includes (Chang et al. 2011):

Chemicals, eye drops, and irritants
Chronic nongranulomatous uveitis (juvenile rheumatoid arthritis)
Congenital hereditary endothelial dystrophy
Discoid lupus erythematosus
Dry eye syndromes
Fanconi's disease
Hypercalcemic states
Hyperparathyroid states
Hyperphosphatasia
Hypophosphatasia
Ichthyosis
Idiopathic causes
Inherited disease
Interstitial keratitis
Intraocular silicone oil
Lithium
Mercury vapors
Metastatic disease (lung and bone disease with increased calcium)
Milk-alkali syndrome (Albright-Burnett)
Multiple myeloma
Nephropathic cystinosis
Norrie's disease
Other chronic ocular diseases
Other systemic diseases
Paget's disease
Phthisis bulbi (degenerated globe)
Prolonged corneal edema
Prolonged glaucoma
Proteus syndrome
Sarcoidosis
Spheroid degeneration
Still's disease
Thiazides
Trachoma
Tuberous sclerosis
Tumoral calcinosis
Uremia
Viscoelastics
Vitamin D toxicity

Prophylaxis

Prophylaxis for hypercalcemia-induced calcific band keratopathy includes monitoring systemic and ocular health for prevention of hypercalcemic states that lead to calcium salt deposition in the cornea (Chang et al. 2011).

Therapy

Treatment is indicated if the patient is symptomatic, for example, experiencing limited vision or discomfort. The mainstay of treatment is initial administration of topical anesthetic and subsequent superficial keratectomy with or without calcium deposit chelation via application of 0.4% ethylenediaminetetraacetic acid (EDTA) to the deepithelialized cornea. Superficial keratectomy entails a careful stripping of the calcific scale with forceps, dry cellulose sponges, and diamond burr or number 15 blade until the cornea becomes clear (Kenyon et al. 2014).

Other treatment modalities include the use of excimer laser keratectomy and lamellar keratoplasty or application of amniotic membranes (Kanski et al. 2008). Excimer laser has successfully been used to improve vision through clearing the visual axis. While scalpels are required to remove calcifications of rough band keratopathy, laser has been used directly on some smooth band keratopathies with success. Amniotic membranes may be used in order to quickly establish a stable ocular surface following surgical removal of the calcific band keratopathy (Chang et al. 2011).

Prognosis

Reepithelialization of the cornea may take many days. Recurrence after therapy is not uncommon, especially in those with systemic conditions. In patients with calcific band keratopathy secondary to hypercalcemia, reports exist of incomplete regression upon serum calcium level normalization (Chang et al. 2011).

Epidemiology

The exact prevalence or incidence of calcific band keratopathy secondary to hypercalcemia is not reported.

Hyperemia, Conjunctival

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Conjunctival injection

Definition

Conjunctival hyperemia is a conjunctival reaction that appears as dilation and redness of the conjunctival vessels. The pattern of hyperemia often appears with the greatest redness at the fornices and fades moving toward the limbus.

Etiology

The hyperemia occurs in the conjunctiva. The conjunctiva is divided into bulbar, palpebral, and forniceal conjunctiva. Histologically, this is divided into the epithelium and substantia propria (stroma). The epithelium is a non-keratizing epithelium with goblet cells (Kanski and Bowling 2011). The substantia propria is vascularized with a superficial adenoid layer containing lymphoid tissue and a deeper fibrous layer with connective tissue (Kanski and Bowling 2011;

Lindquist 2011). The conjunctival hyperemia occurs in this vascular substantia propria, and these conjunctival vessels arise from the palpebral and anterior ciliary arteries (Kanski and Bowling 2011; Lindquist 2011). Since the conjunctiva is transparent and the underlying sclera is white, these dilated vessels can easily be seen.

Conjunctival hyperemia can occur actively or passively. Active hyperemia, also called arterial hyperemia, occurs when the blood flow through the conjunctival vessels increases due to vasodilation. Normally, vessels are in a slightly constricted, vascular tone. The vasodilation that deviates from this resting vascular tone may occur because of membrane potentials or action by the autonomic nervous system and norepinephrine (Efron 2012). In contrast, passive hyperemia, also called venous hyperemia, is due to obstruction of flow. The obstructed vessel dilates proximally, becoming a red, dilated vessel.

Occurrence

Conjunctival hyperemia is present in numerous conditions, which makes it a very common symptom. Environmental factors like smoke, wind, allergies, and chemical fumes can cause hyperemia (Kanski and Bowling 2011; Lindquist 2011). Additionally, infections with many types of viruses and bacteria will also cause conjunctival hyperemia. Conjunctival hyperemia is also common in contact lens wearers and is thought to be due to metabolic influences, chemical influences, or allergies to the contacts or the solutions used (Efron 2012).

Classification

The classification of conjunctival hyperemia helps distinguish this symptom from more serious conditions that involve tissue deeper to the conjunctiva. Since the conjunctiva is only firmly attached to the tarsal plate and not firmly attached on the bulbar surface, the conjunctiva and its vasculature are freely mobile over the bulbar surface. That is in contrast to the vessels underling the conjunctiva, which are not mobile. Another test of diagnostic utility is that these conjunctival vessels will blanch with topical phenylephrine (Lindquist 2011). These two characteristics can be important in distinguishing conjunctival hyperemia from other vascular symptoms seen in pathology like scleritis.

Once it is determined that the conjunctival vessels are involved, conjunctival hyperemia often is characterized by numerical grading and location. The physician may also designate the location of hyperemia by the region of the affected conjunctiva (bulbar, forniceal, or palpebral) and by using a clockface description. It is often the presence of other signs and symptoms like pain, papillae, follicles, or discharge that leads to the diagnosis.

Hyperopia

Oliver K. Klaproth and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Farsightedness; Hypermetropia; Longsightedness

Definition

Hyperopia is a disproportion between the axial length of the eye and its refractive power, whereas the individual refractive power is too small in respect to the individual eye's axial length (Fig. 1) (Moore et al. 2008).

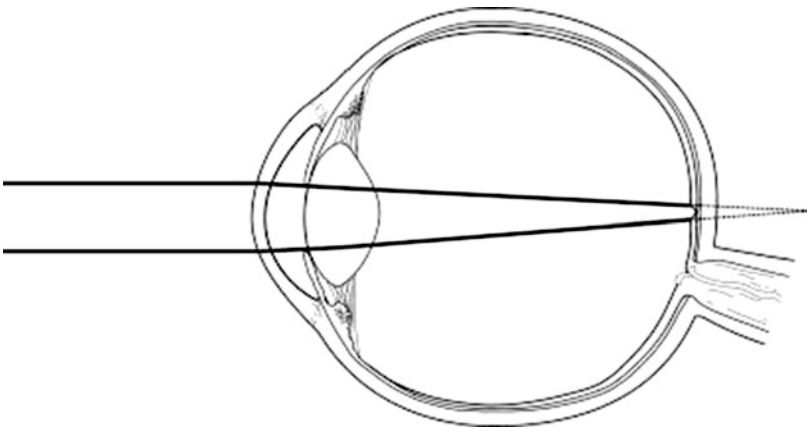
Basic Characteristics

Theoretically hyperopia, and accordingly myopia, can be classified as axial or refractive hyperopia. Whereas axial hyperopia represents a too short axial length of the eye in relation to a "normal" refractive power of the eye, refractive hyperopia represents a "normal" axial length associated with too much refractive power. The phrase "normal" in this context refers to an eye model (i.e., the *Gullstrand's* normal eye). As such eye models are derived from empirical data, the individual's eye usually differs from the "normal" assumptions. Hyperopia thus is usually a combination of both, axial and refractive errors, with axial errors representing the major component.

Table 1 summarizes the different classification schemes of hyperopia, according to the American Optometric Association guidelines (Moore et al. 2008). Looking at this table, it becomes clear that the major difficulty in diagnosing hyperopia is the accommodative ability of young patients' eyes which can only be overcome by cycloplegia.

Incidence

Due to the variations in classifying hyperopia as shown in Table 1, different studies provide different prevalence of hyperopia. Age, however, has a major influence on the prevalence of hyperopia. While infants show a Gaussian distribution of hyperopia, with 4–9% at 6–9 months of age having hyperopia of +3.25D or more (Moore et al. 2008; Atkinson et al. 2007), in the one-year-old population, the value decreases to 3.6% (Moore et al. 2008; Ingram et al. 1986). Higher levels of astigmatism in childhood are also associated with hyperopia, seeming to decrease from the age of five. From then on, the prevalence of hyperopia declines (5–20 years), with increasing prevalences of myopia. Latent hyperopia often



Hyperopia, Fig. 1 Schematic cross-sectional illustration of a hyperopic eye. The refractive power of the eye is too low to focus parallel light rays on the retina. Instead, there is a virtual focus behind the eye

Hyperopia, Table 1 Classification scheme of hyperopia according to (1)

General clinical classification		
Simple hyperopia	*Due to normal biological variation*	*Axial or refractive etiology*
Pathological hyperopia	*Due to abnormal ocular anatomy*	*Maldevelopment, ocular disease, trauma*
Functional hyperopia	*Paralysis of accommodation*	
Classification in accordance to refractive error		
Low hyperopia	*≤ +2.00 D*	
Moderate hyperopia	*+2.25 D to +5.00 D*	
High hyperopia	*> +5.00 D*	
Classification in accordance to the role of accommodation		
Facultative hyperopia	*Can be overcome by accommodation*	
Absolute hyperopia	*Cannot be compensated by accommodation*	
Classification in accordance to the effect of cycloplegia		
Manifest hyperopia	*Determined by noncycloplegic refraction*	*Facultative or absolute*
Latent hyperopia	*Detected only by cycloplegia*	*Facultative*
Simple functional classification		
Significant hyperopia	*Causes symptoms*	
Insignificant hyperopia	*Causes no symptoms*	

becomes significant with the onset of presbyopia. Prevalence differs significantly among certain ethnicities, native Americans, African Africans, and Pacific islanders being among the groups reported to have the highest prevalences, East Asians the lowest (Moore et al. 2008; Post 1962).

Causes

Causes for hyperopia are a combination of hereditary factors and biologic variation (Moore et al. 2008; Hammond et al. 2001). Physiological hyperopia hardly ever develops after childhood. Pathologic hyperopia is associated with diabetes mellitus, contact lens wear, and a host of intraocular and orbital tumors and inflammations; it can thus be acquired at any age (Moore et al. 2008).

Therapy

In case of insignificant hyperopia, no treatment is required, because. In case of significant hyperopia, classical treatment includes first glasses and contact lenses. Surgical options include laser in situ keratomileusis (LASIK) and to a somewhat lesser extent photorefractive keratectomy (PRK), phakic intraocular lens (PIOL) implantation, and refractive lens exchange (RLE) (Kohnen et al. 2008).

Hyperopic Shift

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Farsighted shift

Definition

Hyperopic shift after keratorefractive surgery, especially after radial keratotomy.

Epidemiology

In the Prospective Evaluation of Radial Keratotomy (PERK) study, 43% of 693 eyes underwent a hyperopic shift of one diopter or more 10 years postoperatively (Waring et al. 1994).

History

With the introduction of refractive procedures to ophthalmic surgery, mostly after radial keratotomy was established in the late 1970s (Akpek et al. 2002).

Clinical Features

Shift towards farsighted vision.

Tests

Visual acuity, refraction, corneal topography.

Differential Diagnosis

Physiologic age-related hyperopic shift, hyperopic shift resulting from corneal distortion or trauma, contact lens wear, chemical or thermal burn, Adie's pupil, cycloplegic agents, ectopia lentis, cataract, and retinal or orbital pathologies.

Etiology

Progressive hyperopic shift due to weakening of the paracentral cornea, resulting in iatrogenic keratectasia.

Treatment

Spectacle or contact lens correction (Glazer and Azara 2002).

Hypotony

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Ocular hypotony

Definition

Intraocular pressure lower than episcleral venous pressure.

Differential Diagnosis

Hypotony may be caused by decreased production of aqueous due to inflammation, medications, or proliferative vitreoretinopathy. Hypotony may also result from aqueous loss either external, such as following surgery or trauma, or internal, as in cyclodialysis cleft or retinal detachment. Treatment of hypotony is most effective if the underlying cause can be addressed.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

The ice pack test can sometimes be used to help determine if ptosis (drooping eyelid) is possibly due to myasthenia gravis (MG). MG is an autoimmune neuromuscular disease in which antibodies block, bind, or modulate acetylcholine receptors at the neuromuscular junction. Ocular MG (OMG) leads to variable, fluctuating ptosis and extraocular muscle weakness and fatigue. Ptosis is a common presenting symptom of MG, and the ice pack test can be done easily and safely in the clinic. It is unclear why decreased temperature improves function of the levator palpebrae muscle in myasthenic ptosis but several hypotheses have been proposed.

The Test

An ice pack is placed on the ptotic eyelid for several minutes and if positive may result in transient improvement of ptosis that is secondary to MG. Another common presentation of MG is diplopia due to extraocular muscle weakness and ophthalmoplegia may also improve with ice testing on the eyelid, but the test is less effective for diplopia in MG. The ice test has moderate sensitivity but relatively high specificity for MG-related ptosis.

Ice pick headaches; Ophthalmodynia periodica

Definition

Ice pick pains are a form of primary headache that is characterized by brief and intense episodes of idiopathic stabbing pains (jabs and jolts) that may recur throughout the day. It may be felt primarily or radiate to the eye. The episodes are typically brief lasting between 5 and 30 s. While less prevalent than other primary headaches such as migraines, they may be disabling.

Clinical Presentation

The pain of ice pick headache (IPH) is typically localized and unifocal and often occurs at the temple or orbit. IPH is not usually associated with underlying disease or systemic condition. Interestingly, IPH can occur in up to 40% of individuals with migraines. Symptoms of IPH are usually limited to intermittent, transient, stabbing pains in well-defined areas.

Therapy

Treatment for IPH usually starts with nonsteroidal anti-inflammatory drugs (NSAIDs), but other analgesic therapyies may be required in severe cases.

Benign intracranial hypertension; Pseudotumor cerebri

Definition

Idiopathic intracranial hypertension (IIH), also commonly known as pseudotumor cerebri (PTC), is a neuro-ophthalmological disorder characterized by increased intracranial pressure (ICP) of undetermined cause. IIH is a diagnosis of exclusion defined by the following in the modified Dandy criteria: (1) signs and symptoms only due to increased ICP (e.g., headache, pulsatile tinnitus, diplopia, transient visual obscurations); (2) an absence of ventricular enlargement or intracranial space-occupying lesions on neuroimaging studies (e.g., secondary to an intracranial disorder, a

meningeal process, or cerebral venous sinus thrombosis [CVST]); and (3) an elevated opening pressure with normal cerebrospinal fluid (CSF) composition on lumbar puncture. We consider patients who develop increased ICP secondary to medication side-effects or cerebral venous sinus stenosis to have a form of secondary PTC and not idiopathic (i.e., IIH) per se (Brazis and Lee 1998).

Etiology

While the exact pathogenesis of IIH remains unknown, various hypotheses have been proposed, including abnormal vitamin A metabolism, dysregulation of adipose tissue mediated cytokine pathways (e.g., leptin), and more recently distal stenosis of the cerebral transverse venous sinus. Obesity and female gender are known associations with IIH but the precise mechanism of elevated ICP in these patients remains ill defined.

Epidemiologically, IIH is a disorder that primarily affects obese women of childbearing age (15–44 years) with an annual incidence of 4–21 per 100,000 independent of geographic location and ethnicity. Risk factors associated with IIH include recent weight gain, exogenous medication usage (specifically corticosteroids, growth hormone, tetracycline derivatives (e.g., minocycline), vitamin A derivatives, and lithium), and a variety of systemic conditions (e.g., iron deficiency anemia, renal failure, Addison's disease, polycystic ovarian syndrome, and systemic lupus erythematosus).

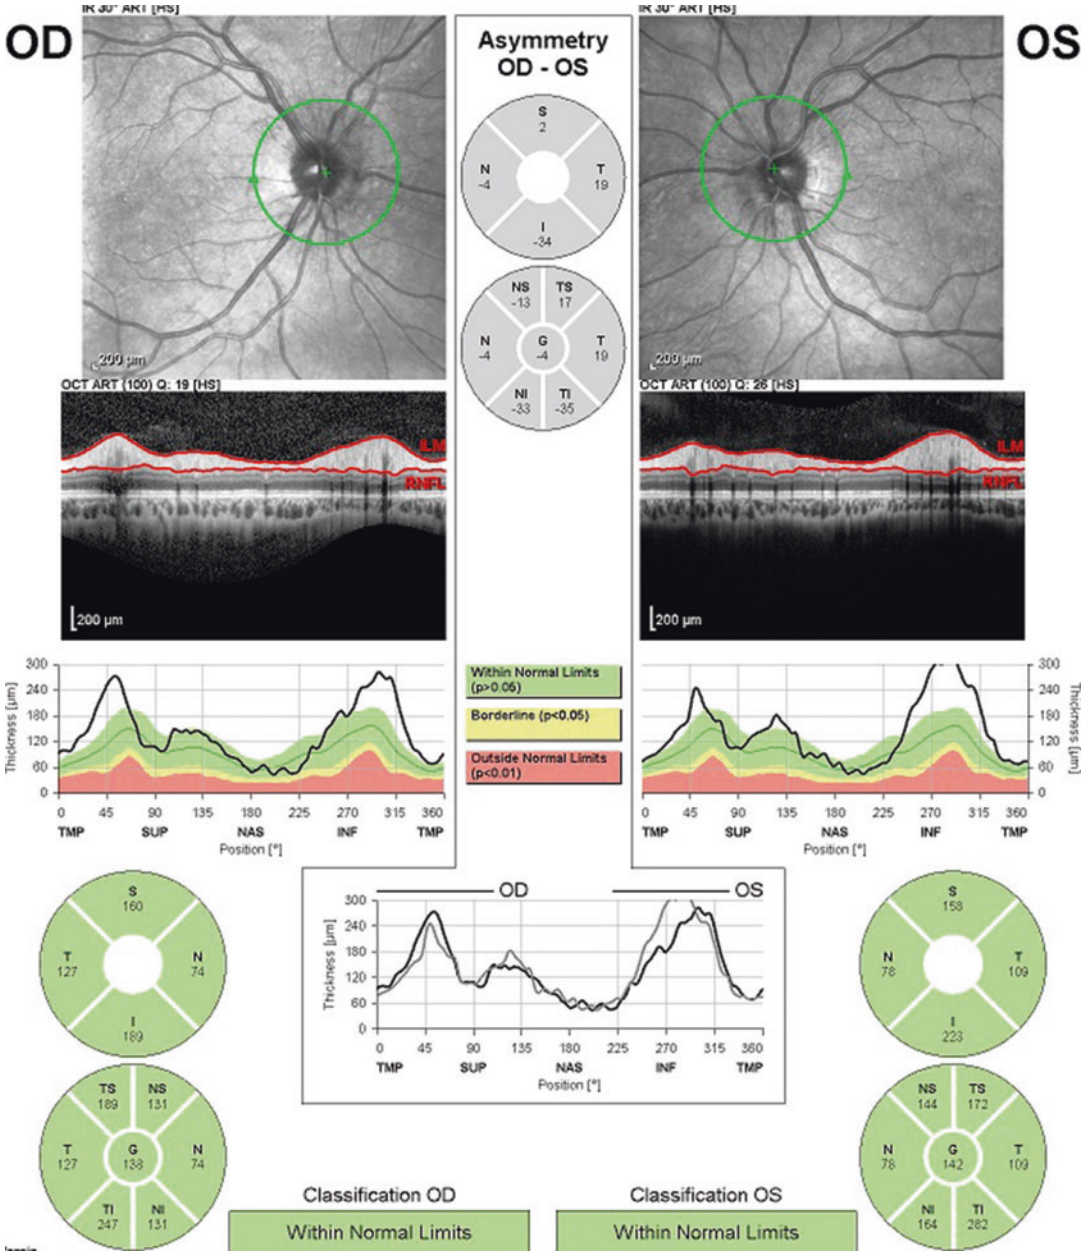
Clinical Presentation

The most common presenting symptom of IIH is a nonspecific headache that may vary in character, location, frequency, and severity. There is no characteristic or defining feature of the headache, however, in IIH. The pain may be facial or retrobulbar in location and may clinically resemble tension, migraine, or rebound headache. In addition, many patients with IIH have concomitant headaches that meet International Headache Society (IHS) criteria for these headache syndromes (e.g., migraine). Other common presenting symptoms of IIH include transient visual obscurations (TVOs) that last for few seconds and may be postural, pulsatile tinnitus, intermittent or constant binocular horizontal diplopia (often due to a sixth nerve palsy as a nonlocalizing sign of increased ICP), and blurred vision.

The most common clinical sign in IIH is bilateral papilledema but papilledema is not required for the diagnosis. Papilledema is often graded using the Frisen scale (from Grade 0 to Grade 5), with higher grades of papilledema and a longer duration of disc edema associated with a higher risk of permanent visual loss. Papilledema, however, may be asymmetric or even absent in IIH. In one study, it was found that up to 10% of patients with IIH had asymmetric papilledema (Spitze et al. 2013). Visual field deficits in IIH most commonly present as enlarged blind spots but any nerve fiber layer type defect can be observed in one or both eyes. Central scotomas (resulting from papillomacular bundle involvement) are rare in patients with IIH and thus patients with a central scotoma should have a careful evaluation of the macula to exclude concomitant macular hemorrhage, edema, subretinal fluid or exudates, or superimposed ischemic optic neuropathy. Patients with unexplained decreased central visual acuity or significant visual field loss from IIH should be considered for more aggressive medical and surgical management including urgent optic nerve sheath fenestration or cerebrospinal fluid (CSF) shunting procedure. Although a nonlocalizing sixth nerve palsy and secondary incomitant esotropia can occur in IIH, any other ocular motility deviation or other cranial neuropathy would be atypical for IIH and should prompt further evaluation for alternative etiologies. In addition, IIH is a noninflammatory condition and the presence of anterior or posterior uveitis should raise the suspicion for an inflammatory mimic of IIH for the findings (e.g., sarcoidosis) (Fig. 1).

Diagnostics

The clinical evaluation of patients with IIH should include a complete history with particular



Idiopathic Intracranial Hypertension, Fig. 1 Optical coherence tomography (OCT) shows mild grade 1–2 papilledema with increased nerve fiber layer on global thickness assessment of 128 microns OD and 142 microns OS. Although the OCT classifies the results as in the "green zone" and "within normal limits" the values in microns are above normal. The black line in the thickness plots represents the patients values and are above the normal thickness for controls

attention paid to secondary causes of increased ICP including medications, hypercoagulable states, infectious processes, and systemic inflammatory processes. An ophthalmic examination should be supplemented with a formal visual field test, dilated funduscopic examination, and (if possible) baseline and follow-up optic nerve photographs. A lumbar puncture (with opening

pressure, cell count and differential, glucose, and protein) is recommended after negative neuroimaging (preferably cranial contrast MRI with MRV) is performed. In patients with papilledema, checking the systemic blood pressure is important to exclude hypertensive optic neuropathy that might mimic papilledema and IIH. Some authors have also recommended a complete blood count (CBC) testing, as severe anemia (typically iron deficiency) may be associated with IIH but this is not yet a universally accepted recommendation. While elevated opening pressure is required for the diagnosis of IIH, some patients have an artificially normal or even low intracranial pressure measurement at the time of lumbar puncture due to faulty technique or perhaps diurnal fluctuation in ICP (e.g., after multiple attempts or fluoroscopic LP performed shortly after failed conventional LP).

Magnetic resonance imaging (MRI) of the brain with and without gadolinium with post-contrast magnetic resonance venography (MRV) is the imaging study of choice for IIH. Several findings on MRI are highly suggestive but not diagnostic of IIH: (1) flattening of the posterior sclera (approximately 80% of patients); (2) empty sella (approximately 70% of patients); (3) distension of the perioptic subarachnoid space by CSF (approximately 50% of patients); and (4) enhancement of the prelaminar optic nerve with gadolinium contrast (approximately 45% of patients). Cerebral venous sinus thrombosis (CVST) should be ruled out prior to the diagnosis of IIH and while MRI may sometimes detect CVST, both computed tomography venogram (CTV) and magnetic resonance venography (MRV) are significantly more sensitive for CVST. We highly recommended an MRV in addition to the cranial MRI even in patients that present as typical IIH. Some patients, however, cannot have an MRI (e.g., extreme obesity, metallic foreign body, pacemaker) or may have contraindication to gadolinium (e.g., renal failure), and in these cases a standard computed tomographic (CT) scan may be the only option.

Differential Diagnosis

Any entity that results in increased ICP may result in a clinical presentation similar to that of IIH. Important secondary causes of increased ICP include:

1. Mass lesions (e.g., tumors, abscesses, hemorrhage)
2. Increased CSF production (e.g., choroid plexus papilloma)
3. Decreased CSF absorption (e.g., subarachnoid hemorrhage, bacterial/fungal meningitis), obstructive hydrocephalus, and cerebral venous sinus outflow obstruction (e.g., cerebral venous sinus thrombosis, jugular vein compression or thrombosis)

In addition, there are conditions that might mimic papilledema (i.e., optic disc edema not due to increased ICP) including malignant hypertension (i.e., hypertensive emergency or urgency), infectious, inflammatory, infiltrative, hereditary, toxic, metabolic, or ischemic optic disc edema, or cases of pseudopapilledema.

Prophylaxis

Non-applicable

Therapy

The mainstay of therapy for IIH is weight loss and medical therapy with acetazolamide (Diamox) typically initially 500 mg QD or BID with increasing dose to maximum tolerance up to 2–4 g as needed. Diamox is our recommended first line agent in treatment of symptomatic IIH (Brazis and Lee 1998; Galgano and Deshaies 2013). Various case series have shown that acetazolamide is effective in symptomatic management and vision stabilization in up to 70% of patients. Although "sulfa allergy" and pregnancy should prompt clinical caution, there is limited evidence to support

not using acetazolamide in patients with non-anaphylactic allergic or adverse reactions to "sulfa" containing agents. Likewise, pregnant patients (especially in the third trimester) might still benefit from medical treatment but consultation with the treating obstetrician should be performed prior to treatment of IIH patients who are pregnant. In general, however, the evaluation and management of pregnant and nonpregnant patients with IIH is the same. Gadolinium contrast for MRI and acetazolamide are FDA class C agents and a risk benefit decision needs to be made on an individual basis for their use in pregnant patients with IIH. In patients on acetazolamide, although serum electrolytes could be routinely followed, most clinicians simply warn the patient and the primary physician about the potential side effects including the risk of metabolic acidosis and kidney stones without routine testing. Furosemide (20–40 mg per day for adults) is often considered a second-line therapy for IIH but has been used effectively in combination with acetazolamide (Brazis and Lee 1998). Thiazide diuretics have yet to show any proven benefit in patients with IIH but might be considered. Topiramate, an antiepileptic medication with carbonic anhydrase inhibition similar in mechanism to that of acetazolamide, is often used as an alternative therapy in patients who cannot tolerate Diamox (Lee and Wall 2012). Clinicians should also be aware that topiramate may cause ocular side effects including angle closure glaucoma and induced myopia. Long-term medical therapy should always be conducted in conjunction with dietary and behavioral modifications (weight loss, exercise, etc.).

The primary indications for surgical intervention in patients with IIH are progressive visual field defects or an intractable headache despite maximum medical therapy (Biousse et al. 2012; Galgano and Deshaies 2013). In addition, some patients may be noncompliant or intolerant to medical treatment. The two main surgical interventions in patients with PTC are cerebrospinal fluid (CSF) shunting procedures (such as ventriculoperitoneal or lumboperitoneal shunt) and optic nerve sheath fenestration (ONSF) (Biousse et al. 2012). Although serial lumbar punctures (LP) may be useful in rare circumstances (e.g., pregnancy, urgent patients prior to surgery, cryptococcal meningitis related papilledema) to temporarily control ICP prior to surgery, we generally advise against serial LP as a sustained or repeated treatment for IIH. The CSF reforms very quickly after an LP and thus there is little theoretic reason for this treatment to work on a long term basis. In addition, serial lumbar punctures are uncomfortable and can result in patient dissatisfaction and various complications, including low-pressure headache, CSF leak, and CSF infection. A lumbar drain, however, might be a reasonable alternative temporizing measure for acute, fulminant IIH with visual loss prior to admission and consideration for definitive surgical treatment of papilledema. Cerebral venous stenting is a relatively new and still controversial procedure based on observations that many typical IIH patients have distal stenosis of the transverse venous sinus. The precise role, indications, and long-term prognosis of stenting in IIH remains to be defined by a controlled clinical trial. The first line surgical intervention for visual loss despite maximum medical therapy in our practice is optic nerve sheath fenestration (ONSF) but CSF shunting may be necessary at institutions where ONSF is not available or perhaps for patients who wish to undergo only a single surgery or who have concomitant intractable headache as the indication for surgery.

Temporary diplopia is the most common complications of ONSF and may be the result of edema or less commonly direct trauma to the extraocular muscles, nerves, or blood supply (Biousse et al. 2012). Transient diplopia occurs in up to 29–35% of ONSF. Other common complications of ONSF include pupillary dysfunction (11%) and temporary decreased visual acuity (11%). Permanent and severe visual loss (e.g., CRAO or optic nerve damage) fortunately are rare after ONSF. Both CSF shunting procedures and ONSF have various other surgical and anesthesia related potential complications, though

ONSF is in general considered a safer and less invasive procedure. ONSF is also the preferred surgical modality in children. Eyes that undergo ONSF often have a recurrence of the initial symptoms (~2 to 32%) and may require repeat surgery.

Although CSF shunting procedures have a higher success rate, the incidence of complications is significantly higher than that of ONSF. Shunt failure occurs in 50–80% of patients, often requiring multiple revisions. Other common complications include shunt infection, abdominal pain, and other postoperative complications. Tonsillar herniation, sunset eyes, and slit ventricle syndrome are rare complications of CSF shunts and, in at least one series, the inpatient mortality for CSF shunting the mortality rate was as high as 0.9% for ventriculoperitoneal shunt and 0.3% for lumboperitoneal shunting.

Prognosis

To date, there is no prospective case series describing the natural history and progression of IIH. In our clinical practice, a clinical course lasting a few months to 1 or 2 years is most common with symptoms gradually regressing with therapy. With treatment, there is often gradual improvement/stabilization within this time interval though most patients are left with persistent residual papilledema and/or residual visual field defects/permanent visual loss. Symptoms recur in as high as 40% of all patients even after years of stability. A small subset of patients present with insidious onset and rapidly progressive IIH (with central visual loss within weeks of symptom onset) classified as fulminant IIH. The visual prognosis is significantly worse for patients with fulminant IIH and aggressive surgical management should be considered at onset in these patients.

Illuminance: Definition

Timo Eppig
Institute of Experimental Ophthalmology, Saarland University, Homburg, Germany

Definition

Illuminance E_v (unit Lux [lx]) is the total luminous flux or amount of light received by a surface. It is used to specify light levels of room illumination for ophthalmological examination procedures such as contrast sensitivity tests or measuring pupil sizes at standardized light levels. Illuminance takes account for the spectral sensitivity of the human photoreceptors and can be derived from irradiance E_e by $E_v = 683 \frac{lm}{W} \cdot \Sigma V(\lambda) \cdot E_e(\lambda)$ if the spectral distribution of the light is known.

Image Quality, General

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Optical quality; Retinal image quality

Definition

The fidelity at which an optical system creates an image of an object. Although the term "optical quality" is used synonymously from time to time, the latter may also include aspects of subjective perception.

Basic Characteristics

Most optical systems are designed to obtain an image that represents the object imaged by the system as exactly as possible. The exactness of imaging and therefore the image quality are affected by the optical phenomena ▶ aberrations, scatter, and diffraction. For measurement, image quality is quantified with reference to the object imaged. Therefore, many image quality metrics are ratios between the characteristics of the actual image and the object. Typical characteristics quantified by metrics are the compactness of the point spread function, the loss of contrast through the optical system, and the unevenness of the ▶ wave front created by the optical system. The image quality of eyes is often referred to as "retinal image quality."

Synonyms

Pneumo-orbitism

Definition

Presence of air in the orbit and/or periorbital tissues following orbital wall fracture.

Etiology

Orbital blowout fractures occur when an impact raises intraorbital pressure to the point where the thin bones of the orbital floor and medial wall are "blown out," pushing orbital contents into the maxillary or ethmoid sinus. Orbital emphysema most commonly results (63% of cases) from an orbital blowout fracture (Key et al. 2008). The resulting communication with the paranasal sinuses allows air to accumulate in the orbital space. Sudden onset of orbital emphysema after Valsalva actions (laughing, sneezing, nose blowing) is occasionally reported and is believed to result from the formation of a one-way valve across the fracture site, permitting air to enter the orbit, but not to leave it.

Clinical Presentation

Classically, patients who have had recent trauma to the orbit, face, or head present with sudden onset of one or more of the following after nose blowing, laughing, or other Valsalva actions: periorbital swelling, pain, lid distension, diplopia, and blurred vision. On examination, patients may demonstrate ophthalmoplegia, decreased visual acuity, a tense, hard globe, and proptosis. Intraocular pressure (IOP) is usually elevated. If high intraorbital air pressure results in decreased perfusion to the retina or optic nerve, an afferent pupillary defect may be present (Muhammad and Simpson 1996).

Orbital emphysema may also present as an incidental finding on radiographic assessment; it is detected in up to 50% of orbital fractures on CT scan (Key et al. 2008).

Diagnostics

The diagnosis of orbital emphysema can usually be made from history and physical examination alone. However, distinguishing orbital emphysema from retrobulbar hemorrhage can be difficult; therefore, the diagnosis should be supported by orbital CT scan. IOP should be measured by tonometry, and an assessment of extraocular muscle function should be made.

Differential Diagnosis

Differential diagnosis includes ▶ retrobulbar hemorrhage, ▶ orbital cellulitis, ▶ preseptal cellulitis, ▶ thyroid orbitopathy, ▶ lymphoma, ▶ cavernous hemangioma, and ▶ Wegener granulomatosis (Nerad et al. 2001).

Prophylaxis

Patients with recent orbital and facial trauma, with or without radiographic evidence of orbital wall fracture, should be advised to avoid nose blowing, heavy lifting, laughing, and other Valsalva activities.

Therapy

Orbital emphysema without visual loss is a benign, self-limited condition, which usually resolves in about 2 weeks. Mildly elevated IOP

with no associated visual deficits can be observed or treated medically with IOP-reducing topical agents. However, compressive orbital emphysema with rapidly decreasing visual acuity is an emergency and must be treated promptly to avoid ischemic damage to the retina and optic nerve. Surgical decompression is achieved via lateral canthotomy and cantholysis, which expands the orbital volume and lowers intraorbital pressure. In rare cases, intraorbital needle aspiration may be necessary to relieve compression (Key et al. 2008).

Antibiotics may reduce the incidence of orbital cellulitis in cases of orbital emphysema; however, the benefit of antibiotics remains unproven (Key et al. 2008).

Prognosis

Orbital emphysema is generally a benign, self-limiting condition with an excellent prognosis with regard to visual acuity (Muhammad and Simpson 1996). Nearly all reported cases of orbital emphysema with subsequent optic nerve compression showed complete recovery of visual acuity.

Epidemiology

Orbital emphysema is detected in up to 50% of orbital wall fractures on CT scan (Key et al. 2008). Very few cases of orbital emphysema with optic nerve compression have been reported.

Synonyms

Biopsy

Definition

An incisional biopsy is the partial removal of a lesion.

Purpose

To sample, diagnose, or to partially remove the lesion.

Principle

First, the tissue surrounding the lesion is anesthetized with local anesthetic with epinephrine. A scalpel or scissors are used to incise and remove a portion of the lesion, usually for histopathologic analysis. A type of incisional biopsy is the shave biopsy, where the base of a lesion is shaved flush with the skin surface. A punch biopsy is an incisional biopsy, commonly used to diagnose

lesions highly suspicious for malignancy, such as squamous or basal cell carcinoma.

Indication

An incisional biopsy is useful for the partial removal of a benign lesion, or one that is suspicious for malignancy.

Contraindication

This type of biopsy is contraindicated with any lesion already confirmed to be malignant. Abnormal bleeding times, due to therapeutic or pathological causes, may also be contraindications. Complete excision is more appropriate when incisional biopsy would create problems with structure or function (Nerad 2001; Albert and Jakobiec 2008).

Advantages/Disadvantages

One of the major advantages of this type of biopsy is that a benign lesion may be properly sampled or made cosmetically pleasing with a very minor surgical intervention. Disadvantages of this type of biopsy include the need for more surgery if the lesion is confirmed to be malignant or to require removal.

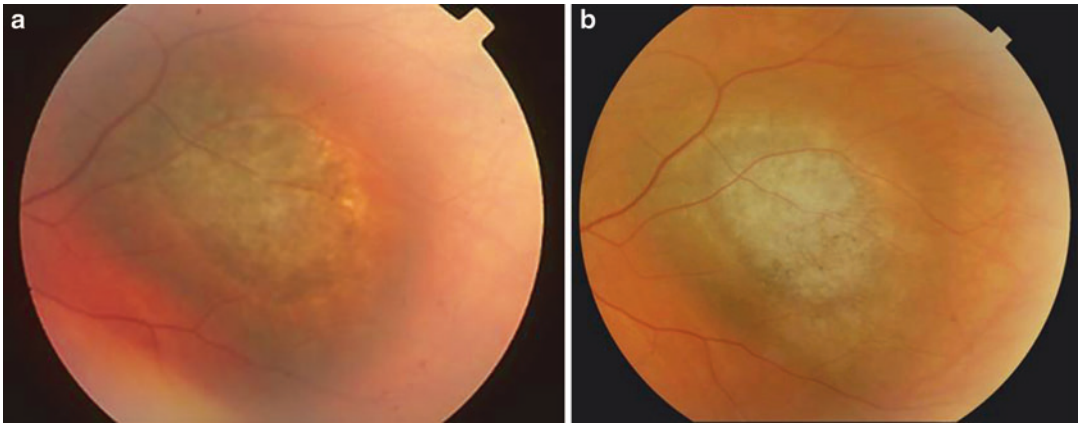
Indeterminate Melanocytic Lesions of the Choroid

Evangelos Gragoudas, Anne Marie Lane and Ivana Kim
Department of Ophthalmology, Retina Service, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, MA, USA

Synonyms

Suspicious pigmented choroidal lesions



Indeterminate Melanocytic Lesions of the Choroid, Fig. 1 (**A**). Patient diagnosed with a suspicious choroidal lesion. (**B**). Lesion remains stable 8 years after observation

Definition

A lesion considered to be intermediate between a nevus and melanoma that may represent a tumor with malignant potential.

Clinical Presentation

The following factors are associated with a significant increase in the risk of transformation: thickness greater than 2 mm, subretinal fluid accumulation, symptoms (decreased vision, presence of flashes), presence of orange pigment, margin touching the optic disc (Shields et al. 2000).

Diagnostics

Uveal nevi are generally flat, slate gray lesions without sharply demarcated margins and a size limited to about 6 mm in diameter. There is considerable overlap in size distributions of nevi, indeterminate lesions, and small melanomas. An observational approach for lesions less than 3 mm in height and 10 mm in diameter is common. When observation is chosen, follow-up at 6-month intervals is necessary, using fundus photography and ultrasound to identify any evidence of malignant transformation. Diagnosis can be especially difficult in borderline cases with characteristics of both lesions (Fig. 1).

Differential Diagnosis

Choroidal nevus, (small) uveal melanoma.

Therapy

Suspicious lesions are followed closely at regular intervals. The strongest sign of malignant transformation is growth of the tumor, and treatment is recommended. Radiotherapy (brachytherapy or proton therapy) is a common treatment modality (Fig. 2).

Epidemiology

Benign nevi of the choroid are common in white populations, and the gender-specific prevalence rates are 8.9% and 8.3% for females and males, respectively (Sumich et al. 1998). Patients with indeterminate lesions are older and more likely to be female than patients with a definite melanoma. It has been estimated that 1 in 8,845 choroidal nevi will transform to a malignant tumor per year in the US white population (Singh 2007).

Indirect Ophthalmoscope

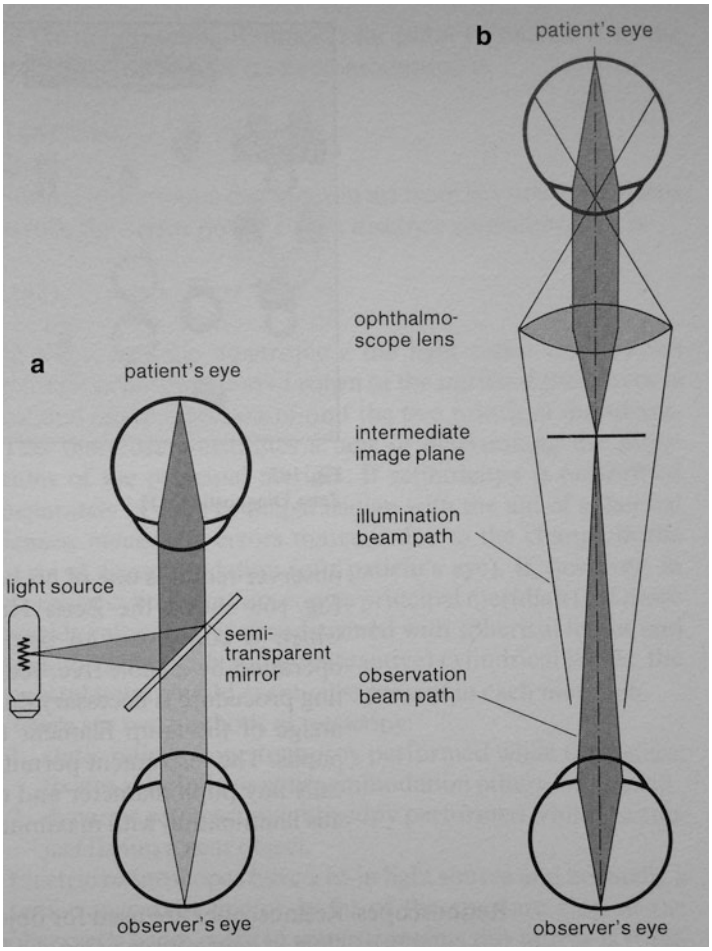
Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Definition

Ophthalmoscopes are used to examine the fundus of the eye. The fundus is illuminated and observed through the pupil by means of mirrors or prisms. Two different methods are used: direct ophthalmoscopy with an upright image and indirect ophthalmoscopy with an inverted image.

In direct ophthalmoscopy, the instrument is brought as close as possible to the eye. In the observation of an emmetropic eye, an upright image of the retina is obtained with a magnification of approximately 15× and a field of view of between 3° und 16°. The Recoss disk with its supplementary lenses used to compensate for ametropia can provide an initial rough estimate for the refraction of the patient's eye. In some ophthalmoscopes, it is also possible to switch a fixation target into the beam path for testing the fixation point of the retina.

In indirect ophthalmoscopy, an ophthalmoscope lens is held between the instrument and the patient's eye. This lens is then traversed by the illumination and observation beam paths at the same time. The light form the ophthalmoscope illuminator reaches the patient's eye through the usually aspheric ophthalmoscope lens in such a way that the lamp filament is imaged in the pupil. The extent of the fundus illuminated is determined by the refractive power (12–30 D) and the diameter of the ophthalmoscope lens. The light reflected off the fundus is combined by the lens to form an inverted, real image in the intermediate



Indirect Ophthalmoscope, Fig. 1 Ophthalmoscopy: (**a**) direct and (**b**) indirect

plane, where it is then viewed by the observer. The total magnification is between 2 and 5× and the field of view between 40° and 60°.

Apart from handheld ophthalmoscopes, head-worn ophthalmoscopes are also available for stereoscopic indirect ophthalmoscopy. They are mostly used for applications where the observer requires one of his hands for manipulation purposes (Fig. 1).

Indocyanine Green

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Definition

Indocyanine green (ICG) is a tricarbocyanine dye (775 Da) with the molecular formula of $C_{43}H_{47}N_2NaO_6S_2$. Following intravenous injection, it remains 98% protein bound within the intravascular space and is an excellent tool for imaging the choroidal circulation. It is cleared by the liver without undergoing enterohepatic

circulation (Gass 1997; Guyer et al. 1999; Klais et al. 2006).

Purpose

Indocyanine green angiography is used to image the choroidal circulation during ocular angiography (Figs. 1 and 2).

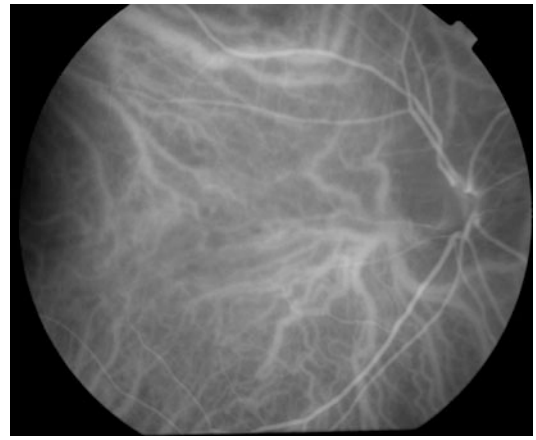
Principle

Indocyanine angiography is based on the ability of indocyanine green to absorb photons of light in the near-infrared wavelength (790–805 nm) and emit them at wavelengths greater than 825 nm. Since it remains highly protein bound in the intravascular space following intravenous administration, it is ideal for imaging choroidal vasculature and pathology. Angiographic images are captured with a fundus camera containing an outbound light filter that only transmits near-infrared light and an inbound image filter that blocks all wavelengths shorter than 825 nm.

Indication

Indications for ICG angiography include choroidal neovascular membranes, pigment epithelial detachments, polypoidal choroidal vasculopathy, retinal angiomatous proliferation, central serous retinopathy, intraocular tumors, and choroidal inflammatory conditions.

The technique of ICG angiography begins with an intravenous injection of indocyanine green dye (5 ml of 5 mg/ml solution) through a peripheral intravenous access. This is followed immediately with fundus photography using a special ICG camera fitted with appropriate outbound and inbound filters. Digital camera systems are primarily used for ICG angiography since 35 mm film-based systems have difficulty capturing weak ICG fluorescent signals at wavelengths of over 825 nm. The latest generations of ICG fundus



Indocyanine Green, Fig. 1 Indocyanine green angiography of the ocular fundus

Indocyanine Green, Fig. 2 Vial of indocyanine green dye

cameras produce high-quality images with digital subtraction software to eliminate static fluorescence and a scanning laser ophthalmoscope with high-resolution video cameras to capture real-time, high-speed images. Indocyanine green angiography can be performed simultaneously with fluorescein angiography by utilizing confocal scanning laser ophthalmoscopy and specialized filters.

Similar to fluorescein angiography, abnormalities on ICG angiography are described as either hypofluorescent or hyperfluorescent, depending on whether they appear darker or brighter than normal, respectively. Hypofluorescent abnormalities represent vascular filling defects or areas where overlying blockage from blood, pigment, or tissue limits fluorescence. Hyperfluorescent abnormalities reflect either areas with increased amounts of ICG dye or areas of increased signal transmission from ICG due to less than normal overlying blockage.

Contraindication

Indocyanine green is generally safe with less than 1% of patients suffering a mild reaction, including nausea, vomiting, or pruritus. However, isolated reports of anaphylactic shock have been described. Clinicians should always inquire about prior reactions before injecting ICG. Indocyanine green should be used with caution in patients with an iodine or shellfish allergy as ICG contains 5% iodine. Indocyanine green should likely be avoided in patients with liver failure or uremia since clearance may be compromised. Although it does not appear to cross the placenta, ICG is classified as a category C drug during pregnancy since adequate safety studies are not available.

Advantages/Disadvantages

Advantages of ICG include its great safety profile and its ability to remain within the choroidal vasculature, making it ideal for imaging choroidal pathology. Since ICG fluoresces in the near-infrared wavelengths, it can readily produce fluorescent images through various opacities, including serosanguineous fluid, hemorrhage, pigment, and lipid exudates. It can also be given before, concurrently, or following sodium fluorescein. One potential disadvantage of ICG is its low efficacy of producing a fluorescent signal (less than 4%) which requires specialized imaging platforms.

Infraciliary Blepharoplasty Incision, for Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Synonyms

Subciliary incision, for anterior orbitotomy

Definition

A transcutaneous orbitotomy designed to access the inferior orbital area in both the preseptal and postseptal planes.

Indications

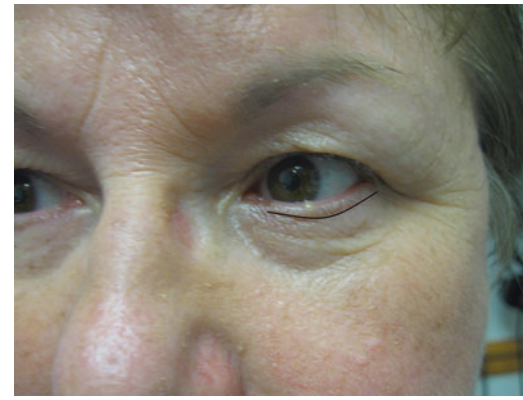
Anteriorly placed lesions or orbital fractures in the inferior orbit can be approached through multiple approaches. Traditionally, an infraciliary blepharoplasty incision has been used to approach these areas. These incisions generally heal well and are hidden in the eyelash line (Nerad 2001; Levine 2003).

Contraindication

Contraindications for patients who wish to avoid a skin incision and for patients who are not medically stable for surgery.

Techniques and Principles

A skin incision is created approximately 1–2 mm beneath the inferior eyelashes (Fig. 1). The



Infraciliary Blepharoplasty Incision, for Anterior Orbitotomy, Fig. 1 Left lower eyelid of patient marked 1–2 mm beneath the eyelash line as an infraciliary incision

incision is then carried out posteriorly to the preseptal tissues or down to the orbital rim to access the extraperiosteal area for orbital decompression, blowout floor fracture repair, etc (Nerad 2001; Levine 2003).

Outcome

Broad visualization of the inferior orbit for lesion biopsy, decompression, or orbital fracture repair.

Complications

Risks include anesthesia, bleeding, pain, infection, scarring, lower eyelid retraction, swelling, loss of vision, damage to adjacent structures, diplopia, and need for additional procedures.

[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

The *infraorbital nerve* is solely a sensory nerve and is the distal extension of the maxillary division of the trigeminal nerve (V2). The infraorbital nerve provides sensory innervation to the skin overlying the maxillary bones and the mucosa of the maxillary sinuses. Distal to the inferior orbital fissure, the maxillary nerve becomes the infraorbital nerve and travels in the infraorbital grove and canal to exit from the infraorbital foramen and then splits into the inferior palpebral nerve and several other cutaneous nerves that serve sensation of the face.

Infrared Digital Photography

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Near-IR digital photography

Definition

Digital photography of ocular structures employing light of near infrared wavelength.

Purpose

To image structures of the eye without causing pupillary constriction (Dekking 1933; Kugelberg 1934).

Principle

IR rays used in ophthalmic photography and digital imaging are near-IR waves IR-A (780–1400 nm). The use of infrared light allows for imaging the pupil without constricting it and without being noticed by the subject.

Indication

Nonmydriatic fundus cameras use an IR viewing system to exploit the patient's natural dilation in a dark room. Furthermore, the technique allows evaluation of the anterior surface of the iris and near-IR subretinal imaging (Saine et al. 2006).

Advantage/Disadvantage

IR light passes easily through the cornea, sclera, and pigment epithelium.

Imaging with Indocyanine Green (ICG) which has a peak spectral absorption in the near infrared range of the light spectrum (approx. 800 nm). Light absorption and fluorescence occur within the near infrared spectrum, which allows for improved visualization through the retinal pigment, hemorrhages, and lipid and subretinal fluid (Chiang et al. 2011; Theelen et al. 2010).

Infrared Pupillographers

- ▶ Infrared Pupillometers

Infrared Pupillometers

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Infrared pupillographers

Definition

Infrared device for measurement of pupil diameter.

Purpose

Assessment of pupil diameter prior to refractive surgery procedures and differentiation of neuro-ophthalmological disorders.

Principle

Infrared light-emitting diodes (IR-LEDs) illuminate the eyes with long-wave light that does not affect pupil size. There are stationary digital infrared devices for binocular simultaneous measurements of pupil diameter at three illuminance levels as well as handheld infrared devices for subjective monocular pupil measurement, where the examiner estimates pupil size by a superimposed millimeter ruler Kohnen et al. 2004; Schnitzler et al. 2000.

Indication

Prior to refractive procedures, for clinical application in neuro-ophthalmology (e.g., distinguishing Horner syndrome from physiologic anisocoria) (Wilhelm and Wilhelm 2003).

Advantage/Disadvantage

Some instruments allow for recording of only one pupil at a time, whereas other devices incorporate binocular systems. Binocular dual channel pupillometers are best suited for clinical application in neuro-ophthalmology to detect possible unequal direct and consensual pupil reactions (Wilhelm and Wilhelm 2003).

Inherited Color Vision Defects

Joseph J. Carroll
Department of Ophthalmology,
Eye Institute- Medical College of WI,
Milwaukee, WI, USA

Synonyms

Congenital color vision defects

Definition

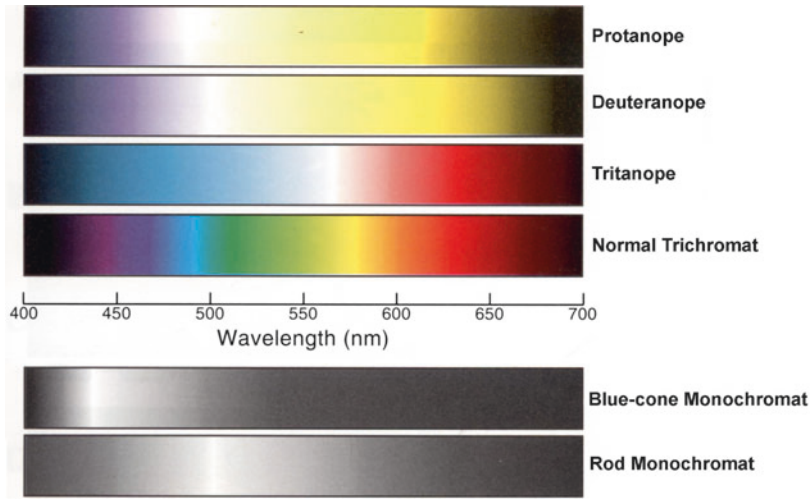
Inherited impairment in color discrimination, ranging from a complete absence of color discrimination to slightly altered color perception. Figure 1 illustrates the visual consequences of the various forms of inherited color vision defect.

Etiology

All inherited color vision defects have a genetic origin and are typically associated with disruptions in the expression of normal cone photopigments. Red-green color vision defects are caused by deletions or mutations in the X-encoded long- (L-) and middle-wavelength sensitive (M-) opsin gene array. Blue cone monochromacy is linked to a complete absence of L- and M-opsin in the retina, usually due to a deletion of cis-regulatory elements in the L-/M-opsin gene array. Blue-yellow defects are associated with mutations in the short-wavelength sensitive (S-) opsin gene on chromosome 7. Rod monochromacy has been linked to numerous mutations in *CNGA3* and *CNGB3* (which encode the α- and β-subunits, respectively, of the cone cyclic nucleotide-gated (CNG) channel), as well as *GNAT2*, which encodes the α-subunit of the cone G-protein transducin, and *PDE6C*, which encodes phosphodiesterase.

Occurrence

Inherited color vision defects have variable occurrence. Owing to their X-linked nature, red-green defects affect predominantly males, with an estimated 1 in 12 males of Western European descent manifesting some form of red-green defect. Males of Asian and African descent have a lower reported incidence. Approximately 1 in 7 females is a carrier of a red-green defect, but only 1 in 200 females manifests a red-green defect. Tritan color vision defects affect males and females equally, and the estimated incidence is around 1 in 30,000. Blue cone monochromacy is transmitted as an X-linked defect, so it selectively affects males at a rate of about 1:100,000. Affected females have not been reported in the literature, which is not surprising given the



Inherited Color Vision Defects, Fig. 1 Perceptual consequences of inherited color vision defects. Shown is a computer simulation of the color spectrum as it would appear to a protanope, deuteranope, tritanope, and normal trichromat. Each color vision deficiency shows greatly reduced chromatic discrimination compared to that of a normal trichromat. The *bottom* two panels reveal the perceptual consequences of monochromacy on the appearance of the spectrum for a blue cone monochromat and rod monochromat (Adapted and reproduced with permission of Cambridge University Press)

estimated frequency of 1 in 10 billion. Rod monochromacy is thought to affect males and females equally and the estimated prevalence is about 1:33,000.

Classification

The red/green defects can be separated based on the dimensionality of the residual color vision (dichromat or anomalous trichromat) and based on the spectral subtype of the remaining cone (protan or deutan). Individuals with an absence of L-cone function are said to have a protan defect. Protanopes are dichromats who possess an S-pigment and an M-pigment. Protanomalous trichromats possess a normal S-pigment and two spectrally distinct M-pigments. Perceptually, the absence of a cone type can have differing effects. Individuals with a protan defect are less sensitive to light in the long-wavelength (red) portion of the spectrum. Therefore, the brightness of red, orange, and yellow is reduced compared with a normal observer. Furthermore, they may have problems in distinguishing red from green, as well as difficulties differentiating a red hue from black. Individuals with an absence of M-cone function are said to have a deutan defect. A deuteranope possesses an S-pigment and an L-pigment, whereas deuteranomalous trichromats possess an S-pigment and two spectrally distinct L-pigments. Deutans suffer similar hue discrimination problems as the protans, but without the long-wavelength dimming.

Blue-yellow defects (tritanopia) are relatively rare and affect the S-cones in the retina. The ability to distinguish colors in the short- and middle-wavelength regions of the spectrum is compromised. It is important to distinguish between an inherited blue-yellow defect and an acquired defect, as many acquired color defects can arise as a consequence of a traumatic event, such as exposure to toxins, a cortical injury, or an ocular disease like glaucoma or retinitis pigmentosa.

In blue cone monochromacy, both L- and M-cone functions are absent. Since L- and M-cones comprise about 95% of the total cone population, these individuals have a severe visual impairment, including photophobia, poor acuity, minimally detectable electroretinogram (ERG) responses, and diminished color discrimination. Any residual color discrimination in these individuals is based solely on the S-cones and rods.

In rod monochromacy, all cone function is absent or severely diminished. It is typically characterized by an absolute lack of color discrimination, photophobia (light sensitivity), reduced acuity, visual nystagmus, and a nondetectable cone ERG.

Interface Fluid Syndrome

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

IFS

Definition

Corneal edema which occurs in eyes that have had lamellar corneal refractive surgery.

Etiology

The most common cause of IFS is steroid-induced ocular hypertension. This results in transudation of fluid through the endothelium and stromal bed with tumor accumulation and swelling in the LASIK wound.

Other known causes for IFS are anterior uveitis, endothelial cell dysfunctions, or trauma.

Occurrence

Little is known about the occurrence of IFS, but due to reports of steroid response ocular hypertension between 5% and 36% in general population, it is believed that the incidence of IFS is significantly higher.

Classification

Up to today no classification for IFS has been made.

Cross-References

Interferometry, General

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Overview

Interferometry is a technique where two or more waves, which originated from the same source but traversed different paths, are interfered in order to retrieve information about the paths travelled by

these waves. Although interference is observed for all types of waves, the technique of interferometry is usually implemented using electromagnetic waves (mostly light). Interferometry is a very broad field and quite old. The initial theories on interferometry were proposed in the seventeenth century and a variety of different interferometers have been proposed since then. In the modern times, these old interferometers have been combined with lasers and electronics to develop extremely precise measuring devices which are being used in various areas of science and technology. Major areas include optical metrology, astronomy, optical communications, spectroscopy, biomedical imaging, surface profiling, mechanical stress/strain measurements, and many more.

Basic Principle

The basic principle behind all the interferometers is the interference of light. Whenever two beams, with a defined phase relationship with each other, are superimposed, interference is observed. If the beams are in phase (i.e., peak of one wave corresponds to the peak of the other), then they add up and constructive interference is observed while when they are out of phase, (i.e., peak of one wave corresponds to the trough of the other) they cancel each other and destructive interference is observed. If the phase relationship is in between the two extreme cases, then the intensities will add up partially. Therefore, by measuring the interference pattern of two beams, the phase relationship between them can be obtained. This phase relationship can then be used to retrieve more information on the path traveled by the interfering beams.

Classification of Interferometers

Interference can be observed by division of wavefront or division of amplitude. This differentiation is commonly used to classify interferometers. The example of interference by division of wavefront is the Young's double-slit interferometer and Fresnel biprism interferometer. The example of interference by the division of amplitude includes Fizeau interferometer or Michelson's interferometer.

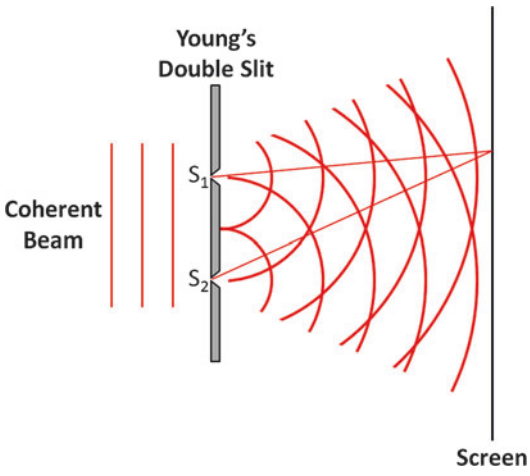
The interferometers could also be categorized based on the paths travelled by the interfering beams. Common path interferometers are the ones where the two interfering beams travel along the same path such as Sagnac interferometer or shearing interferometer, while in double path interferometer the two interfering beams travel different paths, such as Michelson's interferometer or Mach-Zehnder interferometer. Details on many of the interferometers mentioned above are provided below.

I

Common Interferometers

Young's Double Slit Interferometer

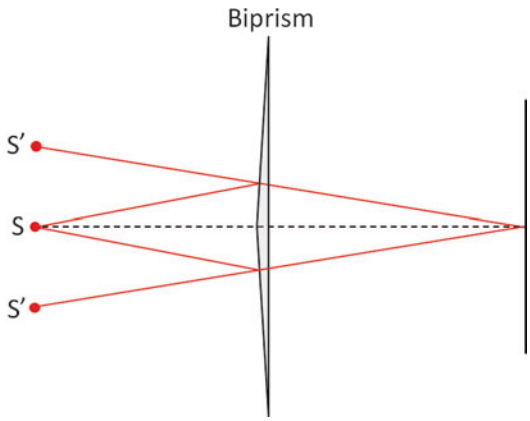
This interferometer was one of the first experiments which described the wave nature of light. A coherent light source illuminates two slits which split the wavefront of the incident light into two. The split wavefronts then interfere on the screen and generate an interference pattern. Figure 1 shows the Young's double slit interferometer.



Interferometry, General, Fig. 1 Young's double slit interferometer

Fresnel Biprism Interferometer

This is an alternative method of implementing Young's double slit configuration. One of the limitations of Young's double slit interferometer is that too little light passes through the two slits to observe interference. This interferometer uses Fresnel biprism to split the wavefront efficiently thus increasing the contrast of interference pattern. The apparatus is shown in Fig. 2. Fresnel biprism has a very small refracting angle; therefore, when the light from a coherent point source is made incident on the Fresnel biprism, it splits the wavefront into two. On the screen it appears that there are two point sources, one each for each split wavefront. These two wavefronts interfere on the screen to generate the interference pattern.



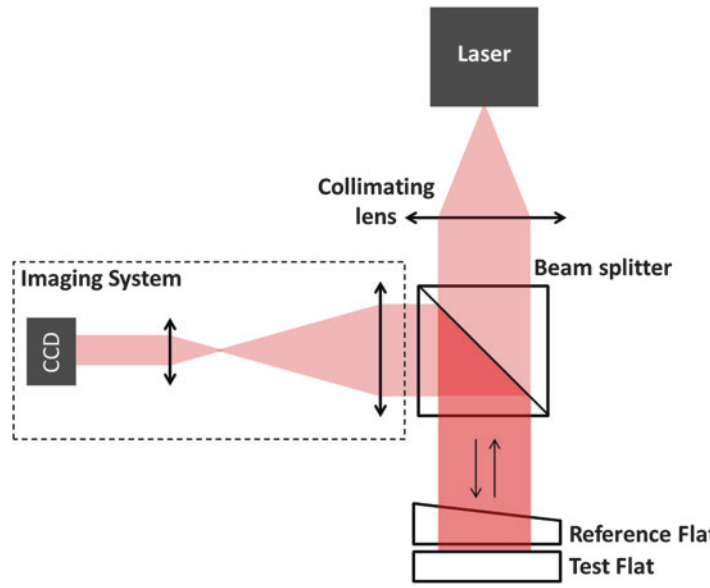
Interferometry, General, Fig. 2 Fresnel biprism interferometer

Fizeau Interferometer

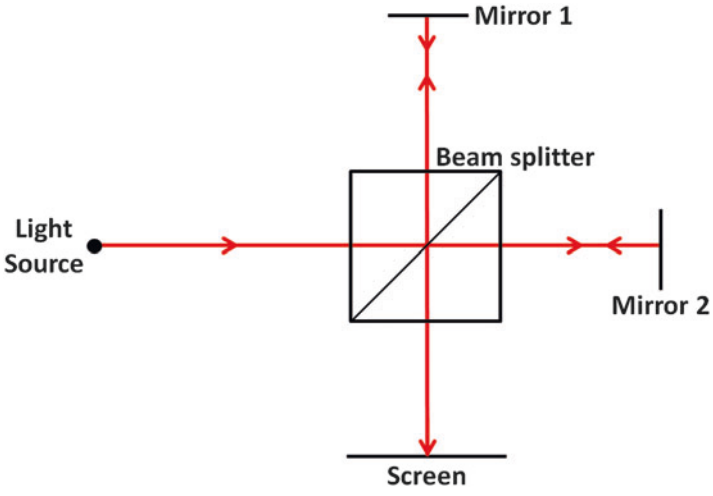
In a Fizeau interferometer, a collimated beam is made incident on two flat surfaces separated by an air gap. The light reflected from the two flat surfaces interfere to generate the fringes of equal thickness. If the flatness of one surface is established (reference flat), then the flatness of the other surface (test flat) can be evaluated on the basis of the fringes of equal thickness. Figure 3 shows the schematic of a Fizeau interferometer, where the reference flat is kept on top of the test flat. Convex and concave surfaces can also be evaluated by Fizeau interferometer by using a converging or diverging beam. Since the two interfering beams are formed by splitting the entire wavefront, this is an interferometer which is based on interference by division of amplitude.

Michelson Interferometer

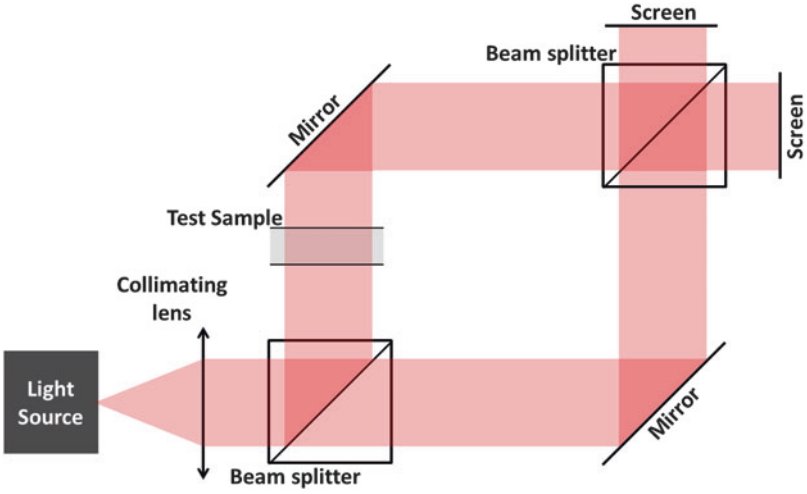
The schematic of the Michelson's interferometer is shown in Fig. 4. Light beam from a light source is split into two beams using a beamsplitter. The



Interferometry, General, Fig. 3 The schematic of Fizeau interferometer



Interferometry, General, Fig. 4 The schematic of the Michelson's interferometer



Interferometry, General, Fig. 5 Schematic of Mach-Zehnder interferometer

two beams are made incident on two mirrors, one reference and other test mirror. Light reflecting back from the two mirrors interfere on the screen. Effectively the interference is observed between the reflections of the light source from two mirrors.

Optical coherence tomography (OCT) is a fiber-based Michelson's interferometer where the test mirror is replaced with the sample. Based on the interference pattern, the information of the sample is obtained.

Mach-Zehnder Interferometer

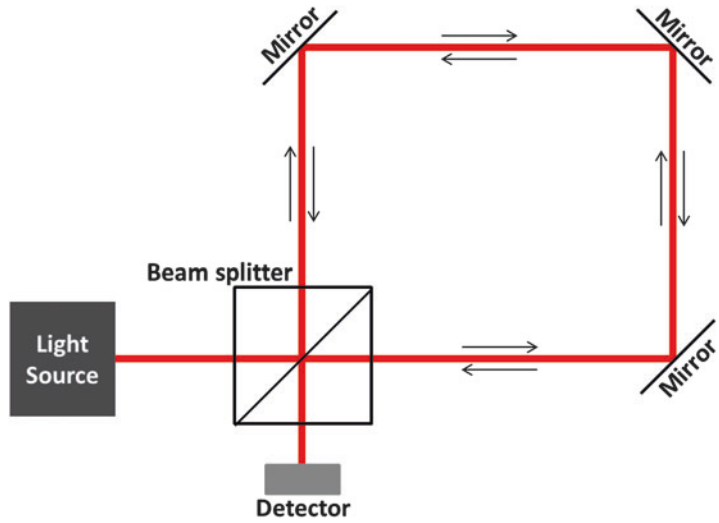
In Mach-Zehnder interferometer, the light from a coherent point source is first collimated by a lens and then split into two paths using a beamsplitter (Fig. 5). In one of the paths, a test sample is placed, while the other path is used as reference. The light from the two paths is then overlapped to interfere the two beams. Based on the interference pattern, the phase shift introduced by the test sample is measured which can then be used to retrieve other physical properties of the sample.

Sagnac Interferometer

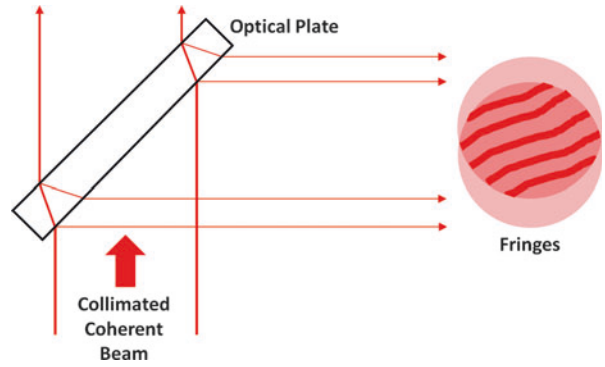
Sagnac interferometer is widely used to measure rotation. In this interferometer, light from a coherent light source is split into two using a beamsplitter. The spit beams are made to travel in the opposite directions along the same path as shown in Fig. 6. Depending on the angular velocity of rotation of the interferometer, phase of the beams traveling in the opposite directions is modified causing a shift in the interference pattern. Measuring this shift provides a measure for angular velocity of rotation.

Shearing Interferometer

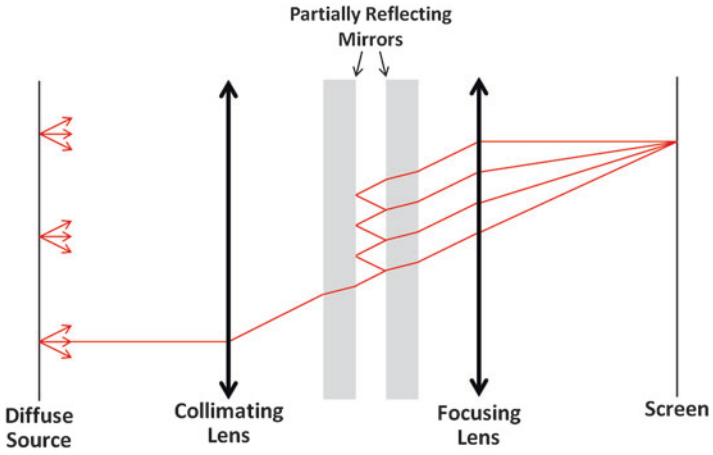
Shearing interferometer is probably the simplest type of interferometer. It consists of an optical plate with extremely flat surfaces, which are slightly wedged with respect to each other. A collimated beam is made incident at 45° on this plate (Fig. 7). The beam reflects from the two interfaces and interferes. Due to the finite thickness of the optical plate and the wedge between the two surfaces, the two beams are separated laterally, hence the name shearing interferometer. The interference is observed only in the



Interferometry, General, Fig. 6 Schematic of Sagnac interferometer



Interferometry, General, Fig. 7 Schematic of the shearing interferometer



Interferometry, General, Fig. 8 Schematic of the Fabry-Perot interferometer

region where the two reflected beams overlap. Most common application of shearing interferometer is to measure the collimation of the laser beams as the interference pattern is only observed if the incident beam is collimated.

Fabry-Perot Interferometer

The Fabry-Perot interferometer consists of two partially reflecting mirrors, which reflect light towards each other thus making an optical cavity. These mirrors are usually separated from each other by several millimeters. In a traditional configuration of Fabry-Perot interferometer, a diffuse light source is used to illuminate the interferometer. A collimating lens collimates the light coming out of a diffuse source. The collimated light enters the cavity and gets reflected from the partially reflecting mirror multiple times, as shown in Fig. 8. Some portion of the light is transmitted at each reflection. This transmitted light is focused onto the screen using a focusing lens. Depending on the thickness of the cavity and the reflectivity of the two partially reflecting surface, a concentric interference pattern is observed on the screen.

White Light Interferometer

White light interferometers as the name suggest use broadband light sources (white light sources). Due to the broadband characteristic of these light sources, the light emitted by them has a small coherence length. Here coherence length is the distance over which the phase relationship of the beam is maintained. Therefore to observe interference, the optical path lengths of the two interfering beams should be matched within the coherence length. White-light interferometers use this phenomenon to extract information from the interference pattern. For a Michelson's interferometer (Fig. 4) with a white-light source, the interference will be observed only if the optical path lengths for the two mirrors is matched to within the coherence length. If one of the mirrors is moved axially, then on the screen the interference will only be observed when the moving mirror is at the position where the path lengths for the two mirrors match. This hence could be used to extract the position of the second mirror.

Interferometry is a broad field; in this essay, we have covered just the basics of interferometry and talked about the most common interferometers. There are many other types of interferometers that have not been discussed. To learn more, please refer to dedicated textbooks on interferometry mentioned in the references.

Interlenticular Opacification

Maike Keintzel[1] and Thomas Kohnen[2]
[1]Goethe-Universität Frankfurt am Main, Frankfurt am Main, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Interpseudophakic opacification; Interpseudophakos Elschnig pearls; Red rock syndrome

Definition

Formation of an opacifying membrane between piggyback intraocular lenses and ingrowth of proliferative crystalline lens material. The major symptom is a decrease in best-corrected visual acuity (BCVA) with a blurred vision and glare. The currently advised therapy consists of the removal of the piggyback IOL and exchange with a single IOL.

Histology

After explantation of piggyback posterior chamber intraocular lenses because of opacification between the lens optics, histopathological examinations showed retained and proliferative lens epithelial cells mixed with lens cortical material in the peripheral interface between the lenses.

Immunohistochemistry

No references in literature.

Electron Microscopy

Scanning electron microscopic photographs obtained from the posterior surface of the anterior lens, the presence of multiple small globules is observed at the midperipheral area.

Definition

An internuclear ophthalmoplegia (INO) is a disorder of conjugate horizontal gaze. When a patient with INO is asked to move their eyes horizontally, the eye contralateral to the gaze direction will be unable to adduct, and the eye ipsilateral to the gaze direction will demonstrate a horizontal, dissociated, abducting nystagmus. For example, a right INO will present with left eye dissociated abducting nystagmus and an impairment in the ability of the right eye to adduct upon gaze to the left.

Etiology

INO is caused by damage to the medial longitudinal fasciculus (MLF), a fiber tract that extends from the rostral midbrain to the spinal cord. The MLF contains many important tracts including the pathway connecting the abducens nucleus and oculomotor nucleus, which is important for coordinating the eyes during horizontal conjugate. For example, a patient with right INO will have damage to the right MLF, preventing communication between the left abducens nucleus and the right oculomotor nucleus. As the patient tries to look to the left, the left eye will abduct, but the right eye will remain stationary. In addition, the left eye will demonstrate horizontal nystagmus due to cortical eye movement control centers attempting to compensate for the lack of adduction of the right eye.

Occurrence

INO can be caused by many conditions including multiple sclerosis (MS), brain stem infarction, tumors, arteriovenous malformations, Wernicke encephalopathy, and encephalitis. INO ranges from a mild form where the adducting eye moves slower than normal resulting in transient diplopia to a severe form where there is constant diplopia upon lateral gaze. In a young patient with a bilateral INO, one would suspect MS, whereas in an older patient one would instead suspect brain stem infarction. There may be a concomitant exotropia in patients with unilateral or bilateral INO leading to a "wall-eyed" monocular INO (WEMINO) or bilateral INO (WEBINO).

Classification

None.

Interstitial Keratitis

Khaled Tuwairqi
Wilmer Eye Institute, Baltimore, MD, USA
Department of Ophthalmology, University of Utah, Salt Lake City, UT, USA

Synonyms

Nonulcerative keratitis; Syphilitic keratitis

Definition

A nonsuppurative (nonmelting) inflammation of the corneal stroma that tends to spare the epithelium and endothelium.

Etiology

Many infective, immunologic, and environmental factors could contribute to this disease. Among the most common etiologic factors are syphilis and herpes viral infections. Other causes include tuberculosis, leprosy, Lyme disease, brucellosis, leptospirosis, influenza, mumps, onchocerciasis, *Acanthamoeba*, leishmaniasis, measles, *vaccinia*/*variola*, sarcoidosis, contact lens keratitis, lymphoma, and exposure to gold or arsenic. An idiopathic form of this disease is called Cogan's syndrome.

Occurrence

The ocular involvement could be seen unilaterally or bilaterally. Additionally, it could range from restricted to wide spread of the cornea. The occurrence of systemic symptoms could vary based on the underlying cause of the disease. Finding the etiologic factor is essential in treating both ocular and systemic conditions.

Classification

During the acute phase of the disease, nonspecific symptoms and signs could be seen in other forms of keratitis which include redness and tearing of the eye, pain, and photophobia followed by new vascular formation of the stoma. However, the late phase that characterizes the interstitial keratitis shows scarring that commonly leads to corneal thinning and empty ghost vessel. The differentiation of the underlying cause could be contributed to the pattern of ocular and stromal involvement, vasculature formation, and associated ocular and systemic findings.

Intracameral Antibiotics

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Administration of antibiotic agents into the anterior chamber of the eye.

Indication

Prophylaxis of postoperative endophthalmitis, therapy of fungal keratitis.

Contraindication

Allergy against applied antibiotics.

Use and Dosage

Intracameral antibiotics are applied as bolus injection into the anterior chamber at the end of cataract surgery. According to a multicenter study, administration of cefuroxime (1 mg in 0.1 ml saline) resulted in a fivefold decrease in the risk for total postoperative endophthalmitis. Other antibiotics such as cefazolin have also been applied for the prevention of postoperative endophthalmitis. For the treatment of fungal keratitis, application of intracameral amphotericin B (10 μg/0.1 mL) has shown a beneficial effect in smaller case series.

Adverse Reactions

Inadequate chemical preparation of intracameral antibiotics might result in toxic anterior segment syndrome.

Interactions

Not assessed

Cross-References

[2]Department of Ophthalmology, Rambam Health Care Campus, Haifa, Israel
[3]HaEmek Medical Center, Afula, Israel

Synonyms

Gas tamponade; Perfluoroethane (C2F6); Perfluoropropane (C3F8); Pneumatic retinopexy; Sulfur hexafluoride (SF6)

Definition

A surgical technique involving the introduction of gases into the vitreous cavity. The gases are used either in their pure form or as a mixture with air, exploiting their different longevity and expansile properties for achieving an effective internal tamponade.

Indication

Retinal detachment surgery with vitrectomy, pneumatic retinopexy, retinal detachment surgery with scleral buckle, macular hole surgery, displacement of subretinal hemorrhage, and post-vitrectomy gas exchange.

Contraindication

Air travel within the time frame of the gas's intravitreal longevity.

Nitrous oxide use during general anesthesia (should be discontinued for at least 15 min prior to intraocular gas injection, to avoid interference in the desired bubble volume).

Techniques and Principles

In this technique the vitreous is filled with a gas bubble for the purpose of restoring the anatomy by re-opposing the retina to the underlying retinal pigment epithelium and choroid. In daily practice, air, sulfur hexafluoride (SF6), perfluoroethane (C2F6), and perfluoropropane (C3F8) are most commonly used.

The main functions of a gas bubble inside the eye are to: (1) provide internal tamponade, (2) flatten the folded retina, (3) enable visualization, (4) replace globe volume, and (5) reduce intraocular currents. Providing internal tamponade for retinal detachments has been the main indication of intraocular gas use. The purpose is to appose the break by utilizing the surface tension of the bubble. The tamponade bubble also acts to seal the break and prevent cellular elements from escaping from under the retina into the vitreous cavity, thus preventing proliferative vitreoretinopathy.

The choice of gas is sometimes based on the availability of gases and the surgeon's experience and preferences. In general, the choice of gas is dependent on the intended duration of tamponade. For simple cases where duration required is short, air could be used. In more complicated cases where longer tamponade is desired, nonexpansile concentration of gas/air mixture (18% SF6 or 14% C3F8) could be used. When a larger bubble is needed, a gas/air mixture with an expansile concentration could be used. A larger bubble has the advantage of being able to unroll the folded retina. Taken together, a clear understanding of the properties of available gases is important to making the right choice for different circumstances.

Intraocular gas injection technique in vitrectomy for retinal detachments is briefly as follows: following full vitrectomy and relieving of tractions, fluid-air exchange is used to flatten the retina, at which point endolaser can be performed. Finally, air-gas exchange is performed.

In pneumatic retinopexy careful patient selection is important, as failure of apposing the retina may subject the patient to further operations. This is an office procedure and can be performed with topical, subconjunctival, or retrobulbar

anesthesia. Gas is then injected transconjunctivally through the pars plana, frequently followed by anterior chamber paracentesis to counter the increase in intraocular volume. A variety of intraocular gases may be used (e.g., air, SF6, C3F8). In practice, 0.3 mL of 100% C3F8 is used most commonly. In cases where apposition is doubtful, subretinal fluid persists, or new breaks were found, a reoperation with either scleral buckling or vitrectomy approach is indicated.

In macular hole surgery, classically intraocular gas tamponade is injected followed by facedown posture for 1 week. This provides a mechanical effect by the buoyancy force of the bubble over the macular hole, in order to assist closure. The injecting technique is identical to that in retinal detachment surgery with vitrectomy approach. Nevertheless, the duration of postoperative posturing has been a topic of debate in recent years.

Pneumatic displacement of subretinal blood clot has been found to be therapeutic in treating polypoidal choroidal vasculopathy, macroaneurysm, choroidal neovascularization, and trauma. It has been shown to allow speedier recovery of vision and may potentially reduce the harmful effect of blood on the photoreceptors. The original procedure was to treat within 1 week from onset of hemorrhage, coupled with tissue plasminogen activator (tPA) injection. There are recent reports showing similar effects without the use of tPA and also of variable duration from onset of up to 30 days. Prior to injection, careful patient selection should be done. Distinction between subretinal blood and intraretinal blood should be made. Injecting gas for intraretinal blood will not displace the clot, but rather increases the chances of blood diffusing into the vitreous.

Postvitrectomy gas exchange may be utilized for recurrent detachment and may avoid the need for reoperation. A fluid-gas exchange could be performed at the slit lamp, using a 30-gauge needle connected to a syringe filled with the desired gas of injection. If the patient is aphakic, the procedure could be performed by inserting the needle into the anterior chamber through the cornea, instead of the pars plana approach.

Outcome

After injection, the gas bubble inside the eye undergoes three phases before complete resorption: expansion, equilibration, and dissolution. This occurs when pure expansile gases (i.e., SF6, C2F6, and C3F8) are injected (i.e., air does not expand).

The time taken for complete resorption of the bubble also depends on other factors such as lens status, aqueous turnover, presence of vitreous, presence of epiretinal membranes, ocular blood flow, and ocular elasticity. The life span of SF6 and C3F8 may be more than twice as long in aphakic nonvitrecomized eyes than in aphakic vitrectomized eyes.

Proper apposition of the break is only ensured by proper posturing of the head. This is done by assuming a facedown or prone posture immediately after surgery such that the break is located at the uppermost part of the eye and in direct contact with the bubble. Another potential advantage of facedown posturing is that this reduces the contact between the posterior surface of the lens in aphakic patient with the gas bubble and reduces the risk of cataract development. If facedown or prone posture is difficult or the patient needs to take rest from prolonged facedown position, lying laterally on the opposite side of the break is also acceptable (i.e., lying on the left for a right side break). This could be facilitated with the use of pillows designed for posturing purposes. As chorioretinal adhesion from laser or cryotherapy requires up to 14 days to become effective, the patient's compliance should be reassured and monitored. Vision is usually poor during the life span of the bubble, mainly due to diffraction and glare.

Complications

Breakup of the gas bubble into a few smaller bubbles (i.e., "fish eggs") by poor injection techniques, resulting in ineffective tamponade/therapeutic effect.

In case PVR has already set in, gas injection may be complicated by formation of new retinal breaks or extension of existing breaks, which usually occur at the edge of laser marks.

Gas-induced cataract, usually in the form of feathery posterior subcapsular cataracts.

Raised intraocular pressure is more frequent when expansile gases or gas/air mixtures of high purity are used. A 26–59% incidence was reported.

Gas leakage from sclerotomies can result in hypotony. Choroidal effusion or hemorrhage may occur with prolonged hypotony.

Migration of gas into the subretinal space can occur both intraoperatively and in the postoperative period at which point it may cause re-detachment.

In aphakic eyes or in pseudophakic eyes with a nonintact posterior capsule, gas may migrate into the anterior chamber. Prolonged contact of the bubble with the corneal endothelium may predispose it to hypoxia and decompensation.

With combined phacovitrectomy and intraocular gas injection, the intraocular lens (IOL) may be pushed forward into the anterior chamber, causing optic capture.

Intraocular Infection

► Endophthalmitis

Intraocular Injection

► Intravitreal Injections

Intraocular Injection of Ocular Drugs

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Indications

Intraocular injections are the fastest growing procedure in ophthalmology. They are commonly used for the treatment age-related macular degeneration (bevacizumab, ranibizumab), iris neovascularization secondary to proliferative diabetic retinopathy (bevacizumab), and macular edema (bevacizumab and triamcinolone acetonide) due to diabetic retinopathy, vein occlusion, or uveitis.

In addition intravitreal methotrexate has been used to treat intraocular lymphoma associated with primary central nervous system lymphoma. Less commonly it has been used in patients with uveitis and advanced proliferative diabetic retinopathy.

Adverse Effects

Intravitreal injections often lead to increased intraocular pressure (IOP) immediately after the procedure. In 2008, Kim et al. demonstrated that eyes injected with ranibizumab, bevacizumab, pegaptanib, and triamcinolone acetonide had transient IOP spikes immediately after the procedure. However, close monitoring is necessary especially in patients with a history of glaucoma, ocular hypertension, or patients that are glaucoma suspects.

Other potential adverse effects include endophthalmitis, intravitreal hemorrhage, cataract, and irreversible loss of visual acuity.

Synonyms

IOL

Definition

Artificial lens made of transparent plastic, silicone, or acrylic that is implanted in the eye and performs in focusing images.

Epidemiology

According to industry data, the worldwide number of implanted IOLs is estimated at between six and ten million a year. The number of cataract operations per one million people per year (cataract surgery rate, CSR) varies highly from one country to another: according to the World Health Organization, the CSR is 4000–5000 in the USA and in Europe but only about 3000 in semi-industrialized countries such as India and as low as 200 in some Third World countries.

History

On November 29, 1949, Sir Harold Ridley implanted the first IOL in a human eye at St. Thomas' Hospital in London, UK. Operating microscopes did not exist at the time so a flashlight held by Ridley's nurse Ms. Clarke provided lighting for the surgery. A planned primary extracapsular procedure was performed using a large incision to implant the IOL in a human eye. Sixty years later, cataract surgery has been transformed into a highly specialized procedure with sub-2.0 mm incision surgery using ultrasound energy, even femtosecond laser technology and foldable IOL materials. The tremendous changes in IOL technology have led surgeons to use today's spherical, aspheric, multifocal, and toric IOL to correct not only aphakia but also astigmatism, higher-order aberrations, and presbyopia (Kohnen and Koch 2009; Kohnen et al. 2009).

Clinical Features

There are four different basic types of IOL:

- Monofocal (also known as standard IOL)
- Multifocal
- Accommodative
- Toric

Each of these types can have additional attributes like asphericity or blue-light filtering. See also section "Cross-References" list below displaying different types of IOL.

Tests

During the decades, IOL have undergone extensive research and testing in Europe, Asia, and the USA and have been proven safe for the treatment of cataracts and refractive errors.

Differential Diagnosis

Clinical aspects of an IOL with its optics and haptics clearly identify an IOL if the quality of the optical media, especially the cornea, is not reduced significantly. Rarely, a silicone bubble after vitreoretinal surgery on the posterior surface of an IOL may be mistaken for a dislocated IOL.

Etiology

See also section "Clinical Features."

Treatment

See also entries "▶ Cataract Surgery" and "▶ Refractive Surgery" describing different IOL implantation techniques.

Intraocular Lymphoma

Jacob Pe'er and Shahar Frenkel
Department of Ophthalmology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel

Synonyms

Intraocular large B-cell lymphoma; Primary intraocular lymphoma; Reticulum cell sarcoma (old)

Definition

Vitreoretinal lymphoma (VRL) is a rare, mostly high-grade B-cell malignancy which can be considered a subset of primary central nervous system lymphoma (PCNSL).

Etiology

The etiology of VRL is unclear. It occurs in approximately one-quarter of patients with PCNSL. As the central nervous system, the intraocular structures lack lymphatics and lymph nodes, and the lymphoma in these cases is probably from an abnormal clone(s) of lymphocytes that is unique to immunoprivileged organs (CNS, eye,

testes) that home into the eye. Most cases of vitreoretinal lymphoma occur in immunocompetent patients. T-cell lymphoma rarely occurs. VRL is the most common type of intraocular lymphoma (Chan and Gonzales 2007; Sagoo et al. 2014).

Clinical Presentation

VRL in most cases is a disease of adults, peaking in the sixth decade, although it is diagnosed also in younger patients in the third and fourth decades. It may be monocular but is more commonly a bilateral disease, although may be asymmetrical in severity. The hallmark of VRL is the presence of cells in the vitreous, often in clumps or sheets, which is often misdiagnosed as a nonresponsive uveitis, and white-yellow retinal and subretinal infiltrates. The optic nerve head can be involved. In 80–90% cases, it appears in patients with PCNSL. The intraocular involvement occurs in approximately one-quarter of patients with PCNSL and can appear before, concomitant with, or even years after the CNS lymphoma.

Differential Diagnosis

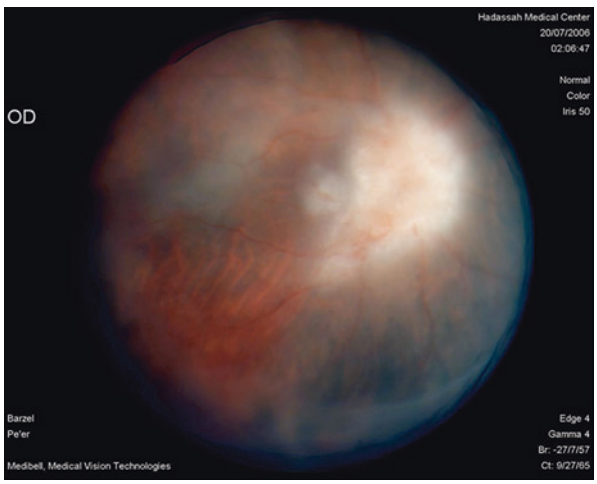
Differential diagnosis includes → all causes of posterior uveitis → noninfectious retinitis and chorioretinitis → infectious retinitis or chorioretinitis → infiltrating choroidal lesions such as metastatic tumors.

Prophylaxis

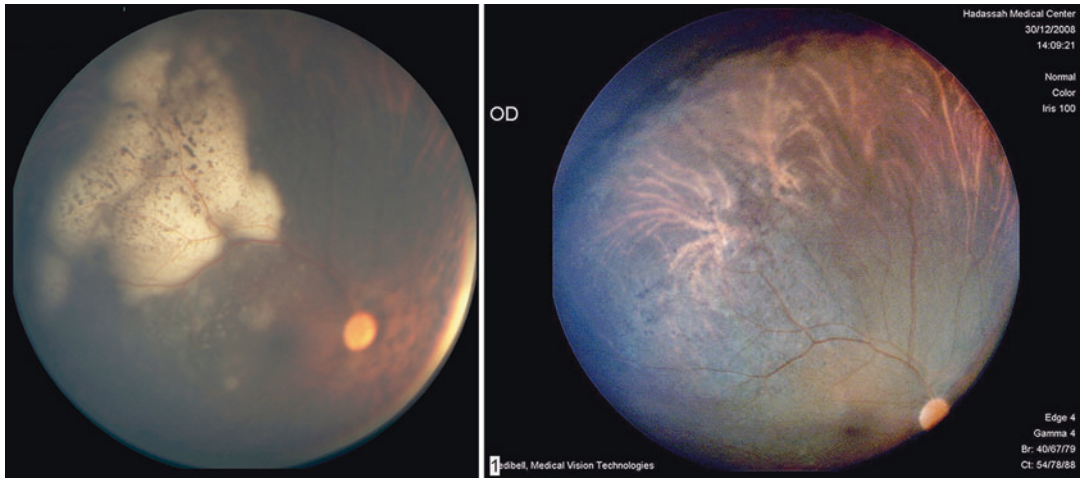
All patients with known PCNSL should be followed up routinely by an ophthalmologist to rule out ocular involvement. Early diagnosis can prevent loss of vision.

Therapy

Radiation therapy alone to the eye, with or without whole-brain radiotherapy, is still practiced in many centers. Systemic or intrathecal chemotherapy alone or in combination with radiation therapy have been used extensively. Because of limited intraocular penetration of drugs administered systemically, and side effects of systemic chemotherapy and radiation, intravitreal chemotherapy – mostly using methotrexate – has become popular since the mid-1990s with excellent local disease control. More recently, biological treatment with intravitreal injections of rituximab with or without methotrexate have been used with good results (Pe'er et al. 2009).



Intraocular Lymphoma, Fig. 1 Fundus photography shows "clouds" of lymphoma cells in the vitreous, and white infiltration of lymphoma in the retina around the optic nerve head



Intraocular Lymphoma, Fig. 2 Fundus photography shows infiltrates of lymphoma cells in the upper part of the retina with early infiltration in the macular area before treatment with intravitreal methotrexate (left) and complete disappearance of the infiltrates after treatment (right)

Prognosis

Vitreoretinal lymphoma is an intraocular disease which is not fatal, but which often accompanies PCNSL which is often fatal. The prognosis for vision depends upon the extent of the disease and the time of diagnosis. A late diagnosis can lead to visual loss, while early diagnosis and treatment can save vision.

Epidemiology

Vitreoretinal lymphoma is a rare disease which involves 20–25% of patients with PCNSL. The incidence of PCNSL is increasing and is currently ranging between 2.5 and 5 per million person-years in the immunocompetent population and is much higher in patients with AIDS (Figs. 1 and 2).

► Uveal Melanoma

Intraocular Pressure

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

IOP

Definition

The intraocular pressure is the pressure within the eye which is determined by aqueous production

and aqueous outflow from the eye. The normal range of IOP is 8–21 mmHg.

Basic Characteristics

The rate of aqueous production is defined by the Goldmann equation as follows: $PO = (F/C) + PV$, where PO is IOP, F is the rate of aqueous formation, C is the facility of outflow, and PV is the episcleral venous pressure (Alward 2000). Elevated intraocular pressure results from a decrease in facility of outflow or an increase in episcleral venous pressure.

There exists diurnal variation of IOP, typically being highest in the early morning and lowest in the late evening, though this is variable (Allingham et al. 2005).

Intraoperative Floppy-Iris Syndrome

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

IFIS

Definition

Intraoperative complication during cataract surgery presenting as flaccidity of the iris is caused by lack of tension of the dilatator muscle. It is associated with the intake of selective α_{1A} adrenergic receptor blockers such as tamsolusin or doxazosin. Intraoperatively, the pupil often dilates poorly or constricts prematurely. The iris is likely to prolapse through the incision or paracentesis and shows a flaccid behavior like billowing and fluttering. IFIS can give rise to intraoperative complications such as iris aspiration and posterior capsule rupture. This phenomenon can be explained by the blocking of α_1 receptors by the drug with subsequent atrophy of the musculature. Up to now, no specific dose–response curve could be established. A preoperative washout period of at least 1 week did not have effect in most cases (Chang and Campbell 2005; Narendran et al. 2009).

Histology

Eyes with a history of tamsolusin use showed a significantly decreased thickness of the iris dilatator muscle. The iris stroma did not seem to be affected (Santaella et al. 2010). To date, there are no reports of immunohistochemistry or electron microscopy features in eyes with intake of α_{1A} adrenergic receptor blockers.

Molecular Diagnostics

No molecular diagnostics are required for diagnosis of IFIS.

Differential Diagnosis

Iris dilatator atrophy due to other reasons can have a similar intraoperative appearance.

Intraorbital Foreign Body (IOFB)

Gary Joseph Lelli[1], Benjamin Levine[1], Christopher Zoumalan[2] and Robert J. Peralta[3]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA
[3]Department of Ophthalmology and Visual Sciences, University of Wisconsin Hospital and Clinics, Madison, WI, USA

Definition

Foreign body of the orbit.

Epidemiology

True epidemiologic data is unavailable due to the relatively uncommon nature of this phenomenon. Recent retrospective consecutive case series show that the majority of patients are young males, perhaps owing to the accidental and sometimes violent nature of these injuries.

Etiology

Penetrating eyelid and orbital trauma.

History

Most patients present at the time of injury. Delayed presentation may occur after seemingly trivial trauma. In these cases, patients may complain of a progressive orbital mass, signs of orbital inflammation and infection, pain on eye movements, diplopia, and/or lagophthalmos. In children or noncommunicative patients, a high index of suspicion must be maintained as this information cannot be elicited.

A thorough history directs clinical management. Mechanism of trauma, associated injury, and loss of consciousness are vital, as they provide clues to the presence of potentially life-threatening injuries. Past medical and ocular history aids in the assessment of premorbid visual function and visual rehabilitative potential.

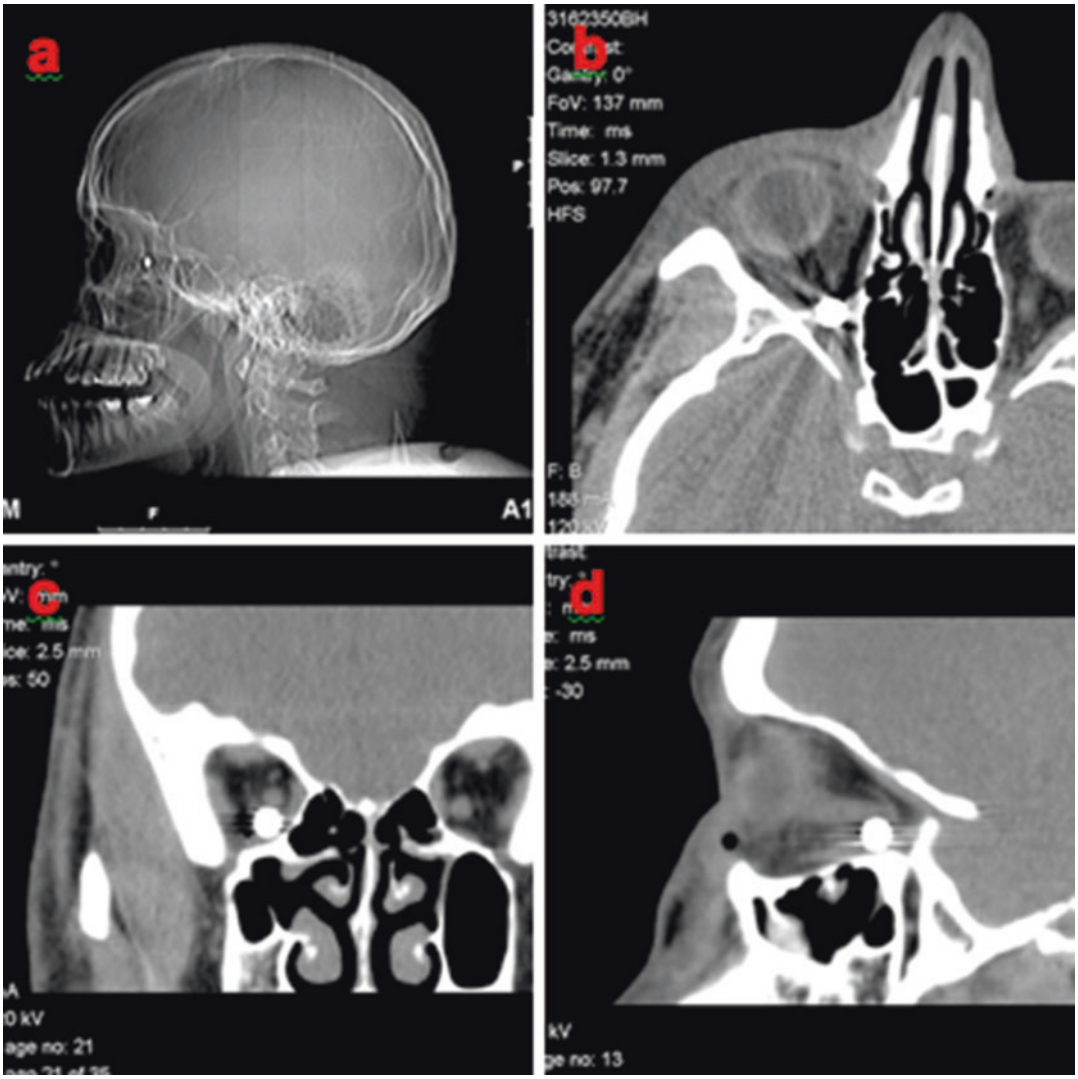
Mechanisms of trauma can broadly be grouped into blunt, sharp, and high-velocity categories. The latter two categories are more likely to result in deeper, penetrating injury. Determining the composition of the foreign body is important, as this information will greatly affect the choice of diagnostic imaging and further management.

Clinical Features

Clinical presentation varies. Decreased vision typically occurs at the time of injury. Gross ophthalmologic exam may reveal diplopia, pain with eye movements, and ophthalmoplegia. An afferent pupillary defect may be present in cases with associated traumatic optic neuropathy or orbital compartment syndrome (i.e., hemorrhage, cellulitis) (Patel et al. 2008).

On external exam, eyelid edema, ecchymoses, and lid laceration are usually present. In the absence of these findings, more subtle signs such as ptosis or lagophthalmos may be noted. Proptosis may manifest secondary to orbital hemorrhage or cellulitis. Parasthesias, point tenderness, subcutaneous emphysema, and step-off orbital rim defects may signal the presence of an orbital fracture.

On slit lamp examination, evidence of anterior segment trauma may include subconjunctival



Intraorbital Foreign Body (IOFB), Fig. 1 Computed tomography of the brain and orbits demonstrates a metallic intraorbital foreign body located deep in the orbit. Axial (b), coronal (c) and sagittal (d) sections further delineate the proximity of the foreign body to the optic nerve

hemorrhage, chemosis, corneal abrasion, hyphema, iris sphincter tear, and iridodialysis. Importantly, a retrospective consecutive case series by Fulcher et al. (2002) showed that ruptured globe was the most commonly associated ocular injury. Fundoscopic examination may reveal traumatic posterior vitreous detachment and vitreous hemorrhage. With more serious compressive injury, retinal breaks, retinodialysis, choroidal rupture, or sclopetaria may develop.

Diagnostics

Computed tomography (CT) is the modality of choice as it provides excellent soft tissue and bony detail, can detect the majority of foreign bodies, and is safe in the presence of metal. Generally, 1.5–3 mm axial and coronal images are preferred. Wooden foreign bodies may be missed on CT or misdiagnosed as intraorbital air. Magnetic resonance imaging (MRI) is better at

detecting these types of foreign bodies but should be performed only after the presence of metal is ruled out. Ultrasonography may be useful as an adjunctive study should CT and MRI prove equivocal.

Differential Diagnosis

Orbital tumor, idiopathic orbital inflammation, orbital or preseptal cellulitis.

Prophylaxis

Protective eyewear.

Treatment

A general management algorithm is outlined in Fig. 1. As mentioned previously, it is most important to first complete a systemic evaluation to rule out potentially life-threatening injuries and to rule out an ophthalmic emergency such as a ruptured globe. Afterwards, the extent of any ocular, adnexal, orbital, and adjacent sinocranial injuries can be addressed (Finklestein et al. 1997). Consultation with neurosurgery or otolaryngology may be required.

Empiric broad-spectrum antibiotics, often with the guidance of an infectious diseases specialist, should be administered. If concomitant traumatic optic neuropathy is present, the use of systemic corticosteroids remains controversial (Yu-Wai-Man and Griffiths 2007). There is currently insufficient evidence that systemic corticosteroids provide benefit in these cases. Appropriate imaging, as outlined above, can then be obtained to identify the foreign body.

Composition and location of the foreign body determine further management. Because of the increased risk for infection and inflammation, all organic foreign bodies should be removed, although there is a paucity of data on those located in the posterior orbit (Ho et al. 2004). The approach to inorganic foreign bodies is more complex. Those that are freely palpable and located in the anterior orbit should be removed. Those that are nonpalpable, biologically inert, and located in the anterior, epibulbar, or posterior orbit can usually be managed conservatively given the risk of hemorrhage and iatrogenic functional deficit during surgical extraction.

Although most metals are inert, there are three notable exceptions. Copper may induce a large degree of inflammation. Iron may cause localized siderosis and subsequent retinal degeneration detectable on electroretinogram (ERG). Lead may lead to systemic toxicity. Thus, for inorganic foreign bodies, removal should be considered in cases associated with severe inflammation, infection, functional deficit, or one of the above biologically intolerable metals.

Intravitreal Injections

John E. Legarreta, Karen B. Schaal and Philip J. Rosenfeld
Department of Ophthalmology, Bascom Palmer Eye Institute, Miller School of Medicine, University of Miami, Miami, FL, USA

Synonyms

Intraocular injection; Intravitreous injection

Definition

An intravitreal injection is the process in which a substance is directly deposited into the vitreous cavity by inserting a needle through the pars plana. The needle is attached to a syringe containing an agent that is then released into the vitreous cavity.

Several agents can be administered with intravitreal injections. Examples include:

- Antibiotics
- Gases (C3F8, SF6)
- Clot disrupting agents (recombinant tissue plasminogen activator, rTPA)
- Immunosuppressants (methotrexate, steroids)
- Enzymes (ocriplasmin)
- Antibodies, antigen-binding fragments, and soluble receptors

Inhibitors of vascular endothelial growth factor (VEGF) are the most common agents injected into the vitreous worldwide. These agents include Avastin (bevacizumab), Lucentis (ranibizumab), and Eylea (aflibercept) and are used for the treatment of exudative eye diseases such neovascular age-related macular degeneration, diabetic macular edema, and retinal edema associated with venous occlusions.

Procedure Technique

In order to minimize complications from intravitreal injections, proper sterile technique should be utilized. Below are the summarized steps to performing an intravitreal injection:

1. Informed consent and appropriate eye identified and marked for injection.
2. Instill the following series of drops several times:
   - One (1) drop of proparacaine
   - One (1) drop of lidocaine (4%)
   - One (1) drop of ophthalmic povidone–iodine (Betadine) (5%)
3. A Betadine swap to clean the eyelashes and eyelids is recommended. Clean from the inner canthus to the outer canthus, and then clean off the Betadine from the eyelids and eyelashes with a sterile eye pad.
4. Place an eyelid speculum in the eye.
5. Perform the following series of steps several times to lower the intraocular pressure and anesthetize the injection site:
   - Apply a cotton tip applicator soaked with 4% lidocaine approximately 3.5–4 mm posterior to the limbus in the superior of inferior temporal quadrants for a duration of 20–30 s. Most injectors prefer the inferior quadrant.
   - Apply the cotton tip applicator with firm pressure in the quadrant where the injection will be performed.
   - Lubricate the cornea surface with artificial tears.
6. Instill one (1) drop of 5% Betadine into the eye. To minimize the postinjection discomfort from 5% Betadine, pretreatment with topical ketorolac is recommended.
7. Use a sterile caliper to measure the site of injection (optional).
8. Instill one (1) drop of Betadine into the eye.
9. Prepare the medication in the appropriate syringe and needle (typically a 1 cc syringe with a 30- or 32-gauge needle, and needle length should be around ½ or 5/8 in.).
10. Prior to inserting the needle, everyone (physician, assistant, and patient) should refrain from speaking or should wear surgical masks to reduce the risk of infection.
11. Using a one-handed technique with a cotton tip swab in the fellow hand, the injector inserts the needle at the marked injection site, perpendicular to the sclera, and through the pars plana (typically 3.5 mm posterior to the limbus in pseudophakic eyes and 4 mm posterior to the limbus in phakic eyes). The needle should be directed toward the center of the vitreous cavity and buried until its hub touches the eye. The medication is then injected.
12. The needle is removed and the cotton tip swab is placed over the injection site.
13. Check for counting fingers or hand motion vision after the injection. If light perception

is not detectable within 5 min, then an anterior segment paracentesis is performed. A check of the intraocular pressure (IOP) within 5 min of the injection is optional, but recommended especially if vision is impaired.

Complications

The complications associated with intravitreal injections are few and are usually attributed to the injection technique, the volume injected, or the agent injected. The actual insertion of the needle is associated with complications that include damage to the natural crystalline lens, lens zonules, lens capsule, and retina, such as a retinal tear or detachment, which is related to the direction of the needle as it enters the eye. The volume injected into the eye is associated with an elevated intraocular pressure, which is usually transient, but if it persists, a paracentesis is needed or permanent damage to the vision could result. A recent study by Gregori et al. (2014) showed that decompressing the eye with a cotton tip applicator prior to the injection during the anesthetic step produced a significantly lower IOP spike postinjection.

Endophthalmitis can result from bacterial contamination from the surface of the eye, due to inadequate preparation of the eye, or from the needle if it becomes inadvertently contaminated. In addition, the agent injected into the eye could be contaminated during the preparation process, whether it is performed in the clinic or operating room when the drug is withdrawn from the vial or when the drug is prepared in the compounding pharmacy. Infectious endophthalmitis is rare, but is an emergency situation when it occurs and needs to be treated promptly with a vitreous tap and injection of antibiotics. Symptoms usually do not develop for several days depending on the type of bacteria and the bacterial load at the time of injection. Typical complaints include ocular pain, decreased vision, and a red, swollen eye. However, not all of these symptoms need to be present. It is crucial to differentiate an infectious endophthalmitis from a noninfectious or "sterile endophthalmitis," and this distinction may be challenging due to the overlap of signs and symptoms. In a sterile endophthalmitis, the eye is usually not as red and is less painful. It is also very rare to see fibrin or a hypopyon. The treatment for sterile endophthalmitis is usually topical steroids, and the condition may take several weeks to fully resolve.

Milder complications of intravitreal injections are small conjunctival hemorrhages that occur from the injection and transient ocular irritation, which can result in a "burning" sensation described by some patients after the injection. These conditions are self-limited and usually resolve within several days. Artificial tears are often helpful after an injection to help alleviate the irritation.

In the setting of a periocular infection such as an active chalazion, canaliculitis, or a severe case of blepharitis, it is advisable to postpone the injection until the infection has resolved. However, in certain patient situations, there are some exceptions when the benefits of the injection outweigh the potential risk of endophthalmitis, and this decision must be determined by the injecting physician (Avery et al. 2014).

Postinjection Antibiotics

No effect has been proven in lowering the risk of an intraocular infection with the use of topical antibiotics after intravitreal injections, and there is insufficient evidence to support the routine use of antibiotics to prevent endophthalmitis (Avery et al. 2014).

Intravitreal Triamcinolone

Yong Tao[1] and Jost B. Jonas[2]
[1]Department of Ophthalmology, Beijing Chaoyang Hospital, Capital Medical University, Beijing, China
[2]Department of Ophthalmology, Medical Faculty Mannheim of the Ruprecht-Karls-University Heidelberg, Mannheim, Germany

Synonyms

The current commercial preparations of triamcinolone acetonide include Aristocort acetonide; Flutex; Kenacort-A; Kenalog; Kenaquart; Ledercort D; Oncilon-A; Respicort; Rineton; Solodelf; Tramacin; Tricinolon; Vetalog; Volonimat.

Definition

Injection of triamcinolone acetonide into vitreous cavity through pars plana.

Indication

(i) Edematous retinal diseases including diffuse diabetic macular edema, macular edema secondary to branch retinal vein occlusion and central retinal vein occlusion, persistent pseudophakic cystoid macular edema, radiation-induced macular edema, cystoid macular edema due to retinitis pigmentosa, panretinal photocoagulation, adult Coat's syndrome, penetrating keratoplasty, and Behcet disease

(ii) Neovascular retinal or choroidal diseases including proliferative diabetic retinopathy, and diabetic retinopathy in general, exudative age-related macular degeneration, myopic choroidal neovascularization, choroidal neovascularization in Sorsby's fundus dystrophy, and neovascular glaucoma without or with cataract surgery

(iii) Intraocular inflammation including chronic uveitis, presumed ocular histoplasmosis syndrome, sympathetic ophthalmia, immunologic corneal graft reaction, Vogt-Koyanagi-Harada syndrome, and chronic prephthisical ocular hypotony

(iv) Others including perifoveal telangiectasia, ischemic ophthalmopathy, extensive exudative retinal detachment, and prevention of proliferative vitreoretinopathy, and in combination with intraocular surgery to visualize the vitreous

Contraindication

(i) Infective endophthalmitis
(ii) History of steroid-induced glaucoma
(iii) Viral retinal diseases including acute retinal necrosis and cytomegalovirus retinitis

Use and Dosage

Intravitreal injection of triamcinolone acetonide with dosage varied from 1.0 to 20.0 mg. In most cases, it is 4.0 mg. In nonvitrectomized patient eyes, the mean elimination half-life was 18.6 days, while in one postvitrectomy patient eye, it decreased to 3.2 days. After single intravitreal injection, peak aqueous humor concentrations ranged from 2.15 to 7.20 μg/ml. Electroretinogram and histologic sections in silicone-filled rabbit eyes after intravitreal injection of triamcinolone acetonide with dosage of 1 mg, 2 mg, or 4 mg were normal (Kivilcim et al. 2000).

Adverse Reactions

(i) Postinjection infectious endophthalmitis: The frequency of postinjection infectious endophthalmitis as reported ranged between 0/700 and 8/992 (0.87%) (Jonas et al. 2005). The risk of an infectious endophthalmitis may partially depend on the setting of the injection itself. Histologically, eyes with intravitreal triamcinolone acetonide and infectious endophthalmitis show a marked destruction of the whole globe. The most striking finding can be that some areas show a massive infiltration by granulocytes, while other areas can be almost completely devoid of inflammatory cells.

(ii) Postinjection pseudo-endophthalmitis: Triamcinolone acetonide crystals can mimic a so-called pseudo-hypopyon, if they penetrate from the vitreous cavity into the anterior chamber. The diagnostic problem is the differentiation between a painless hypopyon caused by a postinjection infectious endophthalmitis and a pseudo-hypopyon due to triamcinolone acetonide crystals. Using high magnification slit lamp biomicroscopy usually reveals the crystalline structure of triamcinolone acetonide.

(iii) Secondary ocular hypertension, secondary steroid-induced open-angle glaucoma: Studies have noted the prevalence of intraocular pressure elevations after intravitreal injection of triamcinolone to vary between 28% and 77%. Young people are mainly involved. The rise in intraocular pressure started at about 1 week after the injection, and the measurements returned to the baseline values after about 9 months. A prospective clinical interventional comparative nonrandomized study included 260 consecutive patients (293 eyes) receiving an intravitreal injection of 20–25 mg triamcinolone acetonide as treatment for diffuse diabetic macular edema, exudative age-related macular degeneration, retinal vein occlusions, uveitis, and cystoid macular edema. Intraocular pressure readings higher than 21 mmHg, 30 mmHg, 35 mmHg, and 40 mmHg, respectively, were measured in 94 (36.2%) patients, 22 (8.5%) patients, 11 (4.2%) patients, and 4 (1.5%) patients, respectively. Triamcinolone-induced elevation of intraocular pressure could be treated by antiglaucomatous medication in all but 3 (1.0%) eyes, for which filtering surgery became necessary (Tao and Jonas 2011). However, postinjection rise in intraocular pressure did not vary significantly between patients with a preinjection diagnosis of chronic open-angle glaucoma and patients without history of glaucoma.

(iv) Rhegmatogenous retinal detachment: Rhegmatogenous retinal detachment is a theoretical risk and rare case report can be found in pervious literature.

(v) Postinjection, steroid-induced cataract: Single intravitreal triamcinolone injection induced posterior subcapsular cataract development, whereas multiple injections resulted in all-layer cataract progression. Thompson studied by linear regression analysis lens scores from lens opacity standards in evaluating 93 eyes with intravitreal injection of 4 mg of triamcinolone acetonide. Lens opacities were graded using the Lens Opacity Classification System II (LOCS II) scale. This scale assigns a number between 0 and 4 for all lens opacities for three cataract types: nuclear sclerosis, posterior subcapsular cataracts, and cortical cataracts. Fractional scores were used if a cataract was between two standards, such as 0.5 for a cataract between the "0" and "1" standards. Nuclear sclerosis increased at a rate of 0.175 U per year, posterior subcapsular cataracts at 0.423 U per year, and cortical cataracts at 0.045 U per year (Thompson 2006).

(vi) Central serous chorioretinopathy: In a previous case report, a patient who developed central serous chorioretinopathy after vitrectomy with intravitreal triamcinolone acetonide for diabetic macular edema was reported (Imasawa et al. 2005).

(vii) Toxic effects: The intraocular use of Kenalog has not been proved by FDA. The preservative in Kenalog-40 is 0.99% benzyl alcohol, which may be potentially toxic to retina and lens, and it was supported by various animal studies from different groups of authors. Direct toxic effects of triamcinolone acetonide on the retina and optic nerve have not been observed yet, independently of the dosage used.

Interactions

Intravitreal triamcinolone has been reported to be safely used to be combined with some other drugs which are generally intravitreally used, such as ranibizumab and bevacizumab. Intravitreally injected triamcinolone acetonide does not mix with silicone oil. Triamcinolone acetonide crystals that sediment at the lower border of a silicone oil bubble may be harmful to retinal cells.

Inverted Follicular Keratosis

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Basosquamous cell acanthoma

Definition

Inverted follicular keratosis (IFK) is a benign usually solitary epithelial tumor that appears predominantly on the skin of the face.

Etiology

Histological studies from the past considered these lesions to be derived from a pilosebaceous unit. Therefore, IFK is an older term, but it is now

believed to represent a type of irritated seborrheic keratosis (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

IFK presents clinically as a circumscribed keratotic growth located on or near the eyelid margin. It may grow up in many patterns: nodular, papillomatous, verrucous (wartlike), cystic, or rarely as a cutaneous horn or is pigmented. After trauma, the epithelium of the lesion may become scab and lead to burning, itching, or bleeding. It occurs most often in white males, middle-aged or older, and may develop rapidly over months.

Diagnostics

Clinical appearance and/or histopathology.

Differential Diagnosis

Differential diagnosis includes ▶ melanoma, ▶ melanocytic nevus ▶ pigmented basal cell carcinoma ▶ cutaneous horn, ▶ verruca vulgaris, and granuloma.

Prophylaxis

Uncertain.

Therapy

Observation, but excision, when the lesion is small, is reasonable for cosmetic reasons.

Prognosis

Excellent prognosis. Recurrence is infrequent after adequate excision.

Epidemiology

Uncertain.

IOL

▶ Intraocular Lens

IOL Haptic

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The part of an ▶ intraocular lens (IOL) that connects the optic of the IOL with the intraocular tissue and thus maintains the desired IOL position.

Basic Characteristics

While Harold Ridley's first IOL from 1949 consisted of just an optical part, modern IOLs consist of an optic (the "lens" itself) and a haptic part that connects the optic to the surrounding

tissue. The haptic design depends from the desired location of the IOL within the eye. The first IOLs with haptics were anterior chamber IOLs with haptics designed to fit in the angle. Correspondingly, there were/are haptic types designed for fit in the pupil (Fyodoroff and Binkhorst), the iris (e.g., ▶ Artisan™/Verisyse™), the ciliary sulcus (e.g., Sulcoflex™, Visian™, and many others), and most importantly the capsular bag. IOLs for the capsular bag and the ciliary sulcus are typically equipped with loop- or plate-shaped haptics, while anterior chamber IOLs have Z-shaped haptics providing high rotational stability. Iris-fixated IOLs need claw haptics that grab a small fold of iris tissue. In single-piece IOLs, the material of the haptics is identical to the material of the IOL optic. Three-piece IOLs have haptics made from a material different from the optic (e.g., polypropylene or PMMA). So-called ▶ "accommodative" IOLs have haptics designed to transmit the action of the ciliary muscle to the IOL optic.

Iridocorneal Endothelial (ICE) Syndrome

- ▶ Chandler Syndrome

Iridocorneal Endothelial Syndrome (ICE)

- ▶ Corneal Dystrophies

Iridocorneo Endothelial Syndrome

Christoph Kniestedt[1] and Marc Töteberg-Harms[2]
[1]TAZZ Talacker Augenzentrum Zurich, Zürich, Switzerland
[2]Department of Ophthalmology, University Hospital Zurich, Zürich, Switzerland

Synonyms

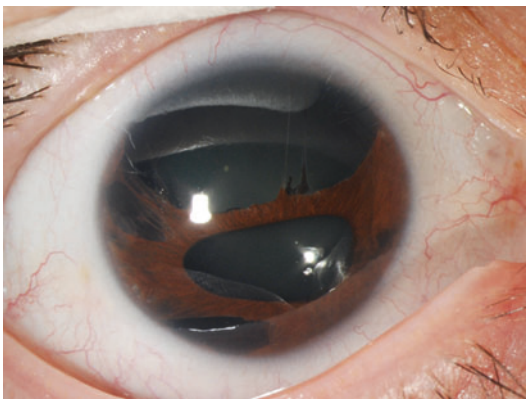
Chandler syndrome; Cogan-Reese syndrome; ICE syndrome; Iris nevus syndrome; Progressive iris atrophy; Proliferative endotheliopathy

Definition

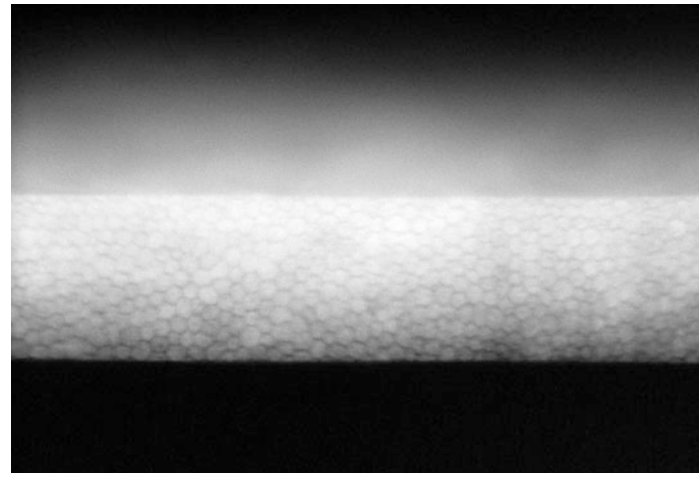
ICE syndrome is typically an unilateral condition with three clinical variants:

- (Fig. 1)
- Iris nevus syndrome (Cogan-Reese syndrome)
- Chandler syndrome

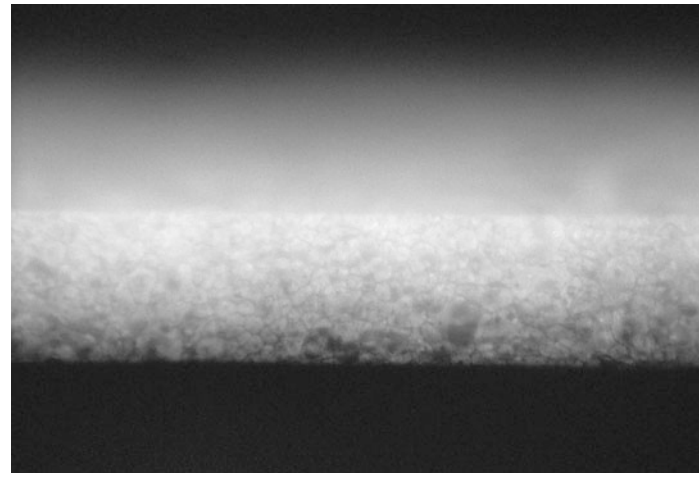
All three entities might be overlapping but have in common an abnormal corneal endothelium (Fig. 2 normal and Fig. 3 abnormal endothelium) that proliferates and migrates across the trabecular meshwork onto the surface of the iris.



Iridocorneo Endothelial Syndrome, Fig. 1 Presenting with progressive irisatrophy in ICE syndrome

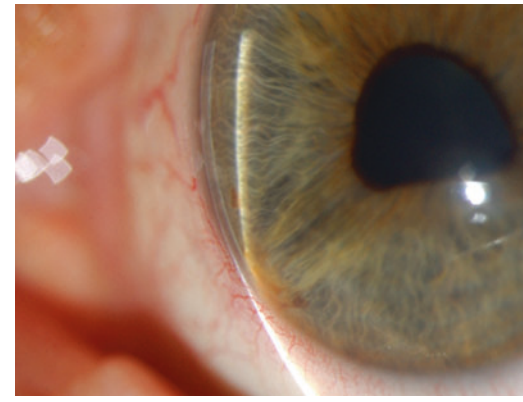


Iridocorneo Endothelial Syndrome, Fig. 2 Norman coneal endothelium with regular size and number of endothelial cells



Iridocorneo Endothelial Syndrome, Fig. 3 In ICE syndrome, corneal endothelial cells are abnormal in number, shape, and size

Contraction of abnormal endothelial tissue on the surface of the trabecular meshwork and iris root leads to anterior synechias (PAS) (Figs. 4 and 5), obstruction of the aqueous outflow and, finally, to secondary angle-closure glaucoma (Fig. 6: UBM of closed angle). Corneal endothelium insufficiency with decompensated corneal edema may be seen with or without glaucoma.



Iridocorneo Endothelial Syndrome, Fig. 4 Anterior synechias are often present

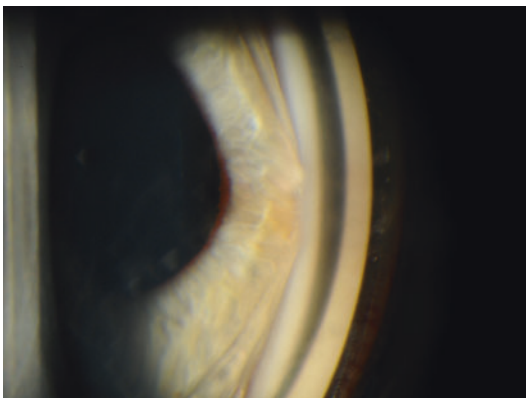
Etiology

Etiology is unknown. However, in some cases of ICE syndrome Epstein-Barr or herpes simplex

viruses are seropositive or might be found by polymerase chain reaction (PCR) in corneal probes. An underlying viral infectious disease is discussed.

Clinical Presentation

ICE syndrome is asymptomatic in its early stages. Later on, iris abnormalities, blurred vision caused by corneal edema, or pain could be found. ICE syndrome typical occurs in young to middle-aged adults (between 20 and 50 years of age). The disease is seen more often in females than in males. A family predisposition is extremely rare.



Iridocorneo Endothelial Syndrome, Fig. 5 Anterior synechias occluding parts of trabecular meshwork

No association with other ocular or systemic disease has been found.

Severe iris atrophy and heterochromia is characteristic for progressive iris atrophy. Also corectopia, ectropion uveae, iris stromal and pigment epithelial atrophy, and iris holes may be found. In Chandler syndrome, the corneal and angle findings are predominant with only minimal iris atrophy. Chandler syndrome is the most common entity with up to 50% of all ICE syndromes. Cogan-Reese syndrome represents with less iris atrophy but nodules or diffuse pigmented lesions on the anterior iris surface.

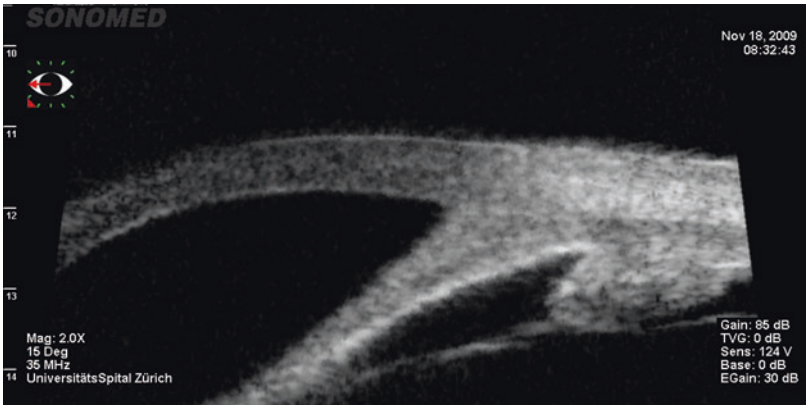
Glaucoma occurs in 50% of all ICE syndrome cases. The glaucoma seems to be more severe in Cogan-Reese syndrome and progressive iris atrophy than in Chandler syndrome. The three entities may overlap.

Diagnosis

Always consider ICE syndrome in cases of chronic and progressive unilateral pressure raise of young to middle-aged patients.

Specular microscopy is able to identify unilateral loss of endothelial cells and migration of endothelium on the trabecular meshwork or on the iris surface. Also consider endothelium cell count to identify an asymmetric cell loss in one eye (Hirst LW et al. 1980).

Iridocorneo Endothelial Syndrome, Fig. 6 Ultrasound biomicroscopy (UBM) reveals angle obstruction (secondary angle-closure)



Differential Diagnosis

- Fuchs' endothelial dystrophy (usually bilateral)
- Iris melanoma
- Axenfeld-Rieger syndrome (Dysgenetic chamber angle)
- Chronic uveitis (associated with endothelial precipitates)
- Posterior polymorphous dystrophy (usually bilateral)

Therapy

Treatment should be initialized when glaucoma or cornea edema occurs. The glaucoma associated with ICE syndrome is often difficult to treat. Possible therapeutical procedures include:

1. Antiglaucomatous medication (laser trabeculoplasty is ineffective)
2. Hypertonic salt solution to reduce corneal edema (e.g., 5% sodium chloride solution)
3. Corneal transplantation
4. Filtering surgery (tube shunts have a better survival rate compared to trabeculectomies (Stamper et al. 2009)) (Doe EA et al. 2001)

Prognosis

Secondary glaucoma in ICE syndromes is often difficult to treat and shows a poorer prognosis compared to other types of open angle and angle-closure glaucoma.

Epidemiology

The rate of glaucoma associated with ICE syndrome ranges between 46% and 82%.

Iridotomy

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Laser iridotomy

Definition

Surgical procedure in which a laser is used to create an artificial hole in the iris periphery. This opening in the iris equalizes the pressure between the front and the back of the iris and is mostly used for treatment of acute angle closure glaucoma.

Epidemiology

Due to the fact that acute angle closure glaucoma occurs in one of 1000 individuals, the incidence of iridotomies has similar numbers. Angle block glaucoma usually appears in individuals with narrow

angle. Most of the laser iridotomies are performed in individuals with 40 years of age or older.

History

The first iridotomies were performed in the late 1960s when ophthalmic laser systems were introduced. Argon laser iridotomies are being done since 1990.

Clinical Features

Selection of the correct laser is crucial for the outcome of the iridotomy. The Nd-YAG laser is used by most of the surgeons. This laser usually emits light with a wavelength of 1064 nm and operates in either pulsed or continuous mode. Usually 1–10 laser bursts with an energy of 4–6 mJ each are used for an iridotomy.

Tests

Slit lamp examination of the eye has to be performed prior to iridotomy. A hazy cornea is a contraindication for iridotomy. Patients also must receive miotic (usually pilocarpine) eye drops as well as topical anesthesia. Finally, an iridotomy treatment contact lens must be used.

Differential Diagnosis

Other intraocular pressure sinking methods are as follows:

- Iridectomy
- Trabeculectomy
- Sclerotomy
- Drainage implants

Etiology

Angle closure is a result of obstruction of the trabecular meshwork by the peripheral iris. This can be due to a narrow anterior chamber angle, a pupillary block mostly in hyperopic patients or mydriasis.

Treatment

After the patient has been brought in the correct position and has received topical anesthesia, an iridotomy lens is placed on the cornea using a coupling agent such as methylcellulose. Then, the surgeon has to localize an iris crypt, usually between 11 and 1 o'clock position, and focus the laser beam slightly anterior to the focus of the aiming beam. When focused properly, the laser energy is applied to the iris. The process is successful when the iris epithelium is perforated and a gush of fluid flows through the iridotomy from the posterior chamber into the anterior chamber.

Iris Coloboma

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Iris defect; Keyhole pupil

Definition

The term coloboma is derived from the Greek word *koloboma* and means a mutilated or curtailed structure. Accordingly an iris coloboma is a notch, gap, hole, or fissure in the iris of varying depth, giving the pupil an irregular shape. Iris coloboma can be due to congenital or traumatic causes (injury/surgical) and can appear complete or incomplete and typical or atypical and may extend to lens, ciliary body, zonula fibers, retina, choroid, or optic nerve. Main symptoms of an iris coloboma can be blurred vision and glare followed by decreased vision acuity.

Histology

Colobomata generally result from a failure of the fetal or choroidal fissure to close during the fifth to seventh week of fetal life, at the 7–14 mm stage. This is the period between the invagination of the optic vesicle and the closure of the fetal fissure. A complete iris coloboma is a full-thickness defect, involving both the pigment epithelium and the iris stroma. An incomplete iris coloboma is usually partial thickness, involving either the pigment epithelium or the iris stroma. The "typical" coloboma is in the inferonasal quadrant, caused by defective closure of the fetal fissure. Iris coloboma located anywhere other than the inferonasal quadrant is termed "atypical." The embryologic basis of this malformation is still unclear, although several theories have been suggested.

Immunohistochemistry

There are no data available in this topic.

Electron Microscopy

There are no data available in this topic.

Molecular Diagnostics

The incidence of isolated iris coloboma is 1:6000. Commonly inheritance is autosomal dominant, but in some singular cases, autosomal recessive heredities or spontaneous mutations have been described.

Differential Diagnosis

A lot of syndromes are associated with iris coloboma such as:

- Autosomal-dominant uveal coloboma
- Cat-eye syndrome
- Edwards' syndrome
- Patau's syndrome
- Linear nevus sebaceous syndrome

Iris retractor

Definition

Iris hooks are small surgical devices that are used in anterior chamber operations for grasping, manipulating, stretching, retracting, or stabilizing the iris. These instruments are long, thin titanium slats with an arcuate end. Their domains are complicated surgical cases with narrow pupils or the intraoperative management of complications of the iris, e.g., iris prolapse or lens-iris diaphragm retropulsion syndrome.

Epidemiology

Iris hooks are not commonly used in ophthalmic surgery. The decision whether to use iris hooks, which require insertion through additional limbal incisions, or to choose another strategy is dependent on surgical skill, preference, and the operative situation.

History

Pupils that do not dilate adequately medicamentally for cataract extraction must be dilated manual. In former times different types of surgical enlargement were described such as radial iridotomy, sector iridectomy, multiple sphincterotomies, and/or iris retraction with a spatula or a suture. In 1990 Fuller et al. announced new instruments for pupil retraction with the aim of reducing or eliminating the need to incise or suture it. This instrument was the translimbal iris retractor, progenitor of the modern iris hook. In 1992 Mackool et al. designed iris retractors that have small hooks connected to small blocks of titanium that can be used without assistance to retract the iris. In 1997 flexible iris hooks made from modified material and in 1999 a double-hook iris retractor were established with the aim to prevent the retractor from dropping out of corneal incision, especially in anterior vitrectomy. In 2009 Böhm et al. described a new, modern irrigating iris retractor for cataract surgery in eyes with small pupils. This device consists of about two standard side-port irrigating openings and a smooth, button-like iris hook in the front designed for bimanual cataract extraction in cases with small pupils.

Clinical Features

A small pupil presents a challenge for cataract surgeons. It is commonly seen in eyes with pseudoexfoliation syndrome, secondary to anterior uveitis with central posterior synechiae; in patients with advanced age, diabetes, or glaucoma with miotic therapy, after trauma or previous surgery; and in the intraoperative floppy iris syndrome (IFIS). Until today there is no general solution for the problems that small pupils bring to cataract surgery.

Etiology/Treatment

See "Clinical Features" section above.

Synonyms

Artificial iris implant; Iris prosthetic implants; Iris reconstructive implant

Definition

Implantable ophthalmic devices for the management of partial or total aniridia. Iris prosthesis devices are developed for the reconstitution of a deformed or imperfectly functioning iris. There are different existing types of iris prosthesis devices made from variable materials. Their domain depends on the degree and severity of the iris defect.

Epidemiology

There exist no data in this topic.

History

In 1956 Peter Choyce developed the first iris prosthetic implant, an anterior lens, in the UK. In the 1970s John Pearce implanted a matutional iris diaphragm. The first reported implantation of the black iris diaphragm intraocular lens was in 1994 by Reinhard and Sandmacher et al. In 1996 Rosenthal K. reported the small-incision technique of iris prosthetic implants. In 2004 Rosenthal K. and Rasch V. invented a series of aniridia and coloboma aperture rings to be implanted in an intact capsular bag, with or without zonular instability and with a separately implanted IOL.

Clinical Features

Iris defects occur in a variety of conditions, including congenital aniridia, coloboma, iridocorneal endothelial syndrome, Axenfeld-Rieger syndrome, trauma (surgical and non-surgical), uveitis, and idiopathic postoperative mydriasis. With iris and lens abnormalities, these conditions lead to cosmetic and optical defects. An intact iris diaphragm is essential as it reduces the optical aberrations arising from the crystalline lens and thereby increases the depth of focus. Thus, total aniridia is known to cause incapacitating glare and photophobia.

Test

Success of an iris prosthesis implant can be tested with the best and uncorrected vision acuity in different illumination shades and detailed slit-lamp examination.

Etiology

See "Clinical Features" section above.

Treatment

For the treatment of partial or total aniridia, there exist several different iris prosthesis implants and their use is dependent on the severity of the iris defect. For cases with partial defects, endocapsular ring prosthetic devices exist with multiple- or single-fin style. Other possibilities for the correction of combined aniridia and aphakia are single-piece (black) iris diaphragm intraocular lenses. Iris diaphragm rings or iris prosthetics with different colors and designs are for used in cases with or without capsular bag or zonular support. Furthermore there are differences in the size of the incision. Small-incision techniques need 3–5 mm incision and other implants or techniques need 10–12 mm incisions.

Iris, Characteristics

Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Definition

The anterior, visible part of the uveal tract composed of two layers – the iris pigment epithelium and the iris stroma.

Basic Characteristics

The iris, named after the Greek goddess of the rainbow, is responsible for eye color. The iris pigment epithelium is derived from the neuroectoderm, and the iris stroma is derived from the neural crest. The stroma contains nonpigmented and pigmented cells in a matrix of collagen fibrils and glycosaminoglycans. In lighter irides, the anterior melanocytes lack pigment and are transparent. In darker irides, the melanocytes are opacified by pigment with an increased number and size of melanin granules.

The thickest portion of the iris is the collarette which separates the peripheral ciliary zone from the papillary zone; the pupillary portion of the iris is thinner due to embryological resorption of the pupillary membrane and formation of the papillary aperture.

The sphincter and dilator muscles of the iris control the amount of light which enters the eye. Short ciliary nerves arising from the ciliary ganglion and containing postganglionic parasympathetic fibers innervate the sphincter muscle; postganglionic sympathetic fibers from superior cervical sympathetic ganglion travel with the long ciliary nerves and innervate the dilator muscle.

The major arterial circle in the ciliary body near the iris root supplies blood to the iris through branches which travel radially toward the collarette where they form an incomplete minor arterial circle from which branches radiate toward the pupil to supply the sphincter muscle and radiate toward the iris root along with the dilator muscle. Histologically unique, iris vessels are cloaked by a thick layer of collagen fibers and are visible in lighter irides.

The iris is affected in many ocular and systemic diseases, and assessment of pupillary function allows one to evaluate normal and abnormal functioning of the afferent and efferent pathways.

Definition

Iron deposit in the corneal epithelium at the leading edge of a pterygium.

Etiology

Iron lines are often believed to form due to abnormal pooling of tear related to surface irregularities in long-standing pterygium (Loh et al. 2009).

Clinical Presentation

Pigmented line at the anterior edge of the pterygium, often best seen with red-free or cobalt blue illumination.

Diagnosis

Stocker line can be diagnosed based on the presence of pterygium and clinical examination.

Differential Diagnosis

Stoker line can be differentiated from other iron deposits in the cornea including Hudson-Stähli line seen in healthy aging cornea, Ferry line anterior to filtering bleb, Fleischer ring in keratoconus, and iron lines in keratorefractive procedures.

Definition

Iron deposit in the corneal epithelium

Etiology

Iron lines are often believed to form due to abnormal pooling of tear related to surface irregularities. But alternative hypotheses including basal-cell-migration theory, tear desiccation hypothesis, senescent basal-cell hypothesis, and lactoferrin/transferrin receptor hypothesis exist (Loh et al. 2009).

Occurrence

The Hudson-Stähli line is formed at the lower third of otherwise healthy corneas and its occurrence increases with age. Fleischer ring is pigmented circumferential line at the base of the cornea in keratoconus. Ferry line is formed anterior to a filtering bleb. Stocker line is iron deposit

at the leading edge of a pterygium. Iron lines have also been associated with corneal trauma, Salzmann's nodular degeneration, and keratorefractive procedures.

Classification

Common iron lines are Hudson-Stähli line, Fleischer ring, Ferry line, and Stocker line.

[2]Cornea and External Diseases, Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Rust ring; Siderosis

Definition

Iron is a magnetic metal that exists in a wide range of oxidation states, although +2 and +3 are most common. Fresh iron surfaces are silver-gray but oxidize in air to yield hydrated iron oxides, known as "rust." Iron oxides occupy more volume than iron metal. Iron plays an important role in the human body including forming complexes with oxygen to produce hemoglobin and myoglobin. It is also the active site of many important enzymes involved in oxidation and reduction reactions. Iron is a frequent cause of foreign bodies embedded within the cornea.

Etiology

Iron-containing foreign bodies (e.g., BB gun pellets, gunshot pellets, household items, nails, bolts, bridges, machinery, etc.) can embed themselves into the corneal substrate by numerous mechanisms. Frequently the edges of these foreign bodies are sharp enabling them to penetrate the cornea, and they may be quite hot as well, allowing them to melt their way into the cornea.

Clinical Presentation

Patients usually present with sudden eye pain, tearing, and redness, coinciding with a suggestive history such as doing metal-on-metal work or being in an environment conducive to flying metal particles. Blurred vision may be present.

Diagnosis

Physicians should obtain a thorough history, focusing on metal-on-metal work with the possibility of metal striking the eye at a high velocity. The metal can often be seen with direct illumination. Slit-lamp examination with fluorescein dye can further characterize the depth and extent of injury. Iron in its neutral form is relatively insoluble in the corneal layers. The metal's surface oxidizes and diffuses into the stroma, causing an immune cellular infiltrate. The combination of oxidized iron and cellular infiltrate clinically

correlate to a rust ring. These rust rings are usually seen at the level of the superficial stroma and can begin to form after just a few hours. Iron has a predilection for the corneal stroma and corneal endothelial cells. The wound site may be cultured if it appears infected. During exam, careful attention should be paid to assure that the metal is confined to the cornea and that there is no intraocular metallic penetration. Imaging modalities such as CT (1 mm sections through orbits) and ultrasound may aid in the diagnosis. MRI is contraindicated in the presence of a metallic foreign body such as iron.

Differential Diagnosis

Differential diagnosis includes non-iron-containing foreign bodies and other iron deposits such the Hudson-Stahli line (interpalpebral fissure), Fleischer ring (keratoconus), Stocker line (pterygium), and Ferry line (filtering blebs).

Prophylaxis

Avoidance of activities conducive to flying small pieces of metal or the use of protective eyewear if those activities are unavoidable.

Therapy

Corneal foreign bodies and rust rings can be removed at the slit lamp under topical anesthesia (e.g., proparacaine) with a cotton-tipped applicator, disposable small-gauge needle, and/or fine forceps. Multiple superficial foreign bodies may be more readily removed by irrigation. Battery-powered burrs with a sterile tip may also be used. The goal of these procedures is to remove the foreign body and rust ring with minimal tissue disruption to minimize complications and scar formation. Not all rust needs to be removed, particularly if removal results in scar tissue affecting the visual axis. It is often easier to remove the foreign body initially and the rust ring after several days. Treatment with topical antibiotics is wise after removal of these foreign bodies. If the clinical examination is suggestive of intraocular foreign body, appropriate surgical referral often with a retina specialist should be instituted immediately.

Prognosis

If left embedded in the cornea, iron-containing corneal foreign bodies may cause continued inflammation and delayed healing. When intraocular, iron may cause siderosis that may manifest as anisocoria, iris heterochromia, corneal endothelial and epithelial deposits, anterior subcapsular cataracts, lens dislocation, retinal degeneration, and optic atrophy.

Epidemiology

This is a common condition, but the exact incidence is unknown. In one prospective study on superficial corneal bodies, 92% of patients were male with a mean age of 35 years. 32.7% of patients had positive cultures. The most common microorganisms isolated were *Streptococcus* and *Staphylococcus* (Fig. 1).

Juvenile Epithelial Dystrophy (Meesmann Dystrophy)

Parisa Emami-Naeini and Nadeem Fatteh
Department of Ophthalmology, Kresge Eye Institute, Wayne State University, Detroit, MI, USA

Synonyms

Meesmann epithelial corneal dystrophy (MECD); Stocker-Holt

Definition

Bilateral corneal dystrophy involving corneal epithelium.

Etiology

MECD is a genetic disorder with an autosomal dominant pattern of inheritance. Mutations in the genes coding cornea-specific keratins, K3 (chromosome 12q13) and K12 (chromosome 17q12), have been linked to disease pathology. These two cytokeratins are mainly found in corneal epithelium, and mutations will lead to epithelial fragility that spares limbal cornea (expressing keratins 5 and 14).

Presentation

MECD presents with bilateral, symmetric intraepithelial cysts involving central visual axis and mid-periphery of the cornea that are visible only with slit lamp biomicroscopy (especially on retroillumination). Although cysts appear in the first decade of life, most patients remain asymptomatic until middle age. Symptoms are usually mild and include recurrent irritation and decrease in visual acuity.

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

Diagnostics

In MECD, microcysts are present throughout the corneal epithelium. These cysts contain degenerated epithelial cells and cellular debris that are periodic acid-Schiff (PAS) positive. Other characteristic findings include presence of electron-dense filamentary and granular material, so-called peculiar substance, in the epithelial cells and vacuolated, homogenous substance in the epithelial cysts (most commonly) and epithelial cells. There is no change in Bowman's layer; however, nonspecific thickening of epithelial basement membrane is usually present.

Differential Diagnosis

Lisch epithelial corneal dystrophy, epithelial basement membrane dystrophy, Reis-Buckler's.

Prophylaxis

Unclear

Treatment

Symptoms are generally mild and topical lubrication will suffice in most cases. In more severe disease, bandage contact lens and superficial keratectomy can be beneficial.

Juvenile Glaucoma

Oliver Schwenn
Bürgerhospital, Frankfurt am Main, Germany

Synonyms

Juvenile glaucoma is called sometimes presenile glaucoma.

Definition

Juvenile glaucoma is defined by a primary open-angle glaucoma appearing between the 10th and 35th year of life.

Etiology

The exact mechanism remains unknown, but a decreased aqueous outflow is observed. In most cases juvenile glaucoma is transmitted in an autosomal dominant fashion, involving the MYOC gene on chromosome 1q21-q31. At the moment more than 70 mutations in this gene are identified. More than one gene is likely to be involved.

Clinical Presentation

The disease is asymptomatic until an advanced visual field loss appears. Some patients have blurred vision and sensitivity to light related to very high intraocular pressure with corneal edema.

Diagnosis

In contrary to normal pressure glaucoma, juvenile glaucoma presents with an elevated IOP $\geq$21 mmHg. Severe intraocular pressure increases are quite often. The optic nerve demonstrates typical glaucomatous changes with diffuse or more rarely focal reduction of neuroretinal rim resulting in progressive glaucomatous visual field defects.

Nerve fiber layer demonstrates a typical diffuse defect. Gonioscopy is characterized by wide open anterior chamber angle. Typical signs of dysgenetic anterior chamber angle such as anterior insertion of the iris and poorly differentiated structures are observed in some cases.

Differential Diagnosis

Close angle, pseudoexfoliation, pigmentary, uveitic, posttraumatic glaucoma and glaucoma associated with intraocular hemorrhage, corticosteroid treatment, and increased episcleral venous pressure.

Therapy

The treatment is primarily medical with topical medications that reduce the aqueous humor production or facilitating its outflow. The inefficient reduction of the IOP often requires incisional surgical procedures used in adult-onset open-angle glaucoma with the addition of goniotomy, any trabecular bypass, or, if ineffective, a glaucoma drainage device.

Prognosis

Juvenile glaucoma with an insufficient treatment can lead to blindness. Usually glaucoma screening is performed after the 40th year of life; therefore, juvenile glaucoma develops undetected at severe stage of disease in most of the cases.

Epidemiology

Valid data are not available. Prevalence of juvenile glaucoma might be underestimated. Nevertheless, juvenile glaucoma represents a low percentage of all glaucoma diseases.

K

Kaposi Sarcoma

Michael T. Yen[1] and Michelle Butler[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Glaucoma Associates of Texas, Dallas, TX, USA

Definition

Kaposi sarcoma is a malignant spindle-cell tumor that most commonly affects the skin, but can also involve mucous membranes, internal organs, lymph nodes, and ocular structures (Brun and Jakobiec 1997).

Background

Hungarian dermatologist Moritz Kaposi first described "idiopathic multiple-pigment sarcomas" of the skin in 1872, later known as Kaposi sarcoma (Brun and Jakobiec 1997). There are four forms of the disease. The "classic form" is seen in elderly Eastern European or Mediterranean men of Jewish ancestry and follows a more benign, indolent course. The "endemic form" is more aggressive with increased visceral involvement and seen predominately in equatorial Africa. The two remaining forms of the disease are immunocompromised and HIV/AIDS related. The immunocompromised form is rare and can follow organ transplantation or immunosuppression. The AIDS-associated form is the most common presentation of Kaposi sarcoma in the USA. Further, Kaposi sarcoma is the most common malignancy of HIV/AIDS patients. Since the AIDS epidemic, there has been a rise in the incidence of Kaposi sarcoma with ocular involvement as well as multiple reports of conjunctival disease as the initial manifestation of HIV (Jeng et al. 2007; Verma et al. 2008).

Etiology/Pathophysiology

Though there are four differing forms of Kaposi sarcoma, all involve some degree of immune system dysregulation (Verma et al. 2008). There is a complex interaction between the immune system, the environment, and infections such as HIV and human herpesvirus 8 (HHV-8)/Kaposi-sarcoma-associated herpesvirus (KSHV) that contribute to the development of this disease. The result of these interactions is the proliferation of spindle cells around abnormal vascular spaces. The cell of origin is controversial; candidates include lymphatic, endothelial, smooth muscle, or neural cells. Patients may have single or multiple lesions. Examination of viral HHV-8 DNA from multiple tumor sites in one patient reveals that each tumor arises independently confirming that this is a multifocal disease, not metastatic. There is growing evidence linking HHV-8 and Kaposi sarcoma. HHV-8

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

DNA has been isolated from all forms of this disease. One study found anti-HHV-8 antibodies present in 88% of the AIDS-associated Kaposi sarcoma patients, in 30% of the HIV-positive sarcoma-free patients, and only in 1–4% of a control HIV-negative group. There are very few ocular-specific Kaposi sarcoma studies exploring this relationship (Jeng et al. 2007; Biswas and Sudharshan 2008). The infection route of HHV-8 is unclear, though circumstantial evidence favors sexual transmission. Coinfection with HIV and HHV-8 is common, and it has been observed that these individuals tend to develop Kaposi sarcoma within 10 years of seroconversion. The pathogenesis of how the HHV-8 infection leads to the development of Kaposi sarcoma is under investigation. HHV-8 has been implicated in other diseases, such as lymphoma and Castleman, and is known to induce the deregulation of oncogenes and oncosuppressor genes. In conjunction with an already weakened immune surveillance system associated with HIV/AIDS, this can lead to cell proliferation.

Epidemiology

Classic Kaposi sarcoma is most common in Sicily in 50–70-year-olds with 30.1 cases per million in men and 7.7 cases per million in women. In Africa, endemic Kaposi sarcoma has a reported prevalence of 37.7 cases per 100,000 in men and 20.5 cases per 100,000 in women. In the USA, Kaposi sarcoma is the most frequent tumor in HIV/AIDS patients with a prevalence of 20–30%. There is a higher risk of Kaposi sarcoma if HIV was contracted though sexual transmission, likely attributed to the increased risk of contracting HHV-8. Homosexual HIV-positive men are 20 times more likely to develop Kaposi sarcoma than those who contracted HIV from blood transfusions (Brun and Jakobiec 1997). The incidence of Kaposi sarcoma is declining, presumably due to the immune reconstitution achieved with highly active antiretroviral therapy (HAART) (Verma et al. 2008). The International Collaboration on HIV and Cancer reported a decline from 15.2 cases per 1000 person-years in 1992–1996 to 4.9 cases per 1000 person-years in 1997–1999. In the 1980s, Kaposi sarcoma was the presenting manifestation of AIDS in 10–15% of HIV-positive homosexual men and in 1–2% of other risk-factor groups. The incidence of Kaposi sarcoma as the presenting manifestation of AIDS has decreased from 2.6 per 100 persons in the early 1990s to 0.75 per 100 person-years in 1997. Prior to the AIDS epidemic, ocular involvement was rare, with fewer than 30 case reports. Since 1982 there was a dramatic increase in ocular involvement. In AIDS patients with Kaposi sarcoma, up to 20% have some form of ocular involvement, with conjunctival lesions accounting for 5–10% (Jeng et al. 2007).

Clinical Presentation

Kaposi sarcoma most commonly presents on the skin. Initially the lesions are dark bluish purple, flat, and nonpalpable or plaque-like with a normal-appearing surface (Brun and Jakobiec 1997). As the disease progresses, the lesions become round or oval and more nodular and may reach up to 3 cm. Usually these lesions are asymptomatic. AIDS-associated Kaposi sarcoma is more aggressive than the classic form with earlier lymph node and visceral involvement. The extent of the cutaneous disease does not correlate to the degree of visceral involvement. Ocular disease has been reported to involve the eyelids; the bulbar, tarsal, and forniceal conjunctivas; the plica semilunaris; the caruncle; the lacrimal sac; and rarely the orbit and lacrimal gland (Jeng et al. 2007, Biswas and Sudharshan 2008). Conjunctival Kaposi sarcoma is most commonly seen in the inferior fornix, then the bulbar conjunctiva, followed by the superior fornix. These lesions are bright red, slightly elevated, and mobile, easily mistaken for subconjunctival hemorrhage. They may change shape over time. Eyelid lesions are similar to other skin lesions, bluish purple, flat, or raised resembling ecchymosis. They may eventually interfere with eyelid function, induce eyelid malposition, and infrequently lead to pain and vision loss (Verma et al. 2008).

Diagnostics

Once Kaposi sarcoma is suspected, a thorough examination of the patient's skin and lymph nodes should be performed as well as blood testing for HIV. Diagnosis is confirmed with an incisional biopsy. Histology reveals a complex arrangement of capillary channels and vascular spaces without endothelium or "slits" often surrounded by malignant spindle cells.

Staging

The standard TMN staging system does not work well with Kaposi sarcoma, so an alternate staging system has been developed to stratify patients into low- and high-risk groups based on immune status, extent of tumor involvement, and presence of systemic disease (Verma et al. 2008). Low-risk patients have tumors confined to the skin, lymph nodes, or oral palate (non-nodular); a CD4 count greater than 150/mm^3; no history of opportunistic infections; thrush; unexplained fevers; more than 10% voluntary weight loss; or diarrhea persisting over 2 weeks. If there is any tumor-associated edema or ulceration, extensive involvement of the oral mucosa, gastrointestinal, or lesions in other viscera, then those patients are considered high risk. Further, if the CD4 count is less than 150/mm^3 and if any of the previous systemic signs or other HIV-related illnesses such as lymphoma or neurologic disease is present, they are considered high risk.

Differential Diagnosis

Subconjunctival hemorrhage
Conjunctival inflammation
Melanosis
Malignant melanoma
Squamous cell carcinoma
Pyogenic granuloma
Lymphangioma
Cavernous hemangioma
Nodular scleritis
Lymphoma

Prophylaxis

Primary prevention of exposure to HIV and HHV-8 includes sexual abstinence, condom use, and avoidance of IV drug use. Secondary prevention of Kaposi sarcoma in HIV-positive patients relies on maintaining immunocompetence through HAART.

Treatment

The restoration of the immune system with HAART can induce the resolution of Kaposi sarcoma even without disease-specific therapy (Verma et al. 2008). However, there is no evidence that any therapy is curative or that a complete response necessarily translates to prolonged disease-free intervals. Therefore, the goal in treatment is palliation when the disease is disfiguring, painful, or impairing function. Most ocular and periorbital lesions follow an indolent course, thus palliative treatment is not always necessary. Indications for treatment include loss of normal eyelid function, discomfort, or cosmesis. The treatment depends on the size and location of the tumor. Treatment options include surgical excision, local radiation, cryotherapy, subconjunctival interferon alpha-2a, and systemic chemotherapy (bleomycin, doxorubicin, and vinblastine as single agents or in combination have been reported). However, local recurrence occurs frequently with any form of treatment.

Prognosis

Prognosis depends on the stage of the Kaposi sarcoma and the status of the patient's immune system. The degree of immune system impairment seems to be the most important factor in survival.

Kayser-Fleischer Ring

Aazim A. Siddiqui[1] and Allen O. Eghrari[2,3]
[1]Imperial College London, School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Definition

Kayser-Fleischer ring (KF ring) is an orange, brown, or green-brown peripheral corneal discoloration secondary to gradual copper accumulation at the level of the Descemet membrane, adjacent to the limbus. It is significant for its presentation in patients with Wilson disease. It is clinically benign but may serve as a valuable screening and diagnostic aid (Brewer 2001; Copeland and Afshari 2013).

Etiology

The KF ring in Wilson disease is a result of systemic copper excess and is associated with autosomal recessive mutations in the *ATP7B* gene. This gene codes for an ATPase in the liver that transports copper into bile for excretion and incorporates it into ceruloplasmin, to be released into the bloodstream. In Wilson disease, copper accumulates in the liver and is released into the bloodstream in a free form not bound to ceruloplasmin. This free form is then deposited in the basal ganglia, kidneys, and eyes. This systemic accumulation manifests as tremor and rigidity in the central nervous system, renal tubular defects, and, in the eyes, KF ring and "sunflower" cataract formation.

Patients homozygous for the *H1069Q* mutation in *ATP7B* are more likely to demonstrate the KF ring; patients with Wilson disease due to this mutation tend to be diagnosed at an older mean age than patients heterozygous or negative for *H1069Q*.

Other etiologies for KF ring formation include primary biliary cirrhosis, progressive intrahepatic cholestasis of childhood, and chronic active hepatitis. Corneal chalcosis (corneal copper deposition) may also occur due to intraocular foreign body, chronic copper poisoning, and multiple myeloma (Smolin and Thoft 2005; Jankovic and Tolosa 2007; Suvarna 2008).

Occurrence

In the cornea, copper accumulation begins peripherally at Schwalbe's line and moves centrally; therefore, gonioscopy may be helpful to locate the ring in its early stage due to its primary peripheral location. The KF ring appears initially in superior and inferior corneal arcs which eventually coalesce to form a 1–3 mm wide, 360°, green-brown zone of copper granule deposits at the level of the Descemet membrane. It is generally bilateral but can present unilaterally if circulation to one eye is affected.

The KF ring is the most characteristic ocular feature in 95% of Wilson disease patients with neurological symptoms. These rings may be present in 50–60% of non-neurologically symptomatic disease and 10% of asymptomatic siblings. Additionally, "sunflower" cataracts may be present in 1 in 5 patients with neurologically symptomatic Wilson disease due to copper deposition in the lens capsule.

In addition, the KF ring may present as the earliest detectable manifestation of Wilson

disease, allowing this sign to serve as a useful screening and diagnostic tool. Examination for the KF ring is part of a screening test in first-degree relatives of affected individuals. In a patient with neurologic and/or psychiatric symptoms of Wilson disease, the presence of the KF ring provides diagnostic certainty. In presymptomatic patients, the KF ring may be present in 30–40% of cases, providing diagnostic certainty. In a patient with unexplained central nervous system disease, psychiatric disorder, deranged liver function tests, chronic active hepatitis, liver cirrhosis, rickets, renal tubular acidosis, or Coombs-negative hemolytic anemia, particularly with a family history of disease, the presence of a KF ring necessitates diagnostic workup (Brewer 2001; Smolin and Thoft 2005; Jankovic and Tolosa 2007; Suvarna 2008; Copeland and Afshari 2013).

Classification

Once diagnosed and identified, the size and intensity of a KF ring may serve as an indicator to classify responsiveness to treatment of Wilson disease. The magnitude of the ring may regress with administration of chelating therapy or following liver transplantation. The KF ring may serve as a monitoring tool for treatment compliance, though not as a prognostic marker (Brewer 2001; Smolin and Thoft 2005; Jankovic and Tolosa 2007; Suvarna 2008; Copeland and Afshari 2013).

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Chronic progressive external ophthalmoplegia plus disease; Kearns-Sayre syndrome (KSS); Oculocraniosomatic disorder; Oculocraniosomatic neuromuscular disorder with ragged red fibers

Definition

It is a mitochondrial neuromuscular disorder affecting multiple parts of the body, classically the eyes and heart.

Etiology

KSS is the result of deletions in mitochondrial DNA. These mutations occur spontaneously in the majority of cases but mitochondrial, autosomal dominant, and autosomal recessive inheritance patterns have been documented. KSS is considered a form of chronic progressive external ophthalmoplegia (CPEO) with additional features. Mitochondrial DNA deletions are larger in KSS than in CPEO without additional features.

Clinical Presentation

The classic triad of KSS includes chronic progressive external ophthalmoplegia (CPEO), pigmentary retinopathy, and cardiac conduction defects. CPEO is a spectrum of clinical findings that include bilateral, slowly progressive ptosis and ophthalmoplegia of the extraocular muscles. Patients can be male or female and symptoms generally appear before the age of 20. Ptosis is the most common initial symptom; however cases have been reported with no ptosis. The condition is generally painless, pupils are spared, and patients rarely develop diplopia. The ophthalmoplegia includes vertical and horizontal gaze with no response to oculocephalic maneuvers; however, down gaze can be partially spared. Patients often adjust to their symptoms with a chin-up head tilt and by using the frontalis muscle to help elevate the eyelids.

Pigmentary retinopathy changes are often referred to as "salt and pepper fundus" and tend to be in the posterior pole. Cardiac problems can occur at any time but ptosis and ophthalmoplegia usually precede them. Complete heart block and sudden cardiac death can occur. A variety of other symptoms have been less commonly associated with KSS, including neurologic abnormalities (i.e., ataxia, hearing loss), somatic muscle weakness, endocrine abnormalities (i.e., hypoparathyroidism, gonadal dysfunction, diabetes mellitus), and other cardiac and ocular abnormalities.

Diagnosis

The diagnosis of KSS is made based on clinical findings. Attention should be focused on ruling out other underlying conditions. There is no specific laboratory test for KSS although some laboratory tests may aid in diagnosis including elevated CSF protein, elevated pyruvic acid, elevated creatine phosphokinase, elevated aldolase, cytochrome C oxidase deficiency, and elevated lactate in CSF and serum. Low magnesium and parathyroid hormone levels have also been reported. Limb and extraocular muscle biopsies may show ragged red fibers on light microscopy with Gomori trichrome stain. Mitochondrial testing can also be performed.

Differential Diagnosis

The differential diagnosis includes neuromuscular junction disease (e.g., myasthenia gravis, botulism), Eaton-Lambert syndrome, inflammatory disease (e.g., thyroid eye disease, idiopathic orbital myositis), infective myositis, neoplasm, infiltrative myopathy (e.g., sarcoidosis, amyloidosis), neurologic disorders (e.g., progressive supranuclear palsy), metabolic disease (e.g., primary cytochrome C oxidase deficiency, carnitine deficiency), Friedreich ataxia, Pierre-Marie disease, and spinocerebellar ataxia.

Prophylaxis

No prophylactic treatment is available. Genetic counseling may be offered.

Therapy

Regular evaluation by a cardiologist is important, and pacemaker implantation may be required in patients with KSS. No medical therapy has been proven to benefit patients with KSS although various treatments (coenzyme Q10, riboflavin, ketogenic diets) have anecdotal success. Steroids should be avoided, if possible as their use has been associated with fatal hyperglycemic metabolic acidosis with respiratory failure in patients with KSS. Supportive therapies for ocular manifestations include adhesive tape or lid crutches for ptosis, lubricants, and eye patch or goggles to prevent exposure keratitis. Possible surgical procedures include frontalis sling for ptosis, strabismus surgery for head tilt, and punctum occlusion for exposure keratitis.

Prognosis

KSS is a progressive disease with no known cure. Potential complications include sudden death from heart block, exposure keratitis, corneal ulceration, and visual loss.

Epidemiology

The prevalence of KSS is approximately 1–3 per 100,000 individuals. Symptom onset is usually before 20 years of age and may occur in infancy. Males and females are equally affected. There is no predilection for race.

Keloids: Corneal and Congenital

Khaled Tuwairqi
Wilmer Eye Institute, Baltimore, MD, USA
Department of Ophthalmology, University of Utah, Salt Lake City, UT, USA

Synonyms

Corneal keloid

Definition

Overgrowth of the fibrous tissue beyond the normal limits that clinically appear as white raised gray-white mass involving the cornea. It often occurs secondary to traumatic or inflammatory reaction. However, it may also occur spontaneously such as in congenital keloids.

On histologic examination, keloid can be differentiated into two different stages. The early inflammatory stage is characterized by increase in vascularity and growth of fibroblasts that leads to the formation of collagen type III fibrils. The later fibrous stage is characterized by reduction of vascularity and fibroblasts with the formation of the densely packed collagen type I.

Character range of chapter: about 1 sentence to a quarter page, 500 characters the most

Few genetic syndromes have been associated with corneal keloid. These include Lowe syndrome and Rubinstein-Taybi syndrome. Furthermore, it has been noted that keloid tends to occur most commonly at the first two decades of life.

Management of corneal keloid can be challenging as it tends to recur after surgical correction. Current treatment modalities include superficial keratectomy, lamellar keratoplasty, or penetrating keratoplasty.

Keratinocytes: Overview

Rabia Karani
Johns Hopkins School of Medicine, John Hopkins University, Baltimore, MD, USA

Synonyms

Basal keratinocytes; Corneocytes; Cornified keratinocytes; Granular keratinocytes; Horn cells; Spinous keratinocytes; Squamous cells (James et al. 2011; Adkinson et al. 2014)

Definition

Keratinocytes are the principal cells of the epidermis, derived from the ectoderm, whose main function is to produce keratin and provide a physical and immunological barrier against the outside environment (James et al. 2011).

Structure

Keratinocytes are the most abundant cell in the epidermis (90%) with a life cycle of approximately 28 days. They are continually renewing cells that can be divided into four types based on the epidermal layer in which they exist: basal, spinous, granular, and cornified. Basal keratinocytes are attached to the basement membrane by hemidesmosomes. A change in keratin composition of these cells precedes their differentiation into spinous keratinocytes, so named for their unique keratin cytoskeleton. The expression of lamellar granules containing the precursors of lipids present in the stratum corneum precedes conversion to granular cells. Granular

keratinocytes precede the stage before terminal differentiation and release their lipid contents to form the cornified lipid envelope (CLE) layer. Cornified keratinocytes are terminally differentiated cells that form the stratum corneum (Adkinson et al. 2014). This layer of cells lends the skin of terrestrial mammals its characteristic appearance (Bolognia et al. 2012).

The process described above is called keratinization, a differentiation process that terminates in cells known as cornified keratinocytes, corneocytes, or horn cells. Differentiation is triggered by a Ca^{2+} gradient that progresses through the layers of the epidermis, increasing steadily from the basal layer to the corneal layer. Keratinocyte stem cell differentiation culminates in cells that have replaced their plasma membrane with the cornified cell envelope (CE), a plethora of cross-linked proteins that lend the epidermis its characteristic appearance. These proteins include desmosomes, filaggrin, repetin, elafin, periplakin, envoplakin, cystatin, loricrin, small proline-rich proteins, late envelope proteins, and involucrin, among others (Bolognia et al. 2012). The cornified cell envelope is coated by lipids, which form the cornified lipid envelope (CLE). Terminally differentiated keratinocytes are flattened cells that have assembled the CE/CLE complex, have a keratin cytoskeleton, and have lost all of their organelles and nucleus. Though corneocytes are dead cells filled with protein, they play an active role in maintaining skin morphology and in carrying out its characteristic functions (Bolognia et al. 2012).

The main function of keratinocytes is to produce keratin, which is primarily a structural protein. There are 54 genes that code for keratin that is divided into two families: Type 1 (acidic) and Type 2 (basic). Different epithelial tissues express a specific keratin profile in a manner specific to tissue function. Type 1 and Type 2 keratins form coiled coil dimers that are the building blocks of the α-helical intermediate filament. Keratin coiled coil dimers are assembled into a complex pattern of parallel and antiparallel protofilaments and protofibrils. Keratohyalin is a proteinaceous substance that contributes to the soft, flexible nature of keratin. Hard keratin in the skin and nails lacks keratohyalin, and these tissues express keratins that contain large amount of cysteine that allows for the formation of cross-links to strengthen the cytoskeleton (James et al. 2011). Desmosomes provide an attachment site for the binding of the keratin cytoskeleton of keratinocytes and are also the key proteins involved in cell-to-cell adhesion (Calonje et al. 2012).

Function

Keratinocytes are critical in maintaining the barrier functions of the epidermis, including protection against pathogens and water loss. In the corneal layer of the epidermis, the formation of glutamyl-lysyl isopeptide bonds between CE proteins of the corneocyte by transglutaminase creates a watertight barrier. Desmosomal proteins are also cross-linked in this layer, adding further strength to the skin barrier. In the granular layer, keratin proteins, which represent most of the mass of the epidermis, are responsible for maintaining the epidermal barrier. Filaggrin proteins are a major component of keratohyalin and allow for the aggregation of keratin filaments (Calonje et al. 2012).

Along with serving a structural role in the epidermis, keratin is also involved in signaling. Keratin signaling is involved in both differentiation of keratinocytes and in basic cell functions such as apoptosis, metabolic activity, cell cycle progression, and the stress response. Keratinocytes coordinate this signaling activity by binding to signaling proteins in the cell (Bolognia et al. 2012).

Clinical Relevance

Keratinocytes, as part of the epidermis, are the first barrier in the body's defense against pathogens. They are essential for immune function, and if there is physical, chemical, or radiant energy insult to the skin, pathogens can invade the organism. Keratinocytes play a critical role in

immune function of the skin by participating in both the innate (constitutive and inducible) and adaptive immune response. Tight junctions between the cells form an impenetrable surface, and shedding of corneocytes allows for the shedding of superficial pathogens on the skin surface. The dryness of the cornified keratinocytes provides a relatively unfavorable environment for pathogenic growth. Keratinocytes also contain IgM antibodies and antimicrobial proteins such as defensins. The inducible innate response is initiated by the release of cytokines such as IL-1α and TNF-α that mediate a signaling cascade that culminates in acute inflammation. Keratinocytes are also amateur antigen-presenting cells that express major histocompatibility complex (MHC) Class II and integrin proteins and are key players in the induction of an adaptive immune response, particularly to allergens (James et al. 2011). Keratinocytes also release cytokines that attract dendritic cells and that help initiate a Th2 immune response (Adkinson et al. 2014).

Mutations in the genes that encode CE proteins, filaggrins/keratohyalins, and especially keratins can lead to skin disease. A few key examples are listed. Mutations in the loricrin and filaggrin genes can cause palmoplantar keratoderma (PPK) and ichthyosis vulgaris (Bolognia et al. 2012). Mutations in the genes that encode keratins 5 and 14 can lead to epidermolysis bullosa simplex. Mutations in the genes that encode keratins 1 and 10 can contribute to epidermolytic hyperkeratosis (James et al. 2011). Deletion of the entire keratin gene complex in mice was shown to be lethal (Bolognia et al. 2012). Additionally, defective keratinization can lead to skin abnormalities such as parakeratosis (retained nuclei), as corps ronds (round, clear to pink, abnormal cells), or as grains (elongated, basophilic, abnormal cells) (James et al. 2011).

Keratinoid (Spheroidal) Degeneration

Jay J. Meyer
Duke University Eye Center, Durham, NC, USA

Synonyms

Keratinoid corneal degeneration was a name originally proposed to describe the histologic appearance of abnormal proteins resembling prekeratin in corneal specimens from patients with globular deposits in the cornea (Garner 1970). Later reports disputed the evidence that this represented a keratinoid change and this entity fits the classification of the clinical term "spheroidal degeneration" (Fraunfelder and Hanna 1973). Several other reported clinical entities describe globular deposits of the cornea that may represent the same condition, with geographic variations or subtypes:

Band-shaped keratopathy; Band-shaped nodular dystrophy of the cornea; Bietti corneal degeneration; Chronic actinic keratopathy; Climatic droplet keratopathy; Colloid degeneration of the cornea; Degeneratio hyaloidea grannuliformis corneae; Elastoid degeneration; Elastotic degeneration; Eskimo corneal degeneration; Fisherman's keratopathy; Hyaline corneal degeneration; Keratoid corneal degeneration; Labrador keratopathy; Nodular corneal dystrophy in tropical arid countries; Nodular hyaline; Proteinaceous corneal degeneration; Sphaerularis elaiodes; Spheroid degeneration; Spheroidal keratopathy; Superficial central primary degeneration oleogutta; The blindness of Dahalach

Definition

A degeneration of the cornea and/or conjunctiva characterized by the appearance of golden yellow spherules or globules of varying size at or beneath the epithelium.

Etiology

The exact source of the protein material forming the spherules is unknown. It has been postulated that the material may result from the actions of ultraviolet light on serum proteins that diffuse into the cornea from limbal vessels (Farjo and Sugar 2009). Age and exposure to ultraviolet light are the most common associated factors. Other proposed risk factors include dry eyes, corneal trauma or microtrauma (wind, sand, ice), low humidity, and extremes of temperature. Associated ocular diseases include keratitis, lattice corneal dystrophy, and glaucoma (Fraunfelder and Hanna 1973).

Clinical Presentation

Spheroidal degeneration is characterized by the presence of yellow or golden spherules at or beneath the corneal or conjunctival epithelium. The spherules, or globules, are generally clear but may become more opaque over time and range in size from approximately 0.1 to 0.6 mm in diameter. These lesions are located in the superficial corneal stroma, bowman membrane, subepithelium, and occasionally in the epithelium in advanced degeneration (Magovern et al. 2004).

The clinical presentation has been described as either a primary corneal type associated with age, a secondary corneal type associated with other ocular pathologies, or a conjunctival form that may or may not be associated with either type of corneal degeneration (Fraunfelder and Hanna 1973). In the primary form, the lesions are typically seen at the horizontal limbus within the palpebral fissure, and with progression, the spherules enlarge and spread toward the central cornea. In the secondary corneal form, the lesions are less likely to assume a band-shaped configuration and may be concentrated around areas of prior scarring, neovascularization or inflammation. The lesions are generally bilateral except in secondary cases where there is associated unilateral pathology such as scars, trauma, or keratitis. In the conjunctival form, lesions occur interpalpebrally at the 3 and 9 o'clock positions and are frequently found in association with pinguecula.

Diagnosis

Diagnosis is made clinically based on the characteristic appearance. Biopsy with histologic examination can support or confirm the diagnosis but is not typically required. Histologically, deposits appear as extracellular amorphous globules, which may coalesce to form larger masses in Bowman's membrane (Farjo and Sugar 2009).

Differential Diagnosis

Similar appearing clinical entities include corneal amyloid degeneration, gelatinous drop-like corneal dystrophy (familial subepithelial amyloidosis), band keratopathy, climatic proteoglycan stromal keratopathy, primary lipoidal degeneration of the cornea, Salzmann nodular degeneration, and limbal girdle of Vogt (type II).

Prophylaxis

Unknown. Based on the recognized association with sunlight exposure, it is plausible that methods to reduce sunlight exposure could potentially reduce the development or progression of spheroidal degeneration.

Therapy

Treatment is rarely required since the majority of individuals are asymptomatic. In patients with loss of vision from central corneal lesions, treatment can be considered. Possible treatment

options include superficial keratectomy, phototherapeutic keratectomy, lamellar keratoplasty, or penetrating keratoplasty depending on the depth and density of the lesions.

Prognosis

The majority of individuals do not develop any symptoms and progression is slow in the primary form. However, progression may result in loss of vision, particularly in areas of the world where climatic exposure is severe. Visual acuity may be affected due to involvement of the visual axis of the cornea or from irregular astigmatism. In advanced disease, accumulation of globular masses or plaques may cause heaping up of the corneal surface, epithelial defects, and recurrent corneal erosions. Corneal sensation may be reduced and sterile ulceration may rapidly progress to microbial keratitis or perforation.

Epidemiology

The prevalence of spheroidal degeneration varies based on geographic location with rates of 6% in England and over 60% in males in Labrador (Farjo and Sugar 2009). It is approximately three times more common in males and increases with age, being found in roughly 50% of patients over 70 years of age (Fraunfelder and Hanna 1973). It is most frequently seen in areas with high sunlight exposure. While the primary form is generally considered a degeneration, there are rare reported cases describing a more dystrophic form that may be familial and occurs in relatively young patients without a history of other ocular disease or environmental exposure (Santo et al. 1993).

Keratitis

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Corneal inflammation

Definition

Keratitis may be caused by noninfectious agents or from exposure to or invasion by infectious organisms. Keratitis in general can affect all layers of the cornea.

Histology

Histological studies in some cases help in finding the underlying cause for keratitis. A granulomatous

reaction against Descemet's membrane can be seen in herpetic stromal keratitis, while a loss of keratocytes in the anterior part of the stroma is found in neurotrophic keratitis. In acanthamoeba keratitis, corneal edema, loss of Bowman's membrane, and inflammatory infiltrate consisting of leucocytes can be present in the superficial corneal stroma. Amoeba oocysts can be stained and is found in the deeper layers of the stroma (Cursiefen and Kruse 2007; O'Brien 2005).

Immunohistochemistry

To differentiate between acanthamoeba and viral keratitis, and in some cases, between immunological disorders such as Terrien's or Mooren's ulcer, immunohistochemistry is employed (Lopez et al. 1991).

Electron Microscopy

Electron microscopy has been used to demonstrate the structure of the viral particles of herpes simplex, bacterial structures, and acanthamoeba as well as the affected corneal layers.

Molecular Diagnosis

To differentiate between various infectious agents, polymerase chain reaction (PCR) is available.

Differential Diagnosis

Infectious causes: Bacterial/viral/fungal/acanthamoeba keratitis.

Noninfectious: filamentary/superficial punctuate/photoelectric/neurotrophic/immunologic (phlyctenular and staphylococcal)/autoimmune keratitis.

Keratoacanthoma

Jeremiah Tao[1] and Betina Wachter[2]
[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Molluscum sebaceum

Definition

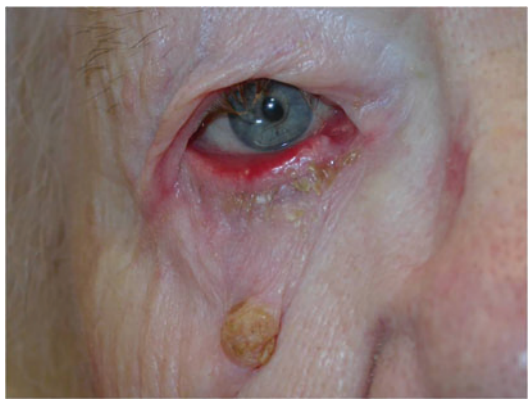
A skin tumor characterized by a very rapid growth phase, followed by gradual involution. Some consider keratoacanthoma (KA) a subtype of squamous cell carcinoma. The tumor is most commonly seen on sun-exposed areas and in white elderly patients. Males are more often affected than females (Leibovitch et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Etiology

Unclear, however, several potentiating factors should be considered such as trauma, exposure to chemical agents, human papilloma virus infection, and immunocompromised status. Keratoacanthomas may also develop after laser resurfacing, radiation therapy, and at the donor site after skin grafting (Albert and Jakobiec 2008; Shields and Shields 2008).

Clinical Presentation

The classical appearance is a well-defined, solitary, firm, skin-colored, or reddish papule that rapidly progress to dome-shaped nodule, with central keratotic crater and elevated rolled margins (Fig. 1). Usually solitary lesions; however, there are a number of syndromes that feature multiple keratoacanthomas, including the Muir-Torre syndrome, a generalized eruptive variant of Grzybowski, and the Ferguson Smith syndrome. Multiple keratoacanthomas may be associated with visceral malignancies (Albert and Jakobiec 2008; Shields and Shields 2008).



Keratoacanthoma, Fig. 1 Keratoacanthoma in malar area of an elderly man

Diagnostics

Despite KA's distinctive morphological features, differentiation from invasive SCC can only be made histologically. A biopsy should be obtained in order to establish a definitive diagnosis (Leibovitch et al. 2005; Albert and Jakobiec 2008; Shields and Shields 2008).

Differential Diagnosis

Differential Diagnosis includes ▶ basal cell carcinoma, ▶ squamous cell carcinoma, ▶ actinic keratosis, ▶ inverted follicular keratosis, and ▶ molluscum contagiosum.

Prophylaxis

Avoidance of sun and UV exposure (use of sunscreens, sunglasses, umbrellas, and hats).

Therapy

KA may regress spontaneously over a period of 3–6 months. Observation of periocular KA carries some risk, especially when histologic differentiation is important to rule out malignancy. The primary therapy is surgical excision of the tumor with frozen section control. It is essential not only to maintain normal eyelid function but also to prevent further tissue destruction and invasion into deeper tissues.

Prognosis

KA infrequently presents as multiple tumors and may enlarge (5–15 cm), become aggressive locally, or rarely, metastasize.

Epidemiology

Uncertain.

Dry eye disease

Definition

Keratoconjunctivitis sicca is defined as a multifactorial disease of the tears and ocular surface that leads to discomfort, visual disturbance, and tear film instability with potential damage to the ocular surface. The disease is often accompanied by increased osmolarity of the tear film and inflammation of the ocular surface (Nassiri et al. 2011). Dry eye disease is far from just a dysfunction of the lacrimal glands. It is a result of dysfunction of the complex interplay of factors involving the lacrimal glands, lids, ocular surface, lacrimal drainage ducts, medications, contact lens wear, and the environment (Lemp 2005).

The tear film is composed of three components. There is a mucin layer, aqueous layer, and lipid layer. These components work together to maintain a normal ocular surface in health and repair in response to injury. The tear film also forms the anterior refracting surface of the eye. Thus, a dysfunctional tear film degrades the visual image perceived by the retina and compromises visual acuity. The tear film also provides hydration to the ocular surface and functions as a lubricant between the eyelid and ocular surface. Studies have shown that tear films break up prior to the next blink in patients with keratoconjunctivitis sicca. In keratoconjunctivitis sicca, the tear film is disrupted, leading to symptoms varying from irritation to severe pain. The discomfort of dry eye disease has been described as dryness, grittiness, stinging, foreign body sensation, itching, burning, and stinging (Lemp 2005).

Two main divisions of keratoconjunctivitis sicca are aqueous tear deficiency and evaporative tear deficiency. Over 60% of patients with Sjogren's syndrome associated keratoconjunctivitis sicca have both forms of dry eye. Additionally, many of the patients with severe forms of keratoconjunctivitis sicca have evidence of Sjogren's syndrome (Lemp 2005).

The prevalence of clinically diagnosed dry eye disease in the United States is 0.4–0.5%, highest amongst women and the elderly (Nassiri et al. 2011). Age-related changes in the lacrimal and meibomian gland functions have been reported. The correlation with advancing age and

changes in hormone status suggests that sex hormones may be involved in the maintenance of tear secretion (Lemp 2005). Tens of millions of individuals have a less severe form of the disease that may be episodic, occurring only during adverse conditions, such as contact lens wear and low humidity. Due to its significant prevalence, keratoconjunctivitis sicca is considered a significant public health issue, which will have a considerable economic impact (Nassiri et al. 2011).

The mainstay of treatment has been palliative with lubricant eye drops and artificial tears. However, the US Food and Drug Administration has approved cyclosporine-A (Restasis-Allergan) for the treatment of keratoconjunctivitis sicca. Systemic food supplements, such as flax seed oil and omega-3 fatty acids, are in wide use. They may function by suppressing inflammation and contributing to the synthesis of lipids of the meibomian glands (Lemp 2005).

Keratoconjunctivitis: Overview

Matthew B. Goren
Cornea and External Diseases, Department of Ophthalmology, Northwestern University, Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Dry eye; Dry eye syndrome; Keratitis sicca; Keratoconjunctivitis sicca (KCS); Sicca syndrome; Tear deficiency

Definition

An insufficient tear film to maintain ocular surface health, comfort, or luster required for optimal visual acuity.

Etiology

The pathogenesis is multifactorial, but is broken down into aqueous deficiency (inadequate lacrimal gland function) and increased evaporative state (insufficient lipophilic tear layer which normally prevents aqueous tear evaporation) (2007). Aqueous deficiency may be related to normal aging, hormonal imbalances, collagen vascular disease, autonomic neuropathy, systemic or local inflammatory conditions, systemic medications, or vitamin deficiency. Increased evaporative states may be caused by blepharitis (meibomitis especially), ineffective blinking or abnormal lid anatomy (ectropion), topical medications, contact lens wear, or surface inflammation.

Clinical Presentation

Patients typically present with ocular irritation (foreign body sensation, itching, burning, dryness) and fluctuating visual accuity that is often improved by blinking (Goren and Goren 1988). Redness, mucoid discharge, epiphora (from reflex tearing), and photophobia might also be seen.

Diagnosis

Numerous tests may aid in the diagnosis such as tear film breakup time (BUT), Schirmer testing, corneal vital staining, tear osmolarity, and tear immunoassays for lactoferrin and lysozyme. However, all these tests suffer from less than ideal predictive values. Diagnosis is best made by history and a careful slit lamp examination of the quality of the tear film and adnexal structures. Blood tests may be used to diagnose underlying systemic inflammatory conditions resulting in secondary dry eye.

Differential Diagnosis

The differential diagnosis of KCS is extensive and includes all forms of blepharitis, lid malpositions, infectious keratoconjunctivitis, ocular allergy, medicamentosa, and other forms of keratitis and degenerative keratopathies.

Prophylaxis

Avoidance of known precipitators can help. Daily warm compresses keep meibomian orifices open in evaporative dry eye. Avoidance of dry environments and humidifiers are useful. Alternative medications that do not cause drying if possible is of benefit.

Therapy

Therapy depends on underlying cause (Behrens et al. 2006). For evaporative states associated with meibomitis, warm compresses, lid hygiene, and systemic medications like tetracyclines or azolides can be useful. For aqueous-deficient states, the mainstay of treatment is artificial teardrops. Punctal occlusion is extremely useful and probably underutilized. Topical cyclosporin and steroids may be of use in inflammatory states. Oral omega-3 fatty acids have been shown to be of benefit. Autologous serum eye drops are useful in the most severe cases. Chronic treatment is generally required and relapses expected with discontinuation of treatment.

Prognosis

Mild to moderate KCS is generally controllable with therapeutic intervention and these patients will function normally. More severe cases, however, can cause significant morbidity and seriously impact quality of life. Severe KCS may result in profound vision loss and secondary corneal infection which can threaten vision and the integrity of the globe; fortunately, these cases are far more rare.

Epidemiology

The classic KCS patient is a postmenopausal female, but this condition can occur in either sex and at any age (2007). The exact prevalance of this condition is unknown, but it is estimated that between 10% and 30% of the population (more so in older groups) is affected. Females are affected over men approximately 2:1. KCS associated with autoimmune disease is far more common in women.

Keratoconus

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

KC

Definition

An ectatic, noninflammatory corneal dystrophy leading to progressive corneal thinning with subsequent development of irregular astigmatism (higher-order aberrations) and decrease of best-corrected visual acuity. The name is derived from the cone shape of the cornea at later stages of the disease.

Etiology

While there is evidence for formal pathogenetic mechanisms, the underlying etiology is unknown yet. Immunohistochemistry uncovered different expression patterns of α_1-proteinase inhibitor and matrix metalloproteinases (MMP) in normal and KC eyes. KC showed lower levels of α_1-proteinase inhibitor and higher levels of MMP-1 compared to normal eyes (Cristina Kenney and Brown 2003; Meghpara et al. 2008; Balasubramanian et al. 2010). Apart from a multifactorial hereditary component, severe eye rubbing is still discussed as one etiologic risk factor (Carlson 2010), which is suggested by clinical experience with patients with Leber's congenital amaurosis or Tourette's syndrome (Mashor et al. 2011). A study involving a multivariable analysis did not confirm atopic diathesis itself (another condition known to be associated with KC) but eye rubbing, which is often present, as a risk factor for KC (Bawazeer et al. 2000).

Clinical Presentation

Typical early signs and symptoms include blurry vision, myopization, increase of astigmatism, a difficult subjective refraction, and loss of best-corrected visual acuity. Later, corneal abnormalities can be detected at the slit lamp. The earliest of these slit-lamp signs is a pronounced reflex of the endothelium, followed by vertical striae of Descemet's layer (Vogt's striae). At later stages, corneal scarring, corneal hydrops (often referred to as "acute KC"), and the eponymous cone-like shape of the cornea can be observed.

Diagnostics

The gold standard for the diagnosis of KC is corneal topography. Corneal topographic maps of KC eyes show typical characteristics like and asymmetric bow-tie pattern, skewed radial axes, or a centralized ("baby") bow-tie pattern. In the early (subclinical) stage of the disease, these signs are often very subtle and may be overlooked, particularly in asymptomatic patients. Later, with progression of the disease, corneal curvature increases significantly with the typical patterns still present. Metrics computed from corneal topographic data can help to establish the diagnosis of KC in doubtful cases (Maeda et al. 1995; Rabinowitz 1995; Bühren et al. 2010). Newer approaches also use Scheimpflug tomography (Bühren et al. 2010; Ambrosio et al. 2011) or elastometry (Fontes et al. 2011). In default of corneal topography, streak retinoscopy is a very sensitive tool for the detection of early KC forms.

Differential Diagnosis

High regular astigmatism, pellucid marginal degeneration, iatrogenic keratectasia, keratoglobus, and *status post* hyperopic LASIK.

Prophylaxis

There is no established prophylaxis against KC. With eye rubbing getting more into the focus as a significant risk factor, a prevention of pathological eye rubbing could play a role in the future.

Therapy

The gold standard is the correction of myopia, astigmatism, and higher-order aberrations (HOA) in KC eyes with rigid gas-permeable contact lenses (RGPs), often special RGPs for KC eyes. RGPs allow a satisfactory visual acuity for a long time. If RGPs are not tolerated; a correction at least of lower-order aberrations can be achieved with glasses. Newer surgical therapies are the

implantation of ring segments into the cornea in order to achieve a more regular corneal shape (Ertan and Colin 2007) or the implantation of a toric intraocular lens into the phakic eye in order to correct lower-order aberrations (Kato et al. 2011).

With the introduction of corneal collagen cross-linking (CXL), a more causative therapy beyond mere correction of optical aberrations became possible. Studies showed that the CXL treatment is able to halt the progression of KC (Hersh et al. 2011). Thus, the disease could be "frozen" at a stage when RGPs can still be worn by the patient and the necessity for keratoplasty as the *ultima ratio* treatment can be prevented or at least be delayed.

Keratoplasty is performed if the best-corrected visual acuity is low (typically >1.0 logMAR) due to corneal scarring and RGP intolerance. Newer developments include lamellar techniques that preserve the endothelium of the often young patients; however, penetrating keratoplasty is still the gold standard among the keratoplasty techniques for the treatment of KC.

Prognosis

If progression is slow and if RGPs are tolerated, the prognosis is excellent with patients reaching visual acuity values of around 0.1 logMAR. Patients who require keratoplasty may reach lower visual acuity values, particularly in case of high post-keratoplasty astigmatism, elevated HOA levels, and RGP intolerance.

Epidemiology

The medial prevalence is 55:100,000 with a proclivity for the male sex. However, inter-racial differences have been reported (Georgiou et al. 2004).

Definition

Keratoglobus is a rare, degenerative bilateral corneal disease characterized by corneal thinning and hemispherical protrusion that may lead to myopia (Lange and Gareis 2007).

Structure

Keratoglobus is characterized by thinning of the cornea from limbus to limbus (Wallang and Das 2013). Scleral thinning and minimal corneal scarring may also be involved. The cornea tends to be of normal or increased diameter with these physical changes (Karabatsas and Cook 1996). The eye will have normal to low intraocular pressure with a normal disk. Corneal edema is a rare complication of keratoglobus that increases the risk of rupture.

Functions

The cause of keratoglobus is unclear, and the pattern of corneal thinning tends to be unpredictable (Krachmer et al. 1984). Patients may report vision deterioration that affects their daily functioning. Keratoglobus does not cause blindness though.

Clinical Relevance

Keratoglobus is much more rare than keratoconus, the more common corneal dystrophy (Krachmer et al. 1984).

Keratoglobus exists in at least two forms: congenital juvenile and acquired adult form (Wallang and Das 2013). The congenital form presents at birth and has been associated with Ehlers-Danlos type VI, blue sclera syndrome, and Leber congenital amaurosis. The acquired form of keratoglobus presents in adulthood and has been associated with preexisting keratoconus, inflammatory orbital pseudotumor, chronic marginal blepharitis, and post-penetrating keratoplasty glaucoma. It has also been involved in cases of vernal keratoconjunctivitis and hyperthyroidism.

Patients typically present with bilateral visual impairment that does not correct with spectacles or contact lenses. Contact lenses may also be reported to have poor fit or associated with pain. Eye pain may occur in rare cases.

Clinical diagnosis is made using slit lamp exam. Physical exam signs associated with keratoglobus are myopia, irregular astigmatism, diffuse corneal thinning, globular protrusion of the cornea, corneal hydrops, and possible scarring.

Differential diagnosis includes keratoconus, pellucid marginal degeneration, and corneal ectasia following refractive surgery.

There are several avenues for treatment and management of keratoglobus. Spectacles are the first step for visual correction and protection. Success with contact lenses may be difficult due to the

abnormal corneal contours (Wallang and Das 2013). Further, the risk of trauma with continuous manipulation with contact lenses must be weighed. No medical therapy has been found to be effective in treating the underlying pathology of keratoglobus. Treatment of symptoms, such as hydrops, is necessary, with suggested methods being hypertonic saline or bandage soft contact lenses.

Surgical management may be necessary when vision improvement cannot be obtained otherwise. Lamellar epikeratoplasty has been successful in reinforcing thin corneas and improving vision (Jones and Kirkness 2001). Large penetrating keratoplasty has been found to be successful for acquired keratoglobus (Kodjikian et al. 2004). However, these procedures come with several complications, and success of the surgical intervention is not guaranteed.

The prognosis for keratoglobus is poor due to difficult response to spectacles and surgical interventions (Wallang and Das 2013).

Keratolysis (Corneal Melting), Marginal, Systemic Immune-Mediated Disease

Brent Betts
Department of Ophthalmology, Wake Forest Baptist Health, Winston-Salem, NC, USA

Synonyms

Corneal melting; Peripheral ulcerative keratitis; Scleritis-associated peripheral keratopathy

Definition

Thinning of peripheral corneal stroma with an overlying epithelial defect due to autoimmune-induced inflammation.

Etiology

Systemic immune-mediated marginal keratolysis occurs in response to infectious and non-infectious insults. Infectious etiologies include bacteria species (*Staphylococcus* species, *Streptococcus* species, *Treponema pallidum*,

Mycobacterium tuberculosis), viruses (hepatitis C, herpes simplex virus, varicella zoster virus), *Acanthamoeba*, and fungi (Dana et al. 2000). Noninfectious causes include rheumatoid arthritis, Wegener's granulomatosis, relapsing polychondritis, polyarteritis nodosa, and systemic lupus erythematosus (Odorcic et al. 2009). One-third of peripheral ulcerative keratitis cases are associated with rheumatoid arthritis (Tauber et al. 1990).

Marginal keratolysis stems from the peripheral cornea's proximity to limbal vasculature. The capillary bed brings inflammatory cells and mediators in contact with the peripheral cornea, inducing inflammation. It has been theorized that corneal inflammation is due to both T-cell and antibody-mediated responses. T cells induce antibody formation and immune complex deposition in the peripheral cornea. Recruited neutrophils and macrophages secrete collagenases and proteases, which, in turn, destroy the peripheral cornea stroma (Dana et al. 2000).

Occurrence

The incidence is estimated to be three cases per million per year (Knox et al. 2013). Men and women are equally affected (Tauber et al. 1990).

Classification

Symptoms of keratolysis include eye pain, decreased visual acuity (from corneal opacification or astigmatism), redness, tearing, and photophobia. Signs include de-epithelialization, stromal thinning, cellular infiltration, and contiguous inflammation of surrounding conjunctiva and sclera. Thinning typically occurs in the peripheral cornea within 2 mm of the limbus and maintains a curvilinear shape. Corneal melting is a late complication of the disease. Progressive thinning of the cornea can lead to perforation.

Keratomalacia, Vitamin A Deficiency

Aazim A. Siddiqui[1] and Allen O. Eghrari[2,3]
[1]Imperial College London School of Medicine, South Kensington Campus, London, UK
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[3]Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Definition

Keratomalacia is characterized by corneal melting, conjunctival xerosis, and in advanced disease, liquefactive necrosis of the corneal stroma. It is frequently associated with xerophthalmia secondary to vitamin A deficiency, is

generally bilateral, and is most commonly seen in malnourished children less than 5 years of age in developing countries. Its prevalence in economically advanced countries is rare but associated with metabolic, psychiatric, and eating disorders affecting vitamin A intake. Treatment should address reversal of vitamin A deficiency and improvement of general health; perforations may require corneal transplantation.

Keratopathy Actinic (Labrador Keratopathy/Spheroidal Degeneration)

Jay J. Meyer
Duke University Eye Center, Durham, NC, USA

Synonyms

Chronic actinic keratopathy describes a condition associated with conjunctival elastosis and typified by characteristic extracellular concretions (Klintworth 1972). A later publication found this and other entities, including Labrador keratopathy, to fit the classification of the clinical term "spheroidal degeneration" (Fraunfelder and Hanna 1973). Several other reported clinical entities describe globular deposits of the cornea that may represent the same condition, with geographic variations or subtypes:

Band-shaped nodular dystrophy of the cornea; Bietti corneal degeneration; Chronic actinic keratopathy; Climatic droplet keratopathy; Colloid degeneration of the cornea; Degeneratio hyaloidea grannuliformis corneae; Elastoid degeneration; Elastotic degeneration; Eskimo corneal degeneration; Fisherman's keratopathy; Hyaline corneal degeneration; Keratoid corneal degeneration; Labrador keratopathy; Nodular corneal dystrophy in tropical arid countries; Nodular hyaline, band-shaped keratopathy; Proteinaceous corneal degeneration; Sphaerularis elaiodes; Spheroid degeneration; Spheroidal keratopathy; Superficial central primary degeneration oleogutta; The blindness of Dahalach

Definition

A degeneration of the cornea and/or conjunctiva characterized by the appearance of golden yellow spherules or globules of varying size at or beneath the epithelium.

Etiology

The exact source of the protein material forming the spherules is unknown. The initial description suggested this condition was due to the effect of chronic actinic irradiation. It has since been postulated that the material may result from the actions of ultraviolet light on serum proteins that diffuse into the cornea from limbal vessels (Farjo and Sugar 2009). Age and exposure to ultraviolet light are the most common associated factors. Other proposed risk factors include dry eyes, corneal trauma or microtrauma (wind, sand, ice), low humidity, and extremes of temperature. Associated ocular diseases include keratitis, lattice corneal dystrophy, and glaucoma (Fraunfelder and Hanna 1973).

Clinical Presentation

Spheroidal degeneration is characterized by the presence of yellow or golden spherules beneath the corneal or conjunctival epithelium. The spherules, or globules, are generally clear but may become more opaque over time and range in size from approximately 0.1 to 0.6 mm in diameter. These lesions are located in the superficial corneal stroma, bowman membrane, subepithelium, and occasionally in the epithelium in advanced degeneration (Magovern et al. 2004).

The clinical presentation has been described as either a primary corneal type associated with age, a secondary corneal type associated with other ocular pathology, and a conjunctival form that may or may not be associated with either type of corneal degeneration (Fraunfelder and Hanna 1973). In the primary form, the lesions are typically seen at the horizontal limbus within the palpebral fissure, and with progression, the spherules enlarge and spread toward the central cornea. In the secondary corneal form, the lesions are less likely to assume a band-shaped configuration and may be concentrated around areas of prior scarring, neovascularization, or inflammation. The lesions are generally bilateral except in secondary cases where there is associated unilateral pathology such as scars, trauma, or keratitis. In the conjunctival form, lesions occur interpalpebrally at the 3 and 9 o'clock positions and are frequently found in association with pinguecula.

Diagnosis

Diagnosis is made clinically based on the characteristic appearance. Biopsy with histologic examination can support or confirm the diagnosis but is not typically required. Histologically, deposits appear as extracellular amorphous globules, which may coalesce to form larger masses in Bowman's membrane (Farjo and Sugar 2009).

Differential Diagnosis

Similar appearing clinical entities include corneal amyloid degeneration, gelatinous drop-like corneal dystrophy (familial subepithelial amyloidosis), band keratopathy, climatic proteoglycan stromal keratopathy, primary lipoidal degeneration of the cornea, Salzmann nodular degeneration, and limbal girdle of Vogt (type II).

Prophylaxis

Unknown. Based on the recognized association with sunlight exposure, it is plausible that methods to reduce sunlight exposure could potentially reduce the development or progression of spheroidal degeneration.

Therapy

Treatment is rarely required since the majority of individuals are asymptomatic. In patients with loss of vision from central corneal lesions, treatment can be considered. Possible treatment options include superficial keratectomy, phototherapeutic keratectomy, lamellar keratoplasty, or penetrating keratoplasty depending on the depth and density of the lesions.

Prognosis

The majority of individuals do not develop any symptoms and progression is slow in the primary form. However, progression may result in loss of vision, particularly in areas of the world where climatic exposure is severe. Visual acuity may be affected due to involvement of the visual axis of the cornea or from irregular astigmatism. In advanced disease, accumulation of globular masses or plaques may cause heaping up of the corneal surface, epithelial defects, and recurrent corneal erosions. Corneal sensation may be

reduced and sterile ulceration may rapidly progress to microbial keratitis or perforation.

Epidemiology

The prevalence of spheroidal degeneration varies based on geographic location with rates of 6% in England and over 60% in males in Labrador (Farjo and Sugar 2009). It is approximately three times more common in males and increases with age, being found in roughly 50% of patients over 70 years of age (Fraunfelder and Hanna 1973). It is most frequently seen in areas with high sunlight exposure. While the primary form is generally considered a degeneration, there are rare reported cases describing a more dystrophic form that may be familial and occurs in relatively young patients without a history of other ocular disease or environmental exposure (Santo et al. 1993).

Keratoprosthesis

Ron Gutmark
The Wilmer Eye Institute, The Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Artificial cornea; KPro

Definition

An artificially produced ophthalmic device meant to replace the natural cornea. These devices can be completely synthetic, hybrids of synthetic and natural materials, or completely composed of biologic materials.

Indication

There are three basic indications for keratoprostheses: corneal allograft failure, severe chemical injuries affecting the cornea, and severe autoimmune disease affecting the cornea. Not all of these indications apply to all of the various types of keratoprostheses (Chodosh and Dohlman 2011).

Contraindication

Some general contraindications include no light perception vision, posterior segment abnormalities, uncontrolled intraocular pressure, useful vision or functional keratoprosthesis in the fellow eye, eyelid or blink abnormalities, and poor access to ophthalmologist performing or familiar with procedure or poor commitment to frequent follow-up. Other contraindications that may or may not apply depending on the type of keratoprosthesis used include herpes simplex keratitis, autoimmune disorders, and age under 18 years (Chodosh and Dohlman 2011).

Techniques and Principles

Type 1 Boston Keratoprosthesis (BKPro)

The type 1 BKPro consists of four components: a polymethyl methacrylate (PMMA) optical front plate and stem, a corneal graft button with a central trephination, and a back plate and a titanium locking ring. Holes in the back plate allow for aqueous nutrition of the corneal button.

The device is assembled by placing the front plate and stem through a prepared corneal graft button with a central trephination. The back plate is then placed onto the stem and the entire assembly is secured using the titanium locking ring. The host cornea is then trephinated and the corneal graft button is then sutured to the host cornea as in a standard penetrating keratoplasty procedure (Fahd et al. 2013).

Osteo-odonto-keratoprosthesis (OOKP)

The OOKP consists of an optical cylinder held in the patient's tooth root and surrounding alveolar bone. This creates a bed for the optical element that supports the optical element while allowing for integration into the surrounding tissue in order to minimize the risk of extrusion.

Implantation consists of two stages. In the first stage, the patient's tooth is removed with adjacent bone and a hole is then drilled into the center of the tooth root. An optical cylinder is then cemented into the hole. This tooth-optic lamina complex is then implanted into a submuscular location (usually the lower eyelid). A 360-degree peritomy is then performed on the host eye, followed by removal of epithelium and Bowman's layer. A mucous membrane graft, most often obtained from the cheek, is secured to the exposed sclera. The tooth-optic lamina complex and the mucous membrane are left in place for 2–4 months, which allows for formation of a fibrovascular covering over the tooth-optic lamina complex and vascularization of the mucous membrane. In the second stage, the tooth-optic lamina complex is removed from the submuscular bed and a flap is then made in the mucous membrane that had previously been grafted to the sclera. The host cornea is then trephinated, and the lens and iris are removed followed by anterior vitrectomy. The tooth-optic lamina complex is then sutured to the host cornea and the mucous membrane graft is resutured in place. A hole is then cut in the central portion of the mucous membrane graft, exposing the optic (Gomaa et al. 2010; Fahd et al. 2013).

AlphaCor (TM)

The AlphaCor(TM) is made up of two different parts, both made of poly-2-hydroxyethyl methacrylate (pHEMA). This device consists of a central transparent optic and a porous, opaque outer skirt. The porous outer zone allows integration of keratocytes and blood vessels into the outer portion of the device.

Implantation of the AlphaCor(TM) occurs in two stages. In the first stage, a 360-degree peritomy is fashioned and the corneal epithelium is removed. A lamellar corneal flap is then constructed in the superior half of the cornea at approximately 50% thickness. Dissection is then carried through the inferior cornea creating a pocket in the inferior cornea. A trephine is then used to enter the anterior chamber in the middle of the posterior corneal layer. The AlphaCor (TM) device is then placed into the pocket in the inferior cornea and centered over the hole in the posterior cornea. The superior corneal flap is then sutured to the limbus. The second stage of the procedure occurs 8–12 weeks later, at which time the superficial corneal layer overlying the AlphaCor(TM) is trephinated exposing the clear optical zone of the device (Gomaa et al. 2010; Fahd et al. 2013).

Other Types of Keratoprostheses

In addition to the aforementioned types of keratoprostheses, a number of other types of keratoprostheses have been developed. These include the Seoul type KPro (S-KPro), the Pintucci Biointegrable keratoprosthesis, the

supraDescemetic synthetic cornea, the Moscow Eye Microsurgery Complex keratoprosthesis (MICOF), and several others (Gomaa et al. 2010).

Outcome

Keratoprosthesis surgery has varying success depending on a number of factors including the type of keratoprosthesis and indication for which it was used. With OOKP, one study showed that 53% of patients had better than 20/200 vision at 5 years. For BKPro, another study showed that 56% of patients had better than 20/200 vision at 1 year. With regard to retention of the keratoprosthesis, for the OOKP, studies show the probability of retention at 18 years was 85%; for the BKPro, 61% at 2 years; and for the AlphaCor (TM), retention rates at 2 years were 62% (Li et al. 2013).

Complications

Keratoprostheses increase the risk of endophthalmitis. Implantation procedures may be complicated by expulsive or choroidal hemorrhage and retinal detachment due to their open-sky nature. Other significant complications of these devices include increased intraocular pressures and glaucoma, the management of which is challenging because it is difficult to accurately assess intraocular pressure in the presence of these devices. Implant extrusion or rejection is also a risk. Complications specific to the different types of keratoprostheses include injury to the maxillary sinus or facial and jaw bones and the mucous membrane graft ulceration with OOKP, retroprosthetic membranes or persistent epithelial defects with BKPro and corneal stromal melts (both of the anterior lamella and the corneal bed), closure of the posterior lamellar opening, and opacities in the optic portion of the device with AlphaCor(TM) (Gomaa et al. 2010; Fahd et al. 2013; Li et al. 2013).

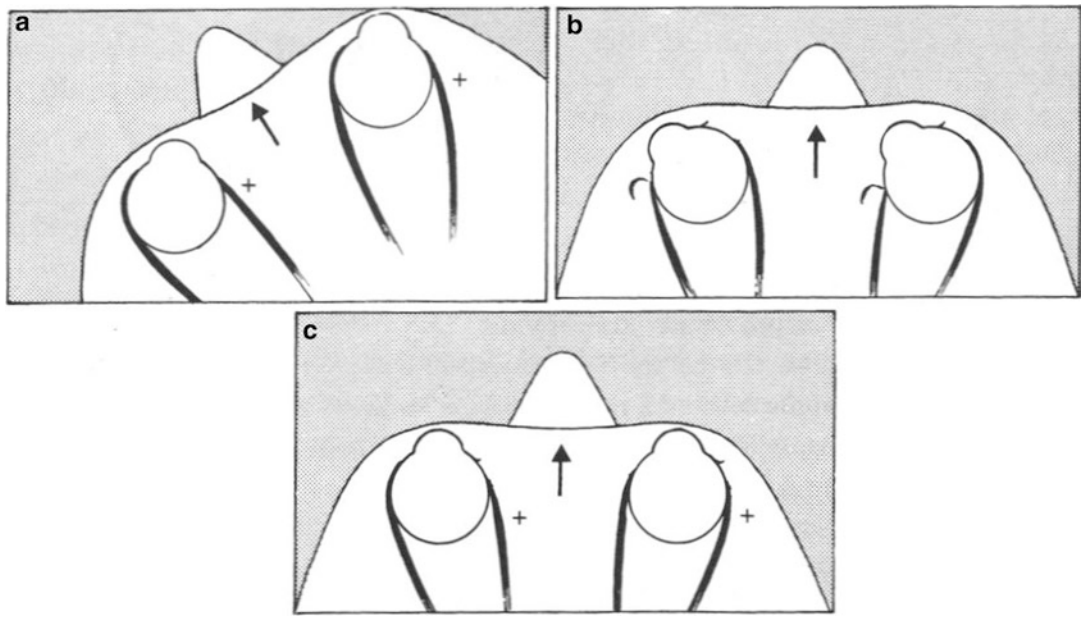
Kestenbaum's

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Definition

Surgery, surgical method for nystagmus-related head turn. Some patients with nystagmus rotate their head in an extreme forced posture because nystagmus is reduced due to mechanical reasons. For this group of patients, Alfred Kestenbaum (1890–1961) recommended a surgical method for a back parallel shift of those straight extraocular muscles which are contracted in this position and a resection for those straight extraocular muscles which are stretched in this position.



Kestenbaum's, Fig. 1 Kestenbaum's operation

The purpose of this rearrangement is to achieve postoperative the same innervation relation like before in the forced head turn position. It is a translator movement of neutral zone into the straight ahead view.

Kestenbaum's Operation:

(a) Preoperative both eyes are turned right. The head is rotated left. In this head forced posture, the left m. rectus medialis and the right m. rectus lateralis are innervated.
(b) Through both sides ensued combined operation, both eyes are brought into left direction.
(c) The left musculus rectus medialis and the right musculus rectus lateralis are innervated to turn the eyes into primary position. This innervation existed preoperative with forced posture head turn and was related with minimal nystagmus. This innervation exists now for straight ahead view and obviates the need of head rotation. The innervation pattern of maximal nystagmus calm is displaced into another viewing direction (Fig. 1).

Ketorolac Tromethamine

Gil Peretz, Ayala Polack and Yoel Greenwald
Department of Ophthalmology, Kaplan Medical Center, Rehovot, Israel

Synonyms

Drops: Acular, Acular PF, Acuvail, Acular LS; Tablets: Ketorolac Tromethamine 10 mg

Definition

Ketorolac tromethamine belongs chemically to the family of heterocyclic acetic acid derivatives in the pyrrolo-pyrrole group of nonsteroidal anti-inflammatory drugs. The active material blocks prostaglandin biosynthesis from arachidonic acid by irreversibly binding to both the cyclooxygenase 1 and 2 enzymes. It is used for pain relief and for treating ocular inflammation. For ocular indications, the drug is mainly used as eye drops and less frequently in tablet form (Drugs.com; Brunton et al. 2011).

Ocular Indications (Donnenfeld et al. 2006; American Academy of Ophthalmology 2014–2015a; American Academy of Ophthalmology 2014–2015b; American Academy of Ophthalmology 2014–2015c)

Ketorolac tromethamine drops are used for treating postoperative inflammation (anterior segment and cystoid macular edema) and allergic conjunctivitis. In the case of allergic conjunctivitis, it reduces conjunctival inflammation, ocular itching, and tearing, but does not have a decongestant effect and does not relieve redness. Ocular conditions that are considered potential indications for Ketorolac treatment include:

Topical (Eye Drops)

- Aphakic/pseudophakic cystoid macular edema (CME). Its effectiveness in treating uveitic CME has not been proven.
- Allergic conjunctivitis.
- Anterior segment inflammation (anterior uveitis).
- Postrefractive surgery pain.
- Given before cataract surgery to reduce intraoperative prostaglandin-induced miosis.
- Contact lens assisted pharmacologically induced keratosteepening (CLAPIKS). A pharmacological method of treating overhyperopic results after refractive surgery.

Topical/Oral

- Episcleritis.
- Scleritis: For nonnecrotizing mild diffuse disease. Nodular or necrotizing disease usually requires more potent drugs.

Contraindications (Drugs.com)

Topical/Oral

- Hypersensitivity to Ketorolac and other NSAID's.
- Asthma patients known to have aspirin-induced asthma.

Topical

- Patients with complicated ocular surgeries, corneal denervation, corneal epithelial defects, diabetes mellitus, ocular surface diseases, rheumatoid arthritis, or repeat ocular surgeries within a short period of time may be at increased risk of corneal adverse reactions such as corneal erosion, corneal thinning, and corneal perforation.
- Children <3 years old: Safety not established.

Oral

- Gastrointestinal disease history: active peptic ulcer disease, recent gastrointestinal bleeding or perforation, history of peptic ulcer disease, or gastrointestinal bleeding
- Renal insufficiency or risk of hypovolemic renal insufficiency
- Patients judged to have a high bleeding risk (inhibits platelet activation)
- Concomitant use with aspirin or other NSAIDs
- Obstetrics: May adversely affect fetal circulation and inhibit uterine contractions. The drug is considered Category C in pregnancy and Category D if used in the third trimester (starting at 30 week gestation). Contraindicated in late pregnancy as it may cause premature closure of the ductus arteriosus
- Breastfeeding: Oral use contraindicated while breast-feeding (excreted in breast milk). Ophthalmic solutions may be used with caution.

Dosing (Drugs.com)

- Oral: 20 mg as first dose, followed by 10 mg every 4–6 h. Do not exceed 40 mg in 24 h. In patients over 65, with renal impairment, or weight < 50 kg use 10 mg as first dose.
- Drops: Have patient tilt head back and instill prescribed number of drops into affected eye (s) as ordered. Have patient close eye(s) for 2–3 min and apply light finger pressure to bridge of nose (nasolacrimal duct) for 1–2 min after instillation to prevent systemic absorption. Do not touch top of dropper bottle to eye, fingers, or other surface.

Usage (Donnenfeld et al. 2006; American Academy of Ophthalmology 2014–2015a; American Academy of Ophthalmology 2014–2015b; American Academy of Ophthalmology 2014–2015c)

- After corneal refractive surgery: for pain relief and burning/stinging 0.4% solution, one drop four times daily for up to 4 days.
- Seasonal allergic conjunctivitis: for relief of ocular itching 0.5% solution, one drop four times daily.
- After cataract extraction: instill one drop to affected eye(s) four times daily beginning 24 h after cataract surgery and continuing through the first 2 weeks of the postoperative period.
- Before cataract surgery: to prevent intraoperative miosis. 0.4% solution four times a day for 1–3 days preoperatively.

Adverse Reactions (Drugs.com)

Ophthalmic

40%: Burning/stinging after instillation.

1–10%: Iritis, ocular inflammation/irritation, conjunctival hyperemia and/or hemorrhage, increased ocular pressure, tearing/vision blurred corneal infiltrates, corneal epithelial breakdown, superficial keratitis, corneal edema, corneal erosion, corneal thinning/ulcer, corneal perforation, allergic reactions.

Oral

Cardiovascular

1–10%: Hypertension.

<1%: Arrhythmia, bradycardia, chest pain, flushing, hypotension, MI, vasculitis.

Central Nervous System

1–10%: Headache, dizziness, drowsiness.

<1%: Aseptic meningitis, coma, convulsions, psychosis.

Dermatologic

1–10%: Pruritus, rash, sweating.

<1%: Exfoliative dermatitis, Lyell syndrome, maculopapular rash, Stevens-Johnson syndrome.

Ear Nose and Throat

1–10%: Tinnitus.

Gastrointestinal

>10%: Abdominal pain, dyspepsia, nausea

1–10%: constipation/diarrhea, flatulence, GI fullness, GI ulcers (gastric/duodenal), gross bleeding/perforation, heartburn, stomatitis, vomiting

<1%: Acute pancreatitis, exacerbation of inflammatory bowel disease, ulcerative stomatitis.

Genitourinary

1–10%: Abnormal renal function

<1%: Flank pain with or without hematuria and/or azotemia, hemolytic uremic syndrome.

Hematologic-Lymphatic

1–10%: Anemia, increased bleeding time, purpura.

<1%: Agranulocytosis, aplastic anemia, hemolytic anemia, lymphadenopathy, pancytopenia, postoperative wound hemorrhage.

Hepatic

1–10%: Elevated liver enzymes.

<1%: Liver failure.

Metabolic

<1%: Hyperglycemia, hyperkalemia, hyponatremia.

Respiratory

<1%: Bronchospasm, pneumonia, respiratory depression.

Miscellaneous
<1%: Edema; angioedema, myalgia, hypersensitivity reactions (e.g., anaphylactoid reaction, anaphylaxis, laryngeal edema, tongue edema).

Drug Interactions (Drugs.com)

ACE inhibitors: increase risk of renal impairment and decrease hypotensive effect.
Alcohol, anticoagulants, corticosteroids: increased tendency for gastric erosion and bleeding.
Aminoglycosides: increase risk of acute renal failure.
Antiepileptic agents: sporadic reports of seizures.
Aspirin, NSAIDs: risk of inducing serious NSAID-related adverse effects. Concomitant use with other NSAID drugs is contraindicated.
Bisphosphonates: may increase risk of gastric ulceration.
Clopidogrel, dextrans, heparin: increase risk of bleeding.
Cyclosporine: increases risk of nephrotoxicity.
Food: Oral administration after a high fat meal may decrease the maximal drug concentration and delay the maximal therapeutic effect.
Furosemide, thiazide diuretics: may decrease diuretic response by 20%.
Lithium and methotrexate: May increase serum levels.
Nondepolarizing muscle relaxants: Case reports of apnea.
Probenecid: increases Ketorolac levels. Concurrent use is contraindicated.
Psychoactive agents: may cause hallucinations.
Quinolones: risk of CNS stimulation and seizures from quinolones may be increased. Quinolone plasma concentrations may be increased. Use with caution.
SSRIs: increase risk of GI adverse events.

Khodadoust Line

Mazeyar Saboori[1] and Nadeem Fatteh[2]
[1]Kresge Eye Institute, Wayne State University School of Medicine, Detroit, MI, USA
[2]Department of Ophthalmology, Kresge Eye Institute, Wayne State University, Detroit, MI, USA

Synonyms

Corneal endothelial rejection line

Definition

Khodadoust line, named after Dr. Ali Asghar Khodadoust, consists of cellular infiltrates that aggregate on the endothelium as a distinct line, which may be observed during corneal allograft endothelial rejection. These inflammatory precipitates can be seen on the endothelial surface in fine precipitates, in random clumps, or in linear

form – Khodadoust line. This line tends to migrate from the peripheral corneal to the central cornea and is typically associated with stromal edema overlying the area traversed by the endothelial rejection line. This line is often considered to be the hallmark of graft rejection. Commonly, endothelial rejection is accompanied by inflammatory cells in the anterior chamber; however, the anterior chamber reaction is usually less severe than expected given the extent of keratic precipitates present. Khodadoust line is also accompanied by corneal stromal thickening and edematous epithelium as endothelial function is hampered during episodes of rejection. The symptoms seen with Khodadoust line are typical of symptoms of inflammation and corneal edema, such as redness, sensitivity to light, decreased vision, discomfort, halos around lights, and pain. Other signs associated with endothelial rejection include ciliary flush and elevated intraocular pressure.

Etiology

Khodadoust line and corneal allograft rejection is an immune-mediated inflammatory process. The rejection line is made of a linearly oriented wave of leukocytes.

Occurrence

The most common form of graft rejection is endothelial rejection, occurring in 8–37% of cases of rejection. As of year 2000, nearly 47,000 corneal transplantations were performed in the United States. The cumulative risk of having allograft rejection has been shown to be 21% at years in large-scale prospective study.

Synonyms

Angioosteohypertrophy syndrome; Hemangiectatic hypertrophy; Klippel-Trenaunay syndrome

Definition

Klippel-Trenaunay-Weber syndrome (KTWS) is a condition that affects the development of blood and lymphatic vessels, soft tissue, and bone.

Etiology

The cause of KTWS is unknown and the disease is sporadic. No specific gene has been associated with the disorder.

Clinical Presentation

The hallmark features of KTWS are "port-wine stains" (i.e., nevus flammeus), venous and lymphatic malformations, and abnormal overgrowth of bone and soft tissue. Vascular malformations are often apparent at birth. Ophthalmic features associated with KTWS include retinal vascular abnormalities, choroidal angiomas, hypertrophy of orbital contents, iris heterochromia, orbital varices, and glaucoma.

The "port-wine stain" is caused by swelling of capillaries near the surface of the skin. They are typically flat and can range from pale to dark maroon in color.

Venous malformations in KTWS include superficial varicose veins that can cause pain, bleeding, and thrombophlebitis and abnormal deep veins that can increase the risk of deep vein thrombosis (DVT) and subsequent pulmonary embolism. Abnormal veins may also be present in the gastrointestinal tract and urinary tract leading to rectal and urinary bleeding. Angiomas of the brainstem, cerebellum, and spinal cord have been associated with KTWS. Lymphatic malformations can be present and cause swelling, pain, tissue breakdown, cellulitis, and ulceration.

The third cardinal feature of KTWS is hypertrophy of bone and soft tissue. Most often this hypertrophy is limited to one leg and can cause pain and a feeling of heaviness. If length discrepancy between legs is large enough, patients can have problems with walking and posture.

Diagnosis

The diagnosis of KTWS is made clinically although imaging studies may assist in the diagnosis. Doppler ultrasonography can be used to evaluate deep venous structures, and magnetic resonance imaging can be used to evaluate soft tissue hypertrophy.

Differential Diagnosis

The differential diagnosis includes Sturge-Weber syndrome, Parkes Weber syndrome, Jahnke syndrome, Schirmer syndrome, Lawford syndrome, Mille syndrome, and Beckwith-Wiedemann syndrome.

Prophylaxis

There is no prophylaxis for this syndrome.

Therapy

Therapy for KTWS is generally supportive and includes compression therapy to help control venous and lymphatic insufficiency, limb elevation, and pain medication. Shoe inserts may be used to manage limb-length discrepancies. Anticoagulant therapy may be indicated to reduce the risk of DVT. Sclerotherapy can be used to eliminate damaged veins and lymphatic vessels, and laser therapy can lighten the color of port-wine stains. Surgery can be used to remove abnormal veins and occasionally to debulk abnormal tissue and correct limb-length discrepancies.

Prognosis

Patients with KTWS generally do well. Care should be taken to avoid complications such as cellulitis, ulceration, skin breakdown, and hemorrhage.

Epidemiology

KTWS is estimated to affect 1 in 100,000 people worldwide. KTWS has no predilection for gender or race.

Knapp's Law

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Synonyms

Aniseikonia correction rule

Definition

Knapp's law is a mathematical calculation that theorizes whether contact lenses or spectacles are best for aniseikonia. According to Knapp:

- Use contact lenses for refractive aniseikonia.
- Use spectacles for axial aniseikonia.

Physiologic and neurologic aniseikonias were not taken into account by Knapp.

Aniseikonia: If the size or shape of an object is perceived differently by the two eyes, aniseikonia exists. Aniseikonia thus means a difference in size or shape between the two monocular visual impressions. This difference is not necessarily due to different retinal images. Aniseikonia can be caused by anatomical, functional (sensory) or geometric-optical factors.

In aniseikonia of anatomical (retinal) origin, the visual elements of the two retinas are differently structured, with the result that the two eyes obtain different perceptions despite identical far point refractions (isometropia) and identical retinal images.

Functional aniseikonia is caused by the central nervous system and can be produced by, for example, fixation disparity. Optical aniseikonia is due to different retinal images in the two eyes.

Different sizes of images on the retinas of the two eyes may be caused by:

1. Different overall lengths of the two eyes despite isometropia.
2. Different magnifications through fully correcting spectacle lenses in the case of anisometropia.
3. Aphakia of the two eyes.
4. Different distances of a near object form the two eyes as a result of oblique fixation of the object.

If an aniseikonia P_{SP} (in %) measured in vision testing at the corneal vertex distance d (in cm) is positive (larger visual impression belongs to the stronger hypermetropic eye or to the weaker myopic eye), a reduction in the corneal vertex distance leads to a decrease in the aniseikonia. If we ignore the shape magnification of the corrective device, the aniseikonia P_{CT} (%) to be expected in the transition to contact lenses can be simply estimated using formula:

$$P_{CT} = P_{SP} - d \cdot \Delta F'_V$$

where $\Delta F'_V$ (in D) is the anisometropic difference. As, however, geometrical-optical considerations regarding the correction of anisometropia neglect anatomical factors (structure of the retinal elements) and physiological factors (processing of the visual stimuli in the visual cortex), exact information can only be obtained by actual measurement of the aniseikonia.

Unilateral aphakia is a special case of refractive anisometropia. Correction with a spectacle lens leads to optical aniseikonia of approximately 25% (if the other eye is emmetropic). A contact lens can reduce the difference in size between the

retinal images to a few percent (about 4%). In numerous cases this permits adequate binocular vision.

Krukenberg Spindles

Kavitha R. Sivaraman[1], Amy Y. Lin[1] and Ahmad A. Aref[2]
[1]Department of Ophthalmology, Illinois Eye and Ear Infirmary, University of Illinois, Chicago, IL, USA
[2]Department of Ophthalmology and Visual Sciences, University of Illinois, Illinois Eye and Ear Infirmary, Chicago, IL, USA

Synonyms

Axenfeld-Krukenberg spindle

Definition

Vertical band of pigment deposition on the posterior corneal surface.

Etiology

German pathologist Friedrich Krukenberg first described a spindle-shaped pigmentation of the cornea in 1899, which he characterized as "bilateral congenital melanosis of the cornea" (Krukenberg 1899; Hartmann 1982). He hypothesized that the retrocorneal pigmentation was a result of abnormal involution of the pupillary membrane during fetal development. However, several decades later, Vogt and others demonstrated that retrocorneal pigmentation was acquired rather than congenital in nature (Hartmann 1982).

Pigment Liberation in the Anterior Chamber

The iris is the primary structure responsible for releasing pigment into the aqueous humor. This can occur due to anatomical predisposition, such as in primary pigment dispersion syndrome (PPDS) when a posteriorly bowed iris results in excessive iridozonular contact. Other etiologies of intraocular pigment liberation include trauma, iritis, intraocular surgery, laser iridotomy, pigmented intraocular tumors, or chaffing from intraocular implants.

Aqueous Humor Convection Current

The circulation of aqueous humor within the anterior segment of a phakic eye is thought to be driven mainly by thermal convection currents. When secreted from the ciliary epithelium in the posterior chamber, the newly produced aqueous humor has a temperature approximately equivalent to core body temperature (37 °C). The cornea is considerably cooler due to exposure to the outside environment and tear film evaporation. This creates a 1.5–2 °C temperature differential across the anterior chamber that in turn generates a thermal convection current. This convection current is thought to govern the circulatory pattern of both the aqueous humor and any pigment granules suspended within (Heys and Barocas 2002).

Recent mathematical models of the human eye support the relationship between the convective flow pattern of the anterior chamber and the pattern of pigment deposition in Krukenberg spindles. In these models, particles emanating from the iris at the pupillary border tend to spend the majority of time circulating along the vertical plane near the central cornea. These particles were also noted to only come into close proximity with the cornea near the vertical midline (Heys and Barocas 2002; Kumar and Acharya 2007).

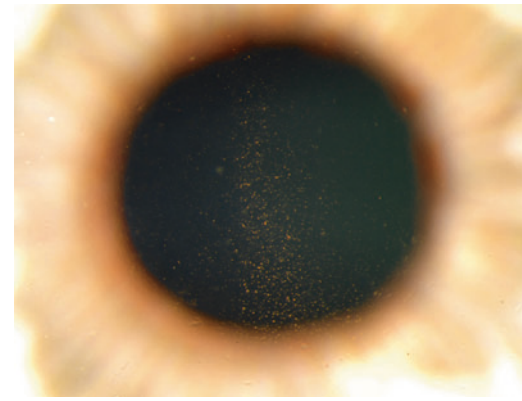
Corneal Endothelial Phagocytosis

Once pigment granules come into contact with the posterior cornea, they adhere to its irregular surface projections. Scanning electron micrograph studies have shown these surface irregularities to be comprised of microvilli, endothelial cilia, and the cellular borders between endothelial cells (Hartmann 1982). Once deposited on the surface, the pigment granules eventually undergo phagocytosis by the endothelial cells and subsequently reside intracellularly (Hartmann 1982).

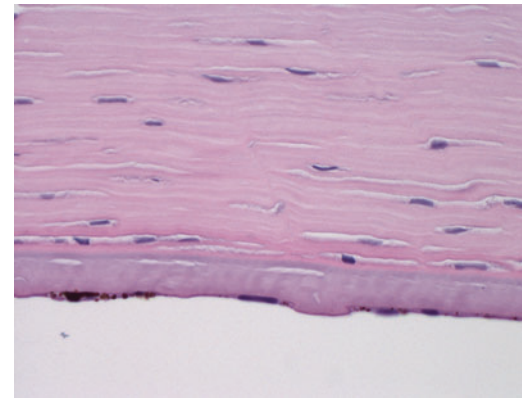
Occurrence

Endothelial pigment deposition in a Krukenberg spindle occurs in the central cornea (Fig. 1). The pigment is arranged in a vertical band measuring 0.5–2.5 mm wide and 2–6 mm in height. The pigment is most dense centrally and tapers off in a vertical fashion, thus creating a "spindle" shape (Evans et al. 1941). Due to the relatively small size and volume of the pigment granules, visual acuity is not affected by the presence of a Krukenberg spindle (Kumar and Acharya 2007).

Krukenberg spindles are classically associated with primary pigment dispersion syndrome (PPDS). However, they are not pathognomonic for this disease as Krukenberg spindles may be found in association with any condition causing pigment dispersion in the anterior chamber. Other conditions that can exhibit a Krukenberg spindle include pseudoexfoliation syndrome, trauma, uveitis, any form of secondary pigment dispersion, and eyes with a history of surgical procedures.



Krukenberg Spindles, Fig. 1 Slit lamp photograph of a Krukenberg spindle. Note the vertical band of central retrocorneal pigment deposition with tapering ends creating a spindle shape (Photo credit: Timothy J. Bennett, CRA, OCT-C, FOPS; Penn State Hershey Eye Center, Hershey, PA)



Krukenberg Spindles, Fig. 2 Hematoxylin and eosin stain of the posterior corneal surface in an eye with primary pigment dispersion syndrome. The Krukenberg spindle is visible histologically as intracellular pigment granules within the endothelial cells (Photo credit: Amy Y. Lin, MD)

Krukenberg spindles should be differentiated from senile retrocorneal pigment deposition which occurs in a diffuse pattern and is more common with increasing age (Hartmann 1982).

Histologically, Krukenberg spindles appear as granules of melanin pigment within the cytoplasm of corneal endothelial cells (Fig. 2). They may

also be seen as extracellular deposits on the posterior corneal surface.

Classification

Krukenberg spindles are an acquired form of retrocorneal pigmentation associated with intraocular pigment dispersion. Due to the association with primary pigment dispersion, the presence of a Krukenberg spindle should alert the clinician to the possibility of pigmentary glaucoma.

Definition

The lacrimal nerve is the smallest of the three major branches of the ophthalmic nerve (CN V1), which in turn is the smallest of the three divisions of the trigeminal nerve (CN V). After it branches from the ophthalmic nerve, the lacrimal nerve enters the orbit through the superior orbital fissure. It follows with the lacrimal artery along the lateral rectus muscle and bifurcates just before penetrating the lacrimal gland. It then passes through the orbital septum and terminates in the skin of the lateral upper eyelid. The lacrimal nerve has only sensory function and provides sensory innervation to the lacrimal gland, conjunctiva, lateral commissure of the eye, and the skin of the lateral upper eyelids. However, before entering the lacrimal gland, the lacrimal nerve communicates with the zygomatic branch of the maxillary nerve and the parasympathetic

https://doi.org/10.1007/978-3-540-69000-9

fibers from the pterygopalatine ganglion that accompany it. These parasympathetic fibers provide some secretory function to the lacrimal gland.

Lagophthalmos

Kirsten Dansey and Ilya Leyngold
Department of Ophthalmology, University of South Florida, Tampa, FL, USA

Definition

A pathological condition that results in the inability to close the eyelids.

Etiology

Lagophthalmos is a common complication associated with other diseases, such as facial nerve palsy (paralytic lagophthalmos) through loss of contraction of the orbicularis oculi muscle, the main muscle responsible for eyelid closure (Latkany et al. 2006). Further etiologies include injuries to the anterior lamella of the eyelid such as trauma, burns, or other cutaneous pathology (e.g., actinic skin damage, skin cancer) where scarring shortens the anterior lamella and does not permit proper eyelid closure (cicatricial lagophthalmos). Iatrogenic causes can also contribute to cicatricial lagophthalmos (e.g., blepharoplasty) where aggressive skin removal does not allow for proper eyelid closure. Proptosis places the individual at a greater risk for developing lagophthalmos, including tumors, thyroid eye disease, or other orbital conditions where the forward displacement of the globe and upper eyelid retraction leads to incomplete eyelid closure (Latkany et al. 2006; Bahn 2010). More recently, sunken upper eyelids and enophthalmos have been identified as causes for lagophthalmos (Latkany et al. 2006). Idiopathic causes account for a minority of the cases of nocturnal lagophthalmos (Latkany et al. 2006).

Occurrence

There are no large-scale studies demonstrating the epidemiology of lagophthalmos; however, the frequency seen within each condition is as follows (Latkany et al. 2006):

The incidence of Bell's palsy is approximately 13–28 per 100,000 individuals (Rowlands et al. 2002). Nocturnal lagophthalmos has been reported to affect every 50 out of 100,000 individuals; meanwhile, Graves' ophthalmopathy has been noted in 16 women and 3 men per 100,000 individuals (Latkany et al. 2006; Bahn 2010).

Classification

The following table lists signs and symptoms of lagophthalmos.

Sign	Symptom
Inability to completely close their eye	Dry eye
Exposure keratopathy	Complaint of foreign body sensation
Corneal scarring or thinning	Visual disturbances
Corneal perforation (rare)	Ocular pain or irritation
Conjunctival injection	Light sensitivity
Vision loss	Tearing
Increased tear film meniscus	
Increased mucous production	

Additional signs and symptoms seen with a seventh cranial nerve palsy include, but are not limited to, lower eyelid ectropion, facial hemiplegia, hearing loss, drooling, posterior auricular loss of sensation, and potential tearing associated with salivation from aberrant regeneration of the facial nerve (crocodile tears). Symptoms associated with Graves' disease include anxiety, palpitations, heat intolerance, and unintentional weight loss. Patients with ichthyosis will describe a personal and family history of dry skin, and the physical exam demonstrates dry skin.

Lamellar Keratoplasty

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Anterior lamellar keratoplasty (ALK); Deep anterior lamellar keratoplasty (DALK); Descemet's membrane endothelial keratoplasty (DMEK); Descemet's stripping endothelial keratoplasty (DSEK); Endothelial keratoplasty (EK); Superficial Anterior Lamellar Keratoplasty (SALK)

Definition

Lamellar keratoplasty (LK) refers to the selective removal of diseased corneal tissue layers and replacement with healthy donor tissue. ALK techniques, such as SALK and DALK, refer to removal of the anterior corneal stromal layers while keeping intact the underlying host Descemet's membrane (DM) and corneal endothelium. EK techniques, such as DSEK and DMEK, refer to the replacement of diseased corneal endothelium and associated DM only while leaving the overlying corneal stroma intact.

Indications

Anterior lamellar transplantation techniques are an option for visual rehabilitation of corneal disease in patients whose endothelium is not

compromised. Examples include superficial stromal dystrophies and degenerations, superficial corneal scars and tumors, corneal stromal thinning (e.g., Terrien marginal degeneration, descemetocele formation, pellucid marginal degeneration), keratoconus, and certain infections (e.g., acanthamoeba), to name a few. On the other hand, EK techniques can be used in patients suffering from endothelial dysfunction without visually significant corneal stromal pathology or scarring, including Fuchs corneal dystrophy, pseudophakic bullous keratopathy, repeat corneal grafts due to endothelial cell failure, iridocorneal endothelial syndrome, and posterior polymorphous dystrophy.

Contraindications

The only absolute contraindication to ALK is endothelial dysfunction. Relative contraindications include deep scars involving DM and preexisting defects and breaks in DM (e.g., acute hydrops). For example, it may be possible to perform pre-descemetic DALK in such conditions if a moderate reduction of vision caused by focal scarring of the DM is an acceptable compromise to the replacement of largely healthy host endothelium. Additionally, depending on the comfort level of the surgeon and degree of DM involvement, defects in DM may be avoided by leaving a thin layer of the stroma in place.

Absolute contraindications to EK include visually significant corneal stromal scarring or opacity and silicone oil in the anterior chamber. There are several relative contraindications; DSEK may be able to be performed if there is adequate space in the anterior chamber with the presence of the following: glaucoma shunt device, peripheral anterior synechiae, iris abnormalities including aniridia, and anterior chamber intraocular lenses. However, DMEK is not recommended in such cases. The thin scroll of DM in DMEK can easily dislodge into the posterior chamber in aphakic and aniridic eyes or eyes with other significant iris abnormalities. In the case of a glaucoma shunt device, the donor endothelium can be damaged by mechanical trauma from the device during donor unfolding. Additionally, the thin donor tissue could potentially lodge in the lumen of the tube if there is excess pressure in the anterior chamber during unfolding.

Techniques and Principles

SALK: A lamellar flap that encompasses the corneal pathology is created and then replaced using a dissection plane of up to 160 um or approximately 30% of the anterior corneal stromal thickness. The flap is trephinated leaving a 1mm rim, and the abnormal tissue is removed. An artificial anterior chamber and microkeratome are used to create the donor disc, which is transferred to the host bed. The donor tissue may adhere spontaneously without sutures, although sutures may be necessary. More recently, femtosecond laser-assisted anterior lamellar keratoplasty (FALK) has been used to perform the lamellar dissections of both host and donor tissues in conjunction with anterior segment OCT, which may allow better matching of the thickness and diameter of the resection.

DALK: Removal of total or near-total corneal stroma in DALK can be achieved in several ways; currently, the Anwar big-bubble technique is the most popular. The cornea is suction trephined and dissected at a depth of approximately 60–80%. Air is injected paracentrally through a 27- or 30-gauge needle or specially designed cannula producing "big-bubble" separation of DM from the stroma. Entry into this space followed by removal of stromal tissue involves a process that meticulously protects and preserves DM. Donor tissue of the same size or oversized by 0.25 mm is sutured in place after donor DM is removed.

DSAEK: A 3–5 mm corneal/scleral or limbal incision is created in the recipient cornea and diseased endothelium, and Descemet's membrane is then removed under air, fluid, or viscoelastic. Lamellar dissection can be performed manually (DSEK), but some surgeons prefer automated means (DSAEK) using a microkeratome. The donor tissue is then trephined to the desired diameter (usually 8–9 mm). The trephined donor posterior lenticule is inserted into the recipient anterior chamber using forceps, glides, or specialized inserters. Once unfolded, an air bubble is used to

appose the graft to the recipient stroma. Methods to facilitate adhesion include scraping the peripheral recipient bed, using midperipheral vent incisions to drain fluid from the interface, and using a roller to sweep the corneal surface. An inferior peripheral iridotomy performed prior to donor insertion can be used to allow nearly full air fill in the anterior chamber at the end of the surgery without producing pupillary block.

DMEK: The donor graft can be prepared by using microforceps to strip DM after trephination of a corneoscleral button or done in more stepwise fashion using an intact corneoscleral rim: (a) DM is scored just inside the trabecular meshwork using a Y-hook and then freed circumferentially with a microfinger; (b) smooth forceps are used to partially peel the DM in quadrants, leaving the center attached; (c) the membrane is floated back into position and the donor trephined lightly into the stroma; and (d) DM is peeled centrally to complete the process. Following a central recipient descemetorhexis, the scrolled donor membrane is inserted using IOL injectors or a glass pipette with an attached bulb to draw up the donor and then inject it into the anterior chamber. Once in the eye, the donor is gently unfolded using techniques such as a combination of short bursts of BSS and air under the graft or using air between the donor and the recipient stroma. Once the donor is unfolded in the correct orientation, air is injected beneath the graft to appose it to the recipient cornea. While some surgeons remove part of the air after 1–2 h to avoid pupillary block, others perform an inferior iridotomy and maintain nearly complete air fill.

Outcomes

SALK/FALK: One series reported improved best corrected visual acuity (BCVA) in all nine eyes at final follow-up with BCVA $\geq$ 20/40 in seven of nine eyes within the first month. Refractive astigmatism also improved by an average of 0.7 diopters. In a series of patients who underwent FALK, 54% of all patients had BCVA greater than 20/30 at the 12-month follow-up, while in another, the mean difference between preoperative and postoperative BCVAs was a gain of 8.0 lines. Graft failure and immunologic rejection episodes are rare with SALK, and an incidence of 0% has been reported in several series.

DALK: Several studies have shown that refractive spherical equivalent, BCVA, contrast sensitivity function, and higher order aberrations in DALK are comparable to PK, especially in keratoconus patients. However, DALK has been shown to significantly reduce the risk of graft rejection and failure relative to PK given the endothelium is not transplanted. Though epithelial and stromal rejection, as well as subepithelial infiltrates can occur, these usually respond well to topical corticosteroids: all 25 patients in two combined reports who suffered from stromal rejection achieved resolution with a clear cornea with the institution of topical corticosteroid therapy.

DSEK/DSAEK: After DSEK, BCVA often ranges from 20/25 to 20/40, precluding other ocular abnormalities. Decreased postoperative visual acuity can be due to superficial irregularities, subepithelial fibrosis, or alterations of the posterior corneal curvature due to irregularities from the lamellar dissection and thickness of the donor tissue. With DSEK, in contrast to PK, there is seldom severe visual loss in an otherwise normal eye from irregular astigmatism or anisometropia. While PK induces on average, 4–5 D of cylinder, the average surgically induced astigmatism with DSEK ranges from −0.4 to +0.6 D with a median of +0.1 D. In addition, DSEK does not require a hard contact lens to achieve best vision. The 5-year graft survival rates for DSEK are reported to be similar to those for PK (95% vs. 93% for Fuchs dystrophy and 76% vs. 73% for pseudophakic or aphakic corneal edema). However, though preexisting glaucoma has been associated with poor long-term PK graft survival, eyes with preexisting glaucoma but no glaucoma surgery have been reported to have a 94% 5-year survival rate. The reported mean endothelial cell loss after PK ranges from 16% to 45% at 1 year, 29–54% at 2 years, and 70% at 5 years. With DSEK, these values range from 13% to 54% at 6 months, 15.6 to 61% at 1 year, and 53% at 5 years (single report).

DMEK: DMEK has been shown to result in visual outcomes that are superior to DSEK and achieved in shorter timeframes. For example, the

3-month rates of 20/20 and 20/25 vision with DMEK exceeded the best rates reported with DSAEK at 6 months and beyond. In one series, at 1 year, 39% of the eyes recovered 20/20 or better BCVA, 79% had 20/25 or better, and 97% could be corrected to 20/30 or better; similar results have been reported by other authors. The risk of rejection was lowest with DMEK in a recent head-to-head comparison of DMEK, DSAEK, and PK performed for the same indications and with the same steroid regimen. Only 1 of 141 DMEK grafts (0.7%) experienced a rejection episode versus 54 of 598 DSAEK grafts (9%) and 5 of 30 PK grafts (17%). The average endothelial cell loss after DMEK was 32% at 6 months (three series), 36% at 1 year (two series), and 34% and 42% at 2 and 3 years, respectively (single report). As with the early DSEK data above, these DMEK results represent early surgical techniques and learning curves in a challenging procedure, and levels of endothelial cell loss may decrease as techniques and surgeon experience improve.

Potential Complications

SALK/FALK: Complications such as residual corneal pathology, interface haze or opacification, anisometropia, recurrence of pathology, haze after adjunctive PRK, dry eye, and epithelial ingrowth have been reported.

DALK: Descemet detachment or pseudo-double anterior chambers can result from fluid in the graft-host interface from a microperforation or retained viscoelastic material. Other potential complications include inflammatory graft necrosis, opacification and vascularization of the interface, epithelial rejection, microbial infections, subepithelial infiltrates, visually significant wrinkles of DM, and stromal rejection.

DSEK/DSAEK: The most common complication is dislocation of the graft, sometimes requiring another air bubble to reattach the tissue; this has been shown in several series to be between 23% and 26%. Other potential complications include pupillary block from air fill of the anterior chamber (avoided with inferior PI), epithelial ingrowth, interface opacification, interface infection, primary graft failure, endothelial cell loss, and cystoid macular edema. Naturally, suture-related complications – some of the main complications after PK, such as infiltrates/abscess, astigmatism, and suture erosions – do not occur with EK procedures.

DMEK: In addition to the complications with DSEK/DSAEK listed above, due to the delicate scroll of graft tissue used with DMEK, the graft itself can be lost. Early studies reported high donor-tissue loss, but this is now rare with improved donor preparation techniques, including the ability of eye banks to prepare DMEK tissue.

Langerhans Cell Histiocytosis

Michael T. Yen[1] and Scott Kelly[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Howerton Eye Clinic, Austin, TX, USA

Definition

Langerhans cell histiocytosis (LCH) is a rare disease involving clonal proliferation of Langerhans

cells (Cotran 2005, Halpern 1997). These abnormal Langerhans cells area derived from bone marrow and capable of migrating to either skin or lymph nodes. LCH is a part of clinical syndromes referred to as histiocytoses, which are characterized by an abnormal proliferation of histiocytes (or activated dendritic cells and macrophages). There are three classes of histiocytoses: Langerhans cell histiocytosis (Class I), non-Langerhans cell histiocytosis (Class II), and malignant histiocytosis (Class III). LCH was previously called histiocytosis X, but was renamed in 1985 (Cotran 2005, Halpern 1997, Satter 2008).

Etiology

Langerhans cells are dendritic cells containing large Birbeck granules found in the epidermis, lymph nodes, and other organs. During infection of an area of skin, Langerhans cells process microbial antigens and become fully-functional MHC class II antigen presenting cells. In LCH, these cells begin to clonally proliferate and can cause damage to skin, bone, lungs, and endocrine glands (Cotran 2005).

Classification

LCH is divided into three types: unifocal, multifocal unisystem, and multifocal multisystem (Cotran 2005).

Unifocal disease involves a slowly progressive, localized disease that may develop in bones, skin, lungs, or the stomach.

Multifocal unisystem disease is usually characterized by fever, bone lesions, and diffuse eruptions often on the scalp. It is usually seen in children. Approximately one half of patients have involvement of the pituitary stalk, causing diabetes insipidus. The triad of diabetes insipidus, exophthalmos, and lytic bone lesions is further classified as Hand-Schuller-Christian disease.

Multifocal multisystem disease involves rapid Langerhans cell proliferation in many tissues. Also known as Letterer-Siwe disease, it is usually seen in children less than 2 years of age, and survival prognosis with chemotherapy is approximately 50%. Fifty-one percent to seventy-one percent of children under age 4 present with multisystem disease, whereas 70% of adults present with disease involvement of a single organ system only (Cotran 2005, Halpern 1997).

A fourth type of LCH is pulmonary Langerhans cell histiocytosis, which occurs exclusively in cigarette smokers. Many patients experience a full recovery with smoking cessation, while others will lead to pulmonary fibrosis and pulmonary hypertension (Cotran 2005, Halpern 1997, Satter 2008).

Prevalence

LCH affects children with a peak incidence between 5 and 10 years of age. The incidence below age 10 is approximately 1/200,000 and is approximately 1/560,000 in adults. It is twice as common in males as in females and is most prevalent in Caucasians (Cotran 2005).

Clinical Features

The proliferation of Langerhans cells invokes an inflammatory response leading to fever, weight loss, and lethargy. Other symptoms depend on site of involvement.

- Skin involvement often leads to scaly, erythematous rash. Extensive rash is seen on the scalp in up to 80% of LCH patients.
- Bone involvement usually involves painful osteolytic bone swelling. The most frequently affected sites are the skull and orbit and then flat bones and long bones of the upper extremities.
- Bone marrow involvement may lead to anemia or pancytopenia.
- Lymph node involvement may lead to enlargement of lymph nodes, liver, or spleen in up to 50% of cases.
- Hypothalamic pituitary axis involvement often leads to diabetes insipidus.
- Other organ involvement leads to deficiencies of that particular organ system. Organs involved in multiorgan disease involve the spleen, liver, lungs, and intestines.

Diagnosis

LCH is confirmed by the presence of Langerhans cells on tissue biopsy. Since 50–80% of patients have skin involvement, a superficial biopsy site is usually accessible. Using light microscopy and hematoxylin-eosin stain, Langerhans cells have pink granular cytoplasm and distinct cell margins. Definitive diagnosis may be determined by the presence of Birbeck Granules on electron microscopy or CD1 positivity on immune-cytochemical stain. Initial workup should include complete blood count with differential and liver function testing (Pinkus et al. 2002). Cranial X-rays should be ordered, as should pulmonary function testing with pulmonary biopsy if a restrictive pattern is found. CT or MRI should be ordered to evaluate for osteolytic bony involvement, as well as for LCH involvement of the Sella Turcica.

Treatment

Treatment is determined by the extent of the disease and the number of organ systems involved. Next, the number of sites of disease involvement (unifocal vs. multifocal) should be determined, as well as whether organ dysfunction is present.

Solitary skin or bone lesions may be treated by excision, topical steroids, or localized radiation. Topical nitrogen mustard is also used for certain unifocal skin eruptions (Halpern 1997, Satter 2008).

Multifocal disease is treated by a combination of chemotherapy and systemic steroids (Halpern 1997, Satter 2008). High-dose, systemic prednisone is considered first-line therapy. Chemotherapy usually includes a combination of alkylating agents, vinca alkaloids, or antimetabolites based upon the LCH III treatment protocol. This protocol has numerous treatment arms based upon location of disease, organ systems involved, and whether organ dysfunction is present. Age is also factored into choosing how aggressively to treat LCH (younger patients have a worse prognosis). An effort has been made to monitor early response to chemotherapy. Patients who respond to chemotherapy have roughly a 90% survival rate, whereas survival rate in patients who do not demonstrate early response drops to 17–34%. Thus, nonresponders need to be started on a more aggressive regimen (Halpern 1997, Satter 2008).

Due to the high prevalence of Pituitary stalk involvement with orbit and/or scalp involvement, orbital lesions are treated locally and systemically with steroids and chemotherapy (Halpern 1997, Satter 2008, Harris 2006). Orbital lesions are often removed through excision, and high-dose prednisone and an appropriate chemotherapy regimen are recommended based on the threat to the central nervous system. Diabetes insipidus resulting from pituitary stalk involvement is often permanent and may need to be treated using lifelong nasal desmopressin supplement.

Prognosis

Prognosis is superb for unifocal disease. Patients who present at a younger age and those with organ dysfunction due to widely disseminated disease have the highest mortality. Lung, liver, spleen, or hematopoietic system involvement portends a worse prognosis. In general, 30% of patients with multifocal disease will achieve remission, 60% will develop chronic disease, and mortality rate is approximately 10%.

Lanthony Tritan Album

Definition

It is a clinical test for rapid detection of blue-yellow color (tritanopic) vision defects.

Basic Characteristics

The Lanthony tritan plates consist of six pseudo-isochromatic plates numbered 0 through 5. Each plate is composed of small gray circles of different shades that together create a square. The circles in one corner of the square are colored to form a smaller square. The patient is asked to determine which corner of the larger square contains the smaller square of a different color. Plate 0 contains a smaller square that is orange and serves as a demonstration plate. Plates 1 through 5 contain violet squares that decrease in saturation progressively from plate 1–5. Thus, the difficulty of reading the plates increases from plates 1–5. The score is on scale of 5 and is determined by the number of the last plate the patient was able to read.

Lanthony tritan plates are used in the clinical setting to detect defects in blue-yellow vision. Blue-yellow vision defects are most often acquired secondary to conditions such as macular disease, optic atrophy, and glaucoma. Defects in red-green vision are not assessed with these plates.

Definition

Ophthalmologists have been using lasers to treat ophthalmic disease since the early 1960s. LASER is an acronym for light amplification by stimulated emission of radiation. There are many types of lasers and most are named for the active medium that they employ to amplify light energy. For example, an argon laser uses ionized argon gas as the active medium. Other examples of active media are rhodamine, carbon dioxide, ruby, Nd:YAG, krypton, and semiconductor materials (termed diode laser). When energy is introduced to the active medium, it is amplified by the excitation of atoms within the medium. The amplified light energy is then emitted as laser energy at a specific wavelength.

Regarding the treatment of ophthalmic diseases, laser energy is used to induce photocoagulation, photodisruption, or photoablation of targeted ocular tissues. We will limit our discussion to the photocoagulative effects of focal laser therapy. When laser energy is absorbed by retinal pigments (melanin, xanthophyll, hemoglobin) and converted to thermal energy, the subsequent temperature rise in the targeted tissue and causes denaturation of tissue proteins and coagulative necrosis.

Indication

While there are many indications for focal laser treatment in ophthalmic diseases, common indications include macular edema due to diabetes or branch retinal vein occlusion and retinal tears/holes requiring retinopexy. Less common indications include choroidal neovascularization (CNV), Coats' disease, arterial macroaneurysm, and retinal hemangioma.

The microvascular insults (e.g., microaneurysms) induced by diabetic retinopathy and/or branch retinal vein occlusion often result in macular edema and decreased visual acuity. Focal laser treatment aims to seal these microvascular insults and decrease the associated macular edema. The Early Treatment Diabetic Retinopathy Study (ETDRS) concluded that all diabetic patients with clinically significant macular edema should receive focal laser treatment.

Due to advances in pharmacological therapy, however, focal laser treatment is less commonly employed for center-involved macular edema associated with diabetes or branch retinal vein occlusion. Nevertheless, it remains as a good therapeutic option in cases with suboptimal response to pharmacological intervention. Similarly, focal laser treatment was previously the primary treatment for CNV; however, it is rarely used currently due to advances in pharmacological therapy for subfoveal CNV.

The goal of prophylactic laser treatment for retinal breaks is to create a chorioretinal scar around the break and prevent fluid from accumulating in the subretinal space. Not all retinal breaks require prophylactic laser retinopexy and there exists a large literature regarding barrier recommendations for the many types of retinal breaks. Examples of retinal breaks include horseshoe tears, retinal dialyses, operculated tears, and atrophic holes. Areas of peripheral retinal degeneration may also be treated with prophylactic laser retinopexy.

Contraindication

None

Techniques and Principles

Focal laser treatment is most often delivered at the slit lamp with the surgeon controlling laser exposure time, power, and spot size. Topical anesthesia is usually employed to facilitate laser treatment, and peribulbar or retrobulbar anesthesia, while rare, may also be used. A contact lens is commonly employed, and surgeons must be careful to understand the orientation (inverted vs upright) of the image as any disorientation during treatment could lead to accidental burns of important retinal anatomy. The surgeon must also be aware of the magnifying effects that the contact lens may have on laser spot size.

When working in sensitive areas such as the macula, the surgeon must optimize laser

parameters to minimize unnecessary damage to adjacent retinal tissue. Examples of laser parameters for focal laser treatment of diabetic macular edema are laser exposure time 0.1 s, laser power 50 mW, and laser spot size 50–100 μm. The surgeon must titrate these settings with the goal of achieving a light retinal burn, evidenced by slight blanching of the targeted retinal tissues.

The choice of optimal wavelength must also be made. The wavelength and absorption characteristics of green and yellow lasers make them useful in treating retinal vascular disease and other ophthalmic conditions. Red laser, with its longer wavelength, can be used to penetrate nuclear sclerotic cataracts, but it causes deeper burns with a higher level of patient discomfort. Conversely, energy from blue lasers is easily scattered by ocular tissues due to its shorter wavelength.

Micropulse photocoagulation involves a series of short laser pulses (approximately 200 μs) separated by a longer rest interval (approximately 1,800 μs). The rest interval allows for heat dissipation and decreased damage to adjacent delicate retinal tissues. Micropulse therapy is often used in a subthreshold manner meaning that no visible intraretinal damage is visible during or after treatment. The goal of subthreshold micropulse laser photocoagulation is to provide treatment while avoiding damage to sensitive photoreceptor cells.

Outcome

ETDRS concluded that focal laser treatment for clinically significant macular edema in diabetes decreased the risk of moderate vision loss by 50%. The Branch Vein Occlusion Study showed that focal laser treatment for macular edema secondary to branch vein occlusion improved vision compared to observation (65% of treatment group gained $\geq$2 lines of vision compared to 37% of observation group).

Advancements in pharmacological therapy for center-involved macular edema have led to a decrease in focal laser treatment; nevertheless, it remains as a good therapeutic option in cases with incomplete response to pharmacological intervention.

Complications

The complications of focal laser treatment are caused by excessive energy use or misdirected laser energy. Corneal, iris, and lenticular burns are possible. Chorioretinal complications of focal laser treatment include foveal/foveolar burns, transient increase of edema, Bruch membrane ruptures, choroidal neovascularization, and subretinal fibrosis. Damage to the optic nerve may also occur.

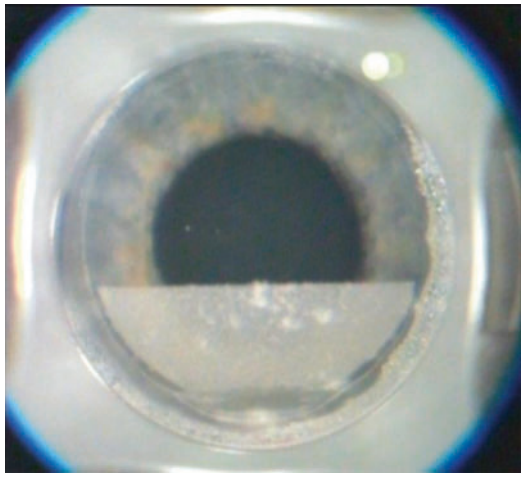
Laser In Situ Keratomileusis

Oliver K. Klaproth and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The ablation of stromal corneal tissue to modify corneal curvature and thus the ocular dioptric



Laser In Situ Keratomileusis, Fig. 1 Flap cut with a femtosecond laser. Shown is the intrastromal lamellar cut at 100 μm depths (Intralase FS60, Abbot)

power to correct ametropia by an excimer laser after cutting and opening of an anterior corneal lamella (flap) is called laser in situ keratomileusis (LASIK) (Kohnen et al. 2008; Fig. 1).

Basic Characteristics

History

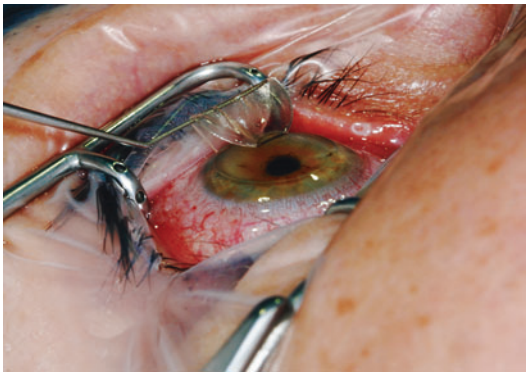
Already in 1980, *Barraquer* introduced a method of lamellar corneal surgery to correct ametropia. His "Keratomileusis In Situ" was basically the mechanical cutting of two central corneal lamellae. The first to open the corneal stroma was not a complete cut but already a flap with a hinge. The second was a complete mechanical keratectomy to change the corneal curvature. However, the flap had to be sutured after the surgery, and the precision of this method was poor. It was in 1990 when *Pallikaris* came up with the idea to combine *Barraquer's* method with the recently developed photorefractive keratectomy (PRK). *Seiler*, *McDonald*, and others proved shortly before that excimer lasers are capable of corneal tissue ablation with μm-precision. Thus, *Pallikaris* could use them to replace *Barraquer's* second total mechanical keratectomy, resulting in precise tissue ablation and thus less complications and better visual results. Since then, the precision of laser systems, ablation profiles, the knowledge of surgical problems, and physiological optics have increased a lot. The mechanical flap cut is at the moment being more and more replaced by more precise femtosecond laser flaps.

Tests/Diagnostics

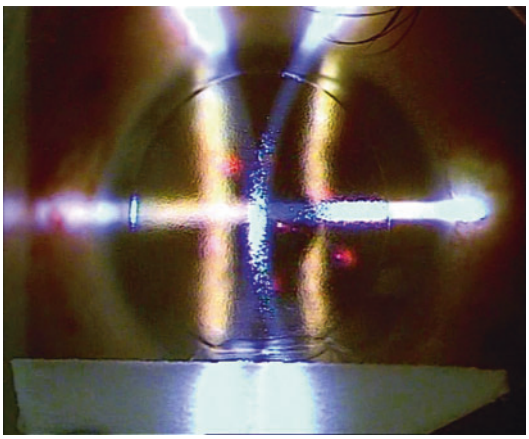
Important preoperative diagnostics to evaluate a patient's eligibility for LASIK and to plan the surgery include manifest refraction, uncorrected and best-corrected visual acuity, pachymetry (optical or ultrasound), corneal topography (Placido) and/or tomography (Scheimpflug), infrared pupillometry for the evaluation of mesopic pupil size, an anamnesis of prior ocular surgery, as well as an ophthalmic inspection to exclude retinal pathology, or blurred intraocular media. Also the patient's expectations and visual requirements need to be taken into consideration. From all these measurements, the decision pro- or contra-LASIK has to be made. Several guidelines exist worldwide, concerning treatment planning, range of possible corrections, and inclusion and exclusion criteria (e.g., by the German Ophthalmological Society and the Professional Association of German Ophthalmologists, Kohnen et al. 2011). These indicate a safe application of LASIK for myopia correction from −1D to −8D (in exceptional cases up to −10D), for hyperopia correction from +1D to +3D (in exceptional cases up to +4D), and astigmatism up to 5D, always considering the absolute refractive power in the strongest meridian, not the spherical equivalent (SE) (Kohnen et al. 2011).

Procedure

The LASIK procedure starts usually with marking of the 0–180° axis after administration of topical anesthesia to avoid intraoperative torsional malpositioning. In case of a cyclotorsional eyetracker, this step can be avoided. Then the patient is placed in a supine position, and the flap cut is being performed, either with a mechanical microkeratome or a femtosecond laser (Fig. 1). This is followed by the opening of the flap with a spatula (Fig. 2), centration of the excimer laser, excimer laser ablation (Fig. 3), and repositioning of the flap including rinsing of the interface. A contact lens can be placed



Laser In Situ Keratomileusis, Fig. 2 LASIK flap in vivo while being opened with a spatula (Geuder)



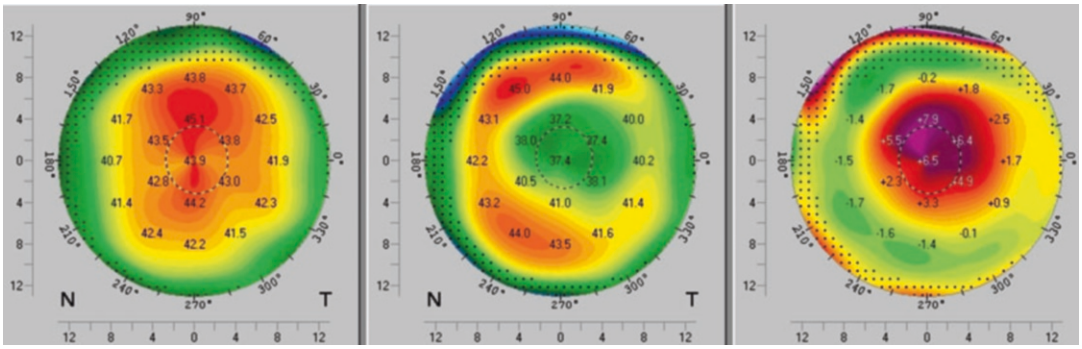
Laser In Situ Keratomileusis, Fig. 3 Excimer laser application in vivo (AMARIS, Schwind)

to protect the cornea for the first 24 postoperative hours. Postoperative medication includes steroids and artificial tears (Kohnen et al. 2008; Fig. 4).

Results

A meta-analysis by *Sakimoto* and colleagues (2006) summarizes the results of different prospective trials on (among others) LASIK. They show that the procedure is precise up to approximately -7D of myopia correction. The percentage of patients within 0.5D of SE is approximately 80%, 3–6 months after surgery. When the treated SE is higher, between -7D and -12D, the rate is only about 60–70%. In case of hyperopia, the threshold lies between 2D and 4D. These results match with the guidelines mentioned above (Kohnen et al. 2011). Another exemplary trial by Rosman and coworkers (Rosman et al. 2010) shows 10-year results of a LASIK cohort. The inclusion criteria were much less restrictive in this trial than they are today. Mean treated SE here was −14.33D. 67% of eyes were within +/−1.00D of emmetropia at 2 years after surgery, compared to 42% at 10 years. Percentages of patients within 0.5D of SE using today's ablation techniques are about 85% in 6–12 months follow-up trials (Kohnen et al. 2008).

According to another meta-analysis (Solomon et al. 2009), comparing different elective surgical



Laser In Situ Keratomileusis, Fig. 4 Corneal topography (anterior axial curvature map [D] pre- (*left*) and post (*middle*) LASIK, as well as the differential map, indicating the change in corneal curvature induced by the LASIK procedure (*right*)). Shown is an aspheric LASIK to correct compound myopic astigmatism (Pentacam HR, Oculus)

procedures, the rate of patient satisfaction after LASIK is 95%, the highest documented rate of all evaluated procedures.

However, there are certain risks and typical complications. These include incomplete or irregular flap cuts (being mainly a problem of mechanical keratomes), over- and undercorrection (which can usually be solved by retreatment), and others like diffuse lamellar keratitis, haze infections, or scars. Nearly all patients suffer from postoperative dry eye, as the flap cut also cuts the corneal nerves resulting in decreased corneal surface sensitivity and less tear film production. The problem usually solves at 1–3 months postoperatively without any therapy. Artificial tears may however be administered. The worst case scenario is the iatrogenic ectasia, a weakening of the cornea; manifestation and therapy are comparable to keratoconus, either by too much tissue ablation or by applying the LASIK procedure to an already weak cornea, e.g., in subclinical forme fruste keratoconus.

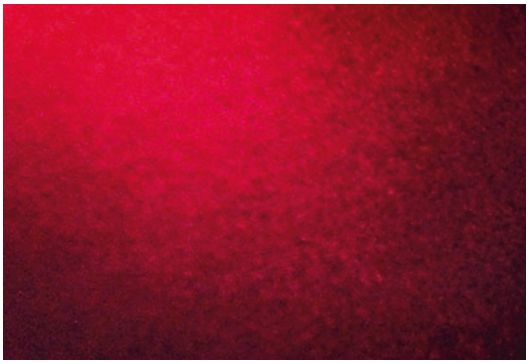
Laser Speckle

Rahul Yadav
Department of Ophthalmology, Center for Visual Sciences, University of Rochester, Rochester, NY, USA

Introduction

Speckle pattern is a highly granular and contrasted intensity pattern that is observed when a coherent wave is scattered from a diffuse object. Since lasers are highly coherent sources of light (an electromagnetic wave), speckle pattern is observed when the laser light is scattered from a diffuse object. This speckle pattern is known as laser speckle.

Laser speckle can be easily observed with a laser pointer and a white paper. Take a laser pointer and shine it on a wall, dim the lights in the room, and bring the paper close to where the laser pointer is hitting the wall. On the paper, a granular pattern can be seen; this granular pattern is laser speckle (Fig. 1).



Laser Speckle, Fig. 1 Laser speckle pattern observed for laser light scattered from a diffuse sample

Explanation

When a monochromatic light is made incident on a diffuse surface, the scattered field at any arbitrary observation point is a superposition of the wavelets reflected from infinitesimal contributors on the incident surface. The infinitesimal contributors produce wavelets which have same wavelength but random phase. If the surface is rough enough such that the phase difference between two wavelets is greater than one wavelength, the superposition of these wavelets can produce a field which could be anything ranging from zero to the sum of all the wavelets. Note that if the observation point is changed then the relative phase shift between individual wavelets will also change, therefore the resulting field at this observation point can have a totally uncorrelated value from the first observation point. This results in the granular pattern observed in speckle where bright spots are observed at locations where the wavelets interfere constructively, dark spots where the wavelets interfere destructively, and intermediate values at locations where the interference is in between the two extremes.

Properties

Speckle pattern from any diffuse surface changes on changing the wavelength of light. This is because the phase relationship between individual wavelets is different for different wavelengths. Similarly, the phase relationship between individual wavelets can change with the angle of incidence of the laser beam. The speckle pattern therefore also changes if the laser is shined at different angles on the diffuse surface.

Speckle pattern has polarization dependence too. If a polarized laser beam is shined onto a rough surface, significant amount of depolarization of the laser beam is observed. If an analyzer is kept in front of the speckle pattern and is rotated, then the speckle pattern observed on the screen changes. This is happening because when a laser beam scatters from a rough surface the polarization of individual wavelets is modified in a random way. When we rotate the polarizer, we change the relative contribution of each wavelet to the interference pattern, thus changing the speckle pattern

Speckle Suppression

Although speckle is now being used for certain applications (see next section), in most of the cases speckle is a problem. The presence of speckle in an image adds noise and reduces the ability to resolve fine details. Speckle noise is a major limitation of coherence-based imaging modalities such as optical coherence tomography. Most of the techniques used to suppress speckle are based on generating a superposition of identically distributed but mutually uncorrelated speckle patterns to wash out the random granularity. The contrast reduction factor for these superposition approaches is proportional to the square root of the number of superposition states used. Typical approaches include spatial diversity, wavelength diversity, and polarization diversity.

Spatial Diversity: By spatially moving the illuminating laser beam or speckle producing sample, we can create mutually uncorrelated speckle patterns, which could then be superimposed to reduce speckle contrast. One approach to do this is to illuminate the speckle producing surface at different angles. Since the speckle pattern is different for different angles of incidence, the cumulative speckle pattern averages out and speckle pattern contrast is reduced. Other

approach is to move or rotate the speckle producing surface. If the detector's integration time is significantly large enough, then the superposition of speckle pattern from different parts of the sample is detected on the detector thus reducing the contrast of the speckle pattern.

Wavelength Diversity: As mentioned previously, speckle pattern changes with wavelength of incident light. This approach reduces the contrast of the speckle pattern by illuminating the sample with different wavelengths.

Polarization Diversity: Since speckle has polarization dependence, speckle is naturally reduced when unpolarized light is used. Although this approach is simple to implement, as polarization diversity is limited to just two orthogonal polarization states, maximum contrast reduction factor that can be achieved is limited to the square root of two.

Besides the hardware related techniques of speckle reduction described above, numerous methods of numerically removing the speckle during image postprocessing have also been proposed. These techniques use a statistical model to predict the properties of speckle pattern and then apply appropriate image processing filters to remove it.

Applications of Laser Speckle

For most applications, speckle pattern is a nuisance; however, speckle pattern can also function as the carrier of information. Since the speckle pattern is observed for rough samples and not for polished surfaces, it can be used as a measure of the surface roughness of the surface. In industrial applications where systems are sensitive to movements or deformations at micron scales, speckle can be used to sense these changes as slight movement of the sample can produce a change in the speckle pattern.

In the medical area, speckle has been used to measure the velocity of blood flow, the idea being that higher the velocity of blood flow higher will be the suppression of speckle. This approach is called laser speckle contrast imaging and has been utilized for tissue perfusion in capillaries of human skin tissue and cerebral blood flow mapping in rodents. Laser speckle has also been used to measure blood coagulation status in wounds. The Brownian motion of proteins in the blood changes with blood coagulation, thus changing the speckle pattern fluctuations, which can be detected and quantified. In ophthalmology, there are proposals to use these laser speckle-based techniques in measuring circulation in retinal blood vessels.

There is a lot of activity and interest in the medical research community to use these speckle-based techniques for medical applications. With its simplicity of implementation and relatively low cost, these speckle-based techniques have a potential to become a popular medical diagnostic technique in future.

Lash Follicle, Tumors Arising in

Jeremiah Tao and Steven J. Yoon
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Pilomatrixoma; Trichilemmoma; Trichoadenoma; Trichoepithelioma; Trichofolliculoma; Tumors of pilar origin

Definition

Tumors affecting the eyelash follicle include trichoepithelioma, trichofolliculoma, trichilemmoma, and pilomatrixoma. All are somewhat uncommon and almost always benign.

Characteristics

Trichoepithelioma is a small, skin-colored nodule that occurs on the forehead or eyelids. Lesions may be misdiagnosed as papillomas or cutaneous horns, and larger lesions may have telangiectasias and resemble basal cell carcinoma. Surgical excision is curative.

Trichofolliculoma is a dome shaped, skin-colored nodule. It is umbilicated centrally and may have white lanugo hairs which may protrude from the lesion. Excisional biopsy is curative.

Trichilemmoma is a solitary lesion with a similar appearance as verrucae. They are composed of glycogen rich cells surrounding the hair follicle. Multiple trichilemmomas may be a sign of Cowden's disease, an autosomal dominant disorder characterized by oral and acral papules, thyroid goiters, lipomas, intestinal polyps, and fibrocystic breast disease. Cowden's disease combined with cerebellar hamartomas is known as Lhermitte-Duclos syndrome.

Pilomatrixoma is a lesion of young adults, arising on the base of hair follicles on the eyebrow or central upper eyelid. It presents as a subcutaneous purplish mass. Surgical excision is curative (Albert and Jakobiec 2008; Shields and Shields 1999).

Differential Diagnosis

Trichoepithelioma
Trichofolliculoma
Trichilemmoma
Pilomatrixoma

Lateral Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

An orbitotomy allowing access to the deep orbit in both extra- and intraconal spaces lateral to the optic nerve.

Indications

To access the lateral and deep posterior orbit for biopsy, orbital decompression, foreign body removal, etc.

Contraindication

Any medical contraindication to surgery.

Techniques and Principles

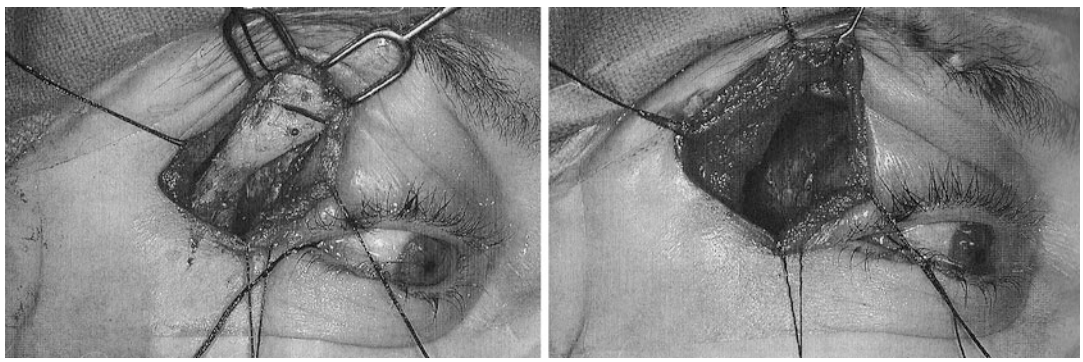
This procedure is generally performed in the operating room under sedation or general anesthesia. Often, this approach involves temporary removal of the lateral orbital rim to maximize exposure for deep lesions. A skin incision is usually placed at the lateral canthus and extended laterally as necessary, for approximately 2 cm. A superior and inferior cantholysis is performed and the lateral orbital wall is exposed. A cutting saw is used to remove the orbital rim and anterior lateral wall (Fig. 1), which is either sutured or plated back in place at the end of the case. With this technique, the surgeon has an unobstructed view into the deep lateral orbit (Cockerham et al. 2001; Nerad 2001; Levine 2003). A coronal scalp flap has also been described to access this area (Paolini et al. 2006).

Outcome

Allows for biopsy, lesion removal, foreign body removal, drainage of orbital abscess, and bony decompression as necessary.

Complications

Risks include anesthesia, bleeding, pain, infection, scarring, lower eyelid retraction, swelling,



Lateral Orbitotomy, Fig. 1 The lateral orbitotomy: Dissection has been carried down to periosteum and the lateral orbital rim has been exposed. A saw cut is shown superiorly with preplaced drill holes to replace the rim at the end of the procedure (*left*). Lattice Dystrophy

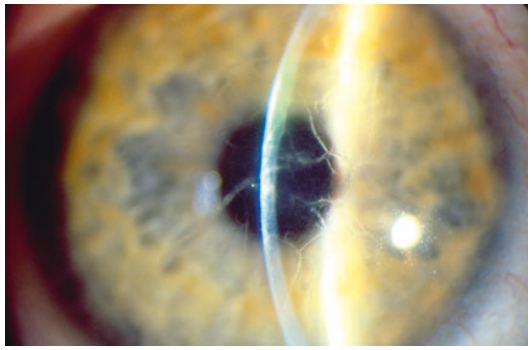
Marcus Neuffer
Department of Ophthalmology, Keesler Medical Center, Biloxi, MS, USA

Synonyms

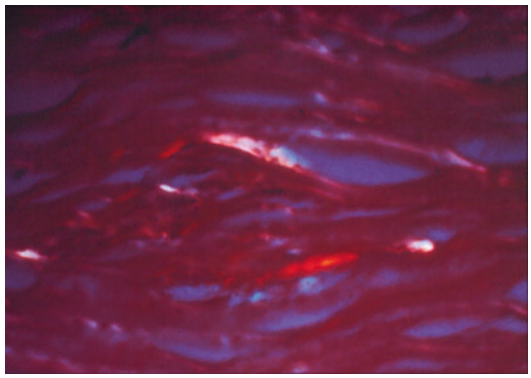
Biber-Haab-Dimmer dystrophy; Classic LCD; Lattice corneal dystrophy (LCD), type 1

Definition

There are two types of lattice dystrophy. LCD type 1 is a bilateral inherited stromal corneal



Lattice Dystrophy, Fig. 1 Central branching lattice lines with anterior stromal haze



Lattice Dystrophy, Fig. 2 Light microscopy demonstrating amyloid deposits

dystrophy involving localized corneal amyloid deposits that lead to recurrent erosion and decreased vision. There are different variants of LCD (III, IIIA, I/IIIA, and IV). Type II (Meretoja's syndrome) is a systemic amyloidosis with corneal involvement and not a true corneal dystrophy (Figs. 1 and 2) (Krachmer et al. 2011).

Etiology

LCD type 1 is autosomal dominant and caused by a genetic mutation at 5q31 gene locus. Type III variant is autosomal recessive. Type IIIA and IV variants are both autosomal dominant. LCD type II is autosomal dominant and caused by a genetic mutation on chromosome 9 (Musch et al. 2011).

Clinical Presentation

LCD type 1 presents in the first decade of life with refractile filamentary lines and anterior stromal opacities. With progression, nodules and thick threadlike spicules develop. The stroma between the lines and opacities is initially clear, but eventually, the opacities coalesce and a progressive corneal haze ensues. Like other corneal dystrophies, painful recurrent erosions and an irregular epithelial surface develop. Decreased corneal sensation and vascularization may also be present. Contrasting, type III variant has a late onset of decreased vision and is usually not accompanied with recurrent erosions (Musch et al. 2011).

LCD type II or Meretoja's syndrome presents later in life and has a systemic presentation. Cranial and peripheral neuropathies develop as abnormalities in the skin, arteries, and other organs. Eye examination reveals fewer and more peripheral filamentary lines than in LCD type I. Recurrent erosions are also more infrequent and vision is not affect until later in life than with LCD type I (Krachmer et al. 2011).

Diagnosis

On slit lamp examination, the line branch overlaps one another making a latticework pattern. In light microscopy an eosinophilic layer separates the epithelial basement membrane from Bowman's layer. This layer is made of amyloid and collagen. Amyloid deposits are also found in the stroma and stain orange red with Congo red. With a polarizing filter, the deposits exhibit green birefringence. Thioflavin T staining demonstrates fluorescence and crystal violet staining demonstrates metachromasia (Musch et al. 2011).

Transmission electron microscopy reveals extracellular masses of randomly aligned fibrils. Confocal microscopy shows linear structures in the stroma with varying reflectivity (Krachmer et al. 2011).

Differential Diagnosis

The differential diagnosis includes recurrent corneal erosion, polymorphic amyloid degeneration,

Avellino dystrophy, granular dystrophy, macular dystrophy, and prominent corneal nerves.

Prophylaxis

There is no known prophylaxis.

Therapy

Recurrent erosions are treated as needed with topical lubricants, topical cycloplegics, antibiotic ointments, bandage contact lenses, and pressure patching. If recurrent erosions are not responsive to conservative treatment, then phototherapeutic keratectomy (PTK) is an option. Lamellar and penetrating keratoplasty is reserved for when the vision deteriorates significantly. Lattice dystrophy recurs more frequently in grafts than granular or macular dystrophy (Musch et al. 2011).

Prognosis

Corneal erosions recur and persist leading to scarring and decreased vision. Visual deterioration is progressive and frequently leads to corneal transplantation in the fourth decade of life (Krachmer et al. 2011).

Epidemiology

Lattice dystrophy is rare with a 5 years prevalence rate of less than 0.001%. The onset is usually in the first decade of life and is more commonly in Caucasians. No gender predilection is noted (Weiss et al. 2008).

Synonyms

Lattice corneal dystrophy; Localized corneal amyloidosis

Definition

Lattice lines are amyloid deposits in the corneal stroma, producing branching fibers that create a latticelike pattern.

Structure

Lattice lines are produced from localized corneal amyloidosis, in which amyloid is deposited in a branching pattern in the cornea. These linear deposits are generally produced from localized intracellular production of amyloid in the cornea, but may also include leakage from serum and extracellular breakdown of corneal collagen.

Amyloid demonstrates a beta-pleated fibrous protein structure, and deposits vary based on the type of amyloidosis. Amyloidosis is divided into the systemic or localized form and further classified into primary and secondary forms. In primary systemic forms of amyloidosis, amyloid deposits contain portions of immunoglobulin light chains (protein AL). In secondary systemic forms of amyloidosis, the amyloid deposits consist of non-immunoglobulin protein (protein AA), otherwise known as a degraded product of serum amyloid A protein, an acute-phase reactant protein present in the serum. In both primary and secondary amyloidosis, amyloid deposition consists of normal protein present in the serum (protein AP). In lattice dystrophy, only the protein AP is present in amyloid deposits. However, lattice corneal dystrophy type III is the exception, in which case some deposits respond weakly to antibodies for amyloid protein AA in immunohistochemical assays.

Histologically, amyloid deposits stain with Congo red, periodic Acid-Schiff, and Masson's trichrome and demonstrate dichroism and apple-green birefringence under polarized light.

Lattice lines can be seen through slit-lamp biomicroscopy, indirect illumination, and retroillumination of the eye. The refractile lines overlap one another, illustrating a latticework pattern. In early manifestations, lattice lines are seen as ovoid subepithelial opacities, anterior stromal white dots, and refractile linear lines. As lesions further progress, they can be appreciated as small nodules, or thicker, radially branching lines. With time the opacities will begin to coalesce, producing stromal haze.

All lattice corneal dystrophies (LCDs) are characterized by the presence of deposits between the epithelial basement membrane and Bowman's layer. However, multiple variants of lattice lines have been described in the different subtypes of lattice corneal dystrophies:

1. LCD1 – Numerous rodlike glassy opacities in a linear, branching pattern with more dense opacities centrally. LCD1 maintains a clear peripheral perilimbal cornea. Ultrastructural examination shows electron-dense fibrils with a diameter of 80–100 Å.
2. LCD2 – Few thick linear lines extending to the limbus.
3. LCD3 – Thick, ropy midstromal lattice lines scattered throughout the corneal stroma, which extend to the limbus.

Lattice Lines, Table 1 Lattice corneal dystrophies due to keratoepithelin gene defects

Dystrophy	Defect
Lattice I	Arg124Cys, Ala546Asp, Pro551Gln, Leu518Pro
Lattice IIIA	Pro501Thr, Arg124Thr, Ala622His, His626Ala
Lattice IV	Leu527Arg

TGFB1/BIGH3 (keratoepithelin gene) genes are responsible for corneal dystrophies inherited in an autosomal-dominant manner. Mutations in the BIGH3 gene cause amyloid deposition in different patterns. Lattice corneal dystrophy type I has an autosomal-dominant inheritance with a disease resulting in mutations at 5q31 locus. The most frequent defect is at codon 124 where the amino acid arginine is replaced by cysteine. It is proposed that common mutations at positions 124 and 555 are likely to affect protein-protein interactions, causing misfolding within the cell. Specific functions of TGFB1 in the cornea are unknown, but it may act as a cell adhesion molecule and a linker protein interconnecting matrix molecules to each other (Table 1).

Function

Lattice lines are small retractile filamentary lines composed of amyloid and contribute to corneal haze. Over time, the lattice lines will grow more

opaque and converge, contributing to central clouding and decreased visual acuity.

Clinical Relevance

Lattice lines are seen in almost all patients with lattice corneal dystrophy. Typically, lattice lines are seen bilaterally; unilateral involvement has been reported. Treatment of the disease is based on the patient's symptoms. Clinical manifestations of the disease vary based on the type of LCD a patient is diagnosed with:

1. LCD1 – Amyloid opacities commonly lead to frequent recurrent erosions and irregularity of epithelial surface, with accompanying decreased visual acuity. Central corneal sensation may also decrease. Occurs in the first decade of life.
2. LCD2 – Recurrent erosions are infrequent and visual disturbance is less than LCD1. These patients have cranial neuropathy and systemic amyloid deposition in addition to corneal amyloidosis.
3. LCD3 – Recurrent erosions are infrequent. LCD3 often occurs later in life, after 40 years of age.

Treatment for lattice lines varies based on the severity. Treatment for recurrent erosions includes patching, artificial tears, and therapeutic soft contact lenses. If visual acuity is impaired significantly, penetrating keratoplasty is the treatment of choice.

Law of Reflection: Definition

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Synonyms

Reflection law

Definition

The law of reflection refers to the reflection of light-rays off smooth conducting surfaces, such as polished metal or metal-coated glass mirrors. Consider a light-ray incident on a plane mirror, the law of reflection states that the incident ray, the reflected ray, and the normal to the surface of the mirror all lie in the same plane. The angle of reflection is equal to the angle of incidence. Both angles are measured with respect to the

normal to the mirror. The law of reflection also holds for nonplane mirrors or rough surfaces (diffuse reflection).

Cross-References

Law of Refraction (Snell's Law)

Achim Langenbucher
Institute of Experimental Ophthalmology, Saarland University, Homburg, Saar, Germany

Synonyms

Law of Snellius; Refraction law

Definition

The law of refraction deals with propagation of light rays across a sharp interface between two transparent dielectric media. The law of refraction states that the incident ray, the refracted ray, and the normal to the interface all lie in the same plane. The angle subtend between the incident ray and the normal to the interface Θ_1 is transformed to an angle Θ_2 of the refracted ray with $n_1 \sin\Theta_1 = n_2 \sin\Theta_2$, where $n_{1/2}$ refers to the refractive indices of the media before/after passing the interface.

Le Fort Fractures

Gary Joseph Lelli[1], Dara Liotta[2], Ashutosh Kacker[2] and Anne Barmettler[1]
[1]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA
[2]Department of Otorhinolaryngology, Weill College of Medicine of Cornell University, New York, NY, USA

Synonyms

Craniofacial disjunction (Le Fort III); Guerin fracture (Le Fort I); Horizontal fracture (Le Fort I); Maxillary fractures; Pyramidal fracture (Le Fort II)

Definition

In 1901, Rene Le Fort categorized fracture patterns of the Maxilla resulting from a single blow to cadaveric skulls. The fracture lines, or "linea minoros resistentiae," described by Le Fort in 1901 are the basis for the modern Le Fort classification. A Le Fort I fracture (also known as a Guerin fracture or horizontal fracture) is a single horizontal fracture through the maxilla that passes through the septum medially, extending laterally through the pyriform rims, passing below the zygomaticomaxillary suture line, and transecting the pterygomaxillary junction to interrupt the pterygoid plates. Le Fort I fractures result in a mobile hard palate. A Le Fort II fracture (pyramidal fracture) passes through the nasal bridge medially (at or around the nasofrontal suture), extending laterally through the frontal process of the maxilla, lacrimal bones, orbital floor, inferior orbital rim, anterior wall of the maxillary sinus, passing below the zygoma, and transecting the pterygomaxillary junction to interrupt the pterygoid plates. Le fort II fractures result in a pyramid-shaped mobile bone fragment that includes the nasal complex and entire maxilla, including the

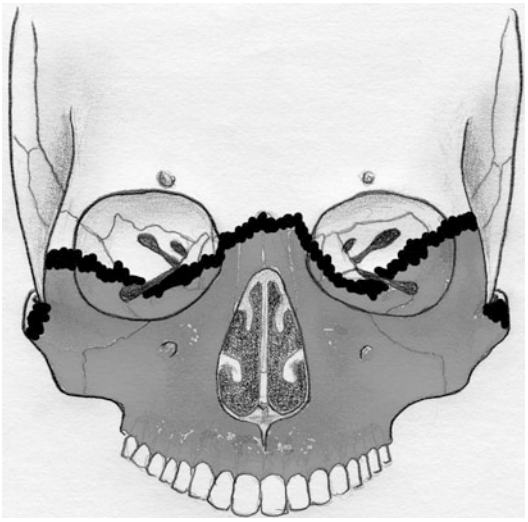
Le Fort Fractures, Fig. 2 Le Fort II fracture (pyramidal fracture). The *shaded area* represents the resultant mobile bone fragment

hard palate. A Le Fort III fracture (craniofacial disjunction) passes through the nasal bridge medially (at or around the nasofrontal suture), extending laterally through the medial orbital rim, medial orbital wall, nasolacrimal groove, ethmoid bones, floor of the orbit, inferior orbital fissure, lateral orbital wall, zygomaticofrontal suture, and zygomatic arch. Internally, the fracture extends though the perpendicular plate of the ethmoid, vomer, and pterygoid plate interface, to the base of the sphenoid posteriorly. A Le Fort III fracture separates the entire midface from the cranium. The resultant mobile bone fragment includes the nasal complex, inferior half of the orbit, zygoma, and entire maxilla, including the hard palate. It is important to realize that pure Le Fort fractures are uncommon in clinical practice and most midfacial fractures are an amalgam of various types of Le Fort fractures. Pure Le Fort fractures occur in less than 50% of midfacial fractures (Figs. 1, 2, and 3).



Le Fort Fractures, Fig. 3 Le Fort III fracture (craniofacial disjunction). The *shaded area* represents the resultant mobile bone fragment

Basic Characteristics

Etiology

Le Fort fractures are generally the result of blunt-force trauma to the midface. Common causes include motor vehicle accidents, interpersonal altercations, assaults, falls, and sports-related injuries.

Clinical Presentation

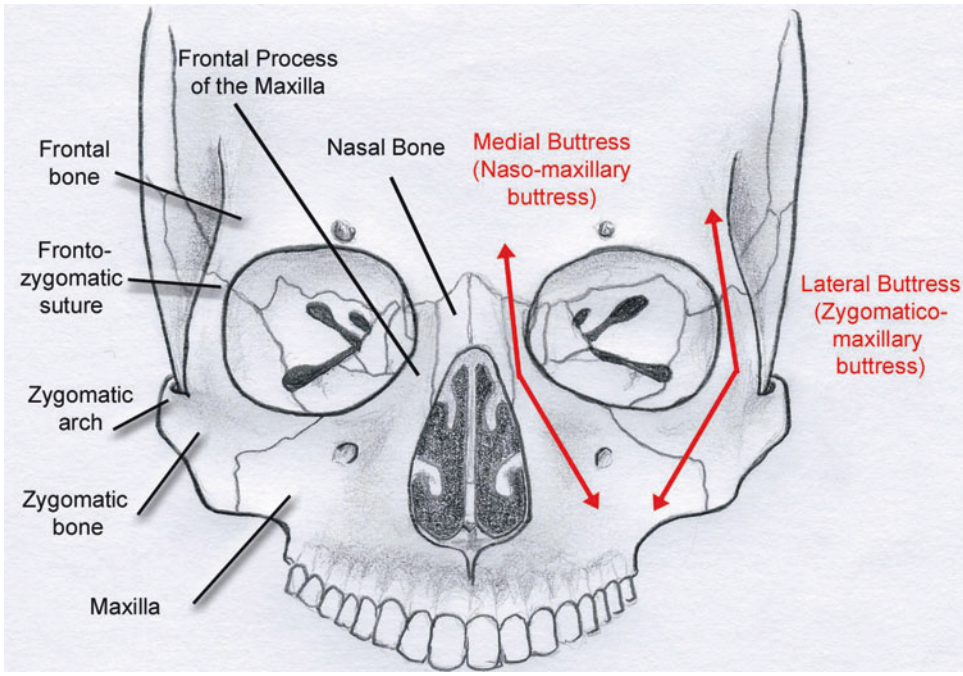
Maxillary fractures often occur as the result of significant trauma, and evaluation should

begin with airway control and hemodynamic stabilization. Serious intracranial injury may be seen in up to 38% of patients with midfacial fractures; serious ophthalmologic injury may be seen in up to 28% of patients. Spinal cord injury should be ruled out, and any overt globe injury should be evaluated. A thorough history and physical, including a complete head and neck exam, may then be performed.

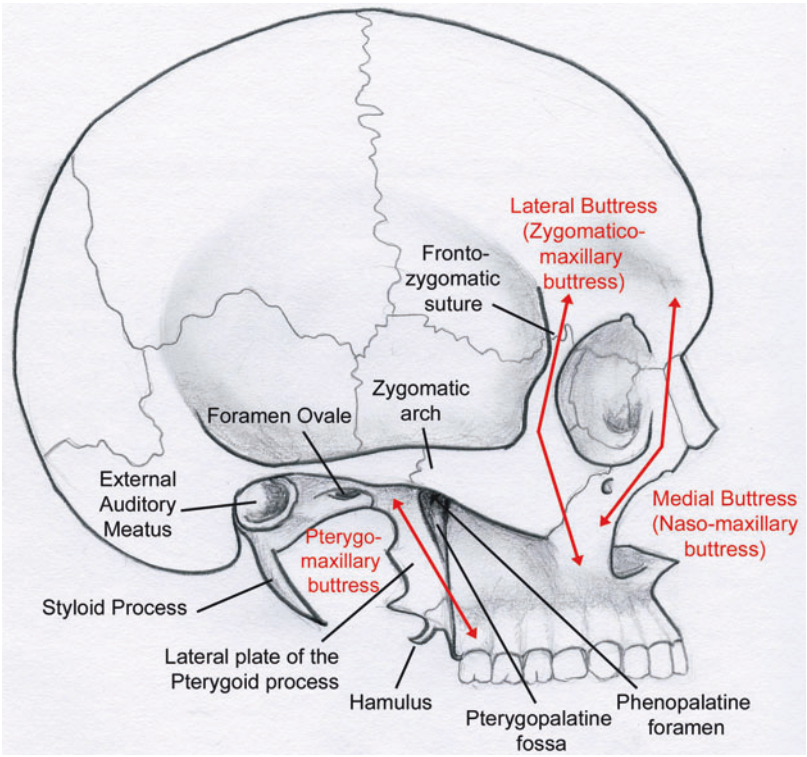
The midface is attached to the cranium by three vertical buttresses that help distribute masticatory forces and stabilize the midface: the medial buttress (frontomaxillary buttress) and lateral buttress (zygomaticomaxillary buttress) anteriorly and the pterygomaxillary buttress posteriorly. Le Fort fractures disrupt these buttresses, resulting in altered vertical height of the midface, malocclusion with open bite, and mobile bone fragments that may cause airway compromise. Mobile bone fragments that result from Le Fort fractures tend to be driven posteroinferiorly along the slope of the skull base, producing a flattened facial appearance. Palatal fractures may occur along with Le Fort fractures and intraoral ecchymosis, lacerations or palpable step-offs may be appreciated. As Le Fort II and III fractures necessarily disrupt the nasal bridge, naso-orbital-ethmoid complex, and orbital rims, these types of fractures result in more obvious external findings such as nasal deformity, subconjunctival and periorbital ecchymosis and edema, infraorbital anesthesia from injury to the infraorbital nerve, possible gaze restriction or diplopia from soft tissue entrapment, or CSF rhinorrhea from disruption of the cribriform plate. Le Fort III fractures may result in bleeding from basilar skull fractures near the stylomastoid foramen. This bleeding may track superficially, resulting in ecchymosis overlying the mastoid process and occiput (Battle's sign). Significant facial edema is common with Le Fort fractures, and it is important to keep in mind that presence of a Le Fort fracture does not rule out presence of additional maxillofacial injuries (Figs. 4 and 5).

Diagnostics

Le Fort II and III fractures involve orbital wall fractures, and the eye must be completely



Le Fort Fractures, Fig. 4 Anteroposterior view of the vertical buttresses of the facial skeleton



Le Fort Fractures, Fig. 5 Lateral view of the vertical buttresses of the facial skeleton

evaluated. Intracranial injury must also be ruled out, and suspicion for CSF rhinorrhea should be high. Maxillofacial CT scan is considered the modality of choice for diagnosis of Le Fort fractures.

Treatment

Treatment of ocular and CNS injuries should precede treatment of Le Fort fracture in the presence of a stable airway. Proper repair of complex midfacial fractures may require a surgical airway. Treatment greatly depends on the extent of the injuries and often requires a multispecialty approach.

Reconstruction of the zygomaticomaxillary buttress (lateral buttress) and fronto-zygomatic buttress (medial buttress) is an important part of restoring normal occlusion and vertical height of the midface and stabilizing the midfacial skeleton against masticatory forces. Palatal fractures may accompany Le Fort fractures, and it is important to recognize when palatal fractures are present, as palatal splints will be required during repair.

Synonyms

Leber optic atrophy; LHON

Definition

Leber hereditary optic neuropathy is an inherited disease that causes degeneration of retinal ganglion cells and bilateral visual loss.

Etiology

LHON is caused by mitochondrial DNA mutations and is maternally inherited. The most frequent disease causing mutation is a single base pair mutation at position 11778. Mutations at positions 3460 and 14484 are the next most common mutations. These mitochondrial mutations lead to impaired mitochondrial adenosine triphosphate production, which affects highly energy-dependent cells such as the retinal ganglion cells and leads to degeneration of the optic nerve and visual loss. Not everyone harboring one of these mitochondrial mutations will develop the disease. It is estimated that up to 50% of males and 85% of females that have a mutations will develop no signs or symptoms of the disease. This variable penetrance and expressivity can make a positive family history hard to elicit. In addition, the mutation may arise de novo.

Clinical Presentation

LHON typically affects males at age 10–30 years but both men and women can be affected. The age of onset is also highly variable. The most common presenting feature in LHON is painless vision loss OU. At onset, the vision loss is most often unilateral and associated with relative afferent pupillary defect (RAPD), but then becomes bilateral eventually. Fundoscopic examination may be normal at onset but classically reveals peripapillary telangiectasia, tortuosity of the medium-sized retinal arterioles, and "pseudoedema" of the optic disc. Pseudoedema is characterized by hyperemia and elevation of the optic disc and thickening of the peripapillary retina, without the leakage on fluorescein angiography. After visual loss the optic disc eventually becomes atrophic. The visual field defect is characterized by central or cecocentral scotomas. Occasionally, some patients may develop cardiac conduction abnormalities or other mild neurologic deficits and further evaluation is warranted.

Diagnosis

The diagnosis is made based on ophthalmologic findings. Testing for the three most common mitochondrial DNA mutations may confirm the diagnosis.

Differential Diagnosis

Optic neuritis, compressive optic neuropathy, and infiltrative optic neuropathy.

Prophylaxis

There is no proven prophylaxis; however, it is theorized that avoiding substances such as tobacco and excess alcohol may be beneficial because these substances increase energy demands.

Therapy

Therapy is largely supportive including visual aids, occupational rehabilitation, and genetic counseling. Agents that may increase mitochondrial energy production such as coenzyme Q10 and succinate have been used but without definite success. Antioxidants have also been used without definitive success and corticosteroids are not beneficial. Idebenone has also shown modest improvement in patients with LHON, but currently no proven effective treatment for LHON exists.

Prognosis

The majority of patients have permanent central vision loss in both eyes; however, central vision may eventually improve in 10–20% of patients depending on mutation. The likelihood of spontaneous visual improvement is higher in patients with a mutation at location 14484 than at location 11778.

Epidemiology

LHON affects males more commonly than females. Women account for only 10–20% of cases. The onset of LHON is typically in the age range of 10–30 years; however, it can occur in early childhood or later in adulthood. The prevalence of LHON has been estimated to be 1 in 30,000–50,000 in Northeast England and Finland.

Legal Blindness: Definition

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The degree of poor visual function that qualifies a person as formally blind. This definition is

relevant in case of social security or insurance issues if the patient is severely visually disabled but has a residual visual function. The definition – determined by a visual acuity threshold and other criteria such as visual field defects – is different from country to country.

The U.S. definition states as follows: "An individual shall be considered to be blind for purposes of this title if he has central visual acuity of 20/200 or less in the better eye with the use of a correcting lens. An eye which is accompanied by a limitation in the fields of vision such that the widest diameter of the visual field subtends an angle no greater than 20 degrees shall be considered for purposes of the first sentence of this subsection as having a central visual acuity of 20/200 or less."

The 20/200 threshold (1.0 logMAR) is also used in Australia, while in the UK 20/400 and Germany 20/1000 is used. The level above legal blindness is referred to as severe visual disability.

Lens Dislocation

Christoph Kniestedt[1] and Marc Töteberg-Harms[2]
[1]TAZZ Talacker Augenzentrum Zurich, Zürich, Switzerland
[2]Department of Ophthalmology, University Hospital Zurich, Zürich, Switzerland

Synonyms

Phacomorphic angle-closure glaucoma

Definition

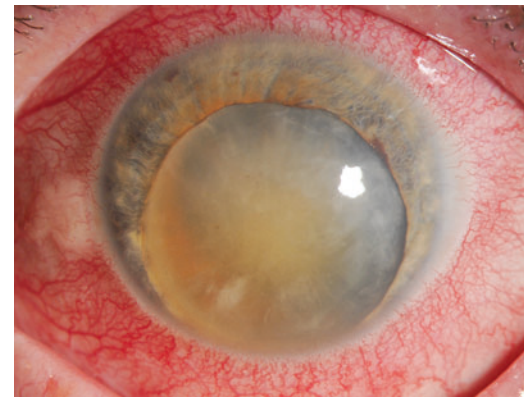
Lens dislocation may cause secondary angle block.

Etiology

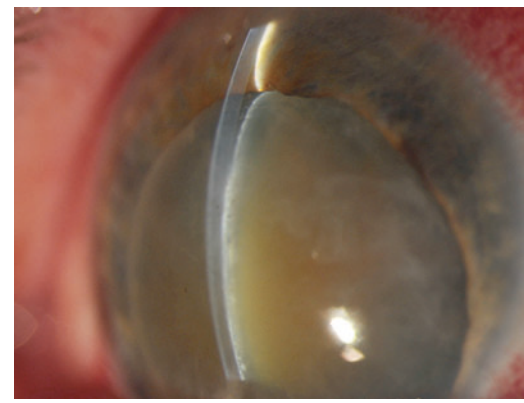
The lens is displaced from its normal anatomic position (ectopia lentis). The reason for the dislocation could be a previous trauma or predisposed insufficient zonula fibers (e.g., PEX, in Marfan syndrome) (Stamper et al. 2009). Anterior displacement of the lens (Figs. 1 and 2) may cause phacomorphic and/or pupillary block configuration (acute mixed mechanism glaucoma).

Causes for ectopia lentis are:

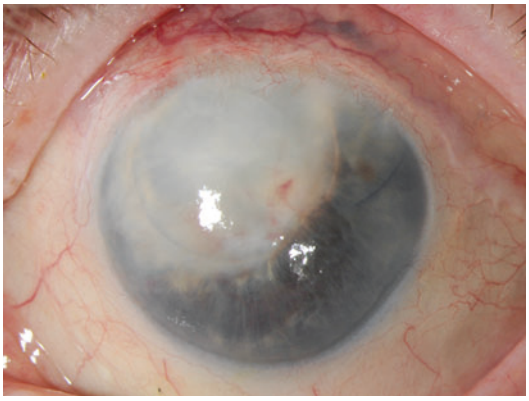
- PEX
- Trauma (Figs. 3 and 4)
- Marfan syndrome
- Homocystinuria (Figs. 5, 6, and 7)
- Microspherophakia
- Weill-Marchesani syndrome (Fig. 8)



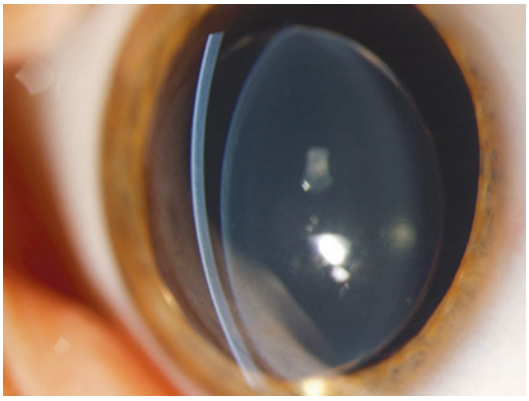
Lens Dislocation, Fig. 1 The lens is anteriorly displaced into the anterior chamber



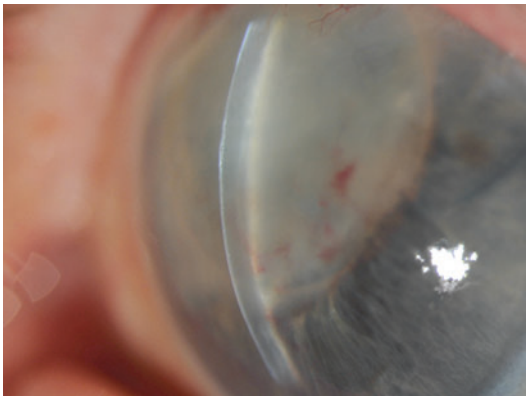
Lens Dislocation, Fig. 2 Slit lamp biomicroscopy shows endothelial-lens-touch with secondary angle obstruction



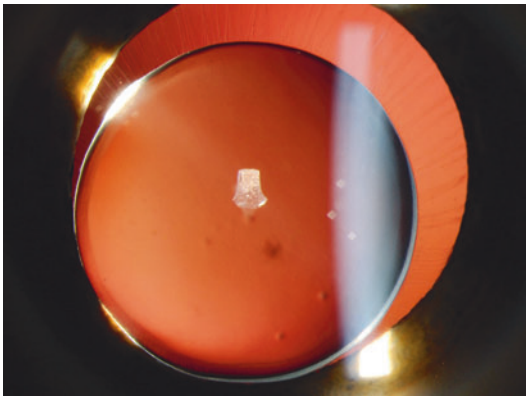
Lens Dislocation, Fig. 3 After trauma, the lens is fully dislocated into the anterior chamber



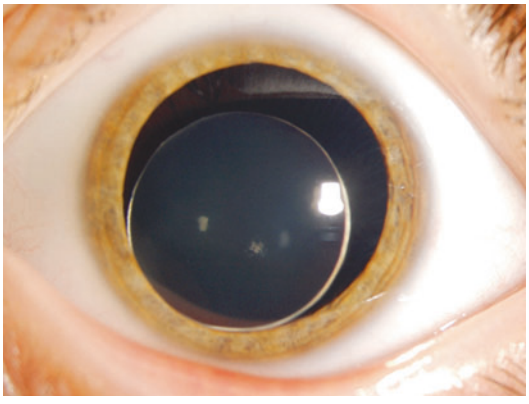
Lens Dislocation, Fig. 6 Anteriorly subdislocation is obvious on slit lamp biomicroscopy examination



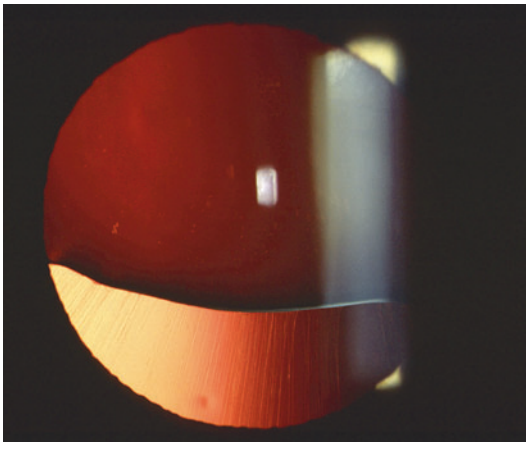
Lens Dislocation, Fig. 4 Endothelial-lens touch after traumatic lens displacement with secondary angle-block



Lens Dislocation, Fig. 7 Overly streched zonulaes visisble in retro-ilumination



Lens Dislocation, Fig. 5 Lens is anteriorly and inferiorly sub-dislocated



Lens Dislocation, Fig. 8 Lens is superiorly sub-dislocated with visable zonulae in retro ilumination

Clinical Presentation

Clinical presentation is similar to any acute angle-closure glaucoma with blurred and reduced visual acuity, halos, and pain.

Diagnosis

A complete luxation of the lens either in the anterior chamber or in the vitreous body is possible. Some lenses are only anteriorly or posteriorly subluxated. In some cases, subluxation of the intraocular lens (IOL) is assumed by deepening of the anterior chamber that is recognized by biomicroscopy, gonioscopy, or ultrasound biomicroscopy (Stamper et al. 2009).

Differential Diagnosis

Pupillary block glaucoma, aqueous misdirection glaucoma, mixed mechanism glaucoma, iris en plateau configuration or syndrome.

Prophylaxis

Early lens extraction in predisposed eyes (e.g., hyperopic eyes, zonule insufficiency, acute phacomorphic block in the fellow eye).

Therapy

Based on the underlying mechanism, peripheral laser iridotomy might not be sufficient. "Clear" lens extraction and implantation of an intraocular lens is the desired treatment to prevent recurrent lens block and damage to the optic nerve (Salehi-Had and Turalaba 2010).

Prognosis

Dependent on the initial damage to the optic nerve.

Epidemiology

- PEX.
- Trauma (often young males).
- Marfan syndrome ca. 1:5000–10,000.
- Homocystinuria ca. 1:200,000.
- Other reasons (e.g., microspherophakia, Weill-Marchesani syndrome) are really rare.

Lens Epithelial Cells

Tanja M. Rabsilber and Gerd U. Auffarth
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Definition

Lens epithelial cells adhere to the anterior lens capsule and extend to the equatorial lens bow. Their proliferative capacity varies according to their location. At the equator constant cell

division is responsible for the formation of new fibers and lens growth throughout life (Boulton and Saxby 2004).

Histology

Lens epithelial cells have a cuboidal shape and a size of approximately 10 μm height and 15 μm width (Boulton and Saxby 2004). A monolayer of anterior cells (A-cells) with minimal mitotic activity is located on the anterior capsule. These cells can proliferate and undergo a pseudofibrous metaplasia under pathological conditions. The E-cells can be found at the lens capsule equator. These cells are not only very active in terms of mitosis but are also able to proliferate and migrate when traumatized (Apple et al. 1992; Pandey et al. 2004). In the phakic healthy eye, the posterior lens capsule is cell-free.

Electron Microscopy

The nuclei of lens epithelial cells are typically large, and lateral adhesion complexes consisting of tight junctions and desmosomes connect the cells to each other. Cytoskeletal elements are microfilaments (actin), intermediate filaments (vimentin), and microtubules (tubulin) forming a network that controls cell shape as well as different functions within the cells (Boulton and Saxby 2004).

Lensectomy

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Lens extraction

Definition

Lensectomy is the surgical extraction of the crystalline lens. This surgical procedure can be

performed as an extracapsular cataract extraction (ECCE) using phacoemulsification or phacofragmentation for the deterioration of the lens by preventing the elastic capsular bag for the implantation of a posterior chamber intraocular lens. Another method for lensectomy is intracapsular cataract extraction (ICCE) done by puncture incision through the ciliary disk. This surgical procedure means the complete removal of the crystalline lens.

Epidemiology

Cataract surgery is the most common surgery worldwide. Detailed data about the incidence of cataract surgery do not exist but there are approximately 18 million operations per year. The frequency and the operation technique varied among developed and undeveloped countries. In the USA nearly 80% of all cataract surgeries are accomplished by phacoemulsification. In undeveloped countries where medical devices are rare, the ICCE (intracapsular cataract extraction) technique is still preferred.

History

Cataract operations are among the oldest recorded surgical procedures; there are references to cataract surgery written around 600 B.C. by Susruta, a famous surgeon from India. In the ancient world, lenses damaged by cataracts were dislocated rather than removed in the strict sense; the surgeon used a lance to push the clouded lens backward into the vitreous body of the eye. Extracapsular cataract extraction by inferior incision and a few years later intracapsular cataract extraction by thumb expression started in the middle of the eighteenth century. In 1967 the elegant method of lensectomy by phacoemulsification was developed and until today this technique is used in most cases of cataract or refractive lensectomy.

Clinical Features

Cataract is clouding of the lens of the eye which impedes the passage of light. Although most cases of cataract are related to the aging process, occasionally children can be born with the condition, or a cataract may develop after eye injuries, inflammation, and some other eye diseases. Gold standard in cataract treatment is the surgical removal of the crystalline lens and the simultaneous implantation of an artificial intraocular lens. In modern cataract surgery, two main surgical techniques dependent on the progression of the cataract can be performed. For further information see treatment section below.

Test

To examine best postoperative results thorough slit lamp examination with dilated pupil, Scheimpflug imaging and measurement of uncorrected and best spectacle-corrected visual acuity are essential.

Etiology

See “Clinical Features” section above.

Treatment

Two main surgical techniques exist for extraction of the crystalline lens. One is called extracapsular cataract extraction (ECCE) and the other is intracapsular cataract extraction (ICCE). Intracapsular cataract expression was performed in former times and this procedure includes the removal of the crystalline lens inclusive the elastic capsule. The eye was left aphakic in this procedure. Since the development of phacoemulsification in the 1970s, intracapsular cataract extraction has not been the procedure of choice because of much higher complication rates such as hemorrhage, vitreous loss, retinal detachment, and cystoid macular edema. Today extracapsular cataract extraction is the most common method for lensectomy. In this method the lens of the eye is removed, while the elastic capsule that covers the lens is left partially intact to allow implantation of an intraocular lens (IOL). Two main types of ECCE exist: manual expression, in which the

lens is removed through an incision made in the cornea or the sclera of the eye, and phacoemulsification, in which the lens is broken into fragments inside the capsule by ultrasound energy and removed by aspiration.

Lens-Induced Angle-Closure Glaucoma

Jörg Stürmer
Kantonsspital Winterthur, Brauerstrasse, Winterthur, Switzerland
Augenklinik Kantonsspital, Winterthur, Switzerland

Synonyms

Acute angle closure in dislocated or intumescent lens

Definition

Two different disorders of the crystalline lens are associated with angle-closure glaucoma (Allingham et al. 2005). Firstly, angle-closure glaucoma may be associated with dislocation of lens. In these conditions the lens may be either subluxated or completely dislocated into the anterior chamber. The dislocation of the lens may be traumatic (which is the most common cause), after minor trauma (as in pseudoexfoliation syndrome), spontaneous, or due to inherited abnormal position of the lens with or without other ocular or systemic abnormalities. Secondly, in eyes with advanced cataract formation, the lens may become swollen or intumescent, with progressive narrowing of the anterior chamber angle eventually leading to a form of angle-closure glaucoma, referred to as phacomorphic glaucoma (Tarongoy et al. 2009).

Etiology

The mechanism of angle-closure glaucoma in cases with subluxated or dislocated lenses is usually pupillary block. The lens may block aqueous flow through the pupil if it is dislocated into the pupil or anterior chamber or if it is subluxed or tilted forward against the iris without entering the anterior chamber. Pupillary block may also be associated with a dislocated lens due to herniation of vitreous into the pupil. Peripheral anterior synechia may develop from long-standing pupillary block and produce chronic IOP elevation. In eyes with advanced mature or hypermature cataracts, as rarely seen in developed countries but quite common in the second or third world, the angle closure may be caused by an enhanced pupillary block mechanism or by forward displacement of the lens-iris diaphragm.

Clinical Presentation

Mainly blunt trauma to the eye can cause dislocation of the lens. The patients present with pain and blurred vision mainly due to the IOP increase. The subluxation of the lens may be initially missed but a very deep anterior chamber should raise the suspicion. In cases of traumatic dislocation of the lens, concomitant trauma to the anterior chamber angle from the initial injury may be the cause of the associated glaucoma. A transient pressure elevation may persist for days or weeks after traumatic dislocation of the lens. In some older individuals, dislocation of the lens may occur spontaneously, usually in association with cataract formation. Spontaneous dislocation has

also been reported in eyes with high myopia, uveitis, buphthalmos, or megalocornea.

Simple ectopia lentis is usually inherited by autosomal dominant mode. The condition is usually bilateral and symmetric, with lens dislocation generally upward and outward and occasionally into the anterior chamber. Ectopia lentis and pupillae is a rare, autosomal recessive condition characterized by small, subluxated lenses and by oval- or slit-shaped pupils that are displaced usually in the opposite direction from that of the lens. The condition is usually bilateral, although marked variation may be seen between eyes of the same patient. The condition is associated with a wide variety of other ocular abnormalities including severe axial myopia, iris transillumination defects, poor pupillary dilatation, and glaucoma. The pathogenesis of this disorder is unknown. Ectopia lentis can also be seen with systemic abnormalities in Marfan syndrome, homocystinuria, and Weill-Marchesani syndrome and other rare congenital disorders including Ehlers-Danlos syndrome, hyperlysinemia, sulfite oxidase deficiency, and aniridia.

Patients with mature or hypermature cataract will present with symptoms very similar to acute angle-closure glaucoma, i.e., redness, pain, grossly reduced visual acuity, and quite often corneal edema. Intraocular pressure is significantly elevated, often exceeding 30–40 mmHg. As this condition is more often seen in the second or third world, there is usually a marked delay in diagnosis, and patients may present with a history of vision loss for several weeks or months.

Diagnostics

In cases with ectopia lentis, slit-lamp examination may reveal lenticular subluxation and dislocation. If zonules are weak, then phacodonesis or iridodonesis may also be present. The nature of the zonular defect may be revealed by ultrasound biomicroscopy (UBM), which enables in vivo imaging of the zonules and can detect zonular loss and stretching directly. In the region of zonular disorders, the lens shows increased lenticular sphericity, which may also be seen clinically.

In cases of phacomorphic angle-closure glaucoma, the diagnosis is usually made by observing a mature, intumescent cataract associated with a central anterior chamber depth that is significantly shallower than that of the fellow eye. The fellow eye, however, may also show a shallow anterior chamber and a gonioscopic angle width of less than 20°.

Differential Diagnosis

In some cases, the lens may dislocate completely into the vitreous cavity and later undergo degenerative changes with release of material that obstructs aqueous outflow. Phacolytic (lens protein) glaucoma may also be seen in patients with advanced cataracts without luxation of the lens. In these cases the chamber angle is open, and there is a marked anterior inflammation with heavy flare in association with iridescent or hyperrefringent particles (calcium oxalate or cholesterol) and sometimes extremely large round cells (macrophages). Lens particle glaucoma after disruption of the lens capsule by cataract extraction or penetrating injury is easily distinguishable by the "fluffed-up" lens cortical material in the anterior chamber. Phacoanaphylaxis with retained nucleus fragments in the vitreous after complicated cataract surgery is easily distinguished because of a chronic, relentless, granulomatous-type inflammation that centers on lens material.

Prophylaxis

In cases with subluxated or luxated lenses, the removal of the lens should be considered as prophylaxis of angle-closure glaucoma. Prophylactic iridotomy in cases of microspherophakia has also been advocated to avoid pupillary block glaucoma. Phacomorphic glaucoma is rarely seen in developed countries because usually cataract surgery is performed before the cataract is mature. Some grade of phacomorphic angle narrowing due to increased thickness and more anterior position of the lens may also be present in a majority of cases

with acute (pupillary block) or chronic angle-closure glaucoma; thus, cataract surgery in these cases has become popular. In eyes with primary angle closure, cataract surgery opened the angle concomitant with the attenuation of the anterior position of the ciliary processes (Nonaka et al. 2006).

Therapy

If the lens is displaced anteriorly in the anterior chamber or partially through the pupil, it may be possible to relieve the condition by dilating the pupil and allowing the lens to reposit back into the posterior chamber. Miotics should be avoided when the pupillary block is caused by loose zonules. If the lens is totally dislocated in the anterior chamber, surgical removal of the lens is indicated. Cycloplegics may help to break the attack by pulling the lens posterior. Hyperosmotic agents, carbonic anhydrase inhibitors, or topical beta-blockers may also be useful in breaking the attack. The definite treatment however is a laser iridotomy. The iridotomy should be placed peripherally to avoid subsequent obstruction by the lens. Argon laser peripheral iridoplasty (ALPI) may also be helpful in some cases of angle-closure glaucoma without a significant pupillary block component (Ritch et al. 2007). The extraction of a subluxated lens is associated with increased surgical risk but should be performed if the lens is in the anterior chamber or lens extraction is needed to relieve the glaucoma or improve vision.

In phacomorphic glaucoma, the treatment is initial medical reduction of the IOP with hyperosmotics, carbonic anhydrase inhibitors, and topical beta-blockers or alpha2-agonists, followed by extraction of the cataract. ALPI is also effective as an initial treatment to break attacks of acute phacomorphic angle closure. In acute phacomorphic angle closure, the eye is very often severely inflamed, as these patients have usually been referred after being treated unsuccessfully for a few days. Breaking the attack with ALPI may allow a week more for the inflammation and folds in Descemet's to clear, permitting cataract extraction under conditions much closer to ideal. Any element of pupillary block is treated with iridotomy as soon as possible (usually within 2–3 days) after breaking the attack.

Prognosis

In cases with subluxated or luxated lenses, the prognosis is dependant on the nature of the causing condition (i.e., severity of the trauma) and the duration and amount of IOP elevation. Immediate diagnosis and adequate treatment is mandatory. In patients with phacomorphic glaucoma, especially often seen in less developed countries, the distance from the hospital, duration of pain, and high level of IOP at presentation were all associated with poor visual outcome (Pradhan et al. 2001). Under these conditions even with very experienced cataract surgeons, only one third of patients regained useful (6/60 or better) visual acuity.

Epidemiology

The major cause of lens-induced angle-closure glaucoma in developed countries is blunt ocular trauma. Inherited ectopia lentis is rare; the most common form is Marfan syndrome. Phacomorphic angle closure is also very rare in the first world, but is not so rare in the second and third world. In a prospective series of 27073 cataract surgeries performed during a 1-year period in a single hospital in southeast Nepal, 296 eyes (1%) presented with phacomorphic glaucoma.

Lensmeter

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

Synonyms

Focimeter; Lensometer

Definition

A lensmeter is a device for measuring the power of a spectacle lens. A target (typically a crossed set of lines) is imaged through a lens of focal length f. The spectacle lens under test is placed at the rear focal point of this lens. Light emerging from the spectacle lens enters an eyepiece with an internal reticle. The user axially shifts the target until it is simultaneously in focus with the reticle. This situation occurs when the light emerging from the spectacle lens is collimated. The target position d is related to the power of the spectacle lens Φ by:

Lensmeter Equation

The target can be rotated to align with the axes of a spherocylinder lens. When cylinder is present, only one set of target lines can be in focus. Readjusting the lensmeter will bring the orthogonal set of lines into focus. The difference in power between the two focus positions is the cylinder power of the lens. The different zones of a progressive addition lens can also be measured with a lensmeter by shifting the position of the lens in front of the aperture of the eyepiece. Modern versions of the device are automated.

Lenticonus

Martin Baumeister
Klinikum Bad Hersfeld, Klinik für Augenheilkunde, Bad Hersfeld, Germany

Definition

Lenticonus is a local bulging of the capsule of the crystalline lens and the underlying lens cortex. It commonly occurs at the anterior or posterior pole of the lens.

Posterior lenticonus is a congenital defect which is limited to the eye and not associated with systemic diseases. Recently, an association of posterior lenticonus with microcornea, persistent fetal vasculature, and coloboma has been described.

Anterior lenticonus is bilateral, acquired, and in most cases associated with Alport's syndrome of nephrotic hematuria and deafness. It is believed to be a manifestation of a generalized basement membrane disorder. Associations of anterior lenticonus with Lowe's and Waardenburg's syndrome have also been described.

Histology

Histological examinations of the capsule in lenticonus showed a thinned and ectatic anterior capsule with accumulation of collagen type IV and type VI and irregular arrangement of collagen fibers. Lens cortical material was found to be protruded into the capsular ectasia (van Setten 2001).

Immunohistochemistry

Immunohistochemistry provided evidence for a defect of the a3 to a6 chains of type IV collagen in anterior lenticonus associated with Alport syndrome (Ohkubo et al. 2003).

Electron Microscopy

Electron microscopy of the lens capsule in anterior lenticonus after cataract surgery revealed abnormal thinning of the capsule and capsular breaks (Junk et al. 2000).

Molecular Diagnostics

Patients with lenticonus associated with Alport syndrome show mutation of genes encoding collagen synthesis, most commonly the COL4A5 gene (Ohkubo et al. 2003).

Differential Diagnosis

The condition is detectable by slitlamp examination. Patients should be examined for associated abnormalities, especially Alport syndrome. Similar appearance of the lens may be caused by ocular trauma.

Lentigo Senile (Liver Spots)

Jeremiah Tao
Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Lentigo simplex; Liver spots; Solar lentigo; Sun spots

Definition

Flat, evenly pigmented benign cutaneous lesions.

Etiology

Chronic sun exposure, resulting in an increased number of melanosomes.

Clinical Presentation

A macule with uniform pigmentation. They are usually 5 mm in size, flat, and increase in size and number with age. Lesions become darker with increased sun exposure. They occur frequently on the forehead and back of the hands.

Diagnostics

Excisional biopsy is not necessary; however, suspicious lesions may be excised to distinguish them from other melanocytic lesions.

Differential Diagnosis

Ephelides
Lentigo simplex
Nevus
Melanoma

Prophylaxis

Appropriate UV-protection and sunscreens may decrease the appearance and pigmentation of senile lentigo.

Therapy

Treatment in not necessary; however, suspicious lesions may be biopsied to distinguish it from other melanocytic lesions. Topical melanin bleaching creams, cryotherapy, and chemical peels may improve cosmetic appearance.

Prognosis

Prognosis for senile lentigo is excellent.

Epidemiology

More common in fair-skinned individuals. They have been reported in 90% of Caucasians by age 60 in the USA (Montagna et al. 1980; Albert and Jakobiec 2008).

Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA

Synonyms

Juvenile lentigo; Lentigo simplex; Simple lentigo

Definition

A flat, pigmented benign lesion, typically found on sun-protected skin.

Etiology

A result of an increased number of melanosomes and increased melanin in basal keratinocytes. It does not appear to be related to sun exposure.

Clinical Presentation

Lentigo simplex presents as evenly pigmented round spots, with jagged or smooth borders (Fig. 1). Lesions tend to be 3–15 mm in size and first appear in childhood.

Lentigo Simplex (Simple Lentigines), Fig. 1 Left cheek well circumscribed lesion (*arrow*) representing lentigo simplex

Eyelid lentigines may be associated with Peutz-Jeghers syndrome, an autosomal dominant disorder characterized by benign harmartomatous polyps of the gastrointestinal tract, also known as hereditary intestinal polyposis syndrome (Albert and Jakobiec 2008).

Diagnostics

Excisional biopsy is not necessary.

Differential Diagnosis

Ephelides
Actinic Keratosis
Seborrheic Keratosis

Prophylaxis

No prophylaxis is known.

Therapy

Treatment is not necessary. Topical melanin bleaching creams may improve cosmetic appearance.

Prognosis

Excellent

Epidemiology

Lentigo simplex is the most common form of lentigo.

Levator Muscle (Levator Palpebrae Superioris)

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

Levator

Definition

The levator is a skeletal muscle responsible for voluntary elevation of the upper eyelid.

Structure

The levator originates at the lesser sphenoid wing of the orbital apex and travels along the underside of the orbital roof (just above the superior rectus muscle) as it extends forward. At the aperture of the orbit, it is supported by the superior transverse orbital ligament of Whitnall and changes from a muscular structure into a fibrous aponeurosis. The aponeurosis extends inferiorly in the eyelid and inserts on the tarsal plate. As the aponeurosis extends inferiorly, it broadens to form the medial and lateral horns which distribute the forces of the levator muscle. The aponeurosis sends out multiple delicate fibers forward and downward through the orbicularis muscle to insert onto the interfascicular septa of the orbicularis muscle and subcutaneous tissue to create the upper eyelid crease. The levator muscle is innervated by the superior division of the third cranial nerve.

Function

It is the primary retractor of the upper eyelid.

Clinical Relevance

Assessment of the function of the levator muscle is crucial when evaluating ptosis. Levator function is measured as the millimeters of movement during eyelid excursion from extreme downgaze to extreme upgaze. Normal levator function is about 15 mm and is an indicator of normal strength of the muscle. In congenital ptosis, levator function is reduced, but in involutional ptosis, normal levator function is maintained. In addition, the appearance of the eyelid crease can aid in differentiating these two main types of eyelid ptosis. In congenital ptosis, the eyelid crease is not well defined, but in involutional ptosis, it is high.

The etiologies of these two disorders explain the above findings. In congenital ptosis, the levator muscle is abnormal, weak, and fibrotic; therefore, it does not move well upward or downward. In primary gaze, the lid is low, and in downgaze, the lid often shows lid lag. In involutional ptosis, the muscle itself is normal, but the aponeurosis

either is disinserted from the tarsal plate or is stretched. This abnormality results in normal measurements of levator function but a high eyelid crease as the tiny fibers of the aponeurosis drag the skin upward. In downgaze, the lid margin remains low as the eyelid is effectively lengthened by the stretched or disinserted aponeurosis.

The levator muscle may also be relevant to the eyelid retraction which can be associated with Graves' disease, as one proposed mechanism for this finding is infiltration and fibrosis of the levator muscle.

Light Adaptation

William J. Wirostko
Eye Institute- Medical College of WI, Milwaukee, WI, USA

Definition

The process by which the retina reduces its sensitivity to light as ambient light is increased.

Structure

Light adaption occurs predominantly in retinal cone cells. It appears to be absent or only minimally present for retinal rod cells in isolation. Nonetheless, retinal rod cells in vivo do appear to demonstrate a wide range of voltage excursions independent of ambient light conditions and thus apparently benefit from the light adaption ability of retinal cone cells (Miller 2006).

Function

Light adaption allows eyes to maintain ideal vision throughout a wide range of illumination conditions. Under typical conditions, an object is visible due to the difference in reflected light from itself as compared to its surroundings, also known as contrast. As the ambient light increase, the absolute difference in reflected light changes, but the ratio of reflected light remains the same. Light adaption provides eyes with a mechanism to maintain vision based on ratio of reflected light rather than absolute amount of reflected light. In animal experiments, light adaption allowed eyes to maintain a stable contrast ratio even though ambient illumination changed by a factor of 50,000.

Clinical Relevance

Light adaption is essential for maintaining ideal vision across a wide range of ambient

light conditions as described above. Since the main mechanisms for this ability involves bleaching of pigments in photoreceptor cone cells, light adaption may be malfunctional in any cell with abnormal photopigments or bleaching mechanisms. Additional mechanisms for light adaption probably also exist. However, these appear to be most influential at low light conditions and likely involve alterations in cGMP and calcium ion channel levels (Miller 2006).

Light adaption directly influences all results from any electrophysiological testing of the retina, including electroretinogram, electrooculogram, and dark adaptation testing (Lam 2005). It is therefore paramount that the process of light adaption be standardized for all labs so that reliable and consistent results are obtained.

It should be noted that light adaption is simply not the converse of dark adaption. Dark adaption occurs over a slower time frame than light adaption and involves regeneration of photopigment in retinal rods and cones, rather than bleaching of photopigments.

Eye Institute- Medical College of WI, Milwaukee, WI, USA

Synonyms

Free radical damage; Light toxicity; Photic damage; Phototoxicity

Definition

Thermal, chemical, or mechanical damage to the retina as a result of exposure to visible or ultraviolet light.

Structure

Being a structure designed to receive images of incoming light energy, the eye contains inherent defense mechanisms to protect itself against damage from high light levels. In certain situations, however, these mechanisms can be overwhelmed, and the retina suffers permanent damage if light energy is high enough.

Function

The manifestation of light toxicity depends on the energy level of incoming light and which ocular structures absorb the energy (Gass 1997). Photothermal (photocoagulation) injury involves the absorption of light by melanin in the retinal pigment epithelium and choroid with the subsequent conversion of this energy to heat. If heat production elevates tissue temperature more than 10° Centigrade, proteins denature and produce cell damage, tissue inflammation, and cell death. Photochemical injury develops when incoming light

produces large amounts of free oxygen radicals or singlets which react with ocular tissue. Photomechanical (photodisruption) damage occurs when extremely powerful light energy produces rapid expansion of water vapor or the ionization of ocular tissue, which mechanically disrupts tissue structure.

Clinical Relevance

Light injury to the retina is a well-known cause of permanent vision loss. Most cases develop following exposure to solar light, laser light, operating microscope light, or welding arc light. Solar retinopathy classically develops following prolonged sun gazing with dilated pupils (Mainster and Turner 2006). Clinical findings include bilateral small yellowish foveolar lesion that fade over several weeks, eventually producing foveolar retinal pigment epithelium atrophy. Optical coherence tomography demonstrates a characteristic hyporeflective space in the outer retina. Visual acuity is usually diminished to the 20/40 through 20/100 range shortly following light exposure but may improve to the 20/20 through 20/40 range over 6 months. Clinical signs of laser light retinopathy vary according to size and intensity of laser beam but generally include foveolar pigment mottling. Operating microscope light toxicity appears as an oval area of retinal pigment mottling several days following intraocular surgery. Welding arc light toxicity appears similar to solar retinopathy (Figs. 1 and 2).

The photic damage of cumulative light exposure in the aging processes of cataract and age-related macular degeneration progression remains unclear. Some studies do suggest that increased sunlight and ultraviolet ray exposure accelerates disease progression, but this effect has been difficult to objectively measure. Currently, intraocular lenses are manufactured with a blue-absorbing and ultraviolet-absorbing coating to help reduce retinal light damage. Sunglasses and a wide brimmed hat may also be helpful for reducing cumulative ultraviolet exposure to one's eyes.

Synonyms

Pupillary light reflex

Definition

The simultaneous and equal constriction of both pupils to light is mediated by an ipsilateral direct response and a contralateral consensual response.

Structure

The structures comprising the afferent limb of the pupillary light reflex in sequential order include the retina, optic nerve, optic chiasm, optic tract, and pretectal nuclei. The Edinger-Westphal nuclei (EWN), preganglionic parasympathetic fibers, ciliary ganglion, postganglionic parasympathetic fibers, sphincter muscle of the iris comprise the efferent pupillary pathway.

Function

The pupillary light reflex has an afferent and an efferent pathway. The afferent pathway begins when light is shone on the eye and activates neurons in the retina. These neurons then send impulses through the optic nerve (CN II) to the optic chiasm where they are carried bilaterally to the optic tracts. Just prior to the lateral geniculate nuclei, fibers branch off of the optic tract and synapse in the pretectal nuclei at the level of the superior colliculus. From the pretectal nuclei, fibers arise and pass to the ipsilateral and contralateral EWN. Here, efferent preganglionic parasympathetic fibers arise and exit the brainstem with the oculomotor nerve (CN III). These fibers synapse in the ciliary ganglion and give rise to the postganglionic short ciliary nerves which go on to innervate the iris sphincter.

Clinical Relevance

The pupillary light reflex can be quickly and easily assessed clinically by shining a handheld light obliquely, from below the nose, into one eye and carefully observing the pupillary response in both eyes. After several seconds the light can be shined in the other eye again while observing the pupillary response in both eyes (i.e., swinging flashlight test). Ideally, this testing should be performed in a dim room and the pupil size can be measured using a pupillary measuring gauge.

The patient should be instructed to look at a distant object to avoid accommodative pupillary constriction. In a normal exam, shining a light into one eye will cause simultaneous and equal constriction of both pupils. The pupillary light reflex is abnormal if one or both of the pupils does not constrict as much as expected and dilates in response to direct stimulus after swinging the light from the normal pupil to the abnormal pupil with the relative afferent pupillary defect (RAPD). Damage to the parasympathetic efferent pathway produces poorly reactive or unreactive pupil(s) and anisocoria that is worse in the light.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Light-near dissociation occurs when near stimulus produces pupillary constriction that exceeds pupillary constriction in response to bright light.

Etiologies

Light-near dissociation is a pathologic finding with several possible etiologies including severe loss of afferent light input to both eyes, a lesion of the dorsal midbrain, tonic pupils, aberrant reinnervation of the third nerve or ciliary ganglion fibers, and Argyll Robertson pupils.

Severe loss of afferent light input to both eyes, such as a bilateral optic neuropathy, is a common cause of light-near dissociation. There is absent or diminished light reflex due to the reduced light impulses being carried to the pretectal nucleus; however, these patients often retain the ability to

determine object distance and have an intact near reflex. A lesion of the dorsal midbrain can result in light-near dissociation by compressing and interrupting the more dorsally located fibers of the light reflex pathway and sparing the more ventrally located fibers of the near reflex pathway. A dorsal midbrain lesion can also be associated with bilateral eyelid retraction (Collier sign), vertical gaze palsy, accommodative paresis, and convergence-retraction nystagmus. These findings together are known as the Parinaud syndrome.

Light-near dissociation can also result from aberrant regeneration of damaged nerves, which can restore the near reflex but not the light reflex. In normal physiology, the ciliary ganglion sends 30 times more nerve fibers to the ciliary muscle than the iris sphincter. Following damage to the ciliary ganglion, regrowth of ciliary nerves can produce reinnervation of the iris sphincter instead of the ciliary muscle. Thus, nerves that previously innervating the ciliary body as part of the near reflex subsequently innervate the iris sphincter and preserve pupillary constriction in response to near stimuli. This process leads to what is known as Adie tonic pupil when idiopathic; however, injury to the oculomotor nerve from trauma, compression, or infections can produce similar clinical manifestations of light-near dissociation.

Argyll Robertson pupil is a manifestation of neurosyphilis. Affected patients have small (<2 mm), often irregular, pupils that exhibit light-near dissociation (small to pinpoint). While the pupils do not react well to light, the near response and subsequent re-dilation are described as normal and brisk. The briskness of the pupillary movement helps distinguish the Argyll Robertson pupil from a chronic-tonic pupil, which has a slow and sustained tonic response. Adie tonic pupils, as described earlier, can become chronic and more miotic-tonic pupils over time (i.e., little old Adie pupils). Although classically described as related to syphilis, Argyll Robertson-like pupils can occur in patients with diabetes, chronic alcoholism, encephalitis, and following panretinal photocoagulation.

Ligneous Conjunctivitis

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Definition

Ligneous conjunctivitis is a recurring, chronic conjunctivitis in which an absence of plasmin results in an inability to break down fibrin clots resulting in the accumulation of fibrinous pseudomembranes on the conjunctiva. This disease process may be associated with systemic pseudomembranes involving the gingiva, ears, respiratory tract, female genital tract, and renal collecting system.

Etiology

Ligneous conjunctivitis is the most common manifestation of type 1 plasminogen deficiency, also known as hypoplasminogenemia. The consequence of decreased plasminogen is a decreased

in plasmin which results in an inability to break down fibrin clots. Thus, wound healing is usually halted at the stage of granulation tissue formation. Ligneous conjunctivitis is usually an autosomal recessive disease stemming from a mutation on chromosome 6q26. Episodes may be triggered by relatively minor trauma or systemic factors such as antifibrinolytic therapy or fever.

Clinical Presentation

Patients may initially present with a nonspecific conjunctivitis in childhood, with a median age of 5 years old. However onset may occur at any age. Ligneous conjunctivitis can present in children of all ethnic groups. Usually, lesions involve the upper palpebral conjunctiva, but may also involve the bulbar and lower palpebral conjunctiva. Lesions generally have a red or yellowish-white appearance and a woody texture, hence the name ligneous, which means consisting of or resembling wood. The lesions can be covered in a thick yellow-white mucoid discharge. This disease may be precipitated by infection, surgery, or trauma. Fifty percent of cases are bilateral. In 30% of cases, the disease progresses to an advanced stage where the cornea is affected. This involves corneal scarring, vascularization, infection, or melting. Although systemic lesions are less common, other sites where lesions can present are the ears, respiratory tract, female genital tract, skin, and renal collecting system. There have been several reports of children with the disease developing hydrocephalus. Ligneous conjunctivitis has also been linked to congenital hydrocephalus and juvenile colloid milium.

Diagnosis

Ligneous conjunctivitis may be initially diagnosed clinical initially based on the patient's history and examination of the eye. However, but it may be confirmed with laboratory data demonstrating decreased plasminogen activity. Pathology specimens demonstrating pseudomembranes with a fibrin-rich component further indicate this diagnosis. A positive family history of ligneous conjunctivitis or involvement in other mucosal sited also can serve to help make this diagnosis.

Differential Diagnosis

The differential diagnosis for ligneous conjunctivitis includes any infectious or inflammatory entity which can cause a chronic pseudomembranous conjunctivitis. These could include amyloidosis, allergic or vernal conjunctivitis, bacterial conjunctivitis (including chlamydia, diphtheria, staphylococcus, and streptococcus), toxic conjunctivitis (secondary to medication use), and viral conjunctivitis (including herpes simplex virus, molluscum contagiosum, or adenovirus-type epidemic keratoconjunctivitis). It is especially important to submit any surgically excised pseudomembranes to pathology to confirm the subepithelial, eosinophilic deposits of fibrin-rich material. This will rule out amyloid, as amyloidosis can mimic this disease closely.

Prophylaxis

There is no prophylaxis for this disease entity as it is genetic in nature.

Therapy

Although the current treatment of choice is plasminogen replacement, historically, treatment success rates of 75% were achieved with surgically removing lesions with careful diathermy at the base of lesions and long-term post-op care. Once the pseudomembranes have been removed, hourly heparin and steroid treatments are begun immediately. This is continued until the wound has reepithelialized. Over the next few weeks, these treatments are then tapered until all signs of inflammation have disappeared. It has been noted that recurrence may be delayed with long-term cyclosporine and steroid administration.

Other treatment modalities such as amniotic membrane transplantation onto the conjunctiva following removal of the lesion have also been tried but with less success. Early recurrence of the ligneous lesions will result if appropriate postoperative care is not given to stem any inflammation or fibrin clotting.

Of note topical plasmin has been shown to be ineffective, because it is rapidly broken down in the tear film. Unfortunately commercial plasminogen concentrate is not currently available for local or systemic treatment. When creating a treatment plan for patients with ligneous conjunctivitis, a hematologist should also be included in management.

Prognosis

Untreated, ligneous conjunctivitis can persist for decades. Spontaneous resolution of lesions is rare. With the older treatment of surgical removal of conjunctival lesions with diathermy followed by weeks of steroid and heparin treatments, success rates of up to 75% have been reported. Currently, with systemic IV therapy of plasminogen, patients are achieving even higher rates of success.

Patients should have close follow-up to monitor for any recurrence of pseudomembranes. Patients will still be at risk for recurrence even years later. Polycarbonate glasses may be helpful in protecting the eyes from environmental trauma and initiating the cascade of damage and repair mechanisms that can release fibrin and cause another episode of ligneous conjunctivitis to recur.

Ultimately, the prognosis of this disease depends on the ability to control the inflammation and recurrence of pseudomembranes. Poorer outcomes are indicated in patients with corneal involvement. In young children, this corneal scarring could result in amblyopia. Topical steroid in the postoperative setting to decrease inflammation can also lead to steroid-induced ocular hypertension. Systemic disease, with respiratory tract pseudomembrane formation, can be life threatening.

Epidemiology

Ligneous conjunctivitis usually presents in infants or young children of all ethnic groups. There is a slight female preponderance. The median age of presentation is 5 years old, but it can present at any age.

Limbal Autograft/Allograft (Limbal Transplantation)

Shilpa Kodati
Laboratory of Immunology, National Eye Institute, National Institutes of Health, Bethesda, MD, USA

Synonyms

Keratolimbal autograft/allograft

Definition

Conjunctival limbal autografting (CLAU) is a procedure that involves the transplantation of

autologous conjunctival and limbal tissue from the contralateral unaffected eye into the limbal stem cell-deficient eye. In contrast, the transplantation of keratolimbal tissue from either cadaveric eyes or living related donors is done in keratolimbal allograft surgery (Liang et al. 2009).

Indication

The limbal stem cell compartment, located at the palisades of Vogt, is responsible for renewal of the corneal epithelium. The corneal epithelium possesses both a critical barrier function, as well as promoting stability in the tear film (Krachmer et al. 2010; Weisenthal et al. 2013). Limbal stem cell deficiency (LSCD) arises due to either congenital or acquired causes. Congenital causes include aniridia, sclerocornea, and xeroderma pigmentosa. Acquired etiologies typically involve either destruction of limbal stem cells or dysfunction of the limbal stem cell compartment. Common acquired causes include contact lens wear, chemical/thermal burns, autoimmune (Stevens-Johnson syndrome, ocular cicatricial pemphigoid), severe dry eye disease, infections, and neoplasms (Ahmed 2012).

The barrier function of the limbus is lost in LSCD. As a result, conjunctival cells migrate onto the cornea, leading to conjunctivalization of the corneal surface. This conjunctivalization is often associated with neovascularization (both deep and superficial). Persistent epithelial defects and surface irregularity also arise due to compromised epithelial wound healing.

Mild cases of LSCD may be treated by removal of underlying triggers and with topical steroids, scleral contact lens wear, and superficial keratectomy. Limbal stem cell transplantation may be performed for more severe cases of LSCD. The goal of this surgery is to replenish the limbal stem cell compartment so that the diseased corneal epithelium can regenerate with normal corneal epithelium.

Contraindication

Limbal stem cell transplantation is contraindicated in the presence of significant active inflammation. This also includes severe dry eye disease (Dua et al. 2010).

Techniques and Principle Outcome

CLAU is performed preferentially for unilateral cases of LSCD. Autografts have the advantage of not requiring treatment with immunosuppression. The procedure involves excision of a conjunctival and peripheral corneal explant from the normal fellow eye. Typically, two clocks hours of tissue superiorly and inferiorly are removed. The graft usually includes 3 mm of conjunctiva and 1 mm of peripheral cornea. In the recipient bed, fibrovascular pannus, conjunctiva, and corneal epithelium are removed. The explants are sutured in corresponding positions superiorly and inferiorly in the recipient bed with 10-0 nylon (Liang et al. 2009; Dua et al. 2010).

Keratolimbal allografts are performed in bilateral LSCD and can be obtained either from cadaveric eyes or from living related donors. The transplantation of allografts from living related donors is procedurally similar to limbal autografting. In contrast, cadaveric allografts can be harvested from either whole globes or corneal scleral discs and involve transplantation of a 360° sclerocorneal ring graft. The ring explant can either be secured to the recipient limbus as a ring, or the ring can be partitioned into sections. The sclerocorneal ring is sutured to the host bed using 10-0 nylon. Allografts from a cadaveric source have the advantage over living related donor grafts of providing a 360-degree supply of limbal stem cells (Dua et al. 2010).

Amniotic membrane can be used in conjunction with both autografts and allografts. The amniotic membrane both has a barrier function and promotes the expansion of host-derived residual limbal stem cells (Dua et al. 2010).

In the initial 2 years following transplantation, the success rate of both limbal autografts and allografts are comparable. However after 2 years, the success rate of limbal allografts is less than the success rate of autografts dropping to less than 60% for allografts. The higher failure rate may be due to allograft rejection, despite the use of

systemic immunosuppressive therapy (Liang et al. 2009). Notably, living related donor allografts have a lower rate of failure compared to cadaveric allografts. This may be due to the explants from living related donors being "fresh" and HLA matched (Dua et al. 2010).

Other factors associated with graft failure include lid malposition, severe dry eye, and chronic inflammation. An improved ocular surface prior to grafting leads to a higher rate of graft survival. Ideally, eyelid abnormalities contributing to ocular surface disease should be addressed prior to limbal stem cell transplantation (Dua et al. 2010).

An improvement in visual acuity may not be seen postoperatively, and penetrating keratoplasty (PKP) may be required to restore vision. Indeed, patient should be counseled preoperatively that the objective of this surgery is not vision improvement, but both symptomatic improvement and restoration of corneal epithelial health. When a PKP is required, this should be done as a two-stage procedure with the limbal cell transplantation first and PKP second, in order to maximize the survival of the PKP graft (Liang et al. 2009; Dua et al. 2010).

Complications

CLAU carries the small risk of the contralateral donor eye developing LSCD. This risk also applies to living related donors. In order to mitigate this risk, smaller-sized grafts are used. Patients with either cadaveric or living related donor allografts need long-term immunosuppressive therapy and are thus at risk of incurring complications secondary to the use of immunosuppressives.

Limbal Relaxing Incisions

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Peripheral corneal relaxing incisions

Definition

Limbal relaxing incisions are a refractive surgical procedure to correct astigmatism, most commonly during phacoemulsification. The procedure consists of making a pair of incisions at the limbus which have the effect of changing corneal astigmatism.

Epidemiology

Due to the fact that cataract surgery is one of the most highly frequented surgical procedures

worldwide, the number of limbal relaxing incisions is very high.

History

Starting in the 1990s, limbal relaxing incisions became popular for correcting corneal astigmatism of 0.5–4.0D. The technique was introduced by JP Gills, who also made nomograms to determine the length, number, and depth of the incisions.

Clinical Features

According to the Gills and Gayton nomograms which determine the length, number, and depth of incisions, generally a 6 mm incision corrects up to 2D of astigmatism. Paired incisions can correct up to 4D.

Tests

Thorough examination of the eyes and keratometric and keratographic readings are required for preoperative planning to assure the best possible correction of astigmatism.

Differential Diagnosis

Other corneal incisional surgeries are:

- Radial keratotomy
- Astigmatic keratotomy

Etiology

See History section above.

Treatment

After fixing the eye, the incision is made with the diamond blade just inside the conjunctiva. The blade should be oriented perpendicular to the surface of the cornea. This procedure should be done at the beginning of surgery to assure achieving a consistent incision depth and consistent intraocular pressure.

LESCs: limbal epithelial stem cells

Definition

Adult cells located in the corneoscleral junction which have the ability to self-renew and repopulate the cells of the corneal epithelium.

Structure

The limbus is located between the clear cornea and the "white" of the sclera and clear conjunctiva. Limbal stem cells are located in special niches which regulate the microenvironment of the LSCs allowing them to remain in an undifferentiated state by providing appropriate growth factors. This niche, also known as palisades of Vogt, is a radially oriented ridge that harbors epithelial stem cells in deep epithelial ingrowths into the limbal stroma. As these stem cells proliferate, they migrate centripetally to ensure a corneal surface with a uniformly arranged epithelium.

Several structural differences exist between limbal epithelial stem cells and regular corneal epithelial cells. The LESCs containing palisades of Vogt are located at the highly pigmented superior and inferior limbus. The presence of the surrounding melanocytes at a unique location that is beneath the upper and lower eyelids provides these stem cells with an additional protection from UV radiation-induced DNA damage and mechanical injury.

The basement membrane of the limbal epithelium differs from that of the cornea in that it is undulated with papillae of the stroma that extend upward creating limbal crypts in between projections. LSCs interact closely with the underlying limbal stroma which increases its surface area. The proximity of the palisades of Vogt to the stromal vasculature enables the infiltration of necessary growth factors, antigen-presenting Langerhans cells, and suppressor T lymphocytes. The BM of the limbus is also unique in its preferential expression of alpha9 integrin and N-cadherin without Cx43. The limbal BM also contains laminin-1 and laminin-5 and a2b2 chains which are not present in the corneal basement membrane further emphasizing the unique niche which allows for limbal stem cells to function.

Although the concept of the limbal stem cell niche is well discussed, a recently published animal study in 2008 has proposed a mix of cells called compound niches. These compound niches consist of cells in different states of differentiation: corneal progenitors, mucin-producing goblet cells, and both proliferating and nonproliferating cells. Similar to the LESC niche, compound niches are thought to be at the limbus and migrate to areas of damaged corneal epithelium. This study also suggests that corneal epithelial progenitors are oligopotent; thus they can give rise to goblet cells in addition to corneal epithelial cells. This study provides an alternative to the existing body of knowledge of limbal stem cells and calls upon further research to clarify this concept in human and animal subjects.

Function

The function of the corneal limbus is bifold; it not only serves as a reservoir for the stem cells involved in the active renewal of the corneal epithelium, but it also serves as a barrier to conjunctivalization of the cornea. Essentially, limbal stem cells are the ultimate source of regeneration for the entire corneal epithelium which is necessary after the sloughing of dead epithelial cells with every blink of the eye or even after corneal epithelial injury. Consequently, when this limbal epithelial regenerative function fails, conjunctival epithelial cells with goblet cells replace the corneal epithelium, and a clear barrier to the eye is opacified by the growth of a vascularized conjunctiva due to chronic inflammation. This often culminates in visual impairment and chronic pain in those afflicted.

Clinical Relevance

Patients afflicted with limbal stem cell deficiency suffer from recurrent epithelial defects as the corneal epithelium is unable to regenerate; persistent pain from continuous breakdown of the ocular surface with concurrent inflammation ensues. This process may ultimately lead to a complete blindness in the affected eye.

Limbal stem cell deficiency can occur due to chemical burns of the eye (alkali and acid),

thermal burns, contact lens usage, or even topically administered drugs. Injury may be acquired if a therapy such as cryotherapy damages the LSCs along with their niche. Systemic diseases such as Stevens-Johnson syndrome and cicatricial pemphigoid can also produce patients with limbal stem cell deficiency.

The management of limbal stem cell deficiency can be medical or surgical. Medical management aims to lessen the symptoms of pain and the inflammation that often occurs with limbal stem cell deficiency. The use of topical lubricants, corticosteroids, and autologous serum drops are well documented as they stimulate corneal healing.

In contrast, the surgical options intend to cure the disease process. It is important to assess whether the patient produces an appropriate tear film and that the patient can completely close his or her eye. These will be important prerequisite for the surgery in order to maintain the corneal epithelium post-corrective surgery. The first step of the surgical procedure is to remove the scarred tissue from the cornea. This tissue is conjunctivalized due to the limbal stem cell deficiency. When the disease is unilateral, limbal tissue from the same patient's healthy eye may be used for autologous transplantation. If bilateral disease exists, then a living related donor or cadaver's limbal stem cells may be used for allogenic transplantation. Of these two methods, autologous transplantation is the preferred method, although the condition is that the other eye must have viable limbal stem cells which can be used.

Limbal stem cell transplantation

Definition

Limbal transplantation refers to the surgical procedure in which one takes autogenic or allogenic stem cells located at the periphery of the cornea (the limbus) and seeds these stem cells on the corneal surface of an eye lacking functioning limbal stem cells.

In the past few decades, several new surgical techniques have emerged which have significantly changed the prognosis of previously debilitating disease due to limbal stem cell dysfunction. In 2008, the Cornea Society's International Committee for the Classification of Ocular Surface Rehabilitation Procedures created a system such that surgeons may classify limbal transplantation procedures based on various divisions. With the advent of ex vivo cultivation of limbal stem cells, it is first important to classify whether this method was used or a simple explant/implant procedure was observed. Secondly, one must address the anatomical source of the tissue and whether the donor is an autograft or allograft. Autograft tissue will include limbal stem cells from an individual's non-diseased eye. Allograft tissue, however, can be further classified into living relative or cadaveric tissue. The following chart will help delineate the aforementioned classification system.

Limbal transplantation		Ex vivo cultivated limbal transplantation	
Procedure	Transplanted tissue	Procedure	Transplanted tissue
Conjunctival limbal autograft	Conjunctival limbus	Ex vivo cultivated cadaveric limbal autograft	Corneal limbus
Cadaveric conjunctival limbal allograft	Conjunctival limbus	Ex vivo cultivated cadaveric limbal allograft	Corneal limbus
Living related conjunctival limbal allograft	Conjunctival limbus	Ex vivo cultivated living related limbal allograft	Corneal limbus
Living non-related conjunctival limbal allograft	Conjunctival limbus	Ex vivo cultivated living non-related limbal allograft	Corneal limbus
Keratolimbal autograft	Corneal limbus		
Keratolimbal allograft	Corneal limbus		

Indication

A lack of functioning limbal stem cells is the sole indication for limbal stem cell transplantation. Conjunctival limbal autograft is the procedure of choice for unilateral stem cell deficiency and unilateral ocular surface injury (traumatic and chemical injury) with an unaffected eye. Living related conjunctival limbal allograft is indicated in patients with bilateral stem cell failure who have conjunctival loss in addition to their stem cell dysfunction: Stevens-Johnson syndrome, ocular cicatricial pemphigoid, and atopic keratoconjunctivitis. Keratolimbal allografts are indicated in the eyes with severe bilateral stem cell deficiency which require large amounts of cadaveric stem cells; it is also indicated in individuals with unilateral disease who fear damage to healthy fellow eye and have no living donor tissue available. Keratolimbal allografts are also good for disease that primarily affects the limbus with minimal conjunctival involvement, such as chemical injury (Stevens-Johnson syndrome and ocular cicatricial pemphigoid if inflammation is controlled beforehand). Ex vivo cultivated limbal transplantation is indicated when there is the need to transplant a large amount of limbal stem cell tissue while harvesting only a small amount. This is most important in autografts who do not want to risk the healthy fellow eye by depleted stem cell reserves which often result in deficiency after the donation.

Contraindication

Conjunctival limbal autografts are contraindicated if the donor eye has any condition that may predispose it to the development of stem cell deficiency: long-term topical medication use or contact lens wear, previous surgery, and uncontrolled inflammation. Cadaveric conjunctival limbal allografts are contraindicated in systemic disease which prevents the use of oral and topical immunosuppression, severe dry eye, and keratinization of the ocular surface. Living related conjunctival limbal allografts are contraindicated in patients with complete stem cell loss; partial stem cell dysfunctions are better candidates than those with complete loss because the amount of limbus that can be transplanted in this procedure is limited compared to keratolimbal transplants. Systemic disease which prevents the use of oral and topical immunosuppression is another contraindication alongside severe dry eye and keratinization of the ocular surface. Living related conjunctival limbal allografts are contraindicated in systemic disease which prevents the use of oral and topical immunosuppression. Keratolimbal allografts are contraindicated in cases where severe stem cell deficiency is present in combination with conjunctival inflammation, scarring, and keratinization. Lack of stable tear film, eyelid abnormalities, uncontrolled inflammation, and systemic disease which prevents the use of oral

and topical immunosuppression are relative contraindications.

Techniques and Principles

Several techniques exist for limbal transplants. Conjunctival limbal autografts (CLAUs) are begun by first performing a conjunctival peritotomy and removing the corneal epithelium. Next, the conjunctiva is recessed posteriorly, and the abnormal fibrovascular epithelium is removed by a superficial keratectomy. Two donor limbal grafts are then delineated at 6 and 12 o'clock areas of the donor limbus. After separating the conjunctiva from Tenon's capsule, the graft is dissected toward the cornea transecting the palisades of Vogt. The proximal margin of this donor tissue is then transected and transferred to the recipient eye. When suturing the graft to the corresponding area of the recipient eye, care must be taken to avoid placing sutures through the limbal margin in order to minimize stem cell damage. This same procedure would be followed for a cadaveric conjunctival limbal allograft (CLAL). A living related CLAL is done in two separate operations. First, the allograft is harvested from the donor as described for the CLAU procedure. While the tissue is immersed in colloidal storage solution, it is of utmost importance to correctly orient the graft while being stored. This is usually done with asymmetric marking of the graft with a gentian violet marker. After the recipient eye is prepared to receive the graft, the graft is sutured into place as done in the CLAU procedure.

A less common type of limbal transplant is the keratolimbal allograft (KLAL). This procedure has the addition of a corneoscleral rim used in the transplant process.

Ex vivo cultivated limbal transplantation is yet another option for limbal stem cell transplantation. The technique and principles are similar for each of these allografts, whether they be cadaveric, living related, or living non-related ex vivo cultivated limbal allografts. First, a small number of stem cells are harvested. Next, they are then allowed to proliferate in favorable growth factors and culture environment on a carrier material such as an amniotic membrane. The rest of the transplantation procedure is similar for all the techniques. A 360° peritotomy is then done with recession of the conjunctiva and Tenon's capsule. Abnormal corneal epithelium and fibrotic tissue are removed with a full superficial keratectomy. The graft is then placed on the now denuded cornea and sutured into place, and a therapeutic soft contact lens is placed overlying the graft.

Outcome

Outcomes are better with autografts as there is less risk for rejection. There are continuing improvements with concurrent immunosuppressive therapy.

Complications

A major complication of living limbal stem cell donors' eyes is the development of stem cell deficiency in that very donor eye. When any allogenic limbal stem cell source is used for transplantation, there is a significant risk of rejection; oral and topical immunosuppressives are often used for long periods.

Limbal vernal conjunctivitis; Limbal Vernal Keratoconjunctivitis

Definition

Limbal Vernal Keratoconjunctivitis is an atopic disease whereby an allergic response is triggered by common environmental allergens such as pollen or dust resulting in a chronic papillary conjunctivitis. As noted by the term vernal, meaning springtime, Limbal Vernal Keratoconjunctivitis tends to be a recurring, seasonal inflammation of the conjunctiva and cornea.

Etiology

The genetic causes of Vernal Keratoconjunctivitis have not been fully determined. However, it is known that the atopy found in the Vernal Keratoconjunctivitis is driven by an overpopulation of Th2 T helper lymphocytes. These cells drive the disease process by a type 1, IgE-medicated hypersensitivity reaction. These Th2 lymphocytes produce interleukins 3, 4, and 13 which promote the synthesis of IgE by B lymphocytes. The papillae formed in Vernal Keratoconjunctivitis are formed by central vascular cores surrounded by edematous connective tissue.

Clinical Presentation

Patients with Vernal Keratoconjunctivitis present with symptoms of mucous discharge, itchy eyes, photophobia, blurred vision, and blepharospasm. Patients may have eczematous skin at the eyelids, with excoriations at the canthi. Papillary hypertrophy overlying the upper tarsal plates may result in giant papillae, greater than 1 mm in diameter. These giant papillae can give a cobblestone appearance. Depending where these giant papillae form, Vernal Keratoconjunctivitis can be classified as limbal, palpebral, or combined disease. Gelatinous collections of deposited eosinophils and epithelial cells can also form at the corneal limbus creating white Horner-Trantas dots.

Corneal changes can occur in the case of mild disease with punctate epithelial erosions, whereas with more intense palpebral involvement, mucus can be build up on the cornea resulting in corneal neovascularization. In severe palpebral disease, the release of toxic substances such as major basic protein from eosinophils can result in corneal epithelial macroerosions. If these erosions are not treated early and allowed to heal, then calcium deposition on Bowman's layer can prevent reepithelialization resulting in a shield ulcer or vernal plaque. Without proper healing, these erosions can be sources of infection such as herpes simplex keratitis or other complications. For example, up to 26% of patients have been found to develop keratoconus.

Diagnosis

Patients with Vernal Keratoconjunctivitis are diagnosed clinically based on presentation of signs and symptoms consistent with the disease as described above. Further investigations or tests to diagnose Vernal Keratoconjunctivitis are not widely available. Allergy testing is not indicated in the majority of these patients.

Differential Diagnosis

The differential diagnoses for Vernal Keratoconjunctivitis include other chronic papillary conjunctivitis, most predominantly Atopic Keratoconjunctivitis. Atopic Keratoconjunctivitis tends to be much less seasonal in nature and does not have an expected outcome resolving on its own after a few years.

Prophylaxis

Patients with mild to moderate disease that is seasonal in nature may attempt to prophylactically treat the disease by starting mast cell stabilizer drops at least 2 weeks prior to when symptoms generally begin. Patients with year-round disease may keep on year-round mast cell stabilizing topical medications.

Therapy

Therapy for this disease is determined based upon the severity of the disease. Mild cases may be treated with simply topical antihistamines. Topical H1 antagonists usually produce relatively quick relief of symptoms. Topical mast cell stabilizers can be used prophylactically for treatment. Combination of H1 antagonists and mast cell stabilizers include olopatadine 0.1%. These medications are safe for long-term use in patients.

Topical acetylcysteine has also been used to decrease mucus adherence to the cornea during episodes of Vernal Keratoconjunctivitis. More severe cases may require topical steroid or even topical immunomodulators such as cyclosporine. Topical steroids are most commonly used every 2 h for 5–7 days. Steroid-related complications can be avoided by using steroids for exacerbations instead of chronic treatment. Interestingly, the precipitation of particulate matter between papillae with prednisolone acetate can be avoided by using dexamethasone phosphate as the preferred steroid for topical treatment.

An alternative steroid treatment is the supratarsal subconjunctival injection of a steroid. However, the patient would have to be monitored for steroid-induced pressure spikes while receiving this treatment. In refractory cases of Vernal Keratoconjunctivitis, topical cyclosporine can also be administered two to four times a day.

Prognosis

The prognosis for Vernal Keratoconjunctivitis is generally positive. Unlike Atopic Keratoconjunctivitis, which presents later in life and tends to be a much more chronic, year-round disease, Vernal Keratoconjunctivitis more commonly presents during the first decade in life and usually resolves by the time the patient reaches his late teens.

Epidemiology

Vernal Keratoconjunctivitis typically develops by age 10 with a mean age of onset by 7 years old. In 95% of cases, the disease subsides by late adolescence.

Vernal Keratoconjunctivitis is more commonly found in young males, but this gender difference is less significant in the tropics. Although 3–10% of children in Africa and the Middle East are estimated to have Vernal Keratoconjunctivitis, the prevalence in children in Western Europe is only 0.03%. Limbal Vernal Keratoconjunctivitis is more common in Asian and African patients, and this difference in prevalence has been noted to remain even after migration to temperate regions.

Lipemia Retinalis

Mingjuan Lisa Zhang
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

Lipemia retinalis is characterized by creamy-white-colored retinal blood vessels in patients with hypertriglyceridemia.

Etiology

The scattering of light by high levels of triglyceride-laden chylomicrons in the plasma accounts for the fundus appearance.

Clinical Presentation

Lipemia retinalis is seen in some hyperlipidemic states (elevated serum triglyceride levels). There may be recurrent abdominal pain due to pancreatitis and/or eruptive xanthomas associated with chylomicronemia. There are no changes in visual acuity, but fundus changes include whitish retinal vessels and a salmon-pink retina (Kanski et al. 2011). Elevated plasma triglyceride levels may have other ocular manifestations (e.g., lipemic aqueous, corneal arcus, xanthelasma, palpebral xanthomas, retinal vein sludging, red cell aggregation).

Diagnosis

A blood test should be performed to detect hyperlipidemia. Fundus examination can reveal:

- Early stage (triglyceride levels 2,500–3,499 mg/dL): creamy and thin peripheral vessels
- Moderate stage (triglyceride levels 3,500–5,000 mg/dL): creamy posterior pole vessels
- Late stage (triglyceride levels >5,000 mg/dL): salmon-colored fundus, creamy vessels

Electroretinogram amplitude may be decreased.

Differential Diagnosis

– Hypertriglyceridemia ± chylomicronemia syndrome
  Primary familial lipid disorder (hyperlipoproteinemia types I, III, IV, or V)

Secondary hyperlipidemia: diabetes mellitus, biliary obstruction, nephrotic syndrome, pancreatitis, hypothyroidism, alcoholism, medications (estrogens, beta-blockers, protease inhibitors), and acquired immunodeficiency syndrome

Prophylaxis

Regular physical activity with a low-fat diet.

Therapy

Treatment is necessary for the systemic effects of hypertriglyceridemia, but no treatment is required for the lipemia retinalis itself. A low-fat diet alone is often sufficient to reverse ocular findings. Medium-chain fatty acids (including medium-chain triglyceride milk for neonates) can provide a source of fat in the diet because they do not rely on chylomicron formation (Zahavi et al. 2013).

Prognosis

Lipemia retinalis quickly improves (within 1 week) as triglyceride levels return to normal.

Epidemiology

Lipemia retinalis is a rare condition that may occur in neonates and children as a result of a primary familial lipid disorder (e.g., ApoC-II deficiency, LPL deficiency) or in adults secondary to other diseases (Hoyt et al. 2013).

Lipid Keratopathy

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Corneal lipid degeneration

Definition

Lipid keratopathy is pathology of the cornea that leads to decreased vision due to intracellular and extracellular corneal lipid deposits and/or neovascularization. Primary lipid keratopathy is often bilateral, hereditary, avascular, and in the absence of any underlying condition. Secondary lipid keratopathy is unilateral, peripheral, non-hereditary, vascular, and associated with an underlying condition.

Etiology

The etiology of lipid keratopathy depends on whether the disease is primary or secondary. Primary lipid keratopathy is a rare disease and has features of a corneal dystrophy. Secondary lipid keratopathy, in contrast, has features characteristic of degeneration. The other major difference is that primary lipid keratopathy has no underlying metabolic disorder, while secondary lipid keratopathy is often linked to an underlying systemic disease.

The deposits of both are formed from triglycerides, cholesterol, and phospholipids (Chang and Ching 2011).

As previously mentioned, primary lipid keratopathy has no underlying disorder of lipid metabolism. In fact, the lipid levels are often normal (Chang and Ching 2011). There is some question as to whether or not primary lipid keratopathy may be an advanced arcus senilis. Both arcus senilis and lipid keratopathy deposit lipids in the posterior stroma and Descemet's membrane (Chang and Ching 2011). It is hypothesized that the lipid deposits are due to increased limbal vessel permeability and the release of fatty products into the stroma as keratocytes die (Chang and Ching 2011).

Secondary lipid keratopathy often occurs very suddenly. Neovascularization is present in secondary lipid keratopathy, and these vessels are more permeable and clear lipids less effectively. This is why when lipid levels in the body rise, progression of the gray/yellow infiltrate can occur (Chang and Ching 2011). When the individual's lipid levels return to normolipoproteinemia, there is an associated regression of the infiltrate (Chang and Ching 2011). Secondary lipid keratopathies are often the result of aging, environmental stimulus, or inflammation (Kanski and Bowling 2011). The most common cause of secondary lipid keratopathy is herpes simplex and herpes zoster (Kenyon et al. 2008). Lipid keratopathy can also be seen with interstitial keratitis, corneal hydrops, trauma, ulceration, and mustard gas injury (Chang and Ching 2011). Some can be inherited dystrophies that deposit lipid and include Tangier disease, apolipoprotein A-1 deficiency, lecithin cholesterol acetyltransferase (LCAT) deficiency, and fish-eye disease (Chang and Ching 2011; Woodward et al. 2014).

There are a few options in treating the symptom of lipid keratopathy. While achieving normolipoproteinemia is associated with regression of secondary lipid keratopathy, there are other options if blood lipid levels are inadequate. Argon laser can be used to induce lipid resorption, or needlepoint cautery can be used to target the feeder vessels (Kenyon et al. 2008). In advanced disease, penetrating keratoplasty can also be used (Kenyon et al. 2008; Chang and Ching 2011). Treatment is often very successful, but recurrence of primary lipid keratopathy has been documented in case reports (Chang and Ching 2011).

Occurrence

Primary lipid keratopathy is a rare disease and shows features of a dystrophy. Dystrophies occur bilaterally and are hereditary. When primary lipid keratopathy occurs, they are bilateral, non-inflammatory, avascular deposits of white/yellow lipid in the central cornea (Kenyon et al. 2008; Chang and Ching 2011; Kanski and Bowling 2011). These dystrophies occur early in life, as compared to degenerations, which often are considered aging effects and occur later in life.

Secondary lipid keratopathy shows features of a degeneration. Degenerations begin with normal function and over time deteriorate in function. Unlike primary lipid keratopathy, the lipid deposits are often unilateral. Also, unlike primary lipid keratopathy, the lipid deposits occur more peripherally, but can also progress to involve the central cornea (Kanski and Bowling 2011). The deposits can either be feathery in post-inflammatory states or discoid when occurring in active inflammation (Chang and Ching 2011).

Lipid keratopathy is more common in women, with a ratio of 70:30. While it is not well understood, it is hypothesized that the higher levels of HDL cholesterol in premenopausal women contributes to this higher prevalence (Chang and Ching 2011).

Classification

Lipid keratopathy is classified either as primary or secondary. These differ in their etiology and

occurrence with the distinctions as discussed above.

Synonyms

Sakurai-Lisch nodules

Definition

Lisch nodules are smooth, dome-shaped, pigmented hamartomas of the iris.

Basic Characteristics

Lisch nodules are commonly found in patients with neurofibromatosis type 1 (NF1) but are not a diagnostic feature of neurofibromatosis type 2. Lisch nodules are not generally present at birth but develop over time in 94–97% of patients with NF1 who are over the age of 6 and in essentially all patients with NF1 by the age of 30. Lisch

nodules can be translucent, tan, or brown and are usually more prevalent on the inferior iris. They are bilateral, elevated, and often gelatinous and typically measure between 0.5 and 1.0 mm in diameter. Lisch nodules are asymptomatic but can be helpful in the diagnosis of NF1, especially when discovered in asymptomatic relatives. The diagnosis of NF1 is made when a patient has at least two of seven established findings, one of which is multiple Lisch nodules.

Lithiasis, Conjunctival

Farhan I. Merali
Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Conjunctival concretions

Definition

Conjunctival lithiasis refers to the small, hardened superficial subepithelial deposits that occur as a result of secondary calcification of conjunctival concretions. Though the two terms are often used synonymously, histopathological evidence has revealed that concretions do not routinely contain calcium or phosphate but are composed of products of cellular degeneration including epithelial and keratin debris. Lithiasis may lead to irritation due to mechanical microtrauma of the corneal epithelium, in which case they can be removed at the slit lamp under topical anesthesia.

Local Anesthesia for Ophthalmic Procedures

Arti Panchal
Department of Anesthesiology, Medical College of Wisconsin, Milwaukee, WI, USA

Synonyms

Regional anesthesia

Definition

(Local) regional anesthesia for ophthalmic procedures refers to the administration of anesthetic agents either topically, intraocularly, or by injection. The route of administration depends on several factors, including surgeon and patient preference, patient's ability to follow commands, type and length of procedure, and amount of akinesia required. Topical anesthesia allows for anesthesia of the conjunctiva, cornea, and anterior sclera. Intraocular anesthesia may be used as an adjunct to topical anesthesia to achieve anesthesia for the intraocular structures, such as the iris, as well as to reduce the sensation of pressure fluctuations in the anterior chamber. Injection anesthesia can be delivered by parabulbar (subtenon's), peribulbar, or retrobulbar routes and provides anesthesia to the ocular surface and intraocular structures. Injection anesthesia also allows for a decrease or elimination of the extraocular movements.

Lower Lid Retraction

Pete Setabutr[1] and Joann Kang[2]
[1]Department of Ophthalmology and Visual Sciences, University of Illinois, Chicago, IL, USA
[2]Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA

Definition

Eyelid retraction is the displacement of the normal position of the lower eyelid margin with respect to the limbus.

Basic Characteristics

Clinical Features

In most normal individuals, the lower eyelid margin rests at the level of the inferior limbus. In lower lid retraction, the eyelid position is depressed below this level, producing inferior scleral show. Eyelid retraction may be unilateral or bilateral. Mild retraction of the eyelids may occur as a normal anatomical variant of eyelid position seen in patients with axial myopia, shallow orbits, maxillary hypoplasia, or certain genetic orbital or eyelid characteristics. Involutional changes with laxity of the tarsal canthal tendons may also manifest as lower lid retraction.

Lid retraction can lead to lagophthalmos and corneal exposure, leading to secondary epiphora and dry eye symptoms.

Diagnostics

Position of lower eyelid with relation to limbus, height of the palpebral fissure, degree of lagophthalmos, associated proptosis, levator muscle function, distance from lower eyelid margin to the central corneal reflex, and radiological studies.

Etiology

The most common cause of lower eyelid retraction is Graves' disease. Although the exact mechanism of retraction associated with Graves' disease is debated, histopathologic changes include inflammation, adipogenesis, and fibrous contraction of eyelid retractors.

Other causes of lower lid retraction include postsurgical complications after vertical rectus muscle surgery, with anatomical connections between the inferior rectus and capsulopalpebral fascia. Lid malposition is also a well-known postoperative complication of lower lid blepharoplasty, occurring more frequently in patients with preexisting lid laxity and excessive skin resection at surgery.

Luminance: Definition

Timo Eppig
Institute of Experimental Ophthalmology, Saarland University, Homburg, Germany

Definition

Luminance is a photometric measure of luminous intensity L [$cd \cdot m^{-2}$]. In contrast to radiance or brightness, luminance defines the amount of light visually perceived by the eye accounting for the spectral sensitivity curve $V(\lambda)$. It is used to specify emission from flat, diffuse emitting/reflecting surfaces such as visual acuity test charts (e.g., 85 $cd \cdot m^{-2}$ for photopic ETDRS test). If the spectral distribution of a light source is known, luminance can be calculated from radiance L_e: $L = 683 \frac{lm}{W} \cdot \sum V(\lambda) \cdot L_e(\lambda)$. Luminance usually used for reporting visually perceived intensity of light sources or displays.

Lutein

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Macular xanthophyll

Definition

Lutein is one of the hundreds of carotenoids found in nature. Carotenoids are lipophilic pigments that absorb light, creating the different colors. Lutein belongs to a subclass of carotenoids called xanthophylls. Xanthophylls have unique biochemical properties due to a free hydroxyl groups at each end of the molecule, differentiating them from other carotenoids with similar structures. These hydroxyl groups allow for specific orientation within cell membranes and lipoproteins.

Lutein is one of the less than 20 carotenoids found in the human body. Carotenoids are not produced in the body and must be consumed through diet. Leafy green vegetables like spinach and kale and egg yolks, due to poultry-feed supplementation, are good sources of lutein.

Lutein and another xanthophyll, zeaxanthin, make up the macular pigment of the eye. Through their antioxidative properties, it is thought that lutein and zeaxanthin act to protect photoreceptors in the macula from potential free radical damage. Lutein and zeaxanthin may also act to filter high-energy blue light wavelengths, reducing the potential oxidative stress from light entering the eye. Lutein is also likely the precursor to meso-zeaxanthin, a third carotenoid found in macular pigment that has a very similar structure to lutein. Meso-zeaxanthin is not found in blood serum and is likely derived from lutein undergoing a photochemical transformation.

Indication

The anti-oxidative properties of lutein and other xanthophylls may be helpful in decreasing age-related changes like macular degeneration and cataract in the eye. In 1994, Seddon et al. showed a direct correlation between dietary intake of carotenoids and the reduced risk of exudative age-related macular degeneration. Report number 22 by the Age-Related Eye Disease Study (AREDS) Research Group also found that high dietary intake of lutein and zeaxanthin is independently associated with decreased likelihood of having extensive intermediate drusen, geographic atrophy, and neovascular age-related macular degeneration. The Carotenoids in the Age-Related Eye Disease Study (CAREDS) group have found that diets rich in lutein and zeaxanthin are also associated with decreased prevalence of nuclear cataract in older women. Dietary supplementation with lutein may prevent or delay the onset of age-related macular degeneration and cataract. A large multicenter trial, the age-related eye disease study II (AREDS 2), studying the effects of oral macular xanthophylls and/or omega-3 fatty acids for the treatment of age-related macular degeneration and cataract is currently underway.

Contraindication

Known sensitivity to lutein.

Use and Dosage

There is no recommended daily allowance (RDA) for lutein. The age-related eye disease study II

(AREDS 2), a large multicenter trial studying the effects of oral macular xanthophylls and/or omega-3 fatty acids for the treatment of age-related macular degeneration and cataract, is using a lutein/zeaxanthin tablet of 10 mg of lutein and 2 mg of zeaxanthin. Average daily intake of lutein/zeaxanthin is 3–4 mg.

Adverse Reactions

There are no known harmful side effects. Minor side effects such as difficulty in swallowing pills and headache have been reported.

Interactions

There are no known serious interactions reported with lutein.

Luxated Lens

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Ectopia lentis; Lens instability, Lens luxation

Definition

Partial or total dislocation of the crystalline lens as a result of instability of the clamping system of the crystalline lens.

Histology

The ciliary body with its zonular fibers represents the fixture of the crystalline lens. Disturbances of this fixture can result in a luxation of the crystalline lens. Fifty percent of all cases of lens luxation are traumatic caused by boisterous beats or injuries. Other causes are genetic disorders accompanied with congenital weakness of connective tissues such as Marfan's syndrome, Marchesani's syndrome, and homocystinuria. Another pathomechanism of lens luxation can be a non-treated mature cataract. In this case, the crystalline becomes progressively thick and heavy. As a result the lens clamping system decompensates. Because of its anatomical position behind the iris,

a luxation backward into the vitreous body is more common than a luxation through the pupil into or the anterior chamber.

Immunohistochemistry

There are no data available in this topic.

Electron Microscopy

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology, University of Texas, Medical School at Houston, Houston, TX, USA
[7]Department of Ophthalmology, The Methodist Hospital, Houston, TX, USA

Synonyms

Borrelia burgdorferi; Lyme borreliosis

Definition

Lyme disease is a tick-borne illness caused by the spirochete bacteria *Borrelia burgdorferi.* Its effects on the body are variable and wide ranging, including clinical manifestations in the skin, heart, nerves, and eyes. Ocular manifestations of Lyme disease include, but are not limited to, keratitis, follicular conjunctivitis, optic neuritis, and retinitis. These ocular findings occur throughout the course of the infection: either early on or during the later manifestations of disease. Ocular manifestations of Lyme disease are estimated to occur in up to 10% of patients with Lyme disease.

Etiology

The spirochete bacteria *Borrelia burgdorferi* is the causative agent in Lyme disease. The bacterium infects human hosts through a bite by the tick *Ixodes scapularis*. Once the bacterium is transmitted to the human host, it travels throughout the body, preferentially affecting tissues of the skin, joints, heart, and peripheral nerves. *Borrelia* is a highly motile bacterium. Its swift penetration through layers of tissue is attributed to its ability to bind host-derived plasmin on cell membranes, which then permits its entry into cells. *Borrelia* likely infects the eye through this mechanism. The most common ocular manifestations of Lyme disease, namely, keratitis and inflammation of the posterior chamber, are thought to occur as part of the generalized inflammation – arthritis, carditis, and peripheral neuritis – that presents a few weeks to months after initial infection. These manifestations occur if the initial presenting signs of infection, namely, the rash of erythema migrans, went undiagnosed and untreated.

Clinical Presentation

The clinical presentation of Lyme disease varies greatly and can have several different presenting signs and symptoms depending on how far away from initial infection the diagnosis is made. At the time of the acute infection, the characteristic rash of erythema migrans is typically visible. Generalized lymphadenopathy, headache, follicular conjunctivitis, and photophobia may follow. A few weeks to months after initial presentation, dissemination of the bacterium occurs and carditis (palpitations, arrhythmias, heart block, myocarditis), arthralgias, and facial nerve palsy all can occur. This is the stage at which the greatest variety of ocular manifestations can be observed. Nonstaining bilateral keratitis is the most common ocular presentation at this stage; however, iritis, uveitis, macular edema, optic disk edema, optic neuritis, and Horner's syndrome have all been described. At the third stage of infection, manifestations of disease are more chronic and include persistent arthritis – usually of large joints – fatigue, stromal keratitis, and episcleritis.

Diagnostics

If a patient presents early while the lesion of erythema migrans is still present, diagnosis based on this clinical criteria alone is sufficient. Serologic testing is likely to be negative this early on because the body has not had sufficient time to mount an immune response. Laboratory study confirmation of infection is needed to definitively establish a diagnosis of Lyme disease at later stages when the classic erythema migrans rash has usually disappeared. The most accurate laboratory test for Lyme disease involves culture and PCR amplification on a sample from the suspected site of infection. However, culture and PCR can only be done in very specialized laboratories, so antibody detection is currently the most common test used to diagnose Lyme borreliosis. A staged approach is typically used to establish diagnosis. First, a screening test such as an ELISA or immunofluorescent assay is performed. If this test is positive, a Western blot is performed to confirm diagnosis. Although ocular findings consistent with Lyme disease can be appreciated on slit lamp or fundoscopic exam, the clinical presentation can mirror many other diagnoses, hence serologic confirmation is necessary.

Differential Diagnosis

The manifestations of Lyme borreliosis, especially ocular Lyme, are very diverse. Therefore, there is a very broad differential diagnosis for each ocular manifestation. Lyme keratitis is probably the most common ocular manifestation. Since generalized inflammation is also present, other inflammatory syndromes that cause ocular findings, such as reactive arthritis, rheumatoid arthritis, and sarcoidosis, must all be considered. Staphylococcal keratitis, contact-lens-associated keratitis, and corneal abrasion are also all in the differential.

Prophylaxis

The best prophylaxis against Lyme disease is prevention of the tick bite by way of wearing long sleeves, DEET-containing insect repellent, and checking the body for ticks daily if someone is in an endemic area. If a person presents with a known tick bite, antibiotic prophylaxis against Lyme disease is not usually recommended unless certain parameters have been met. If the patient is being seen within 72 h of the tick bite, the tick looks like it has been attached for greater than 36 h, it can reliably be identified as an *Ixodes scapularis* tick, and the bite occurred in an area where greater than 20% carry *Borrelia*, 1 dose of 200 mg oral doxycycline has been shown to be very effective in preventing Lyme disease. Otherwise, the best prophylaxis for ocular Lyme borreliosis is early detection of infection and prompt treatment. If Lyme is diagnosed at the initial stage of cutaneous infection, many of the ocular sequelae can be prevented.

Therapy

If Lyme disease is diagnosed and treated early, 100 mg of oral doxycycline two times daily for 14 days is the recommended treatment in adults and nonpregnant, non-lactating women (oral amoxicillin 500 mg three times per day for 14 days is recommended in pregnant or lactating women). If the early conjunctivitis is present at this stage, no other direct ophthalmic treatment is recommended, as it should resolve with oral antibiotic therapy. If Lyme disease is diagnosed during the more advanced stages of disease, including the more severe ocular manifestations of keratitis, uveitis, and episcleritis, IV ceftriaxone for 14 days is typically used. This is the same treatment regimen that is used for late-presenting neurologic manifestations, such as meningitis, radiculopathies, or peripheral or cranial nerve palsies. Topical ophthalmic steroid solutions have occasionally been used in conjunction with the antibiotic regimen, but research is lacking in proving that their application truly speeds resolution of symptoms or prevents recurrence.

Prognosis

As is the case in many illnesses, prognosis is dependent on the stage of disease at which the diagnosis is made. On the whole, the earlier that ocular Lyme is diagnosed and treatment is started, the better the prognosis is. There are several case reports describing the relapsing remitting nature of Lyme-associated uveitis and episcleritis. In most of these cases, the recurrent inflammation was controlled with IV ceftriaxone and occasionally topical steroids. Vision is usually preserved. There are isolated cases of rapid deterioration of vision due to extensive inflammation of the posterior chamber and retinal detachment; however, these are very rare.

Epidemiology

There are varying reports of the prevalence of ocular Lyme disease. It is generally considered rare, especially the later sequelae of disease. However, there are reports describing that up to 10% of patients will have follicular conjunctivitis as part of the initial presentation of Lyme disease.

Lymphoma: Definition

Tin Yan Alvin Liu
Wilmer Eye Institute, Johns Hopkins University, Baltimore, MD, USA

Definition

A hematologic malignancy characterized by monoclonal, neoplastic proliferation of leukocytes of lymphoid origin that is capable of producing masses within the involved lymph nodes and/or in other tissues. The World Health Organization classification, last updated in 2008, divides lymphoma into three broad categories by cell types: B cell, T cell, and natural killer cell (Swerdlow and International Agency for Research on Cancer, World Health Organization 2008).

Lynch Incision, for Anterior Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Synonyms

Frontoethmoidal incision, for anterior orbitotomy

Definition

A transcutaneous orbitotomy designed to access the medial orbital wall and extraperiosteal space.

Indications

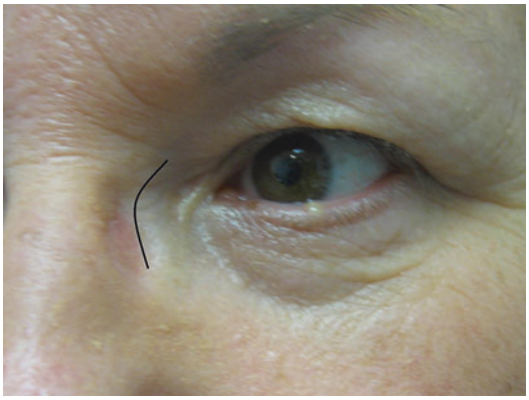
This procedure is used to access the medial wall when a transcaruncular approach does not offer enough exposure. It may be useful in treatment of posttraumatic telecanthus requiring fracture repair or transnasal wiring, or for other nasal fracture repair. It also may be used for drainage of a subperiosteal abscess, for orbital fracture repair, or for bony decompression of the medial orbit.

Contraindication

Contraindications for patients who wish to avoid a skin incision and for patients who are not medically stable for surgery.

Techniques and Principles

This area is approached with a curved skin incision placed approximately half way between the medial canthus and the bridge of the nose extending from the inferior to superior orbital rims as necessary (Fig. 1). Posterior dissection is that carried out to reach the medial orbit. At the end of the procedure, meticulous skin closure is performed in several layers to reduce the risk of scarring.



Lynch Incision, for Anterior Orbitotomy, Fig. 1 Medial canthal area of patient depicting skin marking generally used for lynch incision, showing a curvilinear incision half way between the medial canthus and the bridge of the nose

Outcome

Broad visualization of the subperiosteal spaces of the orbital wall for drainage of an abscess, bony decompression, or orbital or nasal fracture repair.

Complications

Risks include anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, and need for additional procedures.

Macroaneurysms

David Boyer
Department of Ophthalmology, Retina Vitreous Assocsiates Medical Group, Beverly Hills, CA, USA

History

Cases describing isolated retinal arteriole macroaneurysms have been described since the late 1880s. The term retinal arterial macroaneurysm (RAMA) was first coined by Dennis Robertson in 1973 (Robertson 1973).

Definition

Retinal macroaneurysms are acquired round or fusiform dilations of the retinal arterioles occurring in the first three bifurcations of the retinal arteriole (Robertson 1973).

Etiology

The etiology is unknown. Some consider the occurrence of the aneurysm to occur in association with arteriosclerosis, resulting in a decreased elasticity of the vessel wall and with increase in the luminal pressure that causes the dilation. Another hypothesis considers that emboli or thrombus formation causes damage to the vessel wall, which causes the outpouching (Palestine et al. 1982; Wiznia 1992; Gass 1997; Somnez et al. 2012).

Clinical Presentation

Macroaneurysms may occur in any quadrant; however, the superotemporal quadrant is the most commonly reported due to the visual impairment that occurs from lesions in that area. Retinal macroaneurysms may be asymptomatic and picked up only on routine evaluation or present with distortion or loss of vision if blood or serous detachment occurs in the fovea. Hemorrhage is often a presenting feature and may occur subretinal, intraretinal, subhyaloid (or preretinal), or into the vitreous or in an "hourglass" appearance with hemorrhage in multiple layers. They may be present on the optic nerve (Brown and Weinstock 1985) and cilioretinal artery (Giuffre et al. 1987) and may be pulsating.

Diagnostic Testing

The diagnosis is usually made clinically when one sees a small white outpouching associated with exudation or with an hourglass hemorrhage. The diagnosis can be confirmed by fluorescein angiography. If preretinal blood obscures the area of the aneurysm, indocyanine green angiography

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

can be utilized (Townsend-Pico et al. 2000). Blood pressure measurements and lipid profile are recommended.

Differential Diagnoses

Retinal capillary angioma, diabetic retinopathy, cavernous hemangioma, malignant melanoma (Fritsche et al. 2000), hemorrhagic pigment epithelial detachment associated with macular degeneration, Coats' disease, branch vein occlusion (Schulman et al. 1981; Cousins et al. 1990), retinal telangiectasis.

Therapy

Treatment remains controversial. Studies have shown the natural history can be very good. Many macroaneurysms do not leak into the fovea and can be observed; however, chronic leakage in the macula, if left untreated, may lead to permanent visual decrease. In one study, laser photocoagulation to the macroaneurysm was not found to be advantageous. Other studies, however, have shown visual improvement when laser photocoagulation is applied directly to the macroaneurysms and surrounding tissues. Light laser to the macroaneurysm has been recommended to avoid an arterial occlusion distal to the aneurysm. If bleeding occurs under the fovea, treatment to displace the blood may be indicated. Both pneumatic displacement and vitrectomy with subretinal TPA and gas have been described (Somnez et al. 2012). Recent articles have shown an improvement of vision with intravitreal bevacizumab injections (Cho et al. 2013; Zweifel et al. 2013). After macroaneurysms bleed, they usually go on to closing.

Epidemiology

The lesions are usually found in elderly woman (71–80%) with a history of hypertension or arteriolar sclerosis in the sixth decade of life. Macroaneurysms have been reported in younger patients, though rare. Macroaneurysms tend to be unilateral and single. Bilateral macroaneurysms may occur 10% of the time and multiple within the same eye 20% of the time. Macroaneurysms have associated with diabetes elevated lipids, retinal vasculitis (Kincaid and Schatz 1983), collagen vascular disease, and sarcoid though not consistently. Hypertension appears to be the most commonly associated systemic disease (Cleary et al. 1975; Lewis et al. 1976; Abdel-Khalek and Richardson 1986).

Synonyms

Megalopia

Definition

Macropsia is a disorder of visual perception in which a portion of the vision appears larger than normal. Compression of retinal photoreceptors can cause greater stimulation of retinal elements and the resulting perception of macropsia. Macropsia is a type of dysmetropsia (visual illusion).

Etiology

Macropsia usually results from retinal conditions (e.g., epiretinal membrane and macular edema) but can be due to cortical processing defects when bilateral or hemianopic.

Diagnostics

A complete eye exam and an Amsler grid can document the laterality, location, size, and severity of macropsia. A New Aniseikonia Test (NAT) can also be used to detect and quantify the degree of macropsia effect. Brain imaging or EEG may be necessary for patients with cortical macropsia especially if bilateral, simultaneous, or hemianopic.

Therapy

Treatment should be directed at the underlying etiology.

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Hereditary macular dystrophy; Inherited macular dystrophy

Definition

Macular dystrophy is a nonspecific term to describe a heterogeneous variety of inherited ocular disorders in which the posterior pole of the retina is predominantly affected. These disorders may present with characteristic macular abnormalities, decreased visual acuity, or both. Several gene mutations have been identified which result in macula involving changes in the eye, and it is anticipated that more will be identified in the future. The extent of visual acuity changes and macular findings is variable and dependent on the underlying disease, the extent of gene expression and penetration, and the stage of its progression.

Basic Characteristics

Macular findings with macular dystrophies are extremely variable and can range from very minimal to extensive changes. Different layers of the retina, retinal pigment epithelium (RPE), Bruch's membrane, or choriocapillaris may be the predominant site of involvement. Potential findings include cystic macular changes, drusen, vitelliform lesions or other deposits in the posterior pole, atrophic changes, bull's eyelike maculopathy, and pigmentary changes. A list of some macular dystrophies with an attempted classification based on area of involvement is shown below:

Macular dystrophies
Nerve fiber layer
- X-linked juvenile retinoschisis

Photoreceptor and RPE
- Cone (-rod) dystrophy
- Congenital color vision defects
- Best vitelliform dystrophy
- Stargardt's disease/fundus flavimaculatus
- Doyne's honeycomb retinal dystrophy/malattia leventinese
- Pattern dystrophy
- North Carolina macular dystrophy/central areolar pigment epithelial dystrophy
- Dominant cystoid macular dystrophy

Bruch's membrane
- Sorsby fundus dystrophy
- Angioid streaks – associated with several different systemic conditions
- Myopic degeneration

Choroid
- Central areolar choroidal dystrophy

Evaluation of patients with suspected macular dystrophy should include a detailed family, medical, and ocular history and a through ocular exam including color vision, dark adaptation, and Amsler grid testing. Ocular imaging that may be helpful includes visual field testing, fluorescein angiogram (FA), autofluorescence, and optical

coherence tomography (OCT). Electrophysiologic testing with both full-field and multifocal electroretinograms (ERGs) or electrooculograms (EOGs) may also aid in diagnosis. Genetic testing is available for a variety of macular dystrophies.

Macular Edema

Burkhard von Jagow
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Macular swelling; Macular thickening

Definition

Macular edema is an abnormal thickening of the neurosensory retina in the area of the macula with the intra- and/or extracellular accumulation of excess fluid. It represents a common final pathway of numerous retinal disorders, and it is the leading cause of central vision loss in the developed world. In most cases, it consists of a severe disturbance of the blood retina barrier. The diseases-causing macular edema is multiple and includes: choroidal neovascularization, diabetic retinopathy, retinal venous occlusion, postoperative cystoid macular edema, uveitis, tractional maculopathy, inherited retinal dystrophy, vascular and optic nerve abnormality, intraocular tumor, and idiopathic macular edema. Regardless of the etiology and in addition to the macular thickening, the resulting visual acuity depends on many factors, such as duration of edema, perfusion of macular capillaries, photoreceptor loss, retinal pigment epithelium dysfunction, and media opacities.

Histology

Most commonly, macular edema results from pathologic hyperpermeability of retinal blood vessels, particularly the retinal capillary bed. Increased vascular permeability provokes extravasation of fluid, proteins, and other macromolecules in the retinal interstitium. The central area of the retina is predisposed to develop an edema due to its unique anatomy characterized by its increased metabolic activity, loose bindings of the inner connecting fibers in the outer plexiform layer, and the watershed arrangement between the choroidal and retinal circulation with Henle's fiber layer functions as the lateral border. The accumulation of fluid mainly occurs in the outer plexiform layer and the inner nuclear layer. Intracellular accumulation is also found in the Müller cells.

Immunohistochemistry

Numerous molecules may induce the retinal vascular hyperpermeability that leads to macular edema. Depending on the underlying disease entity, these include prostaglandins and leukotrienes, protein kinase C, nitric oxide, and various

cytokines such as vascular endothelial growth factor, tumor necrosis factor alpha, insulin-like growth factor 1, and interleukins.

Optical Coherence Tomography

In the diagnosis and assessment of macular edema, optical coherence tomography (OCT) allows the detection of subretinal and intraretinal fluid and abnormal exudation from the retinal capillary bed. It permits the measurement of foveal retinal thickness and changes in macular edema.

Molecular Diagnostics

Molecular diagnostics exists for a rare cause of macular edema: autosomal dominant cystoid macular edema.

Differential Diagnosis

Inflammatory disorders: intraocular surgery, Irvine-Gass syndrome (cataract surgery), laser procedures, uveitis syndromes, neuroretinitis, idiopathic retinal vasculitis
Retinal vascular disease: diabetic retinopathy, radiation retinopathy, retinal venous occlusion, hypertensive retinopathy, retinal macroaneurysm, macular telangiectasis, Coats' disease
Choroidal vascular disease: choroidal vascular disease, age-related macular degeneration, myopic macular degeneration, etc.
Drug reaction: prostaglandin analogs, epinephrine, nicotinic acid, tamoxifen, thiazides
Retinal dystrophies: retinitis pigmentosa, autosomal dominant cystoid macular edema
Tractional maculopathies: vitreomacular traction syndrome
Retinal detachment: rhegmatogenous, exudative
Intraocular tumors: hemangioma, choroidal malignant tumors, metastasis
Optic nerve abnormalities: cavitary disk anomalies
Idiopathic macular edema

Macular Holes

Jonathan Schell
STL Vision, Saint Louis, MO, USA

Definition

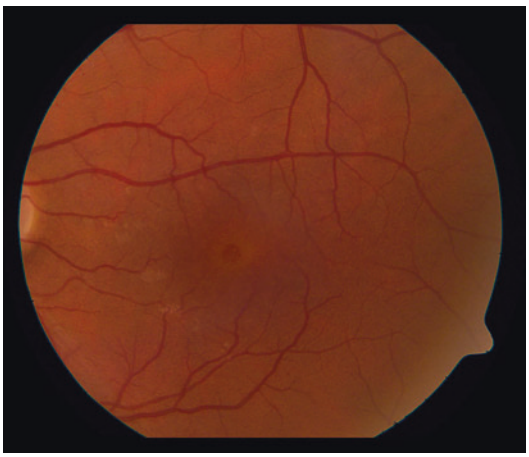
A full thickness defect of the neurosensory retina in the macula region.

Etiology

Most macular holes are idiopathic (Gass 1997; Ho 1999). These holes likely develop from tangential vitreous traction on the fovea. Four stages

of macular hole evolution have been described by Gass (1997). Stage 1 represents an impending macular hole and is further subdivided into stage 1A (detachment of the foveola) and 1B (detachment of the fovea). Approximately, 60% of Stage 1 holes undergo spontaneous resolution and do not progress to Stage 2. Stage 2 follows Stage 1 and is defined as a small full thickness defect in the retina less than 400 micrometers (um) in diameter. The majority of Stage 2 holes progress to Stage 3 holes which are larger (equal to or greater than 400 um) and display a rim of thickened and slightly elevated retina. Stage 4 is defined as a full thickness macular hole in the presence of a posterior vitreous detachment as signified by a Weiss ring (Figs. 1 and 2).

A minority of macular holes develop as sequelae of various vitreoretinal disorders, including trauma, post laser light exposure, lightning strike, hypertensive retinopathy, and cystoid macular edema. The pathogenesis of these secondary macular holes varies according to underlying retinal disease. Macular holes following cystoid macular edema likely develop as the cystic retinal space coalesce and rupture into the vitreous cavity. The cystic retinal edema can be from any etiology, including postsurgical inflammation, infection, uveitis, retinal vascular disease, epiretinal membrane, or chronic retinal detachment. Macular hole following laser light exposure likely develops due to tissue atrophy.



Macular Holes, Fig. 1 Color fundus photograph demonstrating a Stage 3 idiopathic macular hole

Clinical Presentation

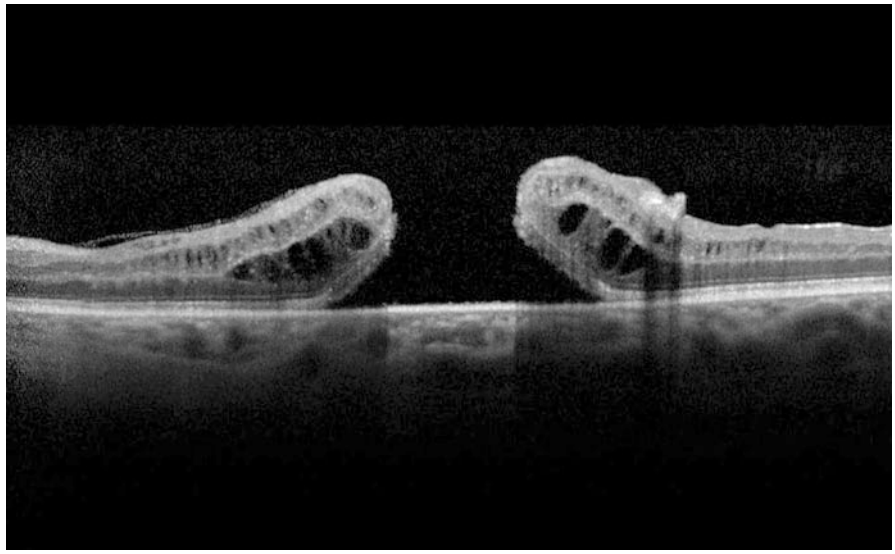
Presenting signs for a macular hole vary according to etiology and stage. Symptoms with idiopathic Stage 1 holes are usually limited to metamorphopsia and a mild decrease in central visual acuity (20/25–20/60). Symptoms from Stage 2 holes are variable and in some cases may actually be less bothersome than those with a Stage 1 hole. Stage 3 holes usually produce significant vision loss with formation of a central scotoma. Stage 4 holes may be associated with new complaint of a "floater" due to the Weiss ring, although patients with poor vision may not notice this.

Diagnostics

Diagnosis of macular hole is made with slit lamp biomicroscopy and confirmed with optical coherence tomography. Stage 1 holes demonstrate loss of the foveal depression with a central yellow spot (Stage 1A) or yellow ring (Stage 1B). Stage 2 and 3 macular holes demonstrate a full thickness retinal defect, while Stage 4 holes involve a Weiss ring in the midvitreous. The clinical Watzke-Allen test is said to be positive if the patient describes a break in a thin beam of light placed on the fovea during slit lamp biomicroscopy. In cases of nonidiopathic macular holes, fluorescein angiography and optical coherence tomography are helpful for identifying any underlying or associated causes, such as cystoid macular edema or epiretinal membrane.

Differential Diagnosis

Differential diagnosis of a macular hole includes cystoid macular edema, solitary drusen, epiretinal membrane with pseudohole, central serous retinopathy, age-related macular degeneration, and solar retinopathy.



Macular Holes, Fig. 2 Optical coherence tomography demonstrating a full thickness Stage 3 macular hole

Prophylaxis

Although no effective prophylaxis against idiopathic macular hole formation is known, prior vitrectomy with removal of cortical vitreous may help decrease risk of hole formation by decreasing the risk of tangential vitreoretinal traction.

Therapy

Pars plana vitrectomy with removal of posterior cortical vitreous and intraocular gas tamponade remains standard of care for symptomatic full thickness macular holes. Peeling of the internal limiting membrane of the retina during vitrectomy is likely beneficial but remains controversial. Success rate of hole closure following vitrectomy surgery ranges from 92% to 100% (Gass 1997; Ho 1999; Sjaarda and Thompson 2006; Wendel et al. 1999).

Prognosis

The prognosis for a macular hole varies according to preoperative visual acuity, stage of hole formation, and underlying etiology. Stage 1 holes undergo spontaneous resolution in up to 60% of cases. Stage 2 through 4 holes can enjoy an improvement in visual acuity following surgical closure in up to 80% of eyes. It has been observed that eyes with a preoperative visual acuity worse than 20/60 improve the most, while eyes with a preoperative acuity better than 20/60 obtain the best final vision. Traumatic macular holes tend to have a worse prognosis than idiopathic macular holes, likely due to associated ocular injury. For almost all eyes following hole closure, vision rarely returns to normal, and some metamorphopsia persists despite visual gains.

Epidemiology

The exact epidemiology of macular holes is unknown. However, idiopathic macular holes occur primarily in the sixth through the eighth decades of life and are more common in women than men.

▶ Corneal Dystrophies

Map-Dot-Fingerprint Dystrophy (Epithelial/Anterior Membrane Dystrophy)

Julia Mathew Padiyedathu and Anita Gupta
Department of Ophthalmology, New York Eye and Ear Infirmary of Mount Sinai, New York, NY, USA

Synonyms

Anterior basement membrane dystrophy; Cogan microcystic epithelial dystrophy; Epithelial basement membrane dystrophy

Definition

Map-dot-fingerprint dystrophy falls into the category of epithelial dystrophies. As a dystrophy, it is a bilateral disease and can be inherited. This condition is defined by a thickened basement membrane that extends into the epithelium and forms "maps" and "fingerprint" lines. Abnormal epithelial cells can degenerate, forming cystoid spaces, or "dots."

Etiology

The inheritance pattern of this dystrophy appears to be autosomal dominant with incomplete penetrance, but most cases are sporadic (American Academy of Ophthalmology 2012a). A subset of patients has a mutation in the *TGFBI* gene (also referred to as *Big-H3*). The involved gene, on locus 5q31, encodes for a protein responsible for cell adhesion. The functional loss of this protein results in poor attachment of the epithelium to the epithelial basement membrane.

Clinical Presentation

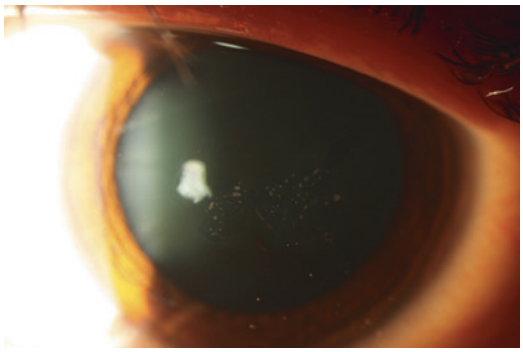
Patients with map-dot-fingerprint dystrophy are generally asymptomatic but can present with symptoms of recurrent corneal erosion, including pain and blurred vision. Other symptoms include tearing, foreign body sensation, and photophobia. These patients will complain of pain on awakening or pain that awakens the patient from sleep. The duration and severity of the pain can vary. Eye rubbing can initiate erosions and exacerbate symptoms. The unpredictable nature of recurrent corneal erosions can be emotionally stressful for patients.

Diagnosis

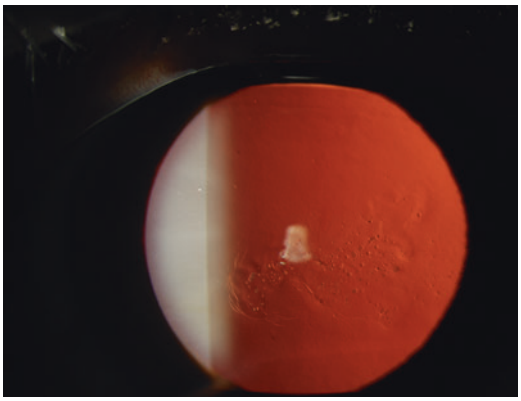
The diagnosis of map-dot-fingerprint dystrophy can generally be made on the slit-lamp examination. Clinical findings including microcysts, gray patches, and linear lesions can be appreciated

by various examination techniques, such as retroillumination, sclerotic scatter, and broad beam illumination. A bilateral exam looking for these clinical features should always be performed, as unilateral findings are more likely related to trauma-associated recurrent corneal erosion syndrome. Both fingerprint lines and map lines are identified in patients with map-dot-fingerprint dystrophy and are differentiated based on morphology. Fingerprint lines are fine lines arranged in a somewhat concentric pattern, whereas map lines are thicker and resemble geographic structures that can be found on maps (Fig. 1). These lines are associated with microcysts in the clinical appearance of patients with this dystrophy (Fig. 2).

Histopathologic findings can aid in diagnosis of map-dot-fingerprint dystrophy, particularly in cases where clinical findings can mimic intraepithelial dysplasia. A thickened epithelial basement membrane is one histopathologic feature that is typical of this epithelial dystrophy (American Academy of Ophthalmology 2012b). Other features include abnormal epithelial cells with absent or abnormal hemidesmosomes and fibrillar material between the basement membrane and Bowman layer.



Map-Dot-Fingerprint Dystrophy (Epithelial/Anterior Membrane Dystrophy), Fig. 1 Map-dot-fingerprint dystrophy, displaying fingerprint lines and microcysts



Map-Dot-Fingerprint Dystrophy (Epithelial/Anterior Membrane Dystrophy), Fig. 2 Map-dot-fingerprint dystrophy, retroillumination view highlights fingerprint lines and microcysts

Differential Diagnosis

The differential diagnosis for map-dot-fingerprint dystrophy is limited. The condition that most commonly mimics map-dot-fingerprint dystrophy is recurrent corneal erosion syndrome from trauma. Studies have found that whereas only 10% of patients with map-dot-fingerprint dystrophy develop recurrent corneal erosions, almost 50% of patients with recurrent corneal erosions have a diagnosis of this epithelial dystrophy. The best way to distinguish traumatic causes of recurrent corneal erosion from those associated with map-dot-fingerprint dystrophy is to do a thorough bilateral exam looking for clinical exam findings such as fingerprint and map lines and microcysts. Traumatic recurrent corneal erosions will most often have findings limited to one eye, whereas map-dot-fingerprint dystrophy will be bilateral.

The nature of traumatic injury that predisposes an eye to recurrent corneal erosion is usually a sharp, sudden injury such as a fingernail poke to the eye. The superficial abrasion heals rapidly but incompletely, making the eye vulnerable to periodic subsequent erosions with minimal to no inciting trauma. Clinical findings during the acute event can include corneal edema and heaped-up epithelium. Oftentimes, however, the epithelial surface has already completely healed at the time of the examination.

Prophylaxis

In order to prevent the occurrence of recurrent corneal erosions in patients with map-dot-fingerprint dystrophy, treatment with 5% sodium chloride drops or ointment can be used at nighttime. In a similar way, lubricating drops or ointment at nighttime can be used. The mechanism of prophylaxis is to create a barrier between the fragile epithelium and the palpebral conjunctiva such that the risk of disrupting the loosely attached epithelium on eyelid opening is minimized.

Therapy

Management of patients with map-dot-fingerprint dystrophy can be classified as medical treatment of acute attacks of recurrent corneal erosion and surgical ablation. The traditional approach to treatment is frequent lubrication, antibiotic ointment, and cycloplegia. In some cases, a bandage contact lens can be beneficial to facilitate healing and to limit pain. Epithelial debridement at the time of acute corneal epithelial erosions can help replace unhealthy epithelium and prevent future episodes. Oral analgesics may also be necessary for the first 24 h after the start of corneal epithelial erosions.

Surgical management should be considered for recalcitrant cases. One effective option is anterior stromal micropuncture. In this procedure, the cornea is punctured about 0.1 mm using a bent 20- or 25- gauge needle in order to create subepithelial scarring and better adhesion of the epithelium to more posterior layers. The central visual axis should be avoided in this procedure in order to limit scarring that can reduce visual acuity. Phototherapeutic keratectomy (PTK) using an excimer laser is another popular option for surgical management of patients with map-dot-fingerprint dystrophy. In this procedure, a large, shallow area of epithelial and anterior Bowman layer ablation is performed. PTK can be used for central erosions but may need to be repeated in 13–44% of cases secondary to a return of symptoms. Other less commonly used surgical approaches to the management of this condition are the Nd/Yag laser and the diamond burr (Aldave 2009). Again, care should be taken to avoid the central visual axis.

Prognosis

The prognosis of patients with map-dot-fingerprint dystrophy is good. Most patients are able to maintain good visual function, except during acute attacks of recurrent corneal erosion.

Epidemiology

Map-dot-fingerprint dystrophy occurs in 6–18% of the population, making it one of the most commonly encountered corneal dystrophies. It occurs more frequently in women and in patients over the age of 50 years.

Synonyms

Relative afferent pupillary defect (RAPD)

Definition

Marcus Gunn pupil or relative afferent pupillary defect (RAPD) presents as a disturbance to the consensual light reflex. In healthy eyes, the reaction of the pupils in both eyes is connected. In other words, a bright light shone into one eye leads to an equal constriction of both pupils (direct and consensual response). When the light source is taken away, the pupils of both eyes enlarge equally (Broadway 2012). In a patient with a RAPD, the pupil of the eye with afferent lesion (e.g., the retina or optic nerve disorder) will constrict less than the other pupil and its corresponding direct response will be less than the consensual response from the fellow eye. Thus, when the light swings (i.e., swinging flashlight test) from the affected pupil to the normal pupil, the pupils both constrict and when the light swings back to the affected pupil the pupils both dilate (i.e., an RAPD).

Etiology

The Marcus Gunn pupil can occur in any lesion affecting significant retina, optic nerve, or optic tract involving the afferent pupillary pathway.

Occurrence

Marcus Gunn pupil can occur in any age, either gender, and any racial group depending on the underlying etiology.

Classification

Marcus Gunn pupil is classified as a pupillary disorder.

Marfan Syndrome

Jörg Stürmer
Kantonsspital Winterthur, Brauerstrasse, Winterthur, Switzerland
Augenklinik Kantonsspital, Winterthur, Switzerland

Definition

Marfan syndrome (MFS) is a multisystem disorder with manifestations typically involving the cardiovascular, skeletal, and ocular systems (De Paepe et al. 1996; Dean 2007). It was first described more than 100 years ago by a French pediatrician, Antoine-Bernard Marfan, who reported the association of long slender digits and other skeletal abnormalities in a 5-year-old girl, Gabrielle. It is the second most common inherited connective tissue disorder, after osteogenesis imperfecta. It is characterized by musculoskeletal abnormalities, cardiovascular disease, and ocular abnormalities, and it can affect many structures of the eye.

Etiology

Transmission of MFS is autosomal dominant with high penetrance, although approximately 25–30% of cases are sporadic (Frydman 2008). Although abnormalities with fibrillin 1 (FBN1) are responsible for the Marfan phenotype in approximately 80% of patients, MFS can also be caused by inactivation mutations in TGF-β receptor 2 (TGFBR2). FBN1 is a main component of extracellular microfibrils found in a wide range of tissues. FBN1 is coded for on chromosome 15 in the q21.1 locus, and TGFBR2 is located at 3p24.2-p25. Currently, more than 500 mutations of FBN1 have been identified and almost all are unique to an affected individual or family. However, even with the same mutation there is clinical heterogeneity among individuals. Not all patients with MFS are tall and thin with long fingers and pectus excavatum. Patients may appear phenotypically normal with only ocular signs, such as dislocated lenses, to suggest the diagnosis.

Clinical Presentation

MFS remains a clinical diagnosis and is established when sufficient features are present.

The main ocular features of MFS, all of which can result in decreased vision, include bilateral ectopia lentis, myopia, and retinal detachments (Nahum and Spierer 2008). About 50% of patients with MFS are diagnosed by an ophthalmologist; some individuals may present with ocular signs suggestive of this syndrome. The presence of ectopia lentis is considered a major criterion for the diagnosis of MFS.

The most striking physical features of patients with MFS are the musculoskeletal defects. The extremities are disproportionately long for the size of the trunk, and patients are usually tall. Overgrowth of the ribs can deform the chest wall causing pectus excavatum or pectus carinatum. Fingers are disproportionately long and thin (arachnodactyly). Kyphoscoliosis is common and can be progressive. Acetabular protrusion and joint laxity are other skeletal manifestations. A generalized muscular hypotony and joint contracture may occur.

Cardiovascular manifestations of MFS include dilations of the aorta at the level of the sinuses of Valsalva, and the predisposition for aortic tear and rupture. These severe complications are the major cause of morbidity and mortality and are the central target for therapy. Mitral valve prolapse, tricuspid valve prolapse, and enlargement of the proximal pulmonary artery are other common but minor criteria for diagnosis.

Integumental manifestations are mainly skin stretch marks (striae) in the absence of rapid weight gain, and recurrent herniae are common minor manifestations.

Progressive lumbosacral dural ectasia is a major diagnostic criterion. This age-dependant feature is present in 92% of patients. Dural ectasia is usually asymptomatic but can lead to bone erosion and nerve entrapment, resulting in low back pain and proximal leg pain, weakness, und numbness. Dural ectasia is the second most common major criterion and can contribute to an unequivocal diagnosis in 23% of cases.

Pulmonary manifestations include spontaneous pneumothorax and apical blebs.

Diagnostics

The last version of diagnostic criteria for MFS is the Ghent criteria published in 1996. This nosology unequivocally diagnoses or excludes Marfan in 86% of cases. The Ghent criteria are divided in seven areas: cardiovascular system, skeletal system, dura mater, pulmonary system, skin and integument, and family or genetic history. For diagnosis, a major criterion in two different areas as well as involvement of a third area are required for an index case. For a family member, presence of a major criterion in the family history and one major criterion in an organ system and involvement of a second organ system is required. The major ocular criterion is ectopia lentis, and the minor ocular criteria include abnormally flat cornea, increased axial length of globe, and hypoplastic iris or ciliary muscle causing decreased miosis. Of the many ocular abnormalities seen in MFS, by far the most common is ectopia lentis, occurring in 50–80% of affected individuals. Ectopia is usually bilateral, symmetric, and nonprogressive. Abnormal production, distribution, and attachment functions of fibrin-rich zonules, as well as their increased susceptibility to proteolytic cleavage have been proposed to play a role in the pathogenesis of ectopia lentis in MFS (Nemet et al. 2006). The dislocation may be subtle and detectable only by observation of phakodonesis or iridodonesis, sometimes visible by gonioscopy. A forward dislocation of the lens into the pupil or anterior chamber may cause pupillary block with acute glaucoma or chronic angle-closure glaucoma. Posterior dislocation can cause harmful vitreous traction on the retina. Premature cataracts and other lens or capsule opacities can also be found in MFS patients. The second most common ocular manifestation in MFS is myopia, which is found in 34–44% of MFS. Retinal detachment continues to be the most serious ocular complication of MFS, occurring in 5–11% of patients. However, the incidence of retinal detachment increases to 8–38% in the presence of ectopia lentis. There is also a high incidence of bilateral retinal detachments, occurring in up to 69% of patients with retinal detachments. Strabismus is a frequent (19–45%) finding in individuals with MFS (compared to 3–5% in the general population). Delayed and inadequate correction of refractive errors that compromise visual input and deficient fibrillin in extraocular muscle pulleys that cause their instability may be the cause of this high incidence. Glaucoma (most common primary open-angle glaucoma) will develop in about 35% of MFS patients during their lifetime. Patients with MFS may have thinner and flatter than average corneas, and megalocornea may also be present. Hypoplastic iris or ciliary muscle causing decreased miosis can be seen and are considered minor criteria.

Differential Diagnosis

Loeys-Dietz syndrome, mutations in TGFRB1 cause aortic aneurisms and a marfanoid phenotype. While aortic dilation is common to both MFS and Loeys-Dietz syndrome, in the latter, ectopia lentis is rare and the patients display ocular hypertelorism (90%), cleft palate or uvula (90%), and arterial tortuosity (84%). Differential diagnosis of the ocular symptoms are Stickler syndrome, homocystinuria, Ehlers-Danlos syndrome, Weill-Marchesani syndrome, autosomal dominant ectopia lentis, and autosomal recessive ectopia lentis with or without ectopic pupils.

Prophylaxis

Beta-adrenergic receptor blockade to delay or prevent aortic aneurysm and dissection is currently regarded as the standard of care of practice for Marfan patients. Aortic growth is slowed in response to treatment but cannot be stopped. Thus, yearly measures of aortic dimensions should be monitored, and if significant dilatation is present, monitoring should be more frequent. Patients with MFS should undergo comprehensive yearly assessment by an ophthalmologist experienced in this disorder. Patients with MFS should be counseled not to engage in contact sports, competitive athletics, or isometric exercise because of increased risk of aortic dilation and

rupture. Pregnancy imposes a risk of aortic enlargement and rupture. The risk is related to the size of the aortic root before risk. If the aortic root measures less than 4 cm, the pregnancy is low.

Therapy

When the aortic diameter reaches 5 cm elective cardiovascular surgery is recommended. In recent years, surgical attempts to maintain the native aortic valve showed encouraging results and is now the preferred surgical treatment, particularly for women in the childbearing age.

Indication for surgical lens extraction include lens opacity with poor visual function, anisometropia or refractive error not amenable to optical correction (i.e., when the equator of the lens is exactly in the optic axis), impending complete luxation and lens-induced glaucoma or uveitis. Lensectomy with limited anterior vitrectomy and subsequent correction of aphakia with glasses or contact lenses has been used for children with ectopic lenses with excellent results. Because of zonular weakness and the resultant capsular instability, correction of aphakia with implantation of an intraocular lens in ectopia lentis is challenging. Options include anterior chamber IOL (iris or chamber angle support), ciliary sulcus posterior chamber IOL fixed to the sclera and/or to the iris, and scleral fixated capsular tension rings. In children, angle-supported anterior chamber lenses and also ciliary sulcus posterior chamber lenses have a high incidence of complications and should therefore be avoided.

Prognosis

In the 1970s, life expectancy of patients with MFS was reduced secondary to the increased risk for dissection and rupture of the ascending aorta. Over the past 30 years, improvement of diagnostic modalities and aggressive medical and surgical therapy for general and ophthalmlic pathology have resulted in considerable improvement of life expectancy and quality of patients with MFS.

Epidemiology

The estimated incidence is between 1/5000 and 1/20,000, and about 25–30% of cases represent new mutations.

Maroteaux-Lamy Syndrome

T. Peter Lindquist and W. Barry Lee
Department of Ophthalmology, Eye Consultants of Atlanta, Atlanta, GA, USA

Synonyms

Arylsulfatase B deficiency, ASB deficiency; MIM # 253200; Mucopolysaccharidosis type VI; MPS VI, MPS 6; *N*-Acetylgalactosamine-4-sulfatase deficiency

Definition

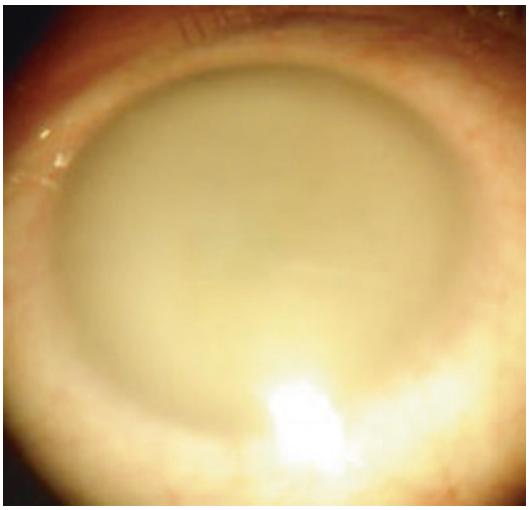
Maroteaux-Lamy syndrome (MPS VI) is an autosomal recessive lysosomal storage disease. Mutations in the arylsulfatase B gene on chromosome 5 cause decreased or absent activity of the enzyme arylsulfatase B (ASB), also called *N*-acetylgalactosamine-4-sulfatase, leading to incomplete degradation and accumulation of the glycosaminoglycan (GAG) dermatan sulfate and cell injury.

Etiology

MPS VI is an autosomal recessive disease from mutations in chromosome 5, position 5q13–5q14. Clinical disease is a result of progressive accumulation of dermatan sulfate in lysosomes, cells, and tissues and manifests only when enzymatic activity is less than 10% of the lower limit of normal.

Clinical Presentation

Phenotypic presentation is varied but typically presents as a rapidly or slowly progressing form, with severity of clinical presentation dependent upon the amount of functional enzymatic activity. The rapidly progressing form usually presents before 3 years of age, while disease may not present until the second or third decade in milder forms. Ophthalmologic findings are present in nearly all patients with Maroteaux-Lamy syndrome at some point in the disease. Progressive corneal clouding occurs in 95% of patients with MPS VI due to accumulation of dermatan sulfate in corneal epithelium, stroma, and endothelium (Ashworth et al. 2006). Clouding is typically more severe than in MPS I and is described as having a ground-glass appearance (Fig. 1). Corneal haze results from GAG accumulation, anterior stromal scarring, abnormal keratocyte morphology, and alteration of collagen fibril arrangement (Alroy et al. 1999). Narrowing of the anterior chamber and poor pupillary dilation may occur secondary to deposition of dermatan sulfate in the trabecular meshwork and iris stroma. Abnormalities in the optic disk are reported to occur in 50% and may be secondary to increased intraocular pressure, GAG accumulation in ganglion cells, or increased intracranial pressure (ICP) causing disk edema (Ashworth et al. 2006). Optic atrophy is reported in 15% and may be related to compression of the optic nerve by thickened dura or bony narrowing along the optic canal.



Maroteaux-Lamy Syndrome, Fig. 1 Corneal clouding in patient with Maroteaux-Lamy syndrome

Systemic manifestations are numerous and include short stature, skeletal deformities (dysostosis multiplex, kyphosis or scoliosis, and degenerative joint disease), coarse facial features (large head, frontal bossing, depressed nasal bridge, enlarged tongue, gingival hyperplasia), hepatosplenomegaly, inguinal and abdominal hernias, middle ear disease and deafness, cardiac valve disease, reduced pulmonary function, sleep apnea, carpal tunnel disease, cervical spine instability, meningeal thickening, and communicating hydrocephalus, among others (Fig. 2). Patients with MPS VI are of normal intellect, which helps distinguish this syndrome from other forms of MPS (Valayannopoulos et al. 2010).

Diagnosis

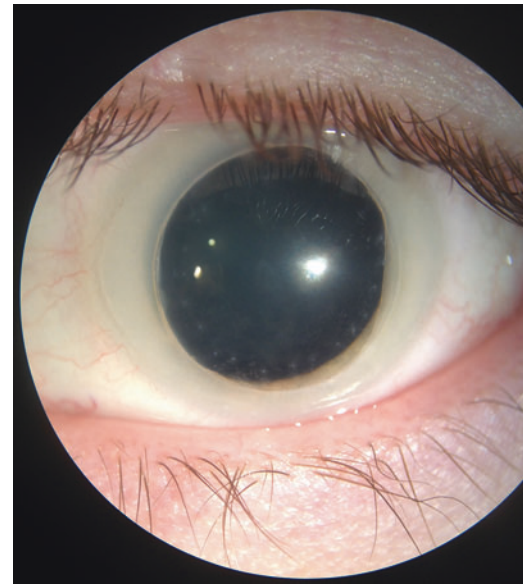
Diagnosis is usually suspected from the conglomeration of clinical findings but may be difficult to

Maroteaux-Lamy Syndrome, Fig. 2 Facial features in patient with MPS VI

detect because of variable presentation, especially in milder forms of disease. Confirmation of fibroblast or leukocyte ASB enzyme activity less than 10% of the lower limit of normal is required for diagnosis (Valayannopoulos et al. 2010). Demonstration of normal activity of a different sulfatase enzyme is also required as it excludes a diagnosis of multiple sulfatase deficiency. Supporting findings for MPS VI include elevated urinary dermatan sulfate, evidence of dysostosis multiplex radiographically, and demonstration of intermediate levels of leukocyte ASB enzyme activity in both parents to support their diagnosis as carriers. Prenatal testing is possible but is limited to those who already have a child with MPS VI.

Differential Diagnosis

- MPS I (Hurler, Scheie, Hurler-Scheie), II (Hunter), IVA (Morquio), and VII (Sly)
- Mucolipidosis I (sialidosis), II, III, and IV
- Multiple sulfatase deficiency (MSD)



Maroteaux-Lamy Syndrome, Fig. 3 Clear graft post-penetrating keratoplasty. Note host corneal clouding

Prophylaxis

Enzyme replacement therapy (ERT) and hematopoietic stem cell transplant can delay progression of clinical symptoms, and avoidance of consanguinity is beneficial.

Therapy

Systemically, ERT with intravenous galsulfase (Naglazyme) effectively replaces the ASB enzyme, but it is unable to reach the central nervous system and cornea due to the blood-brain barrier. Hematopoietic stem cell transplant is also used to replenish the deficient enzyme. Ophthalmologic therapy is directed at control of corneal clouding and glaucoma. Penetrating keratoplasty can be successful, although dermatan sulfate does reaccumulate in the graft at variable rates with resultant corneal clouding (Fig. 3; Bothun et al. 2011). Topical glaucoma medications treat increased intraocular pressure.

Prognosis

Prognosis is variable and depends upon age of onset, rate of disease progression, and age at initiation of ERT. A urine GAG above 100 ug/mg creatinine is a poor prognostic sign (Valayannopoulos et al. 2010). Patients with the slowly progressing form may survive until the third decade or later.

Epidemiology

MPS VI is estimated to occur in 1 in 240,000–400,000 persons worldwide (Valayannopoulos and Wijburg 2011). MPS VI accounts for 2–4% of all MPS in Scandinavia, 3% in the Netherlands, 16% in Portugal, and 18.5% in Brazil. A common mutation 1533del23 in certain populations confers increased risk, as does consanguinity (Valayannopoulos et al. 2010).

McCannel Technique

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Iris suture fixation

Definition

A technique developed in 1976 by Malcolm McCannel, MD, for iris suture fixation for posterior chamber intraocular lenses

Indication

The technique was developed for refixing, resuturing, and stabilizing subluxated posterior chamber intraocular lenses and maintaining iris integrity (Karmel 2014). The procedure is considered if there is insufficient capsular or zonular support or excessive iris defect. This procedure served as a transcorneal, retrievable suture technique.

Contraindication

Though safe, contraindications to cataract surgery are an indication for not pursuing the McCannel technique. The absence of sufficient iris tissue is a contraindication.

Techniques and Principles

The technique is a form of iris suturing that entails passing a long needle on a 10-0 polypropylene suture into the proximal and distal ends of the iris (Krachmer et al. 2011). Following this, the needle tip is guided out of a distal paracentesis by docking into a cannula. After this step, both suture ends are then passed through another paracentesis adjacent to the desired knot position. The knot is then secured and cut close to the surface of the tissue. The knot and iris may then be repositioned if needed. These steps are repeated to secure a defect. Modifications to this suturing technique have been developed to enhance the stability of the lens and iris.

Outcome

Refixing, resuturing, and stabilization of a subluxated posterior chamber intraocular lens and iris defect repair.

Complications

Epithelialization of the anterior chamber (Abbott and Spencer 1978), perforation, detachment of structures, iris defect, hemorrhage, lens dislocation, corneal irregularities (Yanoff and Duker 2014)

Megalocornea

Sayeeda Fatima
Kresge Eye Institute-DMC, Detroit, MI, USA

Definition

Megalocornea: A term used to describe those eyes that have an enlarged cornea, normal IOP, normal optic disk, and no family history of congenital glaucoma; it often occurs in association with other ocular or systemic abnormalities.

Etiology

Megalocornea is a developmental anomaly of unknown etiology. Several mechanisms of development have been postulated including a defect in the growth of the optic cup which leaves a larger space for the development of the cornea.

Clinical Presentation

1Megalocornea presents as a bilateral enlargement of the cornea, with a horizontal diameter of 12 mm or greater at birth and 13 mm or greater after 2 years of age. There are a few variants of this disorder: autosomal dominant being the least common (and is typically not associated with other ocular abnormalities) and X-linked recessive which is more common (thus, accounting for the increased prevalence in males). The X-linked variant is commonly associated with other ocular findings including iris transillumination defects secondary to pigment dispersion, lens subluxation, arcus, and central crocodile shagreen. Other associations include mental retardation and congenital miosis. The enlargement does not arise from corneal stretching but rather from an overgrowth; and, as such, the endothelial cell count is normal. Corneal clarity and thickness are usually normal as well. This is in stark contrast to the enlarged corneal diameter that can be observed with buphthalmos (which presents as elevated IOP and an enlarged globe). Other findings which differentiate megalocornea from buphthalmos include absence of tears in Descemet's membrane and lack of optic disk cupping.

In addition to associated ocular anomalies, various systemic abnormalities have been observed including multiple malformation syndromes, connective tissues diseases, dermatologic abnormalities, and genetic diseases. As such, it is prudent to perform a thorough pediatric exam and to consult physicians from other disciplines based on the associated findings.

Diagnosis

Various diagnostic modalities can be utilized to differentiate megalocornea from buphthalmos and anterior megalophthalmos:

1. Gonioscopy: lack of a widened ciliary band and lack of excessive mesenchymal tissue in the angle in the presence of an enlarged

anterior segment/cornea helps distinguish megalocornea from the other potential diagnoses such as anterior megalophthalmos.
2. A-scan ultrasound biometry: allows for measurements of the axial length of the eye. Increased axial length can be seen in buphthalmos, whereas a normal to short vitreous length can be seen in megalocornea.
3. Specular microscopy: allows for measurement of the corneal endothelial cell count. Normal counts indicate megalocornea, whereas a decrease in the count is consistent with congenital glaucoma.

Pertinent lab testing entails screening for certain genetic markers. The genetic locus for X-linked megalocornea appears to be in the region Xq21–q22.6.

Differential Diagnosis

- Buphthalmos
- Anterior Megalophthalmos

Prophylaxis

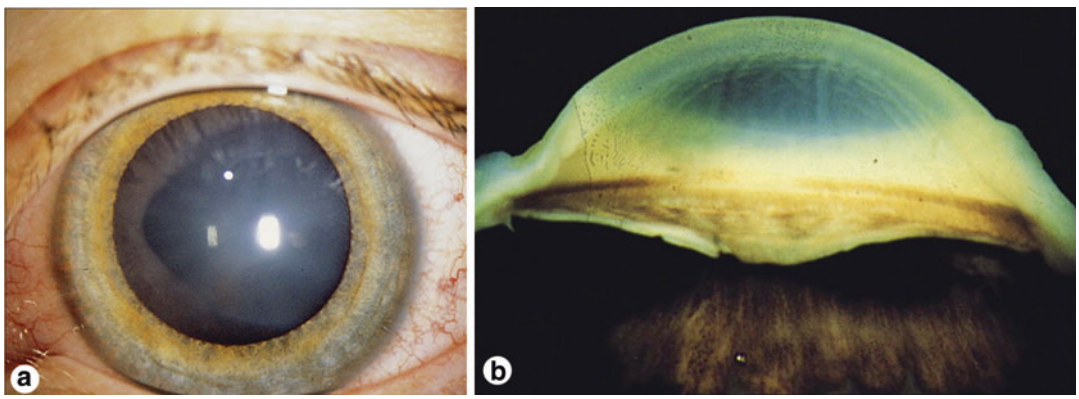
No effective prophylaxis.

Therapy

The condition does not usually require treatment except for management of associated complications including high myopic refractive error, juvenile cataract, and glaucoma. Management of the refractive error is usually via spectacle correction. As for cataracts, this can be challenging given the underlying anterior segment dysgenesis. Various case studies have reported on the success of cataract extraction in patients who have megalocornea; however, care must be taken when considering surgical technique as well as intraocular lens size/type. Another frequently associated complication is secondary glaucoma. Per case reports, elevated IOP usually results from associated spherophakia or ectopic lentis. Thus, surgical treatment for glaucoma secondary to megalocornea is lens removal; this differs from the conventional treatment for primary congenital glaucoma and buphthalmos which requires angle surgery.

Prognosis

Overall prognosis is good; the cornea itself does not continue to enlarge after 2 years of age. There can be associated ocular complications (see sections "Clinical Presentation" and "Therapy")



Megalocornea, Fig. 1 (**a**) Corneal diameters of 14 mm (**b**) Gross specimen showing appearance of enlarged cornea and heavily pigmented trabecular meshwork (Sugar, Joel, Wadia, Hormuz P., Vasaiwala, Roshni A. – Ophthalmology, 173–176.e1 © 2014 Copyright © 2014, Elsevier Inc. All rights reserved)

which are treated accordingly. In the presence of concomitant systemic abnormalities, a more thorough and long-term follow-up needs to be established including scheduled follow-ups with physicians from other specialities.

Epidemiology

Males account for ~90% of cases because of the most common pattern of inheritance (X-linked recessive). According to the literature, 50% of cares are X-linked recessive and 40% are autosomal, whereas the remaining 10% are sporadic. However, the condition itself is rare and the exact incidence is unknown (Fig. 1).

Meibomian Gland Dysfunction

Kathleen Jee
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Meibomianitis; Meibomitis

Definition

It is a common chronic disorder of the meibomian glands and a significant cause of dry eye disease, in which obstruction of the glands and/or abnormalities of glandular secretions occur.

Etiology

Meibomian glands produce the lipid layer of the tear film, which prevents tear evaporation, stabilizes the tear film, and smooths the ocular surface.

Meibomian gland dysfunction (MGD) occurs when the terminal ducts become obstructed. Here, ductal epithelium hyperkeratinization and abnormally viscous meibomian gland secretions, or meibum, block the ducts. This leads to stasis of meibomian gland secretion and inappropriate formation of the lipid layer of the tear film. Consequently, there is an increase in evaporation, instability, and osmolarity of the tear film, with greater bacterial growth on the lid margins, inflammation of the ocular surface, and evaporative dry eye. Factors that affect obstruction of the meibomian glands include age, sex, hormones, and topical medication (Nichols et al. 2011).

Bacterial flora on the eyelids can also contribute to MGD by adversely modifying the lipid composition of the meibum. Bacterial lipases degrade the sterol and wax esters in the meibum, forming inflammatory free fatty acids. This increases the melting point and viscosity of the meibum, causing obstruction of the glands.

Clinical Presentation

Patients with MGD in the early stage may be asymptomatic. As the dysfunction progresses, symptoms of ocular surface irritation and those consistent with dry eyes may manifest, including itching, burning, foreign body sensation, red eyes, photophobia, and filmy vision that is worse in the morning.

Clinical signs of MGD include:

- Meibomian gland orifice plugging and/or posterior displacement
- Meibomian gland dropout or dilation
- Rounded, thickened, erythematous, hyperkeratinized, vascularized, or telangiectatic posterior lid margins
- Excess oil or foam in tear film
- Oily eyelid margins
- Conjunctival injection
- Hordeolum or chalazion
- In severe cases, corneal scarring, thinning, pannus, or neovascularization

MGD can lead to posterior blepharitis and atopic keratoconjunctivitis.

Diagnosis

Routine tests to assess for dry eyes should be conducted, including measuring blink rate, tear volume, tear osmolarity, tear evaporation, tear film breakup time, and tear secretion (Schirmer test). Ocular surface damage can be determined with corneal and conjunctival staining.

Specific tests can be performed to evaluate for MGD. Meibomian gland function is assessed with gland expression using digital pressure over the eyelids. Expressibility and secretion quality of meibum are graded to determine the stage of MGD. Abnormal meibum is excessive, viscous, granular, or toothpaste-like. Meibography, which transilluminates the everted eyelid with infrared photography or video imaging, evaluates for narrowing or occlusion of the orifices, distortion or dilation of the glands, and gland dropout. A meibometer measures meibum excretion. Adhesive tape is used to sample the meibum from the lid margin, and the lipid imprint is analyzed. This is not a commonly performed test in the clinic (Krachmer et al. 2011).

Differential Diagnosis

Keratoconjunctivitis sicca from aqueous-deficient dry eye can present with similar dry eye symptoms as MGD. Tear film examination and Schirmer test can help differentiate the two causes of dry eyes. Although MGD can cause blepharitis, other forms of blepharitis should be ruled out, particularly staphylococcal blepharitis. An internal hordeolum is a staphylococcal infection and inflammation of the meibomian gland that may present similarly but is differentiated by being painful or tender.

Sebaceous carcinoma should be considered in unilateral cases of MGD refractory to therapy with persistent localized inflammation and changes in anatomy, such as loss or distortion of eyelash follicles.

Prophylaxis

Proper daily eyelid hygiene may help reduce the development or recurrence of MGD.

Therapy

Eyelid hygiene is an important long-term treatment of MGD. Warm compresses should be applied to the eyelids for at least 4 min, one to two times a day, in order to break up meibomian gland secretions and crust along the eyelid margin. Lid massage follows the compresses to express secretions. Lid scrub with diluted baby shampoo or eye scrub solution then removes the secretions. Eyelid hygiene maintenance on a long-term basis can effectively treat chronic blepharitis.

Dietary changes are recommended, including increasing intake of omega-3 fatty acids. Environmental changes should be considered, such as improving ambient humidity. If there are symptoms of dry eyes, artificial tears for lubrication may provide relief.

If there are moderate MGD clinical signs and symptoms, consider adding oral tetracyclines for several months, especially if there is concomitant rosacea. Treatment options are oral tetracycline (250 mg four times a day), doxycycline (50–100 mg twice a day), or minocycline (50 mg twice a day). The lipophilic nature of the antibiotic can prevent lipases from altering lipid composition of the meibum.

In more severe cases with significant inflammation of the eyelids, consider using topical antibiotics and anti-inflammatory agents, such as a combination antibiotic-steroid ointment. Topical ciclosporin is used with evidence of posterior blepharitis (Krachmer et al. 2011).

Prognosis

MGD is a chronic disease with frequent recurrences or exacerbations that can negatively affect quality of life with dry eye symptoms. Severe cases can lead to corneal neovascularization. With prompt and appropriate treatment and eyelid hygiene, there can be symptomatic relief and a decrease in recurrences.

Epidemiology

MGD is commonly seen in the clinical setting and is a major cause of dry eye disease. There is variability in the reported prevalence of MGD. The highest prevalence of greater than 60% has been reported in Asian populations, whereas 3.5–19.9% has been reported among Caucasians (Nichols et al. 2011). MGD is more frequent with age and may be a manifestation of meibomian gland degeneration with age.

Risk factors or coexisting conditions that have been associated with MGD include anterior blepharitis, contact lens wear, *Demodex folliculorum*, androgen deficiency, menopause, aging, Sjögren's syndrome, cholesterol levels, psoriasis, atopy, rosacea, hypertension, and benign prostatic hyperplasia (BPH). Medications that can contribute to MGD include antiandrogens, BPH medications, postmenopausal hormone therapy, antihistamines, antidepressants, and retinoids (Nichols et al. 2011).

Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Synonyms

Tarsal glands

Definition

Meibomian glands are holocrine-secreting sebaceous glands that are embedded in the tarsal plate of the eyelids. There are approximately 40 glands in the upper eyelid and 25 arranged in a single row behind the eyelashes.

Structure

This type of sebaceous gland is derived from a common pilosebaceous unit that differentiates during the second month of gestation. However, they do not have a hair follicle. A common duct connecting multiple acini runs the length of the gland and emerges anterior to the mucocutaneous junction. The acini are lined by cuboidal epithelium and synthesize lipids, which are excreted onto the ocular surface, as meibum, through the gland orifice. Contraction of the Riolan muscle which surrounds the meibomian gland ducts compresses the duct when the eye is open, thus preventing meibum outflow. Expression of lipid onto the tear film occurs when contraction of the palpebral portion of the orbicularis muscle contracts and milks the glands. Meibum composed of cholesterol, triglycerides, and free fatty acids is principally formed by nonpolar lipid wax and esters and sterol esters. Its unique characteristic provides a low melting point, which allows the meibum to stay liquid at eyelid temperature. Lipid abnormalities can be caused by bacterial lipases produced by *S. epidermidis* and *S. aureus*. The exoenzymes, triglyceride lipase and cholesterol and wax esterase, produced by bacteria alter the composition of meibum and induce pathologic changes representative of meibomian gland dysfunction (MGD) such as dilatation of the ducts, acini enlargement with squamous metaplasia, granuloma formation, increased inflammatory cells, and abnormal keratinization. The meibum in patients with blepharitis contain low levels of unsaturated fatty acid. These fatty acids are very important in maintaining normal meibomian gland secretions.

Function

Meibomian glands are very important in the stability of the tear film. The meibum excreted by the meibomian glands represents the outer lipid layer of the precorneal tear film. Without it excessive tear evaporation leads to disruption of the optically smooth surface necessary for optimal visual acuity.

Clinical Relevance

Meibomian gland dysfunction is a common cause of chronic inflammation of the corneal surface and conjunctiva. The reduced lipid in the tear film and increased eyelid margin

inflammation leads to meibomitis or posterior blepharitis and progressive scarring of the eyelid margin and tarsal conjunctiva. Ocular surface symptoms and signs can include burning, foreign body sensation, tearing, blurred vision, itching, redness, foamy tear film, and irregularity of the lid margin. It can also lead to recurrent chalazia.

Associated ocular surface inflammation is often seen as conjunctival injection, papillary reaction, episcleritis, superficial punctate keratopathy, pannus, corneal epithelial and subepithelial infiltrates, and corneal thinning. Patients with MGD can also have features of rosacea.

Management usually includes warm compresses, eyelid massage, and lid margin cleansing. Oral doxycycline is indicated if symptoms and signs persist. The presence of infiltrates or neovascularization of the cornea may require topical steroids with close monitoring for side effects. Topical antibiotics may be helpful when the bacterial component is significant.

Melanin in Eyes

Joseph J. Carroll
Department of Ophthalmology, Eye Institute-Medical College of WI, Milwaukee, WI, USA

Definition

High molecular weight pigment present in retinal pigment epithelial cells and choroid. Melanin is produced within melanosomes via the oxidation of tyrosine by tyrosinase. Melanin absorbs radiant energy and improves the retinal image by reducing light scatter and blocking light absorption by the sclera.

Melanocytosis

Zachary Richardson
Department of Ophthalmology, NYU, New York, NY, USA

Oculodermal melanocytosis (ODM) was first described by Hulke in 1861 and later by Ota and Fitzpatrick in 1939 and 1956, respectively (Fitzpatrick et al. 1956; Gonder et al. 1982a; Hulke 1860). It is a pigmentary condition of the ocular structures with or without associated pigmentation of the periorbital skin. Rarely the condition can involve pigmentation of the orbit, meninges, CNS, and soft palate (Fitzpatrick et al. 1956; Gonder et al. 1982a; Shields and Shields 2004; Singh et al. 1998). When pigmentation is limited to the ocular structures, the process is termed ocular melanocytosis. With concurrent hyperpigmentation of the periorbital skin, the term oculodermal melanocytosis is used. Recently, the term oculodermal melanocytosis has been utilized to combine the above two descriptions, as both entities involve the common denominator of ocular melanocytosis (Singh et al. 1998).

Signs and Symptoms

Nearly all patients with oculodermal melanocytosis present with pigmentation of the sclera or episclera (Shields et al. 2013; Teekhasaenee et al. 1990a). These changes appear as well-defined, blue fusiform spots deep to the conjunctiva and are visible at random locations on the globe. Hyperpigmentation and heterochromia of the iris in a generalized, and less commonly sectoral, fashion is also seen in a majority (~87.4%) of cases (Teekhasaenee et al. 1990a). Associated hyperpigmentation of the anterior chamber angle is seen in nearly all cases with iris heterochromia. Gonioscopy reveals a heavily pigmented trabecular meshwork with dense, pigmented iris processes. This dense pigmentation of the angle is speculated to be linked with ipsilateral ocular hypertension and glaucoma (Araie et al. 2002; Khawly et al. 1995; Magarasevic and Abazi 2013; Teekhasaenee et al. 1990a). On funduscopic examination, generalized or sectoral choroidal hyperpigmentation, and less commonly hyperpigmentation of the optic disc margin, can be seen. Rarely, patients can present with a fine dusting of pigment on the anterior surface of the lens capsule or the corneal endothelial surface, mimicking a Krukenberg spindle. The classic skin finding, the nevus of Ota, consists of a hyperpigmented, brown to blue patch of skin in the ophthalmic and/or maxillary distributions of the trigeminal nerve.

Epidemiology

Oculodermal melanocytosis is five times more common among females compared to males and is seen more often in Asians than Africans and is least common among Caucasians (Araie et al. 2002; Singh et al. 1998; Teekhasaenee et al. 1990a). However, the incidence of uveal melanoma among Caucasians with ODM is elevated compared to their non-white counterparts (Araie et al. 2002; Teekhasaenee et al. 1990a). Oculodermal melanocytosis has a bimodal distribution with a majority of cases presenting at birth and more rarely during puberty or pregnancy (Gonder et al. 1982b).

Complications

Uveal melanoma is a rare complication of oculodermal melanocytosis. An estimated 1 in 400 patients with ODM has a lifetime risk of developing uveal melanoma (Shields et al. 2013; Singh et al. 1998). This stands in

contrast to the incidence of uveal melanoma in the general population, which is a much lower 1 in 13,000. In addition, ODM patients diagnosed with uveal melanoma have a twofold higher rate of metastatic disease compared to their non-ODM counterparts (Mashayekhi et al. 2013). For this reason it is recommended that patients with ODM are examined twice yearly to screen for signs of uveal melanoma (Shields et al. 2013).

Ocular hypertension is seen in the ipsilateral eye in 10% of oculodermal melanocytosis cases (Araie et al. 2002; Khawly et al. 1995). Melanocytic infiltration of the filtration angle causing reduced aqueous outflow is thought to be the underlying mechanism (Araie et al. 2002; Khawly et al. 1995; Magarasevic and Abazi 2013). However, no linear correlation has been found between the degree of angle pigmentation and the magnitude of elevated intraocular pressure. An equal 10% of ODM cases show an asymmetry of optic nerve cup to disc ratio of 0.2 or greater in the ipsilateral eye (Araie et al. 2002; Khawly et al. 1995; Magarasevic and Abazi 2013).

More uncommonly, oculodermal melanocytosis has been associated with primary orbital melanoma, meningeal melanocytoma, and primary melanoma of the CNS (Doglietto et al. 2012; Hino et al. 2005; Korányi et al. 2000; Löffler and Witschel 1989; Piercecchi-Marti et al. 2002; Radhadevi et al. 2013; Rice and Brown 1990; Rivers et al. 2001).

Melanokeratosis, Striate

Abdolhossein Ghafourian[1] and
Siamak Zarei-Ghanavati[2]
[1]Department of Ophthalmology, Eye Research Center, Rassoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran
[2]Mashhad University of Medical Sciences, Mashhad, Khora san-Razavi, Iran

Definition

Striate melanokeratosis refers to pigment lines located in the epithelium, which extend from the limbus toward the central cornea (Fig. 1).

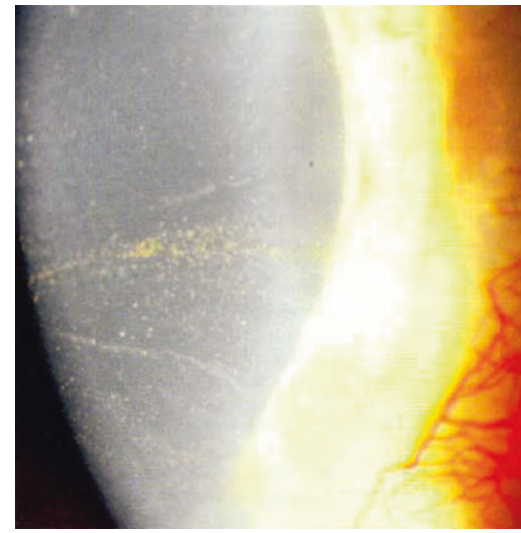
Etiology

Migration of conjunctival melanoblasts into the cornea is the possible etiology. The cornea normally contains no pigmented cells, but melanocytes are present in the limbal area adjacent to blood vessels. It is thought that melanin transfers from these cells to adjacent epithelial cells, which are then carried centripetally forward in the cornea with striate pattern. Injury, cataract extraction, penetrating keratoplasty, inflammation, and subconjunctival usage of 5-fluorouracil are the other possible events predisposing the patients for the migration of melanin or melanoblasts into the cornea and having melanokeratosis (Krachmer et al. 2011).

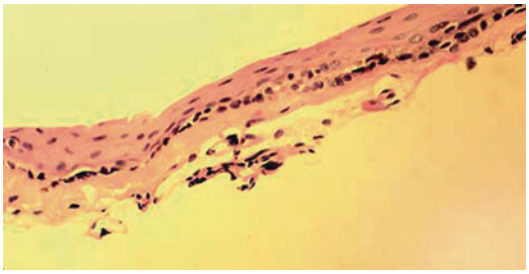
Clinical Presentation

Most commonly it occurs in darkly pigmented individuals but also can occur in lighter pigmented individuals after injury or inflammation. Striate melanokeratosis usually affects black patients with heavy limbal pigmentation and has been described in association with corneal epithelial injury.

Burning sensation can be felt that was due to stimulation of the corneal nerve endings by the



Melanokeratosis, Striate, Fig. 1 Striate Melanokeratosis



Melanokeratosis, Striate, Fig. 2 Corneal biopsy with deposits of melanocytes in the basal layers of the corneal epithelium

invading tissue pigment lines located in the deep layers of the corneal epithelium (Fig. 2). which extend from the limbus toward the center of the cornea, and it tends to assume a curved or whorled form (Lemp 1991; Boto-de-los-bueis et al. 2009).

Diagnosis

Slit lamp exam.

Differential Diagnosis

It could be misdiagnosed with cornea verticillata.

Corneal invasion by pigment can also originate from conjunctival cancerous and precancerous melanosis close to the limbus. Nevus, PAM (primary acquired melanoma), malignant melanoma, and epithelial iron lines are some differential diagnosis of striate corneal melanosis (Boto-de-los-bueis et al. 2009; Krachmer et al. 2011).

Prophylaxis

Unclear.

Therapy

It does not need any treatment except avoiding the stimulus promoted by melanokeratosis.

Prognosis

(Most often) good.

Epidemiology

Unclear.

[1]Division of Oculofacial Plastic and Orbital Surgery, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Malignant melanoma (MM)

Definition

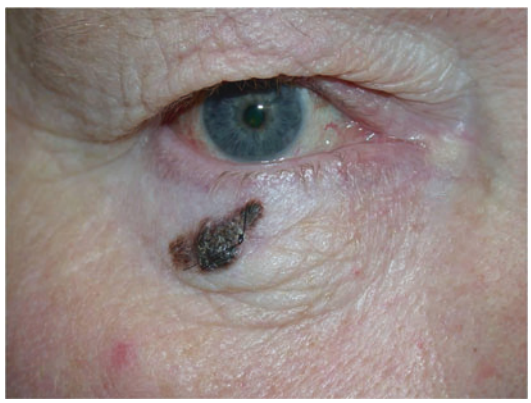
A malignant tumor of melanocytes.

Etiology

Malignant melanoma develops when the melanocytes no longer respond to normal control mechanisms of cellular growth and are capable of invasion locally or spread to other organs in the body (metastasis). Sun exposure definitely increases risk of developing melanoma, especially if a history of severe sunburns during early age is present.

Clinical Presentation

There are several different ▶ types of melanoma, and they vary in appearance. In the eyelid, it can occur in one of the three following forms: superficial spreading malignant melanoma, lentigo maligna melanoma, and nodular melanoma. Lentigo maligna melanoma (LMM) arises in the site of a preexisting lentigo maligna. This lesion is nonpalpable and tan to brown with irregular margins. When dermal invasion occurs, the area becomes elevated and darker (LMN). Nodular melanoma (NM) lesions are slightly elevated, blue-black, or may be amelanotic. MMs tend to be asymmetric, have irregular borders, are associated with changes in color, irritation, ulceration, or bleeding (Fig. 1) (Albert and Jakobiec 2008; Esmaeli et al. 2003; Shields and Shields 2008; Vaziri et al. 2002).



Melanoma of the Eyelid, Fig. 1 Pigmented melanoma of the right lower eyelid

Diagnostics

A biopsy is necessary to make a definitive diagnosis. Biopsy should be considered for pigmented lesions exhibiting changes in size, color, or shape.

Differential Diagnosis

Differential Diagnosis includes ▶ melanocytic nevus, ▶ pigmented basal cell carcinoma, ▶ seborrheic keratosis, ▶ apocrine hidrocystoma, and ▶ varix.

Prophylaxis

Avoidance of sun exposure, use of sunscreens, sunglasses, and hats

Therapy

Wide surgical excision with adequate margins (at least 5 mm) and assessment for the presence of detectable metastatic disease along with short- and long-term follow-up is standard. Other treatments include radiation, cryotherapy, chemotherapy, and immunotherapy.

Prognosis

The prognosis and metastatic potential are related to the level of invasion of the dermis (depth) and the tumor thickness. Nodular melanoma has a vertical growth with early involvement of the dermis, therefore has a worse prognosis (Albert and Jakobiec 2008; Esmaeli et al. 2003; Shields and Shields 2008; Vaziri et al. 2002).

Epidemiology

1% of all malignant neoplasms of the eyelid skin.

Melanomas of the conjunctiva

Definition

Melanocytes normally reside in the basal layer (stratum basale) of the epithelium but can also be found in the subepithelial tissues in some conditions. Conjunctival melanoma is a malignant, neoplastic proliferation of atypical melanocytes that generally starts in the basal layer of conjunctival epithelium, penetrates the underlying epithelial basement membrane, and invades the subepithelial connective tissue.

Etiology

Mutation of the BRAF gene, a gene that encodes a serine/threonine kinase in the mitogen-activated protein kinase (MAPK) pathway, can lead to development of conjunctival melanomas. The MAPK pathway is involved in signal transduction, and dysregulation of the MAPK pathway in turn leads to abnormal cellular proliferation (Kenawy et al. 2013). Other genetic alterations have been implicated in the pathogenesis of conjunctival melanoma, but the significances and details of these abnormalities remain to be fully elucidated.

Clinical Presentation

A classic conjunctival melanoma presents as a unilateral, single, nodular, pigmented lesion on the bulbar conjunctiva at or near the limbus. However, it can also arise at the plica semilunaris or caruncle and be multifocal or nonpigmented. The edges can be discrete, diffuse, or mixed, and corneal involvement may result from direct extension from the limbus. Invasions of the orbit, nasolacrimal duct, and sinuses by conjunctival melanomas have also been reported. Around 70% of conjunctival melanomas arise from preexisting primary acquired melanosis (PAM); less commonly, they can arise from preexisting nevi or de novo (Shields et al. 2011).

Diagnosis

Diagnosis is made by biopsy, showing atypical melanocytes undergoing neoplastic proliferation and invading the subepithelial connective tissue. Immunohistochemical markers for melanocytic cells exist. They include MITF,

Melan-A, HMB-45, and S100. None of them are 100% sensitive or specific, so a combination of these markers, together with morphological features, is often required for diagnosis (Lim et al. 2013). Clinically, conjunctival melanomas are staged according to the tumor-node-metastasis (TNM) staging system developed by the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC).

Differential Diagnosis

1. Hypermelanosis, such as freckle.
2. Secondary melanosis, such as Addison's disease.
3. Congenital ocular melanocytosis.
4. Other conjunctival malignancy, such as pigmented squamous cell carcinoma.

Therapy

Initial treatment for localized disease usually consists of surgical en bloc excisional biopsy to remove all macroscopic tumors. Incisional biopsies should be avoided if possible to minimize chance of tumor seeding. Surgical excision alone, without adjuvant therapy, has been shown to carry a higher risk for recurrence. Frequently, following surgical excision, some forms of adjuvant therapies are applied, such as topical alcohol, cryotherapy, brachytherapy, and topical mitomycin C. Other less common adjuvant therapies, such as carbon dioxide laser and topical interferon alpha 2b, have also been used (Lim et al. 2013). More extensive local disease or persistent recurrence may require exenteration. The role of sentinel lymph node biopsy remains controversial, but may be beneficial in patients with tumors thicker than 2 mm or non-limbal tumors, both of which seem to carry a higher risk for systemic metastasis (Lim et al. 2013). Metastatic disease is treated similarly to metastatic cutaneous melanoma, with systemic immunotherapy, targeted therapy, chemotherapy, or a combination of the aforementioned modalities.

Prognosis

The estimated 5-year mortality rate is 12–19%, whereas the 10-year mortality rate is around 30% (Kenawy et al. 2013). Patients with melanoma arising from PAM or nevus demonstrate better survival than those with melanoma arising de novo (Shields et al. 2011). Local tumor recurrence happens in 36–62% of cases (Lim et al. 2013). Risk factors for local recurrence include: multifocal disease, non-limbal position of the tumor, involvement of the surgical margins, and surgical excision without adjuvant treatment. The frequency of regional lymph node metastases is between 26% and 40%, although not all metastatic disease is preceded by regional lymph node metastases (Lim et al. 2013). Risk factors for metastatic disease include local disease recurrence, tumor thickness of more than 2 mm, and involvement of the non-bulbar conjunctiva, medial bulbar conjunctiva, caruncle, and plica semilunaris. Systemic disease most commonly involves the lungs, brain, liver, skin, bones, and gastrointestinal tract (Kenawy et al. 2013).

Epidemiology

Conjunctival melanoma constitutes about 2–5% of all ocular malignancies and 5–7% of all ocular melanomas. It is the second most common malignant neoplasm of the conjunctiva after squamous cell carcinoma. It has an incidence of 0.2–0.8 per million individuals per year in the Caucasian population, with only rare cases being reported in non-Caucasians (Kenawy et al. 2013). It may have a higher incidence in males, but the data is not conclusive. The median age of diagnosis is around 60 years old.

[1]Department of Ophthalmology, Eye Research Center, Rassoul Akram Hospital, Iran University of Medical Sciences, Tehran, Iran
[2]Mashhad University of Medical Sciences, Mashhad, Khora san-Razavi, Iran

Synonyms

Conjunctival epithelial melanosis; Conjunctival melanosis

Definition

Melanosis refers to excessive melanin production and retention of pigment by epithelial melanocytes. This process, however, does not elevate the surface of the conjunctiva. Nevi usually will cause elevation of the surface (Krachmer et al. 2011; Shields and Shields 2008).

Etiology

Exposure to ultraviolet light, inflammation, trauma, various hormones, toxic, genetic (Krachmer et al. 2011).

Occurrence

Unknown.

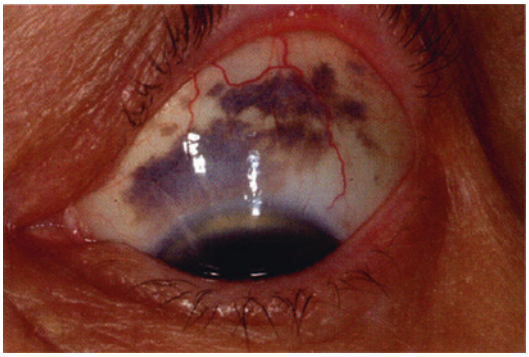
Classification

Classification of conjunctival melanosis is based on three main characteristics (Krachmer et al. 2011; Shields and Shields 2008):

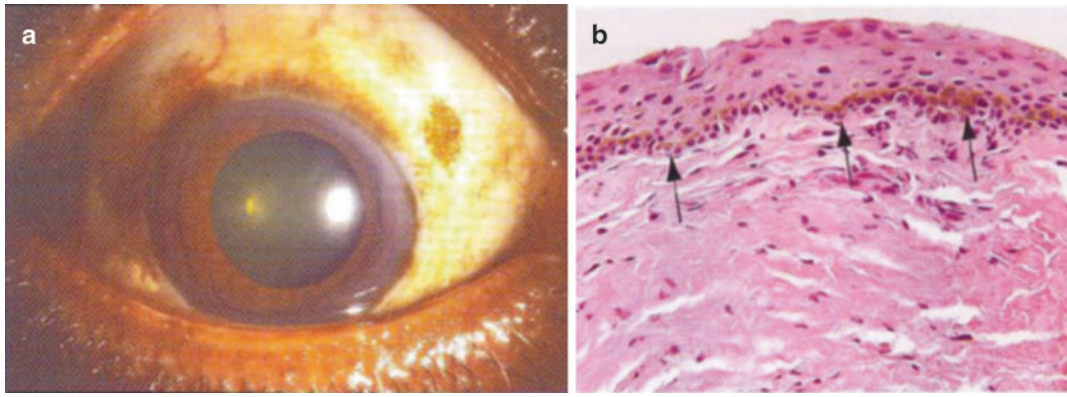
Benign or premalignant
Congenital or acquired
Epithelial or subepithelial
Primary or secondary

Based on the above, melanosis of the conjunctiva could be divided to (Krachmer et al. 2011; Shields and Shields 2008; Rosa and Harocopos et al. 2011):

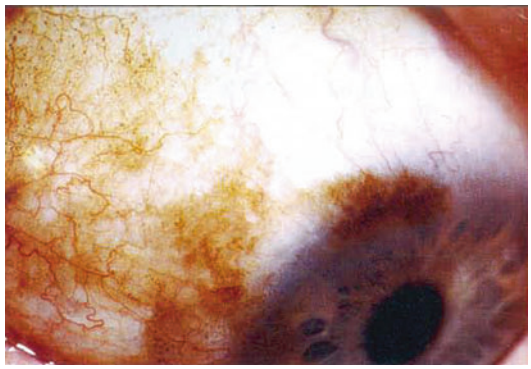
1. Epithelial congenital melanosis
   An ephelis (freckle) is a discrete, stationary lesion (present since birth or early childhood) characterized by excessive melanin production in the base of the epithelium by a normal number of melanocytes. This lesion is not a precursor of malignant melanoma.
2. Subepithelial congenital melanosis
   Subepithelial congenital melanosis is not a lesion of the conjunctiva but the episclera. Ocular melanocytosis or melanosis oculi is pigment change limited to tissues of the eye (Fig. 1).



Melanosis, Fig. 1 Melanocytosis



Melanosis, Fig. 2 Benign acquired melanosis (BAM). (**a**) Clinical appearance. (**b**) Histology shows a proliferation of melanocytes confined to the basal layer of the epithelium (*arrows*). The melanocytes are small, with no cellular atypia



Melanosis, Fig. 3 PAM (primary acquired melanosis)

In addition to increased numbers of pigmented melanocytes in the sclera and episclera, this condition is characterized by a congenital increase in the number, size, and degree of pigmentation of melanocytes of the uvea.

3. Secondary acquired melanosis
   The most frequent form is the acquired melanosis of the limbal and perilimbal conjunctival epithelium with irregular margins. It is also named BAM (benign acquired melanosis) (Fig. 2)
4. Primary acquired melanosis
   Primary acquired melanosis (PAM) is a neoplastic proliferation with potential for malignant transformation of melanocytes within the conjunctival epithelium (Fig. 3).

Definition

A diffuse skin hyperpigmentation that is sometimes associated with pregnancy or the use of oral contraceptives.

Etiology

Thought to be related to female hormonal activity; however, the exact mechanism is unknown. Sun exposure also plays a significant role in precipitating its development. It has been reported in families as an autosomal dominant trait, and it has also been associated with eczema, rosacea, and other inflammatory skin disorders (Grimes 1995).

Clinical Presentation

Diffuse hyperpigmentation of the eyelids and may involve other areas of the face.

Diagnostics

Workup is usually not necessary.

Differential Diagnosis

Addison's disease
Lupus erythematosus
Lichen planus

Prophylaxis

Avoidance of sunlight may prevent exacerbation of melasma.

Therapy

Superficial chemical peels and topical depigmentation agents, such as hydroquinone, have been used to improve the cosmetic appearance of melasma (Grimes 1995).

Prognosis

Good; however, resolution of pigmentation with treatment is very gradual and sometimes suboptimal (Grimes 1995).

Epidemiology

More common in females, during pregnancy or with the use of oral contraceptives.

Meretoja Syndrome

Allen O. Eghrari
Johns Hopkins University School of Medicine, Baltimore, MD, USA
Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Synonyms

AGel amyloidosis; Amyloidosis V; Familial Amyloidosis, Finnish type; Hereditary gelsolin amyloidosis; Kymenlaakso syndrome; Lattice corneal dystrophy, gelsolin type; Lattice corneal dystrophy type 2; Primary hereditary systemic amyloidosis

Definition

Meretoja syndrome, or Lattice corneal dystrophy type 2, is a hereditary systemic amyloidosis that presents with lattice lines in the peripheral cornea.

Etiology

A mutation in gelsolin at chromosome 9q32-34 results in protein misfolding and formation of beta sheets in place of alpha helices. It is autosomal dominant with penetrance of 100%. Amyloid is deposited in fibrillar patterns throughout multiple organs, including the cornea in which lattice lines are present; these linear deposits are secondary to local production of amyloid in the cornea. Neuropathy with associated decrease in corneal sensitivity and facial nerve function is also secondary to amyloidosis.

Clinical Presentation

Patients classically present with lattice-like lines as an early sign. Linear amyloid deposits are present in the anterior to middle stroma and distributed peripherally, in contrast to lattice corneal dystrophy, which is paracentral and maintains a clear peripheral perilimbal cornea. Amyloid deposits between the epithelial basement membrane and Bowman's layer are consistent with all forms of lattice dystrophy, but amyloid deposits directly posterior to an intact Bowman's layer are characteristic for Meretoja syndrome. Involvement of the trigeminal and facial nerve results in dry eyes, reduced corneal sensitivity, diminished blink reflex, paralytic ectropion, blepharochalasis, and decreased contraction of orbicularis muscle. Secondary chronic open-angle glaucoma and cataract are common comorbidities.

Diagnosis

Clinical evidence of lattice lines by slit-lamp biomicroscopy with systemic amyloidosis is consistent with and generally diagnostic of Meretoja syndrome. Genetic analysis can be conducted to confirm mutation in the gelsolin gene. Histologically, amyloid deposits stain with periodic acid Schiff and Congo red and demonstrate apple-green birefringence under polarized light.

Differential Diagnosis

Multiple variants of lattice corneal dystrophy (LCD) have been described:

1. LCD 1 – no systemic association. Presents between 2 and 7 years of age
2. LCD 2 – Systemic amyloidosis
3. LCD 3 – no systemic association. Presents between 70 and 90 years of age

Prophylaxis

Amyloid deposition develops progressively, with no known method of prevention. Corneal haze is thought to increase proportionately with

intraocular pressure, and topical pressure-reducing eyedrops may assist in both reducing haze and decreasing risk of glaucoma.

Therapy

If limited to the anterior cornea, phototherapeutic keratectomy can remove or debulk deposits with improvement in visual acuity. Penetrating keratoplasty or deep anterior lamellar keratoplasty replaces diseased cornea with healthy donor tissue. However, these treatments all serve as temporizing measures, as amyloid deposition often returns after several years.

Prognosis

Patients lead a quality of life comparable to the general population, with vision typically unaffected until middle to older age. Lifespan is reduced secondary to systemic amyloidosis.

Epidemiology

Rare. First described by Meretoja in southern Finland, approximately 500 cases in the region have been documented; however, sporadic cases have been reported throughout the world.

Synonyms

Methanol optic neuropathy; Toxic optic neuropathy

Definition

Methanol is an odorless and colorless liquid found in many household and automotive products (e. g. antifreeze, windshield washer fluid, and copying fluid agents). Methanol intoxication leads to various forms of neurological impairments, one of which is a toxic optic neuropathy that could ultimately result in blindness. Ethylene glycol, a component of antifreeze, also can produce similar symptoms and toxic optic neuropathy to methanol.

Etiology

After ingestion, methanol enters the alcohol dehydrogenase pathway as a substrate and is metabolized to toxic metabolites, formic acid and formaldehyde. Humans have a limited ability to detoxify formic acid, which is a mitochondrial toxin that inhibits cytochrome oxidase (a mitochondrial enzyme), impairing mitochondrial functions. Since the optic nerve has a high energy demand and is especially susceptible to mitochondrial dysfunction, formic acid has been suggested to act as a mitochondrial toxin to the optic nerve and the retina. Methanol may more specifically affect the Muller cells, photoreceptors, and retrolaminar portion of the optic nerve.

Clinical Presentation

After the ingestion of methanol, patients typically present with acute signs of intoxication including abdominal pain, nausea, anion gap metabolic acidosis, vision loss, osmolar gap, and coma that often progress to death. The optic neuropathy is bilateral and typically severe and evolves rapidly, and toxicity may produce other visual symptoms including double vision, blurred vision, changes in color perception, photophobia, constricted visual field, and sometimes a total loss of vision to no light perception.

Diagnostics

The diagnosis of toxic optic neuropathies (such as those caused by methanol) is usually established by a detailed medical history and a complete eye examination. Blood testing for methanol levels may be performed in patients suspected of having methanol toxic neuropathy, but treatment should be initiated before the results return if possible in suspicious cases. Definitive diagnosis of methanol toxicity requires a confirmed increase in serum methanol level with gas chromatography (>20 mg/dl). Peak levels are

achieved 60–90 min after ingestion but do not correlate with the level of toxicity and thus are not a good prognostic indicator. Arterial pH seems to correlate best with formate levels (<7.2 is a severe intoxication).

A complete ocular examination should also be performed, including color vision and visual field testing. Visual field examination, static (Humphrey) or kinetic (Goldmann), is essential in evaluating any patient suspected of having toxic or nutritional optic neuropathy but may not be available in the acute or emergency room setting. Central or cecocentral scotoma with preservation of peripheral field is characteristic. Visual field defects in toxic optic neuropathy tend to be bilateral and relatively symmetric.

Differential Diagnosis

Hereditary optic neuropathies, nutritional optic neuropathy, compressive lesions of the anterior visual pathways, inflammatory optic neuropathies, infiltrative optic neuropathies, or bilateral traumatic optic neuropathy

Prophylaxis

Avoid ingestion of methanol-containing substances. Securing methanol products away from children may reduce poisonings.

Therapy

Treatment is targeted at inhibiting methanol metabolism, managing metabolic acidosis, and enhancing the elimination of toxic metabolites. In the past, ethanol could be administered to prevent further generation of toxic metabolites but safer alternatives exist now. Fomepizole is a potent ADH inhibitor and has largely replaced antidotal ethanol use for methanol toxicity.

Administration of intravenous sodium bicarbonate can correct the metabolic acidosis, and administration of intravenous folinic can enhance formic acid metabolism. Hemodialysis can also be utilized for clearance of methanol and formate.

Hemodialysis should be considered in ethylene glycol poisoning for patients with severe metabolic acidosis (pH 7.3), serum ethylene glycol level 50 mg/dL, and acute kidney injury. Finally, high-dose intravenous steroids may be beneficial when there is a short interval between consumption and treatment.

Prognosis

Some studies have shown that there is good outcome in blurred vision, but the prognosis of blindness was unpredictable. Visual loss is often severe and occasionally irreversible leading to optic nerve atrophy. It appears that the severity of acidosis at presentation is a key factor in determining the final visual acuity, and while early treatment is recommended, it still may not significantly impact the final visual outcome.

Epidemiology

Methanol toxicity remains a common problem in many parts of the developing world, particularly among members of lower socioeconomic classes especially where illegal production of ethanol might be contaminated with methanol (including countries which nominally ban commercial alcohol sales or possession). In addition, accidental and non-accidental poisoning can produce methanol or ethylene glycol toxicity. Toxic optic neuropathies in general are usually associated with employee exposures in a workplace or ingestion of materials containing toxic substances such as methanol. Toxic optic neuropathies have no racial predilection and are found equally in males and females. Any age may be affected. Toxic-nutritional optic neuropathy from ethanol is likely nutritional in origin, but discontinuing ethanol use is recommended.

Microcornea

Hyunjoo Jean Lee
Department of Ophthalmology, School of Medicine, Boston University, Boston, MA, USA

Definition

Microcornea refers to a cornea with a horizontal diameter of less than 10–11 mm (Gupta and Kim 2010). The term microcornea should be reserved for cases of small corneas in an otherwise normal globe. However, one will find the term microcornea used to describe an abnormally small cornea in the setting of nanophthalmos or microphthalmos. Nanophthalmos refers to an abnormally small, but normally organized, globe. Microphthalmos refers to a small and disorganized globe (Gupta and Kim 2010; Sugar 2004; Waheed and Azar 2005).

Etiology

Microcornea is a congenital abnormality. Overgrowth of the anterior tips of the optic cup during eye development has been proposed to result in a smaller than normal corneal size (Gupta and Kim 2010; Waheed and Azar 2005).

Clinical Presentation

Microcornea can occur as an isolated anomaly, or the entire eye may be smaller than normal, with or without disorganization of the eye anatomy. Eyes with microcornea are likely to be hyperopic because their corneas are relatively flat. However, other refractive errors are possible (Gupta and Kim 2010; Waheed and Azar 2005). Twenty percent of patients with microcornea develop open-angle glaucoma later in life (Waheed and Azar 2005). Others may be predisposed to angle-closure glaucoma, as patients with microcornea may have relatively shallow anterior chambers. Other ocular or systemic abnormalities may be associated with microcornea (Table 1) (Gupta and Kim 2010; Sugar 2004; Waheed and Azar 2005).

Diagnosis

The diagnosis of microcornea is made by measuring the horizontal corneal diameter, which can be accomplished using a ruler, caliper, or with topography or biometry machines that measure the white-to-white distance. Slit-lamp examination, gonioscopy, and ultrasonography can help to differentiate simple microcornea from nanophthalmos and microphthalmos.

Differential Diagnosis

Cornea plana, sclerocornea, nanophthalmos, microphthalmos.

Therapy

Supportive measures include refractive correction and treatment of any associated glaucoma.

Prognosis

If microcornea is an isolated finding, the prognosis is generally good with refractive correction and treatment of any amblyopia (Gupta and Kim 2010). In pediatric patients undergoing cataract surgery, microcornea was associated with an increased risk of developing postoperative glaucoma (Rabiah 2004).

Epidemiology

Microcornea is a rare occurrence. Most cases of microcornea are sporadic, although autosomal dominant and autosomal recessive inheritance patterns have been described, particularly in association with syndromes (Khan 2012). For instance, an autosomal dominant inheritance pattern is found in families with congenital cataract – microcornea syndrome. Patients with the "micro" syndrome inherit microcornea, congenital cataract, mental retardation, retinal dystrophy, optic atrophy, hypogenitalism, and microcephaly in an autosomal recessive inheritance pattern.

Microcystic Epitheliopathy

Tulio Abud[1] and Roberto Pineda[2]
[1]MEEI – Harvard Medical School, Boston, MA, USA
[2]Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston, MA, USA

Synonyms

Corneal epithelial cysts; Epithelial microcystic edema

Definition

Condition in which the epithelium develops microcysts in response to acute or chronic stimuli.

Etiology

The formation of microcysts in the corneal epithelium occurs when edema appears within or between the cells with debris-filled cystic spaces formed during epithelial maturation (Krachmer et al. 2011).

Usually, the microcysts are small, typically 10–50 μm in size, with translucent irregular shape and high refractive inclusions, which form in the basal layer of the epithelium and move toward the anterior surface of the cornea. The cysts diameter can reach up to 900 μm depending on the disease (Keay et al. 2001).

The principal causes of cysts formation are:

1. Hypoxia: it leads to depletion of glycogen stores and a gradual decline in oxygen consumption with an increase in lactate accumulation. Intracellular edema indicates that epithelial compensatory abilities are surpassed. Microcysts are the easiest and the most distinctive form to detect corneal hypoxia (Keay et al. 2001; Krachmer et al. 2011).
2. Endothelial dysfunction: epithelial edema is caused by fluid elevating cells from the basement membrane producing a blister-like bullae appear. Desmosomal connections maintain epithelial integrity at this point. There are many grades of edema ending in large dome-shaped elevations in the epithelium (Bron and Tripathi 1973; Keay et al. 2001).
3. Changes in epithelium maturation: epithelial cells in rapid multiplication or degeneration result in formation of cysts due to accumulation of cells (Krachmer et al. 2011).

Occurrence

To identify the cysts formation in the corneal epithelial, a 16× magnification with

retro-illumination should be used to scan the cornea with 1 mm wide slit at an angle of 45° to the microscope. Depending on the etiology of the cyst, size, shape, and content may differ. Microcysts do not produce corneal staining, but when a great amount (>200) approach the corneal surface, areas of fluorescein staining called "negative staining" can be seen with a cobalt blue illumination and a yellow filter (Keay et al. 2001; Krachmer et al. 2011).

When the microcystic changes affect the visual axis, blurred vision may occur as a result of the irregular astigmatism caused by the faintly elevated corneal epithelium, as well as due to light diffraction and scattering. Occasionally, there is foreign body sensation. If the epithelial surface breaks or becomes loose and shifts during blinking, pain can occur. Meanwhile, many patients remain asymptomatic during long periods of time if any of the reported conditions do not occur (Keay et al. 2001; Smolin and Thoft 2005; Krachmer et al. 2011).

The most common cause for microcystic epitheliopathy occurrence is the contact lens-induced hypoxia. Trauma due to improper fitting or overwear and hypercapnia can also contribute to microcystic development. The number of microcysts increases as the oxygen transmissibility of the lens decreases and with longer overnight extended wear (Keay et al. 2001; Krachmer et al. 2011).

Other relevant causes of epithelial cysts are corneal dystrophies, such as Meesmann's and epithelial basement membrane dystrophy. The first presents within the first few months of life with intraepithelial microcysts, consisting of degenerated epithelial cell products due to rapid cell multiplication. The latter, also known as map-dot-fingerprint dystrophy, occurs in adults and appears with cysts (dots or Cogan's microcysts) beneath the basement membrane or within the epithelial layer alone, containing cellular and nuclear debris from cell degeneration (Smolin and Thoft 2005; Krachmer et al. 2011).

Edema caused by endothelial dysfunction leads to a condition called hydrokeratopathy or bullous keratopathy. As described before, there are many levels of edema in this pathology, and cysts commonly appear in the chronic edematous epithelium. Toxic stimulus to the epithelium leads to acute epithelial microcystic edema, which can be reversed after appropriate treatment. Recurrent erosions can also manifest with cystic formation in the edematous epithelium bordering the defect. This usually indicates defective epithelium and anticipates an episode of erosion. Cysts have been described as well in association with virus keratitis, pannus, and disorders that affect the tear film integrity (Keay et al. 2001; Smolin and Thoft 2005).

Classification

The epithelium can be affected focally or diffusely, depending on the etiology and stage of the disease.

Microkeratome

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

The microkeratome is a surgical device with an oscillating blade that is used to create a predetermined thickness corneal flap during laser in situ keratomileusis. The flaps created with this instrument have a thickness of 100–200 μm.

Epidemiology

When in 2007 the number of femtosecond and microkeratome LASIK procedures was nearly 1:1, the microkeratome will probably become less used due to higher precision and faster methods.

History

Jose Barraquer developed the first microkeratome in the 1950s for use in lamellar refractive surgery. About 30 years later, Luis A. Ruiz modified the device and was able to create a flap of corneal tissue.

Clinical Features

Microkeratomes consist of two pieces, a suction ring for fixation and the flexible head with an oscillating blade. Currently, there are three main microkeratomes on the market, Carriazo–Barraquer (Microtech, Doylestown, PA), the M2 of Moria (Moria Surgical, Antony, France), and the Bausch & Lomb/Chiron Hansatome. Each one of these has a motorized rotating head to create the flap.

Tests

Thorough slit-lamp examination of the eyes and keratometric, keratographic, and pachymetric readings are required for preoperative planning to assure the best possible results.

Differential Diagnosis

Other procedures for creating corneal flaps are:

– Femtosecond laser

Etiology

See History section above.

Treatment

After topical anesthesia, the suction ring is brought into the right position. The microkeratome is then fixed onto the suction ring. During suction, visual acuity is lost due to high pressure and compression of the optic nerve. After making the flap, the suction ring and microkeratome are removed and the excimer laser procedure is started.

Micropannus

Shira Simon[1] and Matthew B. Goren[2]
[1]Feinberg School of Medicine, Northwestern University, Department of Ophthalmology, Northwestern Memorial Hospital, Chicago, IL, USA
[2]Cornea and External Diseases, Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Corneal neovascularization; Corneal vascularization

Definition

Micropannus is a form of subepithelial corneal fibrovascular proliferation, which extends beyond the normal vascular arcade at the limbus. Micropannus is differentiated from gross pannus in that its extension is less than 2 mm beyond the vascular arcade, while gross pannus goes beyond 2 mm. Micropannus is associated with many ocular surface disorders and can progress to frank scarring of the ocular surface as well as gross corneal neovascularization (NV). In rare instances it can progress to deep corneal neovascularization affecting the deeper stromal layers of the cornea.

Etiology

Micropannus generally develops as a result of four main processes:

1. Hypoxia. This is most commonly associated with extended contact lens wear, especially softgel contact lenses worn during sleep, as the lens and closed eyelid generate a barrier to corneal oxygenation. The development of neovascularization in this circumstance is an attempt by the cornea to manufacture an alternative source of oxygen supply to the cornea through the blood. Any long-term use of contact lenses will often result in the formation of micropannus. Silicon hydrogels appear to induce fewer hypoxic complications than softgel lenses (Martin 2007).
2. Irritation. Inflammation from allergic limbitis, vernal conjunctivitis, or chronic conjunctivitis can trigger the biochemical cascade of cytokines and other mediators resulting in the formation of pannus (Ellenberg et al. 2010; Chang et al. 2012).
3. Infection. Untreated chlamydial keratoconjunctivitis (inclusion conjunctivitis and trachoma) and staphylococcal blepharoconjunctivitis are common infectious causes, though any chronic infectious process can also trigger inflammation with resultant development of pannus from the mechanism described above (Jones 1975).
4. Aniridia. Patients with aniridia have a chronic keratopathy associated with abnormal limbal stem cells leading to conjunctivalization of the corneal epithelium. Aniridia leads to a complete absence of the palisades of Vogt, causing the epithelium to invade the cornea with resultant neovascularization. This results in gross pannus, but in early stages may appear as micropannus (Akpek et al. 2007).

Occurrence

Corneal vascularization is estimated to affect up to 1.4 million people per year. The incidence of corneal angiogenesis as a result of softgel lenses has been estimated to be between 18.2 and 19.8 per 10,000 individuals.

Classification

Ocular surface disease, corneal disorder, limbal disease

Microphthalmos (Microphthalmia)

Christopher Fecarotta and Tara Uhler
Department of Ophthalmology, Wills Eye Institute, Thomas Jefferson University, Philadelphia, PA, USA

Synonyms

Microphthalmia; Nanophthalmos

Definition

An eye with an axial length more than two standard deviations smaller than the age-adjusted mean (<19 mm in a 1-year-old, <21 mm in an adult)

Etiology

Microphthalmos is a congenital malformation that occurs during embryologic development. It is the end product of an insult to the optic vesicle that results in either incomplete invagination or closure. Causes include infection, ionizing radiation, toxins, or genetic defects. Two main types have been described:

1. Simple: small eye with otherwise normal structure and function (*nanophthalmos*)
2. Complex: small eye associated with other ocular abnormalities

Microphthalmos can occur as an isolated trait or as part of a broader syndrome.

Clinical Presentation

Presentation of microphthalmia varies according to severity and co-existing ocular pathology, but most commonly includes complaints of small eyes, strabismus, poor vision, or leukocoria. The patient may also commonly present as a referral from pediatrics during work-up for associated syndromes. Microphthalmos may be unilateral or bilateral. The most frequently observed associated ocular abnormalities include cataract, coloboma, corneal clouding, microcornea, nystagmus, persistent hyperplastic primary vitreous, orbital cyst, and glaucoma. One variant, posterior microphthalmos, disproportionately affects the posterior segment and may present with a normal looking anterior segment.

Diagnostics

Both A and B scan ultrasonography are used to evaluate axial length as well as the anterior and posterior segments. If clinical presentation is unilateral, the fellow eye should be evaluated for occult disease. The examiner should look for associated abnormalities and consider magnetic resonance imaging if indicated by detection of optic nerve head abnormalities or orbital cysts. In addition, if findings are consistent with an associated

syndrome, referral to appropriate systemic subspecialists for further work-up is important.

Differential Diagnosis

Differential diagnosis includes anophthalmos, or complete absence of ocular structures. Extreme microphthalmos may clinically resemble anophthalmos. The differential diagnosis of diseases associated with microphthalmos is large and includes trisomy 13, congenital rubella syndrome, congenital CMV, fetal alcohol syndrome as well as less common entities such as *m*icrophthalmia with *l*inear *s*kin defects (MLS) syndrome, *mi*crophthalmos, *d*ermal *a*plasia, and *s*clerocornea (MIDAS) syndrome, Waardenburg syndrome, Hurler syndrome, Goltz-Gorlin syndrome, and Hallermann-Streiff syndrome.

Prophylaxis

Avoidance of risk factors or prevention through rubella vaccination and minimization of fetal exposure to excessive alcohol or ionizing radiation. Referral for genetic counseling in appropriate cases

Therapy

Treatment varies according to associated abnormalities; however, effective surgical intervention in microphthalmic eyes is very difficult and often produces disappointing results. Systemic disease must be addressed by the appropriate subspecialists.

Prognosis

Prognosis is highly variable depending on associated ocular and systemic abnormalities. Microphthalmos with cyst, coloboma, or microcornea tends to have the poorest prognoses. Microphthalmic eyes without other abnormalities tend to be highly hyperopic and often develop angle-closure glaucoma later in life.

Epidemiology

Like anophthalmos, microphthalmos is rare, occurring in approximately 10–19 per 100,000 live births. It is often part of a syndrome the phenotypic presentations of which can vary greatly in severity.

Microphthalmos (Microphthalmia), Anterior

Moulaye A. Haidara
Ophthalmology and Vision Sciences, University of Maryland Medical Center, Baltimore, MD, USA

Synonyms

Anterior chamber dysgenesis; Anterior segment dysgenesis; Complex microphthalmia; Microphthalmos with anterior segment dysgenesis

Definition

Microphthalmia refers to a globe that has a total axial length of less than two standard deviations below the mean for the age of the person. Anterior microphthalmia refers to a small eye with a small anterior segment length secondary to a deficit in embryological development of one of more component of the anterior segment of the eye. This is also referred to as complex microphthalmia with anterior segment dysgenesis.

Etiology

Various conditions involving the anterior aspect of eye can lead to shortened axial length. Anterior segment dysgenesis is one of the main causes behind anterior microphthalmos. Various tissues can be affected, including the cornea, iris, and the lens. The anomalies result principally from a defect in the migration of embryonic cells during the development of the eye. The anomaly can be unilateral or bilateral. It can also be an isolated finding, or associated with other malformations. It can also be sporadic or hereditary. Heritable causes can be from chromosomal defects or part of various syndromes.

Clinical Presentation

Anterior microphthalmia presents as an anterior segment length, the distance between the cornea and the back of the lens, that is two standard deviations below the mean for age. Anterior segment dysgenesis, a main cause of anterior microphthalmia, stems from numerous developmental abnormalities. These developmental abnormalities affect the cornea, iris, or ciliary body. There are few described anomalies of the anterior chamber, the main ones being Axenfeld-Rieger anomaly (displaced Schwalbe's line with bands of iris tissue bridging the iridocorneal angle, combined with a spectrum of defects of the iris and pupil), Peters anomaly (circumscribed opacification of the central cornea), and sclerocornea (opacity and vascularization of the cornea).

Diagnosis

The diagnosis of microphthalmia (anterior) is based on clinical and imaging studies. The physical exam consists mainly of detecting abnormalities in various structures of the eyes, as well as measuring corneal diameter. Imaging studies consist of A-scan to measure the axial length of the orbit, B-scan to evaluate internal structures, and MRI/CT to assess for size and structures of the orbits and surrounding structures.

Differential Diagnosis

The main differential diagnosis for anterior microphthalmia is distinguishing it from microcornea. On the other hand, anterior microphthalmia can be associated with various conditions that should be considered wherever the diagnosis is ascertained. The syndromic presentations include microphthalmia with linear skin defects, also known as MIDAS (microphthalmia, dermal aplasia, and sclerocornea), and Gazali-Temple syndrome. Cardiac defects also tend to be present in these syndromic microphthalmia.

Prophylaxis

Causes of microphthalmia may be sporadic or heritable. Prophylaxis consists mainly of avoid prenatal exposures to teratogens, specially alcohol, thalidomide, retinoic acid, and hydantoin. For heritable causes, prophylaxis consists of genetic counseling, along with the above measures.

Therapy

The extent of microphthalmia will dictate the best therapy course. Isolated cases will have

different management scenes than complex cases with associated craniofacial malformations. Surgery is the mainstay for severe microphthalmia and consultation with an oculoplastic surgeons advised.

Prognosis

Prognosis depends on the extent of the abnormalities. Anterior microphthalmia is usually associated with angle closure glaucoma.

Epidemiology

The exact prevalence of anterior microphthalmia is unknown. However, the prevalence of anophthalmia/microphthalmia is less than 1 per 10,000 birth.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Accommodative micropsia; Psychogenic micropsia

Definition

Micropsia is a dysmetropsia (visual illusion) in which objects appear smaller than they are in reality. They are commonly associated with convergence or accommodation of a distance closer than that of the object viewed.

Etiology

The causes for micropsia include optical distortion (e.g., corneal or retinal disease including retinal edema, and macular degeneration) or by brain lesions (e.g., ischemic, neoplastic, or other occipital lesions).

Diagnostics

Patients with micropsia should first undergo evaluation of the eye as retinal causes are the most common. Amsler grid testing might be useful for documenting the laterality, size, location, and extent of the micropsia. Electroencephalogram (EEG) testing or neuroimaging might be necessary for possible intracranial etiologies especially if the ocular exam is normal and the findings are bilateral or hemianopic.

Therapy

Treatment of micropsia should be directed at the underlying condition.

Synonyms

Fisher's syndrome

Definition

The Miller Fisher syndrome (MFS) is characterized by the clinical triad of ataxia, ophthalmoplegia, and areflexia. MFS was first described in 1956 by Miller Fisher as an unusual variant of Guillain-Barre syndrome (GBS) due to its similar cerebrospinal fluid profile and association with *Campylobacter jejuni*. Some authors believe that MFS may be a form of brainstem encephalitis due to the presence in some patients of abnormal electroencephalogram (EEG) findings, multiple cranial nerve palsies, and/or sensory disturbances (Asbury et al. 1995; Fenichel 2005).

Etiology

While the exact etiology of MFS is not clearly defined, many cases occur after a recent viral or bacterial infection, while others follow vaccination. A genetic predisposition (HLA-B39) in association with MFS has also been reported (Darras 2015).

Clinical Presentation

Clinically, MFS often initially presents with febrile illness or viral symptoms 5–10 days before the onset of neurological symptoms. The sequential cascade of ocular motor disturbances (often a paralysis of upgaze, then loss of lateral gaze, followed by loss of downgaze typically within a span of 2–3 days). Loss of tendon reflexes and decreased peripheral sensory input typically occurs 3–4 days after paralysis of eye muscles has reached maximum severity. Abnormal muscle coordination, generalized muscle weakness, ptosis, eyelid retraction, optic neuritis, and migratory paresthesias may also be noted. Some patients may have unilateral or bilateral facial paralysis (Leigh and Zee 1999).

Diagnosis

The diagnosis of MFS is a clinical one characterized by the classic triad of symptoms confirmed by lumbar puncture, electromyogram (EMG), and neuroimaging studies (Miller et al. 2005; Darras 2015).

Differential Diagnosis

The differential diagnosis of MFS includes Bickerstaff encephalitis, GBS with ophthalmoplegia, brainstem lesions, neuromuscular transmission disorders, and metabolic disorders.

Therapy

Treatment, in severe cases, is identical to that for GBS including plasmapheresis and intravenous immunoglobulin (IVIG) (Fenichel 2005).

Prognosis

Prognosis for the MFS is generally benign, but careful observation is highly recommended to monitor the progression of muscle weakness or the onset of respiratory failure. Recovery generally begins 2–4 weeks after symptoms manifest and reaching completion within 6 months, usually with no residual neurological deficits.

Epidemiology

Most patients with MFS are in mid to late adulthood, although children and infants have also been reported to have developed the condition. Annual incidence is estimated at 1/1,000,000 (Darras 2015).

Minimum Angle of Resolution/ Recognition (MAR)

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

MAR; Minimum separable

Definition

One important aspect of vision is spatial resolution, i.e., the ability to recognize differences of luminance between dark and bright object structures. This ability is proportional to the angle between the two structures or objects and the fovea. The angle at which two objects such as two points or two periods of a grating are just perceived as separate is the minimum angle of resolution (MAR). Its logarithmic form (logMAR) is commonly used as a metric for visual acuity.

► Minus Cylinder Form

Minus Cylinder Form

Wolfgang Raab
Klinikum Darmstadt GmbH, Augenklinik, Darmstadt, Germany

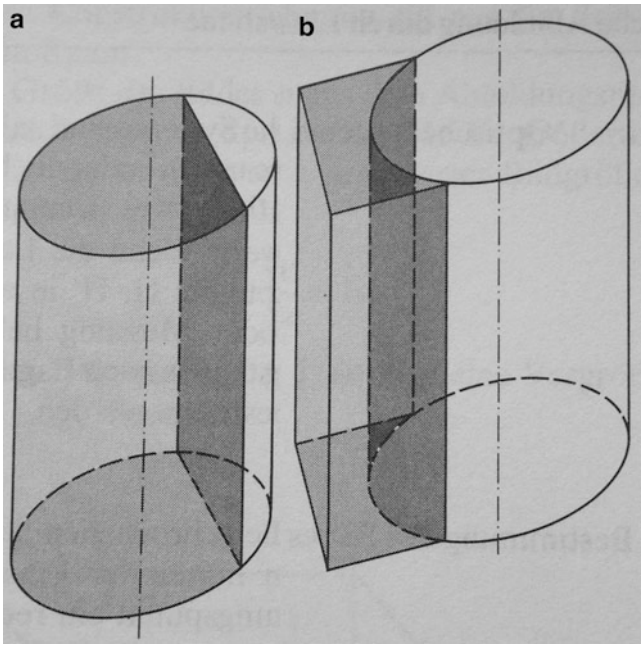
Synonyms

Minus cylinder convention

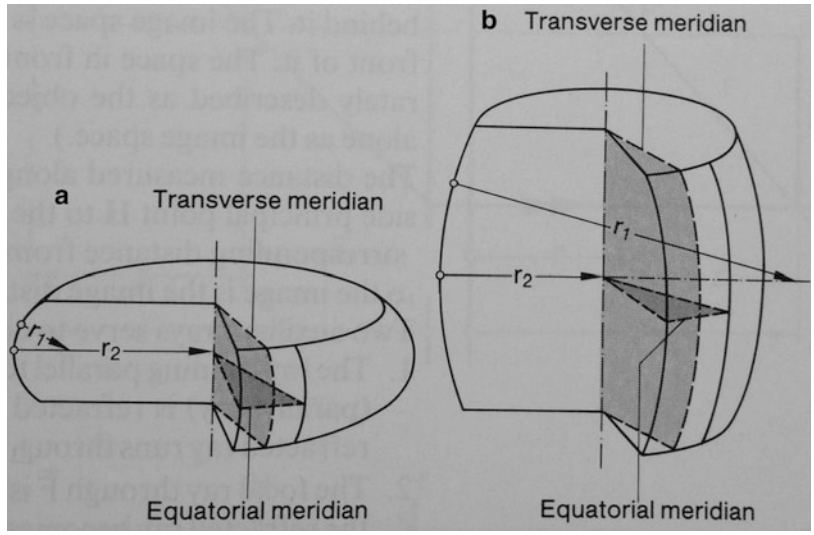
Definition

Lenses with at least one cylindrical, toroidal, or aspheric toroidal surface are not symmetrical to the optical axis and have a different power in each meridian plane. The rays are united in the two planes of the strongest and weakest refraction only. These two planes perpendicular to each other and are known as the principal meridians of the lens. Rays run in one of the meridian planes in front of the lens are at an angle toe each other after refraction (they no longer lie in one plane). For this reason the power of an astigmatic lens can only be measured in the two principal meridians and is given in the form of two equivalent powers or vertex powers F'_{v1} and F'_{v2}. The difference between the two principal powers is known as the astigmatic difference (cylinder): $C = F'_{v2} – F'_{v1}$. The formulae for all lenses with a spherical power apply for each of the two principal meridians. The simplest form of an astigmatic lens is a plano-cylinder (Fig. 1).

A toroidal surface is produced by rotation of a circular arc about an axis which does not run



Minus Cylinder Form, Fig. 1 Plano-cylindrical lenses: (**a**) positive, (**b**) negative



Minus Cylinder Form, Fig. 2 Toroidal Surfaces: (**a**) tyre-shaped, (**b**) barrel-shaped

through the center of this arc. The toroidal surface has different radii of curvature (r1 and r2 in Fig. 2) in the two principal meridians (transverse and equatorial meridians). In an aspheric toroidal (incorrectly, but common, atoroidal) surface, the transverse and equatorial meridians deviate from the circular shape.

Application: For the correction of astigmatic ametropia; also for anamorphic lens systems for motion pictures.

Dominant optic neuropathy (DOA); Leber hereditary optic neuropathy (LHON)

Definition

Mitochondrial optic neuropathy is defined as optic nerve damage in the setting of mitochondrial diseases. Mitochondria are important in cellular energy production, reactive species generation and scavenging, calcium regulation, and other functions to ensure cell integrity. The optic nerve is high in energy demand and is therefore especially susceptible to mitochondrial disease. Different types of mitochondrial optic neuropathies include hereditary optic neuropathies such as dominant optic atrophy (DOA), Leber hereditary optic neuropathy (LHON), and acquired optic neuropathies due to toxic damages to the mitochondria. This chapter will focus on hereditary mitochondrial neuropathies as specific types of toxic neuropathies are addressed in greater detail in other chapters.

Etiology

Mitochondrial optic neuropathies can be divided into hereditary (primary) and acquired (secondary) optic neuropathies. The underlying etiology of hereditary mitochondrial optic neuropathy is direct impairment of mitochondrial functions by either mitochondrial DNA or nuclear DNA. Two important types of mitochondrial optic neuropathies are DOA and LHON. In DOA, about 50% of the cases are due to a mutation in *OPA1* nuclear gene that encodes a dynamin-related GTPase known as OPA1 destined to be on the inner membrane of the mitochondrial cristae. Dysfunction of the OPA1 protein has been correlated to mitochondrial function abnormalities in mitochondrial fusion, oxidative phosphorylation, membrane stabilization, and mitochondrial DNA replication. Due to the high-energy demand nature of the optic nerve, it becomes especially susceptible to mitochondrial dysfunction.

On the other hand, LHON is due to mutations of mitochondrial DNA rather than nuclear DNA as seen in DOA. Three primary point mutations have been implicated in LHON that affects the function of mitochondrial respiratory chain complex I including G11778A, G3460A, and T14484C. Mutations in these genes have been implicated in decreased ATP production and increased free-radical production ultimately resulting in oxidative damage. The optic nerve is affected because of its high-energy demand and sensitivity to oxidative stress, with the most susceptible region being the unmyelinated axons within the papillomacular bundle while exiting the eye at the optic disk.

A rarer cause of hereditary optic neuropathy is a mutation in *OPA3* gene that presents as a multisystem disorder with hypotonia, optic atrophy, ataxia, cognitive impairment, and extrapyramidal signs.

Clinical Presentation

Both hereditary mitochondrial optic neuropathies are characterized by dyschromatopsia and central scotomas, reflecting the selective involvement of the papillomacular bundle. However, in DOA, the mean visual acuity at presentation is 20/80 to 20/120. Visual loss is usually seen in patients between ages 4 and 6 years, classically during vision screening at school. By age 11, the majority of DOA patients would have experienced some visual impairment. Neuroretinal rim thinning is common in DOA, and some patients may also present with peripapillary atrophy, "saucerization" of the disk, and a cup-to-disk ratio exceeding 0.5, mimicking glaucomatous cupping. The optic nerve also presents early with sectoral pallor. In about 20% of the patients with DOA, optic neuropathy may present as part of a syndromal disorder characterized by sensorineural hearing loss, peripheral neuropathy, myopathy, ataxia, ptosis, and/or ophthalmoplegia. These patients are considered to be DOA "plus" cases and often have greater optic nerve damage and worse visual acuities.

In LHON, visual loss is much more severe and is usually bilateral but in a sequential fashion over a period of time. Disease onset is characterized by painless acute loss of central vision with acuity usually worse than 20/200. About half of the patients have sequential visual loss, with the

interval between visual loss of two eyes ranging from 2 to 4 months, though it could be shorter or longer. The majority of patients will experience involvement of the second eye in less than a year. Pupillary light reflexes interestingly are sometimes preserved in patients, and funduscopic exams may reveal vascular tortuosity of central retinal vessels, circumpapillary telangiectatic microangiopathy, and swelling of the retinal nerve fiber layer. However, in about a fifth of the patients with LHON, the optic disk may look normal. In about 6 weeks, optic nerve pallor will become apparent.

Diagnostics

DOA is typically diagnosed during early childhood because of mild, bilateral, unexplained vision loss occurring in the context of a family history of DOA. Diagnostic tests such as optical coherence tomography (OCT) in patients with DOA disclose normal morphology of photoreceptor layer but a nonspecific thinning of the retinal nerve fiber layer. Dysfunction of the retinal ganglion cells and their axons is reflected in abnormal visual-evoked potentials and ERG. Identification of *OPA1* gene mutation in molecular testing also supports the diagnosis of DOA. Diagnosis of LHON includes identifying aforementioned clinical symptoms, as well as neuroimaging of the anterior visual pathway to rule out the possibility of other reversible causes. Molecular genetic testing can also aid in the diagnosis of LHON to detect the mitochondrial mutations, but most commercial laboratories only test for the three most common mutations (e.g., 11778, 14484, 3460).

Differential Diagnosis

Compressive optic neuropathies, inflammatory optic neuropathies, demyelinating optic neuropathies, ischemic optic neuropathies, metabolic optic neuropathies, toxic optic neuropathies, Wolfram syndrome, Costeff syndrome. We recommend consideration for neuroimaging (e.g., cranial MRI) in our patients with LHON.

Prophylaxis

Some studies have shown that smoking may be associated with visual loss in LHON, and others have shown a trend of heavy alcohol intake and visual failure. Therefore patients with LHON are strongly advised to not smoke as well as to moderate their alcohol intake. The role of treatment in asymptomatic carriers (e.g., idebenone) is controversial and unproven, but nonaffected LHON mutation carriers might choose to avoid mitochondrial environmental stressors (e.g., alcohol and tobacco).

Therapy

Treatments for mitochondrial optic neuropathy are limited as there has not been clear evidence to support the efficacy of any intervention. The primary focus for clinicians is to provide supportive measures such as low-vision aids and recognition and therapy of treatable systemic abnormalities. For patients with LHON, treatment with idebenone appears safe and reasonable, especially when given early in the course of their disease, but the drug is not approved for LHON in the United States or Europe. In addition, there have not been any proven DOA treatments, and the use of idebenone in DOA is still being investigated. On the other hand, gene therapy targeting retinal ganglion cells is a promising treatment option for patients with mitochondrial optic neuropathy.

Prognosis

In LHON, some patients may experience color vision and central visual acuity improvement in 6–12 months after visual loss onset. However, a more sudden return of vision characterized as "fenestration" within a central visual field defect could return years after symptom onset. The most important prognostic factor is the type of DNA mutation. The most common mutation 11778 along with mutation 3460 only has 4–22% chance of recovery, while the 14484 mutation has a 37–71% chance of visual recovery. Additionally,

age of onset less than 20 years (especially less than 10 years) is also a possible positive prognostic feature for better visual outcome. There have also been reports that thicker peripapillary retinal nerve fiber layer and large optic-disk vertical diameters may also be positive prognostic factors for LHON. In DOA, worsening of the visual field is insidious but constant and may be quantified as a loss of one Snellen line of acuity about every 10 years. Substantial spontaneous improvement is not common in DOA.

Epidemiology

Visual acuity in DOA typically decreases in the first two decades, and as mentioned previously, about half of the patients have a mutation in the *OPA1* gene. An additional gene identified in DOA patient is *OPA3* gene. DOA prevalence worldwide is estimated to be about 3 out of 100,000 individuals. Penetrance of DOA is at about 70% but can vary. On the other hand, LHON has been linked to multiple mutations of mitochondrial DNA, mainly G11778A, T14484C, and G3460A that comprise 95% of the LHON cases. The prevalence of LHON is estimated to be about 1 in 25,000 in Europe. Males are more commonly affected, and females tend to develop LHON later in life but may be more severely affected.

Mitomycin C

Marko Ostovic and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

MMC

Definition

Antibiotic which was isolated from *Streptococcus caespitosus* in the 1950s. As it has cross-linking properties, it can bind DNA and prevent replication.

Indication

Mitomycin C is used in glaucoma filtering surgery and is able to avoid haze after surface ablation of the cornea as well as in treatment for existing haze. Studies have also shown that it is also useful in the prevention of pterygium.

Contraindication

Wound complications can occur when mitomycin C is used in patients with Sjogren's syndrome, dry eye, meibomian gland dysfunction, neurotrophic keratitis, herples simplex keratitis, as well as

myelosuppression, pregnancy, lactation, and diverse coagulation disorders.

Use and Dosage

The concentrations used vary from 0.04% to 0.1%. See "Indication" section above.

Adverse Reactions

Nausea, vomiting, anorexia, anemia, alopecia, fever, paraesthesia, pneumonia, dyspnea, malaise, pruritus, extravasation, bladder fibrosis, myelosuppression, hemolytic-uremic syndrome. There are reports of scleral necrosis, thin bleb, leaking bleb, infection, and hypotonia in patients who were operated for glaucoma or pterygium.

Interactions

No drug interactions are known for mitomycin C.

[2]Department of Ophthalmology, Gavin Herbert Eye Institute, University of California, Irvine, CA, USA
[3]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Mohs'; Mohs' surgery; Mohs' technique

Definition

An excisional technique developed by Dr Frederic Mohs in 1933. Characterized by the progressive removal of tumor combined with microscopic examination of the removed tissue in order to thoroughly map the tumor margins and the excision site (Nesi et al. 1998; Albert et al. 1999; Nerad 2001; Albert and Jakobiec 2008).

Indication

Conventionally, Mohs' surgery has been used to remove squamous and basal cell carcinomas. However, other types of carcinomas and skin tumors have been excised with Mohs' technique.

Contraindication

Although not an absolute contraindication, Mohs' technique is not recommended for the removal of

melanomas, sebaceous cell carcinoma, or other aggressive malignancies that histologic analysis may be difficult with rapid frozen sectioning.

Techniques and Principle

Mohs' surgery is usually performed as an outpatient procedure. First, the tumor is briefly debulked. Tissue is then removed layer by layer; the tissue was examined immediately after removal utilizing frozen sections. Sometimes curettage of the area of the lesion is performed to bring out the margins as normal skin responds differently to curettage than the abnormal cells. After the removal of a layer, the specimen is divided into sections (usually two sections) and marked with dyes. This provides a detailed map of the specimen. The margins of the specimen are then identified. If any of the margins are clear, the surgeon removes more tissue only from the suspected areas that still contain malignant cells, leaving the areas that have clear margins alone. The process is repeated until the whole lesion has been mapped and removed (Fig. 1).

Outcome

Mohs' technique is intended to preserve more normal tissue surrounding a malignancy. The preservation of essential structures around the eyelids may yield improved function and aesthetic outcomes. Mohs also allows for complete removal of the tumor conferring a high cure rate for certain skin carcinomas.

Complications

Mohs' surgery requires highly specialized equipment and a Mohs' trained surgeon in order to avoid tissue processing errors. The surgery is also lengthy in time, as the tumor is removed microscopic layer by microscopic layer, which may raise the risk for infection. Additionally, complex closure may necessitate the expertise of a specialist surgeon and thus a need for a second surgery (Fig. 2).

Synonyms

Epithelioma contagiosum

Definition

Molluscum contagiosum (MC) is a viral infection (family Poxviridae) that can affect the eyelid.

Etiology

MC lesions are produced by a large DNA poxvirus that is usually transmitted by direct contact or fomites in children and by sexual activity in adults. Multiple lesion formation from autoinoculation is common (Charteris et al. 1995; Albert and Jakobiec 2008; Shields and Shields 2008).

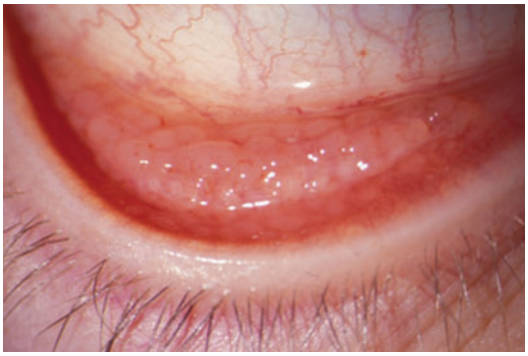
Clinical Presentation

Lesions are typically pale, round, raised, painless skin papules with umbilicated centers, each measuring 3–6 mm (Fig. 1). Some may be as large as 3 cm and more aggressive, especially in immunosuppressed patients (HIV). They are frequently located near the lid margin and conjunctiva and may be associated with a follicular conjunctivitis and corneal changes (superior micropannus and fine epithelial keratitis) (Fig. 2) (Charteris et al. 1995; Albert and Jakobiec 2008; Shields and Shields 2008).

Diagnostics

Clinical, based on the typical appearance of the lesion and histopathologic confirmation.

Molluscum Contagiosum, of Eyelid, Fig. 1 Multiple lower lid lesions with central umbilication



Molluscum Contagiosum, of Eyelid, Fig. 2 Follicular reaction, inferior tarsal conjunctiva

Differential Diagnosis

Differential diagnosis includes ▶ verruca vulgaris, ▶ epidermal cysts, fibromas, ▶ basal cell carcinoma, ▶ squamous cell papilloma, ▶ keratoacanthoma, ▶ milia, and nevus.

Prophylaxis

Avoid skin-to-skin contact with others in order to prevent transmission and avoid scratching to prevent autoinoculation.

Therapy

Treatment is not always mandatory; the local immune response to infection may be sufficient to eliminate the virus and produce regression of the molluscum nodule in many cases. Sometimes, a more aggressive approach may be necessary to arrest symptoms, prevent transmission, and prevent corneal damage. Excision or cryotherapy are the most common interventions (Charteris et al. 1995; Albert and Jakobiec 2008; Shields and Shields 2008).

Prognosis

Excellent, except in the immunocompromised (such as HIV) in which the clinical picture may present as multiple widespread, persistent, disfiguring lesions, especially on the face (Charteris et al. 1995; Albert and Jakobiec 2008; Shields and Shields 2008).

Epidemiology

Uncertain, but commonly seen in healthy individuals or the immunosuppressed.

Molluscum Contagiosum: Overview

Jiawei Zhao
Department of Ophthalmology, Johns Hopkins School of Medicine, Baltimore, MD, USA

Synonyms

Dimple wart; Epithelioma contagiosum

Definition

Molluscum contagiosum (MC) is a poxvirus that causes bengin and self-limiting round papular lesions on the skin and mucous membranes, including the lid margins, skin of the lids, and the brow (Schornack et al. 2006).

Etiology

MC skin eruptions are induced by a poxvirus that is transmitted by direct skin-to-skin contact or through fomite (Schornack et al. 2006; Cherry et al. 2009). It can also spread by autoinoculation through scratching and rubbing of one's lesion (Riordan-Eva and Cunningham 2011).

Clinical Presentation

Infecton of the eyelid may be unilateral or bilateral. Eyelid nodules tend to be isolated with mild surrounding inflammation, ranging from 1 to 3 mm in diameter (Schornack et al. 2006; Riordan-Eva and Cunningham 2011). Older lesions can have central indentation with a white or waxy-appearing core (Schornack et al. 2006; Riordan-Eva and Cunningham 2011). The lesions can be larger and more widespread in human immunodeficiency virus (HIV) infected and other immunocompromised individuals (Cherry et al. 2009). Nodules on the lid margin, skin of the lid, and brow may result in unilateral chronic follicular conjunctivitis, superior keratitis, and superior pannus resembling trachoma (Schornack et al. 2006).

Diagnosis

MC is usually diagnosed clinically by the characteristic appearance of the skin lesion (Schornack et al. 2006). Biopsy can confirm the clinical diagnosis (Schornack et al. 2006). Histology shows eosinophilic inclusions that fill the entire cytoplasm of enlarged cells with their nucleus pushed to the side (Schornack et al. 2006).

Differential Diagnosis

Flat warts, pyogenic granuloma, skin lesions due to cryptococcosis, histoplasmosis or *Penicillium marneffei* infection, basal cell carcinoma, amelanotic melanoma, milia, nevus.

Prophylaxis

Avoid direct contact with contaminated fomite and skin-to-skin contact with infected individuals (Riordan-Eva and Cunningham 2011). Cover the skin lesions to prevent autoinoculation and transmission to others (Riordan-Eva and Cunningham 2011).

Therapy

A Cochrane Review of treatment for MC recommends MC lesions to be left to heal naturally since no mechanimcal treatment (e.g., cryotherapy) and medical treatment (e.g., 1% imiquimod cream) have been found to be effective (van der Wouden et al. 2009). Patients with HIV may see improvement in MC skin lesions after initiation of antiretroviral therapy (van der Wouden et al. 2009).

Prognosis

The infection is self-limited. In immunocompetent individuals, the lesions usually resolve within 2 months and have complete clearance of infection within few months (Schornack et al. 2006). But in immunocompromised invidiuals, the infection may persists for a few years (Schornack et al. 2006).

Epidemiology

MC primary affects children. Children between 0 and 14 years have the highest incidence, ranging from 12 to 14 episodes per 1,000 children per year (Olsen et al. 2013). There was an increased incidence in adults in the 1980s due to the acquired immune deficiency syndrome (AIDS) epidemic (Olsen et al. 2013). The number of adult cases has decreased since the use of highly active antiretroviral therapy (HAART) (Olsen et al. 2013).

Monocular Diplopia

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Ghost image; Shadow image

Definition

The subjective perception of seeing an object twice with one eye. Monocular diplopia typically occurs when the ocular point spread function has two maxima that are apart enough from each other to be perceived as two separate points. Therefore, monocular diplopia is almost exclusively a consequence of ▶ optical aberrations. Typical conditions that cause monocular diplopia are uncorrected ▶ corneal astigmatism (dominant aberration: ▶ astigmatism), ▶ dry eye syndrome, ▶ corneal dystrophies, corneal scars, ▶ keratoconus, and early ▶ cataract (dominant aberration: ▶ coma). Higher-order aberrations of higher frequency such as trefoil and tetrafoil can also cause polyopia that is perceived as multiple images of a single object, often if point-shaped light sources are viewed. Also a double pupil aperture (polycoria), e.g., after iridodialysis or iridectomy can cause monocular diplopia.

In clinical practice, it is imperative that patients who complain about "double vision" undergo a careful anamnesis to differentiate between monocular and binocular diplopia. While monocular diplopia persists if one eye is covered, binocular diplopia disappears. Moreover, monocular diplopia is often reported as a "shadow," "ghost image," or a "second outline" of an object. Besides optical aberrations, also neurological causes are possible. However, cerebral diplopia or polyopia is extremely rare.

Cross-References

- ▶ Keratoconus

Monocular Distortion

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Metamorphopsia

Definition

Monocular distortion is the subjective phenomenon of seeing an object distorted. The underlying causes are multiple. The clinically most important one is also referred to as metamorphopsia (MMO). MMO is the subjective perception of straight objects such as lines appearing distorted or bent. Typically, an uneven macular architecture due to ▶ edema, ▶ drusen, epiretinal gliosis, or traction is the underlying pathology. Much more rarely, MMO is caused by aberrations such as very high-frequent ▶ coma resulting in local broadening of the point spread function. Optical aberrations such as uncorrected high astigmatism and high coma are more likely to cause a distortion of the point spread function along an axis. The corresponding perception is a distortion rendering objects "elongated" or "compressed" over a larger angle. A common and very simple test to detect MMO is the Amsler chart.

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

TMVL in carotid artery disease can be caused by hypoperfusion, thrombosis, or thromboembolic disease. This is usually due to progressive atherosclerotic internal carotid artery (ICA) stenosis, but vasculitis (e.g., giant cell arteritis) and arterial dissection are other mechanisms for disease. The thrombotic disease in the ICA however can lead to thromboemboli which can cause retinal or ocular ischemia leading to the TMVL. Significant stenosis of over 70% can also cause hypoperfusion ischemia. Activities such as postural change can decrease the perfusion pressure and retinal claudication may result from increased bright light exposure.

Diagnostics

Imaging of the head and neck (e.g., MRI) and the carotid arteries (e.g., MR angiography (MRA), computed tomography angiography (CTA), or carotid Doppler) might be diagnostic, but standard catheter angiography might still be needed in some cases.

Treatment

Treatment should be directed at the underlying etiology. Antiplatelet therapy might be indicated as medical treatment, and hemodynamically significant symptomatic ICA stenosis might require carotid angioplasty or stenting or surgical carotid endarterectomy. Carotid dissection may require medical or endovascular treatment. Vasculitis typically requires immunosuppressive therapy.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

The ophthalmic artery (OA) provides the blood supply to the eye and orbit and the inner and outer retina as well as the optic nerve via the posterior ciliary arteries, cilioretinal arteries, central retinal artery or branch retinal arteries). Decreased blood flow in the ophthalmic artery or its branches may lead to hypoperfusion and result in transient monocular vision loss (TMVL) also known as amaurosis fugax. There are several potential causes of hypoperfusion including flow-limiting stenosis, vasculitis, hypovolemia, hypotension, anemia, arrhythmia, and thrombotic, embolic, or thromboembolic disease. Thus, the typical workup for amaurosis fugax (i.e., TMVL) often includes blood studies (e.g., CBC, platelet count, ESR, and C-reactive protein in elderly patients), echocardiogram, EKG, neuroimaging, and carotid imaging (e.g., carotid Doppler studies). TMVL may be exacerbated by decreased ocular perfusion (e.g., changes in posture or neck position) or retinal "claudication" from increased retinal oxygen demand (e.g., exposure to bright light). Postprandial TMVL has also been associated with vascular steal syndrome. Treatment revolves around correcting the underlying cause (e.g., correct anemia, treat vasculitis, address hemodynamically significant stenosis, antiplatelet, or anticoagulation therapy).

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

There are several situations in which transient monocular vision loss (TMVL) can occur due to ocular causes. The specific signs and symptoms to look for include redness or injected conjunctiva, ocular pain, and tearing. Ocular surface etiologies for TMVL often report relief of symptoms with rubbing or blinking of the eye in question. Severe pain, halos around lights, tearing, redness, elevated intraocular pressure, and vision loss are suggestive of acute or intermittent angle-closure glaucoma.

Subluxation or dislocation of an intraocular lens (IOL); spontaneous, traumatic, or IOL-related hyphema (blood in the anterior chamber); intermittent anterior uveitis; or transient glaucoma can cause TMVL. Vitreous floaters or hemorrhage

can also cause TMVL. Congenital optic disk abnormalities, disk drusen, and papilledema are also associated with TMVL.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

Orbital causes of transient monocular vision loss (TMVL) are uncommon. Orbital inflammation, orbital cellulitis, orbital neoplasms, and thyroid eye disease may all produce TMVL. One of the key symptoms of TMVL includes gaze-evoked amaurosis. In these cases, patients may complain of TMVL induced by gaze and caused by orbital lesions compressing the optic nerve in extremes of gaze.

Diagnostics

Orbital imaging (CT or MR) might show the lesion (e.g., optic nerve sheath meningioma, thyroid eye disease, orbital tumors).

Treatment should be directed at the underlying etiology.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Amaurosis fugax; Cerebrovascular accident (CVA); Transient monocular vision loss (TMVL)

Definition

If a patient has a stroke or cerebrovascular accident (CVA) and has a recent history of transient monocular vision loss (TMVL), the cause revolves around a vascular concern. CVAs may be hemorrhagic or ischemic. Cranial computed tomography (CT) or magnetic resonance imaging (MRI) can show the CVA. Embolic or thromboembolic CVAs are often preceded by TMVL. Ischemic TMVL thus serves as a warning sign, similar to a transient ischemic attack (TIA), of the potential for an impending CVA. Thrombosis, emboli, or thromboemboli can originate from uncontrolled atrial fibrillation, atherosclerosis in the carotid arteries, or vasculitides.

Diagnostics

Neuroimaging including diffusion-weighted imaging (DWI) on MRI, evaluation of the carotid arteries (e.g., carotid Doppler, MR angiography of neck, or CT angiography of the neck), cardiac evaluation (e.g., EKG, echocardiogram), and hematologic studies may be necessary in patients with TMVL and/or ischemic stroke related to TMVL.

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

Systemic causes of transient monocular vision loss (TMVL) can be separated into hypoperfusion, vasculitides, hypercoagulable or hyperviscosity states, and other systemic causes.

Giant-cell (temporal) arteritis is the most common vasculitis causing TMVL in the elderly. In younger patients, systemic lupus erythematosus, polyarteritis nodosa, granulomatosis with polyangiitis (formerly Wegener granulomatosis) and eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome), or other anti-neutrophil cytoplasmic antibody (ANCA)-related vasculitides may be the etiology. Hypercoagulable states include coagulation pathway deficiency states (e.g., protein S, protein C, or antithrombin III deficiency), genetic mutations (e.g., factor V Leiden or prothrombin 20210 mutation), antiphospholipid antibody syndrome (due to either lupus anticoagulant or anticardiolipin antibodies), or elevated plasma homocysteine. Hyperviscosity states caused by excess red blood cells (e.g., polycythemia vera), white blood cells (e.g., leukemia), platelets (e.g., thrombocytosis), or protein (e.g., multiple myeloma, Waldenstrom macroglobulinemia) can also lead to thrombosis and TMVL.

Treatment

Treatment should be directed at correcting the underlying etiology (e.g., vasculitis, hypercoagulable or hyperviscosity state).

Synonyms

Amaurosis fugax; Transient monocular vision loss (TMVL)

Definition

Embolic or thromboembolic causes of transient monocular vision loss (TMVL) can be due to atherosclerosis (mainly in the elderly), dissection of the carotid artery, cardiac thromboemboli formation (less common), or hypercoagulability (such as antiphospholipid antibody syndrome). Other less common causes of emboli include air, amniotic membrane, fat, and talc. Emboli usually

cause TMVL because of the temporary ischemia to the retina or optic nerve. Although most arterial emboli to the retina arise from the internal carotid artery, heart, or aorta, sometimes the external carotid artery is implicated (e.g., carotid stump syndrome). The emboli can sometimes be visualized on dilated fundus exam as refractile cholesterol bodies (e.g., Hollenhorst plaques), platelet thrombin complexes, or calcific emboli. Most patients with a possible embolic source for TMVL require carotid imaging such as ultrasound, neuroimaging (e.g., MRI with diffusion weighted imaging (DWI)), as well as head and neck vasculature imaging (e.g., CTA or MRA, carotid Doppler), EKG, and echocardiography.

Treatment

Treatment involves treating the underlying embolic source and may require anticoagulation and/or antiplatelet therapy. Some embolic sources require endovascular or surgical management.

Mooren Ulcer

Hemang K. Pandya
Kresge Eye Institute, Wayne State University, Detroit, MI, USA

Synonyms

Chronic serpiginous ulcer of the cornea

Definition

Mooren ulcer is a painful peripheral corneal ulceration occuring in the absence of any associated scleritis or any detectable systemic disease.

Etiology

Mooren ulcer has been casually related to different entities. Infectious causes, such as helminthiasis and hepatitis C, have been previously described (Schanzlin 1994). It was been postulated that the antigen-antobiody reaction to heminthic toxins within the cornea induced keratitis and inflammation (Schanzlin 1994). Also, other infectious associations such as herpes simplex, tuberculosis, and syphillis have been described in Mooren ulcer (Brown and Mondino 1984). Interestingly, Mooren ulcer has been reported following physicial trauma and foreign body injury, following cataract extraction and penetrating keratoplasty (Sangwan et al. 1997).

Occurrence

Mooren ulcer is rare and is usually seen in healthy adult males without any systemic disease. Nevertheless, Mooren ulcer can occur in either sex and at any age. There are two clinical types of Mooren ulcer: benign/unilateral and malignant/bilateral disease (Wilson et al. 1994). It was also found that 43% of older patients had bilateral disease, whereas bilateral disease was present in only one-third of patients below 35 years of age (Lewallen and Courtright 1990).

Morning Glory Disc

Daniel E. Croft[4], Sumayya J. Almarzouqi[1], Michael L. Morgan[1,6] and Andrew G. Lee[1,2,3,4,5]
[1]Department of Ophthalmology, Blanton Eye Institute, Houston Methodist Hospital, Houston, TX, USA
[2]Departments of Ophthalmology, Neurology, and Neurosurgery, Weill Cornell Medical College, Houston, TX, USA
[3]Department of Ophthalmology, The University of Texas Medical Branch, Galveston, TX, USA
[4]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Morning glory disc anomaly; Morning glory syndrome

Definition

The morning glory disc anomaly (MGDA) is a rare congenital optic nerve head malformation eponymously named for its resemblance to the morning glory flower. When presenting in conjunction with commonly associated signs and symptoms, it can be referred to as morning glory syndrome (Kindler 1970).

Etiology

MGDA is believed to be an embryological defect in the development of the lamina cribrosa and the posterior sclera. Histopathological findings support this theory by the characteristic presence of glial tufts with hyaloid vascular components, suggesting a failure of fetal vasculature to regress. To date, no specific genetic defect has been consistently identified in patients with MGDA (Lee and Traboulsi 2008; Manschot 1990).

Clinical Presentation

MGDA patients are often initially referred to the ophthalmologist for strabismus or leukocoria as infants. Ninety percent of patients present with some form of strabismus. On fundus examination, the most defining characteristic of MGDA is an increased number of straight retinal vessels exiting an enlarged optic disc, with excavation of the optic nerve, in a vascular pattern that resembles radial spokes. Other common findings are central glial tufts, peripapillary pigmentation, and microphthalmia. Vision is impaired in the affected eye, with fewer than 30% of patients achieving a visual acuity of 20/40 or better. Macular involvement occurs in approximately 50% of patients. Thus, patients often have visual field defects and enlarged blind spots. Since MGDA is usually unilateral, relative afferent pupillary defects are also common (Lee and Traboulsi 2008).

MGDA has also been associated with several other systemic signs and symptoms: cleft lip, cleft palate, hypertelorism, basal encephalocele (most frequently transsphenoidal), agenesis of the corpus callosum, endocrine abnormalities involving the pituitary gland, Moyamoya disease, and facial capillary hemangiomas (Lee and Traboulsi 2008).

Diagnostics

MGDA is diagnosed on fundus examination, careful to differentiate from optic nerve coloboma and peripapillary staphyloma. Neuroimaging is recommended for MGDA.

Differential Diagnosis

It is critical that MGDA is not mistaken for optic nerve coloboma which is associated with systemic syndromes such as coloboma of the eye, heart defects, choanal atresia, growth retardation, genitourinary abnormalities, and ear abnormalities (CHARGE). Optic nerve coloboma is also a white excavation of the optic nerve; however, it preferentially affects the inferior portion of the nerve and can extend into the choroid and retina. In contrast to MGDA, optic nerve coloboma does not present with central glial tufts or radial retinal vasculature. Peripapillary staphyloma is another condition which is characterized by excavation of the optic disc; however, it lacks the radial retinal vasculature and central glial tufts which define MGDA (Lee and Traboulsi 2008).

Prophylaxis

None currently identified.

Therapy

There is currently no treatment for MGDA. However, accurate diagnosis and proper management is necessary to preserve remaining vision in the affected eye. Early treatment of amblyopia can help. Since MGDA is associated with an increased risk of retinal detachments of the posterior pole, with an incidence of approximately 33% over 10 years, dilated fundus exams should be used for detection. Brain imaging (MRI, MRA, CTA) should be performed to detect associated vascular and structural abnormalities (Lee and Traboulsi 2008).

Prognosis

MGDA is typically static but management of amblyopia and screening for retinal detachment are important. However, each of the associated systemic symptoms which can define morning glory disc syndrome (i.e., Moyamoya) carries its own prognosis and must be identified and treated early (Lee and Traboulsi 2008).

Epidemiology

MGDA is a rare condition which some sources state affects both men and women equally, while other sources state an incidence ratio of 2:1 (women-men) and a decreased risk in African-Americans (Lee and Traboulsi 2008; Brodsky 2010).

Morquio Syndrome

Atif Mohiuddin
Department of Ophthalmology, George Washington University, Washington, DC, USA

Synonyms

Morquio-Brailsford syndrome; MPS-IV; Mucopolysaccharidoses IV

Definition

Morquio syndrome is a lysosomal storage disease involving the failure to break down and therefore the deposition and accumulation of the glycosaminoglycan keratan sulfate in the body.

Etiology

Mucopolysaccharidoses (MPS) result in the accumulation of glycosaminoglycans (GAGs) secondary to the enzyme necessary to break down the GAG being either deficient or defective. Morquio syndrome has a more severe Type A and a more mild Type B form which are caused by the lack of two separate enzymes for each. Patients with Type A Morquio syndrome lack *N* -acetyl-galactosamine-6-sulfate sulfatase. This results in an accumulation of keratin sulfate and also chondroitin sulfate. Patients with the milder Type B Morquio syndrome lack the enzyme b-galactosidase which results in an accumulation of keratan sulfate. Morquio syndrome is inherited in an autosomal recessive pattern.

Clinical Presentation

Patients present primarily with severe skeletal abnormalities and little neurological dysfunction and have urinary excretion of keratan sulfate. Patients may present with the severe Type A form or the mild Type B form. Bone and joint involvement are common in both types. Skeletal manifestations appear in the first year of life and include joint laxity, genu valgum, and pectus carinatum. In addition to the joint laxity, patients may also have odontoid process hypoplasia which can result in atlantoaxial subluxation. This is of particular concern as patients often present with cervical spinal cord compression. Patients will have normal or near-normal intelligence, sensorineural deafness, abnormal facies, aortic valvular disease, and hepatosplenomegaly. They also present with dustlike corneal opacities throughout the corneal stroma. Keratan sulfate is already normally the most abundant GAG in the cornea, making up 65% of the total GAG content of the cornea. Typically, the corneal epithelium and endothelium appear normal.

As can be expected in a disease of accumulating GAGs, these dustlike corneal opacities can recur in patients who have corneal grafts. Retinal findings may be subtle and may only be seen in older patients. Patients with electroretinogram (ERG) abnormalities with or without pigmentary retinal degeneration or optic nerve atrophy have also been reported. Patients with Morquio syndrome present with short-trunk dwarfism, kyphoscoliosis with vertebral defects and spinal compression, and normal or near-normal intelligence.

Patients will usually have moderate corneal clouding by age 10. Patients may or may not have retinal pigmentary degeneration and often do have optic atrophy. However, unlike other mucopolysaccharidoses, Morquio syndrome is not associated with optic nerve swelling.

Diagnosis

Patients with Morquio syndrome will be found to have accumulation and urinary excretion of keratan sulfate. Patients can be screened by testing their urine for the specific GAG. Diagnosis can be made by WBC enzyme assay.

Differential Diagnosis

The differential diagnoses for Morquio syndrome include Hurler syndrome (MPS-I-H), Scheie syndrome (MPS-I-S), Hurler-Scheie compound (MPS – H/S) in which patients are heterozygote for both Hurler and Scheie syndromes, Hunter syndrome (MPS-II), Sanfilippo syndrome (MPS III), Maroteaux-Lamy syndrome (MPS-VI), Sly syndrome (MPS-VII), and Natowicz syndrome (MPS-IX).

Prophylaxis

As this is genetic disease, there is no prophylaxis to prevent getting this disease.

Therapy

Treatments for mucopolysaccharidoses have included bone marrow transplants in the past, but given issues with donor availability and significant donor availability, enzyme replacement therapy has now become the most common treatment for mucopolysacchridoses. In one of the enzymes that can be replaced, laronidase (a-L-iduronidase) has been shown to improve walking and lung function tests. Therefore it has been approved by the FDA for patients with Hurler syndrome or Hurler-Scheie syndrome. However, enzyme replacement therapy also has several limitations.

In additionally to being a very expensive treatment option, a significant drawback for enzyme replacement therapy is the inability to cross the blood-brain barrier. This significantly limits the ability to treat CNS and even ocular complications from these diseases.

Gene therapy may serve as an avenue for future therapy. In the treatment, viral vectors with the therapeutic gene used to incorporate into the host cells and produce the missing enzyme. In animal models of Hurler syndrome (MPS-I), improvements in ocular disease have been noted.

On a separate note, As Morquio syndrome has the combination of odontoid process hypoplasia and joint laxity resulting in atlantoaxial subluxation. Because of the very serious threat of cervical cord compression, posterior spinal fusions have been performed to prevent this.

Prognosis

Morquio syndrome is typically not recognized at birth. Patients tend to present with the disease around the second year of life. Most commonly this is through recognition of gait disturbances and delayed child growth.

Teenagers will advance through puberty normally or slightly later than their peers. The patient's fertility is also unaffected. Depending on the severity of the disease, cardiac or respiratory disease may cause death in the third or fourth decade of life.

Epidemiology

The estimated incidence of Morquio syndrome (MPS-IV) has a wide range, including 1 case per 263,157 births in Germany, 1 case per 200,000 births in British Columbia, and 1 case per 75,000 births in Northern Ireland. There is a 1:1 male to female ratio of patients with Morquio syndrome.

Mosaic Degeneration (Anterior Crocodile Shagreen)

Mahsa Sohrab[1] and Matthew B. Goren[2]
[1]Northwestern University, Evanston, IL, USA
[2]Cornea and External Diseases, Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Anterior crocodile shagreen; Secondary anterior crocodile shagreen of Vogt

Definition

Bilateral central corneal opacification manifesting as a mosaic of polygonal gray opacities separated by clear tissue at the level of Bowman's layer.

Etiology

Thought to be related to the oblique insertion of collagen lamellae in the corneal stroma (Tripathi and Bron 1975; Belliveau et al. 2009).

Clinical Presentation

Patients are asymptomatic and the findings are noted incidentally on routine slit lamp examination. Signs are bilateral, polygonal, gray-white opacities in the deep layers of the epithelium or in Bowman's layer (Vogt 1981).

Diagnostics

Clinical observation using slit lamp biomicroscopy is the standard for diagnosis. More recently, in vivo confocal microscopy has been used which demonstrates dark striae in the extracellular matrix and a mosaic pattern of the collagen lamellae (Woodward et al. 2007).

Differential Diagnosis

Differential diagnosis includes ► posterior crocodile shagreen (central cloudy corneal dystrophy of Francois). It is distinguished from this by its lack of inheritance pattern and its anterior stromal rather than posterior stromal involvement.

Therapy

Observation

Prognosis

Good prognosis without any associated progression or visual disturbance.

Epidemiology

Increasing prevalence in elderly patients, unknown incidence.

Mucopolysaccharidosis

Surajit Saha
Wilmer Eye Institute, The Johns Hopkins Hospital, Baltimore, MD, USA
Ophthalmic Consultants of Long Island Rockville Centre, New York, USA

Definition

The mucopolysaccharidoses (MPS) are a group of autosomal-recessive metabolic diseases that are part of the larger group of lysosomal storage disorders. Mucopolysaccharidosis is estimated to affect 1 in 25,000 babies born in the United States (National Institute of Neurological Disorders and Stroke 2014). It is characterized by a deficiency of lysosomal enzymes that are required to break down glycosaminoglycans (GAGs), molecules that are found in the bone, cartilage, tendon, skin, and the eye. Without sufficient breakdown, glycosaminoglycans accumulate in the cells of connective tissues, thereby causing permanent, progressive cellular damage. These diseases can affect multiple organ systems, causing a combination of neurological deficits, developmental delay, seizures, skeletal irregularities, heart disease, hepatosplenomegaly, respiratory failure, and more. Most patients initially experience normal development and then a progressive decline in physical and/or mental function, eventually leading to premature death in severe cases. Ocular involvement in MPS is very common and has been described in all subtypes of MPS: the cornea, sclera, trabecular meshwork, retina, optic nerve, and posterior visual pathways can all be affected. Ocular manifestations include high hyperopia, corneal clouding, peripheral vascularization of the cornea, retinopathy, glaucoma, optic nerve edema, optic atrophy, progressive pseudoexophthalmos, hypertelorism, amblyopia, and

strabismus. These are all a result of intra- and extracellular GAG accumulation in ocular and periocular tissues and the brain. GAG accumulation in the cornea affects keratocyte size and upsets the regularity of the collagen fibril network in the corneal stroma, thereby clouding the cornea. Central corneal thickness is often within normal range. GAG deposition in trabeculocytes can cause outflow obstruction, high intraocular pressure, and resultant open-angle glaucoma and corneal edema. Narrow-angle glaucoma is theorized to occur from GAG accumulation in the peripheral cornea and other anterior segment structures, with or without ciliary body cysts. Falsely elevated intraocular pressure is probably a result of increased corneal rigidity and can lead to unnecessary pressure-lowering therapy. GAG accumulation occurs in the retinal pigment epithelium and the interphotoreceptor matrix, leading to a retinal dystrophy. Increased intracranial pressure can be a manifestation of MPS and lead to optic nerve swelling. Scleral thickening can impinge the optic nerve, and GAG accumulation in ganglion cells or in the optic nerve sheath can produce optic disk swelling and eventual optic atrophy. Hematopoietic stem cell transplantation is a treatment option for certain MPS patients but can give rise to graft-versus-host disease with its associated ocular surface issues. Enzyme replacement therapy is another treatment option but it is not available for all types of MPS. With respect to the different types of MPS, Hurler syndrome (MPS I H) and Maroteaux-Lamy syndrome (MPS VI) have the most severe corneal clouding. Retinopathy is most severe in Sanfilippo syndrome (MPS III). Corneal transplantation is a surgical therapeutic option to treat corneal clouding but recurrent opacification of the donor cornea has been reported. There is also evidence that systemic therapy with enzyme replacement therapy or hematopoietic stem cell transplantation can slow down or improve the progression of some ocular manifestations such as corneal clouding (Fahnehjelm et al. 2012).

Cornea and Anterior Segment, Wilmer Eye Institute at Johns Hopkins, Baltimore, MD, USA

Definition

Mucus fishing syndrome refers to chronic irritation of the ocular surface and is characterized by digital "fishing" of mucus strands from the inferior conjunctival fornices. Often initiated by dry eye symptoms, symptoms tend to worsen or recur with continuous manipulation. Treatment is conducted by education and avoidance of touching the eye in order to break a positive feedback cycle of abrasion and irritation.

Synonyms

Artifactual illness; Deliberate disability; Hospital addiction syndrome; Surreptitious illness

Definition

Factitious disorder imposed on self (formerly Munchausen syndrome (MS)) or imposed on

others (formerly MS by proxy) is one of the most serious type of factitious disorders in which physical or psychological complaints are produced without an organic etiology in order for the patient to assume the sick role. This is different from malingering per se in that there is no clear secondary gain for the patient. Although the behavior is intentional, the underlying desire and need to secure the sick role is usually out of the patient's control. Even the risk of serious injury or death is not able to deter the patient from these behaviors. Physical symptoms may be completely fabricated, self-inflicted, or reflect genuine organic pathology resulting from intentional abuse or misuse of medications. Generally, their goal is to be admitted to the hospital to have further testing performed on them, and they will often resist being discharged. Many patients may have extensive diagnostic testing and even surgical procedures in an attempt to find the "underlying etiology." This syndrome may be more common in young, unmarried, and well-educated women but may occur in any age group, in either gender, and in any socioeconomic or educational class (Ferri 2015). Interestingly, MS occurs more commonly among those that work in health care, such as physician, nurses, or technicians. The patients commonly have extensive knowledge about medical terminology and may go into elaborate detail when relaying their history (Heer 2014). Some patients may exhibit objective physical exam findings which further complicates their diagnosis and necessitates a diagnostic work-up to rule out any organic cause since sometimes these patient will have medical problems (either self-induced or organic) which require intervention. Onset may occur after a psychological stressor, like the ending of a relationship, but it is generally unknown what causes an individual to begin this behavior (Ferri 2015). Such behavior often lasts for many years and patients may travel from hospital to hospital or city to city to continue their factitious disorder.

A related disorder is factitious disorder imposed on another (formerly known as Munchausen syndrome by proxy) in which a caretaker, unfortunately most commonly by the patient's own mother, simulates or produces an illness in the dependent so that they can vicariously assume the sick role through the dependent. In about a quarter of the cases, illness is simulated without producing any direct harm to the child, but in about half of the cases illness is actually be inflicted upon the child (poisoning, intentional misuse of medication, injection of infectious substance, etc.). This factitious disorder is considered a form of child abuse and should be treated appropriately (Heer 2014). A similar type of abuse may occur in elderly patients and their caretakers.

The American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM), Fifth Edition (DSM-5) classifies factitious disorder within the category of somatic symptom and related disorders. The large majority of factitious disorder patients show physical complaints and have the stated belief that they have a genuine medical illness. Munchausen syndrome by proxy was not formally named until 1977 and was only included in the DSM IV () and is now termed "factitious disorder imposed on another" in DSM V. The defining characteristics of all forms of factitious disorder are as follows:

- Intentional production of feigned physical or psychological signs or symptoms
- Presence of illness behavior reflecting a wish to assume the sick role
- Confronting physicians with self-induced symptoms or disease
- Absence of external incentives for the behavior (e.g., economic gain, avoiding legal responsibility, or improving general well-being) (Heer 2014)

In regards to ophthalmology, loss of visual acuity is the most common complaint of MS, but other common presenting symptoms might include loss of a visual field, transient loss of vision, visual illusions or hallucinations, diplopia, ptosis, blepharospasm, or photophobia (Bose 2008). It is important that when first seeing these patients that the physician remains objective in their evaluation, looking for organic causes for symptoms and identifying inconsistencies that suggest a nonorganic cause (Bose 2008).

Mustarde Cheek Rotation Flap

► Mustarde Flap

Mustarde Flap

Ronald Mancini[1] and Nicole Khadavi Kohan[2]
[1]Department of Ophthalmology, UT Southwestern Medical Center, Dallas, TX, USA
[2]Jules Stein Eye Institute, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA

Synonyms

Cheek rotation skin flap to the lower lid; Mustarde cheek rotation flap; Mustarde rotational cheek flap

Definition

Large rotational skin muscle flap used in the reconstruction of large defects of the lower eyelid.

Indication

The Mustarde flap is indicated for the reconstruction of large (greater than 50 %) full thickness lower eyelid defects. The flap provides a vascularized anterior lamellar flap. It preferred to eyelid sharing techniques for reconstruction of large lower eyelid defects in monocular patients, those with active corneal disease, and in children as it avoids prolonged eyelid closure during healing.

Contraindications

This technique is usually not indicated in lower eyelid defects involving less than 50 % of the eyelid margin or for the reconstruction of partial thickness defects. The skin of cheek/midface region, which will be advanced to fill the lower eyelid defect, should be healthy tissue.

Techniques and Principles

The lower eyelid defect is converted into a base-up triangle to allow for proper advancement and rotation of the flap without excess tissue bunching. The incision is extended laterally from the lateral canthus, extending in an upward fashion to the temporal region and then extending inferiorly in the preauricular area. The dissection plane of the flap is in the deep subcutaneous tissues. This ensures the flap is of appropriate thickness to optimize its viability while avoiding deeper dissection below the level of the SMAS and possible injury to the facial nerve branches. It is important to establish good vertical height for correct positioning of the lateral canthus. The posterior lamella defect is reconstructed with a posterior lamellar substitute such as nasal septum, free tarsoconjunctival graft, hard palate graft, or ear cartilage graft. The advanced Mustarde flap provides the vascularized tissue to allow for viability of the free posterior lamellar graft. The Mustarde flap is then closed with multiple deep sutures to remove tension from the closure and the skin is then closed with sutures. Depending on the degree of intraoperative bleeding, consideration can be given to placement of a drain, but this is usually not needed. Pressure dressing should however be placed over the flap to decrease the likelihood of postoperative hematoma formation.

Outcome

The mustarde flap provides a vascularized anterior lamellar flap for the reconstruction of large full thickness lower eyelid defects with a resultant scar which extends from the lateral canthus arching superiorly over the zygoma and continuing along the preauricular region. The resulting reconstructed lower eyelid is usually capable of providing adequate protection to the globe.

Complications

Lower eyelid malpositions including ectropion or entropion are possible. This can occur from contraction and fibrosis of the flap and is often exacerbated by the lack of orbicularis oculi muscle to provide stability to the reconstructed lower eyelid. The flap raised is large, and postoperative infection or hematoma formation can result in flap necrosis and tissue loss. The scar from the surgery is often obvious and difficult to camouflage. Care must be taken with proper dissection depth as to avoid injury to the branches of the facial nerve and resultant facial paralysis.

Definition

Acquired myasthenia gravis (MG) is an autoimmune neuromuscular disease caused by autoantibodies directed against the postsynaptic acetylcholine (ACh) receptors and characterized

clinically by variability of function and abnormal fatigability of striated muscles.

Etiology

MG can be congenital or acquired. We will not be discussing the congenital or neonatal forms of MG. The acquired form is associated with autoantibodies directed against neuromuscular postsynaptic acetylcholine (ACh) receptors (i.e., binding, blocking, and modulating antibodies) that have a relationship with the thymus gland. These autoantibodies both accelerate the rate of degradation of ACh receptors and bind to the receptors, thereby decreasing the ability of acetylcholine to produce an effective depolarization on the postsynaptic neuron. In addition, the number of postsynaptic ACh receptors is decreased in MG patients, thereby causing the end-plate potential to be inadequate for generating contraction of some muscle fibers.

Clinical Presentation

Ocular symptoms, ptosis and diplopia, are present at onset in MG in approximately 70% of patients and are eventually present in 90% of patients. Patients with MG alone should not present with pain, proptosis, pupil involvement, paresthesia, or loss of vision because the disease only affects striated muscle and not sensory nerves or other organ systems. The ptosis in MG occurs due to the involvement of the levator palpebrae muscle and usually initially presents unilaterally but with eventual progression to bilateral involvement in many cases. The ptosis can be complete or incomplete, variable or intermittent, and unilateral, bilateral, or alternating. Likewise, the diplopia is also variable and fatigable with ophthalmoplegia in any pattern, and involvement of any one or combination of the extraocular muscles can occur in MG. Thus, MG can mimic the presentation of unilateral or bilateral, complete or incomplete ptosis; pupil-spared third, fourth, or sixth cranial nerve palsies; horizontal or vertical gaze palsy; internuclear ophthalmoplegia; chronic progressive external ophthalmoplegia; complete unilateral or bilateral complete ophthalmoplegia; or isolated extraocular muscle palsy (e.g., inferior oblique palsy). The patient may describe the ptosis as progressively worsening throughout the day (or better or even normal upon awakening), and the diplopia may be variable and fluctuating throughout the day. Nystagmus may occur because of muscle fatigue; however, nystagmus in isolation in MG is not typical. MG confined to the lid and extraocular muscles is called ocular MG, but generalized MG eventually develops in approximately 50–70% of patients, while 30–40% of patients remain purely ocular. In most cases, if generalization of ocular MG has not occurred in the first two years after diagnosis, it is less likely to occur.

Diagnostics

MG is a clinical diagnosis that should be suspected based upon the symptoms and findings on physical examination of variable and fatigable ptosis, diplopia, and/or ophthalmoplegia. Although MG can mimic any ophthalmoplegia presentation, the presence of combinations of ptosis or extraocular muscle weakness that do not conform to a specific pattern of ocular motor nerve paresis should prompt suspicion for MG (e.g., right ptosis and left internuclear ophthalmoplegia).

Other helpful ocular signs may be present in MG including the Cogan's lid twitch sign and enhancement of ptosis. When the patient looks down (thus resting the levator and allowing a buildup of ACh) and then looks up to primary position, the upper lid overshoots and then drifts downward or the downward drift can be followed by several twitches of the lids. Enhancement of ptosis may occur (due to Herings' law of equal innervation); by lifting the ptotic lid, the contralateral lid might fall (i.e., enhancing the ptosis). Fatigue with sustained upgaze can manifest as worsening ptosis or ophthalmologia with effort. Orbicularis oculi weakness should also be evaluated in all patients with ptosis or diplopia suspected of harboring MG (see Fig. 1).

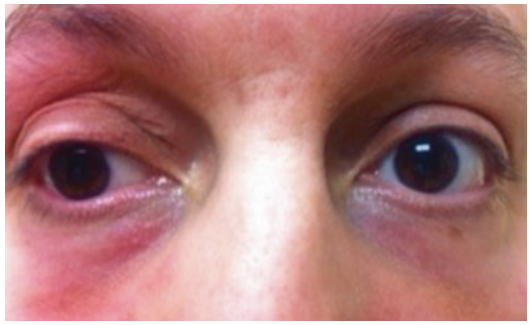
Myasthenia Gravis, Overview, Fig. 1 Myasthenia gravis showing orbicularis oculi weakness

Myasthenia Gravis, Overview, Fig. 2 Myasthenia gravis ice test pre and post

Pharmacological testing in the clinic for MG includes the use of intravenous (IV) edrophonium or intramuscular (IM) neostigmine tests (both are acetylcholinesterase inhibitors). The IV edrophonium (i.e., Tensilon) test requires a good and reliable endpoint (e.g., ptosis or clearly visible ophthalmoplegia). The response to IV edrophonium is rapid (occurring within 30 s to 1 min of administration of the drug) and can be dramatic reversal of ptosis or ophthalmoplegia. The edrophonium (Tensilon) test has a sensitivity of 92% for ocular MG versus a sensitivity of 88% for generalized MG and a specificity of 97% for both ocular and generalized MG. There may be false-negative results with edrophonium testing, however, when long-standing MG is complicated by atrophy. Although rare, some complications associated with the administration of edrophonium can include diaphoresis or heart block; therefore, pre-administration of atropine is suggested and monitoring may be required in select patients. IM prostigmin can be used for longer-lasting effect and allows time to measure the ocular deviation with orthoptic examination. The side effect profile is similar to edrophonium however, and concomitant atropine administration can be used to reduce side effects. Safer and more convenient alternatives to the edrophonium test include the rest/sleep test and the ice test. The rest/sleep test consists of the patient closing his or her eyes for at least 30 min with immediate ptosis (or orthoptic) measurements after the patient opens their eyes. The ice test is another sensitive and specific test for MG. The ptosis in the ice test may show dramatic clinical improvement after ice is placed on a ptotic lid for a few minutes. The ice test is often combined with a rest test clinically. It is not clear what mechanism accounts for the ice test in MG, but some have suggested that cooling the junction prolongs the time that the Ach receptor channels are open (see Figs. 1 and 2).

Serum testing for anti-Ach receptor antibodies is useful for confirming the clinical diagnosis of MG. These antibody tests have a modest sensitivity of 44% for ocular MG, 96% for generalized MG but a higher specificity of 97–99% for MG. The ACh antibody types include binding, modulating, and blocking antibodies, and patients can be positive for one but negative for the others. The most common screening antibody obtained is the binding antibody which is detected in approximately 90% of patients with generalized MG gravis and 70% of patients with purely ocular MG. Muscle-specific tyrosine kinase (MuSK) antibodies is another serologic test that can be performed for patients with seronegative for anti-AChR antibodies. However, this test is positive in only 40% of MG patients. The antibody titer levels do not correlate with disease severity, and we order them for diagnostic purposes at initial evaluation, but we do not follow titers for prognostic or therapeutic purposes.

If the clinical suspicion remains high despite negative or inconclusive clinical and serological testing, then electrophysiological testing may be considered. Repetitive nerve stimulation (RNS), especially of the facial or proximal muscles, produces a decremental response of the muscle action potentials (more than 10% decrease) with an



Myasthenia Gravis, Overview, Fig. 3 Myasthenia gravis ice test pre and post

eventual leveling off of the amplitude. Results are more likely to be positive in patients with severe disease but may be seen in up to 40–90% of patients who have MG. Single-fiber electromyography (SFEMG) may demonstrate increased variability (jitter) in the action potentials indicating the variability of propagation time to individual fibers supplied by the same motor neuron. SFEMG is more sensitive than standard EMG for MG but is not universally available (Fig. 3).

Patients with MG should undergo imaging of the mediastinum to evaluate for the presence of a thymoma. About 10–15% of patients with MG have a thymic tumor. Hyperplasia of the thymus gland may still be present in up to age 30 years, but the persistence of the thymus gland in persons over 40 years of age is abnormal. Surgical biopsy and resection of thymoma should be performed as some of these tumors are invasive or malignant. Patients with generalized MG even without a demonstrable thymoma on chest CT scan might still benefit from thymectomy, and there are cases of complete remission after surgery. We do not recommend thymectomy without thymoma for ocular MG alone, but some benefit in select patients has also been suggested.

Differential Diagnosis

1. Chronic progressive external ophthalmoplegia
2. Oculopharyngeal muscular dystrophy
3. Myotonic dystrophy
4. Ocular motor cranial nerve palsies
5. Brainstem lesions (i.e., encephalitis, botulism, multiple sclerosis)

Prophylaxis

Several medications can cause or worsen MG (e.g., certain antibiotics, anti-arrhythmics (procainamide), ACTH and steroids, antacids with magnesium, anticonvulsants, antihypertensives (like beta-blockers or calcium channel blockers), antimalarials, anesthetic neuromuscular agents, and penicillamine), and patients should be warned about the potential side effects of these drugs on MG function.

Therapy

The main therapies for MG are supportive and conservative measures (e.g., rest, diet, avoiding medicines that worsen MG), acetylcholinesterase inhibitors (e.g., Mestinon), and immunosuppression (e.g., prednisone). We recommend symptomatic treatment of ocular abnormalities, avoidance of agents that worsen neuromuscular transmission, and thymectomy for patients with a thymoma. Pyridostigmine is an acetylcholinesterase inhibitor with a duration of action of 2–8 h. It is most useful in the treatment of systemic weakness, but less effective in the treatment of ocular MG-related ptosis or diplopia. Immunosuppressants, consisting of mainly cytotoxic agents (e.g., azathioprine, cyclophosphamide, etc.) and corticosteroids (prednisone), can be used in patients who do not respond or improve satisfactorily with acetylcholinesterase inhibitors. Prednisone may worsen MG symptoms initially, and we generally use a tapering up schedule and warn the patient about this possibility even in ocular MG patients. Plasmapheresis and IV immune globulin both produce rapid improvement in symptoms and signs, and these therapies are generally reserved for severe or potentially life-threatening MG.

Lid crutches may be used for ptosis, but in may produce severe dry eye or not be tolerated well by

patients. Lid surgery for ptosis should be reserved for patients who have stable measurements and refractory to other conservative and medical treatments. Diplopia may be managed with patching or prisms initially, but strabismus surgery may be considered in patients with stable and chronic ocular deviations who have failed a trial of conservative and medical therapy.

Prognosis

MG is a chronic disease, but some patients go into remission clinically. MG is often relapsing and remitting in course in the initial 10 years and then becomes more stable in many patients thereafter. Unfortunately, MG remains a potentially fatal disease, and patients should be warned about generalized symptoms including respiratory or swallowing difficulties that would prompt more urgent treatment and evaluation. Of MG patients presenting with ocular symptoms alone, 10–20% have spontaneous remission, while 50–70% develop generalized myasthenia gravis, usually within 2 years of onset of the disorder. In general, a younger age at onset of MG carries a better prognosis, while those who present with ocular symptoms over the age of 50 are more likely to progress to generalized MG.

Epidemiology

MG has an incidence of 1:30,000–1:20,000. The disorder has one peak occurring at 20–40 years of age, mostly in women, and another peak at 60–70 years of age, mostly in men. MG, however, may occur at any age, in any race, and in either gender even though there is an overall higher ratio of females affected than to males.

Mycobacterium chelonae Keratitis

Burkhard von Jagow and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

M

Synonyms

Atypic *Mycobacteria* keratitis; Nontuberculous *Mycobacteria* keratitis

Definition

Corneal infection caused by the atypical *Mycobacterium chelonae*. *Mycobacterium chelonae* may be difficult to differentiate in microbiological testing, and medical therapy may be challenging.

Etiology

Atypical keratitis by *Mycobacterium chelonae* is usually associated with trauma, corneal surgery, or contact lens wear. *M. chelonae* keratitis was

reported to occur after LASIK procedures in the stromal interface. *M. chelonae* is a facultative pathogenic saprophytic germ, which may cause severe opportunistic infections.

Clinical Presentation

Atypical mycobacterial keratitis is characterized by a chronic, indolent course. The characteristic presentation is a crystalline keratopathy with multiple radiating lines reminding a "cracked windshield." Mycobacterial keratitis often shows endothelial plaques, satellite lesions, and an immune ring. It may lead to nonsuppurative, indolent corneal ulcers. The post-LASIK mycobacterial keratitis may be mistaken for diffuse lamellar keratitis (DLK).

Diagnostics

Bacteriological testing is possible by direct colony growth and by a molecular test. The specimen is harvested by direct scrape from the lesion or from the smear from a LASIK flap lift.

The colony test is relatively complicated. *Mycobacterium chelonae* must be cultured on blood base agar in 2 days and 4 weeks on Lowenstein–Jensen. Subsequently, a biochemical test (i.e., nitrate reduction and niasin test) can be applied.

The suspension prepared from colonies is respectively stained with Gram staining and Ziehl–Neelsen stain (EZN) and incubated in Lowenstein–Jensen (LJ) and Mycobacterium Growth Indicator Tube (MGIT). The molecular test applies INNO-LIPA.

Differential Diagnosis

Other atypical mycobacterial keratitis
Mycotic keratitis
Nocardia species keratitis
Corynebacteria dyphteriae keratitis
Other bacterial lamellar keratitis
Diffuse lamellar keratitis (DLK)

Prophylaxis

The two main sources of the mycobacteria are air conditions in clinics and tap water. Regular check for sterility of air conditions is necessary. Tap water must be avoided in the sterilization of surgical instruments and the cleaning of contact lenses. LASIK patients should not use swimming pools up to weeks after surgery. Tap water should be avoided for the cleaning of contact lenses.

Treatment

A medical therapy as a single line is often ineffective because of delayed diagnosis, slow response to therapy, inadequate drug penetration, and resistance to most conventional antibiotics. Therefore, a surgical debridement may shorten course. In the most common case of post-LASIK infection, a flap lift and abundant irrigation is necessary and urgent.

Most authors recommend a systemic therapy with clarithromycin 500 mg twice daily combined with topical antibiotics.

The following combinations of topicals are proposed:

1. Topical Tobramycin 15 mg/mL, Azithromycin 2 mg/mL, Amikacin 25 mg/mL, and Cefazolin 50 mg/mL, every 2 h
2. Topical Clarithromycin (1%), Tobramycin (1.4%), and Ofloxacin (0.3%)
3. Tobramycin 0.3%, every 4 h plus either Gatifloxacin 0.3%, every 4 h or Moxifloxacin 0.5%, every 4 h
4. Topical Moxifloxacin 0.5% or topical ophthalmic Gatifloxacin 0.3%

The duration to treatment is 2 months for systemic antibiotics and at least 4 months for topical medication.

The use of topical Fluoroquinolone monotherapy without concomitant systemic Clarithromycin should be avoided to prevent the forming of resistant strains. Ophthalmic steroids should be avoided.

Prognosis

The visual outcome of patients with ***Mycobacterium chelonae*** **keratitis** varies, depending on the location of the infiltrates relative to the visual axis and the size and the severity of the infiltrates. Patients may develop scars with loss of corneal transparency and irregular hyperopic astigmatism. Penetrating keratoplasty may be necessary in some cases.

Epidemiology

Mycobacterium chelonae keratitis can be epidemic if surgical instruments are the source of the infection.

Mydriasis Induced Secondary Angle Closure

Cornelia Hirn
Eye Clinic, City Hospital Triemli, Zurich, Switzerland

Definition

Angle closure is defined by iridotrabecular contact (either reversible apposition of the peripheral iris to the trabecular meshwork or irreversible *peripheral anterior synechiae* (*PAS*)), followed by reduced outflow of aqueous humor through the anterior chamber angle. In susceptible individuals, angle closure may occur due to mydriasis, which can be induced by various factors.

Etiology

Mydriasis induced angle closure is provoked by obstruction of aqueous flow both at the level of the iris and the pupil.

Resistance to transpupillary aqueous flow increases physiologically on dilation, with a maximum at mid-dilated pupil position. Additionally, in susceptible individuals (usually in patients with a narrow or occludable anterior chamber angle), a thick peripheral iris may "roll" into the trabecular meshwork and result in angle closure with subsequent elevation of intraocular pressure (IOP).

Mydriasis can be induced by various factors including not only dilating drops but also systemic drugs with sympathomimetic or parasympatholytic activity, as well as activation of sympathetic system by pain or emotional upset.

Typical systemic drugs with potential for precipitating angle closure in susceptible individuals are nebulized bronchodilators, selective serotonin re-uptake inhibitors, allergy and cold medications, tricyclic antidepressants, muscle relaxants, and some urological drugs.

Clinical Presentation

Angle closure secondary to mydriasis may present as *acute angle closure* with ocular pain and headache, red eye, mild dilated and nonreactive pupil, iris bombé, photophobia, decreased or blurred vision, and halos.

Mydriasis induced angle closure may also present intermittent, with recurrent episodes of blurred vision, halos and mild pain, often beginning in the evening in dark rooms, or during situations of stress with activation of the sympathetic system, and resolving spontaneously, often during sleep, and can therefore be misinterpreted as headache or migraine.

On clinical examination, there may be signs of previous angle closure attacks.

Intermittent angle closure may also progress to chronic angle closure with mild to moderate elevation of IOP and glaucomatous optic neuropathy (GON).

Typically, mydriasis induced angle closure occurs in eyes with a symmetric narrow anterior chamber angle.

Diagnosis

Angle closure is diagnosed on *gonioscopy.* Dynamic gonioscopy helps to distinguish between appositional angle closure and PAS.

Gonioscopy reveals a narrow anterior chamber angle in both eyes.

In chronic angle closure, dynamic gonioscopy may reveal PAS in patients with modest elevation of IOP and GON.

Ultrasound of the anterior segment may reveal additional structural changes of the peripheral iris.

Tonometry reveals elevated IOP.

Biomicroscopy with accurate assessment of the anterior chamber as well as the posterior segment is mandatory in classifying angle closure. Previous ocular and medical history, family history, as well as subjective symptoms should be inquired to exclude or confirm previous attacks in case of acute or intermittent angle closure.

Visual field examination, *retinal nerve fiber layer* assessment, and optic disc imaging should be performed to assess the stage of disease.

Provocative tests with simultaneous miotic therapy and dilator muscle stimulation by phenylephrine (Mapstone provocative test) in patients with narrow angle provide little information, since even when negative they may not rule out the potential for angle closure. In addition, they may trigger an acute angle closure even while the patient is monitored.

Differential Diagnosis

Primary angle closure due to pupillary block should be considered as well as any secondary angle closure with elevated IOP, either neovascular glaucoma, *uveitic glaucoma*, *lens-induced angle closure*, and angle closure due to aqueous misdirection (*malignant glaucoma*) or to choroidal pathologies (e.g., *uveal effusion*).

Also consider any *secondary open angle glaucoma* with acute rise of IOP like inflammatory, *corticosteroid glaucoma*, *Posner-Schlossmann-Syndrome*, *pseudoexfoliative glaucoma*, *pigmentary glaucoma*, *ghost cell glaucoma*, *phacolytic glaucoma*, or open angle glaucoma due to intraocular malignant tumors.

Prophylaxis

Dapiprazole is an alpha-receptor blocker that reverses pharmacological pupil dilation. Although it may not eliminate the possibility of angle closure, it reduces the overall time of dilation and especially the critical period of mid-dilated pupil in patients with narrow angle.

In patients with narrow angle on gonioscopy, a prophylactic iridotomy may be considered (*angle closure suspect*).

Therapy

Treatment of mydriasis induced glaucoma depends on the clinical presentation and stage of disease.

Medical treatment includes topical hypotensive medication like *beta-blocker*, *alpha agonists*, and *prostaglandin analogues*, topical steroids to

prevent PAS formation, and systemic aqueous humor suppressants, either *carbonic anhydrase inhibitors* or hyperosmotic agents.

Mild topical *miotic agents* may be effective by pulling the peripheral iris away from the anterior chamber angle, but they may also have an adverse effect by increasing the iris-lens contact and in consequence a pupillary block mechanism.

Indentation of the cornea may open the anterior chamber angle by shifting the fluid in the anterior chamber into the periphery.

The definitive treatment is iridectomy, either laser or surgical. In some cases, *peripheral laser iridoplasty* may be necessary prior to iridotomy to flatten the peripheral iris.

Prognosis

Only a small percentage of individuals with a narrow angle develop *acute angle closure* on mydriasis. No valid tests exist to predict which patients are at risk.

Epidemiology

Female gender, older age, and hyperopia are factors associated with shallower anterior chambers and may predispose for angle closure secondary to mydriasis, although estimates of risk vary greatly.

Myopic Chorioretinal Atrophy and Lacquer Cracks

Salomon Y. Cohen
Department of Ophthalmology, Centre Ophtalmologique d'Imagerie et de Laser, Paris, France

Introduction

Chorioretinal atrophy corresponds to the dry myopic maculopathy. While its features have been described many years ago, there is no widely accepted definition of the condition and its different stages.

In the present section, tessellated fundus, diffuse and patchy atrophy, and lacquer cracks will be considered as part of the myopic chorioretinal atrophy syndrome.

Epidemiology, Physiopathology

Epidemiological studies consistently show high myopia as the third or the fourth cause of legal blindness in developed countries, with a higher prevalence of affected patients in Asia than in western countries. However, these studies usually mix dry and wet subtypes of myopic maculopathy, i.e., nonneovascular and neovascular cases. Fundus analysis of patients with high myopia (refractive error – 6 dp or higher) showed that three fourth of myopic eyes present with myopic maculopathy with most cases presenting the dry forms: lacquer cracks, tessellated fundus, patchy or diffuse chorioretinal atrophy, and macular

atrophy (3%). Myopic dry maculopathy is usually bilateral (Soubrane and Coscas 2001; Silva 2012; Ohno-Matsui 2014).

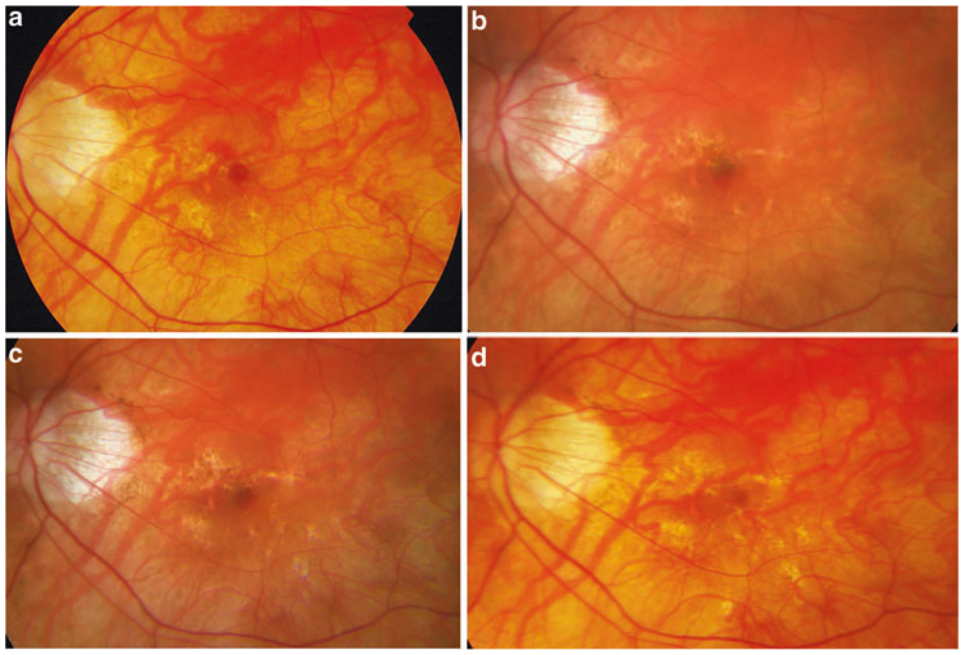
Myopic chorioretinal atrophy is considered as the consequence of the progressive elongation of the eyeball, resulting in a progressive thinning of the retinal pigment epithelium and the choroid. Elongation of the Bruch's membrane may lead to mechanical fissures, resulting in lacquer cracks. Rarefaction of the choroid, with a relative sparring of the retinal pigment epithelium, may account for the occurrence of diffuse chorioretinal atrophy, while disappearances of RPE and choriocapillaris are distinctive features of patchy areas of chorioretinal atrophy.

Progressive elongation of the eyeball explains the progression of the myopic maculopathy with age. Tessellated fundus may be observed in young myopic individuals, but the other stages are more frequently observed later in age. Myopic choroidal neovascularization may complicate the course of the disease at any stage of the myopic maculopathy.

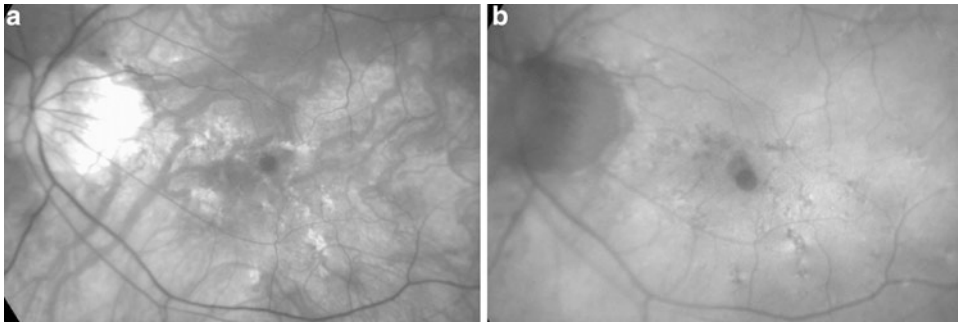
Clinical Description

Tessellated fundus is the consequence of axial elongation which causes a relative hypoplasia of the RPE, allowing an increased visibility of the choroidal vessels (Fig. 1a). Tessellation frequently occurs initially around the optic disk and could extend slowly during life in different directions according to the axis of the staphyloma. In eyes with tessellated fundus, fluorescein angiography shows a decreased contrast of the fundus during dry transit due to a higher reflection of the sclera. This poor contrast may also explain the difficulty of localization of the foveal avascular zone. Optical coherence tomography usually shows a relatively thin retina and choroid.

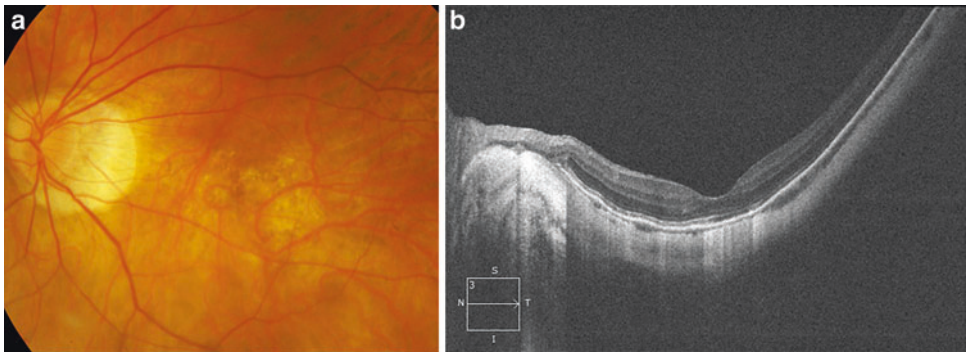
Eyes with tessellated fundus may be relatively stable, without progression toward more severe stages. Visual acuity may be strictly normal, despite reduced amplitude and delayed latency observed in multifocal ERG.



Myopic Chorioretinal Atrophy and Lacquer Cracks, Fig. 1 (**a**) Tessellated fundus with pallor of the fundus and abnormal visibility of the choroidal vessels. (**b**–**d**) Occurrence and extension of lacquer cracks, observed as multiple, horizontally oriented, branching, and crisscrossing *white lines*



Myopic Chorioretinal Atrophy and Lacquer Cracks, Fig. 2 (a) Red-free picture and (b) autofluorescence picture of a myopic female, showing the lacquer cracks as white in red-free light and dark in autofluorescence



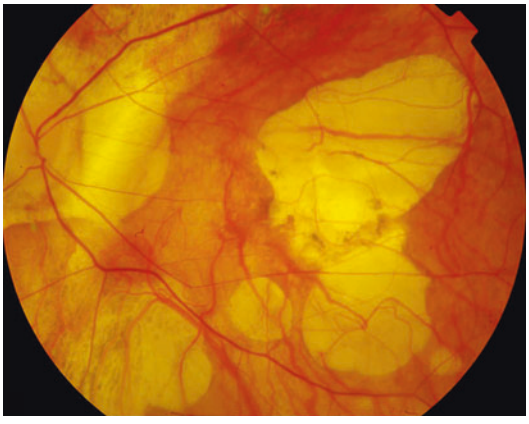
Myopic Chorioretinal Atrophy and Lacquer Cracks, Fig. 3 (**a**, **b**) Color and red-free picture of a myopic fundus showing diffuse myopic atrophy with yellowish appearance of the fundus, more obvious in the area located between the disk and the fovea. (**c**) Horizontal scan of the OCT showed that the choroid is very thin, but that there is no thinning of the retina

M

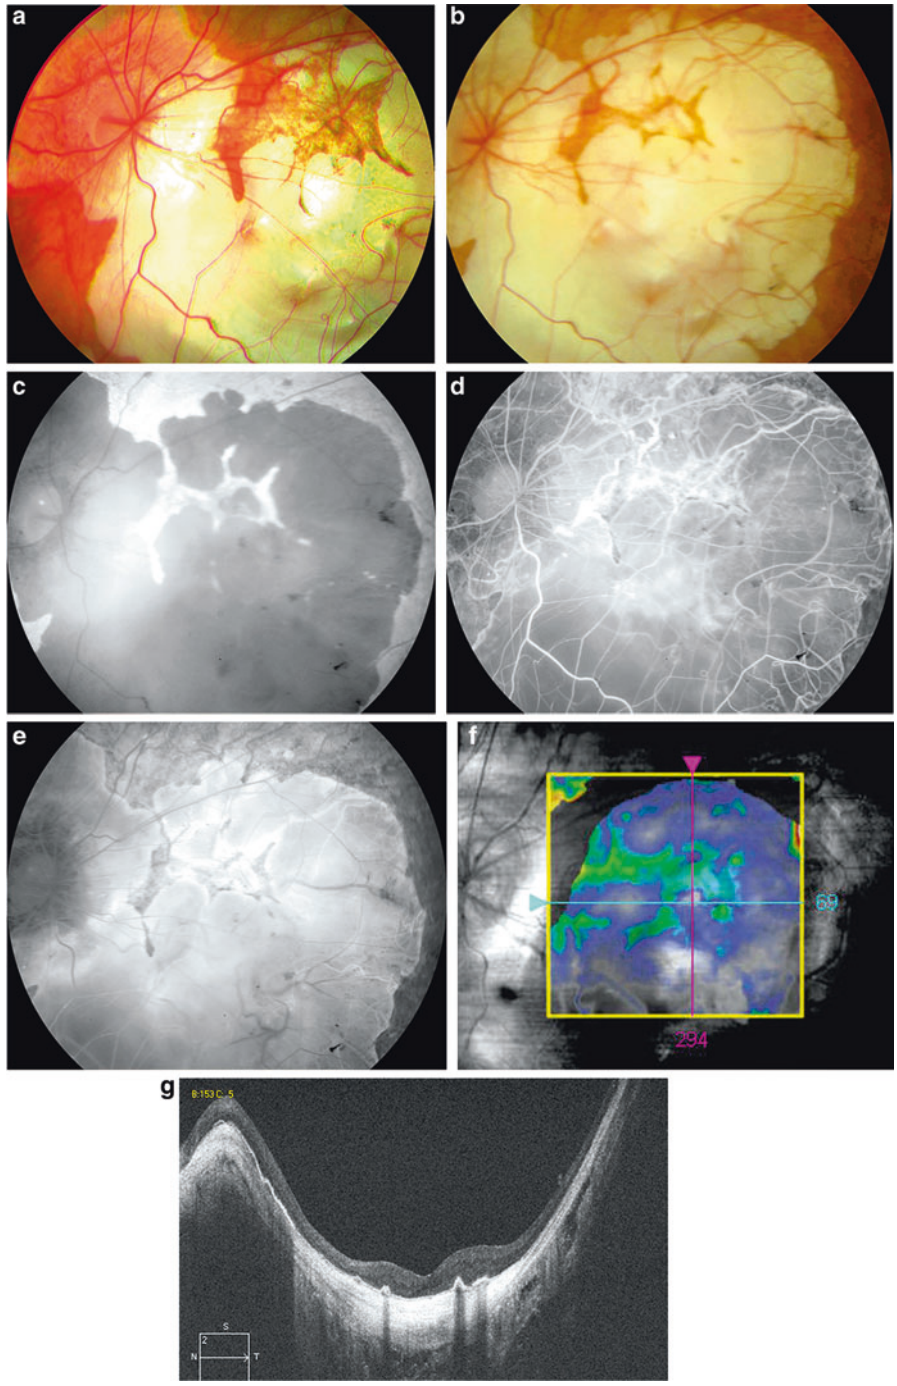
Lacquer Cracks

Lacquer cracks correspond to fine, irregular in caliber, yellowish or white, single and frequently horizontally oriented, or multiple and often branching and crisscrossing lines of the fundus. They are located in the posterior pole in the area of the staphyloma. They are rarely observed in the young age, and their frequency distribution could be with two peaks of age, one before 40 and one after 55.

Occurrence of lacquer cracks is usually associated with subretinal hemorrhages, usually small and regressive (Fig. 1b, c). Visual acuity loss or paracentral scotoma may be the revealing symptoms of the condition, according to the location of the bleeding. Usually, hemorrhages are fine and homogeneous, different from the ones that are



Myopic Chorioretinal Atrophy and Lacquer Cracks, Fig. 4 Patchy chorioretinal atrophy. Large areas of atrophy with lightly pigmented margins



Myopic Chorioretinal Atrophy and Lacquer Cracks, Fig. 5 Patchy chorioretinal atrophy. (**a**, **b**) Color photographs showing the extension of large areas of chorioretinal areas. (**c**) Autofluorescence: the atrophic areas are dark. (**d**, **e**) Fluorescein angiography showing absence of choriocapillaris, increased visibility of choroidal vessels, and progressive staining of the sclera. (**f**, **g**) OCT: irregular thinning of the retinal mapping. Horizontal scan showed that the choroid is almost absent

associated with choroidal neovascularization. Lacquer cracks may be observed after resorption of the hemorrhages. Lacquer cracks are hypo-autofluorescent (Fig. 2). Fluorescein angiography shows the cracks as lines that are hyperfluorescent during the entire sequence. ICGA shows the lines as hypofluorescent during the entire sequence. OCT may miss the lacquer cracks because lesions are narrow. However, attentive examination with multiple scans usually shows the cracks as discontinuities of the RPE and Bruch's membrane with deep hyper-reflectivity due to the deep penetrance of the light signal.

It is frequent that patients with one lacquer cracks develop additional lesions with time (Fig. 1a–d). Lacquer cracks also enlarge with time. Their impact on visual acuity is usually minimal. However, enlargement of subfoveal cracks and/or consequences of subfoveal bleeding may lead to irreversible visual loss.

Diffuse Chorioretinal Atrophy

Diffuse chorioretinal atrophy corresponds to a yellowish appearance of the fundus. Lesions are ill defined and sometimes difficult to observe (Fig. 3a). They typically occur around the optic nerve and slowly extend in the area of the staphyloma. They occur in the midlife and their frequency increases with age and with axial length. They are asymptomatic, and VA is preserved in most cases. Autofluorescence is usually normal. FA may show a tiny late hyperfluorescence of the fundus. In ICGA, eyes usually present a rarefaction of choroidal vessels. OCT may be more informative, showing a marked thinning of the choroid, without thinning of the retina (Fig. 3b).

Focal Chorioretinal Atrophy

Focal or patchy chorioretinal atrophy corresponds do the development of small areas of depigmentation. Patchy atrophy is more frequent with age and in eyes with long axial length. Its prevalence could exceed 50% in eyes with axial length superior to 32 mm. Lesions typically are white or yellowish and correspond to the visualization of the sclera through transparent retina. Large choroidal vessels may be seen in these areas. The margins of these patchy atrophic lesions may be pigmented (Fig. 4). The lesions are hypo-autofluorescent due to lack of RPE. OCT shows the absence of RPE and attenuation of the choroid. Fluorescein angiography shows the choroidal vessels, without the usual hyperfluorescence of the choriocapillaris (Fig. 5). Thus, areas of atrophy are hypofluorescent in the early stages of FA and show slow and progressive hyperfluorescence due to staining of the dye at the scleral level. Course of patchy atrophy is characterized by extension and coalescence of atrophic areas. It could also be complicated by myopic foveoschisis which typically occurs and extends in these areas. Despite extension of patchy atrophy, involvement of the fovea is relatively rare. Thus, visual acuity remains good in most eyes with patchy chorioretinal atrophy.

Conclusion

Dry myopic maculopathy is a common finding in myopic eyes. Most lesions occur and develop with age and elongation of axial length. Visual acuity is preserved in most cases, except when patchy atrophy of central lacquer cracks extends in the subfoveal area. Multimodal imaging of the lesions, including autofluorescence and spectral-domain OCT, helps to better characterize the lesion in order to evaluate the visual prognosis.

Nanophthalmos

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Microphthalmia; Microphthalmos

Definition

An ocular length <20.5 mm with mostly normal function. It is associated with hyperopia and a very shallow anterior chamber (Fried et al. 1982). Since nanophthalmic eyes have a crystalline lens of normal size, there is a high risk of glaucoma due to angular or cilio-lenticular block from the second or third decade of life. The sclera and choroid is often thickened, and serous ablation may occur. Nanophthalmic eyes are at high risk for surgical complications such as cilio-lenticular block and choroidal effusion (Brockhurst 1974).

A congenital nanophthalmos can occur separately or in conjunction with syndromes. Both sporadic occurrence and familiar associations have been described.

Histology

A significantly thickened sclera, with less ordered collagen bundles, and a thickened choroid are typical findings. Immunohistochemistry showed increased levels of fibronectin and proteoglycans in the sclera of nanophthalmic eyes for fibronectin (Yue et al. 1988). Other changes (retinal atrophy, macular edema) can be found as secondary changes.

Molecular Diagnostics

Recently, defects on chromosome 11 have been reported (Othman et al. 1998; Sundin et al. 2005).

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

In the presence of other anomalies, a syndrome has to be considered. There are numerous reports of rare syndromes associated with nanophthalmos. Therefore, the decision for special molecular diagnostics has to be made individually.

Differential Diagnosis

Microphthalmia secondary to other conditions such as persistent primary hyperplastic vitreous, ROP-associated retrolental fibroplasia, and phthisis bulbi.

Synonyms

Nasoethmoid orbital fractures; Naso-orbito-ethmoid fractures; NOE fractures

Definition

The naso-orbital-ethmoid (NOE) region is the region lateral to the nasal bones and medial to the medial canthus. NOE fractures involve the lower 2/3 of the medial orbital rim, where the medial canthal tendon inserts. The classic NOE fracture pattern involves fractures of the lateral nose, the inferior orbital rim, the medial orbital ethmoid wall, the nasal maxillary buttress at the pyriform aperture, and the junction of the frontal

process of the maxilla with the internal angular process of the frontal bone. Though this is the classic fracture pattern, significant variation exists (Cummings 2005). Markowitz classified NOE fractures into three types based on the relationship of the medial canthal tendon to the fracture lines and resulting bone fragments. NOE fractures may be unilateral or bilateral (Figs. 1, 2, 3, 4, and 5).

Basic Characteristics

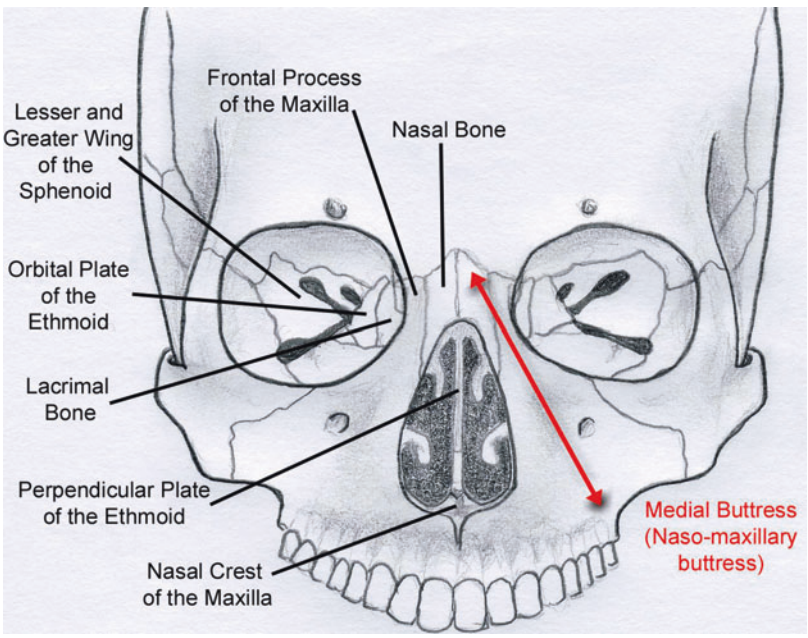
Etiology

NOE fractures are generally the result of blunt-force trauma to the midface. Common causes include motor vehicle accidents, interpersonal altercations, assaults, falls, and sports-related injuries.

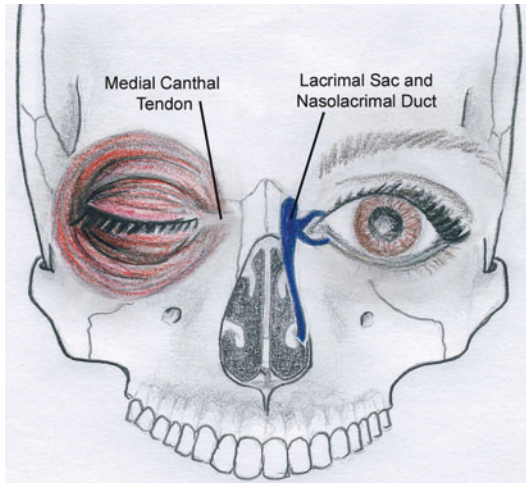
Clinical Presentation

Facial fractures often occur as the result of significant trauma and evaluation should begin with airway control and hemodynamic stabilization. Spinal cord injury should be ruled out, and any overt globe injury should be evaluated. A thorough history and physical, including a complete head and neck exam, may then be performed. With any midfacial fracture, suspicion for CSF rhinorrhea and/or otorrhea should be high.

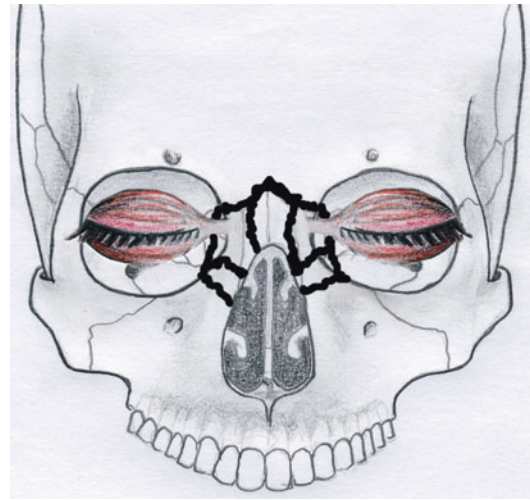
The NOE area plays a key role in midfacial contour and nasal projection and has important relationships to surrounding soft tissue structures that influence the clinical signs of a NOE fracture (Stewart 2005). Patients with NOE fractures may present with a short and sunken nasal bridge. Step-offs may be palpable along the nasal dorsum or medial orbital rim. Crepitus may often be felt over the medial canthus. The medial canthal tendon splits to envelop the lacrimal sac and attaches to the anterior and posterior lacrimal crests, frontal process of the maxilla, and internal angular process of the frontal bone and plays a key role in supporting the globe and eyelid. When the medial canthal tendon attachment is disrupted, the medial canthus retracts laterally leading to an increased intercanthal distance and shortening of the palpebral fissure; an intercanthal distance of greater than 35 mm is suggestive of NOE fracture and a distance of greater than 40 mm is virtually diagnostic (Marcowitz et al. 1991). The lacrimal system may be disrupted by NOE fractures and injury to the lacrimal canaliculi can result in epiphora. The trochlea is located on the internal angular



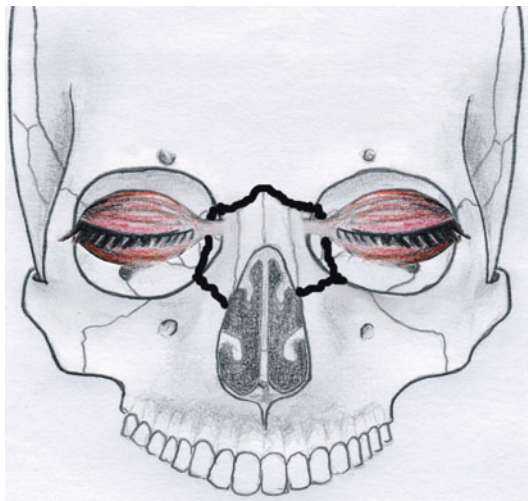
Naso-Orbital-Ethmoid Fractures, Fig. 1 Bony anatomy of the naso-orbital-ethmoid region



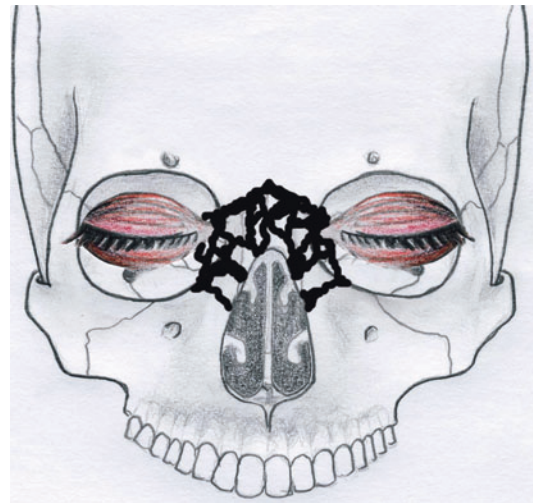
Naso-Orbital-Ethmoid Fractures, Fig. 2 Relationship of the naso-orbital-ethmoid complex to the medial canthal tendon and lacrimal apparatus



Naso-Orbital-Ethmoid Fractures, Fig. 4 Markowitz Type II naso-orbital-ethmoid fractures result in multiple bone fragments, though the fractures do not extend into the area of the attachment of the medial canthal tendon



Naso-Orbital-Ethmoid Fractures, Fig. 3 Markowitz Type I naso-orbital-ethmoid fractures result in a single bone fragment into which the medial canthal tendon inserts



Naso-Orbital-Ethmoid Fractures, Fig. 5 Markowitz Type III naso-orbital-ethmoid fractures result in numerous bone fragments, and importantly, the fracture lines extend through the bone into which the medial canthal tendon inserts, disrupting the medial canthal tendon. In this case, canthal avulsion may be present

process of the frontal bone and injury may cause extraocular muscle disturbance and diplopia. Patients may present with severe epistaxis either from Keisselback's plexus anteriorly, or branches of the sphenopalatine, or anterior ethmoid arteries posteriorly. Bleeding from the ethmoid vessels can also cause periorbital ecchymosis. Significant facial edema is common, and it is important to keep in mind that presence of a NOE fracture does not rule out presence of additional maxillofacial injuries.

Diagnostics

NOE fractures involve orbital wall fractures, and a complete ophthalmic exam is necessary. Intracranial injury must also be ruled out, and suspicion for CSF rhinorrhea should be high. CT scan is considered the modality of choice for diagnosis of NOE fractures (Papel 2002).

Treatment

Treatment of ocular and CNS injuries should precede treatment of NOE fracture in the presence of a stable airway. In patients with multiple facial fractures, most authors advocate repair of associated facial fractures prior to repair of NOE fractures. Reduction of maxillary and frontal fractures can restore important landmarks that are used to guide repair of the NOE fracture. A combination of incisions may be required to gain adequate exposure. Commonly employed incisions include bicoronal, lynch, inferior orbital rim, subciliary, transconjunctival, and sublabial. When possible, existing lacerations should be used to gain access. Repair of NOE fractures should reposition the displaced bony fragments with reattachment of the medial canthal tendon if needed. Perioperative antibiotics should be strongly considered in patients with facial fractures.

Definition

Epithelial ingrowth into the space between the corneal cap and stromal bed may occur in up to 3% of myopic LASIK surgeries (Yanoff and Duker 2013). If left untreated, ingrowth can lead to inflammation mimicking keratitis, irregular astigmatism, and loss of BCVA (Azar 2007). The traditional method for removing epithelial

ingrowth was a surgical flap lift to remove the cells underneath it. This exposed stroma may be treated with alcohol solution to limit epithelial cell regrowth again. The flaw is that the practice of re-lifting the flap results in a high rate of recurrence of epithelial ingrowth (Linfield et al. 2012). The use of laser technology (e.g., Nd:YAG laser), however, has shown promise in eliminating further epithelial ingrowth.

Indication

Early intervention with laser treatment (Nd:YAG laser) for removal of epithelial ingrowth following LASIK is recommended to eliminate further flap lift and epithelial ingrowth (Linfield et al. 2012).

Contraindication

Laser procedure using Nd:YAG is contraindicated if there are corneal scars, irregularity, or edema. Further contraindications include: poor eye stability, known or suspected cystoid macular edema, and possible active inflammation of the eye.

Techniques and Principles

The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is a laser with a wavelength of 1,064 nm. The Nd:YAG laser causes optical breakdown with a short, high-power pulse (Lindfield and Poole 2013). Focusing the laser upon the epithelial ingrowth creates a localized plasma-mediated vacuole, evaporating surrounding tissue.

The eye is initially prepared with topical anesthesia, and then the Nd:YAG laser is focused on the corneal epithelium (Lindfield and Poole 2013). The energy level for the laser ranges from 0.2 to 0.6 mJ. The beam is then defocused to reach the region of epithelial ingrowth. It is recommended that, if apparent, the laser be targeted at the septum that bridges the island of cells and the flap edge to block migration. The treatment begins at the center of this area of epithelial ingrowth and is gradually enlarged to the periphery. A gap should be kept between the tissue bubbles to avoid overlap of targeted areas.

Outcome

Patients report improved vision, resolution of subjective visual complaints and symptoms of glare, and possible diplopia (Linfield et al. 2012). The therapeutic benefits of Nd:YAG laser treatment for epithelial ingrowth has not been fully investigated. Additional studies are necessary to compare Nd:YAG laser versus mechanical treatment of epithelial ingrowth.

Complications

No adverse effects have been reported to date for this laser treatment of epithelial ingrowth (Linfield and Poole 2013). As with any procedure, risk remains for potential further epithelial ingrowth, infection, increased intraocular pressure, retinal detachment, macular edema, hemorrhage, corneal edema, and corneal endothelial loss.

Necrotizing Fasciitis, of Orbit

Michael T. Yen[1] and Elaine Thung[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Houston Eye Associates, Houston, TX, USA

Definition

Necrotizing fasciitis is a bacterial infection that spreads through the subcutaneous tissue planes and results in destruction of the fascia and fat but may spare the skin. It is characterized by symptoms such as edema, crepitus, blisters, subcutaneous gas, and disproportionate pain. It is also distinguished by marked systemic symptoms, such as shock and organ failure, which can lead to death. Necrotizing fasciitis often involves the extremities, abdominal wall, and perineum but may rarely involve the head, neck, and periorbital region (Anaya and Dellinger 2007; Sarani et al. 2009).

Etiology

Two clinical types of necrotizing fasciitis exist. Type 1 infections are polymicrobial and are caused by a mixture of aerobic and anaerobic bacteria, such as *Staphylococcus aureus*, enterobacteriaceae (e.g., *E. coli*, *Pseudomonas* species, and *Klebsiella* species), enterococci, and streptococci. This type usually occurs after surgical procedures or in patients with diabetes and peripheral vascular disease. Type 2 infections are caused by group A streptococcus (GAS), such as *Streptococcus pyogenes. Staphylococcus aureus* and its methicillin resistant form have also been implicated in type 2 necrotizing fasciitis (Wong et al. 2003; Sarani et al. 2009).

Epidemiology

Necrotizing fasciitis has an annual incidence of about 1,000 cases per year in the United States or about 0.04 cases per 1,000 person-years. It has a cumulative mortality rate of about 24–34%. One review found that 10% of necrotizing fasciitis cases involved the head and neck. However, it rarely affects the eyelid due to its rich vascular supply. Only 58 cases of well-documented eyelid necrotizing fasciitis have been reported over 50 years (Wong et al. 2003; Anaya and Dellinger 2007; Sarani et al. 2009).

Risk Factors

Risk factors for developing necrotizing fasciitis include (Wong et al. 2003):

Alcoholism
Diabetes mellitus
Systemic malignancy
Systemic corticosteroid use
Rheumatologic disease
Minor blunt traumas, lacerations, or previous surgery

Clinical Presentation

Early recognition of necrotizing fasciitis is important because the disease can progress rapidly into a systemic illness with significant morbidity and mortality. Necrotizing fasciitis can present with signs and symptoms of cellulitis, including erythema and edema of the affected area. Key features to look for are pain out of proportion to the skin findings, signs of systemic toxicity, and blister or bullae formation. Occasionally, severe pain without any cutaneous findings is the only manifestation of the infection (Wong et al. 2003; Elner et al. 2006).

Within 1–2 days of the initial presentation, erythema can develop or darken into a cyanotic color. Blisters and bullae filled with serous fluid often develop soon afterwards and should raise the suspicion of necrotizing fasciitis. By this stage, extensive deep tissue destruction has already occurred and patients usually present with fever and signs of systemic toxicity.

Necrotizing fasciitis of the eyelid, however, may have a different clinical course compared to

other areas of the body due to its rich blood supply and lack of subcutaneous tissue between the orbital septum and the orbicularis oculi muscle (Lukisch et al. 2002). The rich blood supply spares the eyelid margins from necrosis and allows systemic antibiotics to have better access to infected areas. The close proximity between the skin, orbital septum, and orbicularis oculi muscle also allows the infection to be noticeable earlier in the course of the disease. This allows rapid initiation of treatment. In addition, the orbicularis oculi muscle may serve as a barrier against spread of the infection into the periorbit. Necrotizing fasciitis may involve both eyes because of minimal resistance to spread of infection in the subcutaneous tissue over the nose (Elner et al. 2006).

Diagnostics

The history and clinical findings usually point to the diagnosis of necrotizing fasciitis. It should be considered when patients present with fever, systemic toxicity, and pain out of proportion to the skin findings. One retrospective study devised criteria for diagnosing necrotizing fasciitis based on six common laboratory tests (Wong et al. 2004). Each of the tests has assigned points, and the total score has a range of 0–13. A total score of $\geq$6 raises the suspicion for the infection with a 50–75% chance of developing the disease. A score of $\geq$8 has a >75% chance of accurate diagnosis. The lab values with their scores are as follows:

Serum C-reactive protein $\geq$ 150 mg/L (4 points)
Total white blood cell count 15,000–25,000/μL (1 point) or > 25,000/μL (2 points)
Hemoglobin 11.0–13.5 g/dL (1 point) or $\leq$ 11 g/dL (2 points)
Serum sodium < 135 mEq/L (2 points)
Serum creatinine > 1.6 mg/dL (2 points)
Serum glucose > 180 mg/dL (1 point)

Elevated serum lactate and creatinine kinase can also be seen in necrotizing fasciitis.

In addition, imaging studies can be done to help with the diagnosis, especially in cases of uncertainty. Plain radiography and a CT scan can be done to assess for air or gas along the facial planes. CT scans can also assess for deep tissue infection, particularly deep abscesses. CT and MRI with or without enhancement have also been used to show increased thickness of the facial layer, which can be associated with necrotizing fasciitis. However, obtaining an MRI may be prohibited in clinically unstable patients and can result in inappropriate delays in treatment. An emergent non-contrast CT scan offers a more expeditious option.

Differential Diagnosis

Cellulitis
Abscess
Gas gangrene (clostridial myonecrosis)
Pyomyositis
Myositis (viral/parasitic)

Treatment

Treatment of necrotizing fasciitis includes the use of systemic broad-spectrum antimicrobial therapy, such as β-lactam antibiotics (e.g., penicillin), cephalosporins, and clindamycin. Clindamycin may be more effective than penicillin because it inhibits both toxin production and streptococcal M protein synthesis, an antiphagocytic virulence factor that prevents leukocytic attack. However, clindamycin should be used in combination because rare cases of GAS strains resistant to clindamycin have been observed. In cases suspected of having type 1 disease, clindamycin can be used to provide anaerobic coverage. Other therapeutic options include monotherapy with a beta-lactam-beta-lactamase inhibitor (e.g., pipercillin-tazobactam) or a carbapenem (Anaya and Dellinger 2007; Sarani et al. 2009).

In most cases of necrotizing fasciitis, prompt surgical treatment is important in decreasing mortality. However, the unique anatomy of the eyelid with its rich vascular supply and thin skin allows for conservative treatment with delayed debridement (Lukisch et al. 2002). The vasculature of the eyelid enables

systemic antibiotics to have better access to infected areas and gives the zone of tissue adjacent to necrotic tissue better local blood supply. One study recommended conservative management by observing patients until a clear zone of demarcation is apparent at which time bedside debridement of the necrotic skin can be done. This allows for a significantly less amount of tissue to be removed than the amount that would be excised if aggressive debridement to the edge of the advancing infection were done. However, aggressive debridement is important in severe cases in which infection extends into the orbit and beyond the periorbital area (Elner et al. 2006).

Hyperbaric oxygen has also been evaluated as an adjunctive treatment for necrotizing fasciitis. It may decrease mortality and limit the amount of debridement needed by inhibiting toxin production. However, results from studies are conflicting, and no epidemiology-based studies have been done to show the effect of hyperbaric oxygen on necrotizing fasciitis.

Prognosis

The mortality rate of patients with periorbital spread of necrotizing fasciitis that involves the scalp and upper face is about 12.5%. No deaths have been reported that are solely due to necrotizing fasciitis of the eyelids, but significant morbidity often ensues. The low likelihood of mortality from eyelid infections is presumably due to the eyelid's unique anatomic features. As mentioned previously, the skin of the eyelid is thin, and the lack of subcutaneous fat between the skin and the orbicularis oculi muscle allows necrosis of the eyelid to occur rapidly, making the presence of the infection known. It is thus less likely to spread or be contained in the eyelid for prolonged periods where it could potentially act as a nidus for further infection.

However, cases of deep orbital involvement by spread of the infection along the orbital septum and blood vessels have been reported. In these cases, arterial occlusion due to severe perivascular involvement leading to thrombosis can occur and lead to blindness secondary to retinal arterial occlusion. Further ischemic necrosis can also occur due to increased intraorbital pressure from severe inflammation and edema. Early surgical intervention and medical therapy can prevent visual loss in these cases.

Necrotizing Keratitis

Reza Ghaffari[1] and Siamak Zarei-Ghanavati[2]
[1]Tehran University of Medical Sciences, Tehran, Iran
[2]Mashhad University of Medical Sciences, Mashhad, Khora san-Razavi, Iran

Synonyms

Corneal necrosis; Necrotizing stromal keratitis

Definition

Necrotizing stromal keratitis is a condition characterized by the presence of severe inflammation in the corneal tissue and subsequent damage leading to destruction of the corneal tissue, necrosis, and corneal melting seen in response

to an inflammatory or infectious process. In the more severe forms, the condition can progress to corneal abscess formation (a condition that is referred as suppurative keratitis), thinning, and perforation.

Etiology

A variety of pathologic processes could present as necrotizing keratitis. The major etiologies can be classified into one of these categories:

1. Infectious: a wide spectrum of infectious agents including bacterial, viral, fungal, and protozoal infections of the cornea could be associated with corneal ulceration and necrotizing keratitis. (For a more detailed and in-depth information about each of these entities, the reader is referred to the related section elsewhere in this encyclopedia.)

   A special form of necrotizing keratitis associated with an infectious etiology is necrotizing herpetic keratitis. Intact virions have been detected in stromal keratocytes and lamellae on electron microscopic examination of pathologic tissue from patients with herpetic necrotizing stromal keratitis. The use of topical corticosteroids without antiviral coverage has been implicated as a possible risk factor (Krachmer and Mannis 2010).
2. Immune mediated: a variety of systemic immune-mediated diseases and vasculitic diseases like rheumatoid arthritis (RA), relapsing polychondritis, and Wegener's granulomatosis can be associated with corneal melting and peripheral ulcerative keratitis (PUK). Corneal involvement in these conditions is more commonly associated with an adjacent scleritis, but it can occur as isolated finding. (For a more detailed and in-depth information about each of these entities, the reader is referred to the related section elsewhere in this encyclopedia.)
3. Toxic reaction to certain drugs: corneal melting could be a drug-related complication in conditions like anesthetic abuse or the use of the alkylating agent mitomycin C as an antifibrotic agent in pterygium and glaucoma filtering (Krachmer and Mannis 2010). The topical use of NSAIDs like diclofenac, ketorolac, and bromfenac has also been associated with the risk of corneal melting. However a definitive link between topical NSAIDs and corneal melts has not been documented (Kim et al. 2010). Alkylating agents like mitomycin C are also associated with corneal melting (Copeland and Afshari 2013).

In addition, corneal melting and necrosis may be the final consequence of a prolonged and persistent epithelial defect due to a variety of etiologies including chemical burn, exposure keratopathy, and ocular surface disease like keratoconjunctivitis sicca, Stevens-Johnson syndrome, and graft versus host disease.

In these conditions, the cornea may be the primary site affected by the pathologic process, with or without secondary involvement of adjacent structures like the sclera or anterior chamber in its course, or, sometimes, the cornea may be secondary affected by extension of adjacent pathology like necrotizing scleritis.

Clinical Presentation

Due to the diversity of the etiology of necrotizing keratitis, the clinical presentation may take different forms based on the etiology of the disease.

The symptoms in patients with an infectious keratitis commonly include variable degrees of pain, ocular discomfort, photophobia, blepharospasm, tearing and eye injection, and blurred vision. The onset of symptoms may take an acute and fulminant form (hours to a few days) in cases with virulent bacterial organisms like *Pseudomonas aeruginosa* or a more protected and prolonged course (several days to weeks) in less virulent organisms like fungal, nocardial, and mycobacterial infections.

The clinical findings in these patients include adnexal reaction with erythema and eyelid swelling; conjunctival injection and eyelid edema; ciliary flush dense stromal infiltration with opacification, necrosis, and abscess formation; and ulceration and which may be accompanied

with an overlying epithelial defect. Other signs may include anterior chamber reaction and hypopyon formation. (For more information regarding the specific characteristics of each type of keratitis, the reader is referred to the related sections elsewhere in this encyclopedia.)

The clinical findings in necrotizing herpetic stromal keratitis are corneal necrosis, ulceration, and dense infiltration of the stroma with an overlying epithelial defect. The combination of replicating virus and severe host inflammatory response may progress to corneal thinning and perforation in a short period of time. The clinical findings in this condition may resemble those of infectious keratitis secondary to other infectious keratitides. Therefore, bacterial and fungal pathogens must be ruled out when this diagnosis is considered.

Keratitis in rheumatologic disease like RA occurs most often contiguous with adjacent area of scleritis, but it may occur as an isolated finding. The clinical picture may take different like sclerosing keratitis, acute stromal keratitis, limbal guttering, peripheral ulcerative keratitis, and keratolysis (Krachmer and Mannis 2010).

Diagnosis

The workup for patients with necrotizing keratitis should be tailored for each patient according to the clinical setting to address the possible causative etiologies.

A detailed history with particular attention to drug history, previous surgeries, and ocular and other symptoms suggestive of an underlying ocular disease like herpes simplex and systemic disease is crucial.

A full ophthalmic examination with particular attention to the lids, lid margin, conjunctiva, cornea, and other anterior segment and posterior segment structures is necessary to define the full extent and stage of the disease.

If an infectious etiology is suspected, corneal scraping and obtaining smear and culture with appropriate stain and media are indicated to identify the causative organism. Corneal biopsy and molecular diagnostic tests like polymerase chain reaction (PCR) may be helpful in some patients. (For a more detailed discussion, refer to section "Infectious Keratitis".)

Although herpetic keratitis is most commonly diagnosed clinically, identification of organism with viral culture, antigen detection methods, or PCR can be used to confirm the diagnosis in selected cases (Knickelbein et al. 2009). In patients with an immune-mediated corneal melting, a meticulous workup to rule out an underlying systemic disease is essential, not only to control the eye disease, but the ophthalmologist may play a life-saving role, considering the high mortality rate associated with untreated systemic disease. In patients suspected to have an underlying systemic disease, a systemic examination and adjunctive laboratory tests may be necessary to identify the underlying disease. A battery of tests commonly used includes CBC with diff, urinalysis, chest X-ray, erythrocyte sedimentation rate or C-reactive protein, rheumatoid factor (RF), antinuclear antibody (ANA), and antineutrophil cytoplasmic antibodies (ANCA). However, the workup needs to be individualized based on each clinical setting (Copeland and Afshari 2013).

Differential Diagnosis

- Infectious keratitis due to bacterial, viral, fungal, and protozoal infestations of the cornea
- Immune-mediated corneal disease in the context of systemic autoimmune disease (as previously addressed in the etiology) or local immune-mediated disease like Mooren ulcer and Fuchs marginal keratitis
- Toxic effects related to anesthetic abuse, certain drugs like topical NSAIDs
- Corneal and sclera melts associated with surgeries like pterygium excision particularly with adjunctive use of mitomycin C

Prophylaxis

The Herpetic Eye Disease Study (HEDS) showed the beneficial effects of prophylaxis with oral acyclovir (400 mg BID) in reducing the

recurrence rate in patients with a history of previous epithelial and stromal keratitis. Although the study recommendations do not distinguish between different types of stromal keratitis and the results may not be directly applicable to herpetic necrotizing keratitis considering that this condition probably represents the least common type of herpetic keratitis, the same recommendations probably should be undertaken in herpetic necrotizing keratitis in the view of the pathogenesis of this condition (Knickelbein et al. 2009).

Therapy

The management of a patient presenting with necrotizing keratitis should be individualized based on the possible etiology, severity of the disease, and the presence of other concomitant ocular or systemic diseases and requires a careful implantation of available medical and surgical measures targeted to address the causative etiology and other interventions that may be necessary to save the tectonic structural integrity of the eye. Sometimes, a multidisciplinary approach and consultation with other subspecialities may be required in recalcitrant cases of peripheral ulcerative keratitis associated with other systemic diseases.

If an offending agent or drug could be identified as the trigger for the insult, discontinuation of the exposure could be a very important step in preventing further progression of the disease.

In patients with necrotizing keratitis with an infectious etiology, control of infection with appropriate topical antibiotics in conjugation with systemic antibiotics in selected cases is essential. This generally requires an aggressive and intensive treatment with fortified antibiotic drops, effective against the causative organism. Progressive corneal melting and small perforations may be amenable to tissue adhesives like cyanoacrylate glue. Large perforations and threatened scleral involvement may need therapeutic keratoplasty in an emergent setting to control the infection. Amniotic membrane transplantation has been reported in infectious keratitis patients and may be helpful in some cases. Collagen cross-linking is also being investigated in the treatment of infectious keratitis. (For a more detailed discussion, refer to the section "Infectious Keratitis".)

Necrotizing herpetic stromal keratitis is especially difficult to manage and may rapidly progress to corneal perforation. Necrotizing herpetic keratitis patients are treated with a combination of antivirals and corticosteroids. Due to toxicity of topical antivirals, systemic antivirals are preferred in patients with necrotizing HSV stromal keratitis. Transplantation of amniotic membrane onto the ocular surface that promotes healing of the corneal epithelium and reduces stromal inflammation has been used with promising results in the management of necrotizing HSV stromal keratitis.

Prognosis

Prognosis depends on the underlying disease.

Necrotizing Scleritis

Ben Janson
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Necrotizing scleritis with inflammation

Definition

An aggressive form of scleritis that is an inflammatory disease of the sclera often accompanied by severe pain and risk of vision loss

Etiology

Necrotizing scleritis is caused by antigen-antibody complex deposition in the vessels as part of type II hypersensitivity reaction (Goldstein and Tessler 2009; Biber et al. 2011). There is inflammation of macrophages, B cells, and T cells. Most of the T cells are of the CD4 T helper cell type (Biber et al. 2011). In 50–81% of cases, there is an underlying vasculitic disease (Biber et al. 2011). Necrotizing scleritis may also be induced from surgery or after the use of bisphosphonates or mitomycin (Sharma and Rosenbaum 2010). The necrotizing form of scleritis comprises 75% of surgically induced scleritis (Biber et al. 2011). This can occur after any procedure and can include cataract surgery, penetrating keratoplasty, strabismus surgery, or pterygium excision (Biber et al. 2011).

Clinical Presentation

Patients often present with severe pain and discomfort that wakes them up from sleep. This gradual onset pain may radiate to the brow or jaw (Kanski and Bowling 2011). On examination, there is congestion of the deep vascular plexus of the anterior eye, often with a purplish/blue hue from underlying uvea. These vessels do not blanch with topical phenylephrine, and red-free light may help determine the anatomical level of inflammation (Goldstein and Tessler 2009). There are also areas of white, avascular sclera. Necrotizing scleritis is bilateral in 60% of patients, but may also be unilateral or move from eye to eye (Goldstein and Tessler 2009; Kanski and Bowling 2011). Perforation often does not occur, but can occur in cases of elevated IOP or ocular trauma.

Necrotizing scleritis has three categories: vasoocclusive, granulomatous, and surgically induced. The vasoocclusive form shows patches of scleral edema that may coalesce (Kanski and Bowling 2011). Vasoocclusive necrotizing scleritis is most often associated with rheumatoid arthritis (Kanski and Bowling 2011). The granulomatous form presents with raised, irregular, and edematous sclera and overlying tissue (Kanski and Bowling 2011). The granulomatous form is often associated with Wegener granulomatosis (Kanski and Bowling 2011). Finally, the surgically induced form may present within 3 weeks of procedure up to many months later.

Diagnosis

Lab diagnosis is not specific for scleritis, but may help determine the underlying systemic disease. An incomplete list but important lab tests include rheumatoid factor (RF), antineutrophil cytoplasmic antibody (ANCA), antiphospholipid antibodies, antinuclear antibodies (ANA), complete blood count (CBC), erythrocyte sedimentation rate (ESR), and urinalysis (Biber et al. 2011; Kanski and Bowling 2011).

Differential Diagnosis

Episcleritis

- Mild instead of severe pain
- Fiery, brick red appearance instead of blue/purple color
- Avascular areas absent
- No necrosis or scleral thinning

Conjunctivitis

- Discharge present
- Superficial inflammation blanches with phenylephrine

Anterior uveitis

Prophylaxis

Unclear

Therapy

Oral NSAIDs work well for non-necrotizing scleritis, but in necrotizing scleritis, systemic corticosteroids are indicated. Prednisone is often used. There may also be a need for systemic immunosuppressive drugs in severe cases, and cyclophosphamide is often used in those with Wegener's granulomatosis (Biber et al. 2011). Treatment with immunosuppressive drugs is recommended until scleritis is controlled for 1 year (Biber et al. 2011). These immunosuppressives are often needed for long-term treatment of scleritis after the use of prednisone for 3–6 months (Goldstein and Tessler 2009). TNF-α biologic therapies are less studied but have been used clinically.

Surgical therapy is rarely needed. In cases with emergent perforations, a tectonic scleral and peripheral corneal patch grafting should be used.

Prognosis

Even when treated, necrotizing scleritis carries the greatest risk for vision loss of any type of scleritis. Eighty-two percent of necrotizing scleritis patients lost visual acuity (Biber et al. 2011). Other complications that may present include sclerosing keratitis, peripheral ulcerative keratitis, uveitis, glaucoma, or perforation (Sharma and Rosenbaum 2010; Biber et al. 2011; Kanski and Bowling 2011). Uveitis occurs in one-third of necrotizing scleritis patients (Biber et al. 2011). Cataract may also develop, but cataract treatment is postponed until the scleritis is in remission for at least 2–3 months (Goldstein and Tessler 2009; Sharma and Rosenbaum 2010). If the scleritis is treated and the scleritis resolves, the sclera will heal. Necrotizing scleritis also carries a risk of mortality with an 8-year mortality of 21% (Goldstein and Tessler 2009).

Epidemiology

The average age of onset for necrotizing scleritis is 60 (Kanski and Bowling 2011). It occurs in all races. Many cases have an underlying systemic disorder, which is most often a connective tissue disease. Underlying disease can include psoriatic arthritics, inflammatory bowel disease, rheumatoid arthritis, relapsing polychondritis, Wegener's granulomatosis, and polyarteritis nodosa (Goldstein and Tessler 2009; Biber et al. 2011).

Neodymium:YAG Laser

Tanja M. Rabsilber and Mike P. Holzer
Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Definition

The neodymium-yttrium-aluminum-garnet (Nd:YAG) laser is an example of a pulsed laser concentrating low amounts of energy into very brief periods (Atebara and Thall 2004).

Clinical Features

Besides Nd:YAG laser capsulotomy, the peripheral iridotomies are routine treatments. The frequency-doubled Nd:YAG laser (532 nm green) can be used for photocoagulation treatments.

Treatment

The 1064 nm infrared Nd:YAG laser works on the principle of photodisruption which is mainly a mechanical effect. Highly focused laser pulses induce an optical breakdown. Vapor formed by the lightning bolt expands, quickly collapses, and produces a miniature thunder clap. Acoustic shock waves cause most of the tissue damage (Atebara and Thall 2004). Nd:YAG lasers do often work in the Q-switching mode: a shutter in the laser cavity blocks laser light emission until a large population inversion has been established. The shutter is opened quickly, and the burst lasts about one millionth of a second (Atebara and Thall 2004). Since the infrared light is invisible, a helium-neon laser is implemented causing a red aiming beam. Due to different light bending properties, the focus of the Nd:YAG laser rarely coincides precisely with the aiming beam (Atebara and Thall 2004).

Neovascular glaucoma in proliferative diabetic retinopathy

Definition

Neovascular glaucoma is a blinding disease, difficult to manage and often resulting in disastrous visual loss (Allingham et al. 2005). In 1906, Coats described new vessel formation on the iris in eyes with central retinal vein occlusion. Thus increased intraocular pressure with iris neovascularization and/or angle neovascularization appearing in patients with proliferative diabetic retinopathy (PDR) with and without retinal detachment and with or without any previous intraocular surgery is defined as neovascular glaucoma in diabetes mellitus.

Etiology

Diabetic retinopathy is the most common cause of rubeosis iridis accounting for approximately one third of patients with neovascular glaucoma. Neovascular glaucoma is an advanced manifestation of diabetic retinopathy. Neovascular glaucoma may occur without retinal or optic disk neovascularization; however, it is more commonly seen in association with PDR. The frequency with which rubeosis iridis is associated with diabetic retinopathy is greatly influenced by surgical interventions. After pars plana vitrectomy for diabetic retinopathy, the reported incidence ranges from 10% to 42%, whereas that for neovascular glaucoma ranges from 10% to 23%, with most of the cases developing during the first 6 months after surgery (Hayreh 2007). In these cases, the occurrence of rubeosis iridis and neovascular glaucoma is much higher in aphakic eyes (as compared to phakic or pseudophakic) and when rubeosis is present before the vitrectomy. An unrepaired retinal detachment after vitrectomy for diabetic retinopathy is also a risk factor for postoperative rubeosis iridis. A completely attached retina and aggressive anterior or peripheral photocoagulation therapy have been shown to be the most important factor in controlling or preventing neovascular glaucoma after vitrectomy for PDR. Intraocular silicone oil also reduces the incidence of anterior segment neovascularization, possibly acting as a diffusion or convection barrier. Hypoxia of the retina in areas of capillary nonperfusion causes neovascularization via angiogenic substances, mainly vascular endothelial growth factor (VEGF) produced by Müller cells.

Clinical Presentation

The prevalence of rubeosis iridis among patients with diabetes mellitus ranges from 0.25% to 20% according to various reports. Diabetes usually exists for many years before rubeosis develops, and concomitant PDR is usually found. In patients with PDR, approximately 50% of cases have rubeosis iridis. If rubeosis iridis is seen in a patient with nonproliferative diabetic retinopathy, other causes such as carotid artery disease should be considered. The risk of rubeosis iridis and neovascular glaucoma in patients with diabetic retinopathy greatly increases when arteriolar or capillary nonperfusion is present or after vitrectomy or lensectomy. In looking for the earliest biomicroscopic evidence of anterior segment rubeosis, it is important to pay close attention to the pupillary margin of the iris, where neovascularization is typically seen first. However, gonioscopy is also important, because angle neovascularization may occasionally precede that of the iris.

Diagnostics

In diabetic retinopathy, fluorescein angiography of the retina to confirm (or exclude) proliferations at the optic nerve head or elsewhere is crucial. A careful biomicroscopic examination or indirect ophthalmoscopy should be performed to rule out peripheral retinal detachment. For detection of rubeosis iridis, careful slit-lamp examination and in doubt fluorescein angiography of the iris may help to differentiate dilated iris capillaries from neovascularization. Measuring of intraocular pressure and careful gonioscopy to differentiate between open-angle and angle-closure stage of neovascular glaucoma is mandatory.

Differential Diagnosis

All other causes predisposing to rubeosis iridis and neovascular glaucoma should be considered. They include all retinal ischemic diseases such as ischemic central or hemicentral retinal vein occlusion (CRVO), retinal detachment, hemorrhagic retinal disorders, Coats exudative retinopathy, Eales disease, Leber's congenital amaurosis, retinopathy of prematurity, persistent hyperplastic primary vitreous, sickle cell retinopathy, syphilitic retinal vasculitis, retinoschisis, Stickler syndrome, and optic nerve glioma with subsequent venous stasis retinopathy. Other causes such as irradiation retinopathy, intraocular tumors or lymphoma, and inflammatory diseases or surgically induced rubeosis and extraocular causes such as

carotid artery obstruction or occlusion and fistula should also be considered to cause rubeosis iridis.

Prophylaxis

Panretinal photocoagulation is most effective as prophylaxis against the development of neovascular glaucoma. The mechanism by which panretinal photocoagulation influences neovascularization is uncertain, although it may be related to decreasing the retinal oxygen demand. This hypothesis is consistent with the reported observation that the photoreceptor-retinal pigment epithelial complex accounts for two thirds of the retinal oxygen consumption. Decreased oxygen demand may reduce the stimulus for release of an angiogenesis factor or may reduce the hypoxia in the anterior ocular segment. Panretinal photocoagulation is mandatory in diabetic patients undergoing pars plana vitrectomy for PDR and should be performed during the vitrectomy using endophotocoagulation. Cataract surgery in patients with PDR should be delayed until panretinal photocoagulation has been performed.

Therapy

The first-line treatment is lowering of the IOP with topical or systemic medications, which may indirectly improve retinal perfusion. Suppression of angiogenesis by repeated intravitreal injection of anti-VEGF substances (ranibizumab, bevacizumab, or aflibercept) has been recently shown to significantly decrease anterior segment neovascularization (Beutel et al. 2010; SooHoo et al. 2015). In addition to anti-VEGF, intravitreal injections of steroids (triamcinolone) may reduce the inflammatory stimulus but may increase the IOP especially in steroid responders. Reducing the oxygen demand of the retina by laser coagulation of the ischemic retina significantly reduces or eliminates anterior segment neovascularization. If medical IOP lowering is not effective enough, surgery (trabeculectomy or tube shunts) may be required. Surgically lowering IOP by trabeculectomy has been shown to be very effective in lowering the rate of recurrence of anterior segment neovascularization. When cloudy media precludes panretinal photocoagulation, transscleral panretinal cryotherapy, often combined with cyclocryotherapy, can control the IOP and reduce the neovascularization.

Prognosis

If neovascular glaucoma is diagnosed early enough (before the chamber angle is completely closed), aggressive photocoagulation may reverse the anterior segment rubeosis and the increased IOP in a majority of cases. With modern vitrectomy techniques using endophotocoagulation and when indicated silicone oil, the percentage of postsurgical neovascular glaucoma has been significantly reduced. Maintaining the posterior capsule in cataract surgery has also reduced the risk of postsurgical rubeosis in diabetic patients.

Epidemiology

No exact data are available about the prevalence of neovascular glaucoma in patients with PDR. There is, however, some data on increased mortality rates and reduced life expectancy in patients requiring tube shunt implants for neovascular glaucoma (Blanc et al. 2004).

Neovascular Glaucoma in Ischemic Central Retinal Vein Occlusion

► Neovascular Glaucoma in VOR

Neovascular Glaucoma in Ocular Ischemia, Others

Jörg Stürmer
Kantonsspital Winterthur, Brauerstrasse, Winterthur, Switzerland
Augenklinik Kantonsspital, Winterthur, Switzerland

Definition

Ocular ischemic syndrome is a serious but uncommon blinding condition. Increased intraocular pressure with iris neovascularization and/or angle neovascularization appearing in patients with carotid artery obstruction is defined as neovascular glaucoma (NVG) in ocular ischemia (Allingham et al. 2005). Neovascular glaucoma may also be present in other extraocular vascular disorders such as internal carotid occlusion or carotid-cavernous fistula and in a variety of intraocular disorders such as retinal detachment, hemorrhagic retinal disorders, Coats exudative retinopathy, Eales disease, Leber's congenital amaurosis, retinopathy of prematurity, persistent hyperplastic primary vitreous, sickle cell retinopathy, syphilitic retinal vasculitis, retinoschisis, Stickler syndrome, and optic nerve glioma with subsequent venous stasis retinopathy. Other causes such as irradiation retinopathy, intraocular tumors or lymphoma, and inflammatory diseases or surgically induced rubeosis may also responsible for NVG.

Etiology

Carotid artery obstructive disease is probably the third most common cause of neovascular glaucoma (after proliferative diabetic retinopathy and ischemic central retinal vein occlusion), accounting for 13% of all cases. Neovascularization is caused by reduction of global blood flow to the eyeball, which can produce anterior and/or posterior segment ischemia. Anterior segment ischemia results in development of iris and angle neovascularization and NVG. Most patients with ocular ischemic syndrome have severe carotid artery occlusive disease, but not all; it can be associated with vascular occlusive disease of the aortic arch or of the ophthalmic, central retinal or ciliary arteries. In contrast to the other causes of NVG, not only retinal but also uveal ischemia may be an important contributing factor for neovascularization.

NVG may also be diagnosed following radiation for a variety of ocular and orbital lesions, e.g., iris melanoma, posterior uveal melanomas, choroidal metastatic tumors, retinoblastoma, orbital lymphoma, and nasal and paranasal malignancies. In ocular radiation, in most eyes the main factor responsible for the development of NVG most likely is the development of secondary radiation retinopathy, in which there is development of retinal capillary non-perfusion and retinal ischemia. NVG has been reported, prior to treatment, in ring melanoma of the anterior uvea, adenocarcinoma of the nonpigmented ciliary epithelium, medulloepithelioma, circumscribed choroidal hemangioma, metastatic cutaneous melanoma to the vitreous, retinoblastoma, and metastatic malignant lymphoma. Development of NVG has been observed following anterior as well as posterior uveitis, with or without underlying systemic disease. NVG may also develop in miscellaneous retinal diseases as retinal vasculitis per se or when it is associated with systemic diseases, such as Crohn's disease and Behcet's disease. Other

miscellaneous retinal conditions which may be associated with development of NVG include Coats disease, Eales disease, frosted branch angiitis, giant cell astrocytoma of the retina, peripheral retinal detachment, and X-linked retinoschisis. Similarly other systemic diseases, e.g., cryoglobulinemia and Churg-Strauss syndrome, by causing retinal vascular occlusion, can be associated with (NVG Löffler 2006).

Clinical Presentation

Eyes with neovascularization due to ocular ischemia may initially be normotensive or even hypotensive due to decreased perfusion of the ciliary body with reduced aqueous production, and fluorescein angiography may reveal an increased arm-to-retina time and leakage from the retinal arterioles. Previous to neovascularization, patients may have had one or several episodes of amaurosis fugax, especially if the stenosis of the carotid is more than 50%. The anterior chamber in these eyes often shows the presence of flare. Sometimes a few cells may be seen as well. As in the other forms of NVG, rubeosis iridis starts at the pupillary margin of the iris but may be also present already in the chamber angle (Oderich and Lawrence 2002). Posterior synechia may be seen, and if there is extensive synechia formation, patients may present with acute angle-closure glaucoma due to pupillary seclusion. In a majority of patients there are some lens opacities. However, in a fully developed NVG with very high IOP, the clinical picture may be dramatically different; the eye may be painful, and, when the IOP goes very high fairly fast, there is usually corneal epithelial edema which can make examination for iris and angle neovascularization difficult.

Diagnostics

For detection of rubeosis iridis, careful slit-lamp examination and in doubt fluorescein angiography of the iris may help to differentiate dilated iris capillaries from neovascularization. Measuring of intraocular pressure and careful gonioscopy to differentiate between open-angle and angle-closure stage of neovascular glaucoma is mandatory. A careful biomicroscopic examination or indirect ophthalmoscopy should be performed to find the cause of retinal hypoxia and to rule out peripheral retinal detachment or intraocular tumors. Fluorescein angiography should be performed to measure arm-to-retina time and to exclude other causes of anterior segment neovascularization especially proliferative diabetic retinopathy and ischemic central retinal vein occlusion.

In cases of suspected ocular ischemic syndrome due to carotid artery obstruction, it is not uncommon in clinical practice to find that carotid artery disease is ruled out as the cause of ocular ischemia based on the findings of absence of occlusion or severe stenosis of the internal carotid artery on carotid Doppler. However, carotid Doppler evaluates only the artery in the neck and not above or below that, where it may be markedly stenosed. Cerebral angiography or magnetic resonance angiography may be necessary to provide information which carotid Doppler cannot demonstrate, such as significant stenosis in the carotid siphon or ophthalmic artery (Hayreh 2007).

Differential Diagnosis

From time to time, NVG has been confused with other ocular conditions. For example, eyes with severe non-granulomatous uveitis with dilated iris vessels and proteinous aqueous and high IOP can be misdiagnosed to have NVG. There are some eyes where normal iris vessels are seen easily, particularly in blue eyes, which may be mistaken for iris neovascularization or even angle neovascularization when the vessels are seen near the root of the iris. Eyes with carotid-cavernous fistula erroneously may be diagnosed to have NVG because of the blood in Schlemm's canal and the elevated IOP.

Prophylaxis

There is no primary prophylaxis for NVG in ocular ischemic syndrome. A high index of suspicion

of its development is important for early diagnosis and treatment to prevent irreversible visual loss. Ocular ischemic syndrome may be overlooked or misdiagnosed, primarily because of its diverse and sometimes subtle presentation. Ocular ischemic syndrome can also masquerade as several other ocular conditions. In patients who develop NVG from any cause, it is important to avoid development of nocturnal arterial hypotension, to prevent visual loss.

Therapy

Management of ocular ischemic syndrome remains difficult and controversial. As the main cause for neovascularization is uveal vascular insufficiency, the conventional use of panretinal photocoagulation will not control the disease. Moreover, rise of IOP following panretinal photocoagualtion may further compromise the already highly precarious ocular and optic nerve head circulation and result in severe visual loss due to development of anterior ischemic optic neuropathy or retinal ischemia. Since internal carotid artery occlusive disease is the most common cause of ocular ischemic syndrome, carotid endarterectomy seems a logical management. However, the benefit of carotid endarterectomy in patients with ocular ischemic syndrome is unknown and controversial, especially patients with initially good visual acuity may profit. Clinical decision for carotid endarterectomy is usually driven by the patient's entire clinical picture, as determined by neurologists and the vascular surgeon. Since, in ocular ischemic syndrome, perfusion pressure in the various ocular vascular beds is low, lowering IOP to as low level as possible is crucial to improve the blood flow and thereby to prevent visual loss from various types of ocular vascular occlusion (including central retinal artery occlusion and anterior ischemic optic neuropathy) and/or glaucoma.

Eyes with uveitis and retinal vasculitis are at risk of developing NVG. Thus, their appropriate management is important to prevent development of NVG. The treatment depends upon cause of these inflammatory diseases. In most of the eyes with uveitis, topical steroids and mydriatics are primary management tools; however, some patients with uveitis require systemic corticosteroids or other immunosuppressive therapies. Since most of these patients have an associated systemic disease, management of that is also essential.

Prognosis

If neovascular glaucoma is diagnosed early enough (in the stage of rubeosis iridis or open-angle glaucoma stage), aggressive treatment of the underlying cause (i.e., carotid endarterectomy in carotid occlusive disease) may reverse anterior segment neovascularization or even NVG (Shazly and Latina 2009). Once the angle is closed, prognosis is very poor despite all conventional and surgical IOP-lowering treatments. In this stage, the majority of eyes may go blind because of absolute glaucoma or phthisis bulbi.

Epidemiology

Neovascular glaucoma is a rare form of glaucoma, accounting for less than 5% of glaucoma cases. Because of its bad prognosis, NVG is one of the most frequent diagnoses (16–42%) among eyes that have to be enucleated.

Neovascular glaucoma in ischemic central retinal vein occlusion

Definition

In 1906, Coats described new vessel formation on the iris in eyes with central retinal vein occlusion. Rubeosis iridis is frequently associated with a severe form of glaucoma, which may best described with the term neovascular glaucoma (proposed by Weiss in 1963). Thus increased intraocular pressure with iris neovascularization and/or angle neovascularization appearing after ischemic central retinal vein occlusion (CRVO) is defined as neovascular glaucoma in vaso-occlusive retinopathy (Allingham et al. 2005).

Etiology

Ischemic central retinal vein occlusion is a frequent cause of neovascular glaucoma. The cumulative risk of ocular neovascularization in ischemic CRVO is about 70% for iris neovascularization, 60% for angle neovascularization, and 45% for neovascular glaucoma after 3 years of follow-up. In contrast to proliferative diabetic retinopathy, neovascularization at the disk (15%) and retina (10%) is rarely seen in ischemic CRVO. Hypoxia in areas of capillary non-perfusion causes neovascularization via angiogenic substances, mainly vascular endothelial growth factor (VEGF) produced by Müller cells (Hayreh 2005; Hayreh 2007).

In patients developing neovascularization after nonischemic CRVO, other causes of neovascularization such as diabetic retinopathy or ocular ischemia should be ruled out. Neovascular glaucoma may also be seen after central retinal artery occlusion, but only if ocular ischemia is the underlying cause.

Clinical Presentation

In the prerubeosis stage (early phases) after ischemic CRVO, the intraocular pressure may be normal or even reduced. The risk of neovascularization of the anterior segment is mainly dependent on the severity and extent (area) of retinal ischemia. Especially eyes with 30 or more disk areas of non-perfusion at fluorescein angiography are at risk. Fluorescein angiography of the iris reveals abnormal, leaking vessels in virtually all eyes with extensive retinal capillary closure. Also some patients with primary nonischemic CRVO may progress to ischemic CRVO. In the early preglaucomatous stage, slit-lamp biomicroscopy reveals dilated tufts of preexisting capillaries and fine, randomly oriented vessels on the surface of the iris near the pupillary margin. Gonioscopy may show a variable amount of angle neovascularization. In the open-angle glaucoma stage, typically occurring 8–15 weeks after the vascular occlusive event (therefore called 90-day glaucoma), there is florid rubeosis iridis, and the

aqueous reveals inflammatory reaction. By gonioscopy, the angle is still open, but the neovascularization may be intense. The IOP is elevated and may rise suddenly, and a hyphema may be present. In the angle-closure glaucoma stage, the stroma of the iris has become flattened, with a smooth, glistening appearance. Ectropion uvea is frequently present, and the pupil is often dilated. Gonioscopy shows peripheral anterior synechia leading eventually to total synechial closure of the chamber angle. The glaucoma in this stage is typically severe and usually requires surgical intervention (McIntosh et al. 2010).

Diagnostics

Various clinical tests have been evaluated to predict the severity of CRVO and thus the risk of anterior segment neovascularization. Besides visual acuity (VA) testing and ophthalmoscopy, manual kinetic perimetry (Goldmann), testing of relative afferent pupillary defects using neutral density filters, electroretinography (b-wave implicit time delay and a reduced b-wave/a-wave amplitude ratio), and fluorescein angiography have been used to predict the amount of retinal ischemia. The four functional tests (VA, visual fields, relative afferent pupillary defect, and electroretinography) are especially in early phases far more reliable than fluorescein angiography in differentiating nonischemic from ischemic CRVO. For detection of rubeosis iridis, careful slit-lamp examination and in doubt fluorescein angiography of the iris may help to differentiate dilated iris capillaries from neovascularization. Measuring of intraocular pressure and careful gonioscopy to differentiate between open-angle and angle-closure stage of neovascular glaucoma is mandatory.

Differential Diagnosis

All other causes predisposing to rubeosis iridis and neovascular glaucoma should be considered. They include all retinal ischemic diseases such as diabetic retinopathy, retinal detachment, hemorrhagic retinal disorders, Coats exudative retinopathy, Eales disease, Leber's congenital amaurosis, retinopathy of prematurity, persistent hyperplastic primary vitreous, sickle cell retinopathy, syphilitic retinal vasculitis, retinoschisis, Stickler syndrome, and optic nerve glioma with subsequent venous stasis retinopathy. Other causes such as irradiation retinopathy, intraocular tumors or lymphoma, and inflammatory diseases or surgically induced rubeosis and extraocular causes such as carotid artery obstruction or occlusion and fistula should also be considered to cause rubeosis iridis.

Prophylaxis

If ischemic CRVO is diagnosed, the severity and extent of retinal ischemia should be evaluated using the clinical findings and simple clinical tests. If severe ischemia is present, the risk of developing anterior segment neovascularization is high, and the patient should be monitored closely in the first 3–4 months. If any signs of rubeosis are detected or if there is increasing asymmetry in IOP readings, treatment is indicated. A prospective randomized trial has shown that prophylactic panretinal laser coagulation does not totally prevent anterior segment neovascularization and that prompt regression of the rubeosis is more likely to occur in response to photocoagulation in eyes that have not been treated previously.

Therapy

The first-line treatment is lowering of the IOP with topical or systemic medications, which may indirectly improve retinal perfusion. Suppression of angiogenesis by intravitreal or intracameral injection of anti-VEGF substances (ranibizumab, bevacizumab, or aflibercept) has been recently shown to significantly decrease anterior segment neovascularization. Reducing the oxygen demand of the retina by laser coagulation of the ischemic retina significantly reduces or eliminates anterior segment neovascularization. Laser treatment

should be applied primarily to the area of non-perfusion as panretinal photocoagulation has a negative effect on peripheral visual field. If medical IOP lowering is not effective enough, surgery (trabeculectomy or tube shunts) may be required. Surgically lowering IOP by trabeculectomy has been shown to be very effective in lowering the rate of recurrence of anterior segment neovascularization. When cloudy media precludes panretinal photocoagulation, transscleral panretinal cryotherapy often combined with cyclocryotherapy can control the IOP and reduce the neovascularization (Saito et al. 2010; SooHoo et al. 2015).

Prognosis

The majority of eyes may be saved using adequate treatment early enough in the disease process (before extensive angle-closure is present). Despite medical IOP lowering, intravitreal anti-VEGF injections and panretinal laser photocoagulation about 15–20% of eyes may be caught too late or not adequately respond to treatment and end up in absolute glaucoma or phthisis.

Epidemiology

CRVO may occur in a wide range of ages (14–92 years), but half of the patients are 65 or older. Ischemic CRVO is very rare in young patients. The overall prevalence of CRVO is 0.8 per 1000, which means that worldwide 2.5 million patients are affected. Assuming that only 20% of these CRVO are ischemic and only 45% are at risk of neovascular glaucoma, 225,000 patients are expected to suffer from neovascular glaucoma due to ischemic CRVO.

Neovascularization of the Retina

▶ Neovascularization, Retinal

Neovascularization, Retinal

Shiri Shulman
Ophthalmology Division, Tel-Aviv Medical Centre, Tel-Aviv, Israel

Synonyms

Neovascularization of the retina

Definition

Development of new blood vessels of a different kind or in an abnormal position, especially in tissues where circulation has been impaired by disease or trauma (Lee et al. 1998).

Etiology

Retinal ischemia causes release of angiogenic factors with the most common being vascular endothelial growth factor (VEGF). This, in turn, causes the development of new fine blood vessels.

Clinical Presentation

Retinal neovascularization presents as fine, irregular, fan-shaped, new vessels apparent on the optic disk or elsewhere on the retina. Initially blood vessels have minimal fibrous component and cross and extend beyond the internal limiting membrane. During later stages the vessels increase in size and extent with an increased fibrous component. They might contract and cause traction retinal detachment.

Diagnosis

Retinal neovascularization may be visible on clinical examination. Fluorescein angiography demonstrates a network of fine blood vessels with hyperfluorescence due to leakage.

Differential Diagnosis

1. Diabetic retinopathy
2. Retinal vein occlusion
3. Radiation retinopathy
4. Retinal vasculitis
5. Uveitis
6. Sickle cell retinopathy
7. Retinopathy of prematurity
8. Familial exudative vitreoretinopathy
9. Eales disease

Prophylaxis

In some conditions, such as retinopathy of prematurity, cryotherapy or laser ablation of ischemic retina may reduce oxygen demand, reduce the production of angiogenic factors, and as result prevent or reduce the growth of new retinal vessels (Cryotherapy for retinopathy of Prematurity Cooperative Group 2001; Early Treatment for Retinopathy of Prematurity Cooperative Group 2003).

Intravitreal injections of anti-VEGF drugs have also been shown to prevent the development of retinal neovascularization in diabetic retinopathy as well as in retinal vein occlusion (Brown et al. 2013).

Therapy

The purpose of treatment in cases with retinal neovascularization is to prevent complications that may cause visual loss such as vitreous hemorrhage or traction retinal detachment.

The mainstay of treatment for retinal neovascularization involves mainly the use of thermal laser photocoagulation in a pan retinal pattern to induce regression (Patz et al. 1981).

For patients with high-risk proliferative diabetic retinopathy (PDR), scatter panretinal photocoagulation (PRP) treatment is almost always recommended. The goal of scatter PRP is to cause regression of existing neovascular tissue and to prevent progressive neovascularization in the future. The amount of therapy necessary to achieve these endpoints is determined by the degree of regression of vessels.

Full pan retinal photocoagulation, as used in the Diabetic Retinopathy Study, included 1,200 or more 500 μm burns, separated from each other by one-half burn width, at 0.1 s duration. Treatments may be divided into two or more sessions (Patz et al. 1981).

Prognosis

Untreated retinal neovascularization may cause severe visual loss due to vitreous hemorrhage or traction retinal detachment, regardless of the etiology.

In proliferative diabetic retinopathy, the risk for severe visual loss was reduced by 50% in patients treated with laser PRP compared to untreated control eyes during a follow-up of over 5 years.

Epidemiology

A low estimate of the prevalence of proliferative diabetic retinopathy in a general population was reported at 0.3% in the Framingham Eye Study, representing at least 180,000 people (aged 52–85 years) in the USA with neovascularization. Other studies found the overall prevalence of all diabetic retinal neovascularization, including intraretinal microvascular abnormalities (IRMAs), to be 1.7% of the general population, representing 1.5 million Americans aged 43–84 years.

The incidence of retinal neovascularization associated with retinopathy of prematurity is estimated at 180,000 new cases per year in the USA.

A synthesis of the results of many studies shows that in the youngest category of premature newborns (born at 24–27 weeks of gestation), a neovascular stage of ROP occurred in 12–29% of the newborns; in the middle category (28–31 weeks of gestation), neovascular changes occurred in 2–20%; and in the oldest group (32–35 weeks of gestation), neovascularization was present in only 0–3.5% of infants.

In sickle cell retinopathy, approximately 27,580 (0.14% of adult African-Americans) have sickle cell anemia, and 25,610 (0.13%) have SC disease. It is estimated that the prevalence of neovascularization is 5,500 (20% of 27,580) cases of proliferative sickle retinopathy in African-Americans (aged 18–64 years) with sickle cell anemia.

Synonyms

Fibroma; Neural tumor

Definition

A benign tumor originating in peripheral nerve fibers.

Etiology

Neurofibromas on the eyelid and orbit can present as solitary neurofibroma, multiple localized neurofibromas, and plexiform neurofibroma. Multiple neurofibromas can be associated with neurofibromatosis type 1(NF-1), also called von Recklinghausen disease; plexiform neurofibroma is pathognomonic of this common autosomal dominant genetic disorder (NF-1). The solitary lesion is not associated with systemic disease.

Clinical Presentation

Neurofibromas (solitary or multiples) are flesh-colored lesions that can occur anywhere in the body. Lesions can present as circumscribed, but unencapsulated, masses deep in the subcutaneous plane to projecting as exophytic pedunculated papules. Their sizes also can vary greatly from small lesions 2–3 mm in diameter to larger growths several cm in diameter. Plexiform neurofibroma often presents as a diffuse infiltration of the eyelid and orbit. It produces the typical S-shaped curve and ptosis to the upper eyelid due to thickening and horizontal redundancy of this lesion. Cutaneous neurofibromas usually remain asymptomatic, but neurofibromas that develop in major peripheral or central nerves can cause motor or sensory dysfunction.

Diagnostics

Based on history, clinical examination, and confirmed by histopathological examination.

Differential Diagnosis

Differential diagnosis includes ▶ chalazion, malignant tumor, ▶ actinic keratosis, ▶ inverted follicular keratosis, and ▶ molluscum contagiosum.

Prophylaxis

Unknown

Therapy

Treatment depends on the site and extent of disease. Isolated cutaneous lesions may be easily surgical excised or just followed conservatively. Surgical debulking may be performed for plexiform neurofibromas if they become cosmetically unacceptable. Complete excision usually is impossible due to the infiltrative nature of these lesions.

Prognosis

Malignant degeneration of neurofibroma can occur in individuals with NF-1.

Epidemiology

Neurofibromas represent from 0.5–2.4% of orbital tumors. Plexiform neurofibromas are the most common form of benign neurogenic orbital tumor seen in children.

Definition

Neurotrophic keratopathy is a degenerative disease of decreased corneal sensitivity and healing, resulting from impaired corneal innervation (Bonini et al. 2003).

Etiology

Neurotrophic keratopathy may be caused by anything affecting trigeminal innervation of the cornea (Bonini et al. 2003). Common causes are herpes simplex and herpes zoster infections. Other causes include trigeminal neuralgia surgery, acoustic neuromas, topical anesthetics, and systemic diseases like diabetes.

Clinical Presentation

Neurotrophic keratopathy has been divided into three stages using the Mackie classification (Bonini et al. 2003).

Stage 1 – Patients present with nonspecific symptoms, including rose bengal staining of the inferior palpebral conjunctiva. Tear mucus viscosity is noted to increase, and dry spots may be found on corneal epithelium, suggesting future scarring and vascularization.

Stage 2 – A nonhealing corneal epithelial defect may result, with folding of Descemet's membrane, stromal swelling, and loosening of the surrounding epithelium.

Stage 3 – Progression of the disease to stage 3 continues if not limited at stages 1 or 2. This stage is associated with stromal melting, corneal ulcer, and perforation. The patient typically is asymptomatic though due to corneal denervation.

Diagnostics (Lab Diagnostics)

Clinical history is important for the diagnosis of neurotrophic keratopathy. Systemic diseases, such as diabetes, may lead to corneal trigeminal denervation (Groos 1997). Previous corneal surgeries also may contribute to corneal denervation.

A thorough cranial nerve exam is also necessary for the diagnosis of suspected neurotrophic keratopathy (Bonini et al. 2003). Brain neoplasms, such as acoustic neuromas, may involve the trigeminal nerve. Paresis of multiple nerves, such as CN III, IV, and VI, may suggest cavernous sinus involvement or aneurysm with associated trigeminal nerve involvement.

To successfully diagnose these patients, an accurate ocular examination is necessary. Corneal sensitivity tests for innervation and may be tested either with application of a cotton swab to the cornea or with a Cochet-Bonnet esthesiometer.

Slit lamp exam and dilated fundoscopy can reveal salient diagnostic information. Corneal scarring or epithelial changes may suggest prior infection, possibly herpes zoster or herpes

simplex. Examination of the eyelids may indicate blepharitis or exposure keratitis, factors known to be associated with neurotrophic keratopathy. Fundoscopy can also reveal signs of systemic disease, such as diabetic retinopathy.

To rule out bacterial, viral, or fungal etiology, corneal ulcers should undergo microbiological examination.

Differential Diagnosis

Differential diagnosis includes dry eye syndrome, blepharitis, chronic eye rubbing, exposure keratopathy, topical drug toxicity, ultraviolet keratopathy, mild chemical injury, contact lens-related disorders, corneal limbal stem cell deficiency, and infectious or immune cause for ulceration

Prophylaxis

Prophylactic antibiotics may be recommended if disease has progressed past initial stage (Groos 1997).

Therapy

Therapy is divided according to classification stages and must be initiated immediately to prevent progression (Groos 1997).

Stage 1 – Preservative-free artificial tears and ointment. Discontinue topical medications.

Stage 2 – Treat epithelial defect to prevent ulcers, prophylactic antibiotics, preservative-free artificial tears, and possible lateral tarsorrhaphy.

Stage 3 – Demands immediate attention in order to stop the stromal lysis and prevent perforation. In cases of stromal melting, topical collagenase inhibitors, such as *N*-acetylcysteine, tetracycline, or medroxyprogesterone, may be administered. Corneas that appear to be very thin despite lubrication and tarsorrhaphy often require cyanoacrylate glue and a bandage contact lens. Disease may still progress.

Prognosis

Neurotrophic keratitis remains one of the most challenging ocular diseases to treat. Patient prognosis depends upon several factors, such as etiology and degree of denervation (Bonini et al. 2003). The more severe the corneal denervation, the higher the likelihood of progression of the disease.

Since patients may remain asymptomatic, it is important for frequent check-ups with an ophthalmologist.

Epidemiology

Several etiologies exist for neurotrophic keratopathy, including infectious, iatrogenic, neoplasm, and drug-induced (Bonini et al. 2003). Herpes zoster (8% of patients) and herpes simplex are the most common causes of neurotrophic keratopathy.

[2]Department of Ophthalmology, Porto Alegre, Rio Grande do Sul, Brazil

Synonyms

Acquired melanocytic nevus; Intradermal nevus; Melanocytic nevus

Definition

A type of nevus (benign neoplasms composed of nests of melanocytes) located exclusively within the dermis (Albert and Jakobiec 2008; Barnhill et al. 2004; Shields and Shields 2008).

Etiology

The cause is unknown. A genetic factor is likely in many families, working together with increased sun exposure. Usually present in childhood as small, flat tan macules that increase in size on the basal epithelium. As the lesion increases in diameter, a nest of cells drops into the dermis; later, the cells migrate entirely in the dermis. Therefore, the natural progression from junctional nevus to compound nevus, then to intradermal nevus may occur.

Clinical Presentation

Usually as elevated, fleshy, and slightly or moderately pigmented papules (light brown or flesh tone). Lesions vary in size from a few millimeters to a centimeter. They are frequently raised, dome-shaped, nonpigmented nodules, most commonly seen on the face (Fig. 1). There are some overlying telangiectatic vessels, and outgrowth of one or two coarse terminal hairs is common.

Diagnostics

Usually by clinical presentation. Histopathologic evaluation is confirmatory (Barnhill et al. 2004).

Differential Diagnosis

Differential diagnosis includes ► melanoma, ► basal cell carcinoma, ► neurofibroma, tricoepithelioma, and ► verruca vulgaris.

Prophylaxis

Avoidance of sun exposure and sun education.

Nevus, Intradermal, Fig. 1 Dome-shaped nevus on the left medial eyebrow

Therapy

The majority do not require treatment and can be observed periodically. Indications for removal include cosmetic concerns, chronic irritation (itching and/or bleeding), and changes in appearance (color, size, or shape) that are suspicious for melanoma. Options of surgical therapy when the lesion involves eyelids include shave biopsy, excisional biopsy, or full thickness eyelid biopsy (Albert and Jakobiec 2008).

Prognosis

Most are benign with little malignant potential. The most active nevus is the junctional nevus. As nevi descend further into the dermis (compound and intradermal nevi), they decrease their potential to malignant transformation.

Epidemiology

Benign pigmented nevi in adults are most commonly intradermal. The prevalence of melanocytic nevus varies with age and race. They increase in number gradually during childhood and adolescence, reaching a peak during adult life and declining with increasing age. These lesions are common in patients with light or fair skin (Albert and Jakobiec 2008; Barnhill et al. 2004; Shields and Shields 2008).

NAION; NA-AION

Definition

Non-arteritic anterior ischemic optic neuropathy (NAION) is characterized by a sudden, typically

painless, loss of vision in one eye and a swollen optic disc. Although typically unilateral, bilateral, and sequential, also rarely bilateral, simultaneous NAION can occur. Typically, affected and fellow eyes with NAION demonstrate a small optic nerve cup-to-disc ratio (i.e., the "disc at risk"). There must be optic disc edema on acute presentation in NAION (i.e., anterior optic neuropathy), although chronic and resolving cases may demonstrate optic atrophy and/or sector pallor. The disc edema often presents in a sectoral fashion, although many cases show diffuse edema.

NAION is a presumed ischemic event occurring at the anterior optic nerve (at the level of the lamina cribrosa). There should not be any concomitant retinal or significant choroidal ischemia, and if more than one blood supply affected, an alternative diagnosis (such as ▶ arteritic anterior ischemic optic neuropathy or ▶ giant cell arteritis (GCA)) should be suspected.

Initially localized ischemia of the optic nerve head may result in further ischemia in a patient with no room to expand within the lamina cribrosa (i.e., the "crowded disc at risk"). This "compartment syndrome" might result in further vascular compromise and progressive ischemia. The process eventually results in axonal damage and corresponding ganglion cell death, leading to a corresponding visual field defect.

Etiology

As noted above, a small optic nerve/small cup-to-disc ratio may predispose to the development of NAION after a relatively mild ischemic event to the optic nerve head. Up to 97% of the cases of NAION involve a small optic disc (less than 1.2 mm) with a small or absent physiological cup (0.2 or less).

Additional predisposing risk factors for NAION include vasculopathic conditions (e.g., hypertension/hypotension, hyperlipidemia, cardiovascular disease, atherosclerosis, or diabetes mellitus). Other less common risk factors include hypercoagulable states, anemia, high altitude, sleep apnea, certain medications such as vasodilators (phosphodiesterase-5 inhibitors), high intraocular pressure (which decreases ocular perfusion), renal dialysis, general surgical procedures, iatrogenic hypotension (often nocturnal), and malignant hypertension.

Clinical Presentation

NAION typically presents with acute, monocular, painless, visual field loss. The visual acuity may be normal (up to 50%) or decreased and the severity is quite variable. Typical NAION however does not usually result in light perception (LP) or no light perception (NLP) vision and this scenario should prompt consideration for alternative etiologies including giant cell arteritis (GCA)-related arteritic AION (AAION).

The majority of patients with NAION have a nerve fiber layer visual field defect (commonly inferior altitudinal or inferotemporal field defect), but some have concomitant central visual field loss. Dyschromatopsia is also common in the affected eye. A relative afferent pupillary defect this scenario should be present in unilateral cases but may be absent if bilateral and symmetric afferent disease is present. Posterior segment exam usually reveals sector or diffuse disc edema, and the fellow eye should reveal a small cup-to-disc ratio.

Diagnostics

In patients over the age of 50 years, it is imperative to consider giant cell arteritis (GCA) or arteritic anterior ischemic optic neuropathy (AION). Fluorescein angiography can be performed to evaluate the retinal and/or choroidal circulation in cases suspected of having GCA.

Evaluation

Typical NAION does not usually require extensive testing. Because NAION is not usually an embolic disease, cardiac and carotid evaluations are not necessary unless indicated for other purposes. Evaluation and management of typical vasculopathic risk factors (e.g., hypertension,

diabetes, hyperlipidemia, discontinuation of smoking, sleep apnea) are recommended.

Differential Diagnosis

1. Arteritic anterior ischemic optic neuropathy (AION)
2. Optic neuritis
3. Amiodarone optic neuropathy
4. Posterior ischemic optic neuropathy (PION)
5. Leber hereditary optic neuropathy

Prophylaxis

Treatment of predisposing factors (diabetes, heart disease, hyperlipidemia, anemia, sleep apnea) and prevention of precipitating factors (hypotension, decreased oxygen saturation, increased intraocular/episcleral pressure) may reduce the incidence of NAION in the fellow eye, but there is no head-to-head trial evaluating these recommendations. Daily aspirin is sometimes recommended, but has conflicting reports as to its efficacy in preventing NAION in the partner eye.

Therapy

Oral prednisone treatment remains controversial regarding its efficacy in NAION. Hayreh et al. found an improvement in visual acuity in 69.8% ($n = 236$) of treated eyes versus 40.5% ($n = 301$) of untreated eyes in a non-blinded prospective study (p-0.001), whereas in a 36-patient study (treatment $n = 9$, control $= 27$), Rebolleda et al. found no statistical significance in visual acuity, median deviation on automated Humphrey visual fields, or retinal nerve fiber layer thickness on Stratus optical coherence tomography. Thus, controversy remains within the neuro-ophthalmic community concerning the use of corticosteroids in acute NAION, and the decision to treat with prednisone should be made on a case-by-case basis.

In the ischemic optic nerve decompression trial (IONDT), optic nerve sheath fenestration was not shown to be helpful in nonprogressive NAION, and in fact, the authors concluded they were harmful and should not be performed in this disease. Hyperbaric oxygen therapy has also not been shown to be effective. Aspirin may have a role in preventing NAION in the partner eye (conflicting data), but has not been shown to be efficacious in the affected eye. In addition, use of aspirin in the acute phase of NAION has not been studied. Tissue plasminogen activator has not been studied in NAION, but because the disease is thought to be caused by small vessel ischemia and not a thromboembolic or thrombotic etiology, this would not be a treatment of choice.

Prognosis

Roughly 40% of patients with NAION experience some improvement in their visual acuity in the months to years following their initial ischemic insult. These changes generally stabilize over 6 months from the time of initial insult. There is not a strong correlation in the severity of NAION between one eye and the fellow eye. NAION can occur in approximately 15% of contralateral eyes but typically does not recur in the same eye (<5%). Presumably as atrophy of the axonal nerve fibers occurs, this may create more room within the crowded cup, acting as a protective factor against a recurrent attack in the same eye.

Herpes stromal keratitis

Definition

Herpes stromal keratitis (HSK) can present in necrotizing and non-necrotizing forms. Non-necrotizing keratitis results when inflammation of the cornea occurs in the absence of an infectious virus, usually leaving the epithelium unaffected. It is likely that the two types of HSK simply represent a spectrum of disease rather than two diseases with distinct pathologies.

Etiology

HSK usually results from infection by the herpes simplex virus type 1 (HSV-1) in adults and HSV-2 in neonates, though changing sexual behavior patterns are making HSV-2 an increasingly more common cause in adults. Primary infection especially with HSV-1 arises from exposure to active lesions or virus-laden secretions of close contacts, or more commonly as a secondary site of recurrence. In the former situation, the primary infection can cause a painful lesion that mainly affects the corneal epithelium and lasts for several days or weeks. The condition resolves without permanent damage to the cornea but remains uncured as the virus persists in the ophthalmic branch of the trigeminal ganglia in a dormant state known as latency. In the case that the infection occurs as a secondary site of recurrence, primary infection affects sites innervated by the facial nerve, but when the latent virus reactivates in the trigeminal ganglion, spread to the ophthalmic division may occur, leading to ocular recurrence.

Recurrent lesions often develop into a chronic immunoinflammatory event, termed herpes stromal keratitis. The exact mechanisms by which latency is established, maintained, and revoked are currently poorly understood and represent an active area of research. Most often, the immune-mediated response to nonreplicating virus involves the epithelium but, ultimately, the stroma becomes the main site for inflammatory reaction, edema, angiogenesis, permanent scarring, and impaired vision. If left unattended, corneal ulceration and perforation, or even blindness, may ensue. Non-necrotizing keratitis encompasses these inflammatory events in the cornea that are not explained by a reaction to live viral particles in the corneal stroma.

Clinical Presentation

Pain in the affected eye is the most common. Both inflammatory and reparative events are visible by slit lamp. Cellular infiltration, neovascularization, and scarring may be present as well, with stratified opacities and corneal lamellae leading to stromal opacity. While corneal necrosis and ground-glass appearance of the stroma may be apparent for necrotizing keratitis, the non-necrotizing form should only exhibit varying degrees of corneal scarring, facet formation, and perforation.

Diagnosis

Accurate diagnosis can be made by demonstrating HSV in the corneal tissue samples or ocular secretions by cell culture, by immunofluorescence staining, or by detecting the viral genome through polymerase chain reaction (PCR). Despite PCR's advantages as the most rapid, sensitive, and specific method, high cost often limits the use of the procedure to research centers. Serological diagnosis can confirm a primary infection, but is not useful since the majority of the population is seropositive, including those who experience recurrent lesions.

Differential Diagnosis

Abrasions
Bacterial, chlamydial, parasitic, or fungal keratitis
Graft rejection following keratoplasty
Zoster caused by varicella zoster virus

Prophylaxis

Developing an effective prophylactic or therapeutic vaccine for HSK has been pursued strongly but with no real success to date. The most targeted HSV-induced diseases are genital infections caused by HSV-2, as these are much more common than ocular issues. If the development of the HSV-2 vaccine is successful, this could help reduce the incidence of neonatal ocular herpes. For adults, the more serious clinical consequences of ocular HSV infection arise from recurrences, which often have an immunopathological component. Therapeutic vaccines could make the condition worse rather than better, requiring further examination of the issue to assure safe development of therapeutic vaccines.

Therapy

Treatment of non-necrotizing keratitis addresses the fact that stromal disease is an immune response to viral antigen. Steroid therapy is used to control inflammation, and antivirals may be administered to help reduce the chances of recurrence in general. Typical steroid treatment starts at the lowest therapeutic dose and can be reduced slowly over weeks or even months, but if inflammation recurs, it should be increased.

Prognosis

Prompt and appropriate treatment may minimize the risk of scarring, which represents the major cause of morbidity from corneal HSV infection.

Epidemiology

Herpetic keratitis is the most common infectious cause of impaired vision in adults in the developed world. The disease exhibits no gender bias, and any genetic factors that increase susceptibility are poorly understood.

Definition

Nonorganic vision loss (NOVL) is defined as visual dysfunction that cannot be attributed to an organic, anatomic, or physiological cause and is incompatible or inconsistent with the objective findings. Unfortunately, organic and NOVL are not mutually exclusive and can occur in the same individual and the presence of nonorganic overlay does not preclude the development of organic disease.

Etiology

The actual etiology of NOVL is variable and can be due to deep-seated psychological conflict manifesting unconsciously as NOVL or may be purposeful for secondary gain (malingering). Some patients with NOVL meet the Diagnostic and Statistical Manual of Mental Disorder V (DSM V) criteria for malingering, conversion disorder, factitious, or somatization disorders, but in our experience most patients do not have a clear underlying psychiatric diagnosis or any defined trigger apart from generalized psychosocial stress or nonspecific anxiety or depression. In addition, NOVL is common as an overlay in patients with organic disease.

Clinical Presentation

Patients with NOVL may present in a variety of ways. The most common presenting symptom in NOVL is loss of visual acuity and the second most common is visual field loss. The loss in acuity or visual field may range from mild to moderate, could be unilateral or bilateral, transient or constant. Visual field defects range from a constricted visual field (i.e., tunnel or spiral fields) to diffuse constriction. Less commonly a central scotoma may be the presenting visual field defect to have NOVL, and the presence of a central scotoma or homonymous or bitemporal hemianopsia should be considered to be organic until proven to be NOVL. Other less common symptoms of NOVL

are distorted shapes, abnormal colors, and positive visual phenomenon (e.g., seeing dots or snow, and lines). Most patients with NOVL have isolated visual complaints, but other nonorganic neurologic symptoms and signs may also be present (e.g., pseudoseizures, unexplained weakness or paresthesias, unexplained eye pain or headache).

Diagnostics

The key to making the diagnosis of NOVL is first to complete a thorough history and physical examination to exclude organic etiologies. As noted above, it is also important to keep in mind that both NOVL and an organic disease occurring together (i.e., nonorganic overlay).

The duty of the ophthalmologist in NOVL is to:

1. Prove that the patient has a normal ocular examination and does not show any organic or physiological cause that could account for the patient's symptoms.
2. Demonstrate that the patient has a better visual acuity and or visual field than claimed proving that there is NOVL.

There are several tests that had been designed for testing NOVL. The choice of the best test to use depends on the clinical presentation, laterality, severity, and type of NOVL.

In monocular visual acuity loss with a normal or near normal fellow eye, a monocular vertical prism test using a 4-prism diopters base down vertical prism can be placed in front of the unaffected eye, see Fig. 1. Prior to the test you should explain to the patient that you are going to "test the good eye first" and that the prism will split the image and will produce double image. For instance, a patient with VA 20/20 in the right eye (OD) and 20/100 in left eye (OS) should have the 4-prism diopters base down placed in front of the good eye (OD). A 20/40 single Snellen letter is then shown to the patient with both eyes open but with the prism over the "good eye" (OD). An organic 20/100 OS should produce the response that the patient sees only one 20/40 letter. However, in a case of NOVL the patient will report seeing two vertically displaced letters. This result helps to prove two points: first the nonorganic nature of the vision loss and the second it is an objective way to measure VA in the "bad eye" and prove at least 20/40 vision OU. The duochrome test is another useful method in testing for NOVL. The patient wears red-green glasses and then is shown the Snellen chart with the duochrome test option (i.e., red and green halves of the Snellen line or chart). The green lens should only see the one side of the chart (green). The downside of this test is that the patient can easily figure out which eye is being tested by closing either eye. Fogging is another test that is commonly used but again is susceptible to being defeated by the astute malingerer who closes either eye prior to the testing to determine the "correct" organic response. To perform this test you first will test the VA in both eyes. Then gradually add lenses of progressively higher

Nonorganic Visual Loss, Fig. 1 NOVL a 4-prism diopters base down prism can be placed in front of the unaffected eye

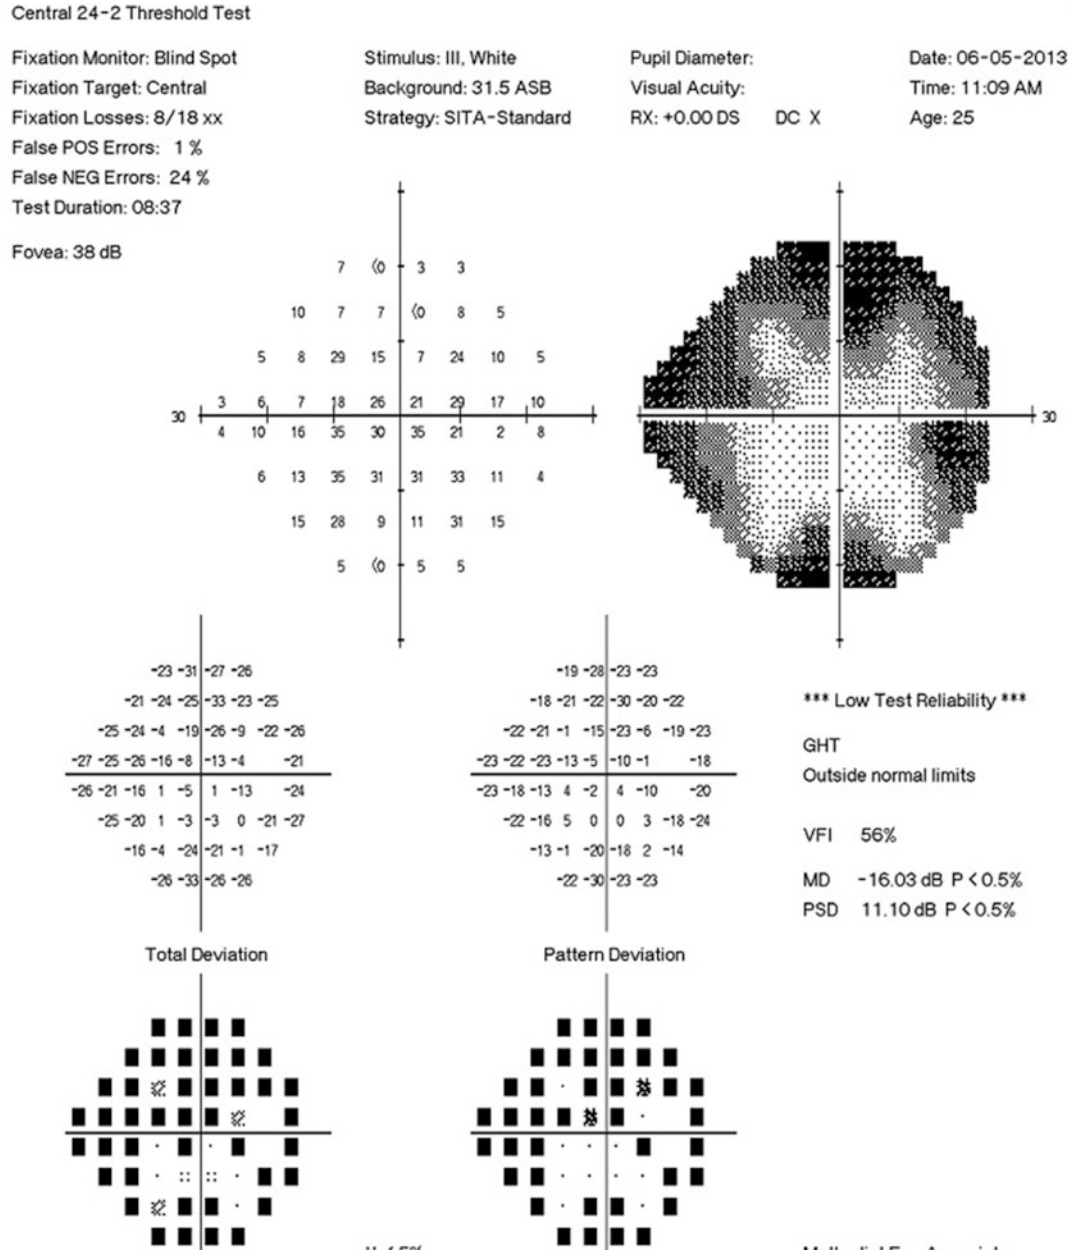
power in front of the good eye. This will gradually blur the vision in the good eye and may allow you to determine the actual acuity of the claimed "bad" eye. An alternative way to perform this fogging test is by using rotating spheres in the "bad eye" and rotating cylinders in the "good eye" to confuse the patient and distract them from detecting the fogging of the "good eye" and force the patient to read the chart with the supposedly visually impaired contralateral eye. Fogging tests often, however, reveal the clinicians' attempts to disprove the visual loss as organic and more subtle testing of NOVL are generally superior.

In a case of binocular VA loss, stereopsis testing can be used to test for NOVL since stereoacuity correlates well with VA. A common example of this is the fact; 40 s of arc of stereoacuity is equivalent to 20/20 visual acuity in both eyes. Standardized tables comparing stereoacuity to projected binocular visual acuity in each eye are available. Color vision testing likewise can be a very useful test in case of binocular VA loss. If the patient is able to correctly identify all of the Ishihara plates this is strong but not absolute evidence against an optic neuropathy as the cause of the degraded visual acuity.

In contrast to cases of mild to moderate visual loss, patients claiming severely impaired vision to light perception or no light perception the tests are easier to deploy to detect NOVL. Proprioception test can be used by asking the patient to touch the right index finger to the left index finger of their hands with both eyes open and with the "good eye" patched. Failures to perform accurate propioceptive tasks (which of course do not require vision) are suggestive of NOVL. The mirror test can be used in patients with monocular or binocular vision severe visual loss (e.g., claimed LP or NLP vision). The test is performed by placing a large mirror close enough to the patient so that they cannot look past it and then rotating the mirror from side to side. If the patient has NOVL their eyes will follow the reflection of their face in the mirror as it moves. Performing the test binocular conditions and then covering the supposed "good eye" should continue to elicit the eye movement in response to the mirror in the "bad eye" suggesting NOVL. In patients with bilateral severe visual loss (e.g., LP or NLP) the mirror test can be performed with both eyes open. As mentioned this test is only useful if the claimed level of visual loss is severe. Therefore, it should not be used if the vision loss is better than 20/200 to counting fingers vision because the test is not valid as the patient might still organically be able to see their face in the mirror. Visual threat test can be used in LP or NLP vision cases using a threatening hand motion towards the patient in an attempt to induce a blink, or withdrawal response which would indicate NOVL. We do not like this test as it involves a threatening motion and could be misinterpreted by the patient or their family if organic visual loss is present and could also provoke an unwelcome or unintentional negative patient response that might damage the legitimate patient-doctor relationship. An optokinetic nystagmus (OKN) drum can be used to demonstrate the physiological response of nystagmus in a supposedly blind eye under monocular or binocular conditions. The presence of an OKN nystagmus in an involved eye(s) with severe visual loss would be a clue suggesting NOVL.

As mentioned previously the majority of NOVL patients claiming a visual field defect describe a constricted visual field in one or both eyes. The constricted visual field or "tunnel field" that is usually present with NOVL can usually be differentiated from a constricted field due to an organic cause, see Fig. 2. The "tunnel field" present in NOVL can be tested for using a tangent screen or with confrontation testing at 1 m and 2 m. The constricted visual field due to an organic cause typically expands at 1 m and 2 m testing demonstrating a "funnel" expansion. In contrast, patients with NOVL do not present with this expansion and instead have a "tunnel field," see Figs. 3 and 4.

Another test for a patient claiming to have a severely reduced visual field is saccade testing into the supposedly blind visual field. When performing this test it is important to instruct the patient that you are testing eye movements (ocular motility). The patient is instructed to look at a primary target such as the examiners nose and then make a saccade to a peripheral target like the examiner's hand or finger which is placed in a claimed blind area of their VF. If the patient is able to make this saccadic movement quickly and



Nonorganic Visual Loss, Fig. 2 NOVL with constricted ("cloverleaf") visual field

accurately, then this is evidence of NOVL. If the cause was organic the patient would not be able to make an accurate saccade to the target in the blind field and instead might use roving or searching movements to find the target. In some cases, patients will tell the examiner they cannot see the peripheral target and thus cannot make the eye movement. In this case the examiner should tell the patient to "use their intact central vision" to look directly at the target. Another way to demonstrate NOVL is if a patient is claiming to have a monocular visual field loss with the other

Nonorganic Visual Loss, Fig. 3 NOVL confrontation testing at 1 m

Nonorganic Visual Loss, Fig. 4 NOVL confrontation testing at 2 m

eye being normal is by testing the visual field with both eyes open. Since the nasal and temporal portions of each visual hemifield overlaps that of the other eye, maintaining the monocular visual field defect under binocular testing conditions would indicate NOVL.

Electrophysiological testing such as full-field ERG or multifocal electroretinogram (ERG) and visual-evoked potential (VEP) may help to exclude other organic causes or confirm NOVL in difficult cases. Other newer tests such as pupil perimetry with normal pupil response could be used to detect NOVL.

Differential Diagnosis

Organic versus NOVL; NOVL with organic visual loss (nonorganic overlay); psychiatric disorders (e.g., conversion disorder, somatization) versus secondary gain (e.g., malingering).

Prophylaxis

Non applicable.

Therapy

The mainstay of treatment of NOVL is to reassure them there is no serious visual pathway diseases causing their symptoms, there is no brain or eye pathology that may lead to blindness, and that a full visual recovery should be expected. In pediatric cases, it is very important that the parents understand the presence of the NOVL and to identify and treat any psychosocial stressors or secondary gain. It is also very crucial to instruct them not to punish their child for the NOVL as this response might hinder recovery and does not allow the child an "easy way out." This philosophy is similar for adults with NOVL as getting

angry or confrontational with the malingering patient will not help and doing so with a conversion disorder patient will not alleviate their deep-seated psychological drivers. We recommend instead providing these patients with reassurance that the issue will resolve. Although psychiatric evaluation may be considered in some cases of NOVL, most patients do not meet any specific DSM V diagnosis. We prefer the use of the term NOVL in ophthalmology over specific DSM V diagnosis codes as these diagnoses are probably left to psychiatrically trained providers.

Prognosis

The visual prognosis is usually excellent in the majority of cases. Most cases of NOVL spontaneously improve within a year after presentation with NOVL. Nevertheless, improvement may be very slow and incomplete in a minority of patients. There is no clear consensus about factors that may influence the visual outcome in cases of NOVL and who will be under the risk of a poor visual recovery.

Nonsteroidal Anti-inflammatory Agents

▶ Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Synonyms

Nonsteroidal anti-inflammatory agents; NSAIDS

Definition

Nonsteroidal anti-inflammatory drugs are a heterogeneous group that block COX enzymes and reduce prostaglandin production. They have analgesic, antipyretic, and anti-inflammatory effects. In addition, some NSAIDs prevent platelet aggregation, which can lead increased bleeding time.

Indications

This group of drugs is used in the treatment of acute and chronic pain, inhibition of platelet aggregation, and reduction of fever. Although most NSAIDs possess anti-inflammatory properties others, such as acetaminophen, do not display clinically significant effects. Topical flurbiprofen is used to prevent papillary constriction during intraocular surgery.

Contraindications

Oral nonsteroidal anti-inflammatory agents are contraindicated in patient with a history of allergic

reaction to aspirin or aspirin-like products. They should also be used with caution in individuals with severe asthma and congestive heart failure. They should be avoided in patients with kidney failure, liver diseases, bleeding disorders, gastrointestinal ulcers, and gastroesophageal reflux disease. In addition, salicylates are contraindicated in children and teenagers with viral illnesses.

Topical nonsteroidal anti-inflammatory agents are contraindicated in patients with dry eye syndrome and dendritic epithelial herpes simplex.

Use and Dosage

Oral NSAIDS are used to treat mild to moderate pain, fever, and inflammation due to musculoskeletal disorders. Acetaminophen, which belongs to the para-aminophenol derivative class of NSAIDs, has analgesic and antipyretic effects but lacks significant anti-inflammatory properties.

Flurbiprofen, a topical NSAID, is commonly used to reduce pupillary constriction during intraocular surgery. Topical NSAIDS are also used to treat postoperative inflammation and cystoid macular edema.

Adverse Reactions

A common adverse effect of oral NSAIDSs is gastrointestinal irritation, which can lead to ulcers. Development of ulcers can lead to gastrointestinal bleeding with subsequent anemia. Certain classes of NSAIDs inhibit platelet aggregation and increase bleeding. Salicylates have the potential to cause acute renal failure in patients with chronic renal disease, congestive heart failure, liver disease associated with ascites, dehydration secondary to diuretics, and in patients with hypotension due to acute hemorrhage.

The use of salicylates in children and teenagers with viral disease has been associated with the development of Reye syndrome.

Topical NSAIDs can lead to stinging and have been associated with delayed surface healing, sterile corneal melts and perforations.

Interactions

The use of non-aspirin NSAIDs and aspirin as well as the combination of corticosteroids and NSAIDs increases the potential for gastrointestinal irritation and ulcers and increases the risk of bleeding. NSAIDs may attenuate the effect of ACE inhibitors. The combination can also lead to bradycardia and syncope in the presence of hyperkalemia. This is particularly true in patients with hypertension, diabetes mellitus, and ischemic heart disease. NSAIDs interfere with warfarin metabolism, which leads to increase levels of the drug. In addition, NSAIDs inhibit platelet aggregation and when given with warfarin lead to increased bleeding time.

Nuclear Fragments

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Nuclear remnants

Definition

During modern cataract surgery, the crystalline lens is divided into smaller fragments which are removed from the eye by phacoemulsification and aspiration. Fragments of the nucleus that remain in the eye may give rise to complications such as prolonged inflammation, cystoid macular edema, and elevation of intraocular pressure (Vajpayee et al. 2001).

Epidemiology

There are no figures about incidence. In a large retrospective review of charts over a time frame of 13 years (Hui et al. 2006), 16 cases of retained nuclear fragments without posterior capsular rupture could be identified.

History

The history of retained nuclear fragments causing problems is linked with the history of phacoemulsification. Normally, during previously used cataract extraction techniques such as extra- and intracapsular cataract extraction (ECCE and ICCE), nuclear fragments are not produced.

Clinical Features

Nuclear fragments in the anterior chamber are often small and could be identified as yellowish chips. Sometimes, gray iris color, a pronounced arcus senilis, and corneal edema may cause difficulties of identifying nuclear fragments. At later stages, a prolonged inflammation raised intraocular pressure and corneal edema and probably a cystoid macular edema occur if nuclear fragments are retained in the anterior chamber. If such symptoms occur without visible fragments, a remnant trapped behind the iris or in the zonula should be suspected.

A rent in the posterior capsule bears the risk of descent of nuclear fragments into the vitreous

cavity (Vajpayee et al. 2001). Although this complication is dreaded and the surgeon's vigilance during phacoemulsification is focused on protecting the posterior capsule, sometimes the loss of smaller fragments into the vitreous remains unnoticed.

Tests

Prolonged inflammation and persistent corneal edema should raise suspicion of retained nuclear material. In those eyes, careful slit lamp examination is needed. Sometimes only gonioscopy can reveal small retained nuclear chips. Early after rupture of the posterior capsule, a fundus exam through the dilated pupil is necessary to rule out retained lens fragments and retinal tears. In the presence of corneal edema, an ultrasound examination may be helpful. Eyes with present or suspected retained nuclear fragments must be monitored closely for hypertension and subsequent glaucoma.

Differential Diagnosis

Although the appearance of nuclear fragments is unique, there may be similarities to other lens material such as cortex or epinuclear remnants.

Etiology

A fragmentation of the nucleus into many smaller chip-like pieces during phacoemulsification increases the risk of retained fragments in the anterior or posterior chamber. Retained nuclear fragments have been observed more frequently in myopic eyes, they probably get trapped in the relatively spacious posterior chamber in those eyes (Hui et al. 2006). Corneal edema, a pronounced arcus lipoides, and gray iris color can cause difficulty of visualization of nuclear fragments during and after phacoemulsification. The rupture of the posterior capsule during phacoemulsification bears a high risk of descent of nuclear fragments into the vitreous.

Treatment

Retained fragments in the anterior chamber should be removed with an irrigation/aspiration system as early as possible. If inflammation is already present, increase of the local steroid dose and systemic steroids can be helpful. While small nuclear fragments in the vitreous cavity can be observed and treated with systemic and local steroids, pars plana vitrectomy and removal is required if the fragments are larger.

Prognosis

The prognosis depends on complications like secondary glaucoma, cystoid macular edema, and corneal decompensation. If remaining fragments are removed from the eye before such complications develop, prognosis is good.

Nyctalopia: Night Blindness

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Night blindness

Definition

Decreased or impaired vision in dark environments due to absence or subnormal activity of rod photoreceptors.

Etiology

Many causes of nyctalopia exist. Potential etiologies can be divided into five different groups of disorders:

Group 1: Congenitally Inherited Diseases

Congenital stationary night blindness (CSNB) refers to a distinct group of diseases that are both genetically and phenotypically diverse and characterized by a severe, nonprogressive, inherited reduction in night vision and rod function. CSNB can have normal or abnormal fundus findings; be autosomal dominant, autosomal recessive, or X-linked in its transmission; and have variable involvement of the cone photoreceptors. Subtypes of CSNB include fundus albipunctatus, Oguchi's disease, flecked retina of Kandori, and familial fleck retina with night blindness. Sometimes reduced visual acuity, myopia, strabismus, or congenital nystagmus may accompany these diseases. Genetic mutations have been identified for several of the different subtypes of CSNB.

Group 2: Inherited Retinal and Choroidal Dystrophies

Several inherited retinal and choroidal dystrophies can cause nyctalopia/night blindness that becomes more symptomatic as the disease progresses. Nyctalopia is usually the initial symptom in retinitis pigmentosa (rod-cone dystrophy). Other inherited ocular diseases with symptoms of nyctalopia include choroideremia and gyrate atrophy.

Group 3: Physiological Aging

Decreased visual function and electrophysiologic responses in the absence of other ocular diseases is a normal part of aging. Factors such as ocular media, pupil size, and physiological changes of the neuronal visual pathway can affect vision, including night vision. Older eyes are also more likely to develop cataracts which may affect vision at night. Full-field electroretinogram (ERG) rod and cone amplitudes have been shown to decline with age, with a more significant decline occurring after age 55 years.

Group 4: Nutritional Factors

Vitamin A deficiency leads to decreased amounts of rhodopsin, an important visual pigment of the rod photoreceptors, with reduced retinal electric activity and resulting nyctalopia/night blindness. Vitamin A deficiency with ocular symptoms of xerophthalmia can be the result of malnutrition with children being more susceptible. Unfortunately this is a major cause of blindness in children in undeveloped countries. Because Vitamin A is a fat-soluble vitamin absorbed in the small intestine and stored in the liver, diseases such as congenital or postsurgical short bowel syndrome, Crohn's disease, liver failure, or alcoholism may also lead to a deficiency.

Group 5: Other Ocular Disorders that Involve Rod Function

Other ocular disorders such as advanced glaucoma and myopia can lead to nyctalopia. Decreased night vision has also been associated with chloroquine toxicity and phenothiazine toxicity.

Clinical Presentation

Presentation of nyctalopia is dependent on the etiology. Patients with congenital hereditary diseases may be unaware of nyctalopia until later in life when they are driving at night. Other patients

may be very sensitive to the fact that they are having more difficulties at night, especially if their disease is progressive.

Visual acuity can range from normal to severely deceased in patients with symptomatic nyctalopia. Clinical exam findings may be normal or may show distinct findings such as bone spicule in the peripheral fundus as seen in retinitis pigmentosa or Bitot's spots on anterior exam seen with Vitamin A deficiency.

Diagnosis

Determining the diagnosis that has led to nyctalopia is helped by a detailed family, medical, and ocular history and complete ocular exam. A targeted work-up can then be conducted. Full-field electroretinograms (ERGs) are helpful in determining photoreceptor functioning. For some inherited diseases such as certain forms of CSNB, retinitis pigmentosa, choroideremia, and gyrate atrophy, genetic testing is available.

Differential Diagnosis

Differential diagnosis of nyctalopia/night blindness should include the potential etiologies discussed above.

Prophylaxis

Genetic counseling exists for families with known inherited ocular diseases. Nutritional causes of nyctalopia can be prevented by monitoring and supplementation in high-risk individuals. Identification of drug retinal toxicities through close monitoring may decrease chances of symptomatic changes.

Patients with hereditary ocular diseases should wear sunglasses in bright light to reduce the likelihood of progression due to oxidative stresses.

Therapy

For inherited causes of nyctalopia, unfortunately no treatments exist. Patients with vitamin A deficiency should be treated with vitamin A supplementation. Stopping drugs with known retinal toxicities may halt or slow retinal changes.

Prognosis

Prognosis is variable dependent on the etiology of the nyctalopia. Nonprogressive, progressive, and reversible forms of nyctalopia exist.

Epidemiology

Epidemiology is very dependent on the cause of nyctalopia and varies between different etiologies.

Synonyms

None, (although some forms of abnormal eye movements are called "nystagmus" when they are "nystagmoid," microtremor (e.g., superior oblique myokymia), or saccadic intrusions (e.g., opsoclonus or ocular flutter)).

Definition

Nystagmus is a rhythmic oscillation of the eyes that, by definition, has a pathologic slow phase, but it is typically named for the corrective fast-phase jerk component or is termed pendular when there is no fast phase. Although typically bilateral, symmetric, and associated, there are forms that are bilateral but asymmetric, unilateral, or dissociated.

Etiology

Nystagmus can be either physiologic or pathologic. Typically, physiologic nystagmus is of low amplitude, is unsustained, symmetric in both eyes, directed horizontally, and only gaze-evoked in extremes of horizontal gaze (e.g., right beating horizontal jerk nystagmus on right gaze). This is sometimes referred to as "end-position" or "end-gaze" nystagmus. It typically dampens rapidly (i.e., unsustained) and stops when the eyes are brought a few degrees back toward primary. In contrast to most forms of pathologic nystagmus, it is not present in primary position.

Physiologic nystagmus can also be induced by vestibular stimulation (by head rotation or cold or warm water irrigation of the ear) and optokinetic stimulation (by use of the optokinetic drum). Primary position nystagmus is always pathologic and is typically sustained, involuntary, and constant.

Pathologic nystagmus can be further characterized based on the amplitude, vector, direction, and frequency of the nystagmus and is named for the fast phase if present. Additional testing is typically necessary to try to narrow the differential diagnosis based upon morphology of the nystagmus and the response of the nystagmus to various maneuvers (e.g., fixation, gaze, near reaction, occlusion of either eye, head position). Nystagmus can be of central or peripheral origin and is typically localized by "the company it keeps" (see below).

Clinical Presentation

Depending on the etiology, it may be present within several months of birth or acutely after an inciting event. Central and peripheral vestibular nystagmus can often be differentiated by accompanying symptoms and signs. Peripheral nystagmus often occurs in the setting of hearing loss, tinnitus, and positional symptoms and signs.

Diagnostics

Diagnosis of different type of nystagmus is based primarily on clinical exam. A common cause of

nystagmus is medication side effect (especially antiseizure medicines) or toxicity. Unexplained nystagmus should be localized based upon accompanying symptoms and signs. Neuroimaging (preferably magnetic resonance imaging of the brain with and without contrast) is generally required as an initial step in the evaluation of central forms of pathologic nystagmus. Peripheral vestibular nystagmus usually presents to and is managed by otolaryngology (neurootology). Typical laboratory studies depending on the clinical scenario might include vitamin testing (e.g., B12, folate, thiamine), electrolyte testing (e.g., magnesium), inflammatory or autoimmune testing, infectious serology, toxin screen, and neoplastic/paraneoplastic evaluation.

Differential Diagnosis

1. Ocular flutter
2. Opsoclonus
3. Microtremor
4. Voluntary nystagmus

Prophylaxis

Depending on the type of nystagmus, discontinuation of reduction of dose of offending exogenous agents could be considered. There is no prophylaxis for nystagmus and treatment should be directed at the underlying etiology.

Therapy

Complete resolution depends on successful treatment of the underlying etiology, and thus nystagmus may not resolve if the underlying condition is chronic, untreatable, or incurable. Acute demyelinating or inflammatory lesions might respond to corticosteroid treatment. Likewise, compressive lesions might be resectable. Medical treatment for nystagmus has shown unpredictable and variable efficacy and is often empiric. Pharmacologic agents with GABAergic properties such as baclofen have been shown to be successful in treating the acquired form of periodic alternating nystagmus (PAN). Clonazepam occasionally damps downbeat and other central vestibular forms of nystagmus. Other agents that have been used with some success include memantine or gabapentin. Nonmedical treatments include base-out prisms, and contact lenses may improve visual acuity in congenital nystagmus and damping the nystagmus. Surgical treatment with Anderson-Kestenbaum procedure can mechanically shift the null point (if present) to primary position and correct anomalous head positions in patients with congenital or acquired nystagmus.

Prognosis

Prognosis is dependent on the underlying etiology.

Epidemiology

The prevalence of nystagmus in the general population was estimated to be 24.0 per 10,000 population in one study.

See Table 1 for different types of nystagmus.

Other topics related to nystagmus.

Heading

Oculopalatal myoclonus (OPM)

Definition

OPM is a form of acquired pendular nystagmus characterized by rhythmic conjugate eye movements in the vertical plane.

Etiology

It can be seen in patients with multiple sclerosis but can occur after any lesion (e.g., hemorrhage, tumor, trauma) in the Guillain-Mollaret triangle (see below).

Nystagmus: Overview, Table 1 Different forms of nystagmus

Heading	Peripheral vestibular nystagmus (PVN)	Seesaw nystagmus (SSN)	Upbeat nystagmus	Periodic alternating nystagmus	Congenital nystagmus	Downbeat nystagmus (DBN)
Definition	Typically related to acute or chronic vestibular neuropathy	SSN is a central form of vestibular nystagmus. It is a combination of vertical and torsional components. It is characterized by disconjugate, alternating depression and extorsion of one eye with concomitant elevation and intorsion of the fellow eye. The oscillations are typically pendular (sinusoidal, with both phases having equal velocity), but can be jerk (slow-phase drift followed by fast-phase correction)	Upbeat nystagmus is often found in patients with lesions in the posterior fossa (most commonly in the medulla or, to a lesser degree, the anterior cerebellar vermis)	A type of central vestibular nystagmus characterized by purely horizontal component that reliably changes direction approximately every 1–2 min	May occur with congenital strabismus	DBN is a type of central vestibular nystagmus characterized by involuntary, slow upward drifting of the eyes immediately followed by a fast, downward saccade. It also obeys Alexander's law in that the DBN increases in downgaze
	Characterized by a combination of horizontal and torsional components			Acquired forms are typically caused by insults to the cerebellar nodulus and uvula, which play an important role in the time constant of rotational velocity storage	Congenital nystagmus is a conjugate horizontal nystagmus that demonstrates increased slow-phase velocity with distant fixation and diminishment by convergence. The horizontal direction of the nystagmus remains horizontal even in up- and downgaze. The movements can be jerk and/or pendular pattern	
	The slow phase is toward the side of the lesion with a corrective saccade away from the side of the lesion. It follows Alexander's law					
Etiologies	Dysfunction of the inner ear labyrinth or vestibular nerve (e.g., benign paroxysmal positional vertigo (BPPV), labyrinthitis, Meniere's disease, trauma, and central etiologies (e.g., cerebellopontine angle tumors), which provides sensory information regarding balance and spatial orientation to the brain. Without normal	SSN may be congenital or acquired but is most commonly found with structural lesions in the parasellar and third ventricular region (especially craniopharyngioma). Other etiologies for SSN include stroke, trauma, congenital Chiari malformation, or demyelinating disease	Common etiologies include tumor, demyelination, stroke, cerebellar degeneration, or tobacco smoking	PAN can be congenital or acquired. In acquired forms, common etiologies include demyelination, stroke, cerebellar degeneration, Chiari type 1, anticonvulsant therapy, or bilateral vision loss	It may be hereditary, genetic (associated with oculocutaneous albinism and aniridia), or spontaneous	Disruption in the neuronal transmission between vestibulocerebellum, the anterior semicircular canals, and the ocular motoneurons usually results in DBN. It may be congenital or acquired and often due to structural lesions at the cervicomedullary junction (most commonly Chiari type 1 malformation). Other

	vestibular afferent inputs, the eye cannot be stabilized in eccentric locations					etiologies for DBN include drugs (e.g., codeine, alcohol, lithium, anticonvulsants), tumors, nutritional problems (e.g., Wernicke syndrome, magnesium deficiency), paraneoplastic syndromes, demyelination, and stroke
Clinical presentation	PVN is usually acute in onset and often associated with marked disequilibrium characterized by vertigo, nausea, vomiting, and tinnitus. Patients may also have oscillopsia and hearing loss. The symptoms are often made worse by particular head postures or head movements	SSN has an obvious and dramatic morphology that makes the diagnosis clinically. Patients often have concomitant visual loss or a bitemporal hemianopsia localizing to the chiasm	Patient usually presents acutely with nystagmus that increases in amplitude with upgaze	The cycle begins with a jerk phase in one direction, with its amplitude and frequency progressively increasing and then decreasing until the nystagmus stops for a period of seconds. Subsequently, the jerk phase begins in the opposite direction following the same crescendo-decrescendo pattern until the nystagmus stops briefly again; then, the cycle repeats itself. Acquired form of PAN has an oscillation cycle of 2–4 min.	Congenital nystagmus is usually acute in onset and develops within the first 6 months of life. Visual acuity may be decreased (probably by the nystagmus itself and seldom below a level of 20/200), but can be normal (especially at near, where convergence effort might dampen the nystagmus and improve near acuity). Unlike patients with acquired nystagmus, patients with congenital nystagmus do not experience oscillopsia (the sensation that the environment is moving). Many cases have superimposed latent component, and the patient might have an anomalous head position to achieve a null point where the nystagmus is least	DBN may be congenital or acquired and is often associated with good vision and normal neurologic findings. If it is the hereditary or degenerative forms, the DBN may precede the clinical or radiographic findings of the spinocerebellar degeneration. More often, it is of acute onset secondary to a structural lesion

Nystagmus: Overview, Table 1 (continued)

Heading	Peripheral vestibular nystagmus (PVN)	Seesaw nystagmus (SSN)	Upbeat nystagmus	Periodic alternating nystagmus	Congenital nystagmus	Downbeat nystagmus (DBN)
Diagnostic	Diagnosis of PVN is based primarily on clinical exam. A typical feature of PVN that helps distinguish it from central causes of nystagmus is suppression of nystagmus with visual fixation. Many different modalities can be used to elicit this response, including Frenzel's glasses, video-oculography, or simply using direct ophthalmoscopy and intermittently covering the fellow eye during viewing. The Dix-Hallpike maneuver might identify a patient with BPPV	Diagnosis of SSN is based primarily on clinical exam. Visual field testing and a full neuro-ophthalmologic examination are indicated	Diagnosis of upbeat nystagmus is based primarily on clinical exam	Diagnosis is based primarily on clinical exam. It is important when evaluating a patient with horizontal nystagmus to watch the patient's eyes for at least 2 min to ensure that PAN is not the cause of the horizontal nystagmus	Diagnosis is based primarily on clinical exam. Two unique features of congenital nystagmus are inversion of optokinetic response and damping of nystagmus with convergence and eyelid closure	Diagnosis of DBN is based primarily on clinical exam
Differential diagnosis	1. Central vestibular nystagmus	1. Downbeat nystagmus	1. Downbeat nystagmus	1. Congenital nystagmus	1. PVN	1. Upbeat nystagmus
	2. Bruns nystagmus	2. Upbeat nystagmus	2. Seesaw nystagmus	2. Seesaw nystagmus	2. Periodic alternating nystagmus (PAN)	2.
				3. Internuclear ophthalmoplegia	3. Internuclear ophthalmoplegia (INO)	2. Seesaw nystagmus
					4. Congenital sensory nystagmus (characterized by a complex searching nystagmus consisting of irregular pendular (sinusoidal) and jerk features secondary to abnormalities of the eyes or optic nerves, present at birth or acquired in childhood)	3. Oculopalatal myoclonus

Therapy	The treatment of PVN acutely is typically supportive, but there are also medications such as meclizine or scopolamine to decrease vertigo symptoms. Vestibular exercise programs and rehabilitation are helpful in many patients. If the diagnosis is BPPV, then repositioning maneuvers can be performed by the ENT specialist	Definitive treatment of SSN depends upon treating the underlying etiology; however, medications such as baclofen, gabapentin, and clonazepam may help to abate the nystagmus	Definitive treatment depends upon the etiology; however, medications such as baclofen, gabapentin, and clonazepam may help to abate the nystagmus	Treatment is depending on the etiology. Acquired form of PAN also responds well to baclofen, which is the first-line therapy for PAN. Gabapentin, clonazepam, and memantine have also been used in PAN anecdotally and in other forms of acquired nystagmus with variable results	Nonmedical treatments include base-out prisms, and contact lenses may improve visual acuity in congenital nystagmus and damping the nystagmus	Treatment is depending on the etiology. If the MRI shows a symptomatic Chiari malformation, then decompression of the area may result in complete resolution of DBN. Other pharmacologic treatment options include 4-aminopyridine, gabapentin, benzodiazepines, memantine, and baclofen. Base-out prisms may also be employed to stimulate fusional convergence and improve visual acuity, which damps the nystagmus. A null point may be present and surgically or medically treated
Prognosis	Depending upon the etiology, PVN symptoms may spontaneously resolve over a few days to weeks; however, resolution may be incomplete requiring further evaluation and treatment by ENT. Even then, patients may experience discomfort with activities that challenge their vestibular system	Prognosis is depending upon the etiology of SSN	Prognosis depends on the etiology of the nystagmus	Prognosis depends on the etiology of the nystagmus	About 15% of congenital nystagmus patients also have congenital strabismus and of which congenital esotropia is the most common type. To utilize a null point, some of these children will adopt a preferred gaze position, and the anomalous head position may become more obvious as the child reaches school age. Surgical or prism therapy might be useful to move the null point to primary position	Prognosis depends on the etiology of the nystagmus

(*continued*)

Nystagmus: Overview, Table 1 (continued)

Heading	Peripheral vestibular nystagmus (PVN)	Seesaw nystagmus (SSN)	Upbeat nystagmus	Periodic alternating nystagmus	Congenital nystagmus	Downbeat nystagmus (DBN)
Epidemiology	BPPV is the most common form of positional vertigo, accounting for nearly one-half of patients with PVN. It represents up to 18% of patients seen in dizziness clinics, and 25% of patients referred for vestibular testing end up with a diagnosis of BPPV. In one population-based survey study, the lifetime prevalence of BPPV was 2.4% with increased frequency with increased age (up to seven times higher in those older than age 60 years), and BPPV is more common in women	SSN can affect any age and either gender	Can affect any age, any patient, and either gender depending on the underlying etiology	Can be congenital or acquired and can affect any age patient, any race, and either gender	CN usually develops within the first 6 months of life and thus is not typically present at birth	
Cross-references	1. Benign paroxysmal positional vertigo	1. Chiari malformation	Alexander's law	Chiari type 1	1. Congenital sensory nystagmus	1. Upbeat nystagmus
	2. Alexander's law	2. Pituitary adenoma			2. Nystagmus blockage syndrome	2. Seesaw nystagmus
	3. Meniere's disease	3. Craniopharyngioma				3. Oculopalatal myoclonus
	4. Cerebellopontine angle					

Clinical Presentation

OPM typically presents with a delayed manifestation that appears months to years after damage to the brainstem (often pontomedullary infarct or hemorrhage) within the Guillain-Mollaret triangle. This anatomic triangle includes pathways between the red nucleus, ipsilateral inferior olivary nucleus, and contralateral dentate nucleus. Patients often complain of severe oscillopsia due to the high-amplitude, vertical, pendular nystagmus. It may be associated with synchronous contractions of the palate, face, pharynx, and other muscle groups.

Diagnostic

In any patient with a vertical, pendular nystagmus (i.e., not clearly upbeat or downbeat nystagmus (DBN)), the key and differentiating feature of oculopalatal myoclonus can be demonstrated by having the patient open their mouth for the clinician to observe the palate (uvula) for abnormal vertical movements. The palatal myoclonus can also occur independent of the eye findings. The typical MRI findings include the primary inciting lesion in the Guillain-Mollaret triangle, and there may be hyperintensity and hypertrophy of the inferior olivary nucleus on T2-weighted images in the medulla.

Differential Diagnosis

1. Torsional nystagmus
2. Downbeat nystagmus
3. Internuclear ophthalmoplegia
4. Congenital pendular nystagmus

Heading

Internuclear ophthalmoplegia

Definition

It is a disconjugate eye movement characterized by a non-sustained, dissociated horizontal abducting nystagmus in the eye contralateral to the medial longitudinal fasciculus (MLF) lesion during lateral gaze away from the side of the lesion. There is also a concomitant slowing, paresis, or absence of adduction in the eye ipsilateral to the lesion.

Etiology

The medial longitudinal fasciculus (MLF) coordinates conjugate eye movements. Lesions to the MLF result in disconjugate movement called internuclear ophthalmoplegia (INO). Common lesions to the MLF are most commonly caused by demyelinating disease, but cerebrovascular accidents or brain tumors may also occur. The INO may be unilateral or bilateral, but bilateral INO in a young patient is typically demyelinating disease.

Clinical Presentation

Typically acute in onset. Patient often complains of double vision.

Diagnostic

Diagnosis of an INO is based primarily on clinical exam. In patients with INO, the eye ipsilateral to the lesion adducts slowly or not at all, and the abducting eye shows a characteristic horizontal nystagmus on contralateral gaze. Upon convergence, both eyes adduct normally (including the eye ipsilateral to the lesion). Skew deviation may be present in addition to exotropia.

Differential Diagnosis

1. Peripheral vestibular nystagmus (PVN)
2. Periodic alternating nystagmus (PAN)

Heading

Opsoclonus

Definition

"Dancing eyes and dancing feet (myoclonus)."

Opsoclonus is a bilateral saccadic intrusion abnormality that is characterized by involuntary, fast (saccadic), multidirectional, conjugate ocular movements. It is not technically a form of nystagmus because it lacks a slow-phase movement. It is considered a more severe form of ocular flutter (which is similar in morphology except that in contrast to the multivectorial opsoclonus, ocular flutter only occurs in the horizontal plane).

Etiology

In adults, the most common etiologies for opsoclonus are postinfectious and paraneoplastic. In children, however, paraneoplastic opsoclonus due to neuroblastoma may be present in up to 50% of cases.

Clinical Presentation

Opsoclonus is usually acute in onset and often associated with markedly rapid, high-frequency, and low-amplitude ocular oscillation.

Diagnostic

Diagnosis of opsoclonus is based primarily on clinical exam. Other nonneoplastic lesions in the brainstem can also produce the finding however (e.g., inflammatory, infectious, traumatic, demyelinating, metabolic, toxic, etc.).

Differential Diagnosis

Infantile nystagmus

Therapy

Opsoclonus in children or adults should prompt a neoplastic and paraneoplastic workup, as approximately 20% of adults with opsoclonus have an underlying malignancy (typically neuroblastoma, small cell lung carcinoma, breast cancer, or ovarian cancer).

Treatment is depending on the etiology. If neuroblastoma is present, surgical removal of the tumor is recommended. Because the mechanism of opsoclonus in neuroblastoma patients is hypothesized to be paraneoplastic, additional treatment includes intravenous corticosteroids, immunoglobulin, or rituximab.

[5]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA
[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Occipital lobe epilepsy (OLE) refers to recurring seizures that originate in the occipital lobe of the brain. OLE is an uncommon form of epilepsy, and patients with this condition may experience a multitude of visual disturbances immediately before, during, and after a seizure has occurred.

Etiology

While the exact etiology is unknown, possible predisposing findings include underlying tumors, vascular malformations, developmental abnormalities, or other pathology in the occipital lobe.

Clinical

Visual auras such as unformed images, flashes, steady white or colored lights, and very complex visual hallucinations are common in patients with occipital lobe seizures. The occipital seizure visual phenomena are often described as geometric, colored figured (especially small circles). Other reported visual distortions include macropsia and micropsia (change in size), metamorphopsia (change in shape), and dyschromatopsia (change in color). The visual aura usually manifests in the contralateral visual field, but bilateral and diffuse symptoms may also occur. These seizures often start in and can remain localized to the occipital lobe but can also spread to affect other areas of the brain.

In the ictal state, patients with OLE may present with bilateral simultaneous transient vision

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

loss, which can extend into the post ictal state that might include incoherence or mental status change. The duration of the vision loss can range from less than 1 min to days, or it can become more constant. Loss of consciousness and progression to more severe generalized seizures with bilateral motor convulsions depends on each individual patient and the extent of central nervous system (CNS) spread of the initial focal seizure. Finally, occipital seizures in children may be benign occipital epilepsy of childhood. Spontaneous remission in these patients usually occurs by 12 or 13 years of age but some patients have persistent OLE.

Differential Diagnosis

The differential diagnosis of OLE is similar to that of any seizure disorder. Other conditions to consider include migraine, sleep disorders, medication side effects, and psychiatric conditions.

Diagnosis

Diagnosis typically includes history, electroencephalogram (EEG), and magnetic resonance imaging of the brain.

Treatment

Treatment for OLE typically includes anticonvulsants like carbamazepine. The use of these medications can improve the vision of patients suffering from vision loss, as well as to help prevent occurrence of future generalized seizures.

Ocular Bobbing

Carla J. Newton[1], Sumayya J. Almarzouqi[2] and Andrew G. Lee[2,3,4,5,6]
[1]Texas A&M Health Science Center, College of Medicine, Bryan, TX, USA
[2]Department of Ophthalmology, Blanton Eye Institute, Houston Methodist Hospital, Houston, TX, USA
[3]Departments of Ophthalmology, Neurology, and Neurosurgery, Weill Cornell Medical College, Houston, TX, USA
[4]Department of Ophthalmology, The University of Texas Medical Branch, Galveston, TX, USA
[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Atypical bobbing; Monocular bobbing

Definition

Ocular bobbing is a type of spontaneous abnormal eye movement that presents as a rapid downward

movement of both eyes followed by a slow drift back into primary position (Lavin 2012). The oscillation typically recurs at irregular intervals between 2 and 15 times per minute (Lavin 2012).

Etiology

Ocular bobbing occurs in patients that are usually comatose or in a stupor due to severe damage to the pons or less commonly a diffuse encephalopathy of toxic or metabolic orgin (Quiros and Yee 2014). In these situations, the brainstem is relatively intact and the bilateral lesions are above the brainstem (Berger 2012). Damage to the pons can occur in severe central pontine ischemic destruction, central pontine myelinolysis, encephalitis, or extra-axial pontine compression (e.g., cerebellar tumor or hematoma) (Quiros and Yee 2014). Toxicity (e.g., organophosphate poisoning) can also ocular bobbing. Although typical ocular bobbing is highly specific for acute pontine lesions, the finding is not pathognomonic.

Classifications

The typical form is associated with paralysis of both reflex and spontaneous horizontal eye movements. Monocular or paretic bobbing occurs when a coexisting ocular motor palsy alters the appearance of typical bilateral ocular bobbing. Atypical bobbing refers to all other variations of bobbing that cannot be explained by ocular palsy superimposed on typical bobbing (Berger 2012).

Ocular Lice

Shira Simon[1] and Matthew B. Goren[2]
[1]Feinberg School of Medicine, Northwestern University, Department of Ophthalmology, Northwestern Memorial Hospital, Chicago, IL USA
[2]Cornea and External Diseases, Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

Synonyms

Eyelash pediculosis; *Pediculosis ciliaris*; *Pediculosis palpebrarum*

Definition

Lice infestation of the eyelashes and/or eyebrows caused by *phthirus pubis*.

Etiology

Phthirus pubis is a hematophagous parasite. *Phthirus* measure up to 2 mm in length and have a broad, crab-like body that distinguishes them from the longer and more slender *pediculosis palpebrarum*, or head louse. *Phthirus* are usually transferred by hand contact from genital areas to the eye but can also be transmitted interpersonally through direct contact (e.g., linens, clothing) (Anderson and Chaney 2009).

Clinical Presentation

Patients present with complaints of itching, crusting, and irritation of eyelid margins. Conjunctival inflammation, usually bilateral, is often present (Barreto et al. 2012). A history of close personal contacts with similar symptoms is often elucidated.

Diagnosis

Visualization of affected eyelashes and eyebrow hair through the slit lamp will uncover the parasites. Translucent eggs (nits) measuring around 0.5 mm can be visualized in the eyelashes. Accumulation of reddish-brown granular fecal material at the base of lashes may assist with diagnosis if the translucent parasite is difficult to see. A follicular conjunctivitis is often seen.

Differential Diagnosis

Allergic contact dermatitis, blepharitis, blepharoconjunctivitis, bacterial or follicular conjunctivitis, eyelid eczema, and ocular rosacea (Turgut et al. 2009).

Prophylaxis

Sexual partners and very close family members can be treated prophylactically as outlined below to prevent cross reinfection. Bedding and perhaps furniture, which is shared by the patient with others, should be thoroughly cleaned at a temperature greater than 130 °F.

Therapy

Mechanical removal of lice and nits using fine tweezers and twice-daily application of petroleum jelly or other ophthalmic ointment to the eyelashes and eyebrows for at least 1 week should be initiated to suffocate the organisms (Chapel et al. 1979). Successful management has been reported with oral ivermectin (two doses of 200 mcg/kg PO 1 week apart), pilocarpine 4% gel drops, 1% yellow oxide of mercury ointment, permethrin 1% cream, malathion 1% shampoo, and lindane 1% lotion (Couch et al. 1982). Other areas of body hair should be treated with gamma benzene hexachloride shampoo. The occurrence of lice in preadolescents may indicate sexual abuse and appropriate investigation should be considered.

Prognosis

Excellent, provided course of treatment is followed. Nits can remain dormant for 7–10 days so eradication of only visible lice is insufficient.

Epidemiology

The exact incidence is unknown, but ranges between 1% and 2% occurrence worldwide among adults is generally reported.

Ocular Medication Absorption Affected by Viscosity

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

Viscosity is one of the several drug vehicle characteristics that can affect the amount of time a drug stays on the cornea, the penetration rate into the cornea, and its bioavailability. All else being constant, the more viscous the ocular drug the longer it stays on the cornea and the better its bioavailability.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Voluntary gaze paresis

Definition

Ocular motor apraxia is defined as a deficit in the voluntary control of purposeful conjugate eye movements without lesion in the extraocular muscles, neuromuscular junction, or ocular motor nerve pathways for eye movements. Children with this condition have difficulty moving their eyes horizontally.

Etiology

The etiology of ocular motor apraxia (OMA) can be congenital or acquired. Congenital ocular motor apraxia (COMA) has been hypothesized to be due to abnormality of the vermis of the cerebellum. Acquired ocular motor apraxia can occur from bilateral lesions of the parieto-occipital region, which controls voluntary visual saccades and pursuit, ataxia-telangiectasia, inherited spinocerebellar ataxia, Joubert syndrome, Gaucher disease, Niemann-Pick disease, Balint syndrome, and rarely following cardiac surgery.

Clinical Presentation

COMA patients present with the characteristic head thrust movement (using the vestibular ocular reflex (VOR)) to compensate for the voluntary deficiency of conjugate eye movement. Some cases of OMA occur in association with perinatal hypoxia, post-infection (e.g., meningitis, encephalitis, sepsis), periventricular leukomalacia, cerebral palsy, and seizure disorders.

Diagnostics

Patients with the supranuclear ocular motor apraxia can be diagnosed clinically by overcoming the deficit with the dolls head maneuver (using VOR). In COMA cases patients may also demonstrate the characteristic head thrust movement.

Differential Diagnosis

- Progressive supranuclear palsy
- Ocular motor palsy, nonorganic

Therapy

There is no therapy for congenital ocular motor apraxia.

Prognosis

Prognosis depends on the etiology. The head thrusts in COMA often diminish over time but may not completely resolve.

Epidemiology

COMA is congenital, but acquired OMA may affect patients of any age, either gender, and any ethnic group.

Ocular Prostheses

Christopher Zoumalan[1] and Gary Joseph Lelli[2]
[1]Department of Ophthalmology, Aesthetic and Reconstructive Oculoplastic Surgery, Keck School of Medicine of USC, American Society of Ophthalmic Plastic and Reconstructive Surgery, American College of Surgeons, Beverly Hills, CA, USA
[2]Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Prosthesis; Scleral shell (to be used only when it covers an eyeball which may be blind, unsightly, and/or phthisical)

Definition

A prosthetic that is designed to fit within the eye socket. Iris, pupil, scleral tint, and vascular pattern are usually hand duplicated in detail to match the fellow eye. A prosthetic can be fitted in a socket that has undergone enucleation or evisceration; it can also be fitted over a disfiguring, blind, or phthisical eye (referred to as a scleral cover shell). Today, most prosthetic eyes are acrylic based; however, glass is still used in certain parts of the world (2008).

Indications

1. Provides an optimal cosmetic appearance and some variable motility after undergoing enucleation or evisceration
2. Covers a disfiguring phthisical eye that is still retained in the socket (scleral cover shell)
3. Provides orbital bone growth in cases of congenital anophthalmos and microphthalmos
4. Prevents contractures from occurring in a socket that has undergone trauma, chemical burn, radiation therapy, or infection

Techniques and Principles

Once the socket is deemed in satisfactory postoperative condition by the surgeon after undergoing enucleation or evisceration, the patient will visit an ocularist for the prosthetic fabrication. Impressions of the socket are made, and the impression is then translated into the creation of an individualized prosthetic. In cases of a blind or phthisical eye, they can be referred to an ocularist once they are free from any active ocular issues (i.e., pain, infection) (Stewart 1995).

Management and Care

The average life of a prosthesis is 4–6 years, but varies widely. Proper polishing should be done by an ocularist approximately once a year. Removal of the prosthetic and evaluation of the socket cavity is essential in an ophthalmologic exam. Chronic irritation and excessive mucous discharge most commonly result from improperly fitted prosthetic, lower lid malposition, or abnormal surface condition of the prosthetic.

Oculodentoosseous Dysplasia

David Loring Nash and Mark M. Fernandez
Eastern Virginia Medical School, Norfolk, VA, USA

Synonyms

Oculodentoosseous dysplasia is more commonly known as oculodentodigital dysplasia. Other synonyms include:

Oculodentodigital (ODD) syndrome; ODD dysplasia (ODDD)

Definition

Oculodentodigital dysplasia (ODDD) is a rare genetic disorder leading to a congenital ectodermal dysplasia, which manifests as developmental abnormalities of the face, eyes, limbs, and teeth (Duke-Elder 1972).

Etiology

ODDD is an autosomal dominant condition resulting from a mutation of the gap junction alpha 1 (GJA1) gene encoding for connexin 43 (Paznekas et al. 2003). There have been reports of an autosomal recessive variant (Frasson et al. 2004).

Clinical Presentation

Patients may present with decrease vision resulting from glaucoma, the most common cause of vision loss in ODDD (Traboulsi and Parks 1990). If there is suspicion for ODDD, family members should be examined to look for signs consistent with ODDD. Patients with glaucoma may present as early as infancy, those without, may never be diagnosed.

Characteristic findings include:

- Nasal abnormalities
  - Narrow nose
  - Hypoplastic alae nasi
  - Small anteverted nostrils
  - Prominent columnella and nasal bridge
- Brittle nails
- Hypotrichosis
- Teeth abnormalities
  - Hypodontia
  - Microdontia
  - Enamel hypoplasia
  - Dental carries
- Digital abnormalities
  - Syndactyly (bilateral of fourth and fifth digits)
  - Clinodactyly

- Ocular abnormalities
  Microcornea
  Microphthalmia
  Reduced palpebral fissure length
  Iris abnormalities
  Cataracts
  Glaucoma (congenital, juvenile, angle closure, and primary open angle)
  Foveal hypoplasia
  Optic nerve head dysplasia
- Neurologic symptoms

Autosomal recessive forms have exhibited intracranial calcifications, hearing loss, and persistent hyperplastic vitreous (Duke-Elder 1972; Frasson et al. 2004; Musa et al. 2009; Gabriel et al. 2011).

Diagnosis

Diagnosis is based on the presence of clinical findings consistent with ODDD and/or the presence of a GJA1 mutation.

Differential Diagnosis

Hallermann-Streiff syndrome, Mohr-Clausen syndrome (oro-facial-digital syndrome type II), keratitis-ichthyosis-deafness (syndrome), ectrodactyly-ectodermal dysplasia-cleft syndrome, congenital glaucoma, juvenile glaucoma.

Prophylaxis

Regular screening for ophthalmic complications, most notably glaucoma, is warranted in a person with ODDD. If a person has ODDD, a discussion with a genetic counselor may assist in the decision process with regard to having children.

Therapy

Therapy is aimed at managing complications of ODDD. Glaucoma is managed depending on the cause (congenital, open angle, or angle closure) (Traboulsi and Parks 1990). Patients should have regular dental examination due to their increased risk for dental carries.

Prognosis

The prognosis is good. Most cases do not have cognitive impairment. The autosomal recessive variant may be more severe and have a poorer prognosis.

Epidemiology

The incidence of ODDD is unknown. It is present equally in males and females and has been reported primarily in white race/ethnicity.

Oculoglandular Syndrome

► Oculoglandular Syndrome, Parinaud

Oculoglandular Syndrome, Parinaud

Mingjuan Lisa Zhang
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Synonyms

Oculoglandular syndrome

Definition

Parinaud's oculoglandular syndrome is the combination of granulomatous conjunctivitis in one eye and ipsilateral preauricular or cervical adenopathy.

Etiology

The most common cause is cat-scratch disease (CSD, *Bartonella henselae*). Other frequent causes are tularemia (*Francisella tularensis*) and sporotrichosis (*Sporotrichum schenckii*). Occasional causes include tuberculosis (*Mycobacterium tuberculosis*), syphilis (*Treponema pallidum*), and coccidioidomycosis (*Coccidioides immitis*). Viruses, fungi, and parasites are also possible causes. The organism may gain entry to the eye through the conjunctiva or from scratches (Krachmer et al. 2011).

Clinical Presentation

The presentation of Parinaud's oculoglandular syndrome differs depending on the etiology. In oculoglandular CSD, conjunctival lesions measuring 3–4 mm in diameter anywhere in the palpebral or bulbar conjunctiva appear within 1–3 weeks. Conjunctival nodules can be red, white, yellow, or gray and may be inflamed. Eyelid swelling is mild, and conjunctival ulceration may occur over the underlying granuloma. Enlarged preauricular, cervical, or submaxillary lymph nodes accompany the conjunctival granulomas. Other causes (e.g., tularemia, tuberculosis) can present with conjunctival ulceration. Symptoms include a red, irritated, painful eye, possibly fever, and a general ill feeling (Tu 2012).

Diagnosis

Patient history should include contact with pets and wild animals, with subsequent workup of serum and conjunctival cultures. Physical examination may show a red, tender, inflamed eye, tender preauricular lymph nodes, and/or conjunctival nodules. A fourfold increase in immunofluorescent antibody (IFA) serum titers and sometimes PCR-based techniques are useful in identifying *Bartonella henselae* and many other bacteria. The diagnosis of CSD is based on the following: (1) lymphadenopathy, (2) history of cat contact or recent cat scratch or bite, (3) presence of primary inoculation site, (4) positive IFA or PCR test for *B. henselae*, and (5) absence of other causes of lymphadenopathy.

Differential Diagnosis

Cat-scratch disease, tularemia, sporotrichosis, tuberculosis, syphilis, coccidioidomycosis, many rare bacterial causes (e.g., sarcoidosis, chancroid, lymphogranuloma venereum, etc.), virus/fungus/parasite.

Prophylaxis

Frequent hand washing after handling pets, avoid being scratched by cats, avoid contact with wild animals.

Therapy

Depending on the cause of the infection, appropriate antibiotics can be used, especially in immunocompromised patients. Rarely, surgery may be necessary to clear infected tissue.

Prognosis

CSD and its oculoglandular complications are usually self-limited in immunocompetent patients. In immunocompromised patients, CSD is more aggressive and can progress to disseminated infection. If diagnosis and treatment occur early, outcomes are generally very good.

Epidemiology

Parinaud's oculoglandular syndrome is generally a rare presentation, e.g., CSD (4–8%) and tularemia (1%).

Oculomandibulofacial Dyscephaly

► Oculomandibulofacial Dyscephaly (Hallermann-Streiff Syndrome)

Oculomandibulofacial Dyscephaly (Hallermann-Streiff Syndrome)

Sherveen Salek
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Francois dyscephalic syndrome; Oculomandibulofacial dyscephaly

Definition

Hallermann-Streiff syndrome (HSS) is clinically defined by its characteristic skull morphology, brachycephaly with frontal bossing, microphthalmia, cataracts, hypotrichosis, micrognathia, beaked nose, dental abnormalities, atrophy of skin, and short stature. The clinical diagnosis is felt to be especially doubtful in the absence of microphthalmia or cataracts.

Etiology

HSS is of rare sporadic inheritance.

Clinical Presentation

Patients typically present at a young age with skeletal and craniofacial abnormalities; poor vision; skin atrophy, especially in the facial regions; and alopecia along suture lines, along with ocular abnormalities. Clouding of the lenses may be seen at birth. Given the association with tracheomalacia, patients may also present with snoring or daytime hypersomnolence. Clinicians should recognize that these patients pose a difficult airway if general anesthesia and intubation are to be attempted.

Additional ophthalmologic manifestations as catalogued by Roulez and colleagues in 2008

include blue sclera, antimongoloid slanting of the palpebral fissures, keratoglobus, iris atrophy, peripheral anterior synechiae, posterior synechiae, persistent fetal vasculature, amorphous retrolenticular membrane, vitreous opacities, optic disc pallor, optic nerve coloboma, chorioretinal pigmentary changes, retinal folds, and glaucoma. The glaucoma in HSS is felt to be of phacolytic etiology from progression of cataract.

Diagnosis

There is no available laboratory diagnosis.

Differential Diagnosis

Hutchinson-Gilford progeria, Werner syndrome, oculodentodigital dysplasia, acromandibular dysplasia, lethal osteocraniostenosis.

Prophylaxis

There is no prophylaxis for this systemic congenital disorder.

Therapy

Early ophthalmologic evaluation in patients with HSS and surgical removal of the congenital cataracts are recommended to optimize visual prognosis. Evaluation should include ultrasound biometry to assess axial length, given the presence of microphthalmia or nanophthalmos. Optical coherence tomography and electroretinography have also been used in isolated cases where HSS patients also had retinal pigmentary changes. Consultation with craniofacial and ear, nose, and throat specialists is recommended to address dental and airway issues, respectively. Patients should receive counseling on the importance of dental hygiene, and surgical correction of clinically significant malocclusion has been recommended, which may also address respiratory issues related to micrognathia.

Prognosis

Patients may experience poor vision and amblyopia if cataract extraction is not performed at an early age. Vision potential is difficult to ascertain given the sporadic nature of the syndrome. The role of corneal opacities and retinal pigmentary changes on final visual outcome has not been definitely ascertained. Feeding difficulties and obstructive sleep apnea should also be recognized and evaluated. Given the sporadic nature of HSS, there is insufficient data on long-term functional outcomes in these patients.

Epidemiology

The disease is of sporadic inheritance, and about 150 cases have been reported globally since its first description in 1893.

Ocusert Delivery System

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Synonyms

Capsule-type drug delivery system

Definition

The ocusert delivery system consists of a drug reservoir surrounded by two thin drug release-controlling membranes, made of ethylene vinyl acetate (EVA) copolymer. This system is held together by a retaining EVA ring. The drug is delivered by dissolving in the EVA and diffusing along a concentration gradient. It is delivered to the eye at a constant rate (zero-order kinetics) for a given time interval.

This is the first rate-controlled and rate-specified drug delivery system and therefore improves the selectivity of the drug's action.

► Oncocytoma

Oncocytoma

Michael Hood
Department of Ophthalmology, Hamilton Eye Institute, University of Tennessee, Memphis, TN, USA

Synonyms

Nodular oncocytosis; Oncocyte; Oxyphile cell adenoma; Oxyphilic cystadenoma

Definition

Oncocytomas are benign proliferations of cells that arise from the epithelium of glandular tissue and are chiefly located in the head and neck region (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Mete and Asa 2010; Say et al. 2012). While these adenomas have been reported to occur in the salivary gland, thyroid, parathyroid, pituitary,

kidney, breast, and gastrointestinal tract (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Mete and Asa 2010; Say et al. 2012), this article will focus on oncocytomas arising in the ocular adnexa. The majority of ocular oncocytic lesions are located in the caruncle, but they have also been reported to arise in the conjunctiva, eyelid, lacrimal sac, lacrimal gland, and plica semilunaris (Biggs and Font 1977; Eglen 1982; Say et al. 2012). Malignant oncocytic adenocarcinomas have been reported in the literature, but they are exceedingly uncommon (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Say et al. 2012).

Etiology

The etiology of oncocytomas is not completely understood, but recent evidence suggests that the formation of these lesions may be related to mutations in the genes affecting oxidative phosphorylation (Say et al. 2012). Histologic and ultrastructural examination supports this theory, showing cells containing a cytoplasm that is filled with an overabundance of structurally abnormal mitochondria (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Say et al. 2012). It has been suggested these altered mitochondria cause metabolic disturbances that play a key role in the formation of these tumors (Morgan et al. 1998; Say et al. 2012).

Clinical Presentation

An oncocytoma typically presents in elderly individuals as a red-tan, painless mass that has developed in the ocular adnexa over a period of several months (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Say et al. 2012). The majority of ocular oncocytomas occur in the caruncle, and most are well-circumscribed, vascular nodules that appear to be subepithelial (Morgan et al. 1998; Say et al. 2012). Other clinical features may vary with the anatomic location of the tumor. Oncocytic lesions arising in the orbit have presented with unilateral proptosis, while those arising in the lacrimal sac have presented with unilateral epiphora, recurrent dacryocystitis, and a palpable mass in the lacrimal sac (Biggs and Font 1977; Say et al. 2012). All reported cases of ocular oncocytomas have been unilateral and solitary (Say et al. 2012).

Diagnosis

While oncocytomas have a typical clinical presentation, microscopic examination is required to make a definitive diagnosis. Histologically, these cells have a darkly eosinophilic cytoplasm arranged in a glandular pattern and frequently contain cystic spaces of inspissated amorphous material (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Say et al. 2012). Electron microscopy shows an overabundance of abnormally shaped mitochondria in the cytoplasm (Biggs and Font 1977; Eglen 1982; Morgan et al. 1998; Say et al. 2012).

Differential Diagnosis

Nevus, conjunctival cyst, and melanoma

Prophylaxis

There is no known prophylaxis for oncocytomas.

Therapy

Treatment of oncocytomas is by local surgical excision with or without cryotherapy. With rare exception, benign oncocytomas do not recur after they are removed (Say et al. 2012).

Prognosis

Excellent. As stated above, local excision is typically curative for benign oncocytomas.

Epidemiology

Ocular adnexal oncocytic lesions are estimated to occur at a rate of 0.3 per million people per year (Say et al. 2012). Oncocytomas most often arise in

the seventh decade of life and are more common in women (Biggs and Font 1977; Morgan et al. 1998).

Synonyms

Fisher's one-and-a-half syndrome

Definition

The one-and-a-half syndrome is a clinical disorder of extraocular movements characterized by a conjugate horizontal gaze palsy in one direction plus an internuclear ophthalmoplegia (INO) in the other direction (Fisher 1967). The syndrome is usually due to a single unilateral lesion of the paramedian pontine reticular formation (PPRF) or the abducens nucleus on one side (causing the conjugate horizontal gaze palsy), with interruption of internuclear fibers of the ipsilateral medial longitudinal fasciculus (MLF) after it has crossed the midline from its site of origin in the contralateral abducens nucleus (causing failure of adduction of the ipsilateral eye) (Wall and Wray 1983). There is also a contralateral horizontal dissociated abducting eye nystagmus on attempted horizontal gaze.

Etiology

One-and-a-half syndrome can be caused by any lesion in the pons including multiple sclerosis (MS), brain stem stroke, brain stem tumors, and arteriovenous malformations (Wall and Wray 1983).

Occurrence

The one-and-a-half syndrome can affect patients of any age, either gender, or any race depending on structural etiology.

Onychoosteodysplasia (Nail-Patella Syndrome)

Sherveen Salek
Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins Hospital, Baltimore, MD, USA

Synonyms

Fong disease; Nail-patella syndrome; NPS; NPS1; Turner-Kieser syndrome

Definition

Onychoosteodysplasia is defined primarily by dysplasia of the nails, or absent or hypoplastic patellae. Other features include iliac horns, abnormality of the elbows interfering with pronation and supination, as well as nephropathy that resembles glomerulonephritis. The disorder is also associated with primary open-angle glaucoma.

Etiology

The disorder is caused by a heterozygous mutation in the LIM-homeodomain protein LMX1B on chromosome 9q34. Lmx1b has a crucial role in dorsal-ventral patterning of the vertebrate limb. Mouse models with LMX1B disruption demonstrate skeletal defects, hypoplastic nails, absent patellae, and renal dysplasia.

Clinical Presentation

The majority of patients presents with skeletal or nail abnormalities, which are present within the first several years of life. Primary open-angle glaucoma is found in 7–31% of NPS1 patients, with a mean age of presentation around 48 years. Lichter and colleagues identified cosegregation of POAG and NPS.

Diagnosis

Prenatal ultrasound has been used for third-trimester diagnosis of NPS, although its clinical utility is limited given the incidence of renal failure of less than 25% in patients. Ultrasound appears to have little prognostic value in diagnosis of NPS1. The disorder can be diagnosed through mutations in the LMX1B gene, although commercial assays are not available at the time of this publication.

Differential Diagnosis

Small patella syndrome (ischiopatellar dysplasia), patella aplasia-hypoplasia, Meier-Gorlin syndrome, genitopatellar syndrome, DOOR syndrome, Coffin-Siris syndrome, RAPADILINO syndrome, Rothmund-Thomson syndrome, Senior-Løken syndrome.

Prophylaxis

Eye screening exams are recommended from an early age, as soon as patients are able to tolerate slit-lamp examination, tonometry, and gonioscopy.

Therapy

Medical therapy with topical ocular antihypertensives and/or surgery may be recommended to manage POAG associated with NPS.

Prognosis

Primary open-angle glaucoma tends to manifest in the fourth decade of life in NPS, with a mean age

of presentation in the late 40s. There is not enough data to demonstrate the likelihood of progression of the glaucoma to requiring surgery or damage to the optic nerve with visual field loss. Optical coherence tomography and Humphrey visual fields can be used as part of routine screening to assess for potential vision loss as part of the annual examination with patients with NPS. Patients should also be monitored for the presence of proteinuria, which can indicate ongoing glomerulonephritic damage from renal dysplasia.

Epidemiology

Skeletal and nail abnormalities are present from childhood, while primary open-angle glaucoma does not manifest until patients are in their late 40s. There is no racial or geographic predisposition to NPS.

Open-Angle Glaucomas

Ronald L. Gross
Department of Ophthalmology, WVU Eye Institute, Morgantown, WV, USA

Definition

It is vitally important to recognize that the title is "glaucomas" not "glaucoma." This establishes the key concept that although glaucoma is defined by the characteristic changes in structure and function of the optic nerve, there are multiple, different underlying causes that result in the disease we call glaucoma (American Academy of Ophthalmology 2012). Many of the contributory factors have been identified, but we hope there are many more that will be identified going forward that will give us greater insight into the pathophysiology and treatment of this potentially blinding condition. In open-angle glaucomas, there is the additional requirement that trabecular meshwork be visible on gonioscopy. Open-angle glaucomas (OAG) are generally divided into primary and secondary causes. Primary (POAG) implies that no known underlying cause can be identified, whereas secondary implies that at least there is support for an identifiable underlying etiology for the optic nerve damage such as pigment dispersion, steroid-induced or exfoliation syndrome (Ritch et al. 1996).

Epidemiology

The World Health Organization estimated the incidence of POAG to be 2.4 million persons per year with the prevalence of blindness to be four million worldwide. Glaucoma was calculated to be the cause of 12.3% of blindness, making it the second leading cause worldwide. OAG has a prevalence of between 0.8% and 7.0% of the adult population, with a significant increase in older individuals and specific ethnic groups. The prevalence among individuals of African or Latino heritage is up to four times greater than

Caucasians; these patients have a greater risk of blindness as well.

Etiology

Open-angle glaucoma is often associated with elevated intraocular pressure (IOP). The increased levels of IOP are essentially always a result of decreased outflow rather than increased aqueous humor production. The decreased outflow is thought to be related to decreased flow through the trabecular meshwork, with the juxtacanalicular tissue being the site of greatest resistance. Once in the canal of Schlemm, there remains some resistance that is further increased in conditions that result in elevation of the episcleral venous pressure.

It is the susceptibility of the optic nerve to damage that ultimately determines if glaucoma is present. This damage affects the axons that comprise the optic nerve and may cause focal and diffuse loss. Focal loss is generally more easily identified and is more common in the superior and inferior poles of the optic disc. In those with normal tension glaucoma (NTG), damage occurs at what would otherwise be "normal" levels of IOP. In those with ocular hypertension, it is presumed that the optic nerve is better able to tolerate elevated IOP and no damage is observed (Alligham 2005).

Clinical Presentation

OAG has been referred to as the "sneak thief of sight" as there are usually minimal if any symptoms until late in the course of the disease. As a chronic disease, the loss of visual field tends to be slow and gradual, primarily affecting the peripheral vision. Many patients adapt to this loss and are unaware of it until it is of such severity that it affects their central vision. Multiple population-based studies have shown that at least 50% of the individuals with glaucoma have not been diagnosed. Since there are essentially no symptoms, an examination is required to make the diagnosis. Factors that increase the risk of developing glaucoma include older age, a positive family history of glaucoma, and African or Latino ancestry (Shaarawy et al. 2009).

Diagnostics

Gonioscopy with visualization of the anterior chamber angle is necessary to make the diagnosis of OAG and differentiate it from angle closure. It also allows identification of potential causes of secondary OAG including increased pigmentation in pigmentary glaucoma, a Sampaolesi's line in exfoliation syndrome, or neovascularization in early neovascular glaucoma. It is preferable to use a 4-mirror lens such as the Posner or Zeiss to facilitate compression gonioscopy. www.gonioscopy.org is an excellent site for further information.

Visual fields measure the functional performance of the visual pathway. In glaucoma, nerve fiber layer defects consistent with damage to the optic nerve are the typical focal findings. Unfortunately, static perimetry is not a very sensitive test to detect early damage. It has been shown that substantial loss of the optic nerve can occur prior to evidence of visual field loss. With severe damage, functional measurements may be more appropriate to determine progression.

Optic disc photographs and nerve fiber layer imaging are very useful to establish the baseline characteristics of structure and evaluate progression. Combined with a critical high magnification, stereoscopic examination, these allow early diagnosis, usually before visual field loss, and can identify increased risk of progression due to the presence of disc hemorrhages or beta-zone parapapillary atrophy.

Tonometry allows measurement of the IOP and can help determine the potential risk of developing glaucoma in the ocular hypertensive patient as well as determine the impact of therapy. Applanation tonometry results can be affected by central corneal thickness; however the exact magnitude of the impact is not currently known.

Comprehensive eye examination allows for the identification of possible etiologies of secondary glaucomas such as iris transillumination defects

and iris neovascularization. Pupillary examination for an afferent pupillary defect can help identify those with asymmetric optic nerve damage.

Differential Diagnosis

Historically, there has been great controversy as to whether normal tension glaucoma (NTG) represents just a part of the spectrum of open-angle glaucomas or is in fact a separate disease. It is defined as glaucomatous damage that occurs at an IOP $\leq$ 21 mm Hg. Since the level of IOP is not part of the definition of glaucomas, NTG is an OAG; however, in many instances the presence and frequency of specific findings and risk factors such as optic disc hemorrhages, systemic hypotension, and an early presentation of dense, paracentral scotomas tend to be different than POAG.

Prophylaxis

The Ocular Hypertension Treatment Study (OHTS) demonstrated a reduction of risk of developing POAG in patients with ocular hypertension with a 20% reduction in IOP. The decision to treat patients with elevated IOP and no glaucoma damage is individualized and based upon risk factors identified in OHTS and the European Glaucoma Prevention Study. A risk calculator is available: http://ohts.wustl.edu/risk/calculator.html

Therapy

Currently, the only modifiable risk factor is IOP. IOP reduction in OAG can be effectively accomplished with topical medications, laser trabeculoplasty, and surgical intervention. Medications can decrease aqueous humor production (beta-adrenergic blockers, carbonic anhydrase inhibitors, alpha-adrenergic agonists) or increase aqueous humor outflow (prostaglandin analogs, alpha-adrenergic agonists). Laser trabeculoplasty increases outflow through the trabecular meshwork. Filtration surgery increases aqueous outflow by either by passing at the normal outflow mechanisms (tube shunts, guarded filtration) or by improving flow through the canal of Schlemm. Multiple studies that include a wide range of patients with OAG have shown the consistent benefit of therapy in decreasing the risk of developing glaucoma or slowing the progression of existing glaucoma (Gross 2001).

Prognosis

The risk of developing POAG has been shown to be increased due to elevated IOP, increasing age, thin central corneal thickness, positive family history, and ethnicity. The risk of progressive glaucoma damage has been shown in multiple studies to be reduced with IOP reduction. In general, the lower the IOP, the less the risk of progression. Additional factors that increase the risk of progressive damage include optic disc hemorrhages, increasing age, more advanced visual field loss, and African ancestry.

Ophthalmic Viscosurgical Devices

Melanie Bödemann and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Viscoelastic substances

Definition

Ophthalmic viscosurgical devices (OVDs) are a class of gel-like, clear substances with different quality characteristics that are used in refractive and intraocular surgery for safer maneuvers in the anterior and posterior chamber. OVDs differ in the rheologic polymer type(s), concentration, and chain length. They are commonly based on sodium hyaluronate, and their different qualities determine their physical and chemical condition, e.g., viscosity, elasticity, and cohesion.

Epidemiology

OVDs are not commonly used in ophthalmic surgery. Its use is subjected in difficult cases and depends on the decision of the surgeon.

History

In 1976 the first commercially available viscoelastic substance sodium hyaluronate (Healon) gained a US Investigational New Drug Application. The explicit perception ophthalmic viscosurgical device was created years later in 2000 by Arshinoff. OVDs were first introduced to maintain space in the eye during the implantation of intraocular lenses. With the development of different properties, additional functions of OVDs were introduced, e.g., protection of corneal endothelium or stabilization of the iris and pupil in patients with an iris floppy syndrome.

Clinical Features

Perfect OVDs should have the possibility to remain in the eye during the surgery and can be removed easily at the end of the process. In former times ophthalmic viscosurgical devices were either cohesive or dispersive depending on their molecular weight, concentration, and viscoelastic profile. Modern OVDs have due to their physical and chemical properties the ability to change from a viscous cohesive profile at low shear rate to fracturable at higher shear rates. This accomplishment is called viscoadaptivity. However, despite having wide spectra in its use, OVDs are not

without well-known side effects as there are intraocular pressure elevation and wound burns.

Etiology

See "History" section above.

Treatment

With the development of different kinds of OVDs with different viscoelastic properties, many branches of appropriateness have been developed. OVDs are used to maintain the space in the eye, they have the ability to protect the corneal endothelium, and they have an inhibitory effect against free radical formation and platelet aggregation. They are used for complicated cataract surgery cases, and their indications have expanded to other surgeries such as corneal lamellar surgery and glaucoma surgery. They are of an important use in intraoperative floppy iris syndrome and capsulorhexis in intumescent and pediatric cataracts.

[6]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Definition

Internuclear ophthalmoplegia (INO) is a disorder of conjugate horizontal gaze. When a patient with INO is asked to move their eyes horizontally, the eye contralateral to the gaze direction will be unable to adduct, and the eye ipsilateral to the gaze direction will demonstrate nystagmus. For example, a right INO will present with left eye nystagmus and an inability of the right eye to adduct upon gaze to the left (Hickey 2003).

Etiology

INO is caused by damage to the medial longitudinal fasciculus (MLF), a fiber tract that extends from the rostral midbrain to the spinal cord. The MLF contains many important tracts including the pathway connecting the abducens nucleus and oculomotor nucleus, which is important for coordinating the eyes during horizontal

conjugate gaze (Riordan-Eva and Hoyt 2011). For example, a patient with right INO will have damage to the right MLF, preventing communication between the left abducens nucleus and the right oculomotor nucleus. As the patient tries to look to left, the left eye will abduct, but the right eye will remain stationary (Hortan 2012). In addition, the left eye will demonstrate horizontal nystagmus due to cortical eye movement control centers attempting to compensate for the lack of adduction of the right eye (Riordan-Eva and Hoyt 2011).

Occurrence

INO can be caused by many conditions including multiple sclerosis (MS), brainstem infarction, tumors, arteriovenous malformations, Wernicke's encephalopathy, and encephalitis. INO ranges from a mild form where the adducting eye moves slower than normal resulting in transient diplopia to a severe form where there is constant diplopia upon lateral gaze. In a young patient with a bilateral INO, one would suspect MS, whereas in an older patient, one would instead suspect brainstem infarction (Riordan-Eva and Hoyt 2011).

Classification

None

Synonyms

Optic neuropathy

Definition

True optic atrophy is a pathologic description of the ophthalmoscopic finding of axon loss at the optic nerve head. The nerve fiber layer and visible optic nerve change can be caused by any lesion along the anterior visual system pathway (retinogeniculate) from the retina to the lateral geniculate nucleus (LGN). Optic atrophy is not a disease by itself, but rather a sign of various disorders in the anterior visual system. Sometimes, an optic nerve appears atrophic but does not have true nerve fiber layer loss (e.g., physiologic optic disc pallor).

Symptoms of Optic Atrophy

Cranial nerve (CN) II is composed of a bundle of nerve fibers that originate in the retina, exit the eye at the optic disc, and then project to the optic chiasm, optic tract, and then the lateral geniculate body. Optic atrophy is typically a sign of ipsilateral retinopathy or optic neuropathy but can result from any lesion anterior to the cell body (e.g., optic chiasm and optic tracts) in the lateral geniculate body.

Thus, patients with optic atrophy can present with visual acuity loss, visual field defect, dyschromatopsia, decreased contrast sensitivity, dimness or decreased light brightness, or complete blindness.

Clinically, optic atrophy presents as an ophthalmoscopically visible change in the color and structure of the optic disc. A healthy optic disc is typically a yellow-pink to reddish color but changes to a washed-out, pale color when it atrophies. These changes are associated with varying degrees of vision loss or dysfunction and may be found as an incidental finding in some cases.

Patients with nasal nerve fiber loss (corresponding to temporal visual field loss) can develop a band of atrophy across the optic nerve called "band" or bowtie optic atrophy. Thus, patients with a bitemporal hemianopsia might have bilateral band atrophy, and patients with a homnonymous hemianopsia from an optic tract lesion can have band atrophy in the eye with the temporal visual field loss (corresponding to the nasal fiber loss in the optic nerve).

Etiology

Many diseases can lead to damage or atrophy of the optic nerve, so it is important to discover the specific cause, for example, glaucoma (usually producing cupping of the disc rather than optic atrophy per se):

- Retinopathy and retinal vascular disease
- Multiple sclerosis (demyelinating optic neuropathy)
- Ischemia (e.g., ischemic optic neuropathy)
- Trauma (traumatic optic neuropathy)
- Inflammatory (e.g., sarcoidosis and vasculitis)
- Infiltrative (leukemic and other malignancies)
- Compression (e.g., pituitary, brain, or optic nerve tumors)
- Toxic (e.g., ethambutol, heavy metals, methanol) exposure or nutritional deficiencies (e.g., B12 or folate deficiency)
- Infections (e.g., syphilis, tuberculosis, Lyme disease, meningitis)
- Congenital, hereditary, or other genetic causes

The mode of onset of visual deficits can be an important indicator of the cause of the optic atrophy. Rapid or acute onset is more typical of ischemia, demyelination, inflammation, and trauma. A gradual onset over several months can be due to compressive tumor, toxic exposure, or nutritional deficiencies.

Occurrence

Some studies show that the prevalence of all blindness attributable to optic atrophy is between 0.04% and 0.8%. Thus of all the probable causes, less than $<1\%$ of all blindness is caused by optic atrophy.

Treatment

Unfortunately, optic atrophy per se cannot be reversed, but there may be variable recovery of function following treatment of the underlying etiology.

Prognosis

The prognosis depends upon the underlying etiology.

Optic Disc

▶ Fundamental Considerations Regarding the Optic Nerve

Optic Disc (Optic Nerve Head)

Annette Giangiacomo
Ophthalmology, Emory University, Atlanta, GA, USA

Synonyms

Optic nerve head

Definition

The optic disc is the most anterior (or distal) portion of the optic nerve and extends from the surface of the retina to the myelinated portion of the optic nerve, which begins just behind the sclera. It is composed of about 1.2 million nerve fibers (axons) that originate in the ganglion cell layer of the retina.

Basic Characteristics

The optic disc is located nasal to and slightly superior to the macula and is an aggregation of fibers of the retinal nerve fiber layer as they exit the intraocular space through the sclera to form the optic nerve. Retinal ganglion axons bend acutely as they enter the optic nerve and are divided into about 1000 fascicles. They then pass through one of a few hundred holes that perforate the lamina cribrosa, the collagenous fenestrated support of the optic disc. The blood supply of the optic disc is the central retinal artery anteriorly but shifts to branches of the ophthalmic artery posteriorly. The average size of the optic disc is 1 mm in the anterior-posterior dimension, 1.5 mm horizontally, and 1.8 mm vertically; however, there exists a wide variation of dimensions seen in normal individuals.

The optic disc has a central depression, or a physiologic cup, which is typically one-fourth to one-third the width of the optic disc and located approximately centrally. The cup is small or nonexistent in small optic discs and can be larger (and still considered normal) in eyes with larger optic discs. The cup-to-disc ratio is a typical way of recording the appearance of the optic disc and is the ratio of cup diameter to disc diameter. The ISNT rule describes the normal appearance of the optic nerve regarding the relationship between the rim thickness of the inferior, superior, nasal, and temporal aspects of the optic disc. The ISNT rule says that the inferior rim should be as thick or more thick than the superior rim which should be as thick or more thick than the nasal rim which should be as thick or more thick than the temporal rim. So in a normal disc, the thickest rim should be the inferior rim, and the others are gradually thinner with the temporal being the thinnest (I → S → N → T). Violation of the ISNT rule should raise suspicion about the presence of glaucoma, in part because in glaucoma the superior and inferior poles are particularly susceptible to damage which can result in relative thinning of one of these rims. For example, if the inferior rim is thinner than the superior rim, there should be suspicion for the presence of glaucoma. The utility of applying the ISNT rule to help detect glaucoma has been supported by research. Aside from the cup-to-disc ratio and the location of the cup relative to the rims of the optic disc, the appearance of the optic disc rim, or the area of the optic disc surrounding the cup, is important. For example, pallor of the optic disc rim, the presence of hemorrhages, abnormal blood vessels, or swelling may help differentiate between diagnoses. It is

recommended that a detailed description of the optic disc be recorded in the medical record, either via drawing or photography.

The optic disc is susceptible to elevated intraocular pressure which can cause glaucomatous optic atrophy characterized by enlargement of the optic disc cup over time or progressive cupping. Progressive cupping may be concentric or appear as a more localized change with focal notching of the rim of the optic disc (hence the ISNT rule). Other forms of optic atrophy cause pallor without increased disc cupping. The development of inferior or superior thinning of the optic disc rim in glaucoma may have a physiologic basis. The mechanical theory holds that because the lamina cribrosa is poorly supported at the superior and inferior edges of the disc, pressure forces acting on the lamina cribrosa may cause the initial damage. Alternatively, microcirculatory abnormalities may play a role in the development of glaucoma.

Optic disc edema occurs when axoplasmic transport of materials needed to maintain the axons of the optic nerve is blocked. Disc edema can be associated with increased intracranial pressure, ocular hypotony, increased intraocular pressure, tumors, or central retinal vein occlusion. Some clinical signs of optic disc edema are blurring of the optic disc margins, decrease in size or loss of the cup, venous congestion, papillary and peripapillary hemorrhages, and hyperemia of the optic disc.

Definition

Optic disc edema can occur in central retinal vein occlusion (CRVO) or hemicentral retinal vein occlusion (HCRVO). Depending on the type and severity of the occlusion, the optic disc may be at risk of developing edema, disc neovascularization (NV), retinochoroidal venous collaterals (optociliary shunt vessel), and disc hemorrhages. Conversely, the anatomy of the optic disc and its surrounding vascular structures can play a role in the development of CRVO and HCRVO.

Etiology

The optic disc is the site of arterial inflow and venous outflow for the retina, with the central retinal artery and vein exiting the eye down the middle of the optic nerve. In most patients, occlusion of this vein results in CRVO. However, in 20% of the population, there are two trunks of the central retinal vein that exit the eye at the optic disc.

Occlusion of only one of these trunks results in HCRVO, leaving half of the retina unaffected. There are two distinct categories of both CRVO and HCRVO, ischemic and nonischemic (sometimes referred to as venous stasis retinopathy). The etiology of any retinal vein occlusion (CRVO, HCRVO, BRVO) is typically multifactorial in origin. However, in younger patients evidence suggests that optic disc vasculitis or hypercoagulable state may be responsible for the thrombosis in RVO.

Edema of the optic disc is a relatively common sign of CRVO/HCRVO. NV of the optic disc (NVD) may occur in ischemic RVO cases and is believed to be the result of vascular growth-promoting cytokines (e.g., FGF, VEGF, Ang1, Ang2, PDFG) released by tissue in response to an ischemic environment. These immature and leaky blood vessels (NV) can subsequently hemorrhage into the vitreous.

Venous disc collaterals can occur in ischemic or more commonly in nonischemic CRVO/HCRVO and may be seen as the only sign in otherwise asymptomatic nonischemic RVO patients. Thus, it has been proposed that collateral formation is evidence of the gradual nature by which some retinal vein occlusions form. It is believed that disc collaterals form between the retinal and choroidal circulation by expansion or recanalization of existing vascular channels in order to bypass the venous occlusion further downstream.

Clinical Presentation

Patients with CRVO may present with sudden unilateral blurred vision. Symptoms are often noticed upon waking up in the morning. In "impending" nonischemic CRVO, the blurring is relatively mild in the morning, but gets better throughout the day. In ischemic CRVO, the vision loss is sudden and severe. In HCRVO, these symptoms are similar, but vision loss may only affect half of the patient's visual field.

Vascular abnormalities of the optic disc such as neovascularization and collaterals can usually be identified with ophthalmoscopy, but can be more easily distinguished with fluorescein angiography (FA). Some nonischemic CRVO/HCRVO patients with disc collaterals may be relatively asymptomatic.

Diagnostics

Indirect or direct ophthalmoscopy can identify swelling of the optic disc, neovascularization, and disc collaterals. OCT should be used to confirm and quantify the presence of disc edema. In patients with suspected CRVO/HCRVO, FA imaging can be used to evaluate the overall status of the retinal vasculature. In relation to disc pathology, FA can evaluate neovascularization, flow through venous collaterals, and non-perfusion of the surrounding retina. Fundus autofluorescence imaging can detect in patients with recent ischemic CRVO a perivenular hypoautofluorescence.

Differential Diagnosis

Retinal vasospasm, migraine, uveitis, closed-angle glaucoma, optic neuritis, and papilledema

Prophylaxis: Treat Risk Factors

Therapy

Treatment should be directed at underlying etiology (e.g., hypertension). Treatment of complications including NV glaucoma and elevated intraocular pressure should be considered.

Anti-VEGF agents have also been proven to be helpful in RVO.

Prognosis

In nonischemic CRVO/HCRVO, the prognosis is relatively good with about 50% of patients having their vision return to normal. However, the chance of converting from nonischemic to ischemic is about 13% in within 18 months. This risk increases with age. In ischemic CRVO/HCRVO, the prognosis is much worse due to permanent damage from macular ischemia. There is also a high risk of neovascular glaucoma (NVG).

Definition

An optic nerve glioma (ONG) is a rare tumor of the glial cells of the optic nerve. It is usually a pilocytic tumor that may also affect the optic chiasm or optic tract and rarely regresses spontaneously. ONG may cause swelling or atrophy of the optic nerve.

Etiology

Most ONGs are slow growing and histologically benign and occur most commonly in children. ONGs are associated with neurofibromatosis type 1 in up to 30% of patients.

Clinical Presentation

Symptoms include painless, progressive vision loss, proptosis, strabismus, and optic nerve edema or atrophy.

Therapy

Treatment may not be necessary and observation is the recommended first step in ONG especially in cases of NF1. Chemotherapy and in older children radiation therapy are options for patients with clinical and/or radiographic progression. Surgical resection usually results in worsening or complete visual loss and is not generally recommended in seeing eyes. Patients however with nonuseful vision, severe pain, or severe proptosis might benefit from surgical resection or debulking.

Synonyms

Cranial nerve II (CN II); Optic disk; Optic nerve head

Definition

The optic nerve ON (cranial nerve II) is an afferent sensory nerve that transmits visual input from the eye to the occipital cortex. The second of 12 paired cranial nerves, the optic nerve is unique because it is part of the central nervous system and develops from the diencephalon. The ON is surrounded by the meninges of the optic nerve sheath and is myelinated by oligodendrocytes. The ON consists of an average of 1.2 million axons originating from the retinal ganglion cells in the retinal nerve fiber layer which receives visual input from photoreceptors in the retina. The ON is approximately 1.5 mm in diameter and enlarges to 3.5 mm posterior to the lamina cribrosa because of the myelin nerve sheath, which protects and insulates the nerve. The optic nerve about is 45–50 mm long and consists of four portions: intraocular, intraorbital, intracanalicular, and intracranial. The intraocular portion (1 mm), also known as the optic nerve head (or optic disk), lies within the eye and is unmyelinated; this segment of the optic nerve is supplied by the short posterior ciliary arteries from the ophthalmic artery. The intraorbital segment (25 mm) extends from the posterior globe to the optic canal and is thicker in diameter because the optic nerve becomes myelinated posterior to the lamina cribrosa and is supplied by the ophthalmic artery. The intracanalicular segment (9 mm) traverses the optic canal along with the sympathetic plexus and the ophthalmic artery; it is supplied by the ophthalmic artery. The intracranial segment (15 mm) extends from the optic canal to the optic chiasm, and it is supplied by the internal carotid artery, anterior cerebral, and anterior communicating arteries.

The optic nerves from both eyes converge at the optic chiasm of the visual pathway and then separate into the optic tracts, which lead to the lateral geniculate nucleus (LGN) and the visual cortex in the brain. Damage to the optic nerve may cause permanent loss of vision, including visual acuity or visual field loss. Injury located anterior to the optic chiasm causes ipsilateral visual field defect.

Optic Nerve Edema

Anat Kesler
Neurology, Neuro-Ophthalmology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Optic Disc Edema

Swelling of the optic disc occurs when there is obstruction of axonal transport at the level of lamina cribrosa, which may result from compression, ischemia, inflammation, metabolic, or toxic reactions.

Papilledema means optic disc elevation due to increased intracranial pressure. Usually it is bilateral and symmetric, but it may be asymmetric or even unilateral.

The appearance of the optic disc in papilledema is indistinguishable from disc edema resulting from other causes. Regardless of its cause, the following clinical features of optic disc edema may be observed: elevation of the nerve head with variable filling in the physiologic cup; retinal vessels may appear to drape over the elevated disc margin, blurring of the disc margins, peripapillary nerve fiber layer opacifications, the retinal nerve fiber layers become grayish white, and opalescent margins obscuring portions of retinal vessels; hyperemia and dilatation of disc surface, retinal venous dilatation, and tortuosity; peripapillary hemorrhages, exudates or cotton wool spots, and retinal folds or macular edema.

The ophthalmoscope appearance of papilledema helps classify it into four stages:

1. Early papilledema – there is minimal hyperemia, swollen of the superior and inferior pole, and absence of spontaneous venous pulsations.
2. Full-blown papilledema – there is swollen of optic disc with hemorrhages and exudates, and the edematous peripapillary retinal nerve fiber layer is grayish white and opalescent that obscures the disc edge and retinal vessels within.
3. Chronic papilledema – hemorrhages and exudates are scarce, but capillary telangiectasia is evident on disc surface.
4. Atrophic papilledema – optic disc pallor.

Patients with papilledema may complain of transient obscurations of vision, which may occur in one or both eyes, typically lasting seconds; visual acuity loss is a late finding.

Visual field reveals only enlargement of the blind spots in the early stages of papilledema; in the more chronic forms, visual field defects appear most frequently as those of the inferior nasal nerve fiber bundle defects.

Optic Nerve Head Drusen

Anat Kesler
Neurology, Neuro-Ophthalmology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel

Optic Nerve Head Drusen

Optic nerve head drusen represent refractile, often calcified nodules located within optic nerve head.

The prevalence ranges from 0.34% in clinical settings to 2% in autopsy studies. Optic nerve head drusen are often bilateral (75–86%), but can be asymmetric.

The pathophysiology of optic nerve head drusen is unclear, most theories suggesting impaired ganglion cell axonal transport, probably related to a small scleral canal and mechanical obstruction, metabolic abnormalities associated with impaired transport, which may result in intra-axonal mitochondrial damage over time with subsequent calcification of the extruded.

Most patients with optic nerve head drusen do not experience symptoms; however, few patients (8.6%) may have transient visual obscuration. Visual fields defects remain either stable or worsen slowly.

The optic discs of patients with optic nerve head drusen appears elevated with indistinct or irregular margins and with an anomalous vascular branching pattern.

In childhood, optic nerve head drusen begin buried, and over the years the drusen become more discernible. When become visible, optic nerve head drusen appear as round whitish-yellow refractile bodies.

Ancillary tests: ultrasonography – calcified drusen maintain high echogenicity and do not produce widening of the intraorbital nerve.

Neuroimaging – on computerized tomography, calcified drusen can be seen as a bright signal at the junction of posterior globe and optic nerve.

Optical coherence tomography – it can show the discrete hyperrefractive drusen, but these are not evident in all cases.

Optic Neuritis

Definition

Multiple sclerosis (MS) can lead to optic neuritis where demyelination and inflammation of the optic nerve causes vision change or vision loss.

Etiology

Optic neuritis (ON) in MS is caused by inflammatory demyelination of the optic nerve. Acutely, T-cell-mediated inflammatory release of cytokines leads to destruction of oligodendrocytes, while, chronically, B cells and microglia-related inflammation cause damage. Recovery can occur within days to weeks due to remyelination and redistribution of sodium channels; however, the recovery is not 100%, and the redistribution of the sodium channels can leave neurons more vulnerable to future insult.

Clinical Presentation

Up to 90% of patients with ON present with central vision loss in combination with dull retrobulbar, periocular, or mild orbital pain upon eye movement. A loss of color vision and contrast sensitivity often accompany the decline in visual acuity. Less commonly, patients present with peripheral vision loss, flashes, photophobia, and decreased depth perception. The swinging pen light exam will often demonstrate and a relative afferent pupillary defect unless both optic nerves are involved. Typically the fundoscopic exam initially is normal (i.e., retrobulbar optic neuropathy) but sometimes reveals a mildly swollen optic disk if the optic nerve lesion is anteriorly located.

Diagnostics

The primary means of diagnosing ON radiographically is magnetic resonance imaging (MRI) of the orbit and brain with fat suppression. This might show an enhancing ipsilateral optic nerve, and the brain MRI might show periventricular white matter lesions with or without enhancement.

Differential Diagnosis

Many other inflammatory or infiltrative diseases such as acute ischemic optic neuropathy, Leber hereditary optic neuropathy, granulomatous

inflammation, other autoimmune diseases, infection, severe sinusitis, neuroretinitis, posterior uveitis, vasculitis, malignancies, and paraneoplastic syndromes and cause optic neuritis-like symptoms.

Prophylaxis

Immunomodulatory therapy might reduce the number of MS attacks including recurrent ON.

Therapy

Much like MS, the mainstay therapy for optic neuritis due to MS is initial intravenous (IV) corticosteroids such as methylprednisolone followed by a course of oral corticosteroids. IV immunoglobulin has also been shown to have possible benefit and, in some rare cases of optic neuritis unresponsive to corticosteroids plasmapheresis, has been used. In the ONTT, IV steroids sped the rate of recovery but did not change visual outcome compared with oral steroids or placebo. Oral steroids in conventional doses however were associated with a higher rate of recurrence of ON and are not recommended in conventional doses for ON.

Prognosis

The symptoms of optic neuritis typically peak within a few days but take several weeks to fully disappear. More importantly, though, optic neuritis is an indicator of current MS or possible future onset of MS. According to the longitudinal Optic Neuritis Study Group, the 15 year probability for developing MS after optic neuritis is 50%, but in patients with multiple white matter lesions, the risk is higher (>70%) This probability increases with every white matter abnormality detected by MRI at the time of the optic neuritis episode.

Epidemiology

The incidence of unilateral optic neuritis is between 0.94 and 2.18 per 100,000 per year around the world with the incidence of bilateral optic neuritis much lower than unilateral optic neuritis.

Synonyms

Demyelinating optic neuropathy; Idiopathic optic neuritis; Inflammatory optic neuropathy; Retrobulbar optic neuritis

Definition

The term optic neuritis (ON) for the purposes of this entry will refer to idiopathic or demyelinating dysfunction of the optic nerve.

Etiology

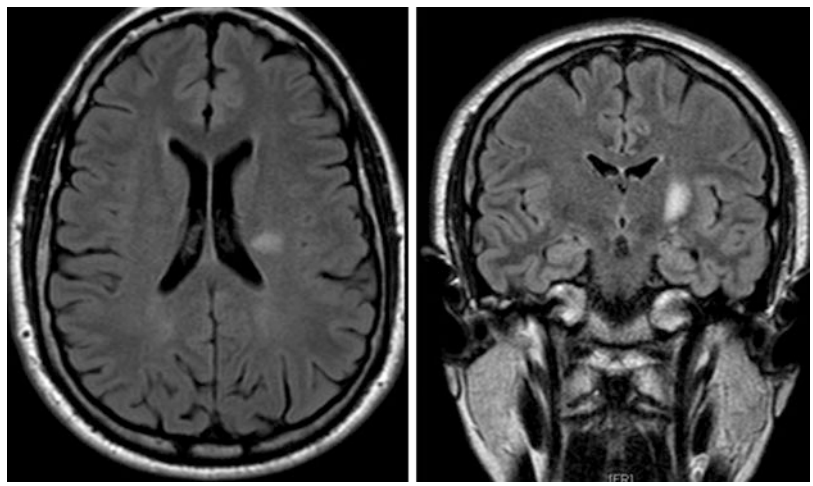
Although we use the term ON to typically describe idiopathic or demyelinating optic neuropathy, other optic neuropathies can result from non-demyelinating processes and can mimic the clinical presentation of ON. These optic neuropathies include autoimmune or inflammatory (e.g., systemic lupus erythematosus and sarcoidosis), infectious (e.g., cat scratch neuroretinitis), toxic (e.g., ethambutol), neoplastic or compressive (e.g., meningioma), nutritional (e.g., B12 or folate deficiency), ischemic (e.g., anterior ischemic optic neuropathy (AION)), and hereditary (e.g., Leber hereditary optic neuropathy (LHON)) disease. For the purposes of this entry, we reserve the term ON for idiopathic or demyelinating ON and prefer the term "optic neuropathy" for other non-ON etiologies (Fig. 1).

Clinical Presentation

The typical presentation of ON is acute to subacute (hours to days) onset of a unilateral, painful loss of vision (usually described as pain with eye movement in 92% of the cases). Demyelinating ON typically affects Caucasian adults between 15 and 45 years, but the epidemiology of ON is different depending on the incidence and prevalence of demyelinating disease (i.e., MS) compared with other etiologies (e.g., infectious). A female predominance is noted in ON in up to 75% of the cases, but ON may affect either gender. Although the majority of ON is unilateral at presentation in adults, bilateral cases are more common pediatric patients, and in some populations of non-European descent, the presentation of ON is often different (e.g., African, Indian, and Asian populations). In the Asian population, for example, ON may occur in the setting of an opticospinal presentation (neuromyelitis optica (NMO)) than typical "Western" MS.

In a large, National Eye Institute (NEI)-sponsored trial, the Optic Neuritis Treatment Trial (ONTT), the most common symptom of ON was central vision loss (92.2%), and the second most common symptom was pain, typically retro-orbital pain worse with eye movement (92%).

The visual acuity in ON is variable and may range from normal (20/20) to no light perception. A relative afferent pupillary defect (RAPD) is usually seen in the affected eye unless the disease is bilateral and symmetric. Color vision loss (dyschromatopsia) is also a common finding and may be out of proportion to the visual acuity loss. The visual field in ON is likewise variable and can



Optic Neuritis: Overview, Fig. 1 Fluid attenuation inversion recovery (*FLAIR*) T2-weighted magnetic resonance imaging of the head shows a typical periventricular white matter lesion consistent with demyelination

include ipsilateral central or any nerve fiber layer-type defect. Asymptomatic contralateral eye involvement may also be seen in patients presenting acutely with unilateral ON. The remainder of the ocular examination in ON is typically normal in demyelinating disease, and the presence of anterior or posterior segment inflammatory signs (e.g., uveitis) should prompt consideration for inflammatory or infectious etiologies. In addition, although clinically there is an optic neuropathy, the fundus is typically normal in demyelinating ON (e.g., retrobulbar optic neuropathy). Optic disc edema however can be seen in up to one third of cases, but typically the disc edema when present is only mild. The presence of severe disc edema, marked peripapillary hemorrhages, cotton wool patches, or retinal exudates with macular star should prompt consideration for non-demyelinating etiologies for the optic neuropathy.

Diagnostics

The diagnosis of ON is a clinical one, but further evaluation is recommended for patients with ON. In the United States, the primary recommended imaging modality for ON is magnetic resonance imaging (MRI) of the brain with gadolinium to evaluate for demyelinating disease. A concomitant orbital MRI with fat suppression and gadolinium might be useful to show enhancement of the optic nerve and to exclude alternative etiologies in atypical cases. Up to 94% of patients with active acute ON will show an enhancing (i.e., active) optic nerve on the post-contrast MRI, and the absence of this radiographic finding should make the diagnosis of typical ON suspect. Although rarely compressive etiologies may mimic the clinical presentation of ON (e.g., pituitary apoplexy or ophthalmic artery aneurysm), the primary purpose of the MRI in typical ON is for diagnostic and prognostic purposes for demyelination (i.e., MS).

The cranial MRI in MS may show the typical demyelinating periventricular, white matter lesions. These lesions are often transversely oriented, oval shaped, and located in key areas such as the corpus callosum. The presence of different aged lesions (enhancing T1-weighted MRI lesions versus other T2 lesions) may be useful for demonstrating radiographic dissemination in space and time. Cerebrospinal fluid (CSF) testing for oligoclonal bands and elevated immunoglobulin although not required in typical ON may be useful for supporting a diagnosis of demyelinating disease, but in general these decisions and discussions are best left to the consultant neurologist and not the ophthalmologist. In the ONTT, other laboratory testings (e.g., syphilis serology, antinuclear antibody, chest radiography) in typical ON cases did not provide any additional diagnostic information, and likewise in those patients who had undergone CSF analysis, no additional diagnosis beyond demyelinating disease was confirmed.

In contrast, atypical ON cases (e.g., painless, recurrent, bilateral, or non-recovering ON, marked disc edema, uveitis, macular star figure), laboratory and CSF analysis might be necessary. Patients with atypical ON should be evaluated for MS variants (e.g., neuromyelitis optica or Devic's disease) or MS mimics (e.g., sarcoidosis, syphilis, tuberculosis (TB), Lyme disease, systemic lupus erythematosus (SLE), etc.). Laboratory testing in these cases depending on the clinical presentation including complete blood count, antinuclear antibody, syphilis, Lyme or Bartonella serology, chest radiography, *angiotensin*-converting *enzyme* (ACE) and aquaporin-4-specific serum autoantibody (NMO), etc., could be considered.

Differential Diagnosis

1. Inflammatory optic neuropathy (e.g., sarcoidosis, lupus)
2. Infectious optic neuropathy (post-viral, syphilis, Lyme disease, TB)
3. Other optic neuropathies (e.g., toxic, nutritional, compressive, ischemic, radiation induced, hereditary)

Prophylaxis

Not applicable.

Therapy

ON is a self-limiting disease and the visual loss typically resolves partly or completely. Although some cases have a residual visual deficit, this should be considered an atypical feature as most patients recover vision better than 20/40. In the ONTT, the intravenous (IV) corticosteroids 1 g per day for 3 days followed by an oral (PO) prednisone or taper to a total of 11 days sped the rate of recovery but did not change final visual outcome (which was good in all patients in the ONTT) compared with placebo or oral steroids alone. Interestingly however, oral steroids alone did increase the frequency of recurrent attacks of ON, and oral steroids in conventional doses are therefore not recommended for typical ON.

Prognosis

In the ONTT, at 15 years following onset of ON, patients with a normal brain MRI had a 25% risk of developing MS when compared to patients with demyelinating white matter lesions of MS who had a 72% risk of developing clinically definite MS at year 15. Thus, patients with ON who have a normal MRI at onset should not be told that they do not have MS (the ONTT risk of MS is 25% at year 15) and patients with an abnormal MRI should not be told that they do have MS (the ONTT risk of MS is 72% at year 15).

Epidemiology

Typically ON in the United States affects younger adults (age range from 20 to 40 years) with a strong female predominance (two-thirds) of the cases and a predilection for Caucasians. The annual incidence of ON in the United States is approximately 6.4 per 100,000, and the prevalence is 115/100,000. The incidence of ON is higher in the populations in the northern United States and Western Europe with higher latitudes and is lowest in regions closer to the equator. The demographics of ON is different globally however, and in some parts of the world (e.g., Asia), ON may be more likely to be idiopathic or infectious than demyelinating in origin and when demyelinating may be more likely to be of the opticospinal variant (NMO) compared with countries with populations of European descent.

Optic Neuropathy: Ischemic, Arteritic

Anat Kesler[1] and Gad Dotan[2]
[1]Neurology, Neuro-Ophthalmology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel
[2]Department of Ophthalmology, Sourasky Tel Aviv Medical Center, Tel Aviv, Israel

Definition

Ischemic optic neuropathy is the most common acute optic neuropathy in adults over the age of 50 years, accounting for many cases of blindness or seriously impaired vision in that age group; however, no age is immune as this disorder has been reported in younger patients as well, including children.

Etiology

A typical classification divides anterior ischemic optic neuropathy into an arteritic (AAION) and non-arteritic (NAION) variants, which has important clinical and prognostic implications. AAION is associated with temporal (giant cell) arteritis and NAION is often related to atherosclerosis.

Clinical Presentation

The typical presentation of both AAION and NAION is painless loss of vision typically associated with optic disk swelling accompanied by flame-shaped (splinter) hemorrhages. However, vision is usually much worse in AAION compared to NAION (light perception vs. 20/200 vision). The visual loss is commonly described as sudden but progression over several days is also possible. Some patients report on transient visual loss in the days to weeks preceding the event. NAION is presumed to result from circulatory insufficiency within the optic nerve head. Histological studies show the area of infarction is located within the sclera canal alone supporting thus the compartment syndrome theory.

Diagnosis

The diagnosis of anterior ischemic optic neuropathy is clinical and is based on typical findings including abrupt loss of vision, usually unilaterally, accompanied by swollen optic disk with splinter hemorrhages.

AAION is less frequent than NAAION accounting for approximately 5–10% of all cases of anterior ischemic optic neuropathy. AAION usually occurs in older patients, over the age of 70 years, and is related to inflammatory and thrombotic occlusion of the short posterior ciliary arteries. Many patients have systemic symptoms of temporal arteritis including headache, malaise, pain after chewing, and scalp tenderness. Typical findings in blood tests include elevated sedimentation rate and/or C-reactive protein levels, thrombocytosis, and anemia. Confirmation of the clinical suspicion of temporal arteritis requires a temporal artery biopsy that may be delayed for 7–10 days following initiation of steroid therapy.

In NAAION, visual loss is usually less severe than in AAION; it occurs over hours to days often described as blurring, dimness in the affected region of visual field, and with altitudinal defect as the most common visual field loss. The optic disk edema may be diffused or segmental hyperemic or pale. In NAAION, the optic disk in the contralateral eye is typically small in diameter and there is absent of physiologic cup (disk at risk).

Neuroimaging is usually unnecessary in typical cases; however, if atypical features exist, such as severe optic disk edema, bilateral presentation, young age, or associated pain, imaging is warranted.

Differential Diagnosis

1. Other optic neuropathies: optic neuritis, compressive optic neuropathy, inflammatory, and infectious optic neuropathies
2. Increased intracranial pressure (especially if there is bilateral involvement of both optic nerves)

Prophylaxis

There is no effective medical or surgical treatment for NAION or for prevention of second eye involvement following unilateral presentation. Control of vasculopathic risk factors (i.e., hypertension, hyperlipidemia, diabetes and smoking) and aspirin are usually advised; however, there is no evidence to support that they reduce the risk of occurrence of NAION in the initially uninvolved eye.

Following unilateral AAION, there is high risk for second eye involvement within days of presentation. Therefore, following unilateral AAION treatment with systemic steroids should be initiated promptly.

Therapy

NAAION: No effective therapy exists. Aspirin, control of underlying medical conditions, and avoidance of smoking are commonly recommended.

AAION: A common treatment regime is with intravenous methylprednisolone 1 g/day for 3 days followed by oral prednisone 1 mg/kg/day that is continued for 3–12 month and tapered slowly depending on the response and sedimentation rate.

Prognosis

Although the damage to the optic nerve is often permanent, mild improvement of vision is possible in the initial first months following the event. The typical visual field defect of NAION is an altitudinal defect, and in AAION, visual field constriction is usually worse, leaving a small island of vision if any. Up to 40% of patients with NAAION show spontaneous improvement in vision compared to presentation, but this is usually limited to several lines of visual acuity and residual damage is commonly present.

Epidemiology

AAION occurs almost exclusively in patients over the age of 60 years, more often in women.

NAAION is the most common optic neuropathy in patients over 50 years of age with an estimated annual incidence in the United States of 2/3–10/2 per 100,000 populations. There is no gender predisposition. The mean age at onset ranges from 57 to 65 years. NAION usually occurs in disks that have no central cup and which are considered "disk at risk." Vasculopathic risk factors, mainly systemic hypertension, diabetes, and hyperlipidemia are common. Sleep apnea and nocturnal hypotension are possibly associated with NAION, but further research is needed to confirm this association. Another possible connection is with the use of phosphodiesterase inhibitors (such as sildenafil) because of their hypotensive effect; however, proof of causation is still lacking.

Definition

The optic tract (OT) is the portion of the optic pathway that connects the optic chiasm to the

lateral geniculate body (LGB) (Cummings 2013). Each OT contains the ipsilateral uncrossed temporal nerve fibers and contralateral nasal crossed nerve fibers that originate from the axons of the retinal ganglion cells (Binder et al. 2010). The blood supply of the OT derives from the anterior choroidal and posterior communicating arteries (Kanski and Bowling 2013). Damage to the OT may cause a contralateral relative afferent pupillary defect (RAPD), contralateral homonymous hemianopsia, and band optic atrophy (Friedman and Kaiser 2007).

Optical Aberrations

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Deviations from a diffraction-limited optical system causing deterioration of the optical image. Aberrations can be divided into chromatic (longitudinal) and monochromatic (wavefront) aberrations.

Basic Characteristics

An ideal optical system unites rays emerging from an object in a single point. Real optical systems like the human eye contain optical aberrations that cause a blur figure. *Chromatic* or *longitudinal aberration* is caused by the wavelength-dependence of dispersion of optical media. This results in different foci for different wavelengths. Chromatic aberration has effects also in the paraxial region and typically causes colored rims around objects. In contrast, *monochromatic* or *wavefront aberrations* are present if optical properties lead to different optical path lengths. Monochromatic aberrations vary with the angle of incidence of light rays and with the aperture diameter and cause an often asymmetric blur figure.

In physiological optics and ophthalmology, monochromatic aberrations play an important role. The human eye is afflicted mostly with defocus and astigmatism. The term *ametropia* applies, if the presence of defocus and astigmatism significantly affects the visual function of the uncorrected eye. While defocus causes a rotationally symmetric blur figure, astigmatism is characterized by different refraction along two orthogonal meridians. The resulting blur figure is cross-shaped and line-shaped if combined with defocus. Defocus and astigmatism can be corrected with glasses and are also referred to as *lower-order aberrations* (LOA). Correspondingly, *higher-order aberrations* (HOA) which cannot be corrected with conventional glasses exist. Presence of HOA causes an asymmetric blur figure, also if LOA are corrected with a sphero-cylindrical lens combination. The two most significant HOA are *coma* and *spherical aberration*. Coma describes an asymmetry of refraction along an axis through the middle of the pupil while spherical aberration is a rotational symmetric aberration characterized by difference of refraction from pupil center to the periphery. Other HOA are trefoil and other astigmatisms of higher frequency. In physiological optics, the polynomial expansion introduced by Zernike is typically used for description and quantification of the monochromatic aberrations of the eye (Thibos et al. 2002a). The Zernike expansion

allows an approximation and hence a reproducible quantification of the wavefront and its deviation from ideal optics (wavefront error). From the coefficients of the Zernike expansion, the optical transfer function and the point spread function can be calculated using Fourier transforms.

The normal human eye possesses both LOA and HOA in a characteristic pattern with rather insignificant contribution of HOA (Thibos et al. 2002b; Salmon and van de Pol 2006). In pathological conditions (keratoconus, cataract, corneal scars), HOA can reach high levels which affect visual function (Applegate et al. 2000; Fujikado et al. 2004). In clinical and laboratory settings, monochromatic aberrations of the eye are measured with aberrometers (Hartmann-Shack sensor, ray tracing, dynamic retinoscopy).

Optical Biometry

- ▶ Partial Coherence Interferometry

Optical Coherence Tomography

Yesim Haeussler-Sinangin and Thomas Kohnen
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Definition

Optical coherence tomography (OCT) is a non-contact optical imaging technology that allows high-resolution cross-sectional imaging of an object.

Purpose

Based on low-coherence interferometry, interference of light is shortened to a distance of µm, thus enabling "optical biopsy" (Drexler and Fujimoto 2008).

Principle

Time-domain OCT uses a scanning laser interferometer and an 820-nm infrared light source which is split into two separate beams. One of these beams scans the object of interest, whereas the other one serves as a reference beam which is reflected by a reference mirror. The distance of the reference mirror can be adapted and thus the time it takes for the reference beam to reach the sensor may be modified.

By comparing these two light beams, the backscattered light is measured and by this a cross-sectional image of the tested object is generated. The axial resolution of OCT is determined by the coherence length of the light, hence the name optical coherence tomography (Drexler and Fujimoto 2008).

A more recent development, spectral-domain OCT, also known as Fourier-domain OCT, allows retinal imaging at a scan speed 100 times faster and at a resolution up to five times higher than

TD-OCT. It is an imaging technique that makes use of the Fourier transformation to gather depth data from the spectra of the OCT signal. Hereby, the formerly required axial translation of the reference mirror to obtain depth information can be waived (Huang et al. 2008).

Indication

Imaging of anterior and posterior segments of the eye.

Contraindication

None.

Advantage/Disadvantage

Noncontact, real-time, in situ visualization of the internal microstructure of biological tissue, without the need to remove and process specimens.

[5]Department of Ophthalmology, Baylor College of Medicine, Houston Methodist Hospital, Houston, TX, USA
[6]Department of Ophthalmology, The University of Iowa Hospitals and Clinics, Iowa City, IA, USA

Synonyms

Optokinetic reflex

Definition

Optokinetic nystagmus (OKN) is a rhythmic involuntary conjugate ocular oscillation provoked by a compelling full visual field stimulus that is characterized by a set of alternating slow pursuit movement followed by a set of alternating slow (compensatory) and corrective fast (saccadic) phase of movement where the quick saccade brings the eyes back to the primary position once the eyes approach the limit of their rotation (Lavin 2012; May and Corbett 2013). The slow phases are in direction of the stimulation (Lavin 2012). As the head moves and a visual scene moves

across the retina (retinal slip) the eyes automatically compensate to stabilize the image on the retina, by undergoing optokinetic nystagmus (May and Corbett 2013).

The reflex begins with afferents from the wide-field retinal ganglion cells sensitive to slow movements of the whole receptive fields that are turned to directions comparable to the orientations of the vestibular semicircular canals (May and Corbett 2013). Retinal ganglion cells terminate in small nuclei along the incoming optic tract, composing the accessory optic system (AOS) (May and Corbett 2013). The AOS also receives input from the visual association cortex and projects to the nucleus reticularis tegmenti pontis and the inferior olive that supply the vestibulocerebellum and vestibular nuclei (May and Corbett 2013). Optokinetic neurons from the vestibular nuclei influence extraocular motor neurons and are required for a functional optokinetic reflex (May and Corbett 2013). The OKN reflex can be evoked by turning the patient in a revolving chair or using bedside optokinetic tape or an OKN drum. OKN testing can be used to evaluate foveal pursuit and refixation saccades in the circumstance of subtle internuclear ophthalmoplegia, provocation of convergence-retraction nystagmus, congenital nystagmus, psychogenic blindness or ophthalmoplegia, or homonymous hemianopia caused by a parieto-temporo-occipital lesion (Lavin 2012; Hullar et al. 2015).

Ora Serrata

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Peripheral retina

Definition

The ora serrata is the serrated anterior border of the neurosensory retina. It's dentate or "teeth-like" processes extend anteriorly into the pars plana of the ciliary body. Anatomically, it is located approximately 5–6 mm posterior to the limbus. Ora bays are created by extensions of the pars plana into the ora serrata, creating scalloped-shape borders.

Definition

An orbital apex syndrome (OAS) is clinically defined by a combination of the involvement of orbital apex structures (e.g., orbital tissues, fat, and extraocular muscles) and several cranial nerves (i.e., oculomotor nerve (III), trochlear nerve (IV), abducens nerve (VI), trigeminal nerve (V1 branch)) and the optic nerve (II). There may be concomitant proptosis or other anterior orbital signs such as chemosis, proptosis, or periorbital edema and erythema from involvement of adjacent orbital tissues.

Etiology

OAS may be caused by inflammatory, infiltrative, infectious, neoplastic, iatrogenic, traumatic, or vascular processes. Typically iatrogenic/surgical, neoplastic, and inflammatory are the most common causes followed by vascular, infections, and other etiologies.

Inflammatory OAS

Inflammatory OAS may be idiopathic (idiopathic orbital inflammatory syndrome (IOIS)) or secondary to underlying systemic inflammation (e.g., granulomatosis with polyangiitis (formerly Wegener granulomatosis)), sarcoidosis, systemic lupus erythematosus, polyarteritis nodosa, and eosinophilic granulomatosis with polyangiitis (formerly Churg–Strauss syndrome). Typical inflammatory OAS occurs acutely with ipsilateral pain, ophthalmoplegia, and optic neuropathy. Steroids are the first-line therapy in presumptive IOIS but may be used for secondary OIS as well.

Infectious

Infectious diseases involving the central nervous system, paranasal sinuses, and periorbital structures may cause adjacent OAS. These can include fungal (e.g., mucormycosis and *Aspergillus*), bacterial (e.g., syphilis, bacterial orbital cellulitis, tuberculosis), viral (e.g., herpes zoster virus), or rarely parasitic disease. Mucormycosis should be suspected in individuals with a compromised immune system (e.g., diabetes mellitus (especially in diabetic ketoacidosis)), alcoholism, hematologic malignancies, solid organ (e.g., renal, lung, cardiac transplant) or bone marrow transplant survivors, and chronic immunosuppression (e.g., steroids or chemotherapy). These infectious etiologies for OAS can mimic the presentation of OIS and may present with ipsilateral pain, ophthalmoplegia, proptosis, and evidence for local tissue invasion. Thus, infectious etiologies should be excluded before starting corticosteroid therapy for presumed OAS due to OIS. Some fungal organisms are angioinvasive and can produce secondary tissue necrosis (i.e., "the black eschar"), but while distinctive this sign of necrosis is a late finding and often portends a negative prognosis. Bacterial orbital cellulitis is also a relatively common infectious cause of OAS (especially with concomitant adjacent sinusitis) and can be due to *Staphylococcus aureus*,

Streptococcus pneumoniae, other streptococci, gram-negative bacilli, and anaerobic bacteria.

Neoplastic

Neoplasms should be included in the differential of OAS. Primary ocular or orbital tumors, neoplasms of the paranasal sinuses, or central nervous system tumors may secondarily invade the orbital apex. These neoplasms include nasopharyngeal cancer, lymphoma, meningioma, and metastatic disease (breast, lung, kidney, and malignant melanoma). Typically, neoplastic etiologies for OAS produce slowly progressive, painless ophthalmoplegia and optic neuropathy, but some lesions (e.g., lymphoma or metastasis) may present acutely and mimic infectious or inflammatory presentations of OAS.

Iatrogenic/Traumatic

OAS has been reported with the following sinonasal and periorbital procedures: ethmoidal artery ligation, intranasal ethmoidectomy, and septorhinoplasty. OAS has also been observed after penetrating or blunt orbital trauma, usually accompanied by bone fracture.

Vascular

Vascular etiologies of OAS include cavernous carotid aneurysm, carotid–cavernous fistulas, and cavernous sinus thrombosis.

Table 1 summarizes the common etiologies for OAS.

Orbital Apex Syndrome in Neuro-Ophthalmology, Table 1 Common etiologies for OAS

Inflammatory
1. Sarcoidosis
2. Systemic lupus erythematosus
3. Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)
4. Granulomatosis with polyangiitis (Wegener granulomatosis)
5. Idiopathic granulomatous cavernous sinus syndrome (Tolosa–Hunt syndrome)
6. Giant cell arteritis (orbital ischemia)
7. Idiopathic orbital inflammatory syndrome (i.e., orbital inflammatory pseudotumor)
8. Thyroid eye disease (TED)
Infectious
1. Fungi: Aspergillosis, mucormycosis
2. Bacteria: *Streptococcus* spp., *Staphylococcus* spp., *Actinomyces* spp., gram-negative bacilli, anaerobes, *Mycobacterium tuberculosis*
3. Spirochetes: *Treponema pallidum*
4. Viruses: Herpes zoster
Neoplastic
1. Head and neck tumors: nasopharyngeal carcinoma, adenoid cystic carcinoma, squamous cell carcinoma
2. Neural or nerve sheath tumors: neurofibroma, meningioma, ciliary neurinoma, schwannoma
3. Metastatic lesions: lung, breast, renal cell, malignant melanoma
4. Hematologic: Burkitt lymphoma, non-Hodgkin lymphoma, leukemia
5. Perineural invasion of cutaneous malignancy
Iatrogenic/traumatic
A. Iatrogenic
1. Sinonasal surgery
2. Orbital/facial surgery
B. Traumatic
1. Penetrating injury
2. Nonpenetrating injury
3. Orbital apex fracture
4. Retained foreign body
Vascular
1. Carotid cavernous aneurysm
2. Carotid cavernous fistula
3. Cavernous sinus thrombosis
4. Sickle cell anemia (orbital ischemia)
5. Giant cell arteritis
Others
Mucocele

Clinical Presentation

The most common initial symptoms of OAS are visual dysfunction due to optic neuropathy with variable partial or complete ophthalmoplegia with or without lid and pupil involvement. Optic nerve dysfunction can be documented by loss of vision, a relative afferent pupillary defect, loss of color vision or visual field, and optic disc edema or optic atrophy. Optic atrophy usually takes several weeks to months to develop and the disc may appear normal at onset (i.e., retrobulbar optic

neuropathy). Diplopia is also a common symptom in OAS but may be absent in cases with severe visual loss who are unable to appreciate diplopia or in cases of complete ptosis. Since multiple cranial nerves or extraocular muscles are usually affected in OAS, any degree of ophthalmoplegia from single or a combination of ocular motor cranial nerve palsies may occur.

Proptosis is present in up to 72% of OAS patients and depends on the degree of anterior orbital involvement. Smaller lesions in the orbital apex however may not have any appreciable proptosis and some orbital etiologies producing an OAS might produce enophthalmos (e.g., scirrhous breast carcinoma). Periorbital pain is also a common symptom in OAS. It is present in up to 50% of patients and may be seen secondary to generalized orbital inflammation or edema or be neurogenic in the distribution of the ipsilateral ophthalmic V1 nerve. Numbness or paresthesias may also occur in the trigeminal (V1) distribution. Some etiologies (e.g., adenoid cystic carcinoma, squamous cell carcinoma) may have a predilection for perineural involvement and are often painful. The absence of pain however does not exclude the diagnosis of OAS.

Diagnostics

Neuroimaging should be performed in all suspected OAS patients. Computed tomography (CT) of the orbit and head is the faster option. CT also plays an important role in the evaluation of patients who cannot have an MRI, for evaluation of sinus disease, bone, sinus disease, trauma patients, and those with suspected metallic foreign bodies. It is important to remember that CT is superior to MRI in evaluation or bony anatomy. MRI of the brain and orbit (with fat suppression) with and without contrast is superior for showing soft tissue involvement and intracranial extension. If a vascular lesion is suspected, MRA (or CTA) could also be included but has variable sensitivity. Thus, even if the MRA/CTA is negative but the clinical suspicion remains high, then a standard catheter angiography should still be considered.

Depending on the clinical suspicion, laboratory tests for suspected inflammatory or infectious etiology might include erythrocyte sedimentation rate and C-reactive protein (especially in elderly patients suspected of harboring giant cell arteritis), complete blood count, syphilis serology (e.g., rapid plasma regain (RPR), microhemagglutination assay for *Treponema pallidum (MHA-TP)*), angiotensin-converting enzyme, perinuclear antineutrophil cytoplasmic antibody (p-ANCA), cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA), antinuclear antibody (AMA), purified protein derivative (PPD), and HIV testing. Chest radiography or chest CT scan (for sarcoid and granulomatosis with polyangiitis) and lumber puncture could also be considered depending on the clinical presentation.

Differential Diagnosis

Differential Diagnosis includes:

- Cavernous sinus syndrome (without optic neuropathy)
- Superior orbital fissure syndrome (with optic neuropathy)

Prophylaxis

Non-applicable.

Therapy

The management of OAS depends on the underlying etiology. Corticosteroids are usually indicated in inflammatory cases. Infectious etiologies require antibiotic therapy, and often broad spectrum antibiotic therapy is deployed until the results of gram staining and cultures are

known. Fungal disease (mucormycosis) especially in diabetic ketoacidosis or other immunosuppressed patients should be ruled out before corticosteroids are started, and in general, antifungal therapy requires a confirmatory fungal biopsy or culture. Methotrexate, azathioprine, and radiotherapy have all been used in inflammatory disease resistant to steroids. Neoplastic lesions typically require biopsy confirmation and treatment depends on the underlying histopathology.

Prognosis

The prognosis varies according to etiology. In general infectious and inflammatory conditions (except *Mucor*) respond to early and aggressive treatment with up to 75% of patients experiencing some improvement. Neoplastic and vascular etiologies have variable prognosis.

Epidemiology

OAS may affect any age, either gender, and any race. Some neoplastic conditions are more common in children (e.g., neuroblastoma, rhabdomyosarcoma, optic glioma) or in adults (e.g., meningioma). The etiologies of orbital cellulitis also might vary according to age.

Orbital Cellulitis

Michael T. Yen[1] and Ashvini Reddy[2]
[1]Department of Ophthalmology, Cullen Eye Institute, Baylor College of Medicine, Houston, TX, USA
[2]Wilmer Eye Institute, The Johns Hopkins University, Baltimore, MD, USA

Synonyms

Abscesses, orbital; Orbit, inflammation of

Definition

Orbital cellulitis is a sight-threatening and potentially life-threatening infection of the orbital fat, muscles, and/or bones posterior to the orbital septum more common in young children than adults. Inflammation within the orbit may affect the orbital tissues (resulting in chemosis and proptosis), extraocular muscles (resulting in dysmotility and diplopia), and/or the optic nerve at the orbital apex (resulting in decreased visual acuity and an afferent pupillary defect). It must be distinguished from preseptal cellulitis (inflammation anterior to the orbital septum) as mortality, risk of vision loss, and other complications are higher with orbital cellulitis than preseptal cellulitis (Garcia and Harris 2000).

Etiology

Orbital cellulitis commonly occurs secondary to direct extension from an ipsilateral sinus infection – especially the ethmoid sinus, which is separated from the orbit only by the thin lamina papyracea (Osguthorpe and Hochman 1993).

Other risk factors for orbital cellulitis include ophthalmic or sinus surgery, trauma, infected mucocele, and areas of infection in close proximity (face, teeth, middle ear, lacrimal system, globe).

Historically, *Staphylococcus aureus*, *Streptococcus* species, *Haemophilus* species, and anaerobes have been the most commonly reported organisms in culture-positive cases. However, since the implementation of vaccination against *Haemophilus influenzae* type B in the USA, this particular pathogen has been rarely reported (Ambati et al. 2000). Antibiotic-resistant strains of bacteria, particularly methicillin-resistant *Staphylococcus aureus* (MRSA), are increasingly encountered and may be more likely to present in an atypical location in the orbit and extend intracranially (McKinley et al. 2007). Mycobacteria, *Bacillus* species, fungi, and *Pseudomonas* are less common isolates. Diabetics and immunocompromised patients are predisposed to *Mucor*/zygomycosis.

Epidemiology

Orbital cellulitis is more common in children than adults. There is an associated mortality of 1–2% and a risk vision loss of up to 11%; such complications are extremely rare in preseptal cellulitis. In a retrospective case series of 315 children admitted to a hospital with preseptal or orbital cellulitis, 18 patients were diagnosed with orbital cellulitis and all of these had a history of sinusitis. The incidence of sinusitis in the remaining 297 patients with preseptal cellulitis was only 14.5% (Osguthorpe and Hochman 1993).

Clinical Presentation

Orbital cellulitis may be clinically indistinguishable from preseptal cellulitis, periosteal abscess, and orbital abscess but should be suspected in any patient presenting with chemosis, elevated intraocular pressure, globe displacement, pain with eye movement, motility defects, and change in vision, especially if the history is suggestive of recent febrile upper respiratory or sinus infection. A complete eye examination is indicated for evaluation of disease severity and to exclude other causes of proptosis with decreased vision (namely, retinoblastoma, rhabdomyosarcoma, and orbital inflammatory syndrome).

Preseptal cellulitis more commonly arises from contiguous infection from the upper face or local trauma, is rarely associated with sinusitis, and is less likely to result in globe displacement, motility defects, or vision disturbance. Limitation of eye movement and vision loss in particular suggest orbital involvement.

Subperiosteal abscesses or orbital abscesses can be sequelae of orbital cellulitis, though subperiosteal abscesses are sometimes the first sign of extension of a sinus infection into the orbit and may rupture causing orbital cellulitis (McKinley et al. 2007).

Diagnostics

Clinical examination (especially visual acuity and motility) should be used to arrive at an initial diagnosis and guide treatment. Most clinicians also recommend CT imaging to evaluate the extent and severity of disease and rule out less common entities (i.e., orbital inflammatory syndrome, Wegener's granulomatosis, posterior scleritis), though some feel that exposing a child to radiation is unnecessary if the clinical exam and history are consistent and the child responds well to an empiric antibiotic regimen.

Differential Diagnosis

Posterior scleritis
Tumors (retinoblastoma, rhabdomyosarcoma)
Wegener's granulomatosis
Idiopathic orbital inflammation
Tolosa-Hunt syndrome
Thyroid eye disease
Mucormycosis/zygomycosis
Severe allergic reaction

The differential for preseptal cellulitis includes: conjunctivitis, hordeolum, trauma, insect bites, and herpetic infections.

Treatment

If orbital cellulitis is suspected, expedient diagnostic imaging or surgical exploration may be required as timely intervention is necessary to prevent complications such as retinal artery occlusion and intracranial extension, which can result in meningitis, cavernous sinus thrombosis, or intracranial abscesses. Blood cultures are frequently negative and cultures from mucosal surfaces may show only normal flora. Cultures obtained by sinusotomy and orbitotomy have the highest yield (McKinley et al. 2007).

Broad-spectrum intravenous antibiotics and hospitalization with frequent bedside examinations are indicated in cases of orbital cellulitis and severe preseptal cellulitis. Initial antibiotic coverage should be guided by local epidemiologic data. Patients should be switched to other antibiotics, if indicated, based on culture sensitivities as they become available. In areas where the prevalence of MRSA is high, empiric coverage with parenteral vancomycin, clindamycin, and cefotaxime may be preferred and should be continued until the patient shows clinical improvement (including resolution of fevers and leukocytosis) and can be switched to an oral regimen.

Aggressive nasal hygiene with nasal corticosteroids, saline irrigation, and decongestants is indicated. Intravenous dexamethasone reduces inflammation, reduces the development of septations, and does not appear to increase the incidence of complications (Yen and Yen 2005). Serial CT imaging may be required to evaluate for subperiosteal/orbital abscess and efficacy of treatment, though imaging tends to lag behind clinical response (Harris 1996).

Orbital surgery is indicated if the organism cannot be isolated from other cultures or if the patient fails to respond to conservative measures, clinically deteriorates, or develops an abscess along the lateral, superior, or inferior orbital wall. Small medial subperiosteal abscesses may be drained endoscopically or managed medically (Garcia and Harris 2000). Drain placement following surgery reduces the risk of abscess formation. An interdisciplinary approach may be necessary for the management of complications such as persistent sinus infection, intracranial spread, or cavernous sinus thrombosis.

Mild preseptal cellulitis can be managed with oral antibiotics (such as amoxicillin and clavulanate) on an outpatient basis with close follow-up.

Prognosis

A patient's prognosis depends on many factors including age, disease extent and severity at the time of presentation, duration of symptoms, microorganism, and immunodeficiency status. With timely intervention, vision loss and death are rare.

Orbital Compartment Syndrome

Gary Joseph Lelli and Benjamin Levine
Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Increased orbital pressure; Orbital compression syndrome; Orbital tension syndrome

Definition

An acute elevation of intraorbital pressure resulting in damage to ocular and other intraorbital structures.

Etiology

The orbit is a confined space which follows a pressure-volume curve. The orbit may compensate for small increases in orbital volume by forward movement of the globe and orbital fat prolapse. However, once the intraorbital pressure rises beyond the orbit's capacity to compensate, there is a rapid rise in intraorbital tissue pressure. This increase in tissue pressure is associated with a decrease in perfusion of orbital tissues, including the optic nerve and globe. The most common cause of orbital compartment syndrome (OCS) is a retrobulbar hematoma as a result of trauma or surgery. Orbital infection, emphysema, tumor, or inflammation may also cause an increase in orbital pressure leading to a compartment syndrome. Other less common causes of OCS include large-volume resuscitation, traumatic asphyxia syndrome, extravasated contrast material, foreign body, spinal surgery in the prone position, spontaneous bleeding from orbital vascular anomalies or complications related to sclerotherapy for such disorders, and disseminated intravascular coagulation.

Clinical Presentation

Patients with orbital compartment syndrome often report an acute onset of eye pain and proptosis. They may also report vision loss, double vision, nausea, and vomiting. These symptoms may develop over a period of minutes to hours. The patient may have a history of recent trauma, surgery, sinusitis, or a bleeding disorder. On external examination, there is usually periorbital edema and ecchymosis, limited extraocular motility, and resistance to retropulsion. There may also be conjunctival chemosis and hemorrhage. Vision may be decreased, and there may also be an afferent pupillary defect and increased intraocular pressure. Fundus examination may reveal disk edema, choroidal folds, central retinal artery pulsations, and a central retinal artery occlusion with a cherry red spot.

Diagnosis

Diagnosis is often made in the context of a medical history and physical examination which are consistent with orbital compartment syndrome. A complete ophthalmic exam must be performed. Special attention should be given to looking for an afferent pupillary defect, loss of color vision, increased intraocular pressure, central retinal artery pulsations, disk edema, and choroidal folds. Computed tomography (CT) or magnetic resonance imaging (MRI) of the orbit may help to elucidate the cause of the compartment syndrome; however, OCS is a clinical diagnosis, and therapeutic intervention should not be delayed to obtain imaging.

Differential Diagnosis

The differential diagnosis for orbital compartment syndrome includes autoimmune orbital inflammation, thyroid eye disease, ruptured dermoid cyst, progressively enlarging orbital masses, orbital fractures, and traumatic optic neuropathy.

Prophylaxis

The use of restraints, seat belts, and protective headgear can help prevent orbital compartment syndrome caused by trauma.

To minimize the risk of orbital hematoma and OCS associated with orbital and periorbital surgery, the following measures should be taken:

1. Perioperative anticoagulants should be avoided, when possible.
2. During surgery, special attention should be given to achieving hemostasis and avoiding large blood pressure fluctuations.
3. Awakening from general anesthesia should be performed with adequate pain and nausea control and suppression of the cough reflex to reduce straining and the risk of orbital hemorrhage.

Therapy

The presence of vision loss or an afferent pupillary defect in association with orbital compartment syndrome necessitates immediate therapy with soft tissue decompression of the orbit by lateral canthotomy and cantholysis. If OCS is suspected, decompression should not be delayed to obtain confirmatory imaging. To release the lateral canthus, first inject a local anesthetic in the region of the lateral commissure. Next, clamp a hemostat horizontally at the lateral canthus for 60 s to compress the tissues and reduce bleeding. The clamp is then released, and a scissor is used to create a horizontal incision of approximately 1 cm into the compressed tissue. Then the inferior crus of the lateral canthal tendon is located and lysed. Successful release of the inferior crus will allow the eyelid to easily evert and the globe to sublux forward. This subluxation is beneficial, as it releases intraorbital pressure on the optic nerve. If releasing the inferior crus of the lateral canthal tendon does not provide the desired amount of decompression, the superior crus of the lateral canthal tendon may also be severed in a similar fashion. Finally, a bony orbital decompression may be required in extreme cases of OCS which do not adequately respond to soft tissue decompression.

Additionally, the following medical treatments may be instituted concurrently with surgical treatment of OCS, assuming no contraindications:

1. Oral carbonic anhydrase inhibitor (e.g., acetazolamide)
2. Topical beta-blocker, alpha-agonist, or topical carbonic anhydrase inhibitor
3. Hyperosmotic agent (e.g., mannitol)

Prognosis

The amount of time elapsed until treatment of orbital compartment syndrome appears to be the most significant factor in predicting visual outcome. Prompt treatment of orbital compartment syndrome with orbital decompression and medical management is much more likely to result in visual recovery. Several studies show that delayed treatment is more likely to result in permanent vision loss. Younger patients are also more likely to recover vision after treatment of OCS.

Epidemiology

Orbital compartment syndrome is a rare complication of facial trauma or surgery. The exact incidence is unknown. Orbital hemorrhage from a variety of causes accounts for the majority of orbital compartment syndrome cases. The incidence of orbital hemorrhage after blepharoplasty is 0.055% (1/2000) and that with permanent visual loss is 0.0045% (1/10,000). Orbital hemorrhage has an incidence of approximately 1% from retrobulbar and peribulbar anesthetic injections, and it is also the most frequent ophthalmic complication of endoscopic sinus surgery, with an incidence of 0.12%.

Orbital Hemorrhages

Gary Joseph Lelli
Department of Ophthalmology, Weill Cornell Medical College, Cornell University, New York, NY, USA

Synonyms

Orbital compartment syndrome; Orbital compression syndrome; Orbital tension syndrome; Retrobulbar hemorrhage

Definition

Hemorrhage within the orbital space.

Etiology

Orbital hemorrhage usually occurs in the setting of trauma or secondary to periocular or intraocular surgery with retrobulbar anesthesia. Spontaneous hemorrhage can occur from valsalva maneuvers, coughing, sneezing, exertion, or bleeding from an orbital vascular tumor or malformation.

Clinical Presentation

Patients with retrobulbar hemorrhages present with the acute onset of pain, pressure, vision change, diplopia, nausea, or vomiting, usually in the setting of trauma or recent periocular or intraocular surgery. The most common presenting signs are: decreased visual acuity, extraocular muscle limitation, periocular ecchymoses, subconjunctival hemorrhagic chemosis, pupillary abnormalities, increased resistance to retropulsion, increased intraocular pressure, and dyschromatopsia.

Diagnosis

Diagnosis is made clinically by evaluating for the typical signs and symptoms of orbital hemorrhages. Diagnosis can be confirmed by orbital imaging, but imaging is not necessary and should not delay potential treatment of an orbital hemorrhage in the acute setting of threat to vision.

Differential Diagnosis

The differential diagnosis of an orbital hemorrhage includes an orbital hematoma, orbital cellulitis, orbital inflammation, an orbital mass, ruptured dermoid cyst, orbital vascular tumors and malformations, and orbital fractures (Ehlers et al. 2008).

Prophylaxis

The use of restraints, seat belts, and protective headgear can help prevent orbital hemorrhage caused by trauma.

To minimize the risk of orbital bleeding associated with periocular and intraocular surgery, the following measures should be taken (Hass et al. 2004):

1. Perioperative anticoagulants should be avoided, when possible.
2. During surgery, special attention should be given to achieving hemostasis and avoiding large blood pressure fluctuations.
3. Awakening from general anesthesia should be performed with adequate pain and nausea control and suppression of the cough reflex to reduce straining.

Therapy

In the setting of progressive orbital signs and/or vision loss, treatment should be instituted emergently (see Table 1).

Assuming no contraindications, medical treatment options include the use of intravenous steroids and therapies aimed at decreasing the intraocular pressure such as:

1. Oral carbonic anhydrase inhibitor (e.g., acetazolamide)
2. Topical beta-blocker, alpha-agonist, or topical carbonic anhydrase inhibitor
3. Hyperosmotic agent (e.g., mannitol)

Surgical treatment in the setting of recent orbital or eyelid surgery may involve opening of the wound to evacuate hematoma and to search for and control the source of bleeding. In cases related to trauma or retrobulbar injections, a lateral canthotomy with inferior cantholysis should be performed. In refractory cases, the superior canthal tendon can also be disinserted. Rarely, persistent vision loss with posteriorly collecting hemorrhage may respond to orbital decompression surgery.

Prognosis

The amount of time elapsed until treatment of an orbital hemorrhage appears to be the most significant factor in predicting visual outcome. Prompt treatment of an orbital bleed is much more likely to result in visual recovery. Several studies show that delayed treatment is more likely to result in permanent vision loss.

Epidemiology

The incidence of orbital hemorrhage after blepharoplasty is 0.055% (1/2000) and subsequent permanent visual loss is 0.0045% (1/10,000). Orbital hemorrhage has an incidence of approximately 1% from retrobulbar and peribulbar anesthetic injections, and it is also the most frequent ophthalmic complication of endoscopic sinus surgery, with an incidence of 0.12%.

Orbitotomy

Yasaman Mohadjer
The Aesthetic Institute of West Florida, Largo, FL, USA

Definition

A surgical procedure to obtain access and exposure to a particular area of the orbit.

Indications

It is performed for multiple reasons, including biopsy or excision of a lesion, decompressing the optic nerve or canal, draining an abscess, removing a foreign body, and removing bone or fat for decompression of the orbit or for orbital fracture repair (Cockerham et al. 2001; Levine 2003; Nerad 2001).

Contraindication

Contraindication for patients unable to medically tolerate surgery.

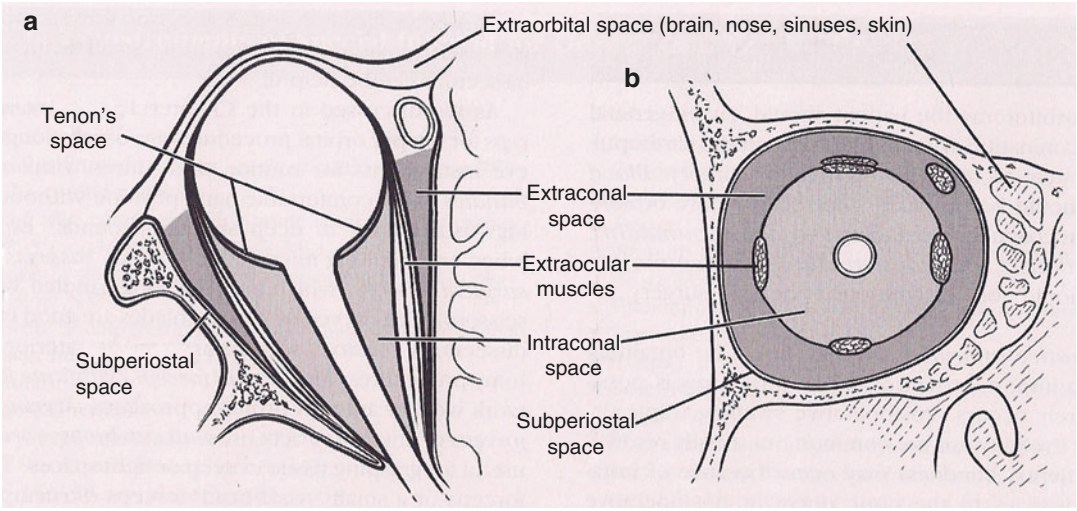
Techniques and Principles

An anterior orbitotomy is planned for a lesion in the anterior 2/3 of the orbit. A medial orbitotomy is useful for medial intra- and extraconal lesions, and a lateral orbitotomy is useful for lesions in the posterior orbit lateral to the optic nerve.

There are specifically defined surgical spaces in the orbit (Fig. 1)

1. The intraconal (central) space is the space between the muscle cone.
2. The extraconal (peripheral) space is the area between the periosteum and the muscle cone.
3. The subperiosteal, or extraperiosteal, space is the area beneath the peri-orbita or periosteum of the orbit.
4. The episcleral space is the area between Tenon's capsule and the globe.

The appropriate surgical approach is often determined by considering the location, type and size of lesion and surgical goals (biopsy vs. total excision) and is often driven by clinical findings as well as imaging studies. The most direct route should be used, keeping in mind normal anatomical structures in the orbit that may be nearby. Occasionally, help from other



Orbitotomy, Fig. 1 Surgical spaces of the orbit in coronal (**a**) and axial (**b**) view (Printed with permission from Nerad JA, ed. Oculoplastic Surgery. The requisites in ophthalmology. St. Louis: Mosby, Inc. 2001: 391)

specialists, such as neurosurgeons or otolaryngologists, is required to accomplish the goal and to provide alternative approaches to orbital spaces (Cockerham et al. 2001; Levine 2003; Nerad 2001).

Outcome

Access to the orbit for biopsy, excision, decompression, or fracture repair.

Complications

Risks of an orbitotomy include risks associated with anesthesia, bleeding, pain, infection, scarring, swelling, loss of vision, damage to adjacent structures, diplopia, and need for additional procedures.

Definition

Oscillopsia is a patient symptom of an illusory to-and-fro movement of a known stable environment and may be the result of ocular instability or impaired spatial constancy. These perceived environmental movements can be in any plane – vertical, horizontal, or torsional (Miller et al. 2008; Straube et al. 2012).

Etiology

Oscillopsia usually results from ocular instability or impaired spatial constancy. When oscillopsia is identified as a result of ocular instability, it can be characterized as constant or paroxysmal (Miller et al. 2008). Constant or permanent oscillopsia can be further divided into three deficiency areas: the fixation system, the visuo-vestibular stabilizing system, and the neural integrator (Miller et al. 2008; Tilikete and Vighetto 2011; Straube et al. 2012).

The fixation system, through visual and cerebellar feedback loops, allows for maintained gaze on a single point or object in space (Miller et al. 2008). Disruption of this control system can result in nystagmus (Straube et al. 2012). Acquired pendular nystagmus (nystagmus with back-to-back slow phases) stems from a variety of causes, most notably multiple sclerosis (MS) and oculopalatal tremor (OPT) (Tilikete and Vighetto 2011; Straube et al. 2012). MS is responsible for disrupting the visual/motor feedback loops resulting in the nystagmus, while OPT is involved with the cerebellar feedback loops likewise disrupting the fixation system (Tilikete and Vighetto 2011).

The visuo-vestibular stabilizing system allows one to maintain a stable gaze regardless of head/body movement with respect to the environment. The vestibulo-ocular reflex (VOR) induces ocular movements which compensate for these head movements, while the fixation system inhibits these movements in the case of tracking a moving object (Miller et al. 2008; Tilikete and Vighetto 2011). Disruption of this stabilizing system may manifest as a type of jerk nystagmus (fast and slow phases) resulting from cerebellar or brain stem dysfunction. Primary position downbeat nystagmus (PPDN) or primary position upbeat nystagmus (PPUN) may reveal disruption of the visuo-vestibular reflex, resulting in oscillopsia (Straube et al. 2012).

The neural integrator is responsible for extraocular muscle control during eccentric eye position (gaze away from the center of the eye). Disruption of this system, primarily the result of cerebellar or brain stem lesions, results in gaze-evoked nystagmus (eyes drifting back toward midline during eccentric gaze) (Miller et al. 2008; Tilikete and Vighetto 2011).

Spatial constancy is the culmination of anticipation and compensation of movements during focus on an object. Paroxysmal oscillopsia resulting from peripheral ocular motor or vestibular hyperactivity can also occur (Straube et al. 2012). Superior oblique myokymia results in episodes of monocular oscillopsia from trochlear nerve hyperactivity. Superior canal dehiscence syndrome may result in episodes of oscillopsia triggered by loud sounds (Tullio phenomenon) or other maneuvers which increase intracranial pressure (Miller et al. 2008; Tilikete and Vighetto 2011; Straube et al. 2012).

Treatment

Treatment should be directed at the underlying etiology of the oscillopsia (Tilikete and Vighetto 2011).

Prognosis

The recovery of oscillopsia is highly dependent on the underlying etiology (Miller et al. 2008; Tilikete and Vighetto 2011).

Osteogenesis Imperfecta, Blue Sclera

Sina Vahedi[1] and Allen O. Eghrari[2]
[1]Jefferson Medical College, Philadelphia, PA, USA
[2]Johns Hopkins University School of Medicine, Baltimore, MD, USA

Definition

The sclera is composed of type I collagen and is not blue in color; rather, this term refers to its blue-gray appearance due to thinning that reveals the uveal color underneath.

Etiology

Thinning of the sclera due to mutations in COL1A1 and COL1A2 reveal the underlying blood and uveal pigment. Abnormalities in type I collagen fibers reduce their diameter and affect their cross-striation, thus generating a more translucent collagen (Rajendran 2009). This allows visualization of the underlying uvea which appears blue.

Occurrence

Blue sclera that persists throughout life is a feature of type I osteogenesis imperfecta. Osteogenesis imperfecta type II is a lethal perinatal form that also causes a blue sclera sign. Patients with type III-IV may initially present with a light blue sclera that resolves by adulthood (Traboulsi 2006).

Osteogenesis Imperfecta, Blue Sclera, Table 1 Clinical findings in OI

Type of osteogenesis imperfecta	Clinical findings
OI – I (nondeforming OI with blue sclera)	Blue sclera. Hearing loss in 50% of patients
OI – II (perinatally lethal OI)	Dark blue sclera. 90% dies before 4 weeks of age. In utero fractures in 100% of patients
OI – III (progressively deforming OI)	Sclera may be blue at birth, but gradually normalizes with age. Progressive deformity of the skeleton
OI – IV (common variable OI with normal sclera)	Normal sclera. A blue tinge might be seen at birth in some cases and normalizes in childhood
OI – V (OI with calcification in interosseous membranes)	Normal sclera. Calcification of interosseous membranes in forearm in childhood leading to problems with pronation and supination

Classification

Although blue sclera is most frequently associated with osteogenesis imperfecta type I, other types may demonstrate subtle findings, as evidenced in Table 1.

Blue Sclera associated with osteogenesis imperfecta is a chronic and long-standing sign, in contrast to acute thinning of sclera which can be associated with systemic and/or inflammatory conditions (Van Dijk and Sillence 2014).

Other Uveitic Etiologies

Friederike Mackensen
Interdisciplinary Uveitis Center, Department of Ophthalmology, University of Heidelberg, Heidelberg, Germany

Synonyms

Inflammatory eye disease; Secondary glaucoma in uveitis; Uveitic glaucoma

Definition

Intraocular pressure (IOP) rises due to intraocular inflammation, which may lead to optic nerve damage.

Etiology

Mostly infectious but also some noninfectious uveitis entities that can lead to a secondary IOP rise. A direct obstruction of the trabecular meshwork or trabeculitis is thought to be responsible (Radhakrishnan et al. 2010). This has to be distinguished from secondary glaucoma caused by complications of long-standing uveitis.

The prevalence of secondary glaucoma increases with chronicity and severity of disease.

- Infectious: herpetic anterior uveitis (HSV, VZV, and CMV) is the leading entity, but also other infectious uveitis forms as, e.g., toxoplasmic chorioretinitis, syphilis, or tuberculosis, can be accompanied by anterior chamber reaction and subsequent pressure rise.
- Noninfectious: the most typical is sarcoidosis-associated anterior uveitis or panuveitis.

Clinical Presentation

Patients with infectious uveitis present with unilateral uveitis of sudden onset and most often granulomatous keratic precipitates (KP). In the case of herpetic origin, segmental or patchy iris atrophy can be seen and often corneal involvement in the form of endotheliitis and/or corneal edema (Filho and Liesegang 2010a; b).

Patients with noninfectious uveitis and elevated IOP more frequently show bilateral disease. Granulomatous KP and Koeppe or Busacca nodules are a hallmark of sarcoidosis-associated uveitis.

Diagnosis

Tonometry should be performed in all uveitis patients at presentation. Return of ciliary body function with subsidence of uveitis may be associated with a rise in IOP. Therefore, it is important to continue monitoring IOP long enough as the inflammation resolves. Where herpetic uveitis is suspected, corneal sensitivity testing before administering local anesthesia should be performed. Gonioscopy is obligatory to find out the pathogenesis (open angle or angle closure) of IOP elevation.

Friederike Mackensen: deceased.

Differential Diagnosis

Entities, where noninflammatory material blocks the trabecular pores, as lens material in phacolytic glaucoma, red blood cells in hyphema, or photoreceptor segments in retinal detachment (Schwartz-Matsuo syndrome).

Prophylaxis

Antiherpetic therapy should be given for an appropriate length of time; sometimes many years of low-dose therapy are needed. Low-dose corticosteroid drops should be given in all cases, e.g., 1–2 drops of prednisolone acetate 1% daily. Visual field examination and structural measurements of the optic nerve head and RNFL should be repeated in regular intervals.

Therapy

IOP normalizes with control of inflammation. Thus, infectious uveitis has to be treated according to the pathogen involved, adding local and sometimes oral corticosteroids. Noninfectious uveitis should be treated with local and/or oral corticosteroids. Sometimes it will be difficult, especially in noninfectious uveitis, to distinguish secondary glaucoma caused by inflammatory activity or scarring from corticosteroid-induced IOP raise. Gonioscopy should be performed, and if in doubt local treatment may be changed to oral corticosteroids or to loteprednol with lesser probability of causing an IOP rise. Only few patients where complications as anterior synechia have taken place will require continued antiglaucomatous treatment or surgery.

Prognosis

Prognosis is generally good, but it depends on the time of inflammation, equalling the likelihood of complications having taken place. Relapsing herpetic anterior uveitis that is not properly treated will lead to optic nerve damage as well as scarring of the trabecular meshwork, so pressure control in some cases may only be achieved by surgical methods.

Epidemiology

IOP rise is observed in about 20% of uveitis patients, but only 35% of them had glaucoma (Sallam et al. 2009). In herpetic anterior uveitis, HSV is found more frequently than VZV, and patients with HSV-associated uveitis seem to be younger than those where VZV is involved (Van der Lelij et al. 2000). Still manifest secondary glaucoma is a rare complication in only 2–4% of cases (Tugal-Tutkun et al. 2010).

Definition

Measurement of the thickness of the cornea, by means of a pachymeter.

Purpose

To measure the thickness of the cornea.

Principle

An instrument used for this purpose is called a pachymeter. Earlier forms of pachymetry are based on optical methods, while modern ones are based on ultrasound methods. Some methods require contact with the cornea, whereas others do not. A conventional pachymeter uses an ultrasonic transducer that touches the cornea and displays the thickness of the cornea, usually in micrometers, at the point of contact. By knowing the speed of sound through corneal tissue and the time it takes for the sound to travel through the cornea, one can calculate the thickness of the cornea. Other methods include confocal microscopy, optical coherence tomography (OCT), scheimpflug, and corneal waveform. OCT can provide a thickness map of the entire cornea.

Indication

It is useful in the screening and management of diseases such as glaucoma, Fuch's corneal dystrophy, and keratoconus and is pertinent for the planning of refractive surgery. Average corneal

U. Schmidt-Erfurth, T. Kohnen (eds.), *Encyclopedia of Ophthalmology*,
https://doi.org/10.1007/978-3-540-69000-9

thickness is approximately 530–545 μm in non-glaucomatous eyes.

Contraindication

There are no contraindications per se as pachymetry is noninvasive. However, some methods require corneal contact with the probe of the pachymeter.

[6]College of Medicine, Texas A&M University, College Station, TX, USA
[7]Department of Ophthalmology and Visual Sciences, University Hospitals Eye Institute, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

Synonyms

Afterimages; Visual perseveration

Definition

Palinopsia is a visual disturbance where images persist after their corresponding environmental stimulus is no longer present (Bender et al. 1968). Typically palinopsia is categorized into two different subgroups, illusory and hallucinatory. Illusory palinopsia consists of prolonged indistinct afterimages, light streaking, visual trailing, and momentarily formed image perseveration (Gersztenkorn and Lee 2014). Hallucinatory palinopsia consists of formed image perseveration, scene perseveration, categorical incorporation (a patient seeing an object or feature and then superimposing it onto comparable objects or people), and patterned visual spread (Gersztenkorn and Lee 2014).

Etiology

Palinopsia has many different etiologies. Some of these etiologies include: post-geniculate cortical lesions, metabolic or systemic disease, idiopathic seizures, diffuse cortical pathology, drug induced, migraine, head trauma, psychiatric conditions, and visual snow clinical syndrome (Gersztenkorn and Lee 2014).

Clinical Presentation

Palinopsia is a constellation of symptoms that are ascertained by a detailed medical history. The physician will need to determine if the afterimages are best described as a hallucinatory or illusory palinopsia. Some key indicators include: content, duration, and quality (e.g., color, shape, motion) of the persisting images or scenes. The episodes may vary by time of day, the number and frequency of episodes, and the location in the visual field of the original and perseverated images. Sometimes light or motion exacerbates or precipitates the palinopsia (Abert and Ilsen 2010). It is important to obtain a careful neurological history of migraines, cerebrovascular accidents, seizure disorder, or neoplasm because these disorders can all cause palinopsia. The examiner should

also ask about prescription drug use, head trauma, and hallucinogenic drug use (Abert and Ilsen 2010).

Diagnostics

Visual fields and neuroimaging should be obtained in patients with palinopsia. Routine labs such as a complete metabolic panel and complete blood count (CBC) may be done to check for metabolic disturbances or hint at the presence of a neoplasm (Gersztenkorn and Lee 2014). Other diagnostic tests can be performed as needed. These would include structural or functional neuroimaging, electroencephalogram (EEG), electroretinogram (ERG), visual evoked potential (VEP), lumbar puncture, or drug screen (Gersztenkorn and Lee 2014).

Differential Diagnosis

(a) Physiological afterimages
(b) Visual hallucinations
(c) Illusions
(d) Polyopia
(e) Diplopia

Prophylaxis

Therapy

The treatment of palinopsia greatly differs according to the etiology, but many forms of treatment have shown anecdotal but variable positive results.

Prognosis

The prognosis for palinopsia differs according to the etiology.

Epidemiology

Palinopsia can affect patients of any age, either gender, and all races.

Synonyms

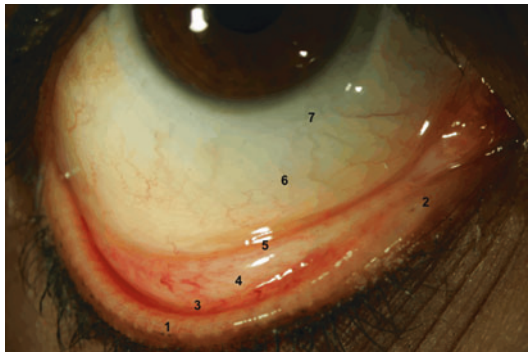
Conjunctiva; Tarsal conjunctiva

Definition

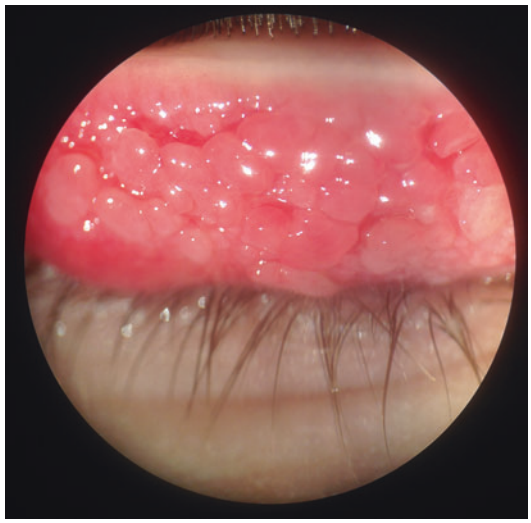
The conjunctiva is a mucous membrane that can be divided into three anatomical subdivisions: (1) palpebral, (2) forniceal, and (3) bulbar. The palpebral conjunctiva is firmly attached to both the upper and lower tarsi; however it is more firmly attached to the upper tarsus.

Structure

The palpebral conjunctiva begins at the posterior third of the meibomian gland openings of each eyelid. At this mucocutaneous junction, the cells change from a keratinized stratified squamous



Palpebral Conjunctiva, Fig. 1 Colored slit-lamp photograph of right lower eyelid. (*1*) Mucocutaneous junction, (*2*) lacrimal punctum, (*3*) subtarsal groove, (*4*) tarsal conjunctiva, (*5*) forniceal conjunctiva, (*6*) bulbar conjunctiva, and (*7*) contact lens on limbus



Palpebral Conjunctiva, Fig. 2 Clinical photograph of giant papillary conjunctivitis (attached)

epithelium of the skin to a nonkeratinized stratified squamous epithelium of the marginal conjunctiva. Nasally, this mucocutaneous junction is where the conjunctiva connects to the lacrimal puncta (Figs. 1 and 2).

Two millimeters from the eyelid margin on the palpebral conjunctiva is a shallow grove known as the subtarsal groove. This groove lies parallel to the eyelid margin and marks the transition from a stratified squamous epithelium of the marginal conjunctiva to a cuboidal epithelium of the palpebral conjunctiva. This groove acts as a trap for foreign bodies, bacteria, and cellular debris before they reach the cornea and bulbar conjunctiva. There are a series of small saccular mucus glands between the eyelid margin and tarsal groove that open to the conjunctival surface.

All three geographic areas of the conjunctiva consist of nonkeratinized epithelium over the substantia propria. The nasal palpebral conjunctiva contains numerous crypts known as Henle's mucus crypts. In the central palpebral conjunctiva, these crypts form a network of subepithelial grooves. The grooves become tunnels with interconnections that open onto the ocular surface. These grooves and tunnels divide the conjunctiva into papillae. Mucin-secreting goblet cells, mucous glands, and clusters of cells known as the glands of Manz are also scattered within the epithelium. The fornices contain more goblet cells than the tarsal and bulbar conjunctivas; the inferior and nasal conjunctivas have more goblet cells than the superior and temporal conjunctiva.

The palpebral conjunctiva has a rich sensory innervation from the ophthalmic division of the trigeminal nerve (V1). These nerves are nociceptors that are sensitive to energy, heat, chemical irritants, and chemical mediators. There are no motor fibers in the conjunctiva. The conjunctiva receives blood from the muscular, medial palpebral, and lacrimal branches of the ophthalmic artery.

Function

The palpebral conjunctiva plays a key role in:

- Ocular surface integrity
- Ocular surface lubrication
- Protection of the globe
- Absorption of topical medications

Clinical Relevance

The conjunctiva is best examined using slit-lamp biomicroscopy by lowering the lower eyelid and everting the upper eyelid.

Local and systemic diseases may manifest themselves in the palpebral conjunctiva. The palpebral conjunctiva is examined for follicles and papillae. Follicles represent hypertrophy of the underlying lymphoid tissue and do not have prominent central vessels. Papillae are tiny, dome-shaped nodules with a central core of hyperemic blood vessels surrounded by edema and inflammatory cells; papillary conjunctivitis may show a cobblestone arrangement of these flattened nodules.

Follicular reactions are most commonly due to viral, chlamydial, allergic, and toxic etiologies. Topical medications such as brimonidine or over-the-counter ophthalmic decongestants have been reported to cause follicular conjunctivitis. Papillary reactions are most commonly associated with allergic immune responses (e.g., vernal and atopic keratoconjunctivitis) or foreign bodies (e.g., contact lens wear).

In addition to follicular and papillary reactions, other common pathologies found in the palpebral conjunctiva are granulomas, membranes, pseudomembranes, scarring, and foreign bodies. Though rare, nevi, dysplasias, and carcinomas involving the palpebral conjunctiva have been reported.

Palpebral Vernal Conjunctivitis/ Keratoconjunctivitis

Kevin C. Chen
Department of Ophthalmology, New York University Langone Medical Center, New York, NY, USA

Synonyms

Vernal conjunctivitis

Definition

Vernal keratoconjunctivitis (VKC) is a chronic, bilateral form of ocular surface allergic inflammation. There are two forms of VKC: palpebral and limbal. The palpebral type predominantly involves the upper tarsal conjunctiva, while the limbal form affects the cornea, limbus, and sclera. The two types are not exclusive and patients may present with signs of both.

Etiology

Vernal keratoconjunctivitis is an immune-mediated hypersensitivity reaction. The primary pathway likely involves a type I immediate hypersensitivity response. Lymphoid follicles in the conjunctiva are stimulated to produce IgE, which leads to mast cell degranulation and release of histamine in addition to other compounds. This results in vasodilation and recruitment of inflammatory cells such as eosinophils. Type IV delayed hypersensitivity may also play a role, resulting in

a common pathway of IgE production, mast cell degranulation, and inflammatory cell recruitment (De Smedt et al. 2013).

Clinical Presentation

Patients with VKC typically have bilateral complaints of photophobia, intense itching, tearing, and a thick mucus discharge. They may also experience burning, foreign body sensation, pain, and blurred vision (De Smedt et al. 2013).

The hallmark of palpebral VKC is the presence of discrete, giant cobblestone-like papillae on the upper palpebral conjunctiva. Examination may also reveal conjunctival hyperemia, a sticky nonpurulent mucus discharge, blepharospasm, and ptosis.

Diagnosis

The diagnosis of palpebral VKC is made clinically, with typical signs on external examination in the classic patient population. Diagnosis may be aided by conjunctival scrapings showing eosinophilic predominance and tear analysis showing increased IgE levels, but these laboratory tests have low sensitivity and specificity. Conjunctival biopsies can show increased mast cells, eosinophils, and lymphocytes (Bonini et al. 2004). Histologically, giant papillae are characterized by a squamous epithelial hyperplasia with an extensive inflammatory infiltrate into the fibrous tissue (De Smedt et al. 2013).

Differential Diagnosis

Atopic keratoconjunctivitis (perennial, lower tarsus).

Giant papillary conjunctivitis (related to contact lens use).

Therapy

First-line therapy for VKC is with dual-acting topical antihistamines and mast cell stabilizers. These inhibit mast cell degranulation as well as block histamine receptors in the conjunctiva and eyelids. Topical corticosteroids can be considered if there is poor response. Topical calcineurin inhibitors such as cyclosporine have also been shown to be effective (Kumar 2009).

Nonspecific therapy includes avoidance of triggers, avoidance of eye rubbing to decrease mast cell degranulation, artificial tears, and cool compresses.

Prognosis

The prognosis of palpebral VKC is generally excellent, as it is most often a self-limiting disease with spontaneous resolution after puberty.

Epidemiology

Vernal keratoconjunctivitis is typically seen in young male patients in their first decade of life who live in warm, dry, subtropical climates. Exacerbations of this disease usually occur in the spring, but in a minority of patients may also occur in the winter and can develop into a chronic, perennial disease (De Smedt et al. 2013). There is an association of this disease with other atopic diseases such as asthma and allergic rhinitis, as well as with a family history of atopy (Kumar 2009).

Pannus/Micropannus

Alireza Eslampoor
Eye Research Center, Khatam-al-anbia Eye Hospital, Mashhad, Razavi Khorasan, Iran

Synonyms

Corneal neovascularization; Corneal vascularization; Fibrovascular pannus

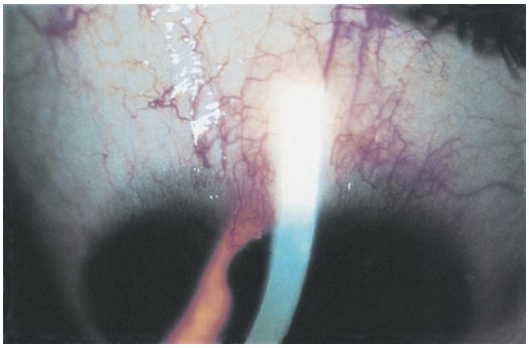
Definition

Pathologic ingrowth of vessels from the limbal vascular plexus into the cornea (pannus is a Latin word meaning carpet).

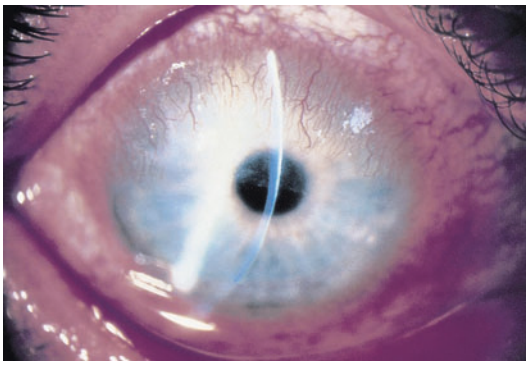
In general, the mainspring of this pathology is ocular surface inflammation. When blood vessels and fibrous connective tissue from the limbus grow onto the peripheral cornea, secondary to inflammation, the result is a *fibrovascular pannus*. A vascular pannus could be seen in any corneal location depending upon the inciting inflammation. In adults, pannus usually extends from the peripheral cornea toward the central cornea and is generally flat. In infants and small children, pannus may develop as a hyperplastic reaction to the inflammation, and it could be seen as an elevated lesion.

There are three basic cells involving in formation of subepithelial vascular fibrosis: leukocytes, proliferating vascular endothelial cells, and active fibroblasts that secrete an extracellular connective tissue matrix. Also, there are three basic ways for generation of this pathology:

1. Following mild insults (e.g., contact lens-induced hypoxia), in which a very fine sheet of fibrovascular tissue slowly migrates from the limbus
2. After severe insults (e.g., alkali burns) in which a thick layer of exuberant fibrovascular tissue may develop across the entire cornea
3. In the base of chronic long-standing insult such as trachomatous eyelid scarring and entropion where a progressive dense pannus spreads centrally from the limbus (Krachmer et al. 2011).



Pannus/Micropannus, Fig. 1 Superior corneal micropannus. American Academy of Ophthalmology, ONE Network Image Collection

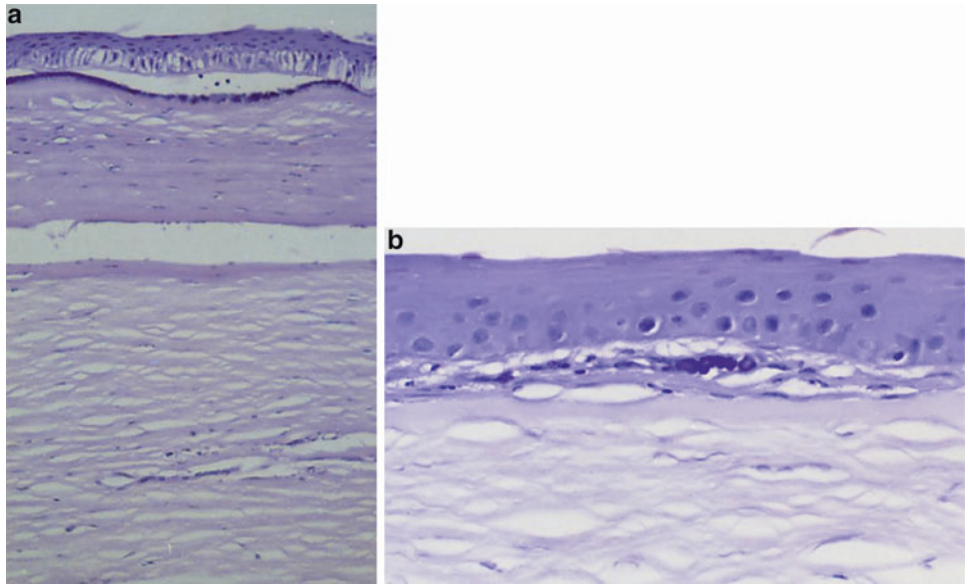


Pannus/Micropannus, Fig. 2 Corneal pannus, subepithelial fibrous ingrowth. American Academy of Ophthalmology, ONE Network Image Collection

In general, fibrous or vascular tissue spread between the epithelial basement membrane and Bowman's layer, but neither of them become fibrotic or vascularized. Sometimes, a fibrovascular tissue replaces the Bowman's layer or grows into the anterior stroma immediately posterior to Bowman's layer (Figs. 1, 2, and 3).

Etiology

There are so many situations that could eventuate to pannus formation: infection such as inclusion conjunctivitis, trachoma, herpes simplex



Pannus/Micropannus, Fig. 3 Pannus, degenerative, and fibrovascular. American Academy of Ophthalmology, ONE Network Image Collection

infection, contact lens wear, trauma, chemical burn, immunologic diseases such as ocular rosacea, staphylococcal hypersensitivity, vernal keratoconjunctivitis, superior limbic keratoconjunctivitis, degeneration or intraocular events such as uveitis, glaucoma, and phthisis bulbi.

Several theories have been proposed for the development of contact lens-induced pannus. Mechanical rubbing from poorly fitting contact lenses could damage the limbal stem cells. This may cause perilimbal capillaries to grow between the corneal epithelium and Bowman's layer, forming a pannus.

These capillaries are usually accompanied by fibroblasts which produce collagen and induce Bowman's layer destruction, producing a superficial corneal scar and irregular astigmatism.

Mechanical pressure from blinking over contact lens may contribute to superior pannus formation. Long-term hypoxia from low oxygen-permeable soft contact lenses or chronic use of tight-fitted lenses could also result in pannus.

In the background of limbal stem cell deficiency, fibrovascular pannus formation is categorized as a type III corneal healing pattern which corresponds to a grade III injury. In this grade of injury, there has been complete loss of limbal stem cells but preservation of source of proximal conjunctival epithelium (Copeland and Afshari 2013).

In this pattern, delayed reepithelialization with conjunctival epithelium may occur in the next few weeks or months, although it will be with fibrovascular pannus (conjunctivalization) of the ocular surface, and the ultimate outcome is a vascularized cornea (Krachmer et al. 2011).

Clinical Presentation

Symptoms: may be asymptomatic or may result in mild to severe visual loss, ocular redness, stinging, and foreign body sensation

Signs:

Two patterns of pannus may be seen:

- Fine, superficial neovascularization of the cornea that is most commonly seen in contact lens wearers and also can be associated with blepharitis, superior limbic keratoconjunctivitis, vernal conjunctivitis, and many others

- Deep stromal neovascularization that could be seen in patients with extended wear contact lens, chronic blepharoconjunctivitis, keratitis, trachoma, toxic chemical injuries, graft rejection, and phlyctenulosis (Krachmer et al. 2011).

Diagnostics (Lab Diagnostics)

Diagnosis of pannus is usually made on the basis of characteristic clinical signs. Confocal microscopy and optical coherence tomography (OCT) could be used in difficult cases. Pathologic study could be confirmatory after fibrovascular sheet excision over the cornea.

Differential Diagnosis

Corneal neovascularization could occur in so many situations: infections (such as inclusion conjunctivitis, trachoma, and herpes simplex infection), contact lens wear, trauma, chemical burn, immunologic diseases (such as ocular rosacea, staphylococcal hypersensitivity, and vernal keratoconjunctivitis), superior limbic keratoconjunctivitis, degeneration or intraocular events such as uveitis, glaucoma, and phthisis bulbi.

Subepithelial opacities can be seen in epidemic keratoconjunctivitis, chlamydia, herpes simplex, staphylococcal disease, and nummular keratitis (Krachmer et al. 2011).

Prophylaxis

The main resource for prophylaxis is subsiding background inflammation and treating triggering condition.

Therapy

- Supportive, which directed at eliminating the underlying condition.
- Topical corticosteroid may be applied for subsiding background inflammation.
- Diathermy and thermal cautery of large feeding vessels could be used for ligating intrastromal vessels.
- Corneal laser photocoagulation has been among the surgical modalities to treat pannus.
- Intrastromal injection of anti-vascular endothelial growth factor (VEGF) agents could be used for regressing corneal neovascularization.
- Limbal stem cell grafting may be required in eyes with severe limbal stem cell deficiency such as chemical injuries and Steven-Johnson syndrome (Krachmer et al. 2011).

Prognosis

The prognosis could be differed from mild cases of micropannus formation with minimal change in corneal surface and good visual acuity to severe cases of extensive fibrovascular pannus with corneal surface destruction and severe visual loss.

Epidemiology

Unknown, it is dependent to underlying disorder.

Papilla Nervi Optici

► Fundamental Considerations Regarding the Optic Nerve

Papillae: Overview

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Raised conjunctival lesions

Definition

Papillae are raised inflammatory lesions that present typically in the palpebral conjunctiva and in the limbal bulbar conjunctiva attached to the deeper fibrous layer (Kanski and Bowling 2011). Papillae contain a vascular core, differentiating them from follicles. Follicles are lymphatic structures.

Structure

Papillae can appear in several forms and sizes. Micropapillae present as an eclectic, mosaic pattern of raised red dots, or a "goose-pimple" appearance (Yanoff and Duker 2014). This presentation is seen to be due to a central vascular channel (Kanski and Bowling 2011). Macropapillae (<1 mm) and giant papillae (>1 mm) occur in tandem with inflammation. These larger papillae may have a cobblestone appearance.

Histology of the papillae reveals hyperplastic conjunctival epithelium with a fibrovascular core and subepithelial stromal infiltration with inflammatory cells (Kanski and Bowling 2011). Prolongation of inflammatory changes can result in crypt formation with goblet cells, superficial stromal hyalinization, and scarring.

Function

Papillae occur due to conjunctival inflammation that is limited by the fibrous septa, resulting in the appearance of raised, vascular red dots (Kanski and Bowling 2011).

Clinical Relevance

Several ophthalmological diseases may present with papillae. These include but are not limited to bacterial conjunctivitis, allergic conjunctivitis, giant papillary conjunctivitis, vernal conjunctivitis, chronic marginal blepharitis, and contact lens wear (Kanski 2009).

Papilloma

- ▶ Papillomas, Eyelid
- ▶ Squamous Cell Papillomas of Eyelid

Papillomas, Conjunctival

Sidharth Puri
University of Louisville Ophthalmology, Louisville, KY, USA

Synonyms

Conjunctival squamous cell papilloma

Definition

Conjunctival papillomas are benign squamous epithelial growths of viral origin (human papillomavirus) with limited tendency toward malignancy (Bailey and Guethlein 1990). They may develop from the bulbar or palpebral conjunctiva. They are categorized as infectious, squamous, limbal, or inverted based upon clinical and patient history. They may also be classified according to gross appearance as either pedunculated or sessile.

Etiology

Infectious squamous conjunctival papillomas have a strong association with human papillomavirus (HPV) types 6 and 11 (Minchiotti et al. 2006). HPV is transmitted via direct human contact and typically produces benign tumor growths with minimal risk for malignancy. HPV 33 is also associated with conjunctival papillomas. The recurrence rate for conjunctival papillomas of viral etiology is quite high; limbal papillomas have a 40% recurrence rate.

Noninfectious causes of conjunctival papillomas may include UV radiation exposure (Bailey and Guethlein 1990).

Clinical Presentation

Clinical History

Squamous cell papillomas are associated with younger populations (<20 years), HPV infection, prior tumor excision, history of extraocular warts, similar history in a sibling, and no decrease in visual acuity (Bailey and Guethlein 1990).

Limbal papillomas are found in older adults, history of UV radiation, possible decrease in visual acuity, history of refractive chronic conjunctivitis, and recurrence after excision.

Physical Exam

Tumor location: Most conjunctival papillomas are isolated lesions. About 25% of lesions involving the caruncle are papillomas. Squamous cell carcinoma is commonly found only at the interpalpebral zone and rarely found far from the limbus.

Tumor color: Pigmented lesion hints at melanocytic origin. Yellow lesions may indicate a xanthoma. Salmon-coloration suggests lymphoid tumors.

Tumor growth pattern: Papillomas have solitary growth patterns as opposed to more diffusely growing lesions like sebaceous carcinomas with pagetoid growth.

Tumor texture: Conjunctival epithelial tumors tend to have raised, cobblestone appearance. Tumors with smoother epithelial surface tend to arise from the substantia propria. Moreover, abrupt borders exist between normal conjunctiva and tumor.

Squamous cell and limbal papillomas can be differentiated further by physical exam. Squamous papillomas tend to occur bilaterally and numerous at the inferior fornix commonly. Limbal are unilateral and solitary and occur at the limbus or bulbar conjunctiva.

Diagnostics (Lab Diagnostics)

Definitive diagnosis is typically obtained via biopsy (Eagle 1999). Biopsy is conducted to rule out malignancy and to determine surgical margins in poorly defined lesions. Frozen sections may also be acquired to rule out surgical margins for tumor.

Histology will help to determine the type of lesion. Squamous cell papillomas tend to have multiple branching fronds spreading outward from a narrow pedunculated base. Inflammation may be associated with these fronds, and the basement membrane is intact. In contrast, limbal papillomas tend to be sessile lesions that emerge from a broad base. The basement membrane is intact. Less commonly found, inverted papillomas exhibit exophytic and endophytic growth patterns.

Differential Diagnosis

Ichthyosis
Sebaceous Gland Carcinoma
Squamous Cell Carcinoma of the Conjunctiva

Prophylaxis

HPV vaccine and avoidance

Therapy

Surgery is indicated for conjunctival papillomas (Bailey and Guethlein 1990). Excisional biopsy is preferred to incisional biopsy when possible for patients. Seeding is a risk following excision. Observation and coordination with patient's wishes is important for deciding on therapy.

Squamous cell papillomas may regress over time. However, cryotherapy is indicated for squamous cell papillomas to reduce scarring and recurrence rate (Omohundro and Elliott 1970). This procedure is contraindicated for limbal papillomas because it does not help rule out malignant changes.

In cases where surgical excision, cryoablation, and other modalities have failed, suggested adjunctive therapies include interferon alpha (Schechter et al. 2002).

Prognosis

Positive prognosis for patients (Bailey and Guethlein 1990). However, recurrence is not uncommon for viral papillomas. Patients should receive follow-up to track recurrences.

Epidemiology

Limited prevalence data exists for conjunctival papillomas. However, it is well established that there is a strong association between HPV and squamous cell conjunctival papillomas (Minchiotti et al. 2006).

Squamous cell papillomas are found in typically children and young adults less than 20 years of age. Limbal cell papillomas typically occur in older adults.

Conjunctival papillomas are not life threatening and rather may cause cosmetic and visual discomfort for patients.

Cutaneous horn; Follicular keratosis; Papilloma; Pseudoepitheliomatous hyperplasia; Seborrheic keratosis; Squamous papilloma; Verruca vulgaris

Definition

Papilloma is a nonspecific term that describes benign epithelial proliferations of the eyelid.

Characteristics

Squamous papilloma is the most common benign growth of the eyelid. It may present as sessile or pedunculated, solitary or multiple lesions. Lesions tend to be slow growing. Verruca vulgaris is a specific squamous papilloma associated with the human papilloma virus (type VI and XI). The differential diagnosis for papillomas includes nevi, fibroma, epithelioma, actinic keratosis, verruca vulgaris, and seborrheic keratosis. Treatment involves observation, surgical excision, or carbon dioxide laser ablation.

Seborrheic keratosis is a common lesion of the eyelid that has a characteristic smooth, greasy, stuck-on appearance, with variable pigmentation. It may resemble squamous cell carcinoma. Treatment involves superficial shave excision at the junction between the dermis and epidermis. Inverted follicular keratosis is a term associated with irritated seborrheic lesions.

Pseudoepitheliomatous hyperplasia or pseudocarcinomatous hyperplasia refers to reactive changes in the epidermis adjacent to areas of previously treated cryosurgery or surgical wounds. It may be mistaken as a malignant lesion.

Cutaneous horn describes changes related to hyperkeratosis. These changes may be associated with a variety of benign or malignant epithelial lesions (Fig. 1) (Shields and Shields 1999; Albert and Jakobiec 2008).

Marcelo Cerullo
School of Medicine, Johns Hopkins University, Baltimore, MD, USA

Synonyms

Parasitic diseases; Parasitic infections

Definition

Parasitic disease of the eye includes any infection, infestation, or inflammation (e.g., neuro- and chorioretinitis, uveitis, keratitis) caused by any number of organisms (ranging from protozoans to helminths).

Structure

The manifestations of parasitic infections can either stem from systemic infection or be ocularly localized. Infections are wide ranging in their presentation. Detailed below are some of the most common etiologic agents and their ocular manifestations.

Clinical Relevance

(A) Parasitic retinitis and its causative organisms.

Toxoplasmosis (causative agent: *Toxoplasma gondii*) produces a necrotizing retinitis and is the most common cause of infectious retinitis in immunocompetent patients. Common signs include decreased vision, photophobia, floaters, vascular sheathing, full-thickness retinal necrosis, and a fluffy, yellow-white retinal lesion with overlying vitreous reaction. Toxoplasmosis infection is categorized as either **acquired** (from eating undercooked meat) or **congenital** (from transplacental transmission). *T. gondii* is an obligate intracellular protozoan, and its most definitive host is domesticated felines, though it can also infest other mammals (principally livestock) as well as humans. Infection is initiated by ingestion of the oocysts from feces of the definitive host in contaminated food or water or from the ingestion of tissue cysts (which include bradyzoites), that are the product of infection in the animal itself. Tissue disruption is caused by the active form of the protozoan, called tachyzoites.

Complications of toxoplasma infection include direct involvement of the macula or secondary optic nerve head involvement due to a juxtapapillary lesion. Less common complications include primary optic nerve head involvement, which can present as anterior ischemic optic neuropathy or if the inflammatory focus of the primary infection can induce occlusion of a larger blood vessel, triggering ischemia. Cases of choroidal neovascularization, serous retinal detachment, tractional retinal detachment, and macular edema have all been reported in conjunction with toxoplasma.

Treatment is geared toward reducing the acute inflammation and the risk of permanent visual loss by reducing scarring. Small lesions do not usually require treatment if they are peripherally located, though severe or posterior infections are treated for up to 6 weeks with pyrimethamine and

trisulfapyrimidine, and patients are usually given leucovorin calcium to prevent bone marrow suppression. Clindamycin is an alternative therapy. Complications (including increased intraocular pressure) are managed as they would be otherwise.

Taenia solium is a common tapeworm that infects swine and humans. Like many cestodes, its life cycle begins in humans with the ingestion of eggs or gravid proglottids. Larvae migrate into the host tissue to cause cysticercosis. It can occasionally cause conjunctivitis but usually invades the retina, choroid, or vitreous. Diagnosis is made from a positive complement fixation or precipitin test or by demonstrating the presence of the organism in the gastrointestinal tract. Eosinophilia is usually present as well.

Treatment for *T. solium* requires excision of the ocular lesion and niclosamide (or praziquantel) for the tapeworm infection. Parasitic conjunctivitis and its causative organisms (Garcia et al. 2013).

Pthirus pubis infection is caused by pubic lice and may infest the cilia and the margins of the eyelids. A toxic follicular conjunctivitis in children and a papillary conjunctivitis in adults is caused by the release of an chemical irritant. Intense itching is usually present. Diagnosis is confirmed by finding either the adult organism or oval-shaped nits.

Treatment for *P. pubis* includes lindane or pyrethrins, applied to both the pubic area and the lash margins after removal of the nits. All clothes and accessories that may have come in contact should be washed carefully.

Ophthalmomyiasis is an infection caused by the larvae of flies (common species include *Musca domestica*, *Fannia*, and *Oestrus ovis*), which can invade either necrotic or healthy tissue. External wounds and ingestion are the most common routes of transmission. The infection usually occurs on the surface of the eye, though cases have been reported with infection in intraocular tissues.

Treatment is the removal of the larvae after the application of a topical anesthetic (Kean et al. 1991).

Thelazia californiensis is a roundworm that usually inhabits the eyes of domesticated dogs, but also infects a range of mammals (feral and domestic). Accidental infection through contact has been reported. Treatment is the removal of the larvae after the application of a topical anesthetic.

Loa loa is a common eye worm in sub-Saharan Africa and resides in the connective tissue of primates. A vector fly (such as the horse or mango fly) ingests microfilariae from an infected human host, which then move to the fat body of the insect and develop into larvae. The infective form of the larvae travels to the proboscis and is then transmitted to an uninfected host upon a bite. The infective form matures into microfilariae which disseminate in various host tissues. Diagnosis is made by identifying the organism in a blood smear, usually corroborated by mild eosinophilia (Cook et al. 2009). Treatment is diethylcarbamazine.

Ascaris lumbricoides is a roundworm that can cause a very painful and toxic conjunctivitis from the exposure to infected tissue of other animals and must be treated by rapid and thorough irrigation of the conjunctiva (Gunn and Pitt 2012).

Trichinella spiralis is a nematode parasite and more commonly the cause of trichinosis, which can be asymptomatic or cause general enteric symptoms. It completes its life cycle in a single host, beginning with the ingestion of cysts in infected meat. The larvae in these cysts are released in the stomach and migrate to the intestines, where they reproduce as anaerobic or facultative anaerobes. The larvae then gain access to the circulation and migrate throughout the host tissues and can cause myocarditis or encephalitis as well as infection of the muscle and cutaneous tissue. Most patients have a chemosis (a pale swelling over the lateral and medial rectus muscles) which may last a week or more (Gunn and Pitt 2012).

Schistosoma haematobium is more commonly the cause of schistosomiasis (bilharziasis), which is endemic in the regions bordering the Nile River. It is a

trematode (flatworm) that uses snails as its intermediate host. Infective free-swimming larval cercariae burrow into the human skin and enter the bloodstream and migrate to the liver. They then migrate to the urinary bladder to reproduce and be further disseminated. *S. haematobium* infection results in a characteristic granuloma that has lymphocytes, plasma cells, giant cells, and eosinophils surrounding the ova's various different stages. Conjunctival lesions are similar to *Trichinella* (Cook et al. 2009).

Treatment of choice includes praziquantel or antimonials and excision of the granuloma.

Synonyms

Dorsal midbrain syndrome; Parinaud's syndrome; Vertical gaze palsy

Definition

Parinaud syndrome (PS) is a collection of eye movement and pupillary response dysfunction most commonly caused by compression or lesion of the dorsal midbrain. Named after the French ophthalmologist Henri Parinaud (1844–1905), it is most commonly associated with vertical gaze palsy.

Etiology

PS can be caused by any lesion (e.g., compression, ischemia, inflammatory) of the dorsal midbrain. In young patients, the most common cause is a tumor of the pineal region (e.g., dysgerminoma or pinealoma). In younger to middle-aged women, multiple sclerosis and, in older patients, stroke are common causes of PS. However, any damage to the riMLF, mesencephalic tectum, including the superior colliculus, oculomotor nuclei, and Edinger-Westphal nuclei can present with PS including trauma, obstructive hydrocephalus (ventriculoperitoneal shunt failure), hemorrhage, cerebral arteriovenous malformation, toxoplasmosis, neoplasms of the posterior cranial fossa, and aneurysms.

Clinical Presentation

The defining characteristics of PS are upgaze paralysis (downward gaze is often preserved), light-near dissociation of the pupils, accommodative paresis, convergence-retraction nystagmus, and eyelid retraction (Collier's sign). Later conjugate downgaze palsy or downgaze preference (setting-sun sign) may occur. Less common clinical findings in PS include: papilledema, spasm of accommodation, thalamic esotropia, seesaw nystagmus, skew deviation, oculomotor nerve palsy, trochlear nerve palsy, and internuclear ophthalmoplegia.

Diagnostics

Neuroimaging is essential to accurately diagnose and effectively treat patients with PS.

Differential Diagnosis

Any lesion in the dorsal midbrain can produce PS including neoplasm (e.g., pinealoma, pineal cysts, tumors of the midbrain), multiple sclerosis, stroke, aneurysm, obstructive hydrocephalus (commonly ventriculoperitoneal shunt failure), hemorrhage, cerebral arteriovenous malformation, and infection (e.g., toxoplasmosis, syphilis).

Prophylaxis

No method of prophylaxis has been established.

Therapy

Therapy for PS should be directed to the underlying etiology.

Prognosis

The prognosis depends on the underlying etiology.

Epidemiology

PS in children is commonly caused by pinealomas or hydrocephalus. In middle-aged women, multiple sclerosis is often the cause. In older patients, stroke and hydrocephalus are the most common etiological agents.

Pars Plana Vitrectomy

Armin Wolf
Department of Ophthalmology,
Ludwig-Maximilians Universität München,
München, Germany

Definition

Surgical procedure to remove the vitreous or part thereof by accessing vitreous cave via pars plana.

Epidemiology

Formerly related to a large variety of serious complications, vitrectomy – especially small-gauge pars plana vitrectomy – has become a widely used technique for a large number of pathologies. To date approximately 200,000 vitrectomies are performed in the USA per year.

History

Robert Machemer first established pars plana vitrectomy as a single-port 19-gauge procedure in 1969. Using this technique, it was possible to remove part of the vitreous in case of vitreous opacities (Fabian and Moisseiev 2011). Further technical improvement established pars plana vitrectomy as a widely used technique for a large variety of pathologies. Nowadays pars plana vitrectomy is used for surgery of retinal detachment, of vitreous pathologies, and of vitreoretinal interface pathologies (such as macular pucker or macular hole formation).

Clinical Features

In pars plana vitrectomy, accession of the vitreous cave is via pars plana. In this anatomical region posterior of the ciliary body, perforation of the eye is possible, as no retinal tear has to be feared. Thus, sclerostomy (either using an incisional knife or a trocar) is performed 3.5–4 mm from the limbus. In a usual setting, pars plana vitrectomy is performed as a three-port vitrectomy: While the temporal lower quadrant is site for the infusion providing constant pressure, two additional sclerostomies are within the upper quadrants providing bimanual accession for the surgeon.

Excision of the vitreous is usually performed using a specially designed cutter. This cutting tool usually consists of a tube with an oscillating knife. By applying suction, the vitreous is sucked into the tube and cut by the oscillating knife.

Critical steps during vitrectomy include induction of posterior vitreous detachment and excision of the anterior part of the vitreous (vitreous base).

While for a long time, pars plana vitrectomy has been performed using 20-gauge instruments, the majority of vitrectomies nowadays are performed using a trocar system and smaller instruments (23 gauge, 25 gauge, or 27 gauge) Recchia et al. (2010).

There are a large variety of instruments for surgery such as forceps, lights, and different cutters.

Tests

Efficacy of this surgical procedure for a large number of pathologies has been demonstrated.

Etiology

See "History."

Treatment

There are several indications for pars plana vitrectomy: vitreous hemorrhage, retinal detachment, macular pucker, or complications during cataract extraction to name a few.

Pars Plana; Pars Plicata

Kimberly E. Stepien
Department of Ophthalmology and Visual Sciences, Medical College of Wisconsin Eye Institute, Milwaukee, WI, USA

Synonyms

Ciliary body

Definition

The ciliary body is divided into an anterior ring, the pars plicata, and a posterior ring, the pars plana. The pars plicata is 1.5 mm wide and contains 70–75 fingerlike projections called ciliary processes. The pars plana is 3.5–4.0 mm wide in an adult eye and is an ideal location for instrument insertion or intravitreal injection due to minimal potential damage to the eye. Both the pars plicata and pars plana are covered by a bilayered ciliary epithelium. The inner nonpigmented epithelium is the main source of aqueous humor in the eye. The outer pigmented epithelium creates the blood-aqueous barrier.

Partial Coherence Interferometry

Wolfgang Herrmann[1] and Thomas Kohnen[2]
[1]Department of Ophthalmology, University of Regensburg Medical Center, Regensburg, Germany
[2]Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Optical biometry

Definition

Partial coherence interferometry is an optical biometry of intraocular distances in the eye.

Purpose

Partial coherence interferometry allows precise measurement of central corneal thickness, anterior chamber depth, lens thickness, and axial length of the eye.

Principle

In dual-beam partial coherence interferometry, a Michelson interferometer splits an infrared light beam of high spatial coherence but very short coherence length into two parts, forming a coaxial dual beam. This dual light beam, containing two

beam components with a mutual time delay of twice the interferometer arm length difference introduced by the interferometer, illuminates the eye. Both components are reflected at several intraocular interfaces that separate media of different refractive indices. If the delay of these two light beam components produced by the interferometer equals an intraocular distance within the coherence length of the light source, an interference signal (called partial coherence interferometry signal) is detected, similar to that of ultrasound A-scan. In anterior segment partial coherence interferometry, longer wavelengths are applied as compared to measurement of the axial length.

Indication

Optical biometry of the eye prior to cataract or refractive surgery.

Contraindication

Patients with dense cataracts or patients unable to cooperate or fixate during the measurement process.

Advantage/Disadvantage

Partial coherence interferometry is a highly precise and reliable method for biometry of the eye. The precision of measurement seems to be higher than in ultrasound biometry. In contrast to ultrasound contact biometry, the measurement is independent of the examiner's ability to locate the correct position of the eye during measurement. In contrast to ultrasonic biometry, noncontact anterior segment partial coherence interferometry reduces the risk of injuring the cornea during measurement. However, partial coherence interferometry cannot be applied in patients with opaque media.

Pathologic Myopia

Maurizio Battaglia Parodi and
Alessandro Rabiolo
Department of Ophthalmology, University Vita-Salute, IRCCS San Raffaele Hospital, Milan, Italy

Synonyms

Degenerative myopia

Definition

Myopia (shortsightedness or nearsightedness) is a refractive error where light is focused in front of the retina, instead of on retina itself, leading to blurring of distant objects.

Myopia can be classified as simple (physiologic) and pathologic (or degenerative).

Eyes with simple myopia have a refractive error of less than 6 diopters (D) and lack pathological changes, whereas eyes with pathologic myopia (PM) present a refractive error of at least 6 D and/or axial length greater than 26.5 mm in association with degenerative changes occurring especially in the posterior segment of the globe.

Etiology

The etiology of PM is still unclear, but both hereditary and environmental factors seem to play a role. It may be determined by genetic factors to a greater extent than simple myopia and the genetic profile of PM might differ from that of simple myopia.

Several evidences suggested a genetic role in myopia. Twin studies have shown high concordance for myopia. Moreover, children of myopic parents have a higher incidence of myopia and the incidence is greater if both parents suffer from myopia. Multiple loci for susceptibility to myopia have been mapped, most of which are autosomal dominant. These loci include MYP3 on 12q, MYP5 on 17q, MYP6 on 22q12, MYP7 on 11p13, MYP8 on 3q26, MYP9 on 4q12, MYP10 on 8p23, MYP11 on 4q22-q27, MYP12 on 2q37.1, MYP14 on 1p36, MYP15 on 10q21.1, MYP16 on 5p15.33-p15.2, MYP17 (formerly MYP4) on 7p15, MYP19 on 5p15.1-p13.3, and MYP20 on 13q12.12. An autosomal recessive locus, MYP18, maps to 14q21-q24. X-linked loci include MYP1 on Xq28 and MYP13 on Xq23-q25. More than 30 different genes have been linked to myopia, including PAX6, COL1A1, COL2A1, TGFB1, and TGFB2. Two recently published genome-wide association studies (GWAS), namely, CREAM and 23andMe, enrolling 45,771 patients discovered 20 novel genes associated with myopia. Furthermore, PM occurs commonly in association with Marfan, Ehlers-Danlos, Down, and Stickler syndromes.

Environmental factors include close work, emotional stress, and increasing formal education. Prolonged accommodation and intraocular pressure are suspected of influencing axial elongation in eyes with decreased scleral resistance. Many factors including scleral growth and remodeling along with vitreous synthesis might be involved in the development of myopia.

Histology

In PM, several ocular structures differ from normal eyes (e.g., sclera, choroid, Bruch's membrane, and optic nerve head). In eyes with high axial myopia, scleral thickness posterior to equator is diminished in comparison to emmetropic eyes, while anterior scleral and central corneal thickness do not seem to be dependent on axial length. Subfoveal choroidal thickness is markedly decreased in eyes with high axial lengths, decreasing by 15 μm for every −1 D change. The thickness of Bruch's membrane is preserved in patients affected by high myopia. However, Bruch's membrane, together with retinal pigment epithelium (RPE) and choriocapillaris, may be absent in the temporal optic disk border and this area has been named "parapapillary gamma zone."

Regarding optic nerve head, a positive relationship has been proved between its size and axial length above 26.5 mm or refractive error below −8 D. Interestingly, such relationship does not apply to non-highly myopic eyes. Moreover, the lamina cribrosa of eyes with PM is significantly thinner than emmetropic ones.

Epidemiology

Myopia is one of the leading causes of visual impairment in the world, especially between the ages of 20–50 years. The prevalence of myopia varies between 2% and 33%, depending on the race and age of the population analyzed. The prevalence of PM has been reported to be 1–2% of the total population of the United States, but is higher in Asia and the Middle East. According to a survey conducted on Taiwanese schoolchildren, the prevalence of myopia in urban area reaches 80–90% of students aged between 16 and 18 years, whereas 10–20% have PM.

Diagnosis

The diagnosis of PM is exquisitely clinical and it depends on the refractive status and/or axial length of the patient eye. However, different imaging modalities are extremely useful to characterize myopic complication. Mydriatic fundus examination is indispensable in order to evaluate macula, optic nerve, peripapillary area, and retinal periphery. OCT is an essential tool to identify, characterize, and stage PM complications, whereas fluorescein angiography is still the gold standard for diagnosis of many macular complications.

Clinical Presentation

Several retinal abnormalities have been recognized in PM involving macula, peripapillary area, vitreoretinal interface, peripheral retina, and optic nerve. The posterior staphyloma is a paradigmatic feature of PM, consisting of thinning and ectasia of the sclera at the posterior pole, and it can be further classified in ten subforms. Posterior staphyloma incidence increases with age, and it can be found up to 80–90% of highly myopic patients over 40 years and can be complicated by chorioretinal folds in about 1% of cases. The classification of the pathologic conditions associated with degenerative myopia includes alteration at the level of the macula, optic disk, vitreoretinal interface, and peripheral retina. Additional diseases related to PM include glaucoma and cataract.

Macula

Myopic maculopathy is a potentially sight-threatening complication, characterized by one or more of the following lesions: (i) tessellated fundus, due to the visualization of choroidal vessels through the retina; (ii) lacquer cracks, which are linear breakage of the Bruch's membrane; (iii) diffuse atrophy, caused by the diffuse pigment loss of the macular pigment epithelium; (iv) patchy atrophy, which are focal round-shaped areas of chorioretinal atrophy; (v) CNV, where choroidal neovessels spread into the retina; and (vi) macular atrophy, which is a wide area of chorioretinal atrophy. In a long-term natural history study, Hayashi and colleagues observed a disease progression in approximately 40% of the eyes enrolled with a linear progression pattern from tessellated fundus to macular atrophy. Macular involvement consists of CNV, dome-shaped macula, submacular hemorrhage, and intrachoroidal cavitation.

Choroidal Neovascularization

Choroidal neovascularization (CNV) represents a major cause of visual loss in myopic eyes. Myopic CNV prevalence has been reported to be between 5% and 10%, with subfoveal location being quite frequent, accounting for 58–74% of cases, whereas juxtafoveal CNV has been described in 32% of cases. Myopic CNVs are generally small (<1 disk area), flat, grayish, and with hyperpigmented margin. Most CNVs are less than 1,000 μ in diameter, perhaps related to the underlying attenuation of the blood supply from the thinner choroid. Moreover, myopic CNVs are type II (located in the subretinal space between the sensory retina and the retinal pigment epithelium), in most cases, as opposed to CNVs associated with age-related macular degeneration, which are mostly type I (situated in the subretinal pigment epithelium space). CNVs may occur adjacent to a lacquer crack, in an area of geographic atrophy of the retinal pigment epithelium (RPE) or in an area of generalized attenuation of RPE and choroid. Among myopic patients with preexisting CNV, more than 30% will develop CNV in the fellow eye within 8 years.

Fluorescein angiography (FA) is still the gold standard for the identification of myopic CNV and can show a pattern characterized by early hyperfluorescence, with little to moderate leakage in the late phases. Previous accounts of the natural history of myopic CNV have been conflicting because this kind of lesion has often been described as having a relatively self-limiting course in the short-term follow-up. Even though

the short-term visual prognosis may be relatively good, the long-term visual outcome is frequently poor. A recent survey showed that visual acuity does not significantly change during the first 3 years from the onset of CNV but gets worse after 5 years. Indeed, visual acuity at 5 years after the onset of CNV decreased to $\leq$20/200 in 89% of the eyes and in 96% of the eyes after 10 years. This poor long-term myopic CNV prognosis has been recently confirmed by another survey.

Dome-Shaped Macula

Dome-shaped macula is a scleral protrusion within the posterior staphyloma involving the macular region. The scleral area below the DSM exhibits focal thickness. According to a recent study comparing highly myopic eyes with and without DSM, its incidence is around 20% in PM. Moreover, patients with DSM showed younger age, better visual acuity, higher refractive error, and axial length in comparison to those without DSM. Notably, DSM can be associated with macular pigmentation, foveal or extrafoveal retinoschisis, and serous retinal detachment. Since the association with serous RD and the presence of central scotoma and metamorphopsia, the differential diagnosis between dome-shaped macula and CNV may not be straightforward.

Myopic Submacular Hemorrhage

Myopic submacular hemorrhage without CNV can be found in approximately 3% of highly myopic eyes. It seems to be caused by a small breakage of Bruch's membrane with consequent bleeding. It has been hypothesized that healing of that ruptures results in lacquer cracks. The onset of myopic submacular hemorrhage is accompanied with visual acuity (VA) reduction, which usually recovers with blood reabsorption within 6 months. However, VA cannot be entirely restored, especially in eyes with disruption of inner and outer segment junction (IS/OS) line and external limiting membrane (ELM) line.

Intrachoroidal Cavitation

Macular intrachoroidal cavitation appears as an orange-colored patchy atrophic lesion within the staphyloma. It shares similar fundoscopic and optical coherence tomography (OCT) features with peripapillary cavitation. Macular intrachoroidal cavitation is linked to a higher incidence of retinoschisis within and around the patchy atrophic area.

Optic Disk and Peripapillary Area

In a study conducted in Singapore on 359 adult patients suffering from PM, peripapillary atrophy (PPA) was the most common disk finding (81.2%), followed by tilted disk (57.4%). PPA can be differentiated on OCT images into peripheral beta zone, defined as lacking of RPE with preserved Bruch's membrane, and inner gamma zone, which involves also choroid, Bruch's membrane, and deep retinal layers. Both areas are associated with long axial length, while only beta zone is linked to glaucoma.

Retrobulbar subarachnoid space (SAS) can be identified in 90% of highly myopic eyes. SAS appears on OCT scans as a hypo-reflective triangle containing weakly hyperreflective arachnoid trabeculae with the base toward the eye neighboring the optic nerve. The enlarged SAS causes an increased pressure gradient across the lamina cribrosa and this, along with the scleral and lamina cribrosa thinning, might explain the higher glaucoma incidence in highly myopic eyes.

Peripapillary intrachoroidal cavitation, formerly known as "peripapillary detachment," is an orange-yellow lesion usually below the optic nerve, which corresponds on OCT to an intrachoroidal hypo-reflective space with normal overlying retina and RPE. The estimated prevalence in highly myopic eyes ranges from 4.9% to 16.9%. Although intrachoroidal cavitation is observed only in PM, its pathogenesis is still unclear. Interestingly, ICC is associated with optic disk tilting and posterior staphyloma but not with axial length or refractive error.

Optic nerve pits are invagination in the superior or inferior border of the papilla. Their

estimated prevalence is around 16% of highly myopic eyes, whereas they are absent in emmetropic patients. Optic nerve pits can involve the optic disk or the conus if they are inside or outside the papilla, respectively. Regarding their pathogenesis, it has been postulated that the *primum movens* is the enlargement of the optic disk and, thus, the stretching of lamina cribrosa and peripapillary sclera. Since these structures are thinned in highly myopic eyes, the stretching strength might result in the focal bowing of the lamina cribrosa, accompanied by interruption of nerve fibers above the defect. Optic nerve pits are positively correlated with refractive error, axial length, and conus area.

Vitreo-Retina Interface

Macular hole is a common complication of PM. Kobayashi and colleagues demonstrated that macular holes occur in myopic patients at a younger age compared to emmetropic ones. Due to the posterior staphyloma and chorioretinal atrophy, the biomicroscopical diagnosis of macular holes can be trivial. Interestingly, 6% of patients affected by severe myopia (< -14 D) exhibited on OCT macular holes with preserved VA (asymptomatic macular holes). During 30 months of follow-up, one out of five asymptomatic macular holes developed symptoms due to hole enlargement or retinal detachment.

Macular retinoschisis (or foveoschisis) is the splitting of the inner retinal layers at the macula. Its estimated prevalence is 9–34% of the highly myopic eyes with posterior staphyloma. Macular retinoschisis can be isolated or mostly accompanied by other macular anomalies, such as premacular structure, foveal detachment, and lamellar macular holes. OCT shows macular retinoschisis as intraretinal cysts dividing retina into a thinner outer and a thicker inner retinal layer with residual tissue interposed seen as thin hyperreflective columns. Eyes with macular retinoschisis often maintain a good VA for several years. However, association with premacular structure is linked to reduction in VA.

Several studies outlined the association between epiretinal membrane and PM. It has been suggested that ERMs are the most important PM macular change in determining VA reduction.

PM is associated with peripheral retinal degeneration (i.e., lattice degeneration), retinal tears and holes. Prevalence of lattice degeneration in PM is around 14%.

Peripheral Retina

Myopia is a well-known risk factor for rhegmatogenous retinal detachment (RD). Peripheral retina diseases and macular holes, together with early vitreous degeneration and posterior vitreous detachment, account for the higher incidence of rhegmatogenous RD in eyes with PM. The relative risk of RD in PM is increased by tenfold. According to the Eye Disease Case-Control Study Group, 55% of nontraumatic RD in eyes surgically naïve occurs in myopic eyes. The degree of myopia is correlated to the risk of RD. In addition, visual prognosis of RD is significantly worse than emmetropic eyes.

Glaucoma

Several epidemiological studies in different ethnic groups revealed that open-angle glaucoma incidence is two to four times higher in eyes with PM. However, establishing the diagnosis of glaucoma in eyes with PM can be challenging due to confounding features that can be observed also in non-glaucomatous myopic eyes (e.g., tilted disk, peripapillary atrophy, deeper excavation and reduction of retinal nerve fiber layer thickness).

Cataract

The incidence of nuclear and posterior subcapsular cataract is higher in PM. Moreover, myopic eyes require more often cataract surgery than emmetropic ones. Notably, rhegmatogenous retinal detachment following cataract extraction is more common in highly myopic eyes.

Prophylaxis

Several strategies have been proposed in order to prevent myopia onset and progression, including outdoor activities, pharmacological agents, optical intervention, contact lenses, and scleral

reinforcement. A recent meta-analysis by Sherwin and colleagues pointed out that spending time outdoor is a moderate protective factor against myopia.

Although effective in slowing the myopia progression, atropine has not spread into clinical practice because of its side effects. However, very low dosage (0.01%) of atropine seems to have a significant effect together with low incidence of rebound and side effects and rebound.

Despite contact lenses have been shown to temporarily slow myopia, their effect seems to be caused by the mechanical flattening of the cornea.

Scleral reinforcement has been proposed in patients with extremely high progressive PM. However, no rigorous trial concerning this technique has been published.

Therapy

The management of myopia aims to treat (i) visual symptoms and (ii) complications.

In order to treat visual symptoms of myopia, several strategies can be employed, including glasses, contact lenses, refractive surgery, and phakic intraocular lens (IOL) implant.

Eyeglasses are a widespread tool to correct refractive error in myopic eyes. However, patients affected by PM need very high power negative lenses, which can result in optical aberrations. At the contrary, contact lenses do not cause any aberration since the distance lens to cornea is negligible.

Refractive surgery refers to a group of procedures altering the cornea shape and curvature so that light can focus on the retina. Since refractive surgery does not interfere with axial length, it does not prevent all the clinical manifestations typical of PM. The two most used techniques are photorefractive keratectomy (PRK) and laser in situ keratomileusis (LASIK).

In phakic IOL implantation, an artificial IOL is inserted in addition to the natural lens in various positions (angle-fixed, iris-fixed, posterior chamber). The visual result is good with phakic IOL and complications are uncommon and related to IOL position and type.

As previously discussed, PM is associated with several ocular complications and their management is crucial to maintain the vision.

The management of myopic CNV has recently improved. In the past decades, laser photocoagulation has been successfully applied in extrafoveal and juxtafoveal CNV. A randomized controlled trial employing krypton red laser photocoagulation demonstrated that 40% in the treated group compared to 13% in the observed group had a visual acuity improvement of at least two lines. The CNV recurrence rate was high, reaching 31.4% of all cases, especially during the first 12 months of follow-up. Another important concern regarding the laser photocoagulation of CNV is the expansion of the atrophic scar, especially toward the myopic crescent, which occurs in 92–100% of cases and can induce a severe visual deterioration when it involves the foveal center. Laser photocoagulation was not indicated when the CNV was subfoveally located, in order to avoid damage to the foveal center. Surgical interventions consisting of CNV removal and macular translocation was reported to improve visual acuity in a variable number of patients but was burdened with an 18–57% recurrence rate, with possible expansion of RPE atrophy. The purpose of macular translocation was to displace the sensory retina originally lying over the subfoveal CNV onto a healthy RPE. Limited macular translocation had the advantage of less tissue manipulation but the disadvantage of slighter foveal displacement in comparison to macular translocation with 360° retinotomy. Overall, best long-term results could be achieved by means of macular translocation with 360° retinotomy. However, macular translocation surgery was associated with severe complications, including retinal detachment, proliferative vitreoretinopathy, macular hole, and corneal astigmatism.

VIP trials demonstrated that photodynamic therapy with verteporfin was effective in retaining quality of vision by stabilizing or improving visual acuity and contrast sensitivity. In particular, median visual acuity was stable in the verteporfin-treated group, whereas patients in the placebo group lost almost two lines after the first year of follow-up. This benefit was maintained at

24 months when the median visual acuity of the treated and the placebo patients had changed from baseline by +0.2 lines and −1.6 lines, respectively. Overall, vision turned out to have improved by at least one line from baseline at month 24 in 39% of verteporfin-treated patients, compared with 13% of controls; an improvement of at least three lines was noted in 12% of treated patients, as opposed to none in the placebo patient. Photodynamic therapy with verteporfin has also been found to be beneficial for patients presenting recurrent CNV after thermal laser treatment.

The advent of anti-vascular endothelium growth factor (VEGF) treatment has completely changed the current management of degenerative myopia-related CNV. Many studies have demonstrated clinically that an anti-VEGF approach can halt the progression of myopic CNV, prompting varying degrees of improvement in visual acuity.

The rationale behind anti-VEGF therapy is related to histopathological evidence that myopic CNV can express VEGF and that the VEGF aqueous level in eyes hosting myopic CNV can be reduced after intravitreal injection of bevacizumab. Moreover, many studies have been reported describing the positive effects of the anti-VEGF approach to CNV related to AMD on FA and optical coherence tomography (OCT). In particular, the results of the RADIANCE trial assessed both efficacy and safety of ranibizumab, administered under two different pro re nata (PRN) schedules for myopic CNV compared with vPDT.52 Patients receiving PRN ranibizumab were treated according to two criteria: visual acuity stabilization criteria (no treatment if no change in BCVA compared with two preceding monthly visits) or disease activity criteria (treatment administered if there is vision impairment attributable to intraretinal or subretinal fluid or active leakage as assessed by OCT and/or FA). The results showed that both PRN regimens of ranibizumab induced significantly greater gains in BCVA than PDT (10.5 (visual acuity stabilization criteria) and 10.6 (disease activity criteria) vs 2.2 letter change (PDT)) at month 3. By month 12, the mean changes in BCVA were 13.8 (visual acuity stabilization criteria) and 14.4 (disease activity criteria) letters for the two ranibizumab groups (with a median of 4.0 and 2.0 injections, respectively), compared with 9.3 letters for patients receiving PDT who could be switched to ranibizumab from month 3 onwards (with a median of 2.0 injections between months 3 and 12). The REPAIR trial showed eyes with myopic CNV receiving a baseline injection of ranibizumab followed by monthly monitoring and a PRN treatment regimen based on disease activity, achieved a mean BCVA gain of 13.8 letters with a median of 3.0 injections, over a 12-month follow-up.

The efficacy and safety of aflibercept for myopic CNV was evaluated in the MYRROR trial, over a 12-month follow-up. Patients received aflibercept according to a PRN schedule based on visual and anatomical criteria, and the interim 6-month results reported a 12.1-letter improvement in BCVA compared with a 2-letter loss in those receiving sham injection.

Although bevacizumab is not approved for intraocular use and evidence on its safety and efficacy profile is limited, many studies published the interesting results, with increases in visual acuity of between 4 and 18 letters after 12 months.

Although at risk for rhegmatogenous RD, laser treatment of lattice degeneration and asymptomatic retinal breaks is not currently endorsed by the scientific community due to insufficient evidences. However, laser treatment of symptomatic breaks is strongly recommended due to high incidence (35%) of RD.

The treatment of rhegmatogenous RD in myopic eyes does not significantly differ from those of non-myopic eyes and it includes PPV with gas or silicone oil tamponade, scleral buckling, pneumatic retinopexy, and combinations of above techniques. However, if a MH is associated with RD, cryotherapy, diathermy, or laser photocoagulation can be additionally performed.

Macular hole can be treated by means of numerous surgical techniques, including pars plana vitrectomy (PPV) with gas or silicone oil tamponade, episcleral posterior buckling, suprachoroidal buckling, and scleral shortening. Despite myopic refractive error does not seem to

affect the whole repair surgical outcomes, the concomitant presence of macular retinoschisis could be a poor prognostic factor for anatomical success rate and visual recovery.

Surgery of macula retinoschisis is warranted when VA is impaired. Several surgical procedures have been proposed and no standardized procedure to treat retinoschisis is currently available. However, vitrectomy with or without internal limiting membrane (ILM) peeling seems to be effective.

Epiretinal membrane surgery is indicated whether severe significant visual symptoms occur. Epiretinal membrane peeling improves VA and metamorphopsia. Notably, ERM surgery outcomes do not differ between patients with and without PM.

Prognosis

Visual prognosis is good unless one or more complications develop. If no complication occurs, visual acuity can be restored by means of eyeglasses or contact lenses; otherwise, vision can be irreversibly compromised.

Conclusion

Pathologic myopia is defined as refractive error of at least 6 D and/or axial length greater than 26.5 mm. It is associated with degenerative changes involving several ocular structures, including macula, optic nerve, peripapillary area, retinal periphery, vitreo-retinal interface and lens. Myopia therapy aims to treat visual symptoms and complications, if they occur.

Pediatric Glaucoma

Teresa C. Chen
Glaucoma Service, Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA, USA

Synonyms

Childhood glaucoma

Epidemiology

Glaucoma in the pediatric population is not common but can have devastating visual consequences. Estimates of the proportion of pediatric

glaucomas represented by congenital glaucoma have varied from 38% to 70%. In the Western world, congenital glaucoma has been reported to occur in about 1 in 10,000–30,000 births, but the incidence is greater in Saudi Arabia and areas with high rates of consanguinity. Since it has been estimated that a general ophthalmologist in the Western world may see a single case of congenital glaucoma every 5 years, this paucity of experience with the disease likely contributes to misdiagnosis and/or suboptimal treatment. This may in turn result in the occurrence of irreversible corneal and optic nerve damage prior to a correct diagnosis. Consequently, congenital glaucoma accounts for a disproportionately high proportion (up to 18%) of children in blind institutions around the world. Overall glaucoma is responsible for 5% of blindness in children worldwide.

Definition

Although there are many classification systems for the pediatric glaucomas, it is generally accepted that pediatric glaucoma is *primary* when there is an isolated developmental abnormality of the angle. Primary pediatric glaucomas include newborn primary congenital glaucoma, infantile primary congenital glaucoma, late-recognized primary congenital glaucoma, and juvenile open-angle glaucoma. Historically, the childhood glaucomas have been labeled *developmental* glaucomas based on the associated presence of developmental defects of the eye.

Etiology

The most common causes of glaucoma in the pediatric population have most consistently been reported as being primary congenital glaucoma and aphakic glaucoma. Aphakic glaucoma is a complication of pediatric lensectomy surgery and can occur following up to 41% of congenital cataract surgeries. A review of the literature suggests that aphakic glaucoma most commonly occurs several years after congenital cataract surgery, especially if the surgery was performed in the first year of life, if corneal diameters are less than 10 mm, and if there are other ocular abnormalities (Chen et al. 2004).

Clinical Presentation

Early diagnosis is the cornerstone of glaucoma management, particularly given that glaucoma is the leading cause of irreversible blindness worldwide (Tham et al. 2014). Every ophthalmologist should be familiar with the cardinal signs and symptoms of primary congenital glaucoma, which include photophobia, epiphora, and blepharospasm. Other associated signs for this disease include cloudy cornea and buphthalmos. All ophthalmologists should also be aware of the need for lifelong screening for glaucoma after congenital cataract surgery, even if the surgery is uneventful. The ocular or systemic diseases commonly associated with glaucoma should be recognized and include trauma, uveitis, anterior segment dysgenesis, aniridia, Sturge-Weber syndrome, neurofibromatosis, and persistent hyperplastic primary vitreous (or persistent fetal vasculature).

Once glaucoma is diagnosed, it is important to refer the patient to an ophthalmologist who has experience with the full range of medical and surgical treatments for the disease.

Diagnosis

Measuring intraocular pressure accurately is integral for glaucoma diagnosis. Even though Goldmann applanation tonometry represents the gold standard for pressure measurement, this method is particularly challenging in the office for both infants and young children. Perkins applanation tonometry offers another gold standard alternative that is portable and can be used in the upright and supine position, which has obvious advantages in infants. Other methods of tonometry may have pressure readings that differ from the Goldmann and Perkins devices, but these methods still have certain advantages in specific situations. For example, pneumatonometry and Tonopen devices are useful in patients with

corneal scarring and edema. Rebound technology with the iCare device affords another portable alternative which does not require topical anesthesia. Schiotz tonometry is uncommon but affords another low-cost, portable alternative.

When diagnosing buphthalmos in a newborn, it is important to remember that the normal newborn has a corneal diameter of 10 mm. When glaucoma occurs in the first 2–3 years of life, buphthalmos can occur and is often associated with Haab's striae, or Descemet's membrane breaks, which can be associated with a cloudy cornea, photophobia, epiphora, and blepharospasm. After 2–3 years of age, the corneal diameter should normally be 12 mm (Bruce 1992). Glaucoma presenting after 2–3 years of age is not usually associated with buphthalmos or cloudy corneas but instead may be relatively asymptomatic, as the eye no longer easily distends with increased intraocular pressure.

An exam under anesthesia (EUA) often affords the best opportunity for a critical examination of the eye, which should include refraction, gonioscopy, and optic nerve evaluation. Buphthalmos may be associated with axial lengths and myopia that are greater than expected for a particular patient. Notably, intraocular pressure evaluation during an EUA may be inaccurate, and every opportunity to measure the intraocular pressure in the office should be done. When planning an EUA, the doctor should be aware that intraocular pressure may increase during intubation and extubation. Inhalational anesthetics may decrease intraocular pressure, and these agents include halothane, nitrous, propofol, sevoflurane, isoflurane, and enflurane. Other medications used during an EUA may increase intraocular pressure and include ketamine, succinylcholine, and suxamethonium.

Differential Diagnosis

The differential diagnosis for epiphora includes nasolacrimal duct obstruction, conjunctivitis, and trauma. The differential diagnosis for buphthalmos includes megalocornea.

The differential diagnosis for a cloudy cornea is often best remembered by the mnemonic STUMPED. STUMPED stands for Sclerocornea, birth Trauma (with vertical breaks in Descemet's), corneal Ulcers, Mucopolysaccharidoses, Peter's anomaly, Endothelial dystrophies (e.g., CHED or congenital hereditary endothelial dystrophy), and Dermoids. Therefore, when examining a baby with cloudy cornea, one should always remember congenital glaucoma and should also never be STUMPED or at a loss in coming up with a differential diagnosis for a cloudy cornea.

An elevated intraocular pressure often distinguishes pediatric glaucoma from these other entities.

Prophylaxis

The best prophylaxis for irreversible optic nerve damage and vision loss is early diagnosis. Since one of the leading causes of vision loss in pediatric glaucoma is amblyopia, aggressive amblyopia treatment is critical in the management of these patients.

Surgically, there may be only one procedure that may decrease the chance of glaucoma development in aniridic patients. Serial gonioscopy after 1 year of age may reveal progressive aniridic angle changes, which may lead to glaucoma later in life. However, prophylactic goniosurgery to peel the iris stump away from the angle may decrease or prevent the future development of aniridic glaucoma in this select group of patients with documented progressive angle changes (Chen and Walton 1999).

Therapy

The treatment of the pediatric glaucomas is primarily surgical, because medications are often ineffective and poorly tolerated long-term in the pediatric population. For example, alpha-adrenergic agonists, such as brimonidine, can cause central nervous system depression with resultant somnolence, hypotension, bradycardia, and respiratory difficulty. Therefore, brimonidine is contraindicated in infants and should be avoided in children under the age of about

6 years. Although oral acetazolamide appears to be more effective than topical carbonic anhydrase inhibitors, systemic acetazolamide may be associated with clinically significant metabolic acidosis in infants and children. Because of their associated side effects in infants and children, intraocular pressure-lowering medications are often used as temporizing agents prior to more definitive surgical treatment.

A review of the literature suggests that goniotomy is a safe and effective procedure for the treatment of primary congenital glaucoma (Chen et al. 2014). It is also effective in cases of uveitic glaucoma, especially in children under 10 years of age and in those with minimal peripheral anterior synechiae. Trabeculotomy is also a good option for primary congenital glaucoma, especially in cases where corneal opacity precludes the ability to perform goniotomy. Both standard and suture trabeculotomy are good options in such situations. The use of an illuminated microcatheter may facilitate trabeculotomy surgery.

The literature suggests that congenital glaucoma is more common and severe in regions where consanguinity is more common relative to other regions of the world. In these cases which often present with a greater degree of corneal opacity and buphthalmos, combined trabeculotomy-trabeculectomy may result in better intraocular pressure control than angle surgery alone.

Although success rates for trabeculectomy are poor in the first year of life and in children who are aphakic, this procedure remains an option in older children and for those who have failed primary angle surgery. While the adjunctive use of mitomycin (MMC) may increase the success rate of this procedure, the results are less clear with the adjunctive use of 5-fluorouracil (5-FU). The long-term risk of bleb-related infection, which appears to be more common in children, should be considered in the surgical decision process.

Tube shunt surgery may be a good option in aphakic patients who have lower success rates with trabeculectomy and who may require contact lens wear for visual rehabilitation. Tube surgery complications that may be more common in the pediatric population include tube migration, tube erosion, and infection.

Cyclodestruction may be used in the pediatric population when other surgical modalities have failed.

Nonpenetrating deep sclerectomy surgery in the pediatric population appears to have modest success, because a significant proportion of cases are associated with an inability to find Schlemm's canal, which makes the surgery technically challenging to perform. The studies also suggest that efficacy increases with conversion to a penetrating or trabeculectomy surgery, but conversion to a trabeculectomy surgery or a penetrating surgery is associated with increased postoperative complications.

Less commonly reported procedures in the pediatric population include endoscopic goniotomy, trabeculodialysis, and trabeculopuncture.

Prognosis

Despite aggressive management, congenital glaucoma may still produce severe visual loss due to amblyopia, corneal scarring, refractive error, and/or optic nerve damage. Prognosis is optimized with early diagnosis and aggressive amblyopia management.

Synonyms

Pediculosis ciliaris; Pediculosis palpebrarum Phthiriasis; Phthiriasis palpebrarum

Definition

An eyelash infestation most commonly due to *Phthirus pubis* (pubic lice.) *Pediculosis humanus corporis* (body lice) or *Pediculus humanus capitis* (head lice) can also cause pediculosis.

Etiology

Eyelash infestation with lice is associated with sexual transmission (pubic lice) or from direct contact with other affected individuals (body or head lice).

Clinical Presentation

Infestation of eyelashes may occur at any age, with the highest frequency noted among men between the ages of 15 and 40. Affected individuals present with pruritus, irritation, and foreign body sensation.

Slit-lamp examination reveals lice and nits visible on eyelashes and lids. Lice may be identified by a distinct appearance, with pubic lice measuring 1–2 mm in length with round, flattened, crab-like bodies and three pairs of legs; body and hair lice are elongated, measuring 2–3 mm in length with three pairs of legs anteriorly. Nits are ovoid and opaque, measuring 0.5–1 mm in size, and adherent to lashes, seen often near the base. Erythematous lesions from louse bites are seen on the lids along with reddish-brown deposits (lice feces) on lashes (Lacarrubba and Micali 2013).

Pediculosis can also present as blepharitis or a chronic, follicular conjunctivitis. Lice may also cause secondary bacterial infections.

Diagnosis

Pediculosis is diagnosed by direct observation of lice and nits on eyelashes with handlight or slit-lamp examination. Lice are more easily distinguishable with use of a Wood's lamp, which causes lice to fluoresce.

Differential Diagnosis

Chronic blepharitis and conjunctivitis with mattering of the lashes are seen in infestation with *Demodex folliculorum*. In contrast to lice, however, organisms are eight legged, transparent, 300–400 μm in size, and most easily visualized through examination of an epilated eyelash under a microscope. These mites are harbored in a majority of elderly individuals, in contrast to lice which are more prevalent among the young.

Prophylaxis

Pediculosis is spread by close personal contact or sharing of towels and bedding with an affected individual; prophylaxis is dependent on avoiding exposure. Treatment of affected partners and family members is important to avoid recurrent infestation.

Therapy

Initial, first-line therapy starts in the office with mechanical removal of lice and nits at the

slit-lamp biomicroscope using jeweler's forceps. Trimming of eyelashes may also be considered to reduce the burden of nits. However, lice and nits at the base of the lashes may be missed if mechanical treatment is utilized alone.

Medical therapy is based on a 7–10 day period of incubation and subsequent hatching of nits, with a 48 h feeding period required for survival. Treatment periods are therefore utilized for 1–2 weeks. Topical antibiotic ointment such as bacitracin or erythromycin, applied to the eyelids three times daily, may smother lice and nits. If unavailable, petroleum jelly has been reported as an alternative. While therapy with physostigmine ophthalmic ointment (0.25–1%) twice daily is directed toward the organism, successful use of pilocarpine gel (4%) has also been reported; these may be effective due to either smothering of organisms, paralysis of lice, or both. Treatment with yellow mercuric oxide (1–2%) ophthalmic ointment applied to the lashes four times daily or oral therapy with ivermectin in two doses 1 week apart are also directed toward current lice (Kumar et al. 2003).

To prevent re-infestation or to prevent spread, anti-lice shampoo and lotion for non-ocular areas and treatment of family members and sexual partners, as well as thorough washing of clothing and linens, are recommended.

Prognosis

Overall, prognosis is favorable with removal of lice and nits. Medical therapy directed toward systemic eradication of the organism and spread to others is helpful to prevent re-infestation (Rapuano 2011).

Epidemiology

Pediculosis of the eyelashes most frequently occurs from pubic lice, with infestation from body and head lice reported less frequently. Spread of pubic lice is most frequent among young and middle-age adults. Infection with head and body lice is more often reported in school-age children, particularly in areas of high population density and low socioeconomic status, associated with poor hygiene (Dunphy et al. 2007).

Pedigree Analysis, Symbols Used in

Laura L. Wayman
Department of Ophthalmology, Vanderbilt University Medical Center, Vanderbilt Eye Institute, Nashville, TN, USA

Definition

Standardized symbols used to study the inheritance patterns of a trait or disease.

	Blank circle	Female
	Filled in square or circle	Affected individual
	Square and circle connected by one line	Mating
		Offspring
	Roman numerals (I, II, II, IV)	Generations
	Arabic numerals	Birth order within generations

Purpose

These symbols are used to represent aspects of a pedigree. The pedigree is used in genetic evaluations to document the family history.

Principle

By examining an individual's family history one could determine if a disease is inherited and the mode of inheritance.

Synonyms

Lhermitte peduncular hallucinosis

Definition

Peduncular hallucinosis (PH) is a rare form of complex visual hallucinations which are the result of a lesion in the ventral midbrain. PH may be continuous (lasting hours) or episodic (lasting seconds), eventually resolving, in most cases, within a few days or weeks although some cases may last longer. These hallucinations generally contain vivid imagery and might vary from one episode to the next. Some might experience multimodal hallucinations involving sound, touch,

and body posture. Most patients are able to distinguish their hallucinations from reality. PH closely resembles hallucinations caused by Charles Bonnet syndrome (release hallucinations) associated with visual loss.

Etiology

PH is a result of lesions of the midbrain usually caused by ischemic infarction involving the cerebral peduncles or reticular formation within midbrain. Thalamic infarction can also result in similar symptoms in some cases.

Clinical Presentation

PH is characterized by complex visual hallucinations which occupy the entire visual field. The patient is usually aware that he or she is hallucinating. These episodes may be continuous or episodic over the course of a few days to weeks. Related symptoms, as the result of midbrain lesions, may appear as third nerve palsy, gait ataxia, or hemiparesis.

History

The earliest postmortem reports of peduncular hallucinosis were published by Lhermitte and van Bogaert in 1922 and 1925, respectively. The first diagnosis of peduncular hallucinosis with MRI was described in 1987 by Geller and Bellur.

Diagnosis

Midbrain infraction, and diagnosis of PH, can be identified by cranial magnetic resonance imaging (MRI). Sleep-wake cycle disturbance is prevalent in the majority of cases: daytime sleepiness (diurnal somnolence) and nighttime wakefulness (nocturnal insomnia). Damage in adjacent midbrain structures may also result in unilateral or bilateral third nerve palsy, hemiparkinsonism, hemiparesis, and gait ataxia.

Differential Diagnosis

Charles Bonnet syndrome (release hallucinations) and midbrain infarction third nerve palsy

Treatment

PH caused by midbrain infarction generally subsides after a few days or weeks, though cases lasting years have also been reported. A recent case showed successful treatment of PH with an atypical antipsychotic drug (olanzapine).

Prognosis

Full recovery after a few days or weeks is expected for most patients, though some patients have reported for symptoms of PH for multiple years.

Epidemiology

Peduncular hallucinosis is a rare form of complex hallucinations, and there has been no official report of the frequency of PH in the United States or worldwide.

Pelli-Robson Chart

Jens Bühren
Department of Ophthalmology, Goethe-University Frankfurt am Main, Frankfurt am Main, Germany

Synonyms

Pelli-Robson test

Definition

A test chart introduced by Denis Pelli and John Robson to determine contrast sensitivity using familiar Sloan letter optotypes rather than sinusoidal gratings (Pelli et al. 1988). The chart uses letter triplets spanning a range of 0–2.25 logCS. At the typical testing distance of 1 m, the optotype size equals 1.3 logMAR. The corresponding dominant spatial frequency of 1.5 cycles per degree is near the peak of the contrast sensitivity function for letter optotypes (Bach et al. 2008). The Pelli-Robson chart allows a quick determination of contrast thresholds at a high repeatability (Elliott and Bullimore 1993; Bühren et al. 2006) using optotypes that subjects are familiar with. Potential disadvantages are related to the large optotypes (insensitivity to subtle aberration-induced blur) and to the chart nature (probability of correct guessing, no glare source and dependence from room illumination).

Pellucid Marginal Degeneration

Vitor Maduro
Cornea and External Diseases Section – Ophthalmology Department, Centro Hospitalar Lisboa Central, Lisboa, Portugal

Synonyms

Pellucid corneal marginal degeneration; Pellucid marginal corneal degeneration

Definition

Pellucid marginal degeneration (PMD) is a rare disorder of the peripheral cornea affecting usually the most inferior quadrant. The hallmark of this disease is the inferior corneal thinning localized 1–2 mm from the limbus.

Etiology

At present, the etiology of this disease is not known, and there is a discussion about the fact that PMD, keratoglobus, and keratoconus are different diseases or the same disorder with different clinical presentations. Lately, several authors had proposed that PMD is a peripheral form of keratoconus due to the occurrence of two diseases.

Clinical Presentation

History

Patients with PMD are asymptomatic for a long period of time except when the disease progresses. When this stage arrives, the patient complains about gradual vision decreased in spite of changing spectacles or contact lenses. This is due to the increased irregularity, against the rule astigmatism. Much less frequent can arise red eye, pain, or sudden visual acuity reduction. When this happens, it's the result of corneal hydrops or even much less frequent peripheral corneal perforation.

Physical Examination

When checking visual acuity in the early stages, the patients present with good vision, special with pinhole, even in late-stage disease due to peripheral disease. When trying to do refraction, it shows against the rule astigmatism that can be very irregular.

When examination is done with the slit lamp, PMD is characterized by 1–2 mm inferior peripheral thinning extending from 4 to 8 o'clock that spares 1–2 mm area of normal cornea between the limbus and area of thinning. The area of conical protrusion occurs above the inferior thinning. Other important aspect is that in PMD there is no Vogt's striae, no Fleischer rings, no lipid deposits, no neovascularization nor inflammation nor epithelial defects.

Diagnosis

Classical corneal topography or more recent Orbscan™ or Pentacam™ is the gold-standard diagnostic test for PMD. With the corneal topography only can surface irregularities of the cornea be evaluated, but cannot do corneal pachymetry. With Orbscan™ or Pentacam™, we can use not only the topographic maps but also the pachymetric maps and even the elevation maps. These equipment allow not only an early and subclinical detection of PMD but also the progression of this disease.

The topographic maps usually show abnormalities above the thinned zone, with flattening of the cornea along the vertical meridian with against-the-rule astigmatism. In more advance cases, the inferior peripheral steepening extends into the mid-peripheral with the inferior oblique corneal meridians in a "crab claw" or "butterfly" appearance.

The pachymetry maps are very useful in corroborating the topographic maps, because they

show the inferior corneal thinning where the steepening is maximum, which is the reverse of the typical pattern in normal corneas. So, to have more reliable diagnosis is necessary to obtain the two maps information.

Differential Diagnosis

PMD is most frequently not diagnosed because other ectatic diseases as keratoconus is more common.

Differential diagnosis included:

- Keratoconus
- Keratoglobus
- Terrien's marginal degeneration
- Mooren's ulcer
- Furrow degeneration

Therapy

Nonsurgical Methods.

The management of PMD is dependent on the stage of the disease. In very early stages are used nonsurgical methods in order to improve the visual acuity. The nonsurgical methods include:

- Spectacles
- Soft contact lens
- RGP contact lens
- Hybrid contact lens
- Scleral contact lens

The use of spectacles and soft contact lens is very reduced because it only works in the very early stages of PMD. RGP and hybrid contact lens are good options and provide a good vision; however, they can be very challenging in achieving a good fitting pattern.

Surgical Methods

As PMD progress and if nonsurgical management fails, other solutions are needed to improve patient's visual acuity, that is, methods to reduce the irregular astigmatism. Those methods are called surgical treatment of PMD, which includes:

- Cross-linking
- Intrastromal corneal segment rings
- Deep anterior lamellar keratoplasty
- Lamellar crescentic keratoplasty
- Corneal wedge excision
- Tuck-in lamellar keratoplasty
- Penetrating keratoplasty

Because PMD is so peripheral, choosing penetrating keratoplasty is very challenging due to the obligation of doing a large diameter graft (removing all peripheral thinning cornea). This technique can be more prone to rejection due to the proximity to the limbus and blood vessels. If the choice is decentered grafts, it can be associated with high astigmatism and with rejection due to the proximity to the limbus.

Some publications mentioned that doing first peripheral lamellar crescentic keratoplasty, followed by a central penetrating keratoplasty after a few months, can be a good surgical management of PMD.

Acute Management

Acute hydrops with corneal edema is a possible but rare complication of PMD. Like in keratoconus, this complication happens when there is a rupture in Descemet's membrane. PMD patients with this complication or even with peripheral corneal perforation are really ophthalmological emergencies. These two possible sight-threatening conditions can be managed with application of glue tissue adhesive, associated or not with soft contact lens, lamellar crescentic keratoplasty, or even penetrating keratoplasty.

Prognosis

PMD is a very slow progressive disease that can lead to low vision but only in the fourth or fifth life decade. The most important is to establish the correct diagnosis in order to manage this disease

with the less morbidity as possible. Neither there are no studies that show how many patients need surgical management nor even how many have sight-threatening complications as corneal perforations.

Epidemiology

PMD is a rare disease, much less common than keratoconus but more common than keratoglobus and posterior keratoconus; however, till now there are no studies about prevalence or incidence of PMD. There is no racial and no geographical predisposition. Past studies showed no sex preponderance; however, recent publications show some male predilection. Typically patients are between the age of 20 and 40 when the diagnosis is done.

Synonyms

Mucous membrane pemphigoid (MMP); Ocular cicatricial pemphigoid (OCP)

Definition

Mucous membrane pemphigoid is a chronic inflammatory disease that affects mucous membranes of the eyes, gastrointestinal system, skin, and genitals. When the eyes are involved, the term ocular cicatricial pemphigoid (OCP) is used.

Etiology

OCP is thought to represent a cytotoxic, type II hypersensitivity where autoantibodies are directed against cell surface antigens such as bullous pemphigoid antigen II (BP 180), located in the epithelial basement membrane zone (Weisenthal 2013). When these autoantigens are activated in the eye, resultant inflammation and breakdown of the conjunctival surface occur: a process termed cicatrization. IL-1, TNF-alpha, and macrophage-colony stimulating factor are all found to be overexpressed in OCP (Weisenthal 2013). When severe or left untreated, OCP can result in ocular surface scarring and vision loss.

Clinical Presentation

Ocular Manifestations

Symptoms:
Conjunctivitis, tearing, ocular irritation, burning, foreign body sensation, mucoid discharge, photophobia, and diplopia

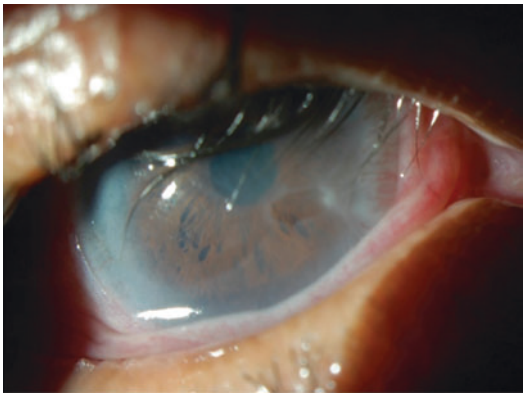
Signs:
Subepithelial fibrosis, conjunctival edema and hyperemia, conjunctival shrinkage/inferior forniceal shortening, symblephara, corneal epithelial defects or ulceration, limbal stem cell deficiency, distichiasis/trichiasis, restriction of EOM, and lagophthalmos (see Fig. 1).

Stage I: chronic conjunctivitis with subepithelial fibrosis

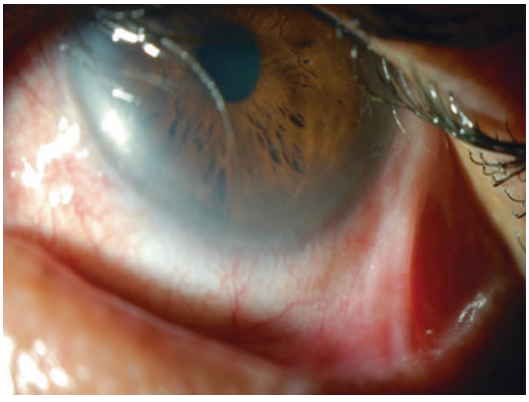
Stage II: shortening of the inferior fornix

Stage III: symblepharon formation (see Fig. 2)

Stage IV: end-stage disease manifesting as ankyloblepharon, severe sicca syndrome, and ocular surface keratinization with limbal stem cell deficiency



Pemphigoid, Cicatricial, Fig. 1 Trichiasis, corneal epithelial defects, conjunctival hyperemia, and chemosis in an OCP patient



Pemphigoid, Cicatricial, Fig. 2 Stage 3 OCP with symblepharon formation

Stage II–III subclassification: a 0–25%, b 25–50%, c 50–75%, and d 75–100% loss of inferior fornix depth

% horizontal involvement of symblephara by (X) number of symblephara

That is: OCP stage IIc IIIb(2) 50–75% loss of inferior fornix and 25–50% involvement by two symblephara

Extraocular Manifestations

Forty percent of patients may have oral involvement and include erosions of the buccal mucosa, gingiva, lip, and/or palate. Other gastrointestinal involvement includes erosions/scarring of the esophagus and anal mucosa. Twenty-five percent of patients may have skin involvement including inflammatory bullae and erosions of the head, neck, and upper trunk (Krachmer et al. 2005). Additionally, urethral and vaginal strictures can be present.

Conjunctival involvement (75%) may occur as early as 10 years before other mucosal or skin lesions develop, or it may occur as late as 20 years after the onset of other lesions (Krachmer et al. 2005).

Diagnostics

Tissue biopsy with immunohistochemical confirmation provides definitive diagnosis and should be obtained prior to institution of therapy (Krachmer et al. 2005). Biopsies can be taken from the skin, oral mucosa, or bulbar conjunctiva. Biopsies should be taken adjacent to active lesions to yield lower false negative results. If extraocular lesions are present, biopsies should first be attempted in these more accessible sites for tissue diagnosis.

Hematoxylin and Eosin

Conjunctival tissue stained with hematoxylin/eosin demonstrates squamous metaplasia with goblet cell loss (without epithelial dysplasia), subepithelial bullae, and a dense plasma cell infiltrate in the substantia propria (Rosa 2013).

Immunohistochemistry

Direct immunofluorescence should be performed on all conjunctival biopsy samples. Direct immunofluorescence demonstrates characteristic linear deposition of IgG, IgA, and/or C3 along the epithelial basement membrane zone. Immunofluorescence has a diagnostic sensitivity of 50% (Rosa 2013) (see Fig. 3).

Differential Diagnosis

Other diagnostic considerations include any disease process that can cause a cicatrizing conjunctivitis:

> Allergic causes include →atopic keratoconjunctivitis and →toxic epidermal necrolysis/Stevens-Johnson syndrome. Autoimmune causes include sjogren's syndrome, lichen planus, linear IgA bullous disease, →sarcoidosis, systemic lupus erythematosus, and scleroderma. Toxic causes include pseudopemphigoid (medicamentosa). Neoplastic causes include conjunctival sebaceous cell carcinoma or damage from ionizing radiation. Sequelae of infectious etiology include trachoma, adenovirus conjunvitivits, and corynebacterium diphtheria conjunctivitis.

Pseudopemphigoid is associated with use of various medications such as sulfa antibiotics, penicillin, phenytoin, topical pilocarpine, epinephrine, timolol, idoxuridine, echothiophate, and demecarium bromide (Weisenthal 2013). In contrast to OCP, symptoms resolve once the offending medication is discontinued.
